DISCUSSION

Healthy volunteers exhibited a larger range of motion across all metrics, lower wall tension and stretch indices. Linear correlation coefficients (R^2) between these metrics and urinary flow rate were found to be higher in the healthy volunteers in most of the cases. Table 1, highlighted in green, shows two BPH subjects without lower urinary tract symptoms (LUTS) that have high correlation values with flow, corresponding to the behavior of healthy subjects. Because of this most of the maximum and minimum metrics are similar but in the case of LAN and CAS, SD values show large disparity in the metrics (highlighted in dark green in Table 1). Thus, Table 1B) was included to show information that might be hidden due to patient-to-patient variability in Table 1A). In Table 1A) the largest differences are highlighted in orange. In addition, measurements taken in the sagittal plane and its derivatives show higher correlation coefficients than metrics taken in the coronal plane. PV curves show higher work measurements during voiding but still exhibit interesting characteristics during the end of filling phase and beginning of voiding phase that could prove to be valuable when coupled with anatomy-based biomechanics.

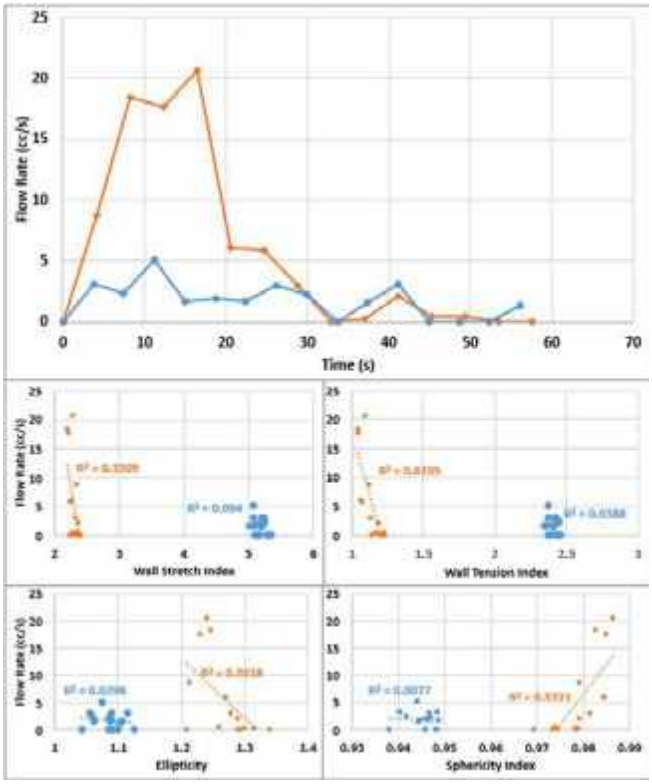

Figure 3: Graph displaying flow rates for Healthy 4 (orange) and BPH 1 (blue). The rest of the graphs show correlation studies with their corresponding correlation coefficients between urine flowrate and calculated bladder shape metrics shown in Table 1.

Uro-Dynamic MRI can capture bladder biomechanics non-invasively both in healthy controls and patients with BPH/LUTS. By adding bladder shape analysis and retrospective UDS, we created a robust framework that could characterize bladder biomechanics and shape and quantify differences between healthy subjects and subjects with LUTS in a more comprehensive way. Limitations include subject orientation during the study, inability to acquire data for more than one void per scanning session and the lack of UDS in healthy volunteers. In addition, to increase the scope of this framework we are currently adding more subjects to both cohorts, performing a comparison between sequences, adding studies in women, and adding different cohorts including overactive bladder (OAB) and neurogenic bladder.

TOWARDS IMPROVED SURGICAL SEALANTS BY INVESTIGATING HUMAN VISCERAL PLEURA MECHANICS

INTRODUCTION

The visceral pleura is a thin tissue layer that encases, protects, and maintains an airtight seal around the lung. Life altering pulmonary conditions, such as chronic obstructive pulmonary disease (COPD) and various forms of lung cancer, may require invasive surgical removal of bulk lung tissue to alleviate symptoms and improve quality of life for patients [1]. These procedures compromise the airtight seal around the organ and injure the visceral pleura network, which may cause air leaks from the lung into the pleural cavity, one of the most common complications in surgical lung procedures [2]; moreover, prolonged air leaks are linked with longer hospital stays and higher mortality rates [3].

To help mitigate air leaks in lung surgery, surgical adhesives are designed to reseal the lung at the injury site [4]. Sealants available on the market show excellent biocompatibility and various magnitudes of elasticity, but the lack of positive outcomes (air leak prevention and length of stay reduction) suggest they are not yet a sustainable solution [5,6]. An effective sealant is expected to adhere to and stretch with the visceral pleura. It should be biocompatible, elastic, and robust enough to maintain a seal for the cyclic and heterogenous strain environment the lung presents. Sealants with mechanics outside of the native tissue properties are likely to delaminate/fail or, in extreme cases, damage neighboring tissue [7]. To address these requirements, sealants in development are tested often on rat and pig tissue for burst pressure and biocompatibility [4,8,9]. Our recent work explored biaxial rat and pig visceral pleura mechanics; however, how the mechanics of pig and rat visceral pleura tissue compares to human visceral pleura tissue is still unknown.

For the first time, in this present study, we explore the biaxial mechanics of human visceral pleura, further comparing healthy and smoker lungs; abnormal lungs were of interest given the likelihood of contracting pulmonary disease and requiring pulmonary surgery [10]. This study supports the development of future sealant design by providing a baseline for mechanical synchrony with visceral pleura mechanics to ultimately help mitigate air leaks in surgical lung procedures.

METHODS

Human healthy lungs (transplant eligible lungs, N = 3: 63M, 48F, 30M) and smoker (non-transplantable lungs, N = 3: 46F, 57F, 44F) were acquired via a donor network (IRB exemption approval HS 20-180; Donor Network West, San Ramon, California). Healthy lungs had no history of smoking while non-transplantable lungs were from donors with a smoking history greater than 20 pack years. Surgical forceps were used to excise visceral pleura samples from each lung, noting the cranial-caudal and ventral-dorsal orientation for anisotropy considerations, while collecting an equal number of specimens from upper and lower lobes on both medial and costal surfaces to consider regional dependencies. Therefore, 12 samples were collected from each lung, totaling 36 samples for the healthy and 36 samples for the smoker groups. Each sample was cut into a square with a 1x1 cm test area in preparation for biaxial testing. Samples were collected and tested within 72-hours post mortem.

Visceral pleura samples were loaded on a biaxial displacement-controlled tensile tester with a 1.5 N load cell (Cellscale Biomaterials Testing, Waterloo, Canada). Each sample was tested in a heated 1X Phosphate Buffered Saline bath (37°C) to prevent tissue dehydration. Samples were elongated to 40% strain via equiaxial displacement at a rate of 0.2%/s, where the analyzed test and stress relaxation hold for 300 seconds were preceded by two cycles of preconditioning.

The first Piola Kirchoff stress was calculated using the force and the cross-sectional area of each specimen (thickness measured via confocal imaging and thickness gauge [11]). The initial and final moduli were determined using a linear fit to $R^2 > 0.90$ for the low and high strain regimes, as previously described [12]. The strain transition between the initial to final moduli, linked to the uncrimping of the collagen fiber microstructure, was defined as the intersection of their respective linear

fits. Stress relaxation was calculated as the percent difference of the initial and final stress value normalized by the initial stress value during the hold.

As an additional limited evaluation, results were compared to findings from pig and rat visceral pleura tissue [13]. While studies on pig and rat tissues allowed a consistent and reproducible maximum strain at 60%, where the secondary slope of the bilinear J-shaped stress-strain curve would only emerge beyond 40% strain, translating these extended strains to human specimens would cause irreparable tissue damage and therefore, forced a tradeoff in interspecies protocol design.

A two-way ANOVA test was used for statistical comparisons (GraphPad Prism, San Diego, California). Corresponding p-values were used to determine statistical significance between groups with the thresholds defined as *p<0.05, **p<0.001, ***p<0.0001, ****p<0.00001.

RESULTS

Human healthy and smoker visceral pleura was found to exhibit a bilinear stress-strain response, which was not dependent on the specimen orientation (and therefore, isotropic) nor region (and therefore, homogenous). The averaged regional and directional (combined) stress-strain responses for healthy and non-transplantable lung visceral pleura were shown in Figure 1. Similar curves were found for pig and rat lungs, where the metrics of each species were reported in Figure 2. The bilinear curve exhibits a compliant initial modulus followed by a stiffer final modulus, as the tissue approached its strain limits. Both healthy and smoker human groups yielded average initial moduli between 1.3-1.5 kPa, which is similar to pig tissue (1.4 ± 0.6 kPa) but disparate from rat tissue (2.7 ± 1.1 kPa) (Figure 2). Further differences were found in the final moduli, where human groups exhibited a significantly stiffer response compared to other species, despite straining to only 40% compared to pig and rat (extended to 60%): both human healthy and smoker groups demonstrated an average final modulus of 135.8 ± 98.8 and 132.8 ± 74.0 kPa respectively. This is significantly larger than the pig (21.8 ±17.7 kPa) and rat (10.13 ± 4.6 kPa).

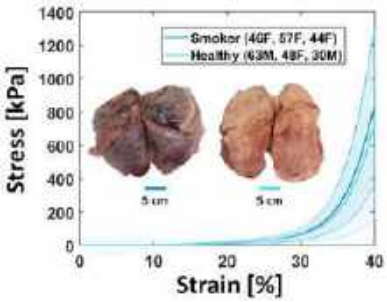

Figure 1: Human healthy and non-transplantable lungs and their average stress strain curves

The difference in strain transition points highlights this alternate extensibility amongst the three species (Figure 2). Human visceral pleura was the least extensible, undergoing the smallest strain transition at 34.2 ± 1.5 and 34.3 ± 1.1 % for healthy and smoker visceral pleura respectively, followed by rat (41.4 ± 4.6 %) and pig (47.8 ± 5.0 %). Finally, the only metric found to significantly differ between healthy and smoker human groups was the stress relaxation was found to be significantly different than smoker counterparts (16.6 ± 3.3 for healthy and 19.0 ± 4.8 % for smoker respectively).

DISCUSSION

This study explores human visceral pleura mechanics for the first time, further comparing elasticity metrics of healthy and smoker lungs. Differences between healthy and smoker lungs were sparce, with percent relaxation being the only metric in which smoker lungs were statistically different from healthy lungs. Each donor had a smoking history greater than 20 pack years but was not diagnosed with pulmonary disease. Lungs with diseases such as COPD, may present mechanical differences when compared to healthy visceral pleura.

We evaluate the potential applicability of quantification metrics between human and common animal models traditionally utilized for sealant testing. We report similar initial stiffness between human lungs and pig lungs. Additionally, we also find significantly larger final modulus and reduced strain transition of human visceral pleura when compared to pig and rat counterparts. This reduced extensibility associated with stiffness is consistent with recent studies reporting the surface strain patterns of inflating human lungs is decreased compared to pig lungs at comparable tidal volumes [14,15]. Despite the variation in surface strain profiles, the pig lung visceral pleura exhibits similar stiffness values when compared to human lungs at lower strains, which indicates it may serve as an effective animal model for investigating the visceral pleura and surgical sealant mechanics (unlike rat tissue).

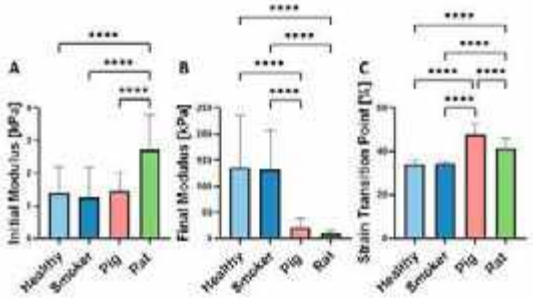

Figure 2: Mechanical metrics of human healthy, human smoker, pig and rat lung visceral pleura: A) Initial Modulus, B) Final Modulus, and C) Strain Transition.

Surgical sealants used in lung surgery have a wide range of elastic moduli ranging from 1 kPa to over 1000 kPa, all with a various range of extensibility, adhesive strength, and burst resistance [4,8,9]. The heterogeneity of the lung surface strains and varying internal pressures, as presented in other studies, present a challenging task for sealants. Modern studies continue to focus on burst pressure and biocompatibility; however, evidence of delamination caused by the asynchronous mechanics of the sealant and the visceral pleura interface merits further investigation [16], and is the subject of future work.

FEASIBILITY AND POST-PROCEDURAL RISK ANALYSIS OF REDO-TRANSCATHETER AORTIC VALVE REPLACEMENT: A PATIENT-SPECIFIC FLUID-STRUCTURE INTERACTION BASED STUDY

Symon Reza (1), Brandon Kovarovic (1), Danny Bluestein (1)

(1) Biomedical Engineering, Stony Brook University, Stony Brook, NY, USA

INTRODUCTION

Transcatheter aortic valve replacement (TAVR), a minimally invasive procedure, has become the standard procedure for high and intermediate-risk aortic stenosis patients. Recently, TAVR has also been approved for use in low-risk patients. However, prosthetic TAVR leaflets are inherently subjected to degeneration, along with calcification and thrombosis [1]. Recent clinical studies have found evidence of early leaflet thrombosis formation that is associated with an earlier risk of structural valve degeneration. Hence, durability remains one of the major concerns for TAVR technology. This evidence of thrombosis and rapid degeneration of TAVR valves poses a significant risk to the increasing number of young and low-risk TAVR recipients who may neccesitate repeat intervention. Transcatheter aortic valve-in-transcatheter aortic valve (TAV-in-TAV), aka redo-TAVR, is being considered as a potential treatment of choice for transcatheter heart valve (THV) degeneration and has shown success in addressing suboptimal outcomes. While current data is insufficient, redo-TAVR holds promise as a rescue option for TAVR valve degeneration, requiring further research. Recently, an *in-vitro* study has suggested combination dependent hemodynamic performance of redo-TAVR in idealized aortic root [2]. Performance of redo-TAVR may also depend upon factors including the diseased patient-specific anatomy and complex flow domain formed by the native leaflets and two TAVR device prostheses. A comprehensive structural and hemodynamic performance analysis of different redo-TAVR combinations in a patient-specific scenario may provide vital insights into the feasibility of redo-TAVR procedures and help identify the optimal combination.

METHODS

A patient with 23.5mm CT-derived annular diameter was selected for this study. The patient model was reconstructed (Figure 1a) following the procedures described in our previous study [3]. The most widely used self-expandable (SE) Evolute (Medtronic plc, Minneapolis, MN, USA) and balloon-expandable (BE) Sapien (Edwards Lifesciences, Irvine CA) TAVR systems were considered for this study where 26 mm Evolut R and Sapien 26 mm TAVR devices were selected as the first TAVR devices and the most recent versions of Evolut and Sapien TAVR systems (26 mm Evolut Pro and 26 mm Sapien 3 Ultra) were used as the second TAVR devices. TAVR implantation simulations were then performed following our previous studies (Figure 1b) [4] using Abaqus Explicit 2019 (SIMULIA, Dassault Systèmes, Providence, RI). The selected TAVR devices result in four TAV-in-TAV combinations (Figure 1c) including - i) SE-in-BE, ii) BE-in-BE, iii) BE-in-SE, and iv) SE-in-SE. A 2-way coupled fluid structure interaction (FSI) using a body-fitted sub-grid geometry resolution (SGGR) method was then performed following our previous study [5]

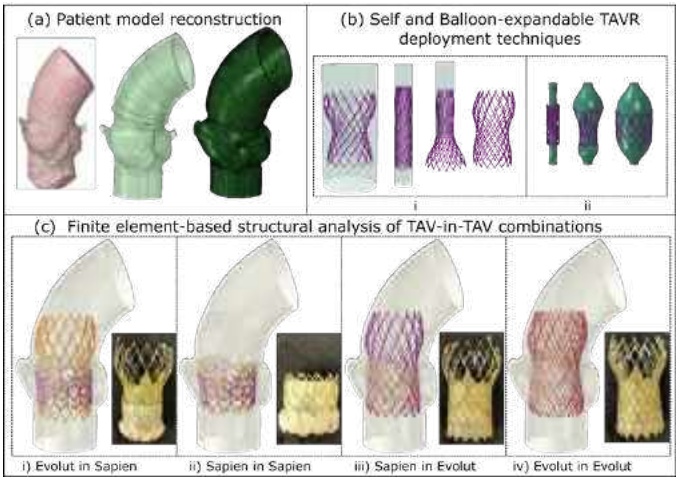

Figure 1: Schematic of the (a) model reconstruction process, (b) implantation process of i) self-expandable, ii) balloon-expandable TAVR devices, (c) four combinations of redo-TAV deployed inside the aortic root of the selected patient model with in-vitro representation [3] of the corresponding redo-TAV combinations.

to analyze the hemodynamic performance of the redo-TAV combinations. FSI simulations were performed coupling the fluid solver, FlowVision 3.12 (Capvidia NV, Leuven, Belgium) and Abaqus

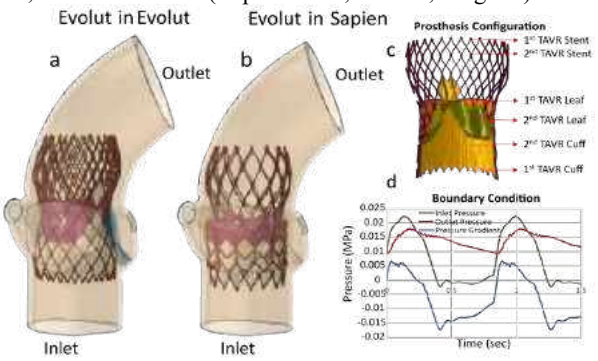

Figure 2: Fluid domain of (a) SE-in-SE and (b) SE-in-BE. (c) Pressure based BC, and redo-TAVR components. A patient with high blood pressure BC was chosen in this study.

Explicit 2019. The thrombogenic risk assessment analysis was performed following our previously developed and validated technique where Lagrangian particles representing platelets are injected into the flow and the stress accumulation (SA) is computed along each particle trajectory. The SA data is then collapsed into a probability density

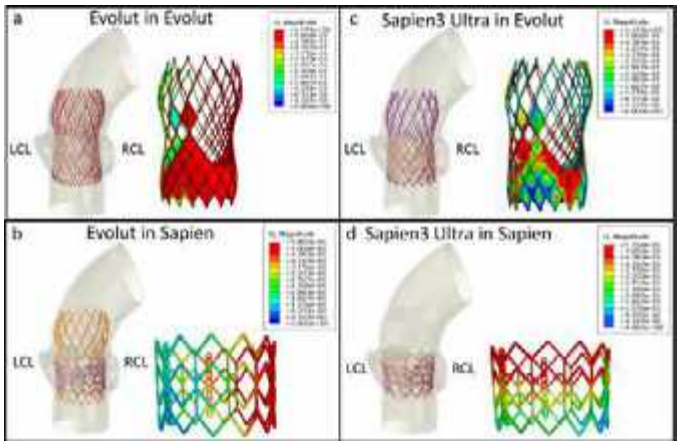

Figure 3: Displacement locations of the damaged THV caused by the second THV.

function (PDF) to compute "thrombogenic footprint" [6] for each TAV-in-TAV combination.

RESULTS

Structural and hemodynamic analyses were performed following redo-TAVR simulations. The SE-in-SE combination demonstrated the highest eccentricity (Figure 2) and the narrowest coronary access (Figure 3). The combinations involving SE devices (BE-in-SE, and SE-

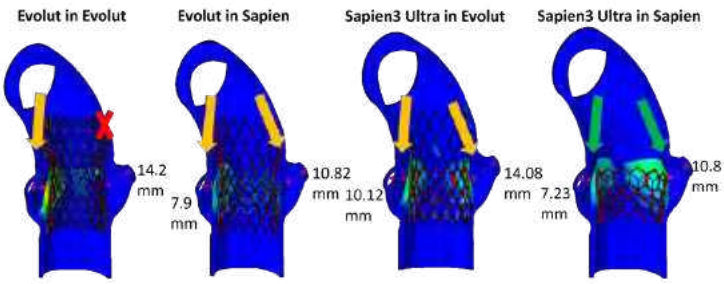

Figure 4: Coronary access impairment analysis.

in-BE) demonstrated limited coronary access (Figure 4). SE-in-BE demonstrated the narrowest opening at the annular plane. BE-in-BE demonstrated superior performance from the structural perspective with the widest coronary access and opening at the annular plane. However, BE-in-SE demonstrated 40% leaflet overhang which may impact the

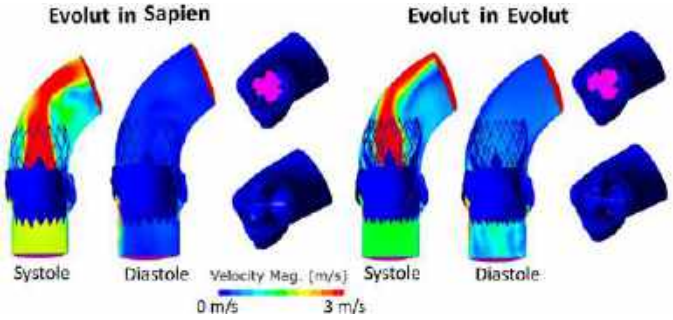

Figure 5: Preliminary FSI results for 2 redo-TAVR combinations.

hemodynamic performance. Initial results from the hemodynamic analysis demonstrated combination-specific performance. SE-in-SE demonstrated higher velocity and paravalvular leakage compared to SE-in-XT. Further investigations are being performed to identify the optimal redo-TAVR device combination with an efficient hemodynamic performance coupled with thrombogenic risk on a patient-specific basis.

DISCUSSION

Successful implantation and optimal hemodynamic performance of redo-TAVR requires careful assessment of specific device characteristics due to the technical and structural differences in TAVR prostheses, including mode of deployment (BE and SE), valve function (intra-annular and supra-annular), and valve design (skirt and stent frame design, and height). Patient-specific features and the interaction between the second THV with the patient anatomy also play a crucial role in the performance of redo-TAVR procedure. Therefore, patient-specific preprocedural planning is critical in minimizing peri-procedural and post-procedural risk. In this study, we addressed the clinical concerns performing a set of computational analyses encompassing finite element based TAVR deployment in patient specific models to FSI based hemodynamic analysis coupled with particle stress accumulation analysis that accounts for blood flow stasis and exposure to high shear. Using these techniques, we analyzed the feasibility and performance of redo-TAVR combinations. The initial results illustrated the pros and cons of different redo-TAVR combinations in a patient model where BE-in-BE, seems to be the optimal combination of redo-TAVR. However, further analysis on the hemodynamic effect of leaflet overhang associated with BE-in-BE is required.

In summary, this study presented a thorough computational protocol to analyze patient-specific structural and hemodynamic performance and assess thrombogenic risk of redo-TAV combinations and generated knowledge addressing current clinical concerns on THV degeneration and its potential solution, redo-TAVR. These techniques can potentially be used to aid the clinicians in lifetime management of aortic stenosis patients through optimal first and second THV selection.

ELEVATED VWF LEVELS DRIVE THROMBUS INSTABILITY

INTRODUCTION

After a stroke, dual antiplatelet therapy (DAPT) is prescribed to prevent a recurrence of thrombosis. However, 5-10% of patients receiving DAPT experience a recurrent thrombotic event. Patients with high levels of von Willebrand factor (VWF) in their blood often show resistance to DAPT. VWF is critical for hemostasis for it binds to collagen at a wound site and becomes elongated under flow, thereby enabling platelets to adhere to it through their GPIb receptors. Conversely, elevated levels of VWF are associated with thrombotic risk due to excessive amounts of platelet adhesion.

DAPT targets the activation of platelets via thromboxane and ADP, but it may not fully address platelet activation by VWF-mediated mechanotransduction. Shear flow creates a force on the GPIb receptor when a platelet is bound to VWF. This force unfolds the mechanosensory domain of GPIb and triggers intracellular calcium signaling and activation of integrin $\alpha_{IIb}\beta_3$ in platelets for adhesion.

Here, we present a microfluidic approach for examining the effectiveness of DAPT in the context of elevated VWF levels. Our microfluidic approach induces platelets to adhere, aggregate, and activate due to shear flow. Platelet-rich thrombi that form in the microfluidic device are contractile and generate nanoscale forces to hold together. They are also fragile and can detach under high shear flow. Thus, the goal of this work is to examine thrombosis and embolization in the context of elevated VWF and DAPT.

METHODS

Studies on VWF are challenging to perform *in vivo* because manipulating VWF levels may cause unintended changes to an animal's physiology; additionally, VWF function is shear-dependent, but it is difficult to control shear rates *in vivo*. Thus, a microfluidic approach addresses these problems and provides a platform that requires small volumes of blood and low consumption of costly reagents. The design is an adaptation of our previous design [1], but contains one rigid block and twelve flexible posts for spatial resolution of platelet forces within a thrombus (Fig. 1A-B).

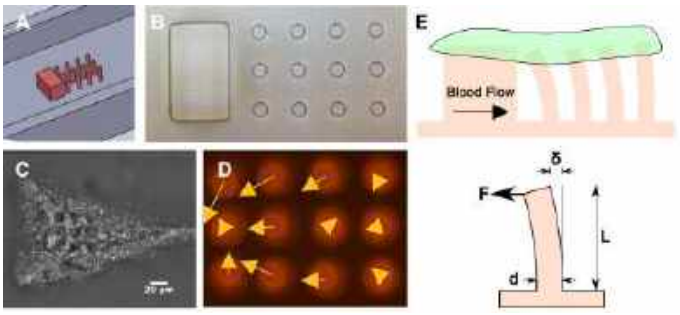

Figure 1: The microfluidic device. (A) Isometric and (B) top views of microfluidic device with one block and twelve posts. (C) Thrombus formed 120 secs after blood entered the channel. Scale bar: 20 µm. (D) High spatial resolution of platelet forces in a thrombus at 120 secs. Yellow arrows are force vectors where $\sum|\boldsymbol{F}| = 478.6\,\boldsymbol{nN}$. (E) Platelets (green) encapsulate the top of the block and post. Post deflection (δ) was measured to calculate platelet forces ($\boldsymbol{F}$) using Hooke's Law ($\boldsymbol{F} = \boldsymbol{k\delta}$), where $\boldsymbol{k} = \boldsymbol{3\pi E d^4/64L^3}$, $\boldsymbol{E}$ is the modulus of elasticity, $\boldsymbol{d}$ is the diameter of the post, and $\boldsymbol{L}$ is the length of the post. [2]

Due to the high shear gradient produced by the rigid block, platelets form a thrombus (Fig. 1C) and generate contractile forces that deflect the posts (Fig. 1D-E). We used the microfluidic device to form platelet-rich thrombi at a wall shear rate of 40,000 s^{-1} for whole blood samples doped with DAPT (0.3 mM acetylsalicylic acid for inhibiting the generation of thromboxane, 10 µM 2-MeSAMP for inhibiting the ADP receptor, $P2Y_{12}$), 50 µg/mL human purified VWF, or both VWF and DAPT. We used quantitative image analysis of brightfield images

to assess platelet aggregation and thrombus stability by the projected area of the thrombi. Additionally, we added FITC-labeled antibodies into whole blood samples to assess platelet activation by granule secretion (P-selectin, 8 µg/mL) and integrin activation (PAC-1, 1 µg/mL). The deflection of the posts was used to assess platelet forces and the drag forces acting on the thrombi.

RESULTS

We find that large thrombi form in all four conditions under the influence of high shear regardless of inhibition with DAPT (Fig. 2A). However, the addition of VWF decreases the stability of the thrombi, leading to frequent detachment events, or emboli (Fig. 2B). Additionally, high VWF levels cause a percentage of thrombi to grow massively large. These emboli are often catastrophic and completely detach from the force sensors (data not shown).

Surprisingly, DAPT did not prevent integrin activation (Fig. 2C) or granule secretion (Fig. 2D), which are both markers of platelet activation. This was unexpected as DAPT is supposed to prevent platelets from activating. However, there are other methods of platelet activation that do not involve soluble agonists, e.g., activation via the GPIb mechanotransduction pathway.

Forces in the opposite direction of flow (contractile force) dominated for the control condition, but drag forces were more dominate when DAPT was added to the sample. This reduction in contractile force with antiplatelet drugs is consistent with what we have observed previously. [1] The drag forces continued to dominate contractile force with the addition of VWF (Fig. 2E). We suspect the dominate drag forces in the high VWF conditions contribute to the instability of the thrombi and frequent detachment events.

DISCUSSION

Our findings suggest that DAPT is not a sufficient suppressant of thrombosis. In a high shear environment, DAPT does not prevent platelet aggregation or activation. When a high VWF concentration is added to the blood, the thrombi become more unstable. Thus, high levels of VWF in a patient can lead to thrombus instability even in the presence of DAPT. These detachment events are consistent with the size of microemboli that are thought to occlude blood flow in the capillaries and arterioles. Furthermore, microemboli are thought to cause damage to areas of the brain and are associated with recurrence of transient ischemic attack and silent strokes.

We hypothesize that the GPIb-mediated platelet activation pathways is able to circumvent any platelet inhibition from soluble agonists. Essentially, platelets bind to VWF via GPIb; VWF also binds to exposed collagen. Under shear flow, the VWF is in tension and pulls on the GPIb receptor, which initiates a mechanotransduction pathway, resulting in platelet activation. Our results suggest this method of platelet activation can overcome other types of inhibition. Additionally, we are curious to explore thrombus formation and instability under lower shear rates. While current stroke treatments may not be effective under certain biological and mechanical conditions, there are not alternatives available. We think it may be more effective to treat thrombosis through other mechanisms, such as VWF self-association, cleavage of VWF into low molecular weight multimers by ADAMTS13, or blocking the GPIb mechanosensory domain. Further investigation is needed to determine the possible effectiveness of these strategies and to identify patients that would benefit from alternate treatments.

This work has three long-term clinical translations: (1) identify better drug targets for individuals with high VWF levels to prevent repeat ischemia and (2) provide additional metrics and diagnostic tests, e.g. protein levels and thrombi behavior under flow, for evaluating how a stroke patient should be treated for more personalized medicine. (3) The microfluidic technology described, could be a point-of-care device to determine a patient's thrombotic risk before ischemia occurs.

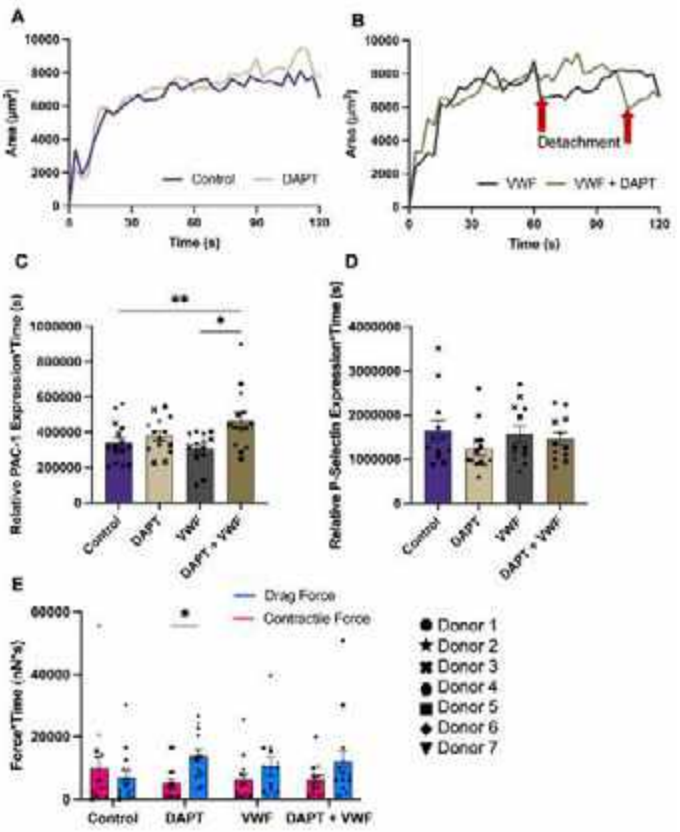

Figure 2: Results of microfluidic experiments. (A) Area vs. time for control and DAPT samples. (B) Area vs. time for VWF and VWF + DAPT samples. Red arrows represent detachment events. (C) Integral of PAC-1 expression vs. time, normalized by area. (D) Integral of P-Selectin expression vs. time, normalized by area. (E) Integral of the positive x-component of force (drag force) and negative x-component of force (contractile force) vs. time. Each symbol represents a unique donor. Statistics were determined using a mixed-effects model with post-hoc analysis (*p < 0.05, **p < 0.01).

INTRODUCTION

Osteoarthritis (OA), a debilitating condition affecting millions of individuals, is characterized by the breakdown of hyaline cartilage, a biphasic, poroviscoelastic tissue, enabling smooth, low friction locomotion of joints. Hyaline cartilage is primarily comprised of a negatively charged sulfated glycosaminoglycans (sGAG) matrix interspersed within a type-II collagen (COL) fibril network and interstitial water, providing remarkable rheological and tribological properties necessitated for joint function. OA progression initiates with sGAG loss, followed by COL matrix breakdown and tissue swelling.[1] As such, many emerging treatments aim to recapitulate this dynamic, multi-component structure of native cartilage to restore healthy joint mechanical functionality and biochemical properties.

One particularly promising treatment is cartilage tissue engineering (CTE), whereby isolated chondrogenic cells are typically seeded in a resorbable scaffold material or pelleted. CTE workflow incorporates a brief 2–6-week *in vitro* culture period of the formed tissue construct in a chondrogenic milieu prior to implantation at the patient's OA-afflicted joint site. CTE outcomes often widely vary on an experimental basis determined by cell source, cell density and scaffold material among other factors.[2] A significant impediment in advancement of CTE treatments is the lack of non-destructive techniques capable of longitudinal assessments of evolving neocartilage composition, structure, and material properties both *in vitro* and *in vivo*. Conventional biochemical assays, histopathological assessments and immunohistochemistry used for *in vitro* growth monitoring are destructive, restricting clinical use, while arthroscopic tissue grading systems (Outerbridge, ICRS) and/or MRI (T1rho, T2*) used for *in vivo* assessments only moderately correlate with tissue biochemical distribution and material properties.

Spectroscopy analysis can successfully bridge this gap for repeated, non-destructive, and highly specific quantification of CTE biochemical content and material properties both *in vitro* and *in vivo*. Raman spectroscopy is an inelastic light scattering technique reflecting vibrational modes of different molecular bonds (amides, sulfates, hydroxyls) that comprise the major cartilage ECM constituents: sGAG, COL, H_2O. We have developed a Raman spectroscopic needle probe (**Fig.1A)** and unique spectral analysis platform capable of extracting ECM-specific compositional biomarkers indicative of the material properties of native and TE cartilage[3-5] (**Fig.1B-C**). In this study, we demonstrate the ability of Raman spectroscopy-derived biomarkers in longitudinal monitoring of evolving TE neocartilage composition utilizing a range of different scaffold materials: agarose, collagen, polyethylene glycol (PEG), hyaluronic acid and scaffold-free.

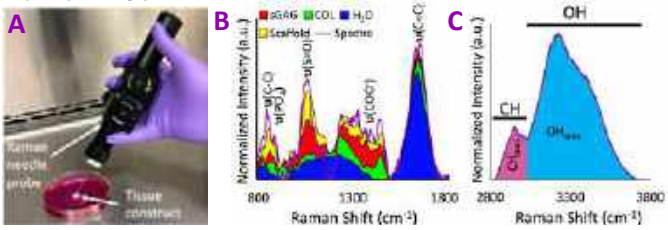

Figure 1: (A) Raman needle probe. (B) Cumulative contribution of ECM constituents and hydrogel scaffold to construct fingerprint spectra. (C) Organic content (CH_{area}) and water (OH_{area}) associated bands within construct highwave spectra.

METHODS

Tissue constructs: Immature bovine chondrocytes were isolated and seeded at a density of 30×10^6 cells/mL in hydrogel scaffolds of agarose (2% w/v; type VII), collagen (3mg/mL; rat tail type-I), or PEG (10% w/v; 4-arm PEG thiol + 4-arm PEG acrylate), or hyaluronan (HA; 2% maleimide-functionalized HA crosslinked with 4-arm PEG thiol) to generate ∅4×2mm cylindrical plugs, or assembled in a scaffold-free pellet (4×10^6 chondrocytes). All constructs were cultured in chondrogenic medium ± TGF-β3 (10ng/mL) for the initial 2 weeks,

except for scaffold-free constructs (cultured -TGF-β3) and PEG constructs (cultured +TGF-β3). Constructs were removed weekly (n=6 per scaffold per TGF-β group) for Raman, mechanical, and biochemical analysis for 56 days for agarose, biweekly for 42 and 56 days for HA and PEG, and weekly for 28 days for other scaffolds. **Raman probe:** A fiber-optic Raman probe (∅10mm; RIP-RPB, OceanOptics) coupled to a NIR diode laser (ex=785nm, 125mW) and a spectrometer (QEPro, OceanOptics). Spectra were collected with the probe focused ~10mm from the construct surface for a 30s exposure. **Spectral analysis:** Construct spectra were divided into fingerprint (800-1800cm^{-1}) **(Fig.1B)** and high-wavenumber regions (2800-3800cm^{-1}) **(Fig.1C)**. The fingerprint region was fit to a multivariate linear regression model:

$$Construct_{spectra} = sGAG_{score} * (sGAG_{REF}) + COL_{score} * (COL_{REF}) + H_2O_{score} * (H_2O_{REF}) + Scaffold_{score} * (Scaffold_{REF}) \quad (1)$$

where $sGAG_{REF}$, COL_{REF}, H_2O_{REF}, and $Scaffold_{REF}$ are reference spectra of purified powder chemicals for each constituent. Biomarker "scores" are regression coefficients reflecting relative contributions of constituents to the composite spectra (**Fig.1B,2A**). In the high-wavenumber region, the area under the OH & CH peaks (OH_{area} & CH_{area}) reflect tissue hydration and organic content deposition (**Fig.1C**)[5]. No $Scaffold_{REF}$ was used for collagen scaffold constructs and a dried cell pellet was used for scaffold-free constructs. **Tissue analysis:** Compressive Young's modulus (E_Y), H_2O content (gravimetric), sGAG content (DMMB) and COL content (OHP) were measured.

RESULTS

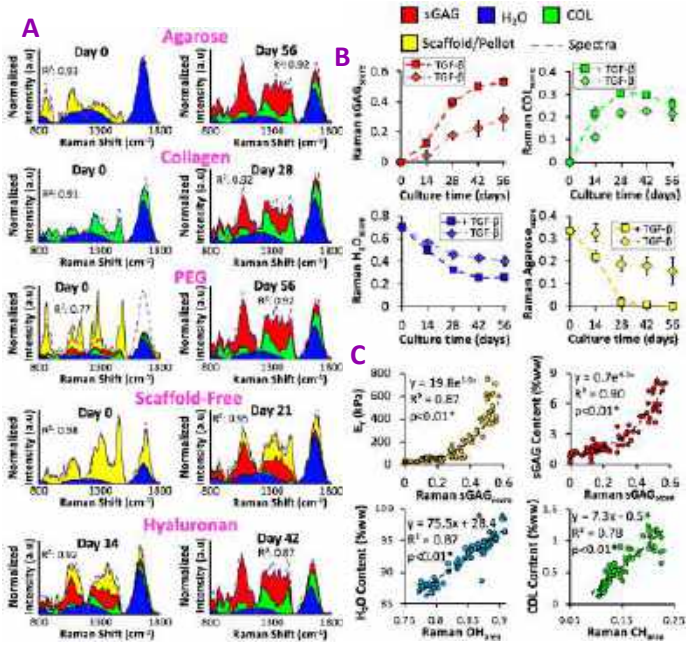

Figure 2: (A) 2D stacked area plots of early/late timepoint constructs depicting contribution of ECM and scaffolds to spectra for each scaffold type, (B) Raman "score" progression, (C) correlation of Raman biomarkers vs E_Y and biochemical content.

Our multivariate regression model reconstructions accounted for 91% ± 4% of the variation in the acquired construct Raman spectra across all scaffolds. For all scaffolds, Raman sGAG and COL biomarker scores increased over time, while H_2O and scaffold scores mostly decreased (H_2O trend not observed for scaffold-free) (**Fig. 2A-B**). Raman $sGAG_{score}$ accounted for 90%, 74%, 76%, 64% and 78% of the variation in sGAG content in agarose, collagen, PEG, scaffold-free and HA, respectively (**Fig.2C & Table 1**). For H_2O content, Raman OH_{area} accounted for 87%, 75%, and 77%, 64% of the variation in agarose, collagen, PEG and HA, respectively, but was not correlated with scaffold-free constructs (p=0.17). For COL content, CH_{area} predicted 78%, 58%, 54%, 54% and 70% of variation for agarose, collagen, PEG, scaffold-free and HA respectively. Raman $sGAG_{score}$ accounted for 87% and 63% of the variation in E_Y for agarose and collagen constructs respectively. Multivariate linear regression combining $sGAG_{score}$ and OH_{area}, improved predictions of the variation in E_Y for collagen scaffold constructs (63% to 77%) and predictions of the variation in sGAG content (64% to 90%) for scaffold-free constructs.

Scaffold	Tissue property	Raman scores

Table 1: Correlations for Raman biomarkers versus assay measured biochemical content and material properties. *p<0.05.

DISCUSSION

Extracted ECM-specific Raman biomarkers allowed for successful longitudinal monitoring of newly deposited ECM (sGAG, COL) and distinction between ECM and a range of scaffold materials with unique spectral signatures, including natural carbohydrates (agarose, HA), natural protein (collagen), and synthetic polymer (PEG) or scaffold-free. Combining biomarkers further improved E_Y and sGAG content predictions. The Raman probe adopted in this study is ideal for *in vitro* monitoring of neocartilage owing to its high spectral collection efficiency and long-distance lens offset from the construct surface. A subsequent study (not shown) exhibited similar biomarker progression, with no cell viability or E_Y loss following weekly, aseptic repeated-measure Raman acquisition of live constructs. Previously, we demonstrated a Raman needle probe (∅2mm, **Fig. 1A**) configured for arthroscopic assessments of cartilage can achieve similar accuracy predicting agarose-scaffold CTE neocartilage composition and material properties (R^2=0.72-0.88)[5], demonstrating *in vivo* monitoring capability in preclinical large animal models and clinically in second-look arthroscopy. Ultimately, this study exhibits a Raman analysis platform successful in monitoring evolving neo-cartilage composition germane to its material properties across a wide variety of CTE protocols, providing the field with a non-destructive, quantitative, and highly sensitive technique for longitudinal *in vitro* and *in vivo* assessments, heretofore to be seen for CTE or other OA treatment modalities.

A MICROMECHANICS BASED MULTISCALE MODEL FOR PLATELET-DRIVEN CLOT CONTRACTION

Chayut Teeraratkul (1), Debanjan Mukherjee (1)

(1) Paul M Rady Department of Mechanical Engineering, University of Colorado Boulder, Boulder, CO, USA

INTRODUCTION

Blood clots undergo a significant extent of volume shrinkage after formation, a phenomenon commonly referred to as clot contraction or retraction. Contraction is driven by activated platelets within the clot, and is related to several key patho-physiological roles. For instance, clot contraction enables forming a tight seal around damaged vascular sites preventing blood loss during hemostasis [1]. Additionally, impaired contraction can be related to embolism risks that underlie severe conditions like acute ischemic stroke [2] and venous thromboembolism. Despite its significance, platelet-driven clot contraction biomechanics remains poorly understood. This is partly due to a lack of existing quantitative approaches that can sufficiently characterize the heterogeneous, multiscale, contraction dynamics originating from microscale contractile activity [3]. Currently, a common methodology to study clot contraction involves taking successive images of whole blood clotting in a cuvette (*in vitro*) [4, 5]. These experiments can be costly to setup [5] and the results are limited to clot contraction kinematics. Micro-scale experimental characterization of platelet contractile forces [6] and fibrin-platelet interactions [1] have been demonstrated; yet extrapolation of these to quantify macroscale contraction behavior is non-trivial. There is presently no viable avenue to obtain information regarding the local state of flow during contraction and the local state of stress inside the clot; both of which are intimately tied to clot structure, clot stability, embolization risks, and resistance to lysis. Furthermore, it remains difficult to accurately recreate the complex human *in vivo* clot-flow interactions in a vessel using *in vitro* experiments. Recent advances in computational modeling can enable viable alternatives to address this gap. In this contribution, we propose an *in silico* modeling approach for clot contraction. This methodology is based on a mesoscopic discrete element clot model coupled with a custom finite element method for fluid flow. We establish here that our technique can robustly capture macroscale contraction behavior, local state of flow, and state of stress in the clot specimen.

METHODS

Discrete element approach for contraction micromechanics: In our methodology, the clot domain is represented by a statistically representative ensemble of discrete particles, with fiber connectors connecting between each particles. Together, these represent a mesoscopic coarse-graining of platelets and fibrin strands which constitute the blood clot. Individual discrete elements interact with each other via inter-element near-field and contact forces, as well as contractile forces along the fiber connectors. The resulting particle dynamics equations are numerically integrated using a Leap Frog scheme.

Platelet-driven contraction force: A time-varying contraction force is applied along the connectors direction which connects the discrete elements. The contraction force model is based on data for single-platelet force which is experimentally obtained from *in vitro* measurements in [6]. This individual platelet-driven contraction force is then coarse-grained into the model as a multiple of the measured force times the platelet-fiber connection density in each discrete elements.

Dynamic coupling with background flow: Each individual mesoscopic discrete element is in turn two-way coupled with the background fluid flow using a custom fictitious domain immersed finite element method. Briefly, a Petrov-Galerkin stabilized finite element algorithm is modified by applying a fluid-particle interaction force at each particle location. This can simultaneously resolve contraction dynamics and associated background flow interactions with the clot.

RESULTS

Proposed method replicates *in vitro* clot contraction kinematics: First, we aim to replicate the 3-phase clot contraction kinematics as observed in [4]. An initial clot filling a cuvette of dimension $7mm \times 12mm \times 1mm$ is reconstructed as a mesoscopic discrete element ensemble, with an average element size of $0.1\ mm$. Each discrete element is connected to its nearest neighbors (*here we chose 4 nearest neighbors*) with a connector. Cuvette walls are treated as impermeable walls, and the top of the clot sample is held fixed, mimicking a surface tension effect noted in the experiments. Resulting *in silico* contraction dynamics is shown in Figure 1 a1-a4. We establish that the resulting clot contraction kinematics (Figure 1.c.) can capture the 3-phase contraction behavior as described in prior works (see Figure 1.b.). We note that an exact quantitative matching

of contraction and contraction rate was not our goal as that would require tuning against exact experiment blood sample data which we did not possess.

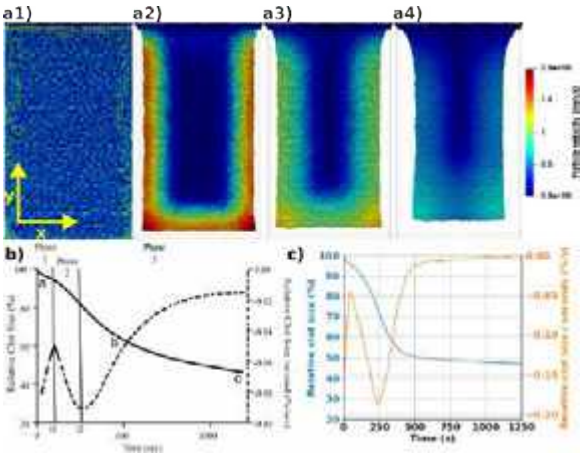

Figure 1: Discrete element simulation of clot contraction in a cuvettes. Panels a1-a4 show the clot at each time point during contraction. The transition from panel a1 to a2 show the lag time in contraction associated with contraction phase 1 in the contraction kinematics shown in panel b). Panel b) show the clot contraction kinematics observed in [4]; panel c) demonstrate the the discrete element representation can capture all 3 phases of the clot contraction kinematics.

Proposed method recovers effective stress during contraction: With the mesoscale representation of the micromechanics of the contraction, we can further post-process the interaction forces across the discrete element ensemble to estimate an effectivs state of internal stress during contraction. The stress is computed using an averaging of the interaction forces across the ensemble as illustrated in Figure 2 (*inset*), where $\underline{\mathbf{l}}^{qp} = \underline{\mathbf{x}}^q - \underline{\mathbf{x}}^p$ is the vector pointing from discrete element p to discrete element q in the ensemble, and the force vector $\underline{\mathbf{f}}^{pq}$ is the pair-wise interaction force between elements p and q; N_v is the total number of particles in the volume V. The resulting stress evolution for the contracting clot represented in Figure 1, is illustrated in Figure 2. We note that the overall state of stress is dilatational, with the shear/deviatoric components approx 4 orders of magnitude lesser (*not shown here for brevity*). Figure 2 presents the normal stress components along x and y (*indicated in Figure 1*), which are compressive stresses that increase as clot contraction progresses, which is intuitively expected.

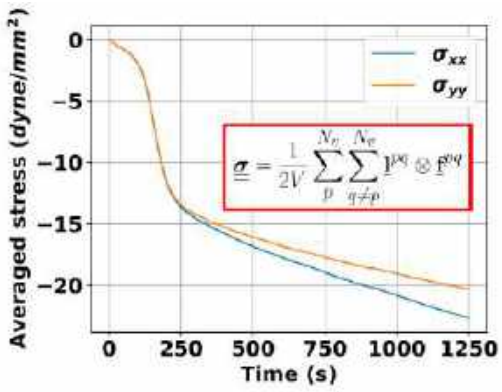

Figure 2: Effective stress state of the discrete element representation of the clot contracting in a cuvette.

Proposed method resolves local flow during contraction dynamics: We present an additional case-study for an idealized 2D hemispherical clot (radius 3 mm) immersed in an initially stagnant background flow, constrained within a channel with impermeable walls (width 6 mm). The fluid density is $\rho = 1.06 g/cu.cm$ and dynamic viscosity is $\mu = 4cP$, matching that of blood. The clot represents a 50% occlusion of the channel. As contraction initiates, the resulting dynamics squeezes out flow from the interstitial space into the clot exterior. Figure 3 shows 4 successive time snapshots of this contraction-mediated expulsion flow. At the initial contraction phase, we get a larger extent of flow expulsion. As contraction progresses, clot porosity rapidly reduces leading to a tightly packed clot, and continuously decreasing extent of fluid expulsion. These demonstrate the high resolution flow information during contraction that our method can quantify; information that is otherwise challenging to obtain *in vitro*.

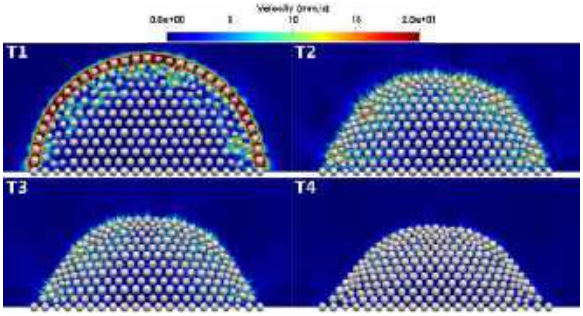

Figure 3: Expulsion flow due to clot contraction across multiple time steps during the simulation. T1 is the early step of the contraction process; T2 show the squeeze flow emanating out of the clot due to contraction; T3 and T4 subsequently correspond to clot approaching equilibrium, resulting in an increasingly tightly compressed clot.

DISCUSSION

Here we have demonstrated a novel *in silico* micromechanics based multiscale model for platelet-based clot contraction. Microscale platelet-level forces are integrated to define the discrete element interactions, and resulting emergent behavior consistently captures the 3-phase clot kinematics as observed experimentally. Owing to the discrete representation of the clot structure, heterogeneities such as spatial porosity evolution within the clot during contraction can be readily obtained (as opposed to continuous media representation of clots). We demonstrate that our proposed method can offer insights into quantities that are otherwise difficult to measure in experiments such as stress in the clot, and squeeze or expulsion of flow during contraction. The results from the case-studies indicate that our *in silico* model can potentially be used to study human blood clot contraction under physiologically realistic flow conditions, an endeavor that is currently not possible experimentally. Additionally, for existing *in vitro* assays or experiments, the proposed *in silico* approach can be used as a virtual twin to rapidly evaluate a range of *what if* scenarios for experiment design, and parameter evaluations. Continued development and refinement of this modeling approach will focus on conducting uncertainty quantification and parameter sensitivity analysis for model parameters, and on systematic contraction biomechanics studies using data-integration from experiments.

A NEW STRATEGY TO ENHANCE RADIOFREQUENCY ABLATION WITHIN THE LOW ELECTRICAL CONDUCTIVITY REGION OF ATHEROSCLEROTIC PLAQUE: A MATHEMATICAL MODELING

Ruizhe Hou, Hongying Wang, Shiqing Zhao, Aili Zhang

School of Biomedical Engineering, Shanghai Jiao Tong University, Shanghai, China

INTRODUCTION

Radiofrequency (RF) ablation of the atherosclerotic plaque has been proven to lead to a major reduction in local smooth muscle cell content. However, there is a large amount of macrophage foam cells would hinder the delivery of electric current and the conduction of heat generated due to the 'oven effect' caused by the containing lipids with lower electrical and thermal conductivity than normal tissue[1, 2], which brings a great challenge to the ablation of the plaque rich of lipid.

To effectively ablate the lipid core, a new RF heating strategy utilizing the collaborative control of the RF sensitizer-loaded thermo-sensitive nanoparticles and a specialized temperature field was proposed to adjust the ablation shape and depth. The role of sensitizers is to enhance the apparent electrical conductivity of tissue by increasing the concentration of free ions in the extracellular space and the thermo-sensitive nanoparticles would break after being heated to a certain temperature so that sensitizers would be released effectively in the target area, reducing their accumulation and damage to healthy tissue. The specialized temperature field was used to reshape the distribution of the sensitizers based on the temperature dependence of its diffusivity.

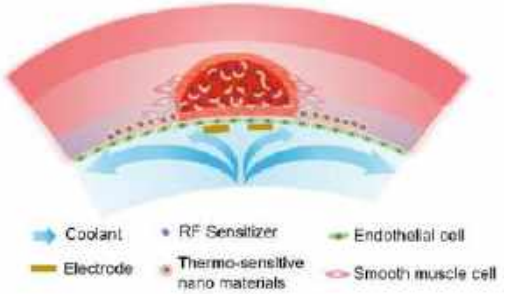

Figure 1: Schematic illustration of the ablation shape controlled by RF sensitizer-loaded thermo-sensitive nanoparticles and the specialized temperature field

METHODS

To evaluate this new strategy, the finite-element method was used and a 2D model that coupled RF propagation, heat transfer, and mass transport of both the nanoparticles and the sensitizers was created with COMSOL Multiphysics 5.4. The model consisted of the blood vessel with intima, media, adventitia, lipid core, and peripheral tissue.

The RF propagation in tissue is:

$$\nabla \cdot (\sigma \nabla V) = 0 \quad (1)$$

The heat-transfer equation was adapted:

$$\rho c_P \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + Q_e \quad (2)$$

where Qe represents the heat generated by RF current and can be expressed as[3]:

$$Q_e = \sigma_{p,i} (\nabla V)^2 \quad (3)$$

It's noted that the apparent electrical conductivity ($\sigma_{p,i}$) of tissue is sensitizer-dependent. A linear relationship was applied to describe the positive correlation between $\sigma_{p,i}$ and the concentration of free sensitizers c_{fd} and it's based on the original electrical conductivity σ_i of different tissues:

$$\sigma_{p,i} = A * c_{fd} + \sigma_i \ (i = vessel, lipid, peripheral\ tissue) \quad (4)$$

in which A is the experimental constant obtained from [4].

The thermo-sensitive nanoparticles are designed to release their contents rapidly upon heating. The extracellular concentration of the released drug c_{fd} and encapsulated drug c_{ed} were modeled as[5]:

$$\frac{\partial c_{fd}}{\partial t} = \nabla \cdot \left(D_{fd} \nabla c_{fd}\right) + c_{ed} K_{rel} \quad (5)$$

$$\frac{\partial c_{ed}}{\partial t} = \nabla \cdot (D_{ed} \nabla c_{ed}) - c_{ed} K_{rel} \quad (6)$$

Here, D_{fd} is the diffusion coefficient of the released drug that is temperature-dependent[6]:

$$D_{fd} = 1.1924 e^{-6} \cdot \exp(-2387/T) \quad (7)$$

K_{rel} refers to the drug release rate calculated from the in-vitro data.

The special temperature field was used to control the release and the diffusion process of the RF sensitizers and nanoparticles, and it was applied as the input boundary condition for the control equations (2) and (3).

RESULTS

As Fig2 a-c shows, when freely diffusing (FD) at body temperature, the pure sensitizers (S) can move to a depth more than just covering the lipid core within 120s. In the case of the RF sensitizer-loaded thermo-sensitive nanoparticles (S-TSNP, Fig2 d-f), after the same time, the released free drug only accumulated near the inner wall of the blood vessel, reaching the lower boundary of the lipid core since the weak release of nanoparticles at 37℃.

When a specialized temperature field (STF) was applied with a couple of electrodes and the coolant on the inner surface of the vessel, the tissue away from the electrodes was cooled while the closer was heated (Fig3 a). Thus, the diffusion of pure sensitizers was more intense in the depth direction in the region between the two electrodes. As for nanoparticles, the concentration of free drug on both sides of the electrode pair was significantly reduced and the distribution range was restricted to the edge and the central area of the electrode pair.

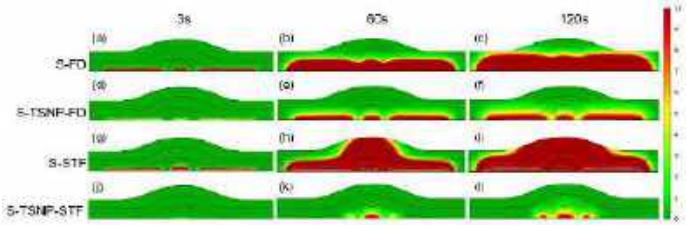

Figure 2: Distribution of free drug with or without a specialized temperature field. Unit: mol/m^3.

Figure 3 shows the temperature distribution of ablation of different cases and the area included in the white lines indicates the ablation margin with a temperature over 60℃.

Compared to the treatment with the specialized temperature field but without the drug (Fig3 a-c), the application of free sensitizer expanded the ablation area greatly in several seconds which penetrated the entire vessel wall by forming a 'deep-pit-like' ablation zone without endothelium protection and extended further in the axial direction of the vessel (Fig3 d-f). However, the use of thermo-sensitive nanoparticles could restrict the destroyed area with the formation of a 'scallop-shaped' ablation zone that covered the lipid core (Fig3 g-i), which had an ablation depth of 0.99mm within the region of media and protection of endothelium of 0.179mm. The lipid ablation ratio (%) could reach up to 70% while none could be ablated in STF and 56.5 times the ablation area in S-STF (Fig4).

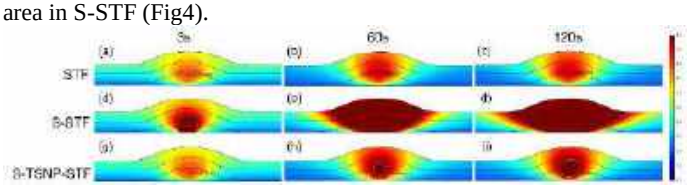

Figure 3: Temperature distribution of ablation processes without drug (a-c), with free drug (d-f), and with nanoparticles (g-i) under a specialized temperature field. Unit: ℃.

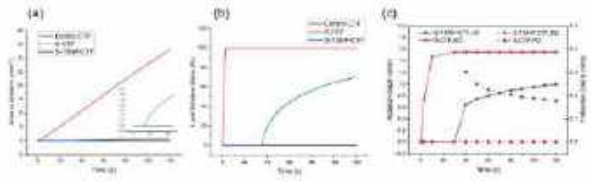

Figure 4: Spatial distribution of free drug with or without a specialized temperature field.

By analyzing the electrical parameters, it was shown that the free sensitizers increased the electrical conductivity and reduced the electric field gradient at the edge of the lipid core significantly, resulting in higher energy conversion efficiency from electromagnetic energy to heat to more area including the lipid core and deeper places in the vessel wall (Fig 5). As for thermo-sensitive nanoparticles, the area of electrical conductivity improvement was limited to the thickened intima and the lipid core (0.11S/m vs 0.04S/m for lipid with and without TSNP, respectively), and the electric field gradient decreased in the core, resulting in more deposition of RF energy in the plaque.

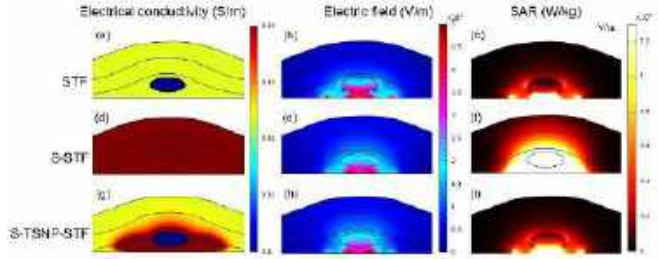

Figure 5: Distribution of electrical conductivity, electric field, and SAR without the drug (a-c), with free drug (d-f), and with nanoparticles (g-i) under a specialized temperature field.

DISCUSSION

With the specialized temperature field, the thermo-sensitive nanoparticles only release RF sensitizers in the center region of the electrodes due to the heat generation of RF current in tissue, and reduce the damage to healthy tissue caused by an ion-overload and a surge of extracellular osmotic pressure due to the excessive ion enrichment on both sides of the electrode pair comparing with the pure free sensitizers' delivery. Simultaneously, the released sensitizers can enhance the electric-to-heat energy conversion efficiency and ablate a major area of the lipid core successfully by increasing the electrical conductivity and decreasing the electric field gradient of the targeted area. Most importantly, effective protection of endothelium and restricted ablation depth and width would not destroy the adventitia and normal part of the vessel due to the controlled drug release and diffusion, which would reduce the risk of restenosis and blood vessel perforation.

Consequently, the new strategy combining a specialized temperature field and the RF sensitizer-loaded thermo-sensitive nanoparticles to enhance the radiofrequency ablation of low electrical conductivity region of atherosclerotic plaque was proved to be feasible mathematically.

In the future, other drugs with abilities like lowering cholesterol levels such as statins could be also loaded in the thermo-sensitive nanoparticles and accumulate to the lipid core directly by this new drug-delivery strategy, resulting in a synergistic effect between RF ablation and chemotherapy.

AGED TENDONS HAVE A HIGHER STRAIN THRESHOLD FOR STIMULATION FROM DYNAMIC COMPRESSION THAN YOUNG TENDONS

Samuel J. Mlawer (1), Brianne K. Connizzo (1)

(1) Department of Biomedical Engineering, Boston University, Boston, MA, USA

INTRODUCTION

Rotator cuff tendinopathy affects over 50% of the population above that age of 60 and is characterized by pain and impaired daily performance [1]. The cause of rotator cuff tendinopathy is multifactorial with previous studies reporting that external impingement of rotator cuff tendons is one of major mechanisms that influences disease onset and progression [2]. While we know that both age-related degenerative changes and external compression influence tendon disease, it is often difficult to decouple these effects *in vivo*. We previously developed an *in vitro* murine explant culture model [3] to examine the effects of a single acute compressive injury [4] on tenocyte health, demonstrating a lack of adaptive response in aged tendons. However, it is more physiologically relevant to consider repeated compressive loading. Therefore, the purpose of this experiment was to use our previously developed *in vitro* compressive injury model to explore the response of tendon to continuous dynamic compressive loads and to discover the effect that age has on this response. Like our work with single acute compressive loads, we expected to see a greater adaptive response in the young mice compared to explants harvested from aged mice.

METHODS

Flexor digitorum longus tendon explants were harvested from young (4 months) and aged (22-24 months) male mice. After harvest, tendons were immediately loaded into grips with a 10-mm gage length and placed into custom-built multiaxial loading bioreactor (Fig. 1). All explants were held at 3% static tensile strain throughout the culture period. The acute injury ("AI") group was pre-loaded in compression to ensure contact, compressed to 50% strain over 1 second, and then the compression was released. The 15% and 50% groups received dynamic compressive loading at their respective strain levels 1 Hz for 1 hour, four times a day, with a rest period of 5 hours between each loading cycle. We also had a non-compression ("NC") group that received only the initial static tensile strain. After one week, metabolic activity was measured through a resazurin reduction assay. Tendons were then removed from culture, digested, and assayed for total DNA content (PicoGreen), sGAG content (DMMB), and collagen content (OHP). Synthesis of sGAG and collagen were measured respectively via incorporation of ^{35}S-Sulfate and ^{3}H-Proline radiolabel [3]. All biochemical assays were normalized to explant dry weight. Statistical analyses were performed via two-way ANOVAs with Bonferroni post-hoc corrected t-tests where significance was set at $p<0.05$ (* or solid lines).

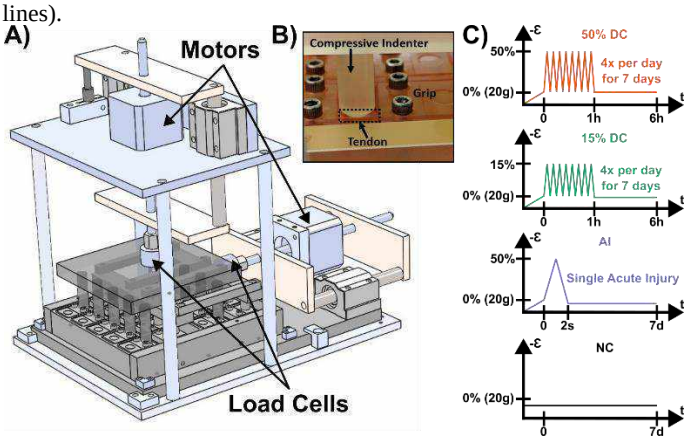

Figure 1. (A) Labelled biaxial loading device with (B) a close-up showing a single well with a tendon being compressively loaded and (C) the compressive loading profiles for each group.

RESULTS

In young explants, metabolic activity in the 15% group was significantly higher than all other groups. Metabolic activity was also lower in the 50% group than the NC group. In aged explants, the 50% group had higher metabolic activity than the NC and AI groups and the

AI group also had decreased metabolic activity compared to the NC group. DNA content was higher in the AI group than the 15% and 50% groups in young animals and higher than the 15% group only in the aged animals.

sGAG content was higher in the AI group compared to other groups in young explants, while there were no differences in groups in aged explants (Figure 2A). In young explants, sGAG synthesis is higher in the 50% and AI group compared to both the NC and 15% group. In aged explants, the 50% group stimulated sGAG synthesis but it was only significantly higher than the NC group (Figure 2B). Both age groups have similar results in collagen content with elevated content in the 50% group compared to other groups. In young groups, collagen synthesis was higher in the AI group than the NC group. In the aged groups, collagen synthesis in the 15% and 50% groups were lower than NC.

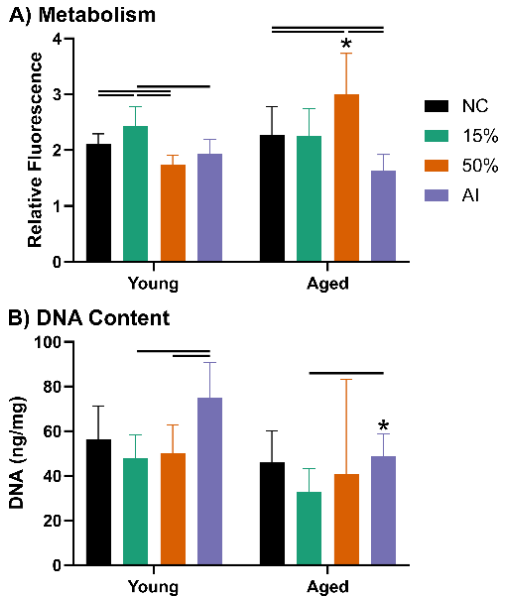

Figure 2. Measurements of (A) metabolic activity and (B) DNA content in the young and aged explants at a variety of strain levels. Data is presented as mean ± 95% confidence interval. Significance between strain levels is denoted with a bar (-) and significance between age groups is denoted with a star (*).

DISCUSSION

Our previous studies on the effects of acute injury on tendon concluded that aged tendons lacked the adaptive response that was found in young tendons [4]. In this study, where we instead look at the effects of dynamic compression, we see differential adaptive responses in both age groups to our two dynamic strain levels. In young mice, we see an increase in metabolic activity due to 15% strain, but in aged mice we only see an increase from 50% strain. This implies that aged mice have a higher strain threshold for stimulation, perhaps due to repeated compressive loads throughout their life cycle muting the adaptive response to smaller loads. This could also be related to insufficient stimulation of glucose metabolism, which appears to be mechanically regulated in tendons, and decreases as mice age [5].

We also found that high compressive strain regardless of timing (AI and 50% DC) stimulated sGAG synthesis in the young groups, while only repeated loading (50% DC) resulted in the same phenomena for aged tendons. Excess sGAGs are often a symptom of tendinopathy, but sGAG accumulation also better regulates fluid flow to help tendon better resist future compressive loads. This suggests that aged tendons may require more sustained loads to stimulate adaptive remodeling. We also saw a reduction of collagen synthesis in both dynamic compression groups, which implies that aged tendon exhibits an inappropriate adaptive response that could leave tendons predisposed to chronic use injuries. In contrast, young tendons exhibit no change in collagen synthesis with dynamic compression.

In summary, we demonstrate age-related differences in the response to dynamic compressive loading leading to aberrant matrix turnover. Aged tendons require higher and more sustained loads than young tendons to adapt, perhaps due to enduring and adapting to repeated compressive loads throughout their longer lifetime. Future studies will aim to use more comprehensive and specific proteomic assays to determine the exact timing and profile of ECM turnover. In addition, we plan to determine the role of sex in the response to compressive injury. We also plan to look at the effects of different loading frequencies and durations to determine how these conditions effect the biological response, and further explore compression versus tension-mediated signaling pathways.

Regardless, our explant system allows us to examine tendon's long-term response to a variety of compressive loading conditions. Our objective is to use this system to identify the main factors involved in tendon degeneration due to compressive damage, and to better understand mechanisms of mechanical adaptation in this complex and multiaxial loading environment. Beyond that, this information could be used to establish rehabilitation strategies or to identify potential signaling pathways relevant to efficient ECM turnover that can be targeted for therapeutics.

SELECTION OF LOADING CONDITIONS FOR RELIABLE VIRTUAL MECHANICAL TESTING OF BONE FRACTURE HEALING IN SHEEP AND HUMANS

Mehran Bahrami (1), Kylie Frew (1), Hannah L. Dailey (1)

(1) Mechanical Engineering & Mechanics, Lehigh University, Bethlehem, PA, USA

INTRODUCTION

In preclinical models of fracture healing, torsional loading is the postmortem mechanical test of choice because it is not sensitive to errors arising from specimen malalignment. Bending and axial loads are arguably more physiologically relevant, but those tests are highly sensitive to alignment due to the natural shape variations in long bones. The irregular curved contours of the diaphysis make repeatable alignment for bending tests difficult to achieve. Curvature along the bone axis also makes achieving pure axial loading without any bending very difficult in experiments. For these reasons, we previously validated our methods for image-based virtual mechanical testing of fracture healing using postmortem physical torsion tests.[1] In a clinical setting, we have also used virtual torsion tests to measure human tibial fracture healing under normal healing conditions.[2] However, the relevance of the torsional test for predicting whole-bone mechanics under physiologic loads is unknown. Accordingly, the purpose of this study was to assess the strength of association between virtual torsion, axial, and bending tests conducted under highly controlled virtual alignment conditions. We developed a methodology for virtually measuring the bending flexural rigidity and axial stiffness of fractured long bones using ovine and human data. The study hypothesis was that virtual axial stiffness (VAS) and flexural rigidity (VFR) are strongly correlated with virtual torsional rigidity (VTR) and capable of detecting differences in healing outcomes ranging from nonunion to fully healed.

METHODS

Two datasets were used in this analysis: ovine tibial osteotomies and human tibial fractures. The study protocols were reviewed and approved by the local ethical committees. The sheep (N = 23) were all stabilized by medial plating, with osteotomy defect sizes from 3-mm to 17-mm with allograft.[2] Postmortem (9 and 12 weeks) micro computed tomography (μCT) scans were down-sampled to 400 μm isotropic resolution. The clinical fractures (N = 29, 7 female, 22 male) were prospectively recruited from a single Level I trauma center and CT scanned at 12 weeks post-op.[2] Clinical scans had an average in-plane resolution of 0.41 mm and average thickness of 1.2 mm. All human patients were treated by intramedullary (IM) nailing.

Scans were processed in Mimics Innovation Suite (v.23, Materialise Inc.) to reconstruct 3D models of the fractures. Regions of cortical bone and callus were thresholded, volumetrically reconstructed, and meshed with quadratic tetrahedral (tet10) elements. All models were carefully aligned to the global coordinate system. Elementwise elastic moduli (E) values were specified using species-specific scaling equations:

$$\text{Human:}\quad E = 0.00704 \times HU \times 1000 \quad [\text{MPa}] \tag{1}$$

$$\text{Ovine:}\quad E = \begin{cases} 10225 \times \left(\frac{\rho_{QCT}}{1000}\right) & \rho_{QCT} > \rho_{cut} \\ 50 & \rho_{QCT} < \rho_{cut} \end{cases} \quad [MPa] \tag{2}$$

$$\rho_{QCT} = 0.38010 \times HU - 7.37444$$

where HU is Hounsfield unit value and ρ_{QCT} is phantom calibration radiodensity.[1]

Finite element (FE) models were exported to ANSYS Workbench Mechanical (R2020, ANSYS Inc., Canonsburg, PA) for virtual mechanical testing. Bending, torsional, and axial loading scenarios were applied to the models (**Figure 1**). Virtual flexural rigidity (VFR) was calculated as follows:

$$VFR = M_b \rho \quad [\text{N.m}^2] \tag{3}$$

where M_b = 31 N-m is the applied bending moment (see **Figure 1c**) and ρ is the bent radius of the curvature of the model. Bending direction was set by defining a local reference coordinate system at the distal end plane. Radius of curvature (ρ) was calculated using a custom MATLAB code that found the line produced by the intersection of the proximal and distal cut surface planes in the deformed model and calculated the distance from this intersection line to the FE model centerline (see **Figure 2**). Virtual torsional rigidity (VTR) was calculated as:

$$VTR = \frac{M_T L}{\phi} \quad [\text{N.m}^2/^\circ] \tag{4}$$

where M_T is the reaction torque calculated in the model, L is the working length of the test segment, and ϕ is the applied 1° angle of twist. Virtual axial stiffness was calculated as:

$$\text{VAS} = \frac{\delta_z}{F_z} \quad \text{[N/mm]} \qquad (5)$$

where δ_Z is the z-deformation of the proximal surface and F_z is the axial load (670N for sheep and 2175N for humans).

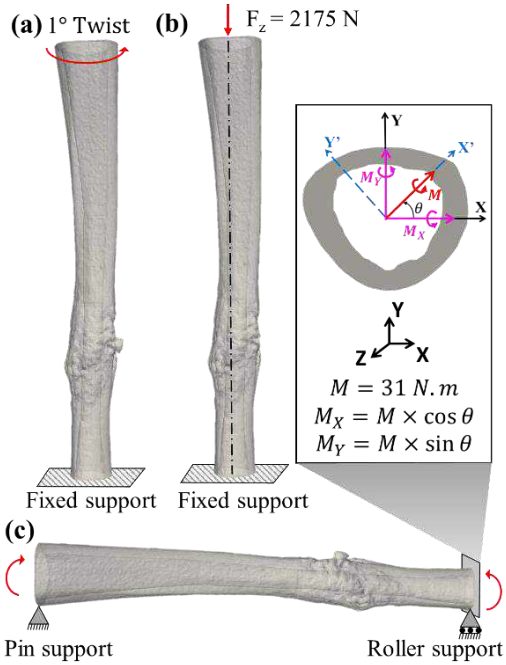

Figure 1: Illustration of different virtual mechanical tests on a representative human tibia: (a) torsion test, (b) axial compression test, and (c) bending test with variable bending direction.

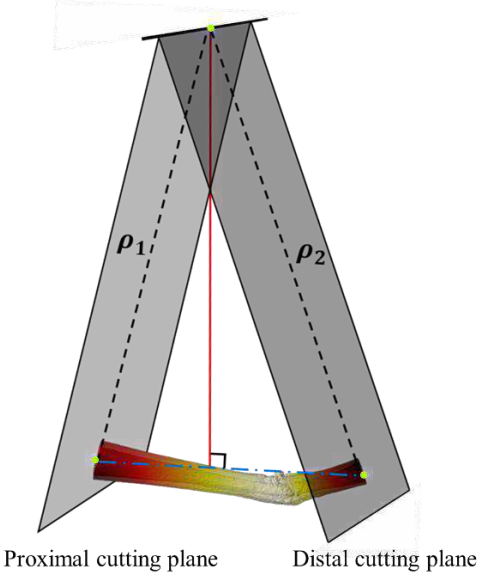

Figure 2: Schematic showing the method for calculating radius of curvature ($\rho = \frac{\rho_1+\rho_2}{2}$) for the bending test.

RESULTS

Correlations between VFR, VTR, and VAS are shown for sheep and human fracture models in **Figure 3.** VFR values are presented for anteroposterior bending only for simplicity (physiologically relevant anterior tension and posterior compression). In both sheep and humans, the bending and torsional rigidities were very strongly and significantly correlated. Axial stiffness was moderately-to-strongly and significantly correlated with torsional rigidity in both species.

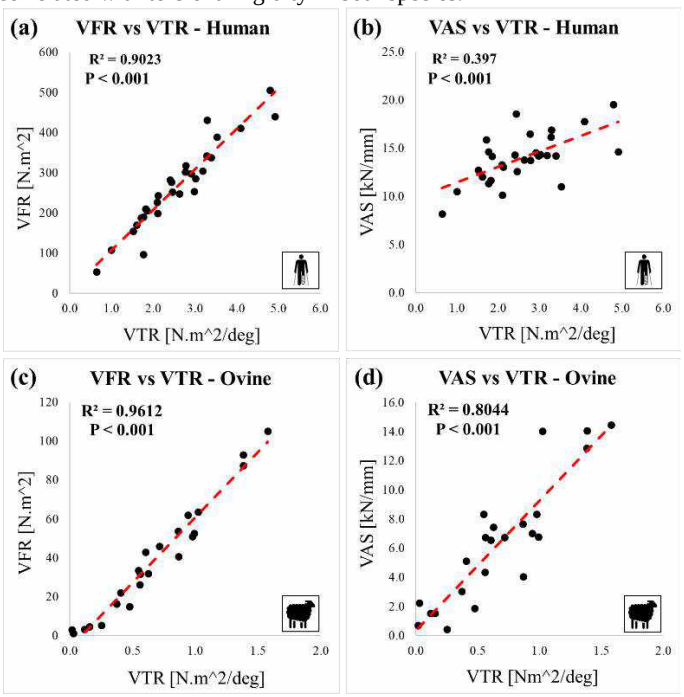

Figure 3: Correlation study between values of (a) VFR and VTR, (b) VAS and VTR for human data, (c) VFR and VTR, (d) VAS and VTR for Ovine data.

DISCUSSION

The results of this study demonstrate that although the torsion is not the predominant physiologic mode of loading, it is the ideal simplified mechanical test because it captures variations in bending rigidity and axial stiffness related to fracture healing without the challenges of direction-dependency. Compared to virtual bending and axial tests, virtual torsion tests are much easier to set up, with very simple post-processing. The virtual torsion test has also been robustly validated to experimental data.[1] In this analysis, there were no obvious outliers, indicating that torsion is a robust surrogate for more complicated physiologic loading states when the goal is to assess whole-bone mechanical integrity ranging from extremely delayed healing to full healed. Stronger correlations between rigidity and stiffness measures in sheep compared to humans were attributed to the regularity of the osteotomy animal model compared to the high variability of fracture patterns in naturally occurring clinical fractures.

AUTOMATIC BOUNDARY DETECTION AND MESHING FOR VIRTUAL MECHANICAL TESTING OF TIBIAL FRACTURE HEALING

Alireza Ariyanfar (1), Mehran Bahrami (1), and Hannah L. Dailey (1)

(1) Department of Mechanical Engineering & Mechanics, Lehigh University, Bethlehem, Pennsylvania, US

INTRODUCTION

Bone fracture healing involves the gradual restoration of structural rigidity by formation of a callus. In animal experiments, postmortem mechanical testing is often used to measure bone rigidity as an indicator of healing status. These tests are destructive and can only be completed postmortem. An image-based alternative known as *virtual mechanical testing* has attracted attention to avoid these limitations.

Previously, we established workflows virtually reconstructing bone models from computed tomography (CT) images for subsequent finite element analysis using several commercial software packages [1-2]. However, the learning curve and license fees associated with the software required to replicate this analysis is a barrier to broader use.

The purpose of this work was to replace the commercial software we used previously for segmentation and meshing (Mimics Innovation Suite - v23.0, Materialize, Leuven, Belgium) with open-source codes. We addressed the challenge of boundary detection using an active contour model and explored approaches to elementwise material property assignment to capture bone gradients and manage partial volume effects. Finally, we performed virtual mechanical testing of long bones in ANSYS Workbench Mechanical (R2020, ANSYS, Inc, Canonsburg, PA) and validated the results.

METHODS

Animal Data: Osteotomized tibiae from N = 13 Swiss alpine sheep were excised at 9-12 weeks post-op and µCT scanned at l = 60.7 µm resolution in a previously completed study [1]. Osteotomy gaps ranged from 3-17 mm (normal and delayed healing models).

Algorithm for Boundary Detection: In each scan, two consecutive cross-sectional images differed only slightly in shape. Hence, the boundary (**B**) detected in one slice (**J**) served as a guess for the subsequent slice and was altered using an active contour model [3] (snake, Figure 1). Each point ($\mathbf{p}_j, 0 \le j < M$) on an old boundary ($\mathbf{B}_{i-1}$) was relocated ($\mathbf{q}_j$) to form the new boundary ($\mathbf{B}_i$). A square

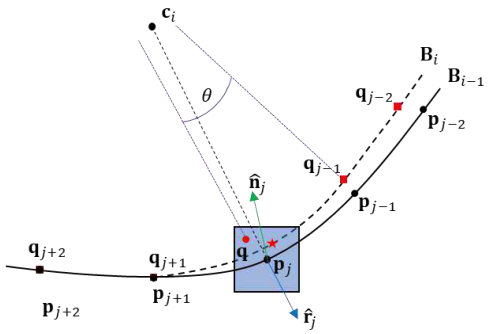

Figure 1. Detecting the outer boundary ($\mathbf{B}_i$) of bone/callus through point-by-point alteration of that ($\mathbf{B}_{i-1}$) in its previous image using an active contour model (snake).

neighborhood (**Q**) was defined as the domain of relocation. The neighborhood (**Q**) was centered at the old point ($\mathbf{p}_j$) unless the evolving new boundary ($\mathbf{B}_i$) became concave at the old point ($\mathbf{p}_j$), in which case the normal vector ($\hat{\mathbf{n}}$) became outward and the neighborhood (**Q**) was shifted along the normal vector ($\hat{\mathbf{n}}$) by a shifting factor (f_s). Every pixel point (**q**) inside the neighborhood (**Q**) underwent an energy (e) evaluation. The old point ($\mathbf{p}_j$) relocated to the pixel position associated with the minimum energy (e_{min}). Energy (e) consisted of normalized terms ($\bar{\boldsymbol{e}}$) with corresponding weights ($\boldsymbol{w}$) for different aspects of the boundary (**B**).

$$e = \boldsymbol{w}^T \bar{\boldsymbol{e}} \tag{1}$$

Angular-distance energy (e_θ) controlled the angular distance (θ) of a point ($\boldsymbol{q}$) with its spatially previous point ($\boldsymbol{q}_{j-1}$) measured with respect to the center of the new boundary ($\mathbf{B}_i$):

$$e_\theta(\boldsymbol{q}) = \left|\frac{2\pi}{M} - \theta\right| \tag{2}$$

Curvature energy (e_κ) contributed boundary smoothness at point ($\boldsymbol{q}$):

$$e_\kappa(\boldsymbol{q}) = \left\| (-1/12)\boldsymbol{q}_{j-2} + (4/3)\boldsymbol{q}_{j-1} + (-5/2)\boldsymbol{q} + (4/3)\boldsymbol{q}_{j+1} + (-1/12)\boldsymbol{q}_{j+2} \right\| \quad (3)$$

Image derivative energy (e_d) created an attraction between edges in the image and the point ($\boldsymbol{q}$):

$$e_d(\boldsymbol{q}) = \|\nabla \mathbf{J}\|(\boldsymbol{q}) \quad (4)$$

Meshing: After boundary detection, meshing was achieved by grouping pixels by a down-sampling factor (f_{ds}) equal to the number of pixels placed along the edge of an 8-node hexahedral element. Low-density pixels were not added to the model if their gray values were less than a threshold (τ). Noise islands were removed. Elementwise material properties were then assigned using our validated dual-zone material model for ovine cortical bone and callus [2].

FE Modeling: Virtual mechanical models were set up in ANSYS by inputting the mesh and material assignment files, fixing the proximal end, and twisting the distal end by 1° to calculate virtual torsional rigidity (VTR) [1].

RESULTS

Preliminary analysis during algorithm development revealed the appropriate values for down-sampling factor (f_{ds}), element formation threshold (τ), and other constants (Table 1).

Table 1. Constant parameters of the model and their calibration

Parameter	Symbol	Value
No. of points on boundary	M	72
Shifting factor	f_s	5
Energy weights	$[w_\theta\ w_\kappa\ w_d]$	[1 0.1 0.2]
Down-sampling factor	f_{ds}	5
Element formation threshold	τ	2750

The snake model successfully captured the outer boundary of images robustly without being affected by artifacts like nutrient artery canal or screw holes, both introducing strong edges (Figure 2).

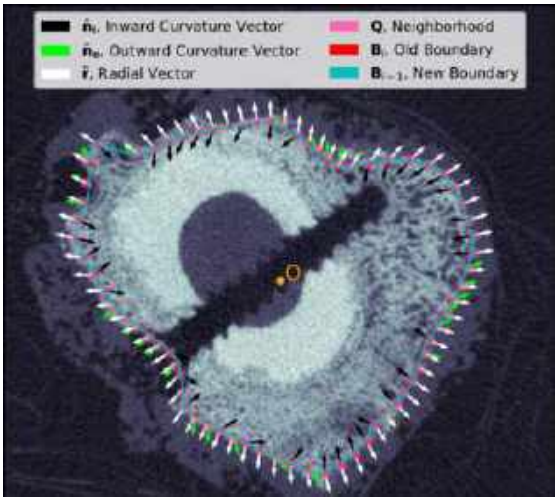

Figure 2. This example slice image shows the cortical cross section with a large callus and a prominent screw hole defect. The snake model identified the boundary by searching for minimal energy over a neighborhood positioned based on the convexity/concavity of the new boundary at that point. The angle between the radial vector and curvature vector determined the direction of curvature.

Figure 3 shows total deformation of an example reconstructed FE model of a fracture bone with callus that was processed and solved in ANSYS in ~10 minutes on a desktop workstation.

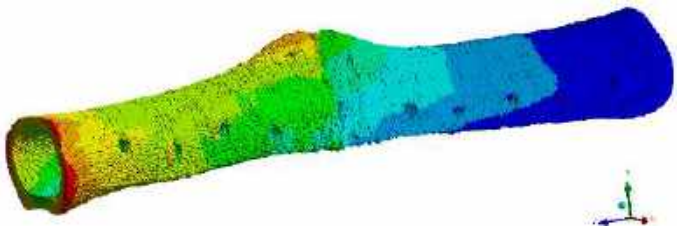

Figure 3. Example FE model created by down-sampling the segmented image and meshing with hexahedral elements. The postmortem biomechanical torsion test was replicated. Contours here illustrate total deformation.

Virtual torsional rigidity (VTR) was very strongly correlated with physical testing torsional rigidity (GJ) (R^2=0.86, p < 0.001), Figure 4. Absolute agreement between VTR and GJ indicated high rest reliability (RMSE = 0.16 Nm^2/° was less than the standard deviation of GJ = 0.41 Nm^2/°).

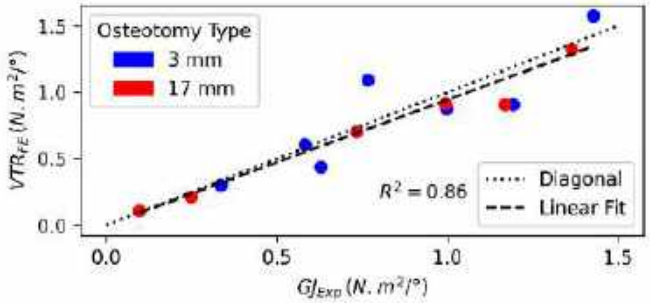

Figure 4. Virtual torsional rigidity (VTR) had very good agreement with torsional rigidity from physical testing (GJ).

DISCUSSION

A novel workflow was presented to eliminate the requirement for commercial software to prepare image-based finite element models for virtual mechanical testing to measure fracture healing in sheep. The similarity of axially consecutive cross-sectional images motivated us to detect boundaries recursively. The complexity of callus shape and image artifacts posed a challenge. The former required a flexible snake which was distracted easily by the latter. This problem was partially addressed by assigning a low value to curvature weight (w_κ) that rendered the snake flexible. To avoid the attraction of the snake to artifacts like nutrient artery canal or screw hole wall, a kick-out mechanism was introduced. When triggered by concavity, it shifted the neighborhood outward and away from the artifact. This strategy avoided attraction to artifacts, but at times deprived the snake from capturing severe concavity of callus and, consequently, took as callus some black background space. These boundary detection defects were subsequently managed at the meshing stage because pixels with such low gray values did not turn into elements because of applying the element formation threshold (τ). Overall, the resulting FE models showed outstanding agreement with benchmark physical tests.

INTRODUCTION

1.74 million people will be affected by Traumatic Brain Injury (TBI) in the United States each year [1]. The prevalence of TBI emphasizes the necessity to reliably measure and predict the material behavior of soft tissues in response to a variety of mechanical loading scenarios in order to better be able to predict the occurrence of injury. Computational modelling toward this effort has seen significant growth in recent years and is a powerful tool to garner crucial knowledge of the brain [2,3]. Computational head models are becoming more widely utilized as a tool to simulate varying types of head insults. While these models provide considerable anatomical accuracy, their ability to make accurate stress and strain predictions is limited by knowledge and accuracy of their underlying constitutive properties [2,3]. To this end, considerable effort has been given to the determination of low and quasi-static strain rate behavior, and whilst not in absolute agreement, promising results, methodologies, and reviews are available [2]. High and ultra-high strain rate material behavior, however, has remained elusive, due largely in part of experimental challenges when dealing with soft materials [2-4]. Soft tissues are highly compliant materials, rendering many existing high-rate characterization techniques difficult, if not completely ineffectual, to employ [2,3]. The absence and ambivalence of high-rate properties is a crucial limitation for the predictive capability of computational head models, specifically toward blast, high-velocity impact, and directed energy insults, and thus motivates the acquisition of quantitative constitutive properties for brain tissue at strain rates greater than 10^3 1/s. To address this, we utilize our previously developed ultra-high-rate rheological method, coined 'Inertial Microcavitation Rheology (IMR)'. IMR was designed to address the deficiency of high-rate properties by creating a tool capable of characterizing the behavior of highly compliant, soft materials under high-rate loading conditions (10^3 - 10^8 1/s) [6-8]. Here, we employ IMR to quantify the shear modulus (G) and viscosity (μ) within the context of a finite deformation, isotropic, hyperelastic constitutive model in five regions of interest (ROIs) in fresh and formalin-fixed porcine brain. It is a widely regarded notion that brain tissue is highly heterogeneous, not just between white and gray matter, but inter-regionally as well [2-5]. To address this, five anatomical regions were selected: Cerebellum, Cortex, Corona Radiata, Corpus Callosum, and Thalamus/Basal Ganglia. From this characterization, we aim to create a regional map showcasing the high-rate material properties and their spatial diversity across the porcine brain.

METHODS

The generation of inertial microcavitation events and the theoretical framework that underlies them has been thoroughly documented in the literature [6-8]. Briefly, inertial microcavitation is generated from a pulsed, 532 nm, frequency-doubled, Q-switched Nd:YAG Minilite II laser (Continuum, Milpitas CA) that is expanded and pathed into the rear port of a Ti2 Eclipse microscope (Nikon Instruments Inc., Japan). The laser pulse is then focused on the sample through a dichroic mirror and Nikon S Plan Fluor 40X/0.6 NA ELWD imaging objective (Nikon Instruments Inc., Japan). Finally, the cavitation event is recorded with bright-field microscopy at 2,000,000 fps on a Shimadzu HPV-X2 (Shimadzu Corporation, Kyoto, Japan).

The porcine brain is sectioned coronally into 5 mm thick segments using an aluminum brain matrix (Zivic Instruments, Pittsburgh PA) and cylindrical samples are extracted from each ROI with an 8 mm tissue biopsy punch. Low-melt agarose is used to embed these samples into a syringe modified with a flat-end before slicing into thin discs around ~150-350 μm thick to maximize optical transparency for each sample. These discs are then wedged between two hydrophilically treated cover glass slips and hydrated with Phosphate-buffered Saline (PBS).

RESULTS

After recording the cavitation event, the bubble's radial evolution is extracted and analyzed using a modified finite element based (FE-

IMR) framework adapted to account for the thin sample geometry. Within this framework, the radial cavitation kinematics are fitted to a Neo-Hookean Kelvin Voigt material model to obtain the shear modulus (G) and viscosity (mu) for each case. The initial findings from three cavitation events in fixed (Figure 1A) and fresh (Figure 1B) porcine cortical gray matter yielded shear moduli of 110 kPa and 11 kPa, and viscosities of 0.05 Pa·s and 0.11 Pa·s for fixed and fresh samples, respectively.

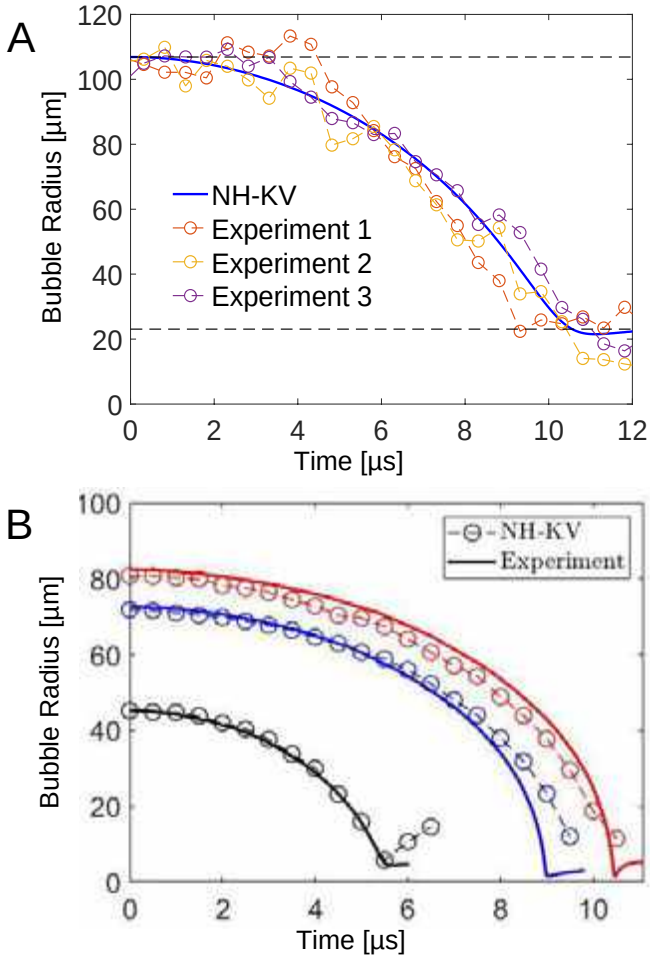

Figure 1: NH-KV model fits for cortical gray matter in (A) fixed and (B) fresh porcine brain.

DISCUSSION

Computational models remain a powerful, promising tool toward understanding the response of the brain to diverse loading conditions. However, their predictive capability is crucially limited by an absence of high-rate constitutive behavior, which stems from a lack of appropriate methods to study soft, highly compliant materials [2-4]. Here, by successfully creating a sample geometry that can be integrated with existing inertial cavitation protocols and by adapting our previously developed IMR framework with finite elements to account for this geometry, constitutive behavior of brain tissue at high rates can be examined, specifically the shear modulus and viscosity.

The deficiency of existing high-rate constitutive data prevents a direct comparison of our initial findings with the literature. However, inferences can be made to gain insight towards understanding if our values are realistic, starting with the fresh tissue findings presented (Figure 1B). At current, the strain rate dependence of brain tissue is unequivocal, specifically showing an increase in stiffness with increasing strain rates [2,9]. A study using MR Elastography considering fresh porcine brain reports a stiffness between 2 and 5 kPa when a range of frequencies between 50 and 300 Hz was investigated [9], making 11 kPa appear reasonable. There are, however, limitations to this inference as constitutive properties of brain tissue varies from region-to-region [2-5]; the preliminary values reported here are specific to cortical gray matter, while the MRE *ex vivo* study was conducted on a cylindrical sample of corpus callosum, a white matter region, with the inclusion of some superior gray matter.

Moving to the initial properties reported for fixed brain tissue (Figure 1A); large differences between the stiffness of fresh and fixed tissue can be expected as a consequence of the fixation procedure. Formalin fixation is done to prevent degradation of the native tissue structure, which is accomplished through the introduction of crosslinks to the tissue. These crosslinks are expected to drastically increase the stiffness response of the tissue, which agrees with our preliminary findings of 110 kPa and 11 kPa in formalin-fixed and fresh brain tissue respectively.

Finally, while isolating the tissue from its native environment inherently limits the ability of *ex vivo* studies to represent the native material behavior, the successful integration of tissues with the FE-IMR framework, overall, holds immense promise towards understanding complex biological systems and their response to mechanical stimuli at high-rates.

INTRODUCTION

Inferior vena cava (IVC) filters play a crucial role in preventing life-threatening complications associated with venous thromboembolism (VTE), a condition affecting 1 out of 1000 individuals [1]. A common subset of VTE, deep vein thrombosis (DVT), involves the formation of blood clots in the deep veins of the lower extremities, which can potentially dislodge and travel to the lungs causing pulmonary embolism (PE). This potentially deadly event occurs in about one-third of all DVT cases [2]. IVC filters are medical devices designed to mitigate the risk of PE by capturing and preventing emboli from traveling to the pulmonary arteries where they could lodge and obstruct blood flow. Typically implanted using a catheter into the inferior vena cava, these filters act as a mechanical barrier and are particularly used in situations where patients do not respond to anticoagulant therapy or anticoagulants are contraindicated.

While IVC filters can be a valuable tool for PE prevention, questions regarding their effectiveness remain. Variation in design and purpose, whether permanent or retrievable, can be seen between filters, leading to the question of how to properly characterize the effectiveness of IVC filters and their ability to catch emboli originating from the lower extremities.

Using a generic IVC filter designed by the U.S. Food and Drug Administration (FDA) and collaborators at Confluent Medical Technologies for research purposes, the objective of this study is to build upon previous *in vitro* research done in the upright orientation [3] and help validate computational research characterizing the clot trapping efficiency of this filter. Specifically, this study characterizes the capture efficiency of the filter for both spherical and cylindrical clots of various clinically relevant sizes in the supine position under worst-case physiological flow conditions.

METHODS

To perform clot trapping experiments, a rigid, three-dimensional IVC model was fabricated based on averaged dimensions from patient computed tomography (CT) scans [4]. The IVC model is simplified while still maintaining the anatomical features of the iliac veins, infrarenal IVC curvature, and non-circular vessel cross-sections, all of which affect IVC hemodynamics and embolus migration. The FDA generic IVC filter (Figure 1A) was inserted into the model for experimentation. The filter is made of nitinol and has 16 identical struts shaped in a conical fashion. The largest gap between these struts is 5 mm and decreases as the struts join in the center at the top of the filter.

An *in vitro* flow loop (Figure 1B) was used to replicate physiological flow conditions. A Newtonian blood analog solution was created using a mixture of water and glycerin to provide a clot-to-fluid density ratio of approximately 1.05-1.1.

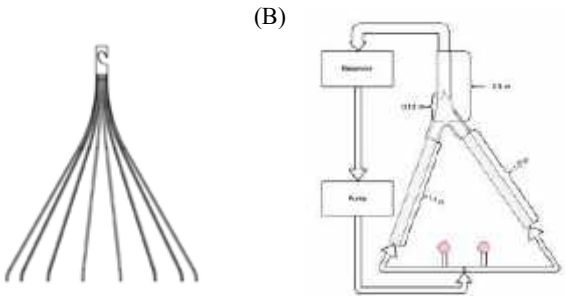

Figure 1: (A) Diagram of *in vitro* experimental flow loop. Red dots indicate injection ports for both iliac veins. (B) FDA generic IVC filter (adapted from [3]).

Physiological exercise conditions were used with an average flow rate of 5.06 liters per minute through the IVC using a centrifugal pump

[5,6]. The flow was split 50/50 between each iliac vein. Clots were introduced into the system upstream of the entrance tubing to the IVC model via a ball valve injection system, with enough tubing to allow for the flow to become fully developed before reaching the model.

Blood clots were formed following a previous experimental protocol [3]. Briefly, clots were created using bovine blood obtained through an approved IACUC protocol. A ratio of 50:50 red blood cells and platelet-rich plasma was used, and the initiation of coagulation was achieved using a 1:50 ratio of the blood solution and 0.5M $CaCl_2$. Clots were allowed to coagulate overnight at 37°C. Spherical clots (n=140) were formed in oversized, custom 3D printed resin molds, accounting for contraction of clots during coagulation. Three sizes were used: 3.26±0.27 mm, 4.81±0.40 mm, and 6.13±0.16 mm diameter. Cylindrical clots (n=90) were formed by injecting the reconstituted blood into Tygon tubing and clamping both ends. Clots of diameters 2.31±0.22 mm, 4.24±0.13 mm, and 4.82±0.14 mm were cut to lengths of 1x, 3x, and 5x the clot diameters. Both clot types were injected into the IVC flow loop, and the iliac vein of origin and trapping outcomes were recorded.

RESULTS

The filter trapping efficiency for spherical clots generally increased with clot diameter. As illustrated in Figure 2, the total clot trapping efficiencies were 35.7%, 85.7%, and 100% for 3.26 mm, 4.82 mm, and 6.13 mm diameter clots, respectively. There were no differences in the trapping efficiencies for clots migrating from the left and right iliac veins.

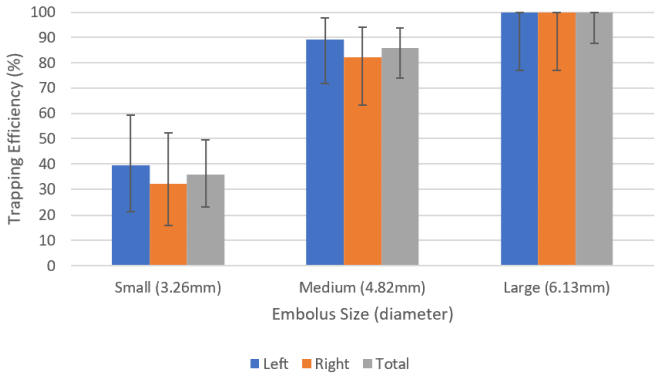

Figure 2: Clot trapping efficiencies for spherical bovine blood clots, categorized by small, medium, or large diameters, corresponding to 3.26 mm, 4.82 mm, and 6.13 mm, respectively. Colors indicate the iliac vein of origin from which clots were injected into the flow loop. Error bars represent Clopper-Pearson 95% binomial confidence intervals.

Figure 3 presents the observed trapping efficiencies of the IVC filter for cylindrical blood clots for various diameters and lengths. Overall, the clot trapping efficiencies increased with both clot diameter and length. The total capture rate for clots of 2.31 mm diameter and 1x diameter was 8.33%. All medium 4.82 mm diameter clots, regardless of length, were caught with 100% efficiency. The remainder of the small and medium diameter clots had capture efficiencies that increase with diameter and length until reaching 100%. The capture efficiency between iliac veins of origin was very similar for all clot sizes.

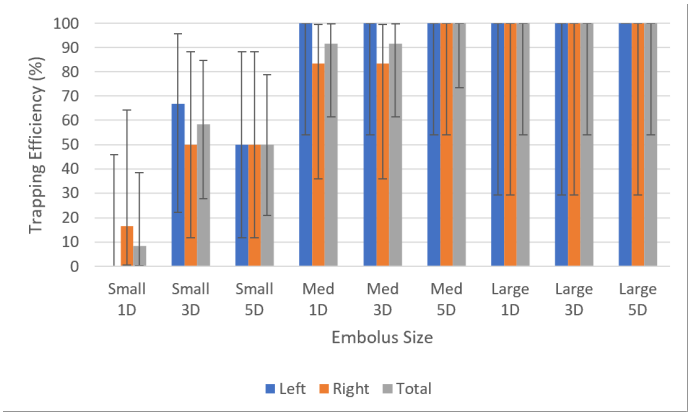

Figure 3: Clot trapping efficiencies for cylindrical bovine blood clots, categorized by diameter and length. Small, medium (Med.), and large, correspond to diameters of 2.31 mm, 4.24 mm, and 4.82 mm, respectively. Clot lengths are 1x (1D), 3x (3D), and 5x (5D) the clot diameters. Colors indicate the iliac vein of origin from which clots were injected into the flow loop. Error bars represent Clopper-Pearson 95% binomial confidence intervals.

DISCUSSION

The objective of this research is to characterize the in vitro clot trapping efficiency of the FDA generic IVC filter in the supine position. A previous study was performed using this experimental setup with the same filter in an upright (i.e., vertical) orientation [3]. As patients spend a significant amount of time during recovery, medical procedures, and sleep in the supine position, understanding the functionality and capture efficiency of filters under these conditions is important. The results of this study help to provide a more comprehensive understanding of the filter trapping efficiency when patients are in this orientation.

There is a clear trend in our results from these experiments showing an increase in trapping efficiency with an increase in clot size for both spherical and cylindrical clots. There is a significant difference in the trapping efficiency of spherical clots with a 6.13 mm diameter and the smaller clots with a diameter of 3.26 mm. The results can be explained by the geometry of the IVC filter. The largest gaps between struts of the IVC filter is 5 mm, thus a clot with a diameter larger than this gap size would be expected to be caught. This trend continues with cylindrical clots for both diameter and length. The cylindrical clots were found to deform as they moved through the flow loop, making them easier to become ensnared in the filter. The larger the clots, the more likely they are to make contact with the struts and, thus, become funneled towards the filter apex where gaps between the struts are smaller.

In this study, we did not find that the iliac vein of origin had a significant effect on the trapping efficiency of the filter in a supine position. These results suggest that with the IVC anatomical model used in this experiment, any subtle differences in flow patterns between the left and right iliac veins do not appreciably affect the filter trapping efficiency.

PREGNANCY AND AGE DIFFERENTIALLY AFFECT STIFFNESS, COLLAGEN MICRODAMAGE SUSCEPTIBILITY, AND COMPOSITION OF UTEROSACRAL LIGAMENTS

INTRODUCTION

Pelvic organ prolapse (POP) is characterized by the descent of any of the pelvic floor organs (i.e., bladder, uterus, rectum) from their natural position, and it affects 50% of women in their lifetime [1]. Uterosacral ligament (USL) injury is a major cause of uterine POP, as USLs provide structural support for the uterus by tethering the cervix to the sacrum. Pregnancy, parturition, and age are known risk factors for POP; the former two are believed to increase the likelihood of USL injury by increasing mechanical stress and strain on the USLs [2]. Extracellular matrix (ECM) components like collagens, elastin, glycosaminoglycans (GAGs), and proteoglycans contribute to the mechanical integrity of the USL. Type I collagen is the major load-bearing ECM component of ligaments, and for that reason, collagen damage is likely implicated in USL injury and POP [3]. However, how stiffness, collagen damage mechanics, and composition of the USL change with pregnancy and maturation has not been explored.

In this study, we employed a murine model to investigate the effects of pregnancy and age on USL stiffness, mechanical injury susceptibility, and biochemical composition. We hypothesized that pregnancy-induced ECM remodeling would enable USLs from late-pregnant and recently post-partum mice to be more resilient to strain-induced collagen damage and more compliant than those from nulliparous mice. We further hypothesized that normal ECM changes that occur with maturation beyond adolescence would both increase the stiffness of USLs and lower their resilience to strain-induced damage.

METHODS

Female C57BL/6J mice were euthanized according to the University of Colorado Boulder's Animal Care and Use Committee. Both young adult (YA, 10-15 weeks, n = 5-6) and adult (A, >17-weeks, n = 3-5) murine USLs were collected at three different stages of pregnancy: nulliparous (NP), embryonic gestation day 18.5 (E18.5), and post-partum day 1 (PP1). USLs were isolated, and a suture was tied at the cervical end. One USL was used for mechanical analysis and left attached to the pelvis and a piece of the cervix, which acted as anchors, and tested while freshly harvested. The contralateral USL was flash frozen with liquid N_2 and later analyzed with Raman spectroscopy.

For mechanical testing, samples were stained in a solution of Ghost Dye Red 780 (Tonbo Bioscience), which stained all free amine groups, for 2 hrs at 4°C. For the last 10 min, Sytox Deep Red (ThermoFisher Scientific) was added into the solution. The sample was placed into a custom loading chamber in a 1×PBS bath, and tested with a 100 mN FemtoTools load cell under an upright confocal microscope (Leica STELLARIS 5) [4]. A ~500 µN pre-load defined the reference state.

Collagen hybridizing peptide (CHP) was used to determine regions with significant fibrillar collagen denaturation (damage) [5]. Prior to mechanical testing, the 1×PBS bath was replaced with a 10 µM solution of CHP for 15 min. This process was repeated after each deformation state to record the change in collagen damage. The samples were imaged at 10× before, during, and after deformation. Deformed configurations were determined by actuator displacements of 1000, 1500 and 2000 µm, and allowed a stress-relaxation period of 5 minutes.

Maximum intensity projections from reference and deformed Ghost Dye and Sytox image stacks were used to estimate 2D displacement fields with MATLAB's *imregdemons* function, from which Lagrange strain fields were derived (Fig. 1). A previously developed moving threshold was used to determine pixels with significant collagen damage [6]. Average axial (E_{11}), transverse (E_{22}), and shear (E_{12}) strains were calculated, as well as percent damaged area, for the intermediate region. Linear mixed models (LMM) were used to determine the effect of pregnancy and age on collagen damage vs. average E_{11} and average axial stress vs. E_{11}.

Raman spectroscopy was used to analyze the biochemical composition of the contralateral USLs. Thawed, the samples were placed in a custom well and evaluated using a confocal Raman microscope system (Renishaw inVia, 758 nm red laser). A grid of 100

μm × 150 μm (~3 × 12) spectra along each USL was obtained, and the average signal for the intermediate section of each sample was computed. Principal component analysis (PCA) was used to evaluate the relative composition of each sample using the MATLAB function *pca* and spectra for fibrillar collagen, GAG, and elastin from the literature [7]. Two-way ANOVA was used to determine whether pregnancy and age had significant effects on USL composition. Asterisks indicate significance in Figs. 2-3.

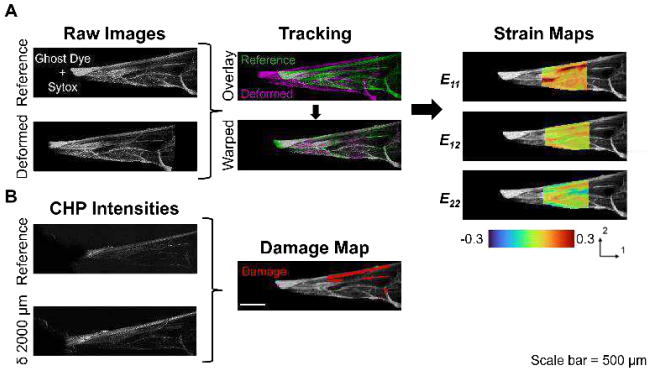

Figure 1: (A) Displacements were tracked with reference and deformed Ghost Dye and Sytox images and differentiated to compute strain fields. (B) Corresponding damage maps from CHP images permitted analysis of injury susceptibility.

RESULTS

Only pregnancy appeared to alter injury susceptibility (Fig. 2A). LMM analysis determined that USLs from NP mice were more susceptible to mechanically-induced collagen damage than those from PP1 ($p<0.05$). However, USLs from E18.5 mice showed no difference in collagen damage vs. strain compared to those from NP mice. Age also did not significantly affect injury susceptibility.

Both pregnancy and age significantly altered USL stiffness (Fig. 2B). Pregnancy was observed to increase USL compliance; USLs from NP mice were stiffer than those from E18 and PP1 mice ($p<0.05$). Conversely, maturation resulted in increased USL stiffness; USLs from A mice were stiffer than USLs from YA mice ($p<0.05$).

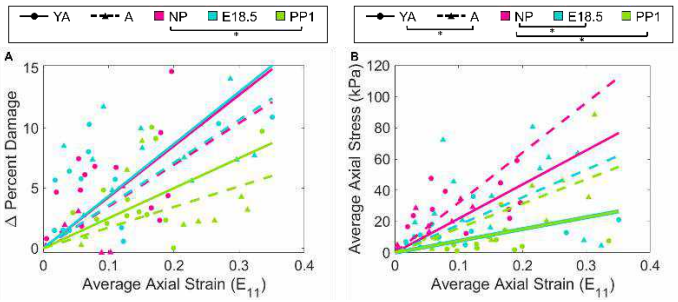

Figure 2: USL injury susceptibility (A) was significantly lower at PP1 compared to NP, while USL stiffness (B) was differentially affected by age and pregnancy.

PCA of Raman spectra determined that 3 Principal Components (PCs) represented 90% of the total variance. PC1 loadings were found to resemble fibrillar collagen spectra, while PC2 and PC3 loadings resembled GAG and elastin spectra, respectively (Fig. 3, right). All PC loadings significantly changed with pregnancy ($p<0.05$), but not with age (Fig. 3, left). Results suggest that the relative amounts of collagens (A) and GAGs (B) increase during pregnancy, while the relative amount of elastin (C) decreases.

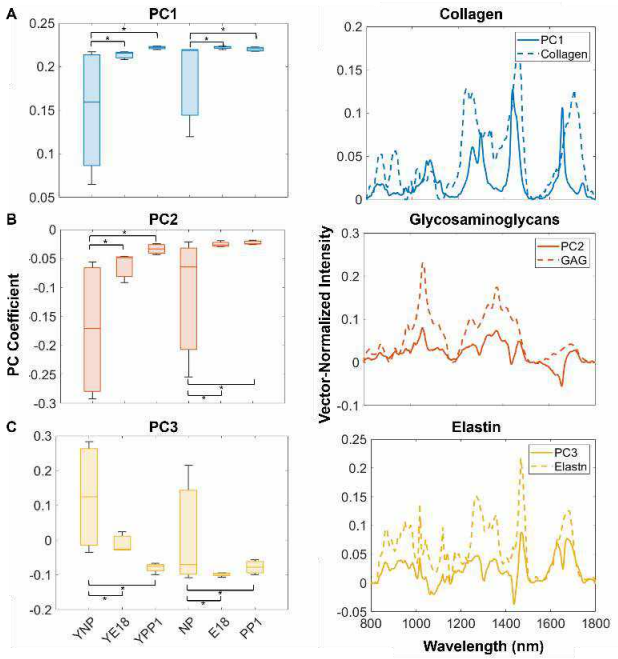

Figure 3: PCA of Raman spectra revealed an effect of pregnancy on USL composition. Comparisons between pure ECM spectra and PC projections for a YA NP sample are shown at right.

DISCUSSION

Our findings indicate that pregnancy causes ECM remodeling in the USL that alters composition, decreases stiffness, and lowers susceptibility to mechanical damage. The relationship between collagen damage and strain was significantly different after parturition, with USLs from PP1 mice sustaining less damage at similar levels of strain than those from NP mice. This suggests that the ECM remodels in late pregnancy to reduce strain-induced injury susceptibility for childbirth. Results from Raman spectroscopy reveal a significant increase in relative fibrillar collagen and GAG content during pregnancy, with a further increase the day following parturition. A similar trend in decreasing relative elastin content was also observed.

Aging and vaginal delivery are key factors in developing POP, and understanding how these factors play a role in the integrity of the USL is important, as our current preventative strategies are limited. This is the first study to investigate the effects of both age and pregnancy on USL mechanics, injury susceptibility, and ECM composition. Limitations in this study include a small sample size, especially for identifying compositional differences. Future work will investigate whether micro-organizational changes also protect the USL from injury.

INTRODUCTION

The principles governing the natural development of vascular geometry have been the interest of biophysical research for over 100 years[1]. A widely popular theory is that proposed in 1926 by Cecil D. Murray, who applied the principle of minimum work to predict optimal two-dimensional vascular geometry at a bifurcation in terms of both vessel caliber and branching angles[2,3]. Although more recent work has been done to generalize the theory as it applies to vessel caliber[4], we are not aware of any efforts to generalize the theory's predictions of ideal branching angles to three dimensions or to more than two daughter vessels. In this study, we present a generalized form of Murray's Law to predict optimal branching angles for any number of daughter vessels in three dimensions and compare these predictions to angles observed in cerebrovascular computed tomography angiograms.

METHODS

The same assumptions that Murray applied in his original derivation in 1926 were utilized to develop a generalized form[3]. Specifically, Poiseuille flow and a metabolic energy cost proportional to the volume of blood were assumed[3]. Measurements of radii and angles were made on 3D models acquired from computed tomography angiograms of M1-M2 middle cerebral artery (MCA) bifurcations and basilar terminus (BT) "tetrafurcations" (where the posterior cerebral arteries (PCA) and superior cerebellar arteries (SCA) were treated as originating from a common point). Comparisons between the measured and predicted geometries and between MCA and BT adherence with predicted ideality were performed using two-tailed t-tests with a critical value of $\alpha = 0.05$.

RESULTS

It was found that branching geometry is ideal when the following relationship is true for a system with n daughter vessels:

$$\frac{r_0^2+\sum_{j=1}^{n} r_j^2}{\sum_{j=1}^{n}\left(\cos\theta_j r_j^2+\cos\theta_j r_0^2-\sum_{a=1}^{j-1}\cos\theta_{a,j} r_a^2-\sum_{a=j+1}^{n}\cos\theta_{j,a} r_a^2\right)} = BI = 1 \qquad (1)$$

where BI is the Branching Index, r_i is the radius of vessel i ($i = 0$ represents the parent vessel and $i > 0$ represents a daughter vessel), θ_i is the angle between the parent vessel's flow axis extended beyond the branching point and the flow axis of daughter vessel i, and $\theta_{i,k}$ is the angle between the flow axes of daughter vessels i and k ($i < k$). These relations are visualized in Figure 1.

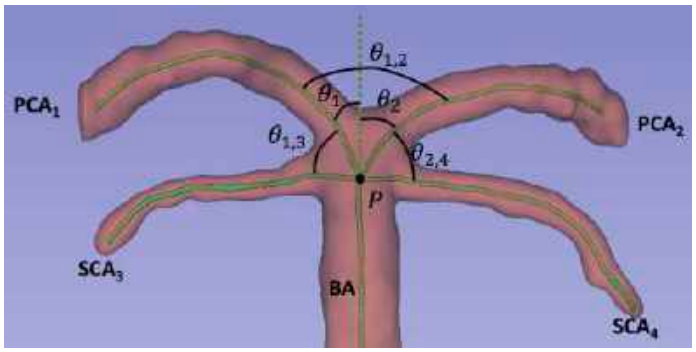

Figure 1A: Example of a 3D model of the basilar tip with illustrated definitions of angles. Some angles have been omitted from the figure for clarity. The model is a coronal view of the basilar tip, with green solid lines representing center flow axes within the visualized arteries. The dotted green line represents extension of the basilar artery flow vector beyond the branching point from which the posterior cerebral and superior cerebellar arteries originate.

BA:	Basilar Artery
PCA:	Posterior Cerebral Artery
SCA:	Superior Cerebellar Artery
P:	Common branching point of PCAs and SCAs from parent BA
θ_1:	Angle between flow vector of PCA_1 and BA
θ_2:	Angle between flow vector of PCA_2 and BA
$\theta_{1,2}$:	Angle between flow vector of PCA_1 and PCA_2
$\theta_{1,3}$:	Angle between flow vector of PCA_1 and SCA_3
$\theta_{2,4}$:	Angle between flow vector of PCA_2 and SCA_4

Figure 1B: Definitions of abbreviations and terms used in Figure 1A.

Using measured values for the radii and angles of 12 BT tetrafurcations, the average value of the equation was found to be $BI_{BT} = 1.20$ ($\sigma = 0.13$), which is significantly larger than the predicted value of $BI = 1$ ($P < 0.001$). For 22 MCA bifurcations, the average value was $BI_{MCA} = 1.09$ ($\sigma = 0.10$), which is also significantly larger than 1 ($P < 0.001$). Comparing BI_{BT} and BI_{MCA} reveals that BI_{BT} was significantly larger than BI_{MCA} ($P = 0.024$).

DISCUSSION

Given that both BI_{BT} and BI_{MCA} were significantly larger than 1, it seems that more than just minimization of work at a branching point determines arterial geometry. However, it should also be noted that both branching points exhibited geometries which produced values for BI close to 1 with small standard deviations. This may indicate that vascular geometry develops in such a way as to minimize energy loss within the confines of other constraints, such as conforming with the gross anatomy of the tissues that the vasculature supplies. This is similar to the theory proposed by Ingebrigtsen et al.[5] Our results also showed that BI_{BT} was significantly greater than BI_{MCA}, which further supports this theory given that the BT participates in the circle of Willis and is thus subject to greater anatomic constraints than is the MCA bifurcation, which is located in the Sylvian fissure[5].

Less ideal branching geometry may manifest as an increased rate of cerebrovascular pathology. For example, it is known that the pathogenesis of intracranial aneurysms is highly influenced by local hemodynamics[6]. Although the rate of formation of intracranial aneurysms is greater at the MCA bifurcation than at the BT, the rate of rupture of existing aneurysms is approximately 4 times greater in the posterior circulation (in which the BT participates) than at the MCA bifurcation[7]. This discrepancy in rupture risk may be attributable to the relative lack of ideality in branching geometry at the BT demonstrated in this study. Future research may further explore this observation by calculating Branching Index values for the most common site of both intracranial aneurysm formation and rupture, the anterior communicating artery[8].

BIOMECHANICAL IMPACT OF NEOCHORDOPLASTY AND LEAFLET RESECTION FOR MITRAL VALVE PROLAPSE REPAIR

Gediminas Gaidulis (1), Muralidhar Padala (2), Lakshmi Dasi (1)

INTRODUCTION

Mitral valve prolapse (MVP) is a valvular heart disease, diagnosed in 2-3% of the general population **[1]**. In MVP patients, one or both mitral valve (MV) leaflets are degenerated, elongated, and override each other during valve closure. Along with leaflet degeneration and elongation, elongation and rupture of the chordae are also seen, contributing to leaflet overriding. In such condition, a gap between the leaflets occurs in systole, causing the backflow of the blood from the left ventricle into the left atrium, and resulting in pulmonary congestion, elevated left atrial pressure and distension, and highly inefficient pumping of the heart leading to heart failure over time **[2]**.

Surgical repair of MVP is the current gold standard of care. The techniques used for MVP repair are generally classified into two categories: (1) non-resective techniques, where the native leaflet tissue is fully preserved, and surgical repair is focused on implanting artificial neochordae into the leaflets and appropriately sizing and tensioning them to restore proper valve closure; and (2) resective techniques, where the native leaflet tissue is cut and reduced in its area, so that the intact chordae are realigned to restore proper valve closure. Both techniques have merit, but post-repair valve biomechanics can differ significantly, and often impact repair durability **[3]**. In addition to these techniques, all repairs are stabilized with an annuloplasty ring, especially when MVP is accompanied by the dilated mitral annulus, usually due to degenerative MV disease **[4]**, to ensure that the valve closure achieved at surgery remains so in the long term **[5]**. The biomechanically optimal approach to repair MVP is often discussed by surgeons, but quantitative studies on this topic are very limited.

In this study, we sought to compare the biomechanical effects of different mitral valve repair strategies to repair the most common form of MVP – posterior leaflet (PL) prolapse. Firstly, the impact of leaflet preserving and leaflet resection approaches on valve biomechanics was assessed. Secondly, the impact of annular stabilizing techniques on both prior MV repair strategies was evaluated.

METHODS

A computational model of the MV was created from transesophageal echocardiography data of a patient. To simulate valve closure, patient-specific motion of the mitral annulus and the papillary muscles was prescribed to the model, and physiological transvalvular pressure gradient was applied to the ventricular surface of the leaflets. MVP was induced by transecting the chordae inserted into the P2 segment of the PL. The annular dilation was mimicked by uniformly displacing annular nodes away from the MV centroid to achieve the annular size inherent to the valve with degenerative MV disease. Dynamic simulation of the MV closure was run in Abaqus and systolic configuration of the valve with P2 prolapse was obtained.

Neochordoplasty was performed by inserting the neochordae into the free edge of the prolapsing leaflet and anchoring them to the papillary muscles. Two repair scenarios were studied, starting with 2 neochordae and then 4 neochordae inserted into the P2 segment. Three annuloplasty ring models of different sizes, i.e., true-sized ring of 36 mm, and two down-sized rings of 34 mm and 32 mm, were created based on the measurements of Carpentier-Edwards Physio I ring. Each ring was positioned near the regions of left and right fibrous trigones, and the mitral annulus was then deformed to the ring configuration (**Fig 1**). The physiological transvalvular pressure gradient was applied to the leaflets and dynamic simulations of the valve closure were run in Abaqus for both neochordoplasty scenarios with each ring size.

Two repair scenarios for leaflet resection were investigated: triangular resection and quadrangular resection. In each scenario, either a triangular or a quadrangular segment of the prolapsing P2 segment was removed. The PL was then reconstructed by approximating the free edges of the resection and applying the tie constraint at the junction site so that there was no relative motion between the resected edges (**Fig 1**). For both leaflet resection scenarios, three annuloplasty rings created previously were used to reshape the mitral annulus in the same manner as described before, and valve closure was simulated in Abaqus.

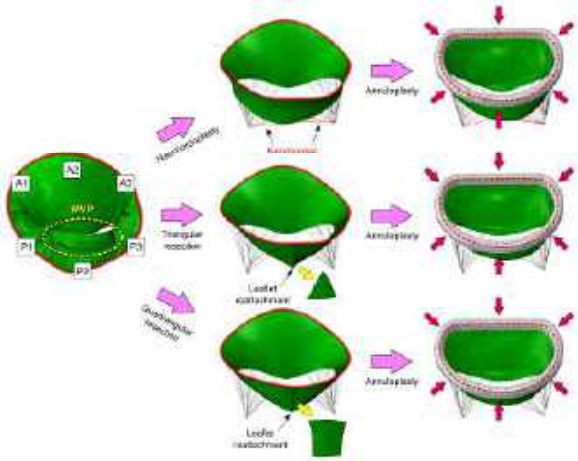

Figure 1: Schematic representation of the study workflow.

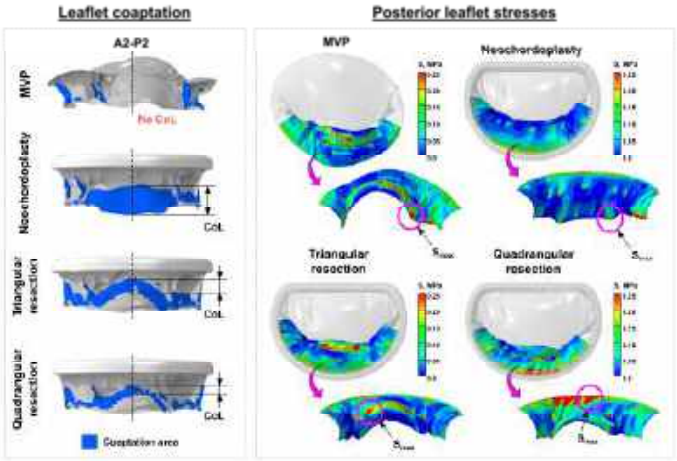

Figure 2: Leaflet coaptation and PL stress distribution before and after neochordoplasty and leaflet resection with true-sized ring.

RESULTS

In pre-repair model, the presence of MVP and annular dilation resulted in the absence of leaflet coaptation at A2-P2, excessive PL mobility, elevated leaflet stresses and chordal tension forces. All investigated MVP repair techniques were able to reduce P2 segment prolapse and restore different levels of leaflet coaptation (**Fig 2**) and clinically acceptable tenting height (< 5 mm). The excessive mobility of the PL seen in the MVP model was also reduced with all repair techniques and annuloplasty ring sizes. With 36 mm and 34 mm rings, stresses on the PL were reduced after neochordoplasty, but increased with both resection techniques (**Fig 2**). Triangular resection reduced PL stresses only with 32 mm ring. Quadrangular resection was not able to reduce stresses on the PL with any ring size. Tension forces in the intact PL marginal chordae were greatly reduced after neochordoplasty. Both leaflet resection techniques reduced chordal forces as well, but the reduction was smaller than after neochordoplasty. The computational results for pre- and post-repair models are presented in **Table 1**.

Table 1: Simulation results for different MVP repair techniques.

	Coaptation length (mm)	Coaptation area (mm^2)	Tenting height (mm)	Tenting area (mm^2)	PL excursion angle (deg)	Peak PL stress (MPa)	Peak PL marginal force (N)
MVP	0	107.9	-	-	89.4	0.75	0.56
	36 mm ring						
2 neochordae	5.86	338.7	3.57	47.5	62	0.47	0.056
4 neochordae	5.9	353.5	3.9	51.9	60.2	0.39	0.038
Triangular	2.78	296.8	1.42	18.9	75.3	0.79	0.3
Quadrangular	1.72	230	2.87	38.2	70.4	2.04	0.35
	34 mm ring						
2 neochordae	6.43	463.8	2.93	37.2	64.5	0.45	0.036
4 neochordae	6.52	483.8	3.19	40.5	63.1	0.31	0.026
Triangular	3.76	449	0.98	12.4	77.2	0.78	0.2
Quadrangular	1.93	349	2.68	34	68.3	1.22	0.27
	32 mm ring						
2 neochordae	7.44	595.9	2.27	26.3	66.5	0.41	0.024
4 neochordae	7.52	630.6	2.42	28.1	65.7	0.28	0.015
Triangular	5.53	593.8	0.59	6.8	78.6	0.57	0.11
Quadrangular	6.07	520.7	2.27	26.3	62.3	0.87	0.094

DISCUSSION

Our MVP model with annular dilation demonstrated the presence of poor leaflet coaptation, excessive PL mobility, elevated stresses on the PL, and increased tension forces in the intact marginal chordae. All repair techniques reduced prolapse and improved contact between the MV leaflets, increasing leaflet coaptation length and area. The better outcomes were observed after neochordoplasty, as clinically adequate coaptation length at A2-P2 (> 5 mm) was achieved with all ring sizes. After leaflet resection, however, annular downsizing with 32 mm ring was required to improve coaptation adequately, as larger rings were not able to ensure clinically acceptable coaptation length. Similarly, better outcomes in leaflet stress reduction were achieved after neochordoplasty as well. Both neochordoplasty scenarios with each ring size reduced peak stresses on the PL, while after leaflet resection stresses on the PL mainly increased. Finally, tension forces in the intact marginal chordae were reduced with both MVP repair techniques, but after leaflet resection peak forces in the marginal chordae were considerably higher than after neochordoplasty.

Between the implantation of 2 and 4 neochordae, the better MVP repair outcomes were achieved with the higher number of neochordae. As 4 neochordae were distributed wider along the free edge of the P2 segment, the larger portion of the leaflet was restricted from the excessive motion, and therefore larger coaptation area and length was observed with each annuloplasty ring size. Similarly, leaflet stresses and chordal forces were lower with the higher number of neochordae, showing that partial force transfer from native chordae to neochordae not only reduces forces in the intact chordae, but also helps to reduce stresses on the leaflets. Downsizing the annulus with a ring reduced leaflet stresses, chordal forces, and increased coaptation even more, thus further improving post-repair valve biomechanics.

In conclusion, our computational results suggest that neochordoplasty for P2 segment prolapse correction is biomechanically optimal and may result in a clinically more durable repair than leaflet resection. However, translational studies will be needed to confirm these findings.

INTRODUCTION

Articular cartilage is a connective tissue that is found in diarthrodial joints, where it facilitates locomotion of the joint by providing a low-friction surface. Articular cartilage injuries are present in up to 66% of knees undergoing cartilage diagnostic procedures for knee pain, where 20% of these lesions are observed in the patella [1]. Full cartilage thickness defects have a prevalence of 4.2% to 6.2% in the general population but increase to 36% in athletes [2]. These defects can impair quality of life and, over time, cause the onset of osteoarthritis. Articular cartilage is both avascular and aneural, with limited regenerative capacity, often requiring surgical intervention to repair defects.

Osteochondral allograft (OCA) transplantation is one of the surgical methods for treating cartilage defects of the knee. The main advantage of this procedure being that a single operation can restore the cartilage surface in the defect site. In this procedure, a donor graft of cartilage along with the underlying bone is transplanted into the cartilage defect site of the patient. The underlying bone allows the graft to be press-fit into the defect for stability. OCA transplants have shown positive patient outcome scores and graft survival rates ranging from 79% to 100% at 5 years and up to 78.7% at 10 years [3]. For the patella, however, this procedure is associated with a high level of reoperation and failure, 51.6% and 20.1% respectively [4]. The mechanism of failure of OCA transplants is currently unknown. Matching the thickness and mechanical properties of the transplanted cartilage to the recipient tissue is not part of the graft selection protocol for OCA transplants. Our hypothesis is that geometric and mechanical mismatches in donor and recipient cartilage will cause local stress concentration on the graft boundary that may lead to OCA transplant failure.

METHODS

Finite element (FE) methods were used to vary several geometric and mechanical properties that could influence failure rates. Simplified 2D axisymmetric FE models were created in ABAQUS (SIMULIA) for this project (Fig 1), where the donor cartilage radius from the center of the OCA graft (rotation axis) is 8 mm. In these models a surface pressure of 1 MPa was applied to the patella cartilage surface, while the subchondral bone surface was fixed. Donor/Recipient (D/R) thickness ratio was varied using 9 combinations, 5 combinations having $D/R \geq 1$ and 4 having $D/R < 1$. The cartilage was assumed to be a linear elastic material with Poisson's ratio of $\upsilon = 0.46$ and the Young's Modulus varied between $E = 2.5$ MPa and 7 MPa for of total 11 different combinations where either the donor or recipient cartilage section was fixed at 7 MPa. The models were meshed with quadratic eight-node axisymmetric (CAX8) elements. Four different outcomes were obtained from all the models; these were compressive stress, compressive strain, shear stress and shear strain. The magnitude for these outcomes were plotted 1 mm from the graft boundary and the peak value was obtained. The model with D/R thickness ratio equal to 1 and equal mechanical properties between cartilage sections was considered as the control. The peak value for each outcome for the different variations in D/R thickness ratio and mechanical properties was compared to that of the control model.

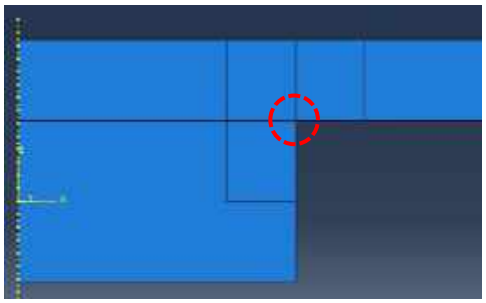

Figure 1: Example of 2D axisymmetric FE models used to vary D/R thickness and mechanical properties. The highlighted section is where local stress concentration occurs.

RESULTS

Based on the number of combinations for the D/R thickness ratio of the cartilage sections and Young's modulus, there were 99 peak value magnitudes for each outcome previously stated. For both stress outcomes, when the mechanical properties were fixed, and the D/R ratio increased in disparity, the magnitude of the stress outcomes increased. A combinatorial effect was present where a high disparity in both D/R ratio and mechanical properties increased stress magnitude. This can be observed in opposite top-right and bottom-left corners of the heatmap on Fig 2(A). The control model had a magnitude of compressive stress of 1 MPa at the graft boundary, while the maximum values occurred when both disparities of D/R ratio were highest. The compressive stress magnitude increased to 6 MPa when D/R is 3.25 and the moduli combination is 2.5/7 (Young's modulus for donor and recipient cartilage is 2.5 MPa and 7 MPa, respectively). The increase in magnitude for the compressive stress of both extrema of the moduli combinations against the control combination can be observed in Fig 3.

The control model had no shear stress present at the graft boundary but when the D/R ratio was increased to 3.25 and the moduli combination is 2.5/7, the shear stress increased to 1.8 MPa. For the strain outcomes, a similar effect was observed where if the mechanical properties are fixed, then increasing the D/R ratio disparity caused an increase in magnitude of the strain in the graft boundary. This increase in magnitude of the strain outcomes was also observed if the D/R thickness ratio was fixed and the moduli of the cartilage sections increased in disparity. Both trends can be observed in the heatmap in Fig 2(B). The control model had a compressive strain of 0.03; however, when both factors increased in disparity the strain increased up to 0.60. While the shear strain control model has a value of 0, once the disparities in both factors were present the value for strain increased up to 0.78 at highest D/R thickness and moduli combination disparity.

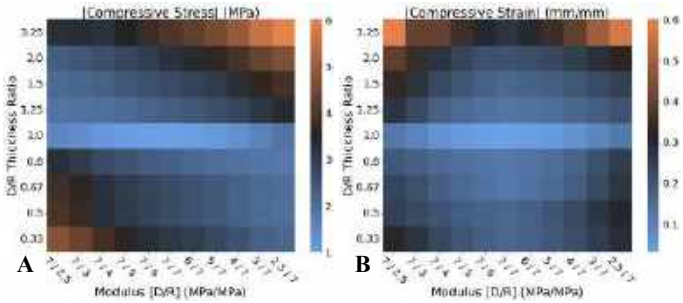

Figure 2: Heat maps for two of the four outcomes for the magnitude of the peak values of (A) compressive stress and (B) compressive strain.

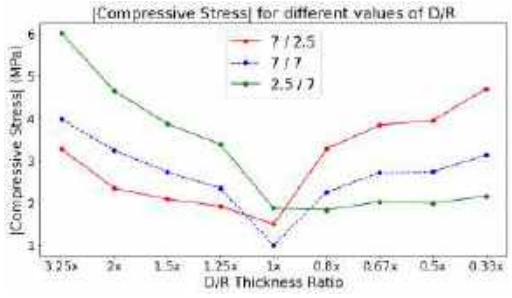

Figure 3: Plots for compressive stress magnitude at different D/R thickness ratios for three D/R moduli combinations.

DISCUSSION

The 2D models used demonstrated increased magnitudes of the stress and strain outcomes when a disparity in D/R thickness ratio and mechanical properties were present. This effect was further exacerbated when a high disparity for both factors was present in the model. Compressive stress values increased sixfold when both factors were mismatched to their maximum. The compressive strain increased from 0.031 to 0.60 at the maximum disparity. According to previous work done [5-6], the observed value of stress and strain could possibly cause apoptosis of the cartilage's chondrocytes. This could lead to the donor and recipient cartilage sections not integrating correctly or the transplant failing altogether.

It is important to also mention the limitations of this study. The articular cartilage was assumed to be a linear elastic material and it is understood that cartilage is an anisotropic material with depth dependent material properties. Utilizing a physiologically accurate material model for the FE models will help further inform on the effect of the mismatched thickness and mechanical properties. This will be addressed by creating a functional gradient of the cartilage through-thickness material properties and using non-linear, anisotropic material models. In addition, simplified 2D axisymmetric models were used to model the patella's cartilage and its loading condition. Due to the axisymmetric models, the load was applied throughout the whole surface of the cartilage. This is not the physiological loading conditions on the patella since its contact with the femur depends on the knee flexion angle and the full surface is never fully engaged. We will address this by utilizing 3D patient-specific FE models which can be accessed through deidentified CT scans of patellae with OCA transplants and varying the surface pressure based on knee flexion angle. Overall, the results from this study support our hypothesis that a greater thickness and mechanical property mismatch between the donor and recipient cartilage create local stress concentration on the graft boundary that exceeds the value that could cause OCA transplant failure.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Jonathan Estrada, Dr. Ulrich Scheven, Nathaly Villacis, Charlotte Andreasen, and Peter Kuetzing for their feedback on the model and data analysis and the results.

INTRODUCTION

Cardiovascular tissues are exposed to constant dynamic mechanical loads *in vivo*. During a normal cardiac cycle, the ventricular myocardium undergoes large multidirectional strains [1], which can be altered by disease, such as post-myocardial infarction [2], or as a result of surgical interventions [3]. Contractile functionality is influenced by these changing strains, thus, there is a need to understand how the heart mechano-adapts to its mechanical environment.

Here we aim to measure and characterize how the force of contraction in single neonatal cardiac myocytes is influenced by biaxial deformation. We previously developed the cellular microbiaxial stretching (CμBS) method to measure single-cell mechanics and characterize the anisotropic mechanical properties of cells exposed to complex loading conditions in vitro [4,5]. We hypothesize that myocyte stress-strain relations are more complex than the typical length-tension relationship used to characterize striated muscle cell contraction. Here, CμBS is used to strain cardiac myocytes micropatterned with in vivo-like geometries to test this hypothesis.

METHODS

Cellular Microbiaxial Stretching. The CμBS device is a custom built, microscope-mounted stretcher consisting of four linear actuators that transfer strains to the cells micropatterned on polyacrylamide (PA) gels on flexible elastomer membranes [5] (Fig 1A). Micropatterned CμBS substrates were prepared as previously described [5] with rectangular features (aspect ratio: 7:1, area: 2400 μm^2) (Fig 1B) for micropatterning cardiac myocytes into an in vivo like geometry. Cardiomyocytes were isolated from pups from timed pregnant Black 6 mice using standard methods [6] and seeded onto the prepared substrates. Four straining protocols were applied to the micropatterned cells such that the cell was extended (tension) or shortened (compression) parallel to its long (axial) or short (transverse) axis (Fig 1C). Strains were applied in 5% increments at 0.5 %/s to a maximum of 30% applied strain for tension or -15% applied strain for compression. At each increment, high temporal resolution (100 frames per second) images of the fluorescent bead layer under the contracting cell were acquired. Myocytes were paced at 1 Hz to induce contraction. Traction force microscopy techniques were used to analyze cell forces using acquired image data.

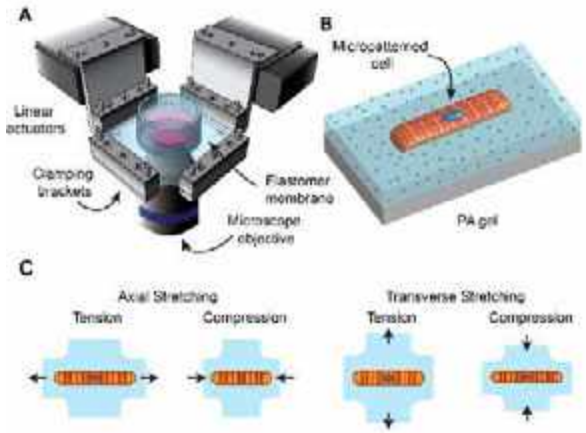

Figure 1: CμBS used to measure strain-dependent forces in single neonatal cardiac myocytes. (A) Schematic of the CμBS device above the microscope objective (B) Schematic of a cardiac myocyte micropatterned in an elongated geometry on a fluorescent bead-doped polyacrylamide gel adhered to an elastomer membrane, (C) Schematics of the stretching protocols applied to myocytes

Strain-dependent contraction model. Two models of strain-dependent contraction were considered: (1) the sarcomere length model in which the force is dependent on the length of the sarcomere as measured from z disc to z disc. This a standard length-tension model [7]. (2) the length-radial spacing model in which the force is dependent

on the length of the sarcomere as well as the radial distance of the actin from the myosin. This is consisten with prior models that suggest that the length-tension relationship is also influenced by acto-myosin lattice spacing. [8]. In both models, the cell was treated as anisotropic and incompressible, undergoing deformation in the principal orientation. The active stress in the cell is a function of the elastic stretch ratio λ^* defined as $\lambda = \lambda^*\lambda_a$, where λ is the observed stretch ratio from CμBS, λ_a is the activation stretch ratio. Active stress is given by

$$\sigma_a = \begin{cases} C_a(\lambda^*)(\lambda^* - 1)(\lambda^*_{crit} - \lambda^*)(1 - R), & \text{for } \lambda^* \le 1 \text{ and } \lambda^* \le \lambda^*_{crit} \\ 0, & \text{for } \lambda^* > 1 \text{ and } \lambda^* > \lambda^*_{crit} \end{cases} \quad (1)$$

where material coefficient C_a is the active cell stiffness. In this model, the active force is zero when the cell is undeformed relative to its zero-stress length, λ^*, or when stretched beyond a maximum value, λ^*_{crit}.

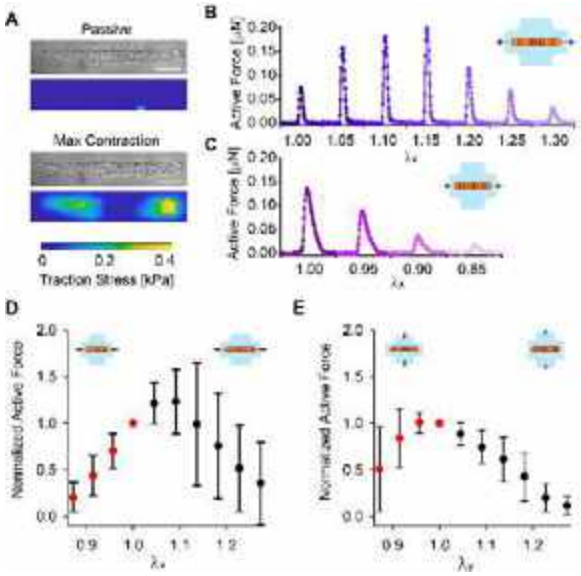

Figure 2: Stretch-mediated contractile force in micropatterned neonatal cardiac myocytes. (A) Bright field images and corresponding traction stress maps for a cardiac myocyte at rest and at maximum contraction (scale bar: 20 μm) (B) Active force for the duration of a single beat in a representative cell paced at 1Hz vs axial stretch ratio, when lengthened. (C) Active force for a representative cell paced at 1Hz vs axial stretch ratio, when shortened (D) Active force - stretch normalized to the unstretched force for cells stretched axially (n=17 stretched, 23 compressed) (E) Active force - stretch data normalized to the unstretched force for cells stretched transversely (n = 15 stretched, 11 compressed). For (D,E) black dots = stretched cells, red dots = shortened cells

In the sarcomere length model, $R = 0$. In the length-radial spacing model, consistent with previous models of lattice spacing and force [8], we assume that contractile force is maximized at an optimal actin-myosin spacing of r_o and that deformation in x alters this spacing as

$$r = r_0\lambda_y\lambda_z\left(\lambda_z^2\cos^2\theta + \lambda_y^2\sin^2\theta\right)^{-1/2} \quad (2)$$

And R is given by

$$R = \frac{1}{\pi/2}\int_0^{\frac{\pi}{2}}\left(C_R\left(1 - \frac{r}{r_0}\right)^2\right)d\theta \quad (3)$$

Where C_R is a scaling parameter to be fit.

RESULTS

Using CμBS, we directly measured the effects of deformation on contractile force generation of micropatterned neonatal cardiac myocytes using traction force microscopy methods to measure the difference in passive and contracted myocytes (Fig 2A) Contraction of two representative cells are shown in Fig 2B,C (Fig 2B shows a cell being stretched axially, Fig 2C shows a cell being shortened axially), demonstrating the high temporal resolution of the force measurements. When all measured myocytes were compiled, a clear trend emerged. When cells were axially extended, the active force initially increased, but then generally decreased for stretch ratios greater than 1.15 (Fig 3D). When the myocytes were axially compressed, the active force decreased as the cells were compressed (Fig 3D). This result is consistent with the length-tension relationship for straited muscle tissue [9]. Surprisingly, a similar trend was observed when the cells were stretched transversely. When the cells were stretched or shortened transversely, the axial force decreased (Fig 3E).

To better understand the force-deformation relationship, we first developed an elasticity-based model that incorporated the sarcomere length-tension relation (Eq (1), $R = 0$). This model showed good agreement with our axial stretching data (Fig 3B), but poor agreement with transverse stretching data (Fig 3C). The radial spacing term (Eqs (1)-(3)) was added to the model to account for the 3D lattice structure of the sarcomere and radial organization of actin thin filaments around myosin thick filaments (Fig 3A). With lattice deformation incorporated, the model better matched all experimental data.

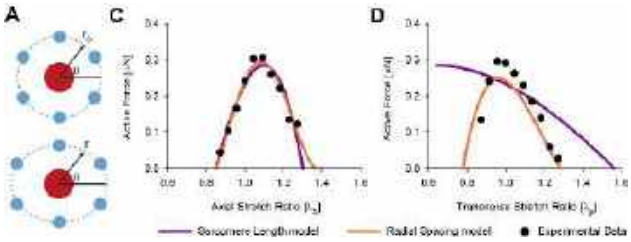

Figure 3: Active-contraction based model considering sarcomere length and lattice spacing recapitulates experimentally observed force trends. (A) Schematic of the rationale behind the radial term for the model, (B,C) Sarcomere length and radial spacing models compared to experimental data for (B) axial stretching, and (C) transverse stretching.

DISCUSSION

The sarcomere cytoskeleton within striated muscle is a three-dimensional lattice of actin and myosin. It has also been theorized that lattice spacing in addition to sarcomere spacing influences the force generation in striated muscle [8]. Because measuring lattice spacing during stretch is complex, teasing out its influence on force is more challenging to accomplish experimentally. Here, we use CμBS to measure single-cell deformation-dependent contraction of cardiomyocyte's and find that standard models that only account for z-line spacing are unable to capture our experimental data. This result suggests that the biaxial nature of cardiac loading should be included in models of cardiac mechanics and mechano-adaptation.

ENHANCING UNDERSTANDING OF DRUG EFFICACY AND CARDIOVASCULAR DIAGNOSTICS THROUGH A COMPUTATIONAL BIOTRANSPORT MODEL

Abhi Roop Reddy. Tokala (1), Dr. Mahsa Dabagh (1)

(1) Biomedical Engineering, College of engineering and applied sciences-University of Wisconsin Milwaukee, Milwaukee, Wisconsin, USA

INTRODUCTION

In the realm of pharmacology and cardiovascular health, accurately predicting the interplay between drug kinetics and body dynamics is pivotal. Existing computational models often fall short in mirroring the intricacies of drug distribution and cardiovascular responses in individuals. This gap underscores the need for a more sophisticated and personalized approach.

Several studies emphasize this point[1], [2], [3]. Siccardi et al., demonstrated in 2016 the effectiveness of physiologically based computational models in optimizing antiretroviral doses, showcasing the potential of such models in predicting pharmacokinetics in complex clinical scenarios[1]. Similarly, Chabiniok et al. emphasized the role of computational modeling in understanding the heart's complex hierarchical structure and function, integrating experimental and clinical data for translational cardiac modeling [2]. Furthermore, [3] proposed a comprehensive public domain resource for cardiovascular researchers, highlighting the need for less computationally intensive model, that can give a general result and later a more personalized and computationally intensive model that would specific result[3].

Our project aims to develop a computational biotransport model that integrates pharmacokinetics, pharmacodynamics, and cardiovascular physiology. This model attempts to enhance the precision of drug behavior predictions and cardiovascular responses, which could make way to personalized digital medicine solutions by providing healthcare professionals with a robust tool for understanding and possibly optimizing treatment efficacy and safety. The evidence from existing research supports the feasibility and necessity of this approach in improving drug safety and efficacy in cardiovascular health[1], [2], [3].

METHODS

Our approach involved developing a MATLAB-based and Simulink-based computational model integrating various biotransport mechanisms. The model employed a physiologically based pharmacokinetic (PBPK) model framework to simulate drug distribution and elimination. The Windkessel model, representing cardiovascular dynamics, was adapted to assess the impact of drug interactions on heart rate and blood pressure. Parameters specific to drugs obtained from publicly available information and patient specific information are incorporated through user input. This integration allowed for the simulation of drug concentration over time and its physiological effects, offering a nuanced view of drug behavior in the cardiovascular system.

Equations:

PBPK model:

$$C(t) = \frac{D}{Vd} e^{-ke*t} \quad (1)$$

$$ke = \frac{ln(2)}{t\left(\frac{1}{2}\right)} \quad (2)$$

$$\frac{dC(t)}{dt} = Q(C_{blood} - C_{tissue}) \quad (3)$$

$$Q = CO \times BF \quad (4)$$

$$Kp = C_{tissue}/C_{plasma} \quad (5)$$

$$clearance = ER_{organ} \times Q_{organ} \quad (6)$$

$$\frac{dP(t)}{dt} = \frac{Q(t) - \frac{P(t)}{R}}{C} \quad (7)$$

$$E(t) = \frac{[A(t)]^n}{[A(t)]^n + EC50^n} E_{max} \quad (8)$$

RESULTS

Results for Sample drug- Amiodarone(Antiarrhythmic):

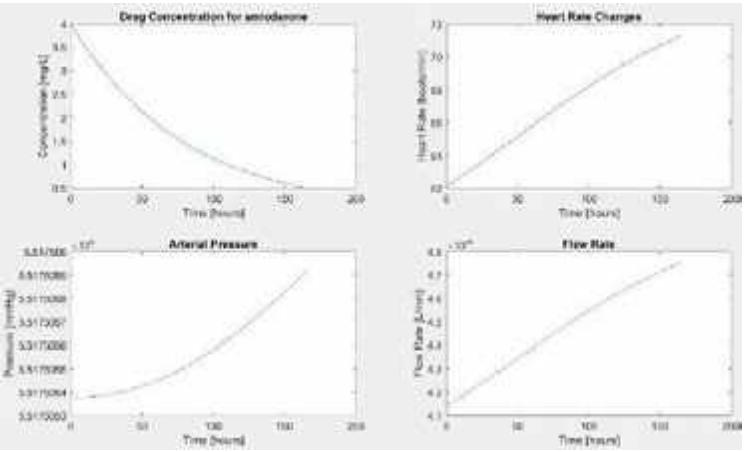

Figure 1: Plots: top left-drug concentration over time in hours, top right-heart rate changes over time in hours, bottom left-arterial pressure over time in hours and bottom right-flow rate over time in hours.

Parameters used:

Drug	Amiodarone
Dose (mg)	300-400 (IV loading dose)
Volume of Distribution (L)	60-140
Drug Half-Life (hours)	40-55
Baseline Heart Rate (beats/min)	75
Maximum Change in Heart Rate (beats/min)	+/- 20
EC50 for Heart Rate Change (mg/L)	2.2

Table 1: Table showing parameters relevant to amiodarone that were input.

DISCUSSION

The model's ability to simulate pharmacokinetics and patient-specific cardiovascular responses under varying conditions align well with current biomedical research trends focusing on personalized medicine. While traditional models often provide a generalized approach, our model's ability to adjust parameters like drug dosage, type, and patient-specific factors allows the model to predict individual responses more accurately, leading to tailored therapeutic strategies.

In a scientific context, while the model provides an advanced simulation of biotransport phenomena, its accuracy is contingent upon the reliability of the input parameters and the model's assumptions. Continued validation with relevant clinical data is essential to refine its predictive capabilities.

With higher computational intensity and numerical complexity, such models have profound implications for digital medical solutions. These models represent a significant step towards personalized healthcare, where treatment plans are optimized based on individual physiological characteristics. This not only enhances the efficacy of therapies but also minimizes the risk of adverse effects like overdosing. In the era of digital health, these models could serve as powerful tools for clinicians and researchers, aiding in drug development, therapeutic planning, and understanding complex biotransport mechanisms.

In conclusion, our findings underscore the potential of computational models in enhancing personalized healthcare, suggesting a future where treatment plans are more accurately tailored to individualized patient needs.

ACKNOWLEDGEMENTS

The model was developed with the guidance of Dr.Mahsa Dabagh, who asked important questions which allowed for the creation of the model. Dr. Mahsa Dabagh has also provided meaningful motivation and enthusiasm toward the project. The model was tested through the use of multiple drugs/drug types by Aaron, Se-jin and Alejandro.

INTRODUCTION

For many years, researchers have been trying to create realistic computational models that accurately represent the mechanical behavior of the heart [1]. However, this is a difficult task involving accounting for the heart's complex dynamics, fiber structure, and material properties. Additionally, modeling efforts are complicated by the need to reproduce the circulatory system and the cyclical function of the heart accurately, which are crucially linked to heart function [2]. Recent technological advancements in individual anatomy reconstruction and computational models have simplified the validation process, facilitating creation of patient-specific models that replicate the characteristics of an individual's heart. These models simulate the cardiac cycle using computational techniques by starting from 3D reconstructions of clinical images and incorporating rule-based fiber orientation for the left ventricle (LV) [3]. They can help identify functional aspects or pathological variations by analyzing patient-specific heart mechanics.

Our goal is to use high resolution (both spatial and temporal) patient-specific magnetic resonance imaging (MRI) data to validate computational models and improve our understanding of left ventricular (LV) mechanics. Traditional cardiac modeling often relies on generalized data (e.g. non-patient specific and static), which may only capture a portion of LV dynamics. In contrast, our approach compares simulation results with patient-specific high temporal resolution MRI data across different cardiac phases. We focus on pressure-volume relationships and variations in LV wall thickness to ensure model accuracy. Analyzing high resolution MRI frames throughout a cardiac cycle can bridge the gap between microscopic and macroscopic changes in response to cardiac dynamics and unlock the potential for more precise patient-specific simulations for diagnosis and treatment [4]. Additionally, this high-resolution capability could enhance machine-learning methods for predicting cardiac mechanics [5].

METHODS

We utilized 4D patient-specific cardiac geometries obtained from MRI scans to perform finite element (FE) simulations of the left ventricle (LV) during the cardiac cycle. To construct a model of the LV, we initially created a 3D representation of the heart's geometry acquired through a high-resolution (1.6 mm × 1.6 mm × 1.6 mm, 30 frames/s) MRI of a patient's (75 year old male with constrictive pericarditis) torso using a 3T MR system (MAGNETOM Cima.X, Siemens Healthineers AG, Erlangen, Germany). We manually segmented the LV using 3D Slicer, an open-source medical image viewing and editing software. We utilized the Cotan smoothing function on Meshmixer [6] with a smoothness setting of 1 and a scale of 4 to improve the 3D LV model while preserving its essential features. The resulting boundary contours were then exported to SolidWorks (Dassault Systemes, MA USA) for geometry reconstruction and subsequently meshed using ABAQUS

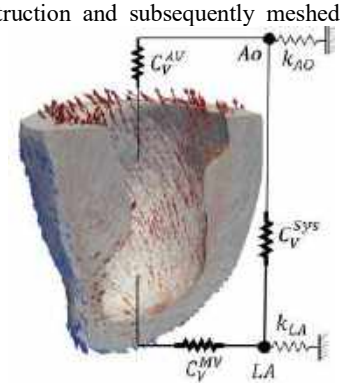

Figure 1. Human LV reconstructed from MRI with a rule-based fiber architecture model and circulatory system.

(Dassault Systemes, Johnston, RI, USA) with 65186 tetrahedron elements (C3D4) having an element edge length of approximately 2.5 mm, resulting in 4–5 layers of elements across the myocardial wall.

To account for the varied fiber distribution within the LV, we generated a layered fiber architecture using a rule-based method (RBM) and the Laplace–Dirichlet Rule-Based (LDRB) algorithm [7], with epicardial–endocardial helix angles ranging from -60° to 60° (Figure 1). The passive behavior of the myocardium was represented as a transversely isotropic hyperelastic model with the Fung strain energy density function [8],

$$\psi(\boldsymbol{E}) = \left(\frac{C_0}{2}\right)\left(e^{Q(\boldsymbol{E})} - 1\right) + \frac{1}{D}\frac{(J^{el})^2 - 1}{2} - ln(J^{el}) \qquad (1)$$

involving parameters such as C_0 (elastic constant), Q as a function of Green-Lagrange strain tensor $\boldsymbol{E}$, D (equal to $\frac{2}{K}$, where K is the bulk modulus), and J^{el} (elastic volume ratio). For details regarding the parameters refer to [3]. A time-dependent active tension or active strain was added to the hyperelastic constitutive model using the ABAQUS Explicit software to simulate active contraction during systole.

This model simulates heart functions by integrating the LV with the pulmonary and systemic circulations (Figure 1). It mimics diastolic filling and systolic ejection using surface-based fluid cavities and exchanges, ensuring accurate physiological pressure and blood flow. Key components include the aorta (Ao), left atrium (LA), aortic (AV), and mitral valves (MV), along with systemic circulation (Sys). The Ao and LA cavities have spring stiffness (k) for compliance, and Cv represents viscous resistance. Valves permit one-way fluid flow. For details refer to [2].

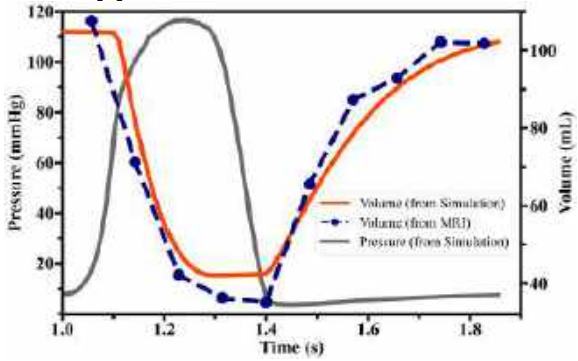

Figure 2. Simulated pressure and volume, and actual volume obtained from MRI

RESULTS

We analyzed myocardial wall thickness by combining data from 10 manually segmented 4D MRI frames with simulated results. First, in Figure 2, we compare LV pressure-volume relationships derived from our FE simulations across various phases of the cardiac cycle with the actual volumes obtained from MRI data at corresponding stages of the left ventricular cycle. Figure 3 shows the variation of the LV wall thickness with time over a cardiac cycle (green line). There is a gradual increase in the median thickness of the LV wall, extending from end-diastole to its peak at end-systole. This aligns with heart physiology, where a decrease in ventricular volume and a simultaneous pressure increase during systole lead to thicker myocardial walls. The initial difference in LV thickness between the simulation and MRI data could be attributed to our simulation methodology. We started the simulations near the end-diastole and then increased the pressure by 8 mmHg to replicate the end-diastolic state.

The wall thickness decreases as the cycle progresses towards end-diastole, indicating ventricular relaxation and volume expansion phases—similarly, the wall thickness increases during systole, followed by a decrease towards diastole. Although the simulation and MRI measurements show a slight (1-2 mm) difference, both datasets demonstrate a consistent pattern. This trend is evidence of the accuracy of our model in representing fiber orientation and active contraction during the systolic phase. The box plots in Figure 3, centered around the median thickness for each frame, highlight the asymmetry in thickness distribution throughout the cardiac cycle. MRI and simulation data show that the minimum values are closer to the median, whereas the maximum values are more distant. For example, during systole, the maximum normalized values reach roughly 1.75 times the median, while the minimum values fall below 0.5 times the median. This difference is slightly more noticeable in diastole, where the maximum values extend to 1.8 times the median. Consistent skewness throughout the cycle offers insights into myocardial wall stress and strain, reflecting how different myocardial regions respond to pressure and volume changes.

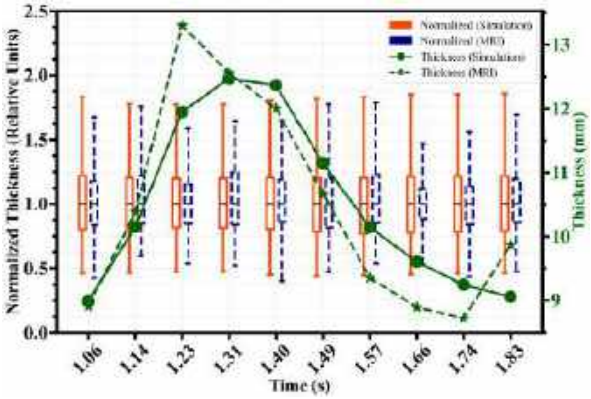

Figure 3. Median myocardial wall thickness and normalized distribution across ten cardiac cycle frames, comparing MRI-derived STL models and simulation data.

The findings mentioned here are crucial for research studies on changes in myocardial thickness. By examining the variability, skewness, and median thickness of the distribution, we can understand the structural dynamics and cardiac function during the cardiac cycle. These results align with physiological principles and provide a basis for advanced modeling in cardiac research.

DISCUSSION

Our study provides a detailed analysis of myocardial wall thickness across the cardiac cycle, offering insights into cardiac mechanics. We observe changes in wall thickness from end-diastole to near-end systole, correlating them with pressure-volume relationships. The pattern of increasing median LV wall thickness during systole, followed by a decrease in diastole, aligns with physiological expectations, highlighting the interplay between ventricular volume, myocardial wall stress, and thickness. These variations indicate differential responses to pressure and volume changes in various myocardial regions, aiding in understanding asymmetric myocardial behavior and potentially detecting cardiac pathologies. Combining simulation and imaging data validates the simulation model, paving the way for enhanced diagnostic and therapeutic strategies in cardiology, bridging theoretical models and clinical imaging, and advancing cardiac research and clinical practice.

INTRODUCTION

Chronic pain is a major health problem with large costs [1,2]. Although degeneration is a primary source of joint pain and can result from trauma [3,4], its specific pain mechanisms are not well-defined. The spinal capsular ligament encloses the facet joint and is primarily composed of collagen with afferents that can transduce nociceptive signals [5-8]. Ligament injury can alter the extracellular matrix (ECM) and induce collagen reorganization, which also induces pain [9-11]. The matrix metalloproteinases (MMPs) are important regulators of ECM modifications, regulate pathological processes of collagen degradation and can cause pain [12-14]. MMP subtypes increase in injured and/or painful joints [14-16]. While MMP-1 and MMP-2 degrade type I collagen [17,18], MMP-9 regulates collagen organization, and its expression is correlated with MMP-1 in painful joints [19-21].

Although the mechanistic role of MMP-1 in mechanical joint pain has been investigated [21,22], such relationships between MMP-9 and collagen biomechanics are not yet defined. This study utilized an existing in vitro model of the capsular ligament [10,23] to investigate the effects of MMP-9 exposure on the biomechanical response of collagen under its uniaxial stretch to failure. Our neuron-collagen construct (NCC) system that simulates the structure of a capsular ligament was exposed to MMP-9 at a dose comparable to levels in the synovial fluid of human joints diagnosed with rheumatoid arthritis [24]. In addition to defining the macroscale biomechanics at failure, after MMP-9 exposure, effects on collagen were measured using immunohistochemistry and quantitative densitometry.

METHODS

NCCs (n=11) were prepared using 2mg/mL rat tail collagen I and dorsal root ganglia neurons ($3x10^5$ cells/mL) extracted from embryonic day 18 rats [10,23]. Neurons were dissociated, seeded on the collagen gel surface, and cultured at 37˚C in 5% CO_2. On day 3, more collagen (150µL) was added to encapsulate the neurons [10,23]. On day 7, the NCCs were transferred to 1xPBS with 1% Pen-Strep and cut into a strip (21mmX8mm). The remaining parts served as unloaded controls (n=2) for immunolabelling. A grid of nodes was drawn on the surface of the NCCs to define elements for strain analysis (Fig. 1). Before stretch, NCCs were exposed for 15mins to 150µL of either 2µg/ml of MMP-9 (R&D Systems) in PBS (n=5) or PBS as a vehicle (n=6). All NCCs were submerged in a 37˚C PBS bath and mounted in a planar testing machine (TestResources) for uniaxial stretch (Fig. 1). The reference state was established for each NCC when slack in the gel was removed. Each loading arm was moved apart by 6mm at 0.5mm/s until failure. During stretch, force-displacement data were recorded at 500Hz, and a high-speed Phantom-v9.1 camera (Vision Research) tracked the NCC and its grid at 500fps; video and transducer data were synchronized.

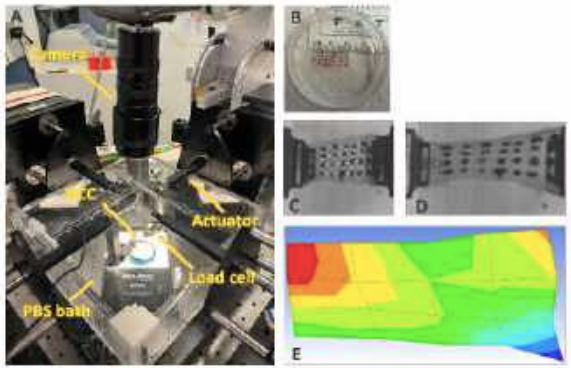

Figure 1. (A) Test set-up. (B) Grid on NCC before mounting in device arms (C) before stretch and (D) at failure. White lines in (C) define elements. (E) Corresponding MPS map at failure.

Force and displacement data were filtered with a 600-point moving average filter in MATLAB. For each NCC, macroscopic mechanical parameters were measured from the force-displacement curves: failure

force, failure displacement, stiffness, toe region, and area under the curve (AUC) of the toe region [10,11]. Failure was defined as the peak of the force-displacement curve; stiffness was calculated as the slope of the linear region of the force-displacement curve from 20-80% of failure (Fig. 2). The toe region was defined as up to 20% of failure (Fig. 2) and the AUC was calculated by the MATLAB trapezoidal numerical integration function. ProAnalyst software (Xcitex) tracked displacements of the marker nodes defining NCC elements during stretch (Fig. 1) [10,11]. LS-DYNA (LSTC) calculated the maximum principal (MPS) and shear strains for each element (Fig. 1) of each NCC; the average across all elements and peak in any NCC of MPS and shear strains were calculated. These mechanical outcomes were compared between MMP-9 and vehicle exposed groups by a Student's t-test.

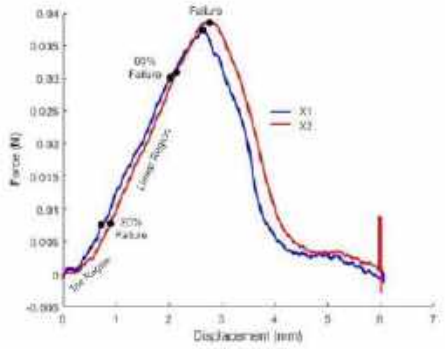

Figure 2. Force-displacement curves for each arm (X1, X2) of NCC exposed to MMP-9 labeling failure, linear region, and toe region.

A subset of NCCs (n=5 MMP-9; n=2 vehicle) was fixed in 4% PFA for 2hrs after loading and then triple-washed by PBS for 10mins each. NCCs were blocked for 2hrs using 0.3% Triton-X and 10% normal goat serum in PBS at room temperature and then incubated with primary antibody mouse anti-collagen antibody (1:200; Abcam) overnight at 4°C to label collagen. The next day they were washed with PBS and incubated for 2hrs in goat anti-mouse AlexaFluor568 antibody (1:500; Invitrogen). Images (n=4-5/NCC) were captured across the grid of nodes using a Leica TCS SP8 confocal microscope at 63X. Quantitative densitometry measured the percent of pixels positive for collagen and averaged across images for each NCC [23]. Averages were determined for both groups of NCCs and compared using a Student's t-test.

RESULTS

Based on the linear region of the force-displacement curves, the MMP-9 group (0.026±0.01 N/mm) is less (p=0.016) stiff than the group exposed only to PBS (0.19±0.14 N/mm). Interestingly, the force at failure is higher (p<0.001) for the MMP-9 group (37.8±4.9mN) than the vehicle group (17.9±7.1mN), while MMP-9 exposure reduces the displacement at failure (2.0±0.5mm) compared to the vehicle group (3.0±1.8mm), but not significantly (p=0.14). The AUC for the toe region is larger (p=0.017) for the vehicle group (0.13±0.12 N·mm) than the MMP-9 (0.002±0.0008 N·mm).

While most NCCs failed with a tear in the gel, 1 of the MMP-9 and 2 of the vehicle NCCs slipped out of a grip. Failure strains increase in NCCs exposed to MMP-9 compared those exposed to vehicle. Both peak MPS (0.89±0.44) and peak shear strain (1.02±0.44) are greater (p<0.006) after MMP-9 exposure than a PBS vehicle exposure (0.30±0.09 MPS; 0.35±0.12 shear strain). When considering average strain responses across elements there are no significant differences between treatment groups for either MPS (0.23±0.07 MMP-9; 0.20±0.06 vehicle) or shear strain (0.28±0.07 MMP-9; 0.25±0.08 vehicle). Consistent with the average strain data, the amount of collagen in NCCs is not different (p=0.25) regardless of whether they are exposed to MMP-9 (49.7±13.1%) or PBS vehicle (42.1±4.3%).

DISCUSSION

The reduced NCC stiffness and AUC for the toe region observed with MMP-9 exposure suggests a weakened state for the NCCs after MMP-9 exposure despite no detectable change in collagen (42-50%) between groups. However, the force at failure nearly doubled after MMP-9 which implies a stronger state. Of note, failure force varies substantively (~39% of mean) for the vehicle group and 2 of the 6 samples slipped out of the grips. It is possible that the increase in failure force that is detected may be due to artefacts of the testing set-up, including the initial positioning and/or mounting in the grips. Since the initial configuration was taken to be the state when the gel had no slack evident, any subjectivity and/or variability across gels could impact the outcomes. In fact, the peak strain data support greater distortion after MMP-9 exposure. Additional studies are needed that better quantify the starting position for both groups and also evaluate additional biomechanical and compositional metrics.

MMPs have a broad range of actions, including MMP-1 affecting the biomechanical and pain responses of ligaments and collagen constructs [21,22]. Although less is known about MMP-9, its active form is related to articular cartilage degradation and pain in human patients and its cleavage effects depend on the timing in vivo [14,25]. This study used human MMP-9 on mouse collagen and exposures of only 15mins for ease of experimental design. Future studies evaluating the temporal effects of the active form of mouse MMP-9 would help elucidate potential mechanisms of degradation, micromechanical responses, and also potential effects on the embedded neurons. Since MMP-9 activates the NR1/NR2B receptor and cleaves IL-1β [26,27], it likely has direct effects on neuronal regulation of pain.

INTRODUCTION

Fibrosis and scarring remain significant problems that impact quality of life for millions of people [1]. A range of treatment options to reduce scarring have been explored that target a variety of cell types, including myofibroblasts due to their central role in synthesizing extracellular matrix (ECM) proteins during the healing process [2]. Recent work indicates that some adipose tissues also contribute to the wound healing process [3]. In addition, there are reports that fat grafting in reconstructive surgery can improve the appearance of existing scars [4]. Adipose tissues are composed of a continuum of cell types that include adipocyte-derived stem cells (ADSCs), preadipocytes, and adipocytes, each of which can contribute to ECM remodeling. To better understand how adipocyte lineage cells interact with fibroblasts during wound healing, we have begun using engineered *in vitro* systems to characterize how these cells interact with each other to remodel the ECM. We have found that adipocytes secrete factors that convert human dermal fibroblasts into highly contractile, ECM producing myofibroblasts through a TGF-β1-independent mechanism [5], and that preadipocytes have a substantially different adipokine secretion profile from adipocytes [6]. Here, we use our *in vitro* system to investigate how fibroblast-adipocyte lineage cell interactions evolve over time via time-lapse imaging and proteomic analysis of the ECM proteins they produce. Our ultimate goal is to use this information to develop an effective adipose-tissue-based therapeutic strategy for reducing scar tissue.

METHODS

Spheroid Formation: Immortalized human dermal fibroblasts were formed into spheroids containing ~20,000 cells and placed on the surface of ~ 6 mg/mL fibrin gels. Immortalized human ADSCs, were converted into pre-adipocytes and formed into spheroids, as described in [5,6]. A subset of these spheroids were also converted into adipocytes by culturing them for 10 days in differentiation medium (PDM2). Six combinations of spheroid pairs were examined: (1) fibroblast-fibroblast (FF), (2) preadipocyte-preadipocyte (PP), (3) adipocyte-adipocyte (AA), (4) fibroblast-preadipocyte (FP), (5) fibroblast-adipocyte (FA), and (6) preadipocyte-adipocyte (PA). Each spheroid pairing involved carefully positioning them 1 mm apart at the center of the fibrin gel with the aid of a stencil. The gel-spheroid system was then incubated at 37 ºC and 5% CO_2 for 3 hours to allow for cell attachment before low serum DMEM with 0.5% fetal bovine serum (FBS), 1% penicillin/streptomycin and 0.1% amphotericin B was added.

Microscopy: Prior to placement on the fibrin gel, cells were stained with either wheat-germ agglutinin conjugated with Alexa Fluor 647, or CellTracker-Red. Collagen was visualized with CNA35 [7] conjugated with AlexaFluor 488. Time-lapse image sequences were acquired over seven days using a Nikon TI-E2 A1 confocal microscope and an Oko Labs environmental control unit. Tiled 4x4 images were acquired with a 10x lambda Plan Apo objective every 3 hours.

Mass Spectrometry: Liquid chromatography-tandem mass spectrometry (LC-MS/MS) was employed, as described previously [8], to identify differences in the ECM proteins produced by each of the spheroid combinations imaged. To enrich for ECM proteins, the experiments were repeated in the absence of fibrin gels on tissue culture plastic. Raw data files were imported into MaxQuant, peak lists were matched against the Homo Sapiens Uniprot FASTA database, and raw protein intensities were filtered and analyzed in Excel and visualized and statistically analyzed in GraphPad Prism 9. Identified proteins were grouped into categories based on lists derived from the Gene Ontology (GO) Consortium and The Matrisome Project.

RESULTS

Within hours of placement, the spheroids begin to remodel the fibrin gel. Differences in fibrin reorganization, cell migration, and CNA35 labeling were apparent between the different pairings (Fig. 1). In particular, CNA35 labeling appeared more prominently in and

around the adipocyte spheroids (Fig. 1B, G). However, because CNA35 binds multiple collagens, including types I-VI with different binding affinities, it is difficult to correlate fluorescence intensity with the amount of collagen present.

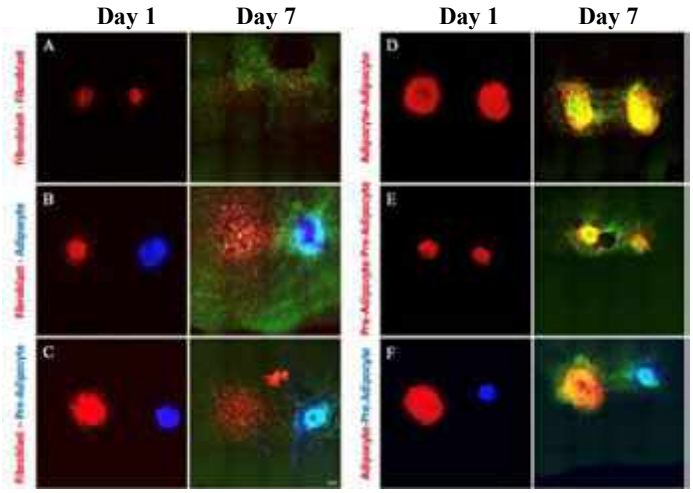

Figure 1: (A-F) Confocal z-projections of spheroid co-cultures on fibrin gels days 1 and 7. Scale bar 100 μm.

Consequently, mass spectrometry was performed to identify and quantify the abundance of collagens and other ECM proteins produced in each spheroid pairing.

For all spheroid pairings, the largest percentage of identified proteins belonged to the *Cytoskeletal* classification, which ranged between 29.3 ± 1.3% (AA) to 47.6 ± 0.8 % (FF), followed by the *Nuclear*, *Cytosolic*, *Matrisome*, and *Membrane* (Fig. 2A).

The distribution of *Matrisome* subcategories differed significantly among the different spheroid pairings (Fig. 2B), with *Collagens* representing the largest subcategory for all cases, except F-F, a behavior consistent for fibroblasts in low serum medium devoid of exogenous growth factors.

The distribution of *Collagens* differed substantially among the groups (Fig. 2C). In total, 9 different collagens (14 total alpha chains) were identified, but in many cases the collagens detected represented less than 1% of all the collagen alpha chains quantified for a given spheroid pairing. In all spheroid combinations, the alpha chains COL4A1, COL4A2, COL12A1, COL14A1, COL18A1 represented 2% or less of the collagens present. The largest percentage of collagen alpha chains identified were associated with type VI and type I collagen. The spheroid combinations of AA, FA, and FF had the most alpha chains associated with type VI collagen, with the sum of the percentage of collagen intensities of COL6A1, COL6A2, COL6A2 being AA – 61.1%, FA – 64.0%, and FF – 73.3%). For FP and PP, the majority of alpha chains were associated with type I collagen (sum of COL1A1 and COL1A2, FP – 76.8%, PP – 75.3%). PA was split between type VI and type I at 44.6% and 46.3%, respectively.

Label free quantification (LFQ) was performed in MaxQuant to facilitate direct comparisons of protein abundance among the six groups. LFQ scales the raw intensities of each sample based on common peptides. The resulting number of matrisome proteins retained for each spheroid pairing was FF - 38, FP - 68, PP - 74, FA - 74, PA - 76, and AA – 97. Of the 38 FF proteins identified, 37 of them were present in all spheroid pairings.

From these data some observations can be made: (1) fibroblasts alone did not deposit basement membrane components. Other than fibulin-2 (FBLN2), basement membrane proteins (e.g., COL4A1, COL4A2, and FBLN1) were only found in parings containing adipocytes or pre-adipocytes. FBLN2 which also associates with elastin in the interstitial matrix, was only present in FF. (2) Proteins affiliated with type I collagen fibrillogenesis were highly abundant in spheroid pairings with adipocytes and preadipocytes. (3) The spheroid pairing that produced the most collagens was FP.

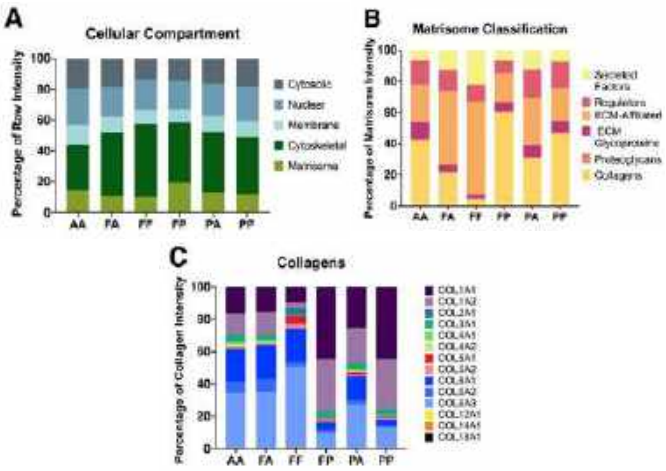

Figure 2: LC-MS/MS distribution of (A) all proteins (B) matrisome proteins (C) collagen alpha chains. AA – adipocyte-adipocyte; FA – fibroblast-adipocyte; FF – fibroblast-fibroblast; FP – fibroblast-preadipocyte; PA – preadipocyte-adipocyte; PP – preadipocyte-preadipocyte.

DISCUSSION

In this study, we used our *in-vitro* fibrin gel system to observe how different combinations of adipocyte lineage cells and dermal fibroblasts remodel fibrin gels. Fibrin gels serve as a simple mimic of a healing wound. Cell spheroids mimic aspects of native tissue function, particularly with respect to adipocyte secretion profiles. Combined the components of our engineered system facilitate manipulation, visualization, and quantification of cell-cell and cell-matrix interactions that coincide with remodeling events, such as those purported to occur with fat grafting. The addition of LC-MS/MS provides an unprecedented view of how these cell types interact to produce ECM proteins. Current efforts are now focused on quantifying how differences in ECM composition relate to mechanical properties. Such data will help us develop adipose-tissue based therapeutic strategies to improve healing and reducing existing scar tissue.

HEMODYNAMIC EVALUATION OF THE SENSITIVITY OF GRAFT MORPHOLOGY ON DIRECT VASCULAR SURGERY FOR MOYAMOYA DISEASE: AN IN VITRO AND IN SILICO STUDY

Cheng Peng (1), Ephraim W. Church (2), Melissa C. Brindise (1)

INTRODUCTION

Moyamoya disease (MMD) is a rare condition marked by reduced brain blood supply due to carotid artery narrowing. This stenosis in the anterior intracranial circulation results in the proliferation of small vessels, resembling a "Puff of Smoke" in angiography [1]. MMD raises the risk of ischemic events and strokes [2]. With no standard drug treatment, direct revascularization surgery is most often used. It involves grafting from extracranial to intracranial to enhance blood supply [3], [4], immediately boosting cerebral perfusion and preventing rebleeding or future strokes [5]. However, significant complications can arise from the direct procedure, including hemorrhage or neural damage leading to neurodegenerative disease onset or cognitive function decline [4], [6]. Hemodynamic abnormalities significantly impact revascularization outcomes. Surgical choices, including donor and recipient vessel selection, graft anastomosis shape, and bypass complex geometry, influence the hemodynamic environment and surgical results. Despite this, few studies have quantitatively assessed the impact of each parameter on bypass hemodynamics. As a result, surgical decisions are often subjective. [7], [8]. In this study, we address this gap by investigating how vessel flow rates and graft vessel attachment angle affect the proportion of back perfusion using both *in vitro* experiments and *in silico* simulations.

METHODS

Three idealized direct bypass surgery models with varying graft angles (30°, 60°, 90°) were manufactured as polydimethylsiloxane (PDMS) blocks (Fig. 1a). An *in vitro* flow loop was designed to simulate the *in vivo* conditions, with a free inlet reverse design (Fig. 1c). The working fluid was water-glycerol-urea mixture with similar viscosity and density as blood [9]. For this study, steady flow was used. Stereo particle image velocimetry (PIV) was used. Particle images were captured in the central plane of the model (Fig. 1b) using a laser (EverGreen, λ=532nm) and two high-speed cameras (ImagePro X,

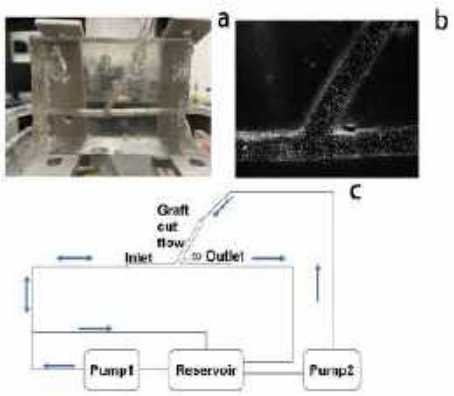

Figure 1. (a) 60º PDMS model, (b) Sample PIV image, (c) Flow loop schematic. Two pumps were used to freely allow inlet backflow.

LaVision). Particle images were processed using Davis 10.0 (LaVision Inc.) using stereo sum of cross-correlation with 150 image pairs.

Computational fluid dynamic (CFD) simulations were performed using Fluent 2023 R2 (ANSYS). Non-Newtonian, incompressible, and laminar flow were assumed. A total of 45 cases are evaluated with inlet flowrates of 0-5 ml/min, graft flowrates of 0-25 ml/min, and 30º, 60º, and 90º angles. Considering the goal of direct revascularization surgery, the best performing scenarios are defined as those which yield the largest backward flowrate in the inlet vessel.

RESULTS

Fig. 2 shows the velocity fields for the 90° and 60° graft angles with inlet/graft flow rates of 5/5 mL/min and 5/20 mL/min. Fig. 2a-d show PIV velocity fields while Fig. 2e and 2f show CFD velocity fields. Comparing Fig. 2a and 2b, the 90º angle yielded only forward perfusion, while the 60º angle resulting in about no perfusion. By increasing the

graft vessel flow rate to 20 mL/min (Fig. 2c and 2d), backflow is observed for both angle cases, with the 60º case still resulting in a larger backflow flowrate. Comparing Fig. 2c and 2d with 2e and 2f, respectively, good agreement between the PIV and CFD velocity fields is observed. Quantitative validation of the CFD is forthcoming. Nonetheless, this validation of our CFD model enables additional test cases to be run using CFD only.

Fig. 3 summarizes the amount of inlet backflow observed across each of the preliminary test cases. The reverse percentage was calculated through the negative(reversed) inlet flow divided by outlet flow. When the inlet flowrate was 0mL/min, no difference in the backflow was observed across graft angle. However, as the graft flowrate increased, the 60° graft angle produced about 5%-20% more back flow than the 90º case with different inlet flow.

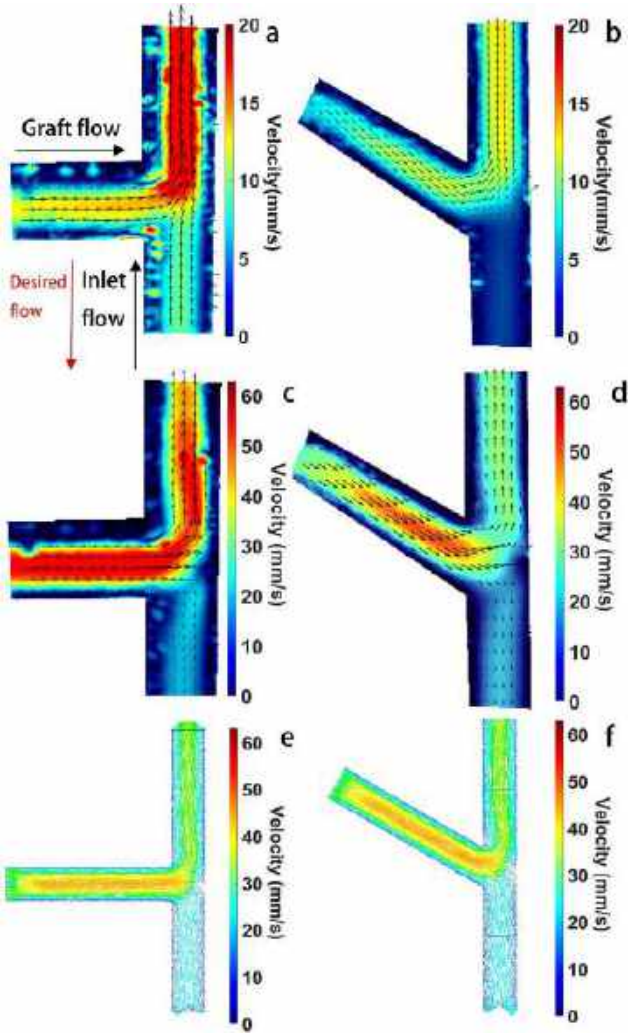

Figure 2. PIV velocity fields for (a) 90°and (b) 60°graft angles with a 5ml/min inlet and 5ml/min graft flowrate. PIV/CFD velocity fields for (c)/(e) 90° and (d)/(f) 60° graft angles with 5ml/min inlet and 20ml/min graft flowrates.

DISCUSSION

This work presents a novel multi-modal investigation aimed at improving the efficacy and outcomes of direct revascularize surgery in MMD. To the best of our knowledge, this is the first such study to evaluate how graft angle affects the bypass hemodynamics. Previous studies have focused on the surgical outcomes and techniques from a statistical point of view.

The main purpose of the surgery is to increase perfusion in the brain regions where the vessels became narrowed. Compared with the 90° cases, the 60° bypass delivered more fluid to the target area, with a higher percentage of reverse flow across the inlet (Fig. 3). Studies [4]–[6] indicate that a high graft flowrate raises complications risk. Therefore, exploring methods to boost backflow without increasing the graft flowrate is crucial. Increased graft angle enhances perfusion without elevating the graft flowrate, potentially improving surgical outcomes. No backflow was observed until the graft (cut) flow was increased to 10ml/min. Currently, extracranial vessels such as carotid artery are most often used; however, the graft vessel flowrate can be adjusted by changing the graft location. This highlights the importance of choosing a proper donor vessel. Because of the natural pressure gradient of the normal inlet, the outlet flowrate was higher than the backflow among all the cases, securing the downstream perfusion. Moreover, Fig. 2 suggests there was no significant increase in the shear stress or high-pressure area, indicating hemolysis or vessel wall damage are not expected for any case.

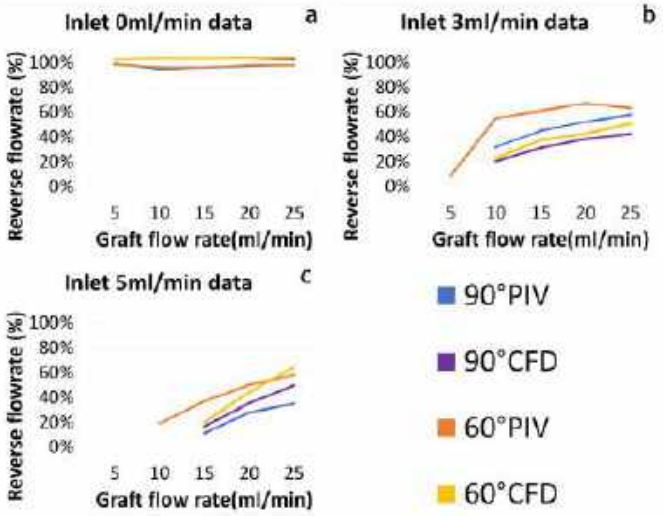

Figure 3. The percentage of reverse flow for (a) 0mL/min (b) 3 mL/min (c) 5ml/min inlet flowrates from PIV experiments & CFD simulations.

Our results emphasize that surgical decisions affecting graft morphology can significantly impact the expected revascularization and thus the surgery outcome. This highlights the importance of our study and need for additional follow up studies aiming to better inform these bypass surgeries. Future studies should focus on using more complex, patient-specific geometries.

AORTIC LOCATION AND SEX SPECIFIC ALTERATIONS IN MECHANICS AND WALL REMODELING IN A MOUSE MODEL OF MARFAN SYNDROME

Krashn Kumar Dwivedi (1), Jacob Rother (1), Jessica E. Wagenseil (1)

(1) Department of Mechanical Engineering and Materials Science, Washington University in St. Louis, St. Louis, MO

INTRODUCTION

Marfan syndrome (MFS) is a hereditary disorder associated with life threatening thoracic aortic aneurysms. MFS results from mutations in fibrillin-1 (*FBN1*), one of the extracellular matrix (ECM) glycoproteins necessary for elastic fiber assembly and their ability to maintain aortic elastic recoil [1,2]. Mutations in *FBN1* cause alterations in ECM constituents, such as fragmentation of elastic fibers and disorganization of collagen fibers, which results in deterioration of aortic mechanics and aneurysm formation. Previous work primarily focused on the mechanics and ECM remodeling of the ascending aorta, where the aneurysm typically occurs, however there is evidence that MFS affects the mechanical function of other segments of the aorta even in the absence of aneurysm [3]. The compromised mechanical properties of the aorta, particularly in distal locations, may affect the overall hemodynamics, which may increase the load on the heart and cyclic stress on the proximal aorta. Additionally, the outcomes of MFS in aneurysm formation are sex specific [4], however, MFS is equally prevalent in males and females. The aim of this work is to investigate sex and aortic location specific alterations of aortic mechanic and ECM remodeling in a mouse model of MFS.

This study presents a comparison of geometry, mechanical properties, and ECM remodeling between the ascending (AA), descending (DA), superior (SAA), and inferior (IAB) abdominal aorta for three months old *Fbln1*$^{mgR/mgR}$ (MU) (model of MFS) [1] and littermate wild type (WT) male and female mice. The results of this work can be used to include the effects of aortic location and sex specific alterations in mechanical properties and structural integrity of the aortic wall on hemodynamic simulations that determine wall stresses and may correlate with aneurysm propensity and outcomes.

METHODS

Mouse model. Three month old male and female MU and WT mice were genotyped, sacrificed, and the AA, DA, SAB, IAB were removed. The tissues were stored in phosphate buffered saline solution at 4°C for up to 3 days before mechanical testing. All experimental protocols were approved by the IACUC.

Mechanical testing. Samples were removed from the fridge and brought to room temperature for 30 min. Samples were cannulated on a pressure myograph for biaxial mechanical tests. The inflation-extension tests on each aorta were performed according to the protocol described previously [5]. Experimental data including pressure, outer diameter, and force corresponding to the in vivo stretch were used to determine the mechanical properties of the aorta. After mechanical tests, three rings from each section were cut and imaged. The images were used to measure the unloaded outer diameter and thickness. Compliance was calculated by,

$$Compliance\ (1/mmHg) = \frac{(D_{i+1}-D_i)}{D_i\times(P_{i+1}-P_i)} \quad \text{, (Eqn. 1)}$$

where P_i and D_i are the applied pressure and corresponding outer diameter at *ith* time point.

Multiphoton imaging. After mechanical testing, a subset of samples was fixed in 4% paraformaldehyde. Samples were flash frozen and 10 µm thick cross sections were cut using a cryostat microtome and cover slipped. Samples were imaged using a Leica Sp-8 DIVE multiphoton microscope with a 40x objective. Collagen, elastin, and cell nuclei were excited at 880 nm and imaged using second-harmonic generation (emission: 420-460 nm), autofluorescence (emission: 495-540 nm), and staining with DAPI (390-460 nm), respectively [6]. Quantitative analyses of the images is ongoing.

Statistics. Statistical analysis was done using GraphPad Prism. Data are presented as mean ± standard deviation. Experimental groups were compared using three-way ANOVA and Sidak's multiple comparisons. P-values <0.05 were considered significant.

RESULTS

Geometry. **Figs. 1A, B** shows the unloaded outer (OD) diameter and thickness of different aortic regions for WT and MU, male and female mice. The results show the increased AA diameter in MU mice compared to WT, associated with aneurysm formation. While both male and female MU mice have overall increased diameters, more individual male mice have increased diameters than female mice. For other aortic regions, OD is almost the same for MU and WT mice, indicating no dilation. There are no significant differences between MU and WT mice for the thickness of any aortic region. OD and thickness values depend significantly on sex (S).

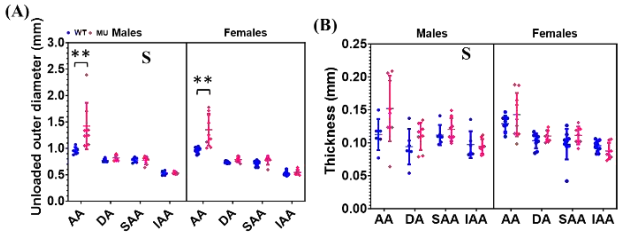

Figure 1: Unloaded outer diameter (A) and thickness (B) of different aortic regions for MU and WT mice. N = 5 – 8/group.

Mechanical testing. Pressure-compliance curves (**Figs. 2A, B**) show a shift of the compliance peak toward lower pressures in MU mice compared to WT, independent of aortic location and sex. At higher pressures, there is reduction in compliance of the aorta which is more significant in MU mice than WT. Based on these observations, we further measured the compliance at low pressure (elastin dominated region) and high pressure (collagen dominated region) (**Figs. 2 B, C**). The significant increase in low pressure compliance in MU aorta (for all sections and in both sexes) indicates possible compromises in elastic fiber integrity. The low pressure compliance increase is greatest in the AA, consistent with dilation of that specific region. The significant decrease in high pressure compliance in MU aorta (for all sections and in both sexes) indicates possible increases in collagen fiber deposition. The AA has the largest decrease in high pressure compliance of all aortic regions, consistent with aneurysm driven wall remodeling in that region. There is a significant interaction between sex (S) and genotype (G) for low and high pressure compliance, indicating sex dependent effects of MFS on aortic mechanics.

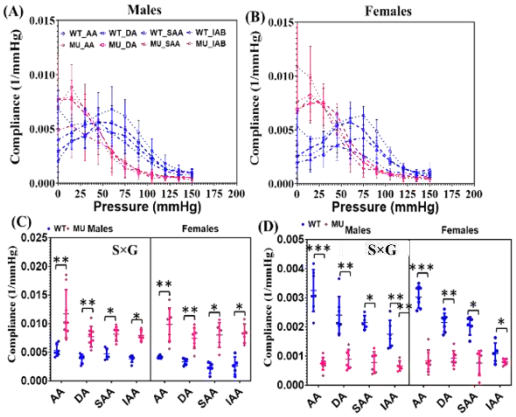

Figure 2: Pressure-compliance curves for WT and MU (A) males and (B) females. Comparison of low pressure (C) and high pressure (D) compliance between MU and WT, male and female mice. N =5-8/group.

Multiphoton imaging. Fig. 3 shows representative multiphoton images of all four aortic regions for WT and MU, male and female mice. In these images, elastic fibers, collagen fibers and cell nuclei are in green, red, and blue/white color, respectively. The images show fragmentation of elastic fibers and deposition of collagen fibers in MU aorta. Quantification of the images is ongoing, however the ECM changes appear to be more apparent in the AA and in male mice.

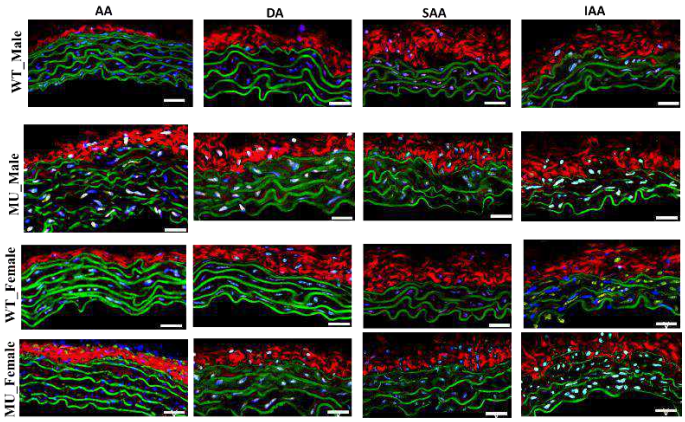

Figure 3: Multiphoton images of AA, DA, SAA and IAA for WT and MU mice. Scale bar = 50 µm.

DISCUSSION

This study investigates sex and aortic location specific differences in a mouse model of MFS. We present data for geometry, mechanics, and wall structure of the AA, DA, SAA, and IAA. The results show that even in the absence of an aneurysm, a mutation in *FBN1* affects the mechanics and ECM remodeling of the aorta throughout the length, and these changes are location and sex specific. The aortic location and sex specific increase in low pressure compliance and decrease in high pressure compliance may be related to location and sex dependent fragmentation of elastic fibers and deposition of collagen fibers, respectively. Qualitatively we observed large fragmentation of elastic fibers and deposition of collagen fibers in MU male AA with aneurysm. The increase in compliance at low pressure may make the aorta susceptible to overdistension in some cases and damage smooth muscle cells within the wall. Further, the decrease in compliance at high (physiologic) pressures for all segments of the aorta can adversely affect cardiovascular hemodynamics. For example, decreased compliance would increase the pulse wave velocity and resulting pulse pressure, leading to an increase in load on the heart and cyclic wall stress on the proximal part of the aorta. Our results indicate that sex specific dilation of AA in MFS may be linked to heterogeneous changes in mechanical properties and structural integrity of the aorta.

AGE AND SEX SPECIFIC BIOMECHANICS AND EXTRACELLULAR MATRIX REMODELING OF THE ASCENDING AORTA IN A MOUSE MODEL OF MARFAN SYNDROME

Krashn Kumar Dwivedi (1), Jacob Rother (1), Jessica E. Wagenseil (1)

(1) Department of Mechanical Engineering and Materials Science, Washington University in St. Louis, St. Louis, MO

INTRODUCTION

Thoracic aortic aneurysm (TAA) is characterized by progressive diameter dilation due to weakening of the aortic wall. TAA is associated with Marfan Syndrome (MFS), caused by mutations in fibrillin-1 (*FBN1*), an extracellular matrix (ECM) macromolecule [1]. Mutations in *FBN1* causes alterations in ECM constituents such as fragmented elastic fibers and improper deposition of collagen fibers, leading to changes in aortic geometry and compromised mechanical properties that contribute to TAA formation and eventual rupture. Male patients with MFS have a higher risk of TAA development, progression, and rupture than age matched female patients with MFS, however the incidence of MFS is not sex dependent [2]. The mechanisms behind the sex specific outcomes of TAA are not clear.

This study presents longitudinal (1, 2, 3 and 4 months old) data on geometry, mechanics, and ECM remodeling of the ascending thoracic aorta in *Fbln1*$^{mgR/mgR}$ (MU) (model of MFS) [3] and littermate wild type (WT) male and female mice. The results are compared amongst age, sex, and genotype to reveal connections between mechanics and ECM remodeling associated with TAA formation and progression. The outcomes of this work can provide biophysical biomarkers for predicting TAA outcomes and its management in males and females.

METHODS

Mouse model. After genotyping, the MU and WT mice were separated according to sex and further divided into age groups of 1, 2, 3 and 4 months. This age range was chosen according to preliminary survival data, as a very low survival rate of MU male mice was found at 4 months of age. All experimental protocols were approved by the IACUC. Each group and experimental measurement has 5-8 mice.

Ultrasound measurement. The in vivo geometry was measured using a small animal ultrasound imaging system (Visualsonics Vevo 2100). Mice were anesthetized with 2% isoflurane, kept warm, and imaged to obtain collect B- mode and M-mode images of the ascending thoracic aorta (ATA) (**Figure 1A**). Images were postprocessed in Visualsonics software to calculate systolic and diastolic diameters. Both diameters were normalized by the mouse weight and in vivo strain was calculated as the % change in diameter from diastole to systole. After imaging, the mice were sacrificed and the ATA was isolated and stored in phosphate buffered saline at 4° C for mechanical testing and ECM imaging.

Mechanical testing. The ATA was cannulated on a pressure myograph for biaxial mechanical tests. The inflation-extension tests on each ATA were performed according to the protocol described previously [4]. Experimental data including pressure, outer diameter, and force corresponding to the in vivo stretch were used to determine the mechanical properties of the ATA. Compliance was measured by,

$$\text{Compliance } (1/\text{mmHg}) = \frac{(D_{i+1}-D_i)}{D_i\times(P_{i+1}-P_i)} \quad \text{, (Eqn. 1)}$$

where D_i = outer diameter at applied pressure P_i at *ith* time step. Mid-wall circumferential stretch and stress were determined from the recorded data and unloaded dimensions assuming an incompressible cylinder with no shear. The toe modulus (TM) (elastic fiber dominated modulus) and linear modulus (LM) (collagen fiber dominated modulus) were calculated by linear regression of the initial 20-30 and last 20 data points of the circumferential stress-stretch curve, respectively.

Multiphoton imaging and ECM analysis. After mechanical testing, ATAs were fixed in 4% paraformaldehyde, flash frozen, and 10 µm thick cross sections were cut using a cryostat microtome. Samples were imaged using a Leica Sp-8 DIVE multiphoton microscope with a 20x objective to visualize elastin and collagen fibers [5]. To quantify the fragmentation of elastic fibers, the elastin channel was isolated and analyzed in ImageJ (NIH) using the skeletonize function [5].

Statistics. Statistical analysis was done using GraphPad Prism. Data are presented as mean ± standard deviation. Experimental groups were compared using three-way ANOVA and Sidak's multiple comparisons. P-values <0.05 were considered significant.

RESULTS

Mouse model and ultrasound measurement. Survival analyses show 60-80% mortality in male and 30-35% mortality in female MU mice by 4 months old. **Figs. 1B, C** illustrate that the ATA starts dilating in male and female MU mice at 1 month old. With age dilation of the ATA is greater in males than females and ATA size is significantly affected by interactions of genotype (G), age (A), and sex (S). In vivo strain (**Fig. 1D**) significantly decreases in MU mice and with age and there are interactions between age (A) and genotype (G). Multiple comparison analyses indicate larger decreases for in vivo strain in male than female MU mice, compared to their respective WT controls, indicating more significant stiffening of the ATA in male MU mice.

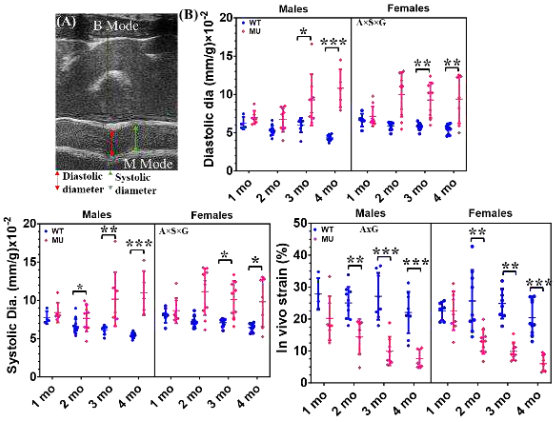

Figure 1: Representative ultrasound B- and M-mode images of the ATA (A). Comparison of diastolic (B) and systolic (C) diameter, and in vivo strain (D).

Mechanical testing. Pressure compliance curves (**Figs. 2A, B**) show that MU ATA is more compliant than WT ATA at low pressures and less compliant at high pressures. This trend is found for male and female mice at all ages. After 1 month old, TM significantly decreases in MU mice and there are significant interactions between age (A) and sex (S) (**Fig. 2C**). After 2 months old, LM significantly increases in MU mice and there are significant interactions between age (A) and genotype (G), and sex (S) and genotype (G) (**Fig. 2D**). There is a larger decrease of TM and a larger increase of LM in MU males than females, compared to WT littermates. These results suggest that male and female mice follow different timelines of alterations in ATA mechanics associated with MFS.

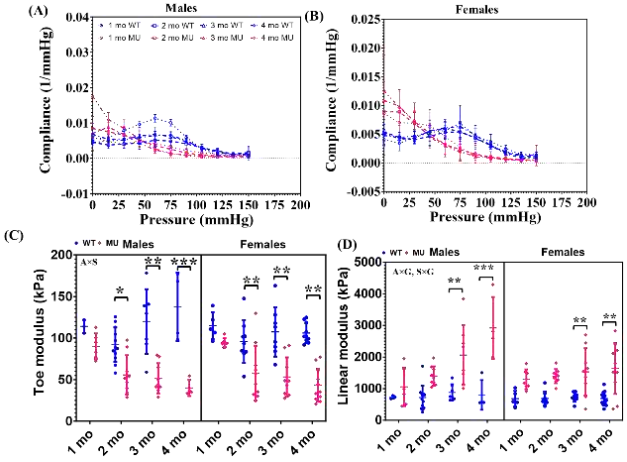

Figure 2: Pressure compliance curve for WT and MU (A) males and (B) females. Comparison of toe modulus (C) and linear modulus (D) of ATA between WT and MU male and female mice.

Multiphoton imaging and ECM analysis. In comparison to WT littermates, the ATA of MU male mice shows fragmentation of elastic fibers, deposition of collagen fibers in the media and adventitia, and loss of cell nuclei (**Figs. 3A, B**). In contrast, in MU female mice, very few fragmented elastic fibers are observed, but there are increased numbers of thin and buckled elastic fibers compared to WT littermates (**Figs. 3C, D**). Elastic fiber fragmentation analyses (**Fig. 3E**) shows a significant reduction in slab size (elastic fiber length) and a significant increase in end points (elastic fiber fragmentation) in the ATA of 3- and 4-month old MU males compared to WT littermates. However, these parameters are almost unchanged between MU and WT female ATA for all age groups. A significant interaction is found between age (A), sex (S), and genotype (G) for the slab size and endpoints.

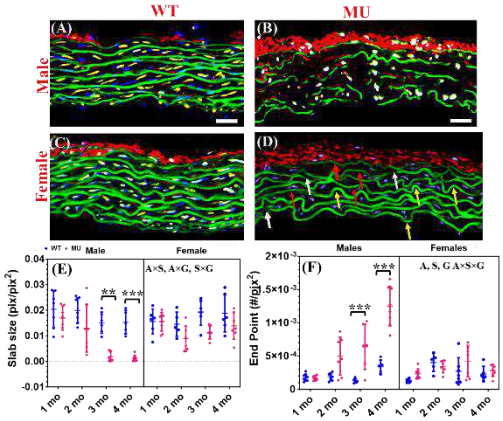

Figure 3: Representative images of 4-month-old WT and MU male and female mice (A-D), red = collagen fibers, green = elastic fibers, blue/white = cells. In panel (D), red, white, and yellow arrows indicate thin, fragmented, and buckled elastic fibers, respectively. Comparison of slab size (E) and end points (F). Scale bar = 50 µm.

DISCUSSION

This study presents longitudinal data of in vivo geometry and strain, ex vivo mechanical properties, and ECM remodeling for the ATA from MU and WT male and female mice. We observed sex and age specific outcomes for ECM remodeling and ATA mechanics. Significant fragmentation of elastic fibers and deposition of collagen fibers in MU male compared to MU female ATA may be the cause of sex-specific alterations in compliance and linear modulus in different pressure regions. The fragmentation of elastic fibers may cause irreversible dilation of the ATA, whereas the increase in collagen fiber deposition may cause plastic deformation during in vivo loading, contributing to TAA formation and eventual rupture in male MU mice. However, in female MU mice, the thin and buckled elastic fibers may be responsible for irreversible dilation of ATA, but at in vivo pressures these elastic fibers become straight and support the load, which may compensate for the reduction in tissue elasticity due to deposition of collagen fibers and protect the ATA from rupture. Overall, our results indicate that age and sex specific ECM remodeling may be a factor accounting for different TAA outcomes between male and female mice.

ENHANCING FLUID INFUSION VIA INTRODUCTION AND ENLARGEMENT OF MICROCRACKS IN TUMORS – THEORETICAL SIMULATIONS

Md Jawed Naseem, Ronghui Ma, Liang Zhu

Department of Mechanical Engineering, University of Maryland Baltimore County, Baltimore, Maryland, USA

INTRODUCTION

In chemical ablation of tumors, convection-enhanced delivery (CED) is commonly used to infuse chemicals such as ethanol via a single cannula inserted into tumors. Unfortunately, very high interstitial fluid pressure (IFP) and small porosity in tumors often cause backflow through the needle track. This leads to leakage of the chemicals to surrounding healthy tissue, resulting in collateral damage or severe pain to patients. In recent years, novel devices have been manufactured to incorporate retractable tines. The original design aimed at using the tines for infusion and the retract ability of the tines allows more infusing sites to enlarge the infused tissue volume. Previous experiments using ethanol for liver tumor ablation demonstrated less pain experienced by patients, implying less leakage.[1] None of the previous studies evaluated a CED system with a retractable needle only for generating microcracks in tumors and the resulting change of flow resistance in tumors during direct fluid infusion.

In this study, we perform theoretical simulation to evaluate how introduction of a microcrack in tissue reduces the overall flow resistance in a porous tumor, as well as further decrease in the flow resistance as this microcrack enlarges in a direct infusion process using CED. Both Darcy's law and the poroelasticity theory are used in the simulation to understand the fluid transport in porous tumors with or without microcrack introduction and/or enlargement. We expected that the study would provide quantitative measures to evaluate whether this approach is effective to enhance the fluid transport in dense porous tumors.

METHODS

A tumor, modeled as a sphere (10 mm in radius), undergoes a direct fluid infusion modeled as a prescribed high pressure on a spherical surface in the tumor center (0.64 mm in radius). The backflow through the infusion needle is not included in this study, since our focus is on the role played by an induced microcrack in tumors. In Figure 1a, model 1 represents a porous tumor without any microcrack. An induced microcrack is included in model 2 as a cylindrical column (0.05 mm in radius, 3 mm long). The microcrack initiates on the infusion surface and extended towards the tumor periphery (Figure 1b). Both the microcrack and the remaining tumor region are each modeled as uniform porous media with different porosities and permeabilities. The obtained fluid pressure field of the tissue region is the input needed for the poroelastic simulation to predict tissue deformation during the infusion process. The geometry of the enlargement of the microcrack is exported from the poroelastic simulation of tissue deformation in model 2. The shape and the geometry of the microcrack after enlargement are then re-generated and introduced to the porous tumor. Finally, we construct model 3 in which the microcrack enlargement is included, shown in Figure 1c. Both the microcrack and the remaining tumor region are again modeled as uniform porous media with different porosities and permeabilities. In model 3 (Figure 1c), only Darcy's law is used to simulate the updated pressure and velocity fields with the enlarged microcrack.

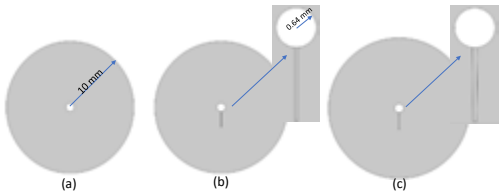

Figure 1. Geometries of the three models

In this study, Darcy's law is used to describe how fluid flows in the porous tumor tissues, which is given by,

$$\nabla \cdot \left(\phi \vec{V}_f\right) = 0, \quad \nabla P_f = -\frac{\mu\phi}{K}\vec{V}_f \qquad (1)$$

where $\vec{V}_f$ is interstitial fluid velocity vector, P_f is interstitial fluid pressure, μ is fluid dynamic viscosity, ϕ is tumor porosity, and K is permeability of the porous tumor medium. Boundary conditions include

a prescribed pressure at the infusion surface (P_0 = 2*10^5 Pa) and zero pressure at the tumor outer surface.[2]

In the porous tumor, the fluid pressure in the interstitial fluid space is not uniform during a direct fluid infusion. The non-uniformity of the fluid pressure would add extra displacements and strains to the tissue. In the poroelasticity theory, the fluid pressure is included in the constitutive equation for tissue deformation as

$$G\nabla^2\vec{u} + (\lambda + G)\nabla(\nabla \cdot \vec{u}) = \nabla \cdot (\phi P_f), \qquad (2)$$

where $\vec{u}$ is the tissue displacement vector, G and λ are Lame constants that can be determined by the Young's modulus E and the Poisson's ratio ν using the follow expressions:

$$\lambda = E\upsilon/((1+\upsilon)(1-2\upsilon)); G = E/(2(1+\upsilon)) \qquad (3)$$

Eq. 2 can be solved once the distribution of the fluid pressure is obtained from Darcy's law. Boundary conditions needed for solving the displacement field are a roller boundary at the infusion surface and zero displacement at the tumor outer surface. The displacement at the interface between the tumor and microcrack is used to generate the enlarged microcrack in model 3.

In each model, the volumetric flow rate is calculated by integrating the normal velocity over the outer surface of the tumor. The flow resistance (R_{flow}) is defined as the pressure difference between the infusion surface and the tumor outer surface divided by the calculated volumetric flow rate, and is given by,

$$R_{flow} = (P_0 - 0) / (\text{volumetric flow rate}) \qquad (4)$$

All the simulations are performed in COMSOL® 6.1 using the sub-surface module. Sensitivities to mesh sizes are checked to ensure that doubling the total number of mesh elements would result in less than 0.1% changes in the simulated results.

RESULTS

The mechanical properties used in the models are listed in Table 1. Note that both the tumor region and the microcrack region are porous media with different properties.

Table 1: Mechanical properties[2]

μ, Pa s	0.001	E_{tumor}, MPa	0.3
K_{tumor}, m^2	5*10^{-16}	E_{crack}, MPa	0.003
K_{crack}, m^2	2.02*10^{-13}	ν_{tumor}	0.4
ϕ_{tumor}	0.2	ν_{crack}	0.4
ϕ_{crack}	0.8	ρ, kg/m^3	1000

Figure 2 illustrates the pressure fields of the three models. Without introduction of a microcrack (Figure 2a), the pressure field is one-dimensional, varying only in the radial direction. The pressure decreases to 50% of P_0 at 0.7 mm away from the infusion surface, and a further decrease to 50% of P_0 occurs at 4.2 mm from the infusion surface. The effect of the introduced microcrack in the tumor is examined in model 2 (Figure 2b). One observes that the maximal pressure again occurs at the tumor central region. Since the permeability of the microcrack domain is much larger than that in the regular tumor region (Table 1), flow through the microcrack is much easier than that through the tumor. Figure 2b shows a very small pressure drop from the infusion surface to the tumor-crack interface, equivalent to an extension of the maximal isobaric contour from the original infusion surface. Therefore, the fluid transport is expedited by the crack due to a shorter distance between the tip of the microcrack to the tumor periphery.

The tissue displacement vector is exported to reconstruct the enlarged microcrack. Overall, the magnitude of the displacement in the lateral direction of the interface varies from 0.025 mm near the infusion surface to 0.0073 mm at the tip of the microcrack, leading to a frustum-shaped crack. The deformation is significant since the original microcrack radius is 0.05 mm. The volume of the frustum is 2.26 times of the original value, due to the fluid infusion-induced tissue deformation. The rapid decrease in the fluid pressure field with the enlarged microcrack is shown in Figure 2c, with a slightly longer push towards the tumor outer surface than that in Figures 2b.

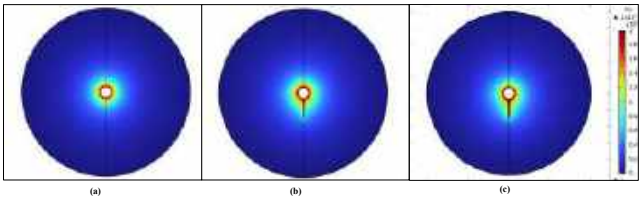

Figure 2. Contours of the fluid pressure field.

The minimal and maximal velocities of the three models are presented in Table 2. Based on the simulation parameters in model 1, the maximal velocity occurring at the infusion surface is 1.66*10^{-4} m/s. The magnitude of the velocity vector decreases in the radial direction, to 6.84*10^{-7} m/s, satisfying fluid mass conservation in the simulation. With the introduction of the microcrack in model 2, the maximal velocity is two orders of magnitude larger than that in model 1. The dispersal of fluid is not uniform in the tissue but concentrated along the microcrack where the fluid is spreading out more intensely than other tumor regions. The minimal velocity at the tumor outer surface increases by 3.9% from 6.84*10^{-7} to 7.11*10^{-7} m/s. Once the microcrack is enlarged in model 3, the maximal velocity is 1.06*10^{-2}, which is at the same order of magnitude of, however, smaller than that in model 2. This result may be explained by the large cross-sectional area due to the lateral enlargement of the microcrack from the original radius of 0.05 mm to 0.085 mm. The minimal velocity in model 3 is 7.29*10^{-7} m/s, the largest in the three models. This implies that model 3 has the largest volumetric flow rate with the enlarged crack among the three models.

Table 2: Velocity and flow resistance in the three models

	model 1	model 2	model 3
V_{max}, m/s	1.66*10^{-4}	1.78*10^{-2}	1.06*10^{-2}
V_{min}, m/s	6.84*10^{-7}	7.11*10^{-7}	7.29*10^{-7}
R_{flow}, Pa.s/m^3	2.33*10^{14}	2.12*10^{14}	2.00*10^{14}

Using Eq. 4, one determines the flow resistance in the tumor. Shown in Table 2, introduction of a microcrack to the spherical tumor decreases the flow resistance from 2.33*10^{14} in model 1 to 2.12*10^{14} Pa.s/m^3 in model 2. With the enlarged microcrack (model 3), the flow resistance is further reduced from that in model 2. Overall, having an enlarged microcrack results in a decrease by 14% from that without microcrack, or 5.7% from that without crack enlargement.

DISCUSSION

The theoretical simulation results have illustrated significantly altered pressure and velocity fields in a porous tumor due to introduction of a microcrack. The non-uniform fluid pressure field enlarges the cylindrical microcrack to a frustum, with a crack volume more than doubled. Due to the large permeability and porosity in the microcrack, flow from the infusion surface to the tumor periphery is much easier than that without microcrack. Overall, the flow resistance with the enlarged microcrack is reduced by 14% from the baseline case. We conclude that introducing a microcrack in porous tumors is an effective way to facilitate fluid flow in porous tumors using CED.

INTRODUCTION

It has been well-established that physical activity has a positive effect on the bone remodeling process. At the macroscopic level, mechanical stimulations such as cyclic stress and strain are found to alter bone mechano-transduction process, where physiological loads convert to mechanical signals sensible to bone cells [1,2]. For example, Javaheri et al. (2020) revealed that bone mechanoadaptation can be restored after applying a threshold primary load by characterizing the load-induced strain using mice tibia bone piece with 3D microCT [3]. In addition, it has been found that compared with static loading, dynamic loading will induce more osteogenic responses [4,5]. While macro-scale mechanical loading on bone matrix has been extensively studied, the intrinsic cellular-level responses under dynamic mechanical loading remain largely unknown. As two main mechanically sensitive bone cells, osteocytes and osteoblasts both contribute positively to bone formation process by translating external mechanical stimuli to biological signals, i.e., mechano-transduction. It has been well defined theoretically and experimentally that the lacuna-canaliculi structure surrounding the osteocyte conveys both matrix force and interstitial fluid shear to osteocyte surface, where the induced fluid shear stress ranges from 0.8 to 3 Pa [6,7]. However, the mechanical environment around osteoblasts and its corresponding effects on cell responses is much less known. Most of the in-vitro experiments have been focusing on impacts of matrix deformation and fluid shear by directly applying stress, strain, or fluid shear to cell surface [8]. Therefore, it is vital to develop a platform which integrates effects of both matrix deformation and fluid shear for characterization of osteoblast mechanical responses.

The current work aims at developing a micro scale three-dimensional cell-matrix system which enables investigating the dynamic effects of matrix deformation and fluid shear stress on mechanical responses of osteoblasts by actin fluorescence intensity after stimulation.

METHODS

In this work, a micro-scale three-dimensional hollow TiO_2 lattice structure is designed as the scaffold with osteoblastic-like (SAOS2) cells seeded on. Four structures with different stiffness are fabricated along a row on a 1 cm by 1cm silicon chip with a 7 mm by 7mm etched down well, where contains the culture media. The cells are seeded on the lattices for 12 days, grow in culture media for 3 days and then be compressed for two consecutive days. Different dynamic loading processes, such as constant strain and constant stress were applied to the four structures with wall thickness ranging from 18 nm to 260 nm, enabling stiffnesses ranging from 0.7 MPa to 35 MPa, shown in Fig. 1. To independently investigate the effect of loading frequency, we choose a structure of E = 5 MPa and performed constant stress experiments on different samples with loading frequency of 0.1 Hz, 1Hz, and 3Hz, which corresponds to standing, slow walking and running. The dynamic compression processes were applied using Nanoindenter with a flat-top diamond tip. The actin responses after stimulation are characterized by fluorescence intensity using confocal microscopy. The fluid field induced by the compression process was estimated using a theoretical squeezing flow model between two parallel plates as shown in Fig. 2.

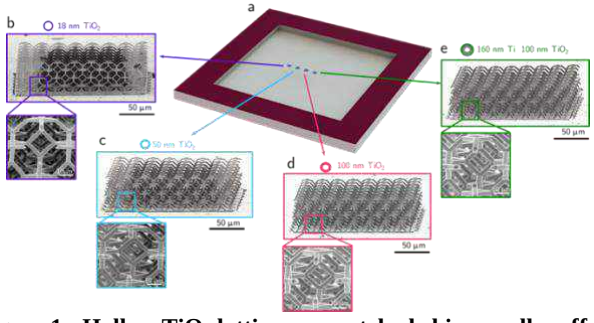

Figure 1: Hollow TiO_2 lattice on an etched chip as cell scaffold.

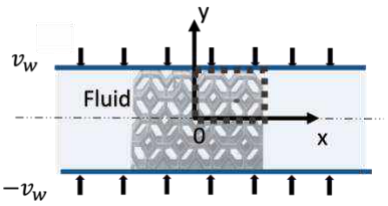

Figure 2: Squeezing flow model between two parallel plates simulates compression-induced fluid field.

GOVERNING EQUATIONS OF THE FLUID FIELD

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \quad (1)$$

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=-\frac{1}{\rho}\frac{\partial P}{\partial x}+\nu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right) \quad (2)$$

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}=-\frac{1}{\rho}\frac{\partial P}{\partial y}+\nu\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right) \quad (3)$$

where u is the fluid velocity component along x direction, v is the fluid velocity component along y direction, t is time, ρ is fluid density, ν is fluid kinematic viscosity, P is pressure. The fluid is assumed to be viscous and incompressible. The boundary conditions are

$$y=a(t): u(x,y,t)=0; v(x,y,t)=V_w(t) \quad (4)$$

$$y=0: \frac{\partial u(x,y,t)}{\partial y}=0; v(x,y,t)=0 \quad (5)$$

where $V_w(t)=da/dt$ is the plate velocity.

RESULTS

Dynamic loading at a constant strain amplitude was applied to the four lattices fabricated in Fig. 1. Because of the increasing modulus, the lattices undergo increasing stress at constant strain amplitude. Fig. 3a, shows the actin intensity (normalized to the lowest stiffness sample) increases with increasing stiffness. This trend is quantitatively similar regardless of whether the samples are the uncompressed or compressed (Fig. 3a). A similar trend was observed with constant stress amplitude, suggesting within the investigated range, 3D substrate stiffness controls cytoskeletal organization rather than external stimulation. However, Fig 3b shows that with increasing loading frequency actin intensity increases on a given structure of one stiffness (E = 5 MPa),. The dynamic, frequency dependent cell response suggests the fluid stimulation is more important than the solid deformation in the 3D scaffold. The estimated fluid shear stress field in Fig. 4 which corresponds to the three loading frequencies, increases with faster plate velocity, i.e. loading frequency.

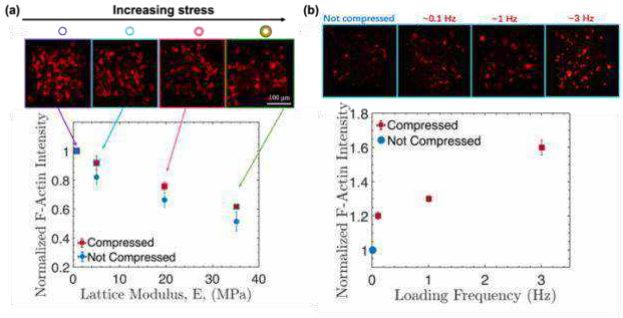

Figure 3: (a) Maximum intensity projection (MIP) images of showing f-actin intensity after constant strain compression on different stiffness structures. (b) MIP results with different loading frequencies on a structure of E = 5 MPa.

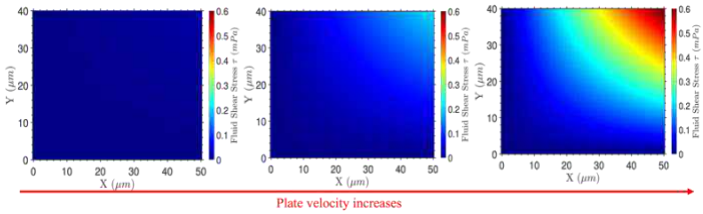

Figure 4: Compression-induced fluid shear stress field increases with faster plate velocity which corresponds to the larger loading frequency.

DISCUSSION

With increasing stress/strain loading, the very similar actin intensity trend before and after loading indicates that in this case the cells are relatively not sensitive to matrix deformation, the fluid shear stress induced by the compression process, which differs more with different frequencies, might be the main stimulator for actin formation of osteoblasts compared with solid deformation of the scaffold. In addition, the magnitude of the fluid shear stress is with the scale of millipascal, which is much smaller than the 0.8-3 Pa range for osteocyte as expected, because of the less constrained mechanical environment around osteoblasts. It is of great interests to dig into the active in-vitro response range of osteoblasts with a 3D bone-like cell-matrix system in the future.

INTRODUCTION

Locomotor training (LT) is a gait rehabilitation treatment method. By placing a patient on a treadmill, and moving their legs in a walking motion, while stimulating the corresponding muscles (through tendon compression), a new pathway for generating movement is formed. Allowing the patient to regain some, if not all, of their legs motor control. Patients who have been rendered immobile due to incomplete spinal cord injuries (SCI), stroke, Cerebral Palsy, and many other neurological conditions have been treated using LT [1]. Despite its success in countries like Germany, Norway, and Switzerland, it is not widely available in America [2,3]. LT is a human-driven rehabilitation method, requiring four physical therapists. The body weight supports used to place the patient above the treadmill holds 30-70% of the patient's body weight [4]. This leaves another 30-70% of the weight for the therapist to overcome to move the patient's legs, taking a considerable amount of physical effort. Resulting in short treatment sessions. The amplitude and duration of the pressure used in LT must be precise; if either the stimuli or coordination are off it may result in an inaccurate stimulation [5]. Limitations of LT can be solved through Mechanicalization. Robots are not subjected to the limitations of human stamina. They are capable of outputting a constant and accurate force, reducing the chances of inaccurate stimulation, leading to higher treatment efficiency. The device itself will contain the LT protocol, decreasing the amount of training and therapists needed. The overall purpose of the lab is to improve LT. The full design will consist of an exoskeleton to physically move the patients' legs, and a tendon stretching device. Currently there are no existing robotic tendon stretching devices. Tendon compression is essential to LT. Thus, the scope of this project was limited to the designing, building, and preliminary testing of a device that will be used to apply pressure to the patellar tendon (PT).

METHODS

The device was designed to mimic the LT treatment protocol. Device specifications included: an output of at least 111N, a compression speed of at least 100ms, a compression mechanism capable of recording force, and a snug fit against the leg. Attachment of the device consisted of a half-circle platform (Fig.1) with straps. Creating a one-size-fits-all design, while providing stability to its platform. The device sits distal to the knee, attaching around the calf, to indent the PT. Preliminary design stages, established that a rack and pinion system is suited for the device's linear compression. A rack and pinion system, using a pinion, 12mm in diameter, requires a motor with at least 404rpm and torque of 17mNm, to generate a force of 111N. In short, the rack and pinion adheres to the design specifications. Attached to the distal end of the rack is the pusher. The pusher portion of the device consists of a pusher head, and a force sensor holder. The pusher head is the part of the device that will physically indent into the skin. The holder allows recording of the impact force.

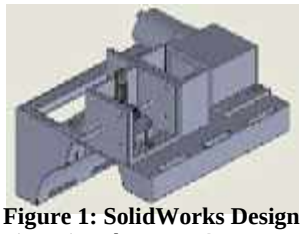

Figure 1: SolidWorks Design

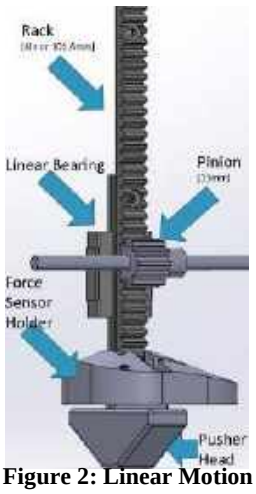

Figure 2: Linear Motion

To control the device's variable parameters and record the outputs, a LabVIEW user interface was developed with an Arduino backend. Variable parameters included the pusher head design, position of device, device input voltage, and holding duration. Output parameters included the impact force

and the recorded action-potential-peak EMG value (AP-EMG). Myolab II (Motion Control, SLC, UT) performed the EMG amplification process. Two electrodes were placed axially on the left leg, at the top and bottom quadrants of the quadricep muscle. Two designs of the pusher head were tested. Design 1 was a simple overall curve. Design 2 was altered to reduce the curved width to a 20mm point. Two device positions were tested. Position 1, the platform is anterior to the leg, hitting in the center of the PT. Position 2 is angled 20 degrees medial (hitting the side of the PT).

Compression of the PT at high levels of stimulation results in the myotatic (knee-jerk) reflex. To confirm the devices effects on the nervous system, EMG of the resulting knee-jerk reflex were recorded. Analyzation of the data was completed using MATLAB. The point of interest is the action potential peak (AP) as it travels up the leg to the spinal cord. A combination of a notch filter and band-stop filter [20-40 Hz] was applied to the EMG. For further analyzation of the data the AP-EMG and max force values were identified. The magnitude of the AP-EMG indicates the magnitude of recruited muscle fibers.

RESULTS

The goal of device testing was to provide its preliminary basis and adherence to the LT treatment protocol. The device's average impact duration (quick hit and retreat) was 50ms. And reached an output of 111N, using a device input voltage of 30volts. EMG experiments were performed as a preliminary check for the device parameters. When comparing the 20mm-curve pointed design to the over-all-curved pusher-head design, it produced significantly higher EMG values (0-2.5volts compared to 0-0.045volts, with a p-value of 0.013). Further testing was conducted using the 20mm-curve pointed design. The device-input-voltage, AP-EMG, and the impact force relationship was examined by testing device input voltages of 12-30volts, in increments of 3. Position 1 produced forces from 2-49N and 62-80N. Position 2 produced forces from 13-80N. Trend lines for both positions displayed a nearly linear increase at lower forces (2-31N and 13-33N), then a steady drop (31-58N and 33-53N), and a subsequent, slight, increase at higher forces (58-80N and 53-80N). Establishing a optimal force range of 18-40N and 22-40N, respectively. Position 1, at lower forces, has higher AP-EMG values than position 2. At higher forces, it has lower AP-EMG values. Position 2 forces have a normal distribution and increase steadily in correlation to the increasing device input voltage. While position 1 has a non-normal distribution, with significantly more forces on the lower range (1-17N). The minimum device input voltage required to elicit an AP, for position 1 and 2 is 14volts and 10volts, respectively. EMG noise approximation is 0.008 volts; values below or equal to 0.008v indicate no AP occurred, consequently no knee-jerk reflex. Further testing was conducted using position 2. In general, the addition of a holding force, post initial impact, with a duration of 100-500ms provided significantly higher EMG values. In regard to producing the highest average AP-EMG value the holding durations are in the order of 0, 200, 400, 500, 100, and 300ms. Forces range 2 to 53N. It is important to note that similar to the original Force-EMG graph, when holding is present there is still an optimal force range. The scaling and shift in its range are holding duration dependent. Holding duration of 1-4s, display a linearly decreasing trend line. Forces ranged 4 to 49N.

DISCUSSION

Preliminary testing confirms that the device adheres to the desired design specifications. As previously mentioned, this is an entirely novel device, lacking an established framework for optimal testing. Thus, our approach involved casting a broad net, encompassing testing of various device parameters on a single subject, to provide basic preliminary data. The goal was not to concretely define the reflex, but rather to serve as a foundation, providing direction for future testing. The 20mm pointed design resulted in higher EMG values due to mechanical and physiological factors. The average width of the patellar tendon is 20mm [6]. A pointed design allows for targeted stimulation of the PT. Due to the shape of the knee, position 1 is hitting a curved surface. If a normal impact force is higher than the friction force, horizontal sliding will occur [7]. This accounts for the alterations seen at higher forces in position 1. Position 2 impacts a relatively flat surface area of the knee. Various studies indicate that an increase in force or holding duration results in an increase in EMG [8]. Our data partially mimics the increasing trend found in current research. At higher forces and holding durations there are noticeable deviations. This is likely due to the force-length relationship of muscles and the inverse myotatic reflex. Striated muscle fibers' have lower force production at higher and lower lengths; the middle ranges correspond to the optimal length which generates max force [9]. Compression of the PT stretches (elongates) the connected quadriceps muscles. At higher forces, the PT is likely stretching the muscle beyond its optimal length (dropping the AP-EMG).

The inverse myotatic reflex acts opposite to the myotatic (knee-jerk) reflex [9]. Continuous force elicits a relaxation reaction of the muscles to prevent injury [10]. The longer the holding duration, the more this reflex comes into play. This is especially prevalent in durations 1-4s, which display a decreasing linear tend line.

Regarding LT, the data analyzed provides conformation that the device is capable of stimulating the muscles proprioception. LT treatment protocol does not elicit the knee-jerk reflex. Instead, low levels of proprioception stimulation, and neuroplasticity, allows the brain to establish a new pathway for lower limb movement [11]. Recording low-stimulation requires complex or invasive techniques. Tendon compression for LT rehabilitation will require additional testing and may differ in outcome. The purpose of this research was to simply confirm the devices capability, not the optimization of the treatment protocol. Thus, high stimulation levels, triggering the reflex, are sufficient. The data not only provided the upper limits for future treatment protocols (<10 or 14volts depending on position), but also helped identified potential relationships of various device parameters. Parameters such as impact force, holding duration, and device input voltage will dramatically affect muscle response. Future testing and quantification of these parameters using this device will not only aid in the optimization of the LT treatment protocol, but also in the general understanding of this reflex. The development of this tendon stimulating device puts us one step closer to an improved LT rehabilitation method.

INTRODUCTION

Optimal mitral function plays a crucial role in the comprehensive cardiovascular performance. The intricacies of the mitral valve (MV), especially the chordae tendineae (CT), exhibit variations among individuals. While prior research has investigated force magnitudes and distributions in the belly and annular chords, limited attention has been given to the marginal chords. In this study, we introduce a technique for quantifying the forces acting on these marginal chords, which are defined as those reaching the anterior or posterior leaflets in the ”rough” / coaptation zone.

METHODS

Weighing, Sizing, and Dissection: Porcine heart, from which MVs were dissected, were obtained from an abattoir. The left ventricular myocardium's papillary muscles (PM) were surgically excised, and the valve separated from the left atrium and ventricle by cutting 5-10mm into the atrial and ventricular myocardium from the annulus. The valve was then trimmed to keep about 10mm of PM tissue beneath fibrous membranes and 5mm of tissue outside the annulus, around the entire circumference.

Annulus Clamp: The dissected MV, trimmed as needed, is secured in a custom 3D-printed annulus clamp [1] (Fig. 1 a+c), which consists of two halves and ensures a physiologically realistic configuration. Each PM is then attached to a stitching ring for connection to the pressurization system, completing the assembly with the fully mounted valve (Fig. 1c).

Vacuum system: The MV, connected to a previously described pressurization system [2], closes via vacuum pressure on the atrial side, creating physiological trans-mitral pressure differences. This inverted setup allows measurement of the ventricular side (CT and PMs), with a small water column above the annulus to maintain moisture. Pressure comes from a pre-charged chamber. A refill system prevents valve leakage, and a clear acrylic front facilitates visual inspection. A standoff with a clear acrylic window allows qualitative measurement of valvular leak rates.

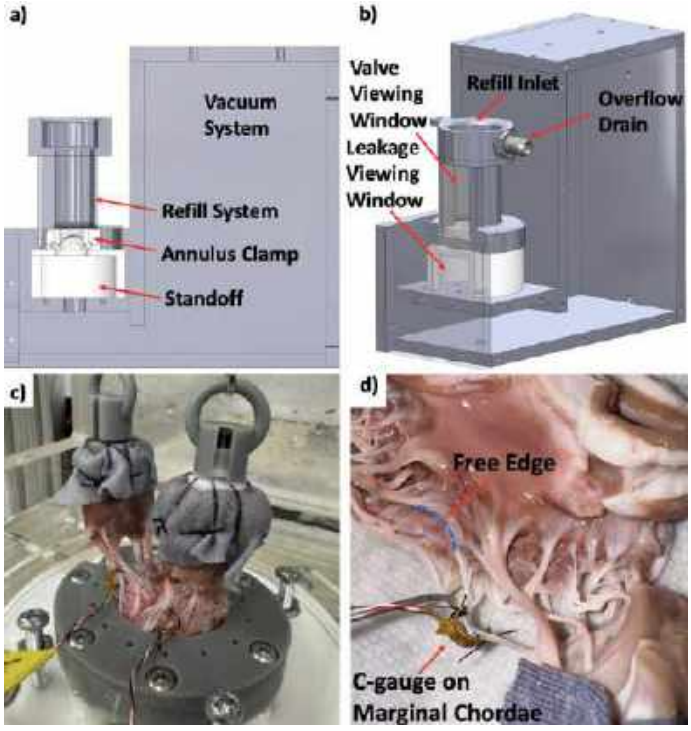

Figure 1: a+b) The vacuum system c) MV in the vacuum closure system without the refill system (for clarity). d) Exemplar image of a C-gauge on a marginal chord. The chord is uncut at time of photograph.

Chordal Force Measurement: Marginal chordae, tendinous structures on MV leaflets, were identified during porcine heart dissection [3], ensuring chords without significant branches and sufficient length for C-gauge mounting. Silk-braided sutures (size 5/0) secured the C-gauge in the frame's perforations at specific length intervals [4]. Careful suturing avoided tension issues that could compromise force measurements. After suturing, chordae were precisely divided between suture points, so that tension was transmitted to the C-gauge in the subsequent vacuum test. Due to documented variability in marginal chordae forces, concurrent measurements with well-established strut chordae force assessments were conducted to validate strain gauge function and placement [2, 5, 6].

RESULTS

Table 1 displays marginal chordal forces measured during the experiments, along with corresponding transvalvular pressure values.

Table 1: Marginal chordal force at transvalvular pressures of 80-110 and 120mmHg (n=5 and 3). Four porcine hearts were utilized, with three hearts having a single C-gauge on a marginal chord, and one heart having two C-gauges on separate marginal chords (data from two more hearts will be presented).

Transvalvular Pressure (mmHg)	Marginal Chordal Force (N) – Mean +/- SD
80	0.0098 +/- 0.0079
90	0.0094 +/- 0.0078
100	0.0106 +/- 0.0086
110	0.0115 +/- 0.0098
120	0.0074 +/- 0.0111

The standard systolic blood pressure, 120 mmHg, is a pivotal value, where the marginal chordal force was measured with a mean value of 0.0074 N, as shown in Table 1. The measurement of strut chordal force was conducted to validate the proper valve function and utilization of C-gauges. Figure 2 illustrates an exemplary dataset derived from measurements on a marginal chordae, a strut chordae, and transvalvular pressure. The observed strut chordal force is recorded as 0.61 N at a transvalvular pressure of 134.6 mmHg, falling within an acceptable range [2, 5, 6].

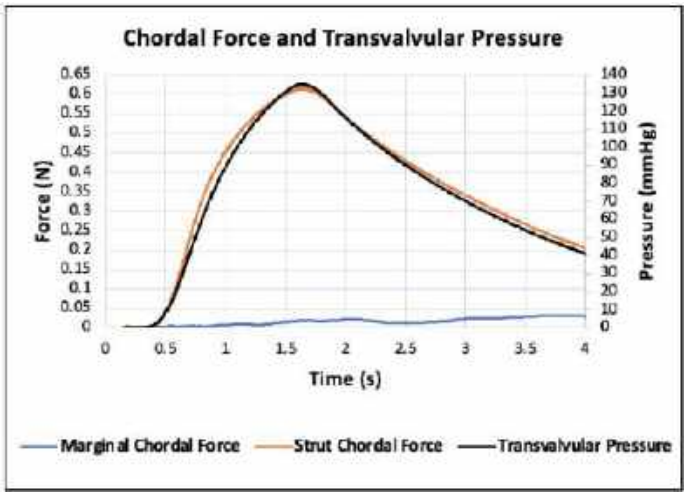

Figure 2: Concurrent force measurements on a marginal chordae, a strut chordae, and the recorded transvalvular pressure.

DISCUSSION

Marginal chord examination shows low forces, aligning with expected contact in the coaptation zones of the self-supporting MV leaflets [7]. Measured forces in marginal chords consistently remain low and show no significant correlation with transvalvular pressure, unlike strut chords. This concept is illustrated in Figure 3.

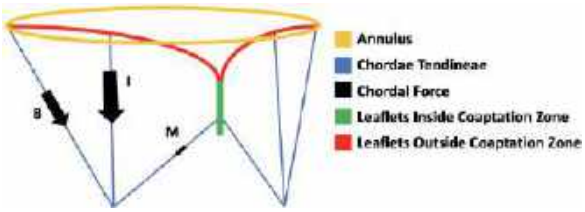

Figure 3: The mitral valve exhibits three chord types: basal (B), intermediate (I), and marginal (M). Force magnitudes in each chord type are represented by arrow size, with intermediate chords (strut chords) showing significantly larger forces than marginal chords.

The inherently low forces in marginal chords are unsurprising due to direct leaflet contact at the insertion point and the convex/concave self-supporting shape of the leaflets [7]. Strut chord forces align with reported ranges in other studies, indicating a valid force measurement setup and proper valve functioning, and that the marginal chordal forces presented in this study are reliable. This implies that strut chord force measurements reflect consistent valve performance based on established scientific benchmarks. Chordal forces and leaflet strain in in vitro models with diverse annulus shapes for both porcine and human valves have been studied previously, indicating higher marginal chordal forces with a flat annulus [8-11]. In this study, the natural shape of the annulus is modeled, which has been shown to enhance valve leaflet self-support [7] and lower strain on the individual valve components [12-13]. Our investigation used a saddle-shaped annulus clamp, aligning more closely with previous results when employing a similar annulus shape [8]. Notably, posterior leaflet marginal chordal forces have been previously found to match those found in the present study, regardless of annulus shape, while anterior leaflet forces were an order of magnitude larger, around 0.2N [9,10]. The annulus, leaflet configuration, and marginal chord spatial arrangement relative to the coaptation zone during valve closure play vital roles in chordal forces under physiological trans-mitral pressures. This underscores the importance of considering anatomical and structural factors, especially varying annulus shapes, in interpreting MV biomechanics.

INTRODUCTION

Patients with acute respiratory failure often require supportive mechanical ventilation to maintain adequate gas exchange. In contrast to conventional mechanical ventilation, oscillatory ventilation relies on low tidal volumes cycled at supraphysiological rates, which produce fundamentally different mechanisms for gas transport and exchange [1]. Multi-frequency ventilation (MFV), a modality that combines desirable features of CMV and oscillatory ventilation, provides more uniform ventilation throughout the lung with asymmetric airway branching and/or heterogeneous mechanical properties. In this study we simulated gas flow in computational porcine lung model, consisting of a central airway tree from the trachea to the fourth generation of airway segments, as well as dynamic peripheral boundary conditions. Simulated flow waveforms at the trachea included CMV cycled at 0.27 Hz, as well as MFV consisting of low-amplitude 3.5 Hz and 7.0 Hz sinusoidal components superimposed on a 0.27 Hz CMV component. Dynamic pressures at various airway segments were predicted based on the interactions of internal flows with downstream elastances and peripheral airway resistances. The resulting internal airflows were simulated and analyzed in both time- and frequency-domains. Our simulations indicate that compared to CMV, MFV results in stronger flow asymmetry at end-inspiration and end-expiration (i.e., "pendelluft"), as well as larger phase differences between the inlet and outlets for pressure and flow. Our data are consistent with the notion that MFV has potential to enhance gas mixing, thus facilitating the efficiency of ventilation in the mammalian lung.

METHODS

A three-dimensional (3D) airway tree was segmented from a thoracic CT image of a healthy porcine subject. The tree was then truncated from the proximal third of the trachea to half of the 4th generation segments. Due to asymmetric branching, the resulting tree consisted of thirteen peripheral outlets. Simulated CMV and MFV airflow waveforms were scaled to yield delivered tidal volumes at the trachea of about 7 mL kg^{-1}. The CMV and MFV waveforms were then imposed in sequence as boundary conditions at the trachea of the CFD model. Dynamic pressure variations at each of the thirteen outlets of the airway tree were induced by the effects of downstream parenchymal tissue elastances, peripheral airway resistances, and gas inertia, which were applied as downstream boundary conditions. All values of downstream airway resistance and gas inertance were estimated by inverse modeling regression [2]. The airway walls were assumed to be rigid, with a no-slip boundary condition. The turbulence was modeled using the Navier-Stokes equations incorporating the k-ω Shear-Stress Transport (SST) model. To address convergence sensitivity challenges in dynamic pressure at the outlets, the equations were solved by employing the Splitting of Operators (PISO) algorithm with a time step size of 0.001 seconds.

RESULTS

In the time-domain, the pressure variations at the thirteen outlets were similar in magnitude and delay, regardless of airway opening waveform. For both CMV and MFV, elastic pressure dominated the outlet pressures by about 7 cmH_2O, with 90^o phase differences observed among the elastic, resistive and inertial pressure components. However, MFV resulted in more turbulent flows and stronger pendelluft at phase shifts between inspiration and expiration, as shown in Figure 1. In the frequency-domain, the pressure and flow magnitudes at the tree outlets were dominated by spectral energy at 0.27 Hz during CMV, but by energy components 0.27 Hz, 3.5 Hz and 7 Hz during MFV. Outlet pressure variations lagged the inlet pressure by only about 1^o at 0.27 Hz

during CMV, but increased to 2.5º during MFV. Phase differences in flow rates between the inlet and outlets ranged from -0.8º to 0.4º for CMV, and from -1.5º to 1.8º during MFV. These results suggest that the slower 0.27 Hz CMV component of the MFV waveform was nonlinearly influenced by the high-frequency oscillations of 3.5 Hz and 7 Hz, thus enhancing inlet-outlet phase differences in low-frequency flow and pressure.

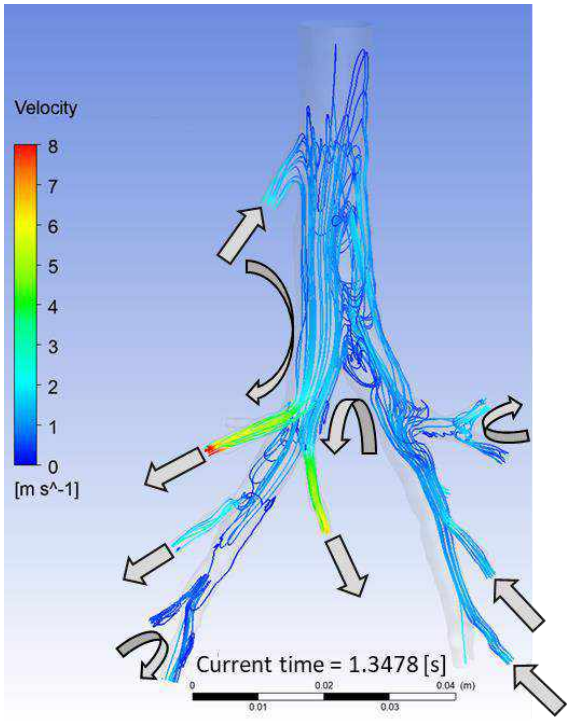

Figure 1: Pendelluft movements across the central airways indicated by streamlines at one of the end-inspirations during MFV (directions of the movements are suggestively marked by grey arrows).

DISCUSSION

In this study, we simulated airflow within a porcine central airway tree during CMV and MFV. The transient 3D Navier-Stokes equations were solved by applying experimentally realistic flow rate boundary condition at the airway inlet and dynamic pressure boundary condition at the outlets. Airflows were simulated and analyzed in both time- and frequency-domains. The high-frequency components of the MFV waveform nonlinearly influence its fundamental low-frequency component, which allow for enhanced pendelluft and gas mixing. Our simulations offer an effective way to reveal flow phenomena for specific airway regions across various ventilation modalities. These results also highlight the importance of applying realistic boundary conditions in such numerical airflow simulations.

INTRODUCTION

The Thoracic Lumbar Sacral Orthosis (TLSO) is widely applied for children with idiopathic scoliosis and provides curve correction or stabilization with derotation and lateral bending using a three-point loading mechanics and circumferential compression. Typically, the TLSO is designed in modular form, including anterior and posterior polymer lateral panels (typically made of Polyethylene), padded with foam and secured with Velcro straps. Some new designs incorporate 3D printing for the lateral panels (but not the padding) [1-4]. By exploiting the accuracy and speed of the 3D printing process, some advancements in brace design and manufacturing have been made [2].

Although the literature suggests extensive research and modeling of the hard polymer layer, research into the effect of the foam padding is virtually non-existent. What knowledge exists is rather empirical, poorly quantified and focused on foams used in foot orthotics [5]. Nonetheless, the foam plays a vital role in correcting the deformity and providing cushioning. Its role needs be investigated, quantified, and understood.

For scoliosis braces and orthotics, the typical foam used is Ethylene-Vinyl Acetate (EVA), which is "rubber-like" in terms of softness and flexibility. Typical values of stiffness for these foams are 1500 N/mm for a medium density and 2600 N/mm for firm density.

EVA is closed cell which has the beneficial property of preventing absorption of moisture which often leads to odor, mildew growth and in some cases Dermatitis [6]. However, closed cell foams do not permit air flow. Lack of air flow makes the device more uncomfortable and hotter which reduces compliance with the brace or orthotic.

An Engineered Foam is 3D Printed using newly developed flexible 3D printing materials (PEBA®, BASF® 88A TPU, etc.). The engineered foam geometry is open cell and is characterized by repeated cells of a lattice structure composed of bars called "struts" that connect vertices together to form the cell (Figure 1). The diameter of the strut is a design parameter. By changing the diameter, a foam with a different stiffness may be produced. The geometry which matches the cellular structure of traditional foam is the octagonal geometry.

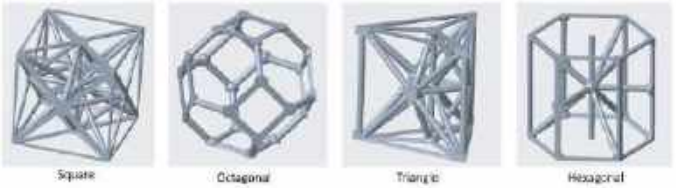

Figure 1: Various lattice geometry cells that may be used for the engineered foam.

Engineered foams may be custom designed to meet the needs of the patient. Already there has been successful implementation of such foams in Riddle 3D printed NFL football and EOS bicycle helmets. However there has been little to no application to orthotics and braces.

Also, it appears that there has been no development of Finite Element (FEA) models for 3D printed engineered foams in Scoliotic braces. The purpose of this study was to create and validate these models.

METHODS

Two recycled brace plaster mold negatives used in the traditional manufacturing of braces and the corresponding braces were acquired from a local facility (Hangar O & P, Milwaukee). The pressure at the plaster wall/foam interface was measured using Tekscan Flexiforce® pressure sensors. Thus the force that should be applied in the FEA was obtained. The average level of force was found to be 156N.

TPU 88A (BASF, Florham Park, NJ) was selected as the printing material. In order to establish the mechanical properties for this

material, a compression test was performed on five 3D printed (SLS) samples. The stress strain curve was obtained for this material and found to be non-linear as expected. The Young's modulus of the material was determined to be 2.869 ksi (19.78 MPa).

For validation, an MTS Alliance RT/50 was used. This frame has a 6 in (15.24 cm) diameter platen. According to ASTM D3574 C, for compression testing of foams the sample must be greater than the platen diameter, so the diameter of the foam was set at 7 in (17.78 cm).

Creo® (PTC, Boston) was implemented to create CAD models of the engineered foam. The models created were round with a 7 in diameter and having the octagonal lattice structure. The size of the cell was varied from 4 to 9 mm and the diameter of the strut was varied from 1 to 2 mm. The number of cells filling the CAD model varied as the cell size varied. The thickness of the foam was set at 7 mm as this value matched the thickness of traditional foam sheets. The optimal design yielding the two target foam stiffness (1500 and 2600 N/mm) was 7 x 7 x 7 mm.

Simulations were carried out using Ansys (Ansys, Canonsburg, PA). Because TPU 88A is non-linear, a multilinear isotropic hardening material model employing true stress and strain was used. Figure 2 shows an edge view of the foam with the applied boundary conditions that generate a mechanical environment comparable to the compression testing. They include a frictionless support over the entire bottom face to simulate the compression plate and a displacement of 0 mm in the direction normal to the faces on the edges of the foam.

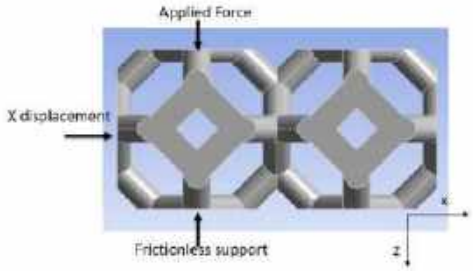

Figure 2: Boundary conditions applied in the FEA model.

The optimal designs were 3D Printed using the SLS method at the MSOE Rapid Prototyping Center using a DTM Sinterstation 2500 plus. Two samples of each stiffness were printed. Figure 3 shows a picture of one of the samples being tested in compression.

Figure 3: Engineered foam undergoing compression testing.

RESULTS

Because stress is not defined in the same way in compression testing as it is in FEA, stiffness was used. The stiffness as predicted by the FEA and as measured from the compression testing is given in Table 1. We see that the values are within experimental and numerical error.

Table 1: Results of the FEA compared to the compression testing.

Foam	Strut diameter (mm)	Stiffness (N/mm)		% difference
		FEA	Testing	
Medium	1.20	1512	1591	5.0
Firm	1.44	2614	2620	0.23

DISCUSSION

As we can see in Table 1, the difference in the prediction of stiffness between the FEA simulations and the compression testing is quite small. This implies that the FEA models are valid and may be used for subsequent simulations involving different values of foam stiffness. As the objective of this study was to generate validated FEA models for the design of Engineered Foam in brace applications, the study goals were achieved.

It was observed that the typical level of force applied to the foam (156N) is actually quite small. And while the behavior of the TPU 88A shows hyperelastic behavior, the deformation under 156N is less than 2% strain. This implies that linear FEA material models may be used. In fact, the optimal design was rerun in Ansys with a linear material model having a Young's Modulus of 2.869 ksi (19.78 MPa) and a Poisson ratio of 0.1 to yield the same stress and strain results as when the multilinear isotropic hardening material model was used. Since a linear model is easier to implement and runs faster, the linear material model is recommended for this application.

ACKNOWLEDGEMENTS

The authors wish to recognize the hard work of Chase Blum and Megan McKee, undergraduate students at the Milwaukee School of Engineering for their hard work in completing the FEA simulations.

INTRODUCTION

Despite recent advances in clinical medical imaging, limitations in spatial resolution prevent depiction of the microvascular arterial network. Adequate myocardial perfusion depends on the intricate balance between the epicardial and microvascular arterial system. Therefore, understanding and accurate mapping this network is required for development of diagnostic and therapeutic strategies in cardiovascular medicine.

Several methodologies for myocardial arterial network generation have been proposed, with each offering unique insights and challenges. Fractal models effectively capture the complex branching nature of vascular networks [1], while optimization methods aim to efficiently represent the vascular system, focusing on critical parameters like tree volume or kinetic energy [2]. Although continuous models using porous media flow simulations complement these methods and broaden our perspectives on myocardial perfusion, they risk oversimplifying structural details [3].

More advanced techniques such as Constraint Constructive Optimization (CCO)-based methods have gained popularity, particularly the adaptive CCO approach, which is tailored to reflect the physiological and anatomical variations of the myocardial arterial network [4]. These methods excel in capturing intricate network topology and accommodating patient-specific physiological variations, which is invaluable for creating personalized models.

The automatic generation of arterial networks in the myocardium, based on myocardial blood volume (MBV) maps [5, 6] may further transform our understanding of the relationship between the coronary circulation and myocardial perfusion. The MBV reflects the autoregulatory adaptation necessary to maintain resting myocardial blood flow over a range of coronary perfusion pressure, whereby additional blood supply requires arteriole vasodilation and capillary recruitment. Despite the advancements in modeling techniques, significant unknowns remain, particularly for generating large physiologically-sound vascular networks that supply blood to various myocardial segments. These unknowns include the precise replication of the myocardial perfusion and their integration into patient-specific arterial network models.

The primary objective of this study is to develop a framework for automatically generating a one-dimensional arterial network in the myocardium, based on MBV maps. This approach aims to bridge the gap between perfusion imaging and vascular modeling to provide a more integrated and accurate representation of the coronary circulation.

METHODS

Myocardium. An ideal left ventricular (LV) myocardial geometry was generated from coronary computed tomography angiograms (CTA) and was segmented according to the American Heart Association (AHA) 17-segment model. Representative MBV maps of the LV were estimated using Kassab's myocardial mass-flow rate relationship [7].

Coronary Tree. The 3D model of left anterior descending (LAD) artery was extracted from the CTA images using Simvascular software package. The centerlines for the LAD were extracted and a 1D model of LAD was reconstructed.

Arterial Network Generation. A modified adaptive, multistage CCO method was developed to generate the vascular network. In brief, locations of virtual terminal nodes were generated randomly, and 15 closest arterial segments were identified. To find the best location for the bifurcation point, physiological and geometrical constraints were incorporated, and an optimization problem was solved where the objective function is the total volume of the arterial tree. The construction of the arterial tree for different myocardial segments continues until the diameter of the terminal segments reaches 150 μm.

Global Optimization of Diameters. An iterative optimization method was developed to correct each arterial segment diameter such that the flow rate supplying each myocardial segment matches the MBV maps with a tolerance of 0.2 %.

Reproducibility and Seed Dependency Analysis. Since the terminal node selection process is based on a random coordinate generator, five arterial networks were generated based on different seeds, and the distributions of arterial segment diameters were compared. Also, the resultant synthetic MBV maps were compared with the prescribed MBV maps.

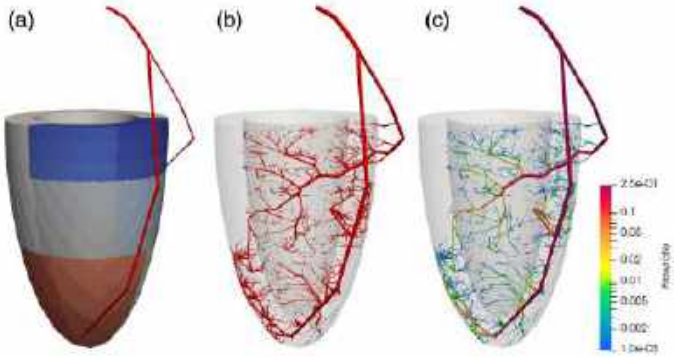

Figure 1: (a) Left ventricular myocardial segments corresponding to the LAD territory and the initial 1D tree; (b) Generated synthetic arterial network consisting of 1500 arterial segments; and (c) Distribution of flow rate (cm^3/s) in the LAD arterial tree.

RESULTS

Shown in Figure 1 is the LAD myocardial territory, along with the corresponding CTA-derived 1D epicardial coronary tree, the generated synthetic arterial network from Seed 1, and the flow distribution. Near uniform flow rate distribution can be seen in the terminal segments.

Figure 2 shows the distribution of terminal segment diameters for five synthetic arterial trees. The terminal segment distributions are similar for all five synthetic networks (coefficient of variation = 0.21). The mean terminal segment diameter for all seeds was 131±28 μm and the average arterial tree volume was 392±13 mm^3.

Figure 3 shows the relationship between the percent flow rate calculated based on myocardial mass [7] and the percent flow rate obtained from the synthetic networks. The trendline indicates minimal discrepancies between the target flow percentages and the flow percentages computed from the synthetic networks (R^2=0.93, and Pearson's r=0.97). The mean error between segment-wise flow percentages was 3.1±2.6%.

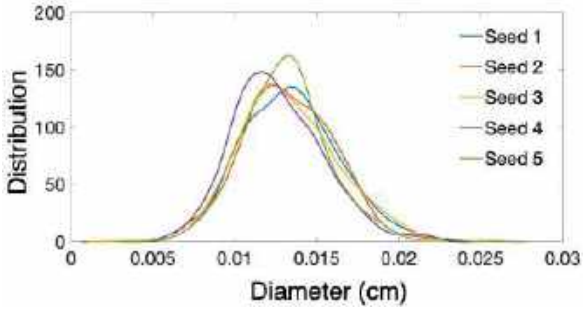

Figure 2: Distribution of terminal segment diameters for five different random seeds.

DISCUSSION

The synthetic arterial trees successfully populated the LAD distribution of the perfused myocardium while meeting all the physiological and anatomical constraints (see Figure 1). The synthetic network conforms to the shape of myocardium while effectively generating larger arteries on the epicardial surface and branching into smaller arterial segments inside the myocardium (Figure 1c). The distribution of the terminal segments for five separate synthetic trees were consistent (coefficient of variation equal to 0.21). To further confirm the reproducibility of our arterial network generation algorithm, we generated synthetic MBV maps for all 5 arterial networks. We compared the absolute difference between the myocardial mass derived MBV maps and the synthetic MBV maps. The median synthetic MBV was within 3% of the myocardial MBV maps. The results (Figures. 2 and 3) support the robustness of our proposed computational framework for simulating the distribution of blood inside the synthetic microvascular tree based on MBV maps. The results imply that our current model can calculate the resistances in the microvascular network accurately.

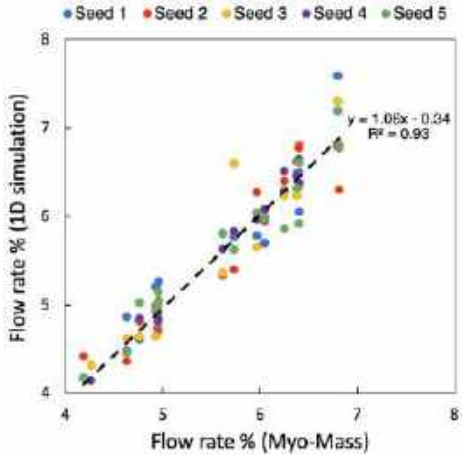

Figure 3: Relationship between flow rate calculated based on the myocardial mass and flow rate obtained from the synthetic arterial network.

The findings of our study have significant implications for epicardial and microvascular ischemic heart disease. The ability of our synthetic arterial networks to accurately replicate the coronary arterial tree and MBV maps underscores its potential to enable further study of the relationships between the epicardial coronaries and microcirculation. The strength of our approach lies in its robustness and reproducibility. However, it is important to consider the limitations of this study. While the synthetic networks showed high fidelity in replicating the physiological and anatomical features, they are based on simplified models and limited physiological data. Work is under way to apply the developed framework to patient-specific MBV maps with patient-specific epicardial coronary arterial tree and myocardial geometry. Despite these limitations, our study represents a significant step forward in filling the gap between perfusion imaging and computational coronary blood flow modeling, providing a more integrated and accurate representation of the coronary arterial network.

INTRODUCTION

The configuration of the vocal folds (VFs) and the surrounding laryngeal tissue is pivotal in voice production as it affects voice quality and may have consequences on vocal health. Laryngeal configurations are modulated by complex interactions between the laryngeal passive tissues, cartilages, and muscles, which are not fully understood. Incomplete glottal closure is a laryngeal configuration wherein the glottis is not fully obstructed prior to phonation, which can exhibit an array of curved VF patterns (see Figure 1).

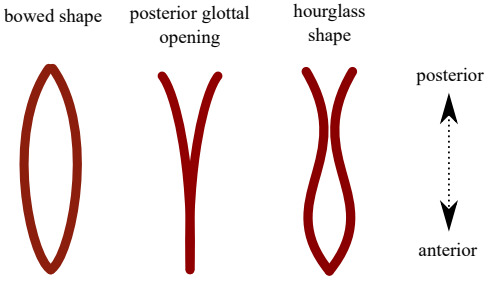

Figure 1: Schematic diagram (superior view) of some incomplete and curved glottal closure patterns that are observed clinically.

The underlying physical mechanisms of curved and incomplete glottal closure patterns are not well understood. However, there exist several experimental and clinical studies in the literature that link certain curved and incomplete glottal closure patterns to particular laryngeal maneuvers [1–4]. Besides, numerical simulations using high-fidelity numerical models [5, 6] qualitatively agree with the aforementioned clinical and experimental studies.

Despite these valuable efforts, there is a lack of comprehensive understanding of the physical mechanisms inducing different glottal patterns. This is due to the difficulty of isolating and controlling the factors underlying posturing mechanics in clinical or experimental setups, and the lack of clear intuitive understanding of the mechanics of posturing when adopting high-fidelity numerical models.

In this work, we present an Euler-Bernoulli composite beam VF model [7] that produces qualitatively similar incomplete glottal closure patterns as those observed in experimental and high-fidelity numerical studies, thus offering insights in to the potential underlying physical mechanisms.

METHODS

We hypothesize that the layered non-homogeneous structure of the VFs underlies, at least in part, the different glottal shapes displayed in Figure 1. As such, we propose an Euler-Bernoulli composite beam model of the VFs (see Figure 2).

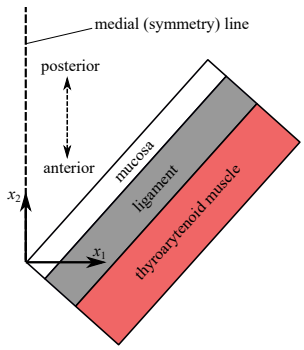

Figure 2: Schematic diagram of the VF composite beam model.

The proposed beam model is integrated with the muscle-controlled posturing model of Titze and Hunter [8] that relies on five normalized muscle activation parameters, a_{ta}, a_{ct}, a_{lca}, a_{ia}, and a_{pca}, which correspond to the thyroarytenoid (TA), cricothyroid (CT), lateral cricoarytenoid (LCA), interarytenoid (IA), and posterior cricoarytenoid (PCA) muscles, respectively. This integration aims at gaining refined physiological insights into how intrinsic laryngeal muscles may influence glottal geometry.

RESULTS

We consider numerical simulations of the proposed model that incorporate laryngeal maneuvers associated with adductory (TA, LCA, and IA) and abductory (PCA) muscles as they have been found to play major roles in inducing curved glottal geometries. Simulation results show that (1) co-activation of the LCA and IA muscles leads to posterior glottal closure with a remaining mid-membranous gap (see Figure 3(top left)); (2) isolated activation of the TA muscle leads to anterior and mid-membranous glottal closure with a remaining posterior opening, while also shortening the folds (see Figure 3(top right)); (3) starting from non-zero coactivation of the LCA and IA muscles, increased TA activation yields a medial bulge, whereas anteriorly the glottal geometry is still convex, resulting in an overall hourglass shape (see Figure 3(bottom left)); and (4) starting from a fully adducted state where all the adductory muscles are co-active, increasing PCA activation leads to posterior opening, while the VFs are sustaining concave shapes similar to those presented when TA is activated solely (see Figure 3(bottom right)). These results are in alignment with previous studies [1, 3, 6].

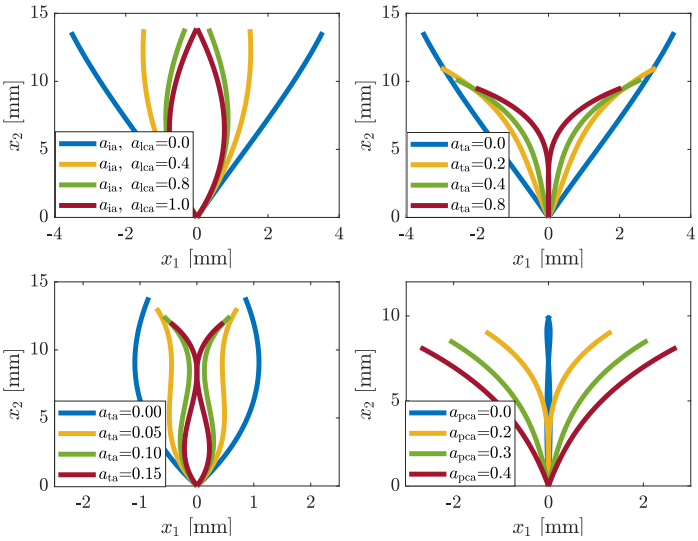

Figure 3: Glottal shapes for (top left) increasing LCA and IA activation levels and other intrinsic muscles being inactive, (top right) increasing TA activation levels and other intrinsic muscles being inactive, (bottom left) increasing TA activation levels and other intrinsic muscle activation levels being at $a_{\text{lca}} = a_{\text{ta}} = 0.6$ and $a_{\text{ct}} = a_{\text{pca}} = 0$, and (bottom right) increasing activation of the PCA muscle with the activation levels of the other muscles being $(a_{\text{lca}}, a_{\text{ia}}, a_{\text{ta}}) = (0.45, 0.45, 0.7)$ and $a_{\text{ct}} = 0$.

DISCUSSION

The predictions from the proposed Euler-Bernoulli beam model highlight potential mechanisms underlying different patterns of incomplete glottal closure observed clinically. In particular, results indicate that bowed VF shapes result, in part, from low or null activation of the TA muscle in combination with co-activation of the LCA and IA muscles. The predominant mechanism in this case is the anterior reactive moments that resists bringing the VFs together during adduction. In addition, the proposed model suggests that posterior glottal opening with combined VF concavity results from high activation of the TA muscle and low or null activation of the LCA and IA muscles. The driving mechanism herein is the internal moments induced by the TA muscle activation. A similar glottal pattern also occurs when all adductory muscles are activated in addition to the activation of the PCA muscle. Finally, our analysis suggests that the hourglass glottal shape may emerge from laryngeal maneuvers that involve, for example, moderate co-activation of all adductory muscles, where both anterior reactive moment and the internal moment due to TA muscle activation are at play and opposing each other.

These implications may help guiding speech therapists to uncover the underlying laryngeal mechanisms associated with some voice disorders. Incomplete glottal closure can be linked to voice disorders that are characterized by excessive, imbalanced, or deficient activity of the intrinsic and extrinsic muscles such as muscle tension dysphonia (MTD) and Parkinson's disease. Our analysis suggests that insufficient activation of the TA muscle may be a potential mechanism underlying bowed VFs in some patients with voice disorders. Furthermore, our analysis posits that patients with abnormal posterior glottal opening and concave VF geometry, either (a) insufficiently activate the LCA and IA muscles, whereas the TA muscle is activated sufficiently (in comparison to normal posturing scenarios), or (2) suffer from excessive activation of all adductory and abductory muscles, where the PCA muscle activation mitigates the effects of the LCA and IA muscles, in agreement with the postulation in Morrison et al. [1] concerning patients with MTD.

INTRODUCTION

Historically, the sclera and other fibrous soft tissues have been modeled within a continuum framework, leading to the development of constitutive material models to describe their properties [1]. Recent advancements of imaging technologies have provided more detailed information of the three-dimensional (3D) organization of tissue fiber architecture, enabling the emergence of discrete approaches that explicitly model the fibrous structures [2]. The fiber bundles within the sclera exhibit complex 3D organization and continuity. To account for this complexity, our group has developed a discrete finite element modeling framework that incorporates long and continuous collagen fiber bundles, utilizing 3D spatial organization data derived from Polarized Light Microscopy (PLM) and considering interactions between fiber bundles [3]. Conventional continuum approaches that utilize constitutive models typically assume affine relationships between individual fibers and macroscopic tissue deformation, without considering fiber-fiber interactions, whereas the fiber model does not enforce this assumption. This raises critical questions about the ability of the continuum model to accurately capture complex fiber deformation behaviors and transmit macroscopic tissue strains through the fibers to the cellular level.

Our goal in this study was to compare a continuum model developed for sclera fiber bundles in the Optic Nerve Head (ONH) region with our previously proposed fiber model [3].

METHODS

Continuum model geometry and boundary conditions. We constructed a continuum model that aimed to mirror the fiber model introduced in [3] in terms of geometries of the sclera, laminar cribrosa and neural tissue, and boundary conditions (Figure 1). The model was subjected to an intraocular pressure (IOP) of 30 mmHg. A radial displacement (RD) of 0.1 mm was applied to the model's periphery to simulate the radial tension of the sclera due to IOP (Figure 1).

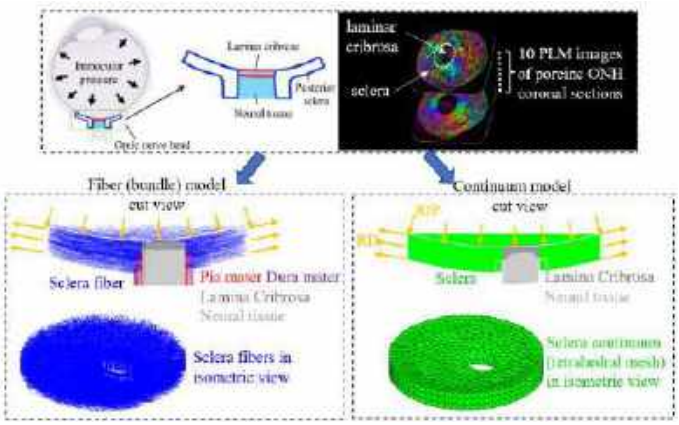

Figure 1: Schematic illustration of the geometry and boundary conditions of the fiber model and continuum model. The same boundary conditions were applied to both models to simulate an inflation experiment. The continuum model was meshed using tetrahedral elements.

Material properties. The lamina cribrosa (LC) and neural tissue (NT) regions were modeled as linear elastic material (ELC = 0.1 MPa, ENT = 0.01 MPa), same as the fiber model. The sclera tissue in the continuum model was characterized using the Holzapfel-Gasser-Ogden (HGO) strain energy function [4]. Element-wise fiber parameters, such as fiber dispersion, fiber volume fraction, and mean fiber direction were determined based on the scleral fiber structure reconstructed in the fiber model based on 10 PLM images of porcine optic nerve head (ONH) coronal sections (Figure 1) and are presented in Figure 2a. Fiber stiffness parameter k_1 and exponential parameter k_2 were inversely identified as $k_1 = 45Mpa$ and $k_2 = 45$ by matching the IOP-induced

peripapillary sclera's (PPS) posterior displacement (Figure 2b) and scleral canal expansion with those derived from ex-vivo inflation experiments documented in the literature [5]. Due to space constraints, we cannot present here the details of the material formulation and fiber mean orientation as well as the scleral canal expansion. These will be shown in the presentation at the conference. The solution was obtained using the FE solver Abaqus/Standard.

Comparison of fiber strains between the continuum and fiber models. We compared the distributions of fiber strains in scleral fiber bundles derived from both the fiber and continuum models. In the fiber model, fiber strain was the axial strain of the fiber element. For the continuum model, fiber strain was determined by mapping the strain tensor in the direction of the fiber element. The standard deviations of fiber strains derived from both models were calculated to quantify the degree of variation in fiber strains for fiber segments within each continuum element and along each entire fiber, respectively.

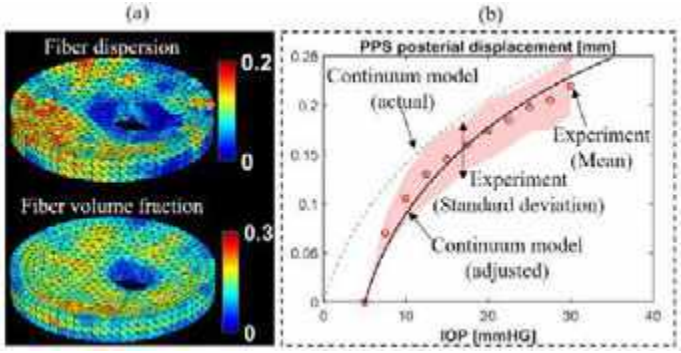

Figure 2: (a) The distributions of calculated element-wise fiber dispersion and volume fraction in the isometric view. Note the fibrous ring surrounding the canal. (b) Plot of the peripapillary sclera's (PPS) average posterior displacement as a function of Intraocular pressure (IOP) as obtained from the continuum model and experiments [5]. The model responses are adjusted by 5 mmHg on the IOP axis for direct comparison with the experimental data. In the experiments, configurations at 5 mmHg were utilized as the reference undeformed state.

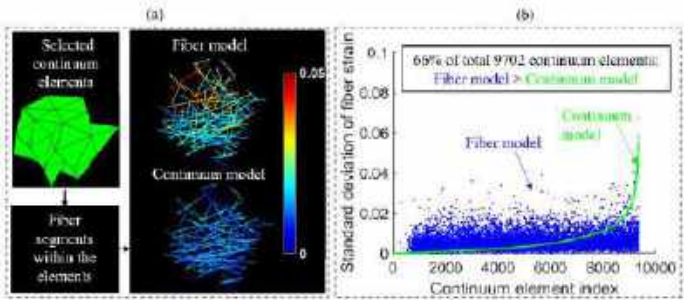

Figure 3: (a) Fiber segments within 10 selected continuum elements are shown colored according to the strains derived from the fiber (top) and continuum (bottom) models. Note how the varied fiber strains in the fiber model are homogenized in the continuum model. (b) Scatterplots of standard deviations of fiber strains derived from two models for fiber segments within each continuum element as a function of the continuum element index for a total of 9702 elements. The indices are sorted based on the standard deviation of fiber strain derived from the continuum model.

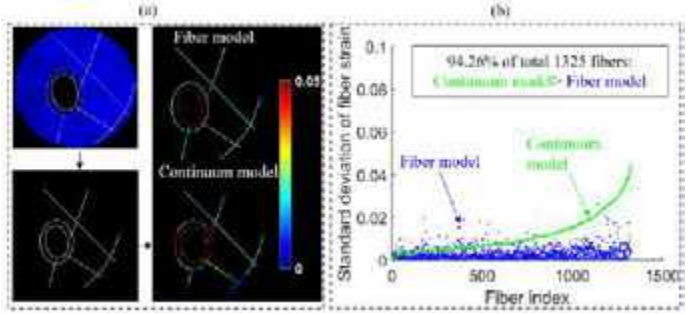

Figure 4: (a) Seven fibers (white) randomly selected from the fiber model are shown here colored according to the strains derived from the fiber (top) and continuum (bottom) models. Note how the smooth strains in the fiber model are disrupted in the continuum model. (b) Standard deviations of fiber strains for fiber segments along each fiber derived from two models, plotted against the fiber index for a total of 1325 scleral fibers. The fibers are indexed based on the standard deviation of fiber strains derived from the continuum model. Notice that the fiber strains derived from the fiber model along each fiber are quite uniform, with 97% of the fibers exhibiting standard deviations less than 0.01.

RESULTS

The degrees of variation in fiber strains derived from the fiber model and the continuum model, for fiber segments within each continuum element and along each whole fiber, are shown in Figure 3 and Figure 4, respectively. Overall, the fiber strains demonstrated a much lower degree of variation in the continuum model than in the fiber model within each continuum element (Figure 3), but the opposite was observed along each fiber (Figure 4).

DISCUSSION

An accurate representation of fiber deformation is essential for models that connect tissue biomechanics to cell mechanobiology. Our overall goal was to investigate whether a developed continuum model can accurately represent the strains of scleral fiber bundles by comparing it with our previously proposed fiber model. Specifically, in this project, we aimed to check if the continuum model could capture the complex local fiber strains and the long-distance strain transmissions. We found that the continuum model tends to homogenize local fiber strains, even after accounting for directions of varied local fiber segments. Additionally, the continuum model disrupts the smooth strain transmission along each fiber. These results suggest that while the continuum model is effective in modeling macroscopic tissue response, it may not faithfully represent the intricate fiber deformation behaviors. Consequently, its ability to link macroscopic tissue responses with cellular and sub-cellular level activities should be carefully evaluated.

INTRODUCTION

Low back pain is the most common musculoskeletal condition worldwide.[1] Although intervertebral disc (IVD) degeneration accounts for over 400 million cases of back pain[2], there are currently no clinically available treatment options that restore the structural or mechanical properties of the native disc. In the last two decades, mesenchymal stromal cells (MSC) have been widely studied for the treatment of degenerative diseases due to their differentiative, immunomodulatory, and trophic properties.[3] Recent clinical trials show that MSCs can improve disc hydration and patient-reported outcomes through direct injections in combination with biomaterial carriers.[4] Despite the promising results, the exact mechanisms employed by MSCs to help promote healing remain unclear.

Previously, MSCs were thought to stimulate regeneration of tissues primarily through differentiation to target cell types.[5] However, only a small fraction of MSCs survive and are retained locally.[6] Therefore, current research is focused on elucidating their paracrine abilities specifically related to growth factors and extracellular vesical (EV) secretion.[6] Within this domain, many groups have demonstrated that MSCs donate mitochondria (MT) through tunneling nanotubes, MT-containing EVs, and cell fusion to injured cells including tenocytes[7], chondrocytes[8], and nucleus pulposus cells (NPCs).[9] Although MT transfer has been shown to prevent inflammation in tenocytes[7] and reduce reactive oxygen species (ROS) and cell apoptosis in NPCs[9], the ability of MSCs to transfer MT to annulus fibrosus cells (AFCs) and its functional consequences for IVD degeneration have not yet been investigated. The goal of this study was to determine (1) whether MSCs donate MT to AFCs and (2) the extent to which the inflammatory mediator, IL-1β, can stimulate MT transfer. We hypothesize that inflammatory stimulation via IL-1β will promote MT transfer from MSCs to AFCs.

METHODS

Cell isolation: Five IVDs were harvested from one neonatal bovine tail and the nucleus pulposus of each IVD was removed using a scalpel. The AF was digested in a 0.3% collagenase solution for 6 hours. Isolated AFCs were expanded in monolayer culture to passage two with Ham's F-12 media supplemented with 10% FBS and 1% AbAm at 37°C and 5% CO_2. MSCs were harvested from neonatal bovine femoral trabecular bone, transduced with a mCherry-Mito lentivirus to allow for mitochondrial visualization, and expanded to passage five.

Coculture: AFCs were plated onto chambered cover slides, allowed to adhere overnight, then cultured in the presence or absence of IL-1β. After 24 hours, AFCs were stained with Vibrant™ CFDA SE. Following AFC staining and washing, MSCs were added using an AFC:MSC ratio of 2:1. During co-culture, 10ng/mL IL-1β was maintained in the IL-1β group. Cells were co-cultured for 24 hours before imaging.

Imaging: Cocultures were imaged using a Zeiss LSM inverted confocal microscope. For each sample, 8-14 imaging fields (resolution: .21-.35 μm/pixel) containing at least one MSC were randomly chosen. All imaging fields contained 10-20 Z-stack slices.

Image analysis: Mitochondrial transfer events were identified by areas of colocalization between the CFDA and mCherry channels. Colocalization was identified using an established ImageJ plugin (Colocalization Image Creator)[10] with custom settings for detecting mitochondrial transfer. The AFC and MSC channels were thresholded using Huang and Isodata automatic thresholds respectively. All colocalized signals above one-pixel unit in area were considered a mitochondrial transfer event and manually counted for each image (Fig. 2). Cell areas were manually calculated using the ImageJ freehand selection tool, while colocalization areas were calculated using automatic particle measurement.

Statistics: Statistical analysis was performed using a one-way ANOVA in Rstudio with a p-value less than 0.05 considered statistically significant (n=8 cocultures per group).

RESULTS

MSCs transfer mitochondria to AFCs in 2D contact co-culture. Confocal microscopy revealed multiple instances of red fluorescent signal within AFCs for both the control and IL-1β groups. These instances of signal overlap appeared as either punctate red signal broadly distributed throughout AFCs (Fig. 1a & 1b), concentrated areas of red signal near AFC membranes (Fig. 1c), or as larger red areas wrapping around and/or blending into AFCs (Fig. 1d). Image analysis confirmed apparent signal colocalization (Fig. 2a-c) through multiple image slices (Fig. 2d), as seen through cell tracing (Fig. 2c) and orthogonal viewing of whole Z-stacks (Fig. 2d).

IL-1β increased the frequency of MT transfer. On average 29% of IL-1β-stimulated AFCS and only 23% of control AFCs exhibited red/green signal colocalization ($p = 0.03$, Fig. 3a). Ratios of colocalization area to cell area indicate the majority of signal colocalization occupied less than 5% of the total cell area for both the IL-1β and control groups.

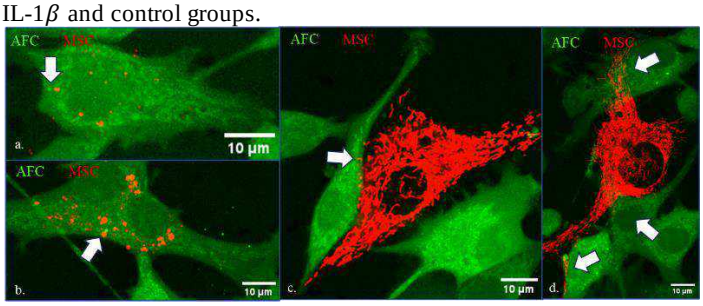

Figure 1: Observed categories of MT transfer. All images are collapsed Z-stacks with arrows pointing to possible transfer events. (a.)(b.) Punctate red signal within AFCs. (c.) Apparent MSC/AFC fusion through cell bodies with concentrated red signals merging with AFCs. (c.) Tunnel nanotubes extending over multiple AFCs.

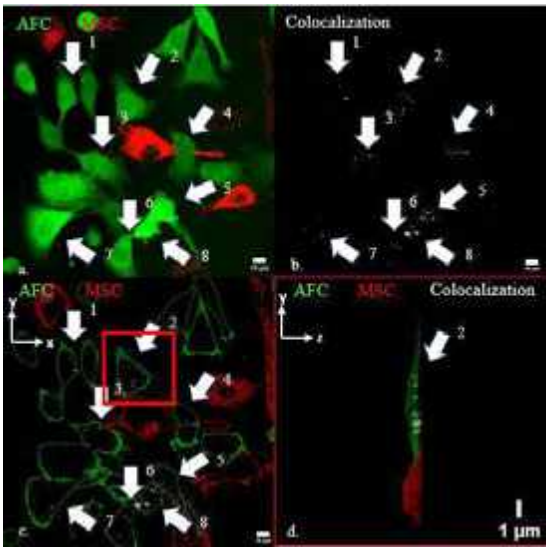

Figure 2: Evidence of MT transfer through signal colocalization. Images a-c are collapsed Z-stacks with arrows pointing to signal colocalization. (a.) Raw composite image. (b.) Processed image containing only specific areas of signal colocalization. (c.) Processed image containing outlined cells and signal colocalization. (d.) Orthogonal view of an AFC with signal colocalization.

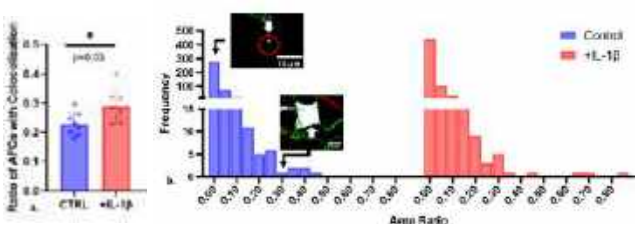

Figure 3: Inflammation stimulates mitochondrial transfer. (a.) IL-1β significantly increases the number of AFCs presenting signal colocalization. (b.) The majority of colocalized signals occupy less than 5% of the total cell area.

DISCUSSION

The goal of this study was to determine the capacity of MSCs to transfer mitochondria to healthy and IL-1β-stimulated AFCs. 24-hour AFC/MSC coculture resulted in multiple instances of red and green signal overlap spanning multiple Z-stack slices, indicating MT transfer events. MT transfer has been shown to occur through cell fusion, tunneling nanotubes, and extracellular vesicle uptake. Herein, there was evidence of cell fusion and tunneling nanotubes (Fig. 1b-c). Although there are no direct signs of MT EVs, AFCs with sparse punctate signal colocalization that are not in direct contact with an MSC (Fig 1a,b) may indicate EV-mediated transfer.[8]

IL-1β stimulation increases the frequency of transfer events between MSCs and AFCs (Fig. 3a). Inflammation is a key characteristic of IVD degeneration and specifically inflammatory cytokines including IL-1β are upregulated in degenerative IVDs.[11,12] IL-1β's effect on transfer may be due to its established ability to cause aberrant intracellular changes in AFCs that include upregulation of matrix-degrading enzymes and ROS.[12] Previous studies show that MSCs are also capable of donating mitochondria to nucleus pulpous cells treated with rotenone.[9] In comparison, we show that a general inflammatory model, rather than specific MT inhibition, of IVD degeneration is sufficient to stimulate MT transfer. To the best of our knowledge, this is the first study to show that MSCs donate MT to healthy and IL-1β stimulated AFCs. Although there were no differences in the area ratio between groups, it is important to note that most transfer events were on the lower end of the histogram, indicating singular or few mitochondrial transfer events per cell (Fig. 3b).

In this study, we show that MSCs donate mitochondria to inflammatory-stressed AFCs. Given that MSC MT transfer has shown great promise in reducing cell stress and promoting cell survival[13], it may prove to be a novel strategy for stimulating the healing of degenerative IVDs. Future areas of investigation should focus on what mechanisms affect transfer and how we may be able to upregulate transfer for improved therapeutic outcomes.

INTRODUCTION

Moderate to severe preterm birth (< 32 wks gestation) exposes the newborn to a relatively hyperoxic (i.e., abnormally high oxygen) environment compared to in utero. The resulting oxidative stress can impair the still-developing heart and lung and lifesaving supplemental oxygen increases this effect. Preterm birth affects cardiopulmonary function across multiple spatial and temporal scales; in fact, it is associated with an up to 17-fold increased risk for heart failure through early adulthood [1]. However, the short- and long-term cardiopulmonary effects are still poorly understood. It is commonly thought that increased right ventricle (RV) afterload from the damaged pulmonary vasculature drives RV dysfunction in preterm birth. Clinical and preclinical studies also suggest that direct injury to the RV itself may be a driver of early dysfunction [2]. Thus, the question is how do direct injuries to the myocardium contribute to long-term RV dysfunction under chronically increased afterload in the setting of preterm birth?

The currently accepted animal model for studying preterm birth uses postnatal hyperoxia (Hx) exposure in rodents. Rat lungs continue to develop after birth thus term-born rat pup lungs are at a similar developmental stage as humans in the third trimester. Hx rats at postnatal day 21 (P21) demonstrate RV hypertrophy and increased pulmonary artery pressures compared to the normoxic (Nx) controls [2]. These organ-scale injuries at P21 for the Hx animals correspond with cellular and subcellular mitochondrial injuries [2]. At postnatal day 90 (P90) these measures normalize in the Hx animals, but organ and subcellular abnormalities return by postnatal day 365 (P365). Thus, experimental results show a dynamic time course of increased afterload and mitochondrial RV injury in response to postnatal Hx, but it remains unclear how these independent factors drive long-term RV dysfunction.

Investigating the mechanisms underlying RV dysfunction in response to postnatal Hx is complicated by the multifactorial nature of pathophysiology and the long timescale of disease progression. When based on robust experimental data, in silico modeling can be used to test proposed mechanisms across multiple age points and predict functional growth curves. Biophysics models can readily integrate multiple data modalities and test mechanistic hypotheses related to functional interactions across different spatial and temporal scales. Here we used a multiscale cardiovascular model to investigate potential multiscale injuries due to preterm birth based on rat data.

METHODS

We used our recently published model of the heart [3] using the TriSeg method [4] and myofiber mechanics from [5], integrated within a lumped cardiovascular system model comprising six arterial, venous, and ventricular compartments. The TriSeg method approximates the ventricles as semi-spherical, thick-walled chambers with a shared septal wall, and the cardiovascular model is a 0D closed-loop circuit model invoking linear pressure-flow and pressure-volume relationships.

The myofiber mechanics model based on [5] integrates crossbridge mechanics to simulate active myocardial wall stress σ_{active} (kPa). The crossbridge model includes five states (calcium unbound, calcium bound, loosely attached, strongly attached, post-ratcheted) and the transition rate between states is regulated by mitochondrial metabolite concentrations of cytosolic adenosine triphosphate (ATP), adenosine diphosphate (ADP), and inorganic phosphate (Pi). The calcium activation is based on [6] and mediates the transition from calcium unbound to calcium bound states and includes a force-dependent transition from unbound to bound states. The actives stress is computed from contributions for pre- and post-ratcheted states, such that

$$\sigma_{active}(t) = OV_{thick}(k_{stiff,1}(p_2^1 + p_3^1) + k_{stiff,2}\Delta rp_3^0$$

where OV_{thick} (unitless) is the fraction of thick filament overlap, $k_{stiff,1}$ and $k_{stiff,2}$ are stiffness constants (mmHg/μm), Δr is the crossbridge strain associated with ratcheting deformation, and p_2^1 (μm), p_3^1 (μm), and p_3^0 (unitless) are state variables of the crossbridge model. The passive stress, $\sigma_{passive}$ (kPa), formulation depends on the time-dependent sarcomere length (SL, μm) and the sarcomere rest length (SL_{rest}, μm), such that

$$\sigma_{passive}(SL) = k_{passive}(SL - SL_{rest}) + \sigma_{passive\ collagen}(SL),$$

and includes an exponential relation for collagen recruitment. A flow chart of our multiscale model is shown in **Figure 1**.

We simulated a Nx case and a Hx case. Geometric, pressure, and volume data including end-diastolic and end-systolic pressures and volumes and animal weights from Nx and Hx rats at P21, further described in [2], are averaged and used to estimate parameters e.g. ventricular refence areas and volumes, systemic and pulmonary resistances, and venous and systemic arterial and pulmonary compliances. The Hx animals had increased pulmonary artery elastance, thus we increased pulmonary arterial resistance in the model by a factor of two from the Nx case to achieve higher pulmonary arterial pressures.

Then, to achieve an increase in RV systolic pressure and reasonable end-diastolic volumes we used three strategies to interrogate the role of RV hypertrophy and mitochondrial dysregulation in RV function in Hx rats at P21. 1) Decreasing ATP, ADP, and Pi concentrations for the RV, with Pi having the largest influence. 2) Increasing RV wall volume. 3) Both decreasing the metabolite concentrations and increasing RV wall volume.

Finally, since the described model does not include regulatory mechanisms like the baroreflex, we employed a compensatory volume overload to maintain mean systemic arterial blood pressure as in [4].

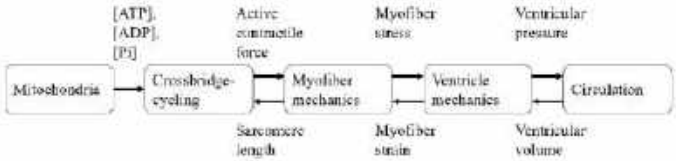

Figure 1. Cardiovascular model schematic.

RESULTS

The top panels of **Figure 2** show the model-predicted pressure volume loops for the group averaged Nx data at P21. For the three strategies used to fit the Hx data, the model-predicted pressure-volume loops are shown in the bottom panels of **Figure 2** and the scaling factors are shown in **Table 1**. Notably all end-systolic and end-diastolic volumes and pressures fall within one standard deviation of the mean values from [4], which were used as inputs to the Nx and Hx models.

Table 1. Scaling factors used to achieve model fits to data.

	[ATP][ADP][Pi]	RV Wall Volume
Strategy 1	0.6	1.0
Strategy 2	1.0	1.6
Strategy 3	0.8	1.3

DISCUSSION

Here we have modeled multiscale right ventricular dysfunction of the preterm heart in silico. The hand-tuned parameters to the average group data provide predictions within one standard deviation of the mean, corresponding to known physiological changes. Namely, the Nx model requires increases in pulmonary elastance and resistance to match Hx data. These changes are consistent with the expected pulmonary damage in preterm-born infants and the findings from Hx rat models of preterm birth. Reducing mitochondrial metabolite concentrations enabled a reasonable model fit to the Hx data, which also corresponds with the dysregulated mitochondrial respiration observed in cells from blood samples of human subjects born preterm [7]. Increasing RV wall volume to simulate hypertrophy, observed clinically [2], also provided a reasonable fit, as did the combination of mitochondrial dysfunction and RV hypertrophy. In the absence of additional experimental data, these results suggest that different injuries and adaptations across scales can explain the impact of Hx and preterm birth on RV function.

The multiscale model adapted from [3] allows investigation of the causes and consequences of preterm birth and their multiscale nature. Since somatic growth is a prominent factor to consider in preterm birth, a lower order model such as ours allows future implementation of somatic growth and remodeling, which is critical for longitudinal modeling efforts.

Limitations of this modeling framework include assumptions and limitations propagated from the TriSeg model and myocyte mechanics model, such as the assumption of spherical ventricular geometry and sarcomere lengths determined from isolated rat trabeculae, respectively. Additionally, we parameterized the model to fit group average values, which obscures features that may be present in individuals.

The work presented here establishes a modeling framework for investigating the multiscale and somatic growth features of RV dysfunction in preterm birth and provides the basis for future subject specific parameterizations at P21 (infant), P90 (adolescent), and P365 (adult).

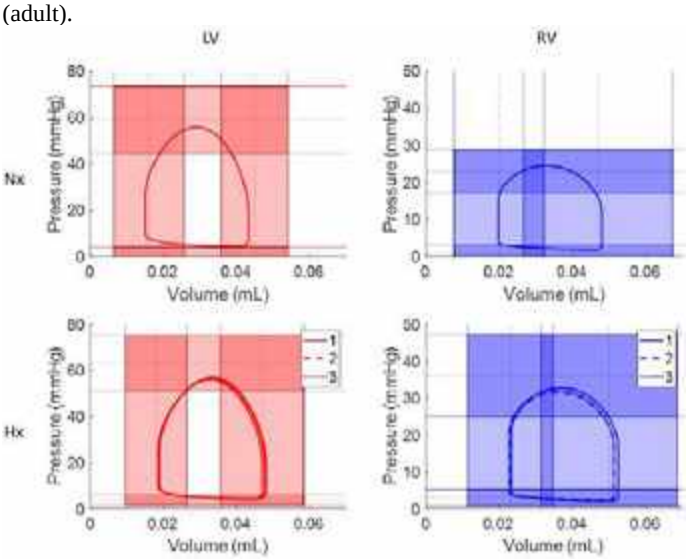

Figure 2. Model-predicted LV (red) and RV (blue) pressure-volume loops for average normoxic (Nx) and hyperoxic (Hx) subjects at P21. Results for Hx strategies 1-3 are indicated in the legend. The dashed lines represent the mean and shaded regions represent ± one standard deviation from the mean.

QUANTIFYING CHANGES IN MORPHOLOGICAL AND BIOCHEMICAL PROPERTIES OF SENESCENT CELLS

INTRODUCTION

Aging is the progressive loss of tissue and organ function over time. Cellular senescence is one of the driving factors for aging and age-related diseases[1]. Senescent cells secrete proinflammatory and matrix-degrading molecules, known as senescence-associated secretory phenotypes (SASPs). Aging can be induced by internal and external stimuli also known as stressors. As of today, only a few biomarkers that can selectively identify aging cells have been established. The aim of this study is to study different stressors that induce senescence and understand the molecular and cellular changes, thereby finding potential biomarkers for aging. SASPs in aging induced cells can be studied by changes in cell morphology and measurement of increased activity of beta-galactosidase (β-gal) in the cells. For example, in 2D culture conditions, senescent cells become larger, more flat, vacuolated and have multiple nuclei[2]. To this end, fluorescence microscopy and novel label free 3D Holotomography will be explored. We aim to study the changes that occur at morphological level and the try find the interconnections between types of stress factors and their functional effect on cells. This study was conducted using two human cell lines, human microglial (HMC3) and embryonic kidney cells (HEK293).

METHODS

Changes in cell morphology and SASP markers like SA-β-gal activity was studied in HMC3 and HEK293 cells with exposure to hydrogen peroxide (H_2O_2) and anti-cancer drugs (Palbociclib and Doxorubicin). Briefly, $1X10^5$ cells per well were seeded in 24 well plate and allowed to attach overnight. Next, they were treated with H_2O_2/Pal/Dox for 1/24/48 h respectively. Post treatment the cells were fixed with paraformaldehyde, stained with phalloidin, DAPI and Senescence green detection kit followed by imaging under fluorescence microscope. Along with the SA-β-gal assay the viability of the cells with the treatment of these stressors was studied *via* MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2H-tetrazolium bromide) assay.

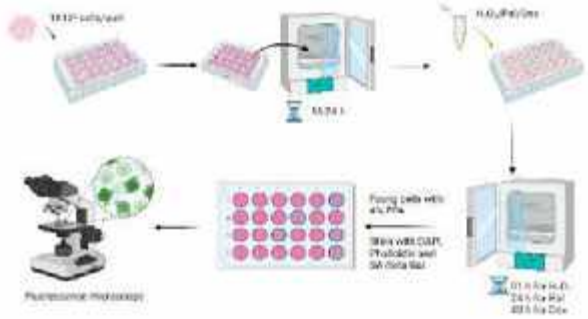

Figure 1: SA-β-gal assay in HMC3 and HEK293 cells.

RESULTS

The SA-β-gal assay confirms aging phenotype in the cells treated with H_2O_2 and anti-cancer drugs (Pal and Dox). From this assay and MTT assay we could establish the concentrations or dosage of the external stress inducers that promote aging in cells. As seen in fig. 2, the MTT assay provided an insight to the threshold concentration of test sample up to which aging can be studied. The conc. below the IC_{50} proved to be inducing aging as confirmed by the SA-β-gal assay. Fig. 3 and 4 depict an increase in green fluorescence intensity with increasing conc. of H_2O_2 and drug (Dox). For instance, the intensity increased around 100 μM for H_2O_2 and 50 nM for Dox. Along with the green intensity other cell morphological parameters like cell shape index, cell size, area, perimeter and nuclear size, area, perimeter were also calculated using imageJ.

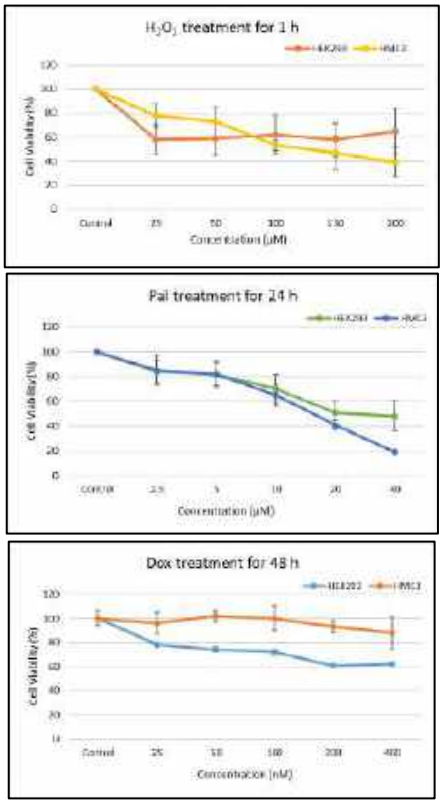

Figure 2: Cell viability performed in HEK293 and HMC3 cells *via* MTT assay.

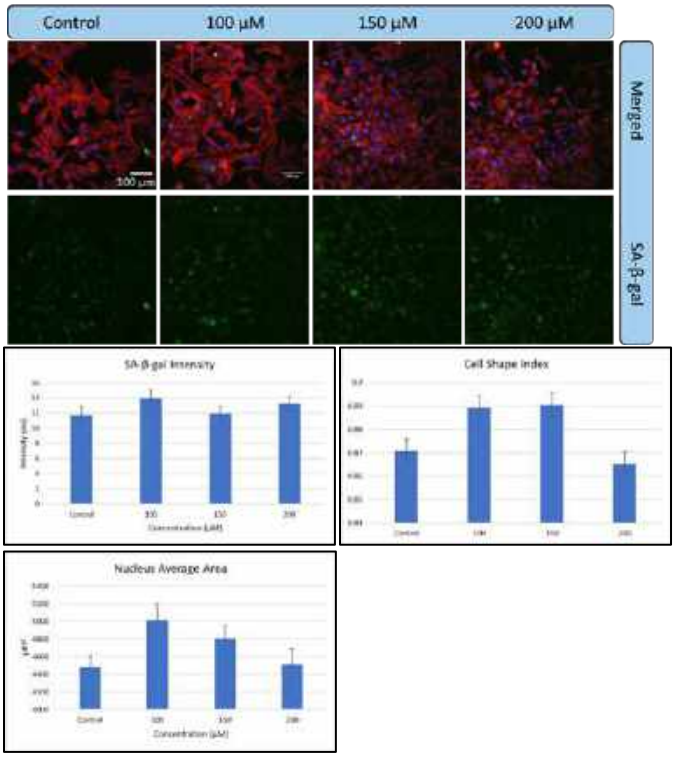

Figure 3: SA-β-gal assay images and quantification data of HMC3 cells treated with varying concentrations of H_2O_2.

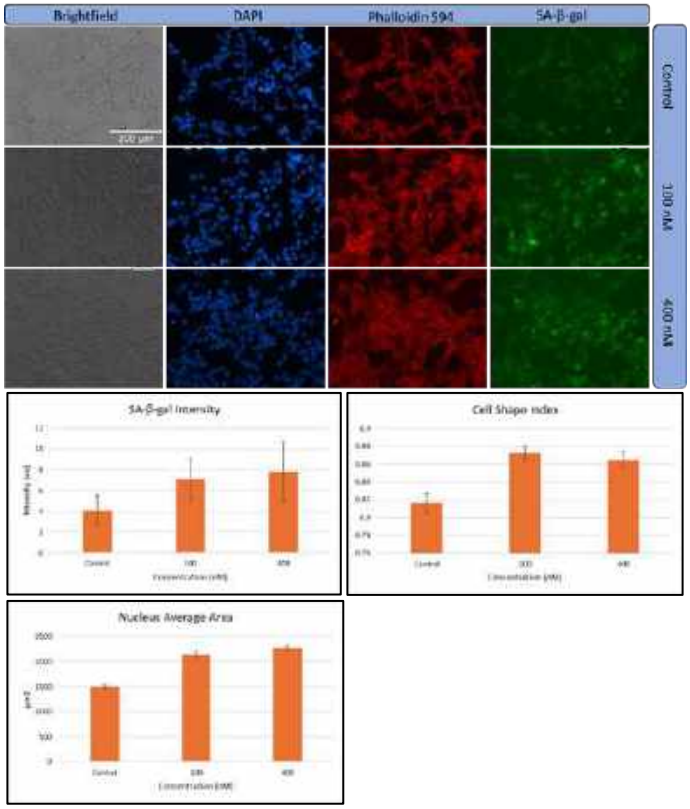

Figure 4: SA-β-gal assay images and quantification data of HEK293 cells treated with varying concentrations of Dox.

DISCUSSION

The cellular and organelle morphology exhibited significant changes following the exposure to H_2O_2, Pal and Dox. The increase in SA-β-gal activity with increasing H_2O_2/drug concentration was observed, suggesting an augmentation of cellular senescence. Changes were also noticed in the actin filament rearrangement with the treatment. In the future, we plan to employ holotomography for the comprehensive 3D quantification of a wide range of functional properties, including morphology, structural, mechanical and biochemical properties.

THE MATERIAL TUNING OF ANNEALING PVA HYDROGELS FOR THE APPLICATION OF TMJ DISC REPLACEMENT

Hassan Mahmoud (1), Christian M. Puttlitz (1,2,3), Kevin M. Labus (2)

INTRODUCTION

Temporomandibular joint (TMJ) disorders involving degeneration of the interpositional disc that fail to respond to conservative treatments are often treated with disc resection. However, disc resection fails to reduce pain in 25% of patients, and the procedure does not fully address the underlying causes of the joint degeneration [1]. Subsequently, disc resection can increase stress in the condylar and fossa surfaces, further progressing the degenerative changes [2]. Therefore, there is great clinical interest in an interpositional implant strategy to replace the function of the TMJ disc for patients that require a disc resection. The purpose of this work was to assess Poly(vinyl) alcohol (PVA) as a material for TMJ disc replacement and evaluate the effects of several synthesis parameters on the mechanical properties of annealed PVA hydrogels. Factors that can influence the mechanical properties of PVA hydrogels include annealing, molecular weight (MW), and percent polymer fraction (PPF). The interdependent effects of these synthesis parameters on hydrogel mechanical properties have not been explored thoroughly. Therefore, this study utilized a full factorial design to test the interactive effects of annealing temperature, MW, and PPF.

METHODS

PVA (MW of 89,000-98,000 & 146,000-186,000 99+% hydrolyzed, Sigma Aldrich, St. Louis, Mo) was mixed with deionized water (DI) in an enclosed beaker for a minimum of two hours at 98°C while stirred. Hydrogel sheets of 10% and 20% PPF by weight were synthesized of each of the two molecular weights of PVA. All testing groups prepared underwent 6 freeze-thaw cycles. The hydrogels were dried in an oven at 60°C in between two perforated plates to maintain their flat shape. The hydrogels were then annealed for an hour at a temperature of either 120°C, 135°C, 150°C, or 165°C and rehydrated in DI water, resulting in a total of 16 groups (2 MWs x 2 PPFs x 4 temperatures).

Tensile tests were conducted on n = 5 dog-bone shaped specimens of each hydrogel variant. Cross-sectional area was measured with calipers for stress calculations, and local strain in the center of the specimens was measured via digital image correlation. A 0.05 N preload was applied, and samples were pre-conditioned to 4% strain for 20 cycles. Samples were loaded to failure at a rate of 0.08 s^{-1}. Ultimate tensile stress and elastic modulus were calculated.

Unconfined compression tests were executed on 2 mm diameter biopsy punch samples of the PVA hydrogel sheets. A sample size of n = 5 was used for each group. Samples were mounted on a hydraulic testing system in between two parallel platens. Each of the samples were loaded to 46% compressive strain, at a strain rate of 0.005 s^{-1}. The tangent moduli at stretch values of $\lambda = 1.00$ to $\lambda = 0.96$ and $\lambda = 0.60$ to $\lambda = 0.54$ were determined using localized linear regression. The first stretch range was chosen in order to represent low strain tangent modulus. The second stretch range was chosen in order to represent a physiologically relevant maximum strain based on a finite element model of the human TMJ during clenching [3]. Results were analyzed via two-way ANOVAs with Tukey's *post-hoc* comparisons. ANOVAs compared MW and annealing temperature interactions as well as PPF and annealing temperature interactions.

RESULTS

Across each combination of MW and PPF, the tensile strength and elastic modulus increased with increasing annealing temperature (Figure 1). The 165°C annealed gels exhibited the greatest elastic modulus and strength (Figure 2). The tensile elastic modulus of the 89 kDa group was significantly greater than for the 145 kDa group ($p < 0.001$); however, the 145 kDa group exhibited a significantly greater tensile strength compared to the 89 kDa group ($p < 0.001$) (Figure 2). The 20% PPF group exhibited a significantly greater elastic modulus compared to the 10% group ($p = 0.009$). There were no significant differences in tensile strength between PPFs. There were no significant

interaction effects between synthesis parameters for either the tensile modulus or strength.

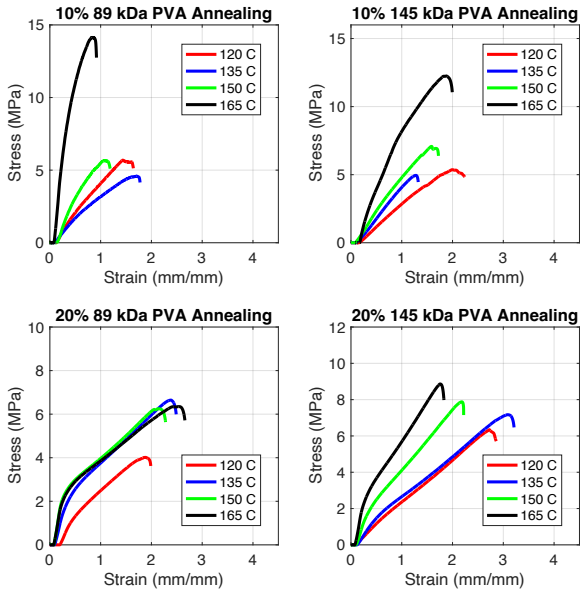

Figure 1: Median tensile stress-strain curves for each group

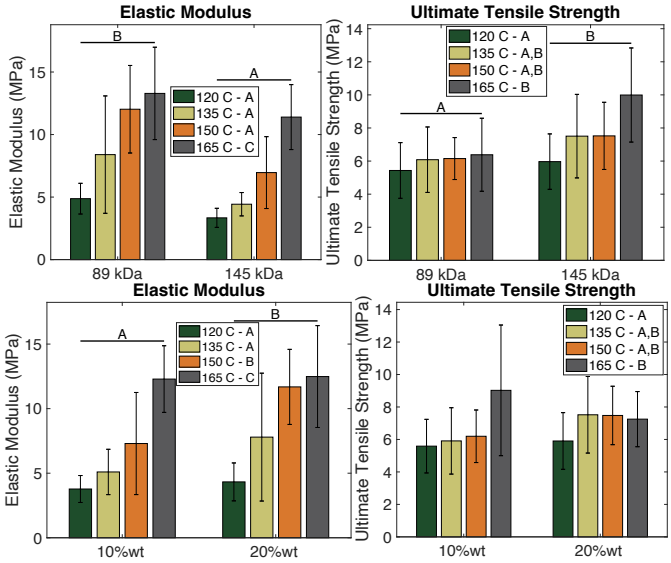

Figure 2: Elastic modulus and ultimate tensile strength results from tensile testing (mean ± standard deviation). Groups that do not share a letter are significantly different.

The results of unconfined compression testing demonstrated no significant differences in low-strain (stretch 1-0.96) tangent moduli between annealing temperatures, but high strain moduli (stretch 0.6-0.56) increased with increasing temperature (Figure 3). The 89 kDa group exhibited a greater low-strain modulus compared to the 145 kDa group ($p < 0.022$). The 20% PPF group exhibited significantly greater low-strain and high-strain moduli compared to the 10% group. There were no significant interaction effects between synthesis parameters for compressive moduli.

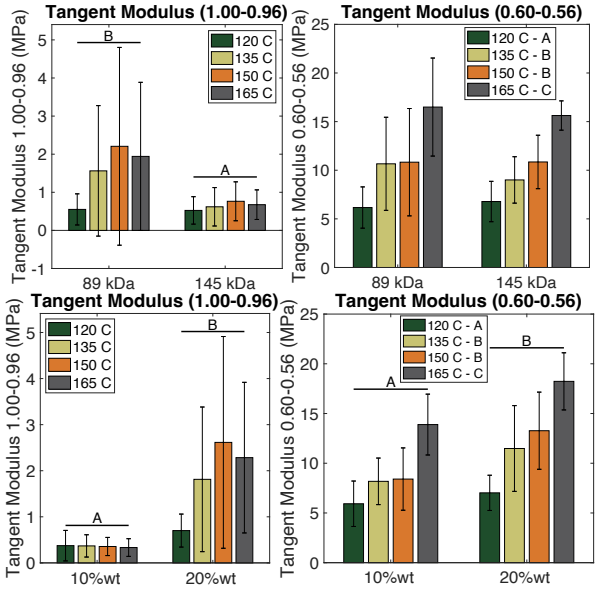

Figure 3: Compressive tangent moduli at λ = 1.00-0.96 and λ = 0.60-0.56 for each hydrogel group (mean ± standard deviation). Groups that do not share a letter are significantly different.

DISCUSSION

Freeze-thaw cycling physically crosslinks PVA hydrogels, and annealing has been shown to further increase crystallinity, which is associated with increased strength and elastic modulus [4]. The mechanical properties can be altered by tuning the MW, PPF, and annealing temperature. No significant interaction effects were seen across the parameters of this study; thus, the main effects of each parameter can be evaluated individually. The results demonstrated that increasing annealing temperature resulted in a significant increase in hydrogel stiffness and strength. The tensile strength of the 145 kDa gels were higher than the 89 kDa gels, but the 89 kDa gels had greater stiffness. The 10% gels exhibited a lower compressive modulus compared to 20% gels, but they had a similar tensile strength. These results indicate that a 145 kDa 10% gel at a 165°C annealing treatment would provide both the compressive softness and high tensile strength most similar to the TMJ disc. Following identical testing methods, the TMJ disc had a mean elastic modulus and strength of 251±75.5 MPa and 26.7±6.49 MPa in the anterior-posterior (primary fiber) direction and an elastic modulus and strength of 21.1±6.12 MPa and 3.31±0.85 MPa respectively, in the transverse direction [5]. In compression, at the stretch ranges of λ = 1.00-0.96 and λ = 0.60-0.56, the average tangent moduli of the TMJ disc were 0.13±0.04 MPa and 3.61±2.75 MPa, respectively [5]. Material properties of the tuned PVA hydrogels were similar to the TMJ disc in compression and in tension in the direction transverse to the fibers but did not match those of the TMJ disc in the fiber direction. These hydrogels may need additional reinforcement to match the fiber-direction properties of the native TMJ disc.

INTRODUCTION

According to the World Health Organization, the prevalence of obesity has tripled over the past 40 years and is continuing to increase at an alarming rate (WHO, 2021). Cardiovascular diseases (CVD) were reported to be the primary cause of death associated with a high body mass index and to be responsible for two-thirds of fatalities caused by obesity (GBD, 2017). Epicardial adipose tissue (EAT) is the visceral fat deposit that directly covers the surface of the myocardium without any fascial structure. In case of obesity, EAT expansion causes an infiltration of adipocytes into the myocardium layer and prevents cardiac excitation. This results in irregular beating patterns called arrhythmia. Atrial fibrillation (AF) is reported to be the most prevalent type of arrhythmia affecting more than 60 million people globally (Essien et al., 2021). Obesity was reported to be associated with a 50% increase in the risk of AF development (Chung et al., 2020). Recent imaging techniques were able to assess the EAT thickness, volume, and density to predict the arrhythmogenic risk in obese individuals. These studies showed that increased EAT thickness and infiltration is associated with worse atrial function, higher hospitalization, and mortality rate (Oduah et al., 2023). Laboratory animals such as mice and rats do not have a cardiac fat depot that shares the same circulation with their myocardium (Bale et al., 2018). For this reason, some studies on EAT accumulation and CVDs were conducted on large mammals such as sheep (O'Connell et al., 2015) and pigs (McKenney et al., 2014) which have EAT. However, there remain gaps and limitations since animal models are incapable of simulating the physiology, and progression of EAT infiltration in the human heart. Thus, there is an urgent need for a better understanding of the underlying pathology of EAT infiltration and to develop new therapies to battle obesity.

METHODS

Primary ADSCs were isolated as described previously (Traktuev et al., 2008) and subjected to the adipogenic differentiation using induction media composed of indomethacin, dexamethasone, and IBMX. Then, obese-like induction (OLI) was applied to the experimental group with media supplemented with BSA-Palmitate as reported before (Pieters et al., 2022). To compare the lipid droplet sizes of the experimental and control group, lipid droplets of adipocytes were stained with Nile Red following the manufacturer's protocol and the imaging was performed with a confocal microscope. The insulin sensitivity of both groups was evaluated through immunostaining for phosphorylated-insulin receptor (p-INSR) expression. Finally, a comparison of adiponectin levels in control and obese-like adipocytes was made using a commercially available ELISA kit, following the manufacturer's protocol.

The DiPS 1016 SevA hiPSC line derived from human skin fibroblasts was cultured as reported before (Acun et al., 2019). A previously established protocol was adapted to induce atrial iCM differentiation (Kleinsorge et al., 2020). After differentiation, atrial iCM culture was characterized by MLC2A (atrial cardiomyocyte marker) /MLC2V (ventricular cardiomyocyte marker), Cardiac Troponin T (TnT, cardiac cell marker), and Sarcomeric alpha-actinin (SAA, muscle cell marker) markers. For this, cells were immunostained using the protocol described in the article published by Acun et al. (2019).

To synthesize the photocrosslinkable GelMA hydrogels, previously established protocols were utilized (Nichol et al., 2010) and the degree of methacrylation was quantified with NMR using an adapted protocol (Li et al., 2016). The frequency sweep test was conducted to evaluate the viscoelastic properties of the hydrogels following a reported protocol (Basara et al., 2019).

CELLINK BioX6 Bioprinter and a custom-made G-Code were employed to print the EAT infiltration model. The bioink was prepared using collagen type 1 (6 mg/ml), 20% GelMA and Irgacure2959 photoinitiator solution. Differentiated adipocytes were detached using trypsin-EDTA. After mixing the atrial cardiomyocytes and adipocytes into separate syringes, 22G nozzles were used and quarter cylindrical

constructs with reported dimensions were printed on a sterilized charged glass. Then, the constructs were photocrosslinked using a UV lamp. To characterize the cell types and their locations in the constructs, iCMs were tagged with CellTracker green and adipocytes were tagged with CellTracker orange dyes following the manufacturer's instructions. The tiles images were taken using a fluorescence microscope.

RESULTS

Increase in the intracellular accumulation of lipid droplets was observed after adipogenic induction (Fig.1a). At the end of OLI, the experimental group exhibited larger, and fewer lipid droplets compared to the control group, mimicking caloric overload and, as a result, an obese phenotype (Fig.1b). According to the results, obese-like adipocytes released significantly less adiponectin (Fig.1c) and had lower p-INSR expression compared to the control (Fig.1d).

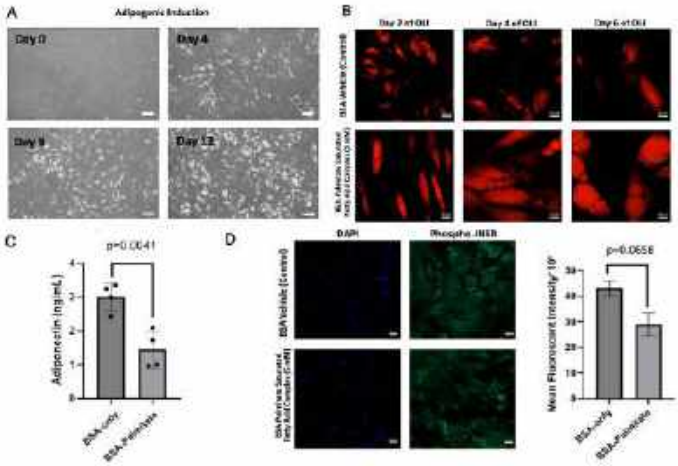

Figure 1: Adipogenic induction of hADSCs and OLI of adipocytes

As reported in the literature, the beating of iCMs was often observed by day 15 of differentiation (Kleinsorge et al., 2020). According to the flow cytometry results, 76% of cardiomyocytes in atrial iCM culture were MLC2A+ (Fig.2b). Results of the immunostaining showed that the culture largely expressed, cardiac Troponin T (TnT, cardiac cell marker), and Sarcomeric alpha-actinin (SAA, muscle cell marker) markers (Fig.2a and Fig.2b). Although atrial and ventricular iCMs were similar in morphology during differentiation, cultures of atrial cardiomyocytes had higher beating frequency than ventricular iCMs.

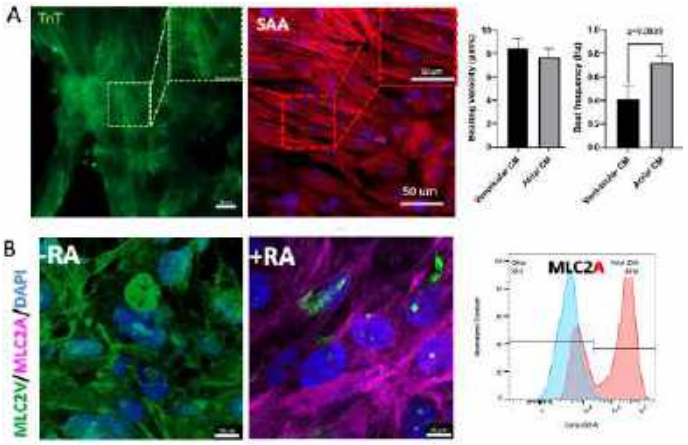

Figure 2: Differentiation of atrial iCMs and characterizations

Lastly, the bioink composed of 10% GelMA 3 mg/mL collagen were characterized in terms of methacrylation degree and viscoelastic properties. The degree of methacrylation of synthesized GelMA hydrogels was determined using NMR as 54%. The bioink had a storage modulus of 2.6 kPa. After bioink characterizations, hydrogels were stained using food coloring and printed using optimized printing parameters (Fig.3b). Then, preliminary printing experiments were conducted and CellTracker tagged cells were localized in the EAT infiltration model (Fig.3d)

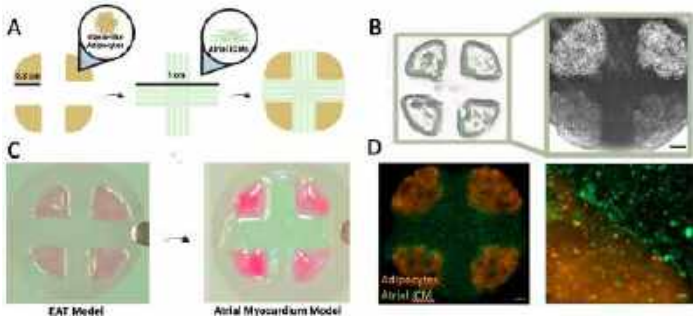

Figure 3: 3D EAT Infiltration model and characterizations

DISCUSSION

Research conducted by The American Obesity Association foresees that half of adults will be affected by obesity by the year 2030. Utilizing human tissues is not feasible and majority of laboratory animals lack EAT. Therefore, engineering an obese heart under laboratory conditions is important to understand underlying pathology and devise new therapies to combat obesity. Here, we observed that the in-vitro obese-like adipocytes are showing important hallmarks of in-vivo obese adipocytes such as the lipid droplet expansion, inhibition of phosphorylation of INSR (p-INSR) and impaired adiponectin release. In a study conducted by Iacobellis et al. (2023), researchers quantified the cytokine levels and analyzed the epicardial adipose tissue thickness measured by echocardiography. They reported that individuals with impaired insulin sensitivity and low adiponectin levels have the highest EAT thickness. This is an indicator that OL adipocytes could be mimicking the cytokine release profile. hiPSC derived atrial cardiomyocytes were reported to have higher beating frequency which was consistent with the literature (Kleinsorge et al., 2020). In flow cytometry results, we showed that the atrial culture was largely expressing MLC2A. Overall, hiPSC-atrial iCMs were showing important characteristics of in-vivo atrial cardiomyocytes.

Type 1 collagen is the most abundant protein in human body and it naturally mimics the ECM (Naomi et al., 2021). However, type 1 collagen alone is not suitable for extrusion bioprinting because of its low viscosity and slow polymerization (Mazzocchi et al., 2018). Multi-component hybrid bioinks are the potential solution for achieving ideal bioprintability with type 1 collagen. The viscosity and printability of type 1 collagen can be enhanced by combining it with semi-synthetic polymers like Gelatin methacryloyl (GelMA) to develop hybrid hydrogels. GelMA is widely used in bioprinting as a bioink due to its printability, tunability, and overall cell activity-enabling properties (Yue et al., 2015). This bioink combination were shown to have suitable viscoelastic properties and ability to be photocrosslinked.

One of the limitations of the study is to struggle of printing adipocytes with high viability and without disturbing the fat droplets. The strength of the study would be that it involves human derived (human iPSC) cells which is important to obtain physiologically relevant results. With this model, we hope to report underlying pathology of EAT infiltration and develop new therapies to battle obesity.

CERVICAL NECK MUSCLE MORPHOLOGY UNDER LOAD-BEARING CONDITIONS AND ITS IMPACT ON SPINAL ALIGNMENT: AN UPRIGHT MAGNETIC RESONANCE IMAGING STUDY

Mahmudur Rahman (1), Ali Warraich (2), Vicky Varghese (3), Aditya Vedantam (1), Narayan Yoganandan (1)

INTRODUCTION

Axial head-neck loading can affect cervical muscle morphology and is linked to increased risk of neck pain and early spinal cord pathologies [1]. The stability of the spinal column relies on the surrounding neck musculature, which maintains functional posture characterized by absence of pain physiologic muscle tone. Changes in muscle morphology can alter the neck's intrinsic biomechanics, influencing load transfer mechanisms and distribution paths [2]. Understanding how altered load distributions through the cervical spine musculature affects the stability of the osteoligamentous cervical column and spinal cord is crucial for assessing the risks and mechanisms underlying neck pain and spinal disorders.

Although previous studies have examined the association between cervical muscle morphology and cervical spine pathology, almost all such studies have used supine Magnetic Resonance Imaging (MRI) to draw conclusions [3]. While clinically most adopted, supine MRI does not yield accurate muscle morphology because the cervical spine muscles are not in a load-bearing condition and the in vivo axial loading on the head is not included in recumbent images.

Our study aims to quantitatively analyze the relationship between cervical neck muscle morphology and spinal column alignment under axial load-bearing conditions by utilizing an upright MRI scanner. Our experimental design simulates load-bearing conditions that are commonly experienced in some occupational settings (head supported mass such as military helmets and mounted devices such as night vision goggles) and recreational activities (virtual reality headsets) more accurately. This approach allows for the examination of musculoskeletal responses in a scenario that mimics real-life stressors on the cervical spine. By analyzing the changes in muscle cross-sectional area and Cobb angle in this controlled setting, the study seeks to examine the relationships between muscle morphology changes and alterations in spinal alignment. Such insights are pivotal in understanding how cervical musculature adapts or responds to external loading and its impact on spinal health, particularly in an asymptomatic population where preemptive insights can be crucial for preventing neck pain and spinal pathologies.

METHODS

Twenty-one healthy volunteers under forty years of age, asymptomatic for neck pain, and no history of cervical injury or abnormalities, were selected for this study. The protocol was approved by the local institutional board and by the United States Department of Defense. All subjects consented for the study. Upright MRIs were used to generate sagittal and axial images of the cervical spine. To simulate load-bearing conditions, participants wore army combat helmet weighing approximately 1.5 kg, which was adjusted for MRI compatibility and individual fit. The participants were given an upright MRI scan before and after four hours of wearing the helmet.

The cross-sectional areas of sternocleidomastoid (SCM) and multifidus (MF) muscles were measured from the C2 to C7 vertebrae at the inferior endplate level using OSIRIX software (Bernex, Switzerland). Although the cross-sectional area for each muscle was measured bilaterally, only the mean of both measurements was used for analysis. Additionally, the Cobb angle of the vertebral body at each level was similarly quantified to assess spinal alignment **(Fig. 1)**.

For statistical analysis, the normal distribution of the data was checked using the Shapiro-Wilk test. For normally distributed data, paired t-tests were used to compare pre- and post-measurements for SCM, MF, and Cobb angle at each spinal level. Wilcoxon signed-rank test was used for non-normally distributed data. Spearman's rank correlation test was applied to assess the correlation between the changes in cross sectional areas of SCM and MF, SCM and Cobb angle, and MF and Cobb angle at each individual spinal cord level. In addition, two observers processed the geometrical measures for intraclass correlation (ICC[3,1]) analysis.

RESULTS

Results of the Shapiro-Wilk test indicated a normal distribution across most spinal levels for both pre and post load-bearing muscle area and Cobb angle measurements, with exceptions noted in the pre-load-bearing cross sectional area of SCM at the C4-C5 level ($p = 0.024$) and the post load-bearing Cobb angle at C2-C3 ($p = 0.058$), suggesting non-normal distributions in these specific cases. Results of the paired t-test or the Wilcoxon signed-rank test (for non-normally distributed data) revealed no statistically significant changes in SCM and MF muscle areas across all spinal levels. Specifically, the Wilcoxon test applied to the SCM C4-C5 region due to its non-normal distribution demonstrated no significant change ($p = 0.838$) **(Fig. 2)**. Similarly, Cobb angle measurements showed no significant variations at any spinal level, including at C2-C3 where a Wilcoxon test was used ($p = 0.441$).

Spearman's rank correlation tests identified a statistically significant and positive correlation between changes in SCM and MF areas at the C7-T1 level ($\rho = 0.679$, $p = 0.0007$). However, no significant correlations were detected between changes in SCM area and Cobb angles, nor between changes in MF area and Cobb angles, across any spinal levels. These results collectively suggest that the load-bearing conditions applied in this study did not lead to significant alterations in muscle areas or spinal curvature from C2-C6 but did have a statistically significant impact at the C7-T1 level.

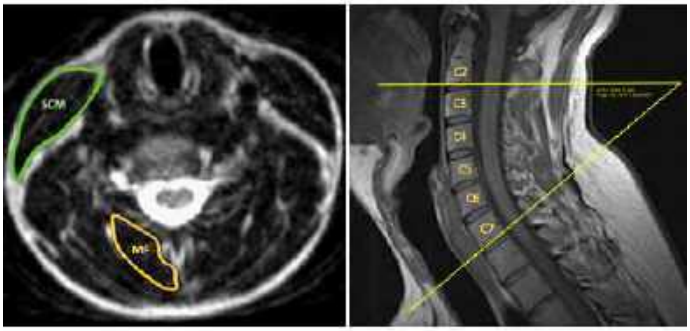

Figure 1: Sternocleidomastoid (SCM) and multifidus (MF) muscles cross-sectional areas at C5 identified in the upright MRI axial scan (left) and the Cobb angle calculated in the sagittal MRI (right).

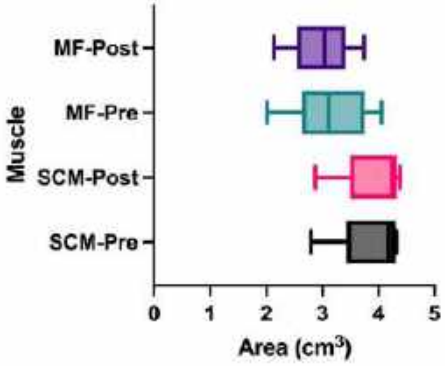

Figure 2: The average cross-sectional area between pre and post MF and SCM muscles are graphed in this figure. The change in cross-sectional are not statistically significant.

DISCUSSION

Upright MRIs were used to study the morphology of two important cervical muscles: the SCM and MF. These muscles were chosen for their significant roles in cervical biomechanics: the SCM for flexion and rotation of the head and neck, and the MF for extension and stabilization of the cervical spine [4]. These upright MRIs were also used to measure the Cobb angle in the vertebral body on a level-by-level basis. The Cobb angle, a standard metric used to assess spinal alignment, is especially relevant in the context of cervical spine health.

This study examined the biomechanical effects of load-bearing headgear on the cervical spine, a topic relevant for occupations requiring protective or heavy headgear. Twenty-one healthy volunteers underwent upright MRI scans before and after axial head loading. The cross-sectional area of SCM and MF muscles, as well as the Cobb angle was measured at each level of the cervical spine. While most of the spinal levels showed no significant changes, our results showed a statistically significant and positive correlation between changes in the SCM and MF muscle areas at the C7-T1 level, suggesting a localized adaptive response to the additional head supported mass in this critical region of the cervical spine.

This relationship between SCM and MF areas at the C7-T1 level underscores the importance of this spinal segment in load-bearing scenarios. The C7-T1 region, positioned at the cervicothoracic junction, is a biomechanically critical region where the cervical spine transitions into the thoracic spine. This junction is known for its unique biomechanical properties, as it marks the transition from the highly mobile cervical region to the relatively rigid thoracic spine [5]. This is also the junction where lordosis of the cervical spine transitions into kyphosis of the thoracic spine.

Furthermore, the SCM and MF muscles at the cervicothoracic junction may respond synergistically to maintain stability and balance in this transitional area under load. These two muscles likely experience altered biomechanical demands when supporting the additional weight of the helmet. This additional load leads to subtle, yet measurable, changes in the muscle areas, especially at segments where mechanical stress is amplified. Musculoskeletal models can be used to determine the change in segmental loads within the osteoligamentous column (disc and facet joints), ligament strains, spinal cord stress-strain profiles, and forces in the selected and other cervical muscles using the data from the present study for a better understanding of the effects of head supported mass.

Further research is necessary to explore these dynamics over a longer duration and in different populations and in different environments (dismounted soldiers, pilots, etc.). Investigating whether these localized changes at the C7-T1 level escalate, stabilize, or reverse over time, and how they correlate with neck pain, fatigue, and function, would provide deeper insights. Additionally, understanding the threshold at which load-bearing begins to significantly impact the osteoligamentous cervical spinal column and spinal cord biomechanics could inform the designers of load-bearing headgear and trainers to develop preventive strategies that mitigate the risk of musculoskeletal disorders in the neck and cervicothoracic region.

Multiscale Mechanoimmunology: From Molecular Mechanisms to Precision Therapies

Therapeutic immune cells have the potential to treat complex diseases. Some therapies, such as CAR T cells, are effective against blood cancers but are not effective against solid cancers, which comprise about 90% of adult cancers. A key requirement of the role of therapeutic cells in tumor eradication is their ability to migrate to and infiltrate the tumor. To accomplish this, cells navigate various mechanoimmunological factors, such as tissue viscoelasticity. One consequence of viscoelasticity is time-dependent stress relaxation - a decrease in stress in response to applied deformation. However, the mechanisms by which viscoelasticity regulates migration are not fully understood. In addition, limited studies have quantitatively compared the transport of cell therapies in tissue-like environments. My research aims to address these research gaps. To address the potential role of viscoelasticity on 3D cell migration, I developed hydrogels that mimic the stress relaxation behavior of native tissues. I found that enhanced stress relaxation potentiates monocyte migration. Mechanistically, our data support a model whereby WASP-mediated actin polymerization generates physical force at the leading edge of the cell to generate micron-sized channels for cells to migrate through. In a separate project, I integrated macrophage migration data with an unsupervised k-means clustering algorithm to demonstrate that the transport properties of macrophages in tumors depend on macrophage phenotype and morphometric transitions. Together, our studies establish a platform to determine the role of mechanical cues in shaping the immune response and to leverage fundamental mechanisms to enable the rational design of “living drugs.”

SIMULATING THE IMPACT OF TUMOR MECHANICAL FORCES ON GLYMPHATIC NETWORKS IN THE BRAIN PARENCHYMA

S. Siri (1), A. Burchett (1), M. Datta (1)

(1) Departement of Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN 46556 USA

INTRODUCTION

While meningeal lymphatics have been extensively studied [1], the understanding of brain parenchymal glymphatic networks is limited. Meningeal lymphatics, crucial for brain waste clearance, have received substantial attention. However, the intricate pathways and mechanisms of glymphatic function within the brain, responsible for metabolite clearance, remain unclear. The complexity of brain interstitial fluid dynamics, especially in paravascular spaces, poses a challenge in unraveling glymphatic networks. Further research is essential to comprehend the significance of these networks in maintaining brain health.

Understanding tumor mechanics involves the interplay between fluid and solid components [2, 3]. Tumors, with heterogeneous composition, consist of solid components (tumor cells and extracellular matrix) and fluid components (interstitial fluid and vasculature). Solid constituents contribute to structural integrity and growth, while fluid elements regulate the tumor microenvironment. Brain tumors pose a formidable challenge to glymphatic function, disrupting brain parenchyma integrity. Tumors alter interstitial fluid dynamics, compromising glymphatic flow and solute transport. Tumor-associated factors worsen disruptions, compromising the microenvironment for neural cells.

Understanding brain tumor-glymphatic system dynamics requires integrating experimental findings with computational modeling. Computational models offer a unique vantage point to simulate complex brain microenvironment interactions. Our computational modeling framework aims to elucidate how brain tumors impede glymphatic solute transport, identifying therapeutic targets for proper brain waste clearance. The model analyzes the effects of brain tumors on glymphatic solute transport, providing insights for future therapeutic interventions.

METHODS

The governing equations for FEM structural analysis involve equilibrium equations and constitutive relations. The equilibrium equations represent the balance of forces within the brain parenchyma. They can be expressed as:

$$\nabla . \sigma + f = 0 \quad (1)$$

Where σ is the stress tensor representing internal forces and f is the body force per unit volume. Constitutive relations describe the relationship between stress and strain in the material. For linear elasticity, Hooke's Law is commonly used:

$$\sigma = D . \epsilon \quad (2)$$

Where ϵ is the strain tensor representing deformations, D is the elasticity tensor (material property). Strain-Displacement Relation defines the relationship between strain and displacement. For small deformations:

$$\epsilon = \frac{1}{2}(\nabla u + (\nabla u)^T) \quad (3)$$

Where u is the displacement vector. When these equations are discretized using FEM, the continuous domain of the brain parenchyma is divided into smaller, simpler elements. The displacement field within each element is approximated using shape functions, and the equilibrium and constitutive equations are formulated for each element. Assembled together, these equations generate a system of linear equations that can be solved numerically to determine the displacement and stress distribution within the brain parenchyma under given loading and boundary conditions.

A 2D geometry (Fig. 1A) was created using COMSOL Multiphysics for Finite Element Method (FEM) modeling, including brain astrocytes, extracellular matrix (ECM), capillaries, tumors, and the prevascular space. The FEM model simulated the brain microenvironment, analyzing astrocyte and ECM properties, tumor size, and location's impact on the glymphatic system. Parametric analyses explored variations in astrocyte and ECM properties, assessing their influence on solute transport and fluid dynamics. Three mechanical scenarios (Fig. 1C) were considered to understand the glymphatic system's behavior under different ratios of astrocyte to extracellular space (ECS) contribution. Simulations in MATLAB Simulink and COMSOL Multiphysics comprehensively analyzed the system's response to variations in astrocytic and ECM characteristics, as well as tumor-induced residual stress on the system's geometry.

Lumped parameter models simplify the complex dynamics of the glymphatic system, representing paravascular spaces, astrocytes, and fluid dynamics as discrete compartments. These models, utilizing principles of flow, diffusion, and clearance rates, simulate solute and fluid movement efficiently, enabling analysis of factors affecting glymphatic transport. The astrocyte network model, adapted from Asgari et al. [4], illustrates connectivity between arterial and venous paravascular spaces. Multiple simulations in MATLAB Simulink analyze geometric and physical changes induced by tumors, revealing their impact on glymphatic solute transport and metabolite clearance in the brain parenchyma.

RESULTS

The parametric analysis in Fig. 3B shows the dynamic relationship between mechanical forces, tumor locations, and sizes concerning the glymphatic system and skull proximity. Results indicate an initial stress level of 18 Pa at far tumor distances, gradually increasing as tumors approach the skull, highlighting a clear correlation between stress distribution and distance. The study reveals two key associations: larger tumors correlate with higher stress levels, suggesting potential structural implications, and as tumors get closer to the skull, stress levels surge, particularly near the glymphatic system, emphasizing the vulnerability of this system to external forces near tumor sites.

Figures 1D and 1E illustrate three scenarios with varying displacement and mechanical stress profiles influenced by Astrocytes (Ast.) and the Extracellular Matrix (ECS). In the first scenario, minimal Astrocyte contribution results in the highest displacement profiles, mainly due to ECS (10% compression). The second scenario shows a balanced Astrocyte and ECS contribution, leading to uniform displacement with a predominant concentration in ECS. In the third scenario, increased Astrocyte involvement with lower ECS contribution results in minimal displacements. Interestingly, mechanical stress on Astrocytes peaks when their contribution is lowest and vice versa.

In summary, the growing prominence of astrocytes in the brain corresponds to increased mechanical stress and displacement, driven by heightened pressure from brain tumors. This highlights the intricate relationship between cellular components and physiological responses in pathological conditions like tumors.

Fig. 1F illustrates the variations in venous side flow rate efflux in response to mechanical compression ranging from 0 to 10%. These simulations comprehensively address the impact of mechanical compression on Glymphatic system transport, specifically considering properties related to astrocytes, AQP-4, ECS, gap junctions (GJ), and capillaries. The results highlight a discernible trend wherein a 10% mechanical compression is associated with an approximate 20% reduction in the venous side flow rate, underscoring the significance of mechanical factors in influencing Glymphatic system dynamics.

DISCUSSION

In this study, we investigated how brain tumors induce residual stress affecting the Glymphatic system's structure. We explored the tumor's impact on tissue properties, including alterations in fluid flow dynamics in paravascular spaces. Our analysis focused on mechanical dynamics in brain parenchyma, examining scenarios with varying displacement magnitudes and stress profiles in Astrocytes (Ast.) and the Extracellular Matrix (ECS). These scenarios revealed the intricate interplay between brain tumors and glymphatic system responses under pathological conditions. These findings highlight the importance of a multidimensional approach to assess tumor biomechanical impact on the Glymphatic system. This information is crucial for medical practitioners to anticipate stress concentrations, guiding treatment strategies. The insights contribute to understanding cranial biomechanics, paving the way for personalized medicine and tailored therapeutic approaches for individuals with tumors near the skull.

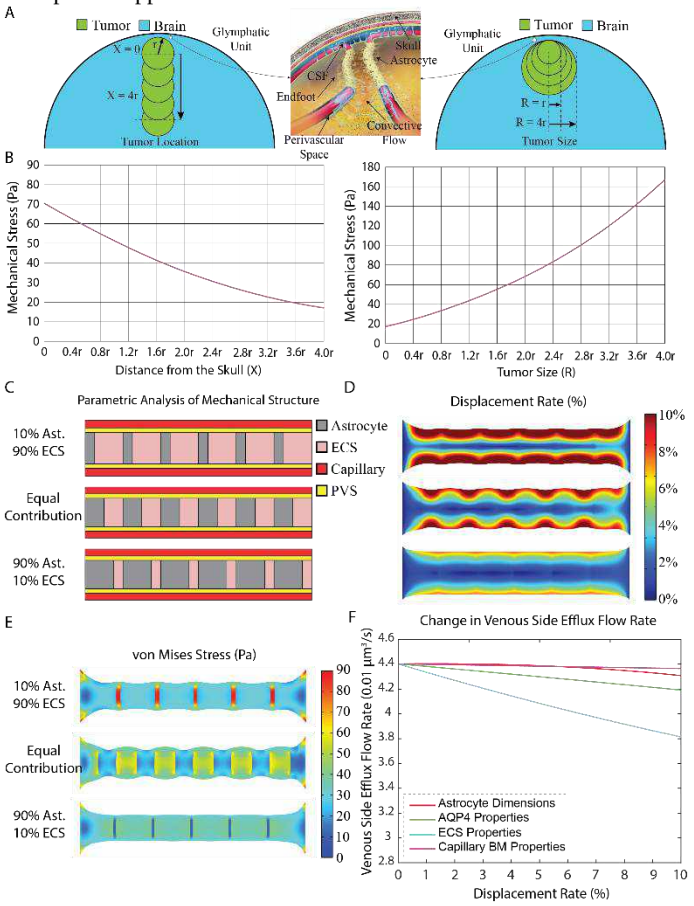

Figure 1: Investigating Brain Tumor Impact on Glymphatic System: (A) 2D brain and tumor model for Finite Element Method (FEM) analysis in COMSOL Multiphysics. (B) Parametric analysis shows stress changes on Glymphatic System at different tumor distances and sizes. X-axis: tumor distances and sizes, Y-axis: mechanical stress. (C) Schematic explores three mechanical scenarios (10% Astrocyte - 90% ECS, Equal Astrocyte-ECS Contribution, 90% Astrocyte - 10% ECS) studying their roles in glymphatic system behavior under brain tumor influence. Simulations cover induced residual stress, altered mechanical properties, tissue deformation, and fluid flow dynamics in paravascular spaces. FEM parametric analyses examine astrocyte and ECM effects on the glymphatic system, demonstrated through (D) Displacement and (E) Mechanical Stress profiles. (F) Exploration of variations in astrocyte, AQP-4, GJ, ECS, and Capillary properties to understand their impact on solute transport and fluid dynamics in brain parenchyma.

IN-SITU AND IN-VITRO HETEROGENEITY OF PORCINE MENINGES: INSIGHTS FROM 2-PHOTON MICROSCOPY AND CORRELATED MICRO-INDENTATION

S.Mohammad Tabatabaei, Ph.D. (1), Lakiesha N. Williams, Ph.D. (1)

(1) J. Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, Florida, USA

INTRODUCTION

The study of meninges, an essential component in neurobiology, faces significant challenges due to its complex and heterogeneous nature. Traditionally, biomechanical characterization of the dura mater has predominantly relied on in vitro one- and two-axis tensile tests[1], [2]. However, these methods have proven insufficient in capturing the intricate structural and mechanical nuances of this tissue. The inconsistencies and limitations in existing research methodologies have led to a fragmented understanding of the meninges' biomechanical properties. Thus, the complexities of meningeal tissue are not included in computational models of the head or in meningeal grafts for reconstruction.

Our research introduces an innovative approach to address these challenges, hypothesizing that a comprehensive understanding of the meninges requires an integrated analysis that considers its interaction with the underlying brain structures. This study aims to bridge the gap in current biomechanical characterization methods by combining advanced in-situ structural analysis with mechanical testing techniques. By doing so, we seek to capture the meninges' properties in its native state, which is crucial for a more accurate and holistic understanding of native dura and the development of biofidelic grafts.

This approach is grounded in the understanding that the biomechanical properties of the meninges are not only a product of its material composition but are also significantly influenced by its structural relationship with the brain. As such, our methodology is designed to elucidate these complex interactions, providing insights into how the meninges' function is shaped by its dynamic, native environment. This study, therefore, represents a significant departure from conventional biomechanical studies, offering a novel perspective on the intricate biomechanical behavior of the meninges in situ.

METHODS

In this study, we employed a comprehensive methodology to investigate the structural and mechanical properties of meninges in two locations of four anatomical regions (anterior, medial, lateral, and posterior). Meningeal tissue denoted as "sulcus" was examined at the sulcus location of the brain and "gyrus" meningeal tissue was examined at the gyrus locations of the brain. Two-photon confocal microscopy was utilized to capture the Second Harmonic Generation (SHG) signal of the tissue in their respective regions[3]. This advanced imaging technique enabled visualization and quantification of the intricate microstructural features of dura mater in its unstained, native state, thus providing insights into its complex pre-stressed architecture.

For structural evaluation, the 4 anatomical regions were studied using 2 pig brains in both in situ and excised states. This was done to evaluate the differences in the tissue structure across each anatomical location. For each of the four regions, 10 images were captured from four distinct samples on each slide. For in situ samples, the cranial meninges was meticulously fixed with 4% Paraformaldehyde for 24h post-skull removal, ensuring the preservation of its natural state. In contrast, excised, in vitro tested, samples were obtained and then fixed with paraformaldehyde, allowing for a comparison of the impact of the excision process on the tissue's structural integrity while in situ.

In situ mechanical properties were obtained via indentation testing on pre-stressed, non-fixed meningeal tissue [4]. This technique was specifically designed to measure the effective Young's modulus of the meninges in the 4 regions, providing a more comprehensive understanding of its biomechanical behavior. The indentation tests were conducted using the Mach-1 micromechanical tester (Biomomentum, Canada) on pig heads immersed in a PBS bath at room temperature to simulate a physiological environment. In this way, the in-situ conditions were closely replicated. For mechanical properties evaluation, 3 pig brains were tested with 10 indentations at each anatomical location. The indentation depth was less than 1000 μm to ensure consistent and reliable measurements. Additionally, the meningeal samples were

subjected to loading rates of 1 mm/s and 5 mm/s to assess their rate-dependent mechanical behavior. This aspect of the methodology was crucial in understanding how the meninges responds to varying mechanical stresses, which is essential for applications in neurobiology and clinical practice.

RESULTS

The results of this study reveal significant insights into the meninges structural (in situ and in vitro) and mechanical properties (in situ). Structural analysis of the four anatomical regions showed notable differences between in situ and excised meninges (Fig. 1-a, b). The average thickness of in situ meninges was notably thinner, measuring 263.97 ± 55.51 μm, compared to 698.042 ± 178.18 μm for excised meninges. Additionally, compared to the in situ gyrus samples, the thickness of the in situ sulcus samples was observed to be 1.3 times greater, and the thickness of excised sulcus meninges was 1.19 times greater than the excised gyrus meninges (Fig. 1-c). This thickness variance suggests substantial changes in structural integrity resulting from the excision process. Two-photon microscopy revealed that excision altered the well-aligned collagenous structures in in situ samples, leading to an exaggerated waviness in collagen. Anisotropy analysis across regions indicated changes post-excision (Fig. 1-d), hinting at mechanical property variations influenced by the extracellular matrix composition.

Mechanical testing revealed a lower effective Young's modulus for the meninges in situ, at 2.2 Kpa, compared to in vitro results previously reported by our lab [5], which averaged 19.9 MPa. Additionally, these results demonstrated a clear strain-rate dependency. (Fig. 2). Variations in mechanical properties were observed, particularly at lower strain rates, suggesting the influence of structural differences on mechanical response, especially in the gyrus region.

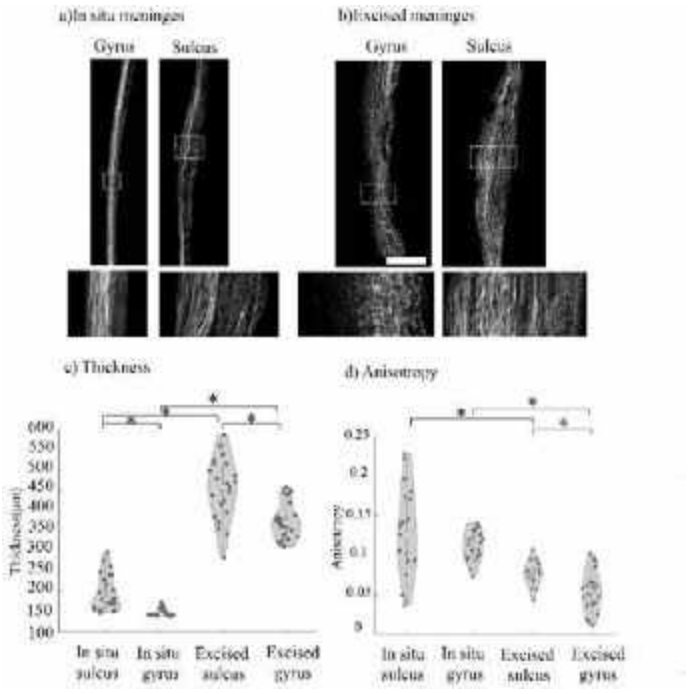

Figure 1**. Comparative SHG imaging of in situ (a) and excised (b) meninges with magnified views and quantification of thickness (c) and anisotropy (d).**

DISCUSSION

The findings from this study offer pivotal insights into the biomechanical complexity of the meninges and cranial meninges overall. The observed thinning in native meninges compared to excised samples underscores the impact of the native microenvironment on the meninges' structural integrity. Additionally, there is significant differences in morphometry of the sulcus and gyrus dura regions, which is important for the meninges role in vivo. This highlights a critical limitation of traditional biomechanical analyses, which often overlook the influence of native tissue states and the role of protection offered in prestressed conditions. The alteration in collagenous structures post-excision and the associated changes in anisotropy emphasize the importance of the meninges' interaction with the brain in maintaining its mechanical properties and providing protection in rotation/translation impact situations.

Moreover, the rate-dependent mechanical behavior observed through indentation illustrates the extent of meningeal viscoelasticity across different regions. The variations in mechanical properties, especially at lower loading rates, point to the significant role of structural differences in influencing the tissue's biomechanical response. These findings suggest that the meninges' function is not solely determined by its material composition but is intricately linked to its structural arrangement and interaction with surrounding brain structures.

This study, therefore, underscores the necessity for integrative biomechanical approaches that consider both structural and mechanical aspects to fully understand the complexities of the meninges.

SPATIO TEMPORAL MODELING OF BIOMARKER EXPRESSION IN NEURONAL CLUSTERS DURING TRAUMATIC BRAIN INJURY

Debabrata Auddya,Shiva Rudraraju

Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

INTRODUCTION

Traumatic Brain Injury (TBI) is associated with an impact or concussion to the head with the injury being specifically characterized through pathological degradation at various biological length scales. To quantify the sequence of events following TBI, classically, various mechanical modeling techniques have been proposed which establish metrics that demonstrate localised to generic neuronal damage. Broadly, the two categories of degradation encompass physiological deterioration and upregulation of chemical entities such as neurotransmitters which causes initiation of downstream pathophysiological effects. The loss of structural and chemical integrity within neurons and neuron clusters release molecules which serve as critical biological markers crucial to injury diagnosis. Aberration in concentration of essential chemical components in the brain such as neurotransmitters, inflammasomes, cytokines and ionic channels lead to activation of necroptotic pathways which eventually causes neurodegeneration. Recent studies have highlighted the pathological effects caused due to upregulation of these chemical species across the brain. The primary aim of this work is to demonstrate a continuum framework which models the multiphysics of mechano-chemical interactions underlying TBI. Using a coupled PDE (partial differential equation) formulation and FEM (finite element method) discretization, the framework highlights evolution of field variables which spatio-temporally resolves mechanical metrics and chemical species across the neuron cluster domain. Using geometric spatial localisation of specific chemical components, we illustrate dynamics of chemical field evolution across different regions of the neuron microstructure. This enables visualisation of initiation, interaction and progression of field variables, highlighting temporal activation of different components in the downstream necroptotic pathway.

METHODS

The proposed neurodegenerative pathway (Fig.1 (left)) begins with mechanical deformation manifested as increased strain to the brain, which triggers opening of the pannexin channels leading to massive ATP efflux into the extracellular region. Increased ATP causes purinergic receptors to activate, particularly the P2X7R, which causes potassium efflux from the intra- to extracellular milieu. Decrease in ionic concentration of potassium initiates formation of the NLRP3 inflammasome comlex. Simultaneously there is a heightened increase in the demand for oxygen causing oxidative stress and production of reactive oxygen species. This causes the NFκB pathway to trigger, also leading to intracellular formation of the NLRP3 inflammasome complex. This complex is responsible for modulating formation of pro-inflammatory products mainly cytokines such as TNFα and ILs. TNFα causes dysregulation in neuronal signalling by blocking EAAT's on astrocytes thereby reducing glutamate uptake. It also intensifies excitatory transmission by increasing permeability of the glutamate receptors to calcium ions. Increased glutamate concentration in the post synaptic region causes excitotoxicity and is considered as the pivotal step towards necroptosis.

Representation of a reduced pathway (Fig.1 (right)) consisting of quantifiable elements which contribute towards necroptosis. Illustrated in this pathway are ATP, TNF-α [1] and glutamate [2] classified as chemical concentration fields and the P2X7 [3] receptor mathematically as a phase field. This is attributed qualitatively to the opening probability of the channel upon prolonged activation by ATP. The shortened pathway enables formulation of advective-diffusive equations to spatio-temporally resolve the chemical species across the inhomogenous neuronal landscape.

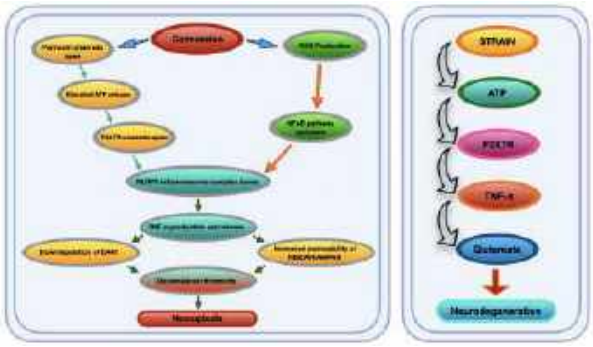

Figure 1: (Left) Proposed Pathway (Right) Modeled Pathway

We consider concentrations of the following chemical species as the primary fields: ATP (c_a), TNF-α (c_t), Glutamate (c_g) and ionic channels represented as a phase field: P2X7 (ϕ_p). The idea behind phase field assumption of ionic channels is the appoximation of gating probability (0-closed, 1-open) due to concentration sensitivity of certain chemical species. The evolution of these chemical species is modeled using the following advection-diffusion equations:

$$\frac{\partial c_a(\mathbf{x},t)}{\partial t} = \nabla \cdot (D_a \nabla c_a) + f(\epsilon), \qquad \mathbf{x} \in \Omega \tag{1}$$

$$\frac{\partial c_t(\mathbf{x},t)}{\partial t} = \nabla \cdot (D_t \nabla c_t) + f(c_a, \phi_p), \qquad \mathbf{x} \in \Omega \tag{2}$$

$$\frac{\partial c_g(\mathbf{x},t)}{\partial t} = \nabla \cdot (D_g \nabla c_g) + f(c_t), \qquad \mathbf{x} \in \Omega \tag{3}$$

$$\phi_p = \Phi(c_a) \tag{4}$$

where the source terms are expressed as $f(\epsilon, c_a, c_t, \dots)$ and Φ represents receptor sensitivity as a function of concentration of ATP. The diffusivity terms are expressed as D_x where the subscript x refers to individual species.

The mechanical response of the underlying viscoelastic framework is modeled using the conservation of linear momentum.

$$\nabla \sigma = 0 \tag{5}$$

A viscoelastic network (Fig.2) consisting of Maxwell elements is used to model the underlying mechanical network as illustrated below:

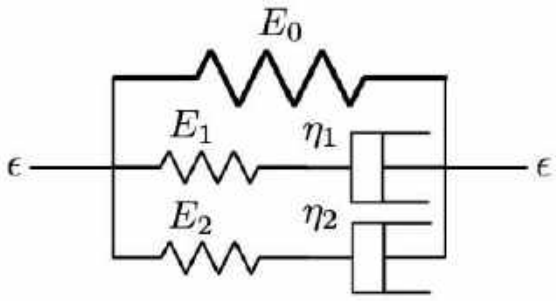

Figure 2: The extracellular matrix and its components is modeled as a viscoelastic network.

The figure below (Fig.3) illustrates the synaptic-microglial region which is further modeled in a FEM framework. This allows compartmentalisation of chemical fields and allows visualisation of diffusive dynamics across the computational domain. The heterogeneity in chemical field concentrations for single neurons and neuron clusters play a pivotal role in demonstrating injury progression driven by mechano-chemical interactions.

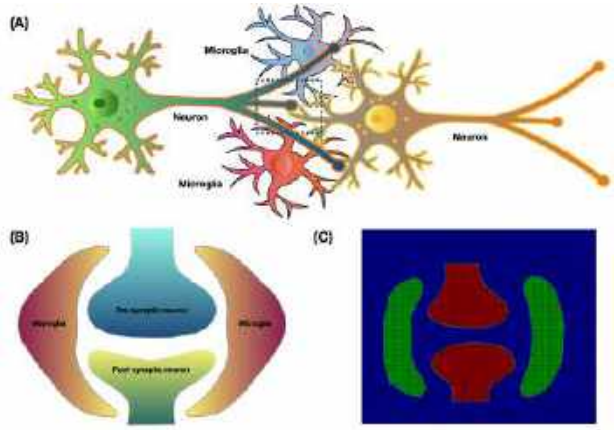

Figure 3: (A) Schematic of neuron synapse and microglial interaction relevant for spatial modeling (B) Specific region under consideration (C) FEM illustration of neuron-microglia assembly

RESULTS

We present some results (Fig.4) from boundary value problems to demonstrate spatio-temporal evolution of biomarkers upon mechanical loading.

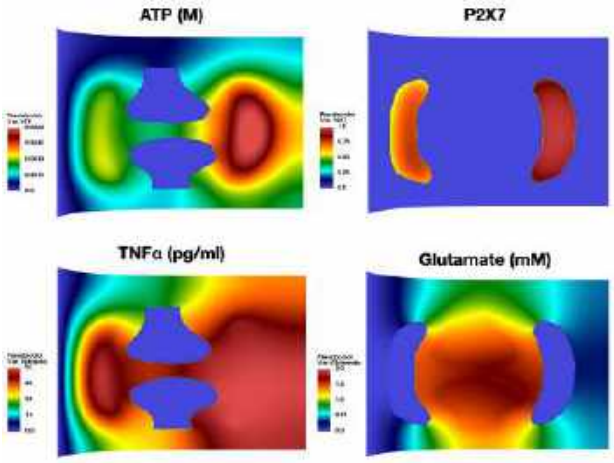

Figure 4: The results are obtained from a tensile loading boundary value problem. The domain is subjected to unaxial tension leading to strain across it. This causes activation of ATP as shown in the first block. At a specific concentration P2X7 receptor opens and the figure highlights those regions. This further triggers the cytokines (TNF-α) to release from the microglial region into the ECM as shown. Finally the cytokine activation causes excess production of glutamate within the synaptic region as illustrated. These simulation results describe a spatio-temporal evolution of biomarkers due to an external mechanical load. The length scale of the domain is in μm and time scale is in ms.

DISCUSSION

We have highlighted a novel mechano-chemical framework which demonstrates mechanical and chemical metrics relevant to traumatic brain injury. The results presented, spatio-temporally resolves these metrics and provides valuable insight and analysis into critical chemical thresholds underlying necroptosis. In a first-of-its-kind representation of mechano-chemical interactions underlying neurons and neuronal clusters we have qualitatively drawn comparison between our results and existing literature and demonstrated injury thresholds. The fidelity of our current modeling approach allows inclusion of additional physics and fields which enables better resolution of injury diagnosis leveraging clinical biomarkers.

OVINE FRACTURE HEALING IS ROBUST TO HIGH GAP STRAIN: A VIRTUAL MECHANICAL TESTING AND IMAGE COLOCALIZATION ANALYSIS

Maham Tanveer (1), Hannah L. Dailey (1)

(1) Mechanical Engineering & Mechanics, Lehigh University, Bethlehem, PA, USA

INTRODUCTION

Evidence from large animal and clinical studies have shown that the mechanical conditions at the fracture site controls callus growth. Modern understanding of the role of interfragmentary strain in the mechanoregulation of bone healing has heavily relied on Stephan Perren's "2-10% strain rule" [1]. The rule suggests tolerance limits for fracture gap strains for successful bone healing based on rupture data from bone and cartilage tissue elongation tests. Any strain below 2% (measured as gap closure/original gap length) is suggested to not provide enough stimulation for callus formation, while any strain above 10% suggested to lead to excessive movement, hindering osteogenesis and increasing the risk of nonunion in fracture.

Due to the challenges of measuring strain *in vivo*, finite element analysis (FEA) offers an opportunity to noninvasively characterize the mechanical strain environment during bone healing. In this study, FEA was performed to measure early interfragmentary strain by first determining boundary conditions that represent physiologic loads and then applying those loads to image-based models of early post-operative ovine tibiae. The hypothesis of this study was that early interfragmentary strains higher than 10% do not cause nonunion.

METHODS

Eight representative animal samples were chosen from a library of microCT scans of excised tibiae of Swiss Alpine sheep (average body weight 68 kg, age 2-3 years), which were part of previously completed research studies. Intact and operated limb scans were processed in Mimics (v23.0, Materialize, Leuven, Belgium). Scans were down sampled to an isotropic resolution of 400µm. Operated bones were segmented to isolate old cortical bone from callus. Bone reconstruction was performed by adding mask around the osteotomy in the regions where remodeling had made the cortical bone less dense. Post-operative X-rays and bone structure above the osteotomy were used as a guide to reconstruct bone accurately. No callus was included for these models.

All 3D bone models were aligned axially to the global coordinate system. Right-side contralateral intact bones were mirrored to reduce variability during load optimization (Figure 1). Medullary void spaces were excluded for both operated and contralateral bones.

Figure 1: Preparation of an intact bone model for physiologic load optimization. This example was mirrored and aligned before defining midshaft normal strain probe locations.

Virtual plate installation was performed in Solidworks 2020 (SolidWorks Corps, Waltham, MA). Screw positions were matched to those in the scans and plate placement was referenced to post-op X-rays. A strain visualization region was added to measure strains within and around the fracture gaps (Figure 2) using our established method [2]. Quadratic tetrahedral (tet-10) meshes were created in 3-Matic with a maximum edge length of 1 mm. Material properties were assigned using our validated dual-zone material model to manage partial volumes:

$$E = \begin{cases} E_{sc} & \rho_{QCT} < \rho_{cut} \\ 10225 \times (\rho_{QCT})^{1.0} & \rho_{QCT} \geq \rho_{cut} \end{cases} \quad (1)$$

where E_{sc} = 50MPa and ρ_{cut} = 665 mgHA/cm^3 and ν = 0.3 [3]. A homogeneous material property of E = 0.5 MPa and ν = 0.45 was assigned to the strain visualization region [2].

Figure 2: Workflow showing model creation, meshing, simulation and submodeling (blue zone) to measure interfragmentary strain.

Finite element analysis was performed in ANSYS Workbench Mechanical (R2020, ANSYS, Inc, Canonsburg, PA). Boundary conditions used remote points on proximal and distal faces, with a roller support defined at the proximal remote point and pinned support defined at the distal remote point (Figure 1).

Physiologic-like loading conditions were defined starting with a bodyweight scaled midstance axial load. Variable anteroposterior (AP) and mediolateral (ML) bending moments were applied in superposition to achieve midshaft normal strains comparable to *in vivo* strain gauge data for intact ovine bones [4] (see strain probe locations in Figure 1). A response surface was generated and moments were selected to minimize root mean square error (RMSE) for midshaft normal strains.

Optimized intact tibia loads were applied to the operated tibia models for each animal. A low-load variation of 20% bodyweight (BW) was also applied to represent the loading situation observed with typical loading restriction in the very early post-operative period [5].

To understand the relationship between strain and healing, voxel Hounsfield Units (HU) were sampled from an AP slice view, including voxels within and around the lateral osteotomy gap. HU for each voxel was categorized into hard/soft callus based on our previously validated threshold of 665 mgHA/cc [6]. Voxel data for each sampling region of interest was then mapped to von Mises strain in strain visualization region. Logistic regression was performed with a binarized outcome variable for hard (1) versus soft (0) callus.

RESULTS

The optimized load combination giving the lowest RMSE was an axial load of -1418N, AP bending moment of 20,000 N-mm and ML bending moment of -15,000 N-mm. Strain contours matched the expected physiologic strains for intact sheep tibiae [4] (Figure 3).

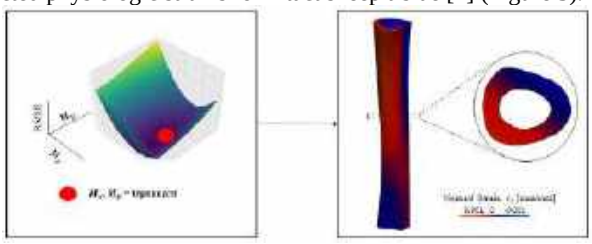

Figure 3: Optimizing the superposition of axial loads and bending moments produced midshaft normal strains with the physiologic isoclines at midstance. Note the slightly medialized anterior tension and lateralized posterior compression state.

At both high and low loading levels, the maximum von Mises strain occurred in/around the fracture gap (Figure 4) and was well above the hypothetical 10% limiting threshold in all eight animals. The peak von Mises strain was 154% ± 28% for full (100%) loading and 36% ± 11% for low (20%) loading. The volume of elements with von Mises strain above 10% was 5.11 ± 3.00 cm^3 for full loading and 0.37 ± 0.19 cm^3 for low loading.

Logistic regression showed hard callus was 2.36 times more likely to form outside the fracture gap compared to inside the gap ($p < 0.05$). Mann-Whitney U test revealed significant differences in von Mises strain between sampling boxes for location "in" versus "around" the fracture gap for both loading cases (20% and 100%) (Figure 5).

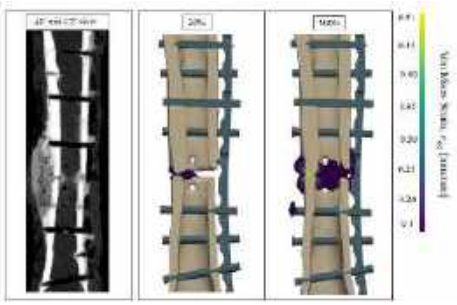

Figure 4: Representative model showing high strains >> 10% under both low (20% BW) and high (100% BW) loads. Von mises strains are illustrated here for simplicity.

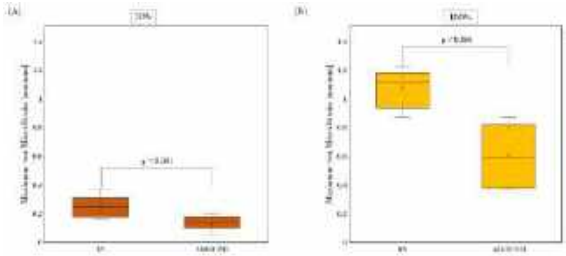

Figure 5: Elements inside the fracture gap had significantly higher strains compared to those around the gap for both partial weightbearing (A) and 100% bodyweight (B).

DISCUSSION

This analysis suggests that fracture gap strains greatly exceed the 2-10% range for physiologically loaded ovine osteotomies, even in the protected low-loading case of 20% BW. Early mineralization was delayed inside the immediate gap zone where von Mises strains were very high, but all animals had successful unions, suggesting that secondary fracture healing is more tolerant to high gap strain values than previously believed. These findings may have a significant implication on the understanding of the effect of strain on bone healing.

POSTURAL STABILITY IN HELICOPTER AIRCREW WITH AND WITHOUT NECK AND BACK PAIN: THE MEDICAL COLLEGE OF WISCONSIN MILITARY AIRCREW NECK AND BACK PAIN STUDY

INTRODUCTION

Neck and back pain are common in military helicopter aircrew. Over a 12-month period, 67% and 80% of helicopter pilots reported neck and back pain (1,2). Aircrew posture during flight was thought to be a contributing factor for these pain symptoms, along with whole body vibrations and head-borne equipment such as night vision goggles (NVG) (2,3). Flight hours, NVG use, and total NVG flying hours were cited as risk factors for pain (1,4).

Postural control can be affected by neck and back pain. The cervical spinal cord plays an important role in the integration of muscle spindle, vestibular, and visual input, which provide information about the current position of the head (5). Damage and fatigue of sensory tissue in the neck and back may lead to reduced signal accuracy and incorrect center of mass positioning (5,6). Pain can also interfere with these signals, leading to more instability (5,6). This can be observed through increased sway in patients with chronic neck and back pain (7-9).

Deficits in postural control were analyzed in civilians with chronic neck and back pain separately, but the interaction between pain in these two areas has not been extensively explored (7-9). Along with this, postural stability is yet to be reported for the military helicopter population. This study has two goals: understand how neck and back pain in military helicopter aircrew affects measures of postural stability, and how the interaction of neck and back pain may further decrease postural control.

METHODS

Wisconsin Army National Guard (WIARNG) helicopter aircrew signed informed consent forms and completed baseline demographic and flight history surveys, pain assessments, and a postural stability assessment. Pain assessments involved the Neck Disability Index (NDI) and the Oswestry Low Back Disability Index (ODI), both scored 0-50, with the purpose of understanding how neck and back pain affect daily activities. A score of 0-4 is considered “no disability”, and a score of 5-14 is considered “mild disability” (10). Helicopter aircrew were placed into one of four groups based on their NDI and ODI scores: no neck or back pain group (NBPG-; NDI:0-4 and ODI:0-4), neck pain group (NPG; NDI:5-14 and ODI:0-4), back pain group (BPG; NDI:0-4 and ODI:5-14), and neck and back pain group (NBPG+; NDI:5-14 and ODI:5-14).

This study incorporated a published postural stability protocol (7). Each subject stood on a force plate with eyes open and eyes closed for 30 sec. Following these quiet standing trials, participants completed a series of dynamic arm movement trials. In each trial, the subject was instructed to stand still with either eyes open or closed. At a randomized time after this command (10-20 seconds), the subject was instructed to rapidly raise either their left or right arm, then hold it up for 20 seconds. They were then told to relax, and the next trial began. Each combination (eyes open right arm: OR; eyes open left arm: OL; eyes closed right arm: CR; eyes closed left arm: CL) was completed three times in random order.

Three-axis forces and moments were collected at a sampling rate of 1024 Hz during each trial using a force plate. The force plate output data were filtered using a fourth order lowpass Butterworth filter with a cutoff frequency of 10 Hz (9,11). The force and moment data were used to compute center of pressure (COP) sway in the mediolateral (ML) and anteroposterior (AP) directions. The ML sway, AP sway, speed of COP, and sway area were calculated for each trial. The average across the three trials was computed for each subject. Eyes closed metrics were

also normalized against respective eyes open metrics to quantify changes attributed to visual input.

Sway metrics were compared between pain groups. All statistical analyses were conducted in RStudio 2023.03.0. All distributions were determined to be non-normal using a Shapiro-Wilk test. Kruskal Wallis tests determined whether a variable was dependent on pain group. When Kruskal Wallis tests were significant ($p<0.05$), pairwise comparisons between pain groups were completed using Wilcoxon rank sum tests.

RESULTS

Seventeen male WIARNG helicopter aircrew (four crew chiefs and thirteen pilots) completed the postural stability assessment with an average age of 36.4 years (range: 26-47), and 1166 (250-2700) total military flight hours. Sixteen participants were right-handed, with one ambidextrous. Five aircrew members were in the NBPG-, three were in the NPG, and nine were in the NBPG+. No aircrew had back pain without neck pain. There was no difference in age between the pain groups ($p=0.18$).

Sway metrics were compared between pain groups. For CL, AP ($p=0.05$) and ML ($p=0.03$) sway were different between pain groups. NBPG+ had larger AP ($p=0.05$) and ML ($p=0.01$) sway compared to the NBPG-. Change in AP and ML sway from eyes open to eyes closed was not different between pain groups ($p>0.05$).

The speed of the COP was different between pain groups for OR ($p=0.02$), CR ($p=0.04$) and CL ($p=0.05$). The NBPG+ had faster COP speed compared to the NBPG- for all three arm raise combinations ($p<0.05$). Change in COP speed on the non-dominant arm movement from eyes open to eyes closed was also different between pain groups ($p=0.03$) (Figure 1). The NBPG+ had a larger increase in COP speed from eyes open to eyes closed compared to the NBPG- ($p=0.09$) and the NPG ($p=0.13$).

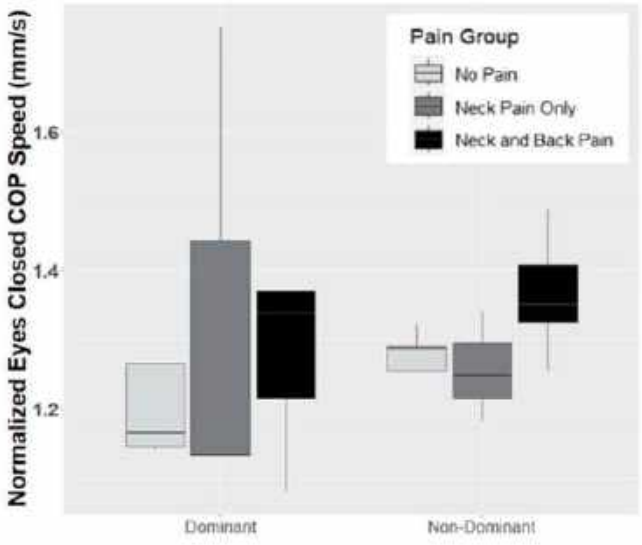

Figure 1: Eyes closed COP speed normalized against eyes open COP speed. Aircrew with neck and back pain exhibited a larger increase in COP speed from eyes open to eyes closed compared to aircrew with neck pain and aircrew with no neck or back pain.

Sway area was different between pain groups for OL ($p=0.01$). The NBPG+ ($p=0.04$) and NPG ($p=0.07$) had larger sway areas than the NBPG-. Change in sway area from eyes open to eyes closed was not different between pain groups ($p>0.05$).

DISCUSSION

This study explored neck and back pain in military helicopter aircrew and related changes in postural stability. This sample of helicopter aircrew with neck and back pain demonstrated decreased postural stability compared to those without neck or back pain. Civilians with chronic neck and back pain also exhibit decreased postural stability compared to healthy civilians (7-9,12). Ruhe et al. reported civilians with chronic neck pain demonstrated increased COP mean velocity and sway area, with a linear relationship between these metrics and the severity of pain score (12). Pain can interfere with proprioceptive information, leading to an incorrect positioning of the center of mass and postural instability (5). Patients with chronic neck or back pain also exhibit delayed muscle response times, which could contribute to the increase in sway (7).

These findings are unique as the postural stability of military helicopter aircrew has not been frequently studied. Studies examining neck position sense were unable to detect any differences between aircrew with and without neck pain (13). While no significant results were found in this study, aircrew with neck pain tended to have increased sway area compared to aircrew members without neck pain ($p<0.2$). These findings are also unique as they explore differences between subjects with neck pain and subjects with both neck and back pain. Previous studies examined neck and back pain separately (7-9,12). The present cohort did not have any aircrew with back pain in the absence of neck pain. This analysis demonstrated individuals with neck and back pain exhibited larger increases in COP speed when vision was removed compared to individuals with only neck pain. This may be due to compounding pain interference from both the neck and back, suggesting that pain management is necessary for this population. Future studies are needed to further explore the relationship between combined neck and back pain on postural stability by utilizing larger sample sizes and a back pain only group.

Decreased postural stability may affect the performance of helicopter aircrew, especially as muscles become fatigued over long duration flights. Deficits in postural stability can be made worse by cervical and low back muscle fatigue (7). Future research may examine how neck and back muscle fatigue from flight affects postural stability for helicopter aircrew with and without pain.

INTRODUCTION

Aging is one of the most significant risk factors for breast cancer. The influence of age-related cellular alterations on breast cancer development has been extensively explored in previous studies. Recently, the significance of the aging breast tumor microenvironment has gained growing attention. Despite the significant advances in breast cancer diagnosis and therapies, screenings for novel breast cancer therapies for patients from different age groups are limited by the lack of an aging-related breast cancer model [1]. Extensive literature has demonstrated the changes in mechanical and chemical properties and collagen structure with aging [2]. Age-related alterations [3] in physical properties and glycation of mouse tail tendon collagen have implied the possibility of modeling the aging breast ECM with collagen from mouse tail tendon. Here, we isolated and characterized collagen extracted from young and aged mice tail tendon and constructed a 3D age-related breast cancer model for novel drug screening.

METHODS

Tails and breast tissues of young (2-6 months) and aged (20-23 months) mice were collected. Soluble type I collagen was isolated from the tail tendons for characterization and engineering 3D breast tissue models. Lectin staining was performed to characterize the glycation of collagen in young and aged mouse breast and tail tendon tissue sections. Circular Dichroism was performed to assess the secondary structure and melting point of the isolated collagen I. A solution containing collagen (3 mg/mL) and transglutaminase (100 mg/mL) was prepared to construct 3D breast tissue models. Total collagen assays were performed to assess the degradation of the hydrogel model. Cancerous and normal human mammary epithelial cells were seeded on or in the 3D aged breast models to evaluate migration and invasion, respectively. Tumor spheroids were prepared with the ultra-low attachment method and successfully embedded in the collagen gels to construct the 3D breast cancer model. 3D invasion assessment and drug screening were performed with the automated BioTek BioSpa Live Cell Analysis System and a Biomek i7 Liquid Handler.

RESULTS

Lectin staining confirmed higher level of glycation in collagen fibers in both native breast ECM and tail tendon of aged mice. Degradation studies confirmed the stability of the 3D model within 7-day incubation. Epithelial cells showed significantly increased migration and invasion behavior in/on the 3D aged breast model, in accordance with our findings in the aged breast ECM sections [4]. mRNA qPCR analysis of cancerous and normal epithelial cells and mammary fibroblasts encapsulated in the 3D aged breast tissue models all demonstrated an increased expression in SERPINE1, an established aging marker [5]. These results have indicated the potential of the established 3D age-related breast cancer model for novel drug screening. Tumor spheroids were successfully embedded in the gels to construct 3D age-related breast cancer models. Tumor spheroids embedded in the aging breast cancer models also demonstrated higher 3D invasion ability over the period of 7 days monitor. Tumor spheroids within the aged and young breast cancer models presented different drug responses to selected drug treatments.

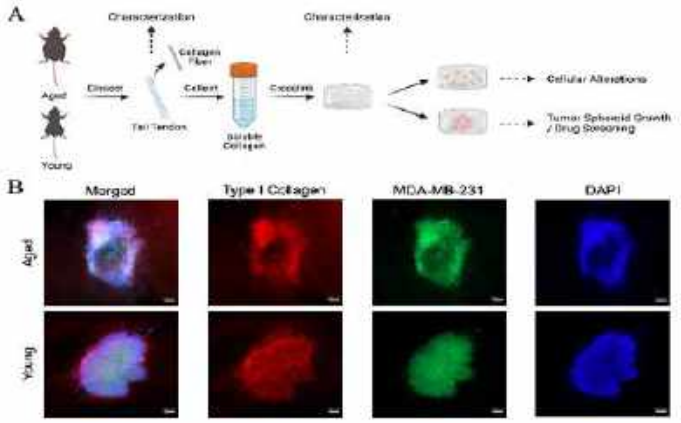

Figure 1: (A) Scheme of the study. (B) Immunostaining of the 3D breast cancer model with the tumor spheroids embedded in extracted type I collagen.

DISCUSSION

In this study, we isolated and characterized soluble collagen I extracted from young and aged mice tail tendon and for the first time in literature utilized the extracted biomaterials to construct a stable 3D age-related breast cancer model for aging-related studies and high-throughput novel drug screening. Our results have indicated the potential of the established 3D age-related breast cancer model for novel drug screening as tumor spheroids within the aged and young breast cancer models presented different drug responses to selected drug treatments.

DEVELOPMENT OF A NON-INVASIVE IMAGING APPROACH FOR ASSESSING RADIATION-INDUCED CHANGES IN INTESTINAL BARRIER FUNCTION

Austen D Nissen[1], Christopher Hansen[1], Guru P Sharma, PhD[2], Brian L Fish[2], Dana Veley[2], Amit Joshi, PhD[1], Heather A Himburg, PhD[1,2]

INTRODUCTION

Casualties of high-dose radiation exposure will experience dose-dependent toxicity to normal tissue. Exposure to whole-body radiation doses above 5 Gy may result in gastrointestinal (GI) death due to denudation of the intestinal mucosal barrier and subsequent fluid loss, hemorrhage, and/or sepsis[1, 2]. Therefore, in the event of a radiation mass casualty scenario, the development of medical countermeasures (MCM) for the treatment of GI acute radiation syndrome (GI-ARS) is essential.

Our laboratory has recently identified a potent small molecule mitigator of GI-ARS called diminazene aceturate (DIZE)[3, 4]. While DIZE is known to promote activation of the transmembrane enzyme ACE2, the mechanism of action and cellular target in mitigating GI injury is known. Since intestinal barrier function may fail to due intestinal villi denudation and/or loss of endothelial integrity, our long-term goal is to non-invasively discriminate changes in transport across the epithelial and endothelial layers using non-invasive near-infrared (NIR) fluorescent imaging.

Here, we performed a pilot study where we performed (NIR) fluorescent imaging of indocyanine green (ICG) dye in irradiated rats. ICG dye was administered either via oral administration or by intravenous injection. Oral administration of ICG dye will allow visualization of dye transit from the GI compartment across both the epithelial and endothelial barriers before entering into circulation. Conversely, intravenous administration of ICG will enable visualization of dye leakage from the intestinal vasculature.

METHODS

Adult female WAG/RijCmcr rats were exposed to either 13.0 Gy partial body irradiation with minimal bone shielding (n=9) or sham irradiation 0 Gy (n=8) as previously described by Fish et al. 2021[5]. At 3 days post-irradiation ICG imaging was performed.

Each cohort was divided to receive either ICG via tail vein injections or provided ICG mixed in pudding and fed orally before imaging. Following a high dose bolus of ICG (5mg/kg) administration, we performed sequential dynamic imaging with a temporal resolution of 50 ms at time intervals of 30 min, 2 hours post, and 4 hours post-ingestion. Imaging was performed on anesthetized rats with 785 nm or 808 nm diode lasers and NIR-2 emission was captured with 950 nm or 1100 nm long pass filters positioned following the holographic notch rejections filters in the optical path.

RESULTS

We were able to image the transit of the ingested ICG through the intestinal tract over time and use principal component analysis (PCA) to define the region of interest (ROI) for the GI space based on this imaging **(Fig 1)**. Principal component analysis (PCA) along the time dimension was used to convert the imaging data to a k-component vector for each pixel, where k is the number of time frames in the original dataset. The first 8-components were used to identify organ ROIs as shown in **Fig 1**. The fluorescence intensity (I) time course data on ROIs

identified by PCA is then regressed with a double exponential function ($I(t) = A\ e^{-\alpha t} + Be^{-\beta t}$) based on two-compartment pharmacokinetic model[6] for quantitatively comparing the dye wash-in and wash-out rates in the GI space. In our pilot imaging analyses of the irradiated gut, we observed ICG intensity in the GI space is altered by radiation injury with increased dye retention in the GI space.

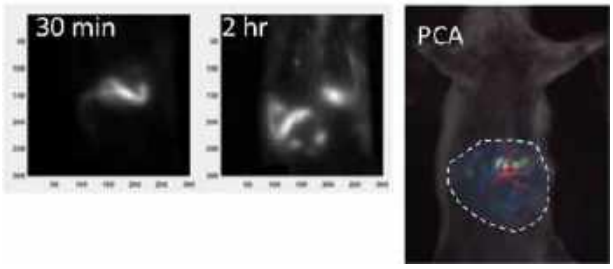

Figure 1: Feasibility study to assess ICG imaging following oral administration. Still images captured from ICG imaging at 30 minutes (left) and 2 hours (middle) post-feeding of ICG in pudding vehicle. PCA analysis of the temporal images was used to define the GI ROI.

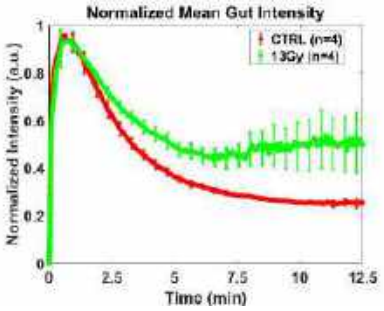

Figure 2: Representative fluorescence time-course data in the GI ROI. Pilot day at day 4 following 13 Gy PBI demonstrates the time course of ICG intensity in the GI space is altered by radiation injury.

DISCUSSION

This pilot experiment aimed to determine the feasibility of non-invasive ICG imaging to characterize radiation-induced changes in intestinal permeability. This work demonstrates the potential of dynamic noninvasive *in vivo* NIR fluorescence imaging for diagnostic motility testing for intestinal disorders or dysfunction and for potential evaluation of therapeutic agents. Future studies will be necessary to evaluate the dysregulation of the intestines post-radiation injury and improvements to imaging techniques.

INTRODUCTION

Society is increasingly dependent on technology, so it is important to build a workforce that can adapt to rapidly changing advances. To this end, there is a strong need for young minds to engage in science, technology, engineering, and math (STEM) fields [1,2]. In recent years, there has been an increased number of programs and funding opportunities to aid with the development of STEM education. Different opportunities are crucial for fostering and sustaining interest in STEM topics amongst young students [3,4].

When outreach programs bridge multiple educational levels (e.g., high school and university) benefits can be twofold. STEM ideas are introduced to a larger group of younger students, but university-based outreach programs also allow undergraduate and graduate students to have unique opportunities to improve their skills as science communicators. Like many universities, our institution – Washington University in St. Louis (i.e., WashU) – has a population of students who have demonstrated interest in volunteering for outreach programs with middle- and high school-aged students. Here, we (a university research lab at WashU) describe our process of establishing a partnership with a high school in our local community to create several opportunities for high school students to engage in STEM educational activities.

Partnering High School: Pattonville High School (PHS) is part of the fully accredited and nationally recognized Pattonville School District in St. Louis County, Missouri. In the 2013-2014 school year, PHS initiated their involvement in the national Project Lead The Way Biomedical Sciences Program (BSP), a rigorous four-year, four-course sequence in which students learn about medicine, physiology, genetics, microbiology, public health, and forensic science. Because BSP courses focus predominantly on health sciences and biological sciences, the partnership with our lab represents a valuable opportunity to introduce BSP students to bioengineering and related topics.

Main Partnering Washington University Laboratory: The Musculoskeletal Soft Tissue Laboratory (mSTL) is in the Department of Mechanical Engineering & Materials Science at Washington University in St. Louis. The lab investigates the biomechanics of orthopedic soft tissues such as tendons and ligaments to enhance fundamental understanding of healthy tissue properties and elucidate changes that occur in injured or diseased tissues.

Establishing a Connection: While writing a National Science Foundation grant proposal (CMMI 2037125), we discussed potential ideas to engage with our local community. With mSTL's lab manager being an alumnus of PHS, the BSP was brought into focus as a potential group who would benefit from connecting with labs at WashU.

Overall Goal: Here, we aimed to promote and teach STEM concepts to high school students by selecting one local high school (PHS) with whom we could build a strong partnership for outreach/education. This overall goal was pursued with three specific opportunities which were designed to be adaptable as the partnership develops and students' interests change.

METHODS/IMPLEMENTATION

Opportunity 1: Senior Students Visit to WashU Campus: The goal was to host 12th grade BSP students for a half-day field trip to WashU's campus to visit engineering labs and tour engineering facilities.

As an initial focus we decided to engage with senior students who were in their beginning stages of planning their capstone research project. Students received a list of potential labs (all studying biomedical research topics) to visit and created a ranked list based on overall class interest. From this ranked list, three labs were invited to participate in the campus activity. The visit began with a brief welcome/introduction session followed by lab visits and a campus tour. During the lab visits, students learned about current research projects and experienced up-close demonstrations of various experimental techniques utilized by each lab. During the campus tour, student/staff guides focused on showing visiting students the resources available to engineering undergraduates and allowed current engineering students time to answer questions.

During this half-day visit, the PHS seniors completed both pre- and post-visit surveys. Receiving feedback allowed us to gauge interest/knowledge of bioengineering and adjust our plans as needed when planning future visits.

Opportunity 2: Biomedical Research Showcase at PHS: After two years of successful senior visits, we decided to increase engagement with a larger group of BSP students. The goal was to present a showcase of bioengineering research topics to all BSP students (9^{th}-12^{th}) at PHS, increasing the total number of student interactions and allowing more graduate students to strengthen their science communication skills.

We invited a group of research-active graduate students from WashU across a range of biomedical research areas to visit PHS and give 10-minute demonstrations related to their research (Figure 1). PHS students were split into two large groups by grade level, then split again into groups of 4-6 students. Over a 90-minute total period, students rotated to a different demonstration every 10 minutes, learning about a wide variety of bioengineering research topics. Graduate students presented their work on virology, women's health, soft tissue biomechanics, acoustofluidics/microfluidics, optical neuroimaging, and biomedical imaging. At the conclusion of the showcase students were given a survey for feedback on the event.

Figure 1: Graduate students presenting at the research showcase.

Opportunity 3: Collaborative Senior Capstone Project: The final component of the BSP requires senior students to design and execute their own capstone research project. Within our partnership, the goal of Opportunity 3 was to host interested senior students at a WashU lab to conduct basic research for their final capstone project.

To date, one senior student elected to participate and conducted research in the Musculoskeletal Soft Tissue Laboratory. After collecting and analyzing all the data, the student created a final presentation summarizing their work and presented their capstone project at PHS.

RESULTS/EVALUATION

Opportunity 1 Evaluation: Data gathered from pre- and post-visit surveys showed an overall increase in knowledge of biomechanics/biomedical engineering when comparing responses before and after the visit (Fig. 2A). There was also a mid-range level of increased interest in the field after the seniors visited campus (Fig. 2B).

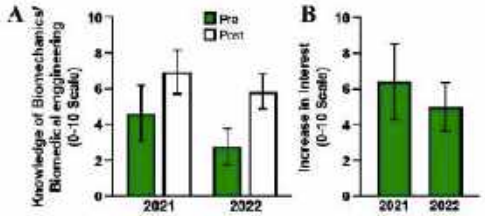

Figure 2: Results of Opportunity 1. (A) Knowledge of bioengineering before and after visit and (B) increase in interest in bioengineering. 0 indicates no knowledge or no increase in interest, 10 indicates total knowledge or max increase in interest. Data shown as mean +/- standard deviation.

Opportunity 2 Evaluation: Post-showcase surveys completed by students (Fig. 3A) show that scores of knowledge prior to the demonstrations were generally lower than scores after the showcase (Fig. 3B). Overall, a majority of the students reported increased interest in biomechanics/biomedical engineering after engaging with the graduate student demonstrations (Fig. 3C).

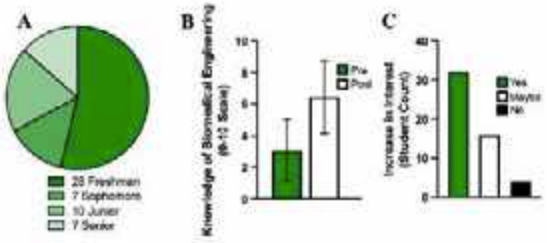

Figure 3: Results from Opportunity 2 showcase. (A) Grade level of students who completed the survey, (B) overall knowledge of biomedical engineering increase from before the showcase to after (0 indicates no knowledge, 10 indicates total knowledge with data shown as mean +/- standard deviation), and (C) number of students demonstrating increase in interest.

Opportunity 3 Evaluation: Although we do not have quantitative data from the student who conducted research in our lab, success of this opportunity can be evaluated based on completion of the student's goals. They successfully built a relationship with their mentor graduate student, planned a project, collected and analyzed data, and completed their final presentation for the BSP.

DISCUSSION

Learning and increased interest in STEM can result from a well-balanced outreach partnership or collaboration. Our goal was to build a mutually beneficial partnership with a local area high school where our university's graduate students could work on becoming better science communicators, while also providing outreach/educational experiences to high school students. We have successfully created three different opportunities that can be repeated each year and built a strong relationship with a high school in our community. To continue increasing interest in bioengineering topics we plan to continue our yearly visit described in Opportunity 1. We also plan to conduct a second annual biomedical research showcase (Opportunity 2) to continue to reach a larger number of students. By connecting with students earlier (freshmen-juniors), we hypothesize that the number of students who complete the four-year BSP will increase, with more students continuing their education within a STEM field. Although only one PHS student has completed a research project through Opportunity 3, additional students have expressed interest; ongoing work involves minimizing logistical challenges to allow more high school students to conduct research in WashU research laboratories. Future work will involve expanding this program to include additional high schools in the local community.

In conclusion, a partnership has been successfully established and grown within the past few years, where we are engaging with over 100 students per year and introducing them to research topics in bioengineering. By sharing these ideas and successes with a larger audience, we aim to provide laboratories at other universities with the tools to build partnerships and outreach opportunities with high schools in their local community.

INTRODUCTION

Understanding the mechanics of upper extremity motions is vital, as these movements are central to numerous normal daily activities. The quality of life of an individual might be significantly affected by impairments in these movements. Consequently, in-depth study of individual muscle forces and joint reaction forces during different upper extremity motions is fundamental. This understanding is essential in sorting out the complexities of neuro-musculoskeletal dysfunctions. In orthopedic and rehabilitation research, computational and modeling software, such as AnyBody Modeling System™ (AMS) and OpenSim, are being more and more used to estimate these forces [1]. These programs, offering diverse modeling environments and musculoskeletal models, are instrumental in biomechanical analysis. It is important to note that OpenSim and AnyBody provide distinct modeling environments and methods for characterizing body parts, Previous studies, notably in gait analysis, have compared the predictions of AMS and OpenSim. These comparisons have highlighted both similarities and differences in kinematics (joint angles) and kinetic (moments, muscle activations and forces) predictions. These results highlight how critical it is to select the right model and parameters to accurately simulate real-world situations in clinical settings [2-4]. It appears that there is a notable gap in research when it comes to the upper extremity; OpenSim provides various user-developed shoulder models while AnyBody lacks a resolute shoulder model. We conclude that there is a lack of direct comparison between OpenSim and AnyBody predictions when it comes to study of upper limb motions.

The purpose of this study is to compare the predictions of muscle forces using this two software during upper extremity motions. This work will primarily focus on simulating static elbow flexion, shoulder flexion, and shoulder abduction maneuvers. It is hypothesized that the muscle forces obtained from AnyBody and OpenSim will show some similarities and differences. This needs to be addressed when using the software to simulate motions involving the upper extremities.

METHODS

A generic model was used in both software that is based on the anthropometry and muscle force-generating characteristics of the 50th percentile adult male. Based on this criteria, Upper Extremity Dynamics Model (UEDM) [5,6] available on OpenSim at SimTk was used. For AnyBody, the Free Posture Full Body Shoulder Rhythm Static model included in the AnyBody Managed Model Repository (AMMR) 2.0.0 was used. In the first step, kinematics for the simulated postures were defined i.e., elbow flexion of 90-degree, shoulder flexion of 80-degree and shoulder abduction of 90 degree.

In OpenSim, the kinematics are defined within the graphical user interface. Forward dynamics simulation was then run for a short duration (1 sec) to generate the motion file, then inverse dynamics and static optimization were run with reserve actuators appended to solve muscle redundancy problem minimizing the sum of the activation levels of the muscles at a discrete time step.

In AMS, customization was made by keeping only the muscles of the right part of the upper extremities, and kinematics were defined on the mannequin.any file under the body model by setting the angular velocities to zero and defining required rotation angles to respective joints. Finally, an initial calibration followed by an inverse dynamics analysis was ran to solve the muscle redundancy problem using a defined polynomial muscle recruitment criterion.

Muscle forces were predicted using OpenSim v4.4 [7,8] and AnyBody v7.1 [9] during the specified upper extremity motions. Predicted muscle forces were then compared with existing literature to evaluate the accuracy of the results and to determine which of the two software is more viable for future research on the upper extremities.

RESULTS

Muscle predictions for the tested conditions using both software are listed in Table 1.

.

Table 1: Predictions of Major Muscle Forces using both software

Motion	Muscle	Forces (Newtons)	
		AnyBody	OpenSim
Elbow Flexion	Brachialis	51	44
	Biceps	20	25
	Brachioradialis	11	9
	Triceps	0	12
	Anconeus	0	3
Shoulder Flexion	Supraspinatus	95	36
	Infraspinatus	94	215
	Deltoid	490	545
	Trapezius	128	N/A
	Serratus	88	N/A
	Triceps	0	422
Shoulder Abduction	Deltoid	508	746
	Trapezius	125	N/A
	Serratus	82	N/A
	Supraspinatus	85	0
	Infraspinatus	132	0
	Subscapularis	510	142
	Triceps	24	571

For elbow flexion, both models predicted the Brachialis as the primary contributor to the muscular activity, with AnyBody and OpenSim predicting 51 N and 44 N, respectively, underscoring its pivotal role in the movement. It is important to note that OpenSim exclusively predicts certain muscle forces in the Triceps and Anconeus during elbow flexion, while AnyBody did not predict any forces in these two muscles.

In shoulder flexion and abduction, high force predictions (highlighted in green in Table 1) for the Deltoid were obtained from both models, illustrating its significance in these movements. Further, AnyBody exclusively provides high force predictions (highlighted in yellow) for the Supraspinatus and Infraspinatus during shoulder abduction contrasting with higher Triceps force predictions from OpenSim (highlighted in yellow) during shoulder flexion and shoulder abduction.

DISCUSSION

In this study muscle forces were predicted using AnyBody and OpenSim during three static postures (elbow flexion, shoulder flexion and shoulder abduction). The major elbow flexor muscles are biceps, brachioradialis, and brachialis [10]. Software predicted relatively large muscle forces for these muscles confirming their role in the static elbow flexion.

While discrepancies were noticed in the triceps, deltoids, rotor cuff, serratus, and trapezius. OpenSim predicts a contractile force for the triceps during elbow flexion indicating that the triceps engages to provide stability and balance to the elbow joint. This likely allows the elbow to be better controlled while the agonist muscles provide the necessary contractile force/load to maintain joint the joint angle against gravity. It was worth noting that the AnyBody did not record this force compared to the OpenSim.

Results from an EMG analysis indicated that the deltoid, pectoralis major, supraspinatus, infraspinatus, serratus anterior, and trapezius were significantly activated during shoulder flexion [11]. Except for the pectolaris major, software predicted forces in these muscles. However, there were differences in the predictions of the muscle contractions during this motion (shoulder flexion) from software. OpenSim does not have the Trapezius and Serratus muscles in their model. Furthermore, OpenSim predicts large muscle forces for the Triceps during both shoulder flexion and shoulder abduction. AnyBody also predicted relatively large muscle forces for all the major shoulder abductors. As indicated above, OpenSim does not have the Trapezius and Serratus muscles in their model which contract during shoulder abduction and predicts high forces for the triceps during this motion, which is not consistent with the literature [12]. Because the Trapezius and Serratus muscles are not included in OpenSim, higher and/or lower forces are predicted in other muscles.

It is hypothesized that the above differences between the software predictions are due to different anthropometric and anatomical definitions (mass and inertia of segments, muscle properties, moment arms) and different scaling procedures between AnyBody (dynamics trial) and OpenSim (static trial). In addition, UEDM of OpenSim does not include several muscles of the upper extremities. This raises concern for its use in simulations related to shoulder motions.

It is important to note that both software couple humeral elevation to scapular rotation which does not accurately predict the muscle forces required to move the scapula and the subsequent upper extremity motions [13]. A more comprehensive model is thus required to be developed that does not couple glenohumeral motions and scapular motions to predict the forces more realistically in all muscles during these motions.

In conclusion, AnyBody appears to be more viable in predicting muscle forces during the simulation of upper extremity motions. This is because OpenSim does not include several muscles in their model.

INTRODUCTION

In the development of a mechanical circulatory system a thorough design evaluation before clinical trials is of utmost importance. Various modalities can provide different bits of information about the functionality and performance of the total artificial heart (TAH) and the effect of the mechanical system on the blood constituents and how it contributes to blood damage.

Hemodynamic blood damage has been linked to disturbed or turbulent flow, and one way to quantify the degree of turbulence is through turbulent kinetic energy (TKE). Simulating TKE using computational fluid dynamics (CFD) is challenging in a pulsatile total artificial heart, and therefore we investigated measurements of the flow and TKE using magnetic resonance imaging (MRI). The findings were then used to provide insights for the iterative design process of the mechanical heart prototype.

The goal of this study was to develop a method to measure and analyze flow patterns and TKE in the complex 3D geometry of the mechanical heart through MRI. For this an MRI compatible test rig was created in which physiological representative flow conditions could be simulated.

METHODS

A 4D flow MRI measurement was performed on a legacy prototype, v11.c, of the Realheart pulsatile TAH, fig.1. This prototype functions as a positive displacement pump with an expanding and contracting chamber analogous to the atrium and ventricle. The movement is driven by a motor moving a cylinder connected to flexible membranes in the chambers.

MR-compatibility was achieved by developing a test-rig in which the motor was placed away from the bore of the magnet. Pressures representative of atrium and aortic pressure were regulated in the rig, simulating realistic *in vivo* conditions. The TAH was operated with a heart rate of 105 bpm, providing a cardiac output of 5.0 l·min^{-1}. A prior study on blood damage within the TAH [1] was conducted under the same operating conditions to allow comparison between results.

Flow data of the mechanical heart was acquired with a 4D flow MRI sequence on a 3.0T MR scanner (Philips Ingenia, Philips Medical Systems, Best, the Netherlands), for three encoding directions with an optimized velocity encoding of 70 cm·s^{-1} for turbulence sensitivity. The acquired spatial resolution was 2.2 mm^3 with a Cartesian k-space filling method. A short TR/TE, 5.9/3.6 ms resulted in an effective temporal resolution of 23.7 ms. Applying a parallel imaging factor of 2.5 with SENSE reduced the measurement time to 5:04 minutes. The data was reconstructed to 40 timeframes per cardiac cycle.

Velocity data was analyzed using path line visualization, while volumetric flow rate was computed by integrating the velocity over a cross-sectional area for each phase in the cardiac cycle.

From the magnitude data intravoxel velocity variation was derived as described in Dyverfeldt et al. [2], following eq. 1.

$$\sigma_i^2 = \frac{2}{k_v} \ln\left(\frac{|S_0|}{|S_i|}\right) \quad (1)$$

This metric is a function of the signal ratio of the velocity encoded direction (S_i) and reference signal (S_0), with respect to the applied motion sensitivity (k_v). Voxel wise turbulent kinetic energy (TKE) was then computed by the normal components in three perpendicular directions of the Reynolds shear stress tensor, and the density of the fluid (ρ) following eq 2.

$$TKE = \frac{\rho}{2} \sum_{i=1:3} \sigma_i^2 \ [\text{Pa}] \quad (2)$$

This voxel-wise TKE was then integrated over the volumes of interest (Ω) to calculate the measured integrated TKE in specific locations.

$$\text{integrated } TKE = \int_\Omega TKE \, dV \ [\text{mJ}] \quad (3)$$

RESULTS

The path line visualization of the velocity field (see fig.1) revealed complex flow patterns in the atrium, ventricle, and outflow tract. A recirculation caused by impingement on the wall in both chambers and separation in the bend of the outflow tract was observed and further evaluated. As the bi-leaflet valves contain non-ferromagnetic material, a signal void was present in the near vicinity where flow information could not be quantified.

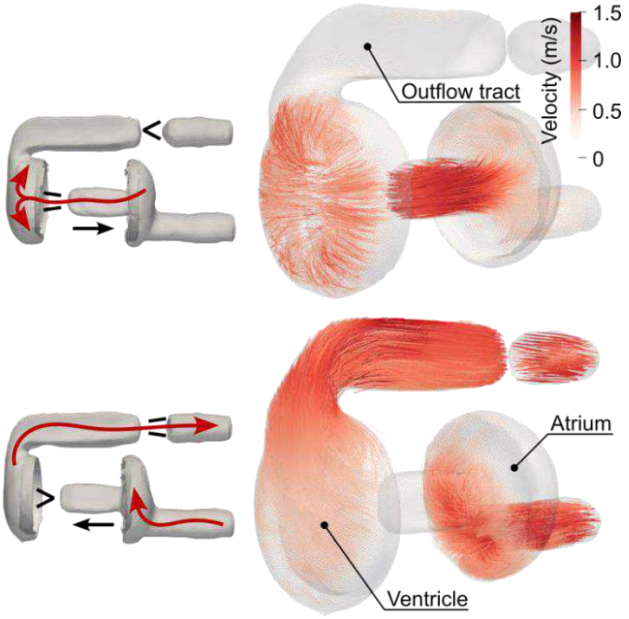

Figure 1: Geometrical changes and valve positions (left), and velocity path lines in diastole (top-right) and systole (bottom-right)

TKE at peak systole and peak diastole are visualized in a maximum intensity projection (MIP), as shown in fig.2. In peak diastole, the MIP reveals increased TKE in the ventricle, which can be explained by the flow passing through the mitral valve and recirculating in this volume. Other regions show low TKE, corresponding to low velocities in these regions. In peak systole, TKE is low in the ventricle, whilst in other regions the levels are elevated. Notable are the atrium with a large region of increased TKE, and outflow tract with the highest peak values that follow along the flow direction.

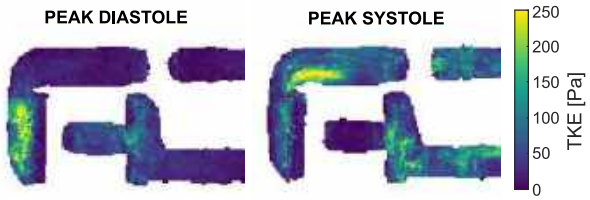

Figure 2: Maximum intensity projection of voxel-wise TKE

Integrated TKE, plotted over time in fig. 3, shows the clear difference between diastole and systole. While peak TKE value was found in the outflow tract, the highest integrated TKE was found in the ventricle, which is a larger volume. In both atrium and outflow tract, the highest values of integrated TKE were found at peak systole albeit with a slight offset. In all three measured locations we see that the measured TKE increased rapidly, during flow deceleration and decreased at a slower rate. The slower decay of TKE afterwards can be related to a conservation of momentum of the fluid which was smoother than the deceleration.

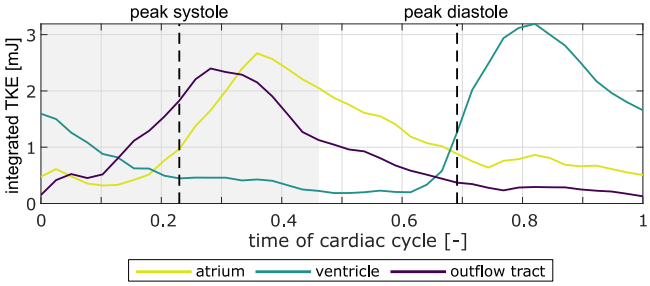

Figure 3: Integrated TKE measures for the atrium, ventricle, and outflow tract in the mechanical heart

DISCUSSION

Evaluation of flow patterns and turbulence is important in the development of a pulsatile TAH. In this study we found flow circulations and revealed turbulence in different cardiac phases that were not reported before. The measured turbulence is slightly higher than measured in a healthy heart, but lower to diseased patients.

Our *in vitro* TKE measurement finds similar values to *in vivo* studies of the human heart. The mean integrated TKE in the atrium of the TAH is equal to the healthy human heart (1.1 vs 1-2 mJ) [2]. In the ventricle and outflow tract where larger recirculation zones are present, slightly higher integrated TKE compared to healthy subjects [3,4] was found. This is however much lower than those found in diseased patients, for instance with pulmonary regurgitation, hypertrophic cardiomyopathy, or aortic stenosis [3,5,6,7].

The velocity field is comparable to a previous CFD study on the same TAH [8]. However, a more in-depth assessment of flow patterns and turbulence was not done in that study. The use of a less resolving turbulence model makes the latter difficult to accurately predict in CFD. The flow rate shows a very similar response and peak value to a previous study on the same TAH under similar operating conditions [9].

The signal void in the MR measurements makes it difficult to evaluate TKE and shear forces in the valves. This might be solved by replacing the valve or part of the valve with non-metallic materials.

Compared to computational fluid dynamics, 4D flow MRI enables the measurement of turbulence with TKE without the need of making modelling simplifications, assuming turbulence models or performing computationally intensive high resolved simulations. The created test-rig in this method required minimal adjustments of the tested prototype and the measurement is fast, compared to other experimental techniques like laser doppler anemometry, allowing for evaluation of fluid dynamics in the TAH in a range of operating conditions in a rapid-prototyping process. In this way, 4D flow MRI measurements, in combination with CFD and blood lab measurements, can enhance the development process of TAH, and reduce the need for donor hearts.

EFFECT OF TYPE I THYROPLASTY IMPLANT LOCATION AND STIFFNESS ON VOICE PRODUCTION

INTRODUCTION

Thyroplasty Type I (TT1) is a common procedure for treating unilateral vocal fold paralysis. The procedure involves creating a window in the thyroid cartilage, allowing for the placement of an implant within the paraglottic space. The objective is to improve voice outcomes by narrowing the glottal gap between the paralyzed and healthy folds, thereby reducing leakage and threshold pressure. Traditionally, surgeons manually carve the implant, determining its specifications, including location, stiffness, and shape, through a trial-and-error approach. The impact of these implant characteristics on voice outcome remains an ongoing research topic.

The TT1 implant offers a range of stiffness options, from soft materials like Gore-Tex to harder one like Silastic. Reddy et al. [1] found that, among these materials, Silastic rectangular implant consistently improved voice quality in canine laryngeal experiments. Cameron et al. [2] reported similar observation that stiffer implant enhances acoustics at similar flow rates. Interestingly, Cameron et al. [2] also noted that softer implants excel at low flow rates. Additional studies by Zhang et al. [3], [4] and Smith et al. [5] suggested that a soft implant, with material properties closely resembling real vocal fold, may be preferable for its consistent acoustic outcomes across various conditions. Wu and Zhang [6] pointed out that the impact of implant stiffness also depends on vocal fold stiffness and paraglottic tissue, highlighting the need to consider individual variations. Regarding implant shape, divergent or rectangular implants are more effective [7] [1], but Zhang et al. [3] argued that implant insertion depth and stiffness have a significantly greater impact on acoustic improvement than implant shape.

Regarding insertion location, the implant window is usually made at the vocal fold level and about 5 mm posterolateral to the midline of the thyroid cartilage [3]. Interestingly, clinical observations indicate that medialization in the infraglottal region tends to yield better voice outcome than medialization in the glottal region, although the exact reason remains unknown. In a study by Zhang and Chhetri [8], local medialization using a 2mm-diameter wood stick on excised human larynges showed improved glottal closure and higher-order harmonic excitation in voice when performed at a more inferior location. They hypothesized that inferior medialization contributed to a thicker vocal fold, but the medial surface's shape, including thickness, wasn't quantified, leaving the hypothesis unconfirmed. Zhang et al. [4] provided detailed structural changes before and after implant insertion using magnetic resonance imaging on ex vivo human larynges. They observed increased vertical thickness and significant stretching of the vocal fold tissue in the coronal plane, leading to a decrease in thyroarytenoid (TA) muscle dimension in the medial-lateral direction. However, since phonation experiments were not conducted, the direct relationship between structural changes and the produced sound is unclear.

This study aims to investigate the impact of TT1 implant location and stiffness on vocal fold dynamics and voice outcomes using numerical methods, establishing a direct link among the implant characteristics, vocal fold pre-phonatory conditions, and sound characteristics. Our hypothesis is that, in comparison to glottal-level medialization, infraglottal medialization will create a slightly divergent pre-phonatory shape and a more substantial vertical stiffness gradient, potentially enhancing the produced sound. Through parametric simulations, we will thoroughly explore how implant vertical location and stiffness influence pre-phonatory conditions (shape and stiffness), vocal fold vibration patterns, and sound characteristics.

METHODS

Geometry model. The geometric models of the larynx and implant were created from computed tomography scans of an ex-vivo canine larynx. Both the cartilages and vocal fold were reconstructed. The vocal fold was represented as a two-layer structure consisting of the cover and body layers (Figure 1(a)).

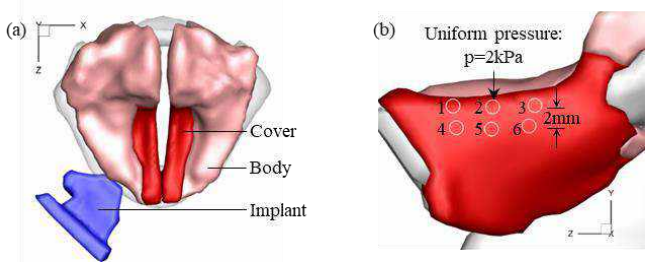

Figure 1. Vocal fold and the implant: (a) Geometric model (b) Indentation locations.

Material property. Fiber reinforced anisotropic material model was employed for both the cover and body layers [9], [10]. To determine material parameters for the body layer, we matched the strain-stress relationship obtained from a canine TA muscle [11]. For the cover layer, material parameters were determined by matching the indentation measurements on the medial surface of a canine vocal fold. Neo-Hookean material model was applied for the cartilages and implant, with implant stiffness provided in Table 1.

Table 1. Implant parameters in parametric simulations.

Parameter	Values
Height	The same and half with the vertical height of the fold.
Location	From superior to inferior side of the vocal fold medial surface.
Stiffness	Four values from 5 to 1400 kPa.

Simulation setup. The simulation comprises two phases. In the initial phase, we conduct a pre-phonatory posturing simulation. Tissue deformation will be modeled using finite element method. The anterior-posterior (AP) insertion location is determined following [3], and the insertion depth is adjusted to ensure appropriate fold adduction. Additional conditions, such as height and vertical location, are outlined in Table 1. Once the implant is inserted, we will assess the shape and stiffness distribution of the medial surface. In the second phase, we will perform a fluid-structure interaction (FSI) simulation to capture vocal fold oscillation, glottal flow waveform, and sound generation [9], [12]. The glottal flow will be modeled by a one-dimensional reduced-order flow model [13].

The stiffness distribution would be obtained through numerical indentation following a prior work [14]. Six indentation locations are denoted in Figure 1(b), distributed along three AP locations. In each AP location, indentation will be performed at the superior and inferior sides of the medial surface. The local stiffness is calculated by $= pR/\Delta x_{max}$, where p = 2kPa is the uniform pressure, R = 0.6mm is the radius of the circular indentation area, Δx_{max} is the displacement at the center of the circle. The stiffness gradient (SG) is calculated by $G = (E_{inf} - E_{sup})/dy$, where E_{inf} and E_{sup} are the stiffness at inferior and superior sides, respectively, dy = 0.2cm is the vertical distance between the two indentation locations.

RESULTS

In the baseline case, we inserted an implant with a height matching the vertical height of the fold at the glottic level. The insertion depth was adjusted so that 80% of the medial surface was adducted to the midline. The implant stiffness is 120 kPa.

Figure 2 illustrates the impact of the implant on the pre-phonatory conditions of the vocal fold at the three AP locations. Figure 2(a) overlays the medial surface profile before (dash) and after (solid) the implant insertion. It shows that the implant effectively adducted the fold toward the midline with only a small leakage in the posterior side. The shape of the medial surface profile does not show a significant difference before and after the implant inserted except that it became slightly more convergent in the posterior side. Vertical thickness is larger in anterior than in posterior side.

Figure 2(b) shows the SG along the three AP locations, measured between the superior and inferior sides of the medial surface as denoted in Figure 2(a). It shows that a stiffness gradient exists before the implant insertion, with the largest value around the mid-coronal location and the smallest value in the anterior side. With the implant inserted, SG increased in all three locations with the largest increase occurred in the anterior side.

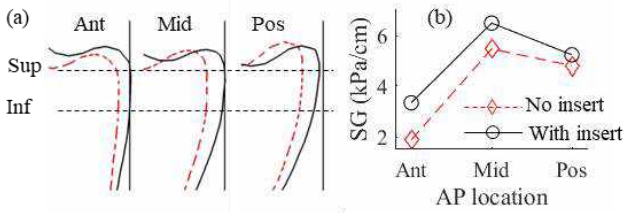

Figure 2. Influence of implant on pre-phonatory status: (a) medial surface profile; (b) stiffness gradient (SG).

DISCUSSION

The preliminary results show that the numerical model is able to simulate the impact of TT1 implant on vocal fold deformation and stiffness distribution before phonation. The simulation results of the baseline case show that when the implant is 120kPa and inserted at the glottis level, it adducted the vocal fold with only small effect on the shape of the medial profile. It increased SG in the whole AP range with the largest increase at the anterior side. In subsequent simulations and analysis, we will change the implant height, vertical location and stiffness as described in Table 1. The effects of these parameters on vocal fold pre-phonatory deformation and stiffness will be investigated. Additionally, FSI simulations will be performed on the obtained pre-phonatory conditions and the relationships among implant characteristics, vocal fold pre-phonatory conditions, vocal fold vibrations and voice acoustics will be studied. We will discuss the results by comparing them with the experimental measurements [8,15,16].

INTRODUCTION

As the global population ages, Alzheimer's disease (AD), the prevalent age-related dementia, emerges as a critical challenge for society. With over 6 million individuals in the US living with AD, this number is projected to triple by 2050 [1]. Despite the urgent need for AD treatments, understanding the mechanisms remains elusive, partially due to limited access to human brains, challenges in translating findings from animal studies to clinical applications, and the absence of physiologically relevant *in vitro* models replicating the complexity of the human brain [1-4].

A major challenge in replicating the human brain *in vitro* is the intricate nature of brain vascular structures, particularly the highly selective blood-brain barrier (BBB). Comprising endothelial cells (ECs), astrocytes (ACs), and pericytes (PCs) (Fig. 1), the BBB regulates the entry of molecules into the brain. The complexity extends to meningeal lymphatics, a network of conventional lymphatic vessels situated parallel to the dural venous sinuses and middle meningeal arteries within the mammalian central nervous system (Fig. 1). These lymphatics play crucial roles in clearing toxic molecules, such as amyloid-β (Aβ) peptides, a main component of the senile plaques in AD patients, from the brain parenchyma. Emerging evidence highlights the pivotal role of BBB dysfunction and meningeal lymphatics disruption in AD pathogenesis [2-5]. However, the complex interplay among neurons, the BBB, and meningeal lymphatics during the onset and progression of AD, as well as the role of fluid transport across the BBB, through the brain parenchyma, and exiting via the lymphatic system, remains poorly understood. Although various *in vitro* brain models have been developed to explore vasculature function in AD [2-5], they often fall short in reproducing the complex three-dimensional (3D) structure of the brain or lack a vascularized system for meningeal lymphatics.

To address the need for a physiologically relevant AD model, we introduce a new 3D *in vitro* human brain model self-assembled within microfluidic devices. Integrating human brain ECs, ACs, PCs [4], meningeal lymphatics [7], and human neural progenitor cells (NPC)-derived AD cell culture [8], our model closely mimics the AD brain environment. Notably, it is the first of its kind to incorporate perfusable BBB networks, lymphatic systems, and AD neurons within a unified platform, providing a valuable tool for advancing fundamental understanding of AD pathophysiology and drug screening for AD treatments. Ongoing studies will explore molecular, cellular, and tissue behaviors in AD patients, revealing biomarkers and mechanisms, and accelerating therapeutic development. Moreover, our model's versatility extends beyond AD, benefiting drug discovery in various human brain-like environments.

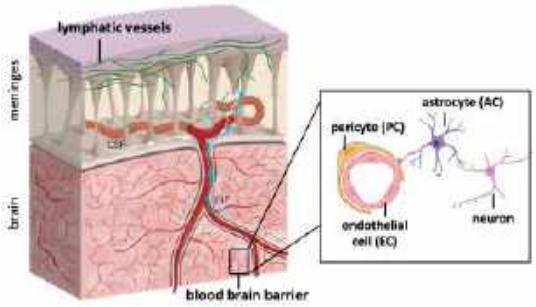

Figure 1. Human brain neurovascular unit with meningeal lymphatics. The blood-brain barrier (BBB), comprising endothelial cells, astrocytes, and pericytes, along with meningeal lymphatics, constitutes the complex entry-exit system within human brain vascular structures. Left schematic adapted from Sweeney *et al.*, 2018 [6].

METHODS

Fabrication of the microfluidic platform. The mold for device fabrication was created using Fusion 360 (Autodesk, Inc.) (Fig. 2a) and subsequently milled on a Delrin block using a micro-CNC milling machine (Bantam Tools). Microfluidic devices based on polydimethylsiloxane (PDMS) were then fabricated following established protocols [4]. The device design includes two 4 mm diameter holes for media channels, two 1.5 mm diameter holes for lymphatic-gel loading, two 2 mm diameter holes for BBB-gel loading, one 2 mm diameter hole for neuron-gel loading, and a top layer with three 4 mm diameter holes for connection to syringes (Fig. 2b). The chamber height is 500 μm.

2D cell culture. Human astrocytes (ScienCell, #1800) and human brain vascular pericytes (ScienCell, #1200) were expanded and cultured in astrocyte media (ScienCell, #1801) and pericyte media (ScienCell, #1201), respectively. GFP expressing human brain microvascular endothelial cells (Angio Proteomie, # cAP-0002GFP) and GFP expressing lymphatic cells were expanded and cultured in VascuLife (LifeLine Technologies, LL-0003) with 10% v/v FBS. Neurons were expanded and cultured using the neural growth media as detailed in [8].

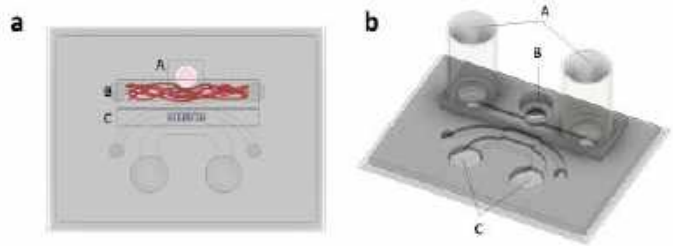

Figure 2. An integrated microfluidic system for modeling the human brain with meningeal lymphatics. a, Schematic showing channels for different cell types. A, neurons; B, self-assembled BBB networks; C, sprouting lymphatic networks. **b,** Schematic showing ports for media addition. A, culture media for the BBB; B, culture media for neurons; C, culture media for lymphatic cells.

3D cell culture in the microfluidic platform. BBB cells were seeded in the central blood vessel culture channel (Fig. 2a, Channel B) in fibrin gel to self-assemble networks. Neurons were seeded in the circular neural culture channel (Fig. 2a, Channel A) in Matrigel (Corning, # 356230). The lymphatic channel (Fig. 2a, Channel C) was filled with fibrin gel for lymphatic cells to sprout and a monolayer of lymphatic cells was deposited onto the side of the lymphatic channel gel. The seeding medium for the BBB (Fig. 2b, Ports A) and lymphatic cells (Fig. 2b, Port C) was made using VascuLife (LifeLine Technologies, LL-0003) with ¼ of the supplemented heparin sulfate and 2% v/v FBS. The seeding medium for neurons (Fig. 2b, Ports B) was the neural differentiation media as detailed in [8].

Imaging. Confocal images were acquired using an Olympus FV1200 confocal laser scanning microscope with 4x and 20x objectives. Images were analyzed using ImageJ.

RESULTS

Perfusable BBB networks and lymphatic sprouts are integrated in one unified flatform. Through meticulous control of media and interstitial flow, self-assembly of BBB cells into networks occurs approximately two days after seeding, with perfusability achieved around the fifth day. Subsequently, lymphatic cells are seeded, and after two days of directed interstitial flow, lymphatic vessels sprout in the designated channel, approaching the BBB networks (Fig. 3a).

Quantification of the perfusable barriers during long-term culture. To quantify the permeability of perfusable barriers, we introduce model large molecules, such as dextran, when the BBB networks become perfusable (Fig. 3b). Monitoring the increase in fluorescence intensity in the surrounding matrix enables quantification of barrier permeability, as detailed in [4]. Our model, designed for extended viability, allows for diverse quantifications over an extended period (Fig. 3c). This longevity feature is pivotal in studying the long-term effects of AD neurons on BBB and lymphatic functions.

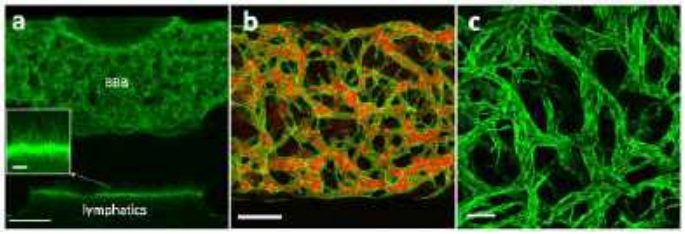

Figure 3. A human brain model with meningeal lymphatics. a, Perfusable BBB networks and sprouting lymphatics are integrated in one device. Green: Top, endothelial cells; bottom, lymphatic cells. Scale bar, 1 mm. Insert, a closer view of the lymphatic sprouts. Scale bar, 200 μm. **b** and **c**, green: endothelial cells. **b**, Dyes are used to visualize and quantify BBB networks. Red, 40k Da dextran. Scale bar, 500 μm. **c**, BBB networks remain perfusable five weeks after seeding. Scale bar, 200 μm.

DISCUSSION

We created a novel microfluidic platform that integrates BBB cells, neurons, and lymphatic cells, which generates physiologically relevant structures to model the human brain. Our model features self-assembled perfusable vascular networks formed by BBB cells and sprouting lymphatic vessels in proximity to BBB networks, mimicking human brain vasculature. The two types of vessels separated by two distinct endothelia, as well as extracellular matrix, allow for the simultaneous measurement of molecular and fluid transport across the vascular and lymphatic endothelia under physiological and pathological conditions. Currently, we are quantifying barrier functions, including molecular and fluid transport. Validation of BBB function involves perfusing large molecules and relevant plasma proteins across the BBB into surrounding matrix, measuring barrier permeability through fluorescence intensity. Lymphatic endothelial permeability will be assessed in the physiologically-relevant basal-to-apical direction by the intensity increase within the lymphatic luminal space after diffusion of molecules in the matrix from the BBB networks. Moreover, the capability to permit the passage of cerebrospinal fluid (CSF) is critical for the correct functioning of the meningeal lymphatics. We will connect the platform to a flow system simulating brain flows. Taken together, this work is the first to incorporate perfusable BBB networks, lymphatic systems, and neurons in one platform, providing a valuable tool for studying human brain pathophysiology. Future integration with *in vivo* studies will enhance understanding of human brain disease mechanisms and expedite therapeutic development.

CHARACTERISTICS OF RESOLVABLE POLYMERS USED FOR DEVELOPING *IN UTERO* FETAL VALVE REPLACEMENTS

Sanchita S. Bhat (1), Julia Toma (1), Lakshmi Prasad Dasi (1)

(1) Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

INTRODUCTION

Congenital heart diseases account for nearly one-third of all congenital defects, and require surgical repair or medical management [1]. Pulmonary atresia with intact ventricular septum (PA/IVS) is one type of extremely rare congenital heart defect that occurs in 1% of total heart defects [2]. In this defect, the pulmonary valve is underdeveloped and atretic leading to hypoplasia of the right side of the heart and limiting flow through the right ventricle and main pulmonary artery. Many of these patients undergo palliation, but are subject to high risks of morbidity and mortality, eventually requiring heart transplantation or a pulmonary valve replacement [3]. Although these replacements are made from biocompatible materials, they can become dysfunctional, requiring further intervention and multiple surgeries.

Fetal cardiac intervention is performed to prevent single ventricle heart disease in pulmonary atresia with intact ventricular septum [4]. Pulmonary valve perforation and balloon valvuloplasty can restore antegrade flow *in utero* and preserve right ventricular size and function. Although mostly successful, recurrent stenosis and atresia *in utero* are common after this procedure. A tissue‒engineered, bioresorbable valve has the potential to prevent this and could grow with the patient postnatally. Understanding the performance characteristics and biomechanics of such a valve could further guide the techniques in developing and testing them. Polymeric materials have been used extensively for their applications in stents. They are ductile and have high tensile strengths, making them excellent candidates for this application [5]. Therefore, this study aims to develop a study polymeric materials to develop a fetal valve replacement and determine characteristics of the materials used, that can aid in anticipating valve performance *in vivo*.

METHODS

Stent Analysis

Three stent designs were developed using SolidWorks (Dassault Systèmes, Vélizy-Villacoublay, France) as shown in **Figure 1** and subject to computational simulations where the prototypes were crimped, balloon expanded (modeled as per commercial NuMed balloons) and deflated using ABAQUS (Dassault Systèmes, Vélizy-Villacoublay, France). Resolvable polymers namely PCL (polycaprolactone) and PLLA (poly-l-lactic acid) were used as stent materials. The simulation pipeline is shown in **Figure 1.** The resultant stress distributions were studied to understand possible areas of failure and deformation due to deployment through stent parameters such as dog boning ratio, foreshortening and recoil. Furthermore, stent width was increased in one of the high stress regions to study the impact of design on stress distributions and overall stent behavior.

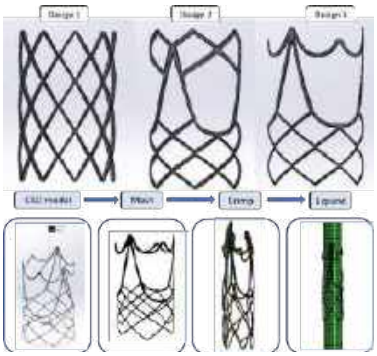

Figure 1: Three candidate designs and simulation pipeline (bottom)

Leaflet Degradation

A stent prototype 5 mm in diameter, 8 mm in height, was manufactured using a laser cutter. PCL (leaflets) were manufactured using solvent casting techniques in chloroform. The leaflets were manufactured with a less dense PCL (0.75% PCL in chloroform) and the commissures and skirt with a high‒density PCL (5% PCL in chloroform), in order to control the degradation and ensure longevity of the valve *in vivo.* Sodium hydroxide (NaOH) is a standard basic agent used for the accelerated degradation of polymers and a 2M NaOH solution was made, which was used in place of the working

fluid in the fetal right heart simulator (FRHS) as shown in **Figure 2**. Setup conditions were tuned as described previously [6]. A camera was placed on the downstream end of the valve, and this camera recorded continuous *en-face* videos of the valve over its degradation period. The degradation experiment was terminated when at least one leaflet failed. N=3 valves were run in this setup and their observations studied.

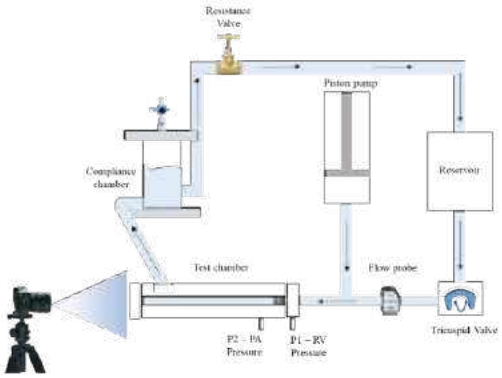

Figure 2: Fetal Right Heart Simulator (FRHS)

RESULTS

Stent Simulations

In the stent simulations, we observed that both polymers overall had good performance characteristics. PLLA had higher recoil and could be a better polymer to use for this application, although it did have higher foreshortening, especially in Design 3. Both materials had good dog boning overall, indicating less potential to stent distortion and good radial expansion (**Table 1**). From the results, Design 2 with PLLA polymer was seen to be the most optimum design and material combination.

Table 1: Deployment characteristics of N=3 designs for PCL and PLLA

Design	Material	Foreshortening (%)	Recoil (%)	Dog boning	
				Side 1	Side 2
1	PCL	12.116	-2.060	0.022	0.032
	PLLA	12.676	-3.270	0.042	0.017
2	PCL	10.186	-0.068	0.001	0.001
	PLLA	-0.621	0.611	-0.013	-0.013
3	PCL	15.738	-4.268	-0.075	0.128
	PLLA	20.039	3.562	0.035	0.002

We were also able to show, that small changes in design parameters such as stent strut width, can cause changes in distribution of stresses and therefore outcome of stent *in vivo.* Figure shows stresses at the stent junction went from 350MPa to 205MPa by only changing the width (**Figure 3**). This indicates that changing design can mitigate risk of stent fracture during deployment.

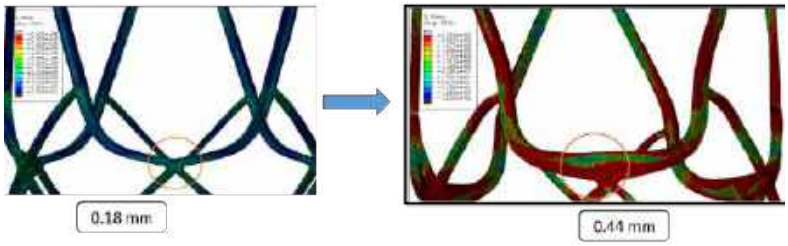

Figure 3: Shown change in peak stresses (MPa) by changing design

Leaflet Degradation

Figure 4 shows the degradation patterns that were recorded and it was observed that the leaflets degraded from the edge and slowly affected coaptation and the overall ability of the valve to maintain steady hemodynamics, up until Stage 6, where multiple tears began to appear on the leaflet free edges and the area adjacent to the commissures. On physical examination, the commissures remained intact even though some of the leaflets catastrophically failed. These results are important and indicate the impact of design on *in vivo* fate of resolvable valve replacements. Due to the unique manufacturing process, we were able to control the degradation and potentially increase the longevity of the valve *in vivo.*

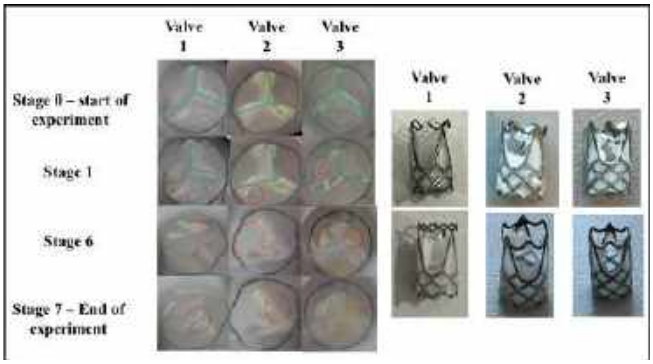

Figure 4: Left - Stages in leaflet degradation (green lines are coaptation lines and red circles show regions of degradation) and right -Valves post-degradation

DISCUSSION

This study improves understanding of fetal sized stent behavior by comparing designs and materials and develops a novel technique that can be optimized and used for sutureless valve assembly. Fetal valve stents are small in size, and therefore extensive biomechanical studies need to be conducted to evaluate their performance. In valve manufacturing, the change in material density can help engineer high importance structures such as the commissures to degrade slower than leaflets.

The development of such a tissue engineered heart valve replacement will eliminate the need for repeat interventions and serve as a permanent solution. Given the few durable options for pediatric patients, this study will improve the feasibility of developing such a device right from the manufacturing to the testing stage. Although these studies need to be supplemented with animal work that will help determine the timeline of valve absorption, by simply looking at biomechanical analyses we can optimize the valve design to ensure that there is no premature failure. This work only studies polymeric materials for stents, however future studies are being done with metal alloys as well which can provide additional advantages and degradation protocols for stents are also underway.

MEDIAL ILIOFEMORAL LIGAMENT STRAIN AND ORIENTATION FOLLOWING THA IMPLANTATION CORRELATE WITH ITS ABILITY TO CONTRIBUTE TO HIP STABILITY

Clarisse M. Zigan (1), Jennifer Bido (1), Kathleen N. Meyers (1), Jose A. Rodriguez (1), Timothy M. Wright (1), Fernando J. Quevedo Gonzalez (1)

INTRODUCTION

Instability of the hip is the second most common cause for revision of total hip arthroplasty (THA) and third most common cause for early revision [1]. The direct anterior approach (DAA) is considered a solution to lower the risk of instability after THA, but the evidence is inconclusive [2,3]. During a DAA, the medial iliofemoral ligament (mIFL) is often incised to gain access to the capsular compartment [4]. In its native state, this ligament serves as a primary restraint to rotation, yet consensus on capsulectomy extent or the need for capsule repair is lacking [5-7].

Our previous work revealed that the mIFL produced as much as 87% of the total torque resisting anterior dislocation with the hip in full extension, but less than 54% following mIFL transection and subsequent repair. This variability is likely influenced by many factors including the material properties and geometry of the mIFL itself. Material properties are innate to the tissue, but the ligament's geometry can be controlled by the surgeon during THA. For example, during implantation, surgeons can manipulate femoral offset, a variable known to influence strain in the surrounding soft tissues [8,9].

Our objective was to relate the change in ligament strain due to implantation and ligament orientation to mIFL contribution to stability during external rotation. We hypothesized that the contribution to stability and its variability across specimens can be explained by jointly considering these geometric factors. A combination of cadaveric testing and computational modelling was used to relate these variables to the mIFL's contribution to hip stability.

METHODS

Seven cadaveric hips from 10 donors underwent THA through a standard DAA while preserving the mIFL. Pre- and post-operative CT-scans were used to create specimen-specific models to predict the rotation needed to achieve contact between femoral and acetabular components. Specimens were tested on a six-degree-of-freedom robotic manipulator (KR 300 R2500 ultra, Kuka) coupled with a hip-specific control system (simVITRO, Cleveland Clinic Biorobotics Lab) using validated procedures [10]. Testing consisted of externally rotating the femur with the hip in full extension until the target rotation for contact was achieved. Testing was performed with the mIFL intact then cut. The maximum change in rotation-torque curves of the cut condition was used to define the extreme of motion. The torque of the mIFL was isolated by subtracting the cut condition from the intact condition, which included the contribution of the rest of the capsule, then normalized to the intact torque to describe the ligament's contribution to hip stability.

Following robotic testing, mIFL origins on the femur and pelvis were marked with radiopaque beads by a board-certified orthopaedic surgeon (JR) and a fifth-year resident (JB) prior to the 3D scanning of the specimens (HandySCAN 3D, Creaform).

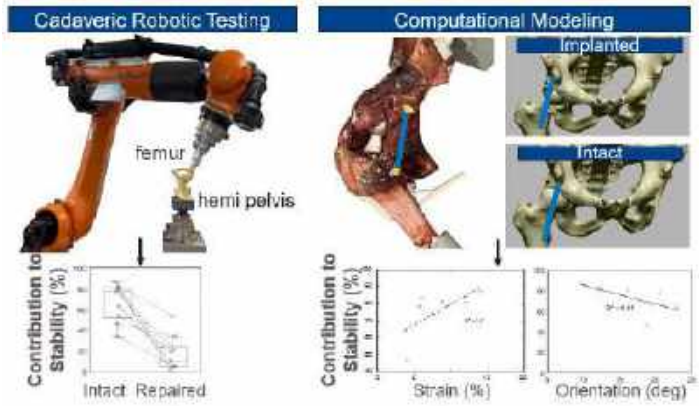

Figure 1: The combination of cadaveric testing and computational modeling was used to describe the influence that mIFL (blue) geometric factors have on its ability to contribute to hip stability.

Scans were aligned to existing specimen computational models and the bead centroids were used to define a vector representing the mIFL (Fig. 1). Ligament vectors were assessed in the intact (pre-implantation) and implanted states.

Implantation strain was calculated as the ratio of the change in ligament length from the intact condition to implanted condition against the intact length. The mIFL orientation relative to the superior-inferior axis of the pelvis was calculated by the dot product of the ligament orientation onto the superior-inferior axis (Eqn. 1) in which a smaller angular deviation was representative of a more vertically oriented vector.

$$Angular\ deviation = \arccos[< \frac{Pelvis_{origin} - Femur_{origin}}{norm(Pelvis_{origin} - Femur_{origin})} > \cdot < S - I\ axis >] \quad (1)$$

For each specimen, implantation strain and angular deviation were compared against the ligament's contribution to stability at the extreme of motion previously measured during cadaveric testing in full extension. Student's t-tests and Pearson's correlations were used for statistical analyses using a significance level of 0.05 (MATLAB vR2023a, MathWorks).

RESULTS

Across all specimens, the mIFL length increased after implantation (p<0.01). We observed a positive relationship between implantation strain and the ligament's resultant contribution to stability during external rotation (R^2= 0.47; Fig. 2).

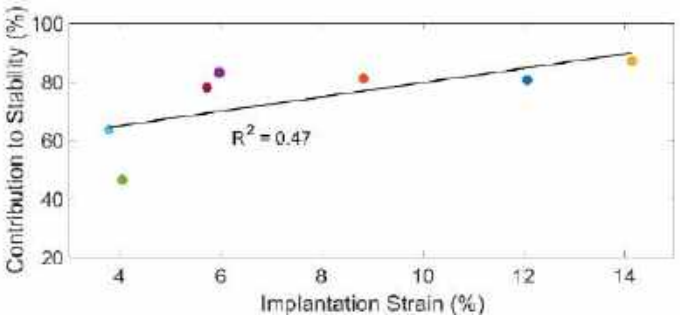

Figure 2: mIFL implantation strain and its contribution to stability demonstrate a positive relationship.

Across all specimens, angular deviations from the superior-inferior axis displayed a negative trend with the ligament's contribution to stability (R^2=0.41; Fig. 3).

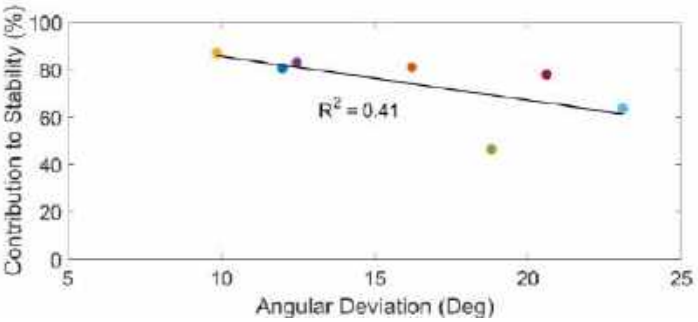

Figure 3: mIFL angular deviation and its contribution to stability demonstrate a negative relationship.

DISCUSSION

Instability following THA remains an unsolved clinical problem. Better understanding how capsular soft tissue relates to joint stability could help identify strategies to minimize instability. To address this question, we combined experimental and computational analyses to investigate the influence of geometric factors of the mIFL (i.e., implantation strain and orientation) on its ability to contribute to hip stability.

Our main finding was that contribution of the mIFL to hip stability tended to be larger for hips that underwent greater ligament stretching after implantation. Ligaments naturally have a slack region during which surrounding muscles can more freely move. A stretched ligament has less slack, therefore is able to resist load more readily, in turn providing stability to the joint. In this way, one of the surgical goals during THA is to achieve sufficient soft tissue tension, and our results corroborate the importance of ligament tension to increase stability. Our results are in line with prior studies that showed direct relationships between soft tissue strains, in particular the quadratus femoris muscle, and the hip torque [8,9].

We also found that the contribution of the mIFL to hip stability tended to be greater in more vertical ligaments following surgery. However, this relationship is confounded by the interdependence between implantation strain and orientation. For example, the specimens with the highest and lowest implantation strains (the yellow and green markers, respectively; Fig. 2) display the reverse relationship between angular deviation and its contribution to stability (Fig. 3). In fact, prior studies of other joints have highlighted the importance of considering orientation alongside material properties when assessing joint mechanics [11,12].

Our study has limitations. First, our sample size was small. According to a post-hoc power calculation, a sample size of at least 10 specimens would be needed to establish a regression between the geometrical variables and the contribution to stability. Second, we assumed the ligament to be linear and did not consider wrapping about the implant or bone. More complex musculoskeletal modeling could help further understand how ligament strains and orientation relate to its contribution to stability.

In conclusion, our results suggest underlying geometric factors (i.e., implantation strain and orientation) play a role in the ligament's ability to contribute to hip stability, thus highlighting the importance of surgical decisions to maximize stability following THA.

INTRODUCTION

In pregnancy, the female reproductive system undergoes substantial growth and remodeling (G&R) to support fetal development and delivery [1]. Notably, the cervix, located at the base of the uterus, connects the uterine cavity and vaginal junctions with the internal os (IO) and external os (EO), respectively (Fig. 1B). In humans, the cervix remains closed throughout pregnancy, serving as a mechanical barrier. Before and during parturition, it undergoes softening and ripening to facilitate fetal passage, exemplifying a physical manifestation of G&R. However, due to ethical concerns with human tissue collection, little is known about the evolution and spatial distribution of cervical tissue properties at mid-gestation timepoints and important anatomical locations. Rhesus macaques, a nonhuman primate (NHP) model with comparable maternal anatomy [2], provides a unique opportunity to study the gestational changes in mechanical behaviors of the cervical tissue at nonpregnant (NP) and three pregnant (PG) timepoints: early 2nd (E2), early 3rd (E3), and late 3rd (L3) trimesters (Fig. 1A). Our previous work examined the mechanical properties of these tissues using single-indent microindentation [3]; this study investigates time-dependent material behaviors of the same tissue groups through nanoindentation (NI) with the addition of the spatial mapping of tissue properties across selected anatomical locations.

METHODS

Per a University of Wisconsin Madison Animal Care and Use Committee protocol, NHP cervical tissue was collected from rhesus macaques following a total hysterectomy for the following groups: NP (n = 3), E2 (n = 3), E3 (n = 3), and L3 (n = 3). Cervical specimens were sliced transversely at IO and EO and dissected into 4 quadrants (Q1–Q4) (Fig. 1C). Following dissection, samples were flash-frozen on dry ice and stored at -80^{o}C until testing. In preparation for NI, cervical tissue was microtomed into 60 µm sections mounted on glass slides and stored in a -80^{o}C freezer. Upon testing, sample slides were glued to Petri dishes and swelled at 4^{o}C in PBS solution at room temperature for 30 mins. Spherical NI (Piuma, Optics11Life, Amsterdam, NL) was utilized to determine the time-dependent material properties of the NHP cervical tissues. Using an indentor with a probe radius of 24 μm and cantilever stiffness of 0.23 N/m, samples were indented to a fixed depth of 3 μm for 15 s, corresponding to a 5% strain, to achieve a load relaxation curve approaching equilibrium (Fig. 1E). The distance between indentation points was fixed at 200 μm. At least 100 indentation measurements were taken for each sample during the full mapping from the cervical canal end to the vaginal wall/ fornix with a fixed width of 1 mm at both ora (Fig. 1C). Load relaxation curves were fit in MATLAB with a combined poroelastic-viscoelastic (PVE) model based on established methods [4-6]. Material parameters of stiffness (E), instantaneous stiffness (E_0), viscoelastic ratio ($\frac{E_\infty}{E_0}$), and intrinsic permeability (k) were determined. Statistical analysis was performed in R using the `lme4` library with significance set at a 95% confidence level. A linear mixed model was implemented to investigate the effects of gestational timepoints (NP, E2, E3, and L3) and anatomical locations (IO and EO) on material properties with the consideration of the dependency due to same-subject sampling. P-value symbols in plots follow a standard GraphPad style $^{*}p \leq 0.05, ^{**}p \leq 0.01, ^{***}p \leq 0.001$.

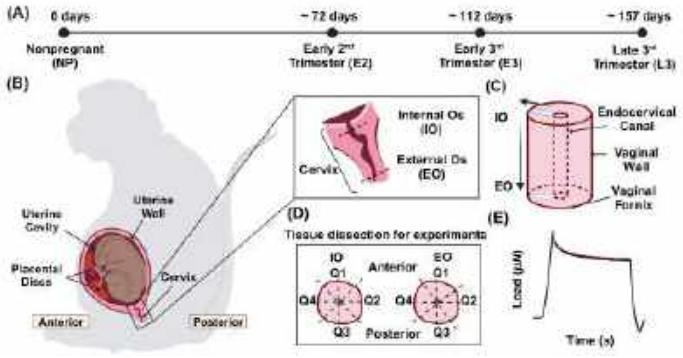

Figure 1: (A) Timeline of NHP pregnancy. (B) Representative illustration of pregnant NHP anatomy in the sagittal plane, including a schematic of the cervix identifying the internal os (IO) and external os (EO). (C) The directions of NI spatial mapping relating to anatomical features. Radial: the cervical canal (connecting the endocervical canal and the vaginal fornix) to the vaginal wall; vertical: IO and EO. (D) Top view of cervical samples dissected for experiments. (E) Representative load relaxation curve (black line) generated from NI testing fit with the PVE model (red line).

RESULTS

Results from Q1–Q4 in both IO and EO across all gestation groups in 1 NHP subject revealed no significant differences in E, E_0, $\frac{E_\infty}{E_0}$, or k; therefore, we tested only Q1 in subsequent samples for feasibility. The complete dataset reveals no significant differences in material parameters measured at this strain level between IO and EO at any timepoint, nor changes across gestation at both locations (Fig. 2). E and E_0 present similar distribution across gestation and anatomical locations, with E_0 consistently greater than E (Fig. 2A & B). $\frac{E_\infty}{E_0}$ ranges from 0.45 to 0.55 across all timepoints and locations, highlighting the viscoelastic nature of the tissue. Permeability shows no trends across all gestation and location groups, with most values around 10^{-16} m^2. We also examined the spatial variation of material properties from the cervical canal to the vaginal wall (Fig. 3) and compared the coefficient of variation (CV), defined as the ratio of the standard deviation to the mean (Fig. 2). No difference in CV values was observed across gestational groups and anatomic regions, suggesting that the cervix exhibits a similar degree of heterogeneity in the radial direction. Among all parameters, $\frac{E_\infty}{E_0}$ displays the lowest level of variation with CV values around 0.18, while k shows the highest level of variation with most CV values above 0.8.

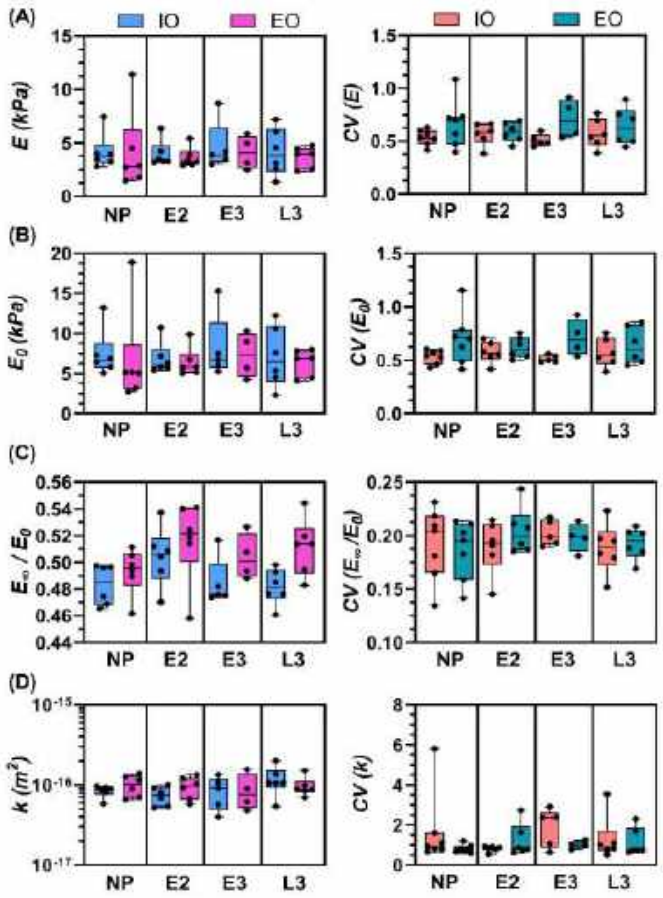

Figure 2: (A) Stiffness, (B) Instantaneous stiffness, (C) Viscoelastic ratio, and (D) Permeability of NP, E2, E3, and L3 NHP cervical tissue at IO and EO. Left: material property. Right: corresponding CV of the material property. Each symbol represents the median value of all indentation points from an individual test.

This unique dataset validates our NI protocol, demonstrating results comparable to established indentation methods. The material properties obtained with NI are compared with PVE results fit with our microindentation (2.5 mm indentor) data from the same NHP subject [3]. Those values are close in scale, especially for elastic properties like E, denoting the validity of NI as a faster, more flexible testing tool compared to microindentation. We also observed a broader distribution in values for time-dependent properties from microindentation, consistent with the findings in studies on indentation size effects [7].

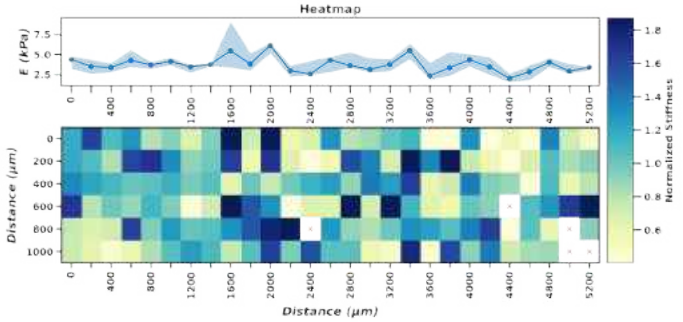

Figure 3: Representative stiffness heatmap of an NI test. Top: the median of stiffness values in each column with the deviation shaded. Bottom: spatial distribution of stiffness from the cervical canal (left) to the vaginal wall (right). Color-plotted values represent stiffness between the 10^{th} and 90^{th} percentiles, normalized to the median. Red crosses indicate failed indentation points.

DISCUSSION

Here, we characterize the time-dependent properties of the NHP cervix at distinct gestational timepoints, addressing a significant knowledge gap in tissue G&R during pregnancy. Specifically, this robust dataset, collected via NI, describes the mechanical properties of the cervix at IO and EO and the spatial variation of those properties from the cervical canal to the vaginal wall. At the length scale of NI, cervical tissue maintains consistent mechanical properties and heterogeneity across gestation and different anatomical locations. This observation agrees with our previous results using microindentation on the same subjects at a small strain regime, although contrary to results from tensile tests with large deformation and another NI study on rat cervix that cervical tissue softens at later stages of pregnancy [3, 9]. During cervical G&R, mature collagen is replaced by newly synthesized collagen to enhance tissue compliance without altering total collagen content in pregnancy [8]. We hypothesize that at the strain level of NI (5%), the collagen fiber network experiencing structural and compositional G&R is not effectively engaged, resulting in similar material property values across gestation. Additionally, the NI study, which observed reduced stiffness in rat cervix during pregnancy, employed the Hertzian contact model. This contrasts with our use of the PVE model, as the Hertzian approach focuses on the linear elastic loading regime, potentially leading to differing results.

We will further our investigation of cervical G&R by examining the gross tissue morphology through histology staining and analyzing the biochemical composition quantitatively.

OPTIMAL LATTICE GEOMETRY FOR IMPLEMENTATION IN SCOLIOTIC BRACES

Robert Rizza (1), Xue-Cheng Liu (2), Vince Anewenter (3)

INTRODUCTION

The prevalence of adolescent idiopathic scoliosis (AIS) is estimated from 2% to 3% for children between 10 and 16 years of age [1]. With this disability not only does a larger spinal curve affect posture and cosmetics but it causes pain and pulmonary function and activity of daily life deficits.

For treatment, the Thoracic Lumbar Sacral Orthosis (TLSO) has become widely used. This brace provides 3D treatment of spinal curvature by implementing a three-point loading principle, elongational, flexural and derotational mechanism. The typical design of the TLSO is a modular one with anterior and posterior polymer panels (typically made of Polyethylene), foam padding and secured with Velcro straps. Newer designs incorporate 3D printing for the panels [2-5] that exploit this manufacturing method's accuracy and speed. This has led to some advancements in manufacturing of Scoliotic braces [5].

Patient compliance with the brace is affected by the bulkiness and weight of the polymer shell. Because the polymer acts as a barrier to air flow the device is often uncomfortable and hotter which reduces compliance.

Often, small hole patterns are placed in the hard-shell of the brace to reduce weight. In addition, these holes allow for air flow which helps in preventing absorption of moisture which may lead to odor, mildew growth and in some cases Dermatitis [6].

In [5], the optimal size, shape and separation distance between the holes was obtained. Implementation of the optimal hole pattern led to a brace design which is 10% lighter than the traditional design.

Lattice structures are characterized by repeated cells of interconnected bars called "struts" that connect vertices together to form the cell. The mechanical properties of the cell is controlled by the size and geometry of the cell as well as the diameter of the strut. By properly optimizing these parameters it is possible minimize the weight of a mechanical component while maintaining the structural efficiency.

Several different geometries are possible for the lattice structure. These include: square, octagonal, triangular and hexagonal geometries.

Unlike holes, lattice structures are truly three dimensional and remove more material from the solid volume compare to hole patterns. Furthermore, lattice structures are more structurally efficient than holes as they have lesser stress concentrations.

While lattice structures have been implemented in other areas of mechanical engineering design there has been no development in utilization of these structures for Scoliotic braces. The objective of this study was to obtain the optimal lattice geometry for implementation in the polymer shell of a Scoliotic brace.

METHODS

Comparison of the various lattice geometries was achieved by constructing CAD models of standard tensile specimens using Creo® (PTC, Boston). Each specimen had a different lattice geometry. For each specimen, the strut diameter (1-3 mm) and cell size (4 - 9 mm) were varied to produce multiple designs of the same geometry.

Linear FEA simulations were carried out using Ansys (Ansys, Canonsburg, PA) for each design variation. A parametric approach was undertaken. An axial tensile force was applied ranging from 0 to 1000 N. The boundary conditions applied to the model were such that they mimic axial tensile loading of the specimen (Figure 1). One end of the specimen was fixed while at the other end, the force was applied.

The axial deformation of the specimen was obtained for each load case. From this data, the stiffness of the lattice geometry was calculated.

Material properties for the 3D printing material Duraform PA (3D Systems, Eden Prairie, MN) was used in the FEA. This material is used in the 3D printing of braces, hence its selection [5]. It exhibits linear behavior. The material has a Secant Modulus of 160 MPa and Poisson ratio of 0.40.

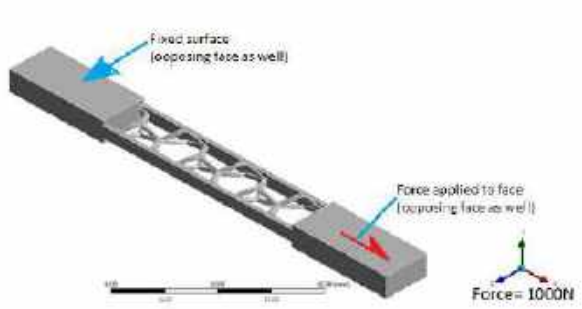

Figure 1: Boundary conditions applied to the model of a lattice specimen with a square lattice geometry.

Each specimen was 3D Printed using the SLS method at the MSOE Rapid Prototyping Center using a DTM Sinterstation 2500 plus. Five samples of each specimen design variation were printed.

For FEA validation, an MTS Alliance RT/50 was used. The specimens were tested in axial tension to fracture using ASTM D638-14 standard. The load-displacement curve was obtained from the test and the stiffness of the lattice geometry was obtained.

Since weight is an important factor in determining the optimal lattice geometry, the stiffness to weight ratio was calculated. The higher the ratio, the greater the capacity of the lattice geometry to carry load at a lower weight.

RESULTS

For the sake of brevity we have listed in Table 1 only the three geometries which give the highest stiffness to weight ratio. We see that the highest ratio was 70.04 N/mm·kg for a square geometry but there is an octagonal design which yields nearly the same value.

Table 1: Lattice geometries with highest strength to weight ratios.

Geometry	Stiffness/Weight (N/mm·kg)
Square	70.04
Octagonal	69.31
Hexagonal	63.52

Table 2 shows the peak load, and maximum extension of the three geometries when loaded to fracture. The square geometry had the highest load capacity to fracture at 295N, whereas the hexagonal geometry had the longest extension at 2.6 mm. Stress and strain are not used as the stress is an average stress in the testing but a localized stress in the FEA and hence not comparable.

Table 2: Peak load and extension to fracture of the three top geometries.

Geometry	Peak Load (N)	Peak Extension (mm)
Square	295	1.7
Octagonal	280	2.25
Hexagonal	247	2.6

In Table 3, we list the stiffness of the top three geometries from Table 1 as obtained from the FEA results and the tensile testing. We see the difference between the FEA results is relatively small. With the largest error being for the hexagonal geometry at 8.32%.

Table 3: Results of the FEA compared to the tensile testing.

Geometry	Stiffness (N/mm)		
	FEA	Testing	% Difference
Square	244.22	232.03	5.25
Octagonal	187.28	196.21	4.55
Hexagonal	245.41	226.56	8.32

DISCUSSION

As we can see in Table 1, the square or octagonal geometries give the highest stiffness to weight ratios. The difference between the two is quite small so either geometry is acceptable as an optimal geometry. The strut diameter for the square geometry is slightly larger at 1.5 mm, while the strut diameter for the octagonal geometry was 1.3 mm. Both values are greater than 1 mm, which is the lower bound for successful printing with SLS. We saw no differences in the quality of the print due to the geometry of the lattice.

In Table 2, the square geometry has the highest load carrying capacity to fracture but the extension is less than the octagonal geometry. Again, there is little difference between the square and octagonal geometries. As the octagonal geometry has a large range of extension, this suggests that the octagonal is more optimal than the square geometry.

Table 3 indicates that the FEA models are valid and may be implemented in the future for continued design of braces with lattice structures.

NECK STRENGTH AND ENDURANCE AFTER 1-HOUR EXPOSURE TO VERTICAL WHOLE-BODY VIBRATION

Ana I. Lorente, Robert S. Salzar

Center for Applied Biomechanics, University of Virginia, Charlottesville, Virginia, USA

INTRODUCTION

The vibrational environment that military helicopter aircrew experience has been related to neck and back pain. This pain may lead to injuries and incapacitations in the most severe cases. Although the prevalence is higher for the lumbar region [1], neck pain has also been related to rotary-wing missions [2, 3]. However, previous studies trying to understand how whole-body vibration (WBV) in helicopters may influence back muscle physiology have only been focused on the lumbar spine, without including any neck muscle [4].

The fatigue in the cervical spine muscles has been studied in military helicopter aircrew [5], but the literature is lacking any performance assessment right before and right after a flying exposure. This information would provide insight into short-term effects on muscle response, which could be related to neck injuries and incapacitations in a long-term scenario.

Specific training programs for the neck muscles could reduce the pain related to flight missions but would be more effective if the effects on the neck musculature of these flights and their vibrational environment were more well understood.

The goal of this study was to quantify if the strength and endurance of neck muscles are altered due to a 1-hour vibrational exposure that simulates a helicopter flight. Our hypothesis was that muscle performance would decrease after the vibrational load exposure.

METHODS

Fourteen healthy subjects (7 males, 7 females) participated in this study (25.7 ± 2.9 years-old, 1.70 ± 0.08 cm, 68.9 ± 13.6 kg). Volunteer exclusion criteria included neck or spine injuries/surgeries, being prone to motion sickness, and being pregnant. All participants gave their consent following the test protocol approved by the University of Virginia Institutional Review Board for Health Sciences Research (HSR220143) and the U.S. Army Office of Human and Animal Research Oversight (OHARO, W81XWH-18-9-0001).

Three isometric strength exercises were performed: (1) head-neck forward pushing, (2) head-neck backward pushing, and (3) unilateral 100° shoulder abduction [6, 7]. The three exercises were performed while being seated, with the two arms (head-neck exercises) or only one arm (shoulder exercise) positioned across the chest. The subjects were instructed to gradually increase their effort to maximum, having 3 seconds to hold that force, and 3 seconds to release it [7]. This rate was indicated with an audio saying “start”, “maximum”, and “release”. There were 3 repetitions for each exercise with a 2-minute rest between repetitions. After the 3 repetitions, the endurance assessment was performed holding 70% of the highest measured force. Participants held this effort as long as possible, up to 3 minutes.

The strength and endurance were evaluated right before and after being exposed to 1-hour of vertical whole-body vibration at 0.2 g and 4 Hz. During the hour, the participants were seated on a metal seat geometrically representative of a H-60 helicopter seat. Their hands and feet were on the hand controls and pedals of a flight simulator. The back support consisted only of two lateral vertical posts joined by two horizontal wires. This back support allowed the use of motion sensors. The participants were wearing an HGU-56/P helmet during the vibrational load exposure. The size of the helmet (small, medium, large) was always individually selected for each subject.

Paired T-test was used to compare the results before and after WBV ($p < 0.05$).

RESULTS

After 1-hour exposure to a vertical vibrational load simulating helicopter flight, there was no significant change in neck muscle strength (Figure 1). A slight increase in the measured force was even observed in the head-neck backward pushing exercise after the vibrational load exposure (from 127.2 ± 59.5 N to 134.6 ± 61.9 N). The same average value was obtained in both measurements for the head-neck forward pushing (108 N, Table 1).

However, a statistically significant decrease in muscle endurance was detected in the three exercises post-vibrational exposure, with the most notable changes in the head-neck forward pushing and the shoulder abduction, both by 34% (Table 1). The decrease in the head-neck backward pushing exercise was 14%.

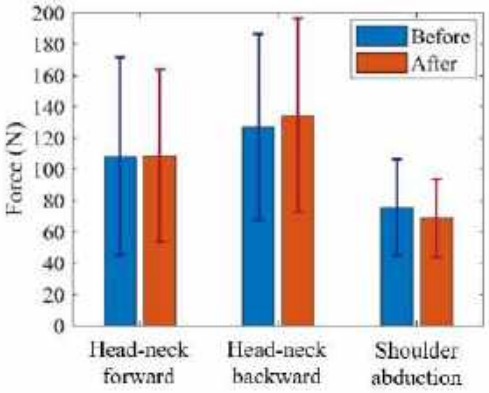

Figure 1: Force before and after the vibrational exposure for the three exercises.

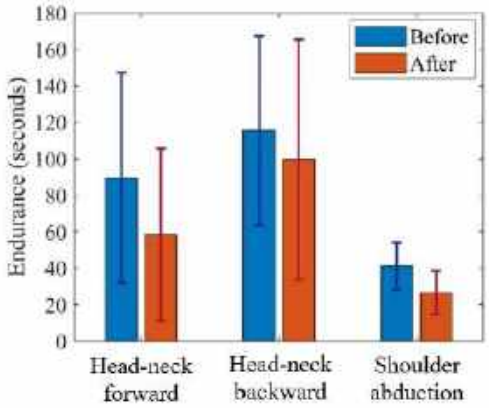

Figure 2: Endurance (seconds holding the effort) before and after the vibrational exposure for the three exercises.

Table 1: Force (Newtons) and endurance (seconds) before and after the vibrational exposure.

	Head-neck forward	Head-neck backward	Shoulder abduction
Force (N)			
Before WBV	108.4 ± 63.3	127.2 ± 59.5	75.6 ± 30.7
Range	27.0 – 244.0	58.0 – 256.9	20.0 – 127.4
After WBV	108.7 ± 55.0	134.6 ± 61.9	68.8 ± 25.1
Range	42.5 – 191.8	66.0 – 285.0	28.0 – 115.0
P-value	0.981	0.260	0.050
Endurance (seconds)			
Before WBV	90 ± 58	116 ± 52	41 ± 13
Range	22 – 180	43 – 180	17 – 58
After WBV	59 ± 48	100 ± 66	27 ± 12
Range	12 – 180	17 – 180	11 – 54
P-value	*0.032*	*0.029*	*< 0.001*

DISCUSSION

The endurance performance decreased after 1-hour of vibrational load exposure while muscle strength remained the same. This result indicates that a focus towards increasing muscle endurance may be relevant to decrease the neck pain seen in military aircrew. Improving endurance instead of strength when working on muscle performance for aircrew members has been previously discussed by Harrison et al. (2009) [5]. Our results support this approach as the maximum force remained equal after the vibrational load exposure.

Opposite to what one might think, lower muscle strength in the neck has not been related to neck pain in aircrew members. A trend showing lower muscle strength in subjects with neck pain was presented with 117 helicopter crew members (29% with neck pain), but the trend had no statistical significance [8]. Two other studies did not find any relationship between neck strength and neck pain: one had 40 pilots and flight engineers (53% with neck pain) [3] and the other had 30 helicopter pilots (50% with neck pain) [2]. However, this last study did find lower strength in the neck extensors in fighter pilots with neck pain, without observing any difference in the neck flexors [2].

Although the WBV exposure of helicopters has been related to back injuries, this may not be the only cause, and the posture held during flights may also contribute [1]. The subjects of the present study were not instructed to hold a specific back posture, but were told to keep their feet on the pedals and to hold the hand controls. The backrest design of the seat did not replicate a real helicopter seat. It only consisted of two horizontal wires at the thoracic and lumbar levels. This modification is unlikely to affect the neck muscle performance. Furthermore, real helicopter pilots often hold a posture with the shoulders leaning forward ("helicopter hunch"), moving the shoulders away from the backrest.

One limitation of the present study is the use of helmets with subjects that are not conditioned to wearing them. The helmets weighed 1.4 kg. The results presented herein may differ if this same protocol is followed by military personnel who are used to wearing helmets.

The vibrational load experienced by the subjects reproduced the vertical load of an actual helicopter in flight, but not the associated motions typical of crew duties. Also, actual flights usually last more than 1 hour and helmets can be heavier than 1.4 kg. This same protocol, along with the strength and endurance exercises, could be applied to personnel before and after real helicopter flights. Actual helicopter flights may also decrease the endurance performance of neck muscles, as it was observed in this 1-hour simulated flight. Understanding how military vibrational environments may affect endurance in the short and long terms would aid in the design of specific training programs with a goal of decreasing neck pain in helicopter aircrew members.

INTRODUCTION

In the late 20th century, metal-on-metal hip implants, primarily made of cobalt and chromium alloys, gained popularity for their durability, especially among younger and more active patients [1,2]. However, the degradation of these implants containing cobalt (Co) and chromium (Cr) has been associated with the release of heavy metal ions and increased risk of bone fracture. Given that the predominant mineral in bone, bioapatite, has a high propensity for cationic substitutions, it is likely that these heavy metals could be up taken by bone mineral during bone formation. This is expected to have significant effects on the crystal mechanics and structure.

The maturation of apatite during and after bone formation involves the transformation of small, disordered crystals of apatite within the collagen matrix into larger crystals with increased carbonate content and crystallinity. This maturation enhances the bone's mineral density and mechanical strength. However, it is unknown how cationic substitutions, such as the inclusion of Co and Cr, affect this maturation process and in turn bone health.

Due to the difficulty in isolating apatite crystals from bone tissues, biomimetic apatite formation, a process replicating natural mineralization processes, becomes a critical tool in understanding mineral behaviors. This approach enables the creation of materials that closely mirror bone mineral composition and structure, facilitating improved integration and functionality in the laboratory.

Here we are exploring two methods for the formation of mature cobalt (Co) and chromium (Cr) substituted apatite's. The Maturation method [3] and the Direct Precipitation method [4] replicate different maturation processes to determine the effects of Co and Cr substitutions.

METHODS

Maturation method for Apatite Formation: Apatites were precipitated by combining phosphate and calcium containing solutions. Solution A was made by dissolving 3.12g calcium nitrate and either 0.53g chromium nitrate or 0.39g of cobalt nitrate in 45mL Milli-Q water. Solution B was formed by dissolving 5.40g sodium bicarbonate and 5.40g ammonium phosphate in 90mL Milli-Q water. The solutions were combined, agitated, and aliquots of apatite were collected after 7, 14, and 21 days of maturation.

Direct Precipitation method for Apatite Formation: Three solutions were prepared. 5.40g sodium bicarbonate in 180mL water was heated to ~70°C in a round bottom flask. Simultaneously, 3.13g calcium nitrate and either 0.39g of cobalt nitrate or 0.53g of chromium nitrate were dissolved in 40mL of water. Additionally, 5.40g of ammonium phosphate was dissolved in 40mL water. These two solutions were placed in burettes and were titrated simultaneously at 1mL/min until exhaustion. pH was maintained at ~9 with 0.5 M sodium hydroxide, and the reaction was digested for 2 hours at pH 9 and 65°C. This process allows for rapid maturation of the crystals.

Filtering and drying: After collection, the powders were filtered, rinsed three times with Milli-Q water, and dried overnight at 60°C. The powders were ground and stored in a closed glass vial.

XRD: Crystals were analyzed via X-ray diffraction using a Bruker D2 Phaser X-ray Diffractometer. Operating at 30kV and 10mA, the mineral powders were analyzed from 20-80° 2θ with a step size of 0.02°, and an acquisition time of 1.5 seconds. The 002 and 310 peaks were fit as pseudo-Voigt peaks in DIFFRACT.EVA software. The crystal d-spacing along the (002) and (310) peaks were determined from the peak locations. The full width half max (FWHM) of the (002) peak was used as an inversely proportional measure of the crystallinity.

Raman: Compositional measures were made using a Witec α300 Raman spectrometer. Ten spectra were acquired for each powder with a 785 nm laser using a 50x objective and an acquisition time of 45x2sec. The 960 cm^{-1} PO_4^{3-} and 1070 cm^{-1} CO_3^{2-} peaks were fit as Lorentzian peaks using Witec Program 5.1. The PO_4^{3-} peak width is inversely proportional to crystal atomic order. Carbonate content was determined from the area ratios of the 1070/960 peaks (CO_3/PO_4). Only cobalt containing apatite's were assessed via Raman due to chromium fluorescence affecting the Raman signal.

RESULTS

Apatite formation: Cobalt and chromium apatites were synthesized using both the maturation method and the direct precipitation method. The maturation method resulted in subtle yet noticeable variations in color, with the most mature apatites at 21-days exhibiting the darkest color for both cobalt and chromium. In contrast, the direct precipitation method yielded a color consistent with the 21-day matured apatites. Both methods produced fine powders.

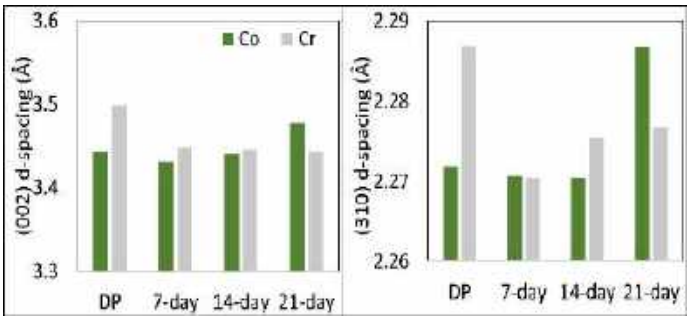

Figure 1: d-spacing of the (left) (002) and (right) (310) peaks for Cr and Co containing apatites.

XRD: The (002) d-spacing decreased with maturation in the chromium apatites while it increased in the cobalt apatites, Fig 1. While the (310) d-spacing also increased with maturation in chromium apatites, it exhibits an initial decrease followed by a sharp rise at 21 days in the cobalt apatites. The width of the (002) and (310) peaks generally decreased with maturation for the Cr apatites, Fig 2. These trends are much less clear for the Co apatites.

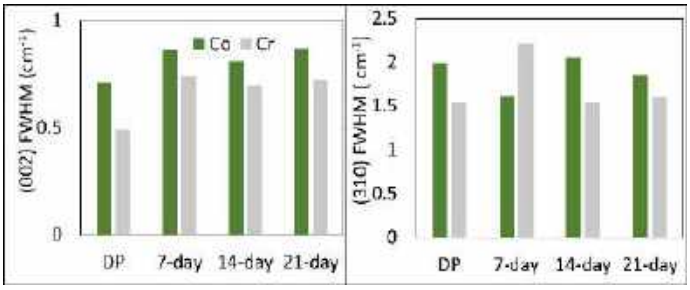

Figure 2: FWHM of the (left) (002) and (right) (310) peaks for Cr and Co containing apatites.

Raman (Co-only): The location of the PO_4^{3-} peak increased in early maturation while the direct precipitation method resulted in peak locations similar to mature apatite (not shown). The width of the PO_4^{3-} peak decreases significantly over time with maturation, while the direct precipitation method consistently yields the smallest width, Fig 3. The carbonate to phosphate ratio (CO_3:PO_4) exhibits an increasing trend over time with the maturation method, with the direct precipitation method having the highest ratio.

DISCUSSION

Traditional biomimetic apatite maturation exhibits a number of key features including increased (002) and (310) d-spacing dimensions, increased crystal size, increased carbonate content and increased crystallinity [5]. The substitution of Co and Cr into the apatite structure could have significant effects on maturation of apatite resulting in compromised bone properties.

Much like traditional maturation, the cobalt containing apatite's exhibit simultaneous expansion of the (002) and (310) d-spacing suggesting that the cobalt does not inhibit lattice modifications associated with maturation. On the contrary, the presence of Cr leads to a decrease in the (002) d-spacing. This points to a modified maturation process possibly resulting from chromium substituting into the apatite as the anion chromate instead of the chromium cation [6]. Interestingly, despite the changes in lattice spacing, there is not an associated change in the mineral crystallinity. Crystallinity is inversely proportional to the FWHM of the (002) peak and thus is expected to decrease with maturation. This decrease is observed in the Cr-apatites but not the Co apatites. Crystallinity can be controlled by either crystal size or ordering of the crystalline core. Changes in the d-spacing could thus be isolated from the crystallinity if the latter is primarily being controlled by changes in crystal size. Interestingly, for the Co apatite's there is a distinct decrease in the width of the PO_4^{3-} peak with increasing maturation suggesting an increase in atomic order. The improved atomic order and changes in d-spacing suggest that Co-apatites may undergo traditional maturation while having limited effects on crystal size. This is further supported by the increase in CO_3^{2-} seen with Co-apatite maturation. Together these results suggest that Co does not significantly affect apatite maturation.

Chromium apatites exhibits the reverse behavior with an unexpected change in d-spacing but the expected increase in crystallinity with maturation This could be indicative of an increase in crystal size with Cr substitutions. Due to Cr fluorescence, it is not possible to comment on the Cr apatite's atomic order or CO_3^{2-} content. To date, the results suggest that Co- has a less impactful effect on the maturation of biomimetic apatites as compared to Cr. Further investigations will include further determinations of crystal atomic order via FTIR, measurement of the crystal size via TEM, compositional investigations with ICP-OES, and finally mechanical testing via synchrotron X-ray diffraction.

INTRODUCTION

In vitro disease modeling strategies enable a better understanding of pathophysiological pathways leading to disease progression and improve decision-making for patient treatments [1-4]. In cancer development, disease modeling platforms have been developed to mimic the mechanistic pathways of cancer progression and drug sensitivity. Nonetheless, most of these strategies rely on 2D arrangements, limiting their physiological relevance [5-9]. Cancer organoids have been shown to be reliable platforms for modeling tumor growth and drug screening due to their ability to preserve physiologically relevant aspects of native tumor microenvironments such as cell-cell interactions, proliferation, mechanical stimuli, and tissue development [10]. However, their widespread usage to guide clinical decisions is hindered by time-limited production of organoids and their inherent lack of reproducibility. Hence, a platform for producing a high quantity of reproducible organoids is required to provide better models for cancer progression and drug screening.

METHODS

We have developed a home-made pipette microfluidic device for the high-quantity generation of cancer micro-organoids via cell encapsulation by droplet emulsion for high-throughput drug screening. We synthesized norbornene-modified hyaluronic acid (NorHA) polymers, which serve as extracellular matrix (ECM) mimics, to create a suitable cell-encapsulation platform. The viscosity of the polymer solution was adjusted to enable its extrusion by a home-made elliptical pipette for droplet generation with suspended ovarian (OVCAR 5) and prostate (LNCaP) cancer cells ($4x10^6$ cells/mL) via water-in-oil (W/O) emulsification.

RESULTS

An automated system for pipetting was used to generate microgels and test the effect of pipetting cycles and flow rate on the droplets sizes (**Fig. 1A**). The results showed that by increasing the pipetting cycles the uniformity of the droplets was improved (**Fig. 1B**). Moreover, for the cell encapsulation we observed that upon separation, a large quantity of droplets coalesced releasing cells that remained floating freely, which suggested that the system was unoptimized (**Fig. 1C**). Hence, further experiments were carried out to increase the polymer concentration up to 20 mg/mL, being able to observe a higher microgels separation efficiency (up to 80%), with fewer free-floating cells (**Fig. 1D**). The permeability of the microgels was evaluated using TRITC-Dextran (4400 Da), which revealed that fluorophore internalization after 30 minutes, with accumulation and aggregation seen after ~1 hour (**Fig. 1E**). The mitochondrial activity assessment exhibited an increase in cell count was ~47% (**Fig. 1F**), with the relative proliferation of encapsulated cells being slightly lower than in monolayer culture (**Fig. 1G**). Screening with doxorubicin (DOX) was used to model the sensitivity of the micro-organoids towards therapies administration.

DISCUSSION

Overall, the developed microgels platform showed suitability for the encapsulation of different cancer cell lines and organoids' growth, which would allow the screening of multiple tumor microenvironment conditions. The versatility of the technology allows it to be scaled up with multi-channel and/or robotic systems and integrated with flow cytometry to realize a high-throughput platform for patient-derived micro-organoids generation and drug screening.

INTRODUCTION

Coronary artery bypass graft (CABG) surgery is one well-established intervention for patients with coronary artery disease, which entails the grafting of harvested blood vessels to bypass stenotic regions of the coronary arteries and improve myocardial perfusion. However, graft remodeling and failure through total occlusion can occur, limiting the long-term treatment efficacy. While the precise mechanisms behind graft failure remain unknown, hemodynamic quantities such as wall shear stress (WSS) are thought to potentially play a role [1]. Despite advances in medical imaging technologies, however, non-invasive measurements of coronary artery flows *in vivo* are difficult to obtain due to the imaging resolution required.

Computational fluid dynamics (CFD) is an emerging method in which the Navier-Stokes equations are numerically solved to estimate blood flow and other hemodynamic quantities in human vasculature. These simulations can be made patient-specific by integrating information from medical images and by tuning simulation boundary conditions based on clinical information. Additional assumptions can be introduced to improve the faithfulness of the simulations, such as the inclusion of vessel wall compliance [2]. However, an open question is how vessel wall compliance would affect hemodynamics in coronary artery bypass grafts, which is an important consideration for clinical translation. Given the additional computational time and uncertainty in vessel wall material properties, researchers often must make a pragmatic consideration of whether the additional computational complexity of implementing a compliant wall model provides more accurate and clinically relevant hemodynamic information that cannot be resolved using a rigid wall model alone.

In this study, we compared hemodynamic measures computed from CFD simulations employing different wall models to quantify the impact of compliance on clinically relevant metrics in a cohort of CABG surgery patients. As we observed differences in the hemodynamic metrics computed from rigid and compliant wall models, we also propose a pragmatic approach to rescale rigid wall WSS based on a population average to estimate compliant wall hemodynamics in a cohort of bypass grafts and evaluate when such an approach may be appropriate to reduce computational time and model complexity.

METHODS

The retrospective study population consisted of 10 patients who underwent coronary artery bypass graft (CABG) surgery at the Sunnybrook Health Sciences Centre from November 2017 to August 2018. Imaging and computational fluid dynamics simulations were performed as described in previous studies [3]. Briefly, cardiac CT and 4D flow MRI were obtained from study participants 3-6 weeks after surgery. Cardiac CT images were segmented using SimVascular (Stanford University, Stanford, California) to generate 3D meshes of each patient's aorta, supra-aortic branches, coronary arteries, and implanted bypass grafts, with local element size determined through spatial resolution studies. Three-element Windkessel models were used as outlet boundary conditions at the descending aorta and supra-aortic branches, while lumped parameter models were used to estimate coronary boundary conditions. Parameter values for boundary conditions were iteratively tuned to match patient cuff-measured blood pressure. Flow to the coronary arteries was assumed to be 4% of the total cardiac output [4].

In this study, three different wall models were compared: compliant, rigid, and rescaled. Compliant wall simulations were performed for each patient on the individual left and right coronary territories using the coupled momentum method implemented in SimVascular. The individual coronary territories were simulated separately due to the prohibitively high computational cost of performing compliant simulations of the full model of the aorta and both coronary trees. Inflow boundary conditions at the origins of the left and right coronary trees were obtained from post-processing of the rigid wall CFD.

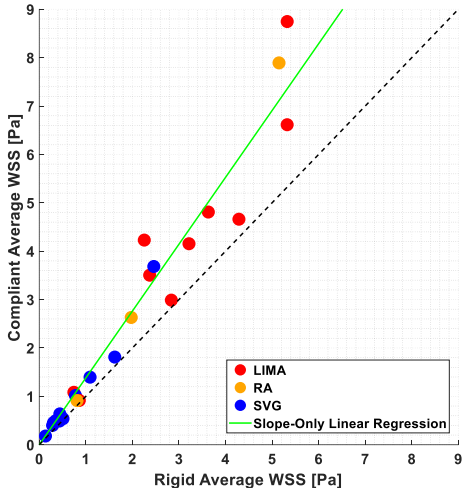

Figure 1: Average WSS from rigid and compliant models.

Rigid wall simulations were also performed for each patient on the full model of the aorta, supra-aortic branches, coronary arteries, and bypass grafts. The inflow boundary condition at the ascending aorta was set to be the pulsatile blood flow rate measured from 4D flow MRI.

Finally, we investigated a linear rescaling approach to reduce some of the discrepancies between rigid and compliant model WSS and to estimate compliant wall hemodynamics using rigid wall simulations alone. To calculate the rescaling factor, the average WSS in each graft was computed for both rigid and compliant wall simulations, and a slope-only linear regression model was applied on data from odd-numbered patients as follows:

$$\tau_c = \beta \tau_r \quad (1),$$

where τ_r is the WSS magnitude from the rigid model, τ_c is the WSS magnitude from the compliant model, and β is the linear regression slope. This rescaling factor was then applied to τ_r in grafts from even-numbered patients. As this rescaling approach requires no additional simulation time, its computational cost is essentially the same as the original rigid wall simulation.

For each wall model, we computed hemodynamic metrics in bypass grafts that may be of clinical interest, including average WSS, the temporal and spatial average of WSS across a vessel over a single cardiac cycle, and abnormal WSS area, the proportion of vessel wall area that is below a clinically relevant threshold (<0.5 Pa and <1 Pa) [5]. Bland-Altman limits of agreement were computed to compare the rigid and rescaled models against the compliant model, providing an estimate of the range of expected discrepancies for each hemodynamic metric.

RESULTS

Figure 1 shows a scatterplot of average WSS in each of the 24 grafts in the study for both the rigid and compliant wall models. In our cohort, although average WSS was correlated between the rigid and compliant models (R^2=0.949), the rigid model tended to underestimate average WSS compared to the compliant model. From a linear regression using only odd-numbered patients, the slope was 1.265. We then applied this slope to τ_r in the rescaled model and compared hemodynamics from even-numbered patients across all 3 models.

Table 1 shows a summary of the hemodynamic metrics computed in each wall model for even-numbered patients, and Table 2 shows the limits of agreement when comparing the rigid and rescaled models to the compliant model. The average WSS and abnormal WSS areas (<0.5 Pa and <1 Pa) in the rescaled model were closer in agreement to the compliant model compared to the rigid model, as seen by the smaller mean differences and the narrower confidence intervals in Table 2.

Table 1: Summary of hemodynamic metrics (mean ± SD).

Graft Type	Wall Model	Average WSS [Pa]	Abnormal WSS Area (<0.5 Pa) [%]	Abnormal WSS Area (<1 Pa) [%]
LIMA (n=5)	Compliant	5.32 ± 1.94	0.4 ± 0.3	1.7. ± 1.4
	Rigid	3.74 ± 1.15	0.8 ± 1.0	3.6 ± 5.9
	Rescaled	4.73 ± 1.46	0.5 ± 0.5	2.3 ± 3.7
RA (n=1)	Compliant	7.89	0.002	0.011
	Rigid	5.15	0.004	0.056
	Rescaled	6.51	0.004	0.004
SVG (n=4)	Compliant	0.89 ± 0.41	29.6 ± 33.6	73.7 ± 22.8
	Rigid	0.69 ± 0.31	44.3 ± 40.5	83.8 ± 14.8
	Rescaled	0.87 ± 0.40	35.8 ± 35.8	72.8 ± 21.7

Table 2: Bias and limits of agreement between wall models.

Hemodynamic Metric	Difference (Rigid – Compliant)		Difference (Rescaled – Compliant)	
	Mean	95% CI	Mean	95% CI
Average WSS [Pa]	-1.13	(-3.48, 1.21)	-0.43	(-2.11, 1.23)
Abnormal WSS Area (<0.5 Pa) [%]	7.5	(-23.9, 38.8)	3.2	(-16.6, 23.1)
Abnormal WSS Area (<1 Pa) [%]	2.5	(-6.6, 11.6)	-0.1	(-4.2, 4.0)

DISCUSSION

Our findings are somewhat in agreement with previous studies that have compared rigid and compliant wall simulations in the coronary arteries, generally concluding that the time-averaged WSS is correlated between the two models [6]. While previous studies showed more agreement between rigid and compliant wall simulations, this discrepancy may be due to differences in anatomy and in study methodology. The present study includes a sample size of 24 bypass grafts from 10 patients, larger than in previous studies. Additionally, the compliant wall simulations in this study were based on the left and right coronary territories alone rather than a full model that includes the aorta and supra-aortic branches due to the high computational cost.

While our findings suggest that rescaling may ameliorate some of the discrepancies in WSS between rigid and compliant models, future work should validate the rescaled model in a prospective and larger patient cohort. Depending on the application, a pragmatic approach of rescaling WSS from rigid wall simulations based on a cohort of patient anatomies may be considered in lieu of performing computationally expensive compliant wall simulations, especially in the absence of patient-specific information on wall material properties.

A NOVEL MILLIFLUIDIC DUAL-FLOW BIOREACTOR FOR RECAPITULATING SHEAR STRESS *IN VITRO*

Fariha N. Ahmad, Katrina Cao, Jane Grande-Allen

Department of Bioengineering, Rice University, Houston, Texas, United States of America

INTRODUCTION

Gastrointestinal diseases (GDs) involving pathogens such as enteroaggregative E. coli (EAEC) lead to child malnutrition and cognitive impairment in low-resource settings.[1–3] Despite the high morbidity and costs associated with bacterial-associated GDs, it is difficult to elucidate the mechanisms involved in the bacterial infection of small intestinal epithelium (SIE) in vitro. This is in part due to the complex microanatomy governing the physiology of the SIE, which cannot be recapitulated using standard cell culture techniques.[4]

The microenvironment of the SIE is affected by a variety of factors, including apical and basolateral flowstreams. Flow above and below the SIE is responsible for transport. Traditional cell culture techniques do not incorporate flow. While new tools have been developed to better represent these factors, none modelling the effects of flow to create representative models of the SIE remains challenging. Thus, cell culture frameworks more closely resembling the anatomy of the small intestine are necessary to effectively study the mechanisms of bacterial infection.

To address this, we have developed a novel biomimetic cell culture platform better representing the shear stress experienced by the SIE. The dual-flow device (DFD) was designed as a millifluidic apparatus capable of applying apical and basolateral flow. Additionally, the DFD was cheaply produced and easily disassembled by users desiring to harvest cells cultured within the device. The goal of this project is to design, manufacture, and validate biocompatibility of the DFD using Caco-2 cells, a model intestinal cell line. We hypothesized that the DFD could yield leak-proof flow following assembly, autoclaving, and perfusion. We also hypothesized that culturing Caco-2 cells in this device will yield a cell viability of at least 90%. In the future, this platform will enable accurate modeling of human intestinal organoid (HIO) response to bacterial infection.

METHODS

DFD Fabrication. Previously, our lab created a millifluidic perfusion cassette which applied flow apically over cell monolayers cultured in a chamber with an area (0.33 cm^2) similar to a 96-well plate well (0.32 cm^2).[6] When designing the DFD, we adopted the design of this cell culture chamber to create a bioreactor to apply physiological flowstreams over and under cells seeded on a semipermeable membrane (Figure 1). The DFD and casing components were designed using Solidworks. Computational fluid modeling (ANSYS) and Equation 1 were used to ensure that resulting shear stresses were within the physiological range (0.002-0.08 dyn/cm2).[7] A variety of flow rates were used for the experiments described below.

$$\tau = \frac{6 \cdot \mu \cdot Q}{w \cdot h^2} \quad (1)$$

Components were fabricated using the Formlabs Form3B printer and were printed using BiomedClear, a medical-grade resin produced by Formlabs. Gasket-like compressors designed using Solidworks were printed on the Form3B printer using Elastic 80A resin. After completing post-processing wash and UV-cure steps, the DFD bioreactor was assembled using 0.4 micron transparent PETE membrane, vacuum grease, eight 4-40x1/2" screws, and two 25x25 mm cover glasses (Figure 1). The assembled bioreactor was then sterilized by autoclaving for 30 min at 121°C. Silicone tubing (1/16" ID x 1/8" OD) was sterilized separately.

DFD Fabrication Validation. To assess sterility and leakproof flow, DI water colored with red and blue liquid food dye was perfused through the system for 48 hours at 100 µL/hr. DI water was loaded into 5 mL syringes, attached to the silicone tubing with female-Luer hose-barb adaptors. The syringes were compressed using a Harvard Apparatus syringe pump. Following perfusion, the DFDs were visually observed for leaking. Perfused DI water will be analyzed for changes in absorbance—demonstrating mixed, leaking flowstreams—using

spectroscopy. Additionally, DI water was added to tryptic soy agar plates, incubated for 2 days, and observed for bacterial colony growth.

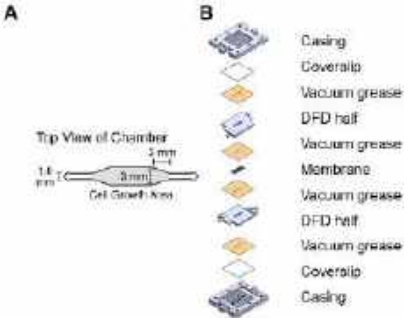

Figure 1: A) DFD cell culture chamber and B) assembly schematic.

Caco-2 Biocompatibility Studies. Following DFD fabrication validation, Caco-2 cells were cultured on the apical side of the membrane in the device for two days to assess the biocompatibility of the DFD. DFDs were coated with collagen-IV (33 mg/mL) diluted in 100 mM acetic acid overnight before seeding cells. Caco-2 cells were cultured for 4 days in media before passaging and seeding at a cell density of $3x10^5$ cells/cm^2. Media included high-glucose DMEM supplemented with 1% (v/v) nonessential amino acids, 10 mM HEPES, 100 U/mL penicillin/100 µg/mL streptomycin, and 10-20% fetal bovine serum. Cells were allowed to adhere to the membrane for one day before media perfusion started. After two days, the DFD was disassembled, and the cell-laden membrane was added to a 6-well plate. Cell viability was evaluated fluorescently using calcein-AM and ethidium homodimer (live-dead), with Hoechst used as a DNA counterstain. Caco-2 monolayer integrity, representing adherence, proliferation, and confluence, will be completed using immunofluorescent staining of the tight junction protein occludin.[8] Caco-2 cells cultured in Transwell inserts will serve as positive controls. All experiments will be conducted in technical triplicates. Data will be summarized using means and standard deviations. Statistical analysis will be performed using a Student's t-test or ANOVA with a post-hoc Tukey's test. Significance will be defined as $p < 0.05$.

RESULTS

Printing and post-processing procedures for the DFD, casing, and compressor components were adapted and optimized from Formlabs materials recommendations. We found that decreasing the size (0.45 mm) and density (0.5) of supports prior to the printing process, and sanding components after UV curing, allowed for the creation of smooth surfaces that enabled replicable assembly of the DFD bioreactor.

We then tested the ability of the DFD to maintain leakproof-flow. Colored DI water was successfully perfused through the DFD, allowing visual confirmation of leakproof-flow (Figure 2). Additionally, Caco-2 media perfused through the DFD and cultured on tryptic soy agar plates showed no sign of bacterial colony growth.

Figure 2: DFD prototype showing leakproof flow.

After culturing Caco-2 cells in the DFD, the cell-laden membranes were transferred to a 6-well plate, necessarily exposing the cells to the vacuum grease on the membrane. Cell viability was analyzed using live-dead staining (Figure 3) and was calculated to be 97% following two days of exposure to vacuum grease. Additionally, the vacuum grease appeared to contain cell growth to the intended cell culture chamber.

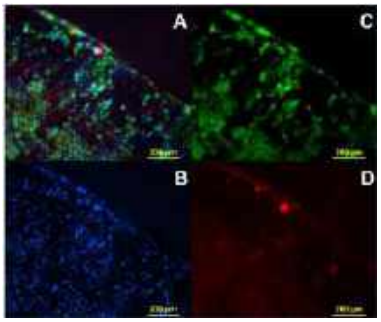

Figure 3: Viability staining of cells cultured in the DFD. A) Overlay of B) Hoechst nuclear, C) live and D) dead staining of Caco-2 cells.

DISCUSSION

We have successfully fabricated the DFD bioreactor and have refined manufacturing techniques to recreate leakproof flow. Preliminary studies have shown that DFD sterilization is successful, with no growth of bacterial colonies or contamination of Caco-2 cultures observed.

Preliminary biocompatibility studies involving Caco-2 cells seeded within the DFD have shown that Caco-2 cells can adhere to and stay viable in the DFD. Caco-2 cells have also shown the ability to survive following perfusion at physiologic shear stress. After subjecting the cells to perfusion, the DFD was disassembled to perform fluorescent staining in a 6-well plate, exposing the Caco-2 cells to vacuum grease for an additional two days. The presence of vacuum grease did not appear to negatively affect the viability of the cells. Additionally, the presence of the vacuum grease, which was used as leakproof sealant, appeared to serve as another control of cell culture area on the membrane. This alleviated any concerns of uncontrolled cell growth in the case of nonvisible leaking. In future studies, Caco-2 cells will be cultured in the DFD for longer time periods, fluorescent staining will be attempted within the assembled DFD, and occludin staining will be completed. Then, HIOs will be cultured in the DFD.

Here we have developed a new biomimetic tool capable of recapitulating the shear stresses of the SIE *in vitro*. Previously developed tools have had significantly smaller cell culture areas, have complicated assemblies, or do not account for apical and basolateral flow.[6,9-10] The DFD resolves these limitations; however, the assembly process can be labor intensive. This is being refined by creating a screwless design, making assembly/disassembly easier. By creating a millifluidic bioreactor with few components, we can create more physiologically-relevant *in vitro* models for studying disease pathology and, in the future, therapeutics.

INTRODUCTION

Traumatic brain injury (TBI) remains a significant burden to the public health system, affecting approximately 1.7 million Americans every year [1, 2].Current technologies to detect TBI rely primarily on the Glasgow Coma Scale, and neuroimaging, but their limitations in terms of accuracy and cost prevent them from effectively assessing the severity of the injury [3]. Thus, a new area of research focused on detection methods using TBI-specific biomarkers has sprung up over the last years. Two notable TBI-biomarkers, GFAP and UCH-L1, have been granted FDA approval to be used in a blood test to identify intracranial lesions, which are indicative of moderate to severe TBI [4]. This is accomplished thanks to the fact that the brain blood barrier (BBB) is compromised in moderate to severe cases of injuries, which facilitates high concentrations of biomarkers to travel through the bloodstream. However, 75-90% of TBI cases in the U.S. are mild-TBI (mTBI) in which the BBB remains largely intact, severely restricting the flow of biomarkers for detection [3, 5], having spurred significant developments toward ultra low concentration detection methods. Furthermore, the temporal profiles of mTBI biomarkers and their relation with injury severity, strain, and strain rate are not well understood. *In vivo* studies have shown considerable variability in the release profile of biomarkers, such as GFAP, UCH-L1, and IL-6, some of which are detected <6 h to several days post-injury and with concentrations as low as 2 pg/mL [6, 7]. Although *in vivo* studies present a more accurate depiction of mTBI, they lack the needed access for resolving the critical spatiotemporal expression profiles for each biomarker of interest.

To address this gap, we have developed a novel *in vitro* microfluidic platform that enables the controlled injury of cortical spheroids at relevant strain and strain rates. This innovative approach allows for a more precise study of the release of mTBI-relevant biomarkers, providing valuable insights into their spatiotemporal expression profiles.

METHODS

Cortical spheroids were selected as an *in vitro* representation of the brain due to their ability to mimic both physiological and mechanical properties observed *in vivo*, including the presence of diverse neural subtypes, electrical activity, and stiffness [8]. Using established protocols, primary cortical tissues from P0-P1 Sprague-Dawley rat pups were isolated and subsequently placed in 2% agarose μ-molds for self-assembly over a period of 14 days. A novel μ-fluidic platform was developed to induce controlled injury to the living spheroids.

The construction of a three-layer PDMS μ-fluidic chip involved designing three master molds: (1) a spheroid distribution layer, (2) a compression layer, and (3) a pressure layer (Figure 1a). After alignment and assembly, the spheroids were introduced into the distribution layer (Figure 1b) and then selectively transported through μ-channels using a microscope-assisted pick-and-place system (Figure 1c). The compression layer, comprising PDMS pillars, could be elevated through a pressure differential in the third layer, effectively trapping the spheroids (Figure 1d). Continuous

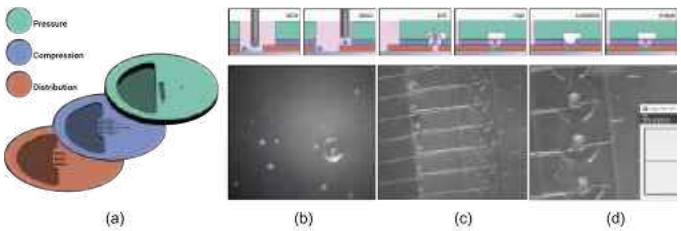

Figure 1: (a) Three-layer chip design. (b) Spheroids being picked and placed into the chip. (c) organoids being placed inside the μ-channels. (d) Trapped spheroids before injury. Microscope images taken with a 4X objective.

media flow through the channels ensured a constant supply of nutrients to the spheroids. To induce compressive injury, the pressure within the third layer was adjusted at a fixed strain and strain rate.

Cell viability assays were deployed at 1 and 24 hours post-injury using Hoechst-33342 for nuclear staining and Ethidium Homodimer-1 to identify deceased cells. These assays were captured using a Nikon confocal microscope. Following imaging, the tissues were fixed and stained for GFAP and β-III tubulin to examine structural changes in astrocytes and microtubules post-injury.

RESULTS

Our innovative μ-fluidic platform, designed for inducing highly controlled and repeatable mechanical injury to cortical spheroids, has demonstrated the ability to simulate mild traumatic brain injury (mTBI). Initial findings for a 25% strain indicate that the custom microscope-assisted pick-and-place system does not impact the viability of the control samples, ensuring a consistent baseline for data collection (Figure 2 left). Furthermore, following the induction of mechanical injury by compressing the cortical spheroids by 25%, an average of 32% of cells exhibited post-injury death, compared to an average of 26% for the control samples (Figure 2 right).

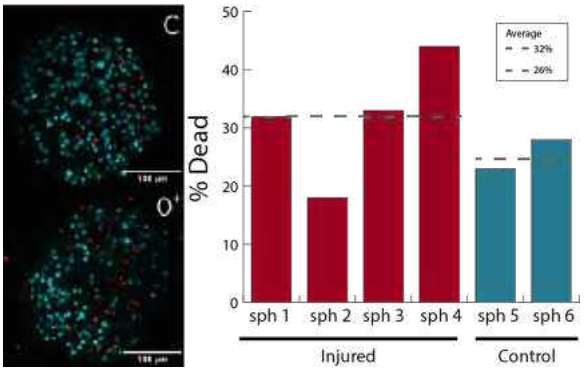

Figure 2: (Left) Control (top) and injured (bottom) spheroids showing cell nuclei in blue and dead cells in red. (Right) Percent dead of spheroids computed as the ratio of dead cells to cell nuclei for 25% strain after 1hr. C: control spheroid. 0^+: injured spheroid after 1 h.

In addition to live/dead assays, this novel platform enables *in situ* immunostaining for various mTBI-specific biomarkers, such as GFAP (Figure 3), under different strain and strain rate conditions. Comparison between the control and injured spheroids showed less astrocyte branching after being injured.

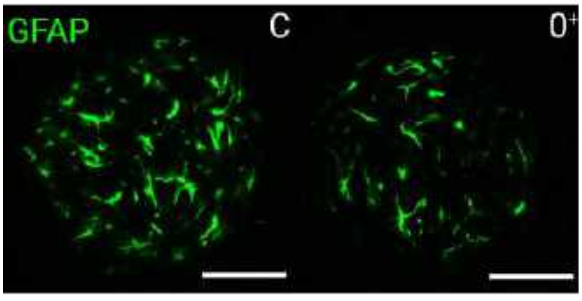

Figure 3: Control (left) and injured (right) spheroids showing less astrocyte branches for 0^+ after being injured by 25% strain. C: control. 0^+: injured spheroid after 1 h. Scale bars for both images are 100 μm.

DISCUSSION

Our novel μ-fluidic chip was capable of successfully injuring cortical spheroids at a strain of 25%. Live/dead results showed that compression caused an increased in percent dead cells, as expected for TBI. It is well known that TBI injuries, specially those of high strain and strain rate, contribute to a decrease in cell viability [9, 10]. Moreover, the same spheroids showed a decrease in astrocyte branches when they were stained for GFAP, which could function as an indicator for TBI. In this study, our μ-fluidic chip has proved effectively at injuring an *in vitro* model of the brain; however, no significant advances have yet been made towards understanding the temporal release profiles of biomarkers. To accomplish this, a kinetic assay using the same platform can be performed by collecting media at the outlet and analyzing the concentrations for GFAP and UCH-L1 for different strain and strain rates.

MORPHOLOGICAL AND HEMODYNAMIC CHANGES TO THE RV MICROVASCULAR NETWORK IN RESPONSE TO CHRONIC PRESSURE OVERLOAD

I, Essafri (1); K, Ichimura (2); KR, Stenmark (1); E, Spiekerkoetter (2); VO, Kheyfets (1)

INTRODUCTION

Right ventricular (RV) failure is a common complication of pulmonary hypertension, manifesting in myocardial thickening, fiber re-orientation, and tissue stiffening [1]. Recent studies from our labs have observed morphological changes of the microvascular network as a characteristic response of the RV to pressure overload, yet little is known about the true nature of these changes, their coupling to coronary hemodynamics, and their role in organ-level functional adaptation or maladaptation. The coronary microcirculation consists of an intricate network of vessels that supply the RV myocardium with oxygen and nutrients to sustain proper heart muscle function. Insights into this process not only refines our understanding of RV adaptation to chronic pressure overload but also holds promise for identifying therapeutic targets aimed at preserving coronary microvascular function and, by extension, supporting overall RV health. While previous investigations have suggested an inadequate adaptative growth of the RV microvasculature in RV failure [2], our study aims to shed light on the lesser-known hemodynamic changes caused by changes in microvascular network properties during the remodeling process by analyzing the microvasculature in 3D.

In this work, we hypothesized that chronic pressure overload led to microvascular morphological changes (e.g., changes in radius, length, tortuosity), which would result in changes to local hemodynamics (e.g., wall shear stress, vascular resistance). We also explored whether this microvascular response is consistent across male and female mice. This hypothesis aims to uncover intricate relationships between chronic pressure challenges, microvascular adaptations, and potential differences between male and female subjects in RV microvascular dynamics, contributing to our understanding of RV health.

METHODS

To address the aforementioned hypothesis, we performed deep tissue imaging on RV free-wall tissue harvested from 11 Sham (C57BL/6, 8-10 weeks) and 10 pulmonary arterial banded (PAB) mice (tissue harvested 7-weeks post PAB). With our custom in-house software (MATLAB 2023b), we generated 3D models of the microcirculation from 2D image stacks, as shown in Fig. 1a and b. A volume mesh was created for vessel centerline computation using VMTK software [3]. Vessel segments, defined as centerlines between two junctions, were analyzed for vascular tortuosity, orientation, length, and radius. We computed tortuosity as the segment curve length divided by the line connecting the segment ends.

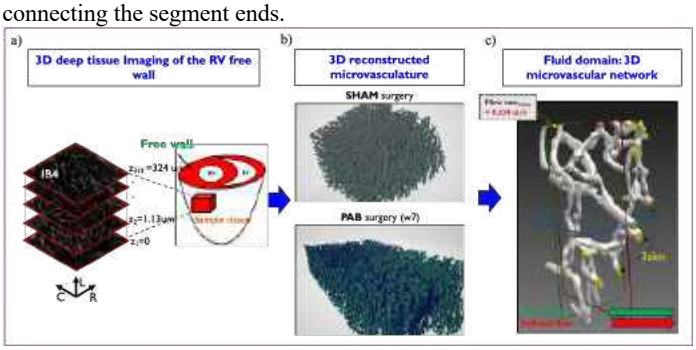

Figure 1: a) deep tissue imaging Procedure: RV free wall to 2D Image stack. b) 3D reconstructed Microvasculature visualization. c) 3D Fluid Domain for Simulations displays the 3D fluid domain with flow rate and differentiation between direct and indirect flow simulations.

Within the entire reconstructed 3D network, we isolated the largest volume for computational fluid dynamics (CFD) simulations using Simvascular (Fig. 1c) [4]. We prescribed for each inlet a constant volumetric flow rate as a parabolic velocity profile and a zero boundary conditions at the outlets. The vessel wall was considered rigid. We maintained uniformity in hemodynamic conditions by applying the same flow rate to both PAB and Sham mice. We deliberately chose this simulation setup to examine how microvascular structural alterations alter hemodynamics yet are aware that our simulations do not mimic the

much for complex in vivo flow parameters. We conducted two sets of simulations: one with direct flow (15 inlet and 15 outlet boundaries) and the other with flipped (a.k.a. "indirect") flow (outlet boundaries inverted) (Fig. 1c). Blood was modeled as a non-Newtonian fluid using Carreau-Yasuda model given by the equation:

$$\eta(\dot{\gamma}) = \eta_0 + (\eta_0 - \eta_\infty)[1 + (\lambda\dot{\gamma})^a]^{(n-1)/a}$$

Where η_∞ is the viscosity at infinite shear rate $\{\eta_\infty = 3.265$ mPa.s$\}$, η_0 is the viscosity at zero shear rate $\{\eta_0 = 14.49$ mPa.s$\}$, λ is the characteristic time $\{\lambda = 01839$ s$\}$ and (a and n) are fitting parameters $\{a = 2.707, n = 0.4136\}$. a, n and λ are empirically determined [5]. After validating mesh independence, we conducted steady-state CFD simulations to assess microvascular resistance, blood velocity and wall shear stress (WSS). Hypothesis testing was done using linear mixed effect modeling to account for repeated measures across two investigated fixed effects: (1) Sham vs. PAB ("condition"); (2) Female vs. Male ("sex"). Significance was set at $p < 0.05$.

RESULTS

Our study reveals significant microvascular adaptations in response to chronic pressure overload, exhibiting sexual dimorphism. The microvascular analysis revealed shorter segments in PAB, with females having the shortest segments (Fig 2a). We also observed a ($p < 0.05$) significant difference in the radius of individual segments between PAB and SHAM, with an increased radius in PAB and females having the largest radius. As illustrated in Fig. 2b, a comparable trend was observed for segment tortuosity, with percentages indicating segments with tortuosity indices ≥0.1, emphasizing distinctions among all microvasculatures. To better understand the impact of RV morphological changes on the local hemodynamic stress, we examined blood flow simulations results. Linear mixed-effects modeling identified a significant spatially averaged WSS (SAWSS) decrease in PAB vs SHAM microcirculations (Fig. 3a), with females exhibiting a lower WSS at baseline and a more pronounced decrease after PAB. Additionally, we identified a statistically significant difference in flow resistance between PAB and SHAM mice, with the lowest microvascular resistance observed in females (Fig. 3b). No significant difference in spatially averaged blood velocity was found between PAB and SHAM or between females and males.

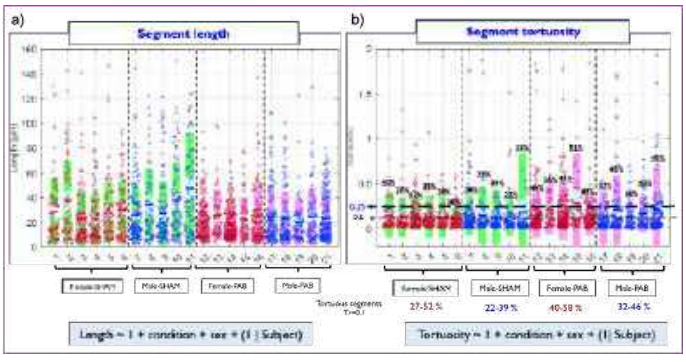

Figure 2: Microvasculature Analysis, featuring a jittered plot displaying a) tortuosity and b) length of the microvascular segments, along with the corresponding statistical models provided below.

DISCUSSION

Putting these findings into context, our study significantly contributes to the understanding of microvascular adaptations to chronic pressure overload, shedding light on sex-specific variations. The observed reduction in SAWSS in PAB mice would suggest a remodeling response that modulates and is possibly coupled to vascular hemodynamic stress. Numerous studies have shown that hemodynamic stress levels outside the normal physiological range can induce endothelial dysfunction and result in morphological and transcriptional changes in endothelial cells [6]. Of particular note is the distinct adaptive response observed in females in terms of microvascular resistance, segment lengths, and radii. Females exhibited a 35% decrease in microvascular resistance, a more modest reduction compared to males' 44.8%. This aligns with our hypothesis that females, potentially benefiting from a more favorable baseline, may necessitate less resistance reduction. In contrast, males, commencing with higher baseline resistances, may require more pronounced structural adaptations to achieve a comparable reduction under chronic pressure overload.

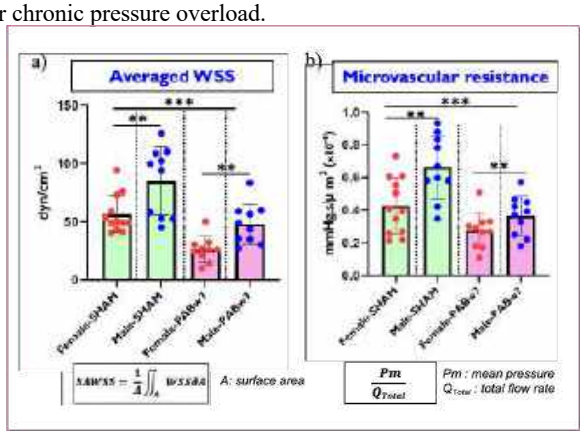

Figure 3: hemodynamic analysis, including a) Spatially Averaged Wall Shear Stress (SAWSS) and b) microvascular resistance, with the corresponding equations provided below. The figures reveal significant differences between PAB and SHAM groups, with sex-specific variations detected and analyzed through a linear mixed-effects model.

Sex-specific variations in remodeling may stem from inherent physiological differences, hormonal influences, or other factors affecting vascular responses to chronic pressure overload [7-10]. The combined microvascular changes, including increased branching, altered segment length and radius, and changes in tortuosity may be viewed as beneficial for maintain blood flow efficiency and minimizing the impact of chronic pressure overload on RV muscle proper function. These adaptations point towards the development of more complex microvascular network. Future work will explore if this increased complexity might lead to improved blood supply to the microvasculature and therefore increased nutrient supply to the surrounding tissue.

In conclusion, our study highlights compelling evidence of sex-specific microvascular adaptations under chronic pressure overload. These changes contribute to maintaining blood supply to RV muscle tissue. Insights from these PAB w7 inspired our ongoing study, which explores additional time points to unravel dynamic microvascular changes.

DIETARY CHOLESTEROL STIFFENS THE STEATOTIC LIVER

David Li (1,2), Abigail E. Loneker (2,3), Paul A. Janmey (2,3,4,5), Rebecca G. Wells (1,2,3)

INTRODUCTION

Hepatic steatosis is the pathological accumulation of fat in the liver. It is the hallmark of fatty liver diseases such as metabolic dysfunction-associated steatotic liver disease (MASLD), which can progress to fibrosis and cirrhosis [1]. Intracellular lipid accumulation into lipid droplets (LDs) precedes other pathological changes in MASLD and has been shown to soften liver tissue, hinting at a mechanical role for lipids in the earliest phases of disease [2]. However, it is unknown whether lipid accumulation can also exert a direct stiffening influence, which is critical as stiffening has been found to be the mechanical driver of fibrotic processes [3]. Changes in hepatic lipid composition observed in MASLD may cause changes in the effects of lipid accumulation on liver mechanics. Increases in hepatic abundance of cholesterol and cholesteryl esters (CEs) are associated with disease progression [4], and can have modifying effects such as ordering of LDs and other lipid aggregates [5]. This ordering is known to affect mechanics in other systems such as atherosclerotic plaques [6]. We thus hypothesize that the mechanical contribution of intrahepatic fat may be dependent on changes in intracellular lipid composition and organization.

Here, we investigate how cholesterol affects both the whole organ and microenvironmental mechanics of steatotic liver. Using dietary rat models of liver steatosis and increased dietary cholesterol, we examine whether cholesterol changes steatotic liver mechanics. We find that increased dietary cholesterol stiffens the steatotic liver while increased fat alone does not. We further find that dietary cholesterol induces formation of lipid crystals, which are sufficient to stiffen their microenvironment. These results may help inform the diagnosis and treatment of steatotic liver diseases in their earliest phases.

METHODS

We used a dietary rat model of simple steatosis (high fat, HF), along with a model of steatosis with increased dietary cholesterol (high fat high cholesterol, HFHC) to investigate the effects of cholesterol on the steatotic liver. All experiments were performed at 3, 6, or 9 weeks after the start of the selected diet to examine the course of disease. Lipid content, inflammation, and fibrosis were quantified by staining with BODIPY 493/503, anti-myeloperoxidase, and picrosirius red and subsequent image analysis. Birefringent lipid crystals were visualized using polarized light microscopy.

Ex vivo parallel plate rheometry was performed to measure whole liver mechanics without fluid pressure confounding [7, 8]. Microindentation with modifications to demarcate measured regions for histological analysis was performed as described previously [2]. Briefly, demarcation with DAPI within a parafilm ring after the microindenter probe was fully indented results in a DAPI ring around the probe-indented region. Liver samples were then stained with Oil Red O and visualized by whole mount epifluoresence microscopy, permitting quantification of lipid content within the indented regions by examining the degree of Oil Red O staining in DAPI demarcated regions. Confocal reflectance microscopy was performed on tissue samples to assess for increased reflectance indicative of changes in the ordering of lipid aggregates.

Lipid droplets and crystals were isolated from HFHC livers using a sucrose density gradient and embedded into fibrin gels made with 17 mg/mL bovine plasma fibrinogen, 2 U/mL bovine plasma thrombin, 30 uM $CaCl_2$, and 50mM HEPES. Rheometry was performed on hydrogels as done previously [9] with a plate diameter of 25mm, gap of 1 mm. The shear modulus was measured at a low oscillatory shear strain of 1% at a frequency of 10 $rad \cdot s^{-1}$, changing the axial strain by adjusting the gap between the plates and allowing the samples to relax.

Statistical significance was determined using a Student's t-test for tissue stiffness at zero compression and a two-way ANOVA for gel stiffness, corrected for multiple comparisons using Holm-Sidak and Dunnett, respectively.

RESULTS

We found that livers from HFHC rats were significantly stiffer than those from rats fed either HF or normal diets by shear rheometry (Figure 1), despite fat accumulation being observed in both HF and HFHC. Staining for markers of fibrosis revealed that the stiffening precedes the onset of fibrosis, first detectable at 9 weeks of diet.

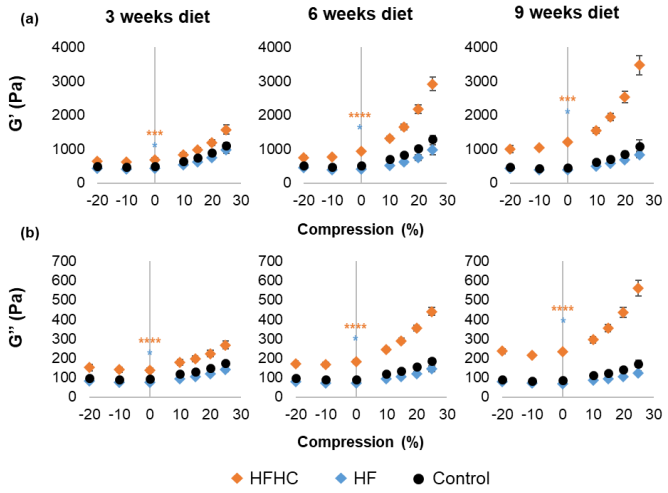

Figure 1: Dietary cholesterol stiffens the steatotic liver.

HFHC steatotic livers were found to contain crystals exhibiting birefringence under polarized light microscopy at room temperature and confocal reflectance microscopy when maintained at 37°C, which were not found in HF steatotic or control livers (Figure 2), suggesting that dietary cholesterol induces crystalline ordering of intracellular lipid droplets. Local stiffness was found to increase with greater local crystal content by demarcated microindentation coupled to microscopy of associated sub-millimeter regions of liver tissue.

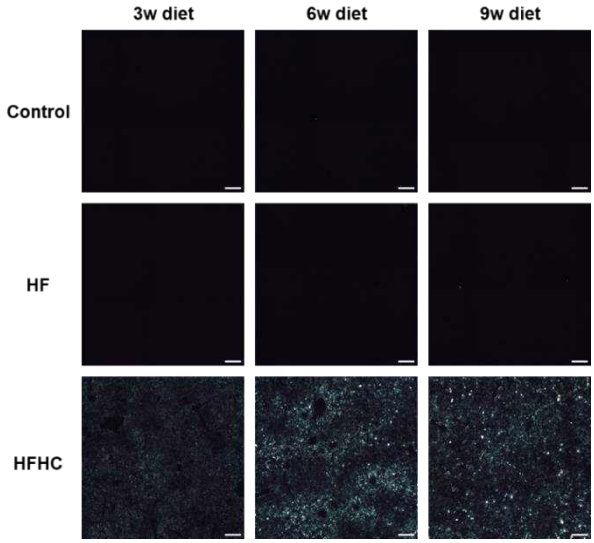

Figure 2: Dietary cholesterol induces formation of birefringent lipid crystals in the steatotic liver.

LDs and birefringent lipid crystals isolated from HFHC livers were found to stiffen fibrin gels in which they were embedded at the concentrations found in the HFHC liver (Figure 3), as opposed to LDs isolated from HF livers which did not affect fibrin mechanics. Together, these results suggest that lipids crystallize within the liver as a result of elevated dietary cholesterol, and that these intrahepatic cholesterol crystals are sufficient to stiffen their microenvironment.

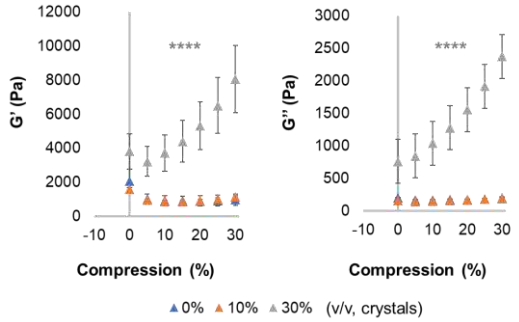

Figure 3: Lipid crystals from HFHC livers stiffen fibrin gels.

DISCUSSION

The finding that a HFHC diet induced liver stiffening while an HF diet alone did not is potentially of great importance in MASLD, in which progression of the disease ranges from fibrosis and cirrhosis to no progression at all [1]. The stiffening caused by the addition of dietary cholesterol could be a key contributor to disease progression, as tissue stiffening is a well-established source of profibrotic stimuli in other models of liver injury [3]. Dietary cholesterol-induced liver stiffening may thus have implications in preventative care and developing therapeutics for MASLD and other fatty liver diseases.

The birefringence observed in fatty livers with added dietary cholesterol suggests increasing order of lipid aggregates in the HFHC liver. Previous *in vitro* work in cell lines has provided evidence that increasing the amount of cholesterol or cholesteryl esters causes intracellular lipid droplets to become more ordered and gain crystalline properties [10]. Free cholesterol has also been observed to form intracellular solid crystals as well [5]. These birefringent crystals may be responsible for the increase in cell and tissue stiffness we observe in HFHC livers. The direct stiffening influence of lipid crystals isolated from HFHC livers on fibrin gels suggest that lipid accumulation may directly stiffen liver tissue, providing a fibrogenic mechanical signal in the earliest stages of steatotic liver diseases.

In conclusion, our results indicate that dietary cholesterol causes stiffening of the fatty liver, and that this stiffening is associated with the ordering of lipid droplets into more crystalline structures within the liver. These findings may open new avenues into novel diagnostics, preventative measures, and therapeutics for diseases of the steatotic liver and of other tissues where crystals may be found.

THE ROLE OF EARLY LIFE (PSYCHOLOGICAL) STRESS ON CENTRAL ARTERY AGING AND REMODELING

Brooks A. Lane (1), Nazli Gharraee (1), Gabrielle Lohrenz (1) Abigail M. Polter (2), Paul J. Marvar (2), John F. Eberth (1)

INTRODUCTION

Psychological stress is a mental or emotional state triggered by adverse life situations that an individual perceives to challenge or exceed their ability to adapt [1]. These stressors can be as simple as chronic environmental irritations accumulating over time, or exposure to acute but traumatic events. Fortunately, the body has evolved to react to stressors through a complex network of nerves, hormones, and feedback mechanisms that regulate important cardiovascular (CV) functions such as blood pressure/volume, heart rate/contractility, vasomotor tone, and blood distribution [2,3]. While these functions play an essential role in human physiology and survival, they are also well-known drivers of vascular remodeling [4]. It is not surprising therefore that psychological stress has been linked to CV disease [1,5] and may contribute broadly to vascular aging (i.e., stiffening, dysfunction, etc.).

Early life stress (ELS) occurs during a vulnerable developmental period where both the body and the brain are rapidly growing and adapting [6,7]. Stressors may include childhood trauma, neglect, abuse, family instability, loss of a caregiver, or exposure to violence [1,6]. Given the established interplay between the brain and the CV system, ELS could manifest as altered structural and functional vascular aging or remodeling. Indeed, early onset vascular stiffening has been observed in individuals living in adverse environments, experiencing childhood trauma, or when exposed to chronic discrimination [3,5]. Unfortunately, initiating factors can be difficult to isolate and in vivo techniques (i.e., human ultrasound) limit correlation with structural mechanics and histology. Despite the strong clinical evidence, surprisingly very few studies have examined the impact of ELS on vascular histomechanics.

Motivated by the need to better understand and improve the human condition, mice permit control over the nature and timing of stressors while maintaining environmental and genetic consistency. A wide range of models are available to help elucidate the underpinnings of vascular pathologies. Here we report the preliminary biaxial mechanics of the descending and infrarenal aortas from a mouse model of ELS [6].

METHODS

The limited bedding and nesting model of ELS is one of neglect and marked by maternal care that is fragmented and unpredictable [5]. To use this model, mouse litters on a C57BL6 background, were culled to four pups and the dam and pups were transferred to a standard-sized cage on postnatal day 4. Control (CTRL) pups were left undisturbed with the dam in standard housing (corncob bedding and one cotton nestlet) while ELS pups were transferred to a cage with limited nesting material (i.e., aluminum mesh bottom, half standard nestlet) for 7 days and then returned to standard housing. All mouse procedures were reviewed and approved by the George Washington University IACUC.

At 13-16 weeks of age, ELS (n=7) and CTRL (n=4) male and female mice were euthanized and the descending thoracic (DTA) and infrarenal abdominal (IAA) aortas were excised and gently cleaned of loose perivascular tissue. Samples were placed in a protease-inhibitor cocktail at 4°C, transported to Drexel University, and mechanically tested within 48 hours using the biaxial inflation-extension testing described in [6]. Briefly, samples underwent five preconditioning cycles of pressurization and axial extension. Then pressure, axial force, and diameter data were measured in triplicate during inflation from 0 to 160 mmHg (10 mmHg increments) at the estimated *in vivo* axial stretch and ± 10% this value. Stress and stretch ratios were calculated as:

$$\sigma_\theta = \frac{pr_i}{h}, \sigma_z = \frac{f}{\pi(r_o^2 - r_i^2)}, \lambda_\theta = \frac{(r_i + r_o)}{(R_i + R_o)}, \lambda_z = \frac{\ell}{L} \qquad (1\text{-}4)$$

where θ and z are the circumferential and axial directions, R and r the unloaded and deformed inner (i) and outer (o) radii, H and h the undeformed and deformed wall thicknesses, ℓ and L the deformed and undeformed lengths, p the transmural pressure, and f the axial force. The lumen area compliance ($c = \pi \Delta r_i^2 / \Delta P$) was calculated between diastolic and systolic pressures and the physiological modulus, M, the slope of the circumferential stress-strain curve at 100 mmHg.

Statistical analysis was performed using GraphPad Prism. Metrics were compared using a two-way ANOVA with post-hoc Tukey's t-test.

RESULTS

Passive mechanical testing was performed successfully on all samples after which vessels were prepped and stored for histological analysis. Although continuous data was collected throughout experimentation, 12 discrete variables of structural or mechanical assessment were compared with all but three (R_i, Ro, H) measured at 100 mmHg and the *in vivo* axial stretch ratio (see also [7]). ANOVA results (**Fig. 1**) revealed sex (Male vs. Female), stressor (ELS vs. CTRL), and aortic location (DTA vs. IAA) as the sources of variation in the data. Stressor-linked data included axial stress and deformed inner and outer radii, compliance, and axial stress and stretch. Interaction metrics included axial stretch, unloaded inner radius, circumferential stress, compliance, and physiological modulus.

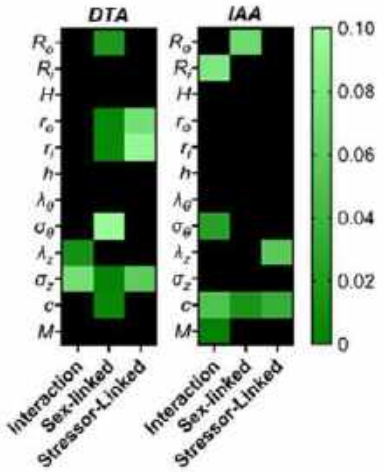

Figure 1: Heatmap results of p-values from two-way ANOVA analysis for identifying sources of variation.

Not surprisingly, sex and anatomical location play important roles in governing the structural and mechanical properties of mice. Therefore, we separated the continuous data in terms of pressure-stretch, force-pressure, and circumferential and axial stress-stretch, by sex and location. Reported here for brevity are the pressure-outer diameter curves of each vessel. DTAs from ELS male (Fig. 2A), and to a lesser extent, female mice, illustrated a rightward shift (dilation) compared to controls. Interestingly, this pattern was not observed in any of the IAAs. In fact, the IAAs of female ELS mice tended to be slightly smaller than controls, albeit not statistically significant. Loaded wall thickness, was unaffected by ELS in any tested segment. Taken together, these geometric results suggest an outward hypertrophic or eutrophic remodeling in the DTAs of ELS mice.

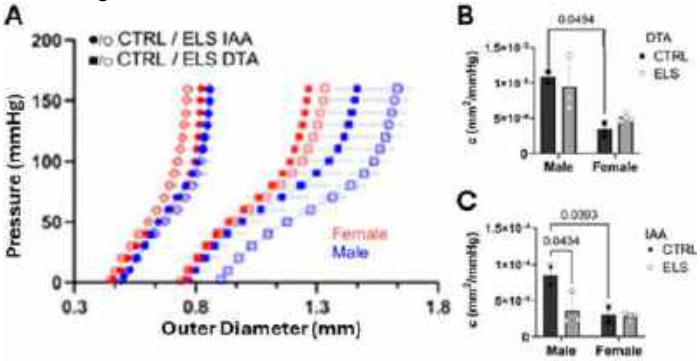

Figure 2: A. Pressure-diameter curves of the DTA and IAAs from CTRL and ELS mice grouped by sex (mean ± SEM). Luminal area compliance of the (B) DTA and (C) IAAs over diastolic-systolic pressures (mean ± STD).

The aortas of all male mice were generally more compliant than their female counterparts (**Fig.2 B, C**). Lumen area compliance depends on the size of the animal and unfortunately, we did not record weight in this preliminary study [8]. Nevertheless, the area compliance was significantly reduced in the IAAs of ELS male mice and may be an indicator of premature vascular aging. (p=0.043).

DISCUSSION

Chronic or early life stress has a long-established role in cardiovascular function and pathology [1,3-6]. Correlating behavioral and structural mechanics is challenging given that many of these changes may be subtle and are often compensatory. *Ex vivo* biaxial micromechanics is more thorough than in vivo ultrasound or isolated ring testing because it captures wall thickness, anisotropy, heterogeneity, and the large strains common to soft biological tissues. To the best of our knowledge, this is the first study linking ELS to biaxial blood vessel mechanics.

Further research is needed to determine if male DTA dilation is compensatory or pathological. Stiffening, on the other hand, is one of many undisputed metrics of vascular aging. To maintain consistency with clinical ultrasound we used lumen area compliance as our comparator. Male mice showed a significant decrease in compliance, supporting the notion of premature vascular aging in ELS [4]. Our data further suggests that ELS outcomes have sex and location dependency and that interactions exist between these variables. Indeed, other researchers have shown sex-dependent neurobiological characteristics, increased sympathetic activation, and changes in blood pressure of male but not female mice using the ELS model [9]. Blood pressure and cardiac output are part of our ongoing study and will later be used to refine our measures of mechanical assessment. It is not surprising, however, that regional differences exist between the DTA and IAA since these have unique functional and pathological characteristics [6]. For the most part, mechanostasis, in terms of mechanical stress-mediated growth and remodeling in DTA and IAAs has been achieved as evidenced by circumferential and axial stress preservation across groups [2]. Despite the common naming convention, mechanical and psychological stresses differ in their nature, origin, and tools used to estimate them. For healthy gene expression, the mechanical stresses on vascular cells must be non-zero but less than a threshold that causes physical damage. The minimum for psychological stress, on the other hand, remains unknown. What is known is that exceeding thresholds of psychological stress leads to the premature onset of cardiovascular disease [1,5].

Gaining insight into the relationship between ELS and aging is crucial to understanding the consequences of stress in brain-vascular function and susceptibility to cardiovascular disease in later years. Such endeavors may contribute to the identification of potential therapeutic interventions. That said, the data reported here is preliminary and care must be taken not to overinterpret our findings based on small sample sizes. Ongoing studies seek to increase numbers and focus on elucidating functional and histopathological variables. Still, the notion that events witnessed during childhood could impact vascular health later in life is profound.

INTRODUCTION

Cardiovascular diseases are the leading cause of morbidity and mortality around the world. In recent years, the field of cardiovascular medicine has seen a transformative shift from a population-centric approach towards personalized and patient-centric treatment strategies. One innovative technology is Polyjet 3D printing that offers the potential to use multi-material mixtures and pixel-level control to 3D print patient-specific cardiovascular structures. Traditional printing strategies, such as stereo-lithography (SLA), only permit a single material with high wall thicknesses, and thus, have limited applicability to mimic mechanical heterogeneity of native vascular structures.

One exciting area of research has been to develop photopolymer materials that can potentially mimic the mechanical and structural properties of native vascular and cardiac tissues. Patient-specific anatomies printed with such materials could open up exciting opportunities, such as pre-planning and simulating surgical scenarios, assessing hemodynamics ex-vivo or optimizing medical device deployment. However, despite recent availability of a range of polyjet materials, especially those marketed as vascular tissue replicas, there still remains a paucity of available data that compares their mechanical response to native tissues.

In this study, we have compared the mechanical response of commercially-available polyjet materials, marketed as vascular tissue replicas, from a popular vendor (Stratasys) and silicone-based elastomers typically used in SLA printing against those of native tissues.

METHODS

Polyjet Material Samples. Twelve tissue-mimicking materials were acquired from Stratasys (Eden Prairie, Minnesota) which are used in their PolyJet J850 Digital Anatomy Printer series. In particular, these materials utilize the Structural Heart TissueMatrix, which is advertised as the softest commercially available 3D printing material that behaves like native tissue providing elastic moduli and failure modes similar to native tissues. All samples were re-sized to 14 x 14 mm to facilitate in biaxial testing. The sample thickness was 3 mm.

Silicone Elastomer Samples: Six silicone-based elastomers with a range of elastic moduli were acquired from Gluck Medical (Seoul, Korea), a 3D printing service provider for cardiothoracic surgical simulations. All samples were resized to 14 x 14 mm to facilitate in biaxial testing. The sample thickness was 5 mm.

Biaxial Testing. Equibiaxial mechanical testing of polyjet and silicone elastomer materials was performed using a CellScale BioTester (Waterloo, Canada). The samples were mounted onto tungsten rakes with 5 attachment points each and a 23 N capacity load cell [1]. Four dots were marked in the middle of the sample for strain tracking in post processing (see Figure 1).

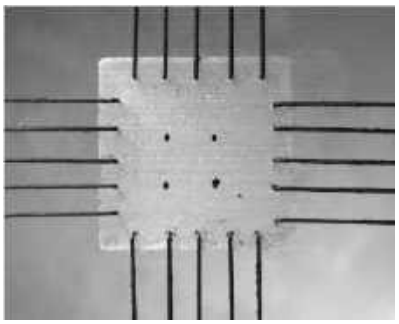

Figure 1. Biaxial testing setup. Four dots mark locations used in strain tracking.

Each test consisted of at least one preconditioning cycle at a strain rate of 0.0088/s followed by one testing cycle, all straining to at least a 5% rake-rake displacement.

Post Processing. The stress-strain curves in the both X and Y directions were obtained for both loading and unloading conditions. The loading curves were linearly fitted to determine the Young's modulus of each material. For each sample, there was a slight deviation in moduli between the two directions ($\mu \pm 15\%$). The direction showing the

higher modulus was used for comparison as this value was more significant when matching to native tissues.

RESULTS

Figure 2 shows the Young's moduli of a subset of polyjet materials and silicone elastomers tested in this study. Note that one of the polyjet material ("valve leaflet – extensively stiff") was not tested due to very high stiffness, which hindered attachment of the biorakes.

As seen in Figure 2, the elastic moduli ranged from 0.5 – 3.4 MPa for polyjet materials and from 0.08 – 0.57 MPa for Gluck Medical's silicone elastomers. Interestingly, the most compliant polyjet material had an elastic modulus that was comparable to the stiffest silicone elastomer (Hardness 20).

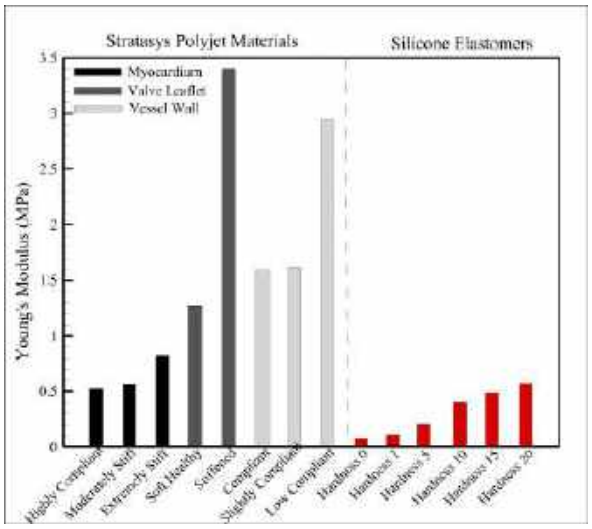

Figure 2: Young's moduli of Stratasys synthetic tissue-mimicking materials and Gluck Medical's silicone-based elastomers.

Figure 3 compares the elastic moduli of the most compliant polyjet material ("Myocardial – Highly Compliant") and silicone elastomers of various stiffnesses against those of native aortic tissues obtained from literature, consisting of mechanical test data performed on three aortic valve and five healthy aortic tissues [2][3]. Note that the elastic moduli of native tissues have been reported for the post-transition, linear elastic region linked with elongation of elastic and collogen fibers. The elastic modulus of the most compliant polyjet material was notably greater than those of native tissues. In contrast, the silicone-based elastomers demonstrated a much wider variation. In particular, the silicone material with "Hardness 5" provided the closest match to the native aortic tissues.

DISCUSSION

We have compared the mechanical properties of polyjet materials used in Stratasys J850 DAP along with Gluck Medical's silicone-based elastomers. Stratasys is the most popular vendor of polyjet technology, offering a range of synthetic tissue-mimicking materials. Stratasys DAP printer has already been used in clinical and surgical applications, such as surgical training [4], and ex-vivo hemodynamic analysis [5] but how well their materials model the biomechanical response of native tissues has not been thoroughly investigated. Verga et al. analyzed the nonlinear viscoelastic properties of Stratasys' synthetic tissues and reported notable deviations between the most compliant material tested

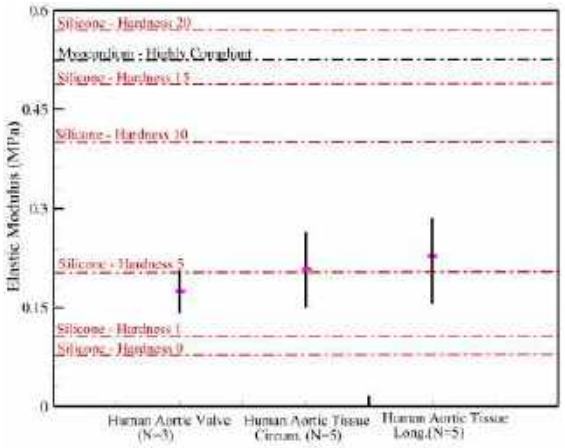

Figure 3: Comparison of elastic moduli of synthetic polyjet (black) and silicone-based materials (red) against healthy aortic valve and aortic wall tissues.

compared to porcine aortic wall specimen [6], consistent with our findings. Our findings also demonstrate that silicone-based elastomers, typically used in SLA printing, have elastic moduli that are much closer to native tissues, and thus, have a distinct advantage in applications such as surgical training. However, SLA has limited capabilities in printing intricate cardiac sub-structures and is limited to a single material.

Our findings have exciting implications for designing patient-centric treatment strategies. In addition to surgical pre-planning, the polyjet materials can be potentially be used to customize grafts in patients, such as to design aortic patches in patients' undergoing Norwood surgeries, or as support materials for tissue-engineered vascular grafts. Future work will focus on hemodynamic characterization of these materials to assess how well these materials can mimic in-vivo blood flow conditions.

INTRODUCTION

Central venous catheters (CVCs) provide long term venous access for blood draws, medication administration, and fluid infusions [1]. However, CVCs are associated with complications such as catheter-related thrombosis (CRT). CRT can present as a deep vein thrombosis (DVT), venous thromboembolism, or a clot on/within a CVC. CVC complication rates vary based on study type and patient risk factors, but the incidence of CRT, specifically in the form of upper extremity DVT, is reported between 14-18% [2]. Multiple risk factors are associated with CRT including cancer, endothelial damage during insertion, and a catheter-to-vein ratio (CVR) > 0.45 [1]. Although the CVR is reported to have a significant effect on thrombosis, previous work has not established a standard value for CVR, with clinical centers using a range from 0.33 - 0.45 [3]. The CVR is defined as the outer diameter of a catheter divided by the inner diameter of a patient's vein (**Equation 1**).

$$CVR = \frac{CVC\ Outer\ Diameter}{Vein\ Inner\ Diameter} \quad (1)$$

The CVR variation stems from a lack of understanding of CRT from a fluid mechanics and hematologic perspective [1, 2]. Previous work has shown the effect of CVC insertion on flow and that a CVR of 0.15 compared to 0.33 has a minimal effect on the fluid mechanics *in silico* when there is no flow through the CVC [4]. The purpose of this study is to quantify the CVR's effect on CRT across multiple flow conditions using particle image velocimetry (PIV) and *in vitro* blood studies.

METHODS

Flow Visualization: A custom acrylic model was fabricated (Atlantic Industrial Models, Essex, MA) and consisted of a rigid outer tube to model the superior vena cava (SVC, ID = 1.6 cm) and three acrylic CVCs for CVRs of 0.20, 0.33, and 0.49. The acrylic CVCs were replicas of Teleflex® Arrow dual lumen CVCs with one side hole and a tapered tip design. A steady flow loop was assembled, and a non-Newtonian blood analog fluid seeded with 10 μm glass particles was used (51.47 wt. % sodium iodide, 15.5 wt. % glycerin, 33 wt. % water, 0.03 wt. % Xanthan gum). A high-speed Terra PIV laser (Continuum, San Jose, CA) was coupled with a laser light arm (TSI Inc., Shoreview, MN) to illuminate the centerline plane. Data were collected at five locations downstream of the incoming flow (**Figure 1**). Two hundred image pairs were collected with a high-speed camera at Reynolds number (Re) = 200, 800, and 1300 for each CVR.

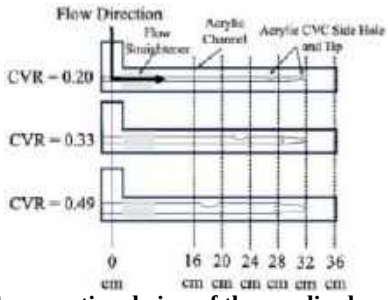

Figure 1. Cross sectional view of the acrylic channels and CVCs for PIV measurements at three CVRs (0.20, 0.33, and 0.49).

Blood Experiments: An *in vitro* flow loop was developed to assess CRT across three CVRs and multiple flow conditions. A 5-French Teleflex® Arrow dual lumen CVC was fixed in the center line of a 3D printed (FormLabs) channel to model a CVC in the SVC; this channel allowed control over CVC location. The inside of the flow loop was soaked in 3% bovine serum albumin (Sigma-Aldrich) prior to experiments. Human blood was collected (Institutional Review Board approved) in 3.2% sodium citrate (J.T. Baker®), reconstituted to 40% hematocrit and 214×10^6 platelets/mL, and recalcified to 20 mM $CaCl_2$

(Sigma-Aldrich). The CVC lumens were filled with 1X phosphate buffered saline and clamped off; blood was then driven through the loop by a peristaltic pump (Cole-Parmer®) for 1 hour at a prescribed Re and CVR (**Table 1**).

Table 1. Flow conditions for blood experiments (n=6).

CVR	Channel Diameter (cm)	Flow Rate (L/min)	Re
0.20	0.80	1.10	800
0.33	0.50	0.14	200
0.33	0.50	0.70	800
0.33	0.50	1.10	1300
0.50	0.34	0.16	200

A fresh CVC was used for each experiment and no flow used through the lumens to match previous work [4]. Any clots formed on the device were analyzed for clot area and location. The CVC was segmented into "Zones" for location data (**Figure 2**). Clot data were analyzed with unpaired two-sample t-tests.

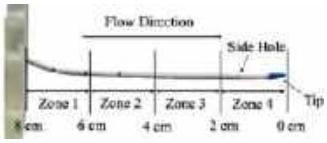

Figure 2. "Zone" segmentation of CVC.

RESULTS

Flow around the acrylic CVCs at Re = 200, 800, and 1300 is shown in **Figure 3**. The flow field is segmented with vertical black lines according to data collection locations (**Figure 1**). There is stagnant flow in the side hole and in the wake distal to the tip in each CVR case, and the effects of each are more pronounced as the CVR increases within each Re.

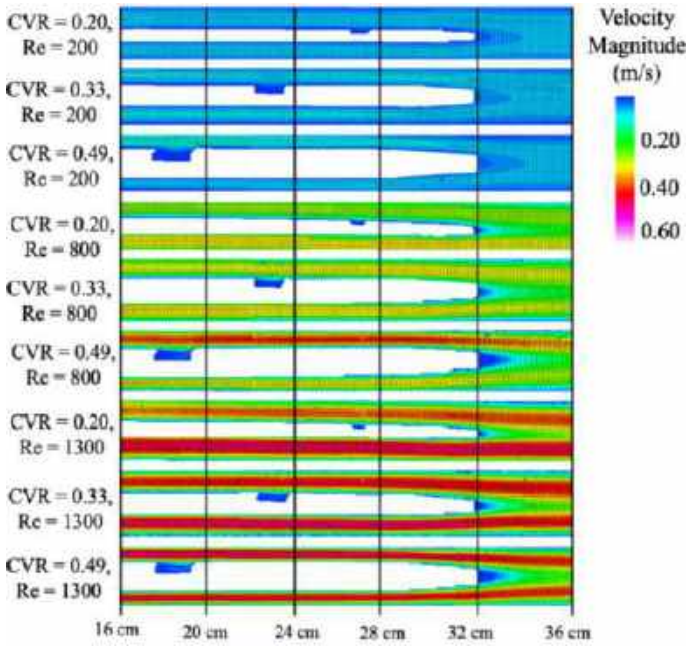

Figure 3. Flow visualization data around acrylic CVCs.

Clot sizes and locations across each CVR and Re in the blood experiments are shown in **Figure 4**. There were significant differences ($p<0.05$) in clot size across multiple cases with different flow conditions and/or CVRs (**Figure 4A**). These results can partly be explained by higher surface velocities for higher Re or CVR conditions (as shown in **Figure 3**), which can promote the washing of platelets and/or adhesive proteins during the experiment and reduce potential thrombus formation compared to lower CVR/Re cases.

Clots formed in Zone 4 were located only at the side hole for the 0.20 CVR case (**Figure 4B**). For all conditions with a CVR higher than 0.20, clots formed at the side hole and the tip, which may be explained by the increased wake size distal to the tip with an increased CVR (**Figure 3**). In both Re = 200 conditions, clots formed in multiple Zones.

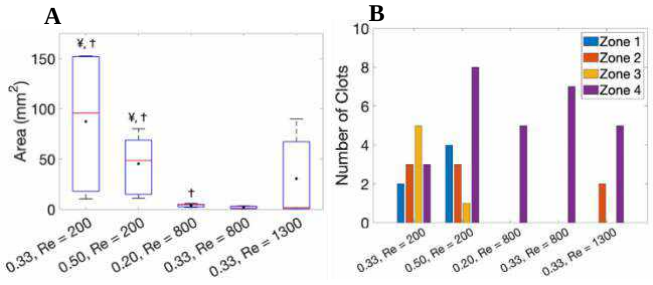

Figure 4. A: Clot area across 5 experimental conditions. ¥ = Significant difference from 0.20, Re = 800; † = Significant difference from 0.33, Re = 800 ($p < 0.05$). B: Clot locations data.

DISCUSSION

CVC insertion will likely obstruct flow in a vessel, increasing hydraulic resistance and potentially slowing the flow around the device. This study shows that with a combined higher CVR and lower flow condition, clot size is larger and formation location is not exclusive to the side hole or tip regions (**Figure 4**). Importantly, the clot size and frequency were higher for both Re = 200 (CVR = 0.33, 0.50) conditions as compared to lower CVR Re = 800 cases. This study, therefore, suggests that if CVC insertion greatly reduces flow in a vessel, an increased CVR may cause increased thrombus size and frequency when compared to a lower CVR case with a higher Re. For the high flow condition (0.33 CVR, Re = 1300), clot formation in Zone 2 and an increased clot size was potentially due to high-shear phenomena, activating platelets and unfurling von Willebrand factor for an increased platelet capture on the CVC.

This study demonstrates that there are multiple aspects to consider regarding CVR on clot formation: the flow condition and CVR both alter thrombus size and location. The tip is currently a location of interest for higher CVR cases: the occurrence of tip clots with an increased CVR can be explained by larger stagnation zones distal to the tip with an increased CVR. Meanwhile, low and high flow conditions can facilitate thrombosis throughout the CVC surface. In total, multiple aspects must be considered for CVC placement, including vein and catheter size, and future work should quantify the impact(s) of CVC insertion on native vessel flow.

INTRODUCTION

The more than 250,000 surgeries occurring annually in the United States, rotator cuff (RC) repair surgeries regrettably fail at unacceptably high rates. Failure rates range from 20-94% depending on the size of the tear, as well as age and the weight of the patient [1,2]. It is estimated that these failed surgeries cost the United States healthcare system roughly $3.4B annually [3]. Histological analysis of these failed repairs show that the surgically repaired tendon is not returning to its original tissue composition and is instead scarring [4]. Tendon healing overall, is a largely unknown cascade, however, it is known that the immune response to the injured tendon has a large effect on whether the tendon scars or heals correctly.

This has brought large interest in modulating the immune response to improve the overall clinical success of these repairs. Our novel approach is to functionalize Pattern Recognition Receptor Agonists (PRRA), which are molecules that have been used in cancer research effectively as an immunotherapy approach [5,6]. These agonists activate the innate immune system through the Toll-like and Nod-like receptor pathways. **We hypothesize that PRRAs can be utilized to activate the immune system to increase clinical outcomes of tendon healing. To investigate this, we aim to examine how gene expression changes in tendon when exposed to PRRAs *in vitro*.**

METHODS

Biopsies (10 mm) were taken (N=3) from (N=4) sheep (ovis aries) supraspinatus tendons. Tendon samples were then cut in half and cultured in media with 50 ng/ml concentrations of the selected PRRAs. PRRAs were NLR3 agonist ALOH (Invivogen), TLR3 agonist Poly(I:C) HMW (Invivogen), STING (Invivogen), and TLR9 agonist CpG ODN (Invivogen); generating n = 6 samples for each experimental group. Tendons were cultured overnight then frozen (-80 °C) to prevent RNA degradation. Tendon samples left in media overnight with no agonists served as control samples. RNA was then extracted, purified, and then sent for genomic sequencing (Novogene Inc.). Gene expression data were processed and analyzed using Partek Flow. Gene Ontology of Biological Processes (GOBP) was used to analyze gene enrichment of each agonist group compared against the controls using gene set enrichment analysis (GSEA) to determine the overall effect of the applied agonists.

RESULTS

Two samples from the control and Poly(I:C) groups were removed due to lack of quality RNA. ALOH, CpG, Poly(I:C), and STING treatments had 82, 110, 168, and 153 significantly upregulated genes and 64, 9, 45, and 101 significantly down regulated genes from control samples respectively (Figure 1). Seventeen of these altered gene expressions were shared between all groups versus the control indicating that there are similarities in the response of each agonist. Poly(I:C) and STING shared the most genes differentially expressed with 65 genes.

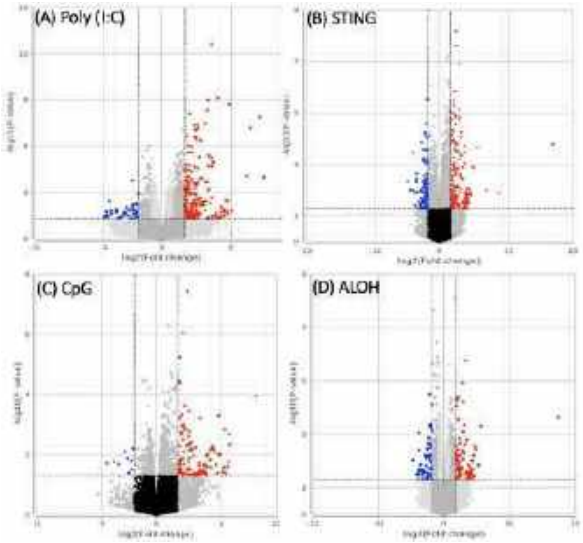

Figure 1: Volcano plots of comparing gene expression of control samples to (A) Poly(I:C), (B) STING, (C) CpG, and (D) ALOH, greater than 2x fold change or p < 0.05 are highlighted.

GOBP analysis of Poly(I:C) revealed upregulation of proinflammatory pathways such as Interferon alpha and gamma (IFNα and IFNγ) responses as well as TNFα signaling (Figure 2). It also upregulated pathways relating to cartilage development such as chondrocyte differentiation and cartilage development and down regulated adipogenesis.

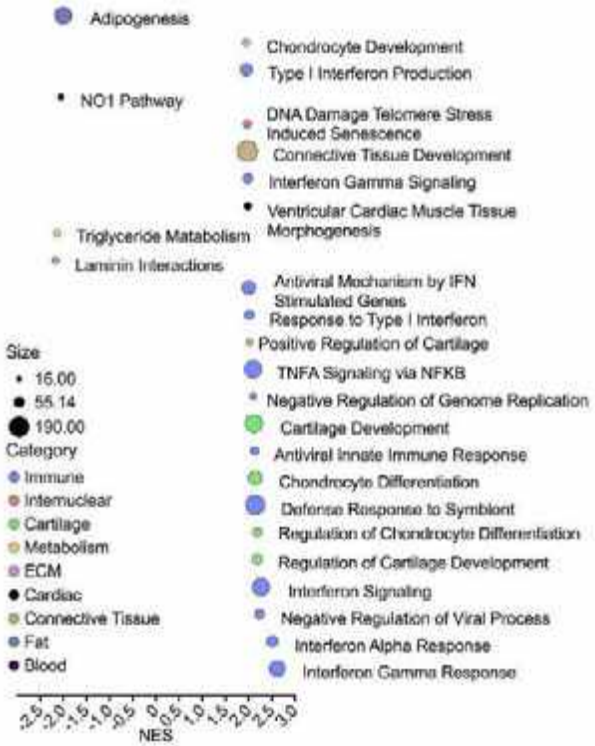

Figure 2: Bubble plot graphing the results of gene set enrichment analysis (GSEA) of Poly(I:C) compared to control. Top 25 results of largest magnitude normalized enrichment scores that had a false discovery rate of < 5%.

DISCUSSION

PRRAs had meaningful effects on genetic changes in the tissues. In the controls TNFα, IFNα, and IFNγ (all proinflammatory cytokines) are known to play an important role in the early stages of wound healing [7], were upregulated. In comparison Poly(I:C), gave a higher proinflammatory response. Poly(I:C) also had a mixed effect on specific tendon healing markers including fatty infiltration and an increase in cartilage formation, which are documented signs of tendon degeneration [8]. Poly(I:C) down regulated adipogenesis and upregulated pathways related to cartilage formation. Taken together these data indicate Poly(I:C) is directly affecting tendon health in a positive way through the limiting of fat production and the increase in immune cytokines that are instrumental in proper wound healing. TLR3 activation through Poly(I:C) has been shown to improve wound healing times in human and mouse skin, but its effects on tendon healing have not been characterized. These preliminary data illustrate that the regulation of extracellular matrix production and immunomodulatory properties of Poly(I:C) have the potential to be a novel tendon therapy.

A 3D MODEL FOR THE STUDY OF MACROPHAGE-INDUCED SOLID STRESS

Alice Burchett (1), Saeed Siri (1), Meenal Datta (1)

(1) Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, USA

INTRODUCTION

Macrophages play a critical role in health and disease, but their response to and generation of mechanical forces is incompletely understood. From atherosclerotic plaques to tuberculosis granulomas to solid tumors, macrophages play an important role not just in immune effector function and orchestration, but also as active constituents of the mechanical microenvironment [1]. This is especially true in cancer, as macrophages accumulate in tumors in large numbers and contribute to tumor growth and disease progression. Macrophage polarization – whether they contribute to an inflammatory or anti-inflammatory immune response – is plastic and can reverse if they are exposed to shear stress, cyclic compression or stretching, or hydrodynamic pressure changes [2]. However, the degree to which macrophages can contribute to mechanical stress in disease, especially compressive stress generated by a growing mass, has not been studied.

This work aims to characterize the solid stress that macrophages generate through proliferation in a confining agarose gel, simulating the mechanics of the tissue microenvironment independent of confounding biological cues. We explore how matrix stiffness, inflammatory and anti-inflammatory cues, drug treatment, and hypoxia affect the generation of compressive solid stress in this novel and high-throughput macrophage spheroid model. Understanding how macrophages generate stress, and how they respond to external cues under chronic compressive stress, will inform strategies to target or reprogram macrophages in the plethora of diseases that involve macrophage accumulation. This platform also has promise for screening macrophage-targeted drugs and is highly tunable to be applicable to a range of diseases.

METHODS

Single-cell suspensions of RAW264.7 murine macrophages were mixed with low-gelling-temperature agarose to create a cell-laden agarose gel. Gels were created with 0.5%, 1%, and 2% to tune the gel stiffness. Small gel pieces were immersed in growth medium and incubated in standard culture conditions.

For polarization of the macrophages, the media was supplemented with IFNγ and LPS to induce an inflammatory M1 phenotype, and IL4 to produce an M2 anti-inflammatory phenotype. Media was supplemented with LPS alone to assess macrophage response to inflammatory stimuli. Dexamethasone and temozolomide were also added to the media as representative treatments given to GBM patients. Hypoxia treatment was achieved using a separate incubator with 1% oxygen.

Brightfield images of the gels were used to quantify differences in size and shape between conditions. We analyzed these images for spheroid area and shape using ImageJ. Gels were stained with calcein-AM and propidium iodide to assess viability. Gels were also fixed in paraformaldehyde and stained with DAPI and CellMask Actin Tracking Stain to assess 3D morphology. These stained gels were imaged with a confocal microscope, and image stacks were then used to create a 3D reconstruction of the spheroid surface.

For computational analyses, the shape of the spheroid was simulated in 2D by creating a line and modeling its expansion into an ellipsoid shape using COMSOL. This models the case where a growing spheroid creates a crack in the agarose gel and grows into an axisymmetric discoid shape. ImageJ was also used to generate 3D files representing the spheroid surface, which will be used for more accurate 3D models that are currently under development.

RESULTS

RAW264.7 cells readily form spheroids when embedded in agarose at a range of concentrations and display excellent long-term viability, with only a small minority of cells staining positive for propidium iodide after 2 weeks (**Fig. 1A**). 3D imaging revealed that most spheroids adopt a flattened discoid shape, rather than a spherical shape (**Fig. 1B**). Because macrophages cannot alter the plant-derived agarose matrix, any

increase in spheroid size must cause displacement of the surrounding gel, generating solid stress. Given an estimate of the spheroid geometry and the mechanical properties of the gel, we generated a simulation of the stress field in the gel surrounding the spheroids (**Fig. 1C**).

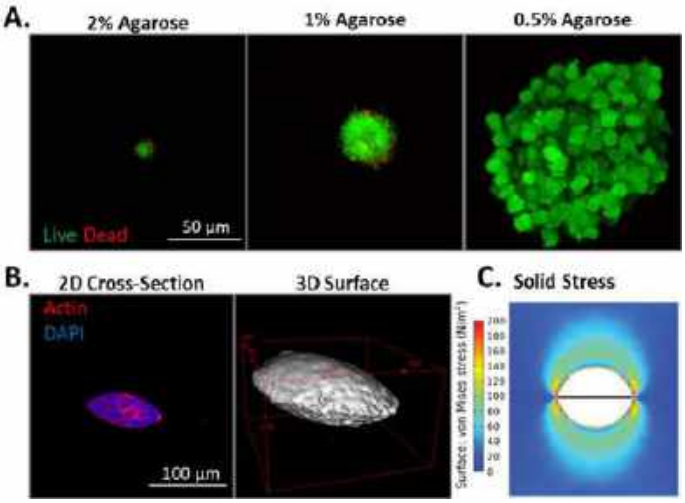

Figure 1: Macrophage spheroids embedded in agarose display sustained viability and generate solid stress. (**A.**) Projections of macrophage spheroids 16 days after seeding show viable cells throughout the spheroid, in three different concentrations of agarose. (**B.**) Most spheroids take on a discoid shape, as illustrated by actin staining of an optical cross-section and the 3D surface reconstruction. (**C.**) This shape is simulated in COMSOL to show the resulting stress field in the surrounding agarose.

As agarose concentration decreases, the average spheroid size increases significantly (**Fig. 2A)**. In 0.5% agarose, spheroids are much less regular in shape than those in 1% and 2%, which is apparent in images and is quantified by perimeter solidity. Treating the agarose-embedded macrophages with 200 ng/ml LPS resulted in significantly increased spheroid size compared to untreated, in all three agarose concentrations. LPS also generally increased ellipticity, a measure of spheroid deviation from a circle. However, treatment with 20 ng/ml IFNγ in addition to 200 ng/mL LPS (M1 treatment) decreased spheroid size (**Fig. 2B**). Treatment with 20 ng/ml of IL-4 (M2 treatment) did not significantly change spheroid size, but did result in a slight increase in solidity, a measure of perimeter regularity. Interestingly, hypoxia, dexamethasone, and temozolomide did not significantly alter spheroid size or shape.

The size and shape comparisons discussed were made based on 2D imaging data. We are currently developing image processing pipelines to analyze 3D data from confocal images for more in-depth morphology comparisons. We are also currently optimizing computational models to obtain quantitative comparisons of the generated solid stress.

These results illustrate the utility of this novel 3D macrophage mechanics culture model. They also highlight an interesting interaction between inflammatory stimuli and the generation of stress, where LPS stimulation increases the ability of macrophages to grow and therefore compress their surroundings. However, the addition of IFNγ is enough to reverse this effect. These results highlight the need for a greater understanding of macrophages and their active contribution to the mechanical microenvironment.

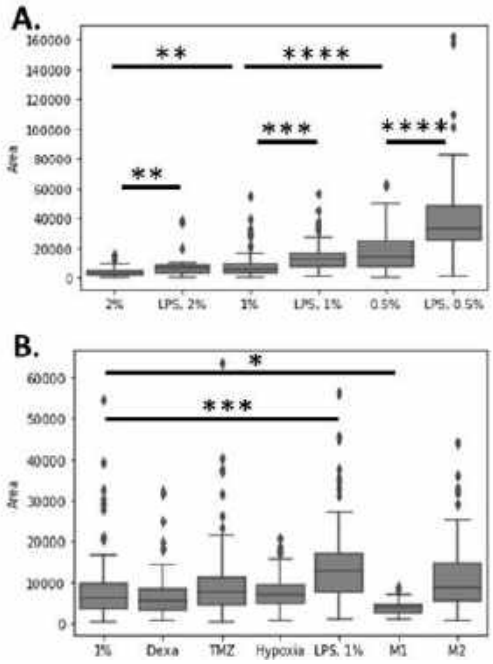

Figure 2: Spheroid area varies with agarose percent and treatment. (**A.**) LPS treatment increases spheroid size compared to untreated at all three agarose concentrations, and reducing the agarose concentration significantly increases spheroid size. (**B.**) Treatment with LPS significantly increases spheroid size, while treatment with LPS plus IFNγ (M1) significantly reduces spheroid size.

DISCUSSION

For the first time, these results show how macrophages respond to various conditions in a 3D confining gel. Interestingly, IFNγ is enough to reverse the effect of LPS on spheroid growth. It is also interesting that relevant doses of temozolomide, dexamethasone, and hypoxia do not significantly impact spheroid stress generation, suggesting that these mechanical processes may occur independently from other biological responses. This work also reveals an interesting 3D growth pattern, as macrophages adopt a flattened discoid shape, rather than a spheroidal shape. This could indicate either a physical process, such as the formation of a planar crack in the gel, or a biological process, such as differential proliferation in different regions of the spheroid. Further work to characterize these spheroids, such as histology, western blot, and PCR is underway to further understand these biological mechanisms, which may have *in vivo* parallels in health and disease.

These constructs have excellent potential for short-term and long-term experiments and are easily tunable to include different cell types or matrix modifications. For example, co-culturing macrophages with cancer cells can easily be implemented, and would elucidate novel mechano-immune interactions in cancer. Overall, this work demonstrates that the agarose-embedded 3D macrophage model is a promising platform to screen different treatments or experimental conditions for their effect on the mechanical activity of macrophages.

INTRODUCTION

Tetralogy of Fallot is a congenital heart disease which results in poorly oxygenated blood flow to the body. A commonly performed intervention is the pulmonary valve replacement surgery; however, patients who undergo these procedures require multiple repeat surgical interventions during their lifetimes. This is attributed to structural valve deterioration [1], a mechanism which is responsible for the mechanical degradation of the valve implant.

Cardiac surgeons are interested in developing strategies to increase the valve implant longevity. One hypothesis is that an optimal valve implant position and orientation exists that results in favorable hemodynamics and valve leaflet dynamics. Additionally, determining optimal orientations has clinical importance, as surgeons are required to constrain multiple degrees of freedom when implanting the valve. Thus, quantifying favorable valve orientations will assist in developing a set of surgical guidelines.

Therefore, the purpose of this study is to develop a novel in-silico pipeline to quantify bioprosthetic pulmonary valve implant geometry, to perform computational fluid dynamics simulations of various pulmonary artery and valve models, and to evaluate the subsequent hemodynamic forces applied to the implanted valve that may impact structural deterioration.

METHODS

To quantify the valve implant orientation, pulmonary artery centerlines along with the valve implant position and orientations were extracted from 3D models. Using these datapoints, an ideal implant plane was constructed from which 2 characteristic valve implant angles α and β were estimated (Figure 1).

In our investigations, we developed both canonical and patient-specific models. The canonical models consisted of idealized pulmonary arteries in which we perturbed the bioprosthetic valves along angles α and β. The patient-specific models were obtained from segmentations of CT and MR angiogram images of 15 patients with repaired tetralogy of Fallot who had undergone pulmonary valve replacements.

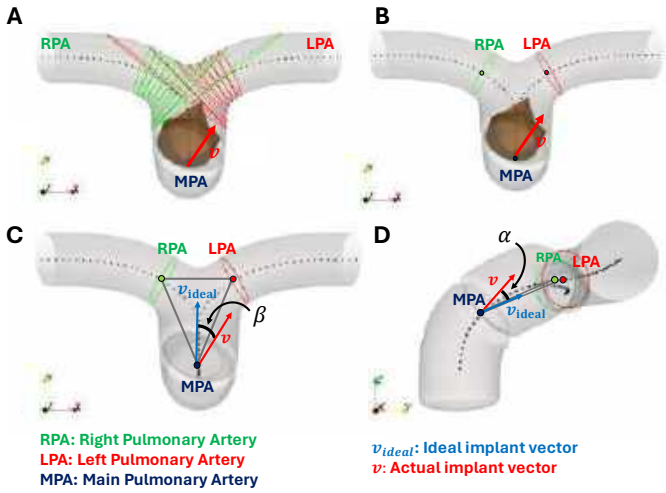

Figure 1: Pipeline to obtain pulmonary valve implant angles α and β. (A) Normal cross-sectional slices of position coordinates. (B) Selection of 3 position coordinates to construct the ideal plane. (C) and (D) Measurement of angles β and α respectively.

We performed computational fluid dynamic simulations of our models using a sharp-interface immersed boundary flow solver which included a reduced-degree-of-freedom fluid-structure interaction (FSI) model of the pulmonary valve. More details of our valve model can be accessed in a previous study [2].

We assessed the flow distributions to the branch pulmonary arteries. Thus, the flow rates were measured at the outlet of the left (LPA) and right (RPA) pulmonary arteries. The flow rates were then integrated and then divided by the common net flow (MPA) applied to the models (Equations 1 and 2).

$$Q_{\mathrm{RPA}} = \int_0^T Q_{\mathrm{RPA}}(t)\,dt \text{ and } Q_{\mathrm{LPA}} = \int_0^T Q_{\mathrm{LPA}}(t) \quad (1)$$

$$\%Q_{\mathrm{RPA}} = \frac{Q_{\mathrm{RPA}}}{Q_{\mathrm{MPA}}} \cdot 100 \text{ and } \%Q_{\mathrm{LPA}} = \frac{Q_{\mathrm{LPA}}}{Q_{\mathrm{MPA}}} \cdot 100 \quad (2)$$

To predict regions of the valve leaflets that had greater potential for structural valve deterioration, we computed the cycle-averaged pressure differentials across the valve leaflets, which is provided as

$$\overline{|\Delta P(X)|} = \frac{1}{T}\int_0^T |\Delta P(X,t)|dt \quad , \quad (3)$$

where X is the triangular element belonging to the valve leaflet surface mesh and $\Delta P(X,t)$ is the local pressure differential forces that the surrounding fluid imposed onto the valve leaflets.

RESULTS

The pressure differential plots of the various valve implant perturbations that were applied to the canonical pulmonary artery model have been provided in Figure 2. Additionally, the flow distributions at the branch arteries have been recorded in Table 1.

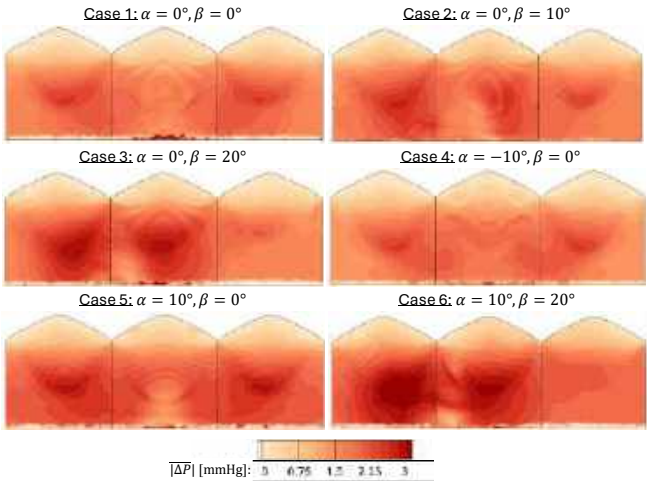

Figure 2: Cycle-averaged pressure differential plots for 6 valve implant orientation cases.

Table 1: Branch Artery Flow Distributions of Various Cases

Case	α [°]	β [°]	$\%Q_{\mathrm{RPA}}$	$\%Q_{\mathrm{LPA}}$	$\lvert\Delta P_{\mathrm{max}}\rvert$ [mmHg]
1	0	0	50.1	49.9	2.55
2	0	10	46.5	53.5	5.22
3	0	20	44.0	56.0	5.14

2315	15.6	29.5	43.4	56.6	9.83

DISCUSSION

Our canonical model simulation results (Figure 2 and Table 1) show that an optimal orientation exists ($\alpha = \beta = 0°$) where there is symmetric flow distribution to the branch arteries as well as the lowest pressure differentials across the valve leaflets. If the valve implant orientation increases along α, a symmetric flow distribution is preserved while the leaflet pressure magnitudes increase. If the valve implant orientation increases along β, then there is increased flow distribution asymmetry as well as asymmetry in the leaflet pressure differentials.

If the patient-specific results are considered (Figure 3 and Table 2), there is additional complexity not observed in the canonical model cases. For instance, although β may indicate flow asymmetry, local vessel geometries such as stenosis and curvature effects also contribute to increasing the observed asymmetries. Thus, valve orientation is not the sole predictor of unfavorable hemodynamics and leaflet dynamics.

Nevertheless, our results indicate that intentional positioning of implanted pulmonary valves could lead to improved hemodynamics for bioprosthetic valve durability. Because pulmonary valve geometries are more controllable than other valve prosthesis, our in-silico pipeline provides a general approach to guide optimal valve position and potentially limit the effects of structural deterioration.

INTRODUCTION

Collective cell migration is a complex biological phenomenon that occurs in cancer metastasis, wound healing, and development [1,2,3]. Cells within the collective move together with coordinated motion, and the interplay between directed motion and mechanical interactions occurs on scales of up to ten cells [4]. Since there can be no holes or overlapping cells within the monolayer, shape change must result from rearrangement events, wherein cells slide past their neighbors, hence rearranging their local positioning. The ability for cells to rearrange defines whether a tissue is solid-like or fluid-like, with a solid-like tissue having a finite energy barrier to rearrangements and a fluid-like tissue having no energy barrier to rearrangements [5,6,7] . The notion of two phases—solid and fluid—is a useful framework to investigate collective motion, but most prior studies have observed epithelial cell layers to be fluid-like. It is not yet clear how to distinguish between different fluid-like systems. A major limitation towards this goal is that there is a lack of well-established methods to control rearrangements within the cell layer for subsequent study.

Here, we describe methods to produce well-controlled regions of rearrangements within a cell layer. To this end, we used micropatterning to confine cells in islands having different shapes. Compared to circular cell islands, elongated cell islands had substantially more rearrangements between neighboring cells. Using optical microscopy, traction force microscopy, and monolayer stress microscopy, we computed the cell velocities, tractions, and stresses in both circular and elongated cell islands.

METHODS

Polyacrylamide (PA) gels were fabricated with an elastic modulus of 6 kPa; fluorescent particles were embedded at the surface as described previously [8]. Traditional lithography techniques were used to create a silicon master mold containing elongated islands with dimensions of 300 μm x 1 mm. This master mold was spin coated with PDMS, which was then cured at 60°C overnight and cut into masks. The masks were then adhered to the PA gels. The areas of the gels that were not covered by a mask were functionalized by collagen I using the crosslinker sulfo-SANPAH as described previously [8]. The masks were removed, and the areas free of collagen were passivized with 3% bovine serum albumin to prevent non-specific cell adhesion to the collagen-free regions. Madin-Darby canine kidney (MDCK) type II cells were seeded onto the gels at a concentration of 1.25×10^6 cells/gel and allowed to come to confluence on each collagen island overnight. Cell proliferation was then inhibited with a treatment of 10 μg/mL mitomycin-C. Cell islands and fluorescent particles were imaged on an Eclipse Ti microscope (Nikon, Melville, NY) and an Orca Flash 4.0 digital camera (Hamamatsu, Bridgewater, NJ) every 10 min for 24 hrs at 37°C. Trypsin was added to remove the cells from each gel, allowing for the gel to return to an undeformed state. Following the return to an undeformed state, a reference image of the fluorescent particles was taken.

Fast Iterative Digital Image Correlation (FIDIC) [9] was used to compute cell-induced substrate displacements (with respect to the undeformed reference image) and cell velocities. Fast Fourier traction cytometry [10] with a correction for finite substrate thickness [11,12] was used to compute cell-substrate tractions, which were subsequently used to compute the cell-cell stresses using monolayer stress microscopy [13,14,15]. Here, we focused on the maximum shear stress, which was computed by taking the difference between the first and second principal stresses and dividing by two.

RESULTS

We began by searching for rearrangement events in a circular island of 1 mm (Fig. 1a). Results showed that motion was uncontrolled, with rearrangement events occurring sporadically at different positions and different points in time. This complex behavior makes it hard to study rearrangements in a controlled way. Within the 1 mm island, there appeared to be a seemingly random distribution of shear stresses, which again indicates the randomness present in these large circular islands (Fig. 1b). A zoomed in view of the cell morphology can be seen in Fig. 1c. Note that a majority of the cells were rounded, and shear stress is relatively uniform across the island,

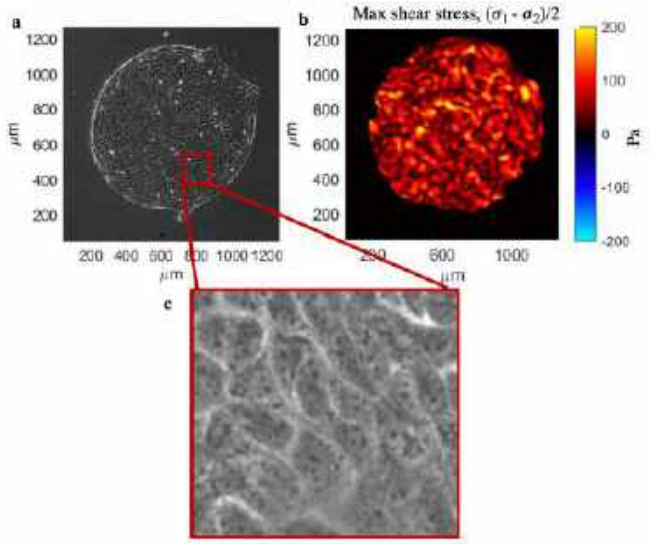

Figure 1: Cell elongation and max shear stress in a 1 mm diameter cell monolayer. (a) Phase contrast image of the cell monolayer. (b) Max shear stress within the cell monolayer. (c) Enlarged view of the phase contrast image in the highlighted region in panel a. Note that the cells are rounded.

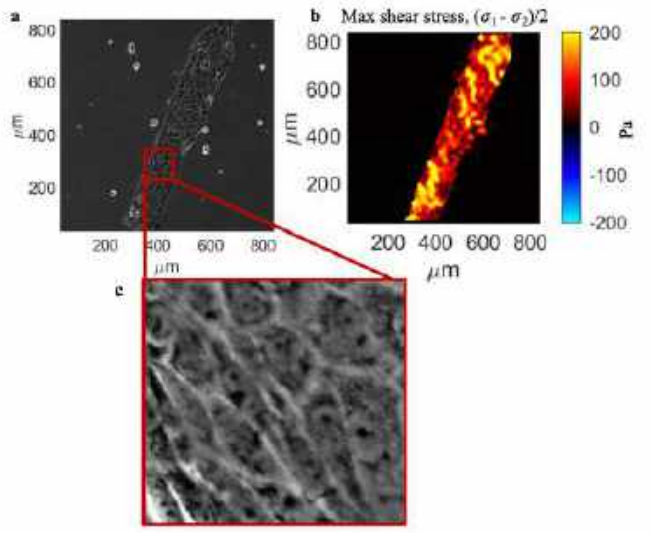

Figure 2: Cell elongation and max shear stress in a micropatterned island. (a) Phase contrast image of the cell monolayer. (b) Max shear stress within the cell monolayer. (c) Enlarged view of the phase contrast image in the highlighted region in panel a. Note that the cells are elongated.

making the dynamics associated with cell elongation and rearrangement challenging to study.

When cells were confined to an ellipsoid island, as seen in Fig. 2a, they had a natural tendency to rotate circularly as a collective. We hypothesized that this would give rise to elongated cells and controlled areas of rearrangement, and in turn, high shear stress relative to an unconfined monolayer [16]. Results showed that the shear stress was not random throughout the island, but rather there were areas of large shear stress with cells undergoing rearrangement events (Fig. 2b.). These areas of large shear stress were organized in space, as they typically occurred at the top and bottom of the elliptical island. Additionally, an enlarged view of the island, seen in Fig. 2c, shows that more than half of the cells elongated with strong alignment between neighboring cells.

DISCUSSION

This study focused on controlling rearrangements within a cell monolayer. To this end, we combined micropatterning techniques with optical microscopy and monolayer stress microscopy. In unconfined 1 mm islands, cells exhibited complex and unpredictable movement. The shear stress fluctuated throughout the island, making it challenging to study the dynamics that are associated with cell elongation and cell-cell interactions during rearrangement events. To address these issues, we patterned cells in elongated islands, in which the cells displayed a natural tendency to migrate collectively around the island. Along with moving rotationally, the cells were elongated, and locations of high shear stresses occurred near the ends of the elongated islands. In future work, we aim to investigate in more detail the stresses associated with rearrangement events within the monolayer.

INTRODUCTION

Remodeling after myocardial infarction requires careful balancing of numerous ensuing phases to achieve an optimal outcome. Within each phase, there are various factors impacting myocardial wall mechanics which can tilt the overall response towards improved or worsened results. Clear relationships between cardiac fibroblasts, environmental stiffness, and dynamic mechanics have been established.[1–5] A better understanding of myocardial mechanics and the resultant cell response during the development and progression of these pathophysiological states is critically needed to enable development of effective therapies and treatment regimens.

We have developed an in vitro engineered heart tissue platform consisting of a fibrin-based hydrogel with embedded cardiofibroblast and cardiomyocyte populations, which are subjected to controlled electrical and mechanical stimulations. In this study, we subjected these engineered-heart tissue constructs to simulated infarctions via cryo-probe injury and evaluated the temporal changes in regional mechanics that developed as a result of the injury and the embedded cell population response.

METHODS

Primary ventricular cardiofibroblasts and cardiomyocytes were isolated directly from neonatal Sprague Dawley rats in accordance with an IACUC approved protocol. Cell-containing fibrin gel solution was pipetted into the wells of the custom-fabricated platform. Wounding was applied via custom manufactured cryo-stamps dipped in liquid nitrogen which ensured a uniform cryo-wound application to each sample. Gels were subjected to cyclical electrical stimulation and a constant mechanical stretch. Stretch was applied via electromagnets acting upon magnetic grips attached to each gel within the platform. Images were acquired during a daily stretching phase consisting of discrete electromagnetic field strength step increases to evaluate stiffness via surface strain mapping. Surface strain mapping analysis was performed via NCORR 2D digital image correlation MATLAB software.[6] Force values resulting from the discrete amperage levels of the electromagnets were previously experimentally generated via spring compression calibration utilizing springs with known material properties.[7]

To assess regional variation in mechanical properties, constructs were segmented into sixteen subregions. Three neighboring subregions were joined to form an analysis region. Three analysis regions were selected corresponding to the infarcted, border, and remote regions of the construct. The stress-strain pairs of each sample were calculated for each analysis region and for the sample as a whole. A regression was performed using the stress-strain pairs to attain the estimated modulus of elasticity value.

For statistical analysis, paired t-tests were performed for all intra-condition comparisons with significance reported at $p < 0.05$. Two-sample t-tests were performed for all inter-condition comparisons with significance reported at $p < 0.05$. The unwounded control treatment group possessed a sample size of $n = 4$ for all calculations. The wounded experimental treatment group possessed a sample size of $n = 6$ for all calculations.

RESULTS

When evaluating the macro-modulus of elasticity, there is a clear trend of stiffening within the unwounded control group that the wounded group does not exhibit. While the maximum modulus values of the wounded group shown in the box plots of Figure 1A do appear to increase day to day starting after wounding on day 1, there is no statistical significance observed between groups. The unwounded control group highlighted in Figure 1B on the other hand exhibited significant levels of stiffening from day 1 to day 3 and 7. When comparing modulus of the control and wounded groups directly at each day, no significant differences are reported. By day 7, the average

modulus of the unwounded group is beginning to separate itself from the wounded constructs.

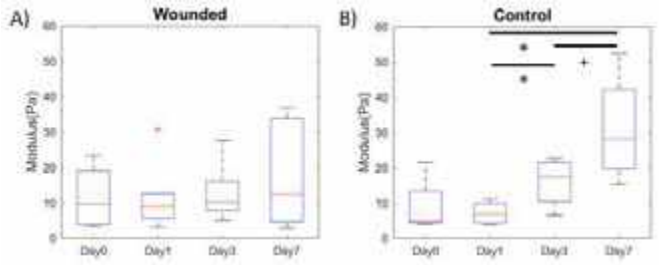

Figure 1: Macro-modulus of wounded and unwounded gels. A) Box plot of wounded whole gel modulus (n = 6). B) Box plots of unwounded control whole gel modulus. (*: p<0.05;+p<0.1 | n = 4).

Regional comparisons of stiffness moduli shown in Figure 2 reveal a mostly uniform unwounded control construct throughout the time course that only exhibits trends towards significance between neighboring regions on day 7. While the wounded group also exhibits an apparent near uniformity of modulus among regions initially, clear differences arise after wounding. By day 1 post-wound, the remote and border regions both exhibit significantly greater stiffness than the wounded region. On day 3, significance persists between the stiffness of the remote and the wounded regions while the disparity between the bordering region and the wound is reduced to near significance. On day 7, the regions of the wounded gel have again reached statistically indistinguishable levels of stiffness.

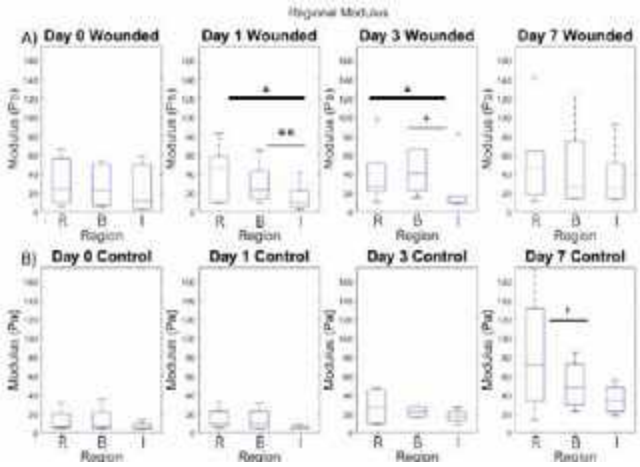

Figure 2: Intra-day comparison of regional moduli across timecourse. Region(R-Remote, B-Border, I-Infarct). A) Wounded gel regional moduli (: p<0.01; *: p<0.05; +: p<0.1 | n = 6). B) Unwounded control gel regional moduli (+: p<0.1 | n = 4).**

Within the unwounded control condition, regions show little variability throughout the time course until day 7 where the remote region appears to be stiffening to a greater value. However, all regions increase in stiffness through day 3 and 7 compared to initial values.

DISCUSSION

The healing infarct is without question a very complicated subject. It is a tumultuous environment with dynamic mechanics, varied geometries, spatial inconsistency, and overall uncertainty. Therefore, simple, effective, and consistent therapeutic strategies evade discovery and enactment. Clarke et al presented a review of literature highlighting that experimental models of myocardial infarction vary wildly in collagen structure, mechanics, and remodeling. The authors concluded that it is difficult to ascertain possible therapeutic efficacy without testing across a range of species, infarct locations, and reperfusion protocols due to the inherent complicated biology and mechanics of the healing infarct that are often counterintuitive and extremely complex.[8] This conclusion was supported by a separate finite element analysis that investigated the effect that infarct location had on traditional functional output measures of cardiac efficiency. It was concluded that tradeoffs exist between therapeutic options of interest and that infarct location likely plays a significant role in what therapeutic route would most appropriately induce recovery in an infarcted myocardium.[9]

These results suggest that again the healing infarct is a very complicated subject matter and that a simpler, more consistent, and more widely applicable methodology of evaluating therapeutic efficacy is desperately needed. These results in part inspired the experimental analysis conducted within our study as a preliminary investigation into the natural progression of a simplified engineered cardiac tissue construct following myocardial injury. As literature findings clearly demonstrate the importance of wall mechanics, investigating the progression of the stress-strain relationship and regional stiffness found within our mechanically active constructs is an important contribution towards the development of an improved understanding of the progression of mechanics within the early infarct. Sample to sample variation within the sample fabrication process can increase the uncertainty in direct value to value comparisons across treatment groups. This variation is believed to be related to the prototype nature of the technology platform. Room for refinement within the protocols exists with some example targets including: thrombin concentration during gelation, final fibrin gel density, cellular density, myocyte to fibroblast ratio, and electrical and mechanical stimulation regimes. When analyzing the gels holistically, the control groups follow a gradual stiffening over the time course while the experimental gels appear to maintain a similar stiffness throughout, only broken up by an increased value range on the ultimate day. These observations seem to suggest that while the wounding did not disrupt the architecture of the underlying gel, wounding is responsible for the disruption of the stiffening process. While evaluating the overall stiffening trends is useful and provides a test bed with parallels to that of the stiffening infarct, gaining insights into the spatial heterogeneity of mechanics from within the infarct to the remote tissue can elucidate the finite and incremental nuance of the recovery process.

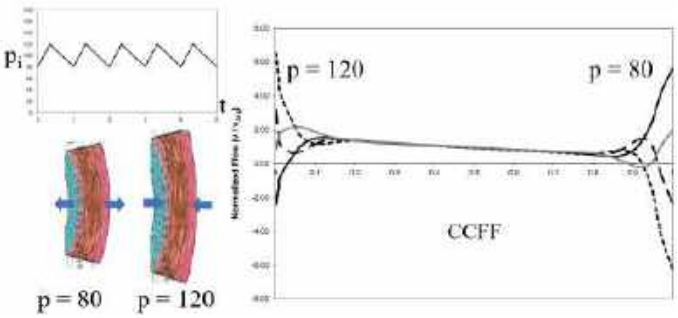
INTRODUCTION

Atherosclerosis is an arterial disease that is the cause of worldwide morbidity and mortality. Atherogenesis occurs in regions of geometric complexity for example in branches, bifurcations, and sharp curvatures where blood flow altered hemodynamic stresses can damage the endothelium. Clinical 'risk factors' for atherosclerosis include high blood pressure, smoking, and elevated levels of LDL in the blood. Atherogenesis has been described as a process of white blood cells (WBCs) entering through damaged endothelium joining with damaged smooth muscle cells (SMCs) to produce plaque. Atherogenesis is related to the vasa vasorum (VV) however its specific role is not yet fully understood [1]. The long-term cyclic pressure response of arteries should produce a cyclic tissue fluid reaction both at the internal and the external surfaces of the artery, however these phenomena, especially in response to vascular damage, has not received significant attention in the literature.

The goal of this abstract is to utilize a computational model to demonstrate that such radial cyclic fluid velocities can and do occur. Furthermore, how these are altered in arteries with varying degrees of endoluminal vascular damage will also be quantified. The relationship between the pore fluid flows and atherogenesis described here is also discussed with the goal of adding to the quantitative biomechanical view of atherogenesis.

METHODS

Poroelasticity is a continuum model for materials composed of a porous elastic solid and a mobile fluid (water/saline) that flows relative to the deforming solid. Consider the solid to be fluid-saturated and described by porosity. The pore fluid pressure is related to interstitial fluid flow by a Darcy law defining hydraulic permeability. PoroHyperElasticity (PHE) includes "large" deformations /strains in a nonlinear hyperelastic porous solid and an incompressible mobile fluid. When quasistatic loading is applied to the poroelastic material, a 'consolidation' response is generated. Application of cyclic internal pressure to a poroelastic cylinder with an impermeable internal surface (hydraulic permeability = 0) would result in moderate cyclic fluid flow at the open external surface. However, if the inner surface is permeable and exposed to prolonged pulsatile pressure, a large convection fluid flow can occur at both the internal and external surfaces, with relative low fluid flow over most of the interior of the cylinder. This condition will be termed here as Cyclic Convective Fluid Filtration (CCFF) and is shown in **Figure 1**. A 'sawtooth' pressure excites CCFF with influx/efflux luminal flow and corresponding efflux/influx outer adventitial flow. This cyclic flow phenomenon is suggested in early works, for example see Wang and Tarbell [1] and Kenyon [2].



2 a **2 b**

Figure 1: Cyclic convective fluid filtration (CCFF) in a Porohyperelastic artery

Plots of relative pore fluid velocity showing CCFF were generated using ABAQUS to develop finite element models (FEMs) of rabbit carotid arteries. PHE FEMs These FEMs were layered cylinders (finite plane strain) subjected to the 'sawtooth" (120/80 cardiac cycles) pulsatile internal pressure. Carotid arterial geometry and structure were

obtained from excised vessels. The FEMs included endothelium, intima, media, SM, elastic, and collagen fibers. Nonlinear anisotropic hyperelastic materials and a coupled Darcy equation with nonlinear permeability, porosity, and saline tissue fluid were incorporated into the PHE FEM. PHE material properties/parameters were taken from experimental data in the literature.

RESULTS

PHE FEMs were used to consider the effects of variable material and structural parameters. **Figure 2** illustrates the effects of endothelial damage (luminal permeability > 0) on CCFF development. The lower plot in the figure shows response when the endothelium is impermeable, i.e. the 'normal' artery. No tissue fluid flow crosses the endothelium, moderately low convection develops in interior and at the external surface. When permeability is nonzero, the CCFF response occurs immediately and is increased as permeability increases, CCFF becomes markedly larger at interior and exterior surfaces. Similar parametric studies showed only small sensitivity of CCFF to hypertension and increased HR.

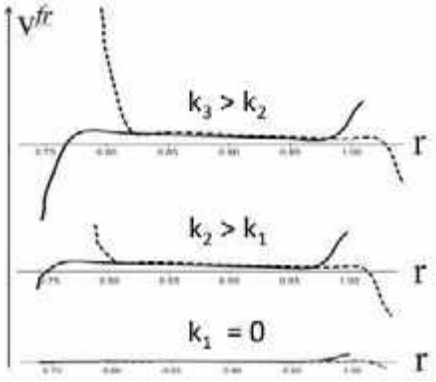


Figure 2: Parametric study on luminal permeability on CCFF

DISCUSSION

The presence of CCFF can provide a unique view of atherogenesis. A 'normal' artery subjected to pulsatile internal pressure will not develop CCFF since the endothelium is impermeable. Oxygen and nutrients are delivered by diffusion from the endothelium to the intima and diffusion from VV located in the externa and adventitia. Damage to the endothelium, if not repaired, will make the endothelium permeable. CCFF, a repeating cyclic convective flow of pore fluid that produces a relatively large influx and efflux occurring at the inner and outer/externa interfaces. CCFF can then be related to the process of atherogenesis in three ways—refer to **Figure 3**. Note that these effects can occur simultaneously but are shown separately for clarity.

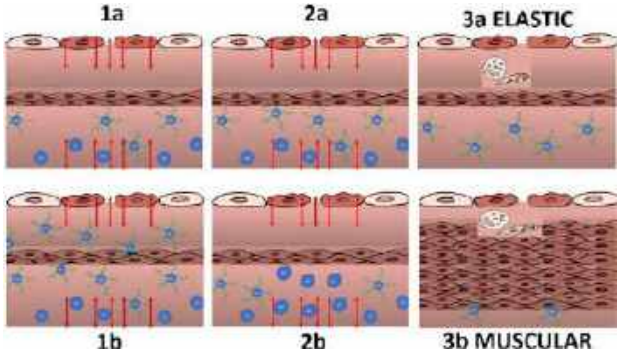

Figure 3. Role of CCFF in atherogenesis

1. The endothelium is 'damaged' and becomes permeable. CCFF can develop and LDL is convected by the influx/eflux into the intima. CCFF will disrupt the normal process of diffusion and the loss of oxygen and nutriments will be compensated by formation of new VV. CCFF also has the potential to draw in more white bloods cells.

2. CCFF at the internal surface will also cause CCFF, i.e. cyclic efflux/influx of tissue fluid, at the externa/adventitia surface. Diffusive transport from the VV would be disrupted by CCFF. This suggests another mechanism by which the VV can be linked to atherogenesis (as described in the literature).

3. In "elastic" arteries, CCFF at internal and external wall surfaces can disrupt delivery of oxygen and nutriments to the SMC layers leading to cell death/detachment and differentiation into foam cells (in addition to foam cells originating from white cells in the blood). In "muscular' arteries, CCFF can impinge directly on the SMCs near the endothelium [1]. PHE FEMs can simulate both cases by developing parametric studies of CCFF over a range of diameter/thickness ratios as well as consideration of CCFF effects ranging from elastic to muscular arteries. Variation of material properties, e.g. elasticity, endothelial permeability (as in **Figure 2**) can also be considered.

Only two relevant poroelastic arterial FEMs were found in the literature, i.e. a biphasic FEM (Johnson and Tarbell, [3]) and a FEM by Koshiba et al [4]. The latter paper used our PHE material model in a combined FSI/FEM of a curved coronary artery with LDL entering from flowing blood. This study considered cyclic pressures but did not report a CCFF pore fluid motion. In this work we have shown here that a PHE model of a carotid artery with injured endothelium, when exposed to a pulsatile pressure, can develop a cyclic interference pattern (CCFF) in tissue fluid flow. This phenomenon has not been extensively explored in the literature. CCFF can be related to atherogenesis by a) developing high cyclic convection at inner and outer surfaces; b) disruption of the normal diffusive transport at the endothelium and VV; promotion of LDL and white blood cells in the media; and c) SMC detachment from the matrix form foam cells. Future research efforts should focus on identifying the relative contributions of the numerous porohyperelastic parameters – including well designed experimental studies to generate and test these novel mechanisms of atherogenesis.

INTRODUCTION

Metastasis relies on the ability of cancer cells to invade areas distal to the original growth. While rare, it is possible for cancer cells to invade through muscle tissue to metastasize [1]. The rarity is because contraction and elongation of muscle fibers cause large deformations to the cells, which often leads to cell death [2]. Interestingly, cells that invade through muscle in collective groups survive at a higher rate than individual cells [3]. These observations suggest that the collective behavior of a group of cells may be necessary for inter-muscular survival, yet the precise explanation remains unknown. Using two prostate cancer cell phenotypes, one exhibiting a low survival rate in muscle (DU145) the other a heightened ability to survive in muscle tissue (DUAA), we explored the question of how groups of cells are able to invade through muscle tissue while avoiding cell death.

Within collective groups, cells can exhibit material qualities classified as solid-like (jammed) or fluid-like (unjammed) [4]. In a fluid-like state, cells can slide past their neighbors, whereas for solid-like, they cannot. These material states are affected by cell-cell adhesions and force production which in turn alter cellular migration. Considering that survival in muscle requires cellular collectives to undergo large shape change, we hypothesized that DUAA cell collectives exhibit a more fluid-like state that allows them to easily slide past their neighbors, in turn enabling large collective shape changes during expansion and contraction of the muscle. By contrast, we hypothesized that DU145 cell collectives are more solid-like, meaning that in muscle the individual cells would undergo large shape changes that frequently lead to cell death. Here, quantify cell movement, shape index, and cellular forces in DU145 and DUAA cells to identify if DUAA cell collectives exhibit a more fluid-like state as compared to DU145 cell collectives.

METHODS

Cell Culture. The cells used were DU145 and DUAA cells, as described previously [3], and both of which are human prostate cancer cell lines. Cells were maintained in Modified DMEM No Glutamine, No beta-Mercaptoethanol (eg, Corning Iscove's Modification of DMEM Corning 15-016-CV) with 10% fetal bovine serum (FBS, Corning) and 1% Penicillin-Streptomycin. Cells were passaged every 4-5 days at 70-90% confluency.

Substrate Fabrication. A protocol previously published by our lab [5] was used to fabricate substrates of Young's modulus 5 kPa with flourescent particles for traction force microscopy. A polyacrylamide solution was prepared with 5% weight/volume (w/v) acrylamide (Biorad Laboratories, Hercules, CA), 0.2% w/v bisacrylamide (Biorad), 0.002% (v/v) TEMED (Biorad), 0.006% (w/v) ammonium persulfate (Biorad), and 18 µm of 2.6×10^{12} particles/mL of 0.2 µm red fluorescent (580/605 nm) 2% solids FluoSpheres Amine-Modified Microspheres (Thermo Fisher Scientific, Waltham, MA). A 20 µL droplet was pipetted onto a #1.5 glass bottom dish (Cellvis, Mountain View, CA). A 18 mm circular glass coverslip was placed over the 20 µL droplet forming a thin gel layer. To localize fluorescent beads to the surface of the gel, gels were placed in a centrifuge upside down and centrifuged at 30 rcf for 16 min.

Micro Patterning Cell Islands. Polydimethysiloxane (PDMS) (Sylgard 184, Dow Corning, Midland, MI) was prepared according to manufacturer instructions and poured into petri dishes at a thickness of 500 µm. The PDMS was then cured in a incubator at 60°C overnight. After curing the PDMS was cut into 16 mm circles which were then punched with a 1 mm biopsy punch. Each resulting PDMS mask was then sterilized by 70% ethanol and incubated in 2% Pluronic F-127 (Sigma-Aldrich, St. Louis, MO) to prevent cell adhesion to the PDMS. The masks were then placed on top of the polyacrylamide substrates, where the open 1 mm circles were functionalized with type I rat tail collagen (BD Biosciences, Franklin Lakes, NJ; 0.01 mg/mL, 1–2 mL per 18 mm diameter gel) using the crosslinker sulfo-SANPAH (Pierce Biotechnology, Waltham, MA; 2 mg in 200 mL 0.05 M HEPES). 8×10^5 cells/mL cell solution was prepared and 200 µL of cell solution pipetted onto each PDMS mask. 1–2 hr after seeding, the PDMS masks were removed and the glass bottom dishes were incubated at 37°C and 5% CO_2 for 12–16 hr, allowing for the cell is-

lands to reach the desired confluency. Only fields of view where the cells were confluent were used, fields of view that were over and under confluent were disregarded. This allowed us to make a more direct comparison between the two cell types.

Time-Lapse Imaging. Dishes with desired density were placed in a custom built cage incubator to maintain environmental conditions of 37°C and 5% CO_2. An Eclipse Ti-E microscope (Nikon, Melville, NY) with a 10×0.5 numerical aperture objective (Nikon) and an Orca Flash 4.0 digital camera (Hamamatsu, Bridgewater, NJ) running on Elements Ar software (Nikon) was used to image the cell islands and fluorescent particles in the substrates every 10 min for 24 hr.

Cell Shape. Using Seedwater Segmenter software [6] on phase contrast images of the two cell types resulted in a watershed. The watershed image was then converted into a binary image from which each cell's area (A) and perimeter (p) were calculated. The resulting areas and perimeters were used to compute the shape index q defined as $p/\sqrt{A}$. A larger q represents a more elongated cell; a smaller value indicates a more rounded cell. The smallest possible value of q is 3.543 for a circle.

Cell Movement. Using Fast Iterative Digital Image Correlation (FIDIC) [7], phase-contrast images of the cells were correlated over time to extract cell motion over time using 64×64 pixel subsets at a spacing of 16 pixels. From this data, we computed the average cell speed and a parameter to quantify rearrangements between neighboring cells, D^2_{min}. For each cell D^2_{min} was calculated according to

$$D^2_{\text{min}} = \frac{1}{N}\sum_{j=1}^{N}\left[\Delta\vec{d}_{ij} - E_i\vec{d}_{ij}\right]^2, \quad (1)$$

where N is a chosen number of nearest neighbors to the i^{th} cell ($N = 8$ was used here), $\vec{d}_{ij}$ is the position vector between cell i and neighbor j, $\Delta\vec{d}_{ij}$ is the change in $\vec{d}_{ij}$ between two consecutive time points, and E_i is the strain tensor defining the average motion undergone by cell i and its N neighbors [8]. Lastly, D^2_{min} was normalized to account for differences in average cell speed between the two cell types.

Traction Force Microscopy. Using FIDIC [7], time-lapse images of fluorescent particles were correlated to a stress-free reference image to compute cell-induced substrate displacements. The displacements were computed using 64×64 pixel subsets at a spacing of 16 pixels. Cell-substrate tractions were calculated using Fourier transform traction microscopy [9].

RESULTS

To explore the hypothesis that DUAA cells exhibit a more fluid-like state allowing them to undergo a collective shape change to avoid large single-cell deformations, we began by studying the movement of the two cell types. Using the velocity data obtained from FIDIC [7], we computed the average single-cell velocity and D^2_{min}. Results of the single-cell velocity data showed that DU145 cells had a higher average speed compared to the more invasive DUAA cells (Fig. 1a). The speed has little implication to a fluid-like state, however, as fluid-like behavior is defined by the ability of cells to rearrange positions with their neighbors. Defined above (Eq. 1), D^2_{min} is representative of each cell's ability to rearrange and slide past its neighboring cells. A low value shows the motion of the i^{th} cell is well coordinated with its neighbors indicating less rearrangements, whereas a higher value indicates less coordination and thus more rearrangements which is an indicator of a more fluid-like system. Compared to DU145 cells, DUAA exhibited a higher average D^2_{min} (Fig. 1b), indicating that DUAA cells exhibited more fluid-like behavior than DU145.

Given the movement measurements studied, we then looked into the shape index of the two cell types. Defined above, q is the shape index used to determine the morphology of the cell types. In the plot of mean q (Fig. 1c), the DUAA cells have a higher value, indicating that they are more elongated than the DU145 cells. More elongated cells indicate a more fluid-like cell monolayer, which allows for more cell rearrangements [4], which is also consistent with our hypothesis.

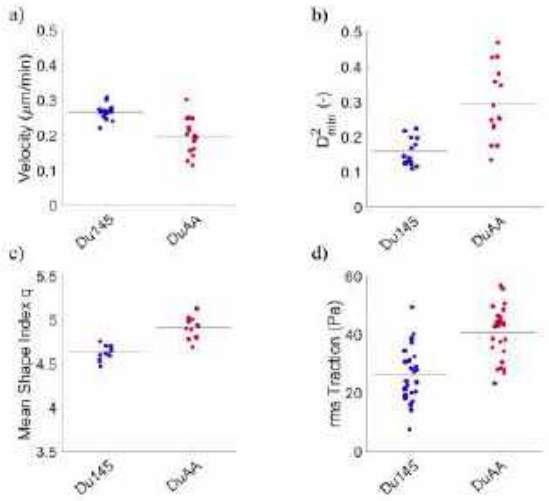

Figure 1: Motion, shape index, and force production plots for the two cell types studied. Each point represents a mean over a field of view, black dashes represent the mean of all fields of view for each given cell type. Data plotted is (a) average cell velocity ($p = 3.75 \times 10^{-4}$), (b) D^2_{min} ($p = 1.90\times10^{-4}$), (c) mean shape index q ($p = 4.74\times10^{-4}$), and (d) root mean square traction ($p = 8.32 \times 10^{-6}$). p values were calculated using rank sum tests.

Lastly we measured the cell-substrate tractions produced by the two cell types, because larger tractions are often the cause of the larger shape index [5], which in turn results in the more fluid-like state. Using Fourier traction force microscopy [9], cell-substrate tractions were computed and averaged for each cell layer by taking the root mean square, which was larger for DUAA compared to control (Fig. 1d). These observations align with our hypothesis of a more fluid-like state.

DISCUSSION

Though the concepts of cell motion, shape index, and force production are well studied [4, 5], our application to the phenomena of cancer cell invasion through muscle provides new insights of how collective cell fluidity may play a role in cancer metastasis. Here, the data point to the conclusion that DUAA cells exhibit a more fluid-like state as compared to DU145. The more fluid behavior would allow these cells rearrange with their neighbors, thereby enabling large changes in the shape in of the collective with minmal shape changes of the individual cells, reducing the likelihood of cell death during invasion through muscle tissue.

INTRODUCTION

Acute ischemic stroke was the fifth leading cause of death in the US in 2022, with nearly a quarter of strokes recurrent within the first two years [1,2]. Due to the high rates of incomplete recanalization in ischemic stroke, researchers have investigated the effect of clot stiffness on endovascular thrombectomy (EVT) outcomes [3]. However, it is unclear whether factors other than hematocrit directly influence EVT. Recent clinical case studies describe calcified cerebral emboli that cause complications in EVT surgeries, yet only present in approximately 3% of cases [4]. Despite the major concern these thrombi pose, little is still known about their mechanical properties, impeding the development of new therapeutics. For this reason, this study focuses on characterizing the rate dependent material properties of aged and calcified clot analogs. In this way, we can study the material properties of these clot analogs to inform future modeling of EVT in AIS to improve surgical outcomes.

METHODS

EA Formation Conditions: To study the effect of calcification on clot mechanical properties, clot analogs were created using human blood, following an approved institutional protocol. Briefly, extracted whole blood was anticoagulated with 0.32% weight sodium citrate. Blood was separated into red blood cells (RBCs), platelet rich plasma (PRP), and platelet poor plasma (PPP) via centrifugation. Blood was reconstituted to 214 x 10^6 platelets per mL, and hematocrit was controlled in clots by addition of 40% volume RBCs. To counter the effects of the anticoagulant, blood was recalcified with 20 mM calcium chloride ($CaCl_2$) and 0.25 NIH Unit/mL thrombin from human plasma (BioPharm, Bluffdale, UT, USA). Clots were then formed in a Chandler loop, which was rotated at 65 rpm for 1 hour at 37°C, and the resultant 4 mm diameter clot was removed from the tubing. Clots were then placed in 0 (cell media), 0.2, and 2 M $CaCl_2$ baths for 1 and 10 days, with control clots tested on day 0.

EA mechanical testing: For compressive testing, clots were sectioned into right cylindrical specimens with a height of 2 mm and mounted on an Instron uniaxial load frame (Instron 68SC, Norwood, MA, USA). Clots were then loaded in compression at 5, 10, and 15% strain per second to 80% strain, with a one-minute relaxation period. Peak stress, percent relaxation, and 10 and 75% tangent stiffnesses were calculated, similar to previous work [3]. For tensile testing, clots were mounted on custom, sandpaper lined grips of a uniaxial load frame. Clots were then loaded, in tension, at 5%, 10%, and 15% strain per second to 80% strain, with a one-minute relaxation period. A fourth tensile test was conducted to measure the fracture stress and strain of the samples, in which the clots were loaded at 10% strain per second until sample failure. Untested clots were embedded in paraffin wax and stained with a Carstairs protocol for histological analysis.

Statistics: Due to variability in coagulation, clot contraction, and variability between donors' blood, multiple sources (n = 6) were collected with replicates (n = 6) tested for each source. Mean values were computed with standard deviation, and a Kruskal-Wallis analysis of variance was applied to compare means. All data analysis was carried out using MATLAB's multiple comparison function.

RESULTS

Average tangent stiffnesses at 75% strain were nearly an order of magnitude higher for the day 1 and day 10, 2 M $CaCl_2$ clots, than for all other conditions, as shown in Figure 1. Low-strain tangent stiffnesses followed a similar trend, with both day 1 and day 10, 2 M calcium clots exhibiting significant increases in stiffnesses. The 2 M calcium clots also showed a significant decrease in compressive percent relaxation, indicating an increase in the viscous behavior of the blood clots. These clots also revealed a significant decrease in mass loss after testing,

suggesting a correlation between extent of calcification and plasma retention.

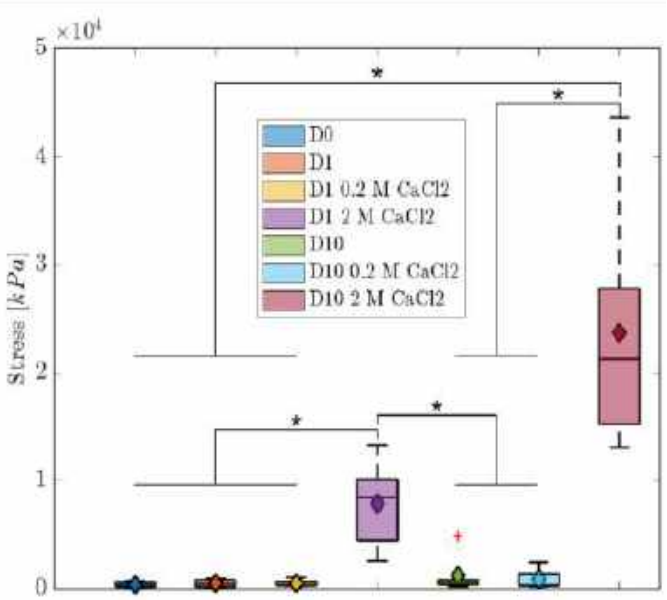

Figure 1: Box plots showing 75% tangent stiffness (at 10% strain per second) for each clot-type in high strain compression tests, with asterisks denoting significant differences (α<0.05), and mean values shown as diamonds.

In tension, the day 10, 2 M $CaCl_2$ clots revealed an order of magnitude increase in stiffness over all other conditions, when loaded to 80% strain at 10% strain per second, as shown in Figure 2. These 2 M $CaCl_2$ clots demonstrated a nonlinear behavior in tension. The 0.2 and 2 M $CaCl_2$ clots also decrease in percent relaxation when compared to the non-calcified counterparts. This suggests that the influence of the viscous element within the clots has decreased with increased calcium content. Despite this, the stiffening effect seen in compression at high strains was not observed in tension. The peak stress at 80% strain was an order of magnitude lower in tension than in compression for all conditions.

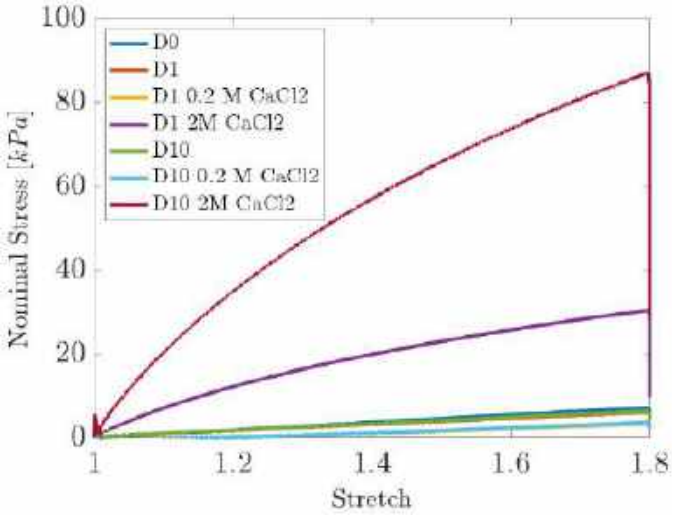

Figure 2: Stress versus stretch tensile curves for each clot type loaded at 10% strain per second to 80% strain.

The Carstairs analysis reveals day 0 and day 1 clots with regions of dense fibrin aggregates along the exterior of the clots. This is a well-known phenomenon of exterior clot sealing with a fibrin dense crust that becomes resistant to thrombolysis. As the clots continue to age, the red blood cell content within the clot (yellow portion) decreases as the red blood cells decay, as shown in Figure 3. This decay seems to be enhanced by the calcification, which seemingly increases the fibrin concentration, but is most likely lysing the red blood cells. Structurally, the red blood cells provide a viscous element to the clot, yet as the clots calcify, their fibrin skeleton becomes predominant.

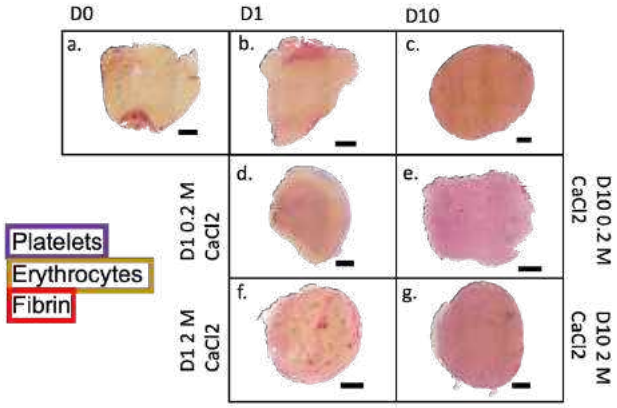

Figure 3: Representative clot images stained with a Carstairs protocol for a. day 0 clots, b. day 1 clots, c. day 10 clots, d. day 1 0.2 M $CaCl_2$ clots, e. day 10 0.2 M $CaCl_2$ clots, f. day 1 2 M $CaCl_2$ clots, and g. day 1 2 M $CaCl_2$ clots. Blue/purple indicates platelets, yellow represents red blood cells, and red represents fibrin.

DISCUSSION

Overall, the calcification process has been shown to significantly increase the tensile and compressive stiffness of blood clots. In compression, both the low and high strain stiffnesses were affected by the clot calcification, suggesting a structural change within the clots. In contrast, a decrease in percent relaxation of the calcified clots in tension corroborates the increase in fibrin density of the calcified clots seen in histology. Histological analysis revealed an overall decrease in the red blood cell content and an increase in the overall fibrin density. This suggests the hypotonicity initiated by the calcium may be altering the load-bearing components of the clot, i.e. the fibrin and red blood cells. The clot analogs have significant stiffening behavior in compression, and a linear-like behavior in tension, with compressive high strain stiffness an order of magnitude greater than in tension. Overall, this suggests that these calcified clots may be prone to *in situ* compressive compaction in the vessel during stent retriever EVT, making them a suitable surrogate for the clot phenotype causing EVT complications.

INTRODUCTION

Heart failure (HF) is an emerging epidemic affecting approximately 1% to 2% of the adult population. Patients with HF often develop mechanical dyssynchrony (MD) that affects regional cardiac function and coronary blood flow in the septum and left ventricular free wall (LVFW), which are fed by the left anterior descending (LAD) and left circumflex (LCx) arteries, respectively [1,2]. The effects of MD on global left ventricular (LV) functions, i.e., LV pressure and volume, and ejection fraction (EF), have been assessed from experimental/clinical studies. However, it remains unclear how MD affects regional contractile function and coronary perfusion in the LV as it is difficult to measure these quantities directly in experiments. The lack of this knowledge is an impediment to improving the current 30% non-responder rate of cardiac resynchronization therapy (CRT), which is frequently used to treat HF patients. Here we seek to address this issue by developing an inverse finite element (FE) modeling framework based on animal-specific 3D echocardiographic (ECHO) images and hemodynamics measurements acquired from a swine MD model to understand the impact of MD on regional contractile function and coronary blood flow distribution in the LV.

METHODS

Animal Experiments and Postprocessing: All animal experiments were performed in accordance with national and local ethical guidelines regarding the use of animals in research. Yorkshire domestic, female swine (n = 9), with body weight of 58.9±3.4 kg, were used in this study. All measurements were acquired under healthy and MD conditions by right atrium pacing (RAP) and right ventricular pacing (RVP), respectively, at heart rates of 100 bpm and 140 bpm (randomly chosen). The heart was paced individually from the RA or RV (apex) at 100 bpm and 140 bpm using temporary pacing electrode catheters (Bard Medical, Covington, GA) connected to an external pacemaker (Pace 203H, Oscor, Palm Harbor, FL, USA). In each condition, 3D ECHO images were acquired with the animals placed in the supine position while simultaneously recording LV end-diastolic volume (EDV), LV end-systolic volume (ESV), stroke volume, EF. Left ventricular pressure and volume were measured using a 5F pressure-volume catheter (Ventri-Cath 507, Millar, Inc., Houston, TX), connected to an MPVS Ultra PV loop system (Millar, Inc., Houston, TX). Pressure and volume waveforms were recorded using a data acquisition system (LabChart Pro, ADInstruments, Colorado Springs, CO). Then the chest was opened through a midline sternotomy and an incision was made in the pericardial sac with the creation of a sling to support the heart. The LAD and LCx arteries were carefully dissected free from their surrounding tissue in their proximal regions and a 3 mm flow probe connected to a flow meter (Transonic, Ithaca, NY) was placed around the coronary arteries to measure the coronary flow rate under regulated condition in the LAD and LCx simultaneously. The passive coronary flow rate was then measured in the fully dilated vessels after the injection of adenosine.

The 3D ECHO images were postprocessed using TomTec Arena (2014-2020) Imaging Systems GmbH (Philips Healthcare, Andover, MA) to calculate systolic dyssynchrony index (SDI) to represent the degree of MD, reconstruct 3D LV geometry corresponding to the ES time point based on segmented endocardial and epicardial surfaces, and derive the regional longitudinal and circumferential strain waveforms in each AHA segment. Left ventricular end-diastolic pressure (EDP) and end-systolic pressure (ESP), $dP/dt_{(max)}$, $dP/dt_{(min)}$, LVEDV, LVESV, and coronary flow rate waveforms were determined and averaged over a minimum of 10 cardiac cycles using LabChart Pro.

Computational Model: An inverse finite FE modeling framework was developed based on the reconstructed LV geometry as well as measurements of the LV pressure-volume (PV) loops, regional longitudinal and circumferential strains to estimate the regional contractile function under the 2 pacing conditions (**Fig. 1A1**). Specifically, parameters associated with the passive myocardium were

first adjusted until the values of LVEDP and LVEDV match the measurements after loading the LV from an unloaded configuration. Thereafter, the local time-dependent active stress parameter in the active constitutive model, which reflects the local myocardial contractility, is estimated by minimizing the mismatch between simulated and measured LV PV loops and regional strains. This is accomplished by solving a PDE-constrained optimization problem as in our previous work [3,4]. Global and regional load-independent contractility was optimized until the model predicted LV PV loops and regional strains match the measurements. All computational frameworks are implemented using the freely available open-source libraries FEniCS and dolfin-adjoint.

RESULTS

The experimental measurements show that RVP produces MD as well as changes in the LV function and coronary flow in the LAD and LCx. Specially, the SDI with RAP was 8.6±1.2% at 100 bpm (p<0.05) and 8.9±2.0% at 140 bpm (p<0.05), whereas SDI with RVP was 14±4.8% at 100 bpm (p<0.05) and 19.4±6.9% at 140 bpm (p<0.01). These results indicate that the degree of MD increases with RVP, and the increase is more significant at higher heart rates. **Fig. 1B** shows the changes in LVEDP and LVESP between RAP and RVP. LVEDP was significantly decreased with RVP (-4.4±1.0 mmHg at 100 bpm, p<0.01, and -6.5±1.5 mmHg at 140 bpm, p<0.01). Similarly, LVESP was also significantly decreased with RVP (-25.6±4.0 mmHg at 100 bpm, p<0.001, and -35.7±5.4 mmHg at 140 bpm, p<0.001). **Fig. 1C** shows the effects of MD on LVEDV and LVESV. LVEDV was significantly decreased with RVP (-14.7±1.8 mL at 100 bpm, p<0.001, and -11.3±3.3 mL at 140 bpm, p<0.05). Similarly, LVESV was significantly decreased with RVP at 100 bpm (-4.6±1.4 mL, p<0.05). At 140 bpm, ΔLVESV was -4.2±2.4 mL but did not reach significance. **Fig. 1D** and **E** show the changes in both regulated and passive mean LAD and LCx flow rates between RAP and RVP. Regulated and passive mean flow rates in the LAD artery (**Fig. 1D**) was significantly decreased with RVP (-7.6±2.3 mL/min, p<0.01 and -33.2±8.9 mL/min, p<0.05 at 100 bpm, respectively, whereas at 140bpm, the change in regulated flow was -5.7±0.8 mL/min, p<0.001, and in passive flow -54.0±7.4 mL/min, p<0.01). On the other hand, regulated flow in the LCX artery (**Fig. 1E**) almost did not change (-0.2±1.3 mL/min at 100 bpm and -3.6±2.6 mL/min at 140 bpm). Passive flow rate, however, was significantly decreased with RVP (-17.5±7.8 mL/min at 100 bpm, p<0.05 and -31.1±8.0 mL/min at 140 bpm, p<0.01). In addition, the inverse FE model predicts the effects of MD on myocardial contractility of the LV. The error between experimental measurements and model predictions of the LV PV loops is less than 5% in each case. The model predicted that global LV contractility is reduced from RA to RV pacing by 70±51, p<0.002 mmHg at 100 bpm and 100±86, p<0.02 mmHg at 140 bpm, respectively. As shown in the AHA segment, the estimated regional contractility in septum is reduced by 16±163 mmHg, p=0.77 at 100 bpm and 93±91 mmHg, p<0.1 at 140 bpm with RVP (compared to RAP) (**Fig. 1F)**. The estimated regional contractility in LVFW is reduced by 120±187 mmHg, p<0.05 at 100 bpm and 46±102 mmHg, p=0.24 at 140 bpm with RVP (compared to RAP) (**Fig. 1F)**.

DISCUSSION

In this study, we have systematically investigated the acute effects of MD on LV hemodynamics, regional contractile function and coronary perfusion based on a clinically-relevant swine model. We show that MD not only negatively affects the LV function and hemodynamics, but also reduces LAD coronary blood flow under both passive and regulated conditions, LCx coronary flow under passive condition. In addition, inverse FE modeling using the measurements show that the estimated global LV contractility is also reduced in MD. The adverse effects of MD on LV contractility and regional coronary hemodynamics may be interrelated based on the "perfusion-contraction matching". Identification of these interrelated factors may have clinical implications in the identification of treatment of MD (i.e., CRT [4]) and improvement in treatment strategies.

INTRODUCTION

The central nervous system is developed from anteroposteriorly patterned neural tube consisting of forebrain, midbrain, hindbrain, and spinal cord. Recently, engineered development models and organoids based on human pluripotent stem cells (hPSCs) have provided opportunities for investigating how the neural tube is developed and patterned in vitro [1-2]. However, none of existing systems consist of regionalized midbrain and hindbrain simultaneously.

The midbrain-hindbrain boundary is an evolutionarily conserved structure that forms at the junction of the anterior OTX2+ midbrain region and the posterior GBX2+ hindbrain region, followed by constriction morphogenesis that separates the adjacent mesencephalon and rostral metencephalon into distinct compartments. Such compartmentalization is essential for proper cell differentiation in later stage development. While developmental biology studies using model systems have established the important roles of key morphogens such as FGF8 in the midbrain-hindbrain patterning [3], it remains unclear if other mechanisms exist in human brain development. Building regionalized midbrain and hindbrain tissues in vitro have not been achieved yet.

In this work, we have developed a self-organized in vitro model for AP neural patterning using micropatterned hPSCs by regulating RA, BMP, SHH, and WNT signals. We found that the reaction-diffusion of BMP/Noggin played a role in AP regionalization of OTX2+FOXA1+ midbrain and HOXB4+ hindbrain tissues. We further demonstrated that the model could predict the effects of different teratogens on the midbrain and hindbrain development. In the future, our platform can be used to investigate the mechanisms of human AP neural regionalization and border formation in neural development at the molecular level.

METHODS

Cell culture: SOX10 :: EGFP bacterial artificial chromosome hES cell reporter line (H9) and human induced pluripotent stem (hiPS) cell line (male; generated from human primary T-cells using episomal reprogramming method) were cultured in Essential 8 growth medium on hES cell-qualified Geltrex. ***Microcontact printing:*** Soft lithography was used to generate micropatterned polydimethylsiloxane (PDMS) stamps from negative SU8 molds that were fabricated using photolithography. These PDMS stamps were used to generate micropatterned cell colonies using microcontact printing, as described previously [4]. ***Image acquisition and analysis:*** Confocal images were collected with NIS-Elements AR software using Nikon A1 Resonant scanning confocal inverted microscope. ***Drug-screening assay:*** Valproic acid (Cat. No. P4543, Sigma-Aldrich) and penicillin G (Cat. No. 13752-1G-F, Sigma-Aldrich) were dissolved in Milli-Q water. Isotretinoin (Cat. No. 21648, Cayman Chemical) was dissolved in DMSO. ***Quantification and statistical analysis***: Data are represented as mean ± s.e.m. All the micropatterning experiments were repeated at least three times independently (biological replicates), with at least two technical replicates within each replicate. Statistical analysis was performed using two-sided unpaired Student's t-test.

RESULTS

We first discovered that by activating RA, Shh, BMP4, and Wnt signals while inhibiting TGF-β signal, geometrically confined hPSCs were differentiated into two distinctly separated domains, i.e., Otx2+ forebrain/midbrain region (center) and HoxB4+ hindbrain region (boundary) on day 6 (Fig. 1a). FOXA1 and FOXG1 (not shown) staining confirmed midbrain fate in the central region, and TTR staining excluded choroid plexus fate. Strikingly, the patterned cells underwent drastic morphological changes and the boundary HoxB4+ cells collectively migrated to the center of the pattern, forming a ring structure (Fig. 1b). Confocal microscopy showed that Otx2+ cells remained at the bottom, forming a sharp boundary with HoxB4+ cells. Compared to randomly distributed cells on unconfined controls, our

data suggest geometrical confinement is sufficient to induce the regionalization of cells with midbrain and hindbrain fate.

To understand the mechanisms of this cell fate separation, we first tested whether differential cell proliferation might lead to boundary cell folding. We stained phospho-histone H3 (pHH3) and found that the peak of pHH3 intensity did not match with the OTX2/HOXB4 boundary (data not shown). In addition, treating cells with aphidicolin did not alter the folding process, further supporting differential growth does not contribute to this separation process. Next, we investigated whether higher mechanical stress in the boundary cells would control the anteroposterior cell fates patterning (Fig. 2a). We found that treating cells with Blebbistatin or Y27632, two small molecules widely used to inhibit cellular actomyosin contractility, did not change the Otx2 and HoxB4 patterns. We found that lowering RA concentration to 0.1 μM led to weaker HOXB4 signals without changing the relative localization of OTX2 and HOXB4 expressions (Fig. 2b). Similarly, lowering CHIR concentration to 30 nM or increasing it to 600 nM did not significantly change the midbrain/hindbrain patterning. Notably, the cells induced with high CHIR concentration (600 nM) on day 6 displayed similar patterns that were observed in cells induced with intermediate CHIR (60 nM) on day 7 (Fig. 2b), which can be explained by the effects of WNT activation on cell proliferation. However, when cells were induced with a high concentration of BMP4 (10 ng/ml), the area covered by OTX2+ cells became significantly smaller and the peak of HOXB4 signals shifted dramatically inwardly to the center of the micropattern (Fig. 2b). Reducing BMP4 concentration to 1 ng/ml led to the expansion of the OTX2+ zones. Together, our data suggest that RA and WNT are permissive signals that are required for the caudalization, while the BMP4 signal instructs the midbrain/hindbrain patterning.

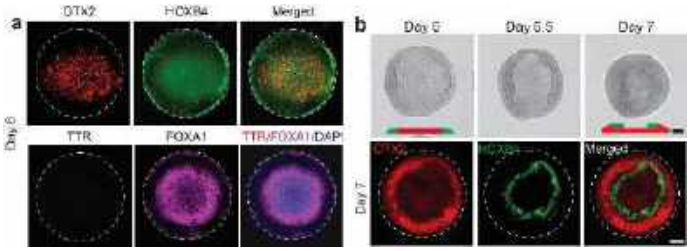

Figure 1: (a) Staining showing midbrain markers OTX2/FOXA1, choroid plexus marker TTR, and hindbrain marker HOXB4 at Day 6; (b) Images/illustrations showing moving of the hindbrain region (green) to the top of the pattern at day 7. Scale bar, 100 μm.

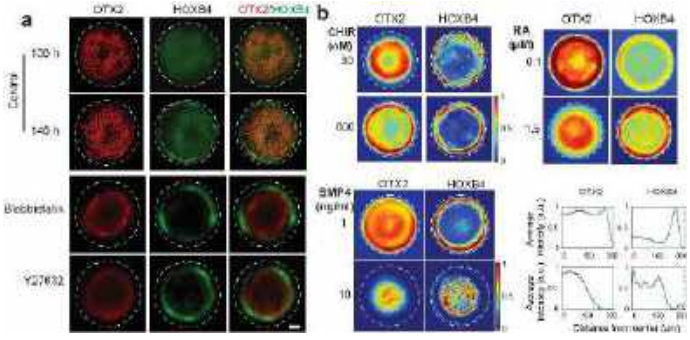

Figure 2: (a) Inhibiting contractility using blebbistatin and Y27632 did not change cell fate patterning. (b) Colorimetric maps and intensity plots showing average intensities of OTX2 and HOXB4 at different CHIR, RA and BMP4 concentrations.

We further demonstrated that our model can be used as a drug screening platform. We tested two known teratogens, VPA [5] and isotretinoin [6], which cause neural tube defects when women was exposed during pregnancy. We found that both VPA and isotretinoin disrupted midbrain-hindbrain boundary formation in our system, with distinct phenotypes, compared to a nonteratogenic drug penicillin G (Fig. 3). VPA treatment led to reduced expression of both OTX2 and HOXB4, while isotretinoin treatment led to randomly distributed OTX2+ and HOXB4+ cells. These findings are consistent with clinical reports that VPA causes smaller midbrain size and an increase in the midline gap of the hindbrain, while isotretinoin was linked to disproportionately long midbrain and dysplasia of the quadrigeminal plate and vermis.

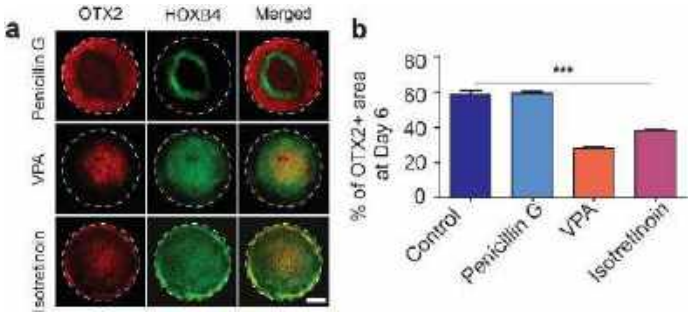

Figure 3: Effects of drugs on cell patterning. Scale bar, 100 μm

DISCUSSION

In this work, we have developed an in vitro model for AP patterned midbrain/hindbrain tissues using hPSCs. Contrary to the traditional view that morphogen gradient of FGF8 is the driving factor for the midbrain-hindbrain boundary formation, here we found that BMP/Noggin reaction-diffusion, rather than differential growth or contractility, played the dominant role in anteroposterior regionalization. Further, our model can be used to quantitatively study the effects of common medications on human early midbrain and hindbrain development. It is notable that our in vitro midbrain/hindbrain model so far can mimic only the early-stage development of the human brain since the total duration of organized cell culture is limited due to the geometrical confinement. Despite these limitations, our model is complementary to current animal models and traditional 2D cell culture systems and provides an excellent experimental platform to investigate the mechanism of human brain development and patterning.

INTRODUCTION

Research on the impact of environmental factors on reproductive health is gaining increasing attention. Parabens, ubiquitous preservatives incorporated in consumer products like cosmetics, food, and pharmaceuticals are one such factor. Prior studies indicated that exposure to paraben is associated with decreased fertility [1] and adverse birth outcomes, like lower birth weight [2]. Yet, while some research suggests that parabens are endocrine disruptors with limited estrogenic effect, there is a notable gap in knowledge of how paraben exposure can influence uterine function.

This study aims to investigate the effects of propylparaben (one of the most prevalently used parabens) on the mechanical properties of the uterus through indentation and the collagen microstructure using quantitative Second Harmonic Generation (qSHG) imaging in a mouse model. By addressing these research questions, we seek to determine the consequences of propylparaben exposure on uterine structure as a potential reason for paraben effects on fertility and pregnancy outcomes.

METHODS

Animal model: Female CD-1 mice aged 3 months were randomly divided into four groups and received daily oral doses of a vehicle control (corn oil) or propylparaben (PP) at doses of 2, 20, and 200 µg/kg/day. Dose selection was guided by women's urinary PP levels in NHANES 2015-2016 database and thus are human relevant. After 6 months of dosing, mice were euthanized during the diestrus stage of the estrous cycle and uterine horns were collected and frozen until use.

SHG microscopy: Uterine horns were thawed, and transverse sections were cut into 2 mm lengths, embedded in an optimal cutting temperature compound, and cryo-sectioned (-20 ◦C) in preparation for both nanoindentation and qSHG imaging. qSHG imaging, which preferentially shows collagen, was performed both in the forward and backward directions using a confocal microscope (Zeiss LSM 710) with a 70-fs laser (MaiTai DeepSee) centered at 780 nm illuminating the sample. A 20x objective was used to image the entire cross section and a 40x water immersion objective for high magnification, volumetric images (212*212*20 µm) from which sub-images (50*50*20 µm, n=6 images/mouse, 2 mice/group) were used for the following quantitative analyses: spherical variance, SV, assesses the degree of collagen fiber organization in 3D (0- aligned, 0.5- disorganized); out-of-plane angle, φ, indicates orientation relative to the imaging plane (0- in-plane, 90- out-of-plane) [3]; and forward to backward ratio, F/B, is the ratio of the forward and backward signal intensity. An increasing F/B indicates collagen that is more disorganized and/or more out-of-plane fibrils and/or larger fibrils [4]. Because of space limitations, data shown are from the indentation-qSHG co-registered data and we reference the data from the two mice per group that were imaged separately.

Nanoindentation (NI): Similar to our work in [3], a Piuma nanoindenter (Optics11, Amsterdam, Netherlands) indented the tissue submerged in PBS at 50 µm increments along a medial-lateral line using a spherical probe of 99 µm radius and 0.5 N/m stiffness. We evaluated the indentation modulus, E*, as a measure of local stiffness using the Hertz model. The Piuma camera captured images allowing the data to be co-registered with the SHG data. For the correlation between local E* and F/B, SV and φ, the sample size was n=8 measurements/mouse and one mouse from each treatment group.

Statistical analysis: A two-way ANOVA with post-hoc Tukey test compared between treatment groups and regions, with significance level set at $p<0.05$. Due to space constraints, box plots indicating significant differences are not shown, but are reported. Pearson's correlation coefficient assessed the linear correlation between E* and SHG parameters.

RESULTS

SHG images (Fig. 1) show the collagen microstructure with overlaid forward and backward signals, with the longitudinal

myometrium (LM) and circumferential myometrium (CM) indicated. The endometrium (E) is shown for reference, but was not analyzed. qSHG data from uterine cross sections co-registered with the indentation data (Fig. 2) indicated a significant increase in E* with increasing exposure.

Fig. 3 shows co-registered indentation and qSHG data. While φ for CM and LM were significantly different within a treatment, the F/B change across regions was not significant (Fig. 3a). In contrast, F/B for all pairs of treatments were significantly different except for the two highest doses. Together, these data suggest that the changes in F/B do not strongly depend on orientation here. SV was only significantly different between the 0 and 20 and 0 and 200 (not shown), indicating similarly that SV does not have a strong influence on F/B.

We observed significant increases in E* with treatment in both regions for all treatment pairs except for 0 vs 20 µg/kg/day=. While higher E* is expected with higher φ based on previous work [3] the difference in E* is much smaller with changes in angle compared to treatment (Fig. 3b). SV does not appear to have a strong influence on E* (Fig. 3c). Interestingly, there is a strong and significant correlation between E* and F/B, with all treatments and regions falling on a single line (Fig. 3d). This contrasts with Fig. 3a-c, in which distinct data clusters are evident. We hypothesize that the increased F/B in the exposed uteri is related to fibril thickening, which is supported by the observed increase in E* with treatment.

There were a number of strong and significant correlations in Fig. 3, which are not indicated here due to space.

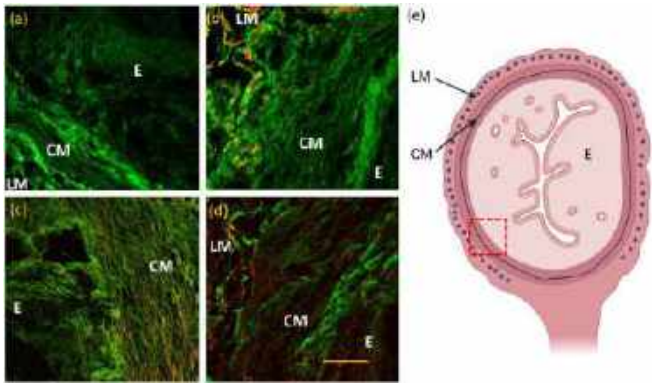

Figure 1: 40X images from mice uteri. (a) control and PP doses (b) 2, (c) 20, and (d) 200 µg/kg/day. Orange indicates overlapping backward (green) and forward (red) signals. Scale bar: 50 µm. (e) schematic transverse cross-section of uterus for reference (Created with BioRender), CM and LM- circumferential and longitudinal myometrium, E- endometrium.

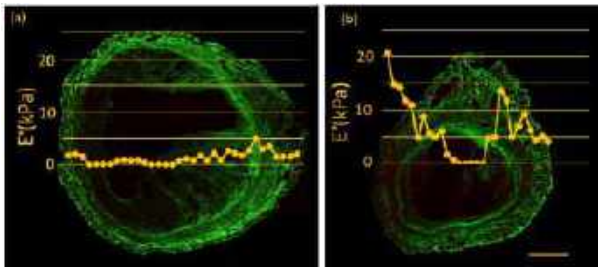

Figure 2: Indentation modulus overlaid on SHG images for (a) control and (b) 200 µg/kg/day PP dose. The line of indentation coincides with the X axis where Y=0. Scale bar: 500 µm.

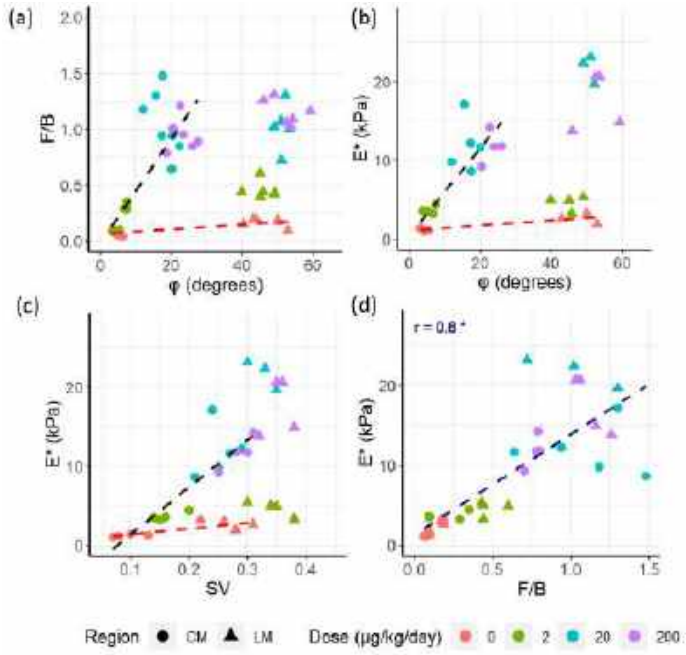

Figure 3: The variation of (a) F/B with φ, and E* with (b) φ, (c) SV, and (d) F/B, for regions CM and LM and with dose. E* and F/B have a strong and significant correlation. There were other strong and significant correlations not shown for brevity.

DISCUSSION

This study investigated the effects of PP exposure on the murine uterus, revealing both microstructural alterations and micromechanical changes by integrating quantitative parameters from SHG imaging and nanoindentation. Our analysis revealed disorganization in the collagen microstructure, accompanied by a stiffer indentation response in the treated groups. We found that not only do the fibrils become more disorganized and more out-of-plane due to the treatment, but there is also indication of fibril thickening, indicating potential fibrosis.

While the primary focus here is understanding the impact of PP exposure on the murine uterus, these discoveries also offer a way to identify fibrosis in other collagenous tissues. Our focus primarily centered on collagen alterations as a response to PP exposure. However, the other components of uterus, such as elastin, muscle, and extracellular matrix proteins, may also have contributed to changes in tissue stiffness. Ongoing studies further examine additional implications of PP exposure on female reproductive health, including pregnancy outcomes in the dams and offspring.

INTRODUCTION

How a developing organ robustly coordinates the cellular mechanics and growth to reach a final size and shape remains poorly understood. Through iterations between experiments and new model simulations that include a mechanistic description of interkinetic nuclear migration, we show that the local curvature, height, and nuclear positioning of cells in the *Drosophila* wing imaginal disc, a model epithelial organ used as a test case, are defined by the concurrent patterning of actomyosin contractility, cell-ECM adhesion, ECM stiffness, and interfacial membrane tension. We show that increasing cell proliferation via different growth-promoting pathways results in two distinct phenotypes. Triggering proliferation through insulin signaling increases basal curvature, but an increase in growth through Bone morphogenetic protein (BMP)/Decapentaplegic (Dpp) signaling and Myc causes tissue flattening. These distinct phenotypic outcomes arise from differences in how each growth pathway regulates the cellular cytoskeleton, including contractility and cell-ECM adhesion. The coupled regulation of proliferation and cytoskeletal regulators is a general strategy to meet the multiple context-dependent criteria defining tissue morphogenesis.

METHODS

We utilized the GAL4-UAS system for tissue-specific gene expression in an accessible and powerful genetic system for studying organ growth control mechanisms, the *Drosophila* wing disc. In parallel, a multi-scale Subcellular Element (SCE) modeling approach was employed to simulate cell mechanics and division dynamics. This involved computational simulations validated against experimental data to predict the impact of various mechanical factors on tissue morphology.

The general SCE modeling approach[1–3] was used as the basis for the model presented here. Our novel SCE-type multi-scale model in detail represents cell deformation and proliferation and integrates mechanical properties, including cell membrane elasticity, cell pressure, polarized actomyosin contractility with nuclear movement, and cell-cell and cell-ECM adhesivity. Another key advantage of this novel SCE modeling approach is that most of the cell mechanical properties considered can be directly or indirectly calibrated based on experimental data[1,4]. This computational modeling framework is used to simulate a two-dimensional (2D) cross-sectional profile of the *Drosophila* wing imaginal disc along the anterior-posterior axis adjacent to the DV compartment boundary. Using a detailed 2D model allows for simulating large numbers of cells with high resolution and with particular attention to mechanical cell properties and small changes in tissue structure and shape. Given that the cross-section is composed of boundary cells, squamous cells, and columnar cells, the model includes a separate description for each cell type. Important distinctions from our previous model[3] are detailed representations of cell division and actomyosin contractility in different parts of a cell. The model includes membrane nodes, nucleus nodes, and ECM nodes. Energy potentials are used to describe interactions between different nodes, as in Nematbakhsh and Levis et al.[3].

RESULTS

In this study, we iterated between quantitative analysis of wing disc morphogenesis unders specific genetic perturbations and computational simulations of wing disc growth, which provides a mechanism for hypothesis generation.

Our results demonstrated that the ratio of apical to basal contractility, ECM stiffness, and cell-ECM adhesion are key determinants of basal curvature. We categorized growth regulators into

two classes based on their impact on tissue curvature: one class increased basal curvature, while the other led to tissue flattening with growth. The simulations confirmed that these outcomes are tied to their differential regulation of the cytoskeleton.

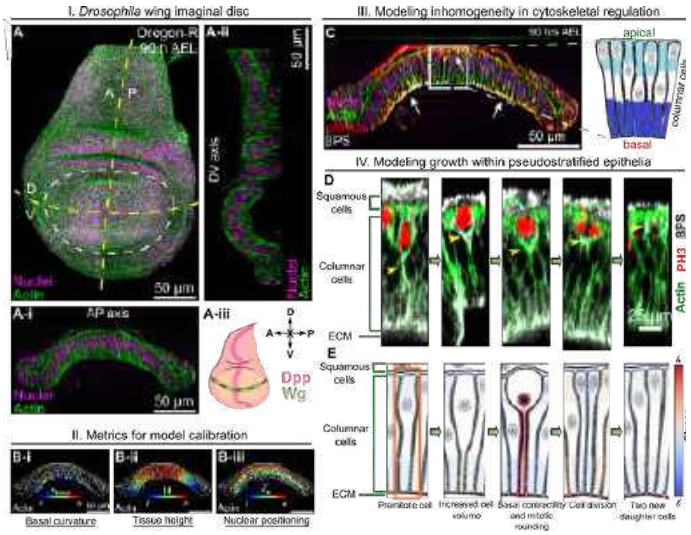

Figure 1: Multi-scale SCE model simulation of proliferation in a pseudostratified epithelium predicts proliferation dynamics and cytoskeletal regulation.

DISCUSSION

The morphogenetic processes observed in the *Drosophila* wing disc are similar to those in other developmental systems, such as the formation of the mammalian optic cup, suggesting a commonality in the underlying mechanisms across species. Our findings underscore the importance of a balanced regulation between proliferation and cytoskeletal dynamics in shaping organs. The study's insights broaden our understanding of developmental biology and provide a foundation for future explorations into organogenesis. Overall, the principal findings identified in our work can be generalized and incorporated into our understanding of development across multiple organ systems in animals due to the underlying biochemical and biomechanical similarities that drive morphogenesis[7,8].

INTRODUCTION

Metastasis is the malignant progression in which the cancer cells collectively migrate away from the primary tumor and localize to the distal secondary organ with invasion and proliferation [1]. The multicellular organoid/spheroid model has been developed for pathophysiology-mimicking metastasis [2]. The metastatic preference for secondary organs is specific to the cancer type [3]. The mechanical properties among these organs differ from 1~2 kPa to 25~40 kPa in Young's modulus [4]. From the mechanobiological perspective, previous studies have shown that tumor cells preferentially migrate toward the stiff matrix by sensing the surrounding 10-20 μm matrix in depth [5,6]. Many of these studies used artificial matrices, including polyacrylamide gels with different stiffness. On the other hand, a latest study attempted to adjust the stiffness of natural ingredients, such as collagen, through compression [7]. The usage of natural ingredients is thought to lead to more pathophysiological behaviors of cancer cells because the cells may change the stiffness and geometry of the matrix in the process of metastasis [8]. However, besides matrix stiffness, the organization of collagen fibers can also promote directional migration [9]. How the mutual interaction of stiffness and fiber organization guides the directional migration remains unclear.

We hypothesize that mixed effects of collagen stiffness, fiber density, and cell-cell interaction modulate the migration preference of tumor spheroids. In this study, we examined the influence of the matrix stiffness and fiber density, which were managed separately, on tumor spheroid migration.

METHODS

A549 adenocarcinoma cells (JCRB0076, Nibiohn), originated from a lung cancer patient, were cultured in T25 flasks with E-MEM (Fujifilm) with 10% FBS (Gibco) under 37℃ in an incubator with 5% CO_2. As the establishment of the spheroid, A549 cells were resuspended by 5 min incubation with 0.05% trypsin and seeded on a low-attachment 96-wells plate (Thermo Fisher) at 1000 cells/well. The plate was centrifuged at 1800 rpm for 20 min for cell precipitation. A549 cells aggregated into the spheroid for 4 days. The diameter of A549 spheroids was analyzed by microscopy (Olympus).

The collagen construct was prepared with 5 mg/ml type I collagen (Koken), reconstruction buffer, and 10xMEMα at the mixed ratio of 8:1:1 in a stretch chamber (Strex) for more than 1 day. The collagen construct was covered with a filter and a silicone membrane and then compressed by centrifugation at 3430 rpm for 20 min [10]. Finally, the A549 spheroids were transferred and cultured on the collagen construct for 4 days. The stiffness of the collagen construct was measured by atomic force microscopy indentation test.

To evaluate the effect of only the fiber density, we also prepared the collagen film which was the thin-collagen gel substrates at different densities and whose thickness was less than 10 μm, on a cover glass. The collagen solution was prepared with 5 mg/ml type I collagen (Koken), reconstruction buffer, and 10xMEMα at the mixed ratio of 8:1:1 or 2:4:4, referred to as 80% or 20%, and smeared on the cover glass with a silicone scraper. The surface image of the collagen was scanned by scanning electron microscopy (KEYENCE). Fiji ImageJ was used for calculating the area fraction of fibers, indicating the fiber density, over the whole image.

After culturing spheroids on the collagen substrate for 4 days, the phase-contrast images of A549 spheroids were captured daily with a microscope. The spreading diameter of the spheroid was analyzed with Fiji ImageJ.

Statistical analyses (ANOVA with Tukey HSD) were performed using R ($\alpha = 0.05$, GNU). Results were presented as the average ± standard errors of the mean.

RESULTS

The compressed collagen construct shared a similar topology with the 80% collagen film but exhibited a different surface structure from

the uncompressed collagen construct and 20% collagen film. The uncompressed collagen construct had a loose fibrous surface though it contained clusters of nodules. The 20% collagen film was the sparse fibrous surface.

The centrifugation stiffened the collagen matrix from 2.9 ± 0.5 kPa to 17.2 ± 2.3 kPa (Figure 1B). Meanwhile, the centrifugation condensed the collagen fiber from 33.9 ± 2.4% to 56.8 ± 3.6% (Figure 1C).

There was no difference in height between 80% and 20% collagen film (data not shown); however, the collagen density of 80% collagen film was higher than the 20% collagen film, which was 56.8 ± 2.6% and 13.8 ± 1.7% separately (Figure 1C). The fiber density of 80% collagen film was analogous to the compressed collagen construct, but more condensed than the uncompressed collagen construct. For 20% collagen film, the fiber density was lower than that of the compressed collagen construct and higher than the uncompressed collagen matrix.

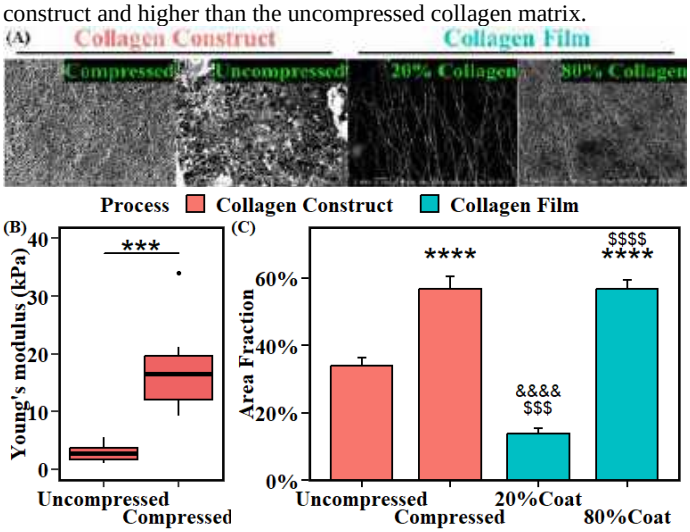

Figure 1: Collagen matrix properties. (A) SEM images, (B) Young's modulus, and (C) Fiber density (N = 5 ~ 10). (**, P < 0.0001 within-process; &&&&, P < 0.0001 vs Compressed; $$$, P < 0.001, $$$$, P < 0.0001 vs Uncompressed)**

A549 spheroids grew into a compact spheroid with a mean diameter of 317.6 ± 4.4 μm in 4 days of spheroid preparation. After being transferred to the collagen matrices, A549 spheroids expanded under the culture of 4 days (Figure 2). On the fourth day, the boundary of A549 spheroids remained sharp on the 80% collagen film and compressed collagen construct, but these became blurred on the 20% collagen film and uncompressed collagen construct.

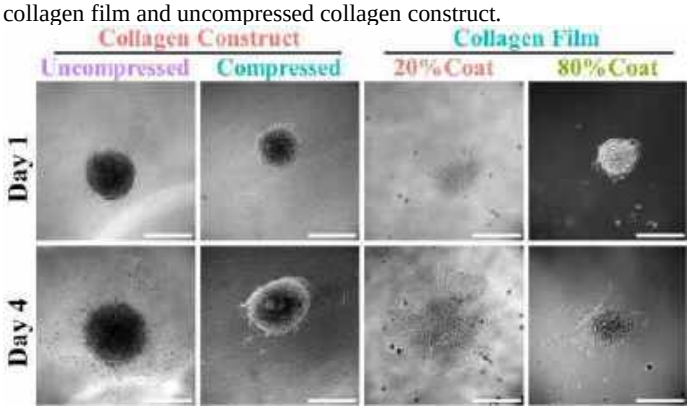

Figure 2: Phase-contrast Spheroid Image (scale = 400 μm)

Quantitatively, the A549 spheroids on the uncompressed collagen construct (D4 = 993.5 ± 59.3 μm) expanded considerably than those on the compressed collagen construct (D4 = 815.3 ± 41.0 μm); however, the spheroids on the 80% collagen film (D4 = 888.1 ± 29.0 μm) expand sedately than those on the 20% collagen film (D4 = 573.9 ± 20.0 μm) (Figure 3).

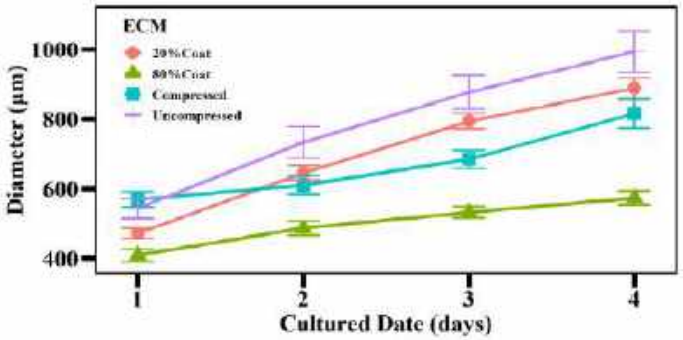

Figure 3: Time-Course of Spheroid Expansion (N = 6 ~ 24)

DISCUSSION

The A549 spheroid expanded more slowly on the compressed collagen construct, which was condensed and stiff collagen matrix condition, than on the loose and soft uncompressed collagen. On the collagen film, assuming the comparable apparent stiffness, the A549 spheroid grew more sedately on the condensed fibrous collagen film (80%) than on the loosened 20% collagen film. Besides that, there was no difference in the fiber density between the compressed construct and the 80% collagen film. The A549 spheroid showed the lowest expansion on the compressed collagen construct. In total, our results suggest that the matrix stiffness and fibrous density contribute to tumor expansion simultaneously and provide mechanobiological insight into tumor metastasis. Tumor invasion requires the disruption of the extracellular matrix (ECM), remodeling the structure, and modulating the stiffness of the ECM [8,11,12]. It implies that the matrix stiffness might be a robust influencer on tumor metastasis compared to collagen fiber density.

The current results did not investigate the cellular interaction with matrix stiffness and fibrous density separately. Further investigation will examine the cellular mechanism of matrix stiffness and fibrous density on tumor migration individually.

INTRODUCTION

Tissue homeostasis is an essential requirement for multicellular life and requires control over cell proliferation, differentiation, paracrine signaling, and physical interactions with other cells and with the surrounding extracellular matrix (ECM). Among the many physiological variables that are under homeostatic control, the physical properties of most cells, tissues, and organs are optimized to operate under a preferred state of mechanical tension [1]. Much of what is known about mechanical homeostasis of tissues under tension, or "tensional homeostasis", is based on experiments on tissue equivalents, that is fibroblast-populated collagen gels [2]. Tissue equivalents cultured in presence of a physical constraint at their boundary develop tensile forces under static conditions [3], which has led to postulate the existence of a homeostatic tensile force [4]. However, it is conceivable that the homeostatic target is a material quantity, such as stress.

To gain a mechanistic understanding of how tensional homeostasis is developed and maintained in healthy soft tissues, and subsequently disrupted by disease processes, there is a need for improved tissue engineering platforms, also known as bioreactors. Recent studies have presented bioreactors capable of culturing fibroblasts in 3D collagen matrices under both uniaxial and biaxial tension [5-6]. However, current bioreactors have limited imaging capabilities, with the acquisition of structural information occurring only at discrete time points (due to the lack of sterility while imaging). To address these limitations, we have developed the first miniaturized computer-controlled biaxial bioreactor fully integrated with a confocal microscope. The bioreactor design was inspired by Eichinger et al. [6] and built with the following objectives: (1) to allow bioreactor functionality outside of a cell culture incubator; (2) to miniaturize the biomechanical testing apparatus; and (3) to enable continuous confocal imaging functionality. Here, we present the bioreactor design and showcase its ability to dynamically measure homeostatic force evolution, structural remodeling of collagen, and cross-sectional area to estimate stresses in uniaxial tissue equivalents.

METHODS

The bioreactor is designed to fit the stage of a Nikon AX confocal microscope (Nikon, Tokyo, Japan). An aluminum base plate is equipped with compact linear actuators (Physik Instrumente, Auburn, MA) [7] and force transducers (Aurora Scientific, Aurora, Canada) to enable both dynamic stretching and continuous force recording. The core of the bioreactor is a circular chamber 3D printed using an autoclavable resin (Formlabs, Somerville, MA) which houses a disposable 100 mm dish (MatTek, Ashland, MA). A constant temperature of 37°C is achieved by combining a plate heater within a heated microscope enclosure, while an external humidifier (Tokai-Hit, Fujinomiya, Japan) supplies 5% CO_2 to the chamber, thus enabling long-term culture. Figure 1a shows the device mounted on a microscope in a uniaxial configuration.

NIH/3T3 fibroblasts (ATCC, Manassas, VA) were serum-starved for 24 hours to minimize proliferation [6] and dispersed in a collagen solution, which was polymerized using established protocols [8]. A dogbone-shaped PDMS mold was used to form cell-laden collagen gels anchored to sterile porous inserts [6]. After one hour of polymerization, the gels were floated using a standard media formulation [6], resulting in uniaxially constrained tissue equivalents. Dynamic force acquisition with simultaneous confocal imaging was carried out every 20 minutes for 24 hours (Figure 1b). Both brightfield and reflection images were acquired using a 10× lens as 1×16 tiled, 2650 μm stacks with a 50 μm step, using an excitation wavelength of 488nm. To estimate the sample cross-sectional area, a calibration experiment was conducted to compare multiphoton and confocal areas in the central region of the sample. Briefly, a set of uniaxial samples was imaged at discrete time points using both confocal and multiphoton microscopy (for increased penetration depth). Cell-endogenous NADH was excited at 740 nm and two-photon excitation fluorescence (TPEF) was collected through a bandpass filter (460-500 nm). The collagen matrix was imaged by exciting samples at 1060 nm and collecting second harmonic generation (SHG) signals through a bandpass filter (520-560 nm).

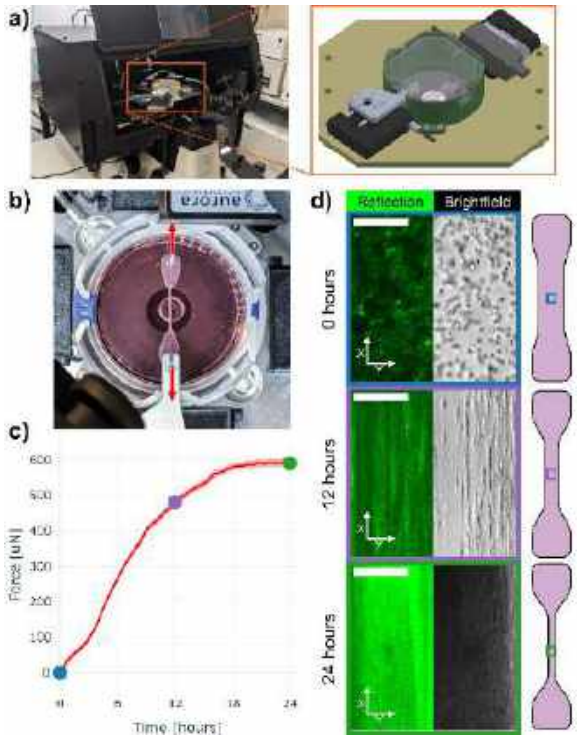

Figure 1: (a) Bioreactor mounted on a confocal microscope and magnified Solidworks assembly. (b) Top view of a uniaxially constrained tissue analog after 24 hours of culture (red arrows indicate contractile forces). (c) Time course of force development by a 0.8 mg/mL collagen gel loaded with 10^6 cells/mL. (d) Confocal images reveal underlying structural changes in both collagen (reflection, green) and cells (brightfield, grey). Scale bars indicate 200 µm while cartoons indicate the approximate imaging location.

RESULTS

Our bioreactor allows long-term NIH/3T3 fibroblast culture, with high cell viability and limited loss of media due to evaporation. Figure 1c displays the tensile forces generated by fibroblasts over 24 hours and shows that our results are comparable to previous reports, both in terms of magnitude and time course [6]. More importantly, confocal imaging captures the structural evolution of the tissue analog over time. Starting from an isotropic collagen matrix populated by circular cells at 0 hours, the construct develops into a highly anisotropic collagen network populated by aligned cells at 12 hours, and ultimately into a high-density tissue when the force steady state is achieved at 24 hours (Figure 1d). As the tissue analog compacts laterally it becomes progressively denser, thereby making optical penetration increasingly difficult. For this reason, we used multiphoton imaging to capture the entire cross-section of the gels (Figure 2a). SHG imaging shows that the bottom surface contracts more than the top surface, which leads to tissue folding. On the other hand, TPEF imaging shows that fibroblasts are evenly distributed at 0 hours, while at later time points occupy only a portion of the gel's cross-section and arrange into a semicircle. Indeed, collagen densification and alignment occur only where cells reside, suggesting that stress is developed only in cell-populated areas. We observe similar geometrical changes using confocal imaging and find that the cell-populated area can be quantified by approximating the top surface using a circular arc (Figure 2a-b). By employing such approximation, we can combine force and effective cross-sectional area measurements at each time point. Our initial stress estimations indicate that NIH/3T3 fibroblasts generate a stress of ~1 kPa at 24 hours (Figure 2c).

DISCUSSION

Stromal fibroblasts remodel their extracellular environment using various mechanisms, including the generation of contractile forces. Here, we propose a new bioreactor design informed by previous approaches [3-6] that combines biomechanical, microstructural, and geometrical measurements. This work focused on the bioreactor design, and on combining force and geometrical data on fixed uniaxial specimens. In the future we plan to conduct studies on both uniaxial and biaxial specimens and to apply external deformations. Our work is limited by the manual estimation of areas, but we plan to automate the cross-section approximation by using a cubic Hermite spline to extrapolate the top surface of the tissue analogs. We conclude that our bioreactor design represents a promising tissue engineering platform to explore tensional homeostasis in both healthy and diseased soft tissues.

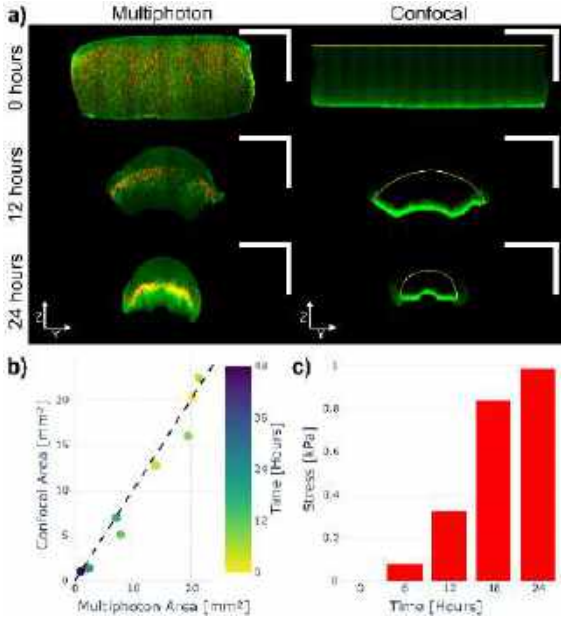

Figure 2: (a) Resliced image stacks show cross-sections of tissue analogs captured using multiphoton (left) and confocal (right) microscopy. Multiphoton images display TPEF signal from cells in red and SHG signal from collagen in green, while confocal images display reflection signal from collagen in green. Scale bars indicate 2000 µm in both directions. To capture the effective area from reflection images, we added a circular arc approximation of the top surface (yellow line). (b) Comparison between cross-sectional areas estimated using the two imaging approaches confirms that confocal areas can be used to calculate stresses as shown in (c).

ACKNOWLEDGEMENTS

QUANTITATIVE ANALYSIS OF THE COMPRESSIVE FORCE APPLIED TO THE ACL TIBIAL ENTHESIS

D. Ishii (1), S. Sato (1), H. Fujie (1)

(1) Graduate School of Systems Design, Tokyo Metropolitan University, Hachioji, Tokyo, Japan

INTRODUCTION

Ligament, tendon, and their attachments (enthesis) have been studied to improve the prevention and treatment of ligament injury and tendon enthesopathy. Anatomical and histological studies have revealed that ligaments and tendons often wrap around bony pulleys and attach to bone via fibrocartilage [1,2]. These studies also suggest that not only tensile but also compressive forces are applied to the enthesis. However, a detailed analysis of the forces acting on the entheses during joint loadings has not been conducted. In this study, focusing on the anterior cruciate ligament (ACL) tibial enthesis in the knee joint, the forces applied to the enthesis due to a joint loading were analyzed.

METHODS

Immature porcine knee joints (n=5) were used. After each knee joint was fixed to the 6-DOF robotic system (FRS-2015, Technology Services) [3], an anterior tibial loading test of 200 N was performed in full extension (approximately 30-40° of flexion) and 60° of flexion. Sagittal sections were performed for the ACL in parallel to the fiber direction with a special care not to damage ligament fibers [4]. The medial part of the sectioned ACL was removed so that the cross section of the ACL enthesis can be observed (Figure 1a,b). Note that the anteromedial (AM) bundle and the intermediate / posterolateral (I/P) bundle were clearly partitioned by the lateral meniscus attachment, as indicated by Tantisricharoenku et al [5]. The deformation behavior of the ACL tibial enthesis was observed by a digital microscope (3R-MSBTVTY, 3R Solution) while the 3D motion recorded in the anterior tibial loading test was reproduced [4]. In the obtained images, the fiber orientation angles of the AM and I/P bundles to the ACL attachment were analyzed using Image J (NIH) (Figure 1c). In addition, a histological examination was performed for the same cross sections to determine the fibrocartilage distribution.

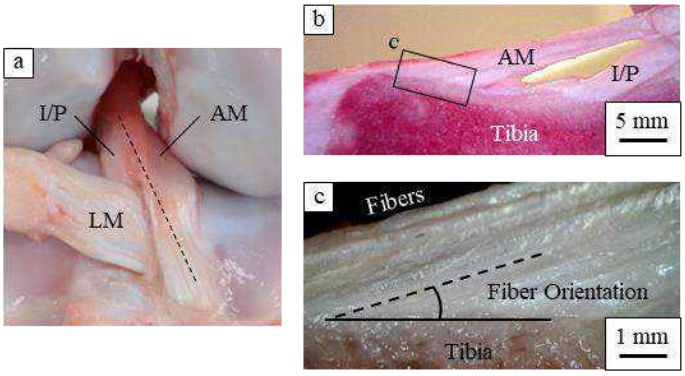

Figure 1: Procedures for sagittal section preparation. (a) The ACL tibial attachment of porcine knee joint. The AM and I/P bundles were divided by lateral meniscus (LM). The sagittal section was made parallel to the fiber direction (dotted line). (b) ACL enthesis observed by digital microscope. (c) The fiber orientation angle of each bundle relative to the attachment was analyzed from this image.

Next, an anterior tibial loading test up to 200 N was performed on other porcine knee joints (n=5) in full extension and 60° of flexion using the robotic system. The resultant force applied to the tibia during the test was determined from the outputs of the 6 DOF load transducer of the robotic system [6], while the attachment positions of the AM and I/P bundles to the ACL tibial attachment plane was analyzed [7].

Using the average of the fiber orientation, attachment position of the bundles, and resultant force, the magnitude and direction of the bundle (tensile) and compressive force applied from the AM and I/P bundles to the ACL tibial enthesis were calculated by subtracting the bundle force from the resultant force (Figure 2). For the calculation, we

assumed that the magnitude of the bundle force was equal to that of the resultant force with no friction between bundle fibers and between fibers and bone. We also assumed that the bundle force was applied to the attachment position in parallel to the fiber orientation.

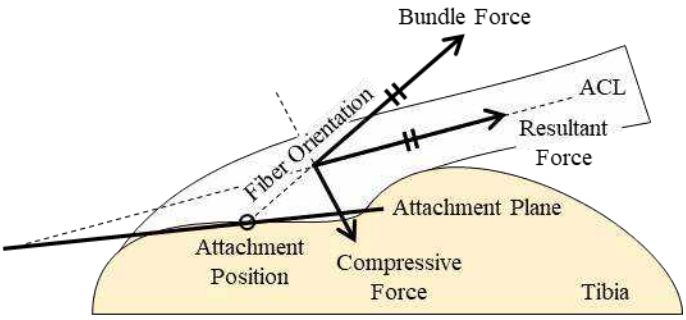

Figure 2: Schematic drawings of bundle (tensile) and compressive force analysis. Bundle and compressive forces were analyzed from the fiber orientation, attachment position of each fiber bundles to the ACL attachment plane, and resultant force under several assumptions.

RESULTS

Histological examination indicated that the cartilage matrix was more clearly observed in the I/P bundle enthesis than in the AM bundle enthesis and on the surface of bony pulley (Figure 3).

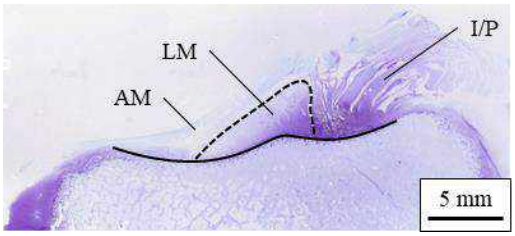

Figure 3: ACL tibial enthesis. Fibrocartilage areas (blue staining area) were clearly observed in the I/P enthesis by toluidine blue staining.

In the ACL tibial enthesis, not only tensile forces of 68-117 N but also compressive forces of 14-51 N were applied from the AM and I/P bundles under an anterior tibial force of 200 N. The compressive forces acted within I/P bundle enthesis or around the bony pulley (Figure 4).

DISCUSSION

Previous studies have suggested that compressive forces are applied to the ligament/tendon attachments during joint motion [1,2,8]. They have also suggested that these compressive forces are related to remodeling of fibrocartilaginous entheses and tendon enthesopathy. Although these are important findings, the compressive forces have not been identified, and thus have remained a matter of speculation. In the present study, the tensile and compressive forces acting on the ACL tibial attachments were quantified using an original method, and it was clarified that the compressive force applying around the ACL tibial enthesis was up to 45 % of the anterior tibial force. In addition, the compressive forces were found to act within I/P bundle enthesis or around the bony pulley.

The ACL peak force of human during gait occurs at about 15° of flexion, not at full extension [9], and the flexion angle of porcine knee joint during gait varies between 43-48° and 85-92° [10]. Therefore, the

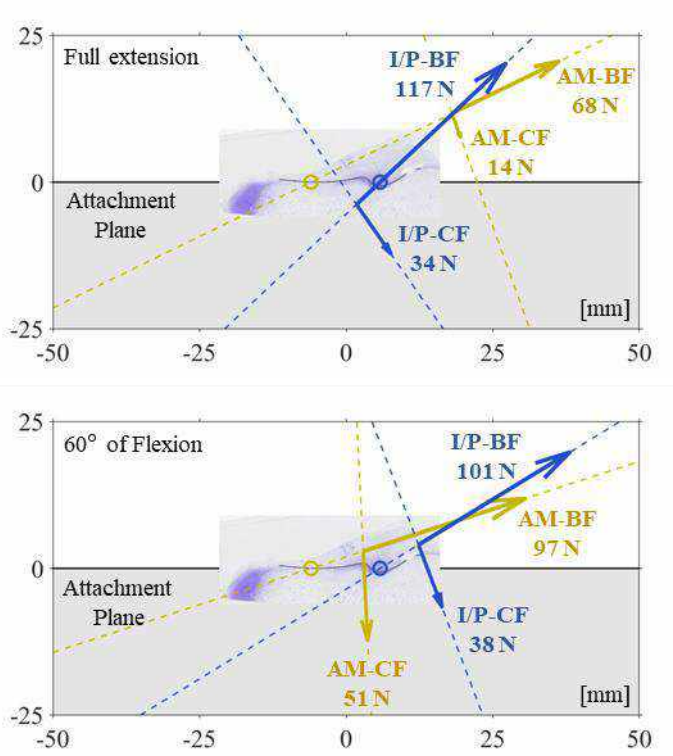

Figure 4: Bundle force (BF) and compressive force (CF) vectors applied to the ACL tibial attachment plane at full extension and 60° flexion in response to 200 N of anterior tibial load. Note that the attachment positions of the AM and I/P bundles are indicated by the yellow and blue circles, respectively. In addition, the histological image with toluidine blue stain is superimposed.

ACL force of pig is expected to be maximum at about 60° of flexion during walking. In the present analysis, the compressive force was greater at 60° flexion than at full extension, and also it was greater within the I/P enthesis than within AM enthesis and posteriorly out of the I/P enthesis (Figure 4). Furthermore, histological examination showed that fibrocartilage was more clearly observed in the I/P enthesis than in other areas (Figure 3). Therefore, it is suggested that fibrocartilage contributes to the compressive forces applied in the ACL tibial enthesis during knee joint motion.

INTRODUCTION

Aortic diseases, including those involving the ascending aorta (AAo), account for significant cardiovascular morbidity and mortality worldwide. Congenital bicuspid aortic valve (BAV) is one of the most common pathological conditions among these, along with AAo dilation and aortic stenosis, which are both often BAV-related. Due to the recognized crucial role played by hemodynamics in the pathophysiology of the aorta, several efforts have been done in the study of aortic flows. However, there is still work to be done to improve risk stratification of aortic diseases, promoting the clinical translation and refining clinical decision making. In this context, the present study adopts a network approach to investigate the impact of the BAV pathological condition on the physiological AAo flow coherence, following a recent study on large-scale coherent motion in the healthy aorta [1]. In detail, in vivo 4D flow MRI data were used to quantify flow coherence in terms of correlation between the blood flow rate waveform at the AAo inlet and the axial velocity waveforms obtained at each voxel in the acquired AAo region of interest. Then, the anatomical persistence length of such correlation was computed through an *ad-hoc* complex network-based approach, and its association with the main AAo canonical hemodynamic and anatomic features was explored.

METHODS

The study population include 64 subjects presenting with a tricuspid aortic valve (TAV) and 43 BAV patients matched in terms of age, sex, body surface area and blood pressure. Both TAV and BAV populations include patients affected by AAo dilation and mild-to-severe aortic valve stenosis. Details on 4D flow MRI acquisition protocol and data processing are reported elsewhere [2]. The study was approved by the ethics committee of the Vall d'Hebron Hospital and written informed consent was obtained from all participants. 3D anatomic models of the aortas were reconstructed from 4D flow MRI-derived angiography. Anatomical landmarks of the sinotubular junction (STJ) and the brachiocephalic artery bifurcation, identified from co-registered 2D cine images, were used to define the AAo region of interest. A network-based approach was adopted to quantify the coherence of large-scale AAo fluid structures in terms of similarity to the subject-specific inlet blood flow rate waveform, here considered as driving waveform of the aortic flow [1]. Briefly, from the phase-contrast velocity data, the blood flow rate $Q(t)$ waveform was computed at the STJ cross-section and the (through-plane) axial velocity component $V_{ax}(t)$ waveform in each voxel of the AAo fluid domain was obtained as proposed in [5]. Then, for each subject, a *"one-to-all"* network (**Fig. 1**) was built, consisting of: (1) one reference node represented by $Q(t)$, located at the STJ section's center of mass; (2) the N nodes represented by the waveforms $V_{ax,i}(t)$ at each voxel (i, for i=1,..,N) belonging to the AAo region of interest.

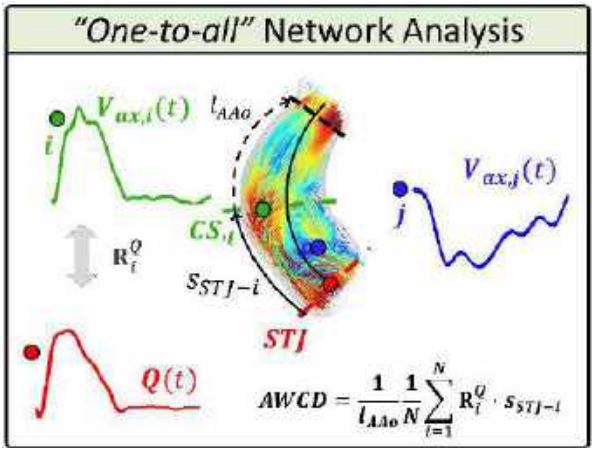

Figure 1: Network-based characterization of AAo flow coherence.

The link between the STJ node and the i-th node was weighted by the Pearson correlation coefficient R_i^Q between $Q(t)$ and $V_{ax,i}(t)$ waveforms, thus measuring the dynamic similarity of the voxel-based $V_{ax}(t)$ waveform with the driving aortic flow rate. Finally, the anatomical length of persistence of the $Q(t)$-$V_{ax}(t)$ correlation was quantified using the network-based metric *Average Weighted Curvilinear Distance* (*AWCD*) defined as [1]:

$$AWCD = \frac{1}{l_{AAo}} \frac{1}{N} \sum_{i=1}^{N} R_i^Q \cdot s_{STJ-i}, \qquad (1)$$

where l_{AAo} is the curvilinear length of the AAo centerline, and s_{STJ-i} is the curvilinear distance between the cross-sections containing the nodes where waveforms $Q(t)$ and $V_{ax,i}(t)$ are defined (**Fig. 1**). To assess the main factors determining the persistence length of the $Q(t)$-$V_{ax}(t)$ correlation, statistical associations of *AWCD* with canonical hemodynamic descriptors quantifying, e.g., $Q(t)$ average value and dynamics, flow eccentricity and blood kinetic energy, and anatomic attributes based on AAo size, curvature, torsion, and aortic arch shape were investigated.

RESULTS

The median and interquartile range of R_i^Q correlation coefficients and *AWCD* are 0.53(0.19-0.75) and 0.24(0.18-0.32) respectively, for the entire population under study. The effect of aortic valve phenotype on AAo flow coherence is presented in **Fig. 2**, where the volume maps of R_i^Q values above the median ($\tilde{R}_i^Q$=0.53) and the *AWCD* values in the AAo are displayed for two explanatory cases. In detail, the healthy TAV subject presenting with the maximum *AWCD*, and the BAV patient, with neither aortic dilation nor stenosis, characterized by the minimum *AWCD* value, are presented here. In the healthy aorta, strong correlations between $V_{ax}(t)$ and $Q(t)$ are uniformly distributed along the entire AAo volume, and the anatomical length of persistence of large-scale flow coherence can reach the 43% of the AAo length (**Fig. 2a**). In a BAV phenotype, *AWCD* is significantly lower compared to TAV (p<0.01), with values down to 15% of the AAo length (**Fig. 2b**).

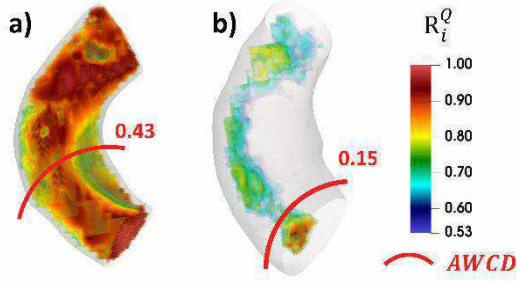

Figure 2: R_i^Q maps and *AWCD* for two explanatory cases.

The analysis revealed that *AWCD* decreases with age (p < 0.001) in the entire population under study (ALL), as well as considering the TAV and BAV subpopulations separately. The scatter plots of the most relevant associations (adjusted with age) of *AWCD* with the canonical hemodynamic and anatomic features are presented in **Fig. 3**. It emerged that *AWCD* is positively correlated with the average flow rate $\bar{Q}$ when considering the entire population and, more strongly, in TAV subjects (R=0.57, p<0.001). In BAV subjects, on the contrary, no association emerged for *AWCD* with $\bar{Q}$, while *AWCD* resulted positively correlated with the peak kinetic energy $\overline{KE}_{peak}$ in AAo (R=0.43, p<0.01). Furthermore, a significant negative correlation emerged between *AWCD* and the flow jet angle *FJA* (a measure of flow eccentricity) [6] in BAV patients (R=-0.54, p<0.001), but not in the TAV group. The aortic anatomic attribute D_{ratio}, defined as the ratio between AAo maximum diameter and the aortic root maximum diameter, presented a significant negative correlation with *AWCD* in both BAV and TAV subjects, with correlation stronger in the former group (**Fig. 3**).

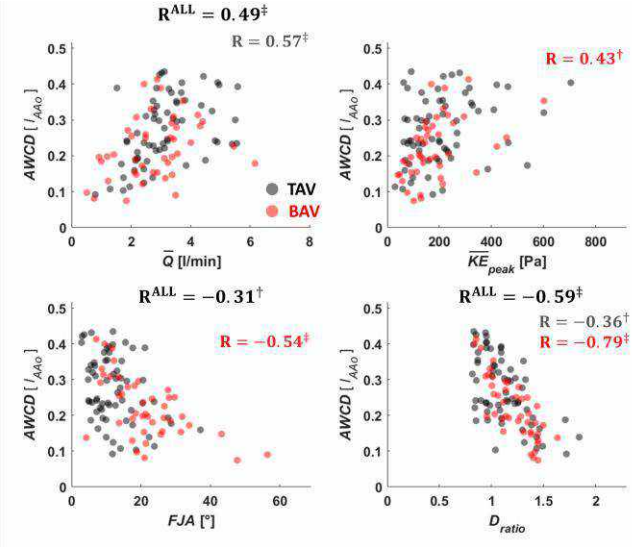

Figure 3: Explanatory scatter plots of *AWCD* with aortic hemodynamic and geometric quantities.
***p<0.05; †p<0.01; ‡p<0.001**

DISCUSSION

A network approach is here adopted to synthesize the 4D complexity of aortic hemodynamics using the concept of large-scale flow coherence, quantified in terms of similarity of the forward flow with the driving aortic flow rate. The main findings suggest that: (1) a BAV phenotype strongly reduces the persistence length of AAo flow coherence, as measured by *AWCD*; (2) the inertial effect of the average aortic flow rate $\bar{Q}$ sustains the transport of coherent fluid structures to the distal AAo, confirming previous observations in healthy subjects [1], and that such effect is cancelled by the presence of BAV phenotype; (3) the aortic dilation, quantified in terms of D_{ratio}, may act as an impediment to the transport of flow coherence regardless of valve phenotype, suggesting that an increasing AAo dilation could progressively compromise the physiological spatiotemporal coherence of large-scale forward flow [3,7]. In conclusion, the present findings contribute to broaden the current mechanistic understanding of the coherence transport of large-scale blood flow in aortic pathophysiology. Future studies may adopt this network approach to evaluate the impact of aortic dilation and/or stenosis on AAo flow coherence.

INTRODUCTION

Patch augmentation of hypoplastic or stenosed vessels is a staple of congenital cardiovascular surgery. Reconstruction of critical anatomic features such as the aortic arch and the pulmonary arteries (PAs) during the newborn and infant periods can have significant impact on long-term outcomes and survival. Reintervention rates due to residual obstruction and/or restenosis are as high as 18% for arch reconstruction [1] and 60% for branch PA plasty [2]. Presently, patches are shaped intraoperatively with reference to the unpressurized native vessel dimensions, which limits the ability to achieve precise reconstructed geometry under physiologic loads.

Our group aimed to develop a preoperative planning workflow that generates patient-specific patch designs via 1D mechanical model, accounting for properties of the vessel and patch materials as well as material uptake at the suture line. Considering these factors through prospective patch design will reduce the burden of intraoperative patch reshaping and enable the surgeon to achieve targeted geometry under postoperative physiologic loads, thereby reducing the need for reintervention and improving patient outcomes. We have conducted preliminary validation with a silicone model of branch PA stenosis.

METHODS

Silicone Model Creation: A physiologically compliant silicone model of an infant branch PA was created with 4.5mm nominal diameter and a central stenosed region of 2mm at zero pressure under 30% prestretch [3], reaching 5.8mm nominal diameter (30% distension) and 2.5mm stenosis at a mean PA pressure of 30mmHg. Molds were fabricated with an SLA printer at 25µm layer height (Form 3, FormLabs, Somerville, MA). Tubes were molded from EcoFlex 00-20 silicone (Smooth-On, Macungie, PA) to achieve high distensibility with a uniform wall thickness of 2mm suitable for suture retention.

Patch Design via 1D Mechanical Model: Molded tubes were prestretched and mounted into an apparatus for CT imaging at 0 and 30mmHg pressure (Fig. 1a). The 30mmHg state represents physiologic loading, while zero pressure reflects the vessel after it has been clamped and depressurized during surgical repair. In the clinical patch-planning setting, only preoperative pressurized measurements of the vessel would be available, so these are used as inputs to the 1D model. Scans taken at 30mmHg were loaded into SimVascular [4] for automatic batch segmentation (Fig. 1b), and the resulting contour groups were imported into MATLAB (MathWorks, Natick, MA) to extract preoperative diameter at fixed increments along the vessel axial length.

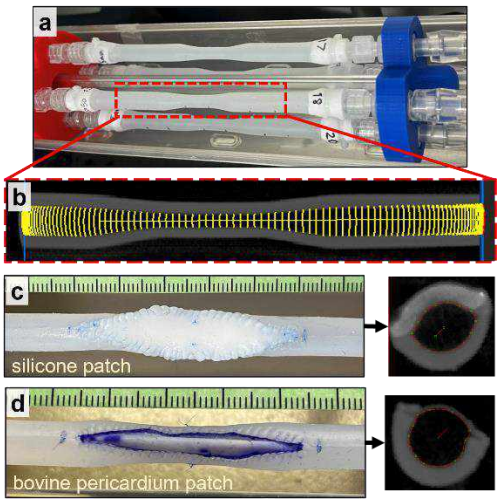

Figure 1: (a) Stenosed branch PA silicone models mounted for pneumatic pressurization during CT scan. (b) Example segmentation from imaging. (c) Silicone and (d) bovine pericardium patches sutured into silicone PA models, with example pressurized CT cross-sectional images on the right.

Using the known pressure (30mmHg), measured diameter, axial prestretch (30%), and unloaded wall thickness (2mm), the circumferential stress was calculated with Law of Laplace, and circumferential stretch was estimated for each cross section of the tube using biaxial data for the silicone material. This stretch estimate was used to calculate the circumference of native tissue at zero pressure. Since the native tissue will be opened to a new, larger diameter following repair, its hoop stress will be higher than preoperatively, meaning that it will stretch to a larger circumference under the same pressure load. To account for this effect, the circumference of native tissue available in the stenosed region opened up to the target diameter (set equal to the proximal non-stenosed diameter) under 30mmHg pressure was estimated following the same procedure. The difference between the target circumference and the extent of native tissue defines the required patch width under load. Using material properties for the patch, the same scaling procedure was performed to determine the unloaded patch size. Finally, a uniform offset was added to the unloaded patch to account for material loss from the suturing process. This suture offset was tuned through measurement of suture uptake between samples of the tube and patch materials.

In this study, two patch materials were tested: 1) a 2mm-thick silicone sheet (with 2% Barium for contrast), representing a pulmonary homograft patch (Fig.1c), and 2) 0.3mm-thick bovine pericardium (BP) (Fig. 1d). For each patch material, one set of tests was initially conducted with tubes reconstructed to target zero pressure dimensions by using the 0mmHg scans as input, isolating the geometric and suture uptake pieces of the procedure. A second set of tubes was then reconstructed to target dimensions at 30mmHg to incorporate the scaling component.

Patch Placement & Measurements: Patch designs were laser projected onto the patch surface and traced [5]. Patches were sutured into tubes with 7-0 Prolene, and the suture line was made airtight with a thin layer of silicone adhesive. Postoperative CT scans were acquired under zero pressure and 30mmHg to assess accuracy of reconstruction. Perimeter of the patched region was averaged over a 20mm axial length and compared to the targeted dimensions. Measurements are reported as mean ± standard deviation across multiple samples.

RESULTS

Four different patch designs were generated with the 1D model for the two targeted loading states (0 and 30mmHg) and two patch materials: silicone and BP. All patches included a 1mm suture bite offset, though BP patches were axially trimmed by 0.5mm due to smaller measured suture-line material uptake in the axial direction versus circumferentially. Compared to the 14.1mm perimeter target, models reconstructed to a zero-pressure target achieved 13.5±0.2mm with silicone patches (n=3) and 14.2±1.1mm with BP (n=7) (Fig. 2a).

Under 30mmHg pressure, circumference of the stenosis was predicted to increase by 1mm when opened to the pressurized target diameter. Patches designed for 30mmHg were both longer and wider than zero-pressure patches for both materials (Fig. 2c). The BP patch was the same length as the silicone patch but 0.2mm wider given its higher stiffness. Compared to the 18.4mm perimeter target, models reconstructed to a 30mmHg pressure target achieved 17.6±0.4mm with silicone patches (n=3) and 19.3±0.4mm with BP (n=6) (Fig. 2b). All silicone-patched samples were within 6% of the targeted dimensions, while BP-patched samples had up to 10% error (Fig. 2d).

DISCUSSION

This study demonstrated the utility of a 1D mechanical model to design vascular patches that achieve vessel dimensions within 2mm maximum of the targeted perimeter. Tissue distensibility, vessel prestretch, and suture uptake are essential factors that must be considered to correctly size the patch for physiologic loading. Patches planned for different pressure levels were completely different sizes in the unloaded state, while using different patch materials had a more modest impact. Suture uptake is a function of bite depth from the tissue edge but also depends on which two materials are being joined (and their thicknesses). In infant-sized anatomy, this factor can have a significant impact on the reconstructed geometry and will require further dedicated studies.

We envision a patch-planning workflow in which patient-specific preoperative imaging is segmented and fed into this model, along with targeted postoperative dimensions based on normative population data. The vessel and patch will be assigned average material properties from our library of biaxial data, and a material-specific, surgeon-specific suture offset will be applied to the unloaded patch design. The design will be laser-projected in the OR for use by the surgeon as a patch template. Prior to implementation, we will rigorously test the model with more complex geometry and additional biologic materials.

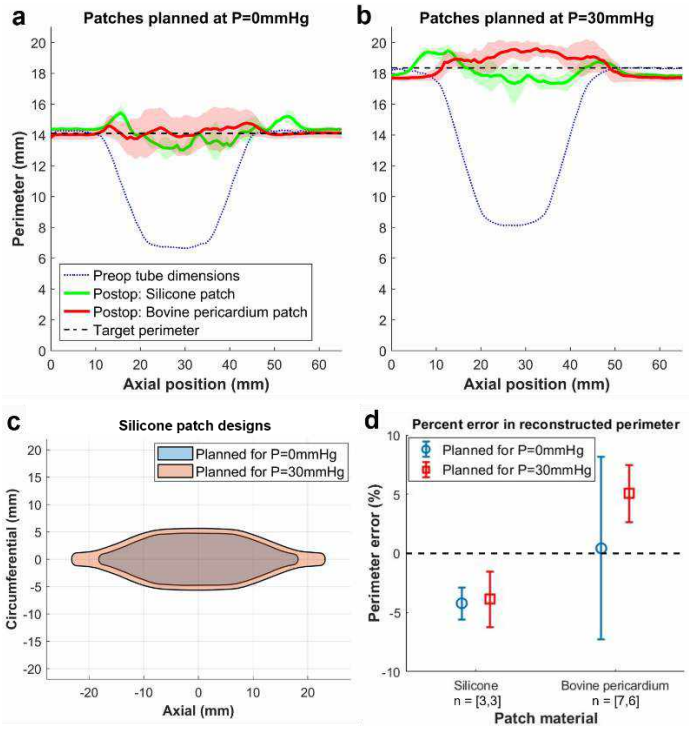

Figure 2: Perimeter measurements for PA model reconstructed with patches designed at either (a) 0 or (b) 30mmHg pressure. Shaded regions show standard deviation across samples. (c) Comparison between unloaded silicone patches designed for 0 vs. 30mmHg pressure state in the same PA model. (d) Error between achieved vs. targeted perimeters for each patch type.

INTRODUCTION

Circumferential alignment of vascular smooth muscle cells (SMCs) in the medial wall of arteries plays a crucial role in vasodilatation and vasoconstriction [1]. Biochemical and biomechanical interactions between vascular endothelial cells (ECs) and SMCs are essential for the formation and maturation of the structure of the arterial wall including the SMC alignment in a development process [2]. Even in matured arteries, these structure and alignment are maintained by quiescent SMCs; however, proliferated and migrated SMCs and their disordered alignment are frequently found in cardiovascular diseases [3,4]. ECs respond to hemodynamic stimuli, including wall shear stress (WSS), thereby changing their functions and bidirectionally communicating with SMC to contribute to vascular physiology and pathology such as angiogenesis, vascular remodeling, and vascular tonus [5,6]. Although interactions between EC and SMC could contribute to the regulation of the SMC alignment, the detailed mechanism is poorly understood.

Here we investigated the effect of EC-SMC interactions under hemodynamic conditions on the morphology of SMCs using the EC-SMC coculture model previously established with a centrifugally compressed cell–collagen combined construct (C6)[7,8].

METHODS

Primary Human Aortic SMCs and Human Aortic ECs were purchased from Lonza (USA). A type I collagen gel in which 450,000 cells of SMCs were embedded was compressed by 1,000 *g* centrifugal force for 10 min with a plate centrifuge (Fig. 1). The compressed collagen gel construct (C6) [7,8] was cultured for 6-7 days in Medium 199 (Thermo Fisher Scientific, USA) supplemented with 20% fetal bovine serum (Nichirei Biosciences Inc., Japan) and 10 ng/mL basic fibroblast growth factor (FUJIFILM Wako, Japan), and then ECs were seeded on the C6 and cocultured 1-2 more days. A SMC model, constructed without ECs, was also prepared for comparison.

The SMC and coculture models were exposed to 2 Pa WSS, which is a representative value of physiological conditions in large arteries, with a parallel-plate flow chamber. After the WSS exposure for 24 h, αSMA as a SMC marker, CD31 as an EC marker, and cell nuclei in the models were fluorescently stained for morphological analysis. The fluorescent images were acquired with a laser-scanning confocal microscope (Olympus, Japan). The orientation angle of cell nuclei against the direction of the flow was calculated on ImageJ software (National Institute of Health, USA).

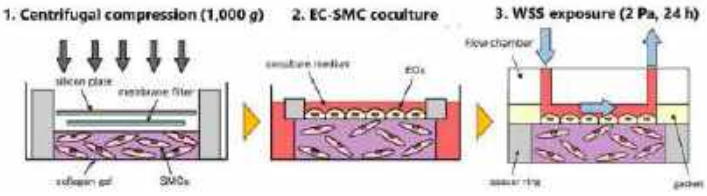

Fig. 1: Schematic diagram of the construction method of the EC-SMC coculture model with C6.

RESULTS

Figure 2 shows representative fluorescent images and the relative frequency of the nuclear orientation angle of ECs and SMCs after the WSS exposure. Morphological analysis of SMCs was performed in 3 different layers: the upper layer near the surface, the middle layer, and the lower layer around the bottom of C6. In the SMC models, only SMCs in the upper layer, which can directly contact with the flow, but

not in the middle layer, tended to align with the direction of the flow. SMCs in the lower layer also did not show orientation in any specific direction (data not shown). In contrast, in the coculture model, SMCs in C6 were found to orientate perpendicularly to the direction of the flow even though the SMCs were below the EC monolayer and not directly exposed to the flow. ECs on the surface of the C6 aligned with the flow.

We subsequently sought to confirm whether WSS-related signaling mediated by ECs causes this SMC orientation or not. The coculture model was treated and exposed to WSS for 24 h with 20 μM DAPT, an inhibitor of Notch signaling, which is known to contribute to sensing and responding to WSS, as well as interaction with neighboring cells [9]. As a result, ECs on the surface of the C6 did not align with the flow by the DAPT treatment (Fig. 2). The perpendicular orientation of SMCs was slightly reduced in the upper layer and suppressed in the middle and lower layers.

DISCUSSION

The alignment of SMCs with the flow was only observed in the upper layer of SMC models. These SMCs are thought to be directly exposed to the WSS, and this result is consistent with a previous report [10]. In contrast, the SMCs in the coculture models orientated perpendicular to the direction of the flow regardless of layers. Since the SMCs in the coculture models were not directly exposed to the flow, our results indicate that SMCs indirectly sense the flow environment, including the direction of WSS, through communications with ECs.

Since bioactive factors mediating EC-SMC communications are generally considered not to transmit the direction of mechanical stimuli, the other unclarified mechanisms may cause the perpendicular orientation of SMCs. We showed the inhibition of mechanical sensitivity of ECs and EC-SMC interactions by the DAPT treatment reduced the perpendicular orientation of SMCs in the coculture model. Therefore, our results imply that responses of ECs to WSS via Notch signaling are involved in the perpendicular orientation of SMCs. On the one hand, it has been reported that the expression and activity of Notch receptors are involved in the responses of SMCs to mechanical stimuli [11]. Since the DAPT treatment in the present study could inhibit the mechanical sensitivity relating to Notch signaling of not only ECs also SMCs, the transmission of mechanical environment information between SMCs was thought to be inhibited. SMC-SMC interactions via Notch signaling may also contribute to the perpendicular orientation of SMCs.

Our future work will be required to identify the role of WSS-related Notch signaling in the regulation of the circumferential alignment of SMCs. Clarifying the underlying mechanisms will contribute to a better understanding of not only vascular physiology but also the pathogenesis of vascular diseases accompanied by abnormal morphological features of SMCs.

INTRODUCTION

Traumatic brain injury (TBI) is a significant public health concern, with more than 25 million new cases of TBI per year globally [1]. The primary causes of TBI are falls, pedestrian road injuries, motor vehicle injuries, military mission injuries, and contact sports injuries. Single and multiple impacts can cause varying degrees of brain injury. In prior studies, we found that high strain rate deformation of neurons can lead to tau mislocalization [2]. Tau mislocalization can cause further hyperphosphorylation which leads to formation of neurofibrillary tangles (NFTs) that characterize chronic traumatic encephalopathy. In the human brain, NFTs tend to accumulate in sulcal depths, which modeling suggests experience the highest stresses during head injury [2]. Mouse brains do not have sulci, but the geometrically similar corpus callosum has been found to have the most tau-associated pathology in closed-head impact experiments performed in mice [3]. However, the mechanical relationships between axonal injuries and traumatic brain injury in these regions are not well understood.

We hypothesize that the temporal stresses generated by impact are highly correlated to the tau-mediated axonal injury of specific regions such as the corpus callosum of the mouse brain. Here, we present a viscoelastic model of mouse brain injury to test this hypothesis.

METHODS

3D geometry model. The brain and skull geometry were generated using data from the Allen Brain Atlas (Fig 1). The 3D brain slice used in this project was built based on the AP0 section of the P56 Mouse Model in the Atlas database [4]. This is the same section that was studied in the experimental studies that we are comparing our model against [3]. The primary region of injury in the experimental model is highlighted in the red circle in Figure 1. And two spots we monitored are highlighted in the red dot (α & β) in Figure 1. The geometry was constrained on two sides of the skull, which simulates the head-fixation device in the prior studies [3] [7].

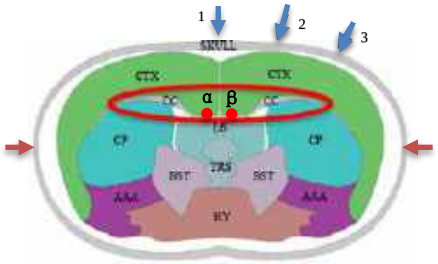

Figure 1: Brain and Skull 3D geometry map. Three impact locations are noted on the map. (Position 1: 0 degrees, middle of the skull; Position 2: 30 degrees off the midline, Position 3: 45 degrees off the midline.) Spots of interest α & β were monitored. CTX: Cerebral Cortex area; CC: Corpus Callosum area; CP: Caudoputamen area; LS: Lateral Septal Nucleus area; TRS: Triangular nucleus of septum area; BST: Bed nuclei of stria terminalis area; HY: Hypothalamus area; AAA: Anterior amygdalar area

Brain and skull material properties. Some material properties used for brain and skull geometry in this study were derived from previous literature [5]. Different methods and research interests affect the material properties of the brain tissues. Therefore, we assumed some properties, and the brain tissues were defined as viscoelastic material. The skull was defined as linear isotropic elastic material [6] (Table 1).

Skull		**Brain**	
Elastic Modulus	$1.8 * 10^7\ kpa$	**Elastic Modulus**	$3.735 * 10^6\ kpa$
Poisson's ratio	0.3	**Poisson's ratio**	0.3229
Mass density	$1920\ kg/m^3$	**Mass density**	$1020\ kg/m^3$
Shear Modulus	$4.2 * 10^4\ kpa$	**Shear Modulus**	$1.41 * 10^6 kpa$
Tensile Strength	$1.65 * 10^4\ kpa$	**Time Value (Bulk & Shear Relaxation Modulus 1)**	10000000
Yield Strength	$1.65 * 10^4\ kpa$	**Bulk & Shear Relaxation Modulus 1**	1

Table 1: Brain and Skull material properties.

Brain stress was taken as

$$\hat{\sigma}(t) = \int_0^t 2G(t-\tau)\frac{\partial \hat{e}}{\partial x}\partial\tau + \hat{I}\int_0^t K(t-\tau)\frac{\partial \emptyset}{\partial x}\partial\tau \quad (1)$$

where G and K are shear and bulk relaxation functions. G_0 and K_0 are initial shear and bulk modulus, and $\hat{e}$ and $\emptyset$ are the deviatoric and volumetric strain. The relaxation functions were taken as.

$$G(t) = G_0[1 - \sum_{i=1}^{N_G} g_i(i - e^{-\frac{t}{\tau_i^G}})] \quad (2)$$

$$K(t) = K_0[1 - \sum_{i=1}^{N_K} k_i(i - e^{-\frac{t}{\tau_i^K}})] \quad (3)$$

where g_i and k_i are shear and bulk relaxation modulus. Time values are presented as τ_i^g and τ_i^k.

Solution. Using SolidWorks, a single impact was modeled as a curved force applied to the skull at 3 locations, middle of the skull, 30 degrees off from the midline, and 45 degrees off from the midline of the skull (see Fig 1). The total duration of the solution is 1 second, and it reaches the peak force at 0.5s.

During the simulation, FFEPlus is the solver used in this study. SolidWorks chose it automatically based on the situation. FFEPlus is the best solver using iterative method since this model has more than 200000 degrees of freedom and more than 40000 elements [6].

Finally, the spatial-temporal stresses were qualitatively compared to the injuries reported in the prior studies [7] to verify the results from this simulation study.

RESULTS

Following impact, stresses vary spatiotemporally throughout the brain tissue (Fig 2). Notably, the stress is elevated in the corpus collosum region where injury has been previously observed experimental (Fig 2B, D, F, H). The stress generated at the corpus callosum reaches the first peak value at 0.26 seconds where the 80 N force was applied at position 1 (Fig. 3(E)). The aligned area of the corpus callosum also has elevated stress following the impact. Other high-stress regions are located at the interface between different regions (Fig. 2).

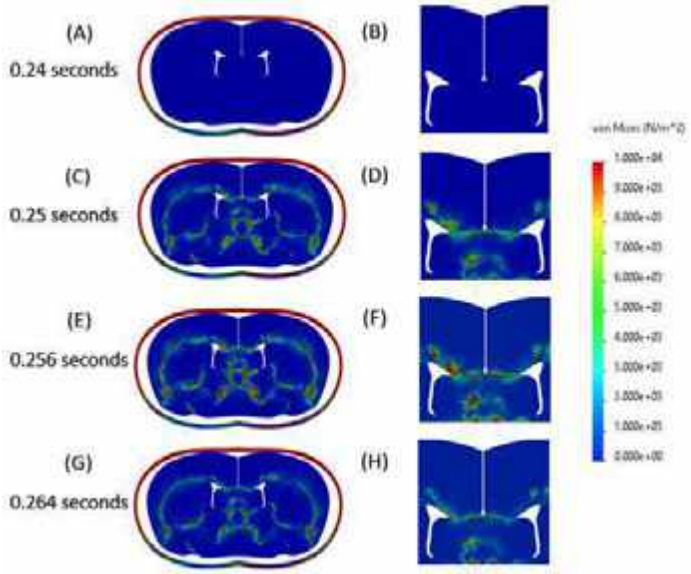

Figure 2: Brain stress heat map at different time steps exposed to 80 N impact at top middle of the skull and the zoomed-in map focusing on corpus callosum region (A)&(B) 0.24s (C)&(D) 0.25s (E)&(F) 0.256s (G)&(F) 0.264s.

Temporal stresses and overall magnitude of stress are influenced by impact location and magnitude. Figure 3 shows the temporal stress in the corpus callosum from t=0.2s to t=0.35s at spots of interest, following single impact at two locations. The stresses generated at spot β during the first contact shown in Fig 3 (B), are more stable and larger than the stresses under position 2 impact in Fig 3(A). Fig 3(C) is comparing the peak stresses at spot β between impact position 1 and impact position 2. Ratio of the stresses elevated at spot α to spot β which follow the impact at position 2 is shown in Fig 4 (D).

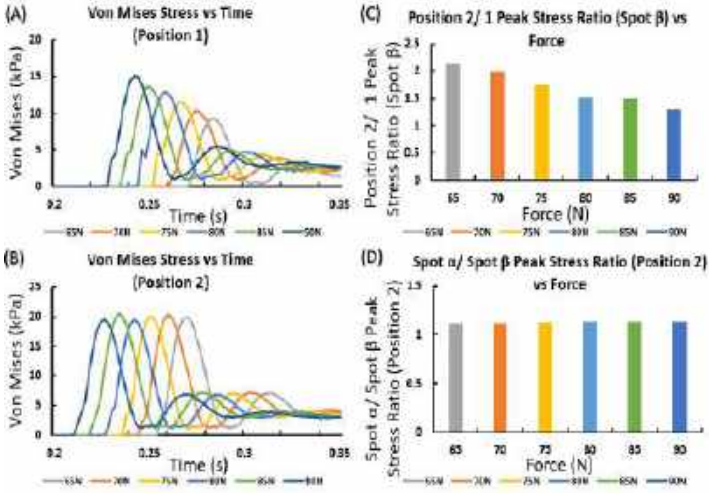

Figure 3: (A) Von Mises Stress vs Time (Impact Position 1, Spot β). (B) Von Mises Stress vs Time (Impact Position 2, Spot β). (C) Ratio of Peak Stress under Impact Position 1 to Position 2 (Spot β) vs Force. (D) Ratio of Peak Stress at Spot α to Spot β (Impact Position 2) vs Force.

DISCUSSION

In this study, we used a viscoelastic model finite element model to study the predicted stresses in a mouse brain during closed-head impact. Consistent with experimentally identified locations of post-injury pathology [3] [7], the model predicts significant elevated stress in the corpus callosum following a single impact on the surface of the skull. Notably, there are some other predicted regions of high stress (Fig 2) which were not studied in the prior experiments.

Limitations: The viscoelastic properties of some brain regions are not known which are based on assumptions. Ongoing parameter studies aim to test the relevance of these assumptions to the overall findings.

Overall. This study suggests that tissue stresses during injury correlate with tau-associated pathology in TBI. Taken together with prior research showing that stresses are elevated in the sulcal depths of human brain, these results are consistent with our hypothesis that the axonal injury following TBI is highly correlated with the high stress.

3D ASSESSMENT OF RAT KNEE JOINT ANATOMY USING HIGH FIELD MRI

Olivia L. Dyer (1), Mackenzie N. Conner (1), Stephanie G. Cone (1)

(1) Biomedical Engineering, University of Delaware, Newark, Delaware, USA

INTRODUCTION

Across species, the knee joint retains a complex arrangement of bones and soft tissues, including ligaments, menisci and cartilage [1]. Identification of healthy knee morphology is important to characterize changes in morphology due to injury and disease. Previously, studies have quantified morphological properties of the bones and completed histological analysis of the ligaments in rat knees [2]. Deepening our understanding of rat knee morphology is valuable because rats are a commonly used preclinical model in orthopaedic research [3]. In this study, a high field 9.4T magnetic resonance imaging (MRI) scanner was used to develop high quality 3D models and quantify rat knee anatomy. The objective of this research was to expand on current knowledge of rat knee morphology, specifically in terms of the 3D anatomical properties of ligaments and menisci. This technique and baseline data will support future work exploring how morphology changes in injury models as well as in growth studies.

METHODS

Knee joints were collected post-mortem from Long Evans rats (n = 8). The knees were stored at -20°C and then thawed to room temperature and imaged in full extension in a 9.4T Bruker Biospec 94/20 AV Neo MRI machine with a T1 FLASH 3D scan sequence (flip angle: 10 degrees , TR: 38.0ms, TE: 4.42ms, acquisition time: 5.004ms, FOV: 16mm x 16mm x 16mm, voxel size: 0.1x0.1x0.1mm, no gap) using a 15mm volumetric coil.

Images were imported into commercial software (Simpleware, Synopsys) for analysis and 3D models of the four ligaments (ACL, PCL, MCL, LCL) and the medial and lateral meniscus were generated [4]. Each model was smoothed using a Gaussian filter before being exported as .stl files and imported into MATLAB (Figure 1). The volumes of the medial and lateral meniscus segmentations were recorded. Width and height measurements of the menisci were recorded at the anterior horn, two central locations, and the posterior horn on both the medial and lateral meniscus [5]. Using a custom MATLAB code, each tissue was converted into point clouds and for each 0.1mm slice along the tissue the cross-sectional area (CSA) was calculated. The middle 50% of the CSA slices along the tissue were averaged together to determine the CSA of the tissue [4].

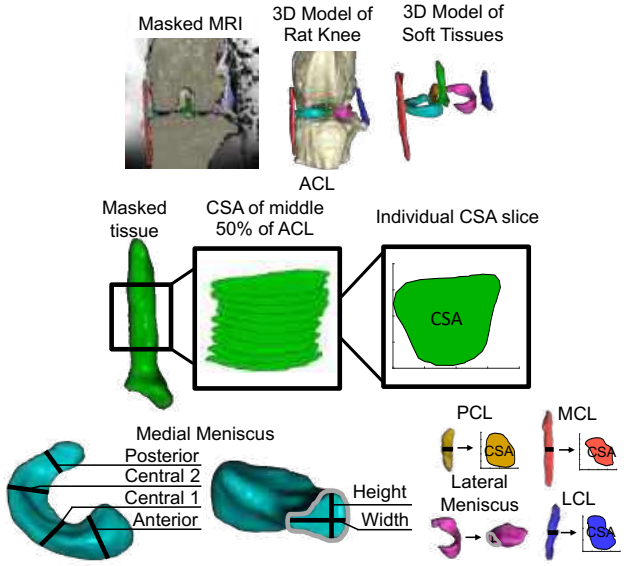

Figure 1: 3D models of the ligaments and menisci of rat knees were generated from MRI scans. CSAs were recorded for each ligament, while height, width and volume of the medial and lateral menisci were recorded at four locations.

Statistical analyses were performed using a custom MATLAB code and included a one-way ANOVA to compare average CSA of the

four ligaments (alpha = 0.05). Meniscus volume was compared using a paired nonparametric t-test. Two -way ANOVAs were used to compare the width and height of the meniscus between locations and between the medial and lateral meniscus (alpha = 0.05).

RESULTS

There was a significant main effect of ligament in CSA measurement ($p = 0.024$). The PCL had a significantly greater CSA compared to the ACL and LCL, with an average CSA of 0.48 ± 0.14mm^2 ($p = 0.015$ and $p = 0.002$, Table 1). Additionally, the MCL had the widest range in variance with CSAs ranging from 0.09mm^2 to 0.80mm^2, while the ACL had the least variability of the four ligaments with CSAs ranging from 0.21mm^2 to 0.45mm^2 (Figure 2).

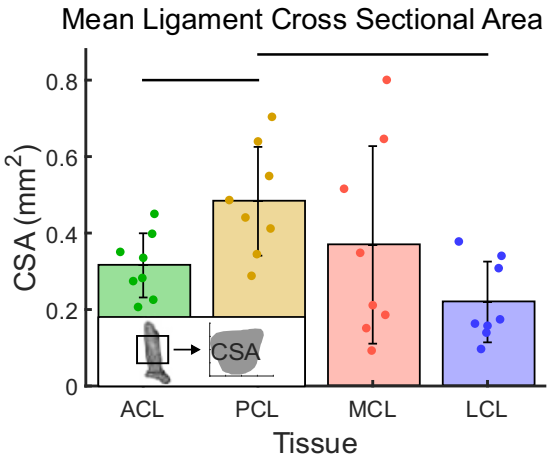

Figure 2: CSA measurements for each of the four ligaments (ACL, PCL, MCL, LCL). Points represent individual tissues, bars and error bars represent mean and standard deviation, image describes the CSA measurement. Bars represent significant differences between tissues.

The average volume of the medial meniscus and lateral meniscus was 2.83mm^3 ± 0.53mm^3 and 3.17mm^3 ± 0.70mm^3, respectively, with no significant difference between sides ($p = 0.46$).

The anterior horn of the medial meniscus had a slightly larger average width of 1.07mm ± 0.11mm, compared to the other three locations along the medial meniscus (Table 1). There was a significant main effect of anatomical location for the heights and widths of the medial and lateral menisci ($p < 0.001$, Figure 3). The height of the medial and lateral meniscus was significantly different at the anterior horn ($p = 0.003$, Figure 3). There was no main effect of the medial and lateral menisci in the widths and heights ($p = 0.18$ and $p = 0.55$).

Table 1: CSA of the four ligaments of the knee (ACL, PCL, MCL, LCL) and the widths and heights of the medial and lateral menisci measured at four locations around the meniscus.

Ligament Geometry (mm^2)				
	ACL	**PCL**	**MCL**	**LCL**
CSA	0.32 ± 0.08	0.48 ± 0.14	0.37 ± 0.26	0.22 ± 0.11
Meniscus Geometry (mm)				
	Anterior	**Central 1**	**Central 2**	**Posterior**
MM width	1.07 ± 0.11	0.60 ± 0.09	0.56 ± 0.08	0.58 ± 0.16
LM width	0.80 ± 0.12	0.78 ± 0.19	0.71 ± 0.16	0.75 ± 0.19
MM height	0.94 ± 0.15	0.83 ± 0.13	0.82 ± 0.09	0.79 ± 0.18
LM height	1.03 ± 0.16	0.79 ± 0.18	0.76 ± 0.18	0.90 ± 0.11

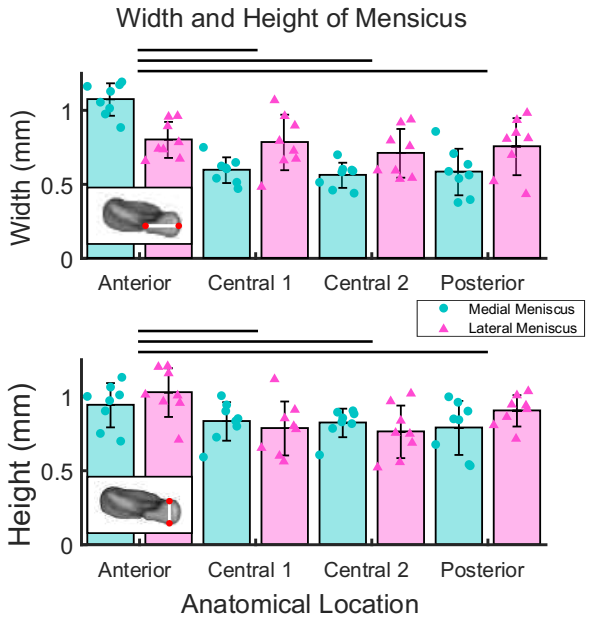

Figure 3: Width and height of the medial and lateral meniscus recorded at four anatomical locations. Points represent individual tissues, bars and error bars represent mean and standard deviation, images describe the measurements. Bars represent significant differences in width and height at anatomical locations.

DISCUSSION

In this study we were able to identify and quantify 3D rat knee tissue morphometry using high field MRI. The PCL had the largest CSA and was significantly different from the ACL and LCL CSA. The heights and widths of the menisci were significantly different at each anatomical location indicating greater tissue size in the anterior aspect of the rat menisci. There were no significant differences in meniscus volume between medial and lateral menisci. The use of high field MRI with a FLASH 3D sequence enabled these findings, as imaging with sub-micron isotropic voxels was necessary for resolving tissue features of this small scale. We found that rat knee morphology retains similar anatomical features to that of human knees and other preclinical models [2,3]. This work followed techniques described in established studies used to characterize knee morphology in large animal models applied to a commonly used preclinical small animal model - rats [4]. Limitations of this work include a relatively small sample size and future work will include increasing sample size, expanding this approach to other small animal models, and comparing healthy knees to injured knees. This study was the first of its kind to establish a methodology to quantify 3D rat knee soft tissue morphometry using high field MRI, enabling future work to explore how knee anatomy changes throughout growth and assess structural effects due to musculoskeletal disorders, such as osteoarthritis.

STUDENTS' PERCEPTIONS ON USING GENERATIVE ARTIFICIAL INTELLIGENCE (GAI) IN ENGINEERING COURSES

Victor K. Lai

Department of Chemical Engineering, University of Minnesota Duluth, Duluth, MN, USA

INTRODUCTION

The introduction of generative artificial intelligence (GAI) tools, notably ChatGPT which became publicly available in November 2022, marks an exciting frontier accompanied by numerous uncertainties in higher education. GAI tools such as ChatGPT have the capability to compose entire essays from a single prompt, eliciting concerns among educators particularly in subjects heavily reliant on writing in their curriculum. In STEM fields, however, ChatGPT is yet unable to accurately perform mathematical operations, although the paid version (ChatGPT 4.0) addresses this limitation through a collaboration with Wolfram Alpha. Aside from the issues of academic integrity, accuracy, and reliability, arguments against the integration of GAI in classrooms include the potential decline in critical thinking and writing skills [1] and perpetuating bias in how content is presented [2].

Despite concerns that GAI will replace jobs, a working paper by the International Labour Organisation (ILO) suggests that GAI may *augment* rather than destroy jobs [3]. Anecdotally, an increasing number of students at the University of Minnesota – Duluth (UMD) returning from internships or co-ops reported tasks involving the use of GAI in their work or contributing to the development of GAI tools for their respective companies. Moreover, the surge in job openings related to GAI highlights the growing significance of these skills in various industries [4]. Consequently, it becomes crucial for higher education instructors to guide students in the ethical use of GAI tools to ensure their relevance upon graduation.

This study delves into students' perspectives on using ChatGPT in two courses at the UMD: ChE 3111 - Fluid Mechanics, a junior-level course which primarily focuses on well-defined engineering problems typically with a single correct numeric answer, and ChE 4502 - Chemical Engineering Design II, the capstone design project course for seniors, characterized by open-ended projects with a substantial report-writing component. This study holds an exemption status approved by the University of Minnesota Institutional Review Board (IRB).

METHODS

At the beginning of the semester, students in both courses were tasked with filling out a pre-course survey to gauge their familiarity with GAI tools such as ChatGPT. The survey aimed to gather insights on how students had previously utilized GAI tools to support their learning, if applicable, and to understand their general perceptions of using such tools in higher education.

For ChE 3111: Fluid Mechanics (n = 24), students were explicitly informed that they had the option to use GAI tools for assignments, provided they declared it through a Google form detailing how GAI was utilized. Additionally, a brief in-class exercise was conducted, where all students attempted to use ChatGPT to solve an engineering problem (calculate a Reynolds number).

In ChE 4502: Chemical Engineering Design II (n = 17), students engaged in a short exercise introducing various ways of employing ChatGPT to aid in report writing. They were assigned the task of conceptualizing a paragraph on GAI by (1) jotting down 3 – 4 key points about GAI, and (2) independently composing the paragraph using those key points. Subsequently, in the following class, students explored the use of ChatGPT in writing through three approaches: (1) prompting ChatGPT to generate a paragraph on GAI and comparing it with their original writing, (2) prompting ChatGPT to edit their written paragraph, and (3) instructing ChatGPT to compose a paragraph using the provided 3 – 4 key points in the prompt. In each scenario, students were tasked with critically evaluating ChatGPT's output and determining whether and how they would edit or use the output.

Towards the end of the semester, students in both courses were invited to complete a post-course survey on how frequently they had used GAI tools for the course (and in what manner, if applicable), as well as their overall perceptions of using such tools. Regrettably, due to the absence of dedicated class time after the final presentations for ChE 4502 to administer the survey, only 3 out of 17 students responded to email requests to complete the post-course survey.

RESULTS

Pre-course survey responses indicated all students in both courses were familiar with GAI tools like ChatGPT, with over half primarily for personal enjoyment rather than coursework. Noteworthy instances of self-reported GAI use involve creating study guides, troubleshooting code, and writing resumes and cover letters (data not shown).

In general, students in both courses express a belief that GAI tools should have a more prominent role in education to some degree. Surprisingly, post-course surveys reveal a decline in these percentages, with more students adopting a neutral stance than a positive one (Figure 1). Regarding the ethical aspect of using AI tools for assignments, most students were either neutral or slightly in agreement, with minimal changes in sentiment from pre-course to post-course surveys (Figure 2).

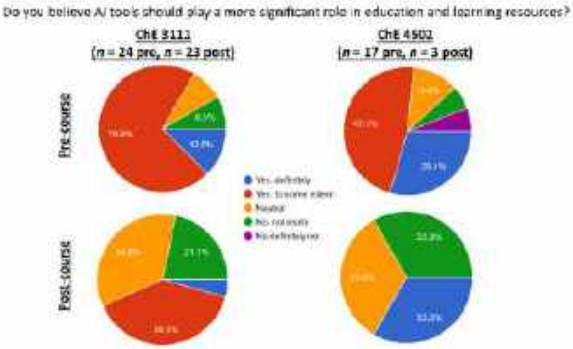

Figure 1: Pre- and post-course survey responses on whether AI tools should play a larger role in education.

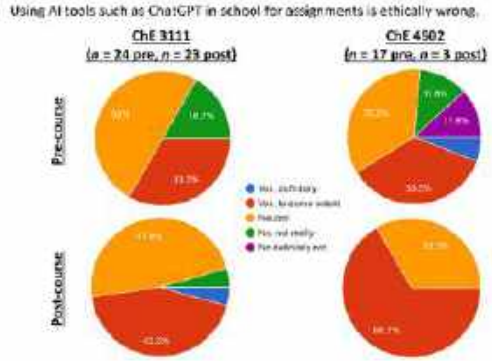

Figure 2: Survey responses on whether using AI tools for assignments is ethically wrong shows little change in sentiment pre- and post-course.

Post-course surveys (Figure 3) indicate infrequent or nonexistent use of GAI tools in both courses, despite students reporting more frequent utilization in other courses. When questioned about the areas in which they employed AI tools in ChE 3111, common responses included information gathering (44%), generating narrative text (26%), developing ideas or outlines for papers (26%), and tackling more complex problems (26%). Despite students' ethical concerns of GAI use in assignments, a majority of students expressed that they would continue to use these tools in future courses if allowed.

Encouragingly, when asked to write any concerns they have with GAI tools, several students demonstrated an awareness of the potential dangers of over-reliance, emphasizing the need to build fundamental skills and creative thinking first (data not shown). At the same time, students felt an urgent need to learn about GAI, with one student saying "that AI learning will be largely implemented across the entire cooperate world within a few short years. I do not want to be lacking of knowledge in this subject when that time comes."

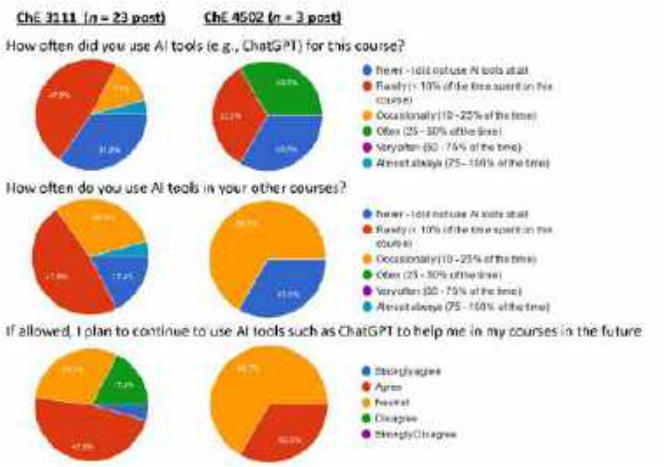

Figure 3: Few students used GAI tools throughout these courses, with slightly higher use in other courses.

DISCUSSION

Overall, few students in these courses utilized GAI tools with their assignments even though they were allowed to. For ChE 3111, this lack of use of could likely be due to students realizing early on during the in-class exercise involving the calculation of Reynolds number that ChatGPT struggled with accurate mathematical calculations. However, they appreciated the tool's ability to provide explanations of the steps involved which were largely correct, and critically evaluated the output to determine where/how ChatGPT was wrong. Consequently, only two students declared using GAI tools for their assignments for the semester, with both instances occurring within the first month. The inability of ChatGPT to perform mathematical functions and solve engineering problems could explain why sentiment towards GAI use in education dropped between pre- and post-course surveys.

For ChE 4502, the lack of responses for the post-course survey rendered the data difficult to interpret. However, I know from meetings with design groups to discuss their reports that ChatGPT was used by several students in report writing. In some instances, I *encouraged* students to use ChatGPT to help edit their drafts. While ChatGPT aided students in report writing, guidance was required for some students in ensuring that the *tone* was suitable for a technical engineering report.

Overall, GAI will likely become a ubiquitous and important tool for many industries in the future. As such, the responsibility lies with educators to train students in the ethical use of such tools, recognizing their limitations and emphasizing the importance of building fundamental skills alongside technological assistance. As one student aptly writes: "I believe it is somewhat synonymous with Simulation Software. It's critically important to understand the underlying functions so that we can discern between accurate and inaccurate outputs. Engineers need to be able to read and write technical information before they rely on something else to do so." From this standpoint, our role in teaching fundamental technical skills and critical thinking remain unchanged, even though the media and tools to do so continue to evolve.

ACKNOWLEDGEMENTS

ChatGPT 3.5 was used to edit this abstract for clarity.

LONGITUDINAL CHANGES IN MECHANICAL PROPERTIES OF AORTA FROM ANGIOTENSIN-II INFUSED MICE OBTAINED BY AN INVERSE FINITE ELEMENT METHOD

Hadi Wiputra (1), Sydney Q. Clark (2), Craig J. Goergen (2), Victor H. Barocas (1), Matthew R. Bersi (3)

INTRODUCTION

Aortic aneurysms affect 17,000 Americans annually and have a 90% mortality rate when the aneurysm ruptures [1]. Mice infused with Angiotensin-II (AngII), are often used as surrogate models of aortic aneurysm development [2-4]. Following infusion of AngII, elevated blood pressure causes the aortic walls to remodel to be thicker and dilated [2]. Given the large variation in the ruptured aorta's mechanical properties [5] and the large extent of remodeling that aortic aneurysm undergoes [6], analyzing the growth and remodeling of aortic aneurysm in a subject-specific application is important.

To achieve mouse-specific characterization of the growth and remodeling process, we require a non-invasive means to track changes in aneurysm's material properties over time. In this study, we used inverse modeling of high frequency ultrasound images to track the changes in material property of aorta over time. We infused wild-type mice with AngII for 28 days, a period during which the aorta was expected to grow and remodel [3,4]. Changes in material properties from 0 to 28 days of AngII infusion were tracked via inverse finite element (FE) methods based on non-invasive image data. After 28 days, the aortas were harvested and tested in a biaxial stretch-inflation test [7] to assess accuracy of the inverse FE method used.

METHODS

Ultrasound images were obtained from ten 16-week-old C57Bl/6J mice, including three saline-infused controls and seven (two have incomplete dataset) infused with 1000ng/kg/min AngII for 4 weeks. 4D ultrasound images of the thoracic aorta were obtained at day 0 and 28 of infusion, with a high frequency ultrasound system (25-55 MHz, Vevo3100, FUJIFILM VisualSonics), resulting in image of approximately 0.03x0.03x0.1mm resolution and 40 timepoints per cardiac cycle. The ascending and proximal descending thoracic aorta were segmented, and deformations were tracked over the cardiac cycle with B-spline Fourier image registration [8]. Inverse FE analysis was performed on the images, where an initial set of material properties was tested and updated repeatedly until the FE-model-calculated changes in vessel geometry matched those obtained from ultrasound. A four-fiber-family material model [3] was used:

$$W = \frac{c}{2}(I_1 - 3) + \sum_{a=1}^{4} \frac{c_1^{(a)}}{4c_2^{(a)}} \left\{ e^{c_2^{(a)}(IV_c - 1)^2} - 1 \right\} \quad (1)$$

where W is the strain energy density and c describes a neo-Hookean matrix stiffness with four embedded fiber families (i.e. a=1..4). c_1(a) and c_2(a) represent the linear and exponential stiffnesses of the four fibers. I_1 is the first invariant, and IV_c is the direction-dependent stretch invariant in the fiber direction. The four families are aligned axially (z), circumferentially (θ), and diagonally (diag) along the aorta. In this study, we assumed that the exponential properties of the fibers (c_2(a)) were constant, obtained from the averages of the two incomplete mouse datasets.

The finite element model used, and the appropriate boundary conditions are illustrated in Fig 1a below. The outer wall was given a Robin boundary to model the surrounding tissue's stiffness; the deformation of the inlet, outlet, and three head branches were prescribed from the tracked ultrasound images. The pressure exerted on the geometry is based on a lumped parameter model of blood flow, with a resistor-capacitor-resistor (RCR) circuit attached to the branched ends of the aorta. The flow models were calibrated to Pulsed Wave Doppler ultrasound and tail-cuff-measured blood pressures.

The unloaded configuration was approximated by progressively shrinking and expanding the aortic mesh geometry until the diameter of the aorta at physiological pressure matched that in the ultrasound image. Biaxial tests were modeled in silico, and the axial pre-stretch was taken as the axial stretch that produces a plateau in the pressure-force curve [5]. Inverse FE analysis results on day 28 and the unloaded geometry configuration were validated against findings from *ex vivo* biaxial testing [7].

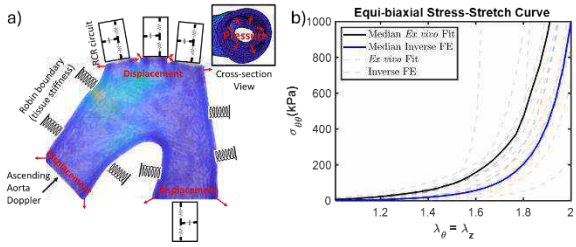

Figure 1a: Boundary condition for the inverse finite element (FE) model. b) Equi-biaxial stress-strain curve comparing the inverse FE model to *ex vivo* biaxial test after 28 days of AngII infusion.

RESULTS

A comparison of the equibiaxial stress-strain relationships obtained from inverse FE modeling and from *ex vivo* biaxial testing is shown in Fig 1b, with an average r^2 between inverse FE and *ex vivo* testing is 0.86±0.23 (mean±sd) at day 28 of infusion. Material stiffness was generally underestimated by the inverse-FE method compared to *ex vivo* stretch-inflation tests, which can be attributed to a smaller unloaded diameter and length estimated by the inverse FE. The smaller initial length and diameter resulted in the obtained material properties being more compliant than that tested *ex vivo*. The difference between inverse FE and ultrasound tracked radius, normalized by ratio of the difference in diastolic to systolic radius, was 13.9 ± 3.9%.

Material properties from AngII infused and control mice are compared in Fig 2. Many measures did not show a significant trend (by a paired 1-tailed t-test), owing to the large variation in the AngII response of mice aorta and uncertainty from the inverse FE method. However, there is a trend towards reduction in axial stiffnesses of AngII mice at 28 days of infusion that was not observed in controls (p=0.097; Fig 2a,b). This trend did not, however, manifest in significant changes in the axial and circumferential tangential stiffness during systole (p=0.16, 0.22; Fig 2c,d), as the less stiff axial fibers were supported by stiffening of diagonal fibers (p=0.84; Fig 2a,b). We also observed a slight, but not statistically significant decrease in systolic axial and circumferential stretches (p= 0.16, 0.21; Fig 2e,f).

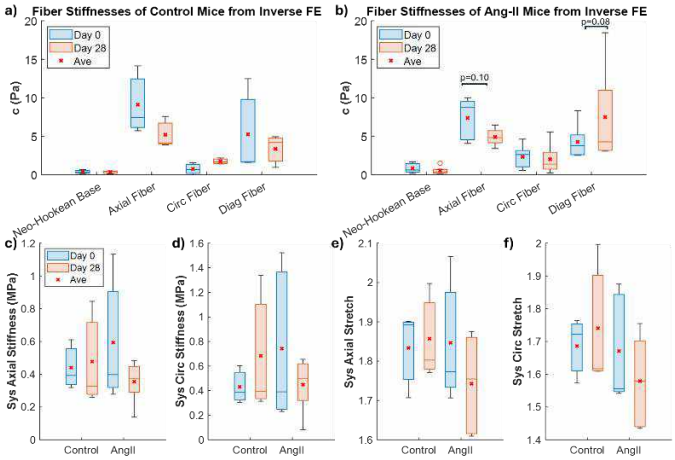

Figure 2: Fiber stiffnesses from the four-fiber family model, obtained from inverse FE model, for a) control mice and b) AngII infused mice. Furthermore, systolic material properties were compared: axial and circumferential stiffness (c,d); axial and circumferential stretch (e,f). P-values were obtained from paired 1-tailed t-test and only p-values below 0.1 are shown.

DISCUSSION

The inverse FE method showed acceptable agreement with *ex vivo* mechanical characterization (Fig. 1b). In addition, certain observations from the AngII-infused mice were consistent with prior studies. Specifically, we saw a decrease in axial fiber stiffness and no change along the circumferential direction between day 0 and day 28 of AngII infusion (Fig. 2b). This is consistent with previous study that compared *ex vivo* mechanical properties of AngII infused mice with the same dosage and dosing period [3]. Furthermore, under increased pressure, the aorta responds by reducing its axial stretch [9, 10], and a similar trend was observed in our study, although not statistically significant. Therefore, the pattern we observed in our study is consistent with previous reports.

Despite the promising results, our study pointed to limitations in the inverse FE approach. The method brings considerable uncertainty in estimation of the material properties, which hindered detection of trends. The amount of information provided from the image is also limited. Unlike the large amount of deformation space that can be explored in *ex vivo* biaxial testing, inverse FE relies only on information from the deformation between diastole to systole, which is often small (diastole-systole radius dilation by 1.06x) and does not allow for controlled axial stretching. These issues highlight the need for validation of inverse FE against ground truth *ex vivo* testing, which can be rare in the literature [11] and is an important part of this study.

Additionally, there is large variation in the effect of AngII on the aorta [3, 12]. The aorta expresses fewer angiotensin receptors compared to smaller vessels, limiting the direct vasoactive effect of AngII on aorta [3]. The effect of AngII on the aorta is primarily indirect, via a systemic effect from changes in peripheral vessels and inflammation [3]. The combination of methodological uncertainty and large variability of the AngII response made it difficult to obtain statistically significant observations. This difficulty is not necessarily problematic in the current study, which aimed primarily at method development, but it draws attention to a potential challenge when using image-based inverse methods of this sort.

The non-invasive nature of this method will be valuable to study the development and evolution of aortic aneurysm in a subject-specific manner. Depending on conditions, aortic aneurysms can develop into similar geometries but with vastly different material properties [13]. Inverse FE models, such as the one employed herein, can be valuable in distinguishing among aneurysms with similar appearance provided one can manage the potential error in the material property estimates.

INTRODUCTION

Chiari Malformation I (CM-I) is a condition characterized by cerebellar tonsil herniation of >5mm through the foramen magnum. CM-I causes a reduction of cerebrospinal fluid (CSF) flow [1] and an increase in cardiac-induced brain tissue motion [2], and is associated with headaches, paresthesia, dysphagia, and sleep apnea [3,4].

In symptomatic cases, posterior fossa decompression (PFD) surgery is often performed, which involves removing bone to enlarge the foramen magnum and cervicomedullary junction to establish normal CSF flow [5] (Figure 1). Successful PFDs improves symptoms in ~70-80% of patients [6]. However, the surgery involves risk, and identifying which candidates will benefit from surgery is important.

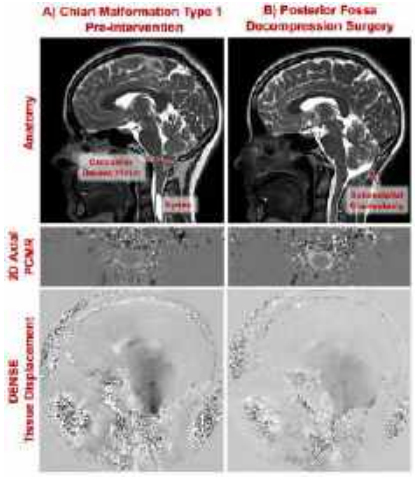

Figure 1: Anatomical images, PCMR images showing CSF flow, and DENSE showing brain motion for A) a symptomatic CM-I patient with syringomyelia and, B) The same individual after posterior fossa decompression surgery, CSF flow is free flowing on both the anterior and posterior of the foramen magnum and syrinx has resolved.

The degree of tonsillar herniation does not correlate with symptom severity or with surgical outcomes [7,8]. Therefore, we seek to use advanced neuroimaging methods to quantify how PFD affects cerebral dynamics. *We hypothesize that CSF flow and brain motion are better metrics to elucidate which patients will have the greatest likelihood of cerebral dynamic improvements from surgery.*

METHODS

We imaged 89 patients (18-71yrs, mean=37.2yrs; M/F=18/71) with a clinical diagnosis of CM-I on a Siemens 3T PrismaFit. Of these patients, 49% (N=44 patients) underwent PFD and participated in a three-month follow-up MRI.

To measure CSF flow, we collected a retrospectively gated, 2D-axial PCMR scan at 1.2x1.2x5mm resolution, VENC=5cm/s, with 25 images per cardiac cycle. CSF was manually segmented, and pixel-wise velocity was integrated to determine flow at each time-point. Stroke volume was defined as the average of the absolute value of the cranial and caudal flow.

To measure brain pulsatile motion, we used displacement-encoding with simulated echoes (DENSE). Images were acquired in the sagittal plane at the midline using a two-dimensional spiral cine sequence with peripherally pulse unit-gating. 13–29 frames were acquired over the cardiac cycle depending on heart rate. Image resolution was 0.9x0.9x8.0mm [9]. Displacement was calculated pixel-wise over the cardiac cycle from the phase images. To measure tonsillar descent, we collected a sagittal T_2-weighted image.

Data was analyzed using both unpaired t-tests, with the pre-surgical group including all patients, and pairwise t-test with just patients who underwent surgery. Pearson correlations were used for continuous variables. $P<0.05$ was considered significant.

RESULTS

CSF stroke volume was 0.86±0.58ml in CM-I patients. CSF stroke volume after PFD surgery was 1.14±0.43ml ($p=0.036$; Figure 2). Pairwise (pre/post-surgery) we saw a 40.5% increase to CSF stroke volume ($p=0.011$).

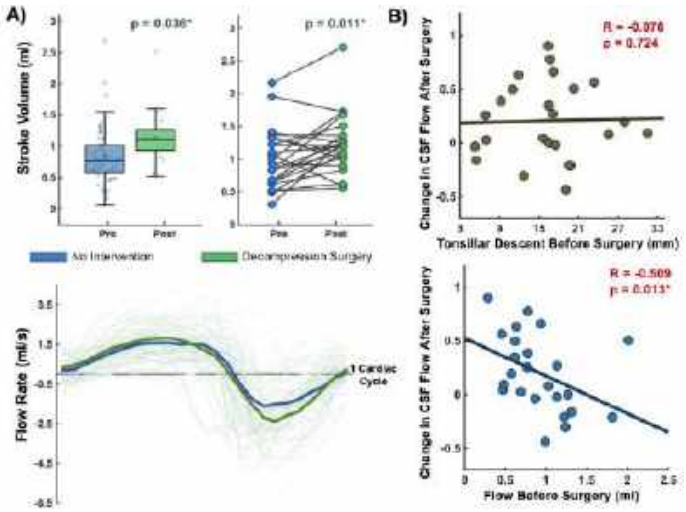

Figure 2: A) CSF stroke volume increases after PFD surgery. B) Change in CSF flow compared to tonsillar descent and presurgical CSF flow respectively. Improvements to CSF is better predicted by presurgical CSF flow, than by tonsillar descent.

Notably, we found that CSF flow increases seen after surgery had *no relationship* to tonsillar descent (R = -0.078, p =0.724), but *did relate* to amount of pre-surgical flow (R = -0.509, p=0.013; Figure 3). *Showing that only subjects with low initial flow had a significant post-surgical increase in flow, regardless of severity of tonsillar descent.*

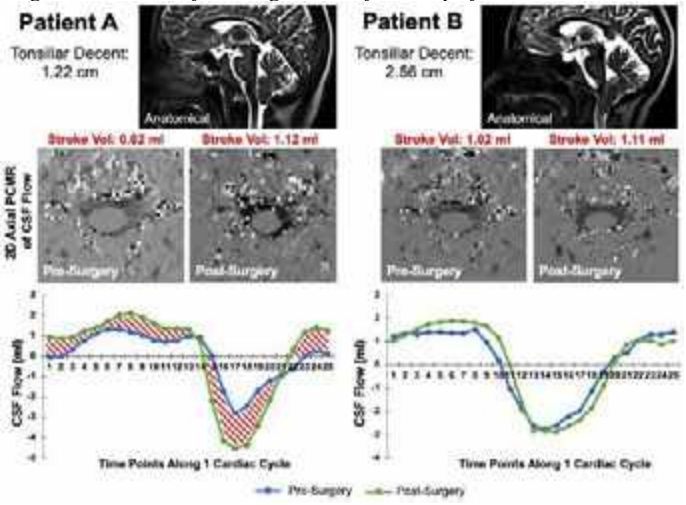

Figure 3: Representative CM-I patients showing presurgical CSF flow better predicts surgical CSF improvements than tonsillar decent. Shaded area represents gain in stroke volume. Patient A has less tonsillar decent but worse initial flow, so benefits more in CSF flow from surgery.

We also found that pulsatile motion decreases significantly after surgery, with brainstem motion decreasing 17.3% (p=0.007) and cerebellum motion decreasing 45.2% with surgery (p<0.001). We again found that improvements were better predicted by the amount of pre-surgical motion (Brainstem: R = -0.638, p<0.001; Cerebellum: R = -0.878, p<0.001) than by tonsillar descent (Brainstem: R = -0.312, p=0.093; Cerebellum: R = -0.620, p<0.001). *This implies that subjects with high initial brain motion had a significant post-surgical decrease in motion, regardless of severity of tonsillar descent.*

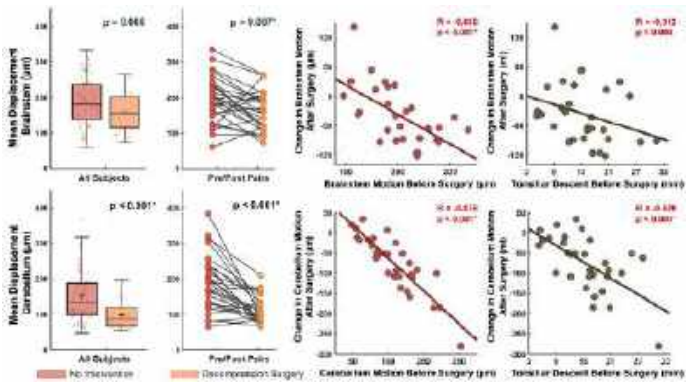

Figure 4: Cardiac related motion in the brainstem (top) and cerebellum (bottom) decreases significantly in both regions after PFD surgery. The amount of change in brain motion is better predicted by presurgical brain motion, than by tonsillar descent.

DISCUSSION

The Monroe-Kellie Doctrine dictates that to maintain normal intracranial pressure, the cranial cavity must maintain consistent volume, and therefore when the arterial pulse leads to systolic expansion of brain tissue, CSF is passively pushed out of the skull [10]. However, in CM-I, the passive flow of CSF is obstructed, and to compensate, the brainstem and cerebellum must displace more to maintain cerebral homeostasis [11]. These changes to cerebral dynamics are presumed to cause clinical symptoms [12]. *With the creation of adequate space for CSF flow through PFD surgery, CSF flow increases and brain motion decreases towards normal*.

While amount of tonsillar decent is the standard imaging marker, it has proven to be a poor measure of CM-I severity, as other factors like foramen magnum size and crowding also affect cerebral dynamics. Here we instead directly measured cerebral dynamics. We showed that only the patients who had severely impacted CSF flow and brain motion realized improved cerebral dynamic after surgery, regardless of tonsillar descent. While CSF flow is frequently assessed in PFD, it is commonly with PCMR acquired in a sagittal plane which is inadequate to characterize flow. Often qualitative assessments of geometric images are used to assess crowding and then infer the CSF flow dynamics for a given subject which may not be reliable. Brain motion has only recently been measured in CM-I, and therefore work in this area is limited [2,13]. Here, we showed cerebral dynamics in CM-I are important indicators of potential benefits from PFD surgery. Further research is needed to determine how cerebral dynamics affect clinical outcome measures.

INTRODUCTION

Atrial fibrillation (AF) is the most common arrythmia that can cause cardioembolic events. Stroke prevention is the main concern in the management of AF. Blood stasis in the atrium is associated with thrombus development and often occurs in the left atrial appendage (LAA). While anticoagulants are effective in mitigating strokes, bleeding risk, noncompliance, and other side effects make them unused in more than 50% of eligible patients. Instead, another method for reducing LAA related cardioembolic stroke, is left atrial appendage occlusion (LAAO) using an occlusion device such as the WATCHMAN™ (Boston Scientific Corporation, St. Paul, Minnesota). Although these devices have shown improved long-term outcomes, studies have also shown that about 4% of patients develop device related thrombosis (DRT)[1]. The factors leading to DRT are still unclear despite several clinical studies investigating potential predictors.

The aim of this study is to evaluate the hemodynamic profiles of the left atrium (LA) in patients who have received a WATCHMAN™ device, and to identify potential predictors for DRT. We hypothesize that DRT is more likely to occur in patients with blood stasis and complex flow patterns at and around the WATCHMAN™ device. We propose a combined finite element analysis (FEA) and computational fluid dynamics (CFD) approach to investigate this hypothesis.

METHODS

Echocardiographic (ECHO) and computed tomography (CT) images were taken before and after device deployment and were provided by Mayo Clinic, Aarhus, and Copenhagen University hospitals under an IRB approved protocol. A total of 38 patients were selected for this study.

The CT images were imported into Mimics Research 23.0 (Materialise, Belgium) for processing and segmented to create a patient-specific 3D digital model of the left atrium (LA). Finite-element simulations were performed by FEops NV (Gent, Belgium) to deploy an LAAO device into each model in a position that matched the post-procedural CT positioning for each patient. The output of the finite-element simulations was retained and used as input for the computational fluid dynamic (CFD) simulations. The mitral valve (MV) was segmented as a saddle shaped opening and the PVs were cut at the ostium. The models were imported into Ansys Workbench 2020 R1 (Canonsburg, PA). Extensions were made at the inlets (n=4) and outlet equal to 10x the diameter of each PV and the MV to overcome entrance effects and to ensure an appropriate velocity profile. The models were meshed with an element size 0.8mm based on the results of a mesh sensitivity study. Transient CFD simulations were completed using Ansys Fluent (Canonsburg, PA). A laminar flow model (Re < 2000) was used. Each PV was set as a pressure inlet with 0 pressure. The MV was set as a velocity waveform outlet with a unique patient-specific profile for each model. A total of 3 cardiac cycles were simulated for each patient and only the last cycle was used for analysis. The workflow used is shown in **Figure 1**. The parameters of interest were time averaged wall shear stress (TAWSS; **EQ1**), oscillatory shear index (OSI; **EQ2**), and endothelial cell activation potential (ECAP; **EQ3**)[2], with T being the cardiac cycle duration.

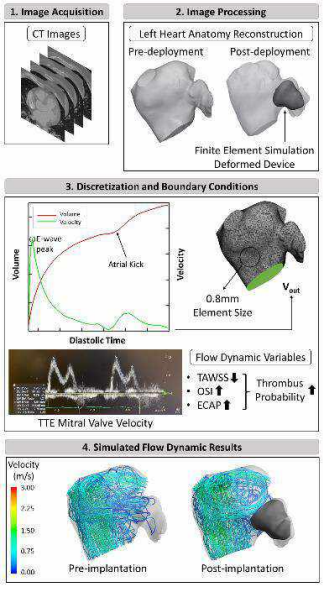

Figure 1. Workflow adopted for this study.

$$TAWSS = \frac{1}{T}\int_0^T |\overline{WSS}|\, dt \qquad \textbf{(EQ1)}$$

$$OSI = 0.5\left(1 - \frac{\left|\int_0^T \overline{WSS}\, dt\right|}{\int_0^T \overline{WSS}\, dt}\right) \qquad \textbf{(EQ2)}$$

$$RRT = \frac{1}{(1-2*OSI)*TAWSS} \qquad \textbf{(EQ3)}$$

RESULTS

Given the cohort size, only a sample of the patients are shown in contour images of **Figure 2**. The TAWSS contour plots are shown in **Figure 2A**. To quantify the differences between patient populations, **Figure 2A** shows a global account of the TAWSS values as a Box and Whisker plot. The mean TAWSS was found to be 1.76±1.24 Pa for the DRT cohort and 2.90±2.70 Pa for the control cohort with p <0.0001.

The OSI contour plots are shown in **Figure 2B**. To quantify the differences between patient populations, **Figure 2B** shows a global account of the OSI values as a Box and Whisker plot. The mean OSI was found to be 0.19±0.11 for the DRT cohort and 0.17±0.11 for the control cohort with p <0.0001.

The ECAP contour plots are shown in **Figure 2C**. To quantify the differences between patient populations, **Figure 2C** shows a global account of the ECAP values as a Box and Whisker plot. The mean ECAP was found to be 0.23±0.58 Pa-1 for the DRT cohort and 0.17±0.30 Pa^{-1} for the control cohort with p <0.0001.

The boundaries of the thrombi found in each DRT patient's post-CT scan are overlayed for each flow dynamic parameter (**Figure 2)**. The thrombi were mainly observed in regions of low WSS, high OSI, and high ECAP. The total mean volume of the thrombi was 1.44±2.01mL.

DISCUSSION

Endothelial cell dysfunction is a known predictor of thrombus formation. Numerous studies have explored WSS as a possible factor in endothelial dysfunction, [3] particularly noting the association of low WSS levels with thrombogenesis[5]. In line with these previous findings, our study shows that DRT patients had a lower TAWSS compared to controls. A low TAWSS indicates a region of blood stasis, which can induce thrombosis due to the accumulation of procoagulant components [4]. Furthermore, our study documented that DRT was mainly located within or close by regions with low levels of TAWSS. These lower TAWSS values may be related to device deployment. Zhong et al.[6] have shown that a deep device deployment depth resulted in lower TAWSS whereas a device deployed at the LAA ostium was higher. Clinical studies have also shown a higher incidence of DRT with deeper device deployments (34,35). When the device is deployed deep into the LAA, a shallow 'valley' is created above the device that serves as a nidus for blood stagnation and thrombus formation.

Another important flow dynamic parameter investigated was OSI. Oscillatory flow can promote an inflammatory state which can result in endothelial cell dysfunction, a potential nidus for thrombus formation [5]. The presence of an LAAO device may influence the flow patterns within the atrium, potentially resulting in increased oscillatory shear. In the case of a deeper device deployment, a recirculation region develops on top of the device increasing the oscillatory shear around the device. In this study, the DRT cohort was observed to have higher OSI than the controls. In addition, there was a correlation between the location of the thrombus identified from in-vivo imaging and regions of high OSI. Although not seen in this study, residual (micro) peri-device leaks may also influence OSI.

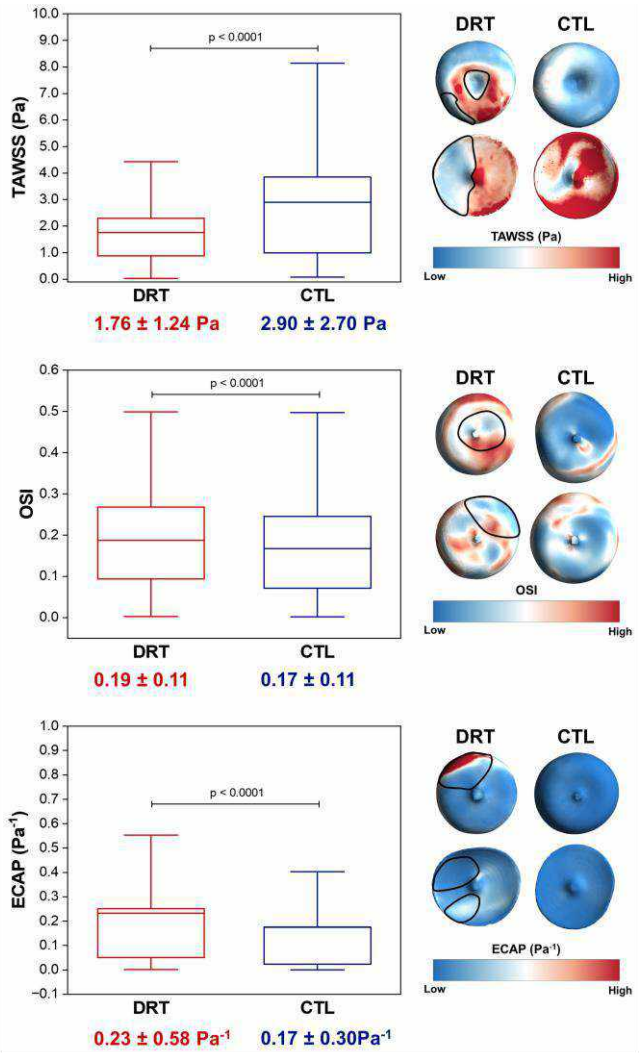

Figure 2. Global account of TAWSS (A), OSI (B), and ECAP (C) for the DRT and control (CTL) populations. Contours of each parameter for the top surface of the device are displayed to the right of each box plot. Thrombus locations from in-vivo imaging are shown by the black line for each DRT patient displayed.

ECAP has been shown in various studies to confer areas of susceptibility at the vessel walls [6]. ECAP is defined as the ratio of OSI and TAWSS, where a high value indicates a high OSI and a low TAWSS, both of which have been shown to be related to thrombogenesis. Endothelial cells naturally provide an antithrombotic surface [7], but when activated, this property is negated, which can result in thrombus formation [7]. In this study, we observed an elevated ECAP for the DRT cohort compared to the controls further confirming the potential role of CFD parameters in predicting DRT.

INTRODUCTION

Atrial fibrillation (AF) is the most common arrhythmia in the world and is associated with adverse cardioembolic events. As a result of the irregular beating of the heart caused by AF, blood stasis is often reported in the left atrium (LA), and in particular the left atrial appendage (LAA). This stasis promotes thrombogenesis and therefore, stroke management is the main concern in these patients. Antiarrhythmic and anticoagulant medications can be used to reduce the risk of stroke; however, their side effects make them unusable in many patients[1]. A possible alternative is the use of radiofrequency (RF) ablation to restore the heart to a normal rhythm. This procedure can be performed invasively (surgical ablation), noninvasively (catheter ablation), or a combination of both (hybrid ablation). In addition, the LAA can also be closed during a surgical ablation, preventing blood flow into it. Compared to the use of only surgical or catheter ablation, hybrid ablation has been shown to have positive outcomes for restoring rhythm with less recurrence of AF and the need for repeat ablations [2]. Although there has been clinical success of a hybrid ablation approach, it remains unclear whether this procedure in combination with LAA closure (LAAC), influences the flow dynamics of the LA. Changes in the flow could potentially cause complications if left unaddressed. We have previously shown that the use of catheter ablation influences the LA geometry and flow dynamics in the LA by changing the velocities and vortex formations [3].

The aim of this study is to evaluate the flow dynamics in the LA after a hybrid ablation procedure with closure of the LAA. We hypothesize that combination of the ablation and closure procedure will have a profound effect on the overall flow dynamics and LA geometry.

METHODS

The hybrid ablation procedure consisted of surgical epicardial RF ablation of the left atrial posterior wall and closure of the LAA, and catheter RF ablation of the pulmonary veins (PV). Echocardiographic (ECHO) and computed tomography (CT) images were taken before and after each procedure and were provided by Mayo Clinic under an IRB approved protocol. A total of 10 patients (thus 30 CT scans), matched by age and sex, were selected for this study. Geometric measurements of the LA and PVs were recorded for each as well.

The workflow used is shown in **Figure 1**. The CT images were imported into Mimics Research 23.0 (Materialise, Belgium) for processing and segmented to create a patient-specific 3D digital model of the LA. The mitral valve (MV) was segmented as a saddle shaped opening and the PVs were cut at the ostium. The models were imported into Ansys Workbench 2020 R1 (Canonsburg, PA). Extensions were made at the inlets (n=4) and outlet equal to 10x the diameter of each PV and the MV to overcome entrance effects and to ensure an appropriate velocity profile. The models were meshed with an element size 1.0 mm based on the results of a mesh sensitivity study. Transient computational fluid dynamic simulations were completed using Ansys Fluent (Canonsburg, PA). A laminar flow

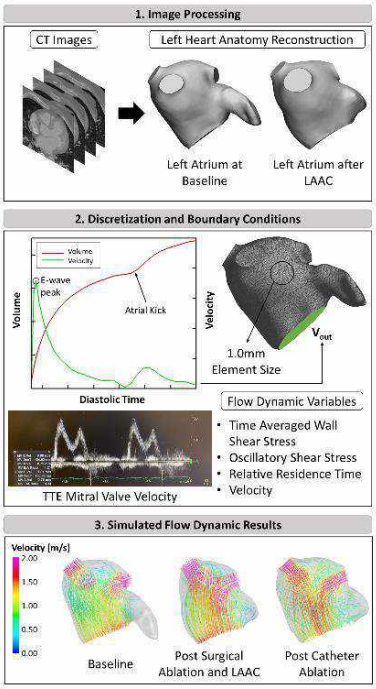

Figure 1. Adopted image processing and CFD workflow.

model (Re < 2000) was used. Each PV was set as a pressure inlet with 0 pressure. The MV was set as a velocity waveform outlet with a patient-specific profile that matched the rhythm (sinus, AF, or atrial flutter) at each procedure from ECHO. A total of 3 cardiac cycles were simulated for each patient and only the last cycle was used for analysis. The parameters of interest were time averaged wall shear stress (TAWSS; **EQ1**), oscillatory shear index (OSI; **EQ2**), relative residence time (RRT; **EQ3**), and velocity in the atrium with T being the cardiac cycle duration.

$$TAWSS = \frac{1}{T}\int_0^T |\overline{WSS}|\, dt \qquad \text{(EQ1)}$$

$$OSI = 0.5\left(1 - \frac{\left|\int_0^T \overline{WSS}\, dt\right|}{\int_0^T \overline{WSS}\, dt}\right) \qquad \text{(EQ2)}$$

$$RRT = \frac{1}{(1-2*OSI)*TAWSS} \qquad \text{(EQ3)}$$

RESULTS

Because of space limitations, we are showing the results of one patient representative of the whole dataset. The average velocity increased from baseline to post catheter ablation (**Figure 2**). Initially, E-wave velocity was 0.39 ± 0.24 m/s at baseline, 0.51 ± 0.28 m/s after the surgical ablation and LAAC, and 0.81 ± 0.52 m/s after catheter ablation. A more centralized flow that increased in magnitude at the E-wave peak was shown after each procedure. Velocities were low and near zero in the LAA at baseline and after LAAC.

The average TAWSS increased with each ablation procedure (**Figure 3**). Initially, TAWSS was 1.69 ± 1.63 Pa at baseline, 1.87 ± 0.73 Pa after the surgical ablation and LAAC, and 3.19 ± 1.20 Pa after catheter ablation. The increase in TAWSS was mostly observed to occur on the posterior portion of the LA. In addition, after catheter ablation, there is a drastic increase in TAWSS at the PVs. Despite the closure of the LAA, the portion of the appendage that remained had lower TAWSS values that were comparable to those at baseline.

There was a negligible change in OSI after each procedure (**Figure 3**). OSI was 0.16 ± 0.09 at baseline, 0.16 ± 0.11 after the surgical ablation and LAAC, and 0.15 ± 0.10 after catheter ablation. The concentration of OSI appeared to increase on the anterior side with each procedure.

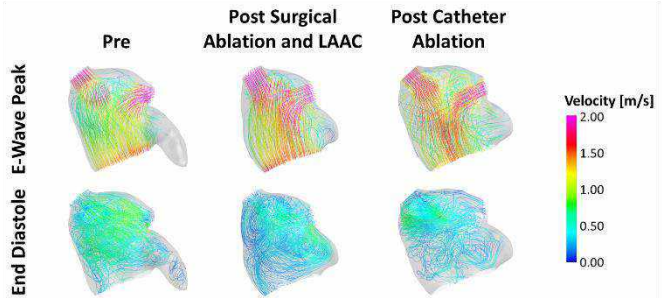

Figure 2. Atrial velocities at the E-wave peak and end diastole after each procedure.

The average RRT drastically decreased after each procedure (**Figure 3**). RRT was 2.93 ± 8.76 Pa^{-1} at baseline, 1.19 ± 1.46 Pa^{-1} after the surgical ablation and LAAC, and 0.66 ± 0.93 Pa^{-1} after catheter ablation. The region with the highest RRT at baseline was at the LAA. After catheter ablation, there was a decrease in RRT at the PVs.

A decrease in overall surface area and volume was seen after each procedure independent of the decrease in volume from the LAAC. The PVs ostia areas decreased from baseline to post catheter ablation.

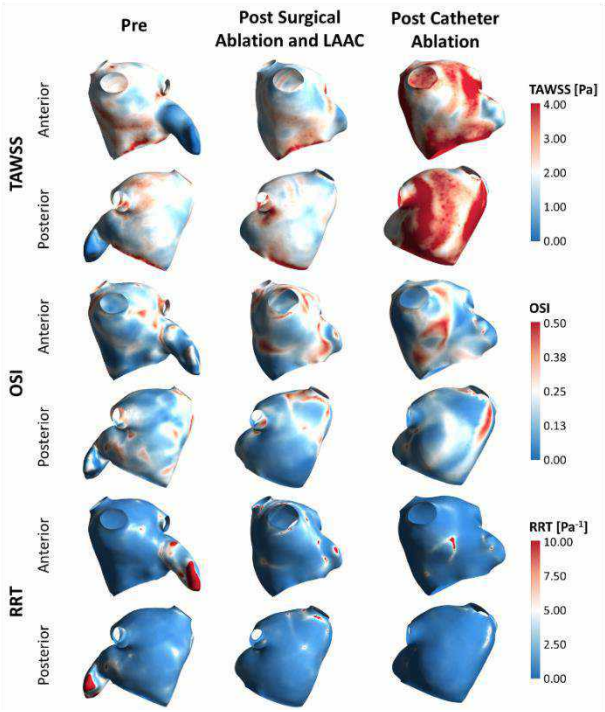

Figure 3. Flow dynamic parameters on the anterior and posterior surfaces at baseline and after each procedure.

DISCUSSION

In this study, several parameters were investigated using CFD to elucidate the effect of hybrid ablation of LA flow dynamics. We observed lower TAWSS in the LAA at baseline, reaffirming the appendage as an ideal location for flow stagnation. After LAAC the remaining portion of the LAA still has a lower TAWSS compared to the rest of the LA. Depending on the size of the remaining LAA, thrombogenesis in this region may still be a concern. Interestingly, a majority of TAWSS increase was observed on the posterior side and near the PVs, the locations where the ablations were performed. A decrease in LA volume has been reported after RF ablation [4], which could result in increased velocities and thus WSS. We also observed this in our study.

Oscillatory shear has been associated with inflammation which can assist the thrombotic process [5]. The average OSI in this study was low however, there was an increasing concentration of high OSI after each ablation procedure. This may indicate potential problem regions within the LA for a higher probability of thrombogenesis after ablation.

The LAA was identified as the region with the highest RRT at baseline, indicating little to no blood flow. The absence of the A-wave results in lower average velocities during diastole. When the heart is restored to normal rhythm after an ablation procedure, there is now an increase in average velocities. As a result, blood is guided out of the LA quicker, ultimately reducing the likelihood of high RRT. This study is a proof of concept to the unique flow features that occur after ablation procedures. More follow-up is needed to connect the findings to actual clinical outcomes.

INTRODUCTION

Ruptured cerebral aneurysms (CAs) are the cause for subarachnoid hemorrhage (SAH) in 7.9 (95% CI: 6.9-9.0) per every 100,000 persons yearly [1]. Considering the great mortality and morbidity associated with SAH, understanding the mechanisms that lead to aneurysm rupture is crucial. Over the years, numerous studies have been conducted to understand risk factors associated with aneurysm rupture, including demographics, CA geometry, and ethnicity [1,2]. However, the role of tissue microstructure and inflammation in CA rupture mechanisms remains unsolved, despite recent efforts [3,4]. In our group, we have previously demonstrated that CAs have heterogenous mechanical properties, which may contribute to aneurysm rupture [5]. Currently, we aim to develop methods to explore the role of *transmural* tissue heterogeneity and macrophage infiltration in the mechanical heterogeneity of CAs. Here, we present characterizations of three different unruptured CAs using biaxial testing, histological orientation analysis, and confocal microscopy, respectively. We found that CAs exhibit the presence of clusters of high cellular organization, which are surrounded by areas of lower organization. We also observed the presence of M1/M2 macrophages in an area of low fibrous organization. We hypothesize that CA mechanical heterogeneity is correlated with the presence of these clusters of high cellular organization and M1/M2 macrophages. Further exploration will shed light on this theory and will potentially elucidate mechanisms of CA rupture and formation.

METHODS

CA Tissue Dissection: Three CA tissues were obtained from a cadaver circle of Willis (n=1, tissue #1) and after surgical clipping in living patients (n=2, tissues #2-3). All patients were female. Tissues #2-3 were fixed in 4% paraformaldehyde for 24h prior to imaging.

Biaxial Testing & Generalized Anisotropic Inverse Mechanics (GAIM): Biaxial testing of tissue #1 was performed in a commercial biaxial tester. Forces were measured using 4 load cells on independent arms during 15 unique loading protocols. Boundary stresses were correlated with strain tracking of the tissue to perform GAIM analysis to characterize mechanical heterogeneity, as described previously [5].

Histology and Orientation Analysis: Histology was performed at the UMN Histology core using standard procedures for hematoxylin and eosin staining of tissue #2. Planar (transmural) sections of 10μm in thickness were used for staining. Cellular orientation analysis was performed using the OrientationJ plugin for Fiji ImageJ. Orientation analysis yielded two measurements: local fiber/cell orientation, and coherence, which is a measure of the local anisotropy. Orientation was obtained for regions of the tissue where coherence>0.55, which indicates a relatively high level of cellular/fibrous alignment. Orientation data was divided in three angular groups for visualization purposes: (i) blue: 0-59º; (ii) red: 60-119º, and (iii) green: 120-180º.

Confocal Microscopy: Tissue #3 was optically cleared using a protocol for SmartBatch+ electrophoretic clearing system. After clearing, tissues were immunostained for CD68 and CD206, which are markers for identification of all macrophages, and M2 macrophages, respectively. Tissue microstructure was imaged using autofluorescence at 488nm. Imaging was performed in a Nikon A1Rsi HD Confocal SIM Super Resolution microscope. Images were denoised and background was subtracted. Images presented here are Z projections of maximum intensity of the obtained multiplanar z-stack.

RESULTS

Biaxial testing of tissue #1 and subsequent GAIM analysis demonstrated mechanical heterogeneity in the tissue. Figure 1 represents a heatmap of the Kelvin moduli, demonstrating neighboring regions of heterogenous stiffness. For example, the top right edge of the tissue demonstrates Kelvin moduli close to 10MPa (in red), while the opposite end of the tissue exhibits magnitudes of ~7MPa. Simultaneously, the area in the center of the tissue is softer (~3MPa). Also, the preferred alignment of these regions demonstrate that the center of the tissue is isotropic while the edges are anisotropic.

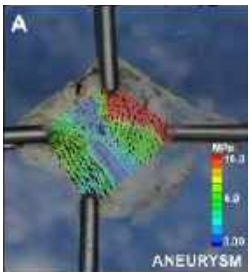

Figure 1: Photograph of tissue #1 mounted on the biaxial testing system. Overlaid heatmap represents the Kelvin moduli (MPa) and the preferred local orientation obtained with GAIM.

Inspired by the mechanical heterogeneity of tissue #1, demonstrated with GAIM, we explored the transmural tissue microstructure using histology. By performing an orientation analysis, we observed the presence of regions with high coherence. These anisotropic clusters were observed at different depths of the vascular wall and appear to shift in position radially (Figure 2).

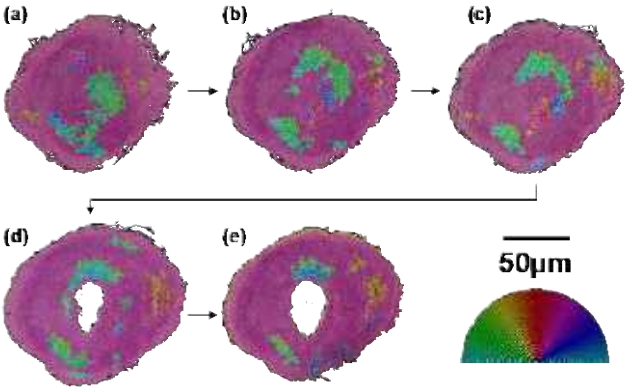

Figure 2: Selected transmural histological sections of tissue #2. Depth from top to bottom of the dome: (a) 0µm, (b) 30µm, (c) 40µm, (d) 60µm, (e) 80µm. Colored regions are clusters of high coherence, and the colors represent preferred local orientation.

By segmenting the regions of coherence>0.55, we observed that anisotropic clusters are surrounded by areas of low cellular organization and no preferred orientation (Figure 3). Further, some neighboring clusters exhibit orthogonal relationships and are separated by areas of low coherence (Figure 3, white ovals).

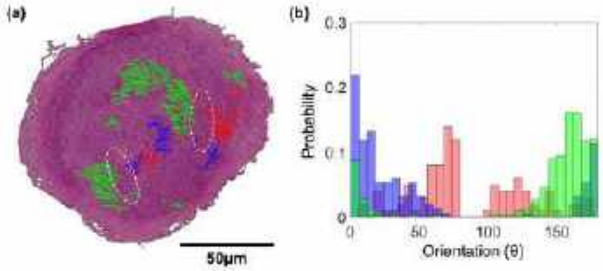

Figure 3: (a) Overlay of preferred direction vectors in high coherence regions of a histological section of tissue #3 (Fig. 2b). Colors of the vectors represent the binned preferred orientation. (b) Histogram of the orientation of the three angular groups.

To explore the potential role of inflammation in the remodeling of the low coherence regions of tissue #2, we immunostained tissue #3 for CD68 and CD206 to explore the presence of M1/M2 macrophages using confocal microscopy. The imaging demonstrated the presence of both M1 ($CD68^{+}CD206^{-}$) and M2 ($CD68^{+}CD206^{+}$) macrophages in a region of low fibrous organization (Figure 4).

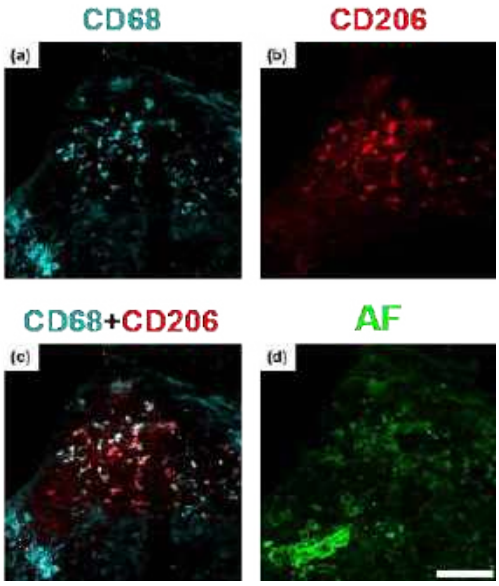

Figure 4: Z projection of the multiplanar stacks obtained for tissue #3. (a) CD68 (all macrophages). (b) CD206. (c) CD68+CD206 (M2 macrophages: CD68+CD206+). (d) Autofluorescence (AF) of the tissue, demonstrating low fibrous organization. Scale bar: 100µm.

DISCUSSION

In this study, we performed exploratory assessments of three different human CA tissues. Through GAIM analysis, we observed mechanical heterogeneity in tissue #1. Histological analysis demonstrated the transmural microstructural heterogeneity of tissue #2. Immunostaining of tissue #3 demonstrated the presence of M1/M2 macrophages in a region of low fibrous organization. These findings agree with the observations made of Robertson et al. [3], who demonstrated great variability in the tissue microstructure of surgically dissected human CA tissues using confocal microscopy. However, Robertson's images are limited to relatively small regions of the tissue (~300x300µm area). Our approach to microstructural characterization using planar histological sections allows for the characterization of the *complete* transmural microstructure. In addition, the presence of M1/M2 has been demonstrated (and their ratios extensively debated) [6-8], but their relationship to the *local* tissue microstructure has not been explored. The findings of this study inspire further *whole tissue* characterization of CAs to understand the relationship of inflammation and microstructural and mechanical heterogeneity. The clusters of high anisotropy observed in this study might explain the great mechanical heterogeneity of CAs. We aim to perform GAIM analysis, light sheet microscopy/immunostaining and orientation analysis in the coming months for at least n = 5 human CAs.

DIFFERENCES IN FLOW DYNAMICS BETWEEN CORONARY ARTERY ANEURYSMS AND ECTASIA

INTRODUCTION

Kawasaki disease (KD) is a rare heart condition often seen in children under the age of 5 that can cause vasculitis (inflammation of the blood vessels). Without early intervention, these children are at risk of developing coronary artery aneurysms (CAA), coronary artery ectasia (CAE), or both. The coronary arteries (CA) are typically monitored after a positive diagnosis to monitor these dilations. Excessive dilation of the CAs is rare but the development of giant CAAs is possible. Patients with dilations, whether it be CAA, CAE, or both, are at a higher risk for myocardial infarction, atherosclerosis, and thrombogenesis[1].

The geometry of CA dilation can induce flow separation and recirculation which increases the risk of blood stagnation and thrombogenesis, atherosclerosis, and sluggish flow. Furthermore, thrombosis occurrence has been associated with CA shape and size, though only CAAs have been assessed [2]. Currently, there is little known about the incidence of CAE-related thrombogenesis from a flow dynamics standpoint and whether clinical outcomes are worsened. Because the geometry dictates the flow patterns, differences should be seen between CAA and CAE. Therefore, this study aims to compare the flow dynamics between these two dilation types (CAA and CAE) and to correlate their differences with clinical outcomes.

METHODS

CT images of 20 CAA, CAE, or both were transferred to Michigan Technological University by Nationwide Childrens Hospital under an approved IRB protocol. The CT images were imported in Mimics Research 23.0 (Materialise, Beligium) for processing. A mask (using a threshold that isolates blood from soft tissue) was applied to the CT images and segmentation was performed to create a patient-specific 3D digital model of the CAs. Each model was trimmed at the coronary ostium and downstream of the aneurysm or ectasia. Geometric measurements of the coronaries were recorded for each patient. The models were imported into Ansys Workbench 2020 R1 (Canonsburg, PA). Extensions were made at the inlet and outlet equal to 10x the diameter of each. These extensions help to overcome entrance effects and to ensure an appropriate velocity profile. The models were meshed with an element size 0.3 mm based on the results of a mesh sensitivity study. Transient computational fluid dynamic simulations were completed using Ansys Fluent (Canonsburg, PA). Each simulation used a laminar flow model (Re < 2000) and an incompressible Newtonian fluid with a density (ρ) of 1060kg/m^3 and a dynamic viscosity (μ) of 3.5cP. Patient-specific boundary conditions from literature were applied to the velocity inlet and pressure outlet. A total of 3 cardiac cycles were simulated for each patient but only the last cycle was used for analysis. An example of the workflow used is shown in **Figure 1**. The parameters of interest were time averaged wall shear stress (TAWSS; **EQ1**), oscillatory shear index (OSI; **EQ2**), relative residence time (RRT; **EQ3**), and velocity.

$$TAWSS = \frac{1}{T}\int_0^T |\overline{WSS}|\, dt \qquad \textbf{(EQ1)}$$

$$OSI = 0.5\left(1 - \frac{\left|\int_0^T \overline{WSS}\, dt\right|}{\int_0^T \overline{WSS}\, dt}\right) \qquad \textbf{\textit{(EQ2)}}$$

$$RRT = \frac{1}{(1-2*OSI)*TAWSS} \qquad \textbf{\textit{(EQ3)}}$$

A percentage of area that exceeded a specified threshold (0.4Pa for TAWSS, 0.2 for OSI and 4.17 Pa^{-1} for RRT)[3] for each parameter was also calculated.

RESULTS

The figures presented herein only show a sample from the patient population, but all values listed are the mean ± standard deviation of the

entire population. The geometric measurements for the population are shown in **Table 1**.

Table 1. Geometric measurements of each CA classification. Neck denotes the entry segment to the dilation.

Classification	Diameter neck (mm)	Diameter max (mm)	Length (mm)
CAA	4.51 ± 2.87	10.56 ± 6.61	15.36 ± 10.63
CAE	3.11 ± 0.61	5.68 ± 1.84	15.22 ± 8.4
CAA and CAE	3.35 ± 2.02	6.97 ± 1.62	10.19 ± 6.42

Lower velocities and circulation were observed in regions where a CAA or CAE was present; this was amplified in the patients with larger dilations (**Figure 2**). As the flow passed the CAA and CAE, some patients saw a drastic increase in velocity in the distal direction.

TAWSS was lower in the regions of CAA and CAE compared to the rest of the CA (**Figure 3**). The average TAWSS was 2.33 ± 3.97 Pa for a CAA, 6.58 ± 6.18 Pa for CAE, and 1.31 ± 2.19 Pa for a combined CAA and CAE. Larger dilations were observed to have lower TAWSS regardless of the type (CAA or CAE). The percentage of area with TAWSS<0.4 Pa was 32.98 ± 19.77 %, 52.22 ± 66.35%, and 48.32 ± 23.5% for CAE, CAA, and both, respectively.

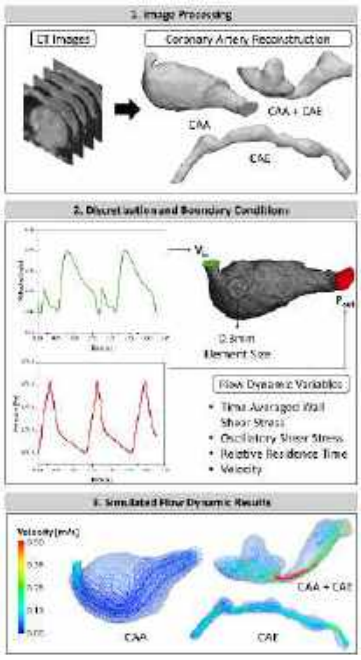

Figure 1. Adopted image processing and CFD workflow.

We observed a higher OSI in the distal portions of the CAA and CAE (**Figure 3**). In addition, OSI was higher in the larger dilations. OSI was low for the regions of the CA that did not have a CAA or CAE. The average OSI was 0.044 ± 0.068 for a CAA, 0.025 ± 0.051 for CAE, and 0.026 ± 0.055 for a combined CAA and CAE. The percentage of area with OSI>0.2 was 3.17 ± 2.95 %, 10.49 ± 11%, and 2.58 ± 2.1% for CAE, CAA, and both, respectively.

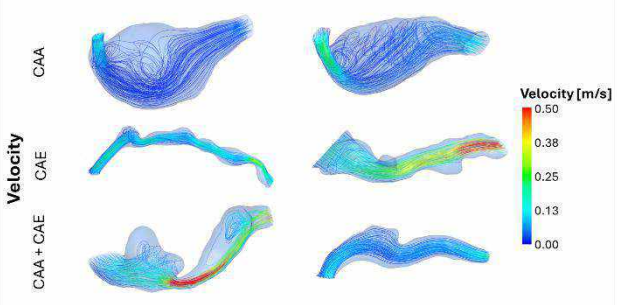

Figure 2. Velocity streamlines for CAs with CAA, CAE, and CAE+CAA.

RRT was higher in the regions of CAA and CAE (**Figure 3**). The average RRT was 6.37 ± 17.95 Pa^{-1} for a CAA, 27.86 ± 52.25 Pa^{-1} for CAE, and 6.55 ± 13.85 Pa^{-1} for a combined CAA and CAE. The larger the dilation, the higher the RRT. The percentage of area with RRT>4.17 Pa^{-1} was 37.3 ± 39.5 %, 50.77 ± 66.36 %, and 32.34 ± 15.68% for CAE, CAA, and both, respectively.

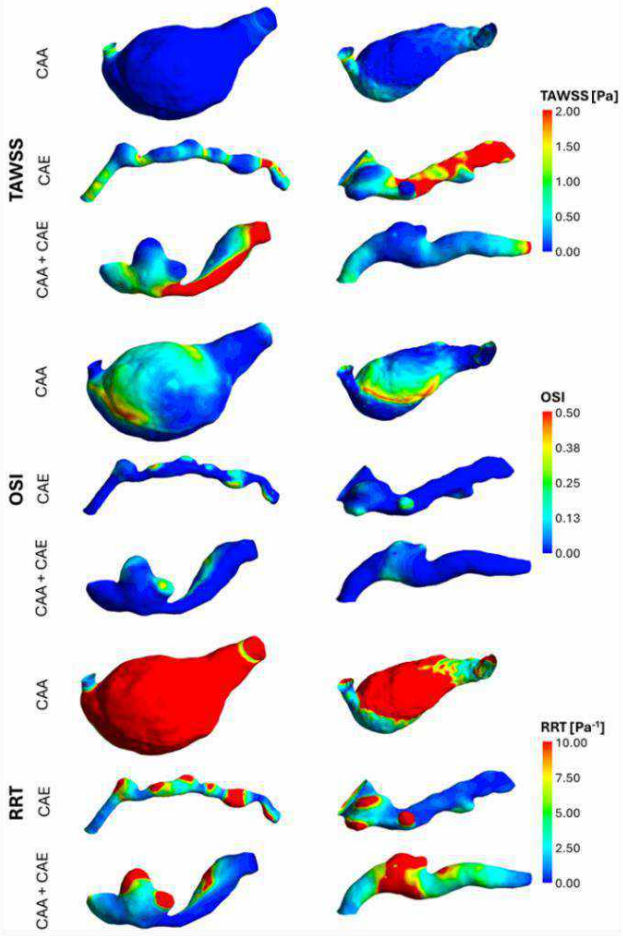

Figure 3. TAWSS, OSI, and RRT for CAs with CAA, CAE, and CAA+CAE.

DISCUSSION

This study assessed the differences in flow dynamics between CAA and CAE. We observed flow separation and recirculation in both types; however, recirculation zones were larger in the CAA cases. The larger volume of the CAAs allows for more of the separated flow to enter the dilation causing more recirculation. Elevated RRT indicates regions where flow stasis may occur. Low TAWSS and high OSI, potential indicators of blood stasis, have been associated with thrombogenesis [4]. We observed that TAWSS was lowest in the models with combined CAA and CAE, but OSI was highest for the CAA only models. OSI is a measure of the unidirectionality of WSS. Due to the "rounder" shape of CAA, more recirculation is seen in addition to lower shear stresses and lack of unidirectionality. Based on the results presented herein, KD patients with CAA are at a higher risk of developing thrombosis, which agrees with clinical findings[5].

3D PRINTING PATIENT-SPECIFIC LEFT-HEART MODELS FOR SURGICAL PLANNING

Jakari C.L. Harris (1), Scott J. Hollister (2), Lakshmi P. Dasi (3)

INTRODUCTION

Medical Errors in the healthcare field are unintentional acts or ones that fail "achieve its intended outcome" [1]. This can be due to several reasons, including "the failure of a planned action to be completed as intended, the use of the wrong plan to achieve an aim, or a deviation from the process of care that may or may not cause harm to the patient." Although medical errors are severely underreported, Makary and Daniel report that the mean rate of medical errors-related deaths from 1999 to 2013 was 251,454 per year. They received reports and information from a number of sources, including the US Department of Health and Human Services, Institute of Medicine, and Agency for Healthcare Quality and Research Patient Safety Indicators. At the time of the 2016 report, medial errors ranked third in leading causes of death in the United States. The reasons why medical errors occur have a common thread in the plan or procedure that is intended to be carried out. Terrentine et al. believe that inability to correctly recognize and interpret imaging information can contribute to errors in diagnosis [2]. Imaging modalities, such as computed tomography (CT) and magnetic resonance imaging (MRI), are limited in the ability to accurately represent organ 3D structures and lack kinesthetic feedback. With imaging modalities being the gold standard for surgical planning and preoperative information, there needs to be a better tool that can fill these gaps.

Cardiovascular disease (CVD) is currently and has been the leading cause of death worldwide for decades. The heart is a complex organ, and no doubt contributes substantially to medical error-related deaths. There needs to be a better diagnostic tool for heart disease and to help make a dent in this looming statistic. Heart failure can be classified into either left-sided heart failure (LSHF) or right-sided heart failure (RSHF). LSHF is more common out of the two and can often lead to RSHF [3]. Due to the complex nature of the heart and the fact that LSHF is more prominent, we will be modeling the left side of the heart solely.

3D modelling and segmentation is the process of converting a 2D image, usually in the form of CT, into a 3D virtual representation [4]. For our model, we will be isolating the following regions of interest (ROI) during segmentation: left ventricle (LV), left atrium (LA), aortic valve (AV), mitral valve (MV), aorta (AO). Segmentation allows for 3D models to be patient-specific and can be exported to a 3D printer after being saved as a stereolithography (STL) file. Additive manufacturing, otherwise known as 3D printing, is the process of creating a 3D object layer-by-layer. There are numerous types of 3D printers, but we will be using a polyjet printer for this model. Polyjet printers can mix different resins to create combinations that exhibit various colors and material properties. This feature will allow us to fine-tune the material properties of each ROI for the left-heart model. Researchers have created various heart models over the years, but they all lack one thing. Most groups have not investigated native heart tissue mechanics and matched that to their heart model materials. Another unexplored area is the lack of validation for these models, specifically an ex-vivo benchtop model to test the functionality of their models.

The objective of this project is to 3D print a patient-specific left-heart model that closely resembles the geometry, material properties, and overall functionality of the patient's native heart. We hypothesize that matching the geometry and materials will be essential to validate the model functionality to patient data.

METHODS

To carry out this objective, the first step was to match native heart tissue mechanical properties to constitutive models. A literature search was conducted where researchers performed planar biaxial testing on human left-heart tissue specimens. The regions of interest were the myocardium, mitral valve, aortic valve, and aorta. After gathering mechanical property data on each ROI, further data analysis was done to fit the raw experimental data to constitutive models (Holmes-Mow (HM), Mooney-Rivlin (MR), Anisotropic Neo-Hookean (ANH),

Holmes-Mow with Fiber (HMF)). Eventually, a comparative analysis was done to conclude which model best fit the native heart tissue data.

Holmes-Mow (HM) Biaxial Test Strain Energy Function

$$\psi = \frac{1}{2}\frac{c_1}{c_2}\left[e^{c_2(\tilde{I}_1-3)}-1\right]+U(J) \Rightarrow \frac{1}{2}\frac{c_1}{c_2}\left[e^{c_2(\tilde{C}_{11}+\tilde{C}_{22}+\tilde{C}_{33}-3-3)}-1\right]+U(J) \quad (1)$$

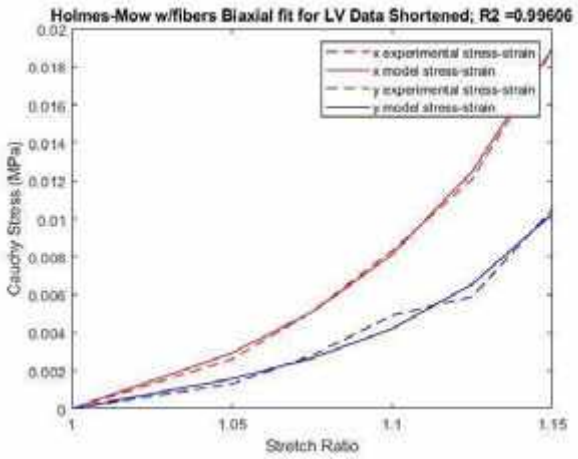

Figure 1: Left Ventricle Data Fit to Holmes-Mow w/fiber Model.

DISCUSSION

All of the ROIs fit best to either the HM or HMF models. The ROIs that are more fibrous and have a more dynamic motion with twisting, contracting, and expanding fit best to the model with fibers incorporated into it. This reflects the known anisotropy of tissue like the left ventricle. This study has fit the most diverse set of constitutive models to human heart tissue. A limitation of this work includes the shortage of mechanical testing data of human heart tissue currently in literature. The studies also could have separated the samples based on demographics. In the future, we will match these tissue mechanical properties to 3D printer material properties and print patient-specific left-heart models with the appropriate materials for each ROI.

INTRODUCTION

Aortic stenosis is one of the most common forms of aortic disease and it necessitates aortic valve replacement in most cases. Surgical and transcatheter aortic valve replacement (SAVR and TAVR, respectively) are the only effective therapy to address aortic stenosis.

Immediately after SAVR and TAVR, patients experience elevated blood pressures (BP) due to the abrupt correction of the flow obstruction (afterload) resulting from stenosis. Lindman et al. have shown that patients with more elevated blood pressures had better outcomes and improved survival rates [1]. They also showed that BPs, as recommended by the current guidelines, in patients with aortic valve replacement, were associated with increased all-cause and cardiovascular mortality [1]. We have shown that epicardial coronary flow drops below the threshold for myocardial ischemia at lower BPs[2]. There is currently no specific guidance for blood pressure regulation after aortic valve replacement and these counter-intuitive findings necessitate more controlled systematic studies to understand the complex ventriculo-aortic-arterial interactions and the flow dynamic environment.

The aim of this study is to investigate the effect of changing systolic and diastolic blood pressures (SBP and DBP, respectively) on epicardial coronary flow, sinus pressure, and energy after TAVR and SAVR.

METHODS

A 26mm SAPIEN 3 transcatheter aortic valve and a 25 mm Magna Ease surgical aortic valve were deployed in an aortic root chamber inside a pulse duplicating left heart flow loop simulator flow. The flow loop consisted of a fluid reservoir to store a blood analog (water-glycerin, 60-40% in volume), a mechanical mitral valve separating the fluid reservoir and pump, a bladder pump controlled by an in-house LabView program, an idealized aortic model, a compliance chamber to simulate arterial distensibility, a gate valve to control the aortic flow, a pinch valve to control the total coronary flow, and ultrasound clamp-on flow rate sensors to measure the flows before the valve and in the total coronary branch. Out of the aortic chamber sinus, we extended a connection that represented the total coronary branch. The total coronary flow was calculated to be 4-5% of the cardiac output that was selected to be 5 L/min, leading to an average coronary flow range between 200 – 250 mL/min. The average coronary flow was calibrated within these physiological limits at 120/60 mmHg, by controlling the resistance of the coronary circuit once the experiment started. Once the baseline physiological coronary conditions were met, the coronary circuit parameters were fixed as the systemic blood pressures were varied. The heart rate selected was 60 bpm and the blood pressure ranges were selected to span a wide interval of SBP (100, 120, and 160mmHg) and DBP (40, 60 and 90mmHg). Millar catheters were used to measure the pressures at the ventricular and aortic sides. Fifty consecutive cardiac cycles of pressure and flow rate data were recorded at a sampling rate of 100 Hz.

Sinus and coronary flow were assessed using particle image velocimetry (PIV). The region of interest captured parts of the sinus, coronary artery, and flow downstream of the valve. These regions were illuminated by a laser sheet created from a solid-state laser. High-speed images of the fluoresced particles displacement and movement within the areas of interest were recorded. The time-resolved PIV images were acquired at a temporal resolution of 4000 Hz. Velocity vectors were calculated in DaVis using advanced PIV cross-correlation approaches. Post processing was performed using adaptive median filtering in DaVis.

The Laplacian of the pressure ($\nabla^2 P$) through the Poisson equation for pressure was computed as follows:

$$\frac{-1}{\rho}\left(\frac{\partial^2 P}{\partial x^2}+\frac{\partial^2 P}{\partial y^2}\right)=\left(\frac{\partial V_x}{\partial x}\right)^2+2\frac{dV_x}{dy}\frac{\partial V_y}{\partial x}+\left(\frac{\partial V_y}{\partial y}\right)^2 \qquad (\boldsymbol{EQ1})$$

Where ρ is the density in Kg/m^3, P is the pressure in Pa, and V_x and V_y are the x and y components of the velocity vector in m/s. The x and y directions are axial and lateral respectively. The Laplacian of the pressure is the divergence of the gradient of the pressure field, and its physical significance is in its ability to help identify the changes in the pressure field [13]. Through $\nabla^2 P$, we can identify how different the field value is from the surrounding sinus regions. The energy dissipation rate (EDR) was computed as follows[3]:

$$EDR = \mu \left[\left(\frac{\partial V_x}{\partial x}\right)^2 + \left(\frac{\partial V_y}{\partial y}\right)^2 + 0.5\left(\left(\frac{\partial V_x}{\partial y}\right) + \left(\frac{\partial V_y}{\partial x}\right)\right)^2 \right] \qquad (\boldsymbol{EQ2})$$

Where μ is the viscosity with a value of 3.5cP.

RESULTS

Elevated SBP and DBP led to higher coronary flow. However, the waveforms were different in that at higher SBP the peaks were larger whereas at a higher DBP, the coronary waveforms' rise, and decay portions were less steep (160/60 compared with 120/90 mmHg). As SBP increased, the slope of the coronary flow waveform increased more sharply during systole and achieved a higher peak during diastole. This applied to all the valve and heart rate cases. As DBP increased, the peaks during diastole were almost unchanged between 120/40, 120/60 and 120/90 mmHg, however, the rise of the coronary flow waveform was steeper as DBP increased.

With changing aortic BP, it is important to assess the changes in the sinus pressure. **Figure 1** shows the contour plots of the Laplacian of pressure in the sinus. The area of $\nabla^2 P$ increased with an increase in SBP for both valves. The coronary ostium was one of the main locations in the sinus where $\nabla^2 P$ was most pronounced, and more negative than the surrounding. As DBP increased, $\nabla^2 P$ areas also increased, especially at the coronary ostium with a more negative $\nabla^2 P$.

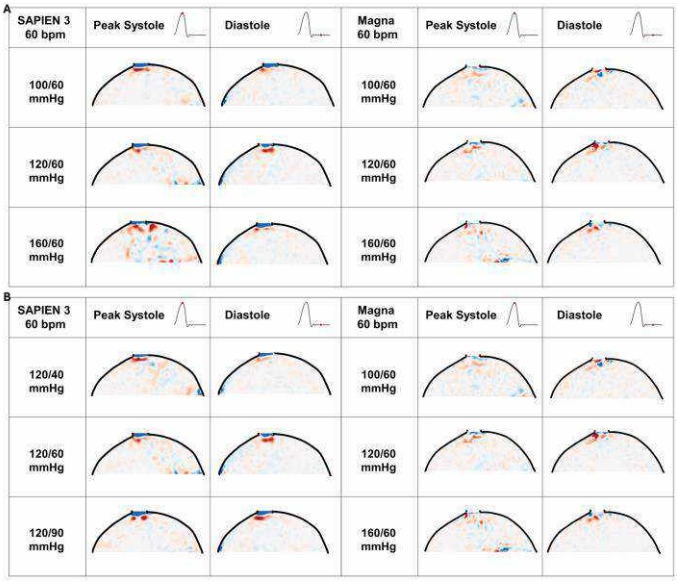

Figure 1. Contour plots of the Laplacian of pressure in the sinus for both valves with an increasing SBP (Top Table, A) and an increasing DBP (Bottom Table, B).

EDR results are shown in **Figure 2**. The total energy (EDR area under the curve) increased from 12.74 ± 0.41 J/m^3 to 17.45 ± 1.39 J/m^3 with an increasing SBP and decreased from 12.05 ± 1.42 J/m^3 to 5.63 ± 9.74 J/m^3 with an increasing DBP for the SAPIEN 3. The MAGNA did not follow the same trend as the SAPIEN 3, instead the total energy increased and decreased with the changing SBPs and DBPs.

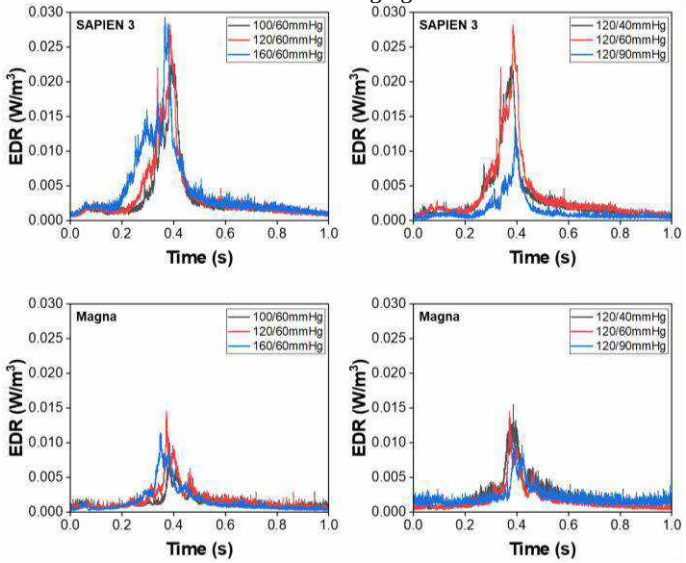

Figure 2. EDR for both valves with an increasing SBP (column 1) and DBP (column 2).

DISCUSSION

The results obtained in this study showed that the rise and decay of the coronary flow waveforms were different as DBP changed. A decrease in DBP led to sharper rise and decay of the waveform, with significantly lower mean flow. These results can be explained through the role of DBP in coronary perfusion. Generally, low DBP has been associated with myocardial ischemia [4] and is a key factor in coronary perfusion pressure. At the coronary ostia in all the cases, a more negative $\nabla^2 P$ was observed at the ostium. This indicates a lower pressure compared with the surrounding regions. As previously mentioned, evaluating $\nabla^2 P$ in the sinus provides information on how different the field value (pressure) is with respect to the surrounding. Therefore, from the results, it seems that as SBP and DBP increase, the flow is encouraged to enter the coronary from the sinus, evident from the much lower pressure at the ostium. An increase in SBP led to a significant upward shift in the coronary flow curve, with a clear increase in mean coronary flow. Also, the rise and decay of the waveforms were almost parallel. Within the aortic BP waveform, SBP occurs due to the stretch that large arteries undergo to accommodate the systolic ejection volume. As SBP increases, the metabolic demands of the myocardium increase, leading to a potential increase in the coronary flow [5]. We have previously shown an increase in sinus velocity with an increase in SBP with a SAPIEN 3[6], which would also correspond to an increase in the kinetic energy. This was reflected in the current study by an increase in the total energy with an increase in SBP. In addition, the increase in SBP is met with an increase in EDR. A possible culprit for this energy dissipation may be the stent frame of the SAPIEN, since this pattern was not observed in the Magna.

INTRODUCTION

Partial meniscectomy (PM) is a commonly performed orthopaedic procedure with over 700,000 cases annually in the United States.[1] However, the mid to long term clinical results are variable, with a subset of patients manifesting silent and relatively rapid knee joint degeneration.[2] Variability in force redistribution across the articular surface after PM may explain this heterogeneous response. We previously observed that the distribution of forces across articular surfaces in uninjured intact human knees is highly variable, with some knees distributing a high proportion of compartmental force through the meniscus during simulated gait – so called 'meniscal dominant loaders', while others largely bypass the meniscus to predominantly load the cartilage-to-cartilage contact zone, so called 'cartilage-cartilage dominant loaders'.[3] The objective of this study was to quantify the effects of PM on joint biomechanics and contact force redistribution across the tibial plateau of human knees during simulated gait. Our hypothesis was knees with higher percent meniscal loading would have a greater decrease in percent meniscal loading after PM throughout the gait cycle.

METHODS

Nine human cadaveric knees with no clinical history of osteoarthritis were denuded of skin, subcutaneous fat, muscle, and patella while maintaining the cruciate ligaments, collateral ligaments, and joint capsule. The femur and tibia were transected ~10 cm above and below the joint line, respectively. With the use of fluoroscopy, a 2.5 mm Kirschner wire was inserted along the femoral epicondylar axis. The femur was then suspended via K-wire, aligned to the rotation of the simulator, and the tibia was centered in the base of the simulator and cemented in place such that the plateau was parallel to the ground in full extension. The knees were mounted on a multi-axis testing apparatus [VIVO, AMTI] programmed to apply dynamic forces that mimic level walking (from ISO standard #14243), **Fig. 1A**. Simulated gait consisted of 12 cycles of multidirectional and dynamic standard gait input waveforms applied at 0.2 Hz and normalized to specimen-specific bodyweight. An electronic pressure sensor [Model 4011, Tekscan] was equilibrated, calibrated, and inserted into each knee underneath the meniscus and attached to the posterior capsule and ACL via suture and used to record joint contact forces.[4]

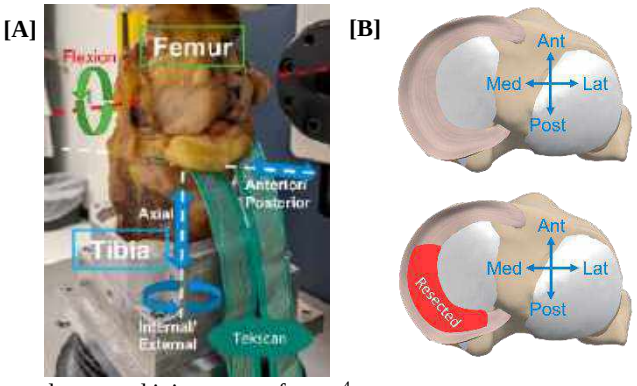

Figure 1: A) Simulator setup with a representative knee and Tekscan sensor attached, B) representation of testing conditions, with the intact condition in the top image and PM in the lower image.

Knees were tested in the following conditions: (1) native meniscus – 'intact', (2) PM, where 75% of the meniscus was removed from the posterior and central region of the medial compartment, **Fig. 1B**. A custom MATLAB program [Mathworks Inc] was used to determine peak contact stress, contact area, and to delineate the meniscal footprint from the cartilage-to-cartilage contact region. The percent of compartment force through the meniscus (percent meniscal loading) throughout the stance phase of simulated gait was calculated by

Equation (1) where ΣF_M is the sum of the force in the meniscal footprint and ΣF_C is the sum of the force in the cartilage-to-cartilage contact region. The difference between the intact state and PM condition was calculated for each metric and each knee. The averages and 95% confidence intervals (CI) were then computed. Significant differences were identified when the 95% CI $\neq$ 0. Correlations between intact percent meniscal loading vs change in percent meniscal loading after PM were explored using linear regression.

$$Percent\ meniscal\ loading = \Sigma F_M/(\Sigma F_M + \Sigma F_C) \quad (1)$$

RESULTS

PM resulted in a significant increase in peak contact stress of 1.5 ± 0.2 MPa in all but the very early stance phase of simulated gait, **Fig. 2**. PM resulted in a significant decrease in contact area of 219 ± 63 mm^2 over the entirety of simulated gait, **Fig. 3**. PM resulted in a significant decrease in percent meniscal loading of 32 ± 19% over the majority of simulated gait, **Fig. 4**. An inverse, proportional relationship was found between percent force through the native meniscal footprint and the change in percent meniscal loading following PM at heel strike, **Fig. 5,** where knees with higher loads through the meniscus in the intact condition had a larger reduction following PM. No other relationship was found throughout simulated gait.

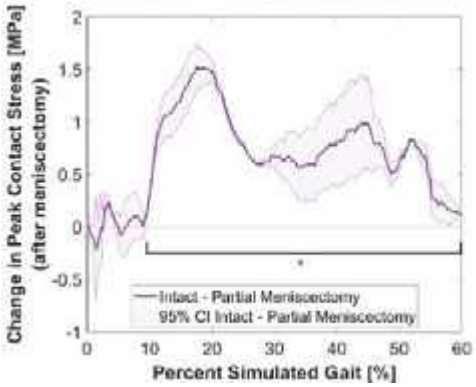

Figure 2: Average and 95% confidence interval of the change in peak contact stress following PM throughout the stance phase of simulated gait. Bracket represents significant difference.

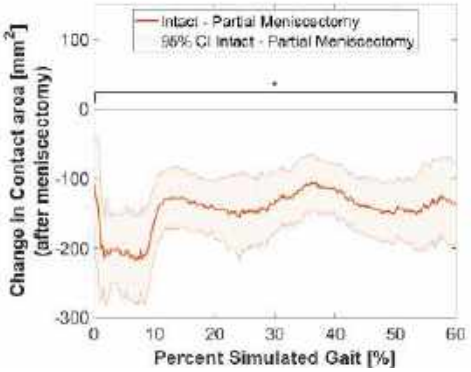

Figure 3: Average and 95% confidence interval of the change in contact area following PM throughout the stance phase of simulated gait. Bracket represents significant difference.

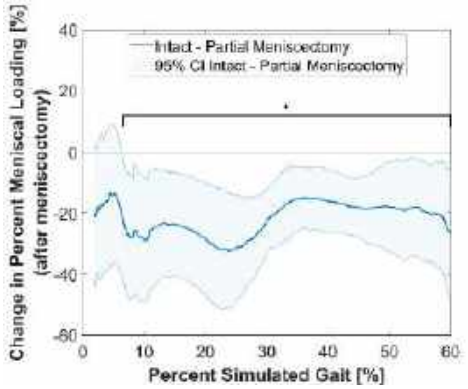

Figure 4: Average and 95% confidence interval of the change in percent meniscal loading following PM throughout the stance phase of simulated gait. Bracket represents significant difference.

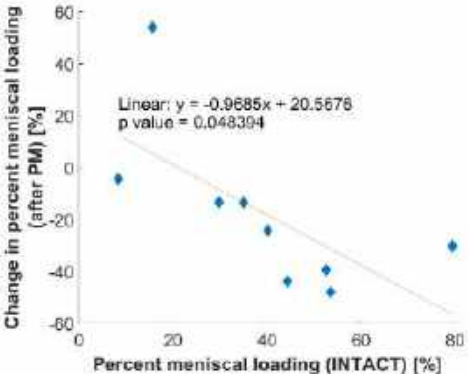

Figure 5: Correlation of intact percent meniscal loading to change in percent meniscal loading after PM with linear regression. Data is shown at 4% simulated gait (heel strike). The higher the initial percent loading, the higher the reduction after PM.

DISCUSSION

Using a multi-directional testing apparatus, we quantified the effects of PM on the redistribution of knee joint contact forces. All knees experienced a significant increase in peak contact stress and a significant decrease in contact area through most of simulated stance phase, with the magnitude of change similar to that reported in static and quasi-static tests[5,6]. All knees experienced a significant decrease in percent meniscal force following PM throughout most of stance phase of gait, with the exception of heel strike. During heel strike, we found that knees with higher loads through the meniscus in the intact condition had a larger reduction following PM. No other relationship was found throughout simulated gait; leading us to reject our hypothesis. Given the increased shear forces and rapid decrease in contact velocity during heel strike, the biomechanical relevance of the variability in this phase of the gait cycle warrants further investigation.

INTRODUCTION

Aortic valve dysfunction led to the death of more than 140,000 people in the U.S. in 2020 [1,2]. Valve dysfunction can be caused by a buildup of calcium and restricting the aortic valve opening leads to reduced blood flow and elevated blood pressure [3]. To treat valve dysfunction, one minimally invasive FDA-approved method is a transcatheter aortic valve (TAV) replacement (TAVR). Despite the overall success of TAVR, blood clot formation (thrombosis) on the TAV remains a relevant adverse event [4,5], which occurs in up to 15 % of patients after TAVR [6]. Leaflet thrombosis can be detected on Computed Tomography (CT) images as hypoattenuating leaflet thickening (HALT) with varying severities based on additional thickening of the leaflet [7]. Thrombosis may lead to early valve deterioration and life-threatening conditions such as reduced leaflet motion [8], elevated transvalvular blood pressure [8], and increased risk of stroke [9,10]. To prevent thrombus formation on prosthetic heart valves, physicians prescribe an anticoagulant regimen [11]. However, anticoagulation therapy increases the risk of excessive bleeding without preventing thrombosis in all cases [12], leading to lower patient quality of life. It is imperative to predict the post-TAVR thrombus formation risk to avoid unnecessary anticoagulant therapy or alter procedural plans to optimize outcomes.

In our prior work, we hypothesized that two main energy sources drive blood out of the neo-sinus area, including the movement of prosthetic leaflets and the backflow [13,14] . We then developed a dimensionless parameter called normalized circulation (NC) and showed that NC was correlated with the risk of post-TAVR thrombosis in six patients. We developed a semi-automatic algorithm to extract anatomical and hemodynamic parameters from pre- and post-TAVR Computed Tomography (CT) images. Then we calculated the normalized circulation for 45 patients and correlated it with the risk of post-TAVR HALT [14].

In this work, we employed various anatomic and hemodynamic parameters as input features in multiple classification Machine Learning (ML) algorithms. The goal was to identify the most relevant anatomical and hemodynamic parameters that could be associated with the risk of post-TAVR leaflet thrombosis.

METHODS

For a dataset consisting of 40 patients (20 HALT$^+$, 20 HALT$^-$), we manually reconstructed the pre-TAVR patient-specific model of the aortic wall, diseased aortic valve, and calcium nodules from pre-TAVR CT images. Then, we applied our reduced order model (ROM) [15] to virtually deploy the TAV and extract the final position of TAV stent and prosthetic leaflets. We used a semi-automated algorithm to extract anatomical parameters such as left coronary height (H_{LC}), right coronary height (H_{RC}), sinotubular junction height (H_{STJ}), peak systolic velocity (V_{max}), ejection volume ($v_{ejection}$), and ejection time ($T_{ejection}$) from pre-TAVR CT images. We used the post-TAVR results from our ROM model to extract stent outflow area (A_{so}), stent deformation index ($I_{deformation}$), and neosinus top area (A_{NS}) (see Fig. 1 (a)). We used several classification ML algorithms to correlate the anatomical and hemodynamic parameters with the risk of post-TAVR thrombosis.

We used a MATLAB code to randomly separate 30% of HALT$^+$ cases (6 patients) and 30% of HALT$^-$ patients (6 patients) for testing the ML algorithms. The rest of the dataset (60% of the cases - 28 patients, 14 HALT$^+$, 14 HALT$^-$) was used for training the ML algorithms. We applied all available classification algorithms in MATLAB, including Support Vector Machines (SVM) and K-Nearest Neighbors (KNN), for each combination of parameters (called features in the context of ML) with a 5-fold validation. We used a combination of features that did not overlap; for example, when the peak systolic velocity was applied as a feature, the ejection volume and ejection time were eliminated from the possible combination of features to avoid overfitting.

RESULTS

The best combination of features was A_{NS}, H_{RC}, $T_{ejection}$, $I_{Deformation}$, and H_{LC} (see Fig. 1 (b)), with 88.9% test accuracy and area under receiver operating characteristic (ROC) curve (AUC) of 1 using a weighted KNN algorithm. An ANOVA analysis was conducted at the same time to rank the impact of these features, and A_{NS}, H_{RC}, $T_{ejection}$ were the top three features. Another promising trained algorithm was a Medium Gaussian SVM algorithm with V_{max}, H_{RC}, and H_{LC} as features. This algorithm had 75% accuracy in the test with an AUC of 0.72 (see Fig 1 (c)).

DISCUSSION

The main challenge in evaluating the post-TAVR thrombosis risk using anatomic and hemodynamic parameters is extracting these data from raw CT images. Using our semi-automated algorithm combined with the ROM TAV deployment model, the key anatomic and hemodynamic parameters are extracted in less than two hours. Then, these parameters are correlated with the risk of thrombosis using classification ML algorithms. The combination of ROM finite element TAV deployment model, the semi-automated algorithm, and classification ML algorithms provides physicians with a powerful tool to predict the risk of post-TAVR thrombosis using pre-TAVR CT images.

The peak systolic velocity and the heights of the right and left coronaries are the most important features in the present dataset. However, this conclusion is subject to change in a different set of patient data. We are aware of the limitation of this work with the small size of our dataset for training ML algorithms. The ML algorithm should be trained with a larger dataset before we can certainly distinguish the best combination of features and correlate them with post-TAVR thrombus formation risk. We are continuously collaborating with physicians to collect and process a larger cohort of patient data to identify the post-TAVR thrombus formation risk factors.

INTRODUCTION

Y-shaped cutting offers a unique combination of cutting and tearing-induced crack-tip loads to understand the threshold fracture-relevant length scale and failure energy of a soft material. Proposed by Lake & Yeoh in 1978 [1], this geometry-independent cutting method offers several advantages over typical tearing or cutting tests, and therefore provides a way to explore the fracture of biological materials. First, blade-induced failure concentrates the zones governing new surface creation [2] relative to tearing geometries [3], resulting in a reduced influence of sample size. A very small sample, therefore, may be possible to characterize via Y-shaped cutting while avoiding interactions between the failure-governing zone and the sample boundary. Second, because of the concentrated failure zone and smaller stretch, Y-shaped cutting facilitates high magnification, *in situ* observation of this critical microstructurally-governed region under a microscope, aiding in the failure mechanism identification including microstructural rearrangement [4] or bond breakage outside of the new surface [5]. Third, by performing tests at a constant propagation rate, fracture initiation effects encountered in many 'tearing' tests are avoided. Finally, despite the introduction of the blade in Y-shaped cutting, the friction between the blade and the sample is frequently limited and even negligible [6], providing a more direct measurement of the intrinsic material response.

Despite these advantages, this technique is not widely used on many materials, including biological and composite materials. Among a few groups applying this technique, most of them primarily compared failure responses between elastomeric solids, instead of exploring the relationship between tearing and cutting. This is likely due to the slightly unusual test geometry, unfamiliarity with Y-shaped cutting conditions and implications, as well as a lack of standards for using this cutting approach.

A primary purpose of this study, therefore, is to provide researchers with a detailed roadmap of the strengths and limitations of Y-shaped cutting as well as a practical guide to designing, performing, and interpreting the results of this class of failure tests. We establish a pseudo-standard for Y-shaped cutting using silicone (Sylgard 184, Dow Corning) as the standard material, hoping this highly tunable cutting method will offer insights into other classes of materials in the future.

METHODS

***In situ* Microscope Y-shaped Cutting Setup** Figure 1 illustrates the Y-shaped cutting method. The method gets its name from an initially rectangular sample transformed into a Y-shape by pulling on the two thin legs B with constant preload f_{pre} at a fixed angle θ from the sample's midline. A pulley system provides force redirection from θ (achieved by the angle adjust system) to vertical (gravity). The blade is mounted on a load cell, which is attached to a vertical adjust system (Figure 1), and aligned with the sample midline. To maintain a constant angle and preload, the intersection of the sample and blade (i.e., the crack tip) is fixed above the microscope objective lens while the sample translates horizontally in the Y direction. A constant XY sample plane is maintained throughout the test by aligning the tension line and the pulley arms in this plane. To precisely position the force sensor, the angle adjust system, and the pulley system, we use a commercial 3-way micro-adjustment stage. We also use a separate blade positioning adjustment and the microscope stage (XY plane) to precisely position the cut within the objective's field of view. Visualization of the full-field deformation and microstructure during cutting could provide insights into failure for a variety of complex materials including composites and tissues.

Cutting Strain Energy Release Rate G_{cut} Calculation The energy release rate due to cutting G_{cut} is derived via the same approach used by Rivlin and Thomas [1, 6, 7], *i.e.,* the differential energy change between work done on the system and strain energy released due to crack growth per unit of crack area produced (Figure 2 (a)). This is expressed as

$$G_{cut} = dU_{work}/dA - dU_{strain}/dA \quad (1)$$

Force, displacement, and time data are collected, though only the force data f_{cut} are needed to calculate G_{cut} using the equation derived by Lake & Yeoh [1], including tearing (T) and cutting (C) terms.

$$G_{cut} = \underbrace{\frac{2f_{pre}\bar{\lambda}}{t}(1-\cos\theta)}_{} + \underbrace{\frac{f_{cut}\bar{\lambda}}{t}}_{} \quad (2)$$

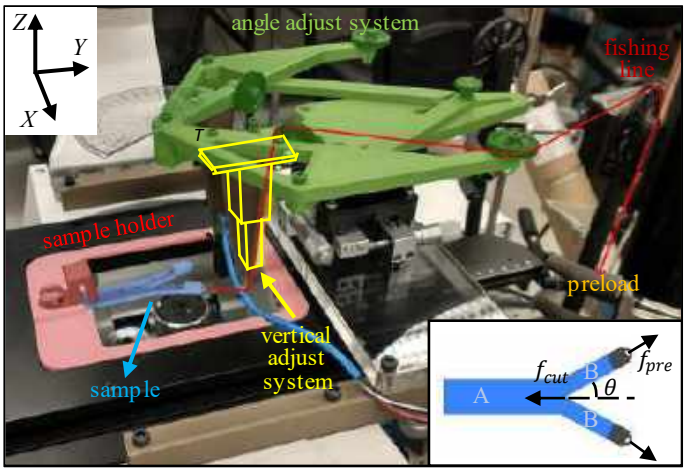

Figure 1: A photograph of the *in situ* Y-shaped cutting device with false-color added to indicate key design features. Inset: Sample with single leg 'A' from which two equal legs 'B' are cut to create a 'Y' shape with leg angle θ.

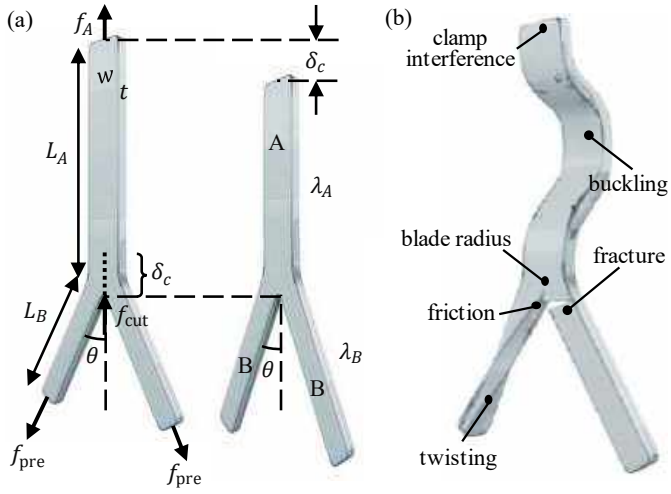

Figure 2: (a) A precut separates a rectangular sample (width w, thickness t) into two parts, body A (length L_A) and legs B length L_B). Preload f_{pre} separates two legs B at a fixed angle θ from the midline and induces prestretch on both body A (λ_A) and legs B (λ_B). During cutting, the blade cuts the sample in the midline with a cutting force f_{cut}. Strain energy release rate derives from the external work done by f_{pre} and clamp reaction force f_A and the stored strain energy within the sample as it translates an incremental crack extension distance δ_c. (b) Typical limitations and challenges when performing Y-shaped cutting tests

RESULTS

Typical Cutting Responses The typical cutting response contains four regimes: 1) loading, 2) cut initiation, 3) cutting, and 4) unloading (Figure 3, left). The blade indents the sample until the cut initiation occurs. Once the crack begins to propagate, the force drops to a relatively constant value during constant rate cutting.

A Pseudo-standard for Y-shaped Cutting By adjusting the tearing contribution via changes in either or both f_{pre}/Ewt and θ, using different sample geometries, we gather the cutting response over a wide range of experimental conditions. Separating the failure energy contributions into C and T produces the dual-regime curve in Figure 3, right. Similar to the behavior reported by Lake & Yeoh [1], as T reduces, Sylgard 184 enters a 'pure cutting' regime for which decreases in applied T are proportionally compensated for by one-to-one increases in C. In this region, C versus T has a slope of -1.

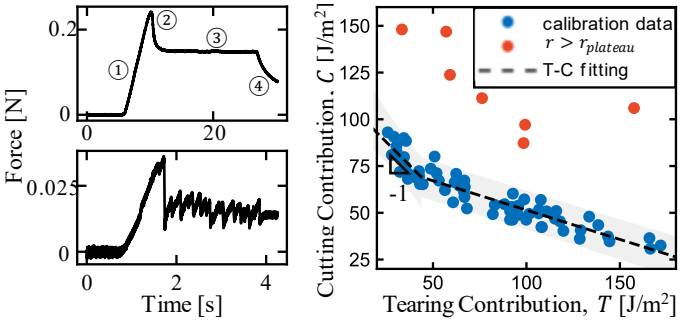

Figure 3: Left: Typical cutting response for PDMS (upper, no slip response) and bovine liver membrane (lower, stick-slip response). Right: A calibration 'standard' C-T curve for Sylgard 184 10:1, with test data (blue dots) and over-estimated data (red dots). The black dashed line is a piece-wise linear fit to the data. The gray shading corresponds to 95% prediction intervals.

DISCUSSION

The pseudo-standard C-T curve can be used to verify the accuracy and reliability of any other setup, and therefore provides a foundation for measuring other materials. Interestingly, our preliminary test on the bovine liver membrane presents a 'stick-slip' constant rate cutting (Figure 3, lower left). We suspect that it is related to the interwoven fibrous microstructure of the membrane. However, practical considerations can also limit Y-shaped cutting's applicability. Typical challenges (Figure 2 (b)) include preload limits (buckling, fracture), angle θ limits (friction, twisting), and over-estimated of G_{cut} (clamp interference, blade radius effect). The solution is to tune the variables carefully, *i.e.*, tearing contribution, blade radius, and sample geometry.

SMOOTH MUSCLE CELL MECHANOADAPTATION IS CHRONICALLY DISRUPTED BY HIGH-VELOCITY STRETCHING

Samuel F. Boland (1) & Patrick W. Alford (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Vascular smooth muscle cells (VSMCs) encircle blood vessels and modulate blood flow through active contraction in response to chemical and mechanical cues. In the vasculature, VSMCs are exposed to deformation rates ranging from 1% per year in aneurysm growth[1] to 1000% per second during traumatic brain injury (TBI).[2] VSMC function and gene expression in response to deformation has been extensively characterized at physiological strain rates,[3–6] but our understanding of how VSMCs respond to trauma-like loading is incomplete. Here, we utilized high-velocity cellular microbiaxial stretching (CμBS) to distinguish VSMC mechanical behavior after deformation at increasing strain rates. Our hypothesis was that VSMCs would behave as viscoelastic solids and stress would increase with strain rate, but in fact we found that VSMCs generated lower stress following high strain rate stretch. Further, we uncovered that VSMCs cannot recover basal stress after trauma-like loading, suggesting chronic mechanical dysfunction.

METHODS

Substrate Fabrication and Cell Culture. Human umbilical artery VSMCs were micropatterned with aspect ratio 1:4 (AR4) on a fluorescent-bead-doped polyacrylamide (PA) gel with a Young's Modulus of 13.5 kPa as previously described.[3,7] VSMCs were cultured using a standard protocol to induce a physiological phenotype.[3,8]

High-Velocity Cellular Microbiaxial Stretching (CμBS). CμBS experiments were performed using a custom-built microscope-mounted device (Fig. 1A) to perform traction force microscopy experiments using PA gels on deformable membranes. VSMCs were stretched to an engineering strain of 0.15 at strain rates of 0.001, 0.01, 0.1, or 10 s^{-1}, with the 10 s^{-1} strain rate most representative of trauma-like loading.[2] The experiment was performed over 5 minutes for each strain rate and recovery period. For example, for stretching performed at a rate of 0.001 s^{-1}, stretching takes 2 minutes (stretching phase) and cells are held static (relaxation phase) at 0.15 strain for 3 minutes (Fig. 2A). While held static, cells were imaged at 40X magnification once under bright field microscopy, and then the underlying fluorescent bead layer at the cell-gel interface (Fig. 1B,D) was imaged with a TRITC filter once per second in a time lapse. Cells were then returned to 0 strain (return phase) and imaged over the same time interval while static (recovery phase). Three cycles of stretching were performed on each cell. Cells were then lysed with sodium dodecylsulfate and the gel bead layer fluorescence was captured again at the location of each cell at 0 and 0.15 strain.

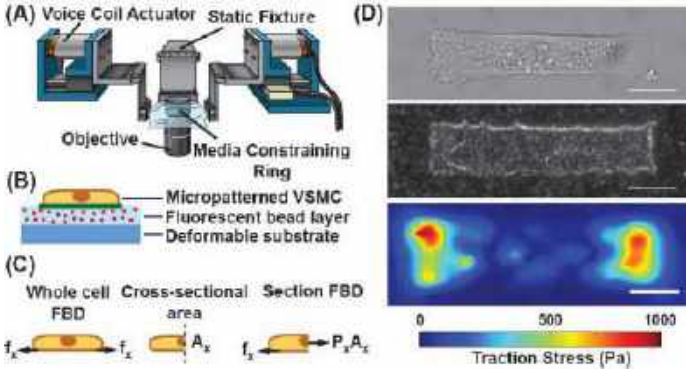

Figure 1: (A) High-velocity CμBS apparatus. (B) AR4 VSMC micropatterned on PA gel. (C) P_x calculation from VSMC free body diagram. Adapted from Rothermel et al.[5] (D) Bright field (top), bead layer (middle), and traction stress map (bottom) for a representative VSMC. Scale bar = 25 μm.

Traction forces at each timepoint were calculated using previously described methods.[3,9] The axial first Piola-Kirchoff stress, represented by $P_x = f_x/A_x$, where f_x is the total traction force in the x-direction and A_x is the undeformed cell cross-sectional area, was calculated at the mid-plane of the cell (Fig. 1C). When comparing data across different treatments, P_x was normalized by dividing the stress at any timepoint by the cell's basal stress. In experiments presented in Fig. 2, all 3 cycles of

stretching were performed at the same strain rate. Peak stress is defined as the stress measured immediately after the stretching phase has completed, and plateau stress is defined as the stress at the end of the relaxation phase (i.e., $t = 5$ min). In the experiments presented in Fig. 3, the first and third stretching cycles were performed at 0.001 s^{-1} and the second at 0.1 or 10 s^{-1}. Peak ratio is defined as the peak stress during cycle 3 divided by the peak stress during cycle 1, and the plateau ratio is defined as the plateau stress during cycle 3 divided by the plateau stress during cycle 1. All statistical comparisons were performed with a student's t-test with a p value < 0.05 considered significant.

RESULTS

Cells were strained according to Fig. 2A. Due to basal tone, cells begin at a non-zero stress. Immediately after stretch, stress reaches a peak, which then decays toward a plateau at $t = 5$ min. After returning to 0 strain, stress reaches a minimum, then recovers back towards the basal stress. During the relaxation phase, P_x vs time curves shift downward with increasing strain rate (Fig. 2B). Notably, for the 10 s^{-1} case, stress after stretching to 0.15 strain remains below the basal stress, suggesting that beyond a certain strain rate threshold, cells soften with deformation. Both the average peak and average plateau stress show statistically significant reductions as strain rate is increased (Fig. 2C,D).

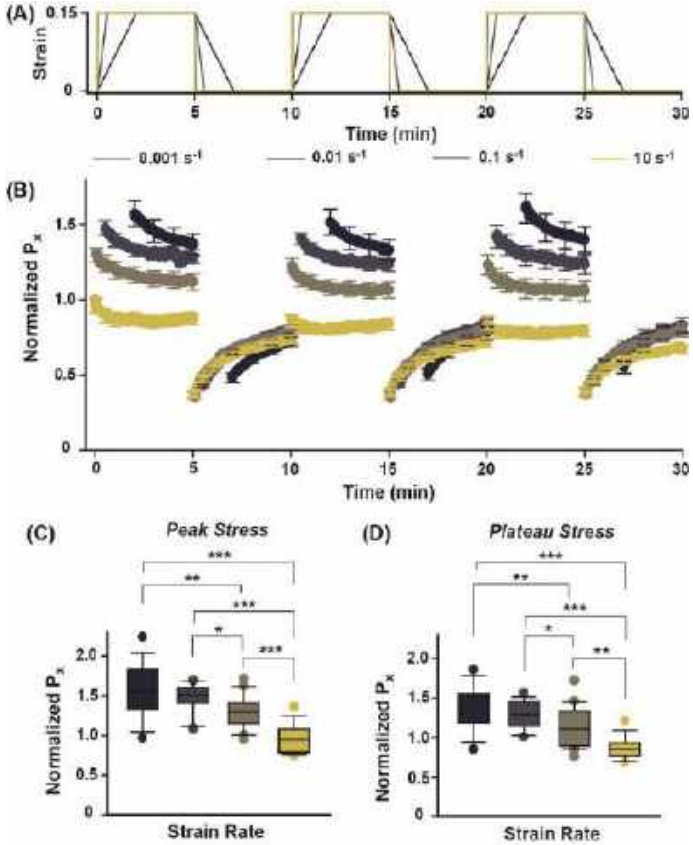

Figure 2. (A) Stretching protocol for four strain rates. (B) Average normalized axial stress (P_x) for cells strained at 0.001, 0.01, 0.1, or 10 s^{-1}. n = 16, 14, 20, 15, respectively. Error bars represent s.e.m. (C) Comparison of average peak stress. (D) Comparison of average plateau stress. Boxes span interquartile range with median marked in black. * p<0.05, ** p<0.01, *** p<0.001.

To investigate whether cells could recover from stretching at high strain rates, cells were stretched in an alternating pattern, with the first and third stretching cycles performed at 0.001 s^{-1} and the second cycle at 0.1 or 10 s^{-1} (Fig. 3A). The ratio of the peak and plateau stress during the third cycle and the first cycle was compared for each cell to determine if cells could recover stress after high strain rate stretch. Both the peak stress and plateau stress ratios showed statistically significant reductions when cells were stretched at 10 s^{-1} during the alternating pattern compared to a second stretch at 0.001 or 0.1 s^{-1} (Fig. 3B,C).

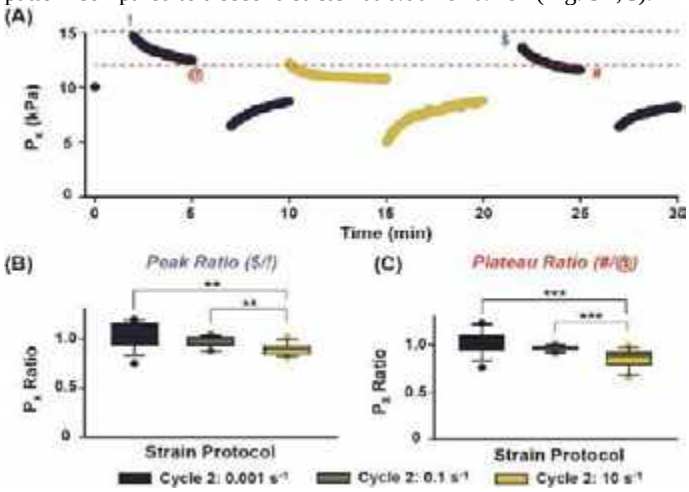

Figure 3. (A) P_x vs time plot for a representative cell stretched in alternating pattern (0.001-10-0.001 s^{-1}). Dashed line marks the peak (blue) and plateau stress (red) of stretch 1. (B) Average ratio of peak stress during third cycle and peak stress during first cycle for cells stretched at 0.001, 0.1, or 10 s^{-1} for second cycle. n = 16, 11, 12, respectively. (C) Average ratio of plateau stress during third cycle and plateau stress during first cycle for cells stretched at increasing rates during second cycle. Symbols in parentheses correspond to points marked in A. Boxes span interquartile range with median marked in black. ** p<0.01, *** p<0.001.

DISCUSSION

In this study, we demonstrated that stress produced by VSMCs stretched to 0.15 strain decreases as the rate of stretching increases. This finding directly contradicts the assumption that cells behave as viscoelastic solids. Our work aligns well with the findings of Trepat et al.,[10] who used magnetic bead twisting cytometry to observe that SMCs soften after a rapid, transient stretch. Importantly, we also found evidence that there is a threshold of strain rate beyond which a cell cannot recover. This is demonstrated by the drop below basal stress in cells stretched at 10 s^{-1} (Fig. 2B), and the inability of cells to recover stress after a 0.001 s^{-1} stretch when stretched at 10 s^{-1} immediately before (Fig. 3B,C). Because 10 s^{-1} stretches commonly occur during TBI, this finding of irreversible contractile dysfunction could help explain vessel remodeling and vasospasm following TBI.[11]

LOW-ENERGY IMPACT INDUCED DAMAGE IN CARTILAGE: A MULTISCALE MODELING STUDY USING FE2M

INTRODUCTION

Osteoarthritis (OA) remains a prevalent and incapacitating ailment with the degeneration of cartilage as a hallmark feature. The underlying causes and anticipated progression of OA remain unknown.

While microcracks in bone have been characterized extensively [1], and sub-millimeter-scale surface fissures are well known for early to advanced osteoarthritis (OA) [2], we recently demonstrated that low-energy impact usually considered non-injurious can in fact cause micrometer-scale cracks in the collagen network of human cartilage [3,4]. Pre-clinical OA may originate with microcracks in the network of collagen, and propagation of these microcracks within the extracellular matrix (ECM) may initiate a cascade of degeneration towards OA . However, the mechanisms of initiation and propagation of microcracks under mechanical loads to cartilage during normal daily activities remains unknown.

We aim to elucidate mechanical damage to collagen and collagen networks in cartilage by leveraging our experimental results and multiscale computational modeling. We simulated, using our custom FE2M modeling framework implemented in FEBio [5], unconfined compression of cartilage explants. We employed Statistically Equivalent Representative Volume Elements (SERVEs) [6] within the superficial zone, while we used standard FE the remaining cartilage volume (middle and deep zones) [7]. We validated the global results of our FE2M simulations by comparing predictions with those recently measured experimentally by us [3]. To better understand our predictions we performed: (1) sensitivity analysis on the modeling framework to quantify prediction sensitivity to input material parameters, and (2) tested stretch and stress within individual collagen fibers as predictors of collagen failure.

METHODS

Experimental Evidence. In previous experiments we examined 76 cylindrical osteochondral plugs (diameter = 3 mm and average thickness = 1.318 mm) [3]. We divided specimens into two low-energy impact groups: low impact (LI) = 1.5-2.5 mJ/mm^3 and high impact (HI): 2.5-4.0 mJ/mm^3). The impact velocity was $V_{\text{imp}} = 0.5$ m/s, the drop height (h) was $(V_{\text{imp}})^2/2g$, and the energy impact (E_{imp}) was mgh/V based on our experimental data, with V the volume of the specimen and g the acceleration constant. We determined the force for impact loading (F) using $F = 2E_{\text{imp}}(V/(V_{\text{imp}})^2)g$. In another study we established the minimum impact energy capable of inducing microcracks in cartilage [4]. From these data we had a third data set corresponding to a maximum impact (MI).

We also independently established the median failure stress for collagen fibers as 41.0 kPa, the maximum failure stress as 47.3 kPa, and the minimum failure stress at 35.8 kPa, along with a median failure stretch as 2.4 [6].

FE2M Modeling Framework. We recently established a 3-D multiscale framework in FEBio which we called FE2M, integrating mixture theory and finite elements for solving two-scale, nonlinear, coupled, and time-dependent boundary value problems (BVPs) in poro-hyperelastic, fluid-saturated porous media [5]. To solve the governing macroscopic partial differential equations we employ the finite element method twice. Initial macroscopic quantities, obtained from an intermediate solution of the macroscopic FE model, serve as boundary conditions on the microscopic Representative Volume Elements (RVEs or SERVEs). These include the deformation gradient $\overline{\mathbf{F}}_{\text{S}}$ and the gradient of pressure times the fluid volume fraction $\nabla(\overline{n^{\text{F}}p})$. After solving the microscopic FE model with these BCs, we evaluate the macroscopic material tangent $\overline{\mathbf{A}}$ and measures $\overline{\mathbf{P}}$, $\overline{(\mathbf{E}_S)'_{\text{S}} \cdot \mathbf{C}_S J_{\text{S}}}$, $\overline{n^{\text{F}}\mathbf{w}_{\text{FS}}}$ at each Gauss integration point through volume averaging of the underlying RVE. We use homogenization of any microscale quantity $\bullet$ over an RVE or a representative surface element to calculate its macroscopic counterpart $\bar{\bullet}$ using 1, where $V_{0\text{S}}$ and $A_{0\text{S}}$ are reference volumes and areas, respectively,

$$\langle\bar{\bullet}\rangle = \frac{1}{V_{0\text{S}}}\int_{\mathcal{B}_{0\text{S}}} \bullet \mathrm{d}V_{0\text{S}}, \quad \lfloor\bar{\bullet}\rfloor = \frac{1}{A_{0\text{S}}}\int_{\mathcal{B}_{0\text{S}}} \bullet \mathrm{d}A_{0\text{S}}. \tag{1}$$

Statistically Equivalent Representative Volume Elements. Leveraging information on the orientation, diameter, and volume fraction of type II collagen fibers within the superfacial zone [8], we generated SERVEs, and used them in the superficial zone of cartilage within our FE2M framework. We included discrete fibers as nonlinear springs, and modeled the

interfibrillar space using a biphasic, neo-Hookean model. We used a two-parameter power law function of stretch to model networked fiber of type II collagen as [6],

$$\Psi = c_1(\sqrt{I_4} - 1)^{c_3},\ \sigma = \lambda c_1 c_3(\lambda - 1)^{(c_3 - 1)}, \quad (2)$$

where c_1 [MPa] and c_3 [−] are model parameters, I_4 is the fourth pseudo-invariant, and λ is the fiber stretch.

Boundary Value Problem. We modeled a 3-D 2° wedge of the cylindrical plug of cartilage with a diameter of 1.5 mm and a thickness of 1.318 mm. In Fig. 1(a) we show a schematic of the model with boundary conditions. We fixed the central node in the *x*-, *y*-, and *z*-directions, and the bottom surface of the model was fixed in the *z*-direction.

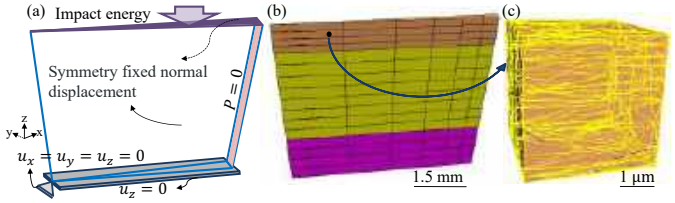

Figure 1: Boundary value problem for cartilage impact and corresponding FE models: (a) schematic of 2° cartilage wedge; (b) mesh of macroscopic structure; (c) SERVE with statistically equivalent orientation, dispersion, and volume fraction of collagen fibers.

We set the fluid pressure to zero on the radial surface, while all other surfaces had flux equals zero. To model impact, we applied a force to a rigid plate placed on top of the cartilage, establishing a contact between the top surface of the cartilage and the plate. Subsequently, we applied forces of 0.08 N, 0.16 N, and 0.20 N with a linear ramp from zero to 1 ms for LI, HI, and MI, respectively. In Fig. 1(b) we show the corresponding mesh used in the two-scale model, while in Fig. 1(c) we illustrate a representative SERVE with statistically equivalent orientation, dispersion, and volume fraction of collagen fibers.

Predictions of Collagen Failure and Microcracking. We concentrate on microcrack density (experimental) and the ratio of failed fibers (computational) as a key parameters for comparison between our experiment and simulation results. Microcrack density is the number of microcracks per unit area #/mm^2 measured in experiments. In our numerical model, we introduced the ratio of failed fibers (number of failed fibers/total number of fibers) to quantify the proportion of failed fibers to the total number of fibers. We established a custom algorithm to identify failed fibers – we compare the stress and stretch of calculated for each fiber to the critical values and then calculates the ratio of failed fibers.

Sensitivity Analyses. We conducted sensitivity analyses on the parameters of the constitutive model for collagen fibers to assess the influence on both macroscopic and microscopic results. To this end we implemented a Monte Carlo sampling method for the random selection of c_1 within the range $[3.82 - 7.82]$ MPa and c_3 within the range $[3.568 - 4.072]$.

RESULTS

In Fig. 2 we show results for the macroscopic structure of cartilage and representative element 76 under HI loading conditions.

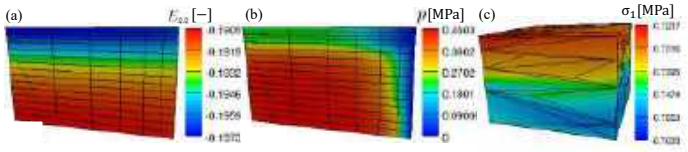

Figure 2: Macroscale and Microscale results for high impact energy: (a) $z-$strain; (b) fluid pressure; (c) first principal stress for representative element 76.

In Fig. 2(a) we show the strain within the cartilage specimen at peak load the *Z*-direction, and in Fig. 2(b) the interstitial fluid pressure. In Fig. 2(c) we show the first principle stress for element 76, which is in the center of the superficial zone.

Utilizing our SERVEs in the superficial zone, we determined the stretch and corresponding stress for each fiber during the impact events. In Fig. 3 the first row shows histograms of the distributions of fiber stretch under LI, HI, and MI, while in the second row we show corresponding histograms of the distributions of fiber stress for the same three tests.

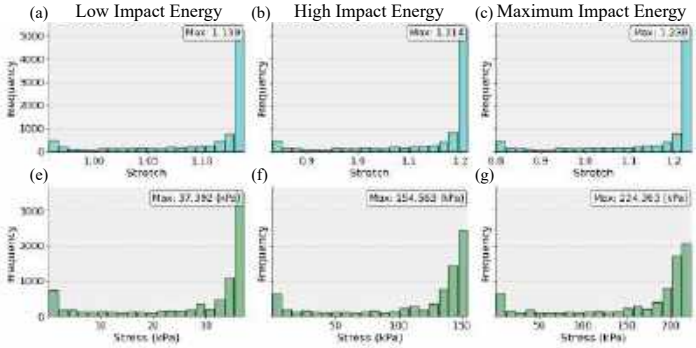

Figure 3: Distributions of stretch and stress for LI, HI, and MI.

Using stress as a predictor of fiber failure, we calculated the ratio of failed fibers as 34.8%, 73.0% and 75.3%, for for LI, HI, and MI respectively. The corresponding experimental values for microcrack density were 2.34 for LI and 3.25 for HI, indicating that microcracks did appear in these impact conditions. Stretch was not a predictor of fiber failure.

In Fig. 4 we show the convergence of the global model with respect to the parameters used to model the stretch-stress response of the collagen fibers (2).

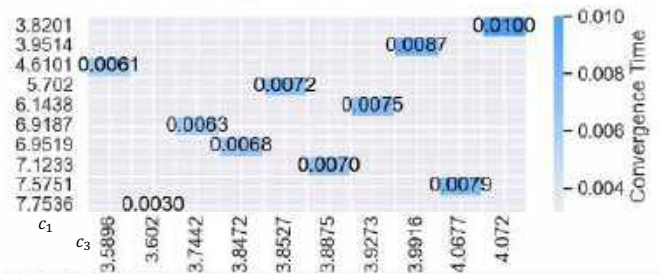

Figure 4: Model sensitivity to constitutive model parameters.

We note that there are combinations of c_1 and c_3 for which the global model will not converge while ramping to the maximum impact load. Additionally, the mechanical response of the global model varies with variations in parameters of the constitutive model for collagen fibers.

DISCUSSION

We present macroscopic and microscopic results for three different impact loadings of cartilage. Our results provide preliminary insights into the mechanical and failure behaviors of type II collagen. Utilizing our SERVEs, we conclude that stress may be a predictor of fiber failure, but stretch is likely not. Sensitivity analyses on constitutive model parameters for collagen reveal their significant impact on the mechanical response of cartilage.

THE IMPACTS OF ESTROGEN AND PROGESTRONE ON EXTRACELLULAR MATRIX REMODELING IN FEMALE MICE ARE STRAIN-DEPENDENT

Allison M. Sander (1), Brianne K. Connizzo (1)

(1) Biomedical Engineering, Boston University, Boston, Massachusetts, USA

INTRODUCTION

Remodeling of the extracellular matrix (ECM) is required for the proper healing, strengthening, and maintenance of tendon. Thus, it is important to investigate the factors which regulate this delicate balance between synthesis and breakdown. There are well documented sex differences in connective tissue injury rates [1][2] and healing outcomes [2][3]. Furthermore, it has been shown that estrogen impedes the increase in protein synthesis rates typically seen in response to exercise [4][5]. However, the individual factors of sex, hormones, and mechanical strain have not been decoupled. In previous work with stress deprived tendon explant cultures, we found that ECM remodeling is dependent on sex hormone signaling when estrogen or progesterone are introduced into the culture media. This work suggested that within the context of stress deprivation, sex hormones were beneficial for female tendons, returning values closer to baseline properties, but detrimental to male tendons, resulting in aberrant matrix turnover [6]. Interestingly, we found that all hormone conditions led to increased breakdown activity in the tendon [6], which had not yet been shown. The objective of this study is to examine the impact of sex hormone induction under different strain conditions to explore the interaction between mechanical strain and hormonal stimulation in female tissues. Based on what is known about estrogen's impact on the response to exercise [4][5], we hypothesized that hormones would have strain-dependent effects on the tendon. We expected breakdown activity to increase in the presence of hormones in all conditions given our previous work.

METHODS

Flexor digitorum longus (FDL) tendons were harvested from young adult (4 month) female C57BL/6J mice. The explants were cultured in either no hormone (89% DMEM +10% FBS + 1% PSA, 'NH'), estrogen-supplemented (1nM 17β-estradiol, 'Est'), progesterone-supplemented (1nM progesterone, 'Pro') or dual hormone (1nM 17β-estradiol + 1nM progesterone, 'Est & Pro') medium. Half of the tendons were cultured in stress deprivation for 7 days and the other half were cultured under 3% static strain in our novel bioreactor system for 12 days. For the static strain condition, tendons were gripped leaving a 10mm gauge distance and tensioned until taught (load reading of 20g). Then, a displacement of 300μm was added to induce a strain of 3% of the tendons. The tendons under static strain were double loaded such that two tendons were present in each media well (Fig. 1).

On the last day of culture, 35S-sulfate and 3H-proline were added for 24 hours to measure the synthesis of sulfated glycosaminoglycans (sGAG) and total protein, respectively. Explant metabolism was measured by a resazurin reduction assay and normalized to day 0 readings from explants of the same sex and hormone treatment. Wet and dry weights were then taken for each explant before digesting with Proteinase K overnight. The sample digests were then assessed for cellularity (PicoGreen assay), GAG content (DMMB assay), and total collagen (OHP assay). Protein synthesis, sGAG synthesis, cellularity, collagen content, and GAG content were normalized to dry weights. Medium was collected on the sixth day of culture for the stress-deprived explants and on the eighth day of culture for the static strain explants to measure matrix degradation using the SensoLyte® 520 Generic MMP Activity Kit. Statistical evaluation was performed through one-way

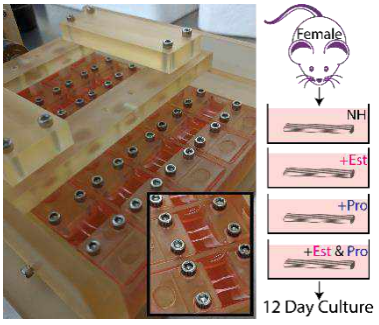

Figure 1: Static tensioning device and study schematic

ANOVAs within each strain condition with post-hoc t-tests where appropriate. Significance is reported at $p<0.05$.

RESULTS

Data from stress deprived cultures is reproduced here for comparison [6]. The effect of estrogen was strain-dependent (Fig. 2A-G). In stress-deprived cultures, estrogen supplementation increased both protein synthesis and breakdown significantly, and also shifted ECM content to decrease collagen and increase GAGs. Estrogen had an opposite effect in static strain conditions, increasing collagen content and decreasing protein synthesis and metabolic activity. Interestingly there was no effect on GAGs or GAG synthesis in static strain conditions and increases in MMP activity were not significant.

Progesterone also had strain-dependent impacts on explant health and ECM synthesis (Fig. 2A-D). Addition of progesterone under stress deprived conditions led to increased protein synthesis and breakdown. Under static strain conditions, metabolic activity and protein synthesis were significantly reduced, and DNA content was increased. Across strain conditions progesterone alone had no impact on sGAG content or synthesis (Fig. 2C, E) and consistently led to an increase in MMP activity and a decrease in collagen content (Fig. 2F-G).

There were some strain-dependent results in the dual hormone condition (Fig. 2B, F), but the impacts remained largely consistent across strain conditions. It is notable that in both strain conditions, only the dual hormone group led to a significant decrease in tendon metabolism and sGAG synthesis (Fig. 2A, C) and returned protein synthesis levels to that of the NH condition (Fig. 2D). In the static strain condition, only progesterone and dual hormone treatments led to increases in MMP activity (Fig. 2G).

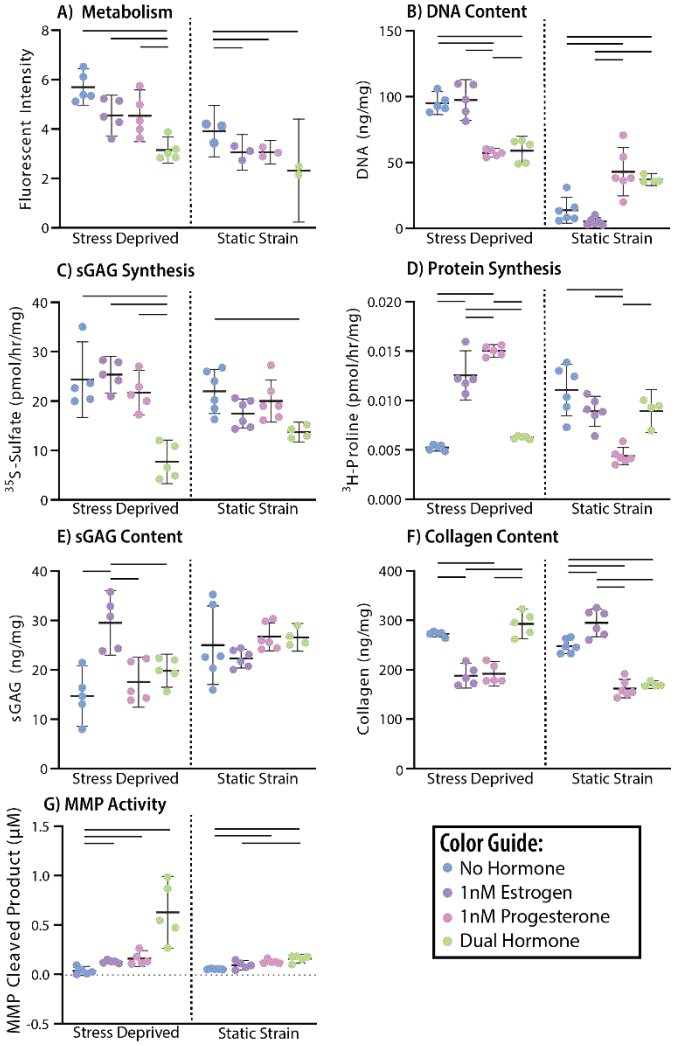

Figure 2: Stress-deprived and 3% static strain culture of female tendons with no hormone, 1nM estrogen, 1nM progesterone, or dual hormone addition. Explant health (A-B), ECM synthesis (C-D), ECM content (E-F) and ECM breakdown (G) were assessed.

DISCUSSION

In agreement with our hypothesis, estrogen and progesterone alone have strain-dependent effects on the biosynthetic parameters we assessed in female tendon tissue. The increase in collagen content with strain and estrogen found in this study is consistent with the current literature based on data from human subjects [7]. Our data validates these findings, as we could remove circulating systemic variables present in *in vivo* studies, but is limited as it does not examine dynamic strain states. The lack of a decrease in protein synthesis may be due to this, as the static strain does not fully represent exercise.

Progesterone has not been studied yet as an independent variable. What is known about progesterone is in the context of the impacts of estrogen and progesterone together in the menstrual cycle [8], where there are apparent differences in musculoskeletal connective tissue injuries based on the phase of the cycle [9]. Interestingly, dual hormone effects in our study appeared to be more influenced by progesterone than estrogen. This could indicate that progesterone may have the dominant effect during cycling, and the balance of tendon remodeling may be altered by the rapid fluctuation of estrogen and progesterone during the menstrual cycle in young females. In stages with higher levels of progesterone (post-ovulatory in humans), our results suggest there would be increased breakdown activity and lower collagen content compared to high estrogen phases (pre-ovulatory). This could result in a more flexible tendon. However, our current study is limited by the constant administration of both hormones at the same concentration, so the focus of future work is to simulate hormone cycling *in vitro* to gain a better understanding of the stage-dependent effects on tendon.

The increased MMP activity with hormones across both strain states is an exciting result, as the breakdown side of ECM remodeling has not been extensively studied. This contributes to the theory that sex hormones increase overall turnover of the matrix, not just synthesis. To further examine this result, we are examining expression of specific ECM molecules and breakdown proteins in the same culture conditions. Our findings lay the groundwork for future work into the impacts of cycling and hormones on tendon healing and repair, as well as the creation of physiologic *in vitro* models to study female tendon biology.

POST-TRANSCATHETER EDGE-TO-EDGE REPAIR PRESSURE GRADIENT PREDICTION AFTER MITRACLIP IN FUNCTIONAL MITRAL REGURGITATION PATIENTS

Shelley C. Gooden (1), Mani A. Vannan (2), Konstantinos D. Boudoulas (3), Vinod H. Thourani (2), Pradeep K. Yadav (2), Lakshmi P. Dasi (1)

(3) Division of Cardiovascular Medicine, Wexner Medical Center, Columbus, Ohio, US

INTRODUCTION

Mitral regurgitation (MR) is present in about 1.7% of the general population, rising to 9.3% in those age 75 and older [1] and occurs when the two leaflets of the mitral valve (MV) do not close properly during systole. In the case of functional MR (FMR), this is due to structural changes in surrounding anatomy that impact valve competence. For treatment of symptomatic moderate-to-severe or severe MR in patients deemed high-risk for surgical treatment, Abbott's MitraClip transcatheter edge-to-edge repair device may be used. Focusing on FMR, MitraClip is the only FDA approved transcatheter device and one of two CE marked. The device clips the two leaflets together, creating a double orifice and reducing regurgitation.

Analyzing MV pressure gradient (MVG), defined as the mean MVG by simplified Bernoulli through diastole measured by CW doppler, during the MitraClip procedure is important. Leaving patients with gradients of 5 mmHg or more is undesirable and can lead to iatrogenic mitral stenosis, worsening patient prognosis [2-3]. The impact of MitraClip on MVG is important in assessing patient candidacy and may aid in procedural planning. However, post-MitraClip MVG is not straightforward, and there is a lack of quantitative algorithms that do not require full, expansive, time-intensive, patient-specific simulations.

The objective of this study is to develop a framework for post-MitraClip MVG prediction immediately after MitraClip deployment for FMR patients based on routine pre-MitraClip transesophageal echocardiogram (TEE).

METHODS

Fourteen patients with cardiomyopathy and moderate-to-severe or severe FMR on maximally tolerated medical therapy underwent MitraClip implantation with central device placement. Pre- and post-MitraClip TEEs were performed on all patients, and data was acquired under IRB approved protocol.

From the pre-MitraClip 3D TEE scan, a representative model of each MV was generated. A parameterization method was developed and applied to simplify each MV geometry based on annular commissural and septolateral dimensions and leaflet lengths, and the simplified pre-MitraClip geometries were generated. An example of the pre-MitraClip geometry is shown in **Figure 1A.**

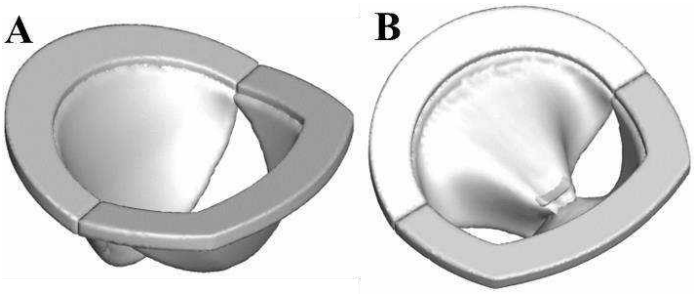

Figure 1: Pre-MitraClip Simplified Mitral Geometry (A) and Post-MitraClip Simulation Geometry (B)

An in-house reduced-order model MitraClip simulation was implemented based on the number of MitraClips implanted in the patient. Because the information of MitraClip size was unavailable, MitraClip NT was assumed based on clinician judgement. The total post-MitraClip MV area (MVA), defined by the leaflet tips, was then measured. An example of the post-MitraClip geometry is shown in **Figure 1B**.

Post-MitraClip MVG for the simulated geometries were calculated. First, the mean diastolic pre-MitraClip mitral volumetric flowrate was calculated for each patient using pre-MitraClip MVA and MVG by manipulation of the simplified Bernoulli's equation, shown in Equation 1.

$$Q_{mean} = MVA_{in\ vivo}\sqrt{\frac{MVG_{in\ vivo}}{4}} \quad (1)$$

In the same manner, this flowrate was then applied to calculate the MVG based on the simulated MVA, as shown in Equation 2.

$$MVG_{simulated} = 4\left[\frac{Q_{mean}}{MVA_{simulated}}\right]^2 \quad (2)$$

Four patients were used to develop a post-MitraClip MVG predictive model to map between the simulated and *in vivo* MVG measures; this equation yields the final predicted MVG. The equation was then assessed on the remaining ten patients. Performance of the predictive model was assessed using a Bland-Altman plot. Acceptance criterion was set to assess the ability of the model to yield a predicted MVG within 1 mmHg of the *in vivo* MVG.

RESULTS

A comparison of the simulation model and patient TEE for pre- and post-MitraClip geometries is shown in **Figure 2**.

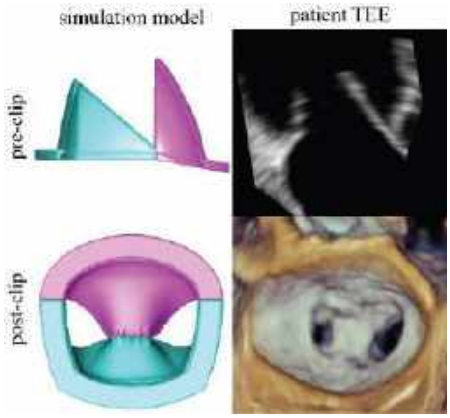

Figure 2: Simulation Model vs Patient TEE

The *in vivo* vs simulated post-MitraClip MVG forming the predictive model is shown in **Figure 3.**

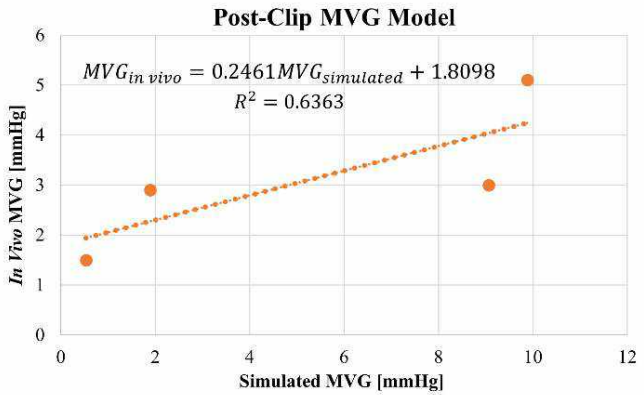

Figure 3: *In Vivo* vs Simulated Post-MitraClip MVG

An equation relating the two measures is formed, shown in Equation 3, with an R-squared of 0.64.

$$MVG_{in\ vivo} = 0.2461MVG_{simulated} + 1.8098 \quad (3)$$

The predictive model was assessed in the Bland-Altman plot shown in **Figure 4**.

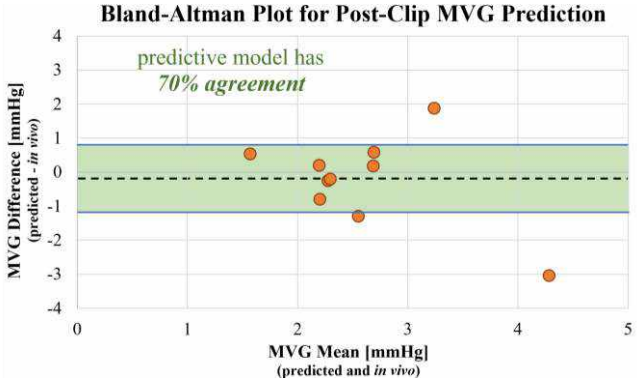

Figure 4: Predictive Model Assessment

The mean difference between the predicted and *in vivo* MVG was -0.22 mmHg, and the predictive model showed 70% agreement across the ten patients assessed.

DISCUSSION

By visual inspection, the MV simplification and simulation yielded geometries representative of patient anatomy (**Figure 3)**.

The predictive model formed had an R-squared of 0.64, indicating the model had a decent correlation between the *in vivo* and simulated post-MitraClip MVG.

Based on the Bland-Altman plot (**Figure 4**), the mean difference between the predicted and *in vivo* MVG was -0.22 mmHg. This shows the predicted MVG was overall slightly lower than *in vivo* MVG. With acceptance criterion of 1 mmHg, the predictive model showed 70% agreement across the ten patients assessed, which shows decent predictive power given the small number of patients used.

This study shows that the MV geometry can be simplified for analysis, and simplified simulations can faithfully capture *in vivo* post-MitraClip geometry and MVG, avoiding expansive simulations commonly performed.

The main limitation of the methodology in this study is the use of a parameterized MV model simulated only for diastole. Incorporation of the full MV apparatus through systole may yield increased predictive efficacy. Only pre-MitraClip MVG was used to assume a mean diastolic flow rate, where effects on post-MitraClip hemodynamics were not accounted for. Another limitation was the assumption of MitraClip NT because implanted device size was not available.

Future work aims to address these shortcomings, in addition to expanding the number of patients assessed and assessing patients with non-central MitraClip placement.

Results from this study lay the basis for the first knowns simplified predictive framework for post-MitraClip MVG. Expanding this model can provide an easy-to-use and important clinical tool for patient candidacy assessment and procedural planning for MitraClip implantation to prevent suboptimal MVG outcomes.

INTRODUCTION

Out-of-hospital cardiac arrest (OHCA) is the unexpected cessation of cardiac mechanical activity and blood circulation that occurs outside of the hospital setting (1). In 2010, there were an estimated 4.4 million OHCA events worldwide (2). In 2020, there were approximately 300,000 reported cases of emergency medical system (EMS)-treated OHCAs in the United States, a significant 33% increase compared to 2015 (3). In Canada, OHCA incidents were estimated at 38,000 cases in 2020 (4), a 16% increase compared to 2017 (5). For unwitnessed OHCAs, only 2-4.1% survive to hospital discharge (6). According to the 2022 US Cardiac Arrest Registry to Enhance Survival report, survival rates in EMS-treated cases were 3 times higher for witnessed vs. unwitnessed events (3). Given that approximately 50% of EMS-treated OHCAs are unwitnessed (3), the main barrier in improving OHCA outcomes is the timely recognition of the event.

Wearable biosensor devices with continuous cardiac monitoring capabilities may serve as witnesses in an otherwise unwitnessed event where no bystanders are present (7). The loss of cardiac function leads to immediate physiological changes, such as cessation of pulsatile blood flow, and drop in oxygenated hemoglobin. One of the most commonly used sensors in consumer wearable devices for continuous cardiac monitoring is photoplethysmogram (PPG) (8). PPG is an optical sensor, capable of monitoring cardiac pulsation. In this study, we hypothesized that PPG waveforms contain relevant information to distinguish between normal cardiac states, occurrence of cardiac arrest (i.e., absence of a pulsatile blood flow), and non-physiologic data (i.e., off-body recordings). Specifically, we investigated the impact of various PPG characteristics, including time- and frequency-domain features, on the performance of cardiac state detection classification models.

METHODS

Our wearable device consisted of 4 Maxim Integrated™ PPGs for synchronized measurements. With this device, we obtained physiologic data on different anatomical locations during normal blood circulation (i.e., cardiac) and interrupted blood flow (i.e., occlusion, representing a cardiac arrest state) as well as non-physiologic (i.e., off-body) measurements. All PPG recordings were split into 10s non-overlapping segments, and filtered (4th-order zero-lag Butterworth filters: 8Hz low-pass cut-off frequency; 0.5-5Hz band-pass cut-off frequency). Time-domain features were extracted from PPG recordings (number of features, n=10). The Welch power spectral density (PSD) analysis was performed to calculate the power distribution of PPG recordings across different frequencies (PSD feature set, n=11). Selected frequency-domain features, such as the total power, frequency center, and spectral spread of PPG signals were extracted from PSD calculations (Frequency feature set, n=5). To diversify feature representations, three additional feature set combinations were created: Time and PSD features (timepsd; n=21), Time and Frequency features (timefreq; n=15), and Time, Frequency, and PSD features (timefreqpsd; n=26). Random forest classification models were trained for each anatomical location to detect between the three possible states of *Normal Cardiac* (NC), *Occlusion* (OCC), and *Off-Body* (OB). Classification pipelines included: 1) feature standardization (subtracting the mean and normalizing to one standard deviation); 2) sequential forward feature selection algorithm; 3) random forest model training with 10-fold cross-validation and hyperparameter tuning using 70% of randomly selected PPG measurements; and, 4) model evaluation using 30% hold-out test dataset.

RESULTS

This study was approved by the Behavioural Research Ethics Board of the University of British Columbia [H22-01587]. Thirty-one healthy volunteers (14 female, 19-58 years old) with no known ongoing cardiac conditions were recruited and provided written informed consent to participate in this study. For each sensor placement (including the fingertip, finger base, and wrist), we compared classification performances when using different feature sets (Figure 1-

left). For all sensor placements, the classification performance of models using both time- and frequency-domain features (i.e., timefreq, timepsd, timefreqpsd) were higher than the models trained on either time- or frequency-domain features (i.e., time, freq, psd). While certain time- or frequency-domain PPG characteristics exhibited similar distributions across cardiac and/or non-cardiac states (e.g., PPG mean of normal cardiac and occlusion measurements), significant differences were observed for all states when considering the combination of time- and frequency-domain features (Figure 2-left). For instance, both the PPG Mean and 1.17 Hz component of the PPG PSD (equivalent to ~70 BPM heart rate) were common features among all sensor placements.

Higher classification performances (macro average F1-Score) were observed on the finger (fingertip: 0.966, finger base: 0.946) compared to the wrist (0.841). Normalized confusion matrices (Figure 1-right) were used to evaluate class-based classification and misclassifications on the hold-out test set. Across all anatomical sites, NC and OB had higher Sensitivity (i.e., lower number of false positives) compared to OCC. Specifically, OCC detection had the lowest performance on the wrist, with over 50% false-negative predictions. Conversely, OCC had higher Specificity compared to NC and OB, indicating low false-positive OCC predictions.

Sample PPG waveforms for normal cardiac and occlusion measurements taken at the fingertip, finger base, and wrist were examined (Figure 2-right). Normal cardiac measurements at the fingertip and finger base had a distinct pulsatile component (PPG AC), differentiating them from pulseless occlusion measurements on those sites. However, normal cardiac measurements on the wrist exhibited a weaker pulsatile component, potentially making it more challenging to distinguish them from pulseless Occlusion measurements.

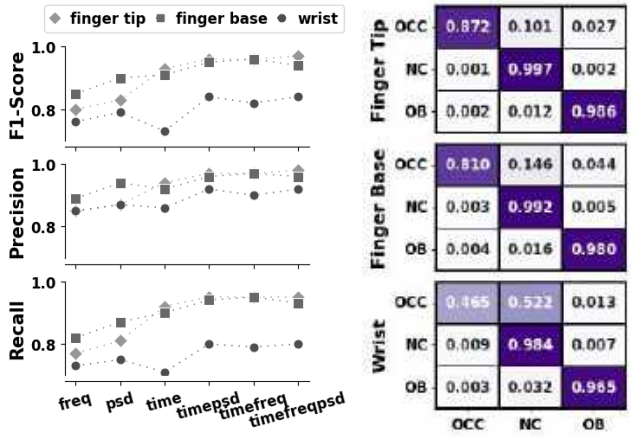

Figure 1. Classification performances across different feature sets and anatomical locations (left). Normalized confusion matrices for each anatomical location (right). NC: Normal Cardiac; OCC: Occlusion; OB: Off-Body.

DISCUSSION

In this study, we developed and tested a PPG wearable device with the capability to detect healthy cardiac, pulseless cardiac, and non-cardiac conditions using machine learning. Classifiers trained and evaluated on PPG recordings on the finger had better performance compared to those using wrist PPG data. While finger clip-type PPG devices are frequently used in clinical settings, obtaining PPG data from the fingertip would not be feasible for everyday use. Our findings suggest that the second-best location to achieve high-classification performance is the finger base. In recent years, wearables adopting a ring form factor with embedded PPG sensors have become available in the market (e.g., Oura ring). While these wearables currently do not have OHCA detection capabilities, our study suggests that they may offer the most suitable form factor for optimal OHCA detection applications. Given the classification performance was significantly lower when using PPG recordings on the wrist, and considering the widespread popularity of wristband wearables in nonclinical settings, it is imperative to employ strategies to enhance classification accuracy in this location. Possible approaches may include training classification models using recordings from multiple PPGs.

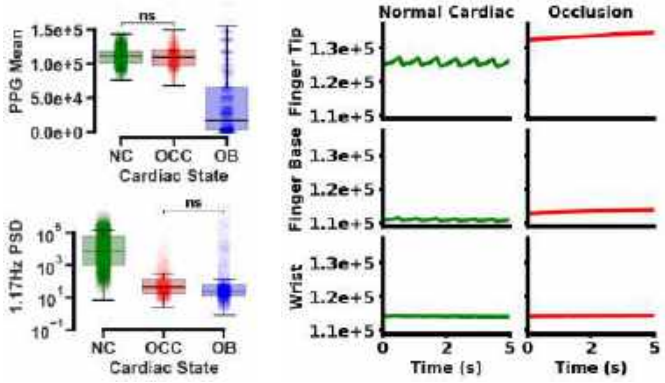

Figure 2. Distribution of sample time- and frequency-domain PPG features across different cardiac and non-cardiac states (left). Sample PPG waveforms on different anatomical locations for cardiac and occlusion states (right). NC: Normal Cardiac; OCC: Occlusion; OB: Off-Body.

INTRODUCTION

Cam morphology of the proximal femur changes the biomechanics of the hip joint and is commonly linked to femoroacetabular impingement syndrome (FAI).[1] This change in the loading pattern has been shown to affect movement at the pubic symphysis and correction of cam morphology can reduce force at the chondrolabral junction.[2,3] However, this line of research has not been extended to the relationship between FAI, cam morphology, and sacroiliac (SI) joint dysfunction. Quantitative biomechanics data of any kind is particularly lacking in this area with only observational data linking poor hip range of motion with low-back pain.[4] Additionally, the prevalence of radiographic SI joint abnormalities in patients with FAI may be as high as 1 in 4 patients.[5]

The purpose of this study was to quantify the relationship between FAI due to cam morphology of the proximal femoral head and SI joint kinematics using a cadaveric model. Our hypothesis is that hips with cam-type FAI will result in significantly different ipsilateral SI joint kinematics versus those of a hip in a native.

METHODS

5 hips from 3 cadaveric human pelves (85±9.2yrs) were approved for testing by the institution's biospecimens review panel. Specimens were screened to be free from arthritis, hip dysplasia, and evidence of prior surgery.

Optical Metrology

To prepare for measurement of SI joint kinematics, an array of 5–8 fiducial tracking landmarks, made of 3mm diameter acrylic rods, were rigidly fixed to the right and left ilia, and sacrum. Specimens then underwent a computed tomography (CT) scan. The right and left ilia and sacrum were then segmented into separate 3D mesh files with the fiducial landmarks included in each mesh (Figure 1). Tracking markers were fixed on the exposed tip of each landmark.

During testing, two, 12-megapixel cameras equipped with Titanar 24mm lenses (Aramis SRX, Trilion Quality Systems, King of Prussia, PA) were positioned such that each camera could see all tracking markers, tracking the markers in 3D space with a resolution of 0.01mm. The marker arrays of the right and left ilia and sacrum enabled each bone to be tracked as a rigid body in 3D space using the Aramis software (Aramis Pro 2018, Trilion Quality Systems, King of Prussia, PA). The 3D meshes attained were then aligned to the tracking markers by matching the tips of the landmark posts in the meshes with the tracking markers, enabling the right and left ilia and sacrum's 3D meshes to be tracked in 3D space as rigid bodies with a resolution of 0.04mm and relative motion between the 3 bones to be quantified. Anatomic coordinate systems, joint kinematics and kinetics of the pelvis and femur were defined according to the recommendations of the International Society of Biomechanics.

Figure 1: 3D CT reconstruction of pelvis demonstrating fiducial markers. Ovals indicate groups of fiducial markers used to track the 2 ilia and sacrum.

Robotic Testing

To prepare for robotic testing, skin and subcutaneous tissues were removed from the distal end of each exposed femur which were then potted in a urethane resin (Smooth-On 300D). The sacrum was augmented to withstand repeated testing with polymethylmethacrylate avoiding the SI articulation and ligamentous attachments. The pelvis was then secured via the sacrum to a rigid plate using a custom fixture such that the sacrum alone was rigidly fixed, allowing the SI joint and pelvic ilia to remain free. Prepared specimens were mounted to a 6 degree-of-freedom robotic system (KUKA, Augsburg, Germany) with one distal femur mounted to the robot's manipulator equipped with a 6-axis load cell and the sacrum to a floor-mounted platform (Figure 2). The robot was controlled using simVITRO software (Cleveland Clinic, Cleveland, OH, USA).

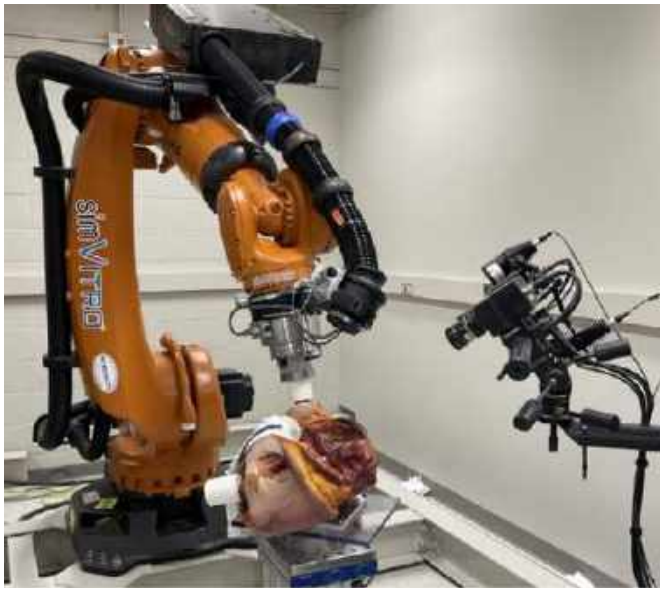

Figure 2: Experimental set-up showing sacrum fixed to pedestal and right femur fixed to robotic arm with optical metrology cameras viewing.

Hips were tested with a starting position of 90° of flexion and neutral adduction and axial rotation. Hips were then internally rotated at a rate of 1°/sec until an internal rotation torque of 18Nm was reached, at which point the joint was returned to its original position. While internally rotating the hip joint, the robot maintained the 90° flexion and abduction angles and allowed joint translation such that 0N of translational forces were maintained at the joint. During each test, the optical metrology and robotic systems were synchronized with the SI kinematics and hip joint kinetics recorded at 8Hz and 100Hz, respectively.

Hip Joint Conditions

Each hip was tested in a native and a simulated cam state. Native hips underwent an anterior longitudinal capsulotomy and subsequent repair prior to testing. The simulated cam state was created with a 3D-printed simulated cam that was designed to contour along the femoral head and neck and placed at the 2 o'clock position at the femoral head-neck junction.

Data Analysis

3D translations and rotations about the SI joint were compared at 6, 12, and 18Nm of hip internal rotation. A within-specimen analysis was performed using a repeated measures ANOVA comparing the effect of the cam with the native state at each of the 3 torque levels and at each of the 6 degrees of freedom.

RESULTS

Amongst all degrees of freedom and both hip joint conditions, motion at the ipsilateral SI joint increased with hip internal rotation torque. Regarding the effect of simulated cam FAI on ipsilateral SI joint kinematics, results are shown in Table 1. The presence of FAI resulted in an anterior, superior, and lateral translation of the ilia relative to the sacrum that increased with hip torque. Rotationally, the presence of the cam resulted in iliac abduction, internal rotation, and extension relative to the sacrum versus the native hip with statistically significant differences present at 12Nm and 18Nm in internal rotation and extension.

DISCUSSION

Limitations of this study include the age of the cadavers, and the simulated cam state as the simulated cam does not perfectly replicate normal joint mechanics. We did not evaluate the native hip head-neck offset nor control for the version of the proximal femur, which may reasonably alter the magnitude of difference between the native and cam states. The precision of our experimental instrumentation allowed us to detect very small movements about the SI joint, and the clinical conclusions of such small movements may be limited. Lastly, our study may have been underpowered to detect differences in some of the outcome variables.

In conclusion, the presence of simulated cam morphology causes identifiable changes in motion at the SI joint relative to a native state. These findings provide a quantitative biomechanical explanation for concomitant SI joint dysfunction in patients with femoroacetabular impingement syndrome. Additionally, this study outlines a method to quantify SI joint behavior resulting from changes in hip biomechanics, enabling further studies on this relationship to be performed.

INTRODUCTION

An abdominal aortic aneurysm (AAA) is a non-homogeneous dilatation of the aortic wall that delves into a progressive weakening, which can lead to its rupture, an event that carries an overall mortality rate of 80%. The U.S. clinical standard to assess the need for AAA repair is a maximum transverse diameter of 5.5 cm for male patients and 5.0 cm to 5.4 cm for females [1]. However, biomechanical markers such as Rupture Potential Index (RPI) have been postulated to be better predictors of rupture risk compared to size alone. To estimate accurately patient-specific RPI, an AAA's wall stress and wall strength are required, for which knowledge of the patient-specific intraluminal blood pressure, wall and intraluminal thrombus (ILT) material properties, is needed at the time of clinical imaging. In addition, wall strength requires knowing the patient-specific familial history of AAA, sex, local diameter, and local ILT thickness. Conversely, geometric measures other than maximum diameter have also been implicated in rupture risk assessment [2, 3]. These were applied with decision tree-based methods to estimate AAA rupture risk [4].

The present work explores the use of a Random Forest (RF) model for classifying AAAs according to their rupture risk. This approach is based on rupture risk assessment performed through biomechanical and geometrical analyses, which can be utilized to assist physicians in assessing the rupture potential of AAAs. We hypothesized that our model achieves a minimum accuracy of 80% in classifying RPI into three categories: low risk, medium risk, and high risk for training, validation, and testing datasets.

METHODS

We retrospectively acquired images from 73 computed tomography angiography (CTA) exams obtained from a preexisting database at Allegheny General Hospital (Pittsburgh, PA) and Northwestern Memorial Hospital (Chicago, IL), following Institutional Review Board (IRB) approval at both clinical centers. The CTA images were manually segmented by previously trained users from the renal arteries to the aorto-iliac bifurcation using a custom in-house MATLAB®-based (MathWorks Inc., Natick, MA) script [5]. The segmentation yielded binary masks containing three contours of interest (lumen, inner wall, and outer wall), which were then used for volume meshing performed by a mesh generation script for AAAs suitable for finite element analysis (FEA) [6]. Consequently, triangular surface meshes of the outer wall surface for each AAA model were generated ranging from 30,500 to 161,700 elements, with a mean of 77,000 elements. The AAA wall thickness was estimated from the segmented images on a spatially distributed basis and applied to each node of the surface mesh. A nonlinear elastic membrane analysis (NEMA) method was used to compute the first principal normal and shear stresses at the wall [7] without the need to specify material properties as an alternative for the commonly used FEA. The proximal and distal ends of the models were fixed, and an intraluminal pressure of 93.33 mmHg was applied. The wall strength was calculated (in N/cm^2) using Eq. (1) proposed by Vande Geest et al. [8],

$$Wall\ Strength = 72.9 - 33.5 * \left(\sqrt{ILT} - 0.79\right) - 12.3 * (NORD - 2.31) - 24 * HIST + 15 * SEX \quad (1)$$

where ILT is the ILT thickness (in cm) and NORD is the normalized local diameter (dimensionless) at each node of the surface mesh, HIST is the familial history of AAA (+0.5 for positive familial history; -0.5 otherwise), and SEX is the sex of the patient (+0.5 for male; -0.5 for female). The maximum and 99th percentile RPI (99th RPI) of the AAAs were calculated using the nodal based RPI calculation, which is defined as the ratio of the first principal normal stress and the wall strength.

A geometric characterization was performed with the sac of all AAA models to calculate 52 geometric indices using previously developed in-house MATLAB® scripts [2], which are described in detail and available elsewhere [4-6]. Finally, three categories were

generated based on the 99th RPI and maximum diameter: low risk for AAAs smaller than 5.5 cm and a 99th RPI < 0.5, high risk for AAAs greater than 5.5 cm and a 99th RPI > 0.5, and medium risk otherwise. Our dataset is composed of 39 low risk, 28 medium risk, and 6 high risk AAAs, as shown graphically in Fig. 1.

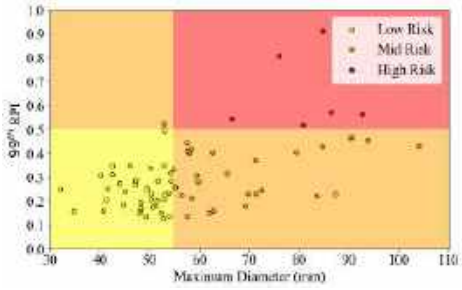

Figure 1. Risk boundaries showing low, medium, and high risk AAAs according to their 99th RPI and maximum diameter values.

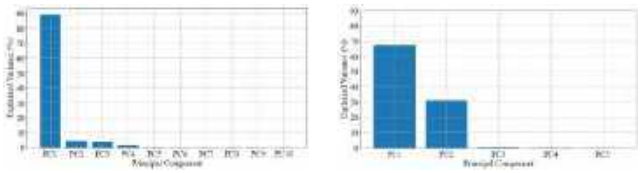
Four RF models were compared, each with n estimators, maximum depth, and random state parameters fixed at 5, 5, and 2, respectively. Model 1 was trained using three principal components derived from principal component analysis (PCA) applied to the entire dataset. Model 2 was trained on the entire dataset without any preprocessing. Model 3 was trained using features extracted through Pearson's correlation coefficients to eliminate redundant features. Lastly, Model 4 was trained on a dataset reduced to two principal components, which were obtained by performing PCA on the dataset used for Model 3. The dataset was split into training, validation, and testing datasets in ratios of 60%, 20% and 20%, respectively.

RESULTS

Dimensionality reduction was performed for Models 1 and 4 using Principal Component Analysis (PCA). For Model 1, the feature dimensionality was reduced from 53 to 3, while for Model 4, it was reduced from 9 to 2. The number of principal components was determined by investigating the explained variance ratio for each component in both models. In Model 1, the first principal component accounts for 89.6% of the dataset's variance, the second for 4.3%, the third for 3.3%, and the rest account for less than 2%, as shown in Fig. 2a. For Model 4, the first principal component covers 67.1% and the second 31.5%, with the remaining components accounting for less than 1% of the variance, as illustrated in Fig. 2b.



(a) (b)

Figure 2. Principal components and their explained variances for (a) Model 1 and (b) Model 4.

Table 1 shows the accuracies for each subsample of the dataset according to the classification model. Models 2 and 3 overfit the training dataset, as evidenced by their perfect performance in training and significant drops in validation and testing accuracies. Model 4 does not overfit (compared to 2 and 3) but struggles with generalization, as indicated by its lower validation and testing accuracies compared to its training accuracy. The principal component of Model 4 covers marginally more variance than Model 1, albeit worse in performance.

Table 1. Accuracies of each classification model.

Accuracy	Model 1	Model 2	Model 3	Model 4
Training	91.30%	100%	100%	95.65%
Validation	83.33%	66.66%	43.75%	50%
Testing	93.33%	73.33%	60%	73.33%

DISCUSSION

Model 3 improves after performing PCA on the extracted feature space. However, accuracy is significantly higher for Model 1, where no feature extraction was performed. Our previous research on the association between geometric indices and RPI has shown that for most indices there is a moderate association [9]. Therefore, a dimensionality reduction technique such as PCA substantially solves the problem of not having strong dependence and correlation on AAA geometric surrogates. Performing PCA generates a linear combination of input features, which may not be physically meaningful but can be used to improve the accuracy and realism of a model, as demonstrated in Model 1 compared to Model 2. It is observed that by eliminating redundant features, the model's accuracy decreases on validation and testing datasets, and it tends to overfit on training information, as seen in Model 3. For Model 4, accuracy is slightly improved by performing PCA. However, feature selection is used when features have disjointed meanings, unlike PCA, which preserves information associated with the dataset and maintains its meaning. In this application, 52 input features, which are geometric indices, show correlation and dependency on the sample space.

Model 1 satisfies the proposed hypothesis, while Models 2-4 do not. The accuracy of a model can be biased by the sample size, which is a limitation of this study. A well-distributed dataset with an equal number of AAAs for each category, as well as a large sample size, will be required for deeper and more precise tuning of the model. Limitations related to biomechanical analysis are related to the NEMA force-based analysis, which neglects bending stresses and stress gradients through the aortic wall, thus yielding lower stresses compared to the widely used FEA. However, it overcomes the requirement of tissue characterization, which is impossible to perform on a non-invasive, patient-specific basis, for instance, in surveillance programs.

The methods of this study can be integrated into an automatic pipeline for assessing AAA rupture risk. This could be accomplished by leveraging deep learning-based segmentation algorithms to expedite the timing of rupture risk assessments. The goal would be to generate a fully automated pipeline for hospitals, particularly benefiting clinicians who lack the specific biomechanical and data science expertise required for these approaches.

INTRODUCTION

Doxorubicin (DOX), an anthracycline, is a powerful chemotherapeutic agent that has historically been used to treat cancers including breast, bladder, lungs, stomach, ovarian, thyroid, soft tissue sarcoma, multiple myeloma, lymphoma, and leukemia. Breast cancer in particular is the most common form of cancer in the United States and globally, affecting 1 in 8 women and comprising nearly 30% of yearly cancer diagnoses. While DOX and its nearly 2000 analogues have shown high success rates in mitigating or otherwise destroying breast cancer, anthracyclines have since demonstrated a high propensity for off-target toxicity. Among the most severe off target effects is off-target cardiotoxicity, with over 10% of women receiving DOX treatment developing acute cardiotoxicity immediately following treatment and approximately 2% of women developing severe cardiotoxicity up to 10 years post-treatment [1]. The mechanisms of this cardiotoxicity have remained elusive, more so in light of established system clearance of DOX within 48 h, and is the subject of intense debate in literature. We suggest that initial DOX exposure pathologically alters paracrine signaling behaviors of some myocardial cells in such a way that propagates DOX-induced cardiac dysfunction and over time results in the onset of cardiotoxic effects.

Local paracrine signaling has been a rising area of study, in part driven by enhanced capabilities to assess small extracellular vesicles (sEVs), commonly extracellular vesicles with diameters of less than 200 μm, as necessary agents of tissue homeostasis and analyze the composition and cargo of these vehicles. Exosomes, a particular subcategory of sEVs with known characteristic surface proteins, and exosome-like sEVs have been widely investigated as targeted agents for delivery of proteins, nucleic acids, and other biosignaling agents. These agents, when transported via sEV, have been shown to be active in angiogenesis, mitochondrial maintenance, immunomodulation, epithelial to mesenchymal transition, and other relevant processes, and have recently been suggested as active contributors to DOX-induced cardiotoxicity [2]. Currently in literature, individual exosomal miRNAs have been investigated as being decisive in this process, but no single miRNA dysfunction has been able to completely recapitulate a similar level of cardiotoxic effects. We suggest that, instead of individual miRNAs, exposure of the cardiac tissue to DOX causes a major shift in the total paracrine miRNA profile. This pathological shift drives further propagation of cardiac dysfunction, exacerbating damage over time. Furthermore, we suggest that the specific features of DOX-cardiotoxicity are mediated by a combination of key miRNAs rather than any single miRNA alone.

METHODS

We first benchmark in 2D culture what the effects of DOX cardiotoxicity are, as this term is poorly defined in literature [---]. We then demonstrate that these effects can be recapitulated in the absence of DOX via treatment of cells in 2D with sEVs in DOX-free media. In both cases, stem cell derived cardiomyocytes (iCMs), cardiac fibroblasts (iCFs), and endothelial cells (iECs) were treated with the treatment (10 nM DOX or 25 μg/mL sEVs) or a PBS blank for 48 h. The beating behaviors of iCMs were assessed by video analysis using in-house software to determine beating strength and rate, as well as by Ca^{2+} staining to obtain a ECG analogue for arrhythmia analysis. Arrythmia analysis was conducted in both time and frequency domains, with supporting sine wave decomposition. The activation and transdifferentiation of iCFs was assessed via immunostaining for α-SMA and cleaved caspace-3. Cell counting and population assessment was performed via ImageJ. Metabolic activity of cells was measured via AlamarBlue, and ROS production was measured via colormetric ROS assay.

3D models were constructed using a combination of gelatin methacrylol (GelMA) and collagen and we seeded with a combination of iCMs and iCFs. Gels were stable and began tissue-like beating within 7 days of seeding. iCMs were kept constant throughout all trials, and

iCFs were treated with a PBS blank or 10 nM DOX for 48 h before seeding. Beating analysis and Ca^{2+} analysis were performed on the 3D models as on the 2D to assess overall beating behavior.

sEVs were isolated from conditioned media via typical exosome ultracentrifugation protocol. Isolated sEVs were assessed via nanoparticle tracking analysis (NTA) and the absence of DOX inside sEVs was verified by UV-Vis spectrophotometry. Surface protein ratios of the sEV population from normal and DOX-treated cell conditioned were assessed via western blot. The contents of sEVs was isolated using a exosomal miRNA isolation kit and purified. miRNA profiling was performed using the Nanostring system to obtain a whole human miRNA profile. Potential target miRNAs were selected via unsupervised analysis of the profile and pathway analysis was performed using the MetaCore pathway analysis software.

RESULTS

Beating analysis of iCMs in 2D culture revealed that treatment with DOX significantly decreased beating velocity ($p < 0.01$, Figure 1A), but not beating rate (Figure 1B). Treatment with sEVs showed an even greater decrease in both beating velocity ($p < 0.001$, Figure 1A) and rate (Figure 1B), though beating rate decrease remained non-significant. ROS production was also increased in DOX-treated iCMs compared to the control ($p < 0.05$), which was recapitulated by sEV treatment ($p < 0.05$). Treatment of iCFs revealed that DOX significantly increased α-SMA expression relative to the control ($p < 0.005$) which was only partially recapitulated by sEV treatment ($p < 0.01$) (Figure 1D). Ca^{2+} analysis of 2D iCM cultures revealed the both DOX and sEV treatment substantially disrupted regular beating patterns despite non-significantly affecting beating rate (Figure 1E). Similar effects were observed in the 3D model comparing control and pre-treated cells.

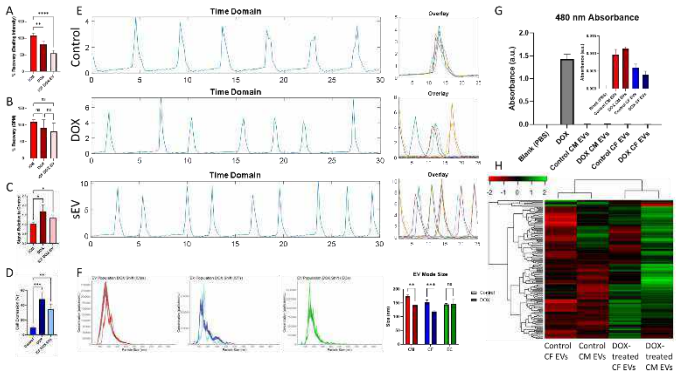

Figure 1: Analysis of iCMs provided beating velocity (A), beating rate (B), and ROS production (C) for control (red), DOX (dark), and sEV (light) treatments. Staining of iCFs for α-SMA expression (D) for control (blue), DOX (dark), and sEV (light) treatments. Ca^{2+} staining of iCMs provided beating signals (E) for the control and treatment conditions, with signals overlaid by average period. NTA of sEVs for control (light) or DOX (dark) size distribution and quantification of mode shift (F). UV-Vis spectrophotometry results to assess the presence or absence of DOX in isolated sEVs (G). Heatmap for unsupervised selected targets from the Nanostring miRNA profiling (H). * $p < 0.05$

Analysis of the sEVs via NTA revealed a significant decrease in the mode size of sEVs of iCMs ($p < 0.01$) and iCFs ($p < 0.005$) in cells treated with DOX for 48 h, but not in iECs. Western blot also showed significantly increased CD63 expression in iCM sEVs ($p < 0.001$) and iCF sEVs ($p < 0.05$), and significantly increased TSG101 expression in iCM sEVs ($p < 0.005$) when comparing DOX-treated cells to negative controls. UV-Vis spectrophotometry revealed that the isolated sEVs did not contain DOX (Figure 1G).

Nanostring analysis revealed a substantial shift in sEV miRNA populations between control and DOX-treated cells (Figure 1H). MetaCore pathway analysis of these miRNAs further implicated 14 miRNA targets as directly contributing to DOX-induced cardiotoxicity, and identified several more miRNAs of interest. MetaCore also revealed sEV miRNA activity in pathways associated with desirable DOX functioning.

DISCUSSION

In 2D culture we were able to first demonstrate results consistent with clinically observed symptoms of DOX cardiotoxicity. In particular, decrease in beating strength and substantial dysregulation of beating behavior without significantly affecting the heart rate overall are common symptoms of DOX cardiotoxicity. We also demonstrated that DOX significantly affects the phenotype of CFs, the cells in the heart primarily responsible for managing the microenvironment and paracrine homeostasis. Furthermore, we showed that these effects were not DOX-dependent, and could be propagated in the absence of DOX via paracrine signaling from cells that had been previously exposed to DOX treatment. This indicates that direct DOX exposure is not vital for the overall onset of cardiotoxicity symptoms, and provides some insight into how symptoms may present in long-term patients (up to 10 years post-treatment).

We also showed that these effects are driven, at least in part, by substantive changes to the sEV profile of cells affected by DOX. DOX-treated cells showed smaller overall sEV profiles, a shift which we have previously shown to be associated with aging and risk of cardiovascular disease. This is corroborated with the increased observable expression of CD63 and TSG101, which we have also previously shown to be correlated with the reperfusion/oxidative stress phase in myocardial infarction. Furthermore, these changes are not driven by the transport of DOX in sEVs, as the isolated sEVs do not contain DOX, but are instead driven by changes in the paracrine miRNA profiles of these cells. In the treatment of cancer this shift is likely advantageous, as we see via pathway analysis that miRNAs can provide a supporting role in the intended function of chemotherapy on a local level. In the heart, however, we also see that DOX treatment stimulates increased expression of miRNAs which inhibit vital pathways of cardiac homeostasis. In particular, 14 miRNAs acting synergistically across 4 pathways, the disruption of which are known to be causal for arrhythmias and heart failure, are likely a major driving force in the propagation and onset of DOX-induced cardiotoxicity. Further study of these target miRNAs, as well as other DOX-induced changes in paracrine signaling, will help elucidate the cause of long-term DOX-cardiotoxicity and aid in the development of preventative measures.

INTRODUCTION

Mechanical softening and dilation of the cervix are necessary for the safe passage of the fetus during labor and rely on a timely process of cervical remodeling [1–2]. Premature cervical remodeling is the final common pathway for many etiologies of preterm birth, occurring in 10% of all pregnancies, and is associated with high rates of perinatal morbidity and mortality [3–4]. Current therapeutic interventions to delay cervical remodeling are extremely limited, and a critical need exists for developing novel, noninvasive solutions [3–4].

Photobiomodulation (PBM) has recently emerged as a technique that utilizes low-level light exposure to alter cell and tissue functionality [5]. Previous work has shown the ability of light on the visible to near-infrared spectrum (400–1100 nm) to promote wound healing, reduce inflammation, and alter the mechanical properties of collagenous soft tissues [6–10]. Notably, ultraviolet (UV) light (100–400 nm), in combination with the photosensitizer riboflavin (Rb), already exists as an FDA-approved method to stiffen the human cornea in cases of keratoconus [6]. Similarly, blue light (450–495 nm), when coupled with Rb, has been shown to increase the stiffness of connective tissues by 1.8–3.5 fold *ex vivo* and is an attractive alternative to UV light due to its decreased cytotoxic effects [7–8]. Collagen cross-linking is well understood to be the primary mechanism of photosensitizer-mediated stiffening in cases of UV and blue light [6–7]. Additionally, red/infared (IR) light (>600 nm) alone has been shown to accelerate collagen deposition and increase the tensile strength of skin tissue by 100–300% [9–10].

It has yet to be investigated whether similar effects of light exposure can be successfully applied to the human cervix as a possible therapy for obstetric disorders. Building off the literature's established methodology, this study seeks to evaluate the effect of low-level light exposure on the stiffness of the human cervix in nonpregnant (NP) and pregnant (PG) states *ex vivo*.

METHODS

In accordance with IRB approval at Columbia University Irving Medical Center, human cervical tissue was collected from NP (N = 5) and third-trimester PG (N = 3) women undergoing total hysterectomies and stored at -80°C. Thawed cervical tissue was dissected in the radial direction into 3-mm-thick specimens and microtomed prior to testing (Fig. 1). Using a customized LED light array, two samples from each patient were exposed to UV (390 nm), blue (450 nm), or red (680 nm) light +/- 1% Rb solution (Table 1, Fig. 1). For each imaging session, one control (No light - Rb) sample was tested per patient. A second control condition (No light + Rb) was not included in this study since preliminary data suggested that Rb alone did not alter tissue stiffness.

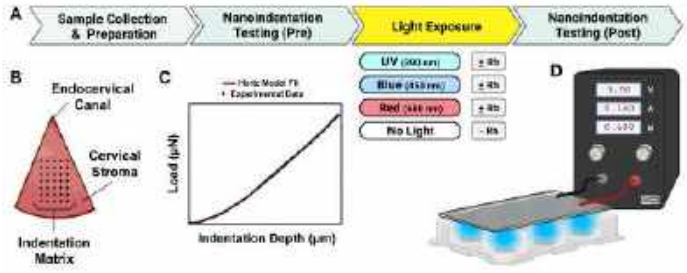

Figure 1: Experimental Methodology: (A) Experimental workflow. (B) Schematic of a cervix tissue specimen marked with a grid of indentation points. (C) Representative load-indentation data fitted with the Hertzian contact model. (D) Schematic of customized light array set-up.

Spherical nanoindentation (Piuma, Optics11Life, Amsterdam, NL) was employed to determine tissue stiffness in this study. Each sample was mechanically tested before and after light treatment to assess relative stiffness changes on an individual basis. Using a 50 μm probe radius (R) and indentation depth (δ) of 4 μm, thirty-five discrete indentation points, spaced 500 μm apart, were measured for each sample with a load-unload protocol (Fig. 1). Tissue stiffness (E_r) in the linear elastic regime was determined by fitting the data with the Hertzian contact model in MATLAB.

Statistical analysis of the nanoindentation data was performed in GraphPad Prism 9.4.0. Normality of the data was first assessed with Q-Q plots. Since the data did not exhibit a Gaussian distribution, a logarithmic transformation was applied to the data prior to statistical analysis. To assess individual sample differences in stiffness before (E_{pre}) and after (E_{post}) light

exposure, a two-tailed t-test was performed on all indentation points ($p < 0.05$). Mean stiffnesses for each sample were calculated and linearly transformed back. Mean relative stiffness change ($\bar{E}_{post}/\bar{E}_{pre}$) was then calculated for each sample. Overall differences across light exposure conditions were assessed with an ordinary one-way ANOVA followed by Šídák multiple comparison tests.

Table 1: Summary of light exposure parameters.

Light Condition	Power (mW/cm^2)	Current (mA)	Time (min)
UV (*385 nm*)	2.26	160	50
Blue (*450 nm*)	2.475	133	45.5
Red (*680 nm*)	1.28	130	88

RESULTS

Prior to light exposure, the baseline stiffness of NP and PG cervical tissue was determined to be 2.258 ± 2.03 kPa and 0.814 ± 0.3 kPa, respectively. In the presence of Rb, UV and blue light stiffened both NP and PG cervical tissue by 2–3 fold on average and were statistically different than their respective no-light controls (Fig. 2). On an individual sample basis, UV + Rb stiffened 8/10 NP and 6/6 PG samples, while Blue + Rb stiffened 6/10 NP and 6/6 PG samples. In the absence of Rb, on average, UV and blue wavelengths had no statistically significant effect on tissue stiffness for NP and PG samples relative to no-light controls (Fig. 2). However, on an individual sample basis, UV - Rb softened 6/10 NP and 1/6 PG samples, while Blue - Rb only softened 1/10 NP and 1/6 PG samples. Interestingly, red light exposure with and without Rb had no consistent effect on tissue stiffness compared to no-light controls (Fig. 2). Yet, individually, Red + Rb only stiffened 1/10 NP and 1/6 PG tissues, while Red - Rb softened 3/10 NP and 1/6 PG samples. As expected, no change in stiffness was observed on average for the no-light control condition, although individual samples exhibited both increases and decreases in stiffness. Given the large degree of both intra- and inter-sample heterogeneity in stiffness for all pre-tested cervix tissues, the effect of light exposure was not statistically significant on unnormalized stiffness values.

DISCUSSION

This study demonstrates, for the first time, the capacity of low-level light therapy to alter the mechanical properties of the NP and PG human cervix *ex vivo*. Specifically, both UV and blue light exposure in the presence of the photosensitizer Rb have a stiffening effect on NP and PG cervix tissue. Relative stiffness changes observed in this study are on par with similar experiments conducted on collagenous soft tissues in the literature [7-10]. Contrary to our expected results, red light treatment had no consistent effect on tissue stiffness with and without Rb.

In line with the existing literature, we posit that the primary mechanism of tissue stiffening by UV and blue light in the cervix is achieved through direct alterations of the extracellular matrix (ECM) components, specifically collagen cross-linking mediated by an oxidative deamination reaction [6–7]. We plan to quantify the amount of collagen cross-linking in our cervical specimens in follow-up experiments with standard biochemical assays. In contrast, given the absence of any mechanical change in tissues

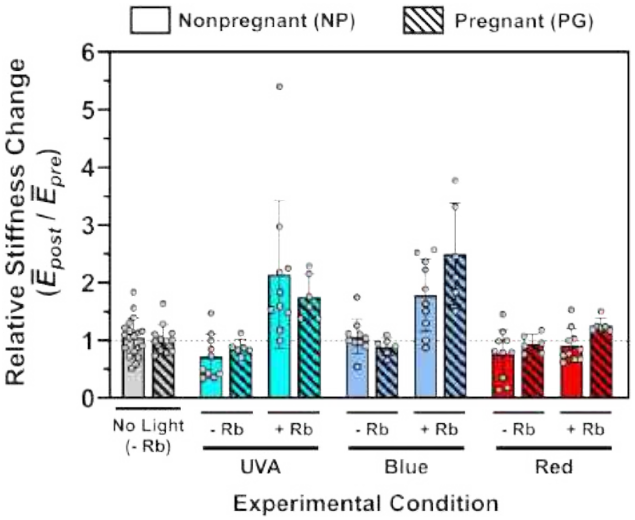

Figure 2: Summary of relative stiffness changes to UV, blue, and red light exposure.

exposed to red light, we hypothesize that an active cellular component is required as an intermediary to generate the stiffening effects reported in the literature and induce ECM remodeling [9–10]. Notably, the cervical tissues utilized in this study underwent multiple freeze-thaw cycles prior to testing and are not believed to contain any viable cellular components. This may explain the lack of any observed mechanical change to red light exposure. Future studies will investigate the contractile and stiffness response of fresh *ex vivo* cervical tissues exposed to UV, blue, and red light in order to disentangle whether the primary mechanism of change is cell- or ECM-mediated.

It is presently unknown whether the stiffening effect measured on the micrometer length scale in this study results in an overall increase in tissue strength under larger deformation. Further, we seek to determine whether light exposure alters the inherent ductility of cervix tissue and results in a material that is more brittle. Follow-up experiments will mechanically test samples in this study under tension with a load-to-break protocol. Lastly, an open question remains as to whether this stiffening effect observed for cervix tissue is maintained over a period of time and is substantial enough to prevent the adverse outcomes associated with spontaneous preterm birth. Additional *in vivo* and *ex vivo* studies are needed to determine if photobiomodulation will be an effective tool to delay human cervical remodeling in pregnancy.

EFFECT OF COLLAGEN ACCUMULATION ON RIGHT VENTRICULAR PASSIVE VISCOELASTICITY WITH PULMONARY HYPERTENSION DEVELOPMENT

Yuecheng, Wang (1) Kristen E. LeBar (2), Zhijie Wang (1,2)

INTRODUCTION

Heart failure, often precipitated by increased right ventricular (RV) afterload in conditions like pulmonary hypertension (PH), is critically influenced by the RV free wall's (RVFW) viscoelastic properties. These properties, defined by the interaction between elasticity and viscosity, are largely determined by the myocardial extracellular matrix (ECM), specifically collagen content [1,2]. While prior ventricular hyperelastic research has delineated the role of collagen in myocardial elasticity [5,6,7], its impact on viscoelasticity, particularly under biaxial stress, is not well established.

It is accepted that the low-strain elasticity of RV is dominated by myofibers whereas the high-strain elasticity is dominated by collagen fibers [5,6,7]. Moreover, our own research on ovine ventricles has shown positive correlations between high-strain elastic modulus and functional decline of the RV [1]. The accumulation of collagen, particularly type III collagen, is identified in PH ovine RVs, and it is negatively correlated with stroke volume and positively correlated with RV hypertrophy indices [4]. Therefore, collagen deposition during PH progression contributes to the RV mechanical changes and may play a role in regulating RV performance. While the role of collagen in cardiac tissue biomechanics has been extensively investigated, its impact on ventricular viscoelasticity remains largely unknown. To our knowledge, the only study investigating the role of collagen in RV viscoelasticity is performed in papillary muscles, where one dimensional passive viscoelasticity was characterized before and after serine protease (plasmin) treatment to degrade collagen [5]. In both healthy and PH groups, collagen degradation led to decreased elasticity and viscosity in cat papillary muscles. However, the viscoelasticity characterization is simplified, and the anisotropic (biaxial) viscoelasticity is not quantified.

In this study, we sought to determine the role of collagen fibers in the passive, biaxial viscoelasticity of the RVFW with PH development. PH was induced in adult rats and biaxial stress relaxation tests were performed on the RV tissues with and without collagenase treatment. Viscoelastic changes after collagen degradation indicated significant decreases in relaxation modulus and stored and dissipated energies, as well as trends of decreased relaxation rate. These findings reveal a novel role of collagen in the viscoelastic properties of the hypertrophied RV.

METHODS

All procedures were approved by Colorado State University IACUC. Adult male Sprague-Dawley rats, aged 9-12 weeks, received a single intraperitoneal injection of monocrotaline (MCT) at a dose of 60 mg/kg to induce PH. The rats were then housed under standard laboratory conditions for 3 weeks post-injection. Following euthanasia, the RVFW was rapidly excised and immersed in a cardioplegic solution containing 30mM 2,3-butanedione monoxime (BDM) maintained at physiological temperature (37°C) for a minimum of 30 minutes. This step ensured the cessation of myocardial contractions. The longitudinal (L) axis of the tissue samples was aligned from apex to base.

Equibiaxial mechanical tests were performed to quantify passive viscoelastic properties of the RVFW. The tissue was preloaded to 0.025N, followed by 15 cycles of equibiaxial preconditioning to stabilize tissue mechanical behavior. Samples were subjected to equibiaxial stretch to 20% strain at physiological stretch rates of 5Hz and 8Hz, simulating resting and acute stress heart rates, respectively. Following baseline mechanical characterization, the tissues were treated with collagenase (6 mg/mL, Sigma-Aldrich) at 37°C for 1 hour to enzymatically degrade the collagen fibers. Subsequent mechanical testing was performed under the same conditions as the baseline measurements. A rest period of 10 times that of the testing period were applied after each test to ensure complete recovery of the tissue.

The Second Piola-Kirchhoff (2nd PK) (S) stress was calculated using the following equation:

$$S = \frac{F}{A_0 \lambda}$$

Where F represents the force, A_0 is the initial cross-sectional area, and λ is the stretch ratio, which was maintained at 1.2 during the relaxation. Next, the relaxation modulus, stored energy (W_S) and dissipated energy (W_d), were computed at 100 seconds post-peak stress to quantify the elasticity and viscosity of the RV myocardium. The V/E ratio was derived as W_d/W_S. The relaxation rate was derived as the slope of the linear fitting to the logarithmic plots of the stress relaxation curve using least square analysis. These methods have been established [2,3]. Paired student t-test was used to compare before and after collagenase treatment. Data is shown as mean ± SD**.** A p-value of less than 0.05 was considered statistically significant.

RESULTS

Collagen Degradation Diminishes Hypertrophied RV Viscosity and Elasticity

The biaxial mechanical testing post-collagenase treatment revealed a pronounced decline in the mechanical strength of the right ventricular (RV) myocardium. Figure 1 illustrates a significant drop of approximately 50% in peak stress at both 5Hz and 8Hz testing frequencies. Correspondingly, W_d and W_S, indicators of viscous and elastic properties respectively, showed substantial decreases (Table 1). Similar changes were observed at the acute stress condition (8Hz) (Table 1) and in the circumferential direction (data not shown). Finally, the relaxation modulus reduced significantly under both testing conditions, with a larger degree of decrease at 8Hz (Table 1).

Stress Relaxation Rate Tends to Decrease and V/E Ratio Remains Constant after Collagen Degradation

The relaxation rate, a measure of the kinetic decay in stress, showed a strong trend of decrease (p=0.1 for n=2 samples) after collagen degradation, although the change did not reach significant values (Table 1). This implies that the rate at which stress dissipates within the RV myocardium is reduced. Meanwhile, we observed no significant changes in the V/E ratio, suggesting similar degrees of reduction in viscosity and elasticity after degradation of collagen.

DISCUSSION

Collagen deposition is a hallmark of RV failure secondary to PH development and contributes to myocardial stiffening. But how it impacts the RV viscoelasticity is unknown. This study originally investigated the impact of collagen on RVFW passive viscoelasticity with PH development. We observed marked reductions in RVFW viscosity and elasticity as well as other viscoelastic changes after collagen degradation. These changes demonstrate a significant role of collagen in the hypertrophied RVFW viscoelastic properties.

The reductions in elasticity and viscosity after collagen degradation were observed in the longitudinal direction (apex-to-base) of the RV (Table 1). We observed marked reductions in W_d and W_S in the circumferential direction as well, and the degree of reduction was more pronounced than the longitudinal direction (data not shown). But more samples are needed to confirm the observation. These changes not only indicate a significant contribution of collagen to RVFW viscoelasticity, but also suggest an anisotropic effect of collagen in different directions.

Moreover, we saw a strong trend of decrease in relaxation rate after collagen removal, which indicates an altered viscous behavior of the tissue. The removal of collagen will make the myofibers to be dominant in the mechanical behavior of the tissue, even at large strains. Thus, this change may reflect the intrinsic viscous behavior of myofibers.

Finally, we did not observe marked changes in the V/E ratio, although the values showed a mild tendency to increase after collagen degradation. The V/E ratio is a parameter that evaluates the relative strength of viscosity and elasticity in a material. A V/E ratio >1 indicates that the viscous behavior overweighs the elastic behavior, and vice versa. Myofibers as muscle cells may exhibit a larger V/E ratio than fibrous collagen protein network due to the presence of cytoplasmic fluid. The further investigation of this parameter may provide a complete view of the combined effects of viscosity and elasticity on cellular or organ functions.

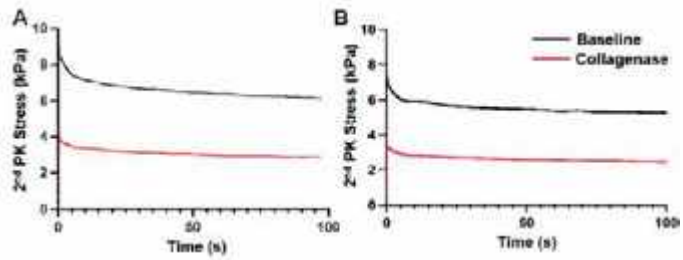

Figure 1. Raw stress-relaxation curves obtained at 5 Hz (A) and 8 Hz (B) before (Baseline) and after collagenase treatment (Collagenase) in the L direction.

Table 1. Changes in diseased RV viscoelasticity with collagen degradation measured by various viscoelastic parameters at 5Hz and 8Hz. Data shown was obtained in the L direction.

	Baseline	Collagenase Treatment	P-Value
At 5 Hz (resting condition)			
W_d (kPa)	**222.3±73.2**	**135.5±14.4**	**0.01**

INTRODUCTION

Airway compromise is the second most common cause of preventable death on the battlefield, accounting for over 10% of total casualties [1]. Portable suction devices are essential in a combat medic's airway management kit. These devices clear the airway by removing blood, vomit, teeth fragments, mud, and other life-threatening obstructions. Designated as a top priority by the Committee on Tactical Combat Casualty Care (CoTCCC), airway control is paramount [2]. Furthermore, suction devices serve additional roles such as tracheal suction for intubated patients, stomach suctioning for patients with nasogastric or orogastric tubes, and addressing fluid accumulation in the chest's pleural cavities [3]. Despite their life-saving capabilities, a significant number of combat medics and civilian first responders opt not to carry these devices due to issues such as excessive weight (in the case of battery-powered devices) and/or insufficient suction (for manually powered ones).

This research assessed the liquid flowrates of three suction devices: the novel Suction Combat Ready Advanced Multifunctional Machine (SCRAMM) and two commercially available devices, Zoll 330 Multifunction Aspirator, and Impact (now Zoll) Ultra-lite 326 / 326M Suction Unit, chosen for their similarity and their higher frequency of use in the US Military Forces.

The goal was to characterize liquid flowrates per the ISO10079-1 standard, anticipating benefits for military end users through SCRAMM's unique modifications. SCRAMM offers high performance with reduced weight.

METHODS

A series of surveys and interviews were conducted by the team through the NSF I-CORPS program to establish priorities in portable suction characteristics relevant to prehospital care. Interviews were conducted (102 in total) with AF end users including paramedics, emergency medical technicians, supply chain personnel, manufacturing representatives, U.S. Food and Drug Administration (FDA) consultants, emergency medicine doctors, US Special Forces, combat medics, and police officers in Texas and the Washington D.C. area [4].

Based on this information, product specifications were defined, and SCRAMM was designed to meet these requirements (due to intellectual property and patent process, some detailed information about SCRAMM was withheld). Liquid Flowrate characterization tests were conducted for the three devices.

To test liquid evacuation flowrates, three solutions were prepared: water, a blood phantom mix (276ml of glycerol + 1224ml of distilled water), and a vomit simulant mix (10g of xanthan gum + 1000ml of distilled water + 100g of glass beads) following ISO 10079-1 standard. The test setups for the three liquids were identical.

A 1L liquid-filled reservoir was placed on a load cell (model LC62SP-6KG, Omega) to track the mass of evacuated fluid during suction. A MATLAB timer was activated when suction started. Simultaneously, a pressure transducer measured vacuum pressure at the suction tube tip. All devices were operated at peak settings for 30 seconds. After the elapsed time, the suction tube was removed, and the experiment reset. Measurements included

time elapsed, initial/final reservoir weight, max. vacuum pressure, liquid volume evacuated, and liquid flowrate.

Each device underwent four tests for each liquid, totaling 36 individual tests. Figure 1 illustrates the experimental setup for liquid flowrate characterization.

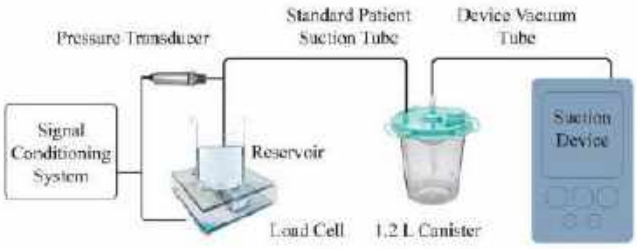

Figure 1: Liquid flowrate test setup

RESULTS

The weight, overall dimensions, and volume of the three devices are shown in Table 1. SCRAMM exhibited a product weight reduction of 29.9% in comparison to its market competitors.

Table 1: Physical properties of the three studied devices

Device	Weight (kg)	Overall Dimensions (cm)	Volume (cm^3)
SCRAMM	3.4	31.5 x 20.5 x 12.5	8071.9
Zoll 330	4.8	31.0 x 23.0 x 11.5	8199.5
Impact 326M	4.9	31.5 x 25.0 x 13.0	10237.5

Liquid flowrates for the three devices across water, blood analog, and vomit simulant with the mean values $\pm$ standard deviation (σ) are illustrated in Figure 2. Specifically, the liquid flowrates for SCRAMM ranged from 4.13 to 1.49 L/min, for Zoll 330 from 6.49 to 2.93 L/min, and for Impact 326M from 6.42 to 2.93 L/min. All devices exceed the ISO 10079-1 standard of 1.2 L/min and the internal specification inferred from AF users of 1 L/min.

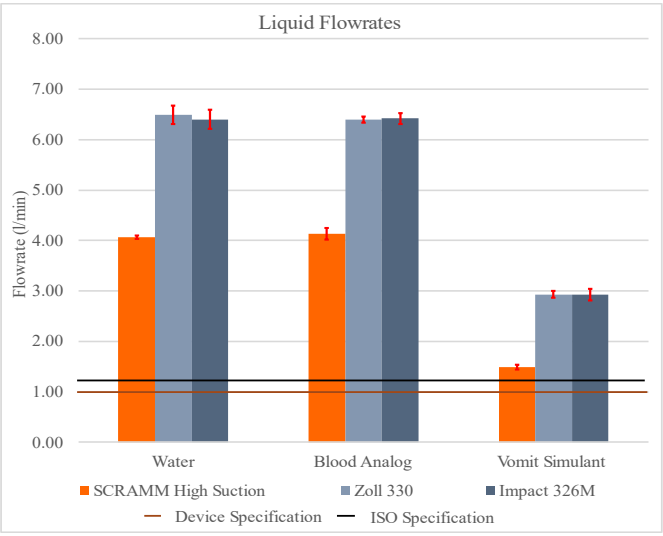

Figure 2: Liquid flowrate results

DISCUSSION

The smaller and lighter SCRAMM unit showed mostly lower flowrate compared to Zoll 330 and Impact 326M, yet still meets the ISO and end-user requirements for oropharyngeal suction. The higher flowrate of the two commercially available devices may be excessive as it is inefficient. Considering the challenges faced by battlefield medics and first responders, who frequently emphasize portability and maneuverability in tough settings, the weight reduction achieved by SCRAMM is especially noteworthy. This reduction fits in with the critical demand for lightweight medical equipment in the field in addition to improving the device's use.

In conclusion, the characterization of liquid flowrates for Impact 326M, Zoll 330, and SCRAMM suction devices highlights improved efficiency of SCRAMM with respect to weight. As future work, further testing will be conducted focusing on characterizing air flowrate, obstruction frequency and noise level during suction for all three devices. Lastly, additional to characterization, end user testing in real and/or simulated environment will be conducted to validate requirements, usability, and standards.

INTRODUCTION

Arterial embolism is a critical global complication that may result in disability and death [1] and occurs when a blood clot becomes lodged in the narrow arterial network. A locally formed clot in an artery or on blood-contacting medical devices may dislodge and travel through the vascular tree, blocking narrower blood vessels. This obstruction can lead to further complications such as myocardial infarctions and stroke [2]. Embolization may depend on the adhesion strength of the clots on the underlying surface. Therefore, this study aims to characterize the adhesion strength of blood clots on endothelial cells and common biocompatible materials using experimental and numerical techniques.

METHODS

Endothelial cells (representing the innermost layer of an artery) and commonly used materials in blood contacting medical devices like Nitinol and Titanium were considered in this study. Human aortic endothelial cells (Millipore Sigma) were passaged on glass slides and grown to confluency (in approximately 3 to 4 days). Material samples of Nitinol and Titanium were cut into 25 mm^2 pieces and cleaned with ethanol to remove any residue.

Clots were created using human blood, following a collection protocol approved by Penn State's institutional review board. Blood was anticoagulated with 0.32% weight sodium citrate. The extracted blood was separated into red blood cells, platelet-rich plasma (PRP), and platelet-poor plasma (PPP) via centrifugation and reconstituted to 214 x 10^6 platelets per mL. Hematocrit was controlled in clots by adding 40% volume of red blood cells to form clots. To counter the effects of the anticoagulant, blood was recalcified with 20 mM calcium chloride ($CaCl_2$) and 0.25 NIH Unit/mL thrombin from human plasma (BioPharm, Bluffdale, UT, USA) to initiate blood coagulation. Recalcified blood (1 mL) was pipetted into cylindrical molds (14 mm diameter), which were placed on the samples. The clots were incubated at 37°C for 1 hour on the endothelial cell layer. Clots were incubated for 30 minutes, 1 hour, and 3 hours on Titanium and Nitinol to evaluate the temporal characteristics of clot adhesion.

Once the clots formed, the samples were removed from molds and attached to the bottom plate of a custom rig on a uniaxial load frame (Instron, Norwood, MA, USA) with a 50 N load cell. A suction pressure of 200 mmHg was applied at the top of the clot to grip the surface. Once the suction was applied, the specimen was loaded at a rate of 10% strain per second (based on sample height) until complete detachment from the sample, where peak stress and strain were recorded. Due to variability in coagulation and clot contraction, Multiple datasets (n = 6) were collected with six replicates (n = 6) from each test.

For the numerical simulation, a Kelvin-Voigt viscoelastic model was applied to the interior of the clot. The clot was assumed to be a circular cylinder of 10 mm in height and 14 mm in diameter, with a mass density of 1080 kg/m^3 [3]. A cohesive zone model, following an Oldroyd-B fluid like behavior, was imposed at the clot-material interface to describe the adhesion [4,5]. A displacement boundary condition is applied at the top surface of the clot using COMSOL Multiphysics (Stockholm, SWE).

RESULTS

The clot adhesion strength was quantified by measuring the stress required to detach the clot from the material surface. Figure 1 shows the distribution of detachment (peak) stress for clots adhered on endothelial cells, Titanium, and Nitinol surfaces. The data showed that incubation time influences the adhesion strength of the clots, and higher adhesion was noticed at longer incubation times for metallic surfaces. A positive correlation between time and detachment stress was observed on the Nitinol surface. On the other hand, a distinct clot adhesive behavior was noticed on the Titanium surface. Statistically, no significant difference was observed in detachment stress data for clots incubated for 30

minutes and 1 hour on the Titanium surface. However, a subsequent significant rise ($p < 0.001$) was observed with further prolonged incubation (3 hours) of the clots. Manivasagam and Popat [6] also reported a similar observation for clotting on non-treated Titanium surfaces. They reported no significant difference in whole blood clotting on the Titanium surface by measuring the plasma-free hemoglobin at 30 minutes and 45 minutes.

At 1 hour of incubation, comparable detachment stress was noticed on Titanium and endothelial cell surface (0.46 ± 0.06 kPa and 0.47 ± 0.20 kPa, respectively). Overall, the strongest adhesion of blood clots was noticed on the Titanium surface with a mean detachment stress of 1.06 ± 0.20 kPa at 3 hours of incubation, which was approximately 42% higher than clots on the Nitinol surface.

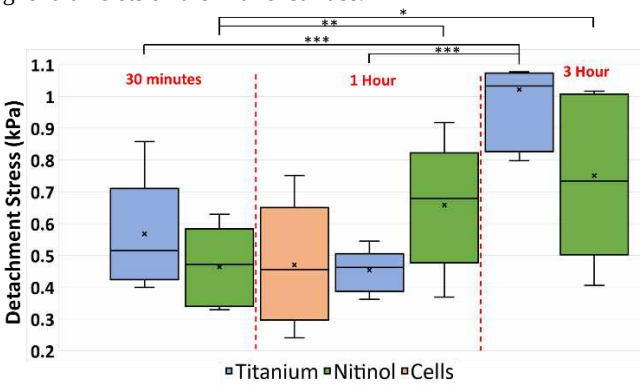

Figure 1: Data showing the distribution of detachment stress for clots attached to different surfaces. Statistical difference is measured in terms of p-value; a lower p-value signifies higher significance. The level of significance difference is represented by an asterisk (*) on the plot, where $p < 0.05$ = *, $p < 0.01$ = ** and $p < 0.001$ = ***.

To characterize clot deformation during detachment, moduli were calculated for clots formed on different surfaces (Figure 2). From the data, it was observed that shorter incubation periods result in lower modulus values. Here, a low modulus value signifies higher axial stretch in the clot. At the same incubation period, clots on endothelial cells undergo higher axial deformation during detachment than those on other materials. Notably, clots on the Titanium surface had higher moduli, were comparatively stable, and exhibited greater stiffness than clots formed on other materials.

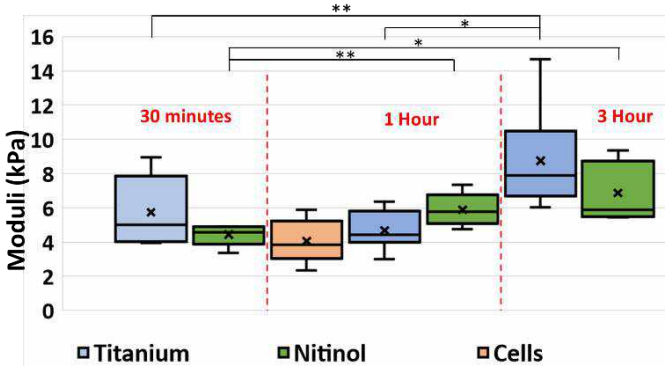

Figure 2: Data showing the distribution of blood clot moduli on Titanium, Nitinol, and endothelial cell layer.

Figure 3 compares the detachment pattern observed in the experimental setup with the viscoelastic simulation framework. From the experimental detachment pattern of clot (Figure 3(a)), it can be observed that the detachment was initiated from the bottom corners and then radiated inward. Further, a non-homogeneous attachment of clots on the surface was observed, leading to irregular detachment (a small clot fragment exhibits prolonged adherence to the substrate compared to the predominant clot mass). Similar detachment initiation is also seen in the displacement contour (in axial-direction) from the simulation prediction (Figure 3(b)).

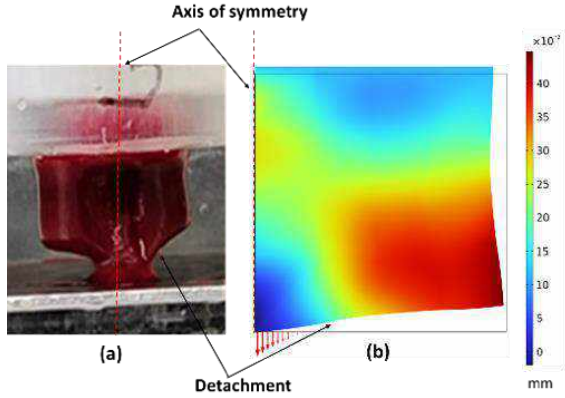

Figure 3: A comparison of clot detachment pattern observed in (a) experimental setup with a (b) Kelvin-Voigt viscoelastic simulation. The axisymmetric center view of a clot detachment simulation with a cohesive zone boundary was taken at t = 0.15 s.

DISCUSSION

The adhesion stress of whole blood clots on different surfaces was quantified. The data showed that clots on the Titanium surface adhered more strongly than other surfaces over time. The characterization of clot deformation in terms of moduli revealed the dynamic nature of its mechanical properties. Clots incubated for a shorter duration showed lower moduli and higher axial strain. In particular, clots on endothelial cells had the lowest moduli than other surfaces. The detachment analysis revealed a non-homogenous clot attachment at the surface, resulting in irregular detachment.

In numerical simulations, the adhesion between the clot and the surface was considered by implementing a cohesive-zone model, exhibiting an Oldroyd-B fluid-like behavior at the interface. The simulations predicted similar detachment patterns as observed in the experiments. Notably, the present simulation framework does not consider the characterization of cohesive zone in relation to material properties. As a future aspect of this work, the cohesive zone model will be tuned with the surface-specific properties. Moreover, in the forthcoming investigations, the temporal behavior of clot adhesion on the endothelial cell layer will also be investigated.

COMPUTATIONAL CONSTRUCTION AND OPTIMIZATION OF A NOVEL TRI-TUBE HEART VALVE DESIGN

J. Li (1), Y. Yu (2), R.T. Tranquillo (2,3)

INTRODUCTION

Tissue-engineered heart valve (TEHV) is a promising strategy to treat cardiovascular diseases by replacing the unfunctional heart valve with a bioprosthetic heart valve made of biological tissues. Our group has developed a novel pediatric tri-tube pulmonary valve that demonstrated growth capability in lambs [1]. Figure 1(a) illustrates the experimental construction of the tri-leaflet valve: three identical tubes were engineered and sutured together to form a closed valve, where tube materials are biologically engineered matrix grown in vitro from donor fibroblasts. However, the optimal design of the valve remains unclear.

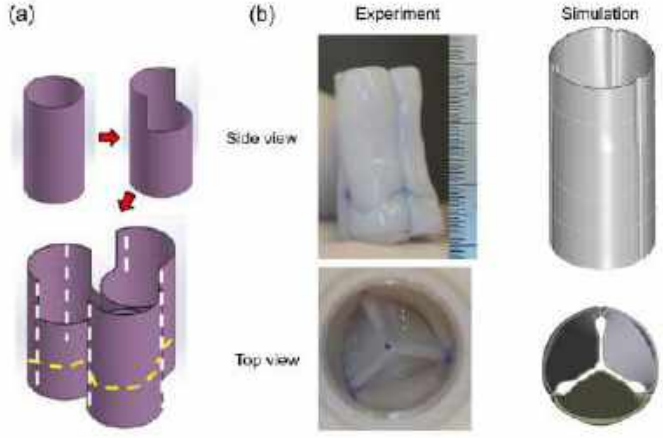

Figure 1: Heart valve conduit consists of three tubes. (a) The schematic of tri-tube constructions [1]. (b) Side and top view of a tri-tube tissue-engineered valve constructed in vitro and in silico.

An ideal design requires proper valve functionality, biocompatibility, and hemocompatibility during the cardiac cycle, which is closely related to the geometric design of the valve [2,3]. To facilitate optimization of the tri-tube valve geometry, we present a robust finite element-based study for in silico construction of the TEHV in Figure 1(a). We aim to identify an optimal design of the tri-tube valve based on the performance in a simulated closure under applied back pressure and gain an understanding of the hemodynamics for the optimal design during a cardiac cycle.

METHODS

In this study, we utilized finite element method (FEM) and optimization techniques to screen multiple valve designs. All simulations and optimization analysis were conducted with ANSYS commercial software.

To construct the valve, we applied an anisotropic hyperelastic material model (AHYPER strain energy law) to account for the highly circumferential alignment of fibers in the tubes and resulting leaflets, mimicking native leaflets [4]. The final geometry of the valve was determined by two design variables of the tube in Figure 2(a): leaflet height H and tube inner diameter D.

Following the experimental procedure in Figure 1(a), each valve was constructed by a two-step construction method using FEM shown in Figure 2(b): three identical engineered tubes were first flattened and then rolled up to form a closed ring. The cut side of each tube was facing inward and fixed to close the tube to form leaflets, mimicking the yellow suture line in Figure 1(a).

The performance of the designed valve was evaluated through a valve closure simulation. A back pressure (Figure 2(c)) ramping up to 1000 Pa (similar to peak pulmonary valve pressure gradient) within 1s was applied on the leaflets and valve wall distal to the leaflets [5]. The goal of the optimization was to identify the design points in the

parameter space of H and D that maximize coaptation area, minimize leaflet pinwheel index, and minimize peak stress, with equal importance placed on each objective.

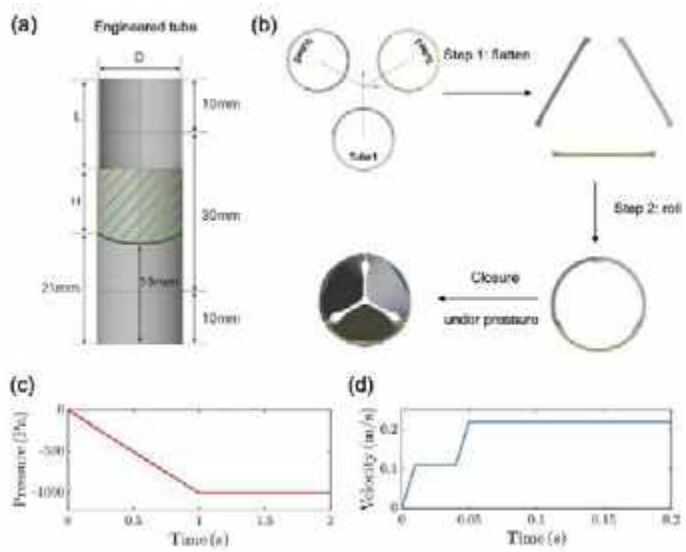

Figure 2: (a) Geometry of an engineered tube used for valve construction. (b) Two-step construction (top view) followed by a valve closure simulation under back pressure. (c) Pressure profile for the closure. (d) Velocity waveform for FSI simulation.

Finally, two-way coupled flow-structure interaction (FSI) simulations were performed for selected optimal designs to examine the hemodynamics. Figure 2(d) shows the velocity waveform for the inlet and the outlet pressure was set to zero. The blood rheology was assumed to be Newtonian. The FSI simulation was done by ANSYS System Coupling with Mechanical and Fluent modules.

RESULTS

Figure 3 presents two design points during the valve closure simulation for comparison. Case 2 indicates a better closure of the valve with a larger coaptation area, while leaflets in Case 1 merely contact that leads to a gap at the center. Case 2 also owns a smaller maximum equivalent stress. Both cases indicate that the peak stress occurred at the commissures.

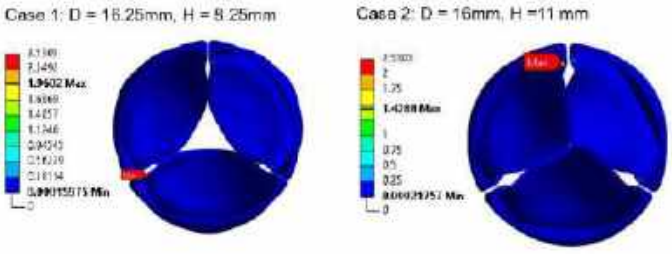

Figure 3: Maximum equivalent stress of two design points during valve closure simulation at t = 1.

Case 2 was further selected to examine the hemodynamics in a steady flow FSI simulation, with the evolution of velocity contour shown in Figure 4. With increasing inlet velocity, leaflets showed evident deformation and were pushed toward wall by the flow. Flow circulations were observed behind the leaflets. The complex fluid-structure interactions and elastic constitutive model also lead to oscillation of leaflets after inlet flow plateaued at t = 0.05s.

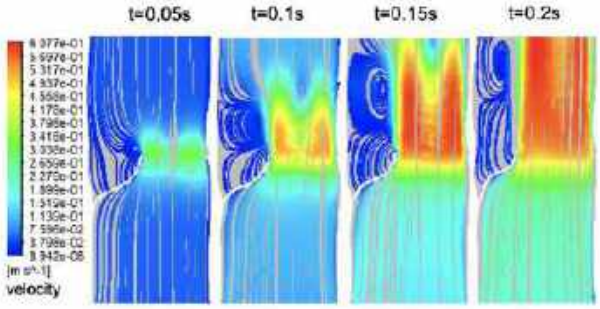

Figure 4: Evolution of velocity contour profile from a selected design point (Case 2 in Figure 3). Snapshots indicate a half slice of the valve, and the white line is a slice of one leaflet.

DISCUSSION

The geometrical design, namely the tube diameter D and the leaflet height H, strongly influences the performance of the tri-tube heart valve during closure simulation. As seen in Figure 3, for two valves with similar tube diameter, the case with larger leaflet height thereby larger leaflet area demonstrated better coaptation under back pressure. This implies a more functional valve that can reduce regurgitation during diastole in a cardiac cycle. Furthermore, lower peak stress in Case 2 is favored because a higher peak stress can lead to tissue failure and valve dysfunction. The following steady flow FSI results also provide more insights into leaflet deformation and hemodynamics, where recirculation behind the leaflet ("washout") is likely important to minimize clotting.

The current study demonstrated an efficient route for the geometrical optimization of a novel tri-tube valve. The in-silico construction and closure simulation largely reduce design variable space and save computation costs to obtain optimal designs for subsequent FSI simulations. Admittedly, important quantities like regurgitation volume cannot be captured in a steady flow simulation. More comprehensive investigation of the full cardiac cycle with pulsatile inlet waveform will be necessary for further optimization of this novel tri-tube valve.

COMPUTATIONAL INSIGHTS ON THE CORRELATION OF MYOFIBER CONTRACTILITY WITH THE DEVELOPED PRESSURE-PRELOAD DYNAMICS IN EX-VIVO BEATING HEARTS

INTRODUCTION

The cardiac developed pressure, governed by the Frank-Starling mechanism, responds to changes in end-diastolic volume (i.e., preload). The pressure increases with increasing preload but reduces when the preload becomes excessive. This phenomenon is reflected at the myocardial level by an increase in twitch force following muscle stretch. At the cellular level, it involves the modulation of the cardiac contractile apparatus's responsiveness to calcium, a key aspect of the Frank-Starling property. Despite extensive studies, the precise correlation from cellular-level to organ-level observations remains unclear, with various theories still unconfirmed.

In this study, we tackle the challenges of experimental research by developing a computational model, inspired by isolated rat heart Langendorff experiments, to explore the underlying mechanisms. Recognizing the gap between organ-level and cellular-level measurements, we employ a finite element (FE) model to bridge these scales. Specifically, we simulate isovolumic heart contractions using a left ventricle (LV) FE model, with material parameters carefully calibrated with measurements from *ex-vivo* Langendorff experiments on rat hearts. The fitting method is performed such that the simulated waveforms closely match the measurements across various preloads. Subsequently, we utilize the model's measurements to determine sarcomere lengths corresponding to each preload, and compare them with existing experimental measurements.

METHODS

Based on the measurements of length, basal inner and outer diameters, and wall thickness of the LV, we constructed a prolate ellipsoid geometry to represent the LV. An LV FE model with myofiber distribution, varying transmurally from -60° at the epicardium to 60° at the endcardium, was developed to simulate the *ex-vivo* beating heart under isovolumic contraction. Following our previous work, e.g. [1], the LV pressures-volumes relationship is obtained by minimizing a functional with components associated with the myocardial tissue strain energy density and the enforcement of constraints on 1) myocardial tissue incompressibility, 2) zero-mean rigid body translation and rotation, and 3) cavity volume. The LV FE model is implemented in FEniCS, a popular open-source computing platform.

Constitutive law of the left ventricular

An active stress formulation was used to describe the mechanical behavior of the LV in the cardiac cycle. In this formulation, the stress tensor $\mathbf{P}$ can be decomposed additively into a passive component $\mathbf{P}_p$ and an active component $\mathbf{P}_a$ (i.e., $\mathbf{P} = \mathbf{P}_p + \mathbf{P}_a$).

The passive stress tensor is defined by $\mathbf{P}_p = \frac{dW}{d\mathbf{F}}$, where $\mathbf{F}$ is the deformation gradient tensor and W is a strain energy function of a Fung-type transversely-isotropic hyperelastic material given by $W = \frac{1}{2}C(e^Q - 1)$ where

$$\begin{aligned} Q =& b_{ff}{E_{ff}}^2 + b_{xx}\left({E_{ss}}^2 + {E_{nn}}^2 + {E_{sn}}^2 + {E_{ns}}^2\right) \\ &+ b_{fx}\left({E_{fn}}^2 + {E_{nf}}^2 + {E_{fs}}^2 + {E_{sf}}^2\right) \end{aligned} \tag{1}$$

where E_{ij} with $(i, j) \in (f, s, n)$ are components of the Green-Lagrange strain tensor $\mathbf{E}$ with f, s, n denoting the myocardial fiber, sheet, and sheet normal directions, respectively. Moreover, material parameters of the passive constitutive model are denoted by $C, Q \propto (b_{ff}, b_{xx}, b_{fx})$.

The active stress $\mathbf{P}_a$ was calculated along the local fiber direction using the active constitutive relationship, where $\mathbf{P}_a \propto T_{max}$, the myocardial contractility.

Results

Isovolumic contraction with different preload corresponding to the experiments is simulated by prescribing a constant LV volume in the model over one cardiac cycle. To calibrate the simulation with experimental data

and subsequently estimate sarcomere length, the following steps are undertaken:

- The measured LV EDPVR (end-diastolic pressure volume relationship) was fitted in the computational model with varying preloads, see Figure 1. Passive parameters C, Q were concurrently calibrated so the model predicted exponential end-diastolic pressure (EDP) matches the measured EDP points using the non-linear least squares fitting technique ($\sum_{\text{preload}} \|EDP_{\text{sim}} - EDP_{\text{exp}}\| < \epsilon$).

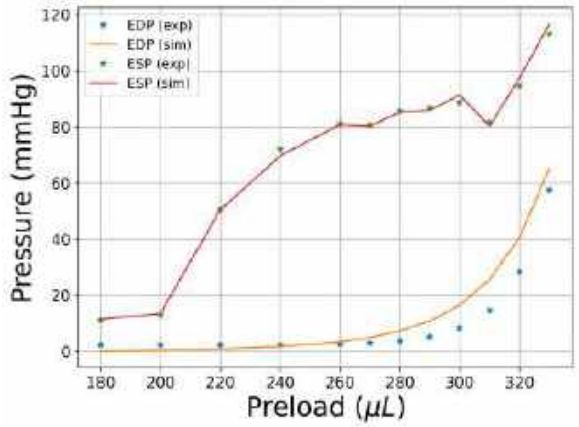

Figure 1: EDP/ESP measurements are indicated by blue/green stars for experimental data (exp) and the orange/red curve for simulations (sim). The passive load shows an exponential behavior, while the ESP is individually tailored to correspond with each preload. The results are depicted from a single rat.

- Unlike passsive parameters, the LV contractility T_{max} was adjusted separately for each preload so that the model predicted LV ESP end-systolic pressure (ESP) agrees with the measured ESP points ($\|ESP_{\text{sim}} - ESP_{\text{exp}}\| < \epsilon$). Consequently, the model predicted LV pressure matches the experimental measurements at different preloads, while T_{max} is varying for each preload. see Figure 1

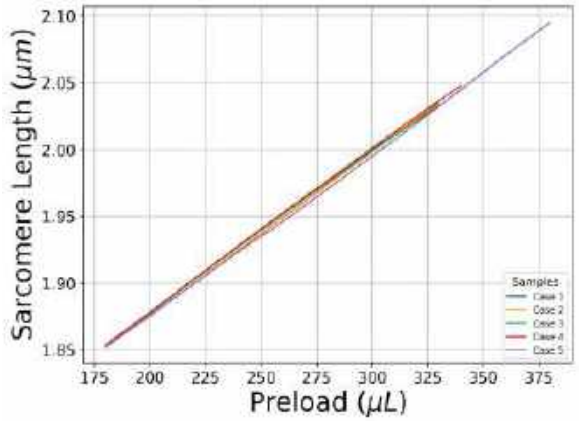

Figure 2: The graph illustrates the relationship between preload and model predicted sarcomere length for five rats.

- After fitting, sarcomere length of the myofiber was computed at different preloads, see Figure 2. The sarcomere length was computed from the fiber strain E_{ff} by the relation $\ell = \ell_0\sqrt{2E_{ff}+1}$ where the sarcomere length in the unloaded reference configuration is prescribed to be 1.85 μm based on previous studies. We note that the mean value of the fiber strain is used to determine the sarcomere length.

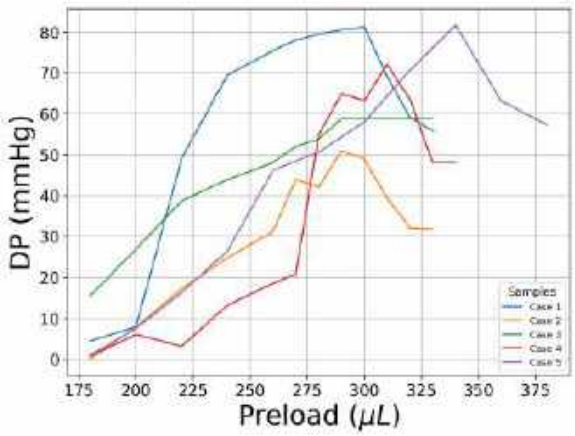

Figure 3: The graph displays developed pressure (DP) as a function of preload for experimental measurements collected from five rats. A non-monotonic trend with peaks occurring at slightly varied locations is observed. Each colored line represents a unique rat case.

DISCUSSION

The overall finding of this study is that the non-monotonic behavior of the developed pressure (DP) with preload is correlated with myocardial contractility, and the transition sarcomere length at which myocardial contractility peaks and starts to reduce is 2.03 μm. This study overcome the challenges associated with measuring the sarcomere length and local active tension in a beating heart. Another study measured that the sarcomere length at the time of peak force is 2.03 from myocardial muscle of rats, which is consistent with our model prediction (mean value of 2.03 μm) [2].

Myocardial contractility (indexed by the active tension) is estimated by fitting the LV FE model prediction with the measured LV pressure waveforms acquired from the hearts at different preloads. We demonstrate that it follows the same behavior as the DP with preload, see Figure 3. The contractility increases first and then start to decrease after the critical balloon volume is reached. This behavior is also similar to the sarcomere-length vs. tension behavior found in isolated myocytes taken from the epicardial muscle of rats [3]. With an increase in sarcomere length from 1.8 μm to 2.2 μm, the active tension increases from 0 to 40 kPa (300 mmHg) at sarcomere length of 2.0 μm and then reduces to 0 μm. Similarly, the model predicted that myocardial contractility increases from a mean value of 20 mmHg at a sarcomere length of 1.85 μm (over 5 rats) to a peak mean value of 150 mmHg at a sarcomere length of 2.03 μm before reducing.

INTRODUCTION

The meniscus is critical for knee joint stability and load distribution. Unfortunately, its limited endogenous cell-mediated repair capacity means that meniscus injuries often fail to heal in adults [1]. Given the superior repair capacity of juvenile meniscus tissues, understanding their initial formation and specialization mechanisms during embryonic development may provide insights that could be harnessed for tissue regeneration in the adult. Our group previously examined the embryonic formation and postnatal maturation of the murine meniscus, revealing that its region-specific matrix composition and cellular phenotypes are established prenatally [2-3]. Furthermore, we showed that mechanical forces that arise from muscle loading and cellular contraction are essential for meniscus formation and specialization [4], while reduced postnatal weightbearing has little effect on meniscus morphology and micromechanics [5]. While these studies provide critical insight to the mechanoregulation of meniscus morphogenesis, translatability of the murine model is limited by its small size and mechanical and morphological distinctions relative to humans. To overcome these limitations, the goal of the present study was to establish a more translationally relevant model of meniscus development using the Yorkshire pig. Here, we established the timeline for key events in knee joint formation in early gestation (28-45 days after fertilization, E28-45) and evaluated matrix micromechanics and emergent mechanoresponsivity of meniscus cells in pigs from early gestation (E45), mid-gestation (E84), and newborn (P1) stages.

METHODS

Timed pregnancies and embryo collection. Adult female Yorkshire pigs were artificially inseminated at the National Swine Research Center (NSRRC, Columbia, MO). Pregnancy was confirmed via ultrasound, and sows were euthanized on embryonic day 45 or 84, or on postnatal day 1. Micromechanics. Freshly dissected left knee joints were embedded in OCT and cryo-sectioned into 10µm coronal sections. AFM nanoindentation was performed in 1X PBS using polystyrene microspherical tips (Ø25µm, k~0.6N/m) at ≥10 different locations within the inner and outer meniscus per specimen. The effective indentation modulus (E_{ind}) was calculated from the finite thickness-corrected Hertz model [3]. Histology. Left hindlimbs were fixed in 4% paraformaldehyde, embedded in paraffin, and sectioned to 5µm (sagittal and coronal orientations). Cellularity and proteoglycan distribution were assessed from Safranin O/Fast Green staining. Cell isolation. Menisci from the right hindlimbs were identified and isolated under a dissecting microscope. At E84 and P0, menisci were segmented into inner and outer regions. All tissues were minced into ~1mm^3 pieces and cultured in basal medium (DMEM, 10% FBS, 1% anti-anti) to allow for cell egress from the tissue fragments. Mechanoresponse assay. Isolated cells were cultured on fibronectin-coated polyacrylamide (PA) hydrogels (5 or 55kPa) or glass for one day in basal medium. Cells were fixed and stained for YAP (AF-488), actin (phalloidin AF-555), and nuclei (Hoechst 33342, excitation 350nm). Imaging. Confocal z-stack images were obtained at 10X magnification and processed in Cell Profiler to quantify cell area and YAP localization. Statistical analyses: Differences between groups were assessed via two-way ANOVA, with significance level at multiple comparison-corrected α=0.05.

RESULTS

Histological assessments of hindlimb development across early gestation timepoints (E28-42) were used to establish the timing of knee joint formation in the Yorkshire pig. Skeletal rudiments were apparent at E28, as indicated by cartilaginous condensations at the prospective femur and tibia locations (**Fig. 1a**).

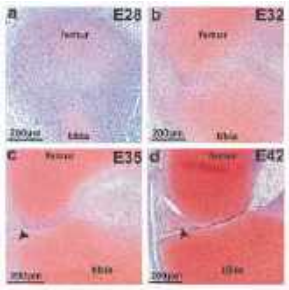

Fig. 1: Knee joint formation during early embryonic development in the pig.

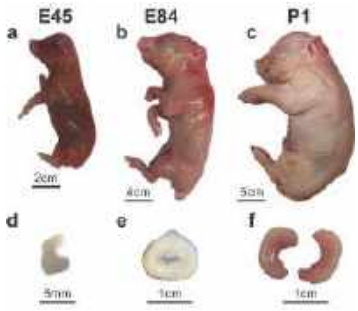

Fig. 2: Gross anatomy (a-c) and isolated menisci (d-f) from embryonic and newborn pigs.

The future joint line was established by E32 (**Fig. 1b**), and primitive menisci were visible, but not yet separated from the adjacent cartilaginous structures at E35 (**Fig. 1c**, arrowhead). The menisci were fully formed and separated from the articular cartilage at E42 (**Fig. 1d**, arrowhead). Subsequent tissue and cellular analyses were performed from E45 onwards, at which point the menisci were readily isolated (**Fig. 2**). Safranin O/fast green staining of menisci from these later timepoints showed that regional matrix specification, namely, proteoglycan enrichment within the inner meniscus, was evident in these tissues (**Fig. 3**).

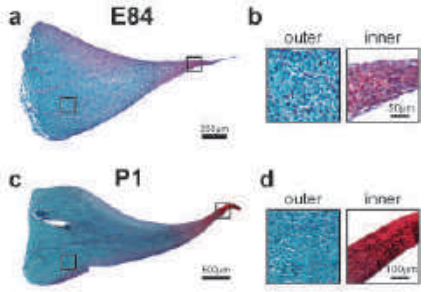

Fig. 3: Regional specification is apparent in the developing pig menisci.

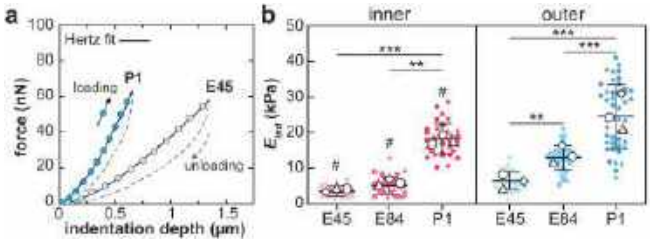

Fig. 4: a) Representative indentation force vs. depth curves for early embryonic and newborn outer meniscus. b) Nanoindentation moduli (E_{ind}) of inner (left) and outer (right) meniscus increase throughout gestation (p<0.001, ***p<0.0001), and E_{ind} of the inner region was less than that of the outer region (#p<0.05). For each animal (n=3), ≥10 indentation locations were tested in each region. White points represent the average E_{ind} from one animal, and colored points of the same shape correspond to multiple indentations from the same animal.**

AFM nanoindentation revealed rapid stiffening of the meniscus primitive matrix throughout gestation (**Fig. 4**) The microscale modulus of the outer zone was significantly greater than the inner zone at all three timepoints (#p<0.03). In the inner meniscus, E_{ind} increased from 3.5±1.4 kPa (mean±SD) at E42 to 18.2±4.3 kPa at P1, while E_{ind} of the outer meniscus increased from 6.5±2.5 kPa to 26.1±8.0 kPa. Together with our histological observations, these data indicate that the inner and outer meniscus develop distinct compositional and mechanical microenvironments early in prenatal development that undergo continued specialization through the end of gestation, and these changes appear to initiate earlier in the outer zone.

Meniscus progenitor cells migrated from isolated meniscus segments onto tissue culture polystyrene over 5-7 days (**Fig. 5**). These cells were allowed to proliferate for an additional 7-10 days, then were passaged and seeded onto PA hydrogels or glass slides. Meniscus progenitors isolated at all three gestational timepoints exhibited increased mechanoactivation (*i.e.,* greater cell area and increased YAP nuclear localization) with increasing substrate stiffness (**Fig. 5**). Interestingly, P1 outer zone cells exhibited higher YAP nuclear localization than P1 inner zone or E42 cells, even on soft substrates.

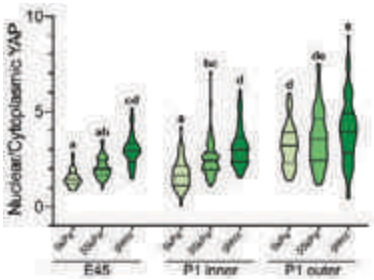

Fig. 5: YAP nuclear:cytoplasmic ratio on substrates of different stiffnesses. Groups not sharing a common letter are significantly different (p<0.05).

DISCUSSION

In the present work, we begin to establish a detailed, multiscale timeline of the coordinated morphological and mechanobiological changes that govern knee joint development in a translationally relevant porcine model. Consistent with prior investigations in the mouse [4-6], we show that meniscus formation and knee joint cavitation proceed rapidly following skeletal rudiment condensation and establishment of the interzone at the prospective joint line. Histological and micromechanical assessments revealed that microenvironmental distinctions between the proteoglycan-rich inner meniscus and type I collagen-rich outer meniscus are apparent as early as E45 in the pig. At this point, embryos and hindlimbs are sufficiently large to allow meniscal tissue isolation with the aid of a dissection microscope. The differing regional matrix composition and micromechanics at this timepoint suggests resident cell identity and matrix synthesis are determined early in embryonic development. Furthermore, cells from E45 exhibited a characteristic mechanosensitive response (*e.g.,* increased cell spreading as a function of substrate stiffness, indicating that resident meniscal cells are able to sense and respond to their mechanical microenvironment as soon as cavitation is complete. Interestingly, P1 outer zone cells showed a distinct mechanoresponse from P1 inner zone and E45 cells, wherein nuclear YAP localization was greater on all substrate stiffnesses, suggesting exposure to a stiffer microenvironment *in vivo* may enhance mechanosensitivity.

Future work will continue probing the phenotypic and mechanosensitive attributes of the developing meniscus, for example, by examining the heterogeneity of these cells and the matrix they synthesize via single cell RNAseq and immunohistochemistry, to establish the spatiotemporal characteristics of meniscus specialization throughout development. By uncovering the mechanisms by which emergent meniscus cells respond to biophysical cues to establish a mature, functional meniscus in the pig, we aim to shed light on mechanobiologic mechanisms that could be harnessed for injury repair and regeneration in adult fibrous tissues.

INTRODUCTION

Experimental modeling and computational simulation have been critical in better understanding cardiovascular diseases and conditions. These tools helped with greatly improving different clinical aspects of cardiovascular health, including the diagnosis, pathogenesis, and treatment of cardiovascular diseases [1, 2, 3, 4, 5, 6, 7]. To truly leverage the power of computational fluid dynamics (CFD), patient specific simulations can lead the way towards cardiac treatment that is tailored to the physiological characteristics of each patient [8]. Patient-specific geometry can be obtained from computed tomography (CT) or Magnetic Resonance (MR) images, and the boundary conditions (BC) for the simulations can be acquired through echocardiography (ECHO) or 4D MR images [9, 10, 11, 12]. However, a reliable classification and better risk stratification require an accurate representation of the hemodynamic conditions. Therefore, as the heart is a dynamic organ, the phase of the cardiac cycle that is chosen for the extraction of geometry and BCs used will dictate a significant part of the flow [13]. Moreover, another issue that is often faced for this kind of study is the incompleteness or lack of patient data. For example, the availability of single-phase CT data instead of multi-phase CT would force the choice of the geometry. The objective of this study is to investigate the impact that the choice of geometry extracted from the CT and the choice of BCs have on the hemodynamics of the left atrium (LA).

METHODS

Multi-phase CT, ECHO, and invasive pressure data from the LA of a patient received from Mayo Clinic under an Institutional Review Boards (IRB) and a data usage agreement (DUA) protocol, were used to perform this study. From the ECHO data, velocity profiles at the mitral valve (MV) and the four pulmonary veins (PV) were extracted. From the CT images, the geometry of the LA was extracted at the E-wave and at the end of diastole. The segmentation and editing of the geometry were done using Mimics Research and 3-matic (Materialise, Belgium). To determine the E-wave and end-diastolic phases, all phases of the CT data were segmented, and the volume of the left ventricle for every phase was recorded to select the E-wave and the end diastole phases as shown in **Fig.1**.

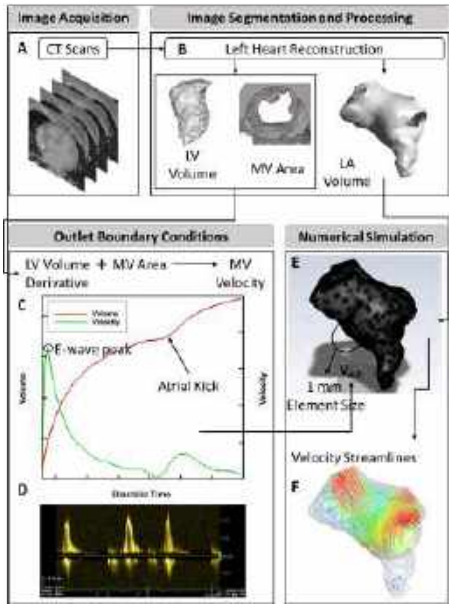

Fig 1. Methodology Pipeline

Each of the two 3D digital models were imported into Ansys Workbench 2020. Then, an extension that is 10 times the diameter of the vessel was added to each PV ostium and to the MV to overcome any entrance effects [14]. A polyhedral mesh of 1 mm element size was

applied to both models, in accordance with the mesh independence study conducted in a previous work [4]. The blood flow was considered to be laminar (Reynolds number < 2000). Each model was simulated with 3 different sets of boundary conditions (BCs):
- BC 1: The velocity profile at the MV was used as the outlet BC while the pressure at the PVs was sent to be constant at 0 Pa [4, 15].
- BC 2: The velocity profiles for the PVs were used as inlet BCs and the mean pressure at the MV was set as outlet BC.
- BC 3: The velocity profiles for the PVs were used as the inlet BC, and 0 pressure was imposed at the MV.

All the simulations were run for 3 cardiac cycles, and all results were extracted from the third cycle [14, 15]. The resulting data from these simulations were LA velocities and the Wall Shear Stress values along its wall. Also, the Time Averaged Wall Shear Stress (TAWSS), Oscillatory Shear Index (OSI), and Relative Resident Time (RRT) were computed [16]. Low TAWSS, high OSI and high RRT Values are associated with the formation of thrombus [17].

RESULTS

EFFECT OF BCs: The velocity at the E-wave and at the end-diastolic phase of the cardiac cycle were extracted and compared as shown in the probability density function (PDF) distribution in **Fig.2**. BC 1 seems to have higher E-wave velocities than BC 2 and BC 3 for both geometries. There does not seem to be any notable differences between BC 2 and BC 3.

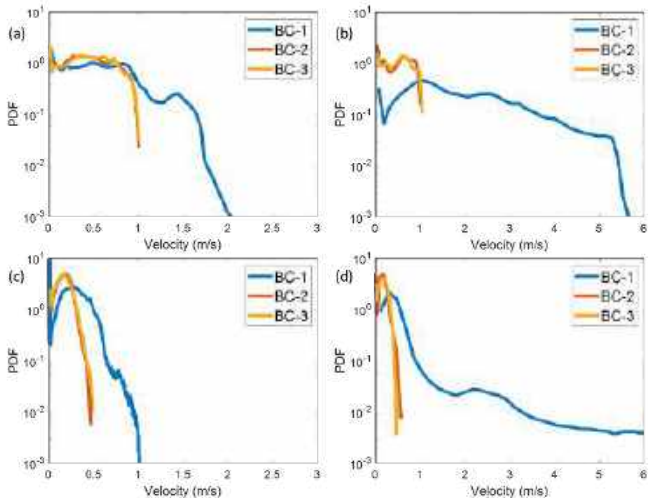

Fig 2. PDF (a) at E-Wave with E-Wave Geometry, (b) at E-Wave with End-Diastole Geometry, (c) at End-Diastole with E-Wave Geometry, and (d) at End-Diastole with End-Diastole Geometry.

The TAWSS contours are presented in **Fig.3** and **Fig.4** for E-wave and end-diastole, respectively. For the E-wave geometry, higher TAWSS were observed for BC 1 compared with BC 2 and BC 3, which appear similar. This was also observed, more prominently, for the end-diastolic geometry. OSI was also extracted and compared. For both geometries, slight differences were shown between the three BCs with an average value that seemed to be close across the BCs. The RRT also seemed to show some differences between the three BCs, especially between BC 1 and the other two. For E-wave geometry, the average value of RRT for BC 1 was slightly lower than those for BC 2 and BC 3. This trend was present more significantly for the end-diastolic geometry.

EFFECT OF GEOMETRY: From **Fig.2**, we notice that the velocity magnitudes, at both phases, seem higher for the end-diastolic geometry than the E-wave geometry when simulated with BC 1.

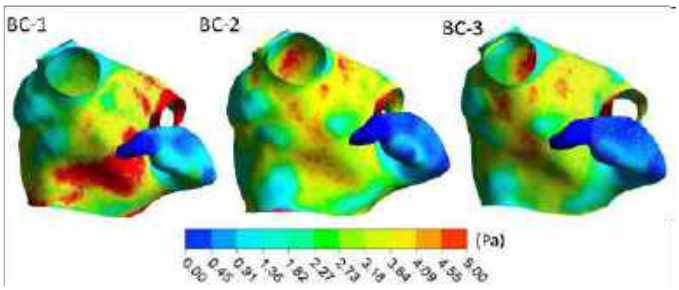

Fig 3. TAWSS Contours with E-Wave Geometry

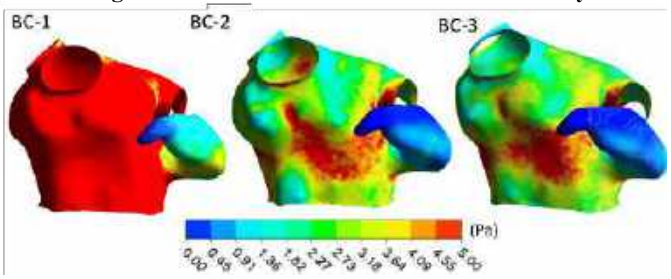

Fig 4. TAWSS Contours with End-Diastole Geometry

However, no notable difference is observed between the two geometries when simulated with BC 2 and BC 3. The velocity and TAWSS distribution for the end-diastolic geometry seemed to have larger values than that for the E-wave geometry when simulated with BC 1. That is still true when simulated with BC 2 and BC 3, but to a much lesser extent. There were some differences in the OSI between E-wave and end-diastolic geometry under all the simulated BCs despite having the average OSI close for both geometries under the 3 different BCs. The RRT indicated a prominent decrease in RRT values for the end-diastolic geometry compared to the E-wave geometry when simulated with BC 1. This is further confirmed as the average RRT value for the end-diastolic geometry was less than that for the E-wave geometry under BC 1. The decrease in RRT was less pronounced with BC 2 and BC 3.

DISCUSSION

The results of this study show how utilizing different types of BCs and geometries can impact the outcomes of patient-specific simulations. Segmentation of the LA at end-diastole led to the occurrence of higher velocities, higher TAWSS, and lower RRT values as compared to the segmentation at the E-Wave. The discrepancy in the results for different BCs highlights the difficulty in obtaining numerical thresholds for parameters and indices when attempting to classify patients for risks of cardiovascular diseases. This highlights the importance of consistency in choosing the appropriate cardiac phase and BCs in future studies.

STRAIN-BASED CELLULAR INJURY THRESHOLDS IN A 3D IN VITRO MODEL OF TRAUMATIC BRAIN INJURY

J. Park (1), A. Daul (1), J. Zhang (1), C. Franck (1)

(1) Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

INTRODUCTION

Traumatic brain injury (TBI) affects over 55 million people worldwide, with both immediate and long-term disabilities as a result. However, the exact mechanism of injury remains unclear [1]. Moderate to severe blunt impact injuries can cause immediate hemorrhaging or contusion, which can be diagnosed using imaging modalities such as MRI. But what about damage that occurs over time? Secondary injury is characterized by cell death that occurs via cellular signaling pathways over a delayed time span after injury. These are more insidious, as a cell does not need to physically rupture to undergo apoptosis. Consequently, diagnosis and prediction of secondary injury after a TBI has remained extremely challenging. Thus, current patient-level evaluation strategies continue to rely on symptom-based reporting, which is highly variable between patients and difficult to standardize [2]. Having a cellular injury threshold, defined as the average strain at which a cell will die, would allow for significant advances in diagnostic and preventive measures for TBI. Here, we present a methodology for determining a cellular injury threshold curve in rat cortical neural cells as a function of sex, cell phenotype, strain magnitude and strain rate.

METHODS

Cortical cells from postnatal day P0-P1 Sprague-Dawley rat pups are dissected and seeded in 3D dog-bone shaped scaffolds made from type-I rat tail collagen. After 7 days in vitro (7 DIV), cells are stained with Calcein AM, a live cell indicator and imaged using multiphoton microscopy with a 20x water immersion objective. Following imaging, samples are stretched in uniaxial tension using a custom on-scope device that utilizes two linear actuators to deliver a controlled impact at programmed strain magnitudes and strain rates (Figure 1). Cells are then returned to the incubator. 24 hours after impact, cells are re-stained with Calcein AM, as well as stained with Hoechst and Ethidium Homodimer-1 (EthD-1), a nuclear stain to streamline analysis, and a dead-cell indicator, respectively, and imaged at the same location as the pre-impact image as shown in the purple box in Figure 2.

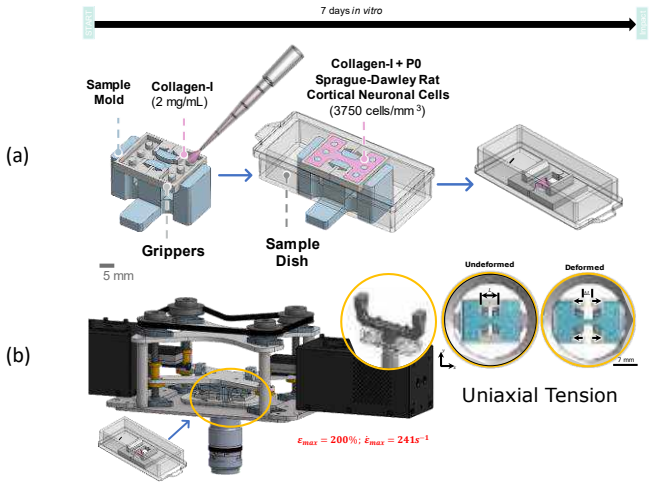

Figure 1:
(a) Dogbone-Shaped, Collagen-I Cell Culture System
(b) On-Scope Impact Device for Controlled Uniaxial Tension

Concurrently, more samples are stained with Calcein AM and imaged following the protocols of a negative control sample. Immediately after imaging, samples are then fixed with 4% paraformaldehyde and sucrose, immunostained for cell phenotype, and imaged at the same location as the live image as shown in the blue box in Figure 2. Both the live image and the immunostained image are then fed into an unsupervised machine learning algorithm to identify cells based on morphology alone.

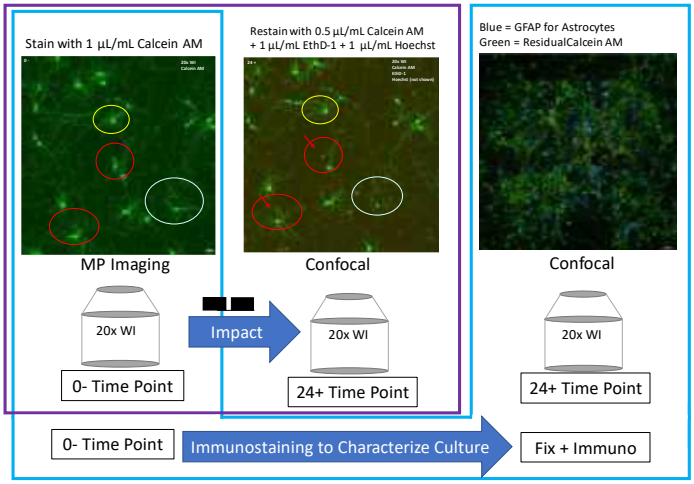

Figure 2: Image Acquisition Workflow

Analysis of acquired images is done following established protocols and processing codes [4]. Images are preprocessed to filter noise, apply gamma correction, and threshold the background to allow for semi-automatic tracing of neurons using a rayburst algorithm based on local image intensity distribution. Traced neurons are then converted to a tree structure in MATLAB. The far field strain, which is well characterized using previously established methods [4,5], is then transformed and mapped onto the local cell structures, represented as the trees in MATLAB. This is done by rotating the far-field strain tensor via a rotation matrix defined by an orthonormal discrete Frenet frame. The average strain experienced by the cell is then associated with whether the cell live or die after impact and is used as a point on the critical injury threshold curve.

RESULTS

We develop a replicable and consistent methodology for applying controlled, measurable uniaxial tension to 3D collagen gels with embedded cortical cells. Furthermore, minor adaptations to a previously established protocol of analysis enable the identification and parsing of strains on individual cells within the scaffold while maintaining a physiologically relevant culture density. The stained live cell image is traced in NeuronStudio, yielding a traced network of cells, output in the form of a SWC file. The SWC file is then used as an input to a machine-learning based algorithm G-Cut, which segments cells, assigning branches to individual cells. These individually tagged cells are then run through the strain-mapping MATLAB code to output a single cell with mapped strains along the branches, mean shear, mean compressive and mean tensile strains across the cell, and branch orientation data (Figure 3).

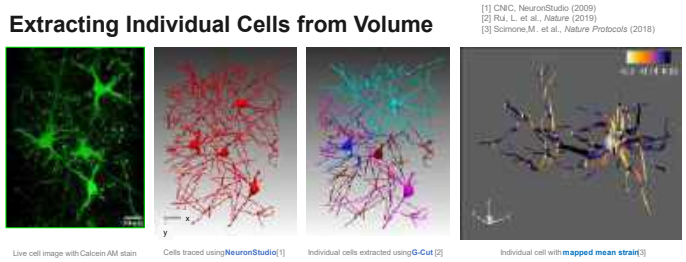

Figure 3: Extracting Individual Cells from Image Volumes using Cell Tracing and Segmentation Software

Preliminary results indicate that cells characterized by having long projections along the x or y orientations exhibited cell death after 24 hours. Conversely, cells with shorter projections did not demonstrate cell death despite experiencing comparable strain magnitudes in both tension and compression. These observations pertain to impacts that occurred at 50 strains/second with a far-field strain magnitude of 30%. Average tension and compression were decoupled as the average tensile values were significantly attenuated by negative values from compression. Furthermore, we develop a methodology for identification of cell phenotypes using a machine learning algorithm that is trained on our datasets (Figure 4).

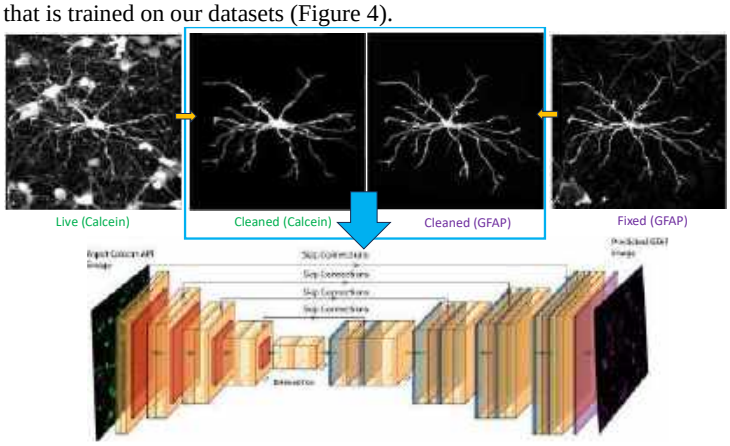

Figure 4: Training Machine Learning to Identify Cell Phenotypes

DISCUSSION

Preliminary results suggest that cell morphology significantly influences cell survival in response to impacts at comparable strain rates and magnitudes, particularly at the cellular level. Comprehensive analysis of factors such as cell phenotype, cell projection length and direction, and other physiological factors are necessary to build a robust and accurate strain injury curve. Next steps include application of our developed methodologies to collect data towards building a secondary injury curve and determining critical injury threshold.

The creation of a secondary injury curve, in combination with existing FE models of the brain and analyses of impact mechanics, will provide enormous potential for development of new predictive injury metrics, diagnostic criteria, and design of protective equipment to prevent not just primary injury but also secondary injury and the enduring consequences associated with it.

SEX DIFFERENCES IN PLACENTA VILLOUS STRUCTURE IN LOW- AND HIGH-RISK PREGNANCIES

INTRODUCTION

Fetal Growth Restriction (FGR) affects 5–10% of all pregnancies and is the leading cause of perinatal mortality [1]. FGR is most often defined as an estimated fetal weight of less than the 10th percentile for a given gestational age and occurs when the placenta is insufficient to sustain the oxygen and nutrient needs of the growing fetus. Efficient exchange of nutrients and oxygen occurs through the vasculature of the placenta, particularly in the microvasculature of the villous tissue, where the vascular membranes have a high surface area and are the thinnest [2]. Since the placenta is fetal tissue, placental efficiency can depend on fetal sex [3]. Although literature reports alterations in villous structure with FGR [4], how the villous structure changes with fetal sex remains largely underexplored. Furthermore, male fetuses are 20% more likely to experience worse outcomes in complicated pregnancies than female fetuses, demonstrating the impact of fetal sex [3]. To understand how fetal outcomes vary based on sex, literature focuses on changes in gene, steroid, and protein expression in the placenta, but whether these alterations lead to structural and functional changes is unknown [3]. Understanding sex-based differences in the placenta villous tissue may elucidate reasons for sex differences in fetal outcomes. Therefore, the objective of this study was to determine the extent fetal sex influences the multiscale changes in the villous structure of the placenta.

METHODS

Ultrasound Imaging and Placenta Collection: Patients were recruited and imaged with Doppler ultrasound under an IRB approved protocol. All patients were imaged at two gestation time points between 28-32 weeks (second trimester) and 34-38 weeks (third trimester) of gestation (Fig. 1A). The pulsatility index (PI) of blood flow in the intervillous space was measured with Doppler ultrasound. Placenta villous biopsies from a total of 12 patients were collected for analysis. Out of the 12 patients, six patients were diagnosed with FGR and six patients were considered low-risk controls. Within each case and control group, three pregnancies had a male fetal sex and three pregnancies had a female fetal sex. **Optical Clearing & Imaging:** Placenta villous biopsies collected from each patient were optically cleared with Visikol Histo-1 [5]. Using optical coherence tomography (OCT), a minimum of eight 3-dimensional images of each placenta biopsy were acquired (cubes 2 mm on a side). **3D Villi Structure Analysis:** OCT images were segmented and volume reconstructed to calculate the volume fraction, surface area, and the number of branches per cubic millimeter using a custom MATLAB code. **Statistics:** A linear mixed effect model with a type II sum of squares ANOVA was used and p-values were adjusted for multiple comparisons using the Tukey method.

RESULTS

Comparison of PI values of the intervillous blood flow in placentas from FGR and low-risk control pregnancies were not significantly different in the second or third trimester. However, when plotting the measured PI values versus the gestational age at the time of imaging, we found that the PI of the intervillous space decreased throughout gestation, but there was no decreasing trend with FGR patients (Fig. 1B). By performing a linear regression analysis, we found that the slope of the best-fit

line for the control patients was negative and was significantly different than zero ($p = 0.004$, $R^2 = 0.573$). The best-fit line for the FGR patient data did not have a slope significantly different than zero and had an R^2 value of 0.007. When comparing the PI measurements in pregnancies with male fetal sex compared to female fetal sex, no significant differences were observed.

Using OCT, the 3D architecture of the villous tissue was imaged to determine the extent villous structural changes were influenced by fetal sex (Fig. 2). The surface area increased significantly in FGR pregnancies compared to controls for both female and male fetuses. The villous tissue surface area of FGR placentas from female fetuses was not significantly different from control placentas from male fetuses (Fig. 2D). While the volume fraction of the villous tissue in placentas from male fetuses increased with FGR, the volume fraction did not significantly increase in placentas from female fetuses (Fig. 2E). The quantified number of branches per cubic millimeter did not significantly increase with FGR compared to male and female controls respectively. However, the number of branches in FGR placentas of male fetuses is greater than the number of branches in control pregnancies of female fetuses (Fig. 2F).

DISCUSSION

Our results demonstrate microscopic changes in the villous tissue of placentas from female versus male fetuses suggesting there may be sex differences resulting in altered oxygen and nutrient transport. However, we did not observe sex differences with macroscopic blood flow measurements in the intervillous space, suggesting these ultrasound measurements may not be sensitive enough to detect microvascular changes. Although the literature suggests that surface area decreases with FGR [4],

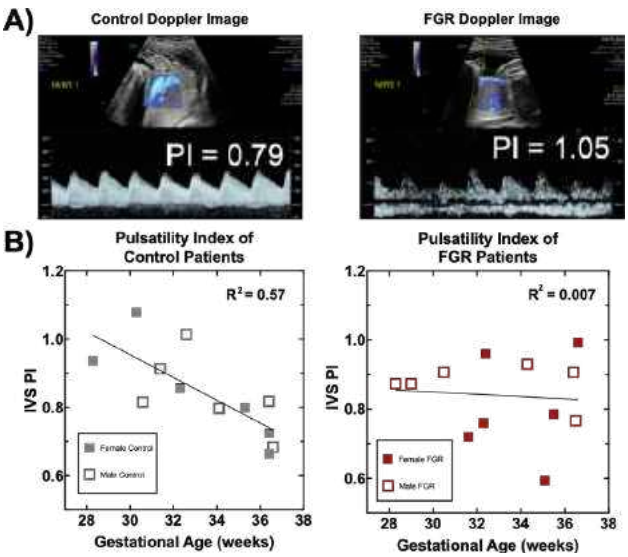

Figure 1: The pulsatility index (PI) of the intervillous (IVS) blood flow decreased throughout gestation for low-risk pregnancies, but not with fetal growth restriction (FGR) pregnancies. A) The PI in the intervillous space of control patients and patients with FGR was measured with Doppler Ultrasound. B) Linear regression analysis demonstrated that the IVS PI decreased throughout gestation only for control patients, but not for FGR patients.

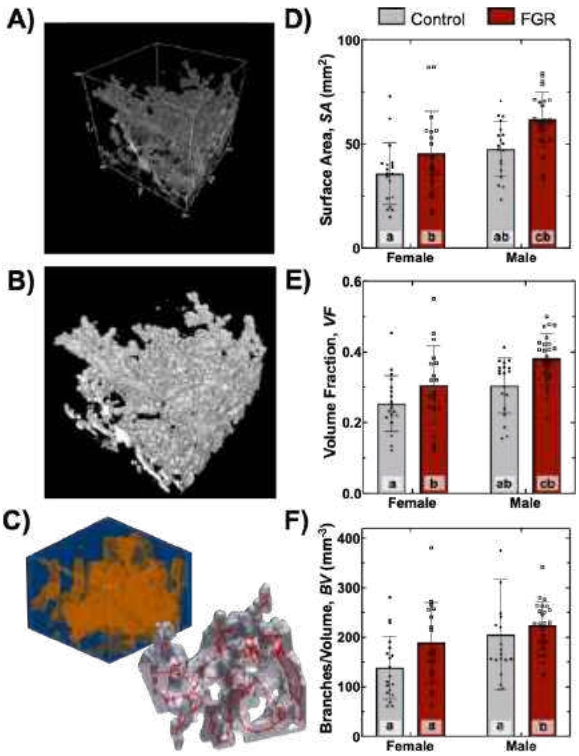

Figure 2: Microscopic changes in surface area, volume fraction, and number of branches per cubic millimeter differed with fetal sex. A) Placenta villous biopsies were imaged with optical coherence tomography (OCT) and B) 3D reconstructed to C) quantify the surface area, volume fraction, and number of branches. D) Fetal sex influenced changes in surface area, E) volume fraction, and F) branching in placentas of patients with and without FGR. ±standard deviation, different letters indicate statistical significance ($p<0.05$)

these results may be contradictory to expectations because our analysis was completed from 3D structures rather than more routinely used 2D histology slides. Interestingly, with surface area and volume fraction, the response was greater in placentas with male fetuses. This observation may help explain why fetal outcomes are typically worse for male fetuses with pregnancy complications. Future work will develop computational models of oxygen transport in the villous structures to understand how sex-dependent changes in villous structure lead to changes in placenta function. Overall, understanding how fetal outcomes are influenced by sex differences will help to better predict and prevent pregnancy complications.

THE IMPORTANCE OF THE LEFT ATRIAL APPENDAGE ON THE FLOW IN THE ATRIUM

INTRODUCTION

The Left Atrial (LA) Appendage (LAA) is a projection from the left atrium that is believed to be a location for the development of thrombus in patients with atrial fibrillation (AF) [1, 2]. Due to having more distensibility than the main body of the left atrium, it is believed that the LAA acts as a decompression chamber to alleviate pressure buildup in the left atrium and handle an overload of blood volume [3]. The embolism of thrombi from the LAA can lead to an ischemic stroke if the thrombus is carried into the cerebral arteries. Since the role of the LAA is not well-established, the solution for avoiding thromboembolism in AF patients has been the exclusion or occlusion of the LAA [3]. However, possible complications can arise after an LAA exclusion procedure, which include procedure-related stroke, device embolization, and device-related thrombus (DRT) after LAA occlusion (LAAO). This may cast doubt on the effectiveness of excluding the LAA as a therapeutic measure. This study aims to assess the role of the LAA on the flow in the LA. To this end, we used patients who underwent an LAAO procedure and compared the flow dynamics in the LA before and after LAAO to isolate any potential role of the LAA.

METHODS

In this study, we obtained clinical data for 6 patients who underwent an LAAO procedure with Watchman or Amulet devices from Mayo Clinic, Copenhagen University Medical Center, and the Aarhus University Hospital. The obtained data included computed tomography (CT) images and doppler echocardiography data both before and after the LAAO procedure. The segmentation of the left atria was performed using Mimics Research 24.0 and 3-Matic 16.0 (Materialise, Belgium) from the CT images of the 6 patients pre- LAAO to generate 3D digital models. The geometry was extracted at the E-wave while conserving the saddle shape of the mitral valve by using a spline function in Mimics, as previously done by Vogl et al [4]. Finite element simulations were performed by FEops (Ghent, Belgium) to deploy an LAAO device into the LA model that would match the clinical deployment seen in the CT images. This allowed for mimicking the geometry of the LA post-deployment, resulting in 6 post-LAAO 3D digital models. The CFD simulations for each of the 6 patients, pre- and post- LAAO, were conducted in Ansys Workbench 2020. The 3D digital models were imported, and extensions were added at the boundaries of the LA to ensure that the flow was fully developed and to overcome any entrance effects. The boundary conditions (BC) were adopted from echocardiographic data including

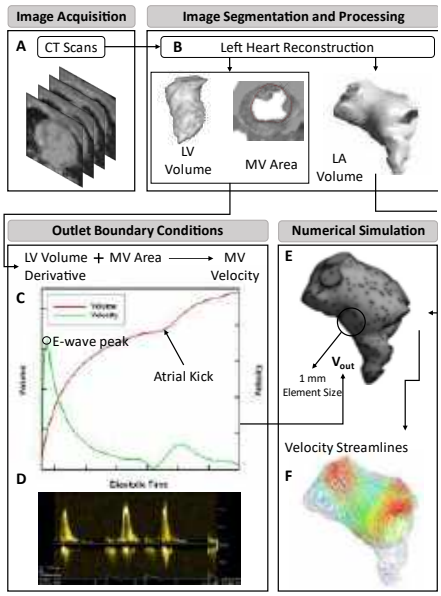

Fig 1. Methodology Workflow

the velocity at the mitral valve for each patient. An element size of 1 mm was chosen for the polyhedral mesh adopted in these simulations based on a previously done mesh independence study [4]. Transient simulations were performed for 3 cardiac cycles each, and the data from the last cycle was used in our analysis [5, 6]. **Fig.1** presents the discussed workflow. From the CFD simulations, we obtained the velocity distribution in the left atrium and the Wall Shear Stress (WSS) distribution along the atrium wall. Using the WSS data, the Time Averaged Wall Shear Stress (TAWSS; EQ1), Oscillatory Shear Index (OSI; EQ2), and Relative Residence Time (RRT; EQ3) were calculated using the below equations:

$$TAWSS = \int_0^T |WSS| \, dt \quad \text{(EQ1)}$$

$$OSI = \frac{1}{2}\left(1 - \frac{\left|\int_0^T WSS \, dt\right|}{TAWSS}\right) \quad \text{(EQ2)}$$

$$RRT = \frac{1}{(1-2 \times OSI) \times TAWSS} \quad \text{(EQ3)}$$

RESULTS

The obtained streamlines and contours for two of the patients are shown in **Fig.2** and **Fig.3**. Velocity streamlines were generated at the E-Wave for both pre- and post- LAAO. This showed a slight decrease in velocity for patient 1, but no appreciable change in patient 2. To better quantify the results, the velocity values were exported and the velocity frequency for each model was plotted. Velocity magnitudes pre- and post- LAAO were close for patient 2, but patient 1 exhibited a difference of 0.6 m/s at low frequencies, where the elevated velocities were more frequent post-LAAO, as well as a different distribution of maximum velocity (**Fig.4**). The TAWSS and OSI contours showed a consistency in the distribution of TAWSS between pre- and post-LAAO. The average value of TAWSS across the LA and across all 6 patients decreased from 2.54 ± 2.61 to 1.36 ± 1.03 post-LAAO ($p < 0.05$). The average value of OSI across the LA and across all 6 patients increased slightly between pre- and post-LAAO (0.16 ± 0.11 and 0.18 ± 0.10, respectively, $p < 0.05$). The RRT contours show a more widespread distribution of elevated RRT post-LAAO. The average value of RRT across the LA and across all patients has increased from 1.57 ± 1.74 to 1.99 ± 1.77 post- LAAO ($p < 0.05$). The two patients also exhibited an elevated pressure post-LAAO.

DISCUSSION

Generally, a decrease in TAWSS was observed post-LAAO. This means that despite occluding the LAA, which is clearly a site of low TAWSS pre-LAAO, the average value of TAWSS decreased in the main body of the atrium. This is perhaps due to an elevated pressure inside the body of the LA due to the loss of its distensible decompression chamber. Previous studies showed that an increase in pressure can lead to an increased intima-media thickness (IMT), which in turn is associated with low WSS, so perhaps a similar mechanism is occurring in the LA [7]. The shear stress imposed by the blood flow on Endothelial cells promotes certain intracellular biochemical signals [7]. It was shown that low TAWSS promotes the expression of vasoconstrictor endothelin-1 (ET-1), which in turn activates the expression of adhesion molecules that initiate thrombus formation [9]. The average decrease in TAWSS pre- and post- LAAO explains the increase in RRT despite a relatively consistent OSI average. The results of this study show that the exclusion/occlusion of the LAA may have adverse effects on the hemodynamics of the LA in the long run, possibly enhancing risks of thrombogenesis (including DRT) and consequently thromboembolic events. More patient data is needed to confirm these findings and long-term follow-ups are needed to have a comprehensive understanding of the LAA removal effects.

A BIOMECHANICAL EVALUATION OF TWO INTERNAL FIXATION METHODS WITH DIFFERENT SCREW DIRECTIONS FOR CAPITELLUM FRACTURES

Hui Zhang, Justin E. Hellwinkel, Kiran J. Agarwal-Harding, Thomas R. Gardner, Susanne M. Roberts

Department of Orthopedic Surgery, Columbia University, New York, New York, USA

INTRODUCTION

The capitellum of the humerus articulates with the radius of the forearm, playing an important role in the forearm's pronation and supination. Fractures of the capitellum are commonly treated with internal fixation, which uses headless compression screws to restore the elbow's native anatomy and stability. Nevertheless, fixation of distal humerus factures remains a clinical challenge when the fracture does not heal anatomically, which can cause serious issues such as long-term pain and disability. The failure is dependent on many factors, including bone density, angle of the fracture plane, screw orientation and trajectory, etc. So far, very few studies have studied the effect of screw orientation on failure fixation.

In this study, we used two internal repair methods with different screw orientations, parallel and non-parallel, and compared their fixation stability. Computerized tomography (CT) scans of fracture patients were used to define the fracture plane.

The objectives were three-fold: 1) to characterize capitellum fractures from patients' CT data; 2) to define two screw orientations from the literature and retrospective case review; 3) to evaluate and compare the stability of the two screw orientations through mechanical testing. Specifically, the average characteristics of capitellum fracture obtained from CT were used to simulate the fractures on biomimetic sawbones first, and then two internal repairs were performed, and lastly cyclic compression was used to evaluate the fixation results. We hypothesized that the non-parallel screw orientation would provide better fixation stability than the parallel orientation in terms of higher ending peak force and larger number of loading cycles.

METHODS

To characterize the fracture, CT images of 11 female patients were used (age 51.8±24.2 years; BMI 27.3±11.7 kg/m^2) with IRB approval. Each humerus with its capitellum fragment was 3-D reconstructed (Figure 1A), and a plane was best-fitted to the fracture edge. To minimize measurement error attributed to misalignment between anatomical planes of the elbow to the corresponding CT planes, a set of local anatomical planes (sagittal, coronal, and transverse) for the humerus were constructed (Figure 1B). The orientation of the fracture plane was quantified by the distance between the most lateral point on the lateral epicondyle and the best-fitting plane (defined by point-to-plane distance), and by three plane-to-plane angles. The average for the 11 patients of the point-to-plane distance and the plane-to-plane angles defined the cutting plane to simulate the capitellum fracture (Figure 1C).

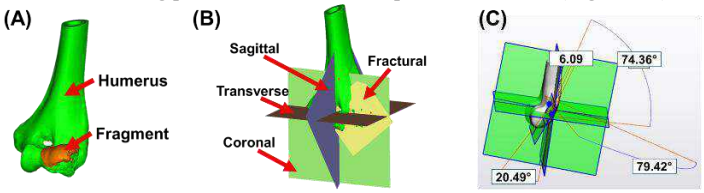

Figure 1: Illustration of (A) reconstructed humerus and fragment from a patient, (B) local anatomical planes (sagittal, coronal, and transverse) and fractural plane, (C) simulated fracture plane on the 3D-scanned biomimetic humerus with plane-to-plane angles of 79.4° (fracture-sagittal), 74.4° (fracture-transverse), 20.6° (fracture-coronal), and 6.1 mm (location).

Capitellar fracture was simulated on 21 biomimetic humeri (Model #3404, Sawbones, Vashon, WA, USA), using a custom-designed, 3D-printed jig. Both methods inserted the screws from the lateral ridge of the capitellum. The paralleled screw orientation was defined as 30˚ off the anteroposterior direction to simulate the clinical setting and to assure the entire screw body embedded in the humerus, whereas the non-parallel method inserted the two screws angled towards the olecranon fossa in diverging directions (Figure 2A). The surgeon secured the jig onto the humerus with K-wires (Figure 2B), and used the slots designed

in the jig to create the fracture plane between the humerus and capitellum with a sagittal saw (blade thickness: 0.38 mm). Afterwards, the surgeon chose randomly between the two sets of screw trajectories in the jig to insert K-wires for directional guidance. The surgeon pre-drilled and inserted the cannulated screws into the sawbones to reattach the capitellum fragment to the humerus. The parallel method was used to repair 10 biomimetic humeri, and non-parallel method was used to repair 11 humeri.

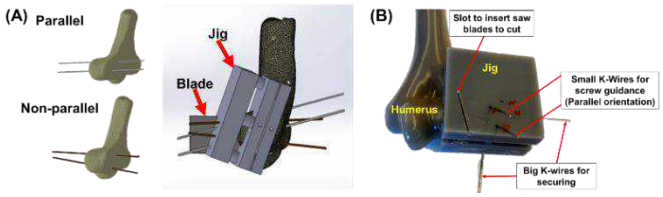

Figure 2: (A) Illustration of the screw orientation of the two repair methods (left) and of the cutting jig mounted on the biomimetic humerus ready for fracture simulation (right). (B) Photograph of a biomimetic humerus with the jig mounted on and with K-wire inserted for parallel-orientation repair.

For mechanical testing, each humerus was cut and potted in a square aluminum cylinder using expansion cement, then mounted in the testing platform (Figure 3), with the angle between the humerus axis and the loading direction of 20 degrees (20-degree flexion, at which maximum load was transmitted through the capitellum [1]). Sinusoidal loads were applied to the fragment, starting with a base of 10 N and peak of 75 N. The amplitude of the load was increased by 75 N every 10,000 cycles until reaching 600 N (total 80,000 cycles) or until clinical failure (defined as the subsidence of the fragment reached 2 mm), whichever came first.

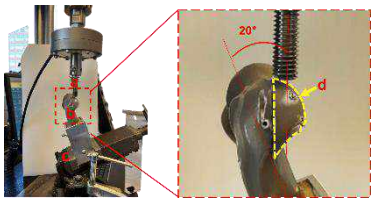

Figure 3: Photograph (left) of testing setup with a closer view (right) of the loading tip and the repaired fragment. (a) Actuator. (b) Potted specimen. (c) Base clamp. (d) Capitellum fragment.

For statistical analysis, maximum applied load, number of cycles, and amount of applied work required to reach clinical failure were analyzed using a Student's t-test to determine if differences existed between the two repair methods. The level of significance was set at $p \leq 0.05$.

RESULTS

The angle between the fracture and sagittal planes, between the fracture and coronal planes, and between the fracture and transverse planes was 79.4±9.0, 20.6±12.2, 74.4±10.8 degrees, respectively (Figure 1C). The distance between the most lateral point on the lateral epicondyle and the fractural plane was 6.1±2.4 mm.

The maximum peak force in the sinusoidal loading until clinical failure for the parallel method was 450.0±106.1 N and 375.0±94.9 N ($p<0.05$) for the non-parallel method. Similarly, the number of cycles reaching clinical failure for was 53,801±16,654 cycles, which was greater than 42,346±14,141 cycles for the parallel method ($p<0.05$). The amount of work applied to the fragment for the parallel method was 330.0±246.5 N·m, and the work for the non-parallel was 287.5±240.3 N·m. There was no significant difference in the amount of work between the two methods ($p = 0.267$).

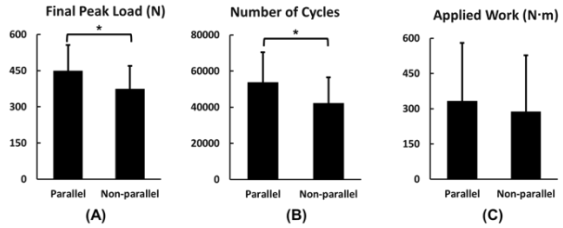

Figure 4: (A) Maximum peak force in sinusoidal loading until clinical failure for each method. (B) Number of cycles. (C) The amount of work applied to the fragment. *p<0.05

DISCUSSION

In this study, we used data from actual patients to simulate the capitellum fracture in biomimetic humeri that were subsequently repaired by one of two internal fixation methods. We found that the method with parallel screw orientation demonstrated better stability than that with non-parallel orientation, in terms of higher final peak force of cyclic loading and larger number of cycle numbers.

The result is opposite to our expectation. Initially, we believed the non-parallel method might be more robust, by embedding the screws using the strongest portion of the humerus i.e. olecranon fossa. The better performance of the parallel method may be explained because the screws, due to their parallel orientation, share the applied load from the actuator. This is in contrast to the screws with non-parallel orientation which resist the load unevenly, with the more superior screw initially absorbing the brunt of the load and exhibiting initial failure, with the load then shifting to the inferior screw.

Compared to a previous study [2], our samples underwent higher force levels (375.0±94.9 N for our Method 2 vs 151.9±52.5 N for their best group) and similar load cycles (42,346±14,141 cycles vs 43,944±21,652 cycles). The high force level may be attributable to the apparently stronger biomimetic humeri used as compared to the cadaveric humeri (from old donors used in [2]). The similar number of load cycle numbers for different humeri maybe be attributable to the application of different clinical failure criteria: subsidence of 2 mm by for this study and 3 mm by their study.

The study has some limitations. First, the sample size of the patients used to generate a representative pattern for capitellar fractures was small. Second, our study is most applicable for younger patients with health bone who are prone to this injury, but the results may be different for the elderly population with decreasing bone density. One advantage of this study is the use of a carefully defined and repeatable fracture plane based on actual patients. Another strength of the study is the use of biomimetic humeri instead of cadaveric humeri to minimize variability due to age, sex, density and geometry.

Therefore, the use of a parallel screw orientation provides a more mechanically robust method of fixation for shear fractures of the capitellum compared to a diverging orientation with purchase in the olecranon fossa. The ability of the capitellum to withstand axial load after internal fixation is paramount to a successful outcome and optimization of fixation constructs may allow earlier range of motion and weight bearing for these patients.

ACKNOWLEDGEMENTS

The study was funded in part by the Orthopaedic Scientific Research Foundation (OSRF 21_006). We also acknowledge Stryker for donating the screws for the project

ESTIMATION OF FLOW RATES FROM CLINICAL PRESSURE MEASUREMENTS FOR INDIVIDUALIZED CFD OF CEREBRAL VENOUS STENOTIC DISEASE

INTRODUCTION

There is increasing interest from clinicians to understand cerebral veins hemodynamically, e.g., transverse sinus (TS) stenosis can cause debilitating symptoms of pulsatile tinnitus (PT) and idiopathic intracranial hypertension (IIH) [1]. Computational fluid dynamics (CFD) can provide insight into the underlying flow instabilities [2]; however, it is not without its challenges [3]. Current clinical workflows for assessing these patients relies solely on computed tomography venograms (CTV) and intra-arterial angiography, which provide anatomical information, and invasive pressure-measurements, which provide some functional information, but leaving CFD engineers without patient-specific flowrates. Unlike cerebral arteries, for which vessel diameters adapt to flow rates in a way that can be used to estimate the latter from the former, low-pressure cerebral venous drainage networks can vary markedly from patient-to-patient, and there is no apparent relationship between vein diameter and flow rate [4].

The primary objective of this study was to develop and employ a simplified Bernoulli method for back-calculating an individual's flow rate from available routine clinical angiography and manometry, and use this to determine the impact of using generic flow rates for venous CFD. A secondary objective was to use CFD to determine how well the Bernoulli-estimated pressure drops agreed with those from the full Navier-Stokes equations.

METHODS

Patient selection: This study included 10 patients with unilateral PT attributed to a moderate to severe ipsilateral TS stenosis, who had undergone endovascular stenting at Toronto's St. Michael's Hospital. Institutional review board approval was obtained for access to the anonymized and de-identified medical records and images. Cases were selected to span a wide range of focal pressure drops obtained during the procedure (see **Table 1**).

Lumen segmentation: CTV datasets were segmented semi-automatically using the seed-driven, gradient-based segmentation algorithm in ITK-SNAP. Intra-arterial angiographic images were used to further guide removal of small cortical veins and smoothing of the surface using MeshMixer. The Vascular Modelling ToolKit was used to remesh and improve the quality of the surface triangulations for subsequent CFD volume meshing.

Flow rate estimation: We simplified Bernoulli's equation along a streamline by assuming centerline stenotic pressure drops are driven primarily by inertial effects, and stenotic velocities are high enough for upstream velocities to be neglected. Exploiting conservation of mass, the following simple formula was derived for cycle-average flow rate:

$$Q = \frac{K}{A_s}\sqrt{\frac{2\Delta p}{\rho}} \quad (1)$$

where Δp is the clinically-measured cycle-average stenotic pressure drop; A_s is the minimum stenosis cross-section area, derived from the CTV segmentation; and ρ is the blood density, assumed to be 1057 kg/m^3. The constant K reflects the assumed velocity profile shape, and can range theoretically from 1 (turbulent/plug) to 2 (laminar/parabolic). Considering that venous Reynolds numbers are O(10^2), we assumed K=1.5 (i.e., halfway between those extremes), which was done prior to performing any CFD calculations so as not be biased by them.

Computational fluid dynamics: The segmented lumens were clipped at the superior sagittal sinus (SSS) inlet proximal to the torcula, and at the internal jugular vein outlets. Fully developed pulsatile flow was imposed at the SSS (and straight sinus, if present, using an 80:20 flow split [5]) by scaling a representative venous waveform [2] by Q. Simulations were performed using a high-fidelity CFD solver and meshing strategy detailed in [6]. Meshes averaged ~4 million tetrahedral and boundary layer elements, with an average ~12,000 time-steps per cardiac cycle to satisfy CFL conditions. Each case was simulated using both the individual Q calculated from Eq. 1. and a generic flowrate of Q=335 mL/min corresponding to average flow in left/right TS [2].

CFD pressure drops were calculated from planes placed at the inlet and stenosis (I-S) to align with the Bernoulli assumptions, as well as from planes proximal and distal to the stenosis (P-D) to reflect the clinical measurement locations. Pressure values were obtained from the point of maximum velocity on the respective planes. Spectral power index (SPI) was calculated from the CFD wall shear stress data, to visualize areas experiencing flow instabilities above 25 Hz [7].

Table 1: Clinical and CFD-derived quantities for the N-10 cases (flow rates in mL/min, pressure drops in mmHg)

Case	Area Stenosis	Clinical Δp	Individual Q	Individual Δp *I-S*	Individual Δp *P-D*	Generic Δp *I-S*	Generic Δp *P-D*
A	83%	3	224	2.75	2.67	5.66	5.39
B	68%	5	491	4.44	3.84	2.26	2.01
C	88%	19	301	18.7	15.9	25.2	23.0
D*	94% 85%	6	320	5.88 6.07	4.72	4.69 6.37	4.75

F	46%	3	479	3.05	1.81	1.72	1.03
G	80%	4	312	3.63	3.18	4.37	3.48
H	72%	5	270	4.99	4.16	7.42	6.88
I	84%	9	324	9.50	8.14	10.0	8.59
J	80%	11	280	11.7	9.87	17.4	14.1

**For fenestrated case, area stenosis and Δp (I-S) are shown for each channel.*

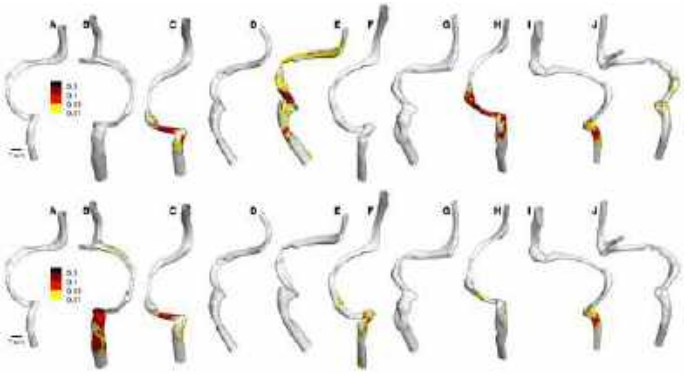

Figure 1: SPI maps of flow instabilities for the N=10 cases, using generic (top) and individual (bottom) flow rates for high-fidelity CFD. Flow direction is top to bottom.

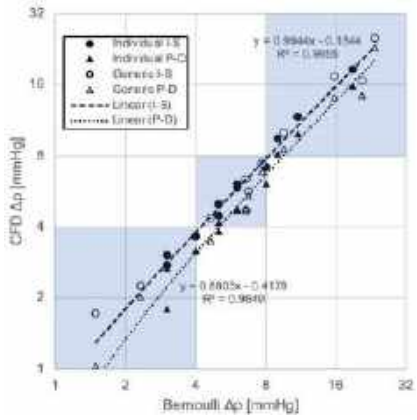

Figure 2: Bernoulli-estimated vs. CFD pressure drops from inlet to stenosis (I-S) and proximal to distal (P-D) to stenosis. Note the log scale of the axes. High sensitivity and specificity are evident from all data points falling within (shaded) clinical categories of low (<4), moderate (4-8), and high (>8) mmHg pressure drop.

RESULTS

Table 1 demonstrates the range of stenosis severities and pressure drops for our cohort, also making it clear that there is no obvious relationship between the two, and hence emphasizing the confounding role of flow rate. Bernoulli-derived Q differed significantly from the generic flow assumption of Q=335 mL/min, with differences of up to 47%. CFD-derived pressures also differed significantly for individual vs. generic simulations, by up to 97%. SPI maps shown in **Figure 1** further demonstrate that the intensity and extent of flow instabilities was not well predicted by the generic flow rates, with apparent differences in all cases expect A, D, G and I.

Table 1 also shows that the pressure drops predicted by CFD using the Bernoulli-derived individual flow rates were remarkably similar to the clinical pressure drops from which the individual flow rates were derived. This is more clearly shown in **Figure 2**, where Bernoulli pressure drops were in near perfect agreement with CFD (I-S) predictions. Regression using the proximal-distal (P-D) data suggests an average pressure recovery (not captured by Bernoulli) of 12%, but with minimal impact on clinical categorization.

DISCUSSION

Our results suggest that individual flowrates have a non-negligible effect on patient specific CFD modelling of venous stenotic flow disturbances. While we have not yet validated the predicted flow rates, we note that they all fall within recently-reported normative values [5]. The near-perfect agreement between CFD and Bernoulli I-S pressure drops confirms our assumption that inertial effects dominate. Minor differences between CFD I-S and P-D pressure drops confirm there is minimal pressure recovery distal to the stenosis. We also note that our Bernoulli formula predicted a 70:30 flow split for fenestrated case D, which was in excellent agreement with the 69:31 actual flow split from CFD. That our educated guess of K=1.5 was reasonable is evidenced by actual values of K=1.42±0.07 from CFD data at the stenosis planes.

An important and exciting corollary of our study is that, given minimum cross-section area and flowrates from, say, MRI, one could readily estimate pressure-drops, providing valuable information to clinicians looking to assess them *non-invasively*. A recent attempt to do so relied on complex post-processing of 4D flow MRI data [8], and while shown to be accurate against invasive manometry, even the editorial introducing this study conceded that the imaging and processing are still too cumbersome from routine clinic use [9].

Our approach is inherently limited to cases with at least mild focal stenoses, or tandem stenoses with limited pressure recovery (e.g., Case J), so is not intended to completely replace cerebral venous manometry. Rather, we believe it shows promise as a *clinically effective* solution for retrospectively estimating (unknown) flow rates *and* prospectively estimating pressure drops in patients with clinically suspect stenoses.

NON-NEWTONIAN EFFECTS ON SINUS FLOW AFTER AORTIC VALVE REPLACEMENT

A. Bshennaty (1), B. Vogl (1), Z. Zhang (1), A. Sularz (2), B. Lee (1), M. Alkhouli (2) and H. Hatoum (1,3)

INTRODUCTION

Aortic Stenosis (AS) is a major complication that affects 5 to 10% of older adults and carries significant health risks [1]. Surgical aortic valve replacement (SAVR) and minimally invasive transcatheter aortic valve replacement (TAVR) are the standard treatments for patients with severe AS [2]. However, both procedures are associated with adverse outcomes such as thrombosis and calcification that can lead to degradation and increase the risk of stroke in case of thrombus embolization [3].

The relationship between hemostasis and thrombus formation has long been established [4]. In-vitro experimental work has been an asset for better understanding blood stasis in the aortic sinus in correlation with thrombosis and calcification [5]. Most of the experimental work often uses saline or water and glycerin mixtures as blood analogs, which fail to capture the non-Newtonian viscoelastic properties of blood. This non-Newtonian behavior is especially important in small vessels and cavities such as the sinus, where blood is subjected to lower shear rates due to recirculation and flow reversal.

This study aims to experimentally investigate the impact of the non-Newtonian properties of blood on flow stasis in the sinus.

METHODS

Two mixtures were considered for the non-Newtonian blood analog, one containing water and xanthan gum (a natural polysaccharide) and another containing water, glycerin, and xanthan gum. The first solution was prepared by adding 0.0375% by weight of xanthan gum to distilled water [6]. The second solution was prepared by adding 37.6% by weight glycerin and 200 ppm xanthan gum to distilled water [7]. The 2 samples were analyzed using a Discovery Hybrid Rheometer (TA Instruments, New Castle, DE, USA) and measurements were recorded for shear rate values between 0 and 300 s^{-1}. Each test for each sample was repeated 3 times. The resulting shear stress and viscosity values were averaged and plotted against the shear rate for all samples. The data was compared with rheological data of whole blood from previous studies by Cherry et al. and Brooks et al. [8, 9].

To test the flow dynamics in the sinus after AVR, we deployed 2 valves (a 25mm Edwards surgical Magna and a 23mm transcatheter Edwards SAPIEN 3 Ultra) in a left heart simulator. Our flow loop is comprised of a reservoir with a valve, representing the left atrium and mitral valve, a bladder pump, representing the left ventricle, and an acrylic chamber, representing the aortic root, in which the bioprosthetic valves were deployed. A LabVIEW code controls a compressed air line which contracts and expands the pump. A compliance chamber and a gate valve were added to emulate arterial compliance and control the flow rate, respectively. The temperature of the solution was set and maintained at 37°C. The cardiac output was 5 L/min under a pressure of 120/80 mmHg. Rhodamine B particles were seeded to perform particle image velocimetry (PIV). A Single Cavity Diode Pumped Solid State, High Repetition Rate Laser (Photonic Industries, NY, USA) was used to illuminate the particles in a plane along the center of the sinus. A high-speed CMOS camera (Photron, Inc) captured time-resolved and phase-locked images of the flow in the sinus at the rate of 4000 frames per second. The images were then run through a multi-pass cross-correlation PIV algorithm to compute the displacement of the particles and their velocities. By post-processing the data, the vorticities and shear stresses were computed.

RESULTS

It was found that the rheology of the non-Newtonian solution comprised of water, glycerin, and xanthan gum was most consistent with that of whole blood (**Fig.1**) compared with different references in literature [8, 9], and this solution was prepared for the PIV experiment.

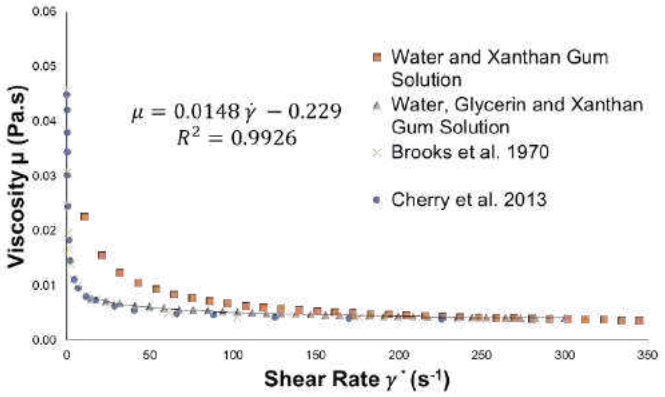

Fig 1. Viscosity vs. Shear Rate plots of the different solutions and comparisons with whole blood from different references [8, 9].

Fig.2 and **Fig.3** show the different phases of the cardiac cycle, namely at peak systole, deceleration, and diastole. For the experiments run using

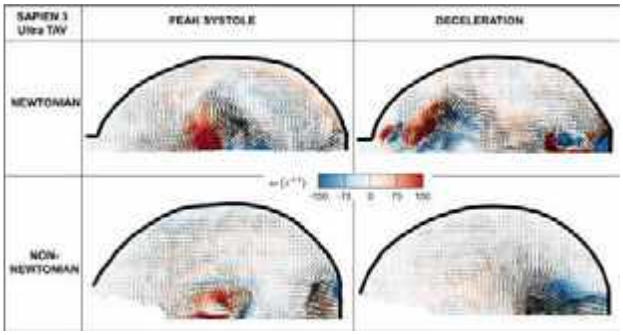

Fig 2. Peak Systole and Deceleration Frames for the SAPIEN 3 Ultra Experiments with Vorticity Contours

the SAPIEN 3 Ultra, there were significant differences in the sinus flow at each of the selected frames. At peak systole, the Newtonian solution exhibited a counterclockwise (CCW) vortex with velocities in the sinus that are higher than those exhibited by the non-Newtonian solution. At

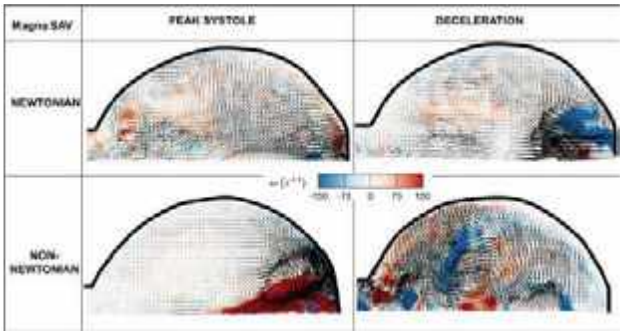

Fig 3. Peak Systole and Deceleration Frames for the Magna Experiments with Vorticity Contours

Deceleration, the interaction of the CCW flow with the returning flow led to high vorticity in the sinus for the Newtonian solution compared to the reverse flow with lower vorticity that was observed for the non-Newtonian solution. Differences in the flow at each frame were also observed for the experiments using the Magna 25mm valve. At peak systole, the non-Newtonian solution led to more elevated vorticity compared with the Newtonian solution. In addition, the location of the CCW vortex was different. At Deceleration, the Newtonian solution had one clockwise vortex by the end of the sinus while the non-Newtonian solution had several vortices. In order to better quantify the results, the

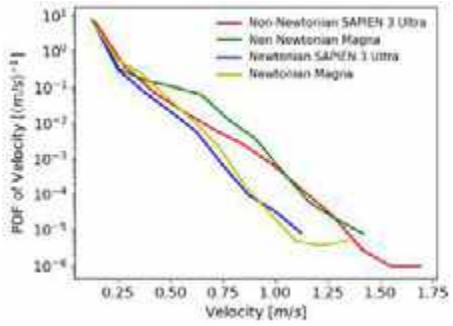

Fig 4. PDF of sinus velocities with the different solutions.

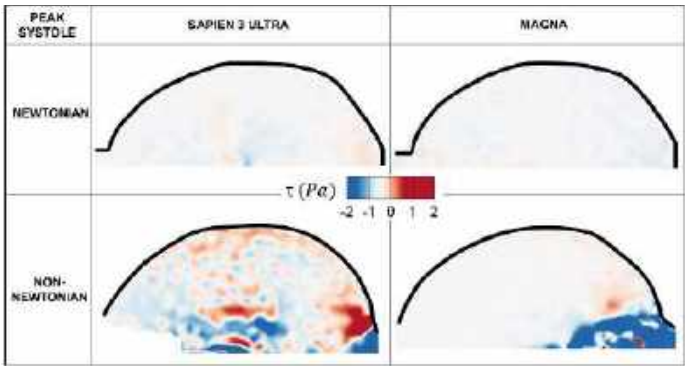

Fig 5. Shear Stress Contours at Peak Systole

probability density function (PDF) of the velocity was plotted in **Fig.4**, showing that higher velocities were more frequent for the non-Newtonian cases than for the Newtonian cases. The contours of the shear stress (**Fig.5**) showed that the shear stress for the non-Newtonian cases was much higher than those for the Newtonian cases.

DISCUSSION

The results of this study have shown considerable differences in the flow dynamics in the sinus between the Newtonian and non-Newtonian solutions. As expected, since the sinus is a region characterized with flow recirculation and in some areas and time points stagnation, the non-Newtonian properties of the fluid at low shear rates should be accounted for in experimental modeling in order to accurately mimic the hemodynamics of the aortic sinus, especially when relevance to potential clinical outcomes is needed. However, it seems that some aspects of flow behavior are impacted more than others. It was found that despite minor differences in the velocity distributions between the Newtonian and non-Newtonian regimes, there are significant differences in the distribution of shear stress. This correlates with the fact that the non-Newtonian solution is expected to exhibit a higher viscosity at low shear rates, which leads to an elevated shear stress. The underestimation of shear stress when using a Newtonian solution should be taken into account when attempting to conduct in-vitro experiments.

INTRODUCTION

Respiratory diseases are a leading cause of morbidity and mortality in the world, resulting in significant healthcare expenditures, as evidenced by the COVID-19 crisis [1]. Research on pulmonary health indicates that the mechanical properties of the lungs undergo alterations in diseased states [2]. However, understanding of basic lung mechanics is highly limited compared to that of other organs (e.g. bone, heart, etc.), highlighting the need for research advancements to ultimately better understand how diseases may affect respiratory system function.

Numerical simulations are an effective tool for exploring lung diseases and developing innovative therapies [3]. However, prior attempts to construct structural lung models either lacked experimental validation or were based on overly restrictive assumptions, and limited to primarily quantifying airflow dynamics within a rigid structure [4,5]. A recent study established the first inverse finite element model (FEM) of an inflating porcine lung specimen using experimental Digital Image Correlation (DIC) for measure deformations [6]. Nevertheless, this study exclusively concentrates on a 3D reduced-order surface of a pig lung and does not represent the entire organ volume (i.e. airways, parenchyma, pleura).

This present study builds upon the previously developed FEM pipeline [6] while proposing the first 3D solid generalized human lung breathing model as informed by global pressure-volume (PV) loads and resulting local tissue deformations. The experimental real-time and continuous expansion dynamics of the lung's pressures, volumes, and local strains—recorded via our custom PV ventilation apparatus system coupled with DIC measurements [7]—are utilized to introduce a novel inverse FEM optimization scheme, robustly calibrated with patient-specific data.

METHODS

Finite Element Model of the Structural Breathing Human Lungs: A commercially available volumetric lung geometry (Zygote Media Group, Inc., USA) was employed. The centerlines of the airways were extracted using 3D Slicer (The Slicer Community). The parenchyma was meshed in Abaqus (Dassault Systemes, France) using 331,996 tetrahedral elements, enveloped by the pleura composed of 50,719 membrane elements with a 0.2 mm section thickness [8]. The airways were modeled using 1,266 beams. The parenchyma was modeled with a generic elastomeric foam material law [9], where the strain density energy function U_{Foam} is as follows:

$$U_{Foam} = \frac{2\mu}{\alpha^2}\left[\lambda_1^{\alpha} + \lambda_2^{\alpha} + \lambda_3^{\alpha} - 3 + \frac{1}{\beta}\left(J_{el}^{-\alpha\beta} - 1\right)\right] \quad (1)$$

where μ is the shear modulus, α a coefficient, λ_i are the principal stretches, J_{el} is the elastic volume ratio, and β is linked to the Poisson's ratio ν such that $\beta = \frac{\nu}{1-2\nu}$.

The hyperfoam law was coupled with permeability p in a poroelastic formulation to represent air diffusion in the lungs [9]. As each lobe may respond differently to airflow [10], permeabilities were individually assigned to each lobe, resulting in five parameters. Pressure was directly applied to the nodes of the parenchyma near the ends of the airways. A Neo-Hookean material law was used to model the airways defined by the strain energy potential U_{NH} such that:

$$U_{NH} = C_{10}(I_1 - 3) + \frac{1}{D}(J_{el} - 1)^2 \quad (2)$$

where C_{10} and D are material parameters and I_1 is the first deviatoric strain invariant.

The pleura was modeled using biaxial experiments from human samples [11] and fitted with a polynomial hyperelastic law through the Abaqus' evaluation tool [9]. The airways were embedded in the parenchyma, and the trachea was constrained. A rigid plate was positioned behind the lungs, and contact was modeled between the lung and the plate, as well as on the surface of the lungs itself for lobar sliding. These iteratively selected and improved modeling approaches enabled the simulations to reflect experimental observations through the PV coupled DIC ventilation system [7].

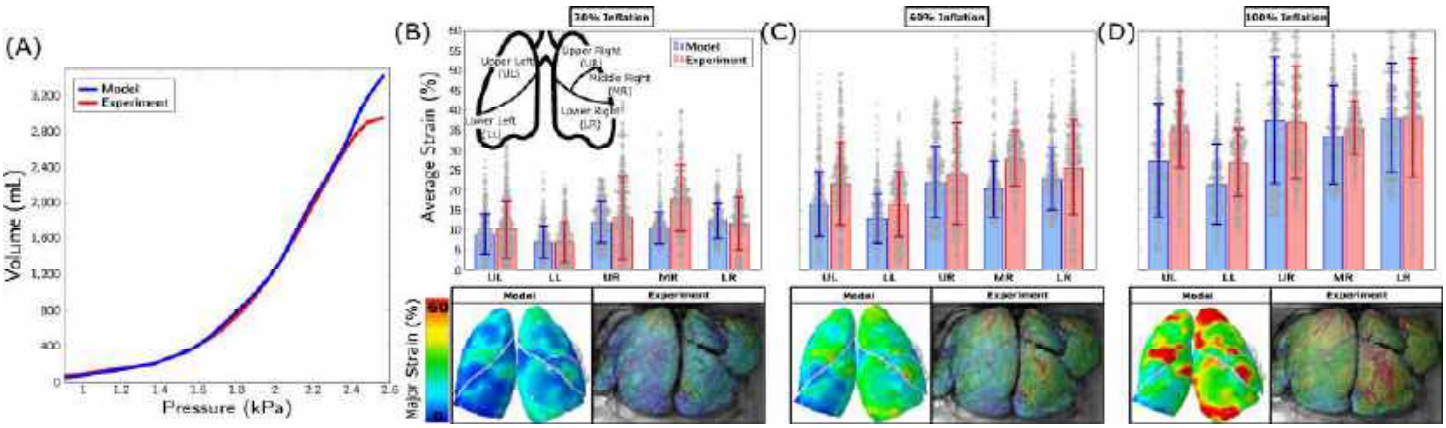

Figure 1: Results obtained after calibrating the model to subject-specific experiments: (A) PV curve during the inflation stage; (B,C,D) show the experimental data versus calibrated model average major strains (± standard deviation) and regional distribution for each lung lobe at 30%, 60%, and 100% of inflation, respectively.

Inverse Finite Element Analysis for Model Calibration: A human lung from a 32-year-old female research-designated donor was tested 48 hours after confirmed brain-stem death (IRB approved exemption, HS 20-180). The lung was placed in a tank and inflated via a volume-control ventilation system at a physiological rate of 15 breaths per minute, where the recorded pressure was used as a model input. Nine material properties (μ and α for the parenchyma, p for each lobe, C_{10} and D for the airways) were calibrated via inverse finite element analysis informed by the experimental global PV and local strains from the DIC [7].

MATLAB's *lsqnonlin* function (MathWorks, USA) minimized the difference between: (i) the model and experimental pressures and volumes at every 0.1 second during inflation resulting in 20 stages to ensure that the PV ventilation curve was adequately represented, and (ii) the average and standard deviation of the major strains calculated for each of the five lobes of the lungs at 30%, 60%, and 100% of total inflation resulting in 15 points of comparison.

RESULTS

The optimization process yielded the material properties listed in Table 1 with 2% and 14% errors for the global PV and local lobe strain, respectively (46hrs on 30 CPUs). The resulting model PV curve accurately represented the shape of experimental inflation trajectory (Figure 1A), especially in capturing the first inflection point commonly observed in expanding human lungs [12]. Similar model average major strain regional distributions and trend values were observed when compared to the three experimental inflation data stages (Figure 1B-D).

Table 1: Initial and calibrated parameters following optimization.

Parameters	Initial Values	Calibrated parameters
μ (kPa)	8.0	4.9
α	1.0	0.8
$p_{UL,LL,UR,MR,LR}$ (10^{-3})(mm s^{-1})	[10;10;10;10;10]	[2.8;2.0;5.0;7.5;4.6]
C_{10} (kPa)	1.0	25
D (MPa^{-1})	1.0	67

DISCUSSION

In this study, we successfully divulge the first 3D structural lung model directly informed by continuous pressures, volumes, and strains experimentally derived from the ventilation of a human lung. While direct one-to-one model-to-experiment comparison is limited, the determined shear modulus for the modeled parenchyma is within the same order of magnitude as results from a previous experimental study that utilized uniaxial tensile tests (when converting the reported elastic modulus with a defined Poisson's ratio of 0.4 to obtain an experimental shear value [13]).

While these preliminary results are promising and highlight the potential of simulating the breathing lung, the model has notable limitations: while it can accurately reproduce the initial PV curve and average strains, the model faces challenges in replicating identical strain patterns, primarily attributed to the strong dependence on areas of pressure distribution and lobe morphology (i.e. initial inflation stages are well represented but then diverge at maximum inflation). Moreover, our model does not yet capture the established anisotropy and viscoelasticity features of the lung [14]. Incorporating these characteristics may enhance our model, particularly when accounting for known heterogeneity in strain patterns [7], and may help to achieve an improved PV match at peak inflation. Nevertheless, the presented results serve as a proof-of-concept for a widely applicable pipeline, intended to be repeated for multiple lungs to create a robust generalized lung model capable of predicting human breathing. Such a model holds the potential to significantly advance the field of pulmonary medicine by deepening our understanding of lung physiology and guiding future research inquiries on both healthy and diseased lung biomechanics.

COMPUTATIONAL MODELING OF THE AORTA IN A MOUSE MODEL OF MARFAN SYNDROME TO DETERMINE TEMPORAL CHANGES IN GEOMETRIC BIOMARKERS AND WALL SHEAR STRESS

Yufan Wu (1), Krashn K. Dwivedi (1), Jessica E. Wagenseil (1)

INTRODUCTION

Thoracic aortic aneurysms (TAAs) are characterized by dilation of the aorta, which can dissect or rupture, leading to sudden cardiac death. About 20% of TAAs are associated with mutations in genes associated with elastic fiber assembly, smooth muscle cell contraction, or TGF-β signaling. Mutations in fibrillin-1, an elastic fiber assembly protein, cause Marfan Syndrome (MFS) where TAA is the main cardiovascular complication. In genetically associated TAAs, including MFS, there is evidence that aortic tortuosity correlates with aortic dilation and aneurysm outcomes[1].

Both aortic diameter and tortuosity are geometric parameters that will affect hemodynamic stresses on the aortic wall, which may contribute to aneurysm outcomes. To investigate the effects of diameter and tortuosity on aortic hemodynamics, we built computational models using SimVascular[2] and performed 0D Reduced Order Model (ROM) simulations on wild-type (WT) and fibrillin-1 hypomorphic (*mgR/mgR*)[3] mouse aortas, which are a model of MFS. We present the aortic models along with their tortuosity and maximum radius at different ages during aneurysm progression and for male and female mice. We also obtained the wall shear stress along the aortic length. Future work will extend the models to 3D and determine a range of hemodynamic stresses on the aortic wall over time that may contribute to aneurysm outcomes.

METHODS

Mouse model. Male and female WT and *mgR/mgR* mice were used. Models were created from imaging data on 1 mouse/group that were imaged at 1, 2, 3, and 4 months old. Imaging and modeling for additional mice are ongoing. All studies were approved by the IACUC.

Imaging. Each mouse was anesthetized with 2% isoflurane for magnetic resonance imaging (MRI) on an Agilent 4.7T machine.

Modeling. Images from MRI were loaded into SimVascular. For each image, the path of the aorta was first extracted by connecting points at the center of the aorta. Segmentations were created by outlining the cross-section at each point. Models that represent the shape of the aorta were created by connecting each segmented ring on the software. A similar process was performed on the major branches of the right and left common carotid arteries, the left subclavian artery, and the iliac arteries.

Radius and tortuosity. Centerlines of the aortae were extracted by SimVascular, which contains information about the coordinates of each point and the radius of each segment. Maximum radius was found using MATLAB. Tortuosity (k) was calculated as the ratio of actual length to geometric length,

$$k = \frac{l_{actual}}{l_{geometric}} \quad . \tag{1}$$

0D ROM Simulation. Models with the aorta and the major branches were used to perform 0D ROM Simulation. The 0D ROM simulation iteratively solves the differential equation[4],

$$E(y,t)\dot{y} + F(y,t) + c(y,t) = 0 \ , \tag{2}$$

where E, F, and c are matrices of pressure and flow to be simulated. A resistance-capacitance-resistance (R, C, R) network at the outlets, which quantifies the resistance encountered by blood at the outlet, was chosen as the boundary condition. These values were optimized using MATLAB, with the resistance, capacitance, and inductance (R, C, L) of the aorta as its input. Unlike R, C, R, the values of R, C, L indicate the resistance to blood flow by the vessel itself[3],

$$R = \frac{8\mu L}{\pi R^4}, C = \frac{3L\pi R^3}{2Eh}, L = \frac{\rho L}{\pi R^2} \quad , \tag{3}$$

where μ is the dynamic viscosity of the blood, ρ is the density of the blood, L is the length of the aorta, R is the radius of the aorta, E is the in vivo Young's Modulus of the aorta, and h is the thickness of the aorta.

Wall shear stress. Blood flow in the mouse aorta has a Reynold's number ~ 200 and is considered laminar[5]. Thus, the wall shear stress (WSS) can be derived from the Darcy-Weisbach equation,

$$\tau = \frac{32\,\mu Q}{\pi D^3} \quad , \tag{4}$$

where τ is the wall shear stress, Q is the volumetric blood flow, and D is the aorta diameter.

RESULTS

At 1 month of age, increased diameter of the ascending thoracic aorta and mild tortuosity along the aortic length are visible in *mgR/mgR* mice. An aneurysm (>50% diameter dilation) and more severe tortuosity are apparent in *mgR/mgR* mice around 2 months of age. The aneurysm continues to grow and tortuosity increases with age in *mgR/mgR* mice (Fig. 1).

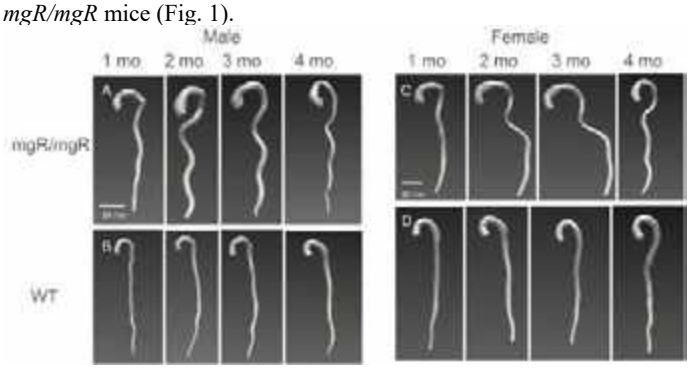

Figure 1: Representative SimVascular models of individual *mgR/mgR* (A, C) and WT (B, D) male (A, B) and female (C, D) mouse aortae at each timepoint (1 – 4 months).

Maximum radius and tortuosity are positively correlated for all mice (Fig. 2A). Maximum radius and tortuosity are lower in WT than *mgR/mgR* aortae and increase with age in both genotypes (Figs. 2B, C).

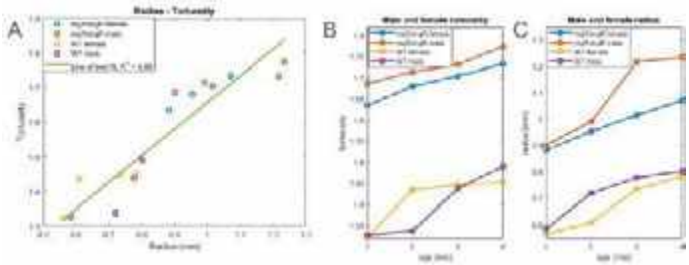

Figure 2: Radius and tortuosity of male and female *mgR/mgR* and WT and mice ages 1-4 months. N = 1 for each sex/genotype.

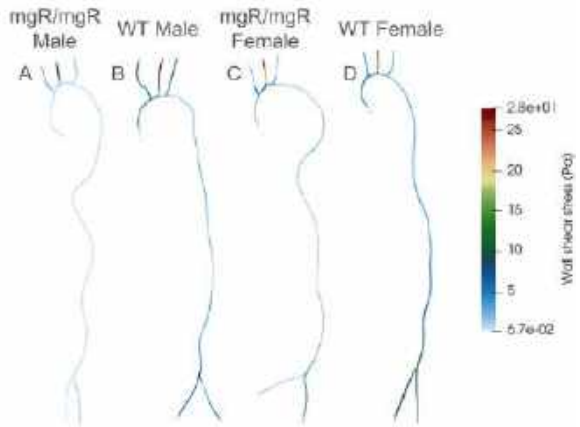

Figure 3: WSS distribution in *mgR/mgR* (A, C) and WT (B, D) male (A, B) and female (C, D) mouse aortae at 4 months old.

From the 0D ROM simulations, lower WSS was observed throughout the aortic length in *mgR/mgR* models than in WT models, as denoted by the lighter blue color on these samples. WSS increased and had a larger variation in WT models around the iliac arteries at the base of the aorta (Fig. 3).

DISCUSSION

Consistent with previous studies, maximum radius and tortuosity increase with age and are larger for *mgR/mgR* mice than WT mice[6]. However, they are simple measurements that indicate only the geometry change during growth and remodeling, and other parameters and computational models are needed to determine how they affect hemodynamic wall stresses in an aneurysmal aorta.

An increase in tortuosity alters the distal pressure and reduces the blood flow[7]. Since WSS and flow are positively related, denoted by Eq. 4, WSS will decrease in more tortuous aortae, which is consistent with our results. Previous studies have indicated that WSS has the potential to be a biomarker for aneurysm outcomes[7]. In our models, the wall shear stress is lower for large aneurysms. Some studies found that lower WSS is related to wall weakening and radius dilation[8, 9], whereas another study found higher WSS to be associated with elastin degeneration and extracellular matrix dysregulation[10].

Although the flow from the 0D simulation can be used to calculate WSS from Eq. 4, the capabilities of 0D simulation are limited, as there are multiple measurements of WSS – time-averaged wall shear stress (TAWSS) and oscillatory wall shear stress (OSI) – that have the potential to be biomarkers for aortic aneurysm outcomes[11]. Therefore, our study presents a preliminary understanding of WSS distribution along the aortic length with and without aneurysms. Additional age and sex dependent simulations on more mice are in progress to examine the temporal development of the disease. Fluid-solid interaction (FSI) simulation will be performed once all data is collected, which will provide a suite of information on biomechanical biomarkers, such as TAWSS and OSI that may be predictive of the growth and eventual rupture of aortic aneurysms.

GEOMETRY AND PHYSICS-INFORMED NEURAL NETWORK MODELING OF FLOWS INSIDE Y-SHAPED BIFURCATED DUCTS

Abdullahi O. Olapojoye (1), Fatemeh Hassanipour(1)

(1) Department of Mechanical Engineering, University of Texas at Dallas, Richardson, TX, USA

INTRODUCTION

Modeling fluid flow in biological structures has significantly benefited from advancements in computational mechanics. Computational tools like Computational Fluid Dynamics (CFD), Fluid-Structure Interactions (FSI), and Finite Element Analysis (FEA) have successfully simulated flows in various biological structures. However, certain challenges arise in solving flows with complex geometries, dynamic boundary conditions, and the high cost of mesh generation and time complexity when applying computational tools to new systems.

To address these limitations, there has been a growing shift toward the application of Deep Learning (DL) solutions. Deep Neural Networks (DNN) excel in generalization by learning to approximate hidden manifolds of input data, allowing interpolation for new inputs. DNN's exceptional approximation capability is crucial for modeling complex spatiotemporal systems [1]. Despite its power, obtaining sufficient training data for DNN in physical problems remains a challenge.

In response to this challenge, Raissi et al. introduced a Physics-Informed Neural Network (PINN) framework [2, 3]. This framework incorporates the governing partial differential equations (PDEs) of fluid flow to constrain the DNN model, enabling consistent predictions even with limited or scarce data. PINN has demonstrated the ability to solve and identify PDEs and has been successfully applied to model various physical systems. For instance, Kissas et al. utilized PINN to model 1D blood flow in cardiovascular vessels using MRI data [4]. Numerous improvements and variations of PINN methods have also been proposed [5–10].

In this study, we propose a Geometry-Informed PINN(G-PINN) method capable of making accurate predictions with or without sparse data. The key advantages of our method include its applicability to complex geometries, such as bifurcated ducts within lung capillaries, the breast ductal system, the ureter, and the aorta; the ability to make predictions without extensive training data; and its suitability for systems with dynamic boundary conditions. We leverage the equations governing flows in conduits, knowledge of flow geometry, and sparse data to predict flows in daughter ducts of a 2D Y-shaped bifurcated structure.

METHODS

We harnessed the capabilities of PINN and modified its framework to deduce solutions at various locations within the computational domain by solving non-linear PDEs that governs fluid flow. A neural network is formulated to encapsulate the solutions of the PDEs within the specified domains. The training process involves instructing the neural network to forecast flows within the system while adhering to physical laws. This is achieved by minimizing the residuals of the PDEs. Details are shown (Figure 1).

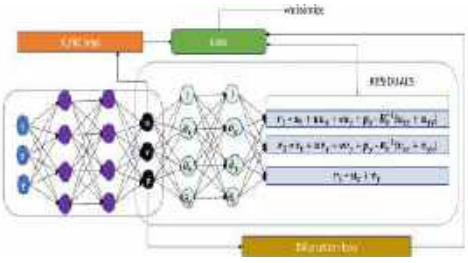

Figure 1: G-PINN architecture for flows through Y-shaped bifurcated structures

Given the nature of the problem we are addressing, which involves splitting geometries (Figure 2), it is imperative to ensure the conservation of mass and momentum at bifurcations. Special attention is devoted to deriving appropriate boundary conditions for the parent and daughter ducts based on the principles of mass and momentum conservation and encoding it as a loss function in the training of our model.

For a simple Y-shaped bifurcated structure containing ducts 1, 2 and 3, the equation for mass conservation at the bifurcation point can be written as:

$$\begin{aligned} U &= (u^2 + v^2)^{1/2} \\ A_1 U_1 &= A_2 U_2 + A_3 U_3 \end{aligned} \tag{1}$$

Where U_1, U_2 and U_3 are the velocity magnitudes in the parent(point 1) and two daughter ducts (point 2 and 3) respectively. A_1, A_2 and A_3 are the cross-sectional areas at points 1, 2 and 3 respectively.

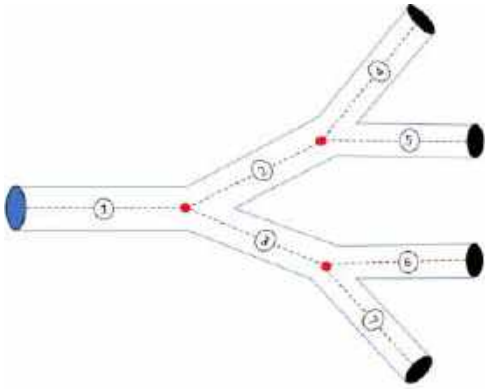

Figure 2: Sample geometry of a 7-ducts Y-shaped bifurcated structure

In the absence of external forces and assuming incompressible flow, the momentum equation can be simplified to:

$$p_1 + \frac{1}{2}\rho(U_1)^2 = p_2 + \frac{1}{2}\rho(U_2)^2 + p_3 + \frac{1}{2}\rho(U_3)^2 \tag{2}$$

Our objective is to integrate these equations as constraints during the training of our model. The model is designed to learn and approximate solutions to these equations throughout the entire computational domain. Through this training process, the model gains the ability to effectively capture and represent the underlying physics described by these equations, enabling it to provide accurate solutions within the given context.

RESULTS

Our model underwent testing in transient flows through Y-shaped structures with one and three bifurcations. The ensuing results are detailed below. It is crucial to emphasize that pressure data was intentionally excluded during the training phase of the model. A periodic velocity is prescribed at the inlet of the parent duct in the geometry, and a no-slip boundary condition is enforced on the walls. At the outlet boundary, a zero-pressure condition is specified. The fluid's density and dynamic viscosity are set to 1028 kg/m³ and 0.02678 kg/(m·s), respectively. The velocity at the inlet is defined as:

$$\begin{aligned} u(t,0,y) &= 0.5Sin^2(2\pi t) \\ v(t,0,y) &= 0. \end{aligned} \tag{3}$$

G-PINN's ability to model flows inside complex structures is accurately described by the snapshots of the evolving flow over time for a simple bifurcated structure having three ducts (Figure 3).

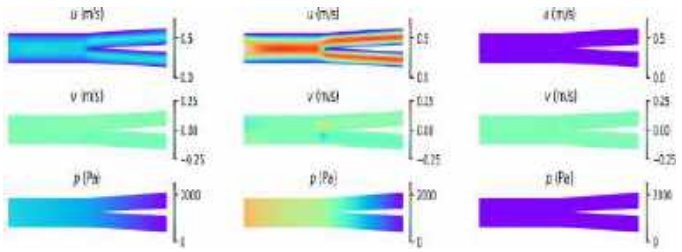

Figure 3: Pressure and velocity predictions snapshots at t = 0s(left), t = 0.25s(center) and t = 0.5s(right).

Advancing our research, we extend the testing of our G-PINN method to a more intricate structure having seven ducts with three bifurcations. The predictions of the G-PINN align closely with the reference solutions, rendering the display of all the reference contours unnecessary. However, we conducted a comparison of the pressure time histories obtained at the midpoints of the parent and daughter ducts with the reference solution from ANSYS Fluent. The pressure time histories for points 4-7 in the distal ducts are illustrated (Figure 4).

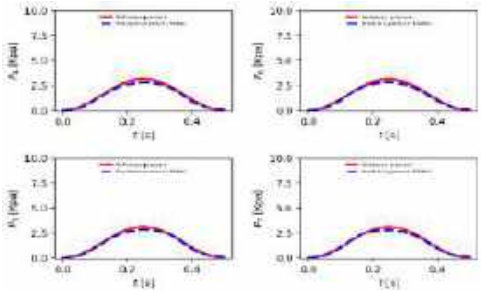

Figure 4: Pressure-time histories for Y-shaped bifurcated ducts with three bifurcation points. Pressure fields at points 4-7.

It is evident that the proposed G-PINN accurately reconstructs the velocity and pressure fields in transient flow through complex geometries such as a Y-shaped bifurcated structure.

DISCUSSION

We introduce a physics-informed and geometry-aware approach for modeling flows in Y-shaped bifurcated structures. The strengths of our proposed scheme include the implementation of peristaltic flow conditions, and the capability to model flows inside intricate structures like a Y-shaped bifurcated duct with limited data. A comparison of predictions with a reference solution demonstrates the high accuracy of the scheme, making it suitable for reconstructing flow fields in complex structures.

It is important to note that the application in this paper is confined to Y-shaped bifurcated structures with symmetrical daughter ducts and constant areas. However, the approach is adaptable for modeling flows through non-symmetric Y-shaped bifurcated structures with varying dimensions. Our future endeavors involve extending this approach to model flows in more intricate bifurcated structures. Additionally, the modeling of the elasticity and versatility of the ducts is left for future work.

BONE FORMATION DEPENDANCE ON MICROSPHERE SIZE IN 3D PRINTED PLGA MICROSPHERE SCAFFOLDS

Roland M. Klar, James C. Cox, Naren Raja, Stefan Lohfeld

Oral and Craniofacial Sciences, School of Dentistry, University of Missouri-Kansas City, MO, USA

INTRODUCTION

Polymeric biodegradable microspheres are readily utilized to support tissue healing by targeted drug delivery and have been suggested for use as tissue engineering scaffolds [1]. 3D printed microsphere scaffolds enable precision health therapies by delivering biomolecules in an optimized spatiotemporal manner to maximize therapeutic effectiveness at the tissue damage site while also providing microporosity and stiffness for improved tissue regeneration in load bearing locations. 3D printed scaffolds consisting only of microspheres allow for multiple 3D gradients and optimized architectures that includes micro- and macroporosity [2]. To an extreme, microspheres with different payloads, made from different materials, and in different sizes can be included in a single scaffold to provide locally an optimal environment for the desired tissue formation. Compared to mold-based microsphere scaffold fabrication, 3D printing allows to design architectures that promote tissue formation and optimized load transfer. Furthermore, in contrast to heat- or solvent-based production methods, 3D printing via extrusion process enables the inclusion of biomolecules or cells that would not withstand the harsh conditions of, e.g., powder bed fabrication utilizing lasers or solvents for material fusion.

The size of the microspheres influences the microporosity of the printed structure by changing the gap size between the spheres, and the surface roughness of the scaffold. Surface roughness has shown to have an effect on bone induction in the scaffold [3].

The objective of this study was thus to determine the effectiveness of 3D printed poly(lactic-co-glycolic acid) (PLGA) microsphere scaffolds, varying in microsphere sizes, on bone induction.

METHODS

A microsphere-based ink was prepared from mixing PLGA microspheres with 3% carboxymethyl cellulose (CMC). Scaffolds of 5 mm diameter and approximately 2 mm height were printed from 50, 100, 200, and 300 µm PLGA microspheres with a 0°/90° layer pattern with 0.97 mm layer height, 1 mm strut width, and 1.7 mm strut distance. The scaffolds were left to dry, causing the CMC to shrink to a neglectable volume. The dried scaffolds were sintered in dichloromethane solvent vapor for stability. After UV light sterilization the scaffolds were implanted into critical size calvarial defects in a murine model (TOPGAL mouse). Scaffolds that were extrusion printed from PLGA with the same design parameters were implanted as controls without microporosity. During and after a 60-day implantation period, quality and quantity of de novo bone formation was assessed via µCT and histomorphometry analysis.

RESULTS

Histology and µCT images showed that the PLGA scaffolds had been resorbed by the surrounding epicranial muscle tissue after 60 days. New epithelial/connective tissue formation and abundant new capillary formation was observed and rudimentary naturally occurring bone formation near the periphery of the calvarial defect was detected. Beyond that, the control and the 50 µm microsphere scaffolds were lacking new osteogenesis. In

contrast, more significant bone formation by induction was detected within the defect region when 100, 200, and particularly 300 µm microsphere scaffolds were implanted. On average, the new bone accumulated to approximately 3%, 4%, and 8-10% of the defect area for the 100, 200, and 300 µm microsphere scaffolds, respectively. Figure 1 shows µCT scans of the defect areas after completion of the *in vivo* study. The defect on the left was filled with a 50 µm microsphere scaffold, while the defect on the right was treated with a 200 µm microsphere scaffold. The white circles mark the original defect size (5 mm), which corresponds to the remaining defect diameter on the left, apart from minor bone formation, while bone ingrowth into this circled area is clearly visible on the right.

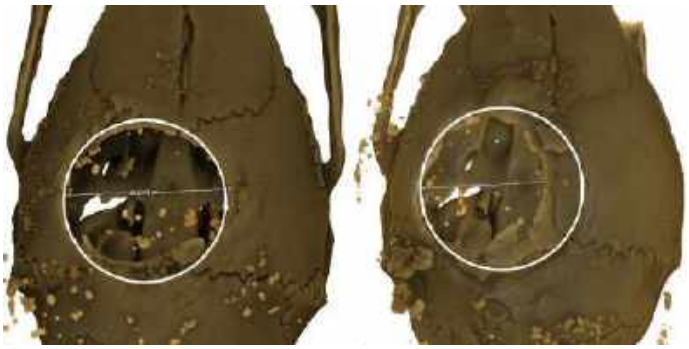

Figure 1: µCT scans of calvarial defect areas in a murine model after 60 days implantation. Defects were treated with scaffolds of microsphere size 50 µm (left) and 200 µm (right). The white circles mark the originally created defects with 5 mm diameter.

DISCUSSION

Our results show that PLGA microsphere-based scaffolds support new bone formation better than scaffolds made from extruded PLGA which do not feature microporosity. Larger microspheres lead to larger micropores and higher surface roughness, which appears to be beneficial for the bone formation. Along with other parameters, a defined macroporosity in a scaffold can better facilitate the formation of the desired tissue [4]. In addition, microporous scaffolds allow for better nutrient flow and removal of metabolic waste and have shown to support vascularization [5]. While the amount of new bone formation in this trial is still limited and the degradation of the PLGA too quick to support bone induction past the 60 days, the results are valuable for understanding the effect of microsphere size in the scaffolds. As the microsphere size influences the printing parameters, the present results help in the optimization of printing microsphere scaffolds targeted at specific tissues. Based on these findings we will develop 3D printed microsphere-based scaffolds with macro- and microarchitectures targeting different tissue types. 3D printing with microspheres allows us to produce multiple 3D gradients in scaffolds with high spatiotemporal control over the release of biomolecules encapsulated in those microspheres, potentially leading to superior tissue regeneration. Scaffolds with 3D gradients are particularly beneficial for tissue interface regions, such as osteochondral defects, where two regenerated tissues need to blend in with their neighboring native tissues.

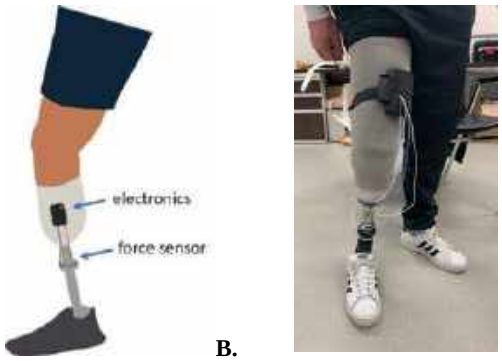
INTRODUCTION

An estimated 1.4 million Americans are currently living with lower extremity amputations [1]. Despite the high rates of prosthesis usage, a significant majority of amputees express dissatisfaction and experience pain while using conventional prosthetic devices [2]. Given the considerable variability in outcomes following amputation, there is a pressing need to develop interventions that can enhance functional performance for prosthesis users.

The primary goal for patients affected by lower limb amputation is to regain walking capabilities. The conventional rehabilitation process involves patients transitioning from strength to gait training with emphasis on weight bearing and coordination. Through each phase of rehabilitation, patients are instructed to bear a specific amount of weight to mitigate the risk of fatigue and discomfort with phase progression being dependent on gait analysis. Despite advancements made on quantitative biomechanical analysis tools, clinicians continue to use qualitative assessments in part due to high-cost equipment, complex protocols, diverse training, and varying biomechanics experience and knowledge [3]. With minimal to no knowledge of key biomechanical metrics such as ground reaction forces (GRF) available to the user or clinician, it is difficult to gauge daily function.

This critical gap in post-amputation rehabilitation highlights the urgent need for a force-sensing system tailored to prosthetic users that is accurate, cost-effective, and adaptable for non-clinical settings. Looking to fill this gap, we developed a new pressure sensor system (PSS) composed of a nonwoven aramid fabric with fibers coated in nanotube-based composite thin film [4]. Taking a unique approach, two polylactic acid plates were used to secure the sensor at the top of the prosthetic pylon and the base of the residual limb socket (Figure 1) to collect force data during activities of daily living. In this study, we look to validate the PSS's capacity to measure GRF during slow and fast loading cycles found in sit-to-stand (STS) and walking (NW) trials.



A. **B.**

Figure 1. (A) Illustration and (B) photograph of PSS placed within a pylon. Electronics includes Arduino nano, battery, and circuit board. Data is collected via blue tooth transmission.

METHODS

A single participant with lower limb amputation performed walking and sit-to-stand trials on a force plate (FP) instrumented treadmill (Bertec Corp, Worthington, OH, USA) with the sensor placed in their pylon. During each trial, the force plates recorded GRF (N, 2000 Hz) and the pressure sensor system recorded resistance (ohms, meaning frequency of 14.5 Hz). One 60-second walking trial was conducted at 'normal' self-selected speed and 5 sit-to-stand cycles were conducted.

Due to the piezoresistive effect employed by the PSS, the resistance measurements have an indirect relationship with force and are not normalized to zero [5]. To account for this, each data point in a PSS data set follows Equation 1: one is divided by the individual data point and is subtracted by one divided by the averaged maximum value of that data set, so the overall minimum is zero.

$$\frac{1}{data\ point} - \frac{1}{mean\ (\max values)} = Normalized\ data\ point \quad (1)$$

To prepare for resistance–force alignment and calibration, the peak forces and loading curves are pulled from the PSS and FP data. To identify the loading curves, the data found between local minimum and maximum values for each loading-off-loading cycle are pulled from PSS and FP data sets. For the selected curves, the IPS and FP timestamps(s) are normalized to a minimum value of zero and rounded to the fourth decimal point. The arrays are then overlaid and the points that have matching time stamps are pulled to create the loading curve used for analysis, given the difference in sampling frequency the number of points in a loading curve array varies. To create the calibration factor, 12 loading curves pulled from the walking cycle were used. This factor was applied to the remaining NW and STS PSS data sets to convert the measurements from resistance (ohms) to force (N).

Peak force measurements were compared between PSS and FP using a paired *t*-test and the loading curves with an R^2 Correlation (NW: n=12, STS n=3).

RESULTS

The peak force values measured by the PSS and FP were not significantly different as shown by the Mann Whitney results for NW (Fig 2A, PSS = 883±49.6 N, FP = 886±26.1 N), indicating a 0.3% measurement difference in peak loads. However significant differences were observed for STS (Fig 2B, PSS = 542±10.1 N, FP = 565±7.9 N), indicating a 4% measurement difference for peak force during STS.

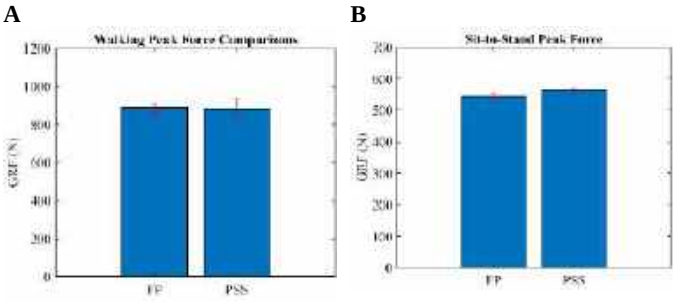


Figure 2: (A) walking (n=12, p = 0.497), (B) Sit-to-Stand (n=3, p = 0.016); note the different axis limits.

The NW loading curves have a moderate correlation of R^2 = 0.494 from no load to peak load between the PSS and FP (Figure 3). However, for STS, there was a high correlation of R^2 = 0.667 (Figure 4).

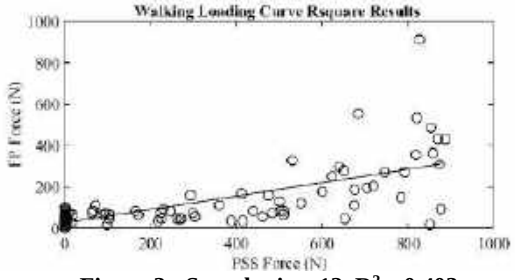

Figure 3: Sample size: 12, R^2 = 0.403

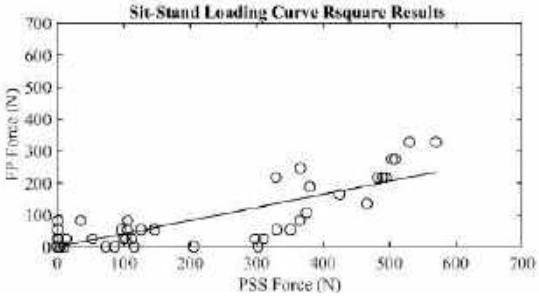

Figure 4: Sample Size: 3, R^2 = 0.667

DISCUSSION

The findings of this study suggest the potential of the newly developed pressure sensor system (PSS) to accurately measure ground reaction force (GRF) during both normal walking and sit-to-stand in an individual with lower-limb amputation.

The study aligns with existing knowledge by emphasizing the importance of quantitative force measurement for prosthetic users, particularly in non-clinical settings. The PSS addresses a critical gap in post-amputation rehabilitation by offering real-time feedback to users outside clinical environments. Comparison to force plate of peak forces for both walking (NW) and sit-to-stand (STS) trials indicate excellent readings by the device with less than a 5% measurement difference between systems. The loading curve correlation between the systems exhibit mixed results with better correlation during the slow STS movement. This may be related to the posture of the limb which is nearly vertical and therefore aligned with the vertical GRF during STS but is more dynamic during normal walking.

The study's strengths lie in the successful validation of the PSS, highlighting its effectiveness in measuring peak force during walking and sit-to-stand. The agreement with force plates adds credibility to the PSS's ability and highlights its potential for broader applications. However, it's essential to acknowledge current limitations, such as the small sample size represented by a single participant out of the anticipated twenty, and the PSS low sampling frequency. The ongoing study will address this limitation, and potentially enhance the generalizability of the findings.

The implications of this study extend to both prosthetic users and healthcare professionals. The PSS has an adaptable design for non-clinical settings, which fills a crucial gap in post-amputation support. Prosthetic users may benefit from real-time feedback on limb loads, improving their ability to manage weight-bearing and enhance functional performance. The successful validation of the PSS opens avenues for future research and development to explore the long-term usability and comfort of the PSS, as well as its integration into different types of prosthetic devices.

In conclusion, this study not only confirms the capacity of the pressure sensor system in measuring pylon load for prosthetic users during daily activities but also lays the foundation for future advancements in sensor technology within the field. The PSS has the potential to revolutionize post-amputation rehabilitation, offering a practical and effective solution for managing limb loads and enhancing the functional performance of prosthetic devices.

A NUMERICAL STUDY ON THE EFFECT OF CORTICAL DIFFUSIVITY ON BRAIN TISSUE GYRIFICATION

Karan Taneja (1), Maria Holland (1)

(1) Department of Aerospace and Mechanical Engineering, University of Notre Dame, South Bend, Indiana, USA

INTRODUCTION

Brain gyrification is a complex phenomenon that is coupled through biology, chemistry and their combined effect on the mechanics of the tissue. Previously, cortical folding has been shown to be affected by variation in cerebrospinal fluid pressure [1], neuronal cell proliferation and migration [2], among other factors. In neurodevelopment, neuronal cells migrate from the inner regions towards the pial surface before spreading out and accumulating [2], indicating spatial variation in their diffusivity throughout the tissue. It has also been observed using Diffusion Tensor Imaging (DTI) of the human fetus during the gestation period that the Mean Diffusivity (MD) of the tissue matter decreases with age, besides showing spatial variation [3, 4].

Previously, Wang et al. [2] incorporated neuronal proliferation of different generations of neurons into a coupled numerical bio-mechanical model of cortical folding by assuming a constant isotropic diffusivity for the young, intermediate and older generations of neurons. This preliminary work investigates the effects of spatial and temporal variation of neuronal migration diffusivity on brain gyrification patterns. As in [2], cortical folding of a 2D Neo-Hookean brain tissue is modelled by coupling neuronal growth and proliferation of three successive generations of neurons, via a user-defined material subroutine in Abaqus [5]. Besides temporal variation, spatial variations in diffusivity are also incorporated and the neuronal cell proliferation and brain gyrification patterns are compared. The simulations indicate that spatio-temporal variations in diffusivity lead to sharper gyrification patterns, indicating the physiological relevance of this phenomena in cortical folding.

METHODS

The kinematics of the biomechanical coupling is defined by splitting the total deformation gradient into the irreversible growth part $\mathbf{F}^{\mathrm{g}}(c)$, defined as a function of the total neuronal cell density c, and, the reversible elastic part $\mathbf{F}^{\mathrm{e}}$ using multiplicative decomposition,

$$\mathbf{F} = \mathbf{F}^{\mathrm{e}}\mathbf{F}^{\mathrm{g}}(c). \tag{1}$$

In this work, three generations (or cohorts) of neurons are considered, such that the total cell density is calculated as,

$$c = \sum_{i=1}^{3} c_i. \tag{2}$$

Further, an advection-diffusion process is used to model the density and migration of the individual neuronal cell cohorts across the brain tissue. The balance of cell density $c_i(\mathbf{x}, t)$, (i.e., the number of cells of the i^{th} cohort per unit current volume) is modelled in the current configuration as

$$\dot{c}_i + c_i \frac{\dot{J}}{J} = f_i^c + \mathrm{div}\mathbf{q}_i, \tag{3}$$

where $J = \det(\mathbf{F})$ is the volume change, f_i^c is the spatial cell source term, and $\mathbf{q}_i$ is the spatial cell density flux term. The term $\mathbf{q}_i$ is written as

$$\mathbf{q}_i = -c_i \hat{H}(c_i - c_0; \alpha_c)\mathbf{v}_i(\mathbf{x}) + \mathbf{D}_i \cdot \mathrm{grad}\, c_i \tag{4}$$

where $\hat{H}(c_i - c_0; \alpha_c)$ is a parameterised heaviside function where c_0 and α_c are the threshold and smoothing parameters, $\mathbf{v}_i(\mathbf{x})$ is the neuronal migration velocity field, and $\mathbf{D}_i$ is the diffusivity tensor.

We assume the standard Fick's first law where cell density flux depends linearly on the cell density gradient. Due to developments in the cortex with gestation age [3, 4] that could potentially affect the neuronal migration, we assume two different forms of the diffusivity $\mathbf{D}_i$ to model the spatio-temporal variation.

Case 1: Constant Spatial Diffusivity

We begin with the assumption that the diffusivity is constant spatially in all directions,

$$\mathbf{D}_i = D_i \mathbf{1}, \tag{5}$$

but for temporal variation each successive cohort has a lower D_i, i.e., $D_1 > D_2 > D_3$. This is based on observations that the MD decreases with gestation age [3, 4], which can potentially affect the neuronal migration and therefore, the brain tissue gyrification.

Case 2: Radially varying Spatial Diffusivity

In this case, the diffusivity coefficient in Equation 5 is considered to vary as an inverse heaviside function of the radial distance,

$$D_i\left(r;\gamma_i,\delta_{r_i}\right)=\gamma_i\left(1.5-0.95\hat{H}\left(-\left(r-\delta_{r_i};\alpha\right)\right)\right) \tag{6}$$

and for temporal variation each successive cohort has a lower γ_i, i.e., $\gamma_1 > \gamma_2 > \gamma_3$, with a similar justification as in Case 1. The threshold value δ_{r_i} for each cohort (calibrated according to Wang et al. [2]), is the position that the diffusivity becomes non-zero, with α being the smoothening parameter and r being the current radial distance from the origin. The parameters from the two cases are mentioned in Table 1, within the physiological range mentioned in Wang et al. [2].

The brain tissue is modelled as a Neo-Hookean material, along with the growth model used in Wang et al. [2]. In this work, a 2D plane-strain half-circle model is considered, with symmetry displacement boundary conditions and zero cell density flux at the boundaries.

Table 1: Parameters used in the two cases.

Case	Parameter	Value
all	R_0	239 µm
	t_{mid}	10 d
	t_{end}	20 d
1	D_1	35×10^3 µm^{2}d^{-1}
	D_2	32×10^3 µm^{2}d^{-1}
	D_3	30×10^3 µm^{2}d^{-1}
2	γ_1	35×10^3 µm^{2}d^{-1}
	γ_2	32×10^3 µm^{2}d^{-1}
	γ_3	30×10^3 µm^{2}d^{-1}
	δ_{r_1}	$0.85R_0$
	δ_{r_2}	$0.90R_0$
	δ_{r_3}	R_0
	α	1.0

RESULTS

Both cases are simulated for a gestation time period (t_{end}) of 20 days (Figure 1), with the 2D half circle having an initial radius of R_0. It is clear that in Case 2, sharper gyrification is observed with larger cell density at the outer layers. The cell density in Case 1 also shows smoother transitions from lower to higher total cell density magnitudes, with lower maximum densities. On the other hand, Case 2 shows sharper transitions of the total cell density magnitude, with large clusters observed near the gyri-like protrusion. A potential explanation for this phenomena is the mechanical interaction of the more pronounced cell clusters with the brain tissue in Case 2 leading to the sharper gyrification as compared to Case 1.

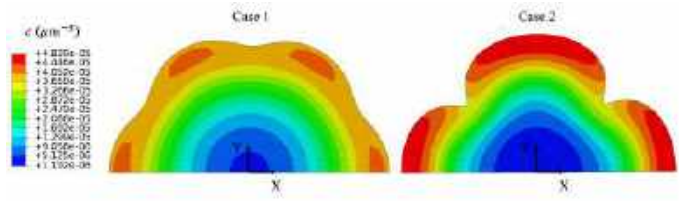

Figure 1: Tissue morphology and cell density in simulations of both homogeneous (left) and spatiotemporally varying (right) diffusivity.

During growth, the outer contours of the brain expand before buckling (Figure 2A). The evolution towards stronger gyrification in Case 2 can be observed with gyri developing in the middle of the simulation whereas the tissue contour remains relatively smooth in Case 1. When looking at the cell densities of the older (c_1), intermediate (c_2) and younger (c_3) neuronal cohorts separately (Figure 2B), Case 2 clearly shows a pronounced clustering behaviour, especially in the youngest neurons.

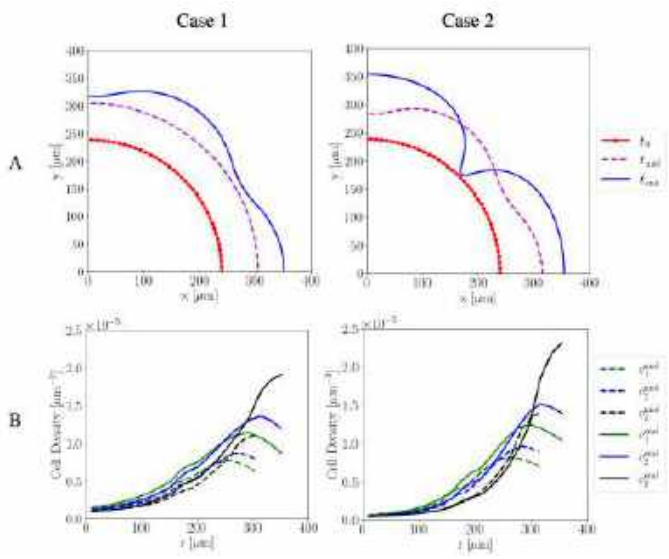

Figure 2: Evolution of tissue morphology and cell density over time for both cases. A: Brain tissue contour at the initial, middle (t_{mid}) and end (t_{end}) of the simulation. B: Radial cell density profiles, calculated along a gyrus, for each of the three cohorts at the middle and end of the simulations.

DISCUSSION

This works numerically investigates whether spatio-temporal variations in neuron migration diffusivity affect brain gyrification. This hypothesis is based on the experimental observations that migrating neurons spread out more as they get closer towards the pial surface, implying a non-linear diffusivity with a higher magnitude closer to the surface [2]. Temporal variation in brain tissue diffusivity has also been observed using DTI [3, 4]. Our results show that including these variations in simulating the coupled biomechanical model leads to distinct gyrification patterns and sharper neuronal cell cluster formations in the tissue. While this indicates a potential correlation between cortical folding and cortical tissue properties such as diffusivity, more rigorous numerical and experimental studies are needed to establish if diffusivity itself is affected by the geometry of the tissue and/or vice-versa. For example, does diffusivity vary more in the gyri than the sulci, indicating a dependence on the tissue deformation? More interestingly, does this variation in diffusivity lead the neurons to stop migrating towards the surface and instead, spread out along the tissue? Investigating these issues will be the focus of our future work.

RADIOFREQUENCY ABLATION FACILITATED BY MICROCHANNEL JETTING

Bo Cao, Hongying Wang, Ruizhe Hou, Shiqing Zhao, and Aili Zhang

Department of Biomedical Engineering
Shanghai Jiao Tong University
Shanghai, China

INTRODUCTION

The radiofrequency (RF) balloon, capable of utilizing its surface microelectrodes to form uniform and regular ablation areas circumferentially, has been widely used for the ablation of transluminal lesions [1]. Cooling media in balloon has been used to reduce the risk of local high temperature, achieving protection of the inner layers of lumen [2]. However, when the lesion area is distant from the lumen surface or forms a certain angle with the lumen, the high temperatures generated by the RF balloon can cause severe irreversible damage to non-target areas [3].

To realize adjustable RF lesions, a RF balloon with tunable jet flow from the microchannel in the balloon catheter is proposed. This design will greatly enhance surface cooling in the region close to the RF electrode, so that the volumetric heating source of the RF heating can be effectively regulated, and thus lesion shape. A model coupling the low temperature jet flow, the RF electrical current and heat transfer in the tissue is then developed. This research examines the impact of various parameters, including jet flow velocity, temperature, and direction, on the morphology of the lesion area. By adjusting the conditions of the cooling medium, it is found RF ablation penetration depth can be increased four times greater than that reported by Wang et al. [4], while offering more versatile lesion shapes across the circumferential and axial dimensions of vascular tissues.

METHODS

The designed dual-layer RF balloon catheter is shown in Figure 1. RF microelectrodes on the surface of the balloon are closely attached to the tissue, while the microchannel on the surface of the inner catheter fosters the low-temperature jet flow toward the inner surface of the balloon. The flow rate and temperature of the inflow are controlled at the inlets and outlets of the dual-layer catheter, and thereby the jet flow condition. The proposed model is built in COMSOL Multiphysics software ((COMSOL, Inc., Burlington, MA, USA)). As shown in Figure 1, a microchannel with a diameter of 0.5 mm is simulated in the model, and it is directed to the middle point of an electrode pair. To simplify computations and enhance the convergence of the model, the space of the balloon's thin wall is neglected, and its heat transfer impact is considered by a thermal thickness approximation.

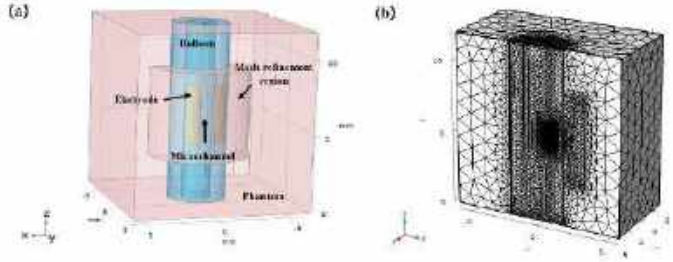

Figure 1: Three-dimensional model of the RFA device.

For fluid dynamics within the conduit, the Reynolds number is around 600-700 which is much smaller than 2100. Hence, a laminar flow model is used. The control equations are:

$$\rho_f \frac{\partial u}{\partial t} + \rho_f (u \cdot \nabla) u = -\nabla \cdot P + \mu_f \nabla^2 V \quad (1)$$

$$\rho_f \nabla \cdot (u) = 0 \quad (2)$$

$$\rho_f C_p \frac{\partial T}{\partial t} + \rho_f C_p u \cdot \nabla T = \nabla \cdot \left(k_f \nabla T\right) \quad (3)$$

Regarding the radiofrequency electric field, under lower RF frequencies (460 kHz), Maxwell's equations can be approximated by the quasi-static field approach.

$$\nabla \cdot [\sigma_a \nabla U] = 0 \quad (4)$$

$$Q_{RF} = \sigma_a |-\nabla U|^2 \quad (5)$$

Finally, the bioheat transfer equation is utilized to integrate the heat transfer effects of the electric and flow fields, focusing on the heating of the target tissue.

$$\rho_a C_p \frac{\partial T}{\partial t} = \nabla \cdot (k_a \nabla \mathrm{T}) + \sigma_a (\nabla U)^2 \quad (6)$$

At the contact boundary between the cooling medium and the balloon, which serves as a fluid-solid coupling interface, a perfect contact condition and no-slip boundary condition are used.

$$k_f \frac{\partial T_f}{\partial \boldsymbol{n}} = k_a \frac{\partial T_a}{\partial \boldsymbol{n}}, r = 2mm \quad (7)$$

$$v = 0, r = 1mm/2mm \quad (8)$$

Table 1: Material properties of the RFA device.

Parameter	Artery	Electrode	Ballon	Fluid(Water)
Electrical conductivity σ (S/m)	0.33+0.0035*（T-20℃）[5]	0	5.76*10^7	5.5X10^-6
Thermal conductivity k (W/m·K^{-1})	0.60+0.0014*(T-0℃)[6]	0.25	386.47	0.63
Density ρ (kg/m^3)	998.2	1300	8935.4	999.8
Specific heat C_p (J/kg·K^{-1})	4183	110	383.9	4202
coefficient of viscosity μ(Pa·s)	/	/	/	0.01779/（1+0.03368T+0.0002210T^2）

RESULTS

To evaluate the effectiveness of jet flow, the ablation results of the RF balloon group (CT Group), the natural convection group (CF Group), and the jet flow group (JF Group) are shown in Fig.2. A 30-second RFA with 27V voltage was simulated. A velocity of 50mm/s and cooling temperature of 5°C is used at the inlet of cooling medium. It is found where there no cooling medium for same RF parameter, the CT Group (Fig. 2a) produces a larger ablation area (60°C isothermal surface，a critical temperature for cell killing [7]) with rapid temperature rise and significant distal expansion. Both the CF Group (Fig. 2b) and the JF Group (Fig. 2c) effectively shaped the ablation area. The JF Group achieved an ablation area further from the electrode, with the region close to the electrode clearly spared from being heated. The ablation area of the JF group is flatter and limited within the lumen (indicated by the pink circle), whereas the CF group penetrates.

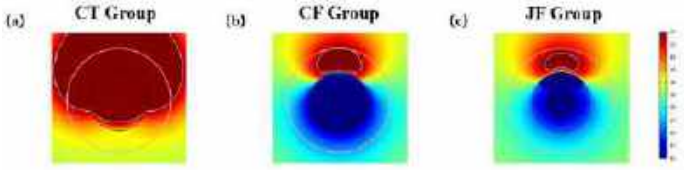

Figure 2: The ablation effect of CT, CF and JF group.

The temperature distribution near the surface of the balloon is shown in Fig.3. The vertical axis of the data graph represents the temperature values near the surface of the balloon, as indicated by the red dashed line in Fig. 3a, while the horizontal axis is the angle formed between the line connecting the points on the dashed line to the center of the circle and the positive X-direction. Temperatures below 60°C are considered safe, as shown by the green rectangular area in Figure 3b. Evidently, lack of a cooling medium, the ablation area of the CT group rapidly exceeded this safe threshold, accounting for approximately 42.6%. In the core ablation area, between two electrodes (from 75.68° to 104.32°), the CF group effectively achieved temperature control. However, the uniform coolant caused a rapid decrease in temperature in the non-ablated areas, dropping as low as 11.1°C and posing a risk of low-temperature damage to the inner layers. The cooling efficiency of the JF group is primarily concentrated in the targeted ablation area, with temperatures in the non-target areas within safe temperatures.

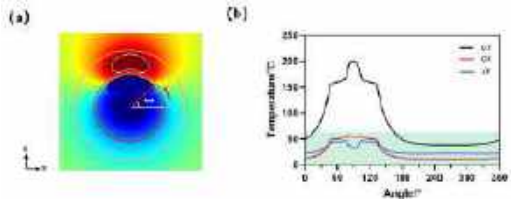

Figure 3: Temperature field distribution around the RF balloon.

When the jet flow was aligned at different angles from the positive X-direction, the morphology of ablation can be adjusted flexibly.
When the jet is directly aligned with the ablation center (angle=90°), it exhibits the highest convective heat transfer intensity, capable of forming a flat and symmetrical ablation area distant from the lumen wall. When the jet is directly facing the position of a single electrode (angle=60°~75°), the ablation area at that position is reduced, resulting in an asymmetrical ablation shape, which better conforms to clinical lesions. The JF Group's ablation morphology was more diverse and flexible, capable of adapting to most RFA scenarios.

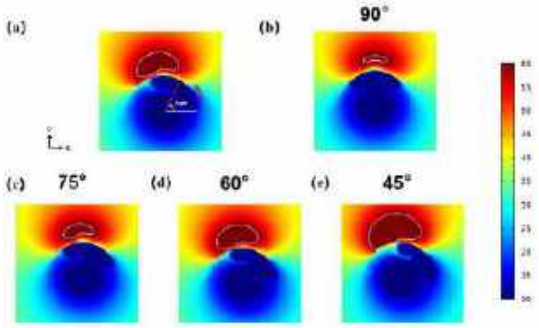

Figure 4: Effect of jet Angle on ablation morphology.

DISCUSSION

This study indicates that the RF balloon with tunable jet flow can achieve localized intense cooling, thereby facilitating high-depth (~0.65mm) transluminal radiofrequency ablation while effectively reducing the risk of low-temperature damage in non-ablated areas. When increasing the flow rate and decreasing the temperature of the cooling medium, the penetration depth can further be enhanced. By adjusting the direction of the jet flow in the inner tube, the morphology of the ablation can be flexibly modified, offering greater adaptability.

This multi-physics coupled simulation results lay the theoretical foundation for the adjustability of RFA morphology by microchannel jetting. In subsequent research, an optimized Shear Stress Transport (SST) model and a porous medium model will be applied to more accurately reflect the heat transfer effects in biological tissues. The efficacy of this design will also be further validated through ex vivo vascular tissue experiments and in vivo animal studies.

INTRODUCTION

Soft tissue injuries, such as ligament and tendon tears, are debilitative, costly, and often necessitate surgeries with suboptimal results. Injury prevention strategies, however, remain elusive due to a lack of understanding of the factors that influence injury risk. For example, in populations with increased injury prevalence, is anatomy (geometry) to blame, or the tissue (material) itself?

Injuries result from a critical accumulation of mechanical damage to the extracellular matrix (ECM) [1]. Fibrillar collagens, in particular, impart most of the tensile strength of soft tissues, and are known to exhibit microdamage at multiple length scales (including molecular denaturation) following subcritical mechanical loading [1-2]. However, the effect of ECM composition on susceptibility to mechanical microdamage is not understood. To address this gap, we recently developed a full-field material characterization method for defining *tissue injury criteria*: multimodal strain thresholds for soft tissues [3].

Here, our objectives were to determine whether compositional changes due to (1) a mutation in the *Col1a2* gene (a model of osteogenesis imperfecta) [4], (2) a *Fbn1* "tight skin" mutation (*Tsk*, a model of fibrosis) [5], (3) sex, and (4) treadmill exercise (known to stimulate ECM remodeling [6]) affect stress- or strain-based injury susceptibility of the murine medial collateral ligament (MCL).

METHODS

To investigate the effect of the *Col1a2* mutation, MCLs from 12 week old male wild-type *Col1a2*$^{+/+}$ (WT, n=3), heterozygous *Col1a2*$^{+/-}$ (HET, n=3), and mutant *Col1a2*$^{-/-}$ (MUT, n=3) mice from the same colony were compared. To investigate the effects of the *Tsk* mutation and sex, MCLs from 10 week old female *Tsk* (TSK♀, n=3), female wild-type (WT♀, n=3), and male wild-type (WT♂, n=3) mice from the same colony were examined. Finally, the effect of exercise was investigated by comparing MCLs from 19 week old cage control (CON, n=3) female wild-type mice (Jackson Laboratory) to those from mice run on a treadmill (Stoelting Co.) with either no incline (EX0, n=4) or at a 15 degree incline (EX15, n=4) for 30 minutes/day, 5 days/week, for 10 weeks. All mice were euthanized with protocols approved by the CU Boulder IACUC.

Following harvest, MCLs were isolated and mechanically tested using our previously developed method [3]. Briefly, tibia-MCL-femur specimens were stained with Ghost Dye (Tonbo Biosciences) and NucBlue (ThermoFisher) for 3 hours to provide a fluorescent trackable pattern. MCL samples were stretched in a 1× PBS bath under a confocal microscope (Leica) with a custom testing device that employed a 10 N load cell (Futek) and custom bone grips. MCLs were stained for collagen denaturation prior to testing and after each applied deformation by replacing the PBS bath with a 5μM solution of collagen hybridizing peptide (CHP) for 15 minutes. Confocal images were taken at 10× in each reference and deformed state. Samples were stretched to applied displacements of 500, 750, and 1000 μm.

Displacement fields were estimated using Ghost Dye and NucBlue images of reference and deformed states, and differentiated to calculate Lagrange strain fields. Binary damage maps were estimated with a moving threshold that accounted for stain time. In-plane strain components and damage data were compiled for every pixel in the sample across all stretch states and all samples within an experimental group. Logistic regression was used to determine strain-based injury criteria: the boundary where the probability that significant collagen damage was sustained, P(damage), as a function of in-plane strains, was equal to the probability that it was not.

Group differences in apparent tangent modulus and stress-based susceptibility to collagen microdamage were assessed with linear mixed models (LMM). For these analyses, average axial stress (global force over cross-sectional area) was computed for each sample and compared to average axial strain (from strain fields) or the percent of pixels with significant collagen damage, respectively. For all analyses, statistical significance was defined as $p<0.05$.

RESULTS

The *Col1a2* mutation lowered stress-based (but not strain-based) injury susceptibility, the *Tsk* mutation lowered strain-based (but not stress-based) susceptibility, sex had no effect on either, and exercise altered both. For all figures, bars with asterisks indicate statistical significance ($p<0.05$) and data from different biological replicates are plotted with different shaped markers.

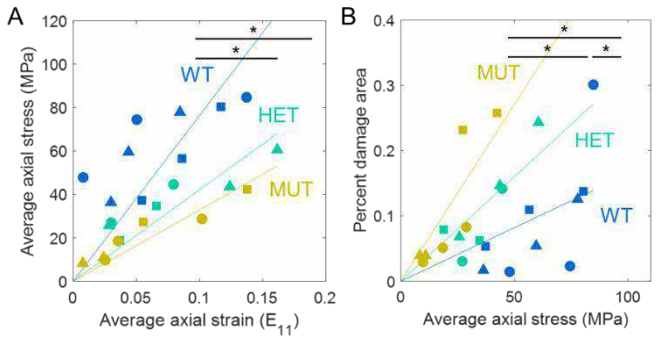

Figure 1: The Col1a2 mutation decreased stiffness (A), increasing stress-based (but not strain-based) injury susceptibility (B).

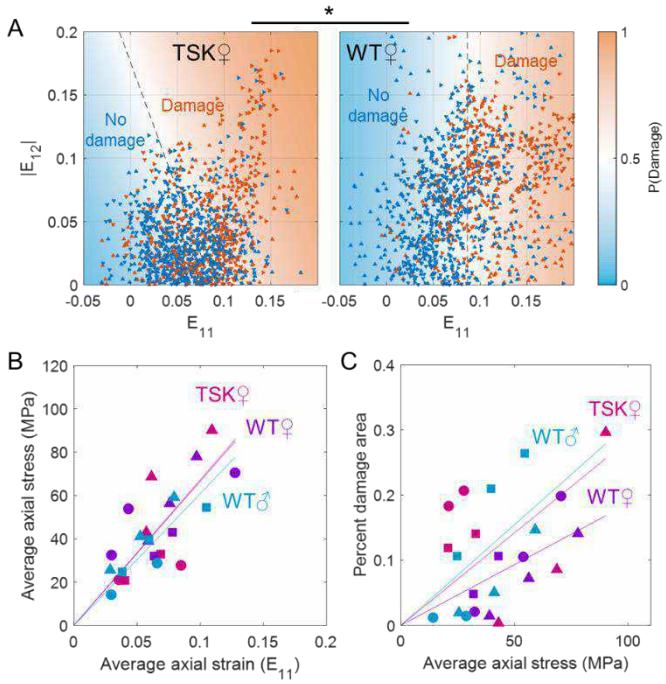

Figure 2: MCLs from Tsk mice were significantly more susceptible to strain-based injury, particularly with respect to shear (A), but showed no difference in stiffness (B) or stress-based injury susceptibility (C) compared to those from WT mice.

MCLs from Col1a2 HET and MUT mice were significantly less stiff than those from WT mice (Fig. 1A). This difference created significant differences in stress-based measures of injury susceptibility across all groups, with MCLs from MUT mice appearing weakest (Fig. 1B). In contrast, MCLs from TSK mice exhibited significantly greater strain-based injury susceptibility than those from WT mice (Fig. 2A), particularly from shear strain (E_{12}). No differences were observed in any measures between MCLs from male and female WT mice (Fig. 2B-C). MCLs from EX0 and EX15 mice exhibited significant differences in all measures compared to those from CON mice (Fig. 3A-C).

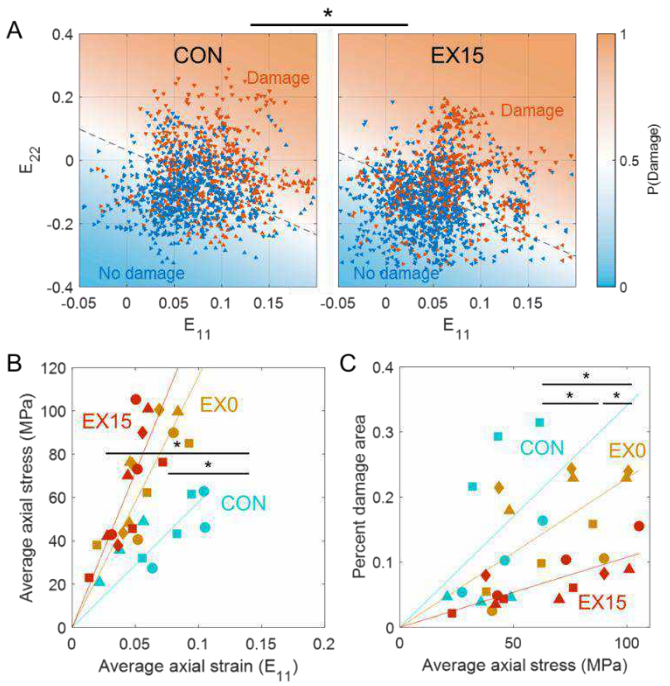

Figure 3: Treadmill exercise slightly increased strain-based injury susceptibility of MCLs (A), but significantly increased stiffness (B) and lowered stress-based injury susceptibility (C).

DISCUSSION

In general, when the axial stress-strain relationship was altered (e.g., Col1a2 mutation and treadmill exercise), stiffer MCLs appeared more robust to stress-based collagen damage, with little or no change in strain-based injury susceptibility. In the case of the Col1a2 mutation, MCLs were less stiff and weaker, but not more brittle. Exercise-induced remodeling, on the other hand, appeared to sacrifice a small loss in ductility in favor of far stiffer and stronger MCLs. In contrast, the Tsk mutation did not affect stiffness or strength, but did result in more brittle ligaments, particularly with respect to shear strain. Raman spectroscopy did not reveal any differences in tissue composition (data not shown), but higher fidelity assessments are currently underway using mass spectrometry to determine the changes in ECM composition that may be responsible for the observed alterations in material properties. This first-of-its-kind study, although limited in terms of sample size, will provide insight into the role of tissue composition in microdamage accumulation and injury of soft tissues. The results will also be important for developing accurate computational models of soft tissue injury and, long-term, have the potential to guide the development of patient-specific injury prevention strategies.

INTRODUCTION

Cardiovascular disease (CVD) remains a significant global health concern [1]. Image-based computational fluid dynamics (CFD) has proven to be an essential tool for diagnosis and treatment planning, providing comprehensive non-invasive hemodynamic flow information [2]. However, conventional image-based CFD methods require substantial computational resources and time making them impractical for many-query simulations involving uncertainty quantification, parameter estimation, and design optimization [3-5].

With the ever-growing computational capabilities and advancements in artificial intelligence, a significant amount of endeavors have been dedicated to developing deep neural networks (DNNs) as CFD surrogates to promote the efficiency and reduce computational cost [6-9]. Regrettably, most of these models are trained in a data-driven manner, requiring datasets comprising hundreds or thousands of samples. However, obtaining such a large dataset is often impractical due to the scarcity of patient samples and the high costs associated with medical image scans. To the best of the author's knowledge, there is presently no sufficiently large patient-specific geometry dataset available for the direct training of a DNN-based CFD surrogate model. Consequently, the synthesis of cardiovascular geometries becomes indispensable for successfully model training.

The relevant research endeavors on the synthesis of cardiovascular geometries trace back to a decade ago, even predating the emergence of DNN-based CFD surrogate models. These studies often involve computing several macroscopic geometry statistics, referred to as biomarkers, tailored to represent specific organs of interest (e.g., heart chambers, vessels) in a patient. Subsequently, a regression algorithm is developed to link these biomarkers to the outcomes of diagnostic activities, such as aneurysm prognosis [10,11], risk assessment [12,13], treatment planning [14,15], and the design of surgical implant devices [16,17], etc. Despite the success of these tasks, they struggle to capture intricate geometric details due to the reliance on macroscopic biomarkers. Recent explorations have addressed this limitation by incorporating microscopic geometric features, such as vessel skeleton/centerline and surface features, a concept commonly referred to as Statistical Shape Model (SSM). Principal Component Analysis (PCA) is frequently applied to the feature matrix in SSM to reduce dimensionality. This further unlocks the capability to geometry synthesis since random sampling of the PCA coefficients can immediately generate new feature vectors that reconstructs to a complete geometry. This paradigm can be divided into two categories based on the geometric features: Centerline points with local polar coordinates [18-21] and surface point coordinates [22-27]. In the former approach, the geometry (i.e., vessel) is often parameterized using a vessel coordinate system, and a corresponding surface reconstruction function is created to reconstruct a synthesized vessel "skeleton" into a complete surface. On the other hand, the latter approach requires point correspondence built beforehand to equalize the length of each feature vector, a necessary premise for PCA. This typically involves a non-rigid registration task where a deformation algorithm is adopted.

Despite the rich literature, these two approaches have several limitations. The centerline-based approach oversimplifies surface geometries, fails to capture surface details especially on vessel junctions, leading to inaccurate CFD simulation results. Whereas the surface-based approach necessitates point correspondence construction which is cumbersome and inevitably produce error due to discrepancy between deformed surface and target surface. Additionally, it uses a linear encoder like PCA for new sample generation, which may produce unphysical samples outside the underlying probability space. While probabilistic generative models can address this issue, exploration in this direction is still rare. Only Romero et al. [26] and Ostenforf [27] have used generative adversarial models (GANs) on a single branch aorta and an aorta with dissection, respectively. To fill this gap, we propose a novel geometry synthesis algorithm based on a diffusion model that generates an aorta with supra-aorta branches.

METHODS

Prior research on applying diffusion models to 3D shapes has predominantly concentrated on casual objects [28-30]. Inspired by [28], we have developed, for the first time, a shape synthesis framework that employs a diffusion mechanism in a multi-branch geometry context. Our approach involves an initial preprocessing step where we generate uniform point clouds directly on the shape's surface, eliminating the need for point correspondence. Subsequently, we utilize a Point-Voxel CNN [32] to parameterize the denoising process, defined by (x, t), and it is trained using a specifically formulated loss function:

$$\min_{x_t,\epsilon\in N(0,I)} ||\epsilon - \epsilon_\theta(x_t, t)|| \quad (1)$$

where $x_t = \sqrt{\bar{\alpha}_t}x_0 + \sqrt{1-\bar{\alpha}_t}\epsilon$ is the disrupted sample at time t. After the model is trained, we can start from a random white noise and iteratively obtain denoised samples using the following equation:

$$x_{t-1} = \frac{1}{\sqrt{\bar{\alpha}_t}}(x_t - \frac{1-\alpha_t}{\sqrt{1-\bar{\alpha}_t}}\epsilon_\theta(x_t, t)) + \sqrt{\beta_t}z,\ z \sim N(0, I) \quad (2)$$

Figure 1 illustrates the complete pipeline of the proposed model.

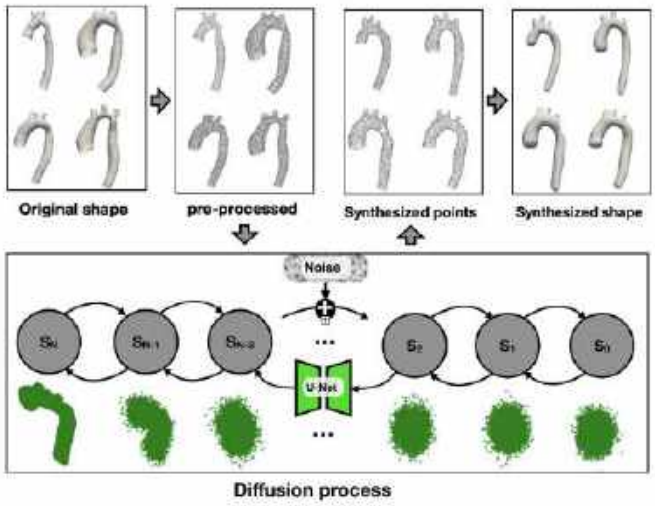

Figure 1: schematic of the proposed model.

RESULTS

To demonstrate the effectiveness of our model. We synthesized 1000 new multi-branch aorta geometries from a dataset in [19]. The original shapes and the synthesized shapes are displayed in Figure 3.

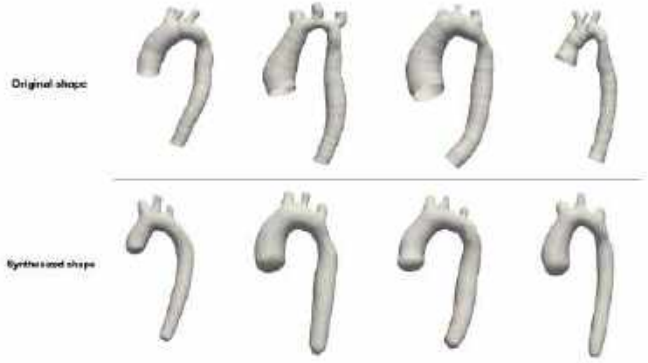

Figure 2: Synthesized aorta shapes

DISCUSSION

From Figure 2, it can be observed that the proposed model generates new multi-branch aorta geometries that differ from the training samples in the dataset, while preserving the geometric characteristics of the original shapes. This demonstrates the strong performance of the proposed model. Future biomarkers will be computed on these newly generated geometries to further verify their validity.

INTRODUCTION

The anatomic structures within the knee – including the tendons, ligaments, meniscus, and articular cartilage – contribute significantly to the movement and stability of the joint (1). Sheep (ovine) are important in preclinical and comparative medicine because their stifles (equivalent to human knees) have a length and load scale that is closest, of commonly used large animal models, to those of the human knee. Multiscale biomechanical studies of the knee joint are therefore critical to designing studies relevant to orthopedic research and late-stage preclinical studies (2). Current computational models, which aim to simulate the joint responses as an ensemble of the component tissues, face certain restrictions in incorporating the tissue geometry and their nonlinear elastic properties. Studies often sample the model inputs from different studies, comprising of different animal models and individuals. This strategy may reduce model reliability due to variability in sampling, specimen size and condition, and variation in measurement techniques (2). To our knowledge, there are yet no studies that adopt a multiscale approach to evaluate the knee biomechanics by determining the individual structural and functional properties of the underlying soft tissues and laxity properties of the same joint in ovine models.

Towards a deeper understanding of such problems, we investigated the relationships between whole joint and individual tissue properties using a combination of mechanical testing and imaging techniques. Specifically, we compared the results from joint laxity measurements and imaging-based joint size parameters to individual tissue mechanical properties collected from the ligaments (ACL, PCL, MCL, LCL), the patellar tendon, menisci, and cartilage. We combined mechanical testing at two length scales and anatomical and quantitative magnetic resonance imaging (MRI) to investigate whether there are any significant correlations between the whole joint mechanics, morphology, and individual tissue properties.

METHODS

Ovine stifles were obtained after humane euthanasia of sheep used for teaching purposes under institutional approval. The collected stifles were cleaned, wrapped in PBS-soaked gauze to maintain hydration, and stored in sealed plastic storage bags at -20°C until testing. Frozen ovine stifles were thawed at 4°C over a period of 24-36 hours before mechanical testing and MRI. Joint laxity testing was performed on ovine stifles using a 10-kN capacity load frame (MTS Systems). Each stifle was preconditioned for twenty cycles, following which they were loaded cyclically to ±1.5-mm sinusoidal displacements for 10 cycles at 0.2mm/s (Figure 1a). The difference between the peak forces at the endpoints of the cyclic displacement input was calculated as a measure of joint laxity force. Stifles were imaged using a Bruker Biospec 70/30 7T MRI (Billerica, MA) in an 86-mm transmit-receive volume coil. Anatomic 3D T_1-weighted FLASH was used to quantify tissue geometry, and a 2D multi-slice, multi-gradient echo sequence was used to determine the T_2* relaxation time within all tissues of interests. T_2* relaxation times were shown to correlate with soft tissue degeneration (4). The femur was manually segmented in Slicer (v5.2.2) to determine the epicondylar distance as a metric of joint size and compared to the force measurements from laxity testing (Figure 1b). MATLAB (v2022b) was used to fit a monoexponential equation (Eqn. 1) of image signal intensity (S) from multi-gradient echo images with multiple echo times (TEs) to estimate maximum signal intensity (S_0) and T_{2*}.

$$S = S_0 e^{-\frac{TE}{T_{2*}}} \quad (1)$$

To quantify tissue-specific biomechanical behavior, specimens were dissected in standardized geometries from the ACL, PCL, MCL, LCL, patellar tendon, menisci, and articular cartilage from the femoral condyles. Stress relaxation tests were performed on these tissues at 5 and 10% strain, with testing under tension for the tendon and ligaments and under compression for the menisci and cartilage. A 3-parameter nonlinear Prony series model (5) was used to quantify the viscoelastic properties of the tissue from the experimental data. The parameters measured from the model fits to data were used to estimate the instantaneous modulus (E_{inst}) and relaxation modulus (E_o) for each

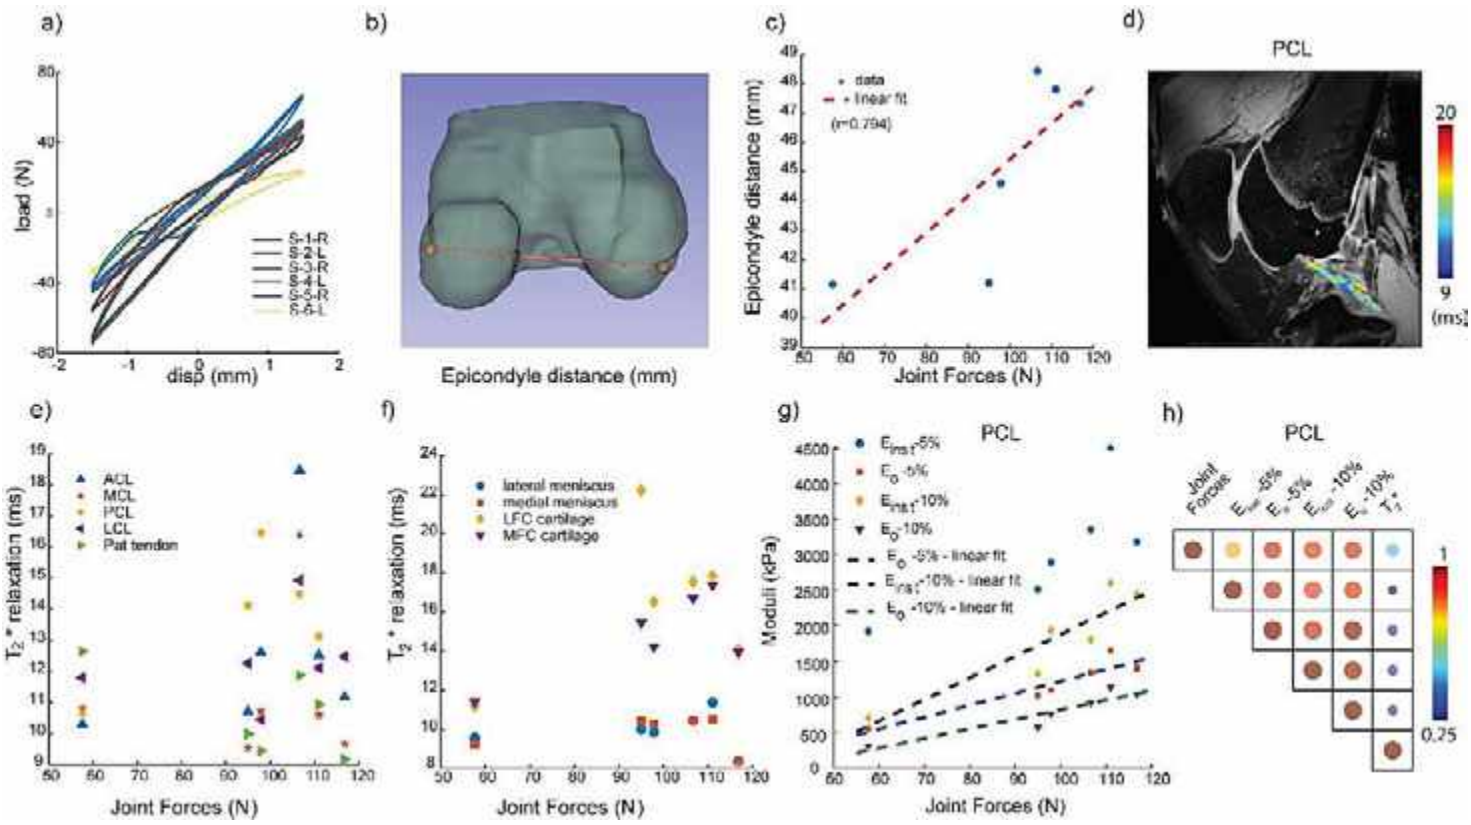

Figure 1: (a) Cyclic load (N) and displacement (mm) profiles over time obtained from joint laxity test. (b) Epicondyle-to-epicondyle distance measured from the segmented femur geometry. (c) Correlations between joint laxity forces and epicondylar distance. (d) Representative T2* relaxation map of ovine PCL (e) & (f) Mean T2* relaxation values (ms) for tissues tested in tension and compression, respectively, plotted against joint forces (g) Variation in PCL viscoelastic moduli (kPa) at 5 and 10% strain plotted against joint forces (N) (h) Pearson's linear correlation (r) between joint forces (N), instantaneous and relaxation tissue moduli (kPa), and mean T2* relaxation times (ms) for PCL.

tissue. These viscoelastic moduli were then compared with joint laxity and MRI-based measurements.

RESULTS

Our results highlight some significant correlations between the whole joint mechanics, joint size metric, and individual tissue properties. We observe a strong positive correlation (r = 0.794) between the joint forces measured from the laxity experiments and the joint morphometric, with the range of measured forces being higher for the stifles having larger femoral epicondylar distance (Figure 1c). From qMRI, we measured the spatial distribution of T_2* relaxation times for each tissue (Figure 1d). Next, we used these measurements to evaluate the variation of the T_2* values against the measured joint forces from laxity tests for tissues tested in tension (Figure 1e) and compression (Figure 1f). Except in articular cartilage from the medial and lateral femoral condyles, we did not observe a significant correlation between the T_2* relaxation and tissue moduli,. Next, we compared tissue-level instantaneous and relaxation moduli and to joint laxity forces for all tested specimens. We noted strong positive correlations (r > 0.8) with the whole-joint forces within the PCL (Figure 1g) and the other ligaments (not shown due to space limitations), as well as the patellar tendon forces. However, no significant correlations or trends were observed between tissue moduli and the corresponding T2* relaxation values in the PCL (Figure 1h) nor other ligaments and tendon. No significant correlations were observed between joint laxity forces and either meniscus or cartilage.

DISCUSSION

In this study, we provide joint laxity forces and tissue viscoelastic parameters for individual tissues from the same joints. Our results show correlations between some of the tested parameters that can provide useful insights into the joint mechanics and facilitate data interpretation for clinical evaluation. Specifically, we observed that the forces measured during whole joint testing correlated directly with the size of the femur bone of the stifles, measured using the inter-epicondylar distance. We also found that the viscoelastic properties of the tendons and ligaments correlated positively with joint laxity forces. These results can provide useful insights into the differential role of individual tissue properties that can be used to design sample specific computational models to assess the knee joint properties as an ensemble of the underlying soft structures for development of better diagnostic techniques and clinical assessment.

IN VIVO LUMBAR INTERVERTEBRAL DISC STRAIN IN FLEXION, EXTENSION, AND DIURNAL MOTIONS: VARIATION WITH AGE IN HEALTHY ADULTS

John M. Peloquin (1), Harrah R. Newman (1), Edward J. Vresilovic (1), Dawn M. Elliott (1)

(1) Biomedical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

Intervertebral disc (IVD) degeneration is an important contributor, among other factors, to low back pain and associated disability. IVD degeneration is also a normal part of aging. Spine MRI typically reveals numerous instances of *structural* IVD degeneration, with significant ambiguity regarding which are clinically relevant or may become so. There is a need for methods to better distinguish between pathology and normal aging. Deterioration of mechanical function, i.e., *mechanical* degeneration, is more difficult to measure *in vivo* but its measurement may nevertheless provide significant benefit [1,2]. We previously developed an image registration method to measure IVD strain from MRI [3–5], with successful application to age 20–30 y adults [6]. As the next step towards clinical application, the objective of this study was to measure IVD strain in asymptomatic adults of all ages (1) to provide a realistic measure of normal variation with age and (2) to identify factors that influence IVD strain and thus would support a subject-specific definition of "normal" IVD mechanics.

METHODS

Lumbar (L1–S1) spine MRI was acquired from 84 healthy human subjects without a history of low back pain, under IRB approval, with 7 males & 7 females per decade from 20 y to 70+ y. To assess mechanical degeneration, 3D T1w MRIs were acquired in supine, flexed, and extended positions ~ 8:00 AM, with another supine MRI acquired late in the same day ~ 7:00 PM. IVD strain was measured for these perturbations (flexion, extension, diurnal; Fig 1), with the AM supine image as the reference state, using our established image registration-based method [3–6] (Fig 2), which produces a diffeomorphic displacement field between each reference and deformed image pair. Axial strain (endplate-to-endplate) was averaged within disc regions (Fig 2B,C). To assess structural degeneration, T2w TSE images were acquired for Pfirrmann degeneration grading and T2 CPMG images were acquired to measure nucleus pulposus (NP) T2. A custom U-Net neural network was used to segment each IVD, with manual corrections when needed. The segmentations were used to measure disc height and anterior–posterior (A–P) width and to verify the image registration strain measurement.

Relationships between IVD strain and disc structural factors were analyzed for each perturbation using a linear mixed model (LMM). Subject was a random effect; all other factors were fixed effects. Continuous factors were centered at their mean. For categorical factors, L3–L4, Pfirrmann grade 2 (which had the best coverage across age), and female sex were used as the reference levels. Grade 5 IVDs (34 out of 420 IVDs) were excluded, being fully collapsed. The expected strain for a given subject is the model's intercept plus each factor's fixed effect × its deviation from the reference level.

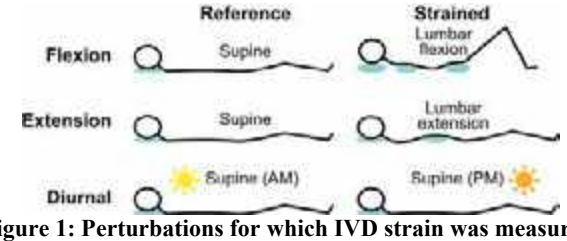

Figure 1: Perturbations for which IVD strain was measured. Flexion and extension were induced with pillows (cyan ellipses).

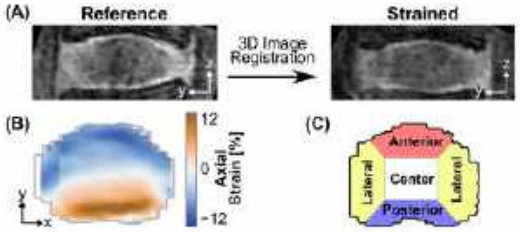

Figure 2: (A) Example reference & strained 3D T1w MRIs (flexion, mid-sagittal slice). (B) Axial slice of resulting axial strain field. (C) Strain field regions used for analysis.

RESULTS

Flexion produced region-dependent strain, with −2.2 ± 0.7 % in the anterior and 3.0 ± 0.7 % in the posterior (Fig 3, Intercept). Because greater flexion causes opposite strains in the anterior and posterior regions, all factors were analyzed as interactions with region (Fig 3). Strain depended on disc level ($p = 0.03$, factor dropout), with lower levels tending to have greater center and lateral compression. Posterior strain differed by −0.5 ± 0.2 % per +10 y of age, 0.22 ± 0.09 % per +1 mm A–P width, and −0.22 ± 0.10 % per +10 lb of body weight. All fixed effects accounted for 30% of the total flexion strain variance.

Extension also produced region-dependent strain, with 3.3 ± 0.6 % in the anterior and −1.3 ± 0.6 % in the posterior (Fig 4, Intercept). Anterior and posterior strain magnitude was greater in the upper levels ($p < 0.001$, dropout). Posterior strain differed by 0.4 ± 0.2 % per +10 y age. Each +1 mm of A–P width was associated with +0.18 ± 0.07 % anterior strain, and each +1 mm disc height with −0.35 ± 0.15 % center strain, with similar trends in the other regions. Pfirrmann grade 4 was associated with +1.7 ± 0.7 % anterior strain, with Pfirrmann grade having a significant overall effect ($p = 0.04$, dropout). The center and posterior regions had lesser strain with greater body height and greater strain with greater body weight, with similar trends for lateral strain. All fixed effects accounted for 45% of the total extension strain variance.

Mean diurnal strain was −4.6 ± 0.6 % in the disc center (Fig 5, Intercept), with the anterior region having 0.9 ± 0.2 % greater strain (less compression) (Fig 5, Region → Anterior). Each +10 y of age was associated with 0.48 ± 0.16 % less compression, each +10 ms NP T2 with 0.14 ± 0.07 % more compression, and each +1 mm A–P width with 0.14 ± 0.05 % more compression. Lower lumbar levels may have had less compression ($p = 0.06$, dropout). All fixed effects accounted for only 8% of the total diurnal strain variance.

DISCUSSION

Disc strain differed with age in all three perturbations despite controlling for structural disc degeneration. The effect of age was consistently opposite the population average strain (intercept); i.e., there was less deformation with age. In contrast, degeneration measures (Pfirrmann ↑ or NP T2 ↓), when they had a significant effect, magnified strain. Thus, disc degeneration as observed by MRI could be interpreted as compensating for latent (unobserved) age-related factors. The effects of disc level and region were consistent with prior observations in age 20–30 y subjects [6,7]. Here, likely due to sampling a broad age range, we additionally found lesser NP T2 (indicating less water and glycosaminoglycan) to be associated with less diurnal compression.

For the purposes of detecting aberrant mechanical function and hence pathology, extension may be especially useful because its LMM accounted for the greatest share of variance; it provides the most stable "normal" baseline. However, the majority of the explained variance was from disc level, possibly due to consistent imposition of extension rather than physiology, so flexion is also a strong candidate. From a basic science perspective, diurnal strain is interesting because its high proportion of unexplained variance suggests influence from unobserved properties (e.g., tissue permeability) uncorrelated with any of the LMM factors. Diurnal strain thus likely provides unique information. Regardless, multivariate modeling is important to isolate each factor's marginal effects, since factors such as age, NP T2, and Pfirrman grade were strongly correlated with each other ($R^2 \sim 0.5$). Ultimately, application to subjects with low back pain will be necessary to establish the method's sensitivity to pathology, and this process is ongoing. As this dataset includes both tension–compression data from flexion & extension and slow (fluid flow related) diurnal deformations from the same IVDs, with an *in vivo* reference state, it is also extremely valuable for the development and validation of spine mechanics models.

REAL-TIME SEGMENTATION, VIRTUAL IMAGE MODIFICATION, SURGICAL INTERVENTION MODELING AND 3D PRINTING (REVISIT-3D): A TREATMENT PLANNING WORKFLOW FOR CONGENITAL HEART DISEASE

INTRODUCTION

Successful surgical treatment of congenital heart disease (CHD) requires intricate understanding of the spatial 3D relationship between complex cardiac structures. While these spatial relationships exist in 3D, preoperative planning has traditionally relied upon imaging modalities viewed in 2D[1]. Translating these 2D views to 3D poses the risk of misunderstanding or underappreciating important intracardiac relationships[2]. As a result, 3D reconstruction, modeling and printing have evolved to improve the understanding of spatial relationships between complex structures, even facilitating virtual treatment planning with current computational tools[3]. The objective of the current work is to use such computational tools through real-time collaboration with clinicians to further advance 3D visualization, better understand intracardiac relationships, and develop an associated surgical plan for patients with complex CHD. We refer to the process as **RE**al-time segmentation, **V**irtual **I**mage modification, **S**urgical **I**n**T**ervention modeling and **3D** printing (**REVISIT-3D**). REVISIT-3D has the goal of improving preoperative understanding of spatial anatomic associations, expanding discussions of surgical options, and improving acute outcomes post-operatively.

METHODS

The workflow for creating visualization products (e.g. virtual and printed 3D structures) from patient data is a multi-step process (Fig 1). De-identified volumetric patient datasets (CT/MRI/3D echo) acquired during routine clinical scans are transferred to biomedical engineering team members following identification of possible visualization products and outcomes/impact measures when possible. The data is then segmented using a combination of modeling and data-processing software, namely 3D Slicer (slicer.org)[4], Blender (www.blender.org), and ITK-SNAP (www.itksnap.org), to isolate cardiac structures of interest. The segments are converted to virtual models and assembled in ParaView (www.paraview.org) for clinical feedback and revision as needed. If necessary, the models are refined, smoothed, or decimated using Blender to emphasize detailed structures or reduce file size based on the clinician-indicated visualization product to be created. If the structures are to be 3D printed, they are then combined in preparation for that process. Baffles and conduits are also created as necessary using specialized modules and extensions in 3D Slicer[5], and then virtually implanted/combined in SolidWorks (www.solidworks.com) while consulting with clinicians. Combining anatomical structures and implementing the conduit/baffle is an iterative process depending on the number and complexity of structures. Structural quantities of interest (e.g. volumes, areas, or distances) are then quantified using SolidWorks, ParaView, or Blender. Dissemination is then performed via one of these software packages.

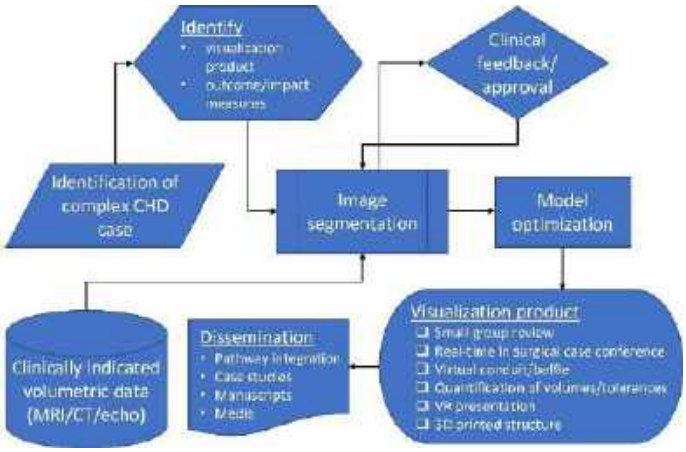

Figure 1: REVISIT-3D workflow showing the steps associated with real-time visualization and collaboration between clinicians and biomedical engineers.

RESULTS

The REVISIT-3D workflow has been applied to three cases with varying forms of CHD since March of 2023, which are further described below.

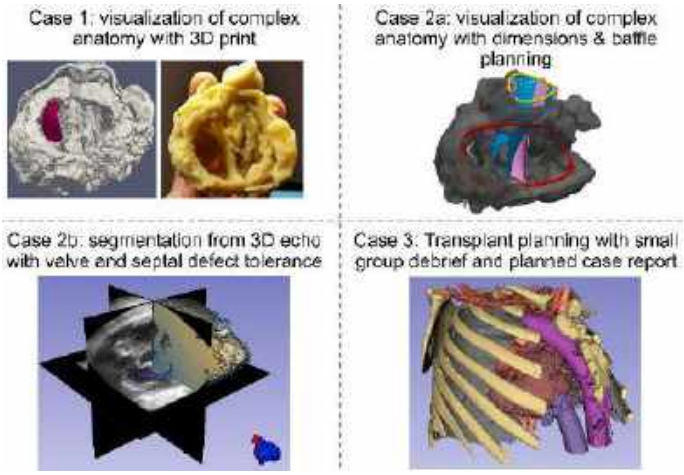

Figure 2: Summary of REVISIT-3D cases to date

Case 1. CT derived model – Virtual reality (VR) analysis and 3D printing provided better clarity of the relationship of a ventricular septal defect to the right ventricular outflow tract. This model served as the testing ground and blueprint for the workflow and provided opportunities to refine and improve each step. The main goal of this case was to create a 3D printed model to better define the ventricular septum and proposed outflow pathways as part of preoperative surgical planning. After the model had been 3D printed, a virtual baffle was implanted into the left ventricle model (Fig 2, in red) to explore the feasibility of the baffle-creation process for potential future use. REVISIT-3D products informed the proposed surgical plan for this patient.

Case 2. MRI derived model – Modeling was conducted to visualize and quantify the relationship of the ventricular septal defect in relation to the left ventricular outflow tract (Case 2a). Visualization products included proposed baffle patches for complex biventricular repair. Three baffle designs were constructed: an ideal (i.e. unrealistic) patch, a best-case patch, and a realistic patch. The quality of each baffle was evaluated based on the minimum distance between baffle and septum (Fig 3). Modeling suggested that the left ventricle-aorta baffle pathway precluded complex biventricular repair and the patient has undergone completion of single ventricle palliation. This case also used 3D echocardiography generated models of the atrioventricular valve to initiate strategies for combining CT/MRI and 3D echocardiography generated models in a single virtual space (Case 2a).

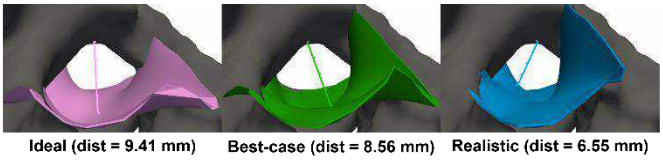

Figure 3: Proposed baffle designs and dimensions for Case2b.

Case 3. CT derived model – The process is being applied for a patient with complex venous anatomy undergoing evaluation for cardiac transplantation. This case required a virtual model only and was used to visualize complex cardiac structures for preoperative planning (Fig 4). The models consisted primarily of the heart, aorta, carotid arteries, pulmonary arteries, and diaphragm. Modeling and planning for optimal transplant strategies is ongoing and planned for conference presentation.

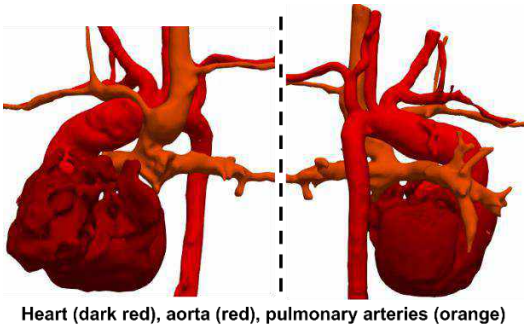

Figure 4: Case 3 virtual model for transplant operative planning: anterior (left), and posterior (right).

DISCUSSION

The REVISIT-3D process has been successfully applied for 3 cases from patents with CHD to create virtual and 3D printed models. Each case demonstrates a specific capability of the process – Case 1 demonstrates the ability to print 3D models from the models created virtually; Case 2 illustrates the value of virtual baffle creation process and comparison of different dimensions with baffle adaptation; Case 3 demonstrates the scalability of the process to larger, more intricate structures. The models have aided clinicians in preoperative planning, providing perspective and tools that have otherwise not been used at our institution to this degree.

Future work to be presented aims to project virtual baffle models as flat representations, which cardiothoracic surgeons can then use as a stencil during surgery[5]. Additional future work involves measuring outcomes of success in response to the implemented processes. For example, we plan to generate anticipated postoperative ventricular volumes based on proposed surgical patch creation and disseminate such data to inform future surgical planning. Moreover, in a subset of patients with double outlet right ventricle undergoing biventricular repair, we plan to compare the proposed/modeled surgical intervention to native postoperative imaging. Differences will be used to better inform future modeling and account for physiologic details arising from observed versus potential ventricular volumes[6].

The work presented here demonstrates the value and potential of the REVISIT-3D process in using computational tools for virtual treatment planning. Future work involves refining and optimizing these tools and measuring outcomes of success in response to the implemented processes.

INTRODUCTION

Behind armor blunt trauma is a topic of importance to the military and law enforcement. The current standard of 44 millimeters of penetration in Roma Plastilina No.1 clay was developed from live animal experiments [1,2]. The original research aimed at human safety and soft body armor development. The same criterion continues to be used for both soft and hard body armor. When an actual round, such as bullet or projectile, impacts the armor-covered human thorax and abdomen, deformation from the backface of the armor transmits the external mechanical energy. Additionally, shock waves from the armor can be transmitted to the human torso. Backface deformations of the body armor are attributed to be the principal cause of injury to the soldier and/or law enforcement personnel.

It is well known that the human body is heterogeneous, exhibiting complex geometry and widely varying structural and material properties, in addition to variations in the functions of different components of the biological system. With reference to the thorax and abdomen regions of the human torso, bone and cartilaginous components of the rib cage are considered as skeletal structures, while the internal contents of the thorax and abdomen are considered as soft tissue structures. The lung is an aerated organ, and the liver is a solid organ; both have different but coupled physiological functions in the human body. The consequences of injuries to skeletal and soft tissue structural systems are generally different. For example, a simple non-displaced uni-cortical rib fracture heals quickly, does not impair normal breathing, and is considered a minor injury. Such injuries will not considerably affect the soldier or law enforcement personnel from normal activities. In contrast, severe lung injuries or bleeding from liver lacerations may require immediate attention and can impact the readiness of soldier or law enforcement personnel. It is important to develop injury criteria to advance human safety, develop less weight body armor, and simultaneously protect different thoraco-abdominal regions and skeletal structures that have varying tolerances. Tests with biological models (live animals) are needed to develop tolerance limits or injury criteria. Since biological tests consume resources, computational models are necessary to assist in the design of experiments. The objective of this study is to parametrically analyze the responses from indentor impact-delivering systems for behind armor blunt trauma to the lung and liver organs.

METHODS

Two indentors, replicating the backface deformation profile of hard body armor from actual round impacts to postmortem human surrogates, were used as load-delivering devices to the thoraco-abdominal region of the mid-size male Global Human Body Models Consortium (M50 - v5.1.1) computational model [3,4,7]. The mass of the two indentors were: 150 g, termed as low mass, and 230 g, termed as high mass. They impacted the left lung and liver regions. Initial velocities of 30 m/s, termed as low velocity, and 60 m/s, termed as high velocity, were used. Totally 8 different parametric cases were simulated. Automatic surface-to-surface contact was defined between the human body model and indentors. Maximum rib strains, strain profiles, and strain energy densities in the liver and lung for the respective simulations were outputted for each parametric case. A strain energy density (SED) threshold of 10.8 $\mu J/mm^3$ in the liver was used to estimate the potential for injury. All simulations were completed using LS-Dyna. An analysis was conducted to investigate the role of indentor mass, velocity, momentum, and kinetic energy on the intrinsic responses of the lung and liver to behind armor blunt trauma, using the above parameters.

RESULTS

The kinematics of the impacts were such that the indentor compressed the respective thoracoabdominal organs via local rib cage deformations. Rib strains were the greatest around the region of the impacting surface of the indentor. Figures 1 and 2 show the strain profiles on the ribs from the lung and liver impacts in the extreme cases: low mass and low velocity, and high mass and high velocity cases. For the liver impact simulations, at the low velocity, the SED in the liver was 1.4 $\mu J/mm^3$

for the lower mass indentor and 4.2 μJ/mm³ for the higher mass indentor. At the high velocity, the SED were 9.8 μJ/mm³ to 23.6 μJ/mm³. The SED had a linear relationship with energy (R^2=0.98). For the lung impact simulations, at the low velocity, the SED in the lung was 0.7 μJ/mm³ for the lower mass indentor and 1.5 μJ/mm³ for the higher mass indentor. At the high velocity, the SED were 4.4 μJ/mm³ and 8.6 μJ/mm³. The relationship between SED and energy was linear (R^2=0.96). As expected, greater energy increased SED in both organs, and this observation is discussed in the next section.

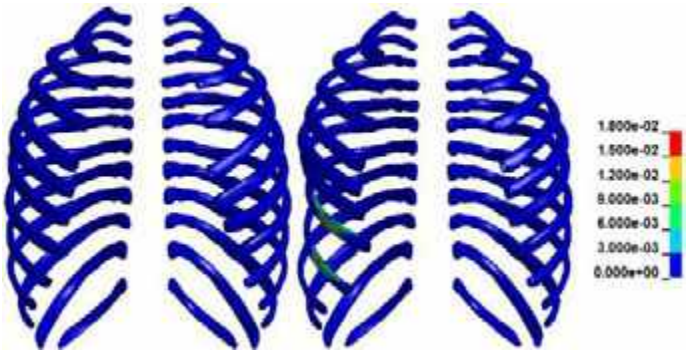

Figure 1: Rib strain patterns for lung (left) and liver (right) impacts for the low mass, low velocity simulations.

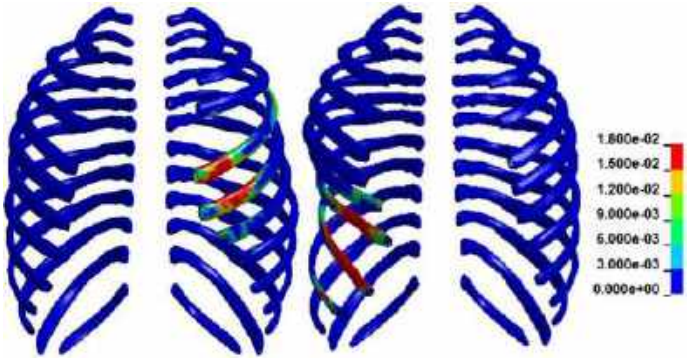

Figure 2: Rib strain patterns for lung (left) and liver (right) impacts for the high mass, high velocity simulations.

DISCUSSION

The objective of the study was to determine the responses of human thorax and abdomen to impacts simulating behind armor blunt trauma. The human body model used in the study has been previously validated using human cadaveric impact tests [4]. Typically, modeling studies use corridors from human cadaver experiments and compare the model-predicted responses via subjective and objective methods. Subjective methods are focused on the predicted response lying within mean plus minus one standard deviation experimental corridors. In contrast, objective methods use correlation analysis that computes the CORA metric between the model-predicted and experimental time history data. The presently used human body model was found to meet both methods of validation in selected test conditions of frontal and side impacts, although they were focused on automotive applications. From this perspective, it would be important to assess the biofidelity of this model to impacts with human cadavers that focus on behind blunt trauma and with the indentors and thoraco-abdominal organs considered in the present study.

The present data may be used to predict injuries to the organs. For the liver, using results from a variety of human cadaver tests conducted by various researchers, a recent study developed injury risk curves using the international standards organization recommendations [5]. At the Abbreviated Injury scale of AIS2+ level, the mid-injury (LD_{50}) cut off for liver injury was estimated at 10.8 μJ/mm^3 [5, 6]. Applying this criterion for the present series of simulations indicated potential for liver injuries at this severity for the high velocity and high mass indentor. This corresponded to the kinetic energy of 414 J. The strain energy density of 9.8 μJ/mm^3 for the low mass indentor at high velocity, corresponding to 270 J, was close to the threshold. A preliminary estimated criterion is that a kinetic energy of 275 J represents the LD_{50} risk for liver trauma under the tested conditions. This may assist the experimentalist in the design of actual experiments/tests.

At a constant velocity, an increase of approximately 1.5 times in the indentor mass increased the strain energy density by 2.7 times for the liver impact cases. For the lung impact cases, the increase was twice, suggesting the differing role of the energy parameter compared to the velocity variable. The inconsistent increases in the strain energy density between the two organs emphasize the role of the type of organ and its placement within the thoraco-abdominal cavity in the human torso and the applied kinetic energy metric. From this perspective, the present parametric study has shown that the responses depend on the region of impact to the thoraco-abdominal complex in behind armor blunt trauma.

While injury risks were estimated for the liver, similar analysis was not possible using the strain energy density metric for the lungs because of lack of data. A similar case was made in a previous study for the spleen organ [5]. Another limitation of this study is that one shape of the indentor was used. The shape was developed based on earlier studies with hard body armor on human cadaver surrogate [2]. The effects of shape variations of the profile of backface deformation were not parametrized in this study. Additional studies are needed to develop tolerances to these organs and conduct parametric analysis to better characterize indentors (mass and geometry). Other injury candidate metrics such as the viscous criterion need further analysis. These topics are being pursued by the authors of this study.

INTRODUCTION

Emerging evidence has revealed fluctuations in DNA motility within the cell nucleus, associated with various gene expression activities such as transcription [1]. Recent reports highlight the influence of the nuclear lamina on DNA motility [2]. Lamin A/C, recognized as a primary component of the nuclear lamina, undergoes changes in both expression levels and nuclear localization in response to the extracellular mechanical environment [3]. This evidence suggests that the regulation of DNA motility by Lamin A/C plays a pivotal role in orchestrating diverse changes in gene expression in response to the extracellular mechanical environment. However, conventional investigations have analyzed DNA motility within the nucleus without considering the spatial dependence. Lamin A/C is proposed to form a finely meshed structure at the nuclear membrane and a coarsely meshed structure in the nuclear interior [2], suggesting potential localized effects on the motility of internal nuclear DNA. In this study, we examined the influence of suppressing Lamin A/C expression on the motility of telomeres localized in nuclear specific regions. Additionally, we investigated the effects of substrate elasticity known to influence Lamin A/C expression on the motility of telomeres.

METHODS

Cell culture

To study the motility of telomeres, we used the mouse teratoma-derived cell line (ATDC5). ATDC5 were maintained in DMEM/F12 medium supplemented with 5% fetal bovine serum and 1% penicillin and streptomycin antibiotics. The cells were cultured on a glass-bottom dish at a density of 10,000 cells/cm^2. After 24 hours, the medium was replaced with Opti-MEM medium containing 10 nM siRNA and Darmafect1. As a control, non-targeting siRNA was transfected instead of the specific siRNA. Following siRNA transfection, the cells were further transfected with the YFP-hTRF1 plasmid using Lipofectamine 2000. For imaging experiments, the cells were cultured for an additional 24 hours after YFP-hTRF1 transfection.

To evaluate the effect of substrate stiffness for DNA motility, ATDC5 were cultured on polyacrylamide gels with elastic modulus of 3.5, 50 and 90 kPa. After 24 hours, YFP-hTRF1 plasmid was transfected following the same method as above.

Particle-tacking for hTRF1-YFP

ATDC5 were incubated at 37°C with a 5% CO_2 level and imaged using an Olympus IX-73 fluorescence microscope with a UPLSAPO 100 x objective, numerical aperture=1.40. The motility of YFP-hTRF1 were recorded at 30 frames per second (30 fps) for 30 seconds by a CCD camera. Intensity-weighted centroids of the hTRF1 were extracted from the time-lapse image of the YFP-hTRF1 with a resolution of 0.058 μm/pixel. The time-averaged mean square displacements (TMSDs) and the anomalous diffusion exponent, defined in Equations (1) and (2), were calculated with τ designating a time lag along the trajectory:

$$< \Delta r^2(\tau) >= \frac{1}{T-\tau}\int_0^{T-\tau}(r(t_0+\tau)-r(t_0))^2 dt_0 \quad (1)$$

$$\alpha(\omega) = \frac{d\ln<\Delta r^2(\tau)>}{d\ln\tau}\Big|_{\tau=\frac{1}{\omega}} \quad (2)$$

where $r(t)$ is the position of YFP-hTRF1 at elapsed time t, and T is the observation time. ω is the reciprocal of t. From the initial image of YFP-hTRF1, bright spots localized within a range of 1 μm from the nuclear membrane were defined as hTRF1 in the nuclear periphery (Periphery), while the bright spots localized in regions further inside than this boundary were defined as hTRF1 in the inner region (Inner).

Immunofluorescence image acquisition

ATDC5 were fixed with 4% paraformaldehyde and immersed in0.5% Triton X-100 in PBS(-) for 5 minutes at room temperature. Samples were blocked in a 0.2% gelatin solution for 60 minutes. And

then, immersed in a 0.2% gelatin solution with a primary antibody against Lamin A/C (1:400) overnight at 4°C, followed by immersion in a 0.2% gelatin solution with a secondary antibody anti-rabbit Alexa-564 (1:1000) for 60 minutes at room temperature. DNA was stained with Hoechst 33258. Finally, samples were imaged by confocal microscopy (FV-3000) with a UPLSAPO 100 x objective.

RESULTS

First, to investigate the contribution of Lamin A/C on DNA motility within local area of nucleus, the motility of telomeres was analyzed in the nucleus of cells which were suppressed expression of Lamin A/C. Fluorescent images of DNA, Lamin A/C and YFP-hTRF1 are shown in Fig.1. The uniform distribution of hTRF1 within the nucleus was confirmed. ATDC5 suppressed Lamin A/C expression (siLamin) exhibited a decrease in Lamin A/C fluorescence intensity compared to the control cells. Quantitative analysis revealed that over 90% of cells showed a decrease in Lamin intensity (data not shown). Additionally, DNA aggregation was increased at interior of the nucleus in Lamin A/C KD cells as opposed to the control cells.

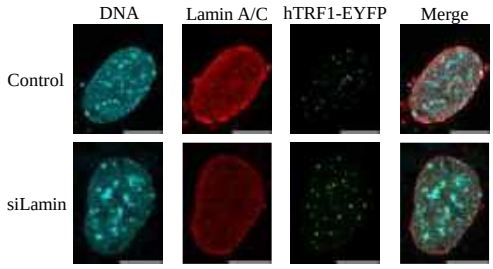

Figure 1: Fluorescence images of DNA, Lamin A/C, and hTRF1-EYFP in Control or siLamin cells. (Cyan: Nucleus, Red: Lamin A/C, Green: hTRF1-EYFP, Bars = 10 µm).

Figure 2 presents representative tracking analysis results of YFP-hTRF1. Individual trajectories of YFP-hTRF1 at both interior and peripheral areas of nucleus were extracted (Fig.2(a-c)). As the anomalous diffusion exponent approaches 1, it indicates random diffusion, while for $\alpha < 1$, slow diffusion is caused by constraints from nuclear structures. The anomalous diffusion exponent α at ω=1[1/s] significantly increased in both nuclear interior and periphery of siLamin cells compared to the Control cells (Fig. 2(d)). From these results, it is suggested that Lamin A/C contributes to DNA confinement in both the nuclear interior and the nuclear periphery areas.

Next, we investigated the effect of substrate stiffness on motility of telomeres within nuclear interior and peripheral areas. As results, anomalous diffusion exponent of the hTRF1 at the nuclear periphery tended to decrease with an increase in substrate elastic modulus. For hTRF1 localized in the nuclear interior, a statistically significant decrease was observed in correlation with an increase in substrate elasticity (Fig.2(e)). These findings suggest that substrate elasticity contributes to the confinement state of DNA in both the nuclear interior and peripheral areas.

DISCUSSION

In this study, we revealed that suppression of Lamin A/C expression affected telomere motility in the entire cell nucleus, and that substrate elastic modulus affected telomere motility in the inner region of the cell nucleus.

The suppression of Lamin A/C expression led to increase in the motility of telomeres in both the nuclear interior and periphery. Lamin A/C is known to possess some chromatin-binding receptors [4]. Also, a previous study indicated that the confinement state of DNA across the

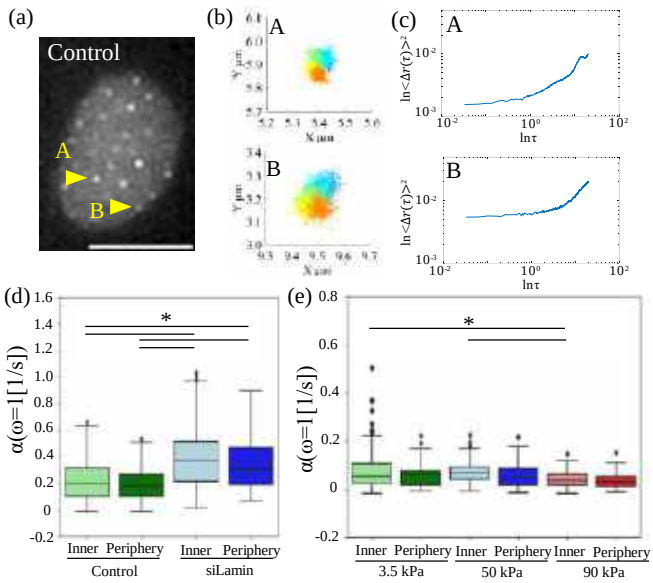

Figure 2: (a) The fluorescent image of typical nucleus of Control cells expressing hTRF1-EYFP marking telomeres (Bar=10µm). (b) Representative two-dimensional trajectories of YFP-hTRF1 (A and B of (a)). (c) Mean square displacement (MSD) of (b). Box plot of the anomalous diffusion exponent α(ω=1[1/s]) in interior and perinuclear area of (d) control and siLamin cells and (e) the cells cultured on substrate with different elastic modulus. (*P<0.05 Bonferroni correction)

entire nuclear area was affected by change in the mesh structure of Lamin A/C [2]. The reduction of Lamin A/C expression might contribute to the disruption of DNA confinement, leading to increase in the anomalous diffusion exponent. Also, changes in substrate elastic modulus caused alternation in motility of telomeres in the nuclear interior region. Previous studies have reported the increase in elastic modulus of culture substrate promotes Lamin A/C expression [5]. DNA might be more restricted in the cells cultured on stiff substrate compared to the cells cultured on soft substrate. On the other hand, the change in DNA motility was larger in the interior area than in each peripheral area of nucleus. This result suggests that changes in substrate elasticity induced localized alterations in nuclear structure.

Although Lamin A/C localized intensively at the nuclear periphery (Fig. 1), no region-dependent differences were observed in motility of telomeres. It was speculated that there are factors other than the local Lamin A/C concentration within the nucleus that control DNA motility. It is also possible that are uniformly secured within the nucleus by the Lamin A/C structure, such as the cell nucleus volume [6], may directly affect the DNA motility. In future study, it is necessary to identify the factor that affect DNA motility directly.

INTRODUCTION

Tissue engineering of pre-organized artificial vascular networks has been demonstrated to produce regenerative scaffolds capable of restoring microvascular circulation in small animal models of ischemic cardiovascular disease [1]. Uniform perfusion of tissues both during ex vivo cell culture and therapeutic application in vivo is critical to deliver oxygen and nutrients at scale. In particular, vascular regions of slow flow velocities and excess or insufficient endothelial shear stress present challenges in scaffold fabrication and sustaining endothelial function at a large organ scale [2]. While biologically occurring vascular trees are optimized for uniform perfusion under Murray's law of bifurcating diameter ratios [3], optimizing the design of artificial vascular networks in non-tree structures is not yet well described. In the present research, we aim to develop a systematic method utilizing reduced order fluid flow modeling to assess and optimize perfusion uniformity in translationally applicable microvascular network designs.

METHODS

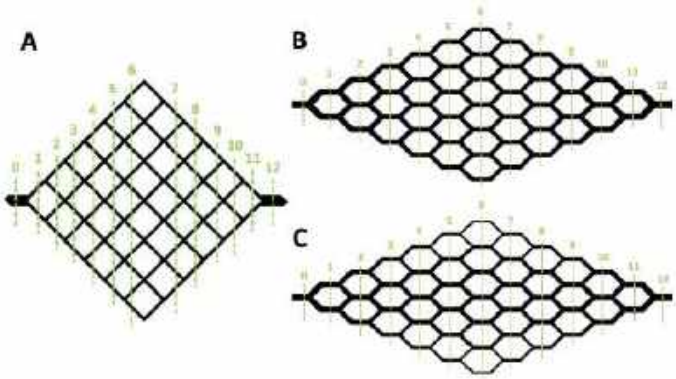

Figure 1: Microvascular network designs with labeled vessel generations. A) 6x6 vascular grid with 100 µm channels B) Vascular lattice with even diameter tapering, and C) Vascular lattice with gradient diameter tapering

Microvascular Network Design: Starting from a root diameter of 400 µm, symmetric vascular networks comprising ~12 generations of vessels were designed (Figure 1). Based on the prevalence of use in tissue engineering applications, a vascular grid pattern was selected as the baseline configuration with constant diameters of 100 µm. Diameters in tapered lattices, hypothesized to improve perfusion uniformity, were either arbitrarily decreased by 50 µm with each generation, or were calculated in accordance with Murray's Law:

$$\sum_{\text{in}} r^3 = \sum_{\text{out}} r^3 \tag{1}$$

where r is the vessel radius. Even taper diameters were calculated with the sum of radii cubed at each generation divided evenly by the number of stems in successive generations. Gradient taper diameters were calculated with the sum of radii cubed divided evenly into daughter branches at each node. Calculated and assigned diameters for the first six vessel generations of respective network designs are shown in Table 1.

Table 1: Diameters by generation in designed vascular networks. Murray's Law calculations for vessel ratios were applied at the generation level (even taper) and the node level (gradient taper).

		Diameter (µm)								
Generation	Stems	Arbitrary Taper	Even Taper	Gradient Taper						
0	1	400	400	400

Perfusion Uniformity Assessment: Blood flow was simulated using the 0D approximation of the Navier-Stokes equations, assuming an inlet flow rate of 115 µl/min and an outlet pressure of 2.14 mBar. Flow rate (Q) simulation results were postprocessed to obtain the mean velocity (v) and wall shear stress (WSS) for each vessel:

$$v = \frac{Q}{\pi r^2} \tag{2}$$

$$\text{WSS} = \frac{4\mu Q}{\pi r^3} \tag{3}$$

where $\mu = 4\,\text{mPa}\cdot\text{s}$ is the blood viscosity. The coefficient of variance ($\text{CV} = \frac{\text{std}}{\text{mean}}$) of mean velocity and WSS was calculated for each vascular network design over all vessels.

RESULTS

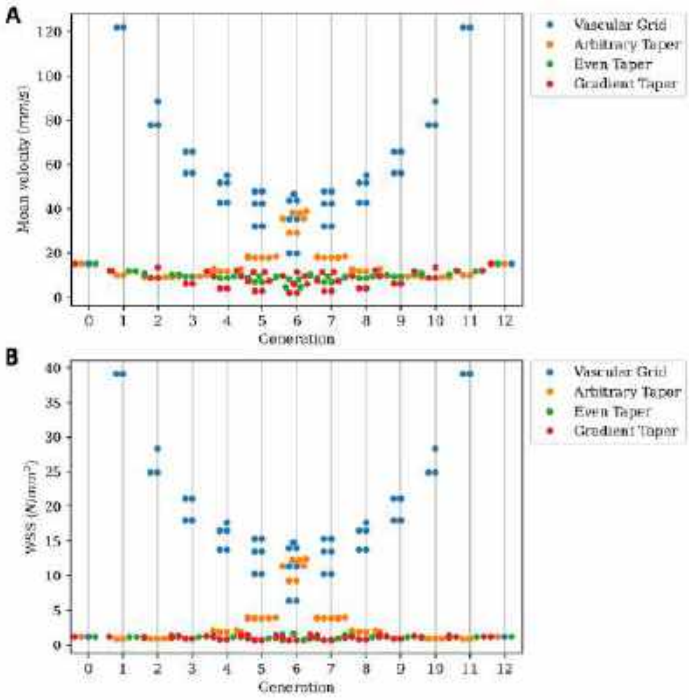

Figure 2: Comparative distributions of A) Flow velocity and B) Wall shear stress across successive vessel generations in distinct vascular network designs

Figure 2 displays the comparative distributions of flow velocity and wall shear stress through designed vascular networks in reduced order blood flow simulation. Simple microvascular grid geometry demonstrated a high variation in flow velocity and shear stress with each successive generation. Tapering vessel diameters in latticed network geometries improved perfusion uniformity, however arbitrary diameter tapering had higher perfusion deviations as compared with diameter tapering determined by Murray's Law correlated ratios. Table 2 displays calculated coefficients of variance for respective vascular network designs, with even diameter tapering demonstrating the most uniform perfusion among simulated networks.

Table 2: Coefficients of variance for flow velocity and wall shear stress across vascular network designs

	Coefficient of variance (std/mean)			
	Vascular Grid	Arbitrary Taper	Even Taper	Gradient Taper
Mean velocity	0.71	0.53	0.20	0.42
Wall Shear Stress	0.72	1.00	0.13	0.20

DISCUSSION

Optimizing microvascular network design can greatly improve perfusion uniformity in engineered microvessel scaffolds. Here we present preliminary results from in-silico analysis of wall shear stress and flow velocity distributions in four microvascular arrangements. Our findings indicate that simple grid geometries, which are prevalently used in current tissue engineering platforms, exhibit suboptimal perfusion distribution that may limit their feasibility of application at scale. Tapering of vessel diameters in correlation with Murray's Law greatly enhances perfusion uniformity in vascular networks. In contrast to prior understanding of Murray's Law in biologic vascular trees, perfusion uniformity in artificial vascular lattices is optimized when the sum of radii cubed is distributed evenly across each network generation as a whole, rather than through each bifurcation point. In future work, we will perform in vitro verification of blood flow modeling within tissue engineered vascular constructs, and explore vascular network optimizations in more complex 3D anatomic space.

THE IMPORTANCE OF THE MENISCUS INNER SEGMENT ON THE MECHANICAL FUNCTION OF THE MENISCUS

INTRODUCTION

The hoop stress is generated in the meniscus under the femoral compression load [1]. We reported that the loss of the inner segment of the meniscus broke the mechanical balance of the meniscus and led to the deformation and extrusion of the meniscus using the material testing apparatus [2]. However, the effect of the inner segment of the meniscus function under knee loading is still unclear. Therefore, the present study aimed to investigate the mechanical function of the inner segment of the meniscus for the knee kinematics and resultant force under knee loading using the robotic testing system.

METHODS

Porcine knee joints (n=5) were used for the test, and the soft tissue around the knee was dissected down except for ligaments, meniscus, and capsule. Before the test, the osteotomy was performed to apply the clinical procedure with a direct view, and it was fixed by metal screws during the test. The varus-valgus (VV) torque was applied to the knees up to 10 Nm at maximum extension using a 6-DOF robotic testing system (FRS2010, Technology Service). During the test, the VV DOF was translated under displacement control at a rate of 0.5 deg/s, and flexion-extension and internal-external DOFs fixed at 30 deg and the neutral position, respectively. All DOFs except those 3 DOFs were set under force control with prescribed force/torque at zero. After the test for intact meniscus, the radial tear with 80% length of the mid-substance width was created from the inner edge at the mid-point of the medial meniscus (MM), and the test was repeated (Figure 1). Finally, the MM had been removed a total of 10 mm anterior-posterior length based on the radial tear and it was defined as partial meniscectomy in the present study, and then the test was repeated. During the test, the knee motion was recorded. After the test for 3 conditions, the recorded knee motion during the test was reproduced to the MM meniscectomized knee, and the resultant force of the meniscus in each condition was calculated based on the principle of the superposition [3, 4].

To measure the deformation and translation of the meniscus during the VV test, a 3-D motion capture system (Prime17W, OptiTrack) was applied to 1 specimen of the test. The total 5 markers for the measurement were placed on the meniscus outer surface at the meniscus-ligament junction of the anterior and posterior horns, the mid-substance, and the mid-point of those 3 points. After the measurement, all soft tissues around the tibia were removed, and the most medial and lateral points of the tibial plateau and the most anterior and posterior points on the line of the tibial eminence were captured by the system. Then, the cross point of the medial-lateral line and anterior-posterior line was determined and defined as the origin of the marker motion. The medial-lateral motion, anterior-posterior motion, and total travel during the test of each marker were determined.

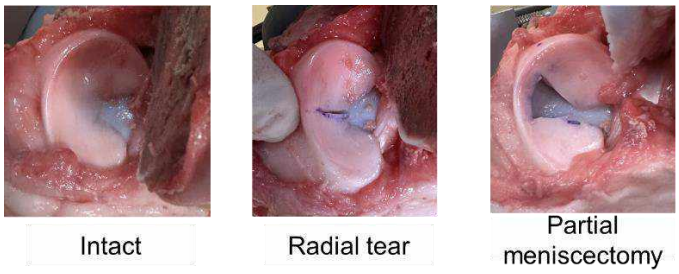

Figure 1 Gross appearance of the medial meniscus in intact, radial tear, and partial meniscectomy conditions

RESULTS

The range of motion (ROM) of the VV was 16.5±5.6 deg in the intact group (Figure 2). In the radial tear group, the ROM was slightly increased, 17.6±5.7 deg, and the partial meniscectomy group showed a significant increase compared to the intact group, 18.7±6.2 deg. The resultant force of the intact meniscus was 123.5±13.5 N (Figure 3). In

the radial tear group, the resultant force was decreased with no significant difference compared to the intact group, 98.2±30.9 N. In the partial meniscectomy group, the resultant force was significantly decreased compared to the intact group, 79.8±28.6 N.

In the meniscus motion, the intact meniscus showed about 1 mm translation in all markers (Figure 4). The radial tear applied and partial meniscectomy performed meniscus showed a similar motion in 3 markers at the anterior horn marker to the mid-substance marker while 0.2-0.5 mm larger translation occurred posterior side markers compared to the intact meniscus.

DISCUSSION

In the present study, the VV ROM and resultant force of the meniscus were determined, and the meniscus motion was measured as a trial. As a result, the radial tear to the inner segment of the mid-substance of the meniscus slightly affected the meniscus function under knee loading, while the loss of the inner segment (partial meniscectomy) was affected significantly.

Our previous report indicated that the inner segment loss leads to V-shape meniscus deformation under compression force to the inner part of the mid-substance using a small sphere indenter, and it results in the extrusion of the mid-substance of the meniscus [2]. In the present study, the inner segment loss led to a decrement in the knee stability and the resultant force of the meniscus, and it was significant compared to the radial tear. In other words, the meniscus function was significantly affected by the partial meniscectomy. In that situation, it is thought that the meniscus extrusion has occurred with V-shape deformation of the meniscus the same as the previous report and it caused the decrement of the meniscus function. However, the meniscus motion indicated an increase of translation at the posterior region of the meniscus compared to the intact while the anterior region did not show the increase. Those data suggested that the meniscus deforms complicated under knee loading differ from the simple V-shape deformation. In the present study, the varus torque applied to the knee and the resultant force was calculated. Although the femur may simply compress the meniscus during the varus torque application, the meniscus motion might be affected by the femur morphology. The femur morphology is generally described as a sphere while it has a complex curved shape in fact. In addition, the femur position is also effective on the location of the center of compression. It is thought that those factors affected the meniscus motion and the motion was complicated. In the present study, internal-external rotation was fixed at the neutral position, and it may also affect the meniscus motion. In future works, the meniscus motion under various knee loading and the relationship between the loss of the inner segment and the motion should be determined.

THE STIFFNESS OF FALSE LUMEN WALL INCREASED IN CHRONIC TYPE B AORTIC DISSECTION VS. NORMAL TISSUE BASED ON THE UNIFIED-FIBER-DISTRIBUTION (UFD) MODEL

INTRODUCTION

Aortic dissection is a serious, potentially life-threatening condition [1] which occurs when a tear develops in the inner lining (intimal layer) of the aorta, causing the layers of the aortic wall to separate (dissect) and creating "true" and "false" lumens. Aortic dissections can be divided into two groups [2], depending the physiological location: 1) Type A aortic dissection (TAAD) when the dissection includes the ascending aorta; and 2) Type B aortic dissection (TBAD) when the dissection only involves the descending aorta. TBAD can be further classified into complicated and uncomplicated types based upon the presence of organ malperfusion and/or aortic rupture. TAAD and complicated TBAD are usually treated with surgical or endovascular intervention immediately after their diagnosis. The Uncomplicated TBAD can be managed conservatively with optimal medical therapy (OMT). In the chronic phase of TBAD (CTBAD), the outer false lumen wall (FLW), despite its partial thickness, plays a key role in preventing rupture of CTBAD. It is important to understand the mechanical properties of the FLW in the chronic phase for estimating the stress and clinical risk of CTBAD. In this work, we investigated the stiffness of CTBAD-FLW vs. normal tissues and acute TAAD-FLW, based on biaxial tension testing and the unified-fiber-distribution (UFD) model [3, 4].

METHODS

Patient data: We retrospectively collected false lumen wall (FLW) tissue samples from 9 patients with chronic Type B Aortic Dissection (CTBAD) and 5 patients with acute Type A Aortic Dissection (ATAAD), who underwent open aortic replacement at Emory University Hospital, Atlanta, Georgia. We simulated the FLW (Control-FLW) by stripping partial media and adventitia from descending aortic tissue obtained from 6 heart transplant donors.

Biaxial tension testing: Planar biaxial tension testing (Fig. 1a) in the circumferential (Circ) and axial directions was performed on each of the FLW samples from the three groups, based on the well-established methods [5]. Briefly, a square section of the FLW (Fig. 1a) was delimited by 16 suture hooks, 4 per side. Four graphite markers delineating a 2 by 2 mm square region were fixed with cyanoacrylate adhesive in the center of the testing region for strain tracking. The sample was mounted onto a testing machine in a trampoline-like fashion, and submerged in a 0.9% saline solution maintained at 37 °C for the duration of the test. A stress-controlled testing protocol was applied, with the ratio of the normal stress components $P_{11}:P_{22}$ predefined and with the shear terms $P_{12} = P_{21} = 0$. Samples were subjected to a minimum of 30 equibiaxial preconditioning cycles. Stress strain curves were obtained for the 5 testing protocols (Figs. 1b), with $P_{11}:P_{22} = 1:1, 0.75:1, 0.5:1, 1:0.75, 1:0.5$.

Constitutive Model: We applied our recently developed unified-fiber-distribution (UFD) model [3, 4] to characterize the mechanical behavior of the arteries, assuming that the tissues are incompressible [6, 7]. The strain energy function of the unified-fiber-distribution (UFD) model can be expressed as $\overline{\Psi} = \frac{1}{2}c(\bar{I}_1 - 3) + \frac{k_1}{2k_2}[\exp\{k_2[\zeta^2(\bar{I}_{4\theta} - 1)^2 + (1-\zeta)^2(\bar{I}_{4z} - 1)^2]\} - 1]$, where c, k_1, k_2 and ζ are four material parameters, representing the matrix stiffness, fiber initial stiffness, arterial stiffening factor, and circumferential fiber component, respectively. $\bar{I}_1$ is the 1st invariant of right Cauchy–Green tensor $\bar{\mathbf{C}}$, $\bar{I}_{4\theta} = (\mathbf{a}_{0\theta} \otimes \mathbf{a}_{0\theta}) : \bar{\mathbf{C}}$, and $\bar{I}_{4z} = (\mathbf{a}_{0z} \otimes \mathbf{a}_{0z}) : \bar{\mathbf{C}}$, where $\{\mathbf{a}_{0\theta}, \mathbf{a}_{0z}\}$ are the unit vectors in the circumferential and axial direction, respectively. The UFD model considers the fibers as a unified distribution, rather than separating the fiber distribution into two/several fiber families. The consideration of a unified distribution for the fibers in the UFD model may be more physically consistent with the real fiber distribution of arterial tissues than existing fiber-family-based models.

Histology: A histologic analysis of the tissue microstructure was performed on the collagen and elastin fibers using second harmonic generation (SHG) imaging. A total of 15 FLW samples were imaged

(n=5 for each group) using a Zeiss 710 NLO inverted confocal microscope (Carl Zeiss Microscopy, LLC, Thornwood, NY, USA). The laser was set to 800 nm and emission was filtered from 380 to 430 nm for collagen fibers and from 500 to 550 nm for elastin fibers [8, 9]. Quantification of the composition of Quantification of the composition of collagen and elastin fibers was performed by calculating the fibers' volume fraction from the Z-Stack scans.

RESULTS

The UFD model obtained good fitting accuracy (Fig. 1b) of the experiments. For the stress-strain derived constitutive parameters (Fig. 1c-f), the stiffening factor (k_2) of CTBAD-FLW was significantly larger than that of Control -FLW and Acute-A-FLW (Fig. 1c). The average fiber component in the circumferential direction (ζ) also significantly increased in the CTBAD-FLW tissue in comparison with those Control -FLW and Acute-A-FLW (Fig. 1d). Though the mean value of the fiber initial stiffness (k_1) of CTBAD-FLW was larger (Fig. 1e), no statistical difference was found in the three groups. The matrix stiffness (parameter c) of the Acute-A-FLW was significantly smaller than that of the Control–FLW (Fig. 1f).

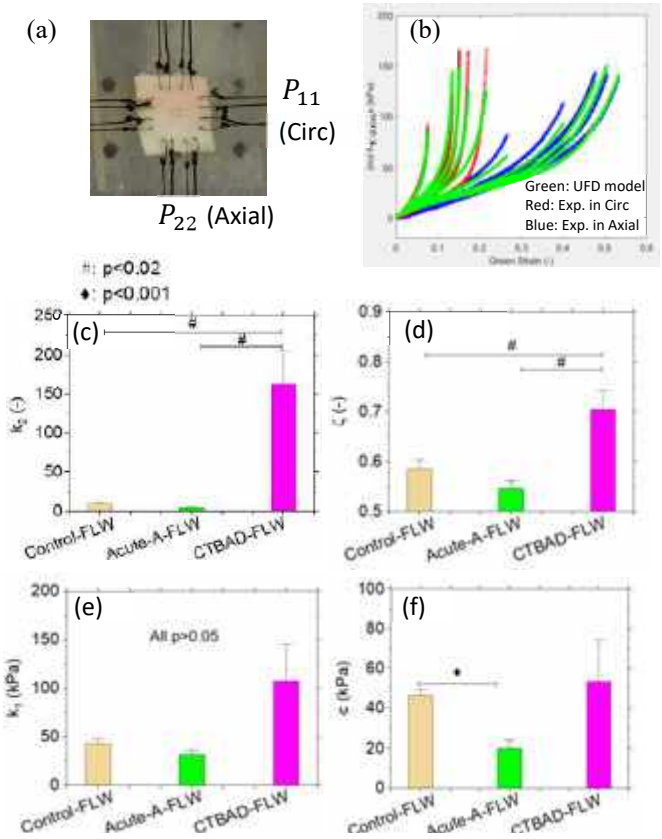

Fig. 1. (a) Biaxial tension testing; (b) Comparison of the fitting results and experimental data; (c-f) Mean and standard error of fitted UFD constitutive parameters.

The histology demonstrated a higher concentration of organized collagen in CTBAD-FLW compared to C-FLW and Acute-A-FLW, and a lower concentration of elastin (Fig. 2a). Quantification of the collagen/elastin profile in the tissue demonstrated a significant increase in the volume fraction of collagen fibers and a significant decrease in the volume fraction of elastin fibers when comparing CTBAD-FLW versus Acute-A-FLW & control-FLW (Fig. 2b). The volume fraction of collagen fiber is larger than that of elastic fibers within CTBAD-FLW, but smaller than that of elastin fibers within Acute-A-FLW & control-FLW (Fig. 2b). The larger volume fraction of collagen and less elastin in CTBAD-FLW explain well the increasing stiffness of CTBAD-FLW vs. Acute-A-FLW & control-FLW.

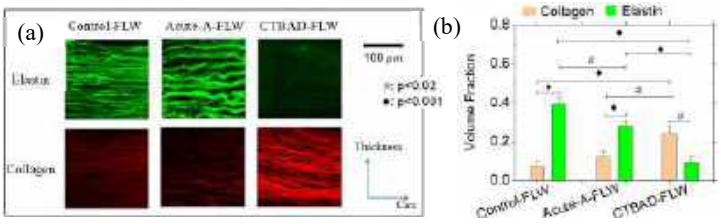

Fig. 3. Microstructure (a) and volume fraction (b) of collagen and elastin fibers.

DISCUSSION

Dissection of the aortic wall results in the outer false lumen wall (FLW) remaining only partial thickness in comparison with the whole wall, which may induce higher wall stress in FLW at the same blood pressure. The change in the composition of FLW extracellular matrix (more collagen and less elastin fibers) may be a protective adaption to the higher wall stress for preventing aortic rupture, which also explains the importance of the adventitia in the surgical repair of aortic dissection (for holding sutures securely).

It has been shown that increasing stiffness of aortic wall can exert an adverse effect on the whole cardiovascular system. For instance, aortic stiffening may result in abnormal ventricular-arterial interactions that promote adverse left ventricular remodeling, dysfunction, and cardiac failure [10]. Stiffening may also induce systolic hypertension and excessive penetration of pulsatile energy into the microvasculature of target organs [11]. It may be worth investigating the effect of the CTBAD-FLW stiffening on the cardiovascular system in future work.

INTRODUCTION

Osteoarthritis (OA) is a common disease that dramatically deteriorates quality of life. Self-healing of articular cartilage is difficult due to its poor blood circulation. Therefore, much attention has been paid to approaches that use tissue-engineered materials containing mesenchymal stem cells (MSCs) [1]. Traditional biomaterials for cartilage repair often used scaffolds. Although it is possible to create relatively large constructs cell distribution is uneven and cell density is low in the traditional scaffold-type biomaterials.

We developed a novel cell-scaffold-combined biomaterial, a centrifugally compressed cell-collagen combined construct (C^6), through the application of centrifuged compression to a MSCs-atelocollagen combined construct. Even distribution and high density of MSCs were observed in C^6 [2]. To improve the mechanical property and chondrogenic ability of C^6, it is necessary to promote chondrogenic differentiation of MSCs within C^6. In the present study, the effects of hyaluronic acid (HA) and proteoglycan (PG) on the chondrogenic matrix production and mechanical property of C^6 were determined.

METHODS

Human bone marrow-derived MSCs (PT2501, Lonza, Japan) were subcultured eight times in a culture medium consisting of Dulbecco's Modified Eagle Medium (DMEM), 10% fetal bovine serum (FBS), 1% penicillin-streptomycin (P/S). Subcultured 7.5×10^5 MSCs were mixed with a neutral collagen solution consisting of porcine dermis-derived type I atelocollagen solution or porcine cartilage-derived type II atelocollagen solution (175 µL at a density of 3.72 mg/mL or 4.49 mg/mL), 50 µL of 5-fold DMEM, and 25 µL of collagen gel reconstitution buffer solution. This solution was placed in an incubator with 5% CO_2 at 37 °C, allowed to self-assemble into a gel-state solution with higher ordered three-dimensional structures over 1 day, and centrifuged at 3500 rpm for 10 min (Figure 1).

In the preparation process of C^6, either HA sodium salt (089-10343, Fujifilm, Japan) or salmon nasal cartilage PG (HQPG-AO121-001, Cosmobio, Japan) was dissolved in 5-fold DMEM. The weight ratio of HA or PG to collagen was 20% to roughly simulate physiological concentration. C^6 samples at 28 days of culture were histochemically processed according to a standard method. A microtome was used to slice the samples and histological examination was performed for the sliced specimens using toluidine blue stains.

C^6 samples at 14 days of culture were fixed on a glass bottom dish with adhesive. Indentation test was performed for randomly selected 5 points on the specimens using an atomic force microscope (AFM) (Nano Wizard 3, JPK Instrument, Germany) to determine the tangent modulus of C^6 under the condition of the indentation depth of 2.0 µm, indentation force of 4.0 nN and extend velocity of 15.0 µm/s. The tangent modulus was determined through a curve fit using a database of Sneddon model [3].

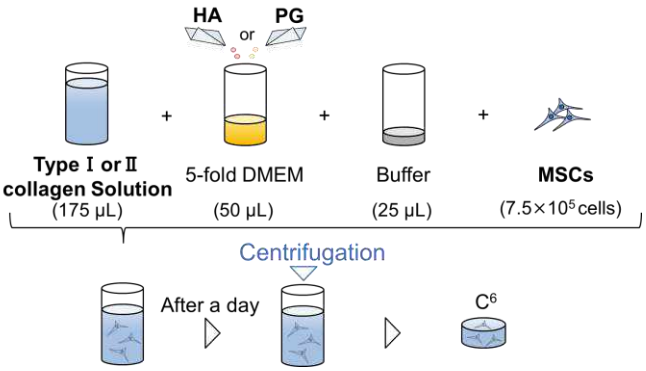

Figure 1: Preparation of the C^6 from the type I or II atelocollagen and MSCs.

RESULTS

Macroscopic observations of C^6 at 14 days and 28 days of culture are shown in Figure 2. It was confirmed that all the samples were contracted as the culture period passed. In particular, the contraction of C^6 mixed with HA was remarkable.

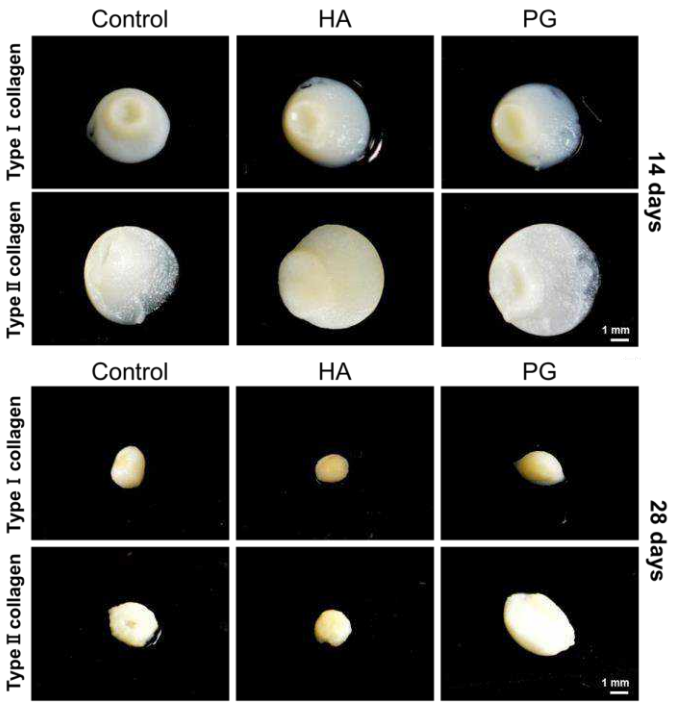

Figure 2: Macroscopic observation of the C^6 after 14 days (upper pictures) and 28 days (lower) of culture (scale bar = 1 mm).

The results of histological examination are shown in Figure 3. Bluish-purple stained areas that indicate chondrogenic matrix production were confirmed under all conditions, with the largest clearly stained area observed in C^6 mixed with HA.

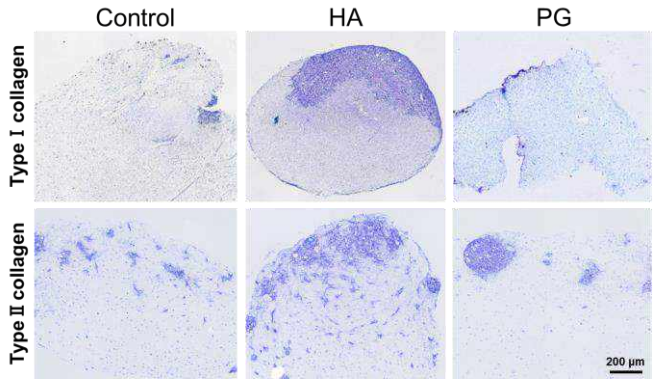

Figure 3: Histological observation with toluidine blue stains of the C^6 after 28 days of culture (scale bar = 200 μm).

The elastic modulus of C^6 at 14 days of culture is shown in Figure 4. The modulus was higher in HA group than in control and PG groups, with the significant increase observed in type I collagen based C^6 in HA group.

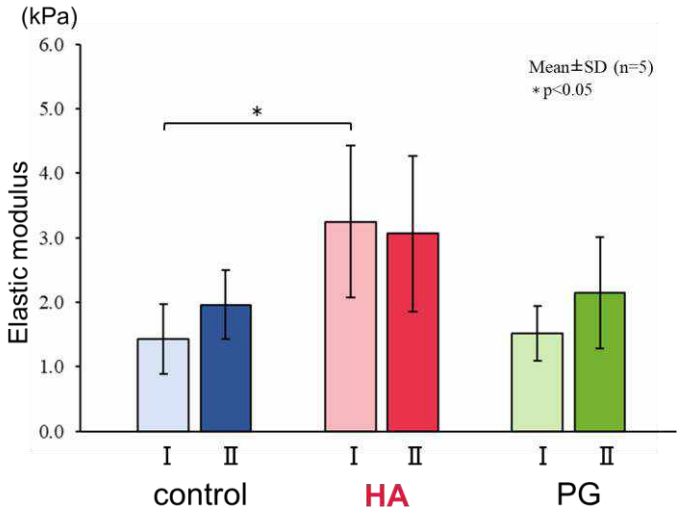

Figure 4: Elastic modulus of the C^6 in control, HA and PG groups.

DISCUSSION

The present study confirmed that the addition of HA improved the chondrogenic matrix production in C^6, with the significantly higher modulus observed in type I collagen based C^6. The present study also confirmed that such effects were not observed for PG. Matsiko et al found that HA interacts with the CD44 receptors on MSCs and contributes to cell migration and chondrogenic differentiation [4]. Such a receptor for PG cannot be found on MSCs. In addition, Ye et al found that the gene expression of SPY-box transcription factor 9 (Sox9), known as a gene relating to chondrogenic differentiation, was significantly higher in type I collagen based C^6 cells than in TEC cells [5]. Their findings imply a molecular level pathway that might happen in HA-containing C^6 in the present study. The present results are consistent with those reported in other biological and biomechanical studies. For example, Davidenko found that HA improved the mechanical property of a freeze dry-processed collagen-containing scaffold [6]. In addition, Uesato et al found that the addition of PG promoted neither chondrogenic differentiation nor resultant chondrogenesis of MSCs in a pellet culture experiment [7]. The present study also confirmed that HA improved chondrogenic matrix production in the type II collagen containing C^6, although modulus increase was not significant. The result is related to our previous finding that Sox9 is upregulated in HA-containing type II collagen based C^6 [8]. In summary, it is suggested that the addition of HA improves the chondrogenic differentiation and matrix production in both the type I collagen based C^6 and type II collagen based C^6.

INTRODUCTION

Heart valve tissue engineering (TE) has emerged as a promising approach to address the limitations of current heart valve replacement methods, using the body's regenerative capabilities to create living, functional tissues. A significant challenge identified in experimental and preclinical studies is the spatial heterogeneity in scaffold degradation and tissue growth, which leads to uncertainty with respect to the long-term viability and functionality of TE heart valves (TEHVs) [1]. However, the causes and consequences of this heterogeneity on the development of a viable and functional living heart valve replacement are still unclear.

Mechanical cues are well-known regulators of the growth and remodeling (G&R) process within living tissues [2]. Currently, there is a plethora of TE approaches, using a wide range of different mechanical stimuli during the in-vitro tissue culturing phase. Given the large variability across these tissue culture protocols, there is a need to assess the effect of different mechanical stimulation protocols within the culture method on the pre-implant tissue geometry and its retention after implantation, as it has been shown that valve geometry has an important effect on the long-term in-vivo remodeling and thereby valve functionality [3].

The aim of this study was to develop an experimentally-informed computational model to (1) analyze the influence of varying in-vitro tissue culturing conditions on the obtained pre-implant geometry and tissue properties of TEHVs, and (2) investigate how the pre-implant properties subsequently affect shape retention and heart valve functionality post-implantation.

METHODS

In this study, we developed a homogenized constrained mixture model (HCMM) based on the work of Cyron et al. [4], integrated with a finite element model of TEHVs, to simulate the G&R response. As an input for our computational model, we used experimental data of tube-shaped TE matrices (TEM) that were cultured for 6 weeks statically in-vitro, and then manufactured into a TEHV geometry [5]. We used this model to predict tissue G&R as a function of varying in-vitro conditions. In the experimental study, the TEM constructs were created by seeding cells using fibrin as a carrier onto a polymeric, electrospun scaffold. Over time, these two constituents were degraded and new extracellular matrix (ECM) components (glycosaminoglycans (GAGs) and collagen) were deposited (Fig. 1).

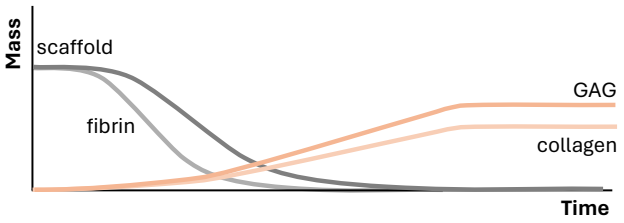

Figure 1: Mass changes during the TE process: degradation of scaffold and fibrin, and production of collagen and GAGs.

Governing equations To describe tissue G&R, a deformation field was determined that satisfies the balance of momentum (Eq. 1), where the total Cauchy stress ($\boldsymbol{\sigma}$) of the tissue is defined as the apparent mass-density (ρ_R^i) weighted constituent stresses ($\boldsymbol{\sigma}^i$).

$$\vec{\nabla} \cdot \Big(\sum_i^n \rho_r^i \boldsymbol{\sigma}^i \Big) = \vec{0}. \tag{1}$$

The apparent mass densities can change as a consequence of the production and removal of each load-bearing constituent (i): collagen, GAGs, fibrin, and the scaffold. For collagen and GAGs we adopted stress-mediated descriptions for mass change given by:

$$\dot{\rho}_R^i(\tau) = M_{\text{dep}}^i \left(1 + k_\sigma^i \Delta\sigma(\tau)\right) - \frac{\rho_R^i}{T^i}, \tag{2}$$

where M_{dep}^i is a basal value of production, $\Delta\sigma(\tau)$ the stress deviation from the original homeostatic target at G&R time τ, k_σ^i a gain-type parameter controlling the sensitivity to the stress-mediated growth response, and T^i the lifetime governing mass removal. Model parameters were assigned from fitting our model to the experimental data [5].

To capture the mechanical behavior of the polymeric scaffold, a Neo-Hookean strain energy density function was adopted. Scaffold degradation was modeled by scaling the scaffold stiffness and scaffold mass using a normalized sigmoid decay function, where k^s and ξ^s describe the offset and speed of degradation, respectively:

$$Q^s(\tau) = \frac{1 + \exp(-k^s \xi^s)}{1 + \exp(k^s(\tau - \xi^s))}. \quad (3)$$

We further assumed a constant tissue density, implying that changes in the total tissue mass were accompanied by equivalent changes in tissue volume. In addition, we applied a constituent-specific kinematic split of the deformation gradient tensor $\mathbf{F}$ to determine the elastic deformation ($\mathbf{F}_e^i$) and stress-free state ($\mathbf{F}_r^i$) of each constituent [4]:

$$\mathbf{F} = \mathbf{F}_e^i \cdot \mathbf{F}_r^i. \quad (4)$$

The turnover-mediated evolution of this stress-free state could then be determined through equation 5, and depends on the difference between the deposition stress and current stress ($\mathbf{S}_{dep}^i$ and $\mathbf{S}^i$) in the constituent, its stiffness ($\frac{\partial \mathbf{S}^i}{\partial \mathbf{C}_e^i}$), and its current elastic deformation ($\mathbf{C}_e^i$):

$$\left[\frac{\dot{\rho}_R^i}{\rho_R^i} + \frac{1}{T^i}\right][\mathbf{S}^i - \mathbf{S}_{dep}^i] = \left[2\frac{\partial \mathbf{S}^i}{\partial \mathbf{C}_e^i} : (\mathbf{C}_e^i \cdot \dot{\mathbf{F}}_r^i \cdot \mathbf{F}_r^{i,-1})\right]_{\mathbf{F}=const}. \quad (5)$$

Simulation plan We first analyzed the tube-shaped geometry, mimicking the TEM constructs in the experiments. Controllable parameters within the in-vitro culture method were varied, particularly focusing on mechanical cues (e.g. the initial load-free tissue formation period, the pressure-driven in-vitro load, and the total in-vitro culturing time). Additionally, in-vivo loading conditions were applied to replicate pulmonary and arterial pressures (Fig. 2). Geometrical parameters were computed after the total in-vitro culture time and after in-vivo implantation. Subsequently, we simulated the impact of the same variations in the in-vitro and in-vivo conditions on the G&R of TEHVs.

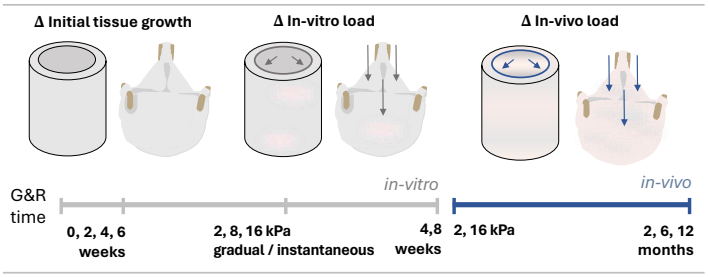

Figure 2: Schematic overview of the simulated in-vitro and in-vivo conditions.

RESULTS

Our simulations reveal that the radius of the tube-shaped constructs is more affected by variations in the initial load-free tissue growth period than by the applied in-vitro pressure, at least for high pressure levels (Fig. 3). Additionally, our results indicate that longer tissue growth periods before in-vitro load application will lead to a lower graft radius.

For TEHVs, our model predicted that the in-vivo geometry is more affected by variations in the applied in-vitro load than by the initial load-free tissue growth time (Fig. 4). A low in-vitro pressure induces leaflet retraction, leading to a valvular insufficiency in-vivo. In contrast, higher in-vitro pressures induce dilation of the leaflets and lead to a decrease in regurgitant orifice area and more sagged, curved valves. Furthermore, the variation in thickness within the valves is much larger than the differences in thickness between the valves for the different in-vitro conditions. Still, the valves with the largest amount of dilation (0w-8kPa and 0w-16kPa) are thinner than the others. All valves show the highest thickness near the commissures due to the high mechanical loads in these regions.

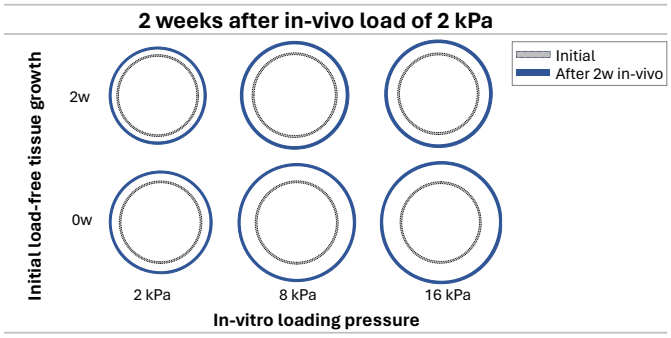

Figure 3: Final cross-section of tube-shaped constructs.

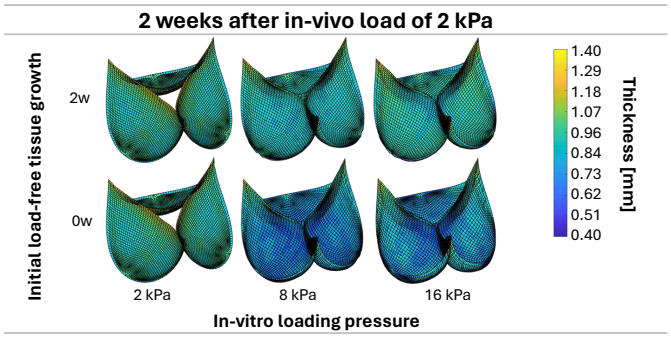

Figure 4: TEHV thickness after 2 weeks of in-vivo implantation.

DISCUSSION

In the present study, we developed a computational model to analyze the degradation of scaffold material and production of ECM constituents in the context of heart valve tissue engineering. We specifically investigated the influence of varying in-vitro culture conditions on the pre-implantation tissue geometry, and the subsequent effects on in-vivo G&R and functionality. We first analyzed the G&R response in tubular-shaped constructs and subsequently simulated the G&R of TEHVs.

Our results showed that higher in-vitro pressures as well as earlier pressure application may lead to tissue dilatation. For the TEHVs, an increase in in-vitro pressure magnitude prevents the valve from regurgitation, and a longer initial load-free tissue growth time limits excessive dilation and thinning of TEHVs. To gain a more comprehensive analysis of the influence of controllable parameters during the in-vitro tissue culture on the G&R response, a broader range of in-vitro loading methods will be investigated in the future, including displacement-driven loading [6], and applying the in-vitro load in an instantaneous manner.

In summary, our model provides a step forward in establishing model-predicted, rational designs for heart valve tissue engineering, which is critical for enabling the successful long-term adaptation and functionality of living valve replacements.

INTRODUCTION

A valuable *in vitro* method for simulating the development process of biological tissue, 3D cell culture is expected to provide shapes and functions akin to those of living tissue. In previous study [1], we represented that the 3D scaffold-free culture of mesenchymal stem cells highly up-regulated the gene expression levels of hypertrophic chondrocyte differentiation within 7 days in the absence of chemical differentiation supplements, compared to a conventional 2D monolayer model. Recently, we also fabricated a cartilage spheroid model reconstructed by pre-chondrocyte cells to examine the effect of spheroid culture in the chondrocyte differentiation [2]. In this study, we aimed to induce hypertrophic chondrocyte differentiation of mouse chondrocyte precursor cells in spheroid culture and carry out 3D imaging analysis using a confocal laser scan microscopy (CLSM). Furthermore, we quantitatively analyze the 3D morphological features and the distribution of nuclei as well as chromatin condensations inside the spheroids.

METHODS

In this study, we subcultured 2,500 cells of mouse chondrocyte precursor ATDC5 cells in each well of U-bottom ultra-low culture plate (ThermoFisher, USA) to fabricate the cartilage spheroids based on the previous study [2]. The spheroids were incubated for 2, 7, or 14 days with DMEM/F12 medium (Gibco, USA) without chondrogenesis differentiation supplements. We then collected for real-time PCR and cryosectioning to stain with anti-collagen X antibody (Abcam, USA), Hoechst 33342 (Invitrogen, USA), and Alexa Fluor 546 Phalloidin (Invitrogen, USA). The staining images with Hoechst 33342 were also observed using a CLSM (ZEISS LSM880 with AiryScan, Germany) and further analyzed with Imaris (Bitplane, Australia) for 3D image analysis to quantify the nuclear morphology.

RESULTS

Corresponding to the previous study [2], the long term-culture up to day 14 provoked the increase in the size of the spheroid. As a result of real-time PCR in Fig. 1, the14-day spheroid culture up-regulated the gene expression levels of the chondrocyte differentiation markers such as *Acan* and *Col2*. As shown in Fig. 2, immunostaining results represented that the COL10 expression was locally detected around the surface of the 2-day-old spheroid, whereas the COL10 expression was entirely detected in the 14-day-old spheroid. The results altogether indicated that the 14-day spheroid culture induced the hypertrophic chondrocyte differentiation of ATDC5 cells.

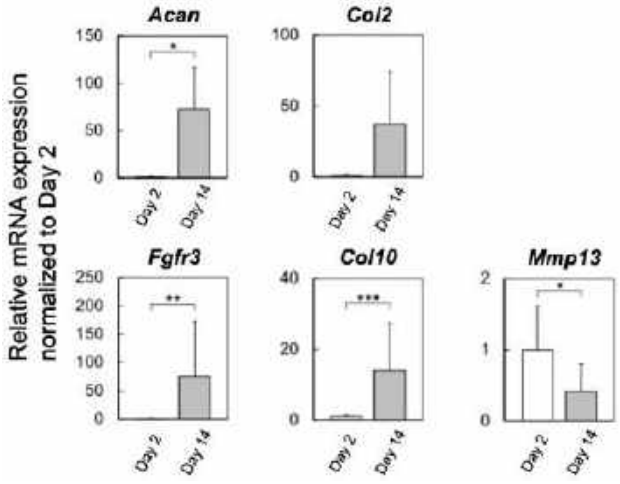

Figure 1: Real-time PCR results to examine chondrocyte differentiation marker (*Acan* and *Col2*) and hypertrophic chondrocyte differentiation marker (*Fgfr3*, *Col10*, and *Mmp13*) of spheroids subcultured for 2 days and 14 days.

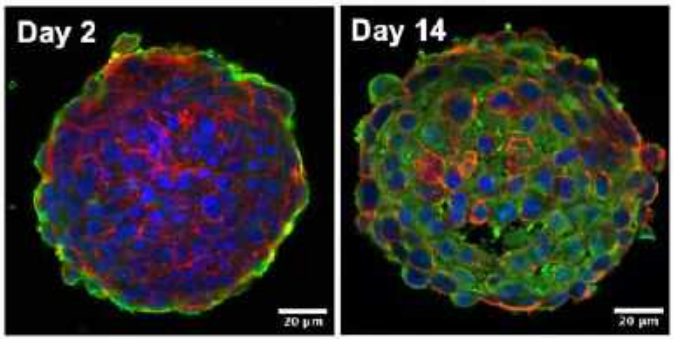

Figure 2: Immunostaining images of COL10 (green), nuclei (blue), and actin filaments (red) in 2-day and 14-day spheroids.

To quantify the nuclear morphology in the spheroid, we then conducted the 3D image analysis using Imaris for segmentation of the nuclei in the spheroid stained by Hoechst 33342. As represented in Fig. 3, each of the nuclei in the 14-day spheroid were hypertrophied than 2-day spheroids.

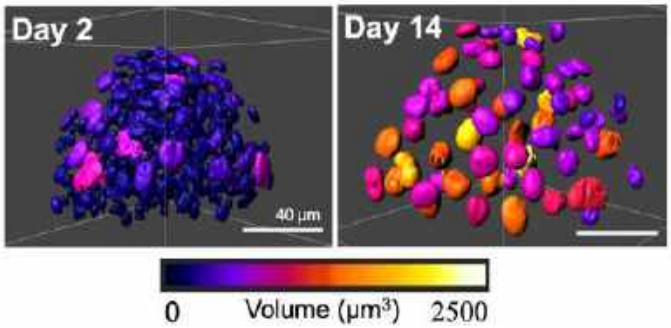

Figure 3: 3D image analysis using Imaris for nuclei in 2-day and 14-day spheroids reconstructed by mouse chondrocyte precursor ATDC5 cells.

As represented in Figs. 4(A) and (B), the chromatin condensations in the nuclei were segmented using 3D image analysis techniques in Imaris. We found out that the number of chromatin condensations in each cell nucleus was greater at day 7 than day 2. However, the total volume of chromatin condensations in each cell nucleus became significantly greater at the day 7 and 14 than day 2. Furthermore, we revealed that the ratio of the chromatin condensation volume in each nucleus was significantly decreased at day 7 and 14 compared to day 2 as shown in Fig. 3(C).

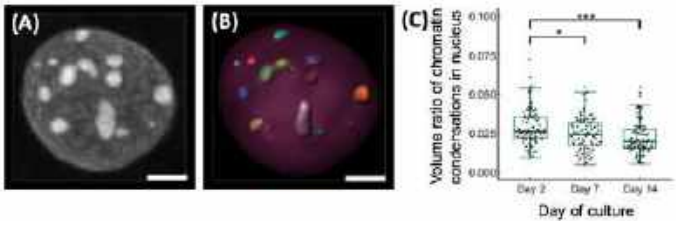

Figure 4: (A) Chromatin condensation in nucleus in the ATDC5 spheroid. (B) 3D image analysis using Imaris for chromatin condensations. (C) Quantification data for volume ratio of chromatin condensation in the nuclei of 2-day, 7-day, and 14-day spheroid.

DISCUSSION

The morphological examination of nuclei and chromatin condensations within a spheroid made from mouse chondrocyte precursor cells was presented in this work. We were able to observe nuclei and chromatin condensations inside the spheroid using CLSM, which also helped us to map out their spatial distribution. Moreover, we used the 3D image analysis method with Imaris to disclose the temporal changes and spatial patterns of the nuclear morphology and chromatin condensations. The current work raised the prospect of integrating biochemical assays with 3D image analysis studies to learn more about the physiology of hypertrophic chondrocyte differentiation.

Our spheroid model exhibited cellular and nuclear hypertrophy as well as the up-regulation of the early hypertrophic chondrocyte differentiation marker genes (*Fgfr3* and *Col10*). In addition, the spheroid demonstrated the expression of COL10, a characteristic of hypertrophic chondrocytes. These findings imply that early hypertrophic chondrocyte development, including morphological changes like those of hypertrophic chondrocyte differentiation *in vivo*, was induced by the spheroid culture of ATDC5 cells. The day 2 spheroid's surface, where relatively large nuclei were located, was where COL10 was expressed. Additionally, on days 7 and 14, when hypertrophied nuclei were present throughout the spheroids, COL10 was found throughout the spheroids. This relationship between nuclear volume and COL10 synthesis is corroborated by the histological characteristic seen in the hypertrophic zone of the epiphyseal plate *in vivo*.

Over the course of 14 days of culture, changes were observed in the amount of heterochromatin, as demonstrated by the quantification of chromatin aggregation volume in individual cell nuclei. Whereas structural study of chromatin condensation in the cell nuclei has been restricted to 2D cultivated cells, our approach is capable of analyzing images of individual chromatin condensations in 3D spheroid model. The ratio of the total chromatin condensation volume to the entire cell nucleus decreased in 7- and 14-day spheroids in comparison to 2-day spheroids. This could imply that as the cell nucleus grew during the spheroid culture, the condensation status of chromatin altered. One explanation is that chromatin condensations may have been in a more relaxed overall state.

In conclusion, we carried out the biomechanical study with an emphasis on morphological and functional alterations for the cartilage spheroid, as well as temporally-varying changes in gene and protein expressions. Thus, we verified that the spheroid culture could induce hypertrophic chondrocyte differentiation, which is a prerequisite for endochondral ossification, even in the absence of chemical differentiation media. We believe our biomechanical analysis will be applicable for other 3D culture model such as organoids.

INTRODUCTION

Bicuspid aortic valve (BAV) is the most common congenital cardiovascular defect and is characterized by formation of two, rather than three, leaflets.[1] Approximately 50% of BAV patients prematurely develop calcification and aortic stenosis (AS) by the age of 35, which is more prominent with fusion of the right and noncoronary (R/NC) leaflets.[2] This holds true for a cohort of 117 patients with R/NC BAV at the Herma Heart Institute (HHI) where 60% developed AS by age 20. Importantly, not all R/NC BAV patients develop AS since some maintain a normal peak aortic gradient into early adulthood (Fig 1).

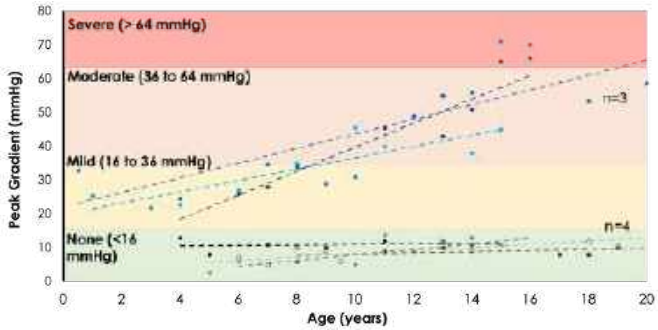

Figure 1. The evolution of peak aortic valve gradients from R/NC BAV patients at our center

The mechanisms underlying premature AS induced by calcification in BAV patients are unknown, but it has been suggested that mechanical stimuli play a role. This is supported by previous computational modeling of adult BAV showing regional differences in mechanical stimuli on BAV leaflets compared to tricuspid aortic valve (TAV) controls.[3] However, studies to date have focused on adult BAV after the onset of calcification and relied on simplified geometry, boundary conditions, and material properties in their models. Our objective is to characterize the mechanical stimuli more accurately in BAV by using patient-specific geometry and boundary conditions, as well as including material properties from biaxial testing of BAV leaflets for the first time. By identifying the BAV-specific regional differences in mechanical stimuli in young patients prior to the onset of calcification and correlating them with known patterns of calcification and downstream gene expression, we can better understand how BAV-induced mechanical stimuli plays a role in premature calcification and AS in R/NC BAV patients.

METHODS

Cardiac MRI data of a 23-year-old patient with R/NC BAV and aged-matched TAV control were obtained following IRB approval. Aortic and coronary artery morphology were extracted using SimVascular (simvascular.github.io). Leaflet geometry was constructed in OnShape (onshape.com) using reported dimensional relationships made patient-specific by scaling to sinus geometry (Fig 2).[4]

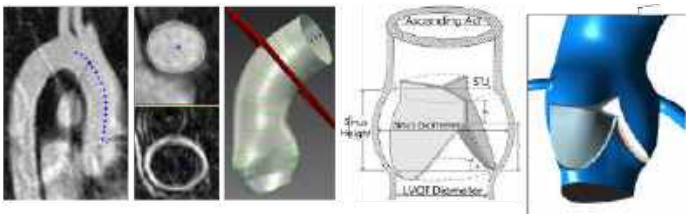

Figure 2. Patient-specific geometry reconstruction.

Physiologic boundary conditions (BCs) were implemented including measured pressure at the aortic inlet, a lumped-parameter model of downstream physiology at the aortic outlet, and flow imposed at coronary artery outlets (Fig 3).

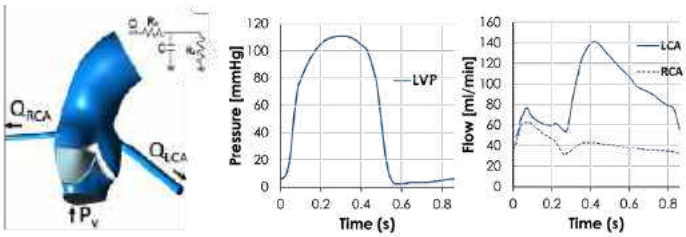

Figure 3. Patient-specific BCs for FSI simulations.

Biaxial testing was performed on aortic valve leaflets obtained from local donors after IRB approval (42-year-old normal control, 79-year-old with BAV). Briefly, samples (~6x6mm) were biaxially stretched at 37° to peak physiological strain in the circumferential (11%) and radial directions (13%) using a BioTester (CellScale) system with a 1.5N load cell using a previously described protocol (Fig 4).[5] Constitutive parameters of the Gasser-Ogden-Holzapfel model for hyperelastic anisotropic material properties were obtained using Hyperfit.[6]

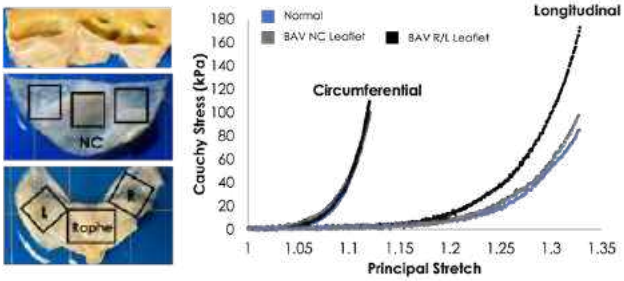

Figure 4: Biaxial testing of normal and BAV patient valve tissue.

Fluid-Structure Interaction (FSI) simulations were performed by coupling FlowVision (Capvidia) with Abaqus/Explicit (Dassault Systems). Wall shear stress (WSS) and von Mises Stress were quantified using Abaqus and ParaView and evaluated for statistical significance using One-Way ANOVA.

RESULTS

FSI studies of the young adult R/NC BAV patient revealed higher WSS magnitude in the coaptation region of the ventricularis surface versus the age-matched TAV control. This is more prominent on the nonfused BAV leaflet compared to the fused leaflet (Fig 5).

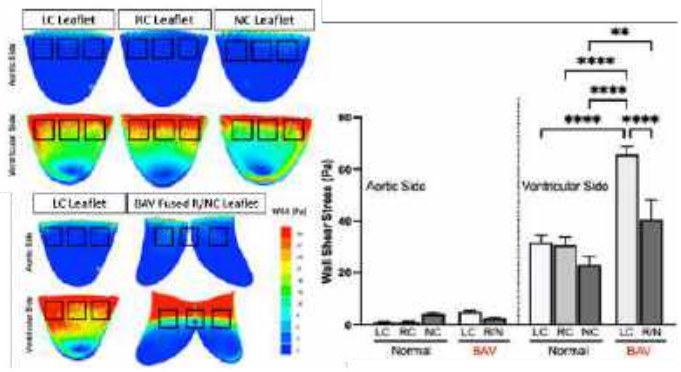

Figure 5. WSS contours & quantification showing higher magnitude in the coaptation region of the ventricularis that is more prominent on the nonfused BAV leaflet.

The magnitude of von Mises stress was higher for BAV leaflets, particularly in the belly/coaptation regions. This is more pronounced in the fused leaflet, primarily near the fusion site (raphe; Fig 6).

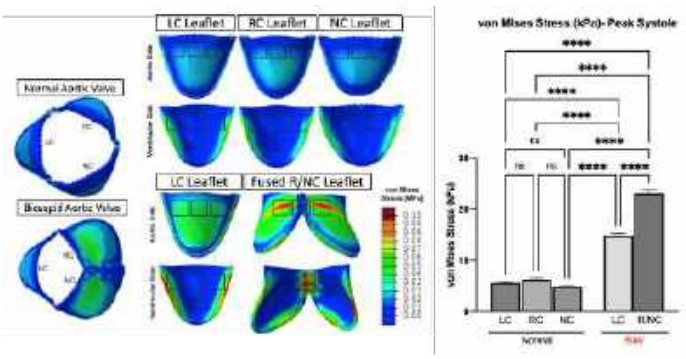

Figure 6. von Mises Stress contours & quantification showing higher magnitude in BAV, mainly at the R/NC fusion site

DISCUSSION

Our FSI studies of a young adult R/NC BAV case revealed pronounced alterations in mechanical stimuli regionalized to the raphe, attachment, and coaptation regions when compared to an age-matched TAV control. Interestingly, previous studies have shown that calcium deposition on aortic valve leaflets typically occurs in those regions.[7] Given that these regionalized changes in mechanical stress are present already at a young age (23-year-old) and localized to regions prone to calcium deposition suggests that BAV-specific mechanical stimuli could be a potential pathogenic contributor. It is believed that these initial findings to be further presented are more accurate since they involve the first ever simulations from biaxial testing of BAV leaflets from patients. Thus we can more accurately characterize BAV-specific mechanical stimuli that may drive the development of premature calcification in BAV. Evaluating the downstream molecular mechanisms in patients remains challenging due to the availability of tissue samples throughout the disease process. To address this we are conducting FSI simulations in a murine model of BAV at equivalent human-to-murine age groups to mimic human progression of premature calcification in BAV.[8] To date we have shown that increased peak aortic gradient driving alterations in WSS precede the increased expression of calcification markers such as *Spp1*, particularly in the attachment and coaptation regions where calcium deposition commonly occurs.[9] This further substantiates our hypothesis that mechanical stimuli could be driving premature calcification in BAV. Future work will translate our findings in the mouse model to our BAV patient cohort to identify predictive indicators for calcification risk and targets for novel molecular therapies.

MODELING HEAT SINK EFFECTS OF CEREBROSPINAL FLUID (CSF) DURING THERMAL THERAPIES FOR TREATMENT OF GLIOBLASTOMA (GBM)

Yash S. Lad (1), Omar Abdulqader (1), Shreeniket M. Pawar (1), Anilchandra Attaluri (1)

INTRODUCTION

GBM is considered as the most lethal brain tumor, which has a high recurrence rate. The main reason for local recurrence is inefficiency of thermal therapies in treatment of 100% tumor margins due to the heterogeneity of tumor. Treatment of GBM requires predefined temperature constraints, based on the thermal therapies, to be maintained within the tumor for a specified time to kill the cancerous cells. However, it is difficult to achieve clinically acceptable temperature distribution due to blood perfusion and presence of CSF [1]. Most of the GBM tumors are in close proximity to the CSF, which carry away most of the heat supplied to the tumor during these therapies. Understanding the heat transfer characteristics and the amount of heat that can be transferred to the fluidic structures is crucial for optimizing thermal therapies and ensuring their effectiveness in targeting brain tumors. The impact of heat sinks produced by the CSF, ventricles, posterior cerebral artery, and suprasellar and ambient cisterns on the local temperature during LITT has been identified in the literature [2] but has not been studied. Computational fluid dynamics (CFD) combined with conjugate heat transfer (CHT) modeling provides a powerful tool to investigate the dynamics of fluid flow and the associated heat transfer processes within the brain.

This study explores the convective heat transfer between the CSF and tumor during thermal therapies to identify the untreated tumor margins.

METHODS

The human head anatomy was modeled as spherical domains representing skull, CSF general, brain, tumor, and heat source. The CSF ventricles were modeled as rectangular fluid channels with velocity inlet and pressure outlet. The CSF was modeled as a fluid with laminar flow based on the calculation of Reynolds number. Boussinesq approximation to the Navier-Stokes equation was used to account for buoyancy driven flows. Four different cases for the tumor location with respect to CSF general and ventricles were studied. A volumetric heat source with pulsed heating was modeled. Thermal damage-dependent blood perfusion was added as a volumetric heat source in the tumor. Variation of temperature penetration depth into the CSF ventricles were studied for different gravity directions, assuming the patient positioning during the treatment.

Figure 1 shows a representation of the system of interest with simplified geometry. The dimensions of the different components of the human head are approximated from the segmented de-identified patient dataset. The CFD simulations utilize the Navier-Stokes equations, coupled with the energy equation, to capture the fluid flow and heat transfer phenomena.

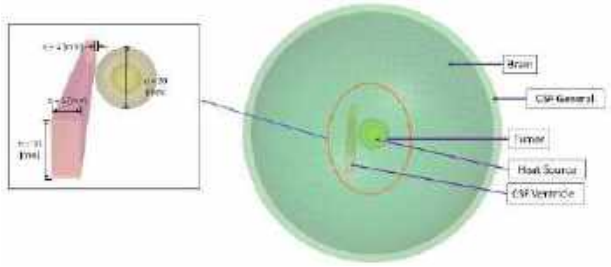

Figure 1: Simplified geometry considering brain, tumor, and CSF ventricles, for model preparation in the CFD software.

Moreover, the Boussinesq approximation to the Navier–Stokes equation, as shown in equation (1), is used to account for buoyancy-driven flow. The temperature change in the fluid region due to the convective heat transfer is given by equation (2). Thermal damage-dependent blood perfusion equation (3), adopted from Pennes' Bioheat equation [3], is applied to the tumor in the form of volumetric heat source. Finally, the convective heat transfer coefficient is calculated from equation (4).

$$\rho\frac{\partial\vec{v}}{\partial t}+\rho\nabla\cdot(\vec{u}\vec{u})=\mu\nabla^2 u-\nabla p+\rho k\vec{g} \quad (1)$$

$$\rho C_p \frac{\partial T}{\partial t} - \nabla(k\nabla T) = -\rho C_p(\vec{u}.\nabla T) \quad (2)$$

$$Q_{Perf} = \rho_b C_{p,b} \omega_{b,tumor}(T_b - T) \quad (3)$$

$$h = \frac{q}{A(T_b - T)} \quad (4)$$

where, ρ is the fluid density [kg/m^3], u is the fluid velocity [m/s], k is the thermal conductivity [W/(m.K)], p is the fluid pressure [Pa], T is the absolute temperature [K], ρ_b is the blood density [kg/m^3], $C_{p,b}$ is specific heat capacity of blood [J/kg.K], ω_b is the blood perfusion rate [1/s], T_b is the blood temperature [K] and g is the gravitational acceleration [m/s^2]. The values of these properties are listed in Table 1.

Table 1: Thermal properties for different domains of the human head anatomy [1,4].

Part	C_p [J/(kg.K)]	ρ [kg/m^3]	k [W/(m.K)]	μ [Pa.s]	u [m/s]
Brain (grey & white matter)	3630	1046	0.51	-	-
Tumor	3700	1056	0.57	-	-
CSF	4096	1007	0.62	7.84×10^{-4}	0.01
Heat Source	750	2200	1.38	-	-
Blood	3617	1050	0.52	3.65×10^{-4}	0.1

RESULTS

Figure 2 shows the simulation results for a tumor located close to the left CSF ventricle. The surface temperature contour in Figure 2b shows the untreated surface with a temperature drop of 2.6 [°C] from the maximum surface temperature of 42.2 [°C]. The temperature contour for the CSF ventricle in figure 2d shows that the CSF ventricle carries away 1.4 [°C] temperature, acting as a heat sink. From the heat transfer report, the convective heat transfer rate for the CSF ventricle was calculated to be 9.32 ×10^{-2} [W]. Therefore, from equation (4), the convective heat-transfer coefficient can be estimated as 7.18 [W/(m^2.K)].

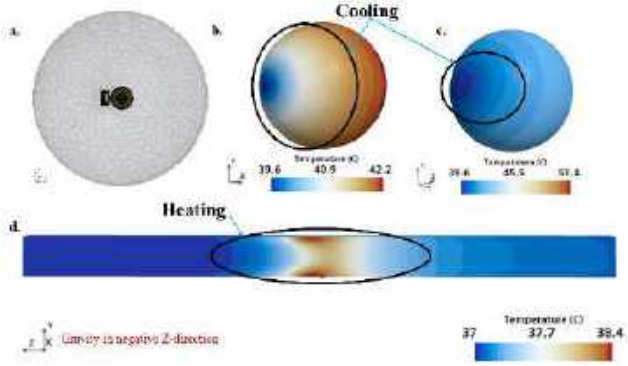

Figure 2: Results for tumor location close to the left CSF ventricle. a. Mesh plot showing the location of the tumor with respect to the CSF. b. Tumor surface temperature shows a 2.6 [°C] drop in temperature closer to the ventricle. c. Tumor domain temperature shows an overall drop of 11.8 [°C] from core to the surface of the tumor. d. CSF ventricle temperature shows a 1.4 [°C] rise in temperature.

To identify the temperature penetration into the CSF ventricle, a line probe was plotted across the width of the ventricle, right at the center of the length exposed to the tumor as shown in Figure 3a. The probe plot (Figure 3b) shows a penetration depth of approximately 1.3 [mm] into the ventricle.

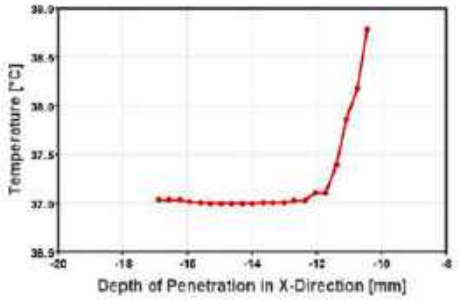

Figure 3: Temperature plot showing the penetration depth of approximately 1.3 [mm] in X-direction.

DISCUSSION

This study demonstrates a substantial heat sink effect of cerebrospinal fluid (CSF) during thermal therapies when the tumor is located in close proximity to the CSF ventricles or CSF general. Hence, accounting for these heat-sink effects of the CSF during thermal therapies is necessary to obtain maximum lesion coverage and avoid tumor recurrence. During the conference presentation, the heat sink effects for different tumor locations will be presented, and the convective heat transfer coefficient will be compared. In addition, the maximum distance between the tumor and CSF, up to which the heat sink effects should be modeled, will be demonstrated, with comparison.

INTRODUCTION

Magnetic nanoparticle hyperthermia (MNPH) therapy is generally used for treatment of tumors in combination with chemotherapy and radiation therapy [1]. In MNPH treatment, heat is generated by the application of alternating magnetic field (AMF) to the magnetic nanoparticles (MNP). Current MNPH treatments are based on the application of pulsed AMF to control the heat within hyperthermia temperatures. However, the major drawback of this method is that there is no feedback control system to prevent the risk of off-target thermal dose deposition and the treatment is entirely based on operator skill and experience [2,3]. In this study we plan to implement thermal damage feedback based PID control system to maintain the tumor temperature within hyperthermia limits, preventing off-target thermal damage. The subcutaneous tumor embedded in muscle is considered as the domain for the study. Uniform distribution of MNP is assumed inside the tumor. Bioheat transfer simulations in combination with the PID controller are carried out for the simplified model. Simulation results show that the PID controller successfully maintains the temperature at the tumor boundary at 43 [°C] with minimal overshoot in the range of 3-5 [%]. The controller output is set to zero once the thermal damage at the tumor boundary reaches the setpoint.

METHODS

A simple geometry assuming spherical tumor and cuboidal muscle, as shown in Figure 1 is modelled for this study. The heat source, i.e., MNP distribution is assumed to be spherical and uniform. The model is built in commercial finite element analyis (FEA) software (COMSOL Multiphysics©) to perform the bioheat transfer simulations. Initially, the muscle, tumor and heat source are assumed to be at 37 [°C]. The convective heat flux of 3.7 [W/(m^{2}K)] is imposed on the part of tumor exposed to surroundings.

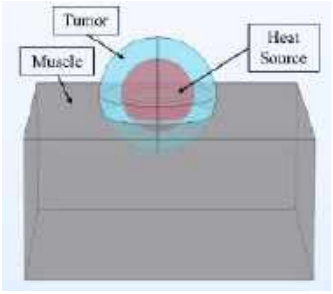

Figure 1: Geometry representing the tumor and heat source as spherical domains embedded in a cuboidal muscle domain.

Pennes' bioheat transfer equation is used to solve heat transfer problem as given in equation 1. Thermal damage dependent blood perfusion was modelled for tumor using equations 2, 3 and 4 [1,4].

$$\rho_i\, C_{p,i}\, \frac{\partial T}{\partial t} - \nabla(k_i \nabla T) = Q_{Perfusion} + Q_{Heatsource} + Q_{met} \quad (1)$$

$$Q_{Perfusion} = \rho_b\, C_{p,b}\, \omega(T)(T_b - T) \quad (2)$$

$$DS = 1 - \exp\left(-A \int_0^t e^{-\frac{E_a}{RT(\tau)}}\right) d\tau \quad (3)$$

$$\omega(T) = \begin{cases} \omega_{b,i}(30DS + 1), (DS \le 0.02) \\ \omega_{b,i}(-13DS + 1.86), (0.02 < DS \le 0.08) \\ \omega_{b,i}(-0.79DS + 0.884), (0.08 < DS \le 0.97) \\ \omega_{b,i}(-3.87DS + 3.87), (0.97 < DS \le 1 \end{cases} \quad (4)$$

where, ρ is the fluid density [kg/m^3], k is the thermal conductivity [W/(m.K)], T is the absolute temperature [K], ρ_b is the blood density [kg/m^3], $C_{p,b}$ is specific heat capacity of blood [J/kg.K], ω_b is the blood perfusion rate [1/s] and T_b is the blood

temperature [K]. The values of these properties are listed in Table 1.

Table 1: Thermal properties for different domains of the human head anatomy [1,4].

Part	C_p [J /(kg. K)]	ρ [kg/ m^3]	k [W /(m. K)]	Q_{met} [W /m^3]
Muscle	3421	1090	0.003	6374.5
Tumor	3760	1045	0.51	31873

Temperature measuring probes were placed at the boundary of the tumor to provide feedback to the PID controller. Cumulative equivalent minutes at 43 [°C] (CEM43) is modelled, as shown in equation (5), and used as a thermal damage feedback for the PID controller. The developed FEA model was exported to MATLAB Simulink® using COMSOL Livelink for Simulink©.

$$\mathrm{CEM43} = \int_{t=0}^{t=final} B^{\frac{43[°C]-T(x,y,t)[°C]}{1[°C]}}, B\begin{cases} 0.5\,, T > 43\ [°C] \\ 0.25,\ T \le 43\ [°C] \end{cases} \quad (5)$$

PID controller was designed in MATLAB Simulink®. Constraints were imposed for temperature at the centre of the tumor to be maintained below 60 [°C] and boundary of the tumor below 43 [°C]. Fuzzy logic control was applied to ensure that once the thermal damage measuring probe at the tumor's boundary registered a CEM43T10 value, the power input was switched off.

RESULTS

Figure 2 shows the simulation results for temperature control using PID. The controller successfully maintains the temperature at the centre of the tumor below 60 [°C]. There is a small overshoot in temperature of about 4 [%] at boundary of the tumor. However, this overshoot is seen only for a small duration. From the figure it is evident that the controller is able to maintain the temperature at boundary of the tumor below 43 [°C] for rest of the treatment time.

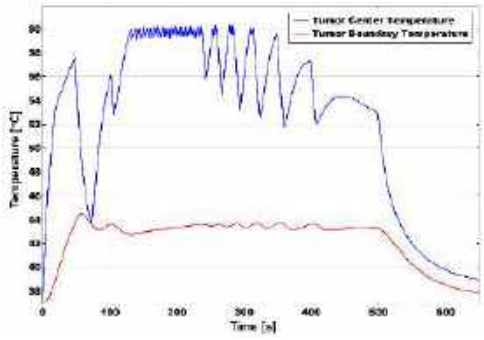

Figure 2: Simulation results for temperature control using PID. The controller successfully maintains tumor centre temperature below 60 [°C] and the boundary below 43 [°C].

Figure 3 shows the CEM43 thermal damage at the tumor boundary. The controller output is zero once the CEM43 reaches value of 10 due to this reason the temperature drop at approximately 600 seconds can be seen in figure 2.

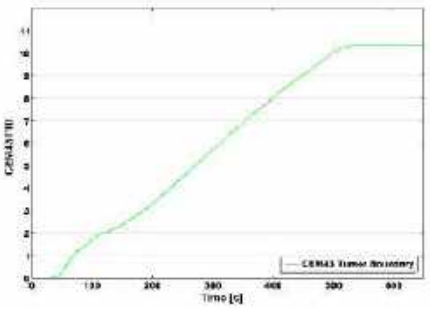

Figure 3: CEM43T10 results using the PID controller the controller output successfully turns off once the target thermal dose of CEM43T10 is reached.

DISCUSSION

This study demonstrates the PID controller design cascaded with fuzzy logic control for MNPH treatments. PID controller is preferred over the conventional pulsed heating as the feedback enhances the control and reduces the dependency on operator skills. In this study PID is designed and implemented to control tumor boundary temperature and stop the heating when the thermal damage reaches the setpoint. However, there is slight overshoot from the setpoint for the tumor boundary temperature. This overshoot might be a concern based on tumor location. This limits the possibility of the controller to be translated into clinical settings. To overcome this limitation, fine tuning of the controller needs to be done based on specific tumor positioning cases.

MECHANICAL CHARACTERIZATION OF HUMAN MESENCHYMAL STEM CELL-DERIVED OSTEOCYTIC SPHEROIDS BY UNIAXIAL COMPRESSION TESTING

T. Inagaki, J. Kim, E. Maeda, T. Matsumoto

Department of Mechanical Systems Engineering, Graduate School of Engineering,

INTRODUCTION

In recent years, three-dimensional (3D) cultures have gained attention as new cell culture models to mimic *in vivo* environments beyond a conventional two-dimensional (2D) culture model. We have fabricated spheroids with a diameter of about 100 µm derived from human mesenchymal stem cells in a medium containing osteogenic supplements. We found that the spheroid significantly up-regulated osteocyte differentiation markers after two days compared to 2D cultures (1). Additionally, it is known that mineralization of the tissue occurs in the spheroid after the long-term culture (2). In order to evaluate the bone-likeness of the mineralized spheroids quantitatively as the mechanical properties, we previously developed a uniaxial compression testing device by a glass plate to measure the stiffness of the spheroid (3). In this study, we further evaluated the viscoelastic behavior of the spheroids for 2-day and 35-day culture after compression release.

METHODS

Human mesenchymal stem cells (Riken BRC, Japan) were cultured in an incubator maintained at 37°C and 5% CO_2. The basal medium consisted of DMEM (Dulbecco's modified Eagle medium, Gibco, USA) supplemented with 10% immobilized bovine fetal serum (Gibco, USA) and 1% penicillin-streptomycin (Nacalai Tesque, Japan). Cells were passaged every 3-4 days. The experiment was performed by cells with less than 10 passage number.

Human mesenchymal stem cell-derived spheroids were fabricated using the method described in a previous study (4). Cell suspension (2,500 cells/spheroid) was placed in an each well of an ultra-low attachment culture plate (ThermoFisher, USA) and cultured for 2 days to form the spheroids. In this study, spheroids were subcultured for 2 days and 35 days after being placed in the well plate were used for observation of viscoelastic behavior. For spheroid culture, osteogenic differentiation was induced by adding chemical osteogenic supplements. The osteogenic supplements consisted of a mixed solution of 10 mM β-glycerophosphate (Sigma, USA), 50 µM ascorbic acid (Wako, Japan), 100 nM dexamethasone (Nacalai Tesque, Japan) in DMEM + GlutaMAXTM-I (Gibco, USA).

The uniaxial compression testing system is shown in Figure 1. A borosilicate glass thin plate (D263 Teco, Schott, Germany) with 100 mm in length, 1.0 mm in width, and 0.14 mm in thickness was bent by heating with a gas lighter in the middle as shown in Figure 1 (A) and attached to a three-axis micromanipulator (MHW-3, Narishige, Japan). The spheroid was transferred to a square culture dish (CS-TECH, Japan) and placed on the stage of an inverted microscope (IX73, Olympus, Japan). The micromanipulator was operated to press the glass thin plate against the spheroid on the wall of the square dish. Further experiment was performed at room temperature within 1 hour after the spheroids in the incubator were transferred to the square dish.

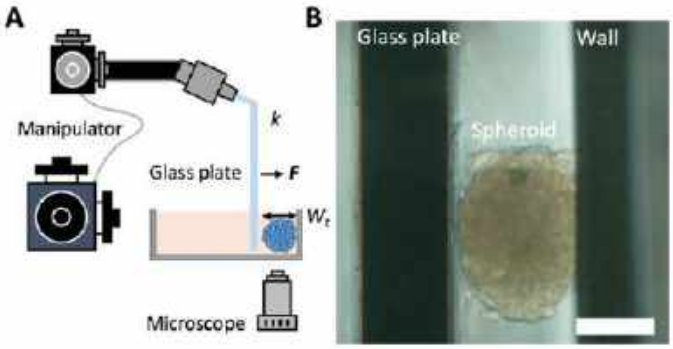

Figure 1: Schematic diagram of a uniaxial compression system using a glass plate controlled by a 3D manipulator (A) and representative images of spheroids derived by human mesenchymal stem cells under compression (B). A white bar indicates 100 µm.

The viscoelastic behavior of the spheroid was investigated using the test system as described in Figure 2. The experiment's outline is as follows: initially, the spheroid was compressed by 50% for 30 seconds (Phase I). Then, the spheroid was kept compressed under the glass plate for either 1 minute or 15 minutes (Phase II) to observe the creep phenomenon of the spheroid. Finally, the glass plate was released from the spheroid, and the recovery of the spheroid strain was observed for 5 minutes (Phase III). The slowness of the strain recovery behavior was determined by approximating the time change of the spheroid width W_t under each condition with an exponential function in equation (1) and calculating the time constant τ.

$$f(t) = a + b\exp^{(-t/\tau)} \quad (1)$$

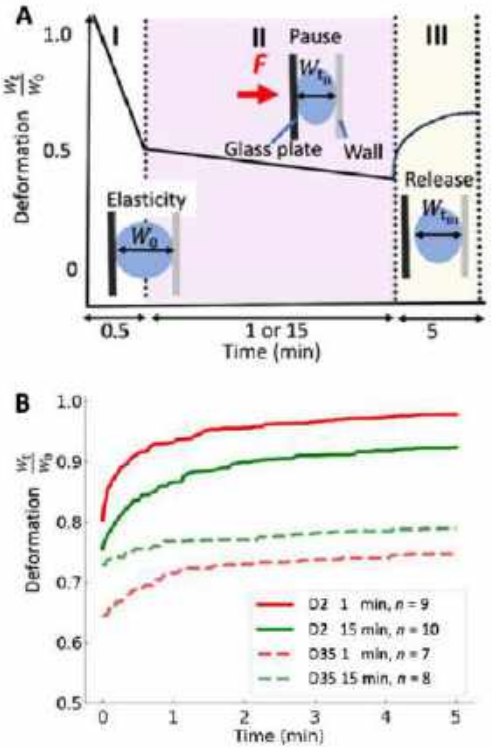

Figure 2: Schema (A) and typical results (B) of creep deformation experiment for 2-day and 35-day spheroids using a glass plate compression system. First, the spheroid was compressed up to 50% strain in 30 s (I), then kept compressed in 1 or 15 minutes (II), and finally released by moving the glass plate apart from the wall (III). Changes in the ratio of the width in the direction of compression of the 2-day and 35-day spheroid 1 min and 15 min after releasing in phase III.

RESULTS

Figure 2(B) shows the strain recovery of human mesenchymal stem cell-derived spheroids for 5 minutes after 50% compression, cultured for both 2 days and 35 days. The ratio of the spheroid width immediately after compression release (W_0) to the spheroid width at the end of observation period III (W_t) was 1.01 ± 0.07 (mean ± SD, N = 3 (number of independent experiments), n = 9 (number of samples)) for spheroids cultured for 2 days with 1 minute of compression (red), indicating recovery to the width before compression. However, for spheroids compressed for 15 minutes (green), the ratio was 0.93 ± 0.07 (N = 3, n = 10), showing a tendency not to return to the original size. On the other hand, for spheroids cultured for 35 days, the ratio was 0.78 ± 0.08 (N = 3, n = 7) for 1 minute of compression (red dashed) and 0.82 ± 0.14 (N = 3, n = 8) for 15 minutes of compression (green dashed), neither of which recovered to the original size.

Additionally, by approximating the time change of the average strain width for each condition of the spheroids with an exponential function, the time constant τ after compression recovery was calculated to be 0.83 and 1.02 for 1 and 15 minutes of compression, respectively, for spheroids cultured for 2 days. For spheroids cultured for 35 days, the time constants were 0.87 for 1 minute and 1.60 for 15 minutes of compression.

DISCUSSION

We established a uniaxial compression test system using a glass plate controlled by a three-axis micromanipulator, and observed the viscous behavior of human mesenchymal stem cell-derived spheroids during compression. Short-term 2-day spheroids underwent plastic deformation by 50% compression, remaining shrunk to approximately 90% of their original size. In other words, they do not return to their original size when compressed for more than 1 minute under compressive strain conditions. Kinoshita's study reported that reconstructing the cytoskeleton actin and the cell adhesion molecule cadherin occurs when African clawed frog embryos are compressed 50% for 5 minutes (5). It is possible that the cytoskeleton and cell adhesion in spheroids cultured for 2 days were thought to be reconstructed while being compressed for more than 1 minute, preventing them from returning to their original shape. Additionally, from the time constant of the width recovery change of the spheroids, it was found that the recovery time for 2-day and 35-day cultures was slower for 15 minutes of compression than for 1 minute. This result might indicate that longer durations of compression contribute to a more noticeable restructuring of the cytoskeleton. Furthermore, spheroids cultured for 35 days underwent greater plastic deformation, remaining shrunk to approximately 70% of their original size, even with 1 minute of short-term compression. The spheroids incubated for 35-day culture are known to induce mineralization from the center of the spheroid (2), implying that the mineralization within the spheroid affected its viscoelastic behavior.

In this study, we utilized a uniaxial compression test system with a glass plate controlled by a three-axis micromanipulator to observe the viscous behavior of human mesenchymal stem cell spheroids. By compressing 2-day and 35-day spheroids and observing the time change of deformation in the compression direction, we evaluated the viscoelastic behavior of the spheroids. The differences in the strain recovery behavior of the spheroids due to culture period and compression time are thought to be influenced by the cytoskeleton, cell adhesion, and extracellular matrix in the spheroids, but their direct involvement is still unclear. To confirm the involvement of the cytoskeleton in the viscoelastic behavior of the spheroids, inhibitor experiments will be required in the future.

INTRODUCTION

A common sequela of cardiovascular disease is partial or total occlusion of blood vessels. In these cases, vascular grafts are often needed to restore tissue perfusion. Arterial bypass surgery using autologous vascular grafts (AVG) remains the gold standard for long term revascularization due to their lower risk of complications, including thrombosis. AVGs are often not a suitable option due to patient co-morbidities and previous vascular harvest. In such patients, synthetic vascular grafts (SVG) are used. The use of small diameter (<6mm) SVGs is complicated by a higher risk of thrombosis and stenosis compared to AVGs (1). This necessitates the use of anti-platelet agents but still often leads to a loss of patency requiring reintervention

Loss of patency due to platelet adhesion and thrombosis occurs as a result of failure to establish an endothelial cell (EC) monolayer to reduce interaction with the synthetic material (2). The physiologic wall shear stress (WSS) conditions experienced by small diameter SVGs usually prevents ECs from forming a monolayer post-implantation. Even in cases where ECs are seeded onto the grafts before implantation, physiologic WSS often leads to EC detachment (2). Collectively these prior findings suggest, reducing WSS within a pre-seeded SVG has the potential to improve EC retention. Micro-patterned channels provide a potential method of achieving this desired reduction in WSS. The objective of this study is to develop and test a method of maintaining EC adhesion under physiologic WSS using a micro-patterned channel surface imprinted onto a vascular graft material. We hypothesize that seeded ECs located within channels will be protected from WSS and consequently exhibit superior retention compared to ECs directly exposed to physiologic WSS.

METHODS

Computational fluid dynamics (CFD) simulations were conducted using flow domain geometry based on the dimensions of a Glycotech circular parallel plate flow chamber. Boundary conditions were imposed to establish WSS at physiologic levels (15 dyn/cm^2), with repeating small channels designed to reduce WSS to <1 dyn/cm^2. The distance between channels and channel depth were adjusted to balance favorable velocity patterns with the manufacturing capabilities described below.

Electrospinning was used to create a thin flat sheet (~0.3mm) of Biospan 2F fluorinated polyurethane (PU) adhered to a glass microscope slide. This technique was used to produce a consistent microporous structure conducive to EC adherence. A 3D printed stamp was fabricated to produce micro-channels based on CFD results. A 3D printed frame was paired with the stamp to provide a consistent stamping method and depth across experiments. Scanning electron microscope (SEM) images of both the stamp and the stamped substrates were obtained to confirm the desired stamp geometry and micro-channels had been produced. A set of channels was produced with the stamp on a sterile electrospun PU substrate in preparation for cell seeding. Human umbilical vein endothelial cells (HUVECs) were then used to seed the substrates. A droplet of 400 μL of 250,000 cells/mL cell suspension was applied to the stamped region of the substrate to provide a consistent layer of cells and allowed to incubate for 48 hr to achieve attachment.

A Glycotech circular parallel plate flow chamber and programmable syringe pump were used to apply physiologic WSS (15 dyn/cm^2) to the seeded substrates for 30 min. Cell seeded substrates not exposed to WSS served as a control. After exposure to WSS, ECs on both samples were fixed and permeabilized. Fluorescence staining was preformed using NucBlue (Hoechst) and Actin Red-555 (F-Actin) to determine localization and number of ECs under fluorescence microscopy. Cell quantification was performed on Hoechst stained nuclei in ImageJ. Three channels and the unstamped surfaces directly adjacent were selected at equivalent points for each group and cell density was recorded. Channel and surface pairs were quantified for each third of the flow domain for a total of three pairs in the upstream, middle, and downstream thirds.

RESULTS

Figure 1 shows the most recent CFD simulation with distributions of WSS. WSS is reduced to <1 dyn/cm^2 within the channels compared to 15 dyn/cm^2 atop the surface between the channels (Fig 1).

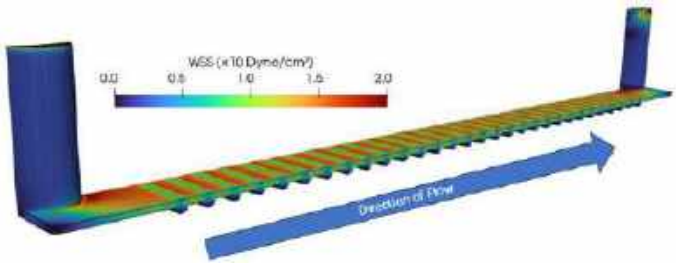

Figure 1: Wall Shear Stress (WSS) contour plot of the parallel plate chamber with stamped surface.

SEM imaging confirmed the fidelity of the stamp and stamped substrate (Fig 2). Side profile imaging of the stamp (Fig 2, left) shows a consistent stamp geometry. The top down image of a stamped substrate (Fig 2, right) displays channels of consistent width, though some channels do not extend to the full width of the flow domain.

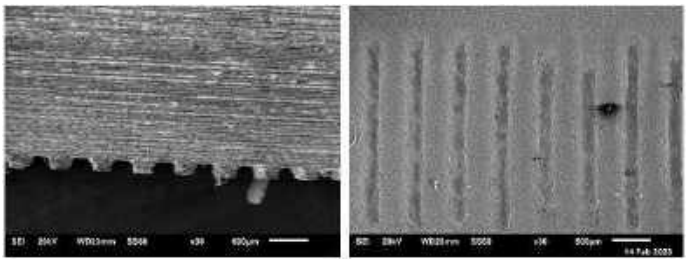

Figure 2: SEM imaging side profile of 3D printed stamp (Left), and the imprint it produces in PU (Right).

When seeded on a stamped PU substrate HUVECs not exposed to WSS are able to adhere evenly across the surface of the stamped region (Fig 3, left). Upon exposure to physiologic WSS, most cells were seen to detach from the substrate when compared to the static control (Fig 3, right). The majority of cells that remained following the application of physiologic WSS were observed within the channels.

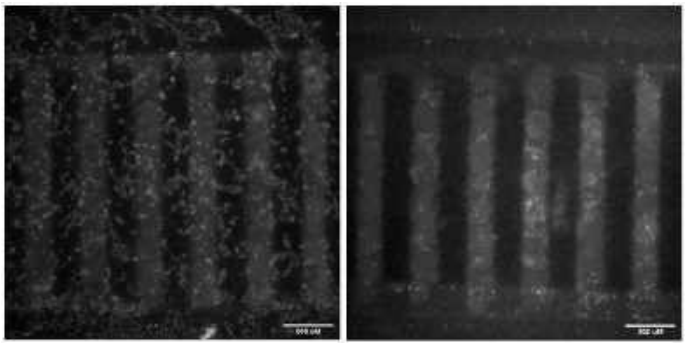

Figure 3: Cells seeded on stamped PU stained with Hoechst, without WSS (left) and after exposure to physiologic WSS of 15 dyn/cm^2 (right).

Quantification shows a significant reduction ($p<0.01$) of cell density both within the channels (channel) and between the channels (surface) of the group exposed to WSS (WSS+) compared to a static control not exposed to WSS (WSS-) (Fig 4, left). Comparing overall cell density between WSS+ within channels and between channels, there is a significant increase ($p<0.05$) in cell retention within the channels (Fig 4, left). Across the flow domain in the same group, there is a trend of increased cell retention within the channels as well, but only differences from the downstream region reached significance ($p<0.05$) (Fig 4, right). The results shown are derived from a single biological replicate of WSS+ and WSS- conditions with significance based on sampling of separate individual channels.

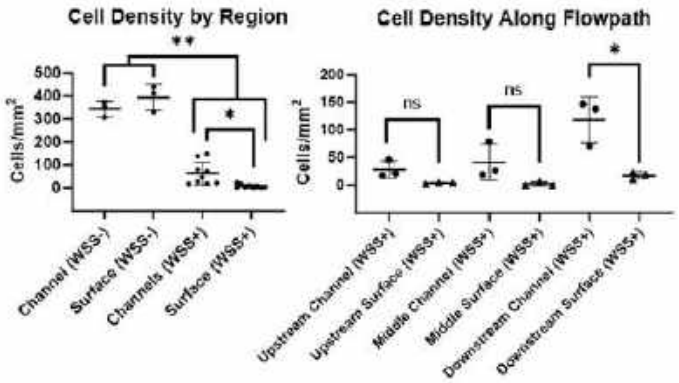

Figure 4: Cell density within channels (channel) and between channels (surface) compared for groups exposed to 15 dyn/cm^2 WSS (WSS+) and static control (WSS-) (left). Cell density within channels (channel) and between channels (surface) across the flow domain subjected to physiologic WSW of 15 dyn/cm^2 (right).

DISCUSSION

Iterative CFD simulation results indicate it is possible to reduce WSS well below physiologic levels within appropriately designed micro-channels. The preservation of some cells within the channels while almost no cells remain outside the channels following exposure to WSS is promising. While EC density is visibly reduced within the channels of the sample exposed to WSS when compared to static control, this finding was dependent upon location in the flow domain. EC retention appeared to vary longitudinally, being lower towards the upstream region compared to the downstream region (Fig 4, right). This suggests inconsistency in WSS across the flow domain and that WSS may not be reduced to the extent predicted by CFD simulations.

Future work will acquire laser scanning microscope images to determine topological variability in the stamped substrate and help improve uniformity during substrate creation. This will allow for confirmatory studies of EC retention within micro-channels. The presented approach will also be adapted to create tubular electrospun constructs for applications in vascular reconstruction.

INTRODUCTION

Articular cartilage is a phenomenal lubricating material, facilitating remarkably low *in vivo* friction coefficients ($\mu \leq 0.005$).[1] Only recently have *ex vivo* studies recapitulated cartilage's unmatched *in vivo* lubricity on the benchtop, via re-deployment of the convergent stationary contact area (cSCA) testing configuration.[2,3] In the cSCA, and in the presence of PBS, physiologically-consistent sliding speeds promote the hydrodynamically-mediated recovery and maintenance of high fluid load support (FLS) and low friction values ($\mu \sim 0.03$) via 'tribological rehydration'.[2] Intriguingly, when synovial fluid (SF) was introduced into high-speed cSCA studies, stable, truly biofidelic equilibrium friction coefficients ($\mu < 0.004$) were recorded on the benchtop for the first time.[3] We've termed this frictional benefit, due to the presence of SF and hydrodynamically-generated behaviors within the cSCA cartilage contact, 'synergistic lubrication'.[4]

SF is composed of numerous macromolecules thought to influence cartilage lubrication, via mechanisms ranging from viscous to boundary effects.[5-10] One putative lubricant molecule is hyaluronic acid (HA), a non-sulfated, high molecular weight (MW) glycosaminoglycan.[5] When HA is introduced into high-speed cSCA studies, its presence alone is sufficient to replicate synergistic lubrication—like that of SF-lubricated cSCA contacts.[4] This synergistic lubrication could be mediated by either HA-specific articular cartilage/surface molecule interactions (e.g., boundary lubrication) or via more generalizable rheological behaviors (e.g., due to lubricant viscosity).[5-10] Delineating aspects of lubricant properties that influence synergistic lubrication behaviors—and the replication of truly biofidelic lubricity—will undoubtably be key to defining how cartilage achieves its unmatched tribomechanical function and resiliency.

The present study investigated whether non-natural macromolecular polymeric lubricants having similar viscosity profiles as HA-based solutions promote synergistic lubrication outcomes in the cSCA (indicating a relationship to lubricant rheological behaviors), or if the replication of truly biofidelic frictional behaviors are unique to HA-containing solutions (indicating a macromolecule-specific interaction).

METHODS

cSCA explants were extracted from the femoral condyles of skeletally mature bovine stifles.[2-4] Φ19mm osteochondral explants were rinsed and stored in 1X PBS supplemented with L-sucrose (to approximate SF's 400mOsm osmolarity) and protease inhibitors.[2-4,11]

The bathing lubricants utilized were polyethylene oxide (PEO) based. PEO powders at 8, 400, 1000, and 4000kDa were dissolved in PBS at 3mg/mL to study PEO molecular weight (MW) effects. 400 and 4000kDa PEO were dissolved in PBS across a range of 0.1-5mg/mL to study PEO concentration effects.

Tribological testing was performed using a custom reciprocating tribometer.[2] All explants, regardless of study group, first underwent preconditioning, consisting of static compression (9N) against a glass counterface for 30 min, load reduction to 5N (~0.25MPa) for 15 min, then 'slide-in' conditioning at 10, 80, and 10mm/s for 15 min each (under 5N).[4]

In study 1, after preconditioning, "speed sweep" sliding tests (1-80mm/s) were conducted (at 5N) for increasing PEO MW. In studies 2 and 3, sliding tests (80mm/s) were conducted (at 5N) for increasing PEO concentrations of 400 or 4000kDa PEO. For all tests, sliding conditions (*e.g.*, sliding speed or bathing solution) were only changed upon reaching deformation and friction equilibria (*i.e.*, rates of change <1um/min & $<0.01\mu$/min or $<0.001\mu$/min [for $\mu > 0.1$ & <0.1, respectively]).[4]

Equilibrium compressions and kinetic friction coefficients were recorded using LABVIEW across all cycles for each sliding speed and bathing lubricant combination for analysis in MATLAB.

Rheological testing of bathing lubricants was performed on a TA Instruments ARES-G2 rheometer using a parallel-plate testing configuration, forward and backward shear rate sweeps were performed

between 1-100,000s^{-1}.[3] Gap error correction (due to the use of small gap sizes) was performed to calculate each lubricant's 'true viscosity'.[3,12]

RESULTS

PEO exhibited shear rate-dependent rheologic behaviors, with the highest viscosities occurring at the slowest shear rates tested. These rheologic behaviors were like those observed for similar concentrations of high MW HA.[3] PBS, on the other hand, a Newtonian fluid, did not demonstrate shear-rate dependent behaviors.[3] Intriguingly, even at the highest shear rates tested (100,000s^{-1}), the viscosity of 4MDa PEO, like HA, was ~4-fold greater than that of PBS. (**Table 1**)

Table 1: Measured viscosity of 4MDa PEO compared to published values for PBS and 1.4MDa HA[3] (All viscosities reported in mPa·s).

	100s^{-1}	100,000s^{-1}
PBS	0.65	--
1.4MDa HA	13.51	4.36
4MDa PEO	7.12 ± 1.48	2.58 ± 0.01

As expected for the cSCA configuration, the lowest observed equilibrium friction (μ_{Eq}) values for all tested lubricants were always observed at 80mm/s, while maximum μ_{Eq} values occurred at sliding speeds ≤10mm/s (**Fig 1**). μ_{Eq} decreased with increasing PEO molecular weight in a sliding speed-dependent manner (**Fig 1**). At 80mm/s, μ_{Eq} were decreased by up to 4-fold at 4000kDa PEO (as compared to PBS); PEO MW ≥1000kDa supported synergistic lubrication, as demonstrated by the achievement of biofidelic friction coefficients (**Fig 1A**). At 1 and 10mm/s (the max μ_{Eq} speeds), friction coefficients decreased with increasing PEO MW, but the maximal reductions were only ~1.7 & ~3.6-fold for 4000kDa PEO (**Fig 1B,C**).

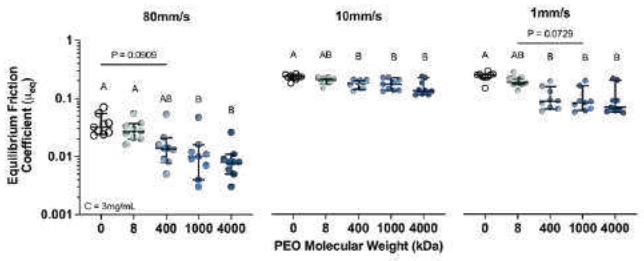

Figure 1: Equilibrium friction coefficients (μ_{Eq}) of bovine cSCA contacts lubricated with PEO solutions (3mg/mL) of increasing molecular weight at sliding speeds of (A) 80, (B) 10, and (C) 1mm/s. Significant differences among groups indicated by dissimilar letters (p<0.05, Friedman's Test).

Changing PEO concentration in our cSCA tests resulted in outcomes consistent with those seen in the variable MW studies. For tests conducted at 80mm/s using an intermediate MW PEO (400kDa), increasing PEO concentration resulted in a maximal ~4.5-fold reduction in friction coefficients (5mg/mL relative to PBS) (**Fig 2**).

DISCUSSION

As this work again demonstrates, the cSCA configuration, through its ability to control interfacial hydrodynamic phenomena in a controllable and sliding speed-dependent manner, represents a valuable tool for exploring cartilage's biofidelic tribomechanical behaviors on the benchtop.[2,3] Furthermore, it has emerged as key platform for exploring lubricant-mediated tribomechanical behaviors across a range of lubrication regimes (spanning 'non-physiological' boundary regimes [μ_{Eq}>0.1] to biofidelic hydrodynamic/synergistic regimes [μ_{Eq}<0.008]).[4]

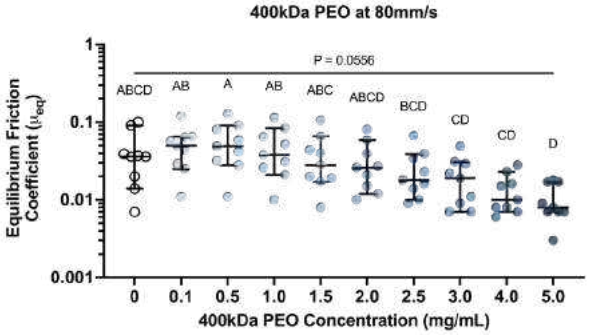

Figure 2: Equilibrium friction coefficients (μ_{Eq}) of cSCA contacts lubricated with increasing concentrations of 400kDa PEO solutions at 80mm/s sliding speed. Significant differences among groups indicated by dissimilar letters (p<0.05, Friedman's Test).

Here, we show that PEO, a synthetic polyether macromolecule derived by the petroleum industry, has qualitatively similar MW- and shear rate-dependent viscosity characteristics as HA.[13,14] However, because it is an exogeneous compound, it should have no biologically informed interactions with cartilage or other lubricating constituents.[10] Nevertheless, PEO demonstrated remarkable synergistic lubricating capabilities, similar to both SF and HA-lubricated cSCA contacts.[4]

Interestingly, in the absence of sliding speed driven interfacial hydrodynamics (*i.e.,* at 10 and 1mm/s), PEO appears to behave similarly to SF and HA as a modest, MW-dependent boundary lubricant.[4] As sliding speeds and hydrodynamically mediated interfacial phenomena increase, the effect of PEO on μ_{Eq} improved dramatically, in a concentration and MW-dependent manner, as with SF and HA-lubricated cSCA contacts. Indeed, at 80mm/s, the fastest sliding speed tested, high concentration (≥4mg/mL), high MW (≥1000kDa) PEO reduced cSCA μ_{Eq} to *in vivo*-like values (μ_{Eq} ~0.008) demonstrating that a synthetic, non-natural polymeric macromolecule (PEO) can function similarly to native SF/HA with regards to synergistic lubrication.[4]

Because lubricant viscosity increases with PEO concentration and MW—like HA—our results suggest an obvious influence of generalizable lubricant rheological behaviors on the biofidelic tribomechanics of articular cartilage.[3,4,14] Complete rheologic characterization of our cSCA lubricants (including SF, HA, and PEO) is being undertaken to permit direct exploration of the effect of lubricant viscosity on articular cartilage function.

Overall, this study once again highlights how sliding driven hydrodynamics and lubricant presence promote a lubrication synergy that generates biofidelic, near frictionless articulation conditions on the benchtop—and presumably *in vivo*. More importantly, this work suggests that synergistic lubrication is not SF-constituent specific, but likely mediated by any large polymeric macromolecule having similar rheological behaviors to SF. Further work will seek to extend these findings to other biologic (e.g., dextran, mucin, cellulose, glycerol) and synthetic (e.g., poly(lactic acid), poly(vinyl alcohol)) 'lubricants'.[15,16] Such insights will continue to advance our understanding cartilage lubrication and how this tissue functions in both health and disease.

INTRODUCTION

Aortic Stenosis (AS) is a prevalent form of valvular heart disease, characterized by hemodynamically significant narrowing of the aortic valve [1]. Recently, transcatheter aortic valve replacement (TAVR) has emerged as a minimally invasive, prominent treatment for both low-risk and high-risk AS patients [2]. Despite the significant improvements in the design over the past decades, procedural complications, particularly subclinical leaflet thrombosis (SLT), remain a clinical concern due to its potential impacts on valve performance and subsequent cardiovascular complications [3]. Virchow's triad associates thrombosis formation with three contributing factors: fluid flow, foreign materials, and biochemistry. Notably, flow patterns in the neo-sinus, a region defined by the native leaflets and transcatheter aortic valve (TAV) leaflets, have been shown to significantly correlate with the post-TAVR thrombosis volume [4]. Thus, various studies have investigated potential factors that may influence such flow patterns, including leaflet mobility, device design, and deployment methods [5-7], as well as patient anatomy [8].

Patient specific anatomy and the displaced native aortic leaflet geometry may critically influence the fluid dynamics in the vicinity of TAV. However, to date, no physiological *in-vitro* studies have been performed to spotlight the link between patient specific ascending aortic geometry and its influence on the flow in the downstream of TAV, as well as native sinus and the neo-sinus. Therefore, this study aims to assess the effects of the patient-specific aortic curvature on the thrombogenic potential by establishing quantitative correlations between the varying patient-specific aortic curvatures with the flow downstream of TAV, neo-sinus, and aortic sinus, using *in vitro* particle image velocimetry (PIV).

METHODS

Patient Specific Models and In-Vitro Circulatory Loop

All patient data was received from Cedars-Sinai Medical Center and was a part of RESOLVE registry through a limited data sharing agreement (Institutional Review Board #H17256). From 111 available datasets, 6 patients were selected for *in vitro* PIV analysis. The post-TAVR CT datasets of the six selected patients were first analyzed using Mimics (Version 24.0, Materialize Mimics) to quantify the ascending aortic curvature and then segmented in ITK-SNAP and 3D printed with a transparent rigid SLA epoxy resin material to ensure clear visual access. The appropriate 26mm SAPIEN 3 valve (Edwards Life sciences, Irvine, CA, USA) with Parafilm (Sigma-Aldrich, St Louis, Mo) attached to mimic the native leaflet was deployed into each model. The patient models were then placed in a validated pulsatile left heart simulator [9], which was tuned to patient specific cardiac output (CO) with frequency of 70beats/min and aortic pressure of 120/80 mmHg (**Figure 1).** The coronary flow was assumed to be 5% of the CO with 80/20 split between the left and right coronary arteries [10]. The working fluid was 3.5 cSt water-glycerin solution to mimic viscosity of blood.

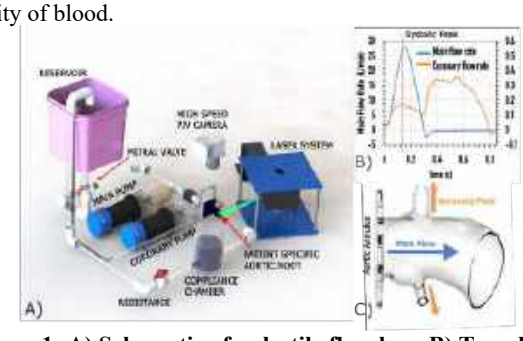

Figure 1: A) Schematic of pulsatile flow loop B) Tuned flow waveforms C) Flow directions through patient-specific models

PIV Setup

The laser planes coincided with the center of each cusp and the center of valve to image each cusp and main jet, respectively (**Figure 2)**. 2D Highspeed Camera was placed orthogonal to the laser plane to

capture the flow through the center of the cusp with frequency of 500Hz for 18 cycles, and the main jet with frequency of 1500Hz for 2 cycles. The flow was seeded with fluorescent PMMA-Rhodamine B particles with diameters ranging from 1 to 20 μm.

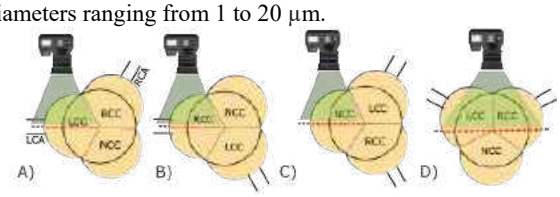

Figure 2: 2D Schematic of Laser Planes to capture A) LCC B) RCC C) NCC D) Main Jet

Hemodynamics Assessment

Acquired PIV images were processed using Davis 8.0 (LaVision GmBH) to acquire instantaneous velocity streamlines and averaged by cardiac cycle using in-house MATLAB code (MATLAB R2021a, MathWorks). To quantify the amount of retrograde backflow from the main jet into the sinus and the neo-sinus, time resolved vector fields were used to calculate vorticity and circulation.

$$\omega_z = -\left(\frac{dV_x}{dy} - \frac{dV_y}{dx}\right) ; \Gamma = \iint \omega \cdot dS_{ROI} \quad (1)$$

Normalized velocity, a comparable dimensionless quantity that accounts for varying patient-specific CO and size of inlet, was calculated, and temporally averaged over the entire cardiac cycle.

$$v_{Normalized} = \frac{v}{CO_{Patient}} * S_{inlet} \quad (2)$$

A Lagrangian particle tracking simulation was used to computationally seed the particles, obtain path lines, and compute neo-sinus and sinus washout times.

Results

The flow downstream of TAV was characterized by recirculation when the central jet hit the proximal ascending aorta due to curvature. The ascending aorta curved towards the left, coupled with the left coronary flow, resulted in the vortices forming in the vicinity of LCC (**Figure 3**). The circulation near LCC in patient 6 (most curved, 0.3248 cm^{-1}) reported 0.018 m^2/s, while patient 4 (least curved, 0.1446 cm^{-1}) reported 0.006 m^2/s.

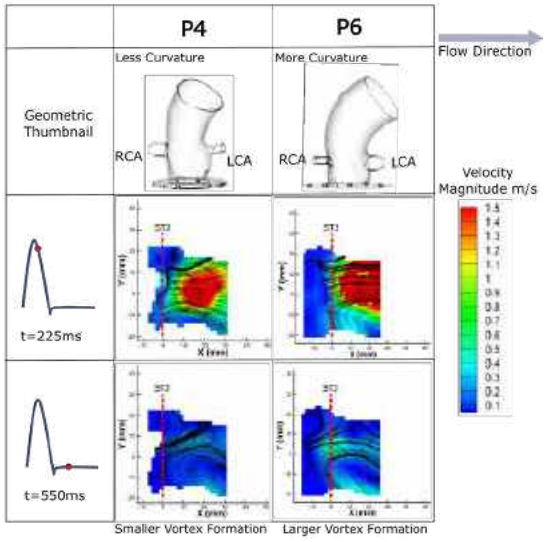

Figure 3: Flow characteristics downstream of TAV between patient with most curved and least curved ascending aorta

The ascending aortic curvature showed significant positive correlation to the circulation proximal to LCC (Rho = 0.771, p = 0.036). Normalized average velocity and washout time in the LCC was overall higher in the patients with higher curvature, while that in RCC was overall higher in the patients with lower curvature. Washout time demonstrated significant negative correlation to circulation (**Figure 4**).

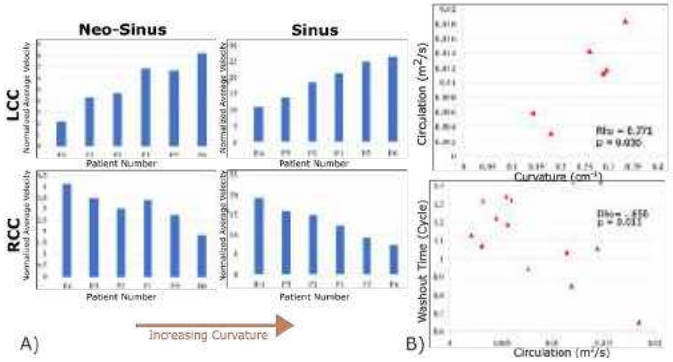

Figure 4: A) Normalized average velocity across patients B) Correlations between circulation, curvature, and washout time

DISCUSSION

The study provides a mechanistic investigation *in vitro* to explore the impact of varying patient-specific aortic curvatures on thrombogenic potentials. The varying curvatures contributed to the development of recirculation zones in the main jet, unique in both relative location and vortex strength. These vortical flow structures in turn influenced the flow velocities in the native sinus and the neo-sinus. In patients with higher curvature, a stronger vortical flow near LCC was observed. This resulted in greater velocities and lower washout time in the sinus and neo-sinus of LCC for patients with higher aortic curvature. These correlations together provide a picture of potential mechanism behind the influence of ascending aorta geometry on the thrombogenic potentials in TAV. As the main jet impinges on the wall of the ascending aorta, the curvature induces a distinct, unique recirculation zone that facilitates the flow back into the proximal cusp, thus influencing the flow velocity and washout time.

The study's results offer clinical considerations for manipulating TAV deployment and directing the main jet in the ascending aorta. This information can help clinicians in pre-TAVR planning to develop optimal deployment strategies and select appropriate valve type based on the frame and impact of jet configuration. Although thrombosis is a multi-factorial phenomenon, the study successfully spotlights a new patient-specific parameter to be considered.

INTRODUCTION

Cancer metastasis is the leading cause of death for cancer patients and metastatic potential is a major consideration during therapy. [1] Active surface proteins like membrane-type matrix metalloproteinases (MT-MMPs) and a-disintegrin and metalloproteinases (ADAMs) have been identified to be highly expressed in cancers. [2] Current bulk plasma activity assays for these enzymes offer little metastatic information and are prone to interfering agents found in plasma. [3, 4] In this study, we overcome these limitations with a Magnetic Nanoporous Membrane (MNM) diagnostic technology which uses superparamagnetic beads to rapidly isolate and enrich specific tumor cell-originated small extracellular vesicles (sEVs). [5, 6] These sEVs inherit their parent cell membrane enzymes and displays them on their lipid bilayer surface. [7] We explore the localization of active ADAM10 in blood plasma and establish that ADAM10$^+$ sEVs serves as an indicator of cancer metastasis. In a pilot clinical study, we demonstrate the potential of ADAM10$^+$ sEVs as a metastatic staging biomarker.

METHODS

ADAM10 activity assay. To quantify ADAM10 activity, a specific peptide sequence was adapted from prior work to serve as the digestible backbone of a molecular beacon. [8] The sequence consists of a DABCYL quencher, the ADAM10-specific peptide sequence, and a 5-FAM fluorophore. The intact beacon does not emit fluorescent signal due to the proximity of the quencher to the fluorophore until the peptide sequence is digested by either free-floating or membrane-bound ADAM10.

Magnetic nanoporous membrane (MNM)-based well-plate platform. Using 3D printing techniques, we developed a sensitive, rapid, multiplexed activity-assay platform and protocol for the quantification of ADAM10 on sEVs using a standard lab plate readers. Multiple wells are concurrently processed for scaleable multiplexing. We can ensure the same 99% capture yield by maintaining the same flux noted in our prior paper. [6] The controlled buffer exchange step allows for the washing and removal of interfering agents. [3, 6] The use of antibody immunocapture allows for the isolation of specific EV subsets of interest characterized by various surface markers. The focus on assaying the enzymatic activity of EV-surface proteins specifically represents of active-form of enzyme, which is the more relevant form in biology.

RESULTS

ADAM10 activity enhancement on sEV carriers. As shown in Figure 1a, approximately all the ADAM10 identified in the CCM is located on the sEV population. This can be seen in that the $10\times$ concentrated CCM ADAM10 concentration approximates the $1\times$ Unlysed sEV ADAM10 concentration and the lack of any ADAM10 found in the ANM FT sample even after enrichment. When the lipid bilayer membrane is disrupted by the surfactant, more ADAM10 is detected by the ELISA affinity assay. Looking at Figure 1b, we find that despite the release of more ADAM10 in the Lysed sEV sample the ADAM10 signal distinctly dropped by four-fold. No ADAM10 signal was detected in the ANM FT sample. These findings demonstrate that all significant ADAM10 activity is localized to the surface of sEVs and lysis of the sEV membrane structure greatly diminishes the activity of the sample's ADAM10 enzymes. Our bulk assays hence indicate that the most sensitive quantification of active ADAM10 is with the sEV activity assay.

Staging metastatic potential in prostate cancer cell cultures with sEV normalized ADAM10 activity assay. Four prostate cancer cell lines with varying metastatic potentials were prepared. In decreasing metastatic potential, these cell lines are PC3, DU145, 22Rv1, and LNCaP. In Fig-

ure 1c, we note that ADAM10 activity signal growth has no correlation to the metastatic potential of the cell lines in either the bulk CCM or the UC-isolated sEVs. Normalizing the ADAM10 activity signal growth to a per-sEV basis, we find that there is a significant difference between the different cell lines correlating to metastatic potential (Fig. 1d). Additionally, we find that the signal growth per sEV isolated from the bulk CCM nearly recapitulates that of the UC-isolated sEVs, meaning nearly all the active ADAM10 in CCM is due to those on sEV surface.

Preliminary pilot study with patients and controls of metastatic colorectal cancer (mCRC) for staging of metastasis using ADAM10-sEV activity. A blinded preliminary clinical metastatic staging experiment using isolated sEVs from the blood of healthy, pre-metastatic, and metastatic colorectal cancer patients. Significant separation is achieved in a 30-minute assay even with small patient pool. Despite the enhanced sensitivity and stage-specificity of bulk sEV ADAM10 activity assay for cancer cell culture media, its sensitivity is insufficient for patient plasma samples. We overcome this issue with another sensitivity enhancement technique – sEV enrichment by MNM.

Benchmarking MNM well-plate platform and activity sensing strategy. Using well-sets lined with MNM at their base, sEVs can be isolated from the sample via magnetic immunocapture with superparamagnetic nanobeads. The overall assay protocol (Figure 2a-d) consists of a 30-60 minute incubation, 60 minute magnetic trapping and buffer exchange, and 30-60 minute read-out. This totals to an assay lasting 2-3 hours. With this MNM well-plate platform, a minimum improvement of sensitivity of 0.5-1 decade in the detection of ADAM10$^+$ sEVs is achieved (Fig 2e-f).

(c-d) Normalization of ADAM10 activity signal to total sEV concentration in prostate cancer cell lines. c Bulk ADAM10 activity assay of raw CCM and sEV samples. d ADAM10 activity signal growth normalized to 10^{10} sEVs. e Preliminary pilot study for metastatic staging of mCRC using ADAM10-sEV activity.

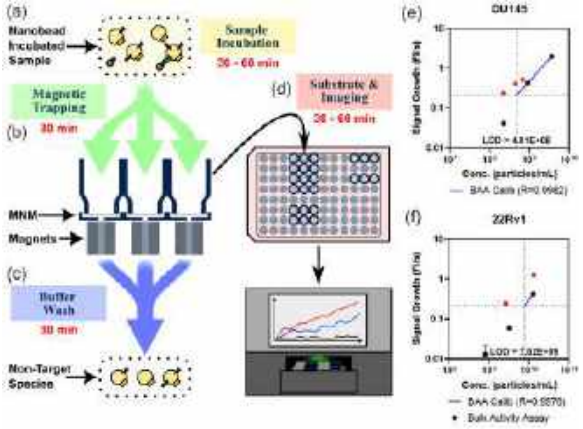

Figure 2: Schematic and Workflow showing assay steps of the MNM well-plate platform. a The sample is incubated with the antibody-functionalized nanobeads and lipophilic dye. b The cocktail is applied to the MNM well-chip and c washed with 1X PBS. d Well-chips are placed in a magnetized 96-well plate. The fluorescent molecular beacon is added and imaging is performed. Preliminary benchmarking of limits of detection for the MNM platform versus the bulk assay with e DU145 and f 22Rv1 sEVs.

DISCUSSION

In this work, we establish the localization of greatest ADAM10 activity from cancer cells to the surface of sEVs. ADAM10$^+$ sEV activity normalized to sEV concentration is indicative of metastatic potential in prostate cancer cell lines. Furthermore, ADAM10$^+$ sEV activity produces significant separation as a general metastatic staging biomarker in mCRC patients. The findings recapitulate existing understandings of ADAM10 in cancer metastasis and focuses the field towards the sEV-bound forms.

Additionally, current work on the MNM well-plate platform is ongoing with significant promise in improving sensitivity down to as low as 1×10^6 sEV/mL. Our group is working on selective pin-down of cancer-specific EGFR$^+$ sEVs in a larger clinical cohort of mCRC patients.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive procedure that offers high risk patients with aortic valve disease an alternative to open heart surgery. However, thrombus (blood clots) forms on these bioprosthetic valves in 10-20% of patients, which can limit leaflet mobility, accelerate valve deterioration, and increase stroke risk [1]. Hypoattenuated leaflet thickening (HALT), an indicator for subclinical leaflet thrombosis (SLT) detected by cardiac computed tomography (CT), has been correlated with several bioprosthetic valve and native aortic root geometry characteristics including neo-sinus and sinus of Valsalva (SoV; native sinuses) volumes, commissural misalignment, stent deformation, and local hemodynamics [2]. HALT severity is currently evaluated using CT, but this method is limited and subjective because it cannot quantify thrombus volume [3,4]. Thrombus also forms in other regions of the aortic root besides the bioprosthetic valve leaflets, which can be difficult to identify in CT and has yet to be quantified and correlated with factors associated with HALT. The goal of this study was to use image-based 3D reconstructions of patient-specific anatomy to visualize and quantify thrombus in all regions of the aortic root and bioprosthetic valve.

METHODS

Pre-TAVR and post-TAVR CT data (n = 4) were collected from Maria Eleonora Hospital [GVM Care&Research, Palermo, Italy]. Using Materialise Innovation Suite 25.0 [Lueven, Belgium], each patient's aortic root, native aortic leaflets, calcium, Evolut R valve, and thrombus were segmented in the post-TAVR CT. The pre-TAVR CT was used as a guide to accurately segment the sinus volume as the contrast between the thrombus and the aortic root wall was typically low. Similarly, the commissures and annular plane were used to guide the native leaflet length and shape as they were pinned against the device stent in the post CT. Calcium was segmented with a patient specific threshold. A previously developed registration technique was used to register a clean CAD model of the stent to the patient specific device stent to avoid blooming and other artifacts [5]. A soft tissue pixel threshold was used to capture any thrombus volume in the neo-sinuses, native sinuses, Evolut R leaflets, and subvalvular region (Figure 1).

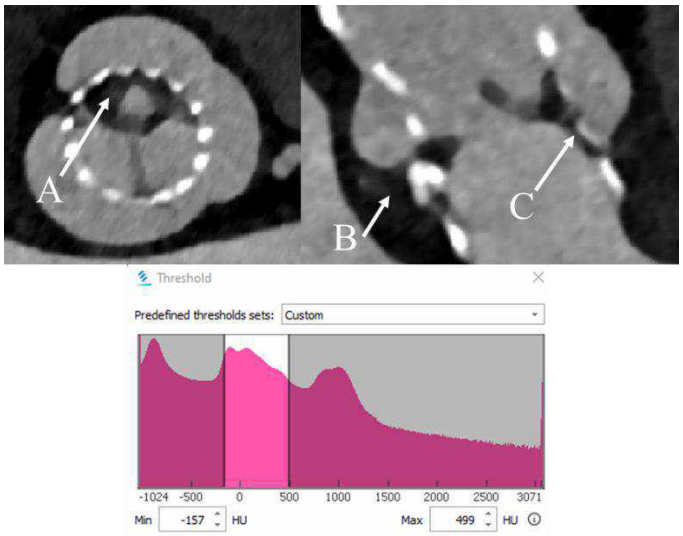

Figure 1: Identification of thrombus in neo-sinus region (A), native sinus region (B), and subvalvular region (C) using a soft tissue pixel threshold.

The registered Evolut R skirt was wrapped to achieve a final thickness of 1mm. The segmented aortic root, stent, native leaflets, calcium, Evolut R leaflets, and registered Evolut R skirt were subtracted from the thrombus segmentation. The remaining thrombus segmentation was trimmed to separate and quantify thrombus volume

located in different regions of the aortic root and valve. Commissural misalignment was measured based on methods previously described [6]. Thrombus volumes, commissural misalignment, and valve depth were then compared across regions and different patients. The final segmentation provided a complete reconstruction of the patient's aortic anatomy and thrombus.

RESULTS

Segmentations (Figure 2) and thrombus volumes with deployment configurations are presented (Table 1). The neo-sinus of the non-coronary cusp had the greatest neo-sinus thrombus volume (SLT) in 3 out of 4 patients. The native non-coronary sinus had the greatest thrombus volume across all patients. The patient with the lowest average SLT volume (Patient 1; 56mm^3) had the lowest average native sinus thrombus volume (133mm^3). Similarly, the patient with the highest average SLT volume (Patient 4; 251mm^3) had the highest average native sinus thrombus volume (592mm^3). Patient 3, who also had high average SLT and native sinus thrombus volumes, had the greatest subvalvular thrombus volume (878mm^3). No trends were observed regarding commissural misalignment and valve depth.

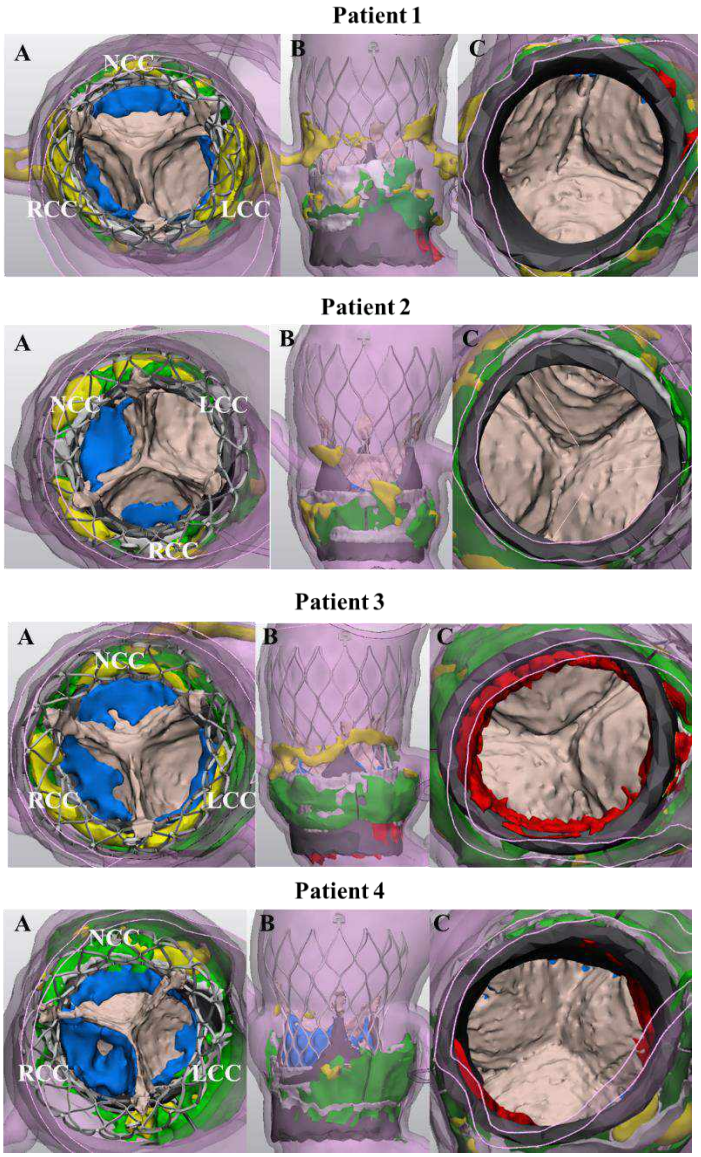

Figure 2: Patient-specific 3D reconstructions of aortic root (pink), Evolut R stent (silver) and skirt (dark grey), native aortic leaflets (white), calcium (yellow) and regional thrombus. A.) SLT (blue) on non-coronary cusp (NCC, brown), right-coronary cusp (RCC, brown), and left-coronary cusp (LCC, brown) in neo-sinus region. B.) Thrombus (green) in native sinus region. C.) Thrombus (red) in subvalvular region.

Table 1: Regional thrombus volumes (mm^3), commissural misalignment (°), and valve depth (mm) for each patient.

Patient #	HALT severity	Neo-Sinus Thrombus Volume (mm^3)			Native Sinus Thrombus Volume (mm^3)			Subvalvular Thrombus Volume (mm^3)
		Non-coronary	Right-coronary	Left-coronary	Non-coronary	Right-coronary	Left-coronary	
1	Mild	93	38	38	177	71	92	15
2	Moderate	139	30	0	411	95	126	0
3	Severe	180	133	87	468	356	446	878
4	Severe	153	502	97	943	256	576	86

Patient #	Left-Right Commissural Misalignment (degrees)	Right-Non Commissural Misalignment (degrees)	Non-Left Commissural Misalignment (degrees)	Valve Depth (mm)
1	0.1	6.3	2.5	-7
2	70.7	38.5	51.4	-3.2
3	0.6	21.7	2.2	-5
4	20.77	2.78	29.86	-4.5

DISCUSSION

Overall, these 3D reconstructions offer a better visualization of the patient-specific anatomy and regional thrombus formation and enable quantification of thrombus in the neo-sinus (SLT), native sinus, and subvalvular regions. The non-coronary cusp of the neo-sinus and native sinus regions were observed to have higher thrombus volumes than other sinuses potentially due to the reduced flow in these regions. Lower velocities in the neo-sinus region have been correlated to increased risk of thrombus formation [7]. Geometric and hemodynamic parameters can be used to develop an equation for normalized circulation that can be correlated to thrombus volume in the Evolut R, similar to previous research with the Sapien 3 valve [7]. Such analysis will be done with the rest of the patient dataset (N=25 total) to support these initial findings. Future studies could include tracking changes in thrombus volume following anti-coagulant treatments and performing cardiovascular fluid dynamic simulations to evaluate patient-specific geometries that influence thrombosis.

INTRODUCTION

Thoracic aortic aneurysms (TAAs), defined as a 50% increase in aortic diameter, are a significant public health concern. The current clinical treatment is continuous monitoring of the aneurysm size and growth rate with an eventual recommendation for surgical intervention. In this study, we used a clinically identified missense mutation in fibulin-4 (*Fbln4*$^{E57K/E57K}$) that causes TAA in mice. These mice have elastic fiber fragmentation, a pathobiological hallmark of TAA, and have 50% aneurysm penetrance. After breeding these mice with *Lox*$^{+/-}$ mice, we observed 100% aneurysm penetrance and formed four experimental groups: *Fbln4*$^{+/+}$;*Lox*$^{+/+}$ (WT), *Fbln4*$^{E57K/E57K}$;*Lox*$^{+/+}$ without an aneurysm (MU-NA), *Fbln4*$^{E57K/E57K}$;*Lox*$^{+/+}$ with aneurysm (MU-A), and *Fbln4*$^{E57K/E57K}$;*Lox*$^{+/-}$ (MU-XA) [1].

Elastic fibers in the aortic wall are organized in layers alternating with smooth muscle cells (SMCs). They provide reversible elasticity and are thought to provide physical isolation to the SMCs [2]. Fragmentation of elastic fibers affects aortic mechanical behavior and transmural transport across the aortic wall, exposing the SMCs to altered fluid and solute flux. While endothelial cells (ECs) lining the lumen play the major role in regulating transmural transport, EC dysfunction and impaired barrier ability are common in TAA. We previously showed experimental differences in transmural transport in mouse models of TAA that depend on aneurysm severity, but are not directly correlated with elastic fiber fragmentation, indicating a complex role of elastic fiber organization and extracellular matrix remodeling in regulating transmural transport [1].

We previously developed a multiphasic continuum model of the carotid artery and determined differences in the effective diffusivity resulting from genetic or chemical injury to the artery [3]. Here we utilized FEBio to develop biphasic and multiphasic models of a denuded (ECs removed) ascending thoracic aorta (ATA) using measured geometries and mass transport data for our four mouse models with varying aneurysm severity [1, 4]. The objective is to provide further insight into the contributing factors regulating transmural transport in the aneurysmal aortic wall.

METHODS

Animals. 3-4 month old male and female WT, MU-NA, MU-A, and MU-XA mice were used. All animal procedures were approved by the IACUC. Experimentally derived geometry for each group and literature based elastic moduli were used in the models (Table 1) [1, 5]. Note that the outer radius is indicative of aneurysm severity (aortic dilation).

Table 1: ATA geometry and moduli for each mouse model.

Mouse Model Name	Length (mm)	Outer Radius (R_o) (mm)	Thickness (t) (mm)	Elastic Modulus (kPa)
WT	1.61	0.420	0.064	400
MU-NA	3.16	0.464	0.110	800
MU-A	3.74	0.760	0.118	800
MU-XA	4.26	0.760	0.118	1200

Biphasic Modeling. A biphasic model of the aortic wall as a porous-fluid-saturated mixture was constructed in FEBio. The aortic wall was modelled as a cylinder with the geometry in Table 1 for each group. The model was meshed using eight-node hexahedral elements refined radially closer to the inner radius. The aortic wall was given a strain dependent Holmes-Mow hydraulic permeability,

$$k(J) = k_0 \left(\frac{J-\varphi_0}{1-\varphi_0}\right)^{\alpha} e^{\frac{1}{2}M(J^2-1)} \quad , \qquad (1)$$

where k_0 is the isotropic hydraulic permeability, M is an exponential strain-dependent coefficient, α is the power-law exponent, and φ_0 is the solid volume fraction of the porous solid matrix. The aortic wall was considered a Neo-Hookean solid with a Poisson's ratio (ν) set to 0.49 to model an incompressible material and an elastic modulus (E) that depends on the mouse model (Table 1). The solid volume fraction (φ_0) was varied to characterize effects on fluid flux. M and α did not have significant effects on model results in preliminary testing and were both

set to unity. The test bath was also modelled as a biphasic material. φ_0 was set to 0, E was set to the minimum value of 0.01 kPa, and ν was set to 0.49 to model an incompressible fluid. k_0 in the bath was set 1000 x higher than k_0 of the aortic wall. The volume of the bath was 7 mL to match experimental conditions.

Zero-displacement boundary conditions in the radial, circumferential, and axial directions were fixed at the ends of the cylinder to match experimental conditions. A zero fluid pressure boundary condition was set in the bath. The total mixture stress (σ) is affected by both the fluid pressure (p) and the stress from the solid matrix strain (σ^e),

$$\sigma = -p\boldsymbol{I} + \sigma^e \quad , \quad (2)$$

The fluid pressure (p) is defined by,

$$p = \tilde{p} + R\theta\phi c \quad , \quad (3)$$

where $\tilde{p}$ is the effective fluid pressure, R is the gas constant, θ is the temperature, ϕ is the osmotic coefficient, and c is the concentration of the solute. In the biphasic case, there is no solute, so the effective and actual fluid pressure are equivalent, and we prescribed an effective fluid pressure of 13.33 kPa in the lumen to match experimental conditions. We prescribed a σ of -13.33 kPa at the aortic inner wall and 0 kPa at the inner wall of the bath fully interfaced with the aorta.

Multiphasic Modeling. A multiphasic model was created using the same procedures and material properties described in the biphasic section. A prescribed concentration of 5 mg/mL 4 kDA FITC Dextran was added to the lumen of the aorta, as in the experiment. The free diffusivity of the solute was calculated using the Stokes-Einstein equation. Using Eqn. 3, we prescribed an effective fluid pressure ($\tilde{p}$) of 10.11 kPa. In the bath, D_0 was set to be 10,000x higher to maintain well mixed conditions in the bath and D_{eff} was set equal to D_0. Effective solubility ($\tilde{\kappa}$), hydraulic permeability (k_0), elastic modulus (E), and solid volume fraction (φ_0) were varied to understand their effects on fluid (J_v) and solute flux (J_s) in each group.

Fitting Transport Material Properties The aortic transmural transport data for the four mouse models have been previously published [1]. Using the constrained Levenberg–Marquardt optimization algorithm in FEBio, we optimized material properties using average J_v and average Dextran concentration versus time ($\Delta C/\Delta t$) data to determine permeability (k_0) and effective diffusivity (D_{eff}) for each group.

RESULTS

A parametric sweep of the model parameters (Fig. 1) reveals that the largest contributing factor to fluid flux is hydraulic permeability (k_0). Our parametric sweep shows that solute flux is also regulated by solid volume fraction (φ_0), hydraulic permeability (k_0), effective diffusivity (D_{eff}) and effective solubility ($\tilde{\kappa}$). Changes to elastic moduli (E) are well characterized in TAA, and we modulated E based on pressure-diameter curves (data not shown) recorded for this mouse model (Table 1) [5]. Our parametric sweep showed that elastic modulus (E) did not affect J_v and had a minor effect on J_s.

After fitting k_0 using J_v from the solute absent experimental data, we found a trending decrease in hydraulic permeability with more severe aneurysm phenotype (Fig. 2A). Using $\varphi_0 = 0.6$, $\tilde{\kappa} = 1$, and model specific k_0 and E, we fitted effective diffusivity (D_{eff}) to the experimental concentration data for each mouse model (Figs. 2B, C) [1]. The effective diffusivity increased in the MU-NA group only, compared to all others.

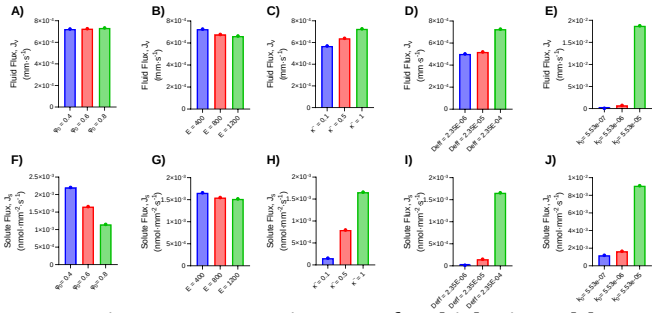

Figure 1. Parametric sweep of multiphasic model illustrating key variables that regulate fluid and solute flux.

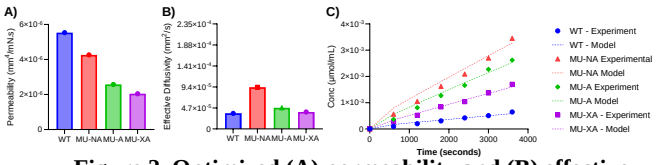

Figure 2. Optimized (A) permeability and (B) effective diffusivity from experimental calculations and (C) model fit to experimental values.

DISCUSSION

We used geometry and elastic moduli specific to each mouse model with varying aneurysm severity in biphasic and multiphasic models to determine mass transport material properties from previous experimental data. Our biphasic results for hydraulic permeability indicate that geometry and elastic modulus alone cannot account for measured changes in fluid flux and that hydraulic permeability varies with aneurysm severity.

Our effective diffusivity results from the multiphasic model illustrate a complex behavior. The MU-NA group has a higher effective diffusivity than the aneurysm groups (MU-A and MU-XA). The higher effective diffusivity could allow for increased transport of cytokines or biologic factors that may be protective or pathological. At early stages of aneurysm formation, when there is elastic fiber fragmentation, but limited dilation, the increased transmural transport may allow cytokine deposition that contributes to protective remodeling of the wall or exacerbates the disease and facilitates aneurysm formation. Future work characterizing transmural transport and wall remodeling over the time course of aneurysm formation will be necessary.

The experimental data used for fitting the hydraulic permeability had a large variability, but we are only using average values from the solute-free experiment [1]. Our model was limited by assuming mass transport properties were isotropic throughout the aorta. Future work is needed to characterize local transport properties. Future work will also investigate whether additional changes to the multiphasic model (i.e solid volume fraction and effective solubility, Fig. 1A, 1E) may be contributing factors to the solute flux in each mouse model. Overall, the model helps to understand contributing factors to changes in mass transport in TAA that may play a role in disease progression or be used for disease treatment.

INTRODUCTION

Adequate thermal dose control during thermal therapies requires reliable 3D temperature information. Thermally significant blood vessels create a cooling effect. The objective of this study was 3D analysis of cooling effects of large blood vessel (> 6 mm) using conjugate heat transfer simulations to develop empirical relationships and guidelines for thermal therapies. The influence of heat source on vessel distance as well as vascular flow rate on thermal dose is studied. Currently, the convective heat transfer to blood is modelled by convectively enhanced thermal conductivity [1]. Liu et. al., Huang et.al. and Chato shows that the temperature at tumor boundaries is less than the predicted temperature [2-4]. However, there are no models that solve conjugate heat transfer between large blood vessel and the tissue using Navier-Stokes and Pennes bioheat transfer equation [5]. Results of this study show that when the tumor is beyond 11 [mm] with respect to the blood vessel, the heat sink effects are negligible. Additionally, difference between highest and lowest temperature when the blood vessel is at 2 [mm] from the tumor is 2.1 [°C].

METHODS

A simple geometry as shown in Figure1 was considered to evaluate the heat carried away by the blood. The blood vessel was assumed to be a cylindrical volume, and the tumor was a sphere that was embedded in cuboidal tissue.

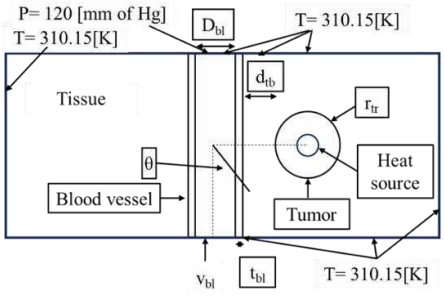

Figure 1: Geometry representing the boundary condition and the inlet and outlet specification for the fluid and solid for the model.

Fluid is assumed Newtonian fluid with an incompressible laminar flow based on Reynolds number calculation. The initial temperature of tissue and fluid is assumed to be 37 [°C]. Secondary flows are neglected as Richardson's number is much less than unity. Governing equations utilized for solving the problem are given in equation (1-3). Equations were solved in commercial finite volume methods (FVM) software (Simcenter STAR-CCM+).

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \vec{V}) = 0 \quad (1)$$

$$\rho \frac{D\vec{V}}{Dt} = \nabla p + \rho \vec{g} + \mu \nabla^2 \vec{V} \quad (2)$$

$$\rho C_p \frac{\partial T}{\partial t} - \nabla(k \nabla T) = Q_{Perfusion} + Q_{Heatsource} + Q_{met} \quad (3)$$

where ρ is the fluid density [kg/m^3], V is the fluid velocity [m/s], k is the thermal conductivity [W/(m.K)], p is the fluid pressure [Pa], T is the absolute temperature [K], ρ is the blood density [kg/m^3], C_p is specific heat capacity of blood [J/kg.K], ω_b is the blood perfusion rate [1/s] and g is the gravitational acceleration [m/s^2].

Thermal damage-dependent perfusion term was added for the tumor (4) with field function which was evaluated from degree of vascular stasis (5), (6).

$$Q_{Perfusion} = \rho_b C_{p,b} \ \omega(T)(T_b - T) \quad (4)$$

$$DS = 1 - exp\left(-A \int_0^t e^{-\frac{E_a}{RT(\tau)}}\right) d\tau \quad (5)$$

$$\omega(T) = \begin{cases} \omega_{b,i}(30DS + 1), (DS \leq 0.02) \\ \omega_{b,i}(-13DS + 1.86), (0.02 < DS \leq 0.08) \\ \omega_{b,i}(-0.79DS + 0.884), (0.08 < DS \leq 0.97) \\ \omega_{b,i}(-3.87DS + 3.87), (0.97 < DS \leq 1 \end{cases} \quad (6)$$

The values of these properties are listed in Table 1.

Part	ρ [kg/m^3]	C_p [J/kg*K]	k [W/m*K]	μ [Pa*s]
Blood	1050	3617	0.52	$3.65*10^{-4}$
Tumor	1046	3630	0.51	-
Tissue	1056	3700	0.57	-
Heat Source	1046	3630	0.51	-

An implicit solver with a SIMPLE algorithm was utilized. The heat carried away by the blood was accounted for as the convective heat

transfer coefficient (HTC). Mesh independence was achieved for the HTC. Initially, the tumor was 2 [mm] from the blood vessel. The distance between the tumor and the blood vessel was increased to observe the effect of this distance on the HTC. The blood velocity was varied between 0.1-0.2 [m/s] to evaluate dependence of blood velocity on the HTC.

RESULTS

Simulation results predicted HTC of 4.37 [W/m^{2}K] on the blood domain carrying away 2.1 [ºC] from the tumor boundary. The solution was verified from the empirical relationship from Consiliegri et. al. [6], and results of this study are within 5 [%] of the solution predicted by the simulation.

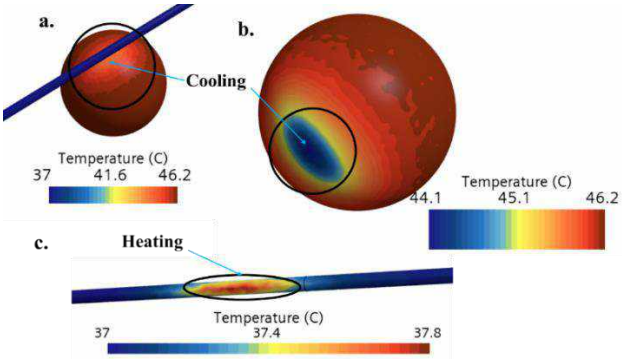

Figure 2: Figure depicting the temperature distribution at tumor and blood surface a. Blood vessel takes away the heat to cool the tumor. b. Cooling of approximately 2.1 [°C] on the tumor is evident due to the presence of blood vessel. c. Heat sink effects observed on the blood vessel by temperature rise of 0.8 [°C].

As the distance between the tumor and blood vessel was increased, the temperature difference was reduced, and at 11 [mm] the HTC was 1.21 [W/m^{2}K] which is negligible as shown in figure 3. Hence, the maximum distance to model HTC can be considered as 11 [mm].

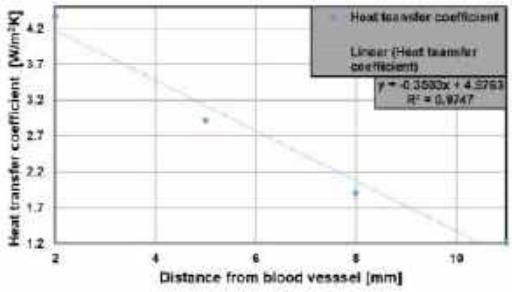

Figure 3: Heat transfer co-efficient as a function of distance from the blood vessel depicting the decrease as the distance is increased from the tumor.

Velocity depicted that as the higher the velocity higher the HTC for the blood which agrees with the HTC predicted by the Consiliegri et. al. [6]. The velocity was limited to 0.2 [m/s] in accordance with the human blood velocity.

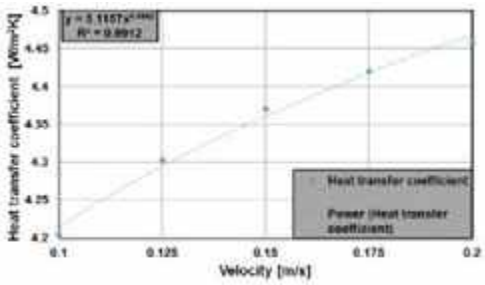

Figure 4: Heat transfer co-efficient as a function of velocity depicting the increased HTC as the velocity if blood is increased.

DISCUSSION

As distance of blood vessel is greater than 11 [mm] from the tumor the heat sink effects can be neglected. Additionally, the maximum velocity of fluid is considered for the equation giving the maximum HTC. The limitation of the study is that the geometry of tumor and fluid domain are kept constant. Further, a study can be set up to vary these parameters. All the dependent variables for the HTC can be evaluated from the study. Additionally, the identified parameters can be made dimensionless by normalizing against the respective parameter which would be the characteristic parameter in the equation. A relationship can be developed for the HTC as a function of characteristic parameters.

DEVELOPMENT AND VALIDATION OF A VEHICLE FRONT PROFILE FINITE ELEMENT MODEL TO EVALUATE PEDESTRIAN IMPACTS

James T. Wolf (1), Karthik Somasundaram (1), Frank A. Pintar (1)

(1) Joint Department of Biomedical Engineering, Maquette University and Medical College of Wisconsin, Milwaukee, WI, USA

INTRODUCTION

In 2021, there were nearly 7500 pedestrians killed in traffic crashes in the U.S., the highest since 1981 [1][2]. Since the year 2000, Europe and Japan have adopted pedestrian crash protection programs for vehicles and have seen a decline in pedestrian fatalities; the U.S. has not yet adopted pedestrian crash protection and has seen an increase in pedestrian fatalities in that same time period [2].

The National Highway Traffic Safety Administration (NHTSA) Fatality Analysis Reporting System (FARS) [2] reported that passenger cars and light trucks were involved in 88% (36,076) of cases where a pedestrian was killed by a single front vehicle crash from the years 2011-2020. From 2015-2021 the number of light trucks registered, and their miles driven steadily increased, while the same criteria for passenger cars decreased [3]. The increased number of trucks on the road in the U.S. may correlate to the increase of pedestrian fatalities.

European New Car Assessment Programme (Euro NCAP) outlines a detailed procedure for evaluations of new vehicles for pedestrian safety through headform, upper legform, and lower legform tests. Euro NCAP also uses generic finite element (FE) vehicle models, representative of different vehicle classes, for safety ratings and analysis of pedestrian kinematics [4][5][6].

While these models are useful, they are not always applicable to the U.S., because they represent the European fleet and do not account for variability in stiffness across the hood and bumper. There are no publicly available FE models representative of a U.S. pickup truck/large SUV that are validated from pedestrian injury data. This study aimed to develop a vehicle front profile FE model, representative of a large U.S. vehicle, and validate the model from pedestrian component test data.

METHODS

Experiment

Raw data from pedestrian headform, upper legform, and lower legform experimental tests on a 2015 Ford F-150 and 2016 Chevrolet Tahoe was acquired from NHTSA's research testing database [7]. A total of thirteen headform, eight upper legform, and six lower legform impacts were analyzed to develop experimental 'target' corridors. Acceleration time corridors were developed for the headform and lower legform tests. Force time corridors were developed for the upper legform tests. All corridors consisted of an average with upper and lower bounds of ± 1 standard deviation. Headform corridors were grouped into categories of "middle", and "front and rear" based upon acceleration data as well as impact locations on the hoods of both test vehicles (**Figure 1**). Lower legform corridors were calculated for the F150 and Tahoe, respectively. One upper legform corridor was calculated for all impacts.

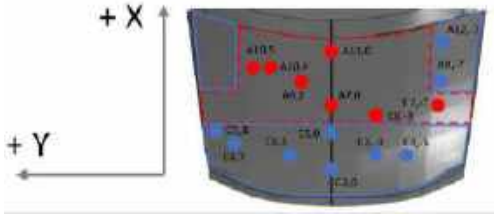

Figure 1: Headform impact locations with an adult ("A") and child ("C") headform. The numbers represent the x- and y-coordinates (x,y) of the impact. Red dots represent "middle" hood impacts, and blue dots represent "front and rear" hood impacts.

FE Model

To capture vehicle geometry, a 3D lidar scan was performed on a high selling U.S. truck. A shell model was created from the scan in Hypermesh (Altair, Troy, MI) and extruded to 10 mm quadrilateral solid elements in Ansa (Beta CAE Systems, Farmington Hills, IL. Material cards and parts were modeled according to Klug et al [6].

Headform, upper legform, and lower legform FE simulations were performed on the vehicle model according to Euro NCAP procedures.

Impact points were the same as those used on the F150 and Tahoe from Suntay et al [8]. LS-Dyna pedestrian child headform, adult headform, upper legform, and lower legform models were used. All simulations were completed using LS-Dyna single precision MPP version R8.0.0 and 64 cores on a cluster. Baseline simulations were run with the model having the same parameters as the Euro NCAP SUV model outlined in Klug et al [7]. Model parameters of stiffness, damping coefficient, and element thickness were optimized to match the calculated experimental corridors. Acceleration (G's) was plotted for the headform and lower legform models. Force (kN) was plotted for the upper legform models.

RESULTS

Baseline parameters of interface thickness, interface stiffness, foam stiffness, and foam damping coefficient were optimized for increased correlation to the experimental corridors for the "middle" hood (**Table 1**), "front and rear" hood (**Table 1**), and bumper (**Table 2**).

For the headform tests, the "middle" and "front and rear" corridors had average peak accelerations of 94.3 g and 140.4 g, respectively. The optimized model had average peak accelerations of 106.9 g and 154.8 g for the "middle" and "front and rear" hood, respectively (**Figure 2**).

Lower legform corridors had average acceleration peaks of 270 g and 367 g for the F150 and Tahoe, respectively. The lower legform exhibited a much stiffer response on the F150, as it reached its peak acceleration in less than 2 ms compared to 4 ms on the Tahoe. The optimized model had an average peak acceleration of 372 g (**Figure 3).**

Upper legform corridors had average peak lower and upper load cell forces of 4.2 kN and 1.0 kN, respectively. The optimized model had average lower and upper load cell forces of 4.7 kN and 2.1 kN, respectively (**Figure 4).** The greater lower load cell force is due to the lower part of the impactor contacting the stiff surface of the bumper. The same bumper properties were used in the upper legform simulations to achieve optimized results.

Table 1: Baseline and optimized hood model properties.

	Middle Hood		*Front and Rear Hood*	
Parameter	**Baseline**	**Optimized**	**Baseline**	**Optimized**
Interface Thickness (mm)	1.3	1.3	1.3	0.8
Foam Damping Coefficient	0	0.14	0	1.0

Table 2: Baseline and optimized bumper model properties.

Parameter	Baseline	Optimized
Interface thickness (mm)	1.86	6.0
Interface stiffness (GPa)	2.5	10
Foam Stiffness (GPa)	6.4E-5	6.5
Foam damping coefficient	0	0.2

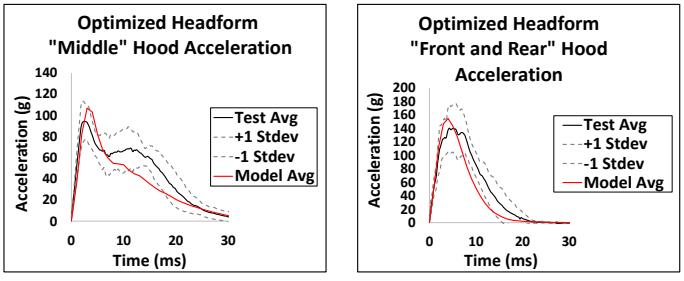

Figure 2: Optimized average headform to hood model acceleration output for "middle" hood corridor (left) and "front and rear" hood corridor (right).

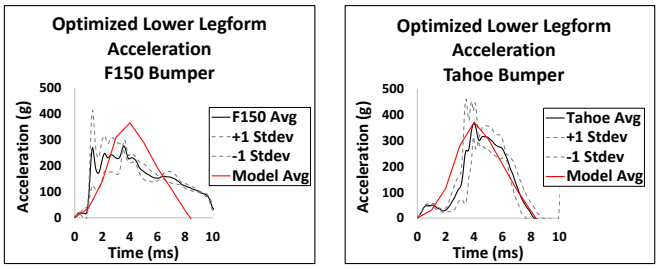

Figure 3: Optimized average lower legform to bumper model acceleration output for F150 (left) and Tahoe (right).

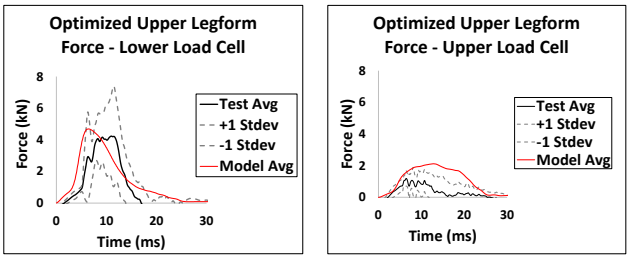

Figure 3: Optimized upper legform to bumper model force output. Lower load cell force (left) and upper load cell force (right).

DISCUSSION

The "front and rear" hood had greater experimental acceleration than the "middle" hood due to rigid under hood parts, such as hinges, that result in a stiffer response [9]. The greater damping coefficient in the optimized "front and rear" hood model allowed for a slower deformation resulting in greater acceleration and a slower time to peak acceleration than the "middle" hood.

The stiff lower legform response on the F150 experiment is likely due to the protruding bumper and its pronounced curvature. The Tahoe bumper has a smoother and flatter surface than the F150. Baseline results from the lower legform model showed small accelerations compared to the corridor since the baseline properties are modeled with low stiffness to represent European bumpers. European vehicles must have compliant, energy absorbing, bumpers to reduce leg injury risk to pedestrians [10]. Increasing the thickness of the interface layer as well as the stiffness and damping of the foam allowed for a more rigid response and increased acceleration, thus better resembling a U.S. vehicle bumper. A larger experiment sample size would improve model validation. Future studies will be performed using Pedestrian Human body models with the FE vehicle to analyze pedestrian kinematics.

SUPER-RESOLVING AND DENOISING 4D FLOW MRI OF CSF USING A PHYSICS-GUIDED TEMPORALLY COHERENT NEURAL NETWORK

INTRODUCTION

Impaired flow of cerebrospinal fluid (CSF) has been associated with cerebroventricular disorders such as idiopathic normal pressure hydrocephalus (iNPH). Computational fluid dynamics (CFD) models have advanced our understanding of these disorders and indicated flow metrics associated with disease initiation and progression. However, CFD relies on modeling assumptions, such as flow boundary conditions [1]. Alternatively, the flow can be measured *in vivo*, with time-resolved, 3-directional phase contrast MRI (4D flow MRI). While originally 4D flow MRI has been used in cardiovascular flow measurements, recent studies have extended its application to the flow of CSF. Yamada et al. showed that patients with iNPH have higher oscillatory shear stress compared to healthy individuals [2]. However, 4D flow MRI requires balancing acquisition time, spatiotemporal resolution, and velocity-to-noise ratio. 4D flow MRI imaging of CSF flow is particularly challenging due to low velocities and long relaxation times. The limited spatial resolution and noise lead to measurement errors which are further propagated through calculations of velocity gradient-based metrics, such as shear stress and vorticity.

To address these limitations of 4D flow MRI, several neural network methods have been recently proposed, particularly focusing on improving cardiovascular flow quantification [3, 4]. However, most of these deep learning-based methods did not incorporate constraints to ensure consistency with flow physics and did not account for the evolution of the flow over the cardiac cycle. Here, we extend the deep learning approach by examining the use of a long-short term memory (LSTM) network architecture and a loss function incorporating the residual of the vorticity transport equation to denoise and super-resolve 4D flow MRI in a physically consistent and temporally coherent manner.

METHODS

We present TransVort, a neural network to super-resolve and denoise 4D flow MRI by leveraging mass conservation and vorticity transport equations. We extend on our previously developed network which used flow divergence regularization to improve velocity data in the near-wall voxels. Our networks are based on a densely connected super-resolution network (DCSRN) architecture as shown in Figure 1 [5]. Here, we integrate convolutional long-short term layers into this network.

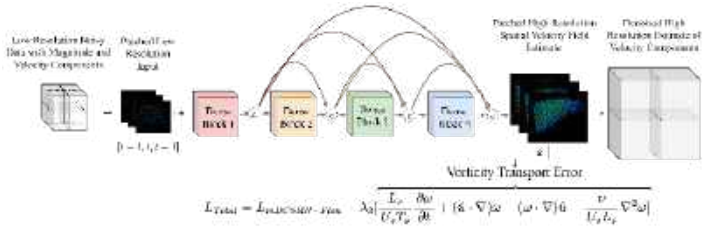

Figure 1: Simplified mDCSRN network architecture trained using a loss function including the residual of the vorticity transport equation

While network training would ideally use paired high- and low-resolution 4D flow MRI datasets, acquiring such data is not practical. Therefore, we train the network using synthetic 4D flow MRI derived from CFD simulations in ten geometries of the third and fourth cerebral ventricles in healthy individuals and in individuals with Alzheimer's disease. The flow domain is subdivided into patches to reduce the dependence on the subject-specific anatomy and focus on intermediate flow scales assumed to be common across the subjects. Three consecutive timeframes of patches are used for the training. For each geometry, CFD is run with four inflow boundary conditions. These 40 simulations of high-resolution flow fields are spatiotemporally

downsampled and converted to synthetic 4D flow MRI cases by manipulating the *venc*, noise, and saturation ratios.

During network training, we examine the use of a loss function which combines our previous divergence regularization term with the residual of the vorticity transport equation. Here, we can express the divergence regularization over a flow region ($\mathcal{F}$) as

$$\mathcal{L}_{div} = \frac{1}{TNI}\sum_{t=0}^{T}\sum_{n=0}^{N}\sum_{i=0}^{I}\left|\nabla\cdot\hat{\boldsymbol{u}}_{i,t}^{(n)}\right| \quad if\ i\in\mathcal{F} \tag{1}$$

where T = 3 is the number of timeframes input into the network, N is the number of patches within a given batch, I is the number of voxels within a given patch, and $\hat{\boldsymbol{u}}$ is the predicted velocity field. We can express the nondimensionalized vorticity transport residual as

$$\mathcal{L}_{VT} = \sum_{n=0}^{N}\sum_{i=0}^{I}\frac{L}{U^{(n)}\Delta}\frac{\partial\hat{\boldsymbol{\omega}}_i^{(n)}}{\partial t} + \left(\hat{\boldsymbol{u}}_i^{(n)}\cdot\nabla\right)\hat{\boldsymbol{\omega}}_i^{(n)} - \left(\hat{\boldsymbol{\omega}}_i^{(n)}\cdot\nabla\right)\hat{\boldsymbol{u}}_i^{(n)} - \frac{\nu}{U^{(n)}L}\nabla^2\hat{\boldsymbol{\omega}}_i^{(n)} \tag{2}$$

Where $\hat{\boldsymbol{\omega}}$ is the vorticity computed from the estimated high-resolution patch normalized velocity fields, L is the high-resolution voxel size, Δ is the temporal resolution, U is the highest component velocity in each patch and ν is the kinematic viscosity.

The network was trained for 100 epochs using the divergence-based loss function. Once pretrained, the LSTM portion of the network was fine-tuned using the full loss function including the residual of the vorticity transport equation. The network was trained using NVIDIA Quadro RTX 6000 graphics processing units.

Once trained, we apply this network to an *in vivo* case of the cerebral ventricles. The cerebral ventricles were imaged structurally using T2 SPACE (1x1x1 mm, TR/TE/flip-angle = 700 ms/11 ms/120°) and functionally using single-*venc* of 10 cm/s (1x1x1 mm, TR/TE/flip-angle = 7.90 ms/5.283 ms/8°).

RESULTS

The results indicate that TransVort outperforms temporally independent methods when assessed on the synthetic 4D flow dataset of CSF flow through the third and fourth ventricles. In comparison to linear interpolation, TransVort outperformed the temporally independent method reducing the error in both core flow voxels (17.9% vs 10.9%) and in edge (near-wall) voxels (39.7% vs 34.5%).

Once the network performance was assessed using CFD data as the ground truth, we applied the network on CSF flow within the 4th ventricle as shown in Figure 2. The raw 4D flow MRI at 1 mm isotropic voxel resolution for four frames are shown on the top and the corresponding 0.5 mm isotropic voxel resolution reconstructions using the TransVort network are shown on the bottom of Figure 2.

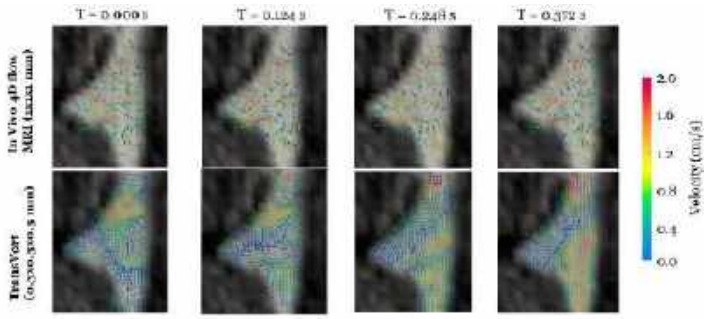

Figure 2: Application of TransVort to CSF flow in the 4th ventricles shows the superior movement of a vortex as well as alignment of near wall velocities.

From the TransVort reconstruction, we see the formation of a vortex in the 4th ventricle around a time of 0.124 s. As the cardiac cycle moves towards diastole, we see that the vortex moves superiorly and dissipates as it approaches the cerebral aqueduct. However, the presence of these structures are difficult to perceive in the raw 4D flow MRI data.

DISCUSSION

In this work, we developed TransVort, a temporally coherent and physics guided neural network that is trained using a loss function that incorporates both divergence regularization and the residual of the vorticity transport equation. The results show that vorticity-based approach enables a better reconstruction of the velocity field in both core and edge voxels. The method was applied to CSF flow in the 4th cerebral ventricle. Improving MRI-based flow quantification in the cerebral ventricles will aid investigation of cerebroventricular diseases such as iNPH.

INTRODUCTION

Osteoarthritis (OA) is a disease of the joint, characterized by the degeneration of articular cartilage from acute or long-term wear. The mechanism of wear that propagates the advancement of OA is not yet understood. It has been established that the primary cause of damage in immature bovine cartilage is fatigue wear through delamination of the superficial zone (SZ) from the middle zone (MZ) [1, 2]. Our recent study expanded upon this result, and determined the cause of the fatigue wear was reciprocating compressive forces and not frictional forces [3]. This finding challenges an implicit assumption that friction coefficient is related to wear severity and progression, but is comprehensively supported by other studies on cartilage wear and friction [4, 5].

Synovial fluid (SF), the fluid that fills the joint space, has recently been shown to decrease the rate of fatigue in immature bovine cartilage [3,6]. In a study designed with a migrating contact area (MCA) configuration (identical to the MCA set-up described in [3]), cartilage samples immersed in PBS damaged at much higher incidence than samples immersed in SF after 24 hours of reciprocating sliding [6]. Paired with the results of [3], which demonstrate that cyclical compressive stresses, but not frictional stresses, cause delamination damage, SF has a beneficial role in wear reduction that is independent of its role as a secondary source of boundary lubrication [7, 8].

On a molecular level, the major constituents of SF, lubricin and hyaluronic acid (HA), have been linked to wear reduction [9]. It has been shown that PRG4 knockout of lubricin results in increased total joint wear in the mouse model [10]. Other studies have found lower levels of lubricin in SF with symptomatic OA, and thus reduced concentration of the molecule may be linked to wear propagation [11]. However, many of these studies link the beneficial effect of lubricin with reduction of the friction coefficient, despite the abundance of evidence that frictional forces do not induce cartilage wear [2-4, 12].

The purpose of this study was to better understand the mechanism by which SF reduces cartilage fatigue wear. To examine this aim, we investigated the effect of SF concentration on the rate of fatigue wear in immature bovine cartilage when subjected to reciprocating compressive stresses in a MCA configuration. This study complements our recent report of wear measurements in pure PBS and pure SF baths [6].

METHODS

Sample Preparation: Full thickness cartilage strips were harvested from the tibial plateaus of ten immature bovine calf knees (five left, five right, 2-3 months old) and microtomed to a thickness of 1.41 ± 0.07 mm. Samples were cut to 10×30 mm rectangular strips, and lightly glued to a ∅ 60 mm petri dish. Prior to testing, samples were kept hydrated in PBS supplemented with inhibitors (0.04% isothiazolone-based biocide and 0.1% protease inhibitor). Three 100 mL batches of mature bovine SF were obtained from a local abattoir, aliquoted into 50 mL tubes, and centrifuged (3000 g, 20 min) to remove excess particulate. The SF was supplemented with the same inhibitors as the PBS. To create a 50% and 25% SF/PBS dilution, 25 mL and 37.5 mL of PBS were added to 25 mL and 12.5 mL of SF, respectively.

Friction Testing: Samples were mounted on two identical custom friction testing devices as described previously [13]. Samples were brought into contact with a hemispherical glass lens (∅25 mm) under a compressive load of 4.45 N and subjected to reciprocating sliding at 1 mm/s. After 24 hours of sliding (~5,400 cycles), samples were taken off the tester and visually assessed for delamination damage. If damage was observed, the test was stopped; if no damaged was observed, the sample was put back on the friction tester and the test was continued to 72 hours (~16,200 cycles). Test groups included 50% SF/PBS (n=8), and 25% SF/PBS (n=8). Throughout testing, samples were hydrated with 15 mL diluted bath solution that was refreshed every 24 hours if applicable.

Sample Assessment: Pressure sensitive Fuji film was used to measure the contact area between the glass platen and the sample prior to testing to ensure consistent contact pressure p_{avg} among test groups. Samples were scanned using a laser scanner to produce a dense point cloud

(50,000 points/cm^2) before and after testing. A custom MATLAB code was used to quantify the root-mean-square roughness (R_q) of sample articular surface. Photographs were taken of the sample, and polarized light microscopy (PLM) was conducted on all samples to analyze subsurface response. One way analysis of variance (ANOVA) tests were conducted to compare R_q (before and after testing), before contact pressures (p_{avg}), and averaged friction coefficient μ_{avg}. Repeated measures ANOVA tests were conducted for R_q for both test groups.

RESULTS

Prior to testing, neither p_{avg} nor R_q was found to be statistically different between the two bath conditions (p_{avg}=0.65 MPa, p=0.57; R_q= 0.52, p=0.59). Similarly, μ_{avg} was not different between the 50% SF/PBS and the 25% SF/PBS groups (p=0.80) (Figure 1).

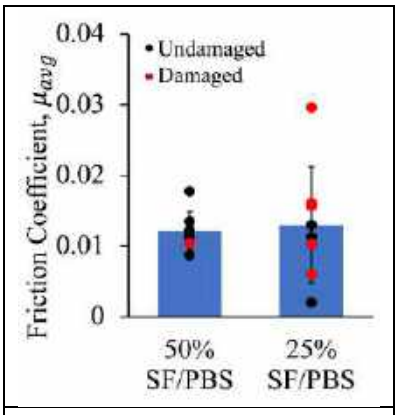

Figure 1: μ_{avg} over all cycles. Markers indicate individual samples. Color indicates damage.

In the 50% SF/PBS group, none of the samples damaged after 24 hours of testing, and all eight samples were subsequently allowed to run for 72 hours (16,200 cycles). In total, two out of eight samples damaged after 72 hours. Surface roughness was not found to be statistically different before and after testing (p=0.43) (Figure 2). In the 25% SF/PBS group, three of the samples damaged after 24 hours of testing, and the test was thus terminated. The other five samples were allowed to run for 72 hours (16,200 cycles), at which time two of five remaining samples damaged. Surface roughness was found to be statistically different before and after testing (p=0.02) (Figure 2). When comparing test groups, the surface roughness after testing was statistically lower in the 50% SF/PBS than the 25% SF/PBS groups (p=0.045) (Figure 3). PLM analysis supported the surface delamination results observed, and indicated no additional subsurface (occult) damage.

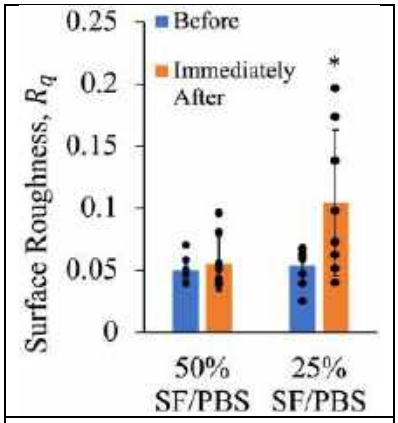

Figure 2: R_q for before and after testing. Markers indicate individual samples. $*$ indicates statistically different before and after testing (p=0.02)

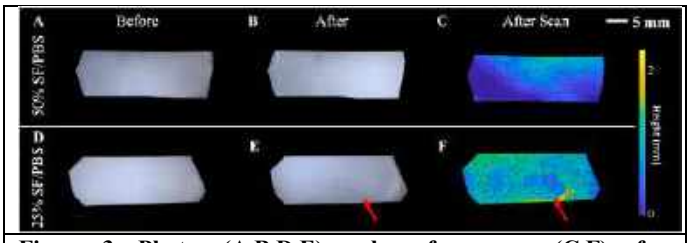

Figure 3: Photos (A,B,D,E) and surface scans (C,F) of a representative 50% SF/PBS (A-C) and 25% SF/PBS diluted samples (D-F). Delamination damage is indicated with red arrows in the 25% SF/PBS sample after photo (E) and scan (F)

DISCUSSION

This study complements our recent report showing that pure SF protects against cartilage wear when compared to pure PBS [6]. Here, results indicated that SF concentration has an effect on fatigue rate in immature bovine articular cartilage. The 50% SF/PBS group had no samples damage after 24 hours and only one sample damage out of eight after 72 hours of sliding. This outcome was very similar to that reported for pure SF [6], which had two samples damage after 72 hours. In contrast, the 25% SF/PBS had a much greater incidence of damage, with three samples delaminated after 24 hours and an additional two after 72 hours. Thus, it can be concluded that a decrease in concentration of SF results in a decrease in SF's protective effect against fatigue wear.

The average friction coefficient for the two bath conditions was not statistically different despite the increased incidence of wear in the 25% SF/PBS group. When compared to previous results with an identical experimental setup [6], the friction coefficient is similar to that of pure SF ($\mu_{avg} \approx 0.012$). This finding is expected as it has previously been shown that SF's effect on friction coefficient is secondary to the effect of interstitial fluid load support on friction coefficient, and thus a dilution should not affect the average coefficient significantly [5, 7]. Despite this statistical similarity in μ_{avg}, the 25% SF/PBS group clearly exhibited a higher degree of damage than the 50% SF/PBS group. This result, paired with the studies cited above [3-5], establish that frictional forces are not responsible for cartilage wear and the friction coefficient is not reflective of damage severity in immature bovine cartilage.

These results are consistent with the hypothesis that molecular constituents of SF (lubricin and HA) are responsible for wear reduction. The samples during testing were immersed in 15 mL of test bath solution, which exceeds the *in situ* value for immature bovine knees (~3 mL). The 50% SF/PBS exhibiting similar damage incidence to pure SF could be attributed to the bath solution (and thus lubricin and HA) being in excess, whereas the 25% SF/PBS was diluted below a critical threshold of available constituents for wear reduction. It has been suggested that lubricin binds to type II collagen in cartilage and sterically charges the extracellular matrix. The repulsive state caused by lubricin coating could correspondingly improve the wear properties of the cartilage during reciprocal sliding [14]. Improved understanding of the beneficial effect of SF could be achieved in future studies, through an examination of evolving lubricin and HA ultrastructure and concentration with reciprocal sliding.

INTRODUCTION

The spleen, an important organ in the human body, plays a key role in immune defense mechanisms, notably in antibody production and the phagocytosis of aging red blood cells. In addition to these functions, the spleen is the most injured organ in instances of blunt abdominal trauma [1]. This high incidence of injury has led to significant advancements in medical procedures aimed at preserving the spleen. Traditionally, splenectomy, the surgical removal of the spleen, was the standard response to such injuries. However, given the spleen's important roles, current medical practice often seeks to avoid splenectomy. The preferred alternative has become endovascular splenic artery embolization, a less invasive procedure that allows for spleen preservation.

Endovascular embolization, however, is a complex procedure that demands a comprehensive understanding of the blood flow environment within the splenic artery. Direct experimental investigation of these blood flow patterns in patients is not an easy task due to the small vessel sizes, vessel tortuosity, and the presence of collaterals. Patient-specific computational fluid dynamics (CFD) simulations are an attractive alternative and enable a detailed assessment. These simulations provide a non-invasive strategy towards understanding the blood flow dynamics, facilitating the planning and execution of precise embolization procedures in a personalized fashion. Nevertheless, the assessment of hemodynamics in the visceral arteries that provide blood to the spleen has been relatively understudied [2]. Particularly, the role of blood flow during the splenic artery embolization procedure is not investigated.

There are two primary methods for splenic artery embolization: proximal embolization, which typically involves the use of coils to block the blood flow at the upstream segment of the artery, and distal embolization, where as an alternative to coiling particles can be released to block the artery closer to the spleen. Each method has its specific indications and applications, depending on the nature and location of the splenic injury. In the case of proximal coil embolization, clinicians are interested in alterations in pressure fields as well as the risk of coil migration. In distal embolization with particles, one is interested in the trajectory of the emboli, particularly in the elderly with tortuous arteries where it is difficult to navigate the catheter close to the target. Our goal in this study is to understand the role of hemodynamics during each procedure and ultimately guide the procedure.

METHODS

In this study, we utilized computed tomography (CT) to construct three models in the open-source SimVascular software and conduct CFD simulations. These simulations were specifically designed to explore the effects of collateral vessels and the placement of coils on the outcomes of embolization procedures. The first model deliberately omits the presence of collateral vessels, providing a baseline to assess their impact on the embolization process. This comparative approach helps in understanding the significance of collateral flow in such procedures. The second model includes all three collateral vessels, making it a more comprehensive representation to better understand the role of collaterals during baseline. The third model introduces a coil as well as the collaterals to examine the hemodynamic consequences of proximal embolization. This inclusion is vital for assessing how coils interact with blood flow and influence the success of the embolization. To simulate pulsatile blood flow, we employed the finite element solver SimVascular. To enhance the accuracy of our simulations, we meticulously selected boundary conditions that closely align with clinical data, ensuring a more realistic representation of blood flow distribution [3,4]. Specifically, 1D blood flow models and steady 3D simulations were used to tune the resistance boundary conditions at the outlets. Consistency in our approach was maintained by applying the same simulation parameters across all three models. Pulsatile flow simulations were conducted and data from the fourth cardiac cycle were used in this study. An overview of the patient-specific model is shown

in Fig. 1. The velocity results from the CFD simulations were used for Lagrangian particle tracking to model distal embolization. Specifically, the Maxey-Riley equation was solved for inertial spherical particles using FlowVC, an in-house code.

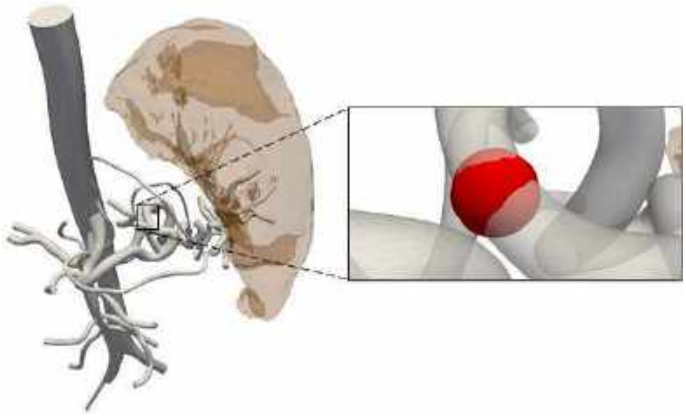

Figure 1: The model with collaterals is shown. On the right side the place of coil for the third case is highlighted. The enlarged spleen is shown in brown color.

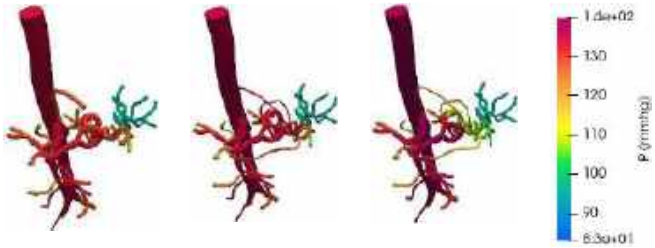

Case 1 Case 2 Case 3

Figure 2: Pressure contour for three models. In the third case which considers the coil there is a higher-pressure difference between the upstream and downstream

RESULTS

Figure 2 shows the pressure distribution results. A closer inspection of the results revealed that the presence of collateral vessels does not significantly alter the pressure distribution when a coil is not in place. This is attributed to their relatively smaller diameter, ranging between 1 and 1.5 mm. However, the hemodynamic environment changes considerably upon the introduction of a coil. In this scenario, collaterals become crucial in maintaining blood supply to the spleen. The application of a coil leads to a substantial increase in maximum velocity within the collaterals up to an order of magnitude (results not shown). Interestingly, the collateral that exhibited relatively lower flow rates in the second case scenario demonstrates an equal flow rate relative to the other two collaterals when a coil is used. Moreover, the introduction of a coil also results in a pronounced increase in the pressure gradient across the celiac trunk, both upstream and downstream. Also, there is a high-pressure difference on the two sides of the coil as expected. These observations underscore the significant impact that coil placement has on the hemodynamic environment within the splenic artery system.

In Fig. 2., It is observed that the collaterals do not significantly impact the pressure distribution, a finding that can be attributed to the application of identical boundary conditions across the models. In contrast, introducing a coil in the splenic artery (as shown in case 3) markedly decreases the overall blood flow rate to the spleen but cannot completely eliminate flow due to collaterals. This reduction in flow is accompanied by a substantial drop in pressure within the splenic artery. Our data demonstrates how the insertion of a coil alters the hemodynamic profile, significantly reducing blood flow (not shown here) and pressure (Fig. 2), important metrics in the embolization procedures.

In the distal embolization case, the percentage of the emboli delivered to the targeted area depends on the place where particles are released. While in certain cases the catheter can be navigated close to the target, in the example here due to the arteries' high curvature, it is difficult for interventional radiologists to navigate very close to the target. Therefore, understanding the particle path and behavior is crucial to determining the amount and size of the particles needed. Figure 3 illustrates a potential release point for these particles. In this figure, the initial particle release location as well as the position of the particles after 0.3 seconds is shown. It is important to note that the particles are represented much larger than their actual size in these images for visualization purposes. Currently, we are in the process of quantifying the optimal release strategy for maximizing the success of particle transport to the spleen.

Figure 3: a) Particle release location and b) their trajectories.

DISCUSSION

We presented one of the early CFD studies on hemodynamics during proximal and distal splenic artery embolization. Our study revealed critical insights into the hemodynamics of splenic artery embolization, emphasizing the influence of collateral vessels and coil placement. Our findings show that collateral vessels have minimal impact on pressure distribution when no coil is used and the introduction of a coil reduces blood flow and pressure in the splenic artery but cannot completely eliminate blood flow to the splenic artery, highlighting the importance of the need for further optimized proximal embolization procedures in future work. This study, while informative, is limited by its reliance on computer models, which may not fully capture the complexities of in-vivo conditions. Future research should aim to validate these simulation results with actual clinical data and further explore the long-term implications of coil embolization on splenic function and collateral vessel adaptation. In summary, our study highlights the potential of using CFD simulations as a predictive tool in planning and executing embolization procedures, and potential for improving their safety and efficacy.

INTRODUCTION

Coarctation of the aorta (CoA) is a congenital cardiovascular defect characterized by narrowing of the proximal descending thoracic aorta and is often associated with long-term hypertension (HTN) even after treatment. The current >20 mmHg peak-to-peak blood pressure gradient (BPGpp) threshold for intervention[1] does not prevent HTN[2]. Thus new guidelines are required to prevent recurrent HTN.

Current methods used to estimate BPGpp in CoA patients have several limitations that can limit application of new treatment guidelines. For example, BPGpp estimation via BP cuffs placed on the arms and leg is difficult in patients clinically due to children who may be upset, crying or scared during measurement, and/or inappropriately sized cuffs[3,4,5]. Moreover, CoA patients frequently have anomalies in their arterial anatomy that limit accurate determination of BPGpp via BP cuffs[6,7]. Doppler ultrasound offers a common non-invasive alternative, but is well-known to over-estimate gradients[8,9].

Despite its limitations, the simplified Bernoulli equation (SBE) is widely implemented due to its ease of use and availability[10]. To rectify this limitation, our team is working to improve the sensitivity and specificity of echocardiogram (echo)-based indices while allowing clinicians to continue using their current workflow and leverage their familiarity with this imaging modality. Therefore, to more accurately estimate BPGpp, avoid unnecessary invasive testing, and intervene before HTN precursors develop, we recently derived and published a new method called the continuous flow pressure gradient (CFPG). The CFPG uses the diastolic phase of conventional echo tracings and has excellent agreement with catheterization[11]. We are optimistic that using CFPG to assess stenosis severity and refine current treatment thresholds will ultimately lead to improved outcomes in CoA patients following intervention. Our objective is to incorporate the CFPG into a user-friendly website and application that can rapidly provide clinicians with a value that better represents the catheter-based (i.e. true) severity of a BPG in clinical and pre-clinical subjects.

METHODS

The process of calculating the CFPG threshold is echo-friendly (**Figure 1**), meaning that all inputs can be quantified using an echo image with Doppler spectrum. The CFPG calculation is as follow:

$$\mathrm{CFPG} = 4\frac{dPHT}{ln(2)}\left(1 - exp\left(-\frac{ln(2)}{dPHT}\right)\right)(1 - DVI)^2 {V_d}^2 \quad (1)$$

Where *DVI*, *dPHT*, and V_d are Doppler velocity index ($DVI = V_p/V_{pk}$)[9], normalized diastolic pressure half-time (time to the half diastolic pressure/diastolic period)[12], and early diastolic velocity, respectively. V_p and V_{pk} used for DVI are the peak velocities proximal to, and within the CoA region, respectively. Including *dPHT* captures the unique representation of diastolic indices based on severity of the CoA.

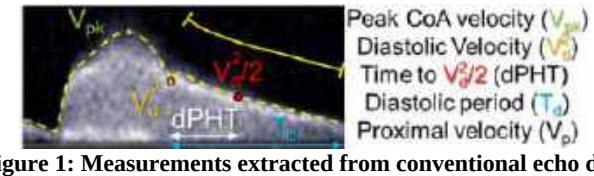

Figure 1: Measurements extracted from conventional echo data for use in the CFPG equation.

The CFPG has been integrated within a newly developed website and IOS application, we refer to as CoACH - Coarctation of the Aorta software to Combat Hypertension. CoACH aims to rapidly provide clinicians with a value that better represents the gold-standard catheter-based severity of a BPGpp in vivo. The developed software obtains values needed to calculate the CFPG in two ways (**Figure 2**): a simple direct entry method, and an Image extraction method. Obtaining values using the direct entry method can be done by hovering the mouse over the tracing on most clinical echo workstations. The values can then be input directly into dedicated fields in CoACH. Values for the image extraction method are obtained from images with a Doppler spectrum

that are uploaded and processed using multiple image processing techniques in Python to obtain the values needed for the CFPG calculation. Image segmentation and color thresholding are used to isolate the EKG signal from the Doppler signal in the images provided. Signal smoothing and peak detection are performed to capture specific values needed for the CFPG equation. Optical character recognition is used to extract data like (e.g. heart rate) from images.

Figure 2: Current welcome page of the CoACH Website (left), IOS launch page (middle), and software algorithm (right).

CoACH uses all available data to date relating the CFPG to catheterization and/or arm leg pressure data in the setting of CoA. Hence, the software is designed to impart meaning from the CFPG value that is calculated to provide clinicians with interpretation relative to the existing treatment thresholds and BPGpp values (**Figure 3**). This software aims to validate the proposed CFPG assessment and any future BPGpp threshold that is recommended for treatment in patients.

CoA Gradient [mmHg]	CoA Patient CFPG cutoff Discrete	Complex
10	0.81	0.73
15	1.46	1.28
20**	**2.52**	**2.14**
25	4.20	3.45
30	6.90	5.49
35	11.22	8.63
40	18.14	13.47

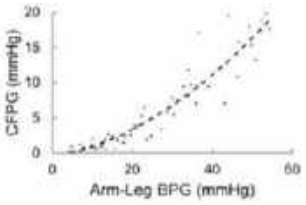

Figure 3: CFPG for a range of clinical CoA gradients (left; ** =current guideline). An example of CFPG to arm-leg cuff BPG in complex CoA patients is shown on the right. This information is incorporated into CoACH to impart meeting from the CFPG value that is calculated, and provide clinicians with interpretation relative to existing treatment thresholds and BPGpp values.

RESULTS

The CoACH software was developed for use on any desired device. The software guides users through the data input process efficiently. After users create their account credentials, they can make a choice between proceeding with clinical or pre-clinical data input. This selection streamlines the subsequent steps tailored to their specific needs. The user then gets the option to choose between the Direct Entry or Image Processing Methods. In the Direct Entry Method, users manually input all required values for the CFPG calculation, with a clear interface illustrated in **Figure 4**. The Image Processing Method prompts users to upload two echo images with Doppler tracings of the subject as shown in Figure 4. Once users complete the input process through either method, they gain access to the database module, which displays a list of all processed subjects, their data and CFPG and interpretation.

Figure 4: Direct Entry method wireframe of the CoACH website (left) and the image processing method wireframe (right).

DISCUSSION

The CFPG formula for assessing CoA severity marks a significant shift from conventional BPGpp guidelines. The current software addresses limitations associated with current approaches, while aiming to foster the eventual rollout and adoption of new treatment guidance, by integrating the CFPG within the CoACH application. The result is expected to be a more accurate, non-invasive, and echo-friendly alternative for assessing BPGpp severity. This advancement is crucial in meeting the demand for precise diagnostic tools in CoA management.

The strengths of CoACH lie in its dual-method CFPG calculation—Direct Entry and Image Extraction—enhancing its versatility across diverse clinical settings. Facilitating assessment of alternative treatment thresholds is a notable advantage, enabling a more nuanced approach to patient care. Also, the image processing method helps limit user variability when determining the values needed from the echo image. Moreover, the use of familiar echo data streamlines the likelihood of adoption to this more accurate and non-invasive diagnostic method. However, the reliance on image processing techniques for the image extraction method may pose challenges in standardization of image masking and segmentation thresholds based on each clinic and their echo image contrast standards, requiring further refinement.

In conclusion, the CoACH software with its included CFPG integration serves as a catalyst to reassess the current BPGpp threshold for CoA. The implementation addresses existing limitations in CoA assessment and lays the groundwork for refining treatment guidelines. This transition holds immense potential in preventing recurrent hypertension in CoA following intervention and enhancing patient care.

PLAQUE LENGTH AND STENOSIS INFLUENCE INSTANTANEOUS WAVE-FREE RATIO AND WALL SHEAR STRESS

Arnav Garcha (1), Noelia Grande Gutiérrez (1)

INTRODUCTION

Choosing between revascularization and non-surgical therapies to treat coronary non-culprit lesions (NCLs) and mitigate major adverse cardiac events (MACE) is a known clinical challenge [1]. Clinical decisions are typically based on data from angiography or invasive measurements, such as fractional flow reserve (FFR). Revascularization may be considered if an NCL is angiographically significant, i.e., stenosis exceeds 70% or is between 50–69% with FFR ≤ 0.8 [2]. However, other topological features of lesions, such as length, are not commonly used to assess MACE risk and guide clinical treatment.

Several clinical studies suggest that plaque length, high wall shear stress (WSS), and low WSS have prognostic value for MACE [3]–[8]. A recent study analyzing NCL reported that plaques causing MACE were longer compared to quiescent lesions [3]. Instantaneous wave-free ratio (iFR), an alternative to FFR without pharmacological vasodilation [6], falls below the hemodynamic significance threshold (<0.89) for long diffuse plaques [9]. High WSS has been considered to improve MACE prediction by identifying lesions at risk of rupture [7], [10]. Also, recent research suggests low WSS areas independently predict regions of plaque growth [8]. Despite these observational findings, there is little insight into how lesion topology, apart from stenosis, influences these hemodynamic metrics that can support MACE risk stratification.

Computational fluid dynamics (CFD) aids in understanding how lesion topology alters local hemodynamics [11]–[13]. At a constant lesion length, increased stenosis reduces FFR [13]. Without controlling for stenosis, longer lesions correlate with lower FFR in patient-specific anatomies [12]. However, no work has assessed the combined effect of both stenosis and length on iFR, low WSS, and high WSS.

We hypothesize that lesion length, in addition to stenosis, can enhance risk stratification for MACE and inform clinical decision-making regarding revascularization. Using CFD, we conducted a sensitivity analysis of hemodynamic metrics to changes in plaque topology in the left coronary arteries (LCA).

METHODS

Computational experiment design: We used a previously developed computational pipeline [14] to automatically create 3D LCA models, meshes, and simulation files with the SimVascular [15] Python API (Figure 1a). We generated 24 synthetic plaque topologies through a combination of six stenoses (10-60% diameter reduction) and four lengths (0.9-2.5 cm) on a baseline LCA model. Geometric features of the LCA model, including branch diameters, bifurcation angles, and arterial segment lengths, were set to match population averages from published angiographic data [16]. We introduced plaque in the proximal left anterior descending (LAD) artery (Figure 1b). Plaque geometric parameters were obtained from the PREDICTION [8] and PROSPECT [17] clinical trials. The average reported plaque length was 1.7 cm [18], and the average stenosis was near 30%. The starting location of plaques was the same in all models, and all plaques surfaces were smooth.

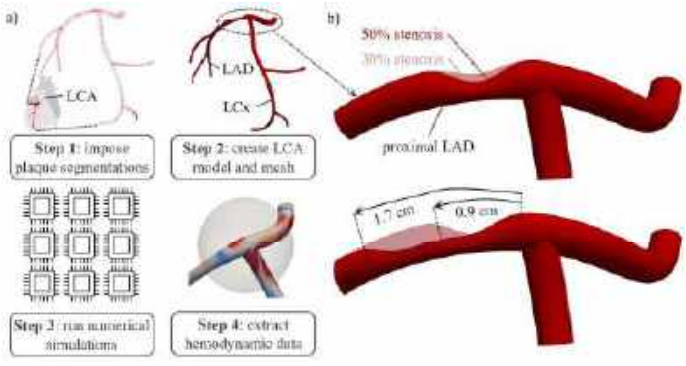

Figure 1: (a) computational pipeline used to build synthetic LCA geometries with varying plaque topologies. (b) Variations in plaque included changes in stenosis and length.

Numerical approach: We used the SimVascular finite element solver to solve the incompressible Navier-Stokes equations that govern blood flow. We employed a tetrahedral mesh with a boundary layer averaging 3 million elements. Mesh parameters were based on a convergence study. The time step was set to 0.001 s. We ran transient CFD simulations for four cardiac cycles to reach a converged solution and used data from the last cycle for the hemodynamic analysis.

Boundary conditions and assumptions: At the inlet, we prescribed a parabolic flow waveform at 70 bpm. Model outlets were coupled to a 0D lumped-parameter model (LPN) to achieve physiological pressures [19]. We manually tuned the LPN to obtain a 120-80 mmHg pressure waveform. Walls were assumed rigid, and zero velocity, no-slip conditions were applied [20]. The flow was assumed laminar as Re $<$ 500. We modeled blood as a Newtonian fluid (dynamic viscosity = 0.04 dynes/cm^2, density = 1.06 g/cm^3), given an average shear rate $>$ 100/s.

Hemodynamic metrics and data analysis: An automatic pipeline was used to analyze hemodynamic simulation results. We computed time averaged WSS (TAWSS), areas of low TAWSS (ALWSS), areas of high TAWSS (AHWSS), and mean velocities at each arterial segment. Low (< 0.5 Pa) and high (> 7 Pa) TAWSS thresholds were defined based on published data for plaque growth and rupture risk, respectively [21]. Since the location of low shear areas varied across models, we measured the percent difference in ALWSS throughout the entire LAD with respect to the mildest plaque geometry (10% stenosis, 0.9 cm). To quantify high shear, we normalized AHWSS to the surface area of the arterial segment with plaque. We measured iFR as the ratio of pressure directly distal to the plaque (P_d) and inlet pressure (P_a) during mid-diastole [22]. Previous studies have reported that the diagnostic potential of iFR is similar to that of FFR [6]. We performed partial correlation coefficient analyses to assess linear correlations between plaque topology and hemodynamic metrics. We used the Mann-Whitney U test to determine if populations were statistically different.

RESULTS

From our simulation results, we obtained iFR < 0.89 for plaques with 60% stenosis across all lengths (Figure 2a). Stenosis strongly correlated with lower iFR (R=-0.82, p=<0.001), while length weakly correlated with iFR (R=-0.38, p=0.078). Normalized AHWSS strongly correlated with both stenosis (R=0.89, p<0.001) and length (R=0.66, p=<0.001) (Figure 2b). Stenosis moderately correlated with ALWSS in the LAD (R=0.59, p=0.0033), while plaque length correlation was weak (R=0.33, p=0.12) (Figure 2c). The spatial distribution of ALWSS varied based on stenosis. ALWSS shifted further downstream of the plaque when stenosis $\geq$ 50% (Figure 2d). ALWSS was larger in models with stenosis $>$ 30% (n=12) than with stenosis $\leq$ 30% (n=12) (p<0.001).

DISCUSSION

Although plaque length weakly correlated with iFR, we observed that iFR substantially decreases with diffuse plaques when stenosis $\geq$ 50%. This may be related to greater AHWSS in these models, which contributes to higher frictional pressure losses. Furthermore, increased AHWSS may suggest that these plaques are at higher risk of rupture. iFR reduction over plaque length was not as pronounced when stenosis $\leq$ 40%. These results encourage the consideration of both plaque length and stenosis when angiographically evaluating lesions. Also, our findings align with a prior observational study in which diffuse plaques accounted for a higher proportion of lesions with iFR $\leq$ 0.89 [9].

For plaques with stenosis $>$ 30%, increased ALWSS may suggest a higher likelihood of *de novo* plaque growth. The ALWSS location greatly varied between the higher stenosed topologies. As such, the location of ALWSS and *de novo* plaque may not occur immediately distal to the NCL of interest, but rather further downstream.

There are some limitations in our work. We did not measure FFR (requiring hyperemia) sensitivity to plaque topology. Given the discordance of iFR and FFR near their thresholds [23], we will evaluate the differences in their hemodynamic sensitivity in future work.

In conclusion, both plaque length and stenosis correlate with iFR and AHWSS, suggesting that length is influential to these metrics and can relate to adverse hemodynamics. ALWSS was significantly larger in topologies with $>$ 30% stenosis and may indicate lesions more prone to distal plaque growth.

IOP-INDUCED LAMINA CRIBROSA ASTROCYTE DEFORMATIONS MEASURED DIRECTLY FROM THE ASTROCYTES ARE LARGER THAN THOSE ESTIMATED FROM THE DEFORMATIONS OF THE COLLAGEN BEAMS

INTRODUCTION

Glaucoma, a leading cause of irreversible blindness globally, is characterized by progressive retinal ganglion cell death and optic nerve degeneration [1]. Degeneration starts within the lamina cribrosa (LC) in the back of the eye (**Figure 1**) [1]. Although elevated intraocular pressure (IOP) is the main risk factor for glaucoma, the mechanisms leading to the neural tissue damage are not well understood. One of the leading theories postulates that elevated IOP causes distortion of the LC astrocytes, which triggers structural and functional changes that contribute to the neural tissue degeneration [2]. Assessing this theory requires characterizing the IOP-induced distortions of the LC astrocytes. Doing this, however, has proven elusive. Some studies have managed to do this in mouse models taking advantage of their small size [3]. While interesting, the mouse LC lacks some of the main features of the primate LC, such as collagenous beams that likely affect how LC astrocytes respond to IOP. Other studies have instead used imaging techniques that reveal the collagenous LC beams, such as optical coherence tomography (OCT) or second harmonic imaging (SHG), and used the effects of IOP on these beams to estimate distortions on astrocytes [4, 5]. While exciting because this allows in vivo and in situ evaluation of the collagenous primate LC, this approach requires major assumptions about the properties and location of the LC astrocytes. It remains unclear whether the approach accurately represents the effects of IOP on the astrocytes themselves.

Our goal was to measure the IOP-induced LC astrocyte deformation directly from images of the astrocytes and compare these with the deformations estimated from images of the LC collagen beams.

METHODS

Six sheep eyes were obtained within 4 hours of death and the LC was exposed coronally. Individual LC astrocytes were stochastically labeled in situ with DiOlistic labeling [6]. LC collagen and labeled astrocytes were imaged with SHG and multiphoton microscopy, respectively, at low (5mmHg) and high (40mmHg) IOPs.

We measured two astrocyte deformations: 1) indirect, based on the images of collagen, and 2) direct, based on the images of astrocyte. For both methods an image morphing technique [7] was used to determine the displacement fields from low to high IOPs. For each astrocyte, for each of the displacement fields we calculated three measures of deformation: stretch (maximum principal strain), compression (minimum principal strain) and shear (maximum shear strain).

Ten LC astrocytes were analyzed. A linear regression model was then fit to use as a calibration between both measurement approaches.

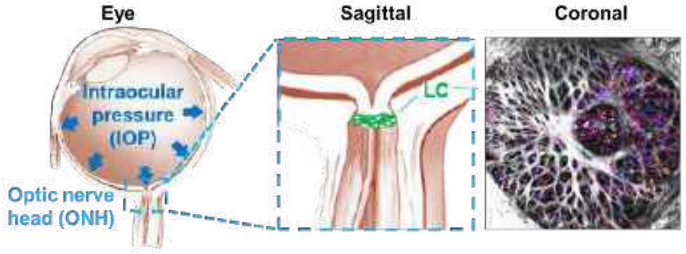

Figure 1. Diagrams of the eye showing the location of the lamina cribrosa (LC), within the optic nerve head in the posterior pole. Image of a coronal section after DiOlistic labeling shows the collagen beams in greyscale and astrocytes in colors.

RESULTS

As IOP was increased from 5 mmHg to 40 mmHg, both collagen and astrocytes deformed (**Figure 2**).

Strain distributions of an example astrocyte calculated directly or indirectly are shown in **Figure 3**. The astrocyte deformation determined directly was greater and more irregular than that obtained indirectly, across all three types of strains. The largest strains were often in the astrocyte branches.

Across the three strains, directly determined astrocyte strains were positively related to indirectly measured strains (**Figure 4**). However, indirect estimates consistently underestimated LC astrocyte strains.

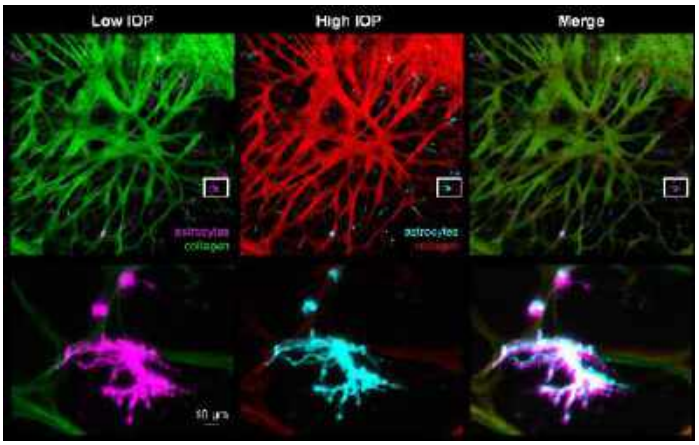

Figure 2. Example LC collagen and astrocytes in situ. Wide views (top) and close-up to an individual LC astrocyte (bottom).

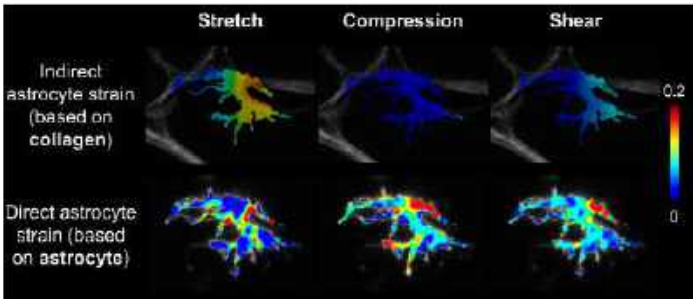

Figure 3. Contour-level plots of IOP-induced strains measured directly (bottom) or estimated indirectly (top). Direct measurement revealed larger and more irregular than indirect estimates.

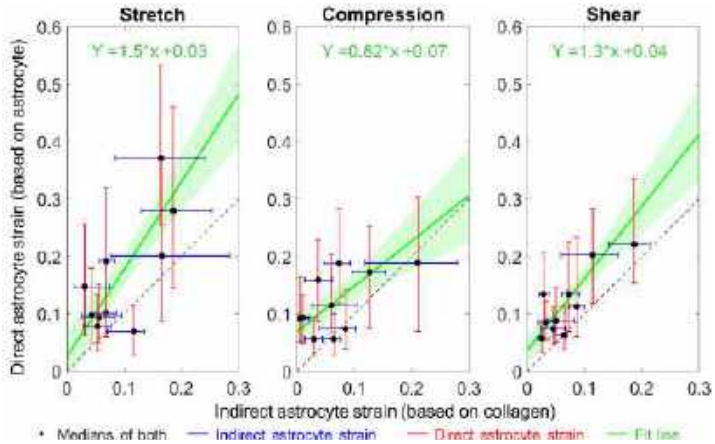

Figure 4. Calibration plots of strain distribution of 10 astrocytes calculated from the collagen and astrocyte images. A black dot is placed at the median values. The blue and red lines indicate the ranges from 25 to 75 percentile of each strain. The green lines show the correlation between the directly and indirectly determined astrocyte strains, with the shaded areas showing the 95% confidence bounds. The grey dashed line is a 1:1 reference. Note how most of the cases are above this line, indicating the overpredicted strains.

DISCUSSION

Our goal was to measure in situ IOP-induced LC astrocyte deformations directly from the astrocytes and compare them with those estimated from the surrounding LC collagen. We point out three main findings arising from this work:

1. It is possible to measure in situ the IOP-induced LC astrocyte and collagen deformations quasi-simultaneously. The techniques we deployed, including DiOlistic labeling allowed visualizing and quantifying LC astrocyte and collagen deformations in the context of their tissue environment. This enables new opportunities to better understand the interplay between mechanical and biological factors involved in glaucomatous neurodegeneration.

2. Elevated IOP induces substantial, large, and highly heterogeneous LC astrocyte deformations. These large deformations may increase the sensitivities of the astrocyte and send messages to the surrounding neural tissue. The heterogenous strain distribution suggested different stiffness within astrocytes. Each astrocyte has a distinct structure, generally comprising the body and the branches. The astrocyte body includes the nucleus and is likely to be stiffer. The astrocyte branches, with thin, long, and wavy structures, are potentially to be softer and more flexible [8]. Astrocytes may potentially also vary in sensitivity to deformation, and thus it remains important to continue to characterize both their mechanical and biological responses.

3. Estimates from LC collagen underestimate LC astrocyte deformations. Across the three types of strains, the median and percentile values (25th and 75th) of indirect measurements were generally lower than direct measurements, indicating that the astrocyte strains are underestimated when indirectly measured from collagen. A potential explanation is the structural role of collagen in supporting the LC neural tissues like astrocyte and axons. However, astrocytes are smaller and softer, they may have more flexibility to move, especially within the pore area. This could have major implications for studies of LC tissue deformation made using OCT [9], where the signal seems to come primarily from LC beam scattering. We are not aware of techniques allowing in vivo visualization of LC astrocytes in the collagenous LC.

In summary, we measured in situ IOP-induced LC astrocyte deformations directly and indirectly. We found substantial IOP-induced deformations that were underestimated when measured indirectly. Results from this study are essential to understanding the mechanisms of the IOP-induced and astrocyte-mediated retinal ganglion cell axon damage in glaucoma.

INTRODUCTION

The current assessment of coronary atherosclerosis is limited in its ability to identify risk of future adverse cardiovascular events and guide clinical management. This is particularly critical in older patients (≥75 years of age) experiencing myocardial infarction (MI) and multi-vessel coronary artery disease (MVD), as both age and presence of MVD are major drivers of adverse cardiovascular events [1]. Moreover, 75% of older MI patients show MVD at coronary angiography [1]. The recent Functional Assessment in Elderly MI Patients with Multivessel Disease (FIRE) clinical trial [2] has shown the benefits of a physiology-guided management of older MI patients with MVD. Such management pursued complete coronary artery revascularization by treating with percutaneous coronary intervention not only the lesion culprit of MI, but also all functionally significant non-culprit lesions. The benefits consisted in a reduction of mortality and risk of adverse events at 1 year [2], despite previous studies suggested an association of procedural and periprocedural complications with both age and number of treated vessels [1]. In line with the currently emerging evidence supporting the assessment of coronary physiology in older MI patients with MVD, we hypothesize that the incorporation of advanced hemodynamic and anatomical analysis into such assessment may help identify patients at higher risk of complications. In detail, wall shear stress (WSS) profiles obtained from angiography-derived computational fluid dynamics (CFD) simulations and anatomical lesion parameters obtained from 3D quantitative coronary angiography (3D QCA) were calculated in a large patient cohort to predict major adverse events at 1 year and prove the clinical utility of computational hemodynamic modelling.

METHODS

Study participants. 327 patients from the FIRE trial [2] were included (Table 1). Patients with age ≥ 75 years had MI in a clearly identifiable culprit lesion and at least 1 lesion in a non-culprit coronary artery different from the culprit one. The study protocol was approved by local ethics committee and patients provided informed consent.

Quantitative coronary angiography (QCA). Non-culprit vessel geometries were reconstructed based on 3D QCA using two end-diastolic frames at least 30° apart (CAAS Workstation WSS software, Pie Medical Imaging, the Netherlands). The lesion was defined as the coronary segment including the minimum lumen area, delimited proximally and distally by the intersection of the QCA vessel diameter function line with the interpolated reference line (Fig. 1) [3]. The lesion was characterized in terms of percentage area stenosis (%AS) and lesion length, namely the curvilinear distance between the proximal and distal boundary of the lesion segment (Fig. 1). When a patient presented with multiple non-culprit lesions, the one with the highest %AS (i.e., the most severe one) was considered.

Computational hemodynamics. CFD simulations were carried out on the reconstructed 3D vessel geometries using a finite element-based code (CAAS Workstation WSS software, Pie Medical Imaging). In addition to the time-average WSS (TAWSS) magnitude, the variability of the contraction/expansion action exerted by WSS on the endothelium along the cardiac cycle was quantified in terms of topological shear variation index (TSVI) [3,4]:

$$\mathrm{TSVI} = \left\{ \frac{1}{\mathrm{T}} \int_0^{\mathrm{T}} [\mathrm{DIV_w} - \overline{\mathrm{DIV_w}}]^2 \mathrm{dt} \right\}^{1/2} \quad (1)$$

where $\mathrm{DIV_w}$ is the divergence of the normalized WSS vector field [3] and T is the duration of the cardiac cycle. On each vessel geometry, TAWSS and TSVI values were averaged over the lesion.

Outcomes and statistical analysis. Outcome events were death, MI, stroke, or ischemia-driven coronary revascularization occurring within 1 year after the baseline MI. These outcomes were combined to define the primary outcome. Further outcomes at 1 year were contrast-associated acute kidney injury, cerebrovascular accident, and bleeding. Cox proportional-hazard univariate models were fitted to estimate

hazard ratios (HR) for "conventional" risk factors (i.e., clinical and patient variables), %AS, lesion length, TAWSS or TSVI with respect to the outcomes. A p-value < 0.05 was considered significant. Variables found to be significant at the univariate analysis entered in multivariate models to identify independent predictors. The concordance index (C-index) was used to assess the predictive capacity of each model through its interpretation as the weighted average of the area under time-dependent receiver operating characteristic curves.

Table 1: Patient, lesion and outcome characteristics.

	(N=327)
Median age (interquartile range) – years	80 (77-84)
Female sex – no. (%)	130 (39.8%)
Patients with ≥2 non-culprit lesions – no. (%)	96 (29.3%)
Left anterior descending artery – no. (%)	122 (37.3%)
Left circumflex artery – no. (%)	105 (32.1%)
Right coronary artery – no. (%)	100 (30.6%)
%AS (mean±standard deviation) – %	57.1±12.2
Median lesion length (interquartile range) – mm	12.2 (8.8-18.2)
Median TAWSS (interquartile range) – Pa	2.9 (2.0-4.2)
Median TSVI (interquartile range) – m^{-1}	58.7 (31.5-98.0)
Primary outcome event – no. (%)	56 (17.1%)
All-cause death – no. (%)	35 (10.7%)
MI – no. (%)	17 (5.2%)
Ischemia-driven revascularization – no. (%)	16 (4.9%)
Bleeding – no. (%)	17 (5.2%)

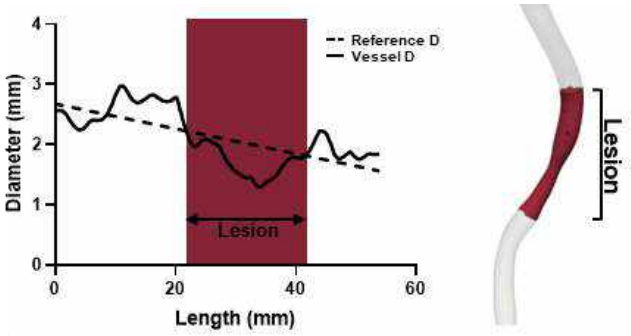

Figure 1: Anatomical definition of the lesion segment.

RESULTS

At the univariate analysis, a higher %AS was associated with a higher risk of the primary outcome (HR 1.02, p=0.041). Longer lesions were associated with a higher risk of all-cause death within 1 year (HR 1.04, p=0.045). TAWSS was not associated with any of the outcomes. Higher lesion TSVI was associated with a higher risk of (i) MI within 1 year (HR 1.01, p=0.012), (ii) ischemia-driven coronary revascularization (HR 1.01, p=0.018), (iii) bleeding (HR 1.01, p=0.012). The addition of anatomic variables (%AS or lesion length) or TSVI to multivariate models based on conventional risk factors led to improvements in the C-index for all predictions (Fig. 2).

DISCUSSION

Lesion severity, length and TSVI represent independent predictors of clinical outcomes within 1 year in elderly patients with MI and MVD, as their predictive ability was maintained in multivariate models with conventional risk factors. The present findings are consistent with the previously reported ability of TSVI in predicting lesion progression over time on swine models [4] and in identifying mild coronary lesions culprit of MI at 5-years follow-up in 80 patients [3]. Despite the shorter follow-up time of 1 year of the present study, the high-risk patient cohort ensured a higher frequency of adverse events compared to previous trials [2]. Notably, no significant predictive ability was found for TAWSS, suggesting that at this advanced stage of coronary disease, the distinct hemodynamic features captured by TAWSS and TSVI may not necessarily concur in determining the risk of complications. The hemodynamic mechanisms contributing to defining that risk are yet to be fully understood. Although the high-risk patient cohort considered here had a high incidence of coexisting illnesses [2], no confounding factors emerged in the analysis.

This study represents the largest investigation to date on the associations between WSS-based haemodynamic quantities and clinical outcomes, an essential step towards proving the clinical utility of computer-based hemodynamic modelling. The present findings may prove helpful to improve the management and the prognosis of patients aged 75 years or older with MI and MVD as it may help identify patients at higher risk of complications, and thus in need of more intensive medical or interventional therapy and close follow-up. Despite the study design is retrospective in nature and based on the ongoing FIRE trial, it offers the advantage of focusing on a patient cohort of relevant clinical interest, paving the way for prospective studies or clinical trials comparing the current best practice with an approach that includes computational hemodynamic modelling.

MODELLING VASCULARIZATION IN THE HEALING CALLUS AFTER FRACTURE

Joseph P. Soldenwagner, Mahsa Dabagh, Priyatha Premnath
Biomedical Engineering, University of Wisconsin Milwaukee, Milwaukee, Wisconsin, United States

INTRODUCTION

Healing of a fracture begins with an inflammatory response that isolates the damaged tissue by generating a hematoma. Then by intramembranous and endochondral ossification new bone is formed. Depending on the local mechanical microenvironment, progenitor cells differentiate into chondrocytes or osteoblasts. Along the periosteal and endosteal surfaces progenitor cells undergo direct bone formation or intramembranous ossification, and where there is motion in the fracture gap the progenitor cells differentiate into chondrocytes and undergo endochondral ossification [1]. During healing, these chondrocytes mature to hypertrophy and produce vascular endothelial growth factor (VEGF) inducing angiogenesis [2]. This causes vascular invasion of the cartilage callus leading to mineralization of the cartilage matrix and formation of trabecular bone. Trabecular bone then turns into cortical bone through the actions of osteoblasts and osteoclasts.

Vascularization is the formation of blood vessels within tissues and is one of the most important factors in promoting bone healing at the fracture site [3]. Angiogenesis, a crucial component, is the process of new blood vessels forming from existing ones. This response is initiated from the damaged tissue caused by the fracture. Blood vessels transport oxygen, blood, and other essential nutrients to bone cells, vital for regeneration. Vasculature is vital for the success of bone healing, as it removes waste products, promotes cell migration, supports angiogenesis, and contributes to the complex processes in bone repair [4].

The objective of this research is to investigate the relationship between vascularization and the chondrocyte-to-osteoblast transdifferentiation pathway. We will generate a model of a tibial fracture callus including bone, callus and blood vessels. Next, we will employ COMSOL to produce a finite element model to assess how various biological and mechanical elements, and vasculature invasion affect the healing of bone.

METHODS

Bilateral tibial fractures were performed on 26 mice, and 3 without for control, all weighing an average of 26 grams. The mice were properly cared for following institutional IACUC guidelines, and sacrificed at 1 week, 2 weeks, 3 weeks, and 4 weeks. The fractured tibias were harvested and imaged using microCT (Xradia, Zeiss) at a resolution of 6um. Bone, callus and vasculature geometries were segmented using MIMICS. Three-dimensional geometry of bone, callus and vasculature were built in MIMICS and exported as .stl files (Figure 1). The geometries were then smoothed in Mesh mixer. After the 3D model was generated of the fracture callus, it was imported into COMSOL to analyze the various mechanical properties of the fracture callus after 4 weeks of healing. The parameters set in COMSOL were elastic modulus (0.1 MPa), stiffness (13.95 N/mm) and Poisson ratio (0.45). These values were based off literature from [5].

RESULTS

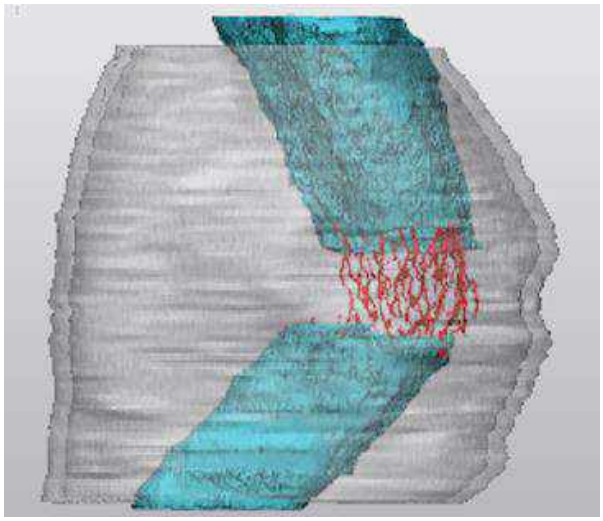

Figure 1: 3-matic model of fracture callus, bone, and vasculature

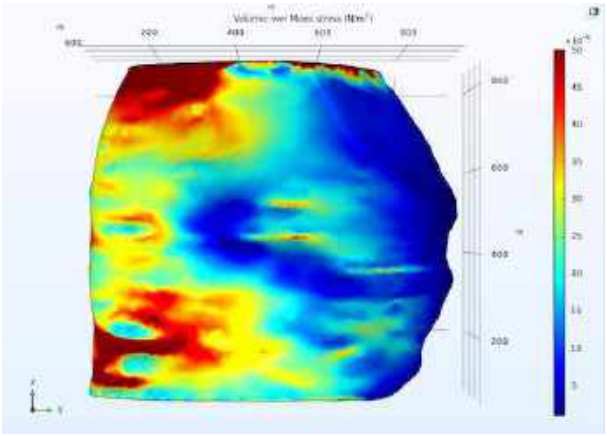

Figure 2: Von Mises stress distribution over the fracture callus

Figure 1 shows a 3D geometry of the fracture containing the vasculature, bone, and callus. The callus is the outer clear gray bubble around the bone, which is blue. The vasculature is in is between where the bone is separated. Figure 2 shows the distribution of Von Mises stresses over the callus surface. Here, we modeled the callus as one homogenous media and presence of bone and vasculature are not included in this model. However, Figure 2 demonstrates that the anatomical geometry of callus leads to significantly different stress values within the callus width and its height.

DISCUSSION

This study is investigating the relationship between vascularization and the chondrocyte-to-osteoblast transdifferentiation pathway in 3D model of a tibial fracture callus. Our results of Von Mises stresses within the callus (Figure 2) show what areas of the callus are under the most stress. We observed high gradients of stresses within the callus width at its central region. Furthermore, the left side (posterior) of the callus is experiencing higher stresses whereas the right side (anterior) is showing lower stresses. A comparison between Figure 1 and 2 demonstrates that the location of bone may impact the stress distribution. This study is the first step in understanding how the stress magnitude correlates with vascularization in the fractured callus. With further research the goal is to include the bone and vasculature in the computational model and observe and compare how they relate to the areas of the callus that are under more stress. Understanding how fractures heal is crucial for developing more effective clinical treatments. This understanding can lead to the creation of therapies that speed up the healing process, which is essential for minimizing patient recovery time, enhancing quality of life, and reducing complications linked to prolonged immobility. Research on fracture healing also plays a key role in advancing our knowledge of bone regeneration, especially in cases involving large bone defects or non-union fractures where traditional healing methods may fall short. Recognizing the factors influencing fracture healing aids in the identification and management of potential complications. Fracture healing research significantly contributes to better patient outcomes, shorter recovery periods, advancements in medical interventions, and overall improvement in the comfort of individuals recovering from fractures [6].

INTRODUCTION

Cartilage tissue engineering is a promising osteoarthritis (OA) treatment strategy whereby cell-seeded scaffolds are cultivated to generate neocartilage repair tissues. The long-term survival of neocartilage is dependent on its ability to recapitulate the complex spatial distribution of the composition, structure, and material properties of native hyaline cartilage, which are requisite for load-supporting functionality. This includes both a stiff extracellular matrix (ECM), comprised of dense glycosaminoglycans (GAG) enmeshed within a fibrous type-II collagen (Col-II) network, and a sparse arrangement of chondrocytes isolated within a soft annular type-VI collagen pericellular matrix (PCM). This configuration modulates the transmission of physiologic loads to cells, allowing for the optimal chondrocyte biosynthetic responses needed to maintain cartilage homeostasis.

Transforming growth factor beta (TGF-β) has emerged as one of the most prominent mediators of cartilage regeneration due to its capability to enhance chondrogenesis and accelerate ECM biosynthesis. Conventionally, TGF-β is administered to construct-embedded cells at highly supraphysiologic doses (10-100 ng/mL of active form), representing activity levels that are 10-1,000-fold higher than those present during native cartilage development. Recently, our group has advanced the novel hypothesis that the recapitulation of physiologic TGF-β doses (0.1-1ng/mL), akin to those presented to cells during native cartilage development[2], can yield improved cartilage regenerative outcomes. Our recent work has illustrated the ability of physiologic TGF-β dose administration to yield native-matched neocartilage mechanical properties and GAG content while producing a tissue quality more characteristic of hyaline cartilage, including notably 1) a reduction in the deposition of fibrocartilage-associated Col-I and 2) a reduction in the degree of clustering of chondrocytes induced by cell hyperplasia. The clustered morphology in response to supraphysiologic TGF-β is a striking, potentially detrimental outcome, given its reminiscence to the clustered chondrocyte morphology observed in OA, cartilage. In consideration of the importance of tissue composition and structure on chondrocyte biosynthesis, the native-like isolated cell morphology achieved by physiologic TGF-β may improve the long-term health of neocartilage post-implantation.

In this study, we aim to better understand the physiologic implications of cell morphology outcomes derived from TGF-β dosing on long-term neocartilage tissue function. Here, we performed computational analyses and experimental measures of chondrocyte strain profiles in response to physiologic loading for neocartilage cultivated with physiologic (0.3 ng/mL) or conventional supraphysiologic (10 ng/mL) TGF-β dosing. Further, in order to better understand the implications of cell morphology on tissue structure, we examined the effect of physiologic and supraphysiologic TGF-β dosing on the spatial distribution of the PCM.

METHODS

Tissue Constructs: Primary immature bovine articular chondrocytes were seeded in 2% w/v type VII agarose at 30×10^6 cells/mL and cultured in chondrogenic media supplemented with active TGF-β3 at a physiologic (0.3ng/mL) or supraphysiologic dose (10ng/mL) for the initial two weeks or maintained free of TGF-β (0ng/mL). **Mechanical Assessment**: After 56 days of culture, E_Y of constructs (n=5 per group) was measured in response to 10% unconfined compression. **Cell Morphology**: After 56 days of culture, live constructs (n=4 per group) were diametrically halved and cross-sections were stained with calcein AM and imaged under a confocal microscope. Cellular regions were identified by adaptive Gaussian thresholding and active contouring[5,6], and the fraction of cells in a clustered morphology (cell cluster area fraction [CAF]) versus isolated was determined based on the area and circularity of cell regions[7] using lab-developed code in MATLAB (MathWorks). **PCM Staining**: Constructs (n=5 per group) were fixed after 56 days of culture, paraffin sectioned, and stained for Col-VI (Invitrogen) to detect the PCM. **FEA Cell Strains**: An FEA model was implemented in MATLAB (MathWorks) to predict stress and strain of cells in native cartilage and TGF-β exposed constructs (0.3 or 10 ng/mL TGF-β) in response to applied physiologic loading (applied

compressive static stress=20 kPa). Confocal-derived cell morphology images were binarized and used in the model. Triangular mesh elements (maximum element size: 1 pixel^2; minimum element size: 0.2 pixel^2; number of elements: 825,000) and a linear elastic constitutive relation for cells and ECM was employed. Cellular region mechanical properties were prescribed from prior work (E_Y =1 kPa[8]; ν =0.4[9]). ECM region properties were prescribed from previously measured bulk tissue stiffness (E_Y; 0.3 ng/mL: 630 kPa; 10 ng/mL: 550 kPa; native cartilage: 590 kPa) and prior work (ν=0.2[10]). **Experimental Cell Strains**: At day 56, constructs were diametrically halved, calcein AM stained, and confocal imaged before and after the application of a 40% platen-to-platen axial compressive strain using a custom-made apparatus. The engineering strain ($L-L_0/L_0$) was computed for cellular regions within groups consisting of isolated cells (constructs treated with 0.3 ng/mL), small clusters (constructs treated with 10 ng/mL), and large clusters (constructs treated with 10 ng/mL) (n=3 per group) via ImageJ.

RESULTS

Neocartilage E_Y was enhanced to a similar degree by 0.3ng/mL (629±58kPa) and 10ng/mL (550±75kPa) doses, relative 0ng/mL (179±65kPa). Cell clustering was significantly enhanced by 10ng/mL exposure (CAF=0.79±0.05), relative to 0ng/mL (CAF=0.10±0.01) (Fig. 1A; $p<0.0001$). In contrast, 0.3 ng/mL significantly mitigated cell clustering (CAF=0.18±0.03; $p<0.03$) at a level only marginally above 0ng/mL levels (Fig. 1B). Col-VI staining illustrated a highly organized annular PCM around isolated chondrocytes, akin to native morphology, while 10ng/mL induced a far less organized PCM around clusters (Fig. 1C). Minimum principal strains for ECM and cellular regions were predicted in response to 20 kPa axial compression (Fig. 2A). Models demonstrated that the clustered cellular regions derived from 10 ng/mL exposure exhibited an elevated and more disperse strain distribution (ε=0.33±0.11) relative to more isolated cellular regions derived from 0.3ng/mL (ε=0.21±0.06) or cells in native cartilage (ε=0.21±0.05) (Fig. 2B). Experimental measures of cell strains exhibited similar trends where cell region strains were elevated in large clusters (ε=0.23±0.02), relative to isolated cells (ε=0.07±0.02; Fig. 2D&E; $p<0.002$).

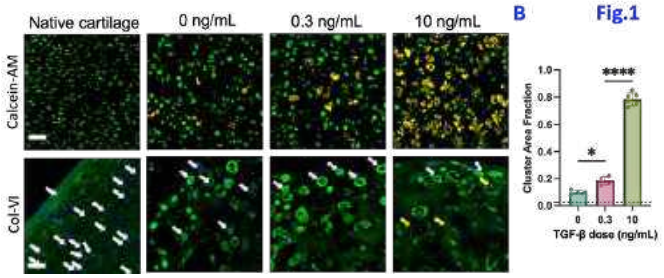

Fig. 1: (A) Representative confocal images showing isolated (green) and clustered (yellow) cell regions in day 56 constructs from physiologic (0.3ng/mL) and supraphysiologic (10ng/mL) TGF-β supplementation doses. Scale bar: 100 µm. (B) Cell cluster area fraction (CAF) of constructs. Dashed line: CAF of native cartilage (<0.01). *p<0.03, ****p<0.001. Fig. 2: (A) FEA model derived color maps of minimum principal strain in cells (green) and ECM (red) regions. (B, C) Frequency plots of minimum principal strain in (B) cellular and (C) ECM regions. Scale bar: 100 mm. (D) Representative confocal images of cellular region of different cell morphology pre- and post- 40% compressive strain. Single cells: constructs treated with 0.3 ng/mL TGF-β. Small and large clusters are from constructs treated with 10 ng/mL TGF-β; (E) Cell strain of different cellular regions: ns p>0.12, * p<0.03, **p<0.002.

DISCUSSION

The formation of dense chondrocyte clusters in response to supraphysiologic TGF-β is a striking outcome when considering their similarity to the morphology of pathologic chondrocyte clusters classically observed in OA[11]. Clusters likely result from TGF-β-induced cell hyperplasia while in the confines of an agarose scaffold that restricts cell expansion. FEA analysis and experimental measures together illustrate an important consequence of this aberrant morphology, whereby clusters exhibit elevated and highly heterogeneous strain profiles in response to physiologic tissue loading. Given the high sensitivity of chondrocytes to strain magnitude, it is reasonable to surmise that clustered cells may lose their ability to respond in unison to physiologic mechanical stimuli. Cell clusters are additionally accompanied by an aberrant PCM morphology that may further exacerbate mechanobiological dysregulation. In future work, we aim to better elucidate potential consequences of these PCM abnormalities by performing investigations into calcium signaling[12] and growth factor release[13] in response to mechanical loading. In contrast, cartilage regeneration in the presence of physiologic TGF-β dosing promotes neocartilage with native-matched mechanical properties while maintaining a healthy, more isolated cell morphology. As such, these cells may retain the ability to provide a harmonious response to loading, thus better recapitulating the mechanobiological behavior needed to maintain long-term tissue health. In the future, we aim to perform investigations into long-term functional consequences of aberrant cell morphology in neocartilage and examine potential benefits of physiologic TGF-β administration in improving the long-term tissue health.

INVESTIGATING THE ROLE OF WALL STRESS IN AORTIC GROWTH OF ACUTE UNCOMPLICATED TYPE B AORTIC DISSECTION USING FLUID-STRUCTURE INTERACTION ANALYSIS

INTRODUCTION

Type B Aortic Dissection (TBAD) is a lethal disease with an incidence of 4 per 100,000 patients per year[1]. TBAD occurs when a tear develops in the inner lining (intimal layer) of the aorta, causing the layers of the aortic wall to separate (dissect) creating "true" and "false" lumens. In the acute setting, patients with TBAD are categorized as either "uncomplicated" or "complicated" based on the presence of organ malperfusion or aortic rupture. Complicated TBADs have a high in-hospital mortality rate and require emergent thoracic endovascular aortic repair (TEVAR). Uncomplicated TBADs have been traditionally managed with optimal medical therapy (OMT) consisting of an aggressive anti-hypertensive regimen and surveillance imaging. OMT results in low-in-hospital mortality rates; however, OMT produces dismal long-term survival rates of 48-66% and overall intervention-free survival rates of < 50% secondary to aortic aneurysm formation and rupture[2]. Aortic expansion is the most important factor that determines the long-term survival of TBAD patients. For about 73.3% TBADs[3], OMT results in aortic expansion and aneurysm formation at five years.

The complex interplay between hemodynamics and tissue biomechanics alters the aortic wall growth and remodeling. The ability to predict aortic growth would help identify patients at risk of aneurysm formation and would benefit from early intervention (e.g., TEVAR) versus those who would have a stable aortic diameter and can be sufficiently treated with OMT. In this study, we analyzed 6 uncomplicated TBAD patients and obtained the initial CT scans of the acute phase taken during their first diagnosis and additional follow-up CT scans. We developed a computationally efficient one-way fluid-structure interaction (FSI) framework to compute wall stress distributions of patient-specific TBAD geometries. Using FSI, we computed structural wall stress distributions of acute uncomplicated TBADs based on the initial baseline CT scan. We investigated whether the wall stress field of the initial CT scan is associated with the distribution of the local aortic growth rate.

METHODS

We retrospectively collected contrast CT images, transthoracic echocardiographic data, and demographics of 3 male and 3 female patients who were initially treated with OMT. Three-dimensional patient-specific geometries of the dissected thoracoabdominal aorta (including arteries that branch from the aorta), dissection flap, and intraluminal thrombosis were segmented from the initial baseline CT scans. The segmentations were then used to construct fluid domain and solid domain meshes for FEA and CFD simulations. The aortic wall and dissection flap were primarily meshed using 3D hexahedral elements, with preserved nodal connectivity between the aortic wall, flap, and thrombus.

Conventional two-way, fully-coupled fluid-structure interaction (FSI) simulation, which couples fluid and solid mechanics solvers, is extremely computationally expensive (e.g., 2 weeks[4]); therefore, two-way FSI analysis usually limits to only ~1 patient in the literature and could be prohibitively time-consuming to be adopted here. Hence, we developed a simplified, one-way FSI workflow, which is significantly less computationally expensive (< 1 hour). As shown in Figure 1, the

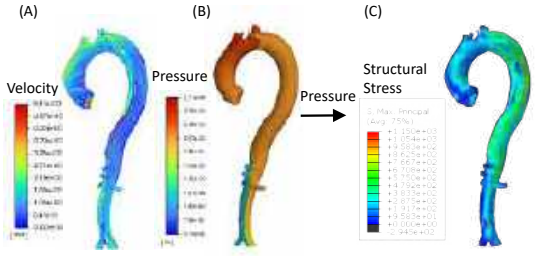

Figure 1: One-way FSI analysis workflow: (A) streamline color-coded with velocity; (B)pressure contour; (C) wall stress field.

one-way FSI analyses were performed using the initial CT scan of each patient with the following steps: (1) patient-specific computational fluid

dynamics (CFD) simulation was performed using velocity inlet flow condition obtained from echocardiography data. Windkessel models with parameters calculated using Murray's law were applied at each pressure outlet to match the blood pressure measurement obtained during the initial hospital admission; (2) the nonuniform pressure distribution of the true and false lumen were extracted from CFD and mapped to the inner aortic wall in the FEA model using an in-house interpolation code; (3) subsequently, stress distributions in the true and false lumen wall, and dissection flap were obtained from structural finite element analysis (FEA) using the CFD-computed pressure distribution as loading condition.

Additionally, distributions of aortic growth rate were quantified using the initial and the most recent follow-up CT scans (range 8-91 months). As can be visualized in Figure 2, the initial TBAD geometry was deformed to match the surface of the follow-up geometry; therefore, the logarithmic strain field can be computed which quantifies the growth in the circumferential direction. The local aortic growth rate was obtained by dividing the strain by the time interval between the initial and follow-up scans. Subsequently, linear regression analysis was performed to investigate the relationship between wall stress and growth rate for each patient.

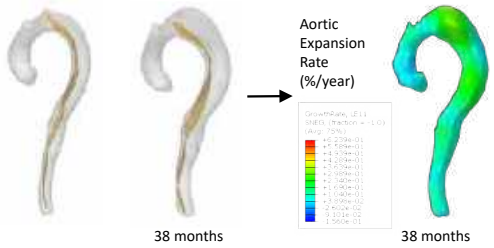

Figure 2: Initial (A) and follow-up TBAD geometries (B) are used to compute the heatmap of local aortic growth rate

RESULTS

FSI simulations indicated a slightly elevated false lumen pressure (137 mmHg) compared to the true lumen (129 mmHg), p=0.59. Structural stress fields computed based on the initial CT scan were compared to the heatmap of the aortic growth rate. 4 representative cases are shown in Figure 3. For all 6 patients, a direct relationship was observed between stress and growth rate: aortic segments experiencing high wall stress exhibited rapid aortic growth. The correlations between stress and growth rate were most evident in P1 and P4.

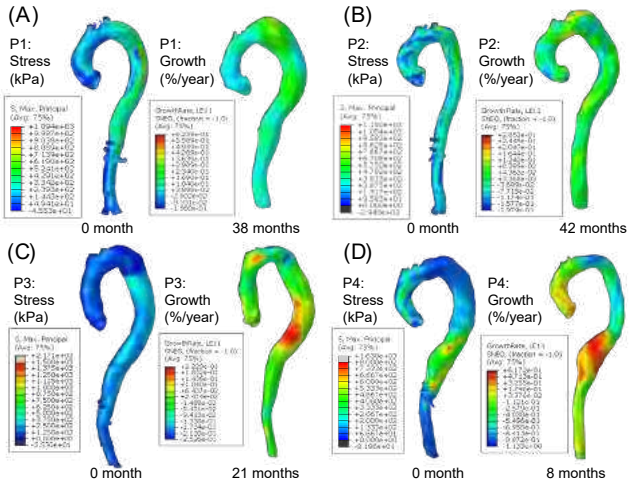

Figure 3: Wall stress distributions and contours of aortic growth rate in 4 representative patients. (A) to (D): P1 to P4.

To quantify their underlying spatial correlation, the wall stress contour and growth rate heatmap were registered to generate scatter data plots. To ensure one-to-one correspondence of the stress and growth data, the stress and growth rate distributions were transformed onto a common mesh template using a non-rigid registration algorithm[5]. Subsequently, the mesh template was divided into 34 equally spaced regions; therefore, the averaged stress and growth rate of each region can be plotted to quantify the spatial correlation. Linear regression analyses were performed which revealed positive slopes between wall stress distributions and growth rate heatmaps for all 6 patients. The positive slopes confirmed the observation that the high-stress region was correlated with a faster aortic growth rate. Figure 4 summarizes the positive correlation between wall stress and growth rate for the 4 representative patients.

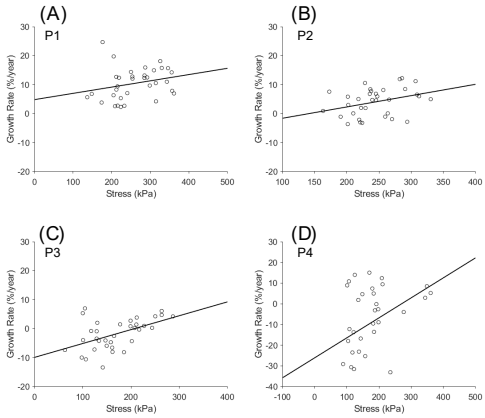

Figure 4: Linear regression analysis demonstrates a positive correlation between wall stress and aortic growth rate in the 4 representative patients. (A) to (D): P1 to P4.

DISCUSSION

In this study, we investigated the association between the wall stress field obtained from the initial CT scan and the distribution of aortic growth rate in uncomplicated TBAD using one-way FSI simulations. Our results indicated that TBAD growth is governed by biomechanical factors. It was found that high wall stress regions were positively associated with high growth rates, which suggests wall stress may be used as a potential predictor for aortic growth rate. By further incorporating growth and remodeling theories into the modeling framework, it is anticipated that the rate and location of aortic growth in acute uncomplicated TBAD may be predicted using information available in the initial baseline CT images.

One-way FSI has been shown to yield accurate true and false pressures compared to two-way FSI in a recent validation study[6].

We are incorporating additional patients into the present FSI study. With more patient data, a threshold stress value may be established to identify patients at risk of fast aortic expansion. Additional biomechanical markers may be identified to predict the risk of aneurysmal formation and the need for early endovascular intervention in acute uncomplicated TBAD.

COMPRESSION STABILITY OF THREE FIXATION MODES FOR INTRAOPERATIVE FEMORAL CONDYLE FRACTURES DURING KNEE REPLACEMENT

Timothy R. Eastep (1), Brady Killham (1), Yi Hong (1), Cheng-Jen Chuong (1), Dane Wukich (3), Jun Liao* (1), Senthil N. Sambandam* (2)

INTRODUCTION

Total knee arthroplasty (TKA) is one of the most performed surgeries to reduce the pain and disability associated with end stage knee osteoarthritis. In total knee replacement surgery, the incidence of intraoperative periprosthetic fracture varies between 0.3% to 4% depending on the patient's risk factors and implants used [1]. Among the fracture types, medial femoral condyle intraoperative fracture is the most common and requires fixation of the fracture [2]. A stable intraoperative fracture fixation is desirable to allow minimal modification to standard total knee replacement protocol. There are various fixation options, but the three commonly used techniques are: (1) Reduce the fracture, fix with screws, and use standard femoral component; (2) reduce the fracture, fix it with plates and screws, and then implant standard component; (3) reduce the fracture and fix it with screws and use a femoral component with a stem attached to the component. The choice of fixation is often determined by surgeon preference with no specific clinical or biomechanical data to support the selection. In this study, we performed incremental cyclic compression testing to assess the mechanical stability of three fixation options.

METHODS

Denuded human right femurs were obtained from Science Care (Phoenix, AZ). Those cadaver femurs are from a similar age range (Male, 65 to 75), with similar size, fresh and no abnormality, and no treatment. Standard knee implants, stem knee implants, bone screws, and locking plates were obtained from Stryker (Addison, TX). With the right femur bones procured and the knee prostheses ready, medial femoral condyle fractures had been created before implantation of the femoral prosthetic component. The fracture had been fixed with three different fixation options, i.e., (1) standard implants with screws alone, (2) Standard implants with locking plate-screws, and (3) Stemmed implants with screws. Instron Machine (Model: 5965) was used for this study. With its TestProfiler software, Instron Machine can apply cyclic loading and unloading, step-by-step loading patterns to mimic the functional use of orthopedic devices. Incremental cyclic compressive loading-unloading protocol up to 1.5 kN (337 lbs) was then programmed to assess the fixation stability and its resistance to cyclic compressive loading.

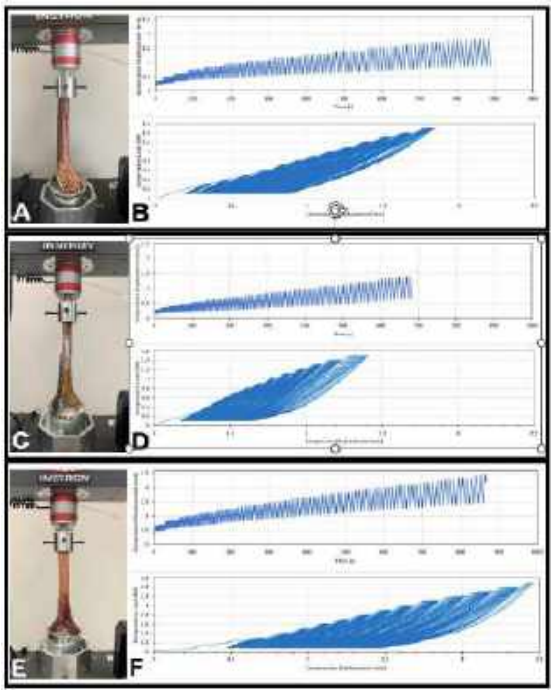

Figure 1: Experimental setup and incremental cyclic compression behavior: (A) & (B) Standard implants with screws alone, (C) &

(D) Standard implants with locking plate-screws, (E) & (F) Stemmed implants with screws.

RESULTS

The mechanical results demonstrated different performances of three fixation options. (1) The locking plate-screws fixation demonstrated the best stability and resistance to cyclic compressive loading. (2) The bone screw-only fixation was able to achieve stability and resistance to cyclic compressive loading similar to the locking plate-screws fixation, only showing slightly lower stability and resistance. (3) The stemmed implants with screws showed the worst stability and resistance to cyclic compressive loading among three fixation options.

DISCUSSION

These important observations point out, under the cyclic axial compressive loading (the dominant, physiologically-relevant loading pattern), the stemmed implants have the worst stability and compressive resistance, the locking plate-screw fixation has the best stability and compressive resistance, and the bone screw only fixation achieves a stability and compressive resistance only slighter lower than the locking plate-screws fixation and might be the most cost-effective fixation option. Furthermore, our observation indicates that the routine use of stemmed implants might not be needed since (i) it is not a stable fixation; (ii) it has disadvantages such as increased bone loss, longer operative time, and higher cost.

AN OPTOGENETIC PLATFORM FOR CONTROLLED RELEASE OF NUCLEOCYTOPLASMIC SHUTTLING PROTEINS

Erin E. Berlew (1,2), Paula Camacho Sierra (1), Joel D. Boerckel (1,2)

(1) Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA 19104, USA

INTRODUCTION

Dynamic localization of proteins is critical in cell- and mechano-biology, particularly for proteins that shuttle between cellular compartments such as the cytosol and nucleus [1]. Traditional overexpression systems fail to provide a baseline "time zero" for studying shuttling dynamics, limiting readouts to absolute levels of localization at equilibrium without access to nuclear import and export rates. To address this gap, we developed an inducible release system specifically tailored for shuttling proteins.

Existing systems for inducible release are not optimized for mammalian cells [2], are designed for constitutive nuclear localization [3], or anchor the protein of interest to endomembrane organelles, potentially distorting natural nuclear entry dynamics [4]. In this study, we report a protein release system for mammalian cells that anchors proteins of interest (POIs) to the plasma membrane, effectively sequestering them from nuclear importers and other cytosolic factors. Optogenetic recruitment of a protease liberates the POI into the cytosol, enabling real-time tracking of shuttling dynamics. This work presents a new tool for spatiotemporal dissection of shuttling protein dynamics in living cells, including the dynamics of mechanotransduction.

METHODS

In our **two-component system**, blue light recruits a protease to the membrane, where it cleaves and releases a tethered protein of interest (POI) into the cytosol. The first **(protease) component** enables protease-mediated POI release. For our protease, we selected a tobacco etch virus protease (TEV) [2], which is small in size and efficiently cleaves target proteins at a conserved 7-amino acid motif. For optogenetic control, we fused TEV, with mScarlet visualization tag, to the light-sensitive protein, BcLOV4, which binds the plasma membrane via electrostatic interaction in response to blue light [5].

The second **(membrane) component** tethers the protein of interest (POI) to the membrane via a peptide containing the TEV-target motif. To prevent off-target proteolytic cleavage prior to TEV activation, we further added a light-sensitive AsLOV2 domain that protects this cut site in the dark state. Activation with blue light TEV cut site and recruits optogenetic TEV to the membrane for POI cleavage and release.

Protease component fusions were Gibson cloned into the pcDNA3.1 backbone. The membrane component was ordered as a custom synthesis from Twist Biosciences in the pTwist backbone under a CMV promoter. Protease and membrane components were co-expressed in HEK293T cells, at a 4:1 ratio, via transient transfection with lipofectamine. Cells were imaged over a 10-minute time course, with red, green, and blue fluorescence channels imaged every 30 seconds. We imaged N = 15 cells per condition per replicate over three biologically independent replicates. Nuclei and cytosolic regions were manually segmented in Fiji, and fluorescence intensity measurements were calculated using a custom Python script.

RESULTS

System design

We engineered our system to enable three-color imaging for near-simultaneous monitoring of the opto-TEV protease component (visualized in red), the membrane anchor component (blue), and the target POI (green) slated for release (Figure 1). For the protease component, we used BcLOV4, which uniquely enables TEV recruitment to the membrane without an additional engineered protein-protein interaction (as with common heterodimerization systems).

For the anchor portion of the membrane component, we used a modified LCK protein, which docks in the membrane via lipid modification. We had first tried Cdh4, which is commonly used in yeast systems, but this exhibited general localization to endomembrane organelles. In contrast, the modified LCK localized specifically to the plasma membrane. To prevent off-target cleavage of the POI from the membrane anchor component, we added an AsLOV2-TEV cut site fusion protein, separated from LCK by a blue fluorescent protein

(BFP2) visualization tag. AsLOV2 protects the TEV cut site from non-specific cleavage, but undergoes a conformational change in response to blue light that exposes the cut site for cleavage by light-recruited TEV protease. For the POI, we here used fluorescent reporter mNeonGreen, fused to a standard nuclear localization signal (biNLS9) [6].

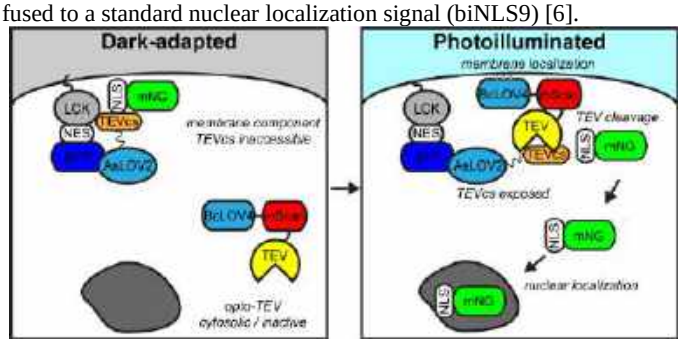

Figure 1: The opto-TEV protease system.

System characterization

We first expressed the membrane component in isolation and quantified its fluorescence within the membrane, cytosol, and nuclear regions, in both blue and green fluorescence channels. We observed a pronounced preferential localization at the membrane in both channels, affirming the specificity of membrane anchoring. After addition of AsLOV2, fluorescence intensities exhibited high correlation across regions, indicating negligible spontaneous cleavage by endogenous cellular proteases.

We identified BcLOV4-mScarlet-uTEV as the protein order permutation with the highest protease activity. We refer to this novel construct as "opto-TEV". We co-expressed the membrane component with either opto-TEV or BcLOV4-mScarlet as a negative control and measured foldchange in nuclear and cytosolic fluorescence of mNeonGreen over the 10-minute optogenetic stimulation time course (Figure 2a-b). Light stimulation had no effect on cytosolic fluorescence in any group, but significantly increase both nuclear fluorescence and nuclear-to-cytosolic ratio in cells that received opto-TEV, indicating proteolytic cleavage of NLS-mNeonGreen by opto-TEV.

To assess the leakiness and off-target cleavage of opto-TEV in the pre-illumination state, we compared mNeonGreen intensities by region at time zero (Figure 2c). We observed no significant differences in the nuclear or cytosolic regions between conditions. We did observe a higher nuclear-to-cytosolic ratio for opto-TEV compared with BcLOV4 control, indicating modest leakiness, but cleavage in the dark state was lower lower than after light activation. Future iterations of the system will minimize the likelihood of productive interactions between the membrane and protease components prior to blue light stimulation, to enhance specificity and efficiency.

DISCUSSION

Here we report a novel system for rapid, inducible release of nuclear and cytosolic proteins from the plasma membrane in mammalian cells via blue light stimulation. This approach enables the direct observation of protein shuttling dynamics from the time of protein release into the cytosol, providing clear advantages in temporal resolution over traditional methods. Importantly, while our proof-of-concept experiments utilized a nuclear localization signal (NLS) fused to a visualization tag as protein of interest (POI), this system is versatile and can be adapted for use with a wide range of POIs, including those without an exogenous NLS, including cytosolic proteins, translocating transcription factors, and proteins containing targeting sequences for other cellular organelles.

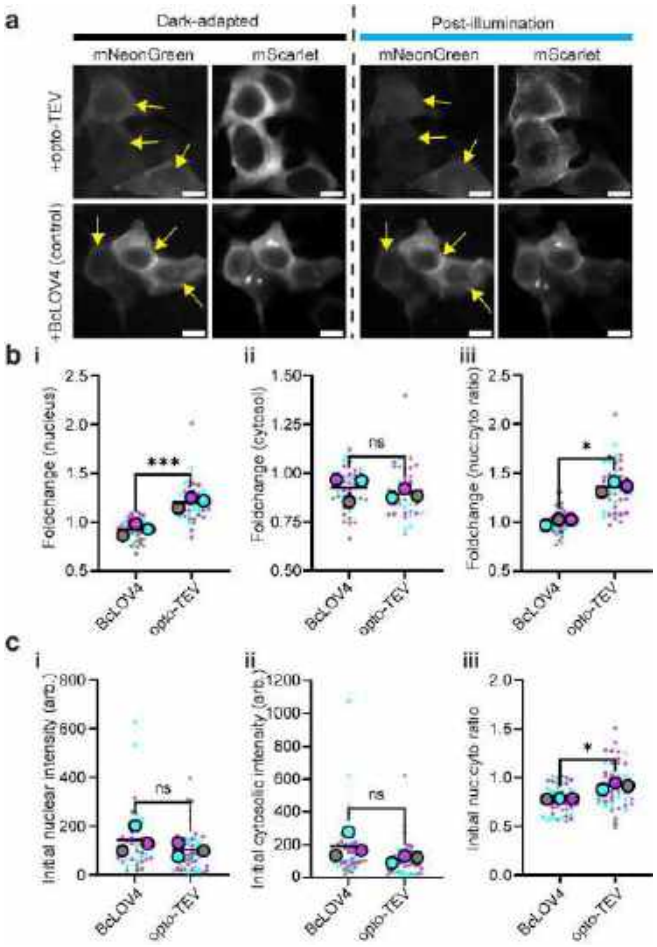

Figure 2: Characterization of the opto-TEV system. (a) opto-TEV and BcLOV4 control co-expressed with the membrane component. Scale = 10 µm. (b) Foldchange in mNeonGreen in by region over a 10-minute stimulation time course. (c) Initial mNeonGreen intensities prior to photoillumination for nuclear (i), cytosolic (ii), and nuclear:cytosolic ratio (iii). (*) = $p < 0.05$, (***) = $p < 0.001$, ns = not significant by T-test.

While dark-state leakiness was low, our future efforts will refine this system to further minimize leakage, enhancing the specificity and efficiency of TEV cleavage. One particularly exciting application of this system, on which we are currently working, is in the study of nuclear import of mechanosensitive proteins, such as the Yes-associated protein (YAP) transcriptional co-activator. Without relying on the fusion of an artificial NLS, we anticipate these applications will provide new insights into YAP transport dynamics and mechanotransduction.

INTRODUCTION

Articular cartilage, crucial for smooth joint movement, faces challenges like chondrocyte apoptosis, extracellular matrix (ECM) degradation, and reduced matrix synthesis, progressing to post-traumatic osteoarthritis (PTOA). PTOA accounts for 12.4% of all osteoarthritis cases, affecting over 32.5 million US adults with healthcare costs exceeding $100 billion [1]. Effective cartilage regeneration is crucial. Autologous chondrocyte implantation is a widely explored approach, but challenges like chondrocyte dedifferentiation and slow ECM synthesis exist [2]. To address these challenges, our study focuses on manipulating the 'tissue engineering triad' components: cells, scaffolds, and biofactors. However, the intricate interactions between these components create a gap in understanding how exogenous cues influence regeneration-specific genomic pathways during cartilage repair.

Our study concentrates on two external cues—scaffold stiffness and cell seeding density. Altering scaffold stiffness reveals that softer scaffolds favor chondrogenesis [3]. Greater cell seeding density tends to favor chondrogenesis, but nutrient permeation limits maximal density [4]. Our objective is to study the impact of material stiffness and seeding density on chondrocyte redifferentiation using a reproducible 3D scaffold culture system, the pre-chondrogenic stem cell niche (PCN). This research enhances our understanding of how exogenous cues influence genomic pathways, offering insights into effective strategies for cartilage regeneration.

METHODS

PCN Culture Human articular chondrocytes (HACs) (male donor, aged 19 years) were mixed with a hydrogel precursor composed of 5 or 10%w/v polyethylene glycol (PEG), 0.02%w/v methacrylated type I collagen and 0.1%w/v thiolated hyaluronic acid, and 0.3%w/v photoinitiator. After a 30-minute incubation for Michael-type additions, 70 µl samples were crosslinked under UV light (365 nm wavelength, 28 mW/cm^2) for 60 seconds to form hydrogels. Final cell seeding densities were 10, 20, and 40 × 10^6 (M) cells/ml in 5/10%PEG gels.

Live/dead Staining Cell viability on days (D) 0, 14 and 28 was assessed using ImageJ, with $n \geq 6$ stacks acquired through confocal microscopy.

qPCR Expression of ACAN, COL2A1, MMP13, COL10A1 and COL1A1 genes was assessed on D0, 7, 14/15 and 28/29.

sGAG Quantification Sulfated glycosaminoglycan (sGAG) accumulation normalized to DNA content was quantified on D14/15 and 28/29 using the dimethymethylene blue and PicoGreen assays [5].

Immunofluorescence D14 and D28 samples underwent antigen retrieval and blocking prior to primary antibodies incubation for COL2A1, ACAN, COL10A1, RUNX2, or MMP13, followed by Goat anti-Rabbit Alexa Fluor™ Plus 488 secondary antibody and DAPI counterstaining. Protein production normalized to DAPI content was quantified using ImageJ, with $n \geq 9$ stacks acquired through confocal microscopy.

Mechanical Testing The tensile modulus of hydrogels was tested using contactless ultrasound technology, Resonant Acoustic Rheometry [6].

Statistical Analysis Two-way ANOVA or mixed models with post-hoc Tukey's multiple comparison test were employed.

RESULTS

Preservation of Chondrogenic Phenotype by PCN The average cell viability on D0, 14 and 28 was ~80%, indicating robust cell survival post-crosslinking for long-term studies (Fig. 1A). This is supported by sustained high-level expression of chondrogenic genes (Fig. 1B) and elevated sGAG accumulation (Fig. 1C).

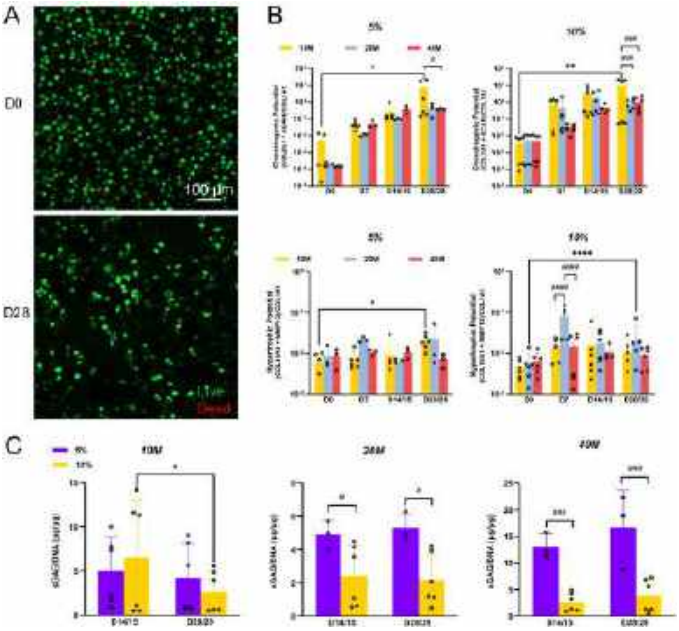

Figure 1: (A) Fluorescent viability images of cells in the PCN. (B) Gene expression ($2^{-\Delta Ct}$ of normalized markers) of cells in 5/10% PEG PCN with varying cell seeding density, showing maintained articular cartilage genotype ('Chondrogenic Potential') and impact on premature cell maturation ('Hypertrophic Potential'). (C) sGAG normalized to DNA of cells with 10/20/40M cells/ml influenced by PCN stiffness.

Promotion of Cartilage Matrix Production by PCN Stiffness In contrast to 10%PEG PCN, the softer 5%PEG facilitated increased sGAG production (Fig. 1C), and elevated expression of ACAN and COL2 (Figs. 2A&B). Moreover, the 5%PEG PCN maintained a stable environment for enhanced matrix production, while the stiffness of the 10%PEG PCN increased faster over time, especially with higher cell seeding density (Figs. 2C).

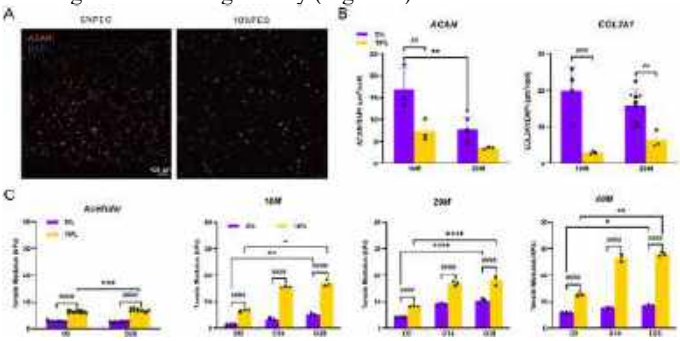

Figure 2: (A) Fluorescent images of ACAN in 5/10%PEG PCN. (B) Quantification of normalized ACAN and COL2 by HACs with 10/20M cells/ml. (C) Tensile modulus of acellular PCN and PCN with 10/20/40M cells/ml.

Promotion of Chondrogenic Phenotype by Lower Cell Density in PCN Compared to 20/40M cells/ml, the PCN with lower seeding density (10M) promoted higher chondrogenic gene expression and lower hypertrophic gene expression (Fig. 1B). Lower density also facilitated increased matrix production of ACAN and COL2 (Fig. 2B). Furthermore, the 10M cells/ml PCN maintained a stable environment for enhanced matrix production, while the PCN with higher cell density increased stiffness more rapidly over time (Figs. 2C).

DISCUSSION

The study showcases the PCN's efficacy in maintaining high cell viability, preserving chondrogenic genes, and promoting sGAG accumulation. The softer PCN (5%PEG) enhances cartilage matrix production, and lower cell seeding density (10M cells/ml) favors chondrogenic gene expression and matrix production, maintaining a more favorable stiffness. This aligns with prior research, indicating increased production of COL2 and proteoglycan in a softer environment, despite minimal influence on chondrogenic gene expression [3]. Low stiffness can reduce cell adhesion and spreading, facilitating the formation of cell aggregates. Our findings diverge from previous studies suggesting higher cell seeding density for matrix production, providing a nuanced explanation linked to the stiffness variation [4]. Future studies will explore hydrogel formulations with lower stiffness and refine cell retrieval methods for deeper insights into HAC redifferentiation. This study underscores the potential of the PCN in advancing cartilage repair methods and contributes to the broader understanding of factors influencing cartilage regeneration.

INTRODUCTION

Aortic coarctation (COA) is a congenital heart disease (CHD) characterized by a narrowing of the aorta, that typically presents distal to the left subclavian artery. Each year, 1 in every 1,800 babies are born with COA in the United States making it one of the most common CHDs[1]. Symptomatic patients typically present at birth and are preferably treated within the first few years of life[2]. Current surgical or catheter-based interventions can restore flow and reduce the blood pressure gradient across the COA to normal levels. However, *successful technical* intervention does not ensure long-term health as one-third of treated COA patients still develop hypertension (HTN) by adolescence[3]. The underlying cause of increased long-term risk for HTN in treated patients is not fully understood. While various factors have been discussed, irreversible vascular remodeling[4] has become a leading hypothesis. Previous animal studies support this proposed mechanism as reduced elastin content in the proximal aorta persisted following COA correction[5,6].

Our team created the first large animal model of COA in which stenosis was induced and corrected at time-points comparable to humans. The objective of this study was to evaluate aortic remodeling near the site of coarctation via quantitative histologic analysis and mechanical testing. We hypothesized that COA, both with and without treatment, would result in stiffer aortas with reduced and fragmented elastin.

METHODS

Animal Model. In this study, pigs were followed from 2-weeks (~4-5kg) to 20-weeks of age (~60kg). In 12 animals, COA was surgically created at approximately 2-weeks of age with 4 additional animals undergoing sham surgery. Each pig underwent cardiac catheterization at 6, 12, and 20-weeks with necropsy at 20-weeks. At 6-weeks a stent was placed at the COA site to relieve the stenosis in the treatment group (n=6). The stent was subsequently dilated at 12- and 20-weeks to match the diameter of the growing aorta. Within 3h of necropsy, the entirety of the aorta was collected, placed in a 1% phosphate buffered saline solution, and frozen at -80°C. Animal experiments were reviewed and approved by the University of Wisconsin Institutional Animal Care and Use Committee.

Histology. Histologic analysis was performed on regions of the aorta directly proximal and distal to the COA site. At necropsy, these cross-sections were fixed in 10% formalin for ~24 hours, rinsed, placed in 70% ethanol, and submitted to UW-Madison's Experimental Animal Pathology Lab. Samples were stained with Masson's trichrome (MTC) or Verhoeff–Van Gieson (VVG) to visualize collagen and elastin, respectively. A custom MATLAB code developed by Bersi et al[7] estimated the collagen and elastin area fractions via colorimetric analysis (Figure 1). Statistical analysis was performed with one-way ANOVAs with Tukey's multiple comparisons tests.

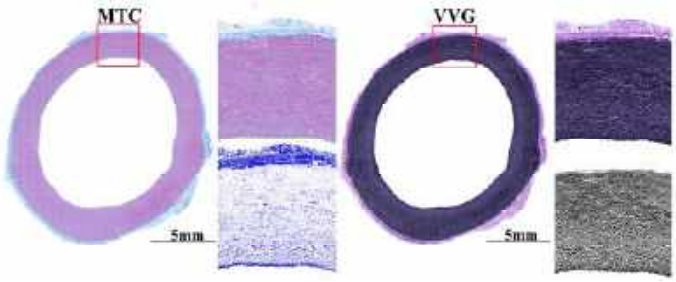

Figure 1: Masson's trichrome (MTC) and Verhoeff–Van Gieson (VVG) with automated visualization of collagen and elastin, respectively, for representative aortic cross sections.

Mechanical Testing. Aortic tissue directly distal to the COA site from all three groups was mechanically tested in both the axial and circumferential directions[4]. Briefly, once thawed, a longitudinal cut was

made and the tissue was divided into 5x20 mm samples, aligned in both directions. Uniaxial, peel, and shear lap tests were performed to failure to characterize the mechanical behavior. Uniaxial tests captured the tensile response along the axial and circumferential axes, peel tests captured the tensile response in the radial axis, while shear lap tests captured the response to shear along the medial lamella. Each test was performed at 3mm/min. Tests in which samples slipped or failed at the clamps were not included in the analysis.

For the uniaxial and shear lap samples, the first Piola-Kirchhoff stress at failure was calculated by dividing the grip force at ultimate failure by the undeformed cross-sectional area of interest. For peel samples, the average peel tension was calculated by dividing the average grip force during peeling, excluding initial extension, by the undeformed sample width.

RESULTS

Mechanical Testing. Uniaxial failure stresses for the sham (3 pigs), COA (1 pig), and treated groups (1 pig) were all higher in the circumferential direction (1902 ± 365, n = 11 samples; 1971 ± 638, n = 3 samples; 1498 ± 296, n = 5 samples), than the axial direction (414 ± 32, n = 4 samples; 898 ± 190, n = 3 samples; 401, n = 1 sample). Failure stresses for the shear lap tests demonstrated a similar trend with the sham, COA, and treated groups, exhibiting higher average stresses in the circumferential direction (274 ± 176, n = 4; 260 ± 178, n = 2; 127 ± 34, n = 4) when compared to the axial direction (133 ± 41, n = 4; 117 ± 53, n = 2; 97 ± 51, n = 3). The sham group displayed a higher peel tension in the circumferential direction (47 ± 15, n = 6) than the axial direction (33 ± 16, n = 4), while the COA and treated groups had a higher peel tension in the axial direction (44 ± 7, n = 2; 40 ± 17, n = 4) than the circumferential direction (29 ± 1, n = 2; 28 ± 17, n = 4).

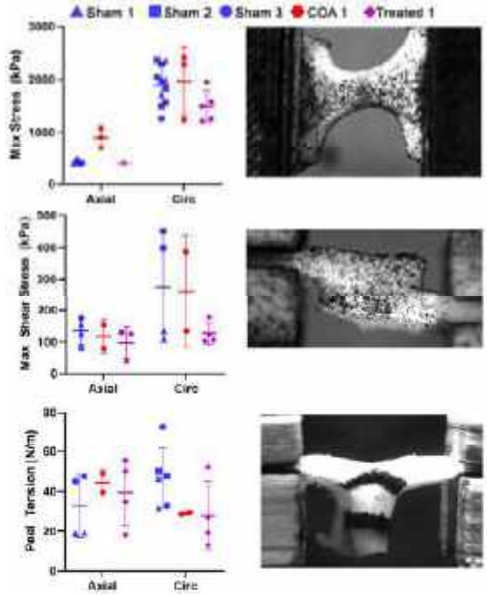

Figure 2. Uniaxial failure stress (left, top), shear lap failure stress (left, middle), and average failure peel tension (left, bottom). Representative images of each test (right).

Histology. The collagen and elastin area fractions were calculated for cross-sections located in the descending aorta both proximal and distal to the COA site from sham (2 pigs), COA (4 pigs), and treated (5 pigs) groups. Note that for this analysis each symbol in Figure 3 represents a cross-section from a different pig. There were no significant differences between the three groups when comparing collagen area fraction for either the proximal or distal descending aorta (Figure 3 top). However, the elastin area fraction proximal to the COA site in the treated group was significantly greater than the sham and COA groups. Distal to the COA site, elastin area fraction was significantly greater in the treated group than the sham and COA groups. It was also significantly greater in the COA group in comparison to the sham group.

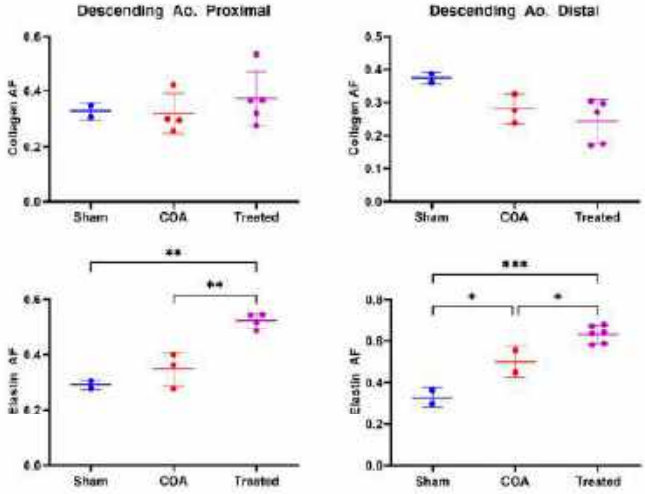

Figure 3: Colorimetric analysis results for the collagen (top) and elastin (bottom) area fractions proximal (left) and distal (right) to the COA site * p < 0.05, ** p < 5e-3, *** p < 5e-4

DISCUSSION

In this study, we quantified the structural and mechanical remodeling of the aorta using a novel pig model of COA. While we have not yet mechanically tested a sufficient number of samples for statistical analysis, initial results suggest that the treated group was slightly weaker, particularly in the circumferential direction, when compared to sham and COA groups. Surprisingly, the histologic analysis yielded the opposite of the expected outcome. We hypothesized that the treated and COA groups would have less elastin than the sham animals, however, elastin content was actually higher in these groups. One potential explanation for this finding is the COA was created early enough in development that the pigs could produce new elastin. Additionally, the placement of the stent may serve as a stimulus for elastin production. The possibility of elastin synthesis in response to COA was supported by the growth of elastin rich collateral vessels in both COA and treated animals near the COA site. This outcome, which is not present in other animal models[5,6] of COA, is further support for this pig model as collaterals are common in humans with COA[8]. To our knowledge, this is the first study to characterize the structural and mechanical changes of COA in an animal model that captures neonatal growth and development.

MICROSTRUCTURAL ABNORMALITIES IN HUMAN HYPERTROPHIC SEPTAL TISSUES

Duc Khang Chung (1), Milad Almasian (2), Houjia Chen (1), Katherine M. Copeland (1), Kytai T. Nguyen (1), Matthias Peltz (3), Pietro Bajona (3), Yi Hong (1), Yichen Ding (2), Jun Liao (1)

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is often caused by genetic mutations, resulting in abnormal thickening of ventricular muscle, particularly the septum, and causing left ventricular outflow tract (LVOT) obstruction. Hypertrophic cardiomyopathy can be microscopically assessed and diagnosed by enlarged cell size of the hypertrophic cardiomyocytes, disarray of those cells, and a dense abnormal fibrotic microenvironment [1]. The thickening of the ventricular wall and septum can cause poor cardiac outcomes, which consequently lead to heart failure and mortality [2]. The extent of cell hypertrophy and fibrosis can directly impact the mechanical behavior of septal tissues. Determining the microstructural abnormalities is hence essential to better understand the biomechanical properties of the hypertrophic septal tissues. In this study, we assessed the microstructural abnormalities of human hypertrophic septal tissues using histological images and light sheet images, with the goal of revealing the underlying structural causes of the poor mechanical performance of HCM tissues.

METHODS

Hypertrophic septal tissues were obtained as surgical waste following septal myectomy surgery performed by Dr. Pietro Bajona (IRB AHN #2020-240). Patients include both males and females and range in age from 19 years to 71 years. Healthy human septal tissues were obtained from a tissue bank under the same IRB protocol. For histology, all samples were fixed in 10% neutral buffered formalin for 24 hours and were processed through a standard histological preparation protocol, including alcohol-dehydration and paraffin-embedment. 5 μm sections were cut, and a standard Masson's trichrome staining protocol was performed. Masson's trichrome protocol stains heart muscle red and collagen blue. Histological images were taken under a bright light field using a Nikon Eclipse Ti Series Microscope (Nikon). For light sheet imaging, the iDISCO method employs a three-step process comprising dehydration, dilapidation, and refractive index matching. The method involves the complete removal of lipids and dehydration of the tissue, which largely minimizes light scattering. The organic solvent solution is then used to replace the dehydrated and delipidated tissue with refractive index matching. The light sheet is created with a cylindrical lens, and ETL moves the focal region of the Gaussian beam which is synchronized with the active sensor on the camera. The auto-fluorescence emitting from the heart is captured by the detection objective lens and sCMOS camera. A customized LabVIEW control algorithm is used to synchronize the propagation of the laser, the stage movement, the sCMOS camera rolling shutter, and the electrically tunable lens (ETL). During the image acquisition process, the inherent trigger and rolling shutter on the sCMOS are employed to capture sequential uniform 2D images, while the stage continuously translates the tissue across the light sheet at a constant velocity that is determined by the step size and exposure time.

RESULTS

Masson's trichrome staining revealed that the HCM septal tissues had hypertrophic cardiomyocytes that were significantly larger and disarrayed when compared with the healthy cardiomyocytes (**Figure 1-A,B**). We further showed that the light sheet imaging was able to capture the microstructural differences in muscle fiber orientations and alignment. As shown by light sheet images, the healthy septum showed normal morphology with highly-aligned heart muscle fibers and evenly distributed small interfibrillar space (Figure **1-C**), while the human hypertrophic septal tissues showed disarrayed muscle fiber configurations, with wider interfibrillar space that was unevenly distributed (Figure **1-D**).

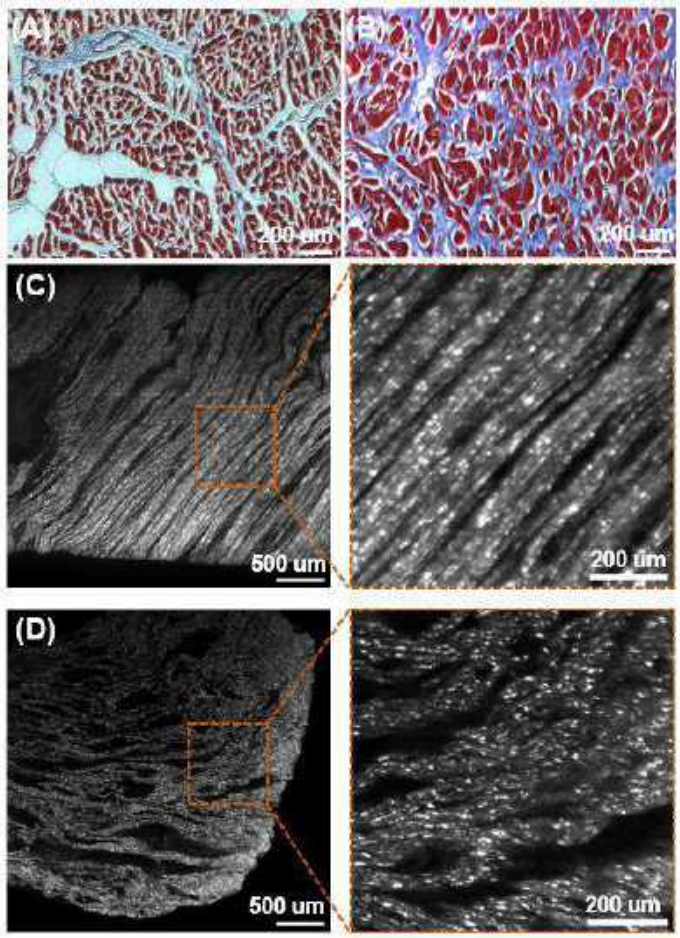

Figure 1: Masson's trichrome images of the healthy (A) and HCM (B) human septal tissues. Light sheet imaging of the healthy (C) and HCM (C) human septal tissues.

DISCUSSION

More detailed quantitative imaging analysis efforts are currently ongoing. In our mechanical study [3], we reported that human hypertrophic septal tissues had larger stress relaxation and larger creep and were stiffer at the initial phase of tissue loading, less nonlinear, less stiff in the linear region, and much weaker in mechanical strength. Both our histological images and light sheet images showed that the hypertrophic septal tissues had a higher degree of disarrayed, enlarged heart muscles and disorganized, higher amount of fibrotic collagen fibers in comparison to the healthy septum. The poorly-organized pathological compositions in the hypertrophic septum resulted in the loss of the benefits of native tissue design. For instance, the higher amount of fibrotic collagen could cause HCM tissues to be stiffer at the initial phase of mechanical loading; however, the pathologically-deposited fibrotic collagen and the disarrayed hypertrophic cardiomyocytes led to a less stiff behavior in the linear region and a much lower mechanical strength of the HCM tissues when compared to the healthy septal tissues [3]. That is to say, the inferior mechanical behavior of the HCM septal tissues can be attributed to microstructural abnormalities.

GENERATIVE MODELING OF CONGENITAL HEART DEFECT ANATOMIES FOR SURROGATE CARDIAC FLOW SIMULATIONS

Fanwei Kong (1), Alison L. Marsden (1, 2, 3)

(1) Department of Pediatrics, Stanford University, Stanford, CA, USA

INTRODUCTION

Congenital heart defects (CHDs) are the most common birth defects and are characterized by abnormal cardiac anatomies that can dramatically impact cardiac functional outcomes. CHD patients often have unique but complex cardiac malformations and anatomical arrangements that warrant patient-specific treatment planning and surgical interventions. Personalized computer models of the heart derived from patient image data can simulate various aspects of cardiac function. They can thus model complex clinical scenarios in CHD patients and have demonstrated the potential to facilitate personalized treatment planning and decision-making [1]. However, creating digital twin models of patients' hearts and tuning computational model parameters to match clinical measurements requires prohibitive time and computational efforts for practical clinical uses.

Deep learning (DL) methods have demonstrated potential in developing surrogate computational fluid dynamics (CFD) models to enable rapid hemodynamic prediction within patient-specific aorta geometries [2]. Such methods train neural networks on a large dataset containing various physiological aorta anatomies and the corresponding CFD solutions to approximate the mapping between the input geometric space and the flow field solution space. However, CHDs, particularly the more complex types (e.g. double outlet right ventricle and hypoplastic left heart syndrome), are rare conditions. This rarity makes it extremely challenging to acquire sufficiently large patient cohorts and develop DL-based surrogate methods. Furthermore, CHDs encompass a broad spectrum of rare topological variations among different defect types, making it practically impossible to assemble a comprehensive training cohort from clinical imaging data alone.

We thus designed a generative model to tackle the complex task of representing whole-heart cardiac anatomies for a wide range of CHD types [3]. We now apply this model to generate synthetic time-series cardiac anatomies, which we use to perform one-way coupled deforming domain CFD simulations to capture changes in the flow patterns and pressure fields within the left and right ventricles in response to variations in cardiac anatomies and structural abnormalities.

METHODS

Our approach, as presented in Figure 1, enables type-controlled generative modeling of cardiac anatomies, allowing us to create synthetic cardiac anatomies tailored to specific CHD types and conditions. We represent the CHD type-specific heart anatomies and the corresponding abnormalities implicitly using a smooth signed distance function (SDF) learned by Lipschitz-regularized neural networks. This function takes in a CHD diagnosis vector as input and outputs a signed distance field to capture the corresponding unique topologies of complex cardiac anatomies. We learn diffeomorphic deformations using neural ordinary differential equations [4] to morph the anatomies to capture shape-specific anatomical variations in patient cardiac models while preserving the CHD structural anomalies.

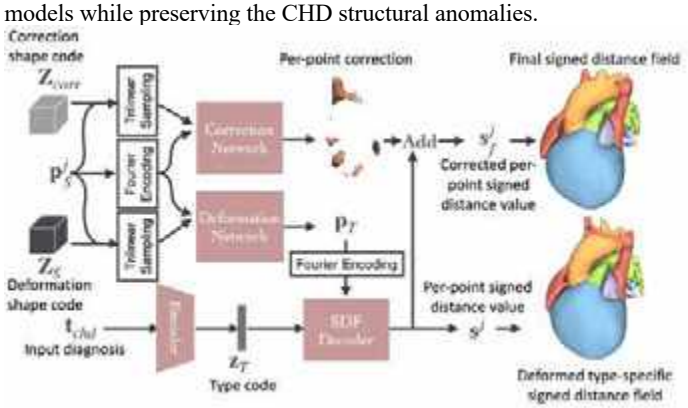

Figure 1: Overview of our generative DL method to generate various types of CHD anatomies.

We used a deformation shape code and a correction shape code to encode the anatomical variations among patients besides the type-

specific abnormalities modeled by the SDF. Leveraging a training dataset containing 67 ground truth anatomies of various CHD types and the corresponding diagnosis information, we learn the posterior probability distribution of the shape codes that best represent the training anatomies. Assuming a Gaussian prior, we can sample a shape code from the prior distribution to construct realistic cardiac anatomies for a specific CHD type beyond those included in the training dataset. Additionally, by interpolating between different CHD-type codes while fixing the shape code, our method can generate meaningful intermediate anatomical representations that are developmentally reasonable and reflect varying degrees of disease severity and anatomy (Figure 2). Further details of this method can be found in [3].

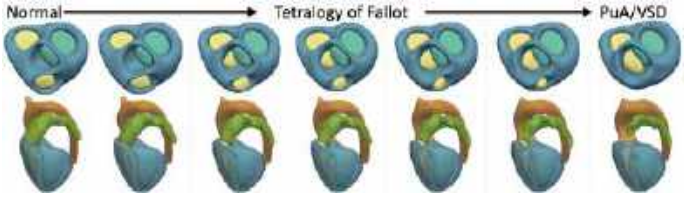

Figure 2: Interpolated cardiac anatomies between normal, Tetralogy of Fallot (ToF) and pulmonary atresia (PuA).

We applied realistic motion obtained from a set of time-series image data (n=10) to the generated CHD cardiac anatomies. Namely, for each time-series image data, we optimize a set of shape codes $\{Z_{time}\}_0^T$ to additionally model the shape changes due to cardiac motion. We then randomly select a set of time-series shape codes and apply them to morph a template mesh derived from the learned CHD type-specific anatomies to generate time-series meshes suitable for CFD simulations. To optimize $\{Z_{time}\}_0^T$, we first freeze the trained network and optimize shape code Z_s to morph the type-specific anatomy to match the patient-specific anatomy obtained from the first time point of the time-series image data. We then freeze both Z_s and the network and optimize Z_{time} to match the deformed type-specific anatomy to the patient anatomy at all other time points. We create template meshes containing the ventricles and the aorta and pulmonary outflow tracks from the CHD type-specific anatomies using SimVascular Python API.

We created volume meshes at the start of systole and simulated the ejection phase of the ventricles. Cubic spline interpolation was applied to obtain 500 interpolated meshes to impose the movement on the volume mesh. We applied the ArbitraryLagrangian-Eulerian (ALE) formulation of the incompressible Navier-Stokes equations with a stabilized FE finite-element Galerkin method implemented in the open-source software package svFSI [5] to simulate the intraventricular flow and account for the moving boundary. Pressure boundary conditions of 100 and 20 mmHg were assumed at the aorta and pulmonary outlets, respectively, for all anatomies.

RESULTS

Our method can generate time-series CHD anatomies meshes for CFD simulations, and the generated cardiac meshes include anatomical abnormalities for specific CHD types. For example, as demonstrated in Figure 3, the generative cardiac mesh for a ToF case presents the overriding aorta, a big ventricular septal defect (VSD, a hole between two ventricles), and pulmonary outflow tract stenosis (PS). To demonstrate the capability of our method in generating synthetic CHD cardiac anatomies and the corresponding flow and pressure field data, we conducted CFD simulations of cardiac ejection for a range of synthetic geometries with increasing severity of the above defects. As shown in Figure 4, the simulated pressure field revealed the increasing trend of right ventricle pressure overload, the flow shunting between the two ventricles through the VSD, and flow acceleration through the narrowed pulmonary outflow tract.

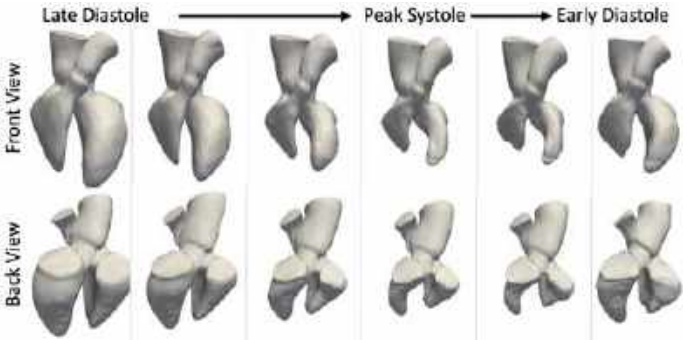

Figure 3: Example time-series meshes of a ToF anatomy.

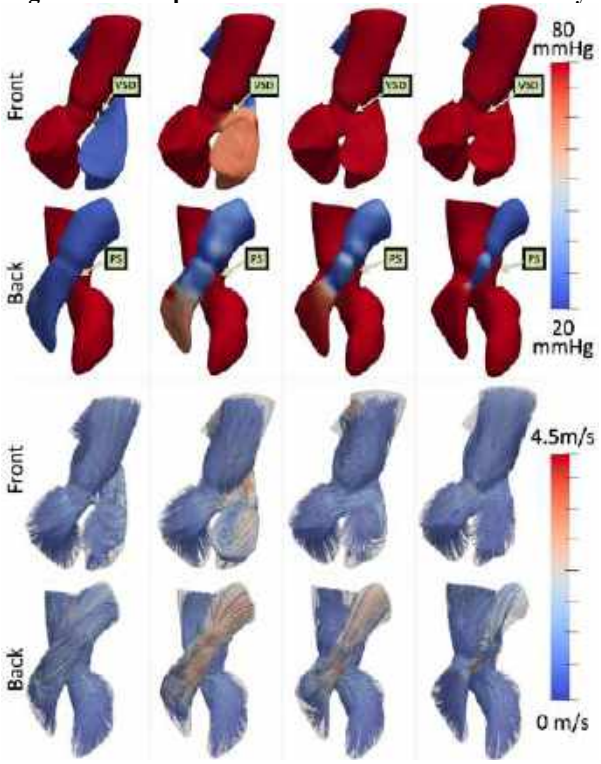

Figure 4: Simulated pressure field and velocity streamlines for CHD anatomies with increasing severity of VSD and PS.

DISCUSSION

DL-based surrogate models can enable rapid flow and pressure field estimation within patient-specific cardiovascular anatomies. However, developing such a model requires a large training dataset, which is challenging to obtain for rare diseases such as CHD. We tackle that challenge with a generative modeling approach to generate synthetic times-series cardiac anatomies that can be used to generate synthetic pressure and flow field data to support DL applications. Future work will include assigning more realistic boundary conditions based on closed-loop lumped parameter models and training neural network models to approximate cardiac flow within CHD anatomies to enable efficient cardiac digital twinning.

LOCALIZED GROWTH RATE ANALYSIS ON A GLOBAL ENSEMBLE AVERAGING OF ABDOMINAL AORTIC ANEURYSM GROWTH

INTRODUCTION

An abdominal aortic aneurysm (AAA) is a socially relevant vascular disease with an unpredictable growth rate an 80% overall mortality rate. It forms as a confined enlargement of the aorta (≥ 3 cm in diameter) that mainly develops between the renal arteries and aorto-iliac bifurcation. The maximum diameter of an AAA is measured as part of the clinical management process using an ultrasound or computed tomography (CT) exam while under surveillance. In the United States, a maximum diameter of 5.5 cm for men and 5.0–5.4 cm for women with a growth rate of 1 cm/year are the accepted thresholds for surgical/endovascular repair [1]. However, AAA growth patterns during the surveillance period are not fully understood due to insufficient or infrequent imaging. To overcome the shortcomings of the conventional diameter-based growth assessment, Ristl *et al.* [2] investigated volume, while Akkoyun *et al.* [3] evaluated various geometric measures as surrogates for growth rates. Hirose and colleagues [4] proposed that AAA growth follows an exponential behavior over time. Nonetheless, Siika and co-authors [5] claim that AAA growth is linear when measured with diameter and volume. To address this discrepancy, we performed a growth rate analysis with AAA patients under surveillance while using twelve geometric measures as surrogates for growth prediction.

METHODS

Contrast-enhanced CT exams for 40 AAA patients under surveillance (10 females, 30 males) were retrospectively acquired from Northwestern Memorial Hospital (Chicago, IL), Allegheny General Hospital (Pittsburgh, PA), and Seoul National University Hospital (Seoul, Korea), in accordance with established Institutional Review Board guidelines at each clinical center. The follow-ups for each patient ranged from three to seven during the surveillance period. Collectively, 140 CT exams were acquired and used for this study. Binary masks were created using AAAVasc [6] (an in-house MATLAB®-based semi-automated segmentation script) after image segmentation. Volume meshes were generated for each AAA at each imaging follow-up using AAAMesh [7] (another in-house MATLAB®-based script used for volume meshing), which consist of 30,000-90,000 quadratic hexahedral elements.

Growth rates

The exponential expression presented in [3] was used to calculate AAA growth rate according to Eqs. (1) and (2),

$$g = (e^{12r} - 1) \times 100 \quad (1)$$

$$r = \frac{1}{t} \ln \frac{X^{followup}}{X_{baseline}} \quad (2)$$

where *X(.)* is the geometric measure, *t* is the time interval between consecutive scans in months, *r* is the logarithmic growth factor, and *g(.)* is the growth rate of the measure. The Spearman's correlation coefficient was used to quantify the strength of the correlation analysis with growth rate, where a coefficient in the range of 1.00–0.90, 0.90–0.75, 0.75–0.50, 0.50–0.25, and 0.25–0.0, corresponds to a very high, high, moderate, weak, and no correlation, respectively [3].

AAA growth model and growth prediction

The best fit between linear and nonlinear growth models was explored and forecasted using Eqs. (3) and (4),

Linear Growth Model: $Y = \alpha + \beta t$ (3)

Nonlinear Growth Model: $Y = \alpha \times e^{\beta t}$ (4)

where *Y* is the prediction, α is the mean value of the measure (see Table 1), and β is the mean value of growth rate using a first-order time derivative.

Table 1. Geometric measures used to predict growth rate.

V	Vessel volume (cm^3)
V_{ILT}	Volume of intraluminal thrombus (ILT) contained within the AAA sac (cm^3)

D_{max}	Maximum transverse diameter of the AAA sac (cm)
DDr	Maximum diameter to neck diameter ratio
S	Vessel surface area (cm^2)
T	Tortuosity
γ	Ratio of AAA ILT volume to vessel volume
H	Height of AAA (cm)
H_{sac}	Height of AAA sac (cm)
L	Centerline length of AAA (cm)
L_{sac}	Centerline length of AAA sac (cm)
DHr	Diameter-Height ratio

RESULTS

Figure 1 shows the exponential growth rate correlations for the 12 geometric measures using Eqs. (1) and (2). Similar measures were used in [6] to investigate nonlinear growth rates. Very high correlations were observed for V vs. S (r = 0.99), V vs. D_{max} (r = 0.91) and γ vs. V_{ILT} (r = 0.91) for the nonlinear growth model. However, Starck et al. [8] found that S does not correlate with growth rate. In addition, γ is a secondary variable dependent on V. Therefore, we considered only V vs. D_{max} for further growth forecasting.

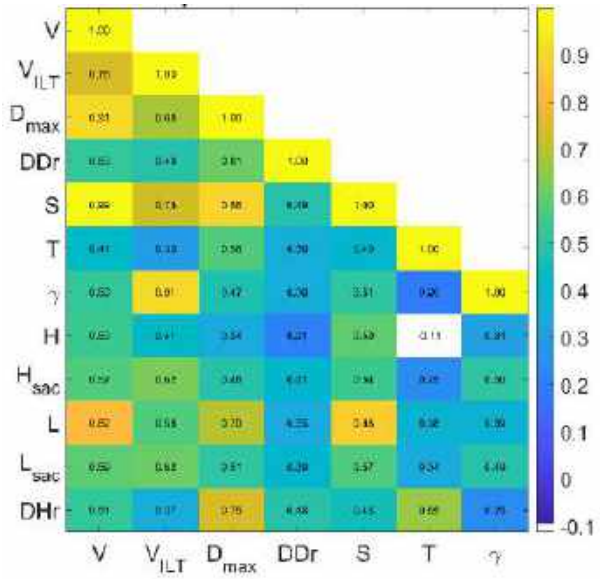

Figure 1. Spearman's correlation coefficients of geometric measures using an exponential growth rate.

Figure 2 illustrates the V vs. D_{max} relationship of the 40 AAA patients over time with a mean (μ) distribution and two standard deviations ($\pm 2\sigma$). The AAA data shows good agreement with the nonlinear growth model, Eq. (4), with almost all within one standard deviation of the mean with a few exceptions. Outliers are observed for 9 patients in the follow-up range of 4 to 6 cm for D_{max}, which is not consistent with other AAA growth models. The follow-up range in volume for these patients is approximately 25 to 75 cm^3. Hence, we investigated the growth of these 9 AAA patients (Group I) in isolation and compared them to the growth of 21 other AAA patients (Group II) that were also within the range of 4 to 6 cm for D_{max} but within one standard deviation of the mean.

Linear and nonlinear growth models were applied to Groups I and II separately using Eqs. (3) and (4), as shown in Table 2. Group II patients, which have a D_{max} between 4 to 6 cm, show R^2 values of 0.708 and 0.699 for the linear and nonlinear growth models, respectively, and with *RMSE* values of 29.72 and 30.17, respectively. Similarly, for Group I, which was outside the two standard deviations of the mean, the linear growth model explains 62.8% of the variance in the growth, with an *RMSE* value of 21.25. Conversely, the nonlinear growth prediction shows that it explains 63.5% of the variance with an *RMSE* value of 21.04.

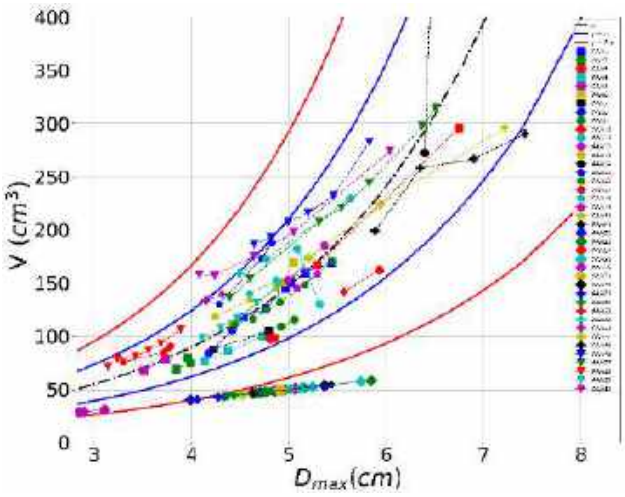

Figure 2. Maximum diameter vs. volume with nonlinear growth model within two standard deviations.

Table 2. Coefficients of determination for Groups I and II according to the predicted growth models.

Growth Model	R^2	
	Group I (n = 9)	Group II (n = 21)
Linear	0.628	0.708
Nonlinear	0.635	0.699

DISCUSSION

An ensemble averaging with curve fitting can define a certain curve that behaves exponentially [4, 9] or linearly [5]. However, the present work indicates that analyzing growth rates locally is necessary for accurate growth prediction. From Fig 2, we observed that Group I patients do not follow the exponential growth rate within two standard deviations of the mean. A separate analysis was performed leading to Group I exhibiting a nonlinear growth while Group II exhibited a linear growth. From these observations, we infer that AAAs with mean volumes of 50 cm^3 during the surveillance experience nonlinear (exponential) growth compared to AAAs with mean volumes of 75 cm^3 or greater, which experience linear growth for the clinically relevant range of maximum diameters of 4 to 6 cm.

INTRODUCTION

Cancer remains to be one of the leading causes of disease-related deaths. To improve cancer treatment, it is critical to identify effective and safe drugs in the early stages of the in vitro drug screening process. However, drug tests relying on 2D/3D static cell culture is inadequate in reaching this goal since physical features of the tissue microenvironment are not incorporated in the assay. In particular, various cell biological functions including drug resistance are modulated by the mechanical environment [1,2]. While the last decade has witnessed development of microfluidic tissue and organ chips as in vitro models with improved physiological relevance [3], examples of such systems that allow systematic and controlled variation of multiple mechanobiological factors e.g. substrate stiffness and fluid shear stress, together with biochemical/drug concentration in multiplexed settings are rare [4,5]. Moreover, prototyping of microfluidic systems typically relies on photolithography that is costly and time consuming, precluding exploration of novel designs to address the drug testing problem.

To address this challenge, this study aims to develop an in vitro multiplexed *mechanochemical gradient chip* (MCGC) in which cell response can be systematically investigated under the influence of controlled gradients of flow-induced shear stress and drug concentration while cells are cultured on surfaces that can be tuned to different levels of uniform physiological stiffness (**Figure 1**). Towards this goal, prototyping of variable-height flow channels as novel design features for shear stress variation is explored in accordance with the capabilities of our recently developed 3D printing-based replica molding micromanufacturing workflow [6]. The current study includes computational design of the microfluidic chip, prototyping of its key features using stereolithography (SLA) as well as cell culture and drug testing on an early device prototype with a focus on mammary carcinoma cells, MCF-7, and chemotherapy drug doxorubicin.

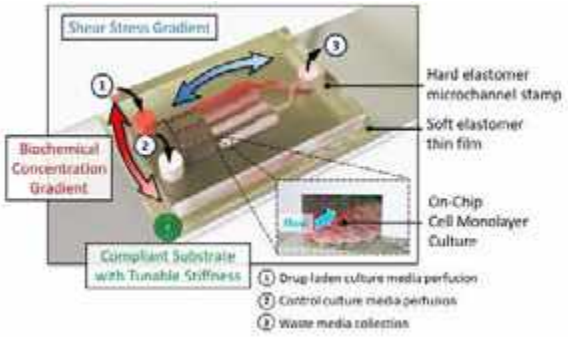

Figure 1: Conceptual design of the mechanochemical gradient chip (MCGC).

METHODS

Computational Modeling: The numerical simulations of fluid flow and species transport were conducted using Comsol Multiphysics under the assumptions of steady-state, laminar flow, and dilute species. Volumetric flow rate and normalized concentration were specified at the inlets and pressure / outflow boundary conditions were specified at the outlets as shown in **Figure 2**.

Device Fabrication: Parametric CAD models of device molds were prepared by a Python program using CadQuery library. Modls were manufactured by Anycubic Photon Mono 4K desktop LCD-SLA 3D printer using 9:1 w/w blend of clear and high-temperature (TR300) resins to prevent mold damage during PDMS baking. Molds were thoroughly washed and cleaned by ultrasonication. PDMS channel stamps were manufactured using Dowsil Slygard 184 using a polymer base to curing agent mixing ratio of 10:1 w/w. The PDMS stamps were bonded on different substrates using air corona treatment. Thin film substrates were produced by spincoating PDMS dielectric gel (Dowsil Slygard 527) on microscopy slides at 750 RPM for 15 seconds. All substrates were cured at 100°C for 210 minutes.

Imaging and Mechanical Characterization: Brightfield and fluoresence imaging of devices and substrates were performed on Nikon Eclipse Ti2 inverted microscope. Elastic moduli of substrates were estimated by measurement of indentation by stainless-steel spheres with diameters ranging between 0.8-4mm under the microscope and use of Hertzian contact theory.

Cell Culture and Drug Testing: Red fluorescent protein (RFP) tagged MCF-7 cells were seeded in channels coated with collagen type I at a concentration of 1 million cell/ml. After 24 hours chips were treated with 10 µM doxorubicin for 2 days. Images were acquired on Days 0 and 3 (0-72 hours) and analyzed by ImageJ.

RESULTS

The conceptual design of the MCGC is provided in **Figure 1**. The device features (i) a tree-like concentration gradient generator for concentration variation within the device, (ii) a culture chamber with single or multiple constant-width variable-height microchannels for shear stress variation within the device, and (iii) a compliant elastomer thin film for culture substrate stiffness variation across devices.

Whether the design leads to the desired functionalities is investigated by numerical modeling of fluid flow and species transport on chip (**Figure 2**). It is found that a well-defined nonlinear concentration gradient can be realized by asymmetric perfusion (1 drug, 2 drug-free media inlets). The nonlinear concentration gradient enables a wide-range drug concentration (20-fold in 6 discrete levels in addition to drug-free control). Similarly, a 10-fold variation of wall shear stress within physiological range is predicted across the bottom surface of the variable-height (step-wise) culture channel. Overall, the model predictions indicate that simultaneous variation of drug concentration and shear stress in orthogonal directions can be realized on MCGC.

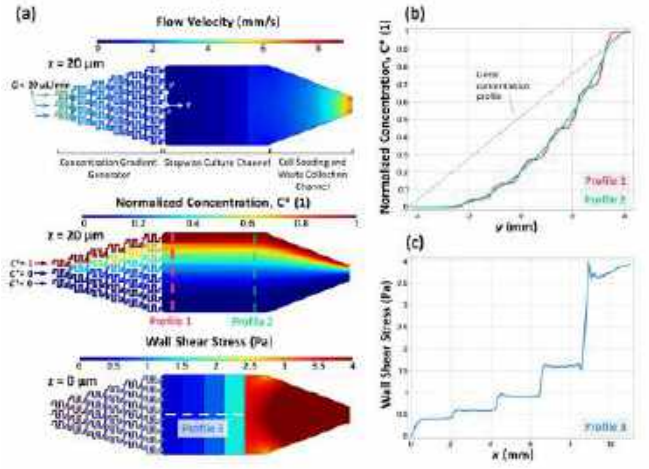

Figure 2: Numerical modeling of fluid flow and species transport. (a) Flow velocity, concentration, shear stress contours. (b) Concentration and (c) wall shear stress across indicated profiles.

Next, major design features of MCGC were fabricated and characterized (**Figure 3**). We recently developed an optimized SLA-based workflow where a CAD model of master molds are prepared by accounting for resolution limits of SLA, printed with temperature resistant resin and thoroughly cleaned by sonication to enable proper curing of PDMS stamps in the mold [6]. With this technique, variable-height microchannels with 5-fold height variation could be produced as intended. For cell culture studies, an initial prototype of the device was produced by assembling a PDMS stamp featuring a single straight microchannel (Slygard 184) with a elastomer thin film (Slygard 527, 61 ± 3 µm thick). The elastic modulus of the film was measured as 1.4 ± 0.3 kPa, in agreement with physiological stiffness [7].

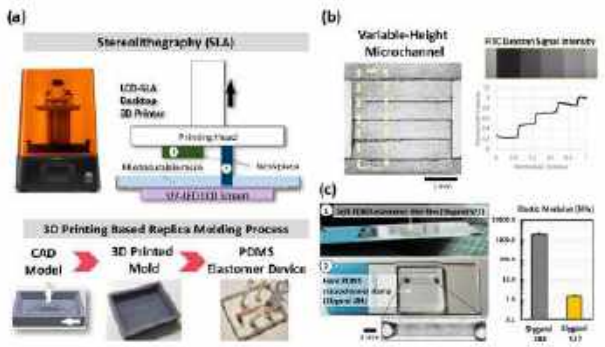

Figure 3: Fabrication characterization of device design features.

Culture of RFP-MCF7 on prototypes where 10 µM doxorubicin was introduced to the channel on day 1 and retained for the next 48 hours indicate that proliferation decreased approximately 2.5-fold in the presence of the drug compared to drug-free control (**Figure 4**).

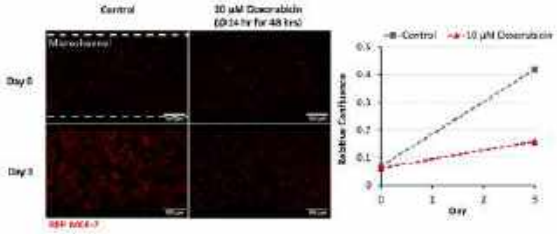

Figure 4: On-chip cell culture and drug treatment on prototype. Proliferation of MCF-7 in microchannel under doxorubicin treatment and untreated control conditions.

DISCUSSION

A microfluidic cell culture platform featuring mechanochemical gradients and physiological substrate stiffness was designed. Novel design features were fabricated and characterized. Cell culture and drug testing on a simplified prototype were illustrated. These early findings provide promising grounds for high-fidelity in vitro models that intersect mechanobiology and drug testing.

INTRODUCTION

Finite element (FE) simulations are an emerging approach to predict *in vivo* heart valve function. Over the past two decades, several research groups developed in-house solvers, leveraged commercial software packages, or contributed to open-source frameworks with the goal of predicting *in vivo* valve function [1-3]. To this end, we established an *open-source pipeline* to create image-derived FE simulations of heart valve function [3]. We demonstrated that this pipeline provides meaningful comparisons of heart valve function independent of leaflet material properties [4]; however, we have not yet demonstrated acquisition of leaflet deformation from 3D images.

Rego *et al*. [5] developed a sub-routine to constrain FE simulations of heart valve function to medial approximations of the leaflet surface from cardiac images. The authors showed that this method provided accurate predictions of leaflet strains when compared to *in vitro* marker-derived strains. This paradigm has significant translational potential for the assessment of image-derived leaflet strains *in vivo* [6-7].

The objective of this work is to establish an open-source FE shape enforcement method in FEBio, leveraging the sliding-elastic interface and using the augmented Lagrangian method for constraint enforcement. Our central goal is to build upon existing efforts to provide a clinically accessible, generalized workflow for obtaining *in vivo* strains. We used two synthetic mitral valve (MV) test cases to evaluate the efficacy of the method. It is then applied in a proof-of-concept prediction of *in vivo* leaflet strains from 3D echocardiographic images of a child with congenital heart disease (CHD).

METHODS

Finite Element Simulations.

FE Mesh and Material Behaviors. The heart valve leaflets were discretized with linear quadrilateral shell elements and constitutive behavior was represented by the Lee-Sacks model [1] (**Fig. 1**). To obtain the target configuration for the synthetic test cases, the chordae tendineae were represented by tension-only linear springs (emulating [8]) connecting the papillary muscle nodes to the leaflets. The target mid-systolic leaflet surface was represented by a fixed rigid body with shell elements.

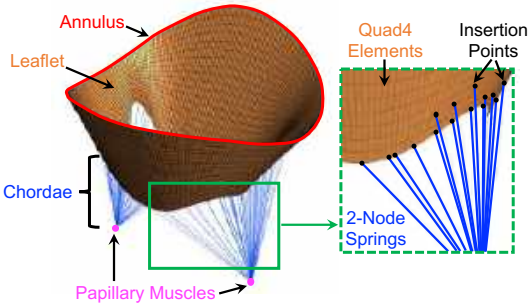

Figure 1: Mitral Valve Simulation in FEBio. The stereotypical MV is modeled using a combination of shell and spring elements.

Boundary and Loading Conditions. Heart valve closure and shape enforcement were simulated in two successive dynamic analysis steps. In the 1st step, a linearly ramped 100 mmHg pressure was applied to the ventricular leaflet surface over 0.05 s and maintained for an additional 0.05 s to achieve steady state. In the 2nd step, the sliding-elastic interface between the simulated and the target leaflet surfaces was enabled.

Chordae Emulating Force. The chordae tendineae were approximated during shape enforcement by a chordae-emulating force (CEF) to improve convergence. The force was applied to the leaflet free edge nodes normal to the annulus plane, and linearly ramped like the applied ventricular pressure. We varied the constitutive model parameters and CEF to determine the optimal CEF that minimizes discrepancies between the shape enforcement results and the known (synthetic) test case. Comparisons were made using the Kolmogorov-Smirnov test.

Sliding-Elastic Interface. The sliding-elastic interface in FEBio seeks

to enforce contact between two surfaces by minimizing the surface-surface gap function [9]. We used a two-step process in which the gap function was: (1) linearly penalized to gradually reduce the surface-surface distance and (2) minimized by approximating the Lagrangian multipliers using the augmented Lagrangian approach.

Simulation Test Cases. We established three test case geometries.

Test Case 1: Simplified Mitral Valve Contact. The first synthetic test case considered contact between the center of two mitral valve leaflets. The target (mid-systolic) surface was achieved by prescribing a ventricular pressure of 13.3 kPa (100 mmHg), and shape enforcement was performed considering one-half pressure (6.66 kPa).

Test Case 2: Stereotypical Mitral Valve. The second synthetic test case considered a stereotypical mitral valve geometry. Like Test Case 1, the target synthetic surface was obtained using a pressure of 13.3 kPa, whereas the shape enforcement considered one-half pressure (6.66 kPa).

Test Case 3: In Vivo Proof-of-Concept. The shape enforcement technique was used to predict *in vivo* leaflet strains for a pediatric patient with CAVC. Unlike the two synthetic cases: (1) the target mid-systolic leaflet surface was obtained from the patient's cardiac images [3], (2) the annulus followed the *in vivo* dynamic motion, and (3) the shape enforcement considered 13.3 kPa approximate ventricular pressure. This was done in accordance with a protocol approved by the Institutional Review Board at the Children's Hospital of Philadelphia.

RESULTS

Tissue Stretch-Dependent Chordae Emulating Force. We found that the optimal CEF depends on the peak stretch of the constitutive model (**Fig. 2**). The relationship for c_0 is independent from that of c_1 and c_2.

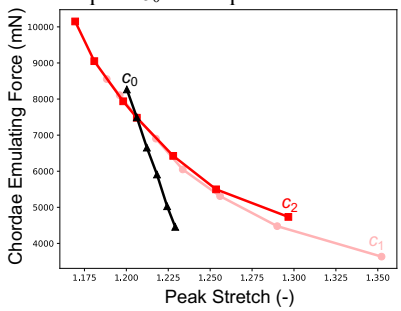

Figure 2: CEF Optimization. The optimal chordae emulating force is related to the tissue stretch, and independently relies on the c_0 term.

Shape Enforcement Accurately Predicts Leaflet Strains. We found that shape enforcement provided good predictions of the synthetic results (**Fig. 3**). The error was larger for the complete MV in the anterior leaflet (~0.1 vs. ~0.03), suggesting there is room for improvement.

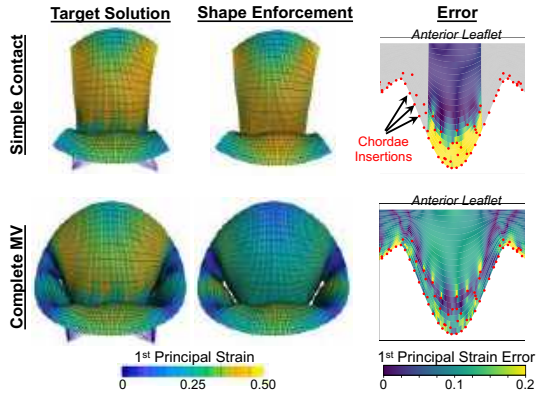

Figure 3: Synthetic Test Cases. Shape enforcement provided excellent agreement with the synthetic test cases.

Patient-Specific Leaflet Strains for Pediatric Patient with CHD. The FE Simulation with shape enforcement for the *in vivo* proof-of-is shown in **Figure 4**. Interestingly, the in-plane principal strains show the valve experiences a combination of tension and compression *in vivo*.

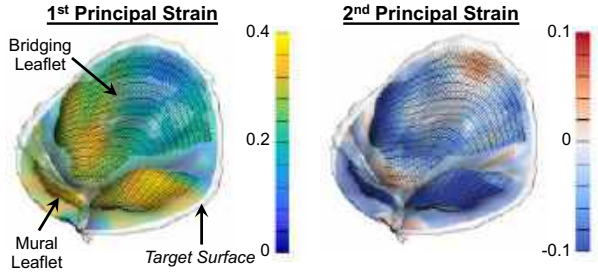

Figure 4: Patient-Specific Shape Enforcement. The simulation provided good visual agreement with the target surface. This patient-specific valve experiences in-plane tension and compression *in vivo*.

DISCUSSION

In this investigation, we evaluated the FEBio sliding-elastic interface for shape enforcement of heart valve simulations fit to mid-systolic leaflet surfaces. The shape enforcement simulations were simplified by replacing the chordae tendineae with a "chordae-emulating force" applied to the free edge of the leaflets [5]. We found that the optimal CEF depends on the tissue extensibility, and the modulus of the Neo-Hookean term (c_0). Next, we showed that our proposed method reproduces the valve leaflet strains for two synthetic test cases. This approach was insensitive to the choice of applied pressure and noise in the target surface (not shown here for brevity). However, we did note the anterior leaflet strain predictions were worse for the complete MV geometry. Finally, we extended the method to predict *in vivo* leaflet strains for a pediatric patient with a complex CHD. This work cumulatively provides a new open-source means for predicting *in vivo* heart valve strains with FE simulations.

There are several limitations and extensions of this work. First, although shape enforcement has been previously validated [5], it would be prudent to perform a similar assessment of our new shape enforcement method. Our forthcoming work will provide the experimental data to accomplish this, and we have currently opted to use synthetic computational data for this purpose. Second, we have only showcased one *in vivo* proof-of-concept. Expanding this effort to consider more patients and different CHD is an ongoing effort in our research group. Third, the CEF must be optimized to minimize its impact on the predicted strains. Future efforts may enhance the method to include additional anatomical constrains (e.g., free edge) between the surfaces. Finally, we only predict the mid-systolic leaflet strains. In the future, we will consider adding multiple time points throughout the cardiac cycle to create true "dynamic" simulations, and improve predictions of complex behaviors (e.g., commissure folding).

INTRODUCTION

Neck and back pain are commonly reported ailments for fighter pilots around the world, with up to 97% of fighter pilots reporting neck pain (1). This pain is often exacerbated by essential neck rotations during flight, such as "checking six," that places the pilot in an awkward and vulnerable position while experiencing high G_z forces on the neck and back (1).

Exposure to high G_z forces may contribute to early functional changes in the spine. Fighter pilots exhibit decreased cervical spine range of motion (CROM) compared to civilians, and older pilots exhibit decreased CROM compared to younger pilots (2,3). Fighter pilots also exhibit signs of increased spinal degeneration compared to civilians (4). Petran-Mallmin demonstrated that even asymptomatic fighter pilots exhibit more osteophytes, disc protrusions, spinal cord compressions, and foraminal stenosis compared to age matched controls (5).

The etiology of neck and back pain experienced by fighter pilots has not been clearly defined. This study aims to determine the etiology of this pain by exploring both chronic and acute pain utilizing pain assessments and MRI scans.

METHODS

Wisconsin Air National Guard (WIANG) fighter pilots completed baseline demographic and flight history surveys, pain assessments, cervical spine supine MRIs, and upright cervical and lumbar spine MRIs. Pilots completed the Pain-DETECT pain assessment at baseline to quantify the nature of their pain. The most common descriptions chosen for the course of pain were "persistent pain with slight fluctuations" and "persistent pain with pain attacks". These two responses were used to place pilots into either a constant pain group or a group that had pain flare ups likely associated with activity.

The Pfirrmann grading scale was used to grade cervical and lumbar intervertebral discs for degeneration (6). Ratings and measurements were completed on mid-sagittal T2-weighted images.

Normalized disc height was quantified for C2-3 to C7-T1 and T12-L1 to L5-S1. The anterior, middle, and posterior disc and vertebral body heights were measured, averaged for the three measurements, and average disc height was divided by average inferior vertebral body height for normalization. Lumbar and cervical posterior disc bulge was measured using a previously described methodology (7).

All statistical analyses were conducted in RStudio 2023.03.0. Non-parametric statistics were utilized when a Shapiro-Wilk normality test revealed a non-normal distribution. Kruskal-Wallis rank sum tests were used to test for differences between supine and upright cervical MRI measurements and differences between the pain type groups. Wilcoxon signed rank tests were used to determine significant pairwise differences. A significance level of $p<0.05$ was used for all tests.

RESULTS

Sixteen WIANG fighter pilots participated in this study with an average age of 39.3 (range: 28-49) years and an average of 2,312 (500-3,500) military flight hours.

Sixteen pilots participated in supine MRI scans and fifteen pilots participated in upright MRI scans. Ninety-six cervical discs (levels C2-3 to C7-T1) and 84 lumbar discs (levels T12-L1 to L5-S1) were analyzed. The total of disc grades for each pilot was not correlated with age (cervical: $p=0.59$, lumbar: $p=0.34$). One pilot had a grade IV disc at C2-3 and seven pilots had a grade IV discs at L5-S1. The most common location of degenerated discs (grade II and above) was C2-3, C3-4 and L5-S1. Fifty-five percent and 67% of cervical and lumbar spine discs were classified as healthy (Pfirrmann grade I) respectively.

The intrarater reliability of disc height measurements was 0.878, using Pearson's correlation coefficient.

Normalized disc height was related to cervical spinal level ($p<0.001$). Normalized C7-T1 disc height was smaller than all other cervical discs ($p<0.001$). The Cobb angle and posterior disc height were dependent on the type of MRI. Cervical Cobb angle was greater for subjects during the upright scan compared to the supine scan ($p=0.05$). Measured posterior disc height was greater in the supine scans at C2-3 ($p=0.007$), C3-4 ($p=0.05$) and C4-5 ($p=0.02$) compared to measured posterior disc height in the upright scans. Disc bulge was different between cervical spinal levels for both supine ($p<0.001$) and upright ($p=0.03$) MRI scans. The largest disc bulge tended to occur between C4-5 and C6-7. There were no differences in disc bulge measurements between the supine and upright scans ($p=0.43$).

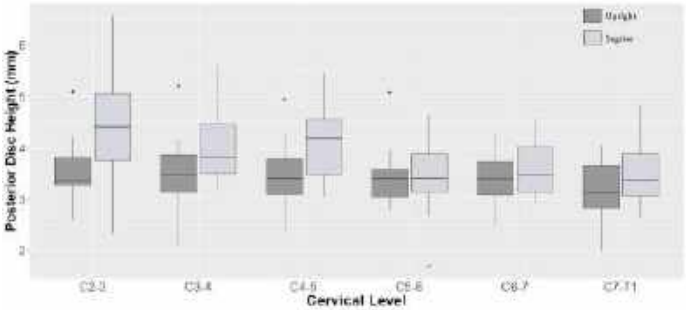

Figure 1: Posterior intervertebral disc heights for the cervical spine for upright and supine scans.

There was no difference in age ($p=0.45$) or total military flight hours ($p=0.51$) between the two pain groups.

There were no differences in normalized disc height across the cervical spine in the supine or upright scans between the pain flare up group and the constant pain group. There was a trend toward decreased disc height at C2-3 (supine: $p=0.18$) and C3-4 (supine: $p=0.22$; upright: $p=0.15$) for the pain flare up group compared to the constant pain group. The pain flare up group displayed a trend toward increased average cervical Pfirrmann grade (median: 1.75; range: 1.5-2.2) compared to the constant pain group (median: 1.42; range: 1-1.83) ($p=0.09$).

Normalized disc height was related to lumbar spinal level ($p<0.001$). Normalized disc height increased from T12-L1 to L3-4, then remained steady until L5-S1, where height decreased ($p's<0.1$). The pain flare up group demonstrated decreased normalized disc height at T12-L1 compared to the constant pain group ($p=0.02$). The constant pain group displayed a trend toward an increased average lumbar Pfirrmann grade (median: 1.83; range: 1-2.17) compared to the pain flare up group (median: 1.25; range: 1-1.83) ($p=0.13$).

Lumbar spine disc bulge size was related to lumbar spinal level ($p=0.02$). The disc bulge size was greater for caudal lumbar discs. The constant pain group had increased disc bulge size at the L5-S1 disc compared to the pain flare up group ($p=0.02$).

DISCUSSION

This study explored cervical and lumbar spine degenerative intervertebral disc changes experienced by fighter pilots and compared those changes between two pain groups: constant pain and pain flare ups. Our sample of fighter pilots exhibited disc degeneration in the upper cervical spine (C2-3 and C3-4). Cervical disc degeneration in fighter pilots has previously been reported to occur at C5-6 (4,8). Our sample of fighter pilots exhibited degeneration at a higher level in the cervical spine compared to previous studies; this may be related to the extreme head positions and rotations necessary during flight.

Our sample of fighter pilots also exhibited the most extreme disc degeneration in the lower lumbar spine, specifically L5-S1. This finding is confirmed by other studies investigating spinal changes in fighter pilots (8,9). Fifty percent (7/14) of the L5-S1 discs examined were given a Pfirrmann grade IV. This high prevalence of severe degeneration is not found in the civilian population at any age. Civilians aged 61-70 have the highest reported prevalence of grade IV degeneration at L5-S1 at around 20% (10). Fighter pilots enrolled in this study demonstrated increased and more severe degeneration in the lower lumbar spine compared to civilians at a much older age.

Differences were also observed in comparing supine and upright measurements. Upright MRI places subjects in a position where the cervical spine bears the weight of the head and the lumbar spine bears the weight of the body. This led to increased cervical lordosis. Accordingly, posterior disc height was also decreased, and disc bulge increased in the upper cervical spine for upright MRI scans. These types of findings may help to explain differing pain symptoms and severity in fighter pilots compared to the civilian population.

To our knowledge, this is the first study to explore structural etiology for differing pain presentations in fighter pilots. These preliminary findings demonstrated that the pain flare up group may have increased upper cervical spine degenerative changes. Three of the four pilots in the pain flare up group had the lowest upper cervical spine disc heights. The lack of statistical significance between the two pain groups is most likely due to the small sample size. Most fighter pilot MRI studies have focused on comparing fighter pilot scans to age-matched control subjects and have not focused on differences related to pain characteristics. Rintala et al. compared cervical and lumbar MRI findings to pain complaints and found no significant associations; this study focused on a much younger sample of pilots (11). Our sample encompassed pilots of various ages, allowing the unique opportunity to more thoroughly explore pain related to functional changes.

Our study will follow the same sample of fighter pilots over the next three years. Previous studies reported that cervical spine degeneration occurred at an increased pace in fighter pilots compared to controls (12). Our study will compare MRI scans at timepoints twice a year for three years to track the accelerated degenerative changes related to high G_z exposure in both the cervical and lumbar spine.

INTRODUCTION

Standardizing spine biomechanical testing is challenging due to a wide array of factors – from testing and measurement equipment variability to specifics of test protocol and specimen handling. In this study, seven international laboratories aimed to characterize the magnitude of variability in biomechanical testing outcomes when each laboratory used their "standard" equipment, experimental procedures, testing protocols, data collection, analysis tools, and data management systems. The objective of this study was to quantify outcome variation during standard practices to identify areas of potential standardization.

METHODS

A total of nine Sawbones synthetic lumbar spinal surrogates were obtained by the labs participating in this study. The group of nine were split into sub-groups of five and four spines, which travelled in opposing order through the seven participating labs. Each lab conducted pure moment testing on the surrogates in Flexion-Extension (FE), Lateral Bending (LB), and Axial Rotation (AR) following whatever protocol was deemed "standard" for the lab. The "standard" approach resulted in a mixture of trapezoidal and sinusoidal loading schemes, testing rigs, bending measurement methods, and fixturing choices, summarized in Table 1. Each lab reported the joint translations and rotations for the overall specimen in a joint coordinate system (JCS). The consortium met monthly to discuss findings as each group completed testing on the set of five spines. R was used to perform a linear mixed effects analysis on the effects of test rig, loading approach, and resetting on the resulting bending measures for each loading direction.

Table 1: Summary of equipment and testing choices for each lab. Quantity of each choice denoted by bolded number.

Summary Equipment Table					
Test Rigs	Testing Approach	Specimen Removal	Software	Load Cell	Measurement Method
Robotic Arm **4** -KUKA (3) -Denso (1)	*Primary:* Trapezoidal, *Secondary:* Sinusoidal **2**	No specimen removal/resetting during testing **5**	simVITRO **4**	ATI **4**	NDI **4**
Universal Testing Systems (UTS) **2** -Instron (1) -MTS 1)	*Primary:* Sinusoidal, *Secondary:* Trapezoidal **3**	Specimen removal/resetting during testing **2**	NDI **1**	AMTI **1**	Motion Analysis Corp **2**
Custom Gantry Robot **1**	Sinusoidal Only **2**		Omron **1**	JR3 **1**	From Testing Rig **1**
			Instron **1**	Instron **1**	

RESULTS

The data in this study is only reported for the group of five spines. All labs reported, at a minimum, the rotation angles (in degrees) in FE, LB, and AR for the JCS kinematics of each of the L2-L5 lumbar spinal surrogates. This resulted in average

rotation values in the six primary testing directions as follows: flexion (14.8±2.7°), extension (9.9±1.7°), left lateral bending (11.2±1.6°), right lateral bending (11.8±1.6°), left axial rotation (4.5±1.0°), and right axial rotation (3.8±0.8°). However, reporting these average values alone does not properly capture the variability in bending measures that the surrogates experienced throughout the testing sequence. The following significant effects were identified:

- Test rig had a significant effect on flexion (p = 0.005), raising it 1°±0.26° when using a UTS system over other choices (Figure 1).

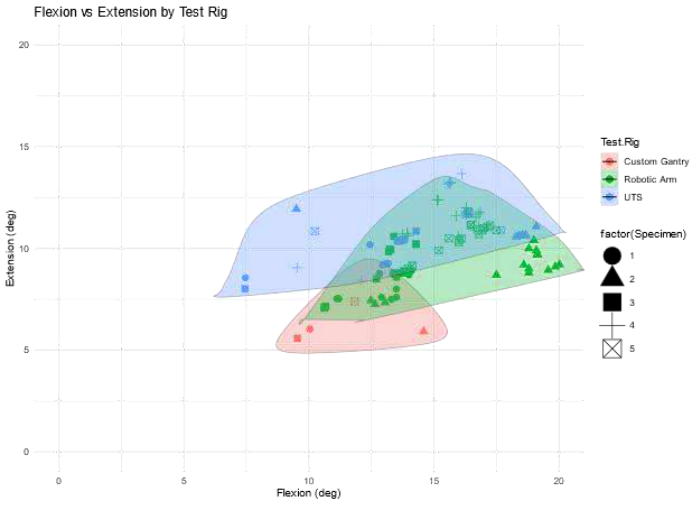

Figure 1: Flexion/Extension data compared against Test Rig.

- Loading approach alone had a significant effect on right axial rotation (p = 0.03), raising it 0.4°±0.17° (Figure 2).

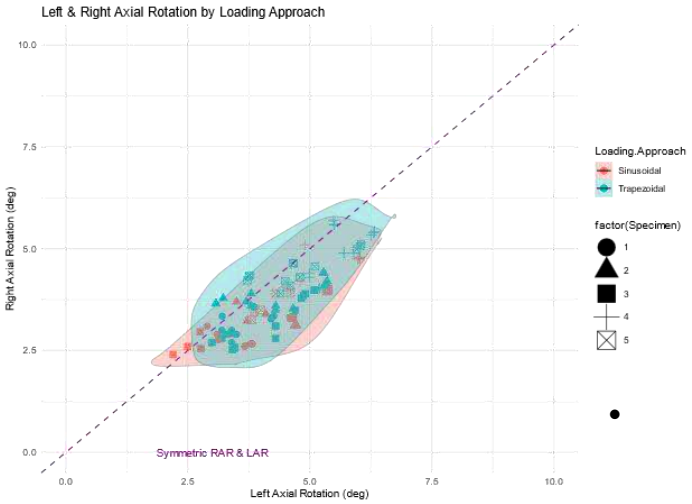

Figure 2: Axial Rotation data compared against Loading Approach.

- Test rig combined with loading approach significantly effected flexion and extension (p = 0.005 and 0.001, respectively).
- Test rig combined with resetting had a significant effect on flexion and extension (p = 0.003 and 0.002, respectively), decreasing flexion but increasing extension by 1.1°±0.3°.

DISCUSSION

This dataset can be used to establish best practices with respect to equipment, procedures, loading protocols, and data analysis. Differences in measured range of motion in each of the testing directions may only be partially accounted for by variability in the specimens themselves. A mixture of testing equipment was used by the participating labs, which may account for differences in both measurement and reporting. Additionally, differences in loading profiles (trapezoidal vs sinusoidal), as well as choices made regarding which trials of testing are representative of true specimen bending, may also impact reported measures.

The group of four spines will also be analyzed for variance in biomechanical behavior and facilitate removal of time as a variable in assessment for the full group of nine specimens due to their alternate path through the participating labs than the group of five spines.

Future work will be conducted to characterize the effects of these factors to identify potential best practices for future spine biomechanical research. Inter-laboratory studies are a crucial part of the standardization of any test protocol and for the wider dissemination of best practices. The labs in this group are representative of global biomechanics labs and will be able to help make recommendations regarding how equipment and protocol execution may impact data accuracy for future spine biomechanics testing.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Sawbones for funding and support of the transportation of the spine surrogates between the participating labs.

IN SITU ROBOTIC MECHANICAL TESTING OF RAT TIBIOFEMORAL JOINTS

Olivia L. Dyer (1), Stephanie G Cone (1)

(1) Biomedical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

Small animal models are frequently employed in orthopaedic research including studies of the tibiofemoral (knee) joint. While there have been many innovations in imaging, biological, and behavioral analyses of rat and mouse models [1], there have been relatively few innovations in the biomechanical testing of small animal joints in recent years. Improved biomechanical analysis techniques are of great importance for the direct translation of findings in preclinical studies to biomedical research in human medicine due to the prioritization of functional outcomes in orthopaedic clinical decision making [2]. The current standard for biomechanical testing in rodent joints involve uniaxial manipulation, isolating the load-deformation relationships in a single plane of motion. However, joint function – for example in the knee – cannot be simplified to a single plane. In healthy motion, and even more so in injured cases, joint alignment varies through a series of rotations and translation in all six degrees of freedom to optimize tissue loading and joint stability. To account for these complex motions in biomechanical assessments, the objective of this study was to establish a multi-axial robotic testing system for small animal joint testing, and to apply the system to an orthopaedic topic of great interest: anterior cruciate ligament (ACL) rupture. We hypothesized that ACL rupture would result in destabilization of the rat knee joint in multiple degrees of freedom as revealed through clinically relevant testing strategies.

METHODS

Tibiofemoral joints were collected post-mortem from mature Long Evans rats (n=6) and stored fresh-frozen wrapped in saline-soaked gauze prior to testing. To prepare the joints for robotic testing, all soft tissue was dissected away above and below the joint capsule, and the femur and tibia were bisected in the center of the diaphysis. The bones were then set in custom printed clamps using dental cement. Specimens were kept hydrated with saline throughout all preparation and testing stages.

Robotic testing was performed using a tabletop 6-degree-of-freedom universal force sensing robotic testing system consisting of a Meca500 robotic arm (Mecademic, Montreal, Canada), a multiaxial load cell (ATI Nano25 IP65), and commercially available software (simVITRO, Cleveland Clinic) (Figure 1). Robotic testing followed a similar workflow to previously published studies in large animal models [3].

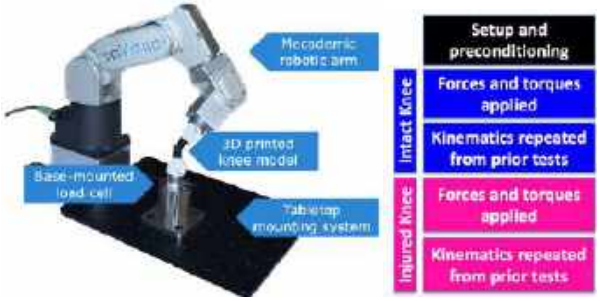

Figure 1: Robotic testing system and testing flowchart.

Briefly, intact joints were affixed proximally to the robotic arm and distally to the load cell and an approximate joint coordinate system was established using digitization of anatomic landmarks based on the Pennock adaptation of the Grood & Suntay convention [4]. The joint was manipulated through passive flexion-extension (20°-60°) and varus-valgus paths (± 0.05 Nm varus torque, @ 40° flexion). For both loading paths, internal rotation was set to 0°, compression loads to 1 N and all other loads minimized. An algorithm was applied to establish functional coordinate systems, redefining the tibia and femur origins and the femur flexion axis [5]. This functional coordinate system was used throughout the remainder of testing to implement the following clinically relevant exams: anterior-posterior (AP) drawer testing at 20°, 40°, and 60° of flexion and varus-valgus (VV) torque testing at 40° of

flexion. Joint flexion angles were limited to a functional working range for the rat knee anatomy, and peak applied forces were set at 2.5N of anterior and posterior force and 0.025N*m of varus and valgus torque due to the size of the joints. This set of AP and VV exams were performed on the intact joint in hybrid control, such that all DOF were controlled with kinetics, except flexion and internal rotation, which were controlled with kinematics. 6DOF kinetics and kinematics were recorded and the resulting kinematics established "intact testing paths". The intact rat knees underwent the "intact testing paths" in kinematic control. Next, the ACL was transected and the AP and VV exams were performed under hybrid control in the injured state. The injured state kinematics were recorded, establishing "injured testing paths". The injured rat knees underwent the "injured testing paths" in kinematic control. Finally, serial dissection was performed with the collateral ligaments, menisci, and posterior cruciate ligament, where the rat knee underwent "intact testing paths" and "injured testing paths" in kinematic control after each sequential dissection. The principle of superposition was used to determine the functional contributions of each tissue under AP forces and VV torques.

Statistical analysis included repeated measures ANOVA testing of joint kinematics and tissue function between injury states (alpha = 0.05).

RESULTS

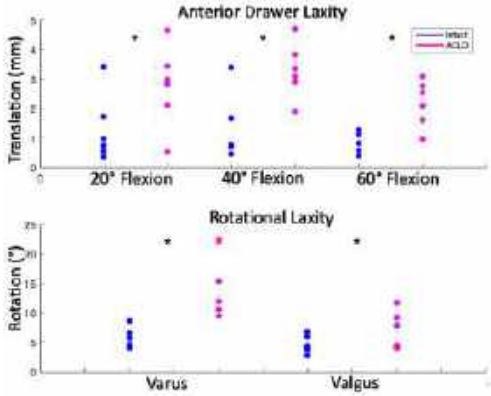

Figure 2: Anterior and rotational laxity increased in all specimens (points) with ACL injury, * represents p<0.05 between states.

Application of anterior-posterior loads (2.5N) and varus-valgus moments (0.025N*m) resulted in mean anterior tibial translations of 1.2 mm and 10.4° of varus-valgus rotation at 40° of flexion (Figure 2, all states summarized in Table 1). Increasing knee flexion during anterior drawer testing resulted in significant decreases in anterior tibial translation within specimens ($p<0.05$ across cases) and decreasing variability between joints. The ACL was the primary soft tissue restraint to anterior tibial drawer across flexion angles (percent load carriage across flexion angles: 51% @ 20°, 94% @ 40°, 97% @ 60°) and contributed significantly to resisting varus-valgus torques.

Table 1: Anterior, varus, and valgus laxity measures (mean ± std).

Anterior translation laxity (mm)			
Flexion angle	20°	40°	60°
Intact	1.30±1.13	1.29±1.10	0.76±0.37
ACL-injured	2.77±1.37	3.31±0.93	2.19±0.79
Rotational laxity at 40° flexion			
	Varus	Valgus	
Intact	5.64°±1.74°	4.71°±1.48°	
ACL-injured	15.34°±5.77°	7.58°±2.94°	

ACL injury resulted in a significant increase in joint laxity across all tests, with 2- to 3-fold increases in anterior tibial translation, 3-fold increases in varus rotation, and 2-fold increases in valgus rotation (Figure 3, Table 1). Following ACL rupture, anterior drawer forces were restrained by the MCL and menisci, varus torques by the medial meniscus and the LCL, and valgus torques by the lateral meniscus and the MCL. Valgus rotations were least affected by ACL rupture.

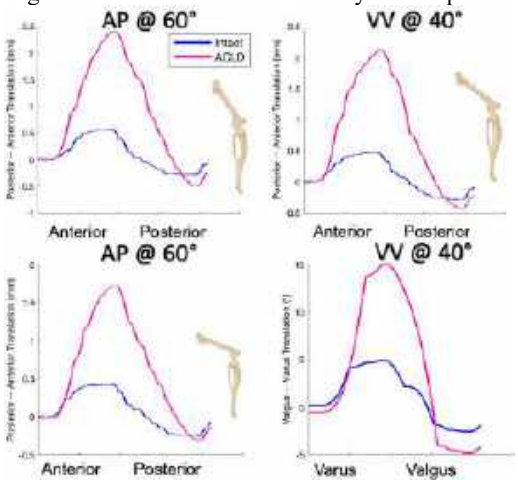

Figure 3: Intact and injured kinematics from a rat knee joint.

DISCUSSION

Multi-axial robotic testing revealed two- to three-fold increases in joint laxity in the rat knee following ACL rupture with both anterior-posterior and varus-valgus challenges. The ACL is the primary passive restraint against anterior tibial drawer across flexion angles, and with the menisci and collateral ligaments the ACL resists varus and valgus torques. This study is the first of its kind, describing multi-axial knee joint mechanics in a rodent model. This innovation is a bridge for functional assessments of orthopaedic studies in common preclinical animal models. The outcomes of this study agree with prior expectations of rat knee function, confirming that the ACL is a pivotal stabilizing tissue in the rat. With the multi-axial hybrid controls demonstrated in this work, more complex testing with rotational controls and dynamic testing modalities are available in the translational biomechanics field. This study was limited in scope due to the availability of specimens, however future work will aim to assess sex- and age-dependent differences in baseline rat knee joint function. Additionally, future studies will address the functional effects of common injury models in rats and mice such as destabilizations of the medial meniscus (DMM).

In summary, this work is the first presentation of multi-axial robotic joint testing in a small animal (rat) model, establishing a new standard of testing for joint laxity in both healthy and injured specimens. This line of study provides value in the translational research field, better informing conclusions from preclinical studies in rodent models and enabling robust assessments of the functional impacts of standard experimental approaches in rodents in future studies.

MEDICAL IMAGING BASED PATIENT-SPECIFIC BLOOD FLOW MODELLING OF CEREBROVASCULATURE

INTRODUCTION

Cerebrovascular diseases refer to conditions that affect the blood vessels in the brain, leading to a decrease in oxygen and nutrient supply. These diseases include ischemic strokes, hemorrhagic strokes, and transient ischemic attacks (TIAs). Stroke is the leading cause of long-term disability and the third most common underlying cause of death in the United States. Moyamoya is a type of cerebrovascular disease that describes an unusual angiographic image revealing blood vessels located at the base of the brain, collaterals formation, and blockage of the internal carotid artery as shown in **Figure 1**. The term "Moyamoya" is of Japanese origin, meaning something hazy, like a puff of cigarette smoke floating in the air [1]. The primary goal of this study is to perform steady-state and pulsatile bio-fluid dynamic simulations of magnetic angiography Moyamoya patient-specific geometries to predict stroke and TIAs [2].

METHODS

The computational modelling of cerebrovascular disease and stroke is based on two equations: the Continuity equation (1) and the Navier-Stokes equation (2). To model blood, the Carreau-Yasuda model is utilized, which considers it as a non-Newtonian fluid. To find out the bio-mechanical parameters, overall computational framework has been designed as depicted in **Figure 2** and patient details have been shown in **Table 1**.

Equations

$$\nabla . v = 0 \quad (1)$$

$$\rho(v.\nabla v) = -\nabla p + \mu\nabla^2 v + f \quad (2)$$

RESULTS

The biomechanical simulation performed *in silico* demonstrated that the Superficial Temporal Artery-Middle Cerebral Artery bypass surgery has enhanced the wall shear stress (WSS) of the artery as shown in **Figure 3**. The distal branches of MCA now have lower total pressure, and the bypass exhibits higher total pressure, which facilitates the blood flow into these veins. The regions with low WSS are more vulnerable to developing atherosclerosis, which can cause ischemic stroke and transient ischemic attack (TIA).

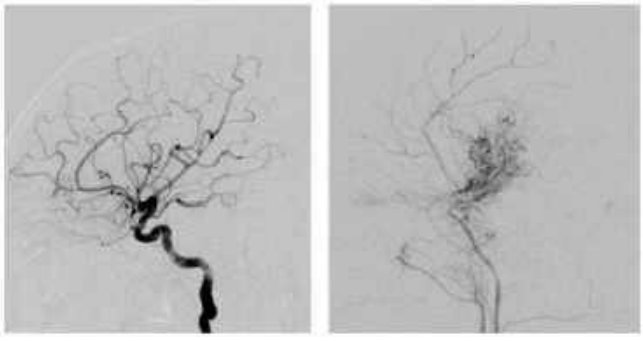

Figure 1: Image on the left showing normal vasculature of a healthy adult and on right hand side of Moyamoya disease patient.

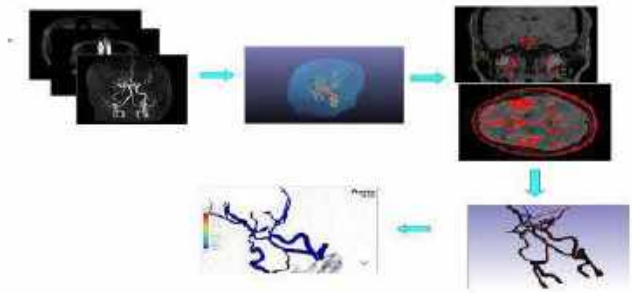

Figure 2: Medical imaging based computational workflow for patient-specific biomechanical analysis.

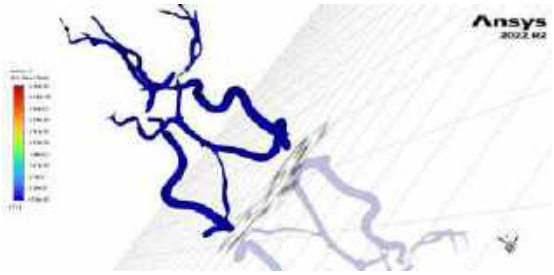

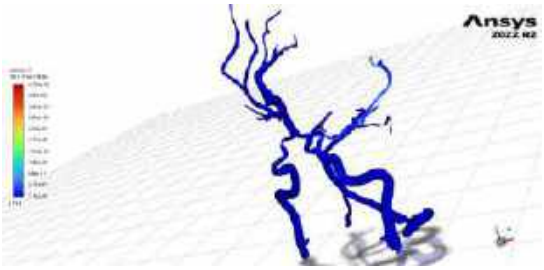

Figure 3: Pre- and post- operative changes in Wall Shear Stress (WSS) in the computational cerebrovascular domain.

Table 1: Radiological details of patient, fluid dynamics modelling and boundary conditions.

1	MRA	Non-Newtonian model	Velocity B.C.	Pressure	Rigid

DISCUSSION

Hemodynamic flow patterns may lead to thrombus formation, increasing the risk of acute ischemic stroke. Artery walls exposed to low WSS are prone to atherosclerosis, which is the deposition of fatty material on their inner walls along with platelet aggregation. Conversely, high WSS induces platelet activation. The current limitation of our study is we have taken artery wall as rigid and have small sample size.

ACKNOWLEDGEMENTS

The findings of this investigation are a outcome of a research endeavor that received financial support from an extramural grant issued by the Department of Health Research (DHR), which is a subdivision of the Ministry of Health and Family Welfare under the Government of India (DHR-ICMR/GIA/18/18/2020).

INTRODUCTION

Structural analysis of transcatheter heart valves (THV) via computational modeling has become popular for better understanding the mechanistic interactions between the prosthetic heart valve and the native aortic anatomy. These computational models of transcatheter aortic valve replacement (TAVR) procedures are composed of multiple stages, where each is modeled using commercial full order model (FOM) solvers. The deformations in response to the applied loads from the valve may cause several adverse complications such as coronary obstruction and paravalvular leakage [1]. Predictive biomechanical models play a pivotal role in helping mitigate the risk of such complications, as they can provide interactive visualizations of the post-TAVR configuration and several simulation-derived clinical metrics to quantitively assess the potential risks [2].

Such analyses become extremely computationally expensive, however, largely due to the mechanical complexities of the aortic valve and the multiphysical nature of the deployment process. In addition, the transient nature of the deployment simulations combined with the highly nonlinear mechanics that govern the THV stent results in computing costs that can range from 12 to 15 hours for an individual deployment simulation. Parametrically evaluating different factors (valve type, deployment depth, balloon-filling volume, etc.) may become a trial-and-error based approach for optimizing the TAVR treatment, causing the entire planning process to potentially take several days to complete for an individual patient.

To this end, reduced order models (ROMs) are a common data-driven paradigm used to simplify complex FOMs to their dominant components. Classical projection-based ROMs are divided into a two-phased approach, the *offline* and *online* phases. In the offline phase, computationally expensive FOM simulations are offloaded to form a *snapshot* library of solution, where each entry represents the solution for different parameters. The snapshot library is immediately recycled in the online phase for a new parameter of interest, with drastically reduced computational costs. We have recently developed a ROM framework based on the Proper Orthogonal Decomposition (POD)-Galerkin approach for real-time structural deformation simulations of the Medtronic Evolut R valve, where radial deformations of the Evolut stent frame are able to be simulated in a matter of seconds [3].

The primary objective of this study is to advance the previously developed POD-based ROM for capturing the full TAVR deployment process and performing real-time, idealized deployment simulations of the Evolut R valve in response to applied radial deformations. This includes incorporating appropriate hyper-reduction techniques for further accelerating nonlinear constitutive models in transient regimes, as well as developing a paradigm based on separate ROM libraries to realistically capture the deployment of the crimped valve stent frame. The goal is to use such an ROM framework to significantly reduce the computing costs of performing these idealized deployment simulations.

METHODS

As an initial attempt to capture the transient deployment process of the crimped valve, separate ROM libraries are constructed for the deformation of the top and bottom halves of the stent frame. In the offline phase of each ROM, a total of 105 traditional finite element (FE) simulations are performed with parameterized applied loads enforced to construct the snapshot libraries. For each FE simulation, a hyperelastic material model in the form of a generalized Neo-Hookean strain-energy density function is prescribed, which serves as an initial approximation of the self-expandable nature of the Evolut stent frame. The stent frame is modeled with a Young's modulus of 50 GPa and Poisson's ratio of 0.33, and in the case of the transient simulations, a semi-implicit approach is utilized ($dt = 0.01\ s, T = 0.3\ s$).

For the first ROM library, zero displacement boundary conditions ($u = 0$) are prescribed at all nodes along the top half of the stent frame. So called "force-pair" conditions are also implemented as seen in Fig. 1, where the normal stress is prescribed at a set of 15 points along the bottom half of the stent frame, i.e. $\sigma \cdot n(P_i) = d_i$ for $i = 1,2, \dots,15$. All

possible pairs among the 15 points are obtained, and the vector d_i is defined such that it is oriented along the line connecting two end points of each pair. These boundary conditions are similar but inverted in the second ROM library, where the fixed conditions are prescribed along the bottom half of the stent frame and the force-pair conditions are prescribed at 15 nodes selected from the top half of the frame. The outline for the prescribed conditions in both ROM libraries are summarized in Fig. 2.

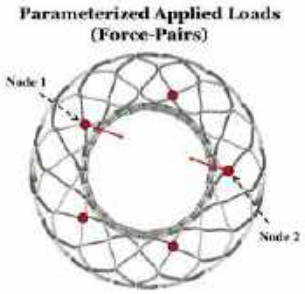

Figure 1. Prescribed force-pair loads for ROM.

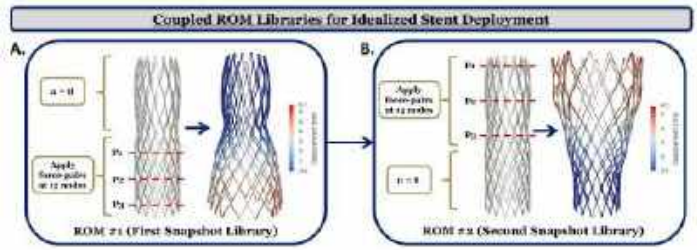

Figure 2. Construction of ROMs for capturing valve deployment.

In the online stage of the ROM frameworks, a filtering step is first performed via the Singular Value Decomposition (SVD) approach to identify the most high-energy principal components of the generated snapshot libraries. A small number of eigenvectors associated with the largest singular values are used to project the elasticity problem to a lower dimensional subspace via the POD approach. When substituted into the traditional linear systems of equations that are obtained from the FE discretization, the reduced order problem reads as follows.

$$W^T A W = W^T b \quad (1)$$

The Galerkin POD approach is naturally stated for linear problems. However, in the case of nonlinear problems such as hyperelasticity, more advanced approximation techniques are required and in this study we employ the Discrete Empirical Interpolation Method (DEIM) for each ROM framework [4]. The DEIM approach allows for an efficient reduction of the nonlinear terms that arise in the governing problem by essentially performing a secondary SVD evaluation on a separate snapshot library that only evaluates the nonlinear terms. More precisely, if we label the matrix N as the secondary snapshot matrix of the nonlinear evaluations (with up to m entries), then the secondary SVD evaluation resembles the following.

$$N = \Xi \Sigma_N V_N \quad (2)$$

The matrix Ξ here consists of the POD modes associated with the nonlinear terms, and from this matrix, a low dimensional basis is formed (Ξ_p) as in the POD approach. Using the entries of the matrix Ξ_p, a series of interpolation indices that form a separate matrix known as the interpolation matrix (P^T) are calculated by computing the residual against Ξ. This interpolation matrix captures the relationship between the selected indices and the original nonlinear snapshot data. Finally, the reduced order system is constructed which reads as follows, where the projection of the nonlinear terms is indicated on the right-hand side.

$$N \sim \Xi_p \left(P^T \Xi_p\right)^{-1} P^T N \quad (3)$$

The two ROM libraries are then coupled together in a sequential manner to capture the deployment. In the online phase of the first library, the bottom half of the stent frame is deformed in a time-dependent manner to mimic the initial release of the crimped stent from the catheter. The online stage of the second library is then used to deform the remaining top half of the stent frame, mimicking the release of the remaining part of the stent as the catheter is pulled back. Using this pipeline, idealized stent deployment simulations were performed in a patient-specific aortic root model. The entirety of the ROM frameworks are implemented in *RBniCS*, an open-source model reduction library which automates all of the above steps (offline stage FE simulations, POD-DEIM model reduction, and online stage).

RESULTS

The von Mises stress distribution along the stent frame as the valve is deployed is shown in Fig. 3. The solutions obtained via the ROM were in strong agreement with full order model (FOM) simulations performed in the FE library *FEniCS*, highlighting the accuracy of the approach. Computational costs of simulating the idealized deployment process using the ROM were significantly reduced as well, requiring only 40-50 seconds to fully simulate depending on the magnitude of the applied loads prescribed in the online stages. Comparing these costs to a previously validated FE-based TAVR deployment simulations performed using commercial FE solvers, which require up to 12-15 hours to complete, the ROM was successfully able to reduce the computing costs with speed-up factors ranging from 92.8% to 99.7%.

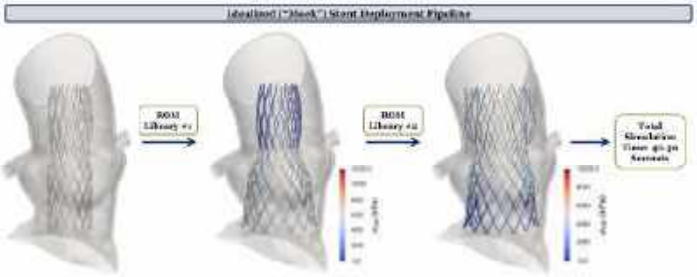

Figure 3. Visualization of the idealized deployment pipeline.

DISCUSSION

In this study we introduce and advance a previously developed ROM framework using a projection-based, POD-DEIM algorithm for performing near real-time idealized stent deployment simulations of the Evolut R valve stent frame. The framework significantly reduced the computational cost of performing the idealized deployment simulations as compared to a previously validated FE-based simulation pipeline, while also providing accurate results as compared to FOM simulations with similarly applied loads. The inclusion of the DEIM algorithm showed especially promising results in the presence of the nonlinear mechanics prescribed here, as especially large reductions in computing costs were seen with the combination of the POD-DEIM approach. A major limitation of the study is the lack of a true superelastic material model that accurately captures the properties of the stent frame. In addition, the framework currently is unable to handle the contact problem as the stent frame collides with the surrounding aortic anatomy. Further refinements are underway to implement both an idealized superelastic constitutive model, as well as a collision detection and response algorithm to simulate the contact of the stent frame with the native leaflets and aortic root. Such a comprehensive framework will provide clinicians with mechanistic insight at a patient-specific level in a real-time fashion via several potential simulation-derived clinical metrics to help mitigate post-TAVR complications.

ASSESSING THE IMPACT OF HYALURONIC ACID ON THE RHEOLOGICAL PROPERTIES OF COLLAGEN HYDROGELS

Nicholas T. Gigliotti (1), Vivian H Su (1), Mitra L. Taheri (1)

(1) Department of Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland, USA

INTRODUCTION

Each year, roughly 1 in 10 pregnancies result in preterm birth (PTB), increasing the risk of negative health outcomes for both mother and child.[1] Although PTB is prevalent, little is known about how or why it occurs. The cervix has emerged as a key research target for PTB due to its role as the barrier between the fetus and the birth canal. Throughout pregnancy, the cervix undergoes significant changes to its mechanical properties, allowing for the passage of the fetus into the birth canal during labor, a process which occurs prematurely in the case of PTB.[2] Uncovering the mechanisms driving cervical remodeling is paramount to understanding why PTB occurs and how to predict and prevent it.

Within the cervix, network-forming fibrillar collagen is primarily responsible for the structure and properties of the tissue. However, basic fiber mechanics alone do not explain the changes in tissue properties that are observed in the cervix, suggesting that the chemical environment of the extracellular matrix (ECM) also contributes to the observed mechanical changes.[2] Hyaluronic acid (HA), a non-sulfated glycosaminoglycan in the cervical ECM, has been well studied throughout pregnancy.[3] In the early stages of pregnancy, HA is mostly present in its low molecular weight form. As pregnancy progresses, the overall concentration of HA increases, as does the chain length of the polymer.[2] Hyaluronic acid contains negatively charged carboxylate groups that bind to water, meaning that the increase in molecular weight and concentration allows for an increase in bound water content within the tissue.[3] It is hypothesized that these changes impact collagen fibrillogenesis and the mechanical properties of the whole tissue. Previous studies have been conducted examining the impact of HA concentration on collagen hydrogel mechanics[4] and on how adding HA to collagen scaffolds impacts cellular viability.[5,6] However, little investigation has been done on how HA impacts the structure of self-assembled collagen and the resulting structure-property relationships in a controlled environment. In this study, collagen hydrogels were chosen to isolate the collagen from the rest of the ECM and provide a tunable platform with complete control over synthesis parameters.[7,8] Hydrogels were prepared with varying biologically relevant molecular weights and concentrations of HA to study the impact of HA on collagen fibrillogenesis and network formation.

METHODS

Hydrogels were prepared by combining 3mg/mL type I collagen and 10X PBS with solutions of 20kDa or 200kDa HA in water to final concentrations of 1X PBS, 1.5mg/mL collagen, and either 1 or 10 nmol HA per mg of collagen. Solutions were pH adjusted with 1N NaOH and placed in an incubator at 37 C for 24 hours for gel formation and equilibration.

Rheology was performed with a frequency sweep at 1% strain from 0.01 to 100 rad/s. Resulting storage moduli, loss moduli, and loss factor (tan(δ)) were examined to determine gel stiffness, degree of cross-linking, and whether the plastic or elastic response was dominant.

Imaging of individual collagen fibers was performed using an environmental SEM at 15keV with a chamber pressure of 70 Pa. Individual fiber diameters were measured by taking 3

randomly spaced measurements per fiber at 90° to the fiber edge using imageJ.

RESULTS

Rheology measurements indicated an increase in storage modulus for low molecular weight (MW) HA samples from the pure collagen gels. High MW HA showed significant decreases in storage modulus as concentration of high MW HA increased. The loss moduli for each of the samples were similar at low frequencies. At higher frequencies, each of the HA containing species showed a decrease in loss modulus, although these results were not statistically significant. Loss factor (or tan(delta)) indicated that the degree of cross-linking increased for samples containing low MW HA compared to pure collagen gels, while the degree of cross-linking significantly decreased with increasing concentration for high MW HA samples.

ESEM imaging suggested no change in fiber diameter between pure collagen and low MW HA samples. The low concentration, high molecular weight sample, however, showed a slight increase in average fiber size, although the results were not statistically significant. No images showing collagen fibers were able to be acquired for the high concentration, high MW sample due to increased water content.

DISCUSSION

The addition of HA to collagen gels has a significant impact on the rheological properties of the collagen network. The large decrease in storage modulus and dominant plastic behavior of the high MW HA samples compared to both pure collagen and low MW samples shows that the larger molecule size is the driving factor in how HA affects tissue properties. Specifically, the decrease in relative degree of cross-linking indicated by tan(delta)>1 demonstrates that high MW HA impedes collagen network formation, whereas low MW HA does not, but rather occupies space within the lattice and assists in stiffening the matrix. Furthermore, imaging of individual fibers suggests that the low molecular weight HA does not impact fiber swelling and may be too small to create noticeable changes in the interfibrillar spacing of collagen. However, the slight increase in size observed in the higher MW sample may indicate that the HA is adhering to the collagen fibrils, resulting in an increase of interfibrillar spacing and a larger fiber diameter. One of the primary mechanisms for deformation of collagen is bundled fibrils sliding past each other within a fiber, so increased interfibrillar spacing may have a large impact on collagen extensibility and tissue properties via this mechanism.

The results of this study agree with previously proposed molecular crowding mechanisms for the opposing impacts of low and high MW HA with collagen.[2,9,10] We were able to demonstrate these competing mechanisms through our hydrogel model at biologically relevant concentrations found in the cervix during pregnancy. Additionally, we were able to gain some limited insight into whether HA is adhering to collagen fibrils within the fibers, causing the fibers to swell. When coupled with the proposed sliding mechanism for collagen deformation, HA could be a significant contributor to the mechanical and structural remodeling of the cervix, although further studies are required to address the limitations of this study.

Future studies will be aimed at increasing the range of molecular weights examined. Although the difference between low and high MWs in this study is an order of magnitude, HA may be present in molecules as large as 2000 kDa, so further investigation into the impact of such high molecular weights should be pursued. Additionally, environmental SEM proved to be a challenging imaging mode as we were unable to identify collagen fibers in one of the samples, likely due to the increased water content from the high MW HA. Alternative imaging modes, such as AFM, may be useful to quantify fibers in their native environment and hydration state, eliminating unwanted changes in hydration and swelling caused by sample processing or imaging under vacuum conditions. Cryo-TEM may also be used to measure interfibrillar distance as a function of HA MW.

INTRODUCTION

Knee hyperextension (genu recurvatum) is a common injury amongst the general population and can result from injury, physiological laxity, or other knee disorders[1,2,3,4]. Hyperextension is classified as normal up to 5° past full extension, and abnormal beyond that[5]. There are few biomechanical studies on hyperextension from which to draw conclusions about the structures responsible for it. Morgan et al attributed the oblique popliteal ligament (OPL) as a crucial hyperextension restraint, carrying 36-41% of load[6]. However, a study by Noyes et al concluded that there is no singular primary structure responsible for preventing knee hyperextension[7].

Varus is a deformity in which an anatomical part is angled toward the midline of the body to an abnormal degree[8]. In a radiographic study conducted by Moreland et al, a knee has a normal varus from 1.1° to 1.5° varus; therefore, abnormal varus can be classified as more than 1.5° varus[9]. Studies from LaPrade and Gollehon explore varus-valgus rotation in flexion and conclude that there are some structures more impactful than others; however, no singular structure is responsible for limiting varus rotation[10,11].

Varus recurvatum has no clear definition in literature but is described as abnormal varus with abnormal hyperextension[5]. The purpose of this study is to investigate and identify what soft tissue structures, if any, are primarily responsible for limiting varus recurvatum. Additional purposes are to see if a varus recurvatum injury can be present with an intact anterior cruciate ligament (ACL) and if either the popliteus tendon (POP) or lateral collateral ligament (LCL) is more effective in varus recurvatum (VR) prevention than the other.

METHODS

In this study, 8 cadaveric knee specimens (mean age, 39.5 years; range 24-49 years) were mounted onto a 6 degrees of freedom (DOF) robotic system designed with the joint coordinate system described by Grood and Suntay[12] that uses a 6-component force-torque transducer (Delta model; ATI Industrial Automation). A 7 Nm varus moment was applied while the specimens were extended from terminal hyperextension using a 25 Nm hyperextension load up to 90°. All other motions were unconstrained to maintain no load unlike the previous study by Noyes[7], which constrained the motions to the positions consistent in the intact knee. The specimens' tissues were dissected in four different cutting sequences (Fig 1). By alternating the cuts of the POP and LCL, the effect of individual and combination cutting can be analyzed. The role of the posterior capsule was investigated by cutting the structures before or after the LCL, POP, and ACL.

Figure 1: All cutting sequences for this study.

The knee joints were prepared and aligned as described in Noyes et al[7]. Additionally, the specimens were cycled through limit tests for each DOF from -5 degrees to 90 degrees flexion. Anteroposterior limits were measured at ±135 N, ab-adduction limits were measured at ±7 Nm, and external-internal limits were measured at ±5 Nm.

All statistical and graphical results were produced with Excel (Microsoft) after importing the data from the robot. Data were analyzed using descriptive statistics for cutting groups and POP/LCL involvement.

RESULTS

The average hyperextension at the peak extension moment in the intact knee ranged from 6.3° to 20.4°, with an average of 11.8° ± 4.7°. Furthermore, an average varus of 3.8° ± 2.4° was found after all cuts were made. In the intact knee, the average was 0.1° ± 1.1° valgus for all specimens at the peak extension moment of 25 Nm.

The preliminary results from this study indicate that varus recurvatum can be present without an ACL injury (Figs 2-5). This agrees with a previously published study by McDonald et al[13] which concluded that the effect of creating an isolated ACL injury did not create a lateral joint opening large enough to be classified as abnormal varus. Each graph below shows the individual cuts for each cutting order (legend) with a black horizontal line that represents where the average varus is for a normal knee. The graphical results demonstrate that for 75% of the specimens, varus recurvatum is present for cuts prior to the ACL which is consistent with McDonald's findings.

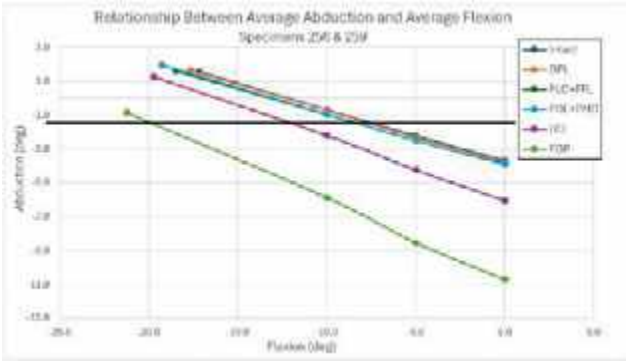

Figure 2:Abduction vs Flexion Averages for Specimens 256 & 259.

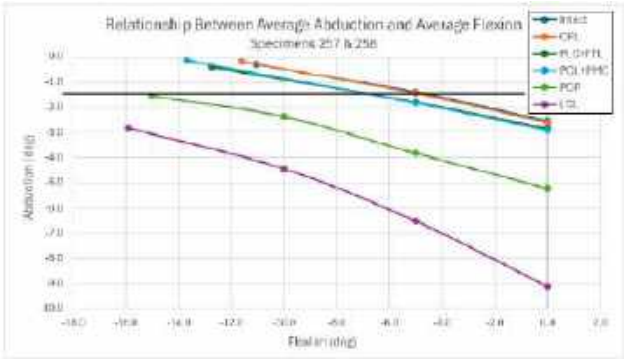

Figure 3:Abduction vs Flexion Averages for Specimens 257 & 258.

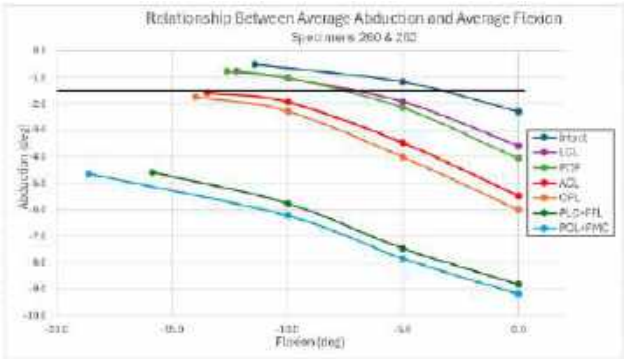

Figure 4:Abduction vs Flexion Averages for Specimens 260 & 262.

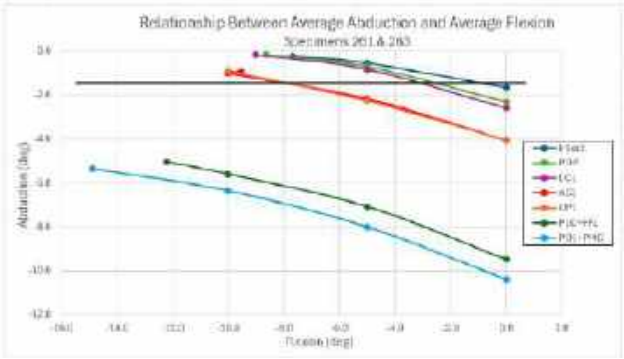

Figure 5:Abduction vs Flexion Averages for Specimens 261 & 263.

DISCUSSION

The preliminary results of this study are consistent with the hypothesis that varus recurvatum can be present in an injured knee with an intact ACL. Moreover, the LCL and POP have individual effects on VR and the magnitude of the effect depends on the order in which they are sectioned. This study can also be used to clearly define varus recurvatum which has not been consistent in the literature and may help clinicians identify such injuries in a patient.

Furthermore, these preliminary findings illustrate that an ACL injury is not required for a person to have a varus recurvatum. Natural hyperextension and varus could be exacerbated by an LCL and/or POP injury without injuring the ACL or posterior capsule. The preliminary findings also suggest that the major restraints for varus recurvatum are likely the popliteus tendon and lateral collateral ligament.

The major limitation of this preliminary study is that it only has an n=2 for each cutting sequence. Ideally, there would be at least 4 specimens per group to do a power analysis and subsequent testing. Subsequent testing will provide more conclusive data on the structures that restrain hyperextension and varus recurvatum.

THE IMPACT OF RIGHT VENTRICULAR FIBER RE-ORIENTATION ON LEFT VENTRICULAR CONTRACTION: A NUMERICAL STUDY

INTRODUCTION

Pulmonary hypertension (PH) results in right ventricular (RV) pressure overload and eventual failure. While most ongoing research has been focused on characterizing the RV's morphological, biomechanical, and metabolic changes, few studies have considered how these changes impact left ventricular (LV) function and contractile mechanics. However, decreased LV torsion and torsion-rate during systole has been reported in children with PH [1,7]. A decline in both LV and RV ejection fraction (EF) in pulmonary artery banding (PAB) mice has also been reported [2]. The underlying mechanism for this observation is unclear. The objective of this study is to develop a computational model of the biventricular heart to study physiological LV contractile mechanics in response to RV remodeling (e.g., fiber re-orientation). The ultimate objective is to enhance our understanding of how various factors of RV remodeling contribute to the observed biomechanical and transcriptional changes in LV contractile mechanics in children and pre-clinical models of PH.

METHODS

A biventricular finite element computational model was developed to study how well-established mechanisms of RV remodeling to pressure overload (e.g., fiber re-orientation) impact LV and RV function, and LV contractile mechanics. The model was reconstructed from short axis cine stack magnetic resonance imaging (MRI) of a healthy 10-year-old male pediatric subject at end systole using ScanIP (Simpleware).

Fiber orientation and remodeling

Since the purpose of the model was to investigate how the LV responded to RV myofiber re-orientation, a well-known phenomenon in RV remodeling [3], we explored 3 RV fiber orientation scenarios (LV fiber orientation was not changed). Baseline endocardium and epicardium fiber assignment for this study is depicted in Fig. 1. Fiber orientation in F1 corresponds to a healthy rat heart, which in response to pressure overload- gradually progresses to F2, and ultimately to F3 [3]. Within the finite element model, fiber orientation was incorporated by solving $-\nabla \cdot (\nabla\theta) = 0.025$ where θ is the fiber angle and Fig. 1 shows epicardial/endocardial boundary conditions [4,5]. To address the specific study questions, only fibers within the RV change orientation from F1 to F3 (see Fig. 1) while LV fiber orientation remains constant.

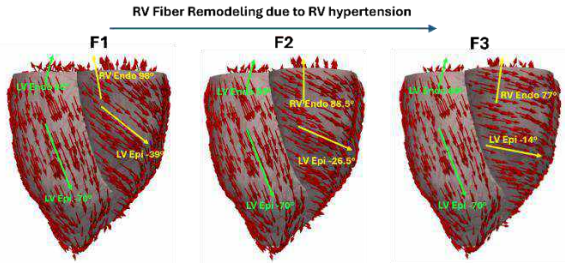

Figure 1 Fiber Assignment

Constitutive model

In this study, we characterized the passive and active properties of myocardial tissue by a transversely isotropic hyperplastic constitutive model [6,8] that incorporates an additive active stress decomposition aligned with the fiber (Eq. (1))

$$\sigma = \sigma^p + \sigma^a \quad (1)$$

The passive stress response (σ^{p}) is governed by a transversely isotropic Fung-type strain energy function (Ψ), with a decomposition into deviatoric (Ψ^{dev}) and volumetric (Ψ^{vol}) components to enforce the constraint of incompressibility.

$$\Psi = \Psi^{dev} + \Psi^{vol} \quad (2)$$

The active contraction stress (σ^{a}) is generated along the fiber direction e_1 by adjusting active fiber stress (T_a):

$$\boldsymbol{\sigma^a} = \boldsymbol{T_a e_1} \otimes \boldsymbol{e_1} \quad (3)$$

All the material parameters were determined and calibrated based on published experimental data but are omitted due to space constraints.

RESULTS

Changes of RV and LV shape during ejection

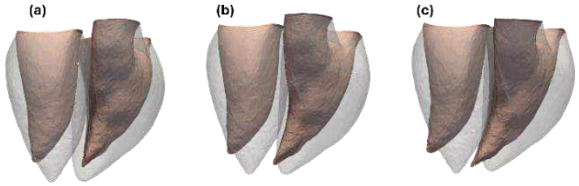

Figure 2 LV and RV structural changes during ejection

For normal fiber orientation, the RV and LV undergo pronounced radial and circumferential contraction, and subtle longitudinal contraction, during ejection (see Fig. 2a). After RV fiber re-orientation (see Fig 2b, c), the RV contract radially without any visible evidence of longitudinal shortening. Changes in the circumferential direction are discussed below.

Changes in RV and LV systolic function, contractile mechanics, and stroke work

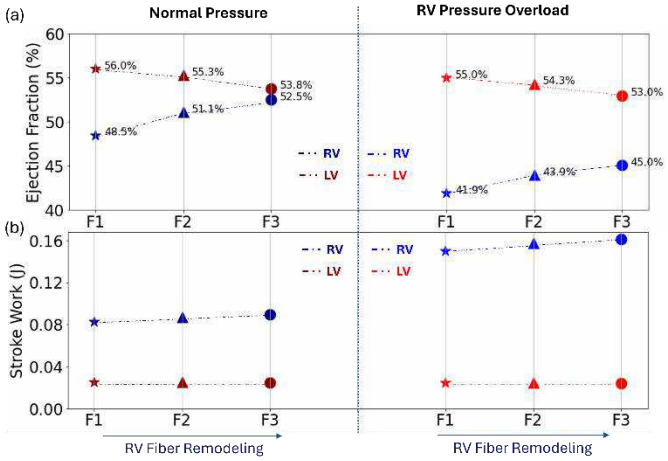

Figure 3 RV and LV systolic function and stroke work

Fig. 3 presents the impact of RV fiber re-orientation on RV and LV systolic function. The figure encompasses six simulation outcomes, wherein three distinct fiber orientation models (F1, F2, F3) are simulated under both normal and hypertensive RV pressure conditions. The hypertensive pressure is considered as a 2-fold increase in RV peak systolic pressure relative to the normal simulation. Fig. 3(a,b) illustrate the alterations in EF and stroke work respectively.

This data shows that, as the remodeling of fiber orientation changes from F1 state to F3 state, the EF of the RV increases by 8.2% while the LV slightly decreases (around 3.9%). Similar trends were observed for the case with hypertensive RV pressure. The simulations show that, under F1 fiber orientation, hypertensive pressure leads to significant RV EF decline compared with normal pressure. Shifting the fiber orientation to F3 is expected to enhance RV function, albeit with a slight decline in LV function. Fig. 3 (b) illustrates that under RV pressure overload, the RV must do substantially more work, but the LV responds with a small decrease in stroke work. This finding aligns with experimental mouse data presented in [2].

Fig. 4 reveals simulation results from a numerical experiment intended to explore how RV fiber re-orientation impacts LV apex rotation rate. Here we see that RV fiber re-orientation and RV pressure overload both have pronounced effects on decreasing LV apex rotation rate. The results agree with our previous [experimental] observation that LV apex rotation rate decreased in mice after PAB [2] and children with PAH [7].

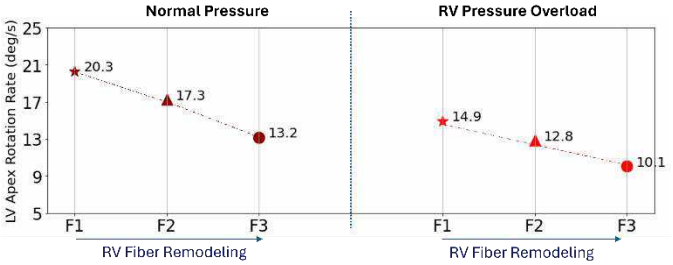

Figure 4 LV apex rotation vs RV fiber re-orientation

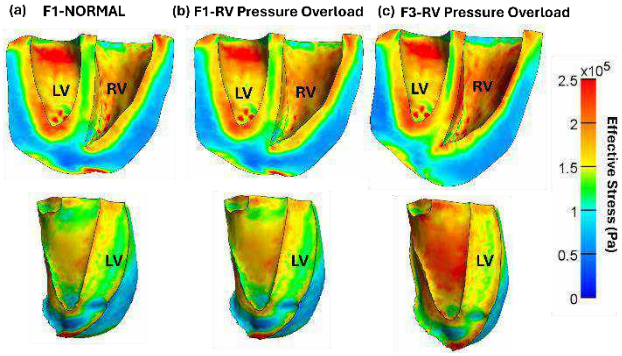

Figure 5 Stress Distribution

Fig. 5 shows the effective stress distribution within the LV (septum and free-wall) and the RV free-wall at end-systole. Under normal circumstances *in vivo*, RV fiber re-orientation would be accompanied by an increase in RV myofiber contractility. Therefore, in this numerical study, we only simulated fiber re-orientation without an increase in contractility to isolate the impact of that remodeling response. Here we see that, without an increase in RV contractility, pressure overload has a minor impact on LV, septal, or RV free wall stress although it understandably reduces RV end-systolic cavity volume. However, after RV fiber re-orientation, septal stress is notably increased (see Fig. 5c).

DISCUSSION

This study was triggered by our previous findings that LV torsion rate is decreased in rodents and children with chronic RV pressure overload [2,7]. In rodents, this decrease in LV torsion rate was accompanied by LV transcriptomic changes and a decrease in LV systolic function [2]. This study found that RV fiber re-orientation, which has been documented in multiple rodent studies [8], is enough to be a mechanistic cause for these clinical and pre-clinical findings in the LV. In conclusion, this study shows how RV structural remodeling impacts LV contractile mechanics and function. Ongoing studies are aimed at identifying how this phenomenon also influences LV-to-RV mechanical energy transfer.

INTRODUCTION

Fontan surgical planning via computational fluid dynamics (CFD) is a well-established technique for pre-operatively characterizing the hemodynamics of the total cavopulmonary connection (TCPC) [1]. The pipeline involves modeling the baseline anatomy of the patient, from which the effects of individual variables on the flow dynamics of the potential surgical option are assessed. These variables are evaluated in a parametric setting and include the caval offset (offset between the superior and inferior vena cavae (SVC, IVC)), the design of the Fontan circuit, and the type of baffle utilized [2]. Two of the most critical endpoints of clinical interest are the hepatic flow distribution (HFD) and power loss (PL). HFD is defined as the amount of hepatic flow carried from the liver via the IVC to the left or right pulmonary arteries (LPA, RPA), while PL is the total energy loss that occurs within the TCPC.

This pipeline essentially represents a shape optimization problem, where different anatomical connections between the IVC and LPA/RPA result in unique hemodynamics. The HFD and PL metrics are used to identify the optimal morphology, where the aim is to provide a balanced HFD split and minimize the PL in the constructed anatomy. Although this surgical planning pipeline is effective in optimizing the TCPC, the computational costs of simulating physiologically accurate conditions becomes extremely expensive. This is especially true for repetitive testing of various TCPC options in a trial-and-error fashion, which may take several weeks or months to complete for a single patient.

To this end, we have recently developed a *reduced order modeling* (ROM) framework using the Proper Orthogonal Decomposition (POD) approach coupled with trust-region optimization methods for real-time shape optimization of idealized TCPC geometries. Projection-based ROMs are traditionally divided into two stages, the *offline* stage, where the computationally expensive simulations are offloaded, and the *online* stage, where the generated *snapshots* are recycled for a rapid, reduced order solution. The POD-ROM framework has shown promising results for real-time shape optimization using a point-based parameterization of the geometry, where the optimal morphology for a desired HFD value or minimization of the PL can be determined in under 15 minutes.

The primary objective of this study is twofold. First, we aim to develop a paradigm for parametric geometrical transformations of idealized TCPC geometries using the free form deformation (FFD) technique. The FFD approach will be coupled with the previously developed POD-ROM framework, allowing for a wide range of smooth, physiologically relevant transformations of the TCPC geometry which aims to be more robust than a point-based boundary variation method. Second, we aim to implement hyper-reduction techniques to the framework in the form of the discrete empirical interpolation method (DEIM), which will allow for greater computational savings in the presence of the highly nonlinear Navier-Stokes equations (NSE) and in turn allow for real-time identification of the optimal TCPC morphology.

METHODS

An initial reference geometry of an idealized 2D TCPC is generated as seen in Fig. 1 and the FFD technique is implemented to perform the parametric shape transformations. FFD is an approach based on tensor products of splines that allows for the deformation of a volume based on a control lattice which encapsulates the mesh of interest. The method allows for smooth deformations of the mesh volume, which is critical for obtaining physiologically relevant configurations of the TCPC (varying caval offsets, flaring or angled

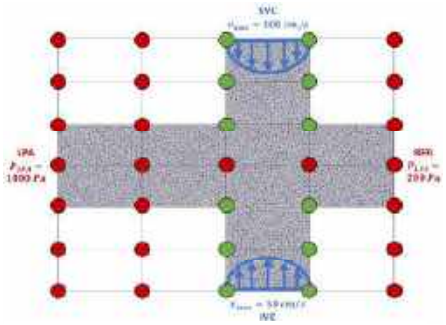

Figure 1. Idealized TCPC geometry with control points overlayed.

connections, etc.). A grid of control points is layered onto the reference mesh (Fig. 1), where only certain control points associated with the IVC and SVC are activated (in green). This allows for varying deformations of the IVC and SVC with respect to the LPA and RPA, serving as a preliminary attempt to capture the variability in which the TCPC can be constructed. Parabolic velocity profiles are prescribed at the inlets, and pressure conditions are employed at the LPA/RPA for each of the geometries (Fig. 1). In the offline stage, a total of 100 finite element based CFD simulations are performed using the parameterized models, where the displacement of the activated control points is varied within a given range to ensure the generation of realistic geometries.

In the online stage of the ROM, a filtering step is first performed via the *Singular Value Decomposition* (SVD) technique. Using a small number of eigenvectors that are associated with the largest singular values of the generated snapshots, the governing problem is projected to a lower dimensional subspace using the POD approach. When substituted into the traditional linear system of equations that results from the discretization of the NSE via the finite element method, the reduced order problem reads as follows.

$$W^T A W = W^T b \quad (1)$$

However, in the case of nonlinear problems such as the NSE, specific approximation techniques are required to rapidly solve the nonlinear terms. Here, we resort to the DEIM approach, which allows for efficient reduction of the nonlinear terms arising in the governing problem, which the traditional POD approach is unable to reduce effectively since it would not be possible to precompute $W^T A W$ once and for all, as the matrix A itself depends on the solution at the previous nonlinear iteration [3]. The DEIM algorithm consists of performing a secondary SVD evaluation on a separate snapshot library that evaluates only the nonlinear terms of the governing problem. The goal is to isolate the nonlinear terms and their evaluations via the secondary snapshots and find its separate low dimensional representation and projection.

The POD-DEIM ROM framework is implemented using the open-source model reduction library *RBniCS*. The FFD approach is implemented within an in-house code which is coupled directly to the ROM framework, allowing for the shape parameterization of the TCPC. In the online phase, new parameters different from those used to generate the snapshot library were applied, and the reduced order solution was compared against the full order model (FOM) solution.

RESULTS

The ROM solution for the parameterized TCPC geometry in the online phase is shown in Fig. 1, with the velocity streamlines displayed. The FFD approach was able to parametrically deform the TCPC geometry in a smooth manner during the offline and online phases, where the IVC (A) and SVC (B) connections to the LPA/RPA was uniquely deformed to achieve various junctions with respect to the connection angle and flaring. In addition, the ROM solutions were in strong agreement with the FOM CFD solution with regards to resultant velocity and pressure contours.

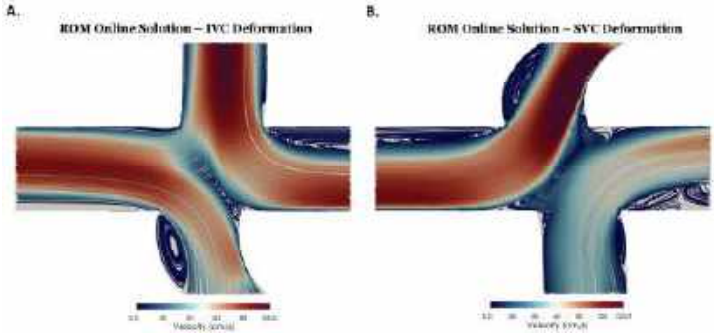

Figure 2. ROM solutions with FFD-based deformations of TCPC.

In terms of computational costs, the POD-ROM was able to reduce the costs of the online simulation to approximately 50.48 seconds, down from an average of 153.46 seconds for the FOM simulation. Even greater speed-ups were seen with the use of the POD-DEIM algorithm, with the online phase solution requiring only an average of 7.94 seconds to simulate, a 94.83% decrease in computing costs (Table 1).

Table 1. Computational details for ROM simulations.

Simulation Type	# of Snapshots	# of FE DOFs	# of ROM DOFs	Wall Clock Time (s)		Speed Up Percentage
				FE	ROM (Online)	
POD	100	25841	u - 99, p - 97	153.46	50.48	67.1%
POD-DEIM	100	25841	u - 99, p - 97	153.46	7.94	94.8%

DISCUSSION

This study introduces a POD-DEIM ROM framework that utilizes a FFD shape parameterization of idealized TCPC geometries. The framework resulted in real-time online stage simulations that were in strong agreement with FOM CFD simulations. The FFD shape parameterization also resulted in robust geometrical transformations of the TCPC as compared to traditional point-based boundary variation approaches explored previously. This is especially critical for capturing variables that are parametrically evaluated in Fontan surgical planning, such as the offset between the IVC and SVC or the angle at which the IVC connects to the LPA/RPA. More importantly, FFD is critical for parameterizing 3D geometries, as boundary variation methods are unable to efficiently evaluate these variables parametrically in a 3D setting. To this end, we have begun adapting this ROM to idealized 3D TCPC geometries as well, with preliminary results shown in Fig. 3.

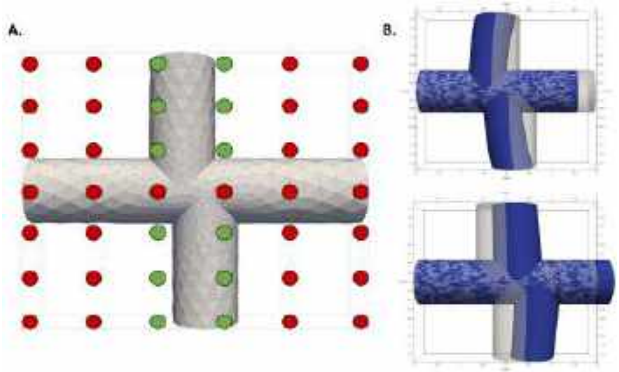

Figure 3. Idealized 3D TCPC with control points overlayed (A). FFD-based parameterization of the geometry (B).

A major limitation of this study is the stability of the applied boundary conditions as the TCPC geometry is parameterized during both phases of the ROM, as evidenced by the presence of potentially unrealistic flow separation zones near the inlets. This may occur due to large displacement ranges of the control points, as well as the stability of the DEIM approach. To overcome these limitations, we will explore adaptive inflow conditions that fit more closely with the deformed TCPC geometries, as well as additional hyper-reduction approaches in the form of regression based or domain decomposition methods.

In conclusion, the presented POD-DEIM ROM framework with an FFD-based parameterization of the geometry resulted in significantly reduced computational costs of simulating flow dynamics within idealized TCPC morphologies. Further refinements are underway to implement the FFD-based shape optimization problem, as well as translate the framework to patient-specific TCPC anatomies.

INTRODUCTION

The remodeling abilities of tissue engineered heart valves (TEHVs) make them promising substitutes for current mechanical or bioprosthetic valves. Upon implantation, host cells enter the TEHV scaffold and initiate a remodeling response to finally integrate a native-like heart valve. The mechanical stimuli emerging from the hemodynamic environment affect this cell-mediated remodeling response [1].

Computational finite element models can be employed to evaluate the mechanical stimuli on TEHV and the subsequent leaflet deformation depending on their geometry. With this, a variety of novel leaflet designs could be generated, all achieving significantly different mechanical stimuli [1-2]. A proof-of-concept in-vivo study showed that computationally-designed TEHVs develop significantly less leaflet retraction than the previous designs, and obtain a circumferential collagen fiber orientation that approached the native-like ones [3]. However, a proper understanding of the specific design attributes that facilitate either effective valve closure, optimal collagen orientation, or a combination of both remain unknown.

This study aims to employ a systematic approach to explore the effect of design features on the remodeling in TEHVs. Furthermore, an evaluation will be conducted to determine the feasibility of concurrently optimizing collagen alignment and retraction. This will be followed by design guidelines, which allow rational and efficient development of next-generation TEHVs.

METHODS

A previously developed bio-inspired remodeling model was used in order to capture the mechano-mediated cellular remodeling [3]. In short, tissue is modeled as a continuum of cells (primarily their actin stress fibers), collagen fibers, and extracellular matrix (ECM). The fibrous materials were described using 30 fiber directions with orientations spanning in the plane between a circumferential and a radially oriented unit vector.

Cellular remodeling was described by (de)polymerization of actin monomers, with decreased polymerization in direction of high stretch, effectively reorienting cells away from directions with high stretch. Collagen fibers were crimped by cells, with a target stress similar to cellular stress fiber stress. Collagen was isotropically deposited initially, and a strain-dependent collagen degradation law was incorporated.

Valve designs with variations in belly curvature and attachment edge curvatures (Figure 1a) were developed, based on a slightly adapted parametrized design [4]. For each curvature, three variations were adopted, resulting in 3*3 design variations (Figure 1b-c). Half of a leaflet was simulated, with a symmetry boundary condition through the belly profile, fixation of the attachment edge and the application of a diastolic pressure of 2 kPa representative of pulmonary pressure conditions.

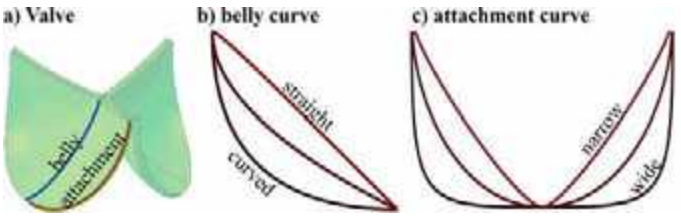

Figure 1 a) Tri leaflet valve geometry. Variations in b) belly and c) attachment curvature.

Valve performance was assessed by the opened area of the valve during diastole (regurgitant orifice area ROA), and a fiber orientation parameter S:

$$S = \int \phi_f(\gamma) \cos(2\gamma)\, d\gamma\,, \qquad (1)$$

with γ the fiber orientation angle with respect to circumferential direction, and ϕ_f the collagen fiber volume fraction.

RESULTS

Deformation of a representative TEHV design before remodeling resulted in marginally positive or negative radial strains and proper valve closure, as shown for two representative design variations (Figure 2a;c). Subsequent remodeling, however, resulted in changes in TEHV appearance and performance, where significant retraction is evident after remodeling under pulmonary conditions (Figure 2b;d), resulting in a loss of the valve's ability to close properly. Importantly, design variation B showed reduced retraction in comparison to variation A.

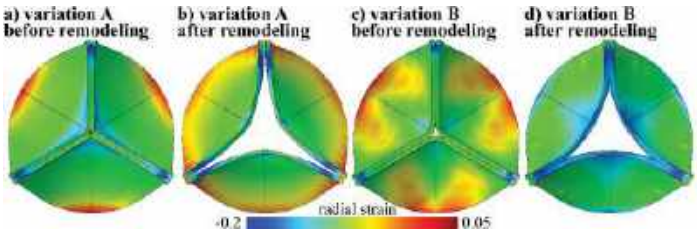

Figure 2 Radial strain in a) design variation A before remodeling and b) after remodeling, c) design variation B before and d) after remodeling.

Additionally, remodeling of these representative TEHV designs induced reorientation of collagen fibers towards a mildly anisotropic (S=0.06 & S=0.12) fiber distribution with the circumferential direction as main fiber angle (Figure 3a). As variation B had higher radial strain, collagen in that direction was less degraded, inducing a lower circumferential anisotropy. Cellular stress fibers also oriented towards the circumferential direction and showed a higher degree of variation in fiber alignment (S=0.14 & S=0.30) (Figure 3b). The pronounced anisotropic alignment observed in design variation A resulted from substantial radial compaction of the TEHV, causing the reorientation of cellular stress fibers which tend to avoid this compaction. Consequently, these fibers aligned more in the circumferential direction. In contrast, the reduced retraction observed in variation B led to a less pronounced anisotropy.

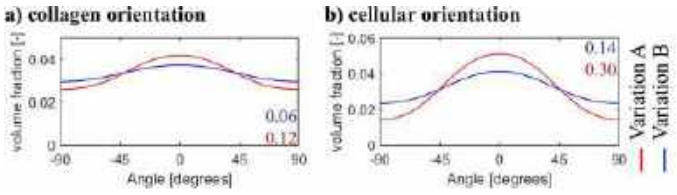

Figure 3 Example of a) collagen and b) cell orientation analysis after remodeling under pulmonary pressure conditions.

Retraction differed significantly for each design variation (Figure 4a), with higher retraction in designs with narrow attachment edges or straight belly curvatures. Collagen and cell alignment for all designs were positive, indicating mild circumferential anisotropic alignment. Generally, the average orientation parameter of cells (0.25) was significantly higher than average alignment of collagen (0.09). A design-dependent effect on collagen and cellular alignment was evident as well, were both had a more anisotropic circumferential alignment with more narrow attachment edges and straight belly curvatures.

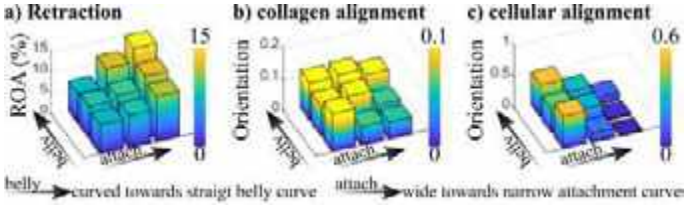

Figure 4 a) retraction, b) collagenous orientation and c) cellular orientation of design variations after remodeling

The predictions of decreased retraction and mild collagen alignment in curved bellied geometries is in line with previous *in-silico* predictions and *in-vivo* results [3]. The findings in the current study have the potential to refine the aforementioned predictions, suggesting that additional improvements might be achieved through optimization of the valvular attachment edge.

DISCUSSION

This study aimed to systematically assess the effect of design features on TEHV remodeling on a functional and tissue level. This was accomplished through the utilization of *in-silico* models that predict mechano-mediated tissue remodeling following *in-vivo* implantation.

The results indicate that in order to prevent retraction, designs with curved bellies and wider attachment edges should be utilized. However, in order to achieve native-like circumferentially anisotropic cell and collagen alignment, straight belly profiles and narrow attachment edges are more efficient. This suggests that design features that decrease leaflet retraction, generate more isotropic collagen and cell alignment. Therefore, during the development of next-generation designs it is essential to ascertain whether it is more critical to prevent TEHV leaflet retraction or induce proper fiber alignment. Thereafter, the design features as suggested here may be utilized in order to optimize the TEHV design.

Even though the current results do not show a decline of TEHV functionality with low circumferential cell and collagen anisotropy, it is possible that over the long-term, these properties could potentially impact valve remodeling and function. Therefore, future (*in-vivo* and *in-silico*) studies could focus on the chronic effect of non-native like fiber alignment on TEHV remodeling.

To conclude, these results increased our understanding of the effect of design features on TEHV remodeling in a systematical manner. This provides practical tools for the development of next-generation designs, thereby enhancing the clinical potential of TEHVs.

MULTIPHYSICS SIMULATION OF FLOW AND OXYGEN TRANSPORT IN A POROELASTIC VOCAL FOLD MODEL

Isabella McCollum (1), Manoela Neves (1), Rana Zakerzadeh (1)

(1) Department of Biomedical Engineering, School of Science and Engineering, Duquesne University, Pittsburgh, PA, USA

INTRODUCTION

Vocals folds (VFs) are two bands of smooth muscle tissue found in the larynx. During voice production, pressurized air from the lungs passes through the larynx causing the folds to self-oscillate, resulting in phonation. Phonation results from the biomechanical fluid-structure interactions (FSI) between the glottal airflow and the poroelastic tissue of the VFs. Computational modeling of this FSI provides a prediction of VF dynamics and glottal flow which can lead to an improved understanding of these interactions. When modeling the VFs, the tissue is commonly assumed to be an elastic model, however, the folds behave more closely as a poroelastic tissue, with an 80% fluid volume fraction [1]. Thus, modeling of the fluid-porous structure interactions is a more realistic model that can better help us understand VF behavior and lead to treatment or prevention of voice-related disorders such as vocal fatigue or dehydration. In our previous research, a poroelastic model was developed to study the liquid dynamics within the VF tissue [2]. In this study, we aim to combine the FSI-porous VF model with a mass transport model to investigate the association of interstitial flow with oxygen transport within the VF. Previous experimental observations report contradictory relationships regarding the effects of phonation on the flow within the tissue and the associated oxygen partial pressure [3]. It has been hypothesized that physiological relationships may influence VF oxygenation, which corresponds with dysfunctions such as hypoxia and localized lesions. This study aims to analyze the role of porous media in modeling the flow and oxygen transport in the context of human phonation modeling. We develop a multiphysics coupled mass transport-FSI computational framework able to numerically simulate the complex flow fields, mechanical stresses, and oxygen delivery.

METHODS

A three-dimensional geometrical model of the VF and larynx domain was created using Autodesk Fusion 360 software. The model was implemented into the commercial modeling ANSYS Workbench software to perform computational analysis. A transient airflow coupled to the porous vocal fold dynamics was simulated. The airflow and interstitial flow dynamics were defined using ANSYS CFX software, and the VF tissue mechanics were modeled in ANSYS Mechanical.

The unsteady incompressible Navier-stokes equation was used to model the glottal airflow. The VF was modeled as homogeneous and isotropic, and its deformation was modeled using the momentum equation for a balance of total forces. Mass and momentum balance equations for the porous media were modeled via the Brinkman equation for the flow inside the VFs combing viscous terms from Stokes with friction terms from Darcy's equation was used to model the interporous flow. Lastly, the advection-diffusion reaction equation was used to model the convective oxygen transport with the consumption of oxygen in smooth muscle cells.

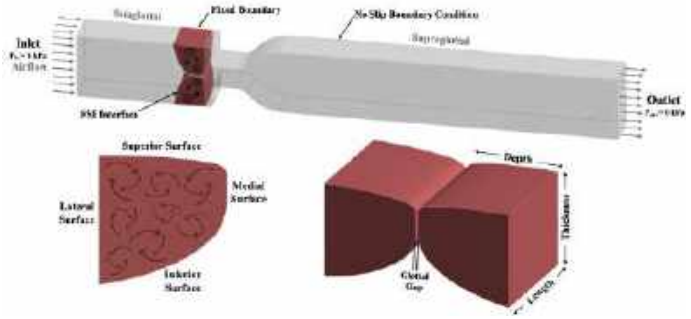

Figure 1: 3D laryngeal model and boundary conditions.

A static inlet pressure of 1 kPa was defined at the subglottal region while the pressure at the outlet of the supraglottal region was fixed at 0 kPa with a zero normal velocity gradient condition applied across the domain. The 3D model and prescribed boundary conditions are shown in **Figure 1**. The surfaces of the VF in contact with the fluid domain are free to move with no-penetration conditions. The lateral surfaces of the

VFs in contact with the outside are treated with opening conditions for fluid to circulate within the folds. All other exterior surfaces of the domains are treated with no-slip and no-penetration conditions. The FSI occurs on the superior, medial, and inferior surfaces of the VF. The material properties of the VFs and airflow used in numerical simulations were derived from our previous study [2]. The permeability constant of the VFs was varied, and the coupled system was solved for each case to provide a prediction of the interstitial fluid flow and oxygen concentration within the VF tissue.

The CFX and Mechanical components were joined along the FSI boundary using the ANSYS Workbench platform System Coupling module, which solves the fluid and solid domains separately to obtain pressure loads from the airflow in CFX that are applied to the VFs on the fluid-solid interface, solving for tissue dynamics in Mechanical. This process of the System Coupling algorithm in ANSYS is illustrated in **Figure 2**. The FSI loads from solving the coupled glottal fluid flow and VF deformation system are exported from the CFX component in the form of the pressure gradient. This data is then imported into the second CFX component containing the permeable VF mass transport model to capture the fluid circulation and the oxygen concentration within the porous tissue.

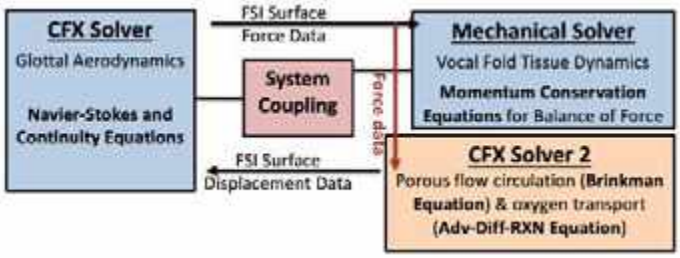

Figure 2: FPSI-mass transport algorithm in ANSYS Workbench.

RESULTS

The results for glottal aerodynamics, specifically the velocity contours at five different timesteps, are shown in **Figure 3**. We can see the velocity reaches the highest magnitude at the glottis region between the folds. We can also see that the airflow recirculates past the glottis region, entering the subglottal region. As time goes on, we can see the airflow increases and dissipates once it reaches the subglottal region.

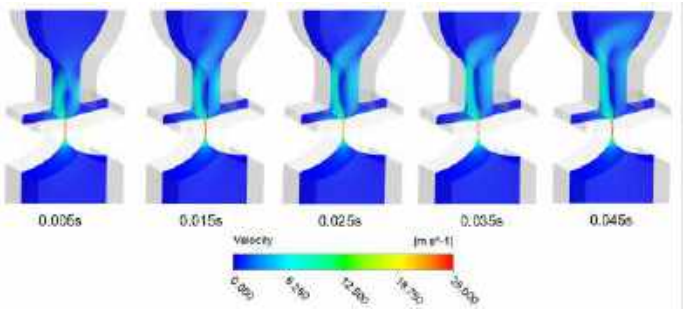

Figure 3: Glottal airflow velocity contours at five timesteps during one phonation cycle.

Next, we look at the results for the VF tissue displacement in one phonation cycle at five different timesteps displayed on the mid-coronal plane as shown in **Figure 4**. The undeformed positions are represented by solid black lines. The T_3 timestep corresponds to the fully open position of the glottis, deforming in the superior direction. The displacement contours are obtained from opening to fully open, then returning to the closed position to complete one phonation cycle. We can see as air flows between the folds, a rhythmic vibration occurs causing the folds to self-oscillate.

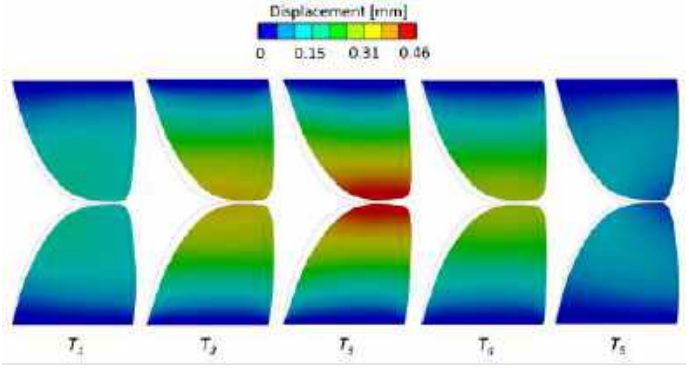

Figure 4: VF displacement pattern profiles at five-time instants during one phonation cycle.

The streamlines of fluid flow through the porous VF and oxygen concentration contours are shown in **Figure 5** for three cases with varying permeability. As the permeability increases, the interstitial velocity increases, thus there is a greater circulation of fluid within the tissue. Likewise, we can see that the amount of oxygenation occurring in the tissue greatly increases with an increase in permeability.

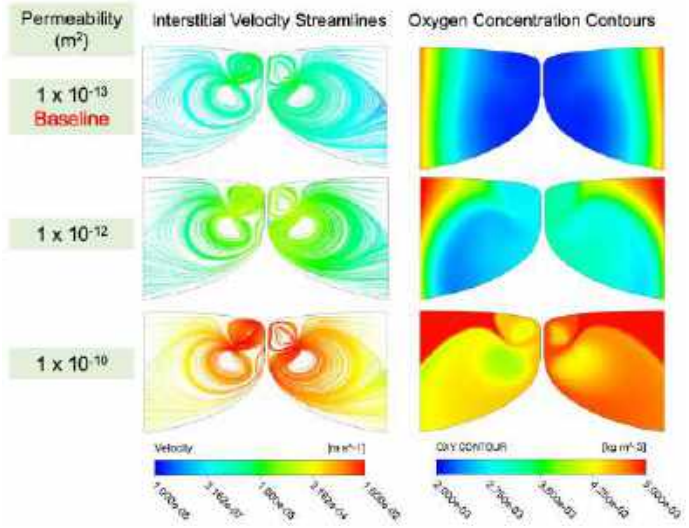

Figure 5: Interstitial velocity streamlines and oxygen concentration contours for cases with varying permeability.

DISCUSSION

An FPSI framework combined with a mass transport model of the VF and larynx domain was developed to investigate the interstitial fluid dynamics and oxygen transport within the VF tissue. Our results in **Figures 3-4** are consistent with previous studies, validating our fluid-structure interaction methodology framework. In **Figure 5**, we observed that the VF permeability was directly related to both the oxygenation of the tissue and filtration velocity. Thus, tissue perfusion is a key characteristic of biotransport in phonation models. Results highlight the association of poroelasticity with oxygen flow, as well as the interplay between permeability and interstitial liquid velocity within the permeable VF structure.

INTRODUCTION

Biomechanical testing of the spine has evolved greatly over the past several decades with the development of new testing techniques, improved testing fixtures and software, novel methods of in vivo measurement, and determination of crucial anatomical structure-function relationships. However, despite previous efforts to capture best practices in spinal biomechanical testing [1], no consensus has been drawn. Artificial composite spine surrogates have been used to counteract some of the challenges with using cadaveric specimens for biomechanical testing standardization and comparison across labs such as degradation over time, inter-specimen variability, storage requirements, and transportation regulations [2]. However, while these composite spines have been used for hundreds of orthopaedic studies, large scale evaluation of these surrogates' performance for use in spine biomechanical testing standardization has not been conducted. The objective of this study was to characterize changes seen in composite surrogates over a long-term, multi-laboratory study to illuminate time-based, repeated testing specimen variation and inform future surrogate development.

METHODS

Seven established biomechanical testing laboratories conducted the testing reported in this study over a total time of 26 months. Five Sawbones synthetic lumbar spinal surrogates were passed through the seven participating labs (Figure 1). Each lab conducted pure moment testing on each of the surrogates in Flexion-Extension (FE), Lateral Bending (LB), and Axial Rotation (AR) through trapezoidal and/or sinusoidal loading schemes (Figure 2).

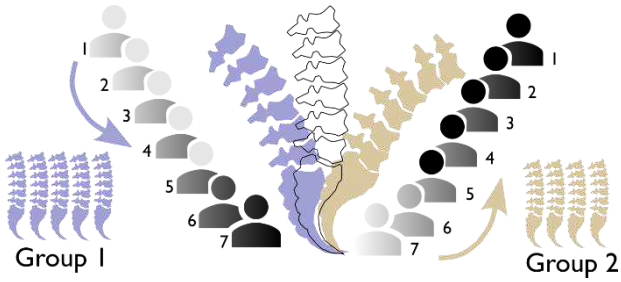

Figure 1: Path of surrogate spines through participating labs.

All labs reported, at a minimum, the bending angles (in degrees) in FE, LB, and AR for the overall joint coordinate system (JCS) kinematics of each of the L2-L5 lumbar spinal surrogates. Most labs were able to report Anterior, Lateral, and Superior translations as well as individual functional spinal unit behavior for the L2-L3, L3-L4, and L4-L5 vertebral pairings. This report is centered on the behavior of the JCS kinematics and specifically the overall L2-L5 spine rotation in the primary direction of loading. The consortium met monthly to discuss findings as each group completed testing on the set of five spines, and to troubleshoot any issues or confusion that arose in testing.

RESULTS

This study resulted in ranges of reported rotation values in the six primary testing directions – flexion (7.4° to 19.8°), extension (5.6° to 13.3°), left LB (4.3° to 15.4°), right LB (7.2° to 16.6°), left AR (2.7° to 6.3°), and right AR (2.6° to 5.6°). The average rotation angle in the primary direction of the loading experienced non-significant increases

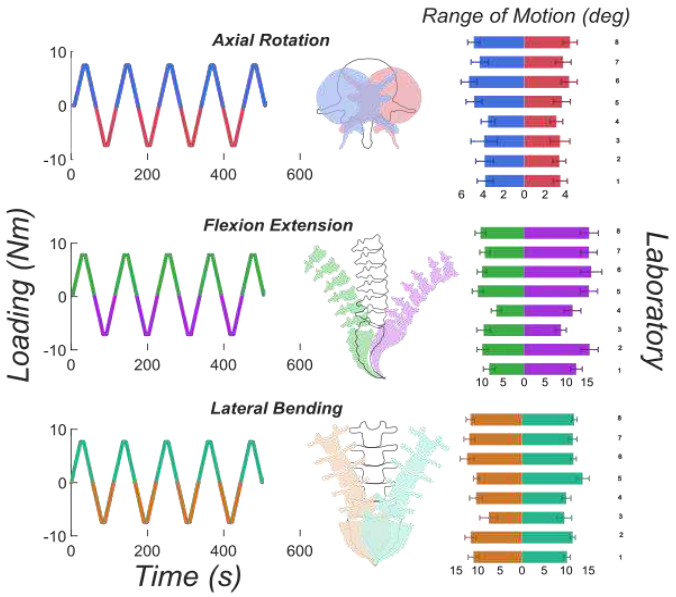

Figure 2: Loading profiles and corresponding data spread by lab.

ranging from 0.9° (right AR) to 3.1° (flexion) between the first and last test (same lab) for all testing directions. Despite an increase in average rotation angle across all testing directions, the standard deviations for each testing direction mostly decreased over time (0.7° to 0.6° for AR, 1.5° to 2.2° for Flexion, 1.4° to 1.3° for Extension, 1.0° to 0.8° for LB). These data are shown in Figure 3.

Figure 3: Surrogate rotation spreads across lab. Note that Lab 1 and 8 were the same lab at the start and end of the testing path.

DISCUSSION

Some of the Sawbones surrogate spines experienced significant visible deterioration shown in Figure 4. However, despite this degradation, the surrogates did not experience significant time-based changes to their range of motion measures in any of the tests reported. Asymmetries in left and right bending (LB, AR) were visible. The highest variation between labs occurred in FE testing while the lowest variation occurred in AR. This both reflects the expected normal variation in these ranges of motion and is consistent with prior testing on these surrogate types [2]. Inter-laboratory variation was larger than temporal variation. Future studies are required to investigate variations in reported rotation angles due to differences in test methods, equipment, etc. Inter-laboratory studies are a crucial part of the standardization of any test protocol and for the wider dissemination of best practices. This is the largest inter-laboratory study conducted on widely used synthetic spinal surrogates, to the knowledge of the authors. These results indicate that additional factors outside of specimen variability play a role in the measured range of motion across laboratories. This study is part of a greater effort to not only provide best practices for spinal biomechanics testing, but also how to manage specimen degradation over time and how to manage a comprehensive spine biomechanics dataset.

Figure 4: Spine surrogate degradation during testing

ACKNOWLEDGEMENTS

The authors would like to acknowledge Sawbones for their funding support of the transportation of the spine surrogates between the participating labs.

Reverse-engineering cancer mechanics: Piezo regulates epithelial topology and promotes precision in organ size control

INTRODUCTION

Mechanosensitive Piezo channels have been implicated in the progression of multiple types of cancer[1,2]. Piezo, a mechanosensitive calcium channel, promotes cell division by activating ERK signaling or can activate Rho signaling to mediate cell extrusion and cell death[3,4]. However, the systems-level functions of Piezo in organogenesis and tissue homeostasis remain poorly understood. To reverse-engineer how Piezo impacts cellular processes in multicellular systems, we focus on a highly accessible model system of organ size control, the *Drosophila* wing imaginal disc. Here, we demonstrate that Piezo controls epithelial cell topology to ensure precise organ growth by integrating methods, including live imaging experiments coupled with pharmacological and genetic perturbations and computational modeling. Our findings demonstrate that Piezo promotes robustness in regulating epithelial topology and is necessary for maintaining precise organ size control. These insights into the multiscale roles of Piezo lay the foundation for identifying new therapeutic strategies crucial for cancer engineering[5].

METHODS

We used the GAL4-UAS system to express RNAi to knockdown (KD) Piezo or overexpress Piezo in the *Drosophila* wing imaginal disc. We also characterized the complete knockout (KO) of Piezo. A hybrid polyethylene terephthalate laminate (PETL) microfluidic device[6] was used in combination with confocal microscopy to ensure extended periods of stable ex vivo imaging and allow the addition of a constant flow of media. Immunohistochemistry was utilized for systematic characterization of cell processes and tissue structure was pursued through immunohistochemistry. Additional analysis included laser ablation and computational modeling.

RESULTS

Our results show that knockout or knockdown of *Piezo* led to bilateral asymmetry in wing phenotypes and increased the variability of organ size, indicating Piezo provides feedback control on organ size regulation (**Fig. 1**). While pharmacological activation of Piezo stimulated an increase in the frequency of spikes in cytosolic Ca^{2+}, we discovered that *Piezo* overexpression counterintuitively reduces Ca^{2+} signaling dynamics. Piezo overexpression also increases the hexagonality of cellular topology. In contrast, Piezo knockdown inhibited proliferation and decreased global apoptosis, resulting in an overall increase in epithelial overcrowding. To further characterize how Piezo regulates cell topology, we formulated computational simulations to investigate how expression levels of Piezo protein regulate cell proliferation and apoptosis through modulation of the cut-off tension required for Piezo channel activation. Quantitative experimental analysis validated computational simulation predictions of how perturbations to *Piezo* impacted epithelial topology.

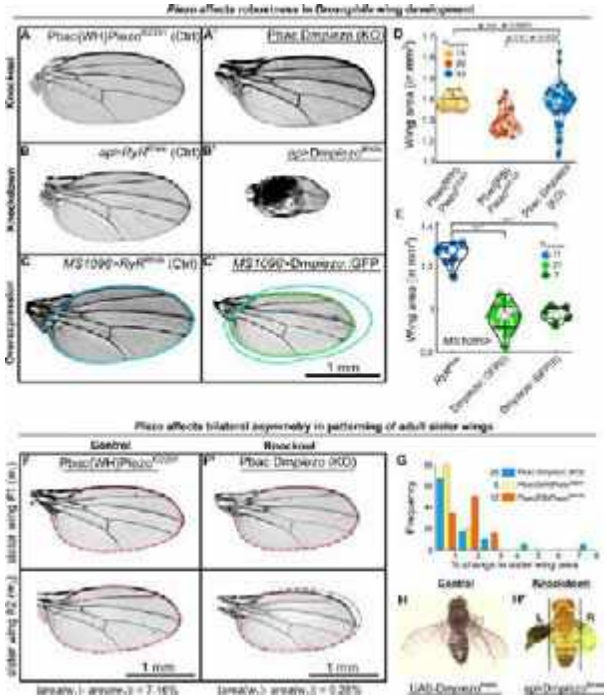

Figure 1: Divergent and spatial effects of Piezo expression in regulating size precision in bilateral organs. Piezo determines size precision in bilateral organs. (A-A') Drosophila wings from a Piezo knockout line do not exhibit significant changes in average wing size compared to the control line used to generate the knockout line. (B-B') Wing phenotypes from RNAi-mediated knockdown of Piezo and a previously characterized cross against RyR^{RNAi}. (C-C') Overexpression of Piezo in the wing disc results in smaller wings than control discs targeting a non-expressed gene with no observed phenotype. (D) Piezo knockout wings exhibit significant heterogeneity in wing size compared to the original Piggybac lines used to generate the knockout. Beeswarm plot showing the distribution of wing area for different perturbations to Piezo. KO represents the Piezo knockout line. The p-value comparing means and variances of populations are indicated. (E) Beeswarm plot showing the quantified distribution of wing area for overexpression of Piezo. Superscripts I and II against the Piezo label indicate two different overexpression lines (detailed in the methods section). (F-F') Sister wings of the control and Piezo knockout lines demonstrate significant variation between bilateral organs. Yellow lines outline the contour of a sister wing. The same contour is depicted as a dashed red line for the other sister wing. (G) The bar graph shows the distribution of differences in the area between the Piezo knockout and knockdown

lines' sister wings. (H) Adult $^{UAS\text{-}PiezoRNAi}$ fly. (H') Adult *ap>Piezo*^{RNAi} fly showing significant patterning and symmetry defects between each wing.

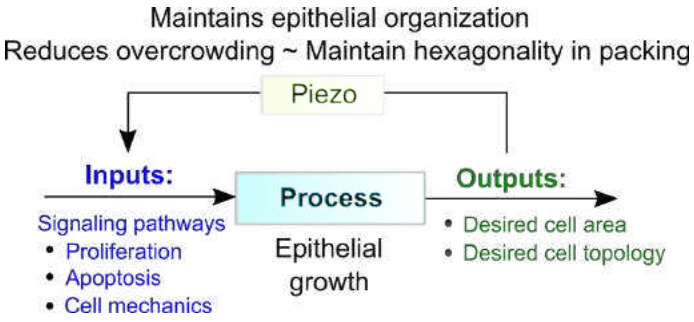

Figure 2: Piezo is a critical component in feedback control to ensure regular epithelial topology and precision in organ size control.

DISCUSSION

This work demonstrates how Piezo channels influence organ size and the structure of epithelia (**Fig. 2**). We posit that Piezo channels act as feedback controllers to regulate cellular topology and epithelial packing through control of downstream processes such as proliferation, apoptosis, and cytoskeletal regulation. Thus, targeting the strength of feedback through Piezo may be an attractive modality for pursuing optogenetics[7] and cancer therapeutics.

ALTERATIONS IN MICROGLIA MORPHOLOGY AND VIABILITY FOLLOWING IN VITRO TRAUMATIC BRAIN INJURY

E. Blick (1), C. Franck (2), A. Hai (1)

(1) Department of Biomedical Engineering, University of Wisconsin - Madison, Madison, WI, United States

INTRODUCTION

Chronic neuroinflammation following Traumatic Brain Injury (TBI) remains an understudied link between a primary injury and neurodegenerative disease, with post-mortem analysis of TBI patients demonstrating a brain-wide immune response up to 18 years after injury [1]. Microglia, the resident immune cells of the brain, are crucial in this process as their prolonged activation is associated with driving secondary injury, cognitive decline, and cell death. Microglia are sensitive to their microenvironment and undergo functional and morphological transitions in response to inflammatory signals, adopting either anti- or proinflammatory roles [1].

Most research on microglia activation relies on using lipopolysaccharide (LPS), a bacterial membrane component that targets microglia-specific receptors, but the research investigating the response of microglia to mechanical impacts is lacking [2]. Furthermore, most TBI studies are conducted *in vivo* and, although biologically complex, they preclude reliable application of strain with the accuracy required to determine a correlation between impact and inflammatory response at a single cell level.

Stretch-based TBI models are commonly used to reproduce mechanical insults linked to the pathological development of diffuse axonal injury [3]. Several previous studies have begun to characterize the response to microglia, but results are inconsistent across studies and lack the evaluation of a range of strain and strain rates [4],[5]. Two studies assessing microglial response to 20% strain at a singular rate observed alterations in microglia migration, cytokine expression, and morphology [4],[5]. In order to further characterize the mechanosensitive properties of microglia, a range of TBI-relevant strain and strain rate parameters must be evaluated. In this study, we utilize a novel and highly precise in vitro model of TBI to evaluate alterations in microglia viability and morphology in response to controlled mechanical stress.

METHODS

Polydimethylsiloxane (PDMS) is used as a substrate for cell seeding due to its nearly linear elastic nature and optical transparency. The PDMS is prepared with a 10:1 mixture of Sylgard 184. The mixture is added to dog bone – shaped molds fabricated on an SU-8 wafer. The dog bone shape enables the use of high strains without disrupting the gripping points and results in the center area hosting the cells to experience a uniform strain field. The PDMS is cured at 80 ℃ for 20 minutes, removed, and adhered with additional PDMS between two 3D printed grippers that were printed with Biomed Clear, a biocompatible resin. Samples are then moved to a culture dish and coated with a 40 µL drop of Poly-D-Lysine for 2 hours (Fig 1.A).

Mixed glial cultures are obtained from P0/P1 Sprague Dawley rat cortices. Cells were suspended in 1 mL of media containing DMEM, 10% FBS, and 1% Pen Strep at a concentration of 5,000,000 cells/mL and added to a T25 flask. The media was refreshed every 2 days for 14 days when flasks were near confluency. Microglia were isolated on DIV 14 using mild trypsinization. Flasks were incubated for approximately 15 minutes in a 1:4 solution of .25% trypsin-EDTA to DMEM/F12 after which the top layer of cells, mainly astrocytes, detached and the media was discarded [6]. Microglia were recovered by a brief 3-minute trypsinization with .25% trypsin-EDTA. The media was collected and centrifuged at 1000 rpm for 10 minutes. The cell pellet was resuspended in 300 µL of media and counted. Microglia were seeded onto the center of the PDMS dog bones at 125,000 cells/mL in a 38 µL drop. Samples were incubated and allowed to adhere for 1 hour, then 3 mL of additional media was added to submerge the dog bone and grippers and cultures were left to settle overnight (Fig 1.B).

The stretch injury was conducted using a micro-tensile impact device built in-house [7]. The customized device consists of two linear actuator motors and 3D-printed “fingers” to contact the sample grippers on either side. The device is placed on the stage of an inverted fluorescent microscope and enables live cell imaging before, during and

after stretch. Samples are stained with Calcein-AM, a live cell indicator, and placed into the device. The device "fingers" are lowered to contact the grippers and aligned. A 10X image is collected as a reference prior to stretch. Applied strain and strain rates are programmed into a macro interfacing with the device and then a brief, symmetric displacement is applied to the sample. For this study, 30% strain at strain rates of 1 s^{-1} and 50 s^{-1} were evaluated. Immediately after stretch the device releases from the sample and the dog bone recovers (Fig 1.C). Samples are then placed back in the incubator for 24 hours prior to subsequential analysis.

At 24 hours post-impact, cultures are restained with Calcien-AM and Ethidium Homodimer-1, a dead cell indicator, and another 10X image is acquired. Samples are then fixed with 4% paraformaldehyde and permeabilized with .5% Triton-X. Cells are stained with Iba-1 to mark microglia and DAPI to assess morphology and sample purity. Stained samples are imaged at 20X magnification. CellProfiler is used to count live and dead cells to calculate percent viability, cell area, perimeter, and form factor.

RESULTS

Preliminary results suggest a rate-dependent reduction in microglia viability 24 hours after stretch. Cultures stained with Calcein-AM and Ethidium Homodimer-1 24 hours after impact are shown. A sham sample is included to account for any cell death related to imaging or placement into the device (Fig.2A). The viability in the sham condition was approximately 78 %. For impact conditions, the sample that underwent a stretch at 30 % strain at 1 s^{-1} demonstrated a comparable viability to the sham sample at around 70 % (Fig.2B). Interestingly, a sample stretched at the same strain of 30 % but at a strain rate of 50 s^{-1} had a large decrease in viability to about 48 % (Fig.2C). Overall, these preliminary findings point to strain rate as a factor to consider when characterizing mechanosensitive of microglia.

DISCUSSION

The presented study begins to address the mechanosensitive response of microglia following TBI-relevant mechanical stimuli using an in vitro model and a micro-tensile impact device. Previous studies have contributed to the understanding of microglial response at singular strain and low strain rate levels. This investigation therefore focuses on the comparison of viability under different impact conditions, particularly the significance of strain rate. The preliminary findings suggest a rate-dependent response in microglia viability, with a reduction in viable cells at a higher strain rate of 50 s^{-1} versus 1 s^{-1} 24 hours after impact. These findings highlight the

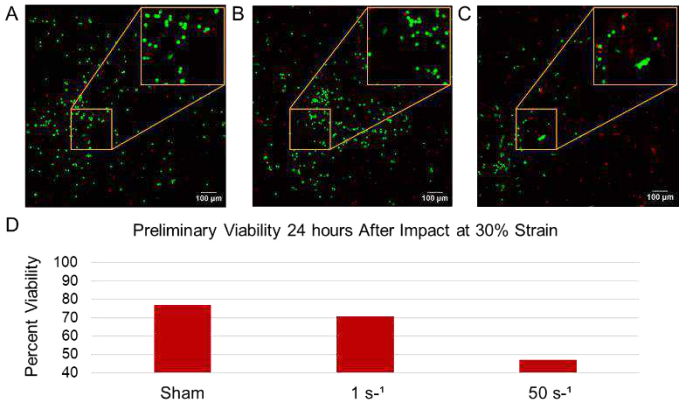

Figure 2: Preliminary Viability Results. Cultures stained 24 hours after impact with Calcein-AM (green) and Etihidum Homodimer-1 (red). (A) Sham (B) 30% strain at 1 s^{-1} (C) 30% strain at 50 s^{-1}

importance of considering strain rate when predicting neuroinflammation.

In order to draw further conclusions about the dose-dependent response of microglia to a range of strain and strain rates, more parameters need to be tested. Additionally, microglia are highly dynamic and collaborative cells and crosstalk with other neural cells must be considered. Therefore, more complex in vitro models containing multiple cell types should be characterized in the future to determine how microglia mechanosensitivity is altered in the presence of neurons and astrocytes. In conclusion, this study introduced a novel in vitro model for applying reproducible mechanical stress to microglia. The results provide preliminary evidence pointing towards the importance of strain rate on microglia viability, contributing to the broader understanding of TBI-related neuroinflammation.

INTRODUCTION

In the United States, one in ten children is born prematurely. Preterm birth (PTB) has been reported to have lifelong effects, such as neurological disorders, feeding difficulties, and vision problems [1]. Makena, a drug previously approved to reduce the risk of PTB, was withdrawn from the market by the FDA in April 2023 [2]. Makena and its generics were determined to be ineffective and there remains an absence of FDA-approved therapeutics addressing PTB. This gap emphasizes the critical need to understand the biological mechanisms of cervical remodeling during pregnancy.

Cervical remodeling is a widely studied phenomenon as it plays a significant role in its structural integrity. There is a lack of comprehensive understanding due to its dynamic and multifactorial nature. In this study, we aim to address this knowledge gap by focusing on the role of progesterone, a hormone that has been shown to play a dominant role in cervical softening. Motivations include evidence of spontaneous birth upon mifepristone-induced progesterone receptor blockage and the impact of progesterone on collagen synthesis in human cervical fibroblast 3D culture [3-5].

Due to ethical and safety considerations, we propose developing a hydrogel system to conduct these studies. Light-based bioprinting was utilized to develop a tunable *in vitro* hydrogel system to mimic the mechanical properties of the human cervix. The development of the hydrogel incorporated gelatin methacryloyl (GelMA), which is gelatin modified with methacryloyl groups in methacrylic anhydride. Previous studies have shown GelMA to have excellent thermostability and cell attachment and proliferation motifs, indicating its promising potential as a bioink with high tunability of mechanical factors [6]. Upon UV-light exposure, GelMA has the ability to polymerize to a desired stiffness.

We hypothesize that a tunable 3D culture system made with GelMA seeded with human cervical fibroblasts will exhibit softening from progesterone exposure. This study aims to elucidate how dynamic mechanical and biological changes during pregnancy drive cell-specific events that modulate cervical remodeling. By addressing this research gap, our work seeks to contribute to the development of effective treatments for PTB.

METHODS

A preliminary study of the photopolymerization and cytocompatibility of the constructed hydrogel system gelatin methacrylate (GelMA) with 0.25% lithium phenyl-2,4,6-trimethylbenzolphosphinate (LAP) photoinitiator was assessed. The prepared bioink was extruded through a 25G nozzle and crosslinked at 405nm to reach mechanical values comparable to previous studies by adjusting the light intensity and duration. The compressive modulus was measured by compression testing with a 5N load cell. The surface topography of the hydrogel was imaged by environmental SEM at 70Pa, which was then used to quantify pore diameters using ImageJ. The degree of hydration was measured using the weights of the dried and wet samples. Human uterine fibroblasts were seeded in the hydrogel and analyzed for cell viability on Day 0, 4, and 7 using a Live/Dead cell assay.

RESULTS

The stiffness of the constructed hydrogel was within 5-15kPa, which reflects the stiffness of the human cervix. It was also observed that the increase of light intensity was directly proportional to the compressive modulus. Pore diameters were greater than 5μm; the duration of the light exposure was inversely proportional to the pore size. The swelling ratio was observed to increase as light intensity decreased. Cells maintained viability throughout the timepoints.

DISCUSSION

In this study, we engineered a hydrogel system using GelMA and achieved stiffness values comparable to those found in literature. The pore sizes were greater than the average cell diameter, which indicates facile transport of cells and nutrients within the network. The observed relations between the light exposure dose and stiffness and pore size values demonstrated the tunability of the hydrogel. With the control of the photoinitiation and production of free radicals, we adjusted the hydrogel's mechanical properties. The hydrogel system was also shown to have cytocompatibility throughout the 7 days from myometrial fibroblasts.

The results of this preliminary study demonstrate the promising potential of utilizing a GelMA-based hydrogel to conduct a progesterone study. Next steps include culturing the GelMA hydrogel construct in progesterone-supplemented media and analyzing for changes within the mechanical properties (stiffness, pore diameter, swelling ratio). An analysis of the collagen concentration and crosslinking would be compared with the current understanding of the native tissue during the remodeling process. To further determine the validity of this engineered hormonally responsive platform, an RNA-seq would be performed similar to the study done by House, et al (2018) [5].

INTRODUCTION

Glaucoma is characterized by progressive degeneration of retinal ganglion cells and their axons [1]. The axon damage is known to start within the lamina cribrosa (LC) region in the back of the eye. Although the mechanisms leading to axon damage remain not fully understood, a leading hypothesis is that insufficient supply of blood or oxygen within the LC would contribute to this process. Currently, it is challenging to experimentally measure in-vivo LC hemodynamics or oxygenation, which are crucial to understanding glaucoma development. Therefore, assessing the structural properties of the LC vasculature, whether in-vivo or ex-vivo, could potentially serve as a predictor for these essential functional parameters.

Our goal was to characterize the vasculature of the monkey LC through several geometrical and functional parameters, including both hemodynamics and oxygenation, and to identify potential correlations between the parameters.

METHODS

Vascular network: We reconstructed detailed 3D models of the LC vascular networks of four healthy monkey eyes using histological techniques, as described before [2]. Each vessel segment was defined as the path between two adjacent branch vertices (or boundary vertex). We calculated four geometric parameters for each vessel: length, tortuosity, inclination, and polar orientation. The detailed definitions of these parameters are shown in figure 1.

Hemodynamics and oxygenation: For each of the four vessel networks we used numerical methods to simulate the hemodynamics and oxygenation using the methods reported elsewhere [3]. Briefly, blood pressure boundary conditions were applied to simulate the physiological blood supply for the LC: Blood inflow from the circle of Zinn-Haller in the periphery, drainage through the central retinal vein, and interactions with the anterior and posterior LC regions. Blood flow was considered as incompressible laminar flow, described by the Poiseuille equation. Oxygen transport in the tissue was described by the diffusion-consumption equation. Three parameters of each vessel were quantified: blood flow, blood pressure, and oxygenation in surrounding tissues.

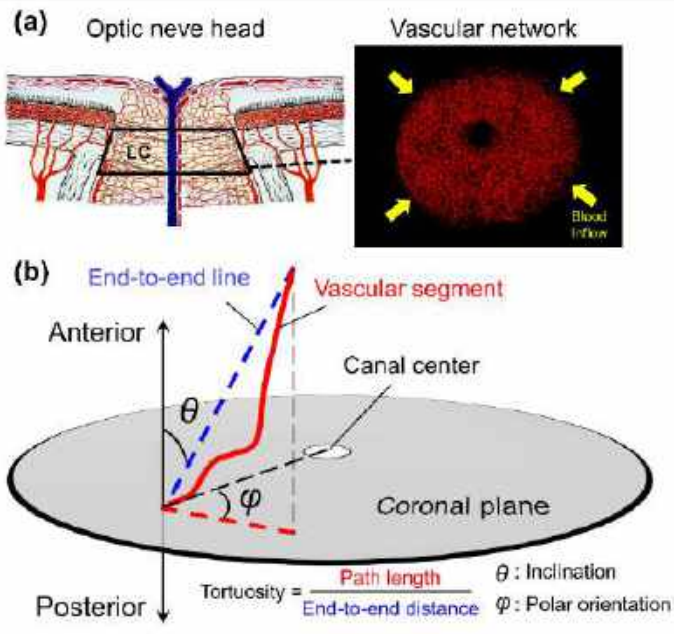

Figure 1: (a) Diagram of the lamina cribrosa (LC) vascular network (left) and example vascular network model. Blood inflow was from the periphery representing the circle of Zinn-Haller (yellow arrows) [4]. (b) Diagram illustrating the definition of the four geometric parameters of a vascular segment [2]: length, tortuosity, inclination, and polar orientation.

Statistical analysis: Using linear mixed effect models we evaluated the correlations between the four geometric parameters (length, tortuosity, inclination, and polar orientation), hemodynamics parameters (blood flow, blood pressure), and oxygenation parameters (oxygenation).

RESULTS

Illustrations of the distribution of all the parameters of one LC vascular network are shown in Figure 2. We did not discern any clear spatial patterns in the geometric parameters. Polar orientations followed a nearly uniform distribution, indicating no preferential polar angle of the capillaries. The hemodynamic and oxygenation parameters exhibited a radial-like spatial distribution. The peripheral region had a higher flow rate, blood pressure, and oxygenation. The central region had a lower flow rate, blood pressure, and oxygenation.

Scatterplots and correlation between the geometric parameters and hemodynamic/oxygenation parameters are shown in Figure 3. All associations shown were significant, although the correlation coefficients were weak ($r < 0.2$). Among the geometric parameters, the length and the tortuosity had weak negative correlations to flows and oxygenation, whereas both orientations were not correlated with flows and oxygenation.

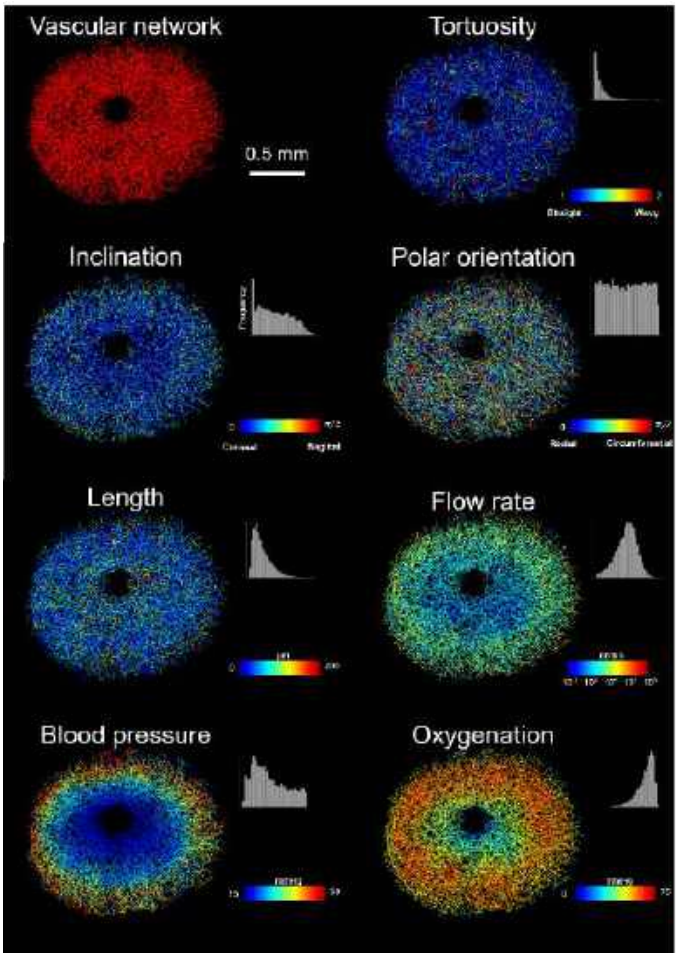

Figure 2: The distributions of the geometric parameters (length, tortuosity, inclination, and polar orientation), hemodynamics parameters (blood flow, blood pressure), and oxygenation parameters (oxygenation) of one healthy monkey LC. All four LCs showed similar features.

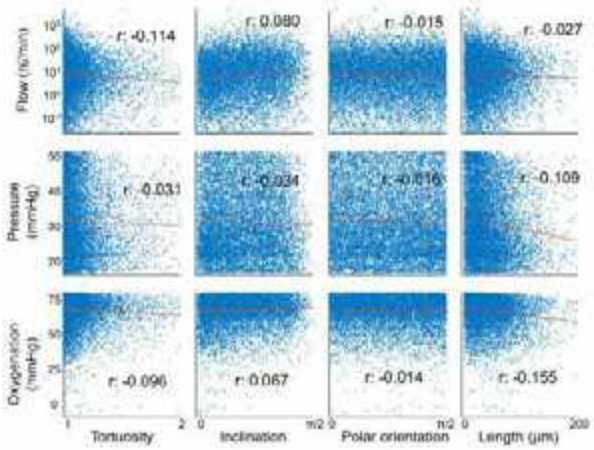

Figure 3: Scatterplots of the geometric parameters (columns) and the hemodynamic/oxygenation parameters (rows) for one eye. Each dot represents a vessel segment, "r" represents the correlation coefficient. The strongest negative correlation was -0.155 between segment length and oxygenation. Correlations between the two orientations and the hemodynamic and oxygenation parameters were quite weak (r<0.1).

DISCUSSION

We leveraged 3D eye-specific numerical models to characterize the geometry, blood supply and oxygenation of the LC vascular network. Specifically, we investigated the distributions and correlations of the geometric, hemodynamics, and oxygenation parameters. Two main findings arise from the work: The geometric parameters did not show any clear spatial patterns, while the hemodynamics/oxygenation parameters exhibited a radial-like spatial distribution. There were some weak associations between structural and functional parameters.

The spatial distribution of geometric parameters suggested a highly random and evenly distributed LC vasculature. The small spatial variations across the LC vasculature may contribute to a smooth blood/oxygen irrigation for the LC region. The radial patterns in hemodynamics/oxygenation parameters can be explained from the LC blood supply, which flows from the periphery to the center.

One may expect that the general radial LC blood supply may lead to correlations between the structural and functional parameters, e.g., radial vessels having higher flow rates and oxygenation. However, our findings indicated only weak associations between those parameters. The weak associations suggest that the geometric parameters are not sufficient to predict the blood or oxygen supply.

In summary, we used 3D eye-specific models to analyze the morphology, hemodynamics, and oxygenation for LC vasculature. Results from this study help us understand the association between the structure and function of LC. It can potentially lead to new biomarkers for LC hemodynamics/oxygenation, which contribute to the glaucoma diagnosis and management.

INTRODUCTION

Hyaline cartilage is a family of cartilaginous tissues whose extracellular matrix (ECM) is characterized by a porous collagen II fibril network entrapping densely packed proteoglycan [1]. In vivo, early skeletal development starts with the formation of transient hyaline cartilage at the epiphysis (Fig. 1a), providing the template that remodels into bone [2]. Unlike epiphyseal cartilage, articular cartilage is not replaced by bone, but retains its hyaline traits throughout lifespan, which endows the joint with its load transmission and energy dissipation functions [3]. These two hyaline cartilages thus follow distinct developmental trajectories and have different functions in vivo. However, due to similarities in their composition, there have been few attempts to delineate differences in their matrix structure-function relationships or assembly/remodeling paths. This study aims to distinguish the molecular, structural and mechanical traits of these two cartilages in small (murine) and large (porcine) animal models during the initial phase of matrix formation.

METHODS

Knee joints were harvested from wild-type (WT) C57BL/6J mice at embryo day 15.5 (E15.5) and postnatal day 0 (P0), and from Yorkshire pigs at E42 and P0. RNAscope in situ hybridization was applied to visualize the spatial expression profiles of *Col2a1* and *Acan* genes on P0 murine joint sections. Safranin-O/Fast Green histology staining was applied to evaluate joint morphology and sulfated glycosaminoglycans (sGAGs) distribution in sagittal and coronal paraffin sections of murine and porcine joints, respectively. Immunofluorescence (IF) staining was performed to assess the protein distributions of collagen VI, perlecan and collagen V. Transmission electron microscopy (TEM) was applied to quantify collagen fibril nanostructure in P0 murine joints. Atomic force microscopy (AFM)-nanoindentation was applied to 10 μm-thick, unfixed cryo-sections to quantify the tissue modulus, following our established methods [4]. Two-sample student's *t*-test was applied to detect differences in fibril diameter and modulus at $\alpha = 0.05$.

RESULTS

In murine joints, we found active expression of *Col2a1* and *Acan* in both articular and epiphyseal cartilage at P0, but with much higher expression in epiphyseal chondrocytes (Fig. 1b). Safranin-O/Fast Green histology also showed stronger sGAGs staining in epiphyseal cartilage at E15.5 and P0 (Fig. 1c). In addition, these two tissues showed differential distributions of key matrix molecules. Collagen VI, the biomarker of pericellular matrix (PCM) [5], was present in articular cartilage, but absent in epiphyseal cartilage. However, perlecan, the other PCM biomarker [6], was present throughout both tissues (Fig. 1d). Surprisingly, we found that collagen V, the initiator of collagen I fibrillogenesis [7], was localized in developing articular cartilage, and absent in epiphyseal cartilage (Fig. 1e). TEM imaging detected thicker collagen fibrils in articular cartilage than epiphyseal cartilage at P0 (arrowheads, Fig. 1f). Meanwhile, epiphyseal cartilage showed moderately higher modulus than articular cartilage at E15.5. By P0, however, these two tissues showed a similar modulus (Fig. 1g).

In E42 and P0 porcine knee joints, we found similarly higher staining of sGAGs in epiphyseal than articular cartilage (Fig. 2a). Also, collagens VI and V were localized in articular cartilage, while perlecan was present in both tissues (Fig. 2b,c). In P0 porcine joints, articular cartilage already developed distinct collagen VI-exclusive PCM domains (Fig. 2b), illustrating differences in the development of porcine versus murine joints. Indeed, in porcine joints, epiphyseal cartilage had similar modulus as articular cartilage at E42 but showed higher modulus at P0 (Fig. 2d), a trend different from that of murine joints.

DISCUSSION

This study highlights that transient (epiphyseal) and permanent (articular) cartilage develop distinct molecular and structural traits upon their initial establishment (~ E15.5 in mice [8]) in both small and large

animals, despite both being characterized by high collagen II and aggrecan contents. For example, the presence of collagen VI in articular cartilage, but not epiphyseal cartilage (Figs. 1d, 2b), suggests differences in their initial cellular microniche, which could contribute to their different cellular mechanosensitive signaling. The high concentration of perlecan in epiphyseal cartilage (Figs. 1d, 2b) could be associated with its potential role in endochondral ossification through FGF signaling [9]. Furthermore, the unexpected presence of collagen V in articular cartilage (Figs. 1e, 2c) suggests that collagen V may participate in the initial templating of permanent cartilage matrix, a role beyond the canonical understanding of collagen II/IX/XI fibrils in hyaline cartilage [1]. Indeed, the different fibril assembly routes of these two tissues are supported by the much thicker collagen fibrils found in articular cartilage (Fig. 1f). As a result, despite the higher sGAGs in epiphyseal cartilage, we found similar modulus in these two tissues at P0 mice (Fig. 1g). Together, our results provide a new knowledge basis for improving cartilage repair. One key roadblock in cartilage regeneration is the adverse effect of aberrant ossification [10], and heterotopic ossification in vivo is initiated with a proteoglycan-rich cartilaginous template [11]. Understanding the initial traits that differentiate permanent versus transient cartilage will provide a path to address these key challenges in musculoskeletal pathology.

THE BALANCE OF VON WILLEBRAND FACTOR AND PLATELET ACTIVATION IN CAUSING BLEEDING IN AN AORTIC STENOSIS

Alice Liu (1), Katrina Ashworth (2), Nina Lasky (2), Yi Qiao (2), Kimsey Platten (2), Jorge Di Paola (2), David Bark (1,2)

INTRODUCTION

An aortic stenosis (AS) occurs when the aortic valve does not fully open, thereby creating a stenosis or restriction to the flow. Severe AS leads to bleeding, initially known as Heyde's syndrome. It was discovered that this may be due to the loss of high molecular weight multimers (HMWM)s of the very large mechanosensitive plasma protein, von Willebrand factor (VWF). This loss is known as acquired von Willebrand syndrome (AVWS). VWF otherwise exists in plasma in a wide range of sizes due to natural cleavage by it's metalloproteinase, ADAMTS13. It plays a crucial role in hemostasis, more commonly known as blood clotting, with the largest multimers providing the greatest hemostatic ability. It does so by tethering platelets to collagen and to each other in regions of high shear flow typical of the arterial side of circulation and in most cases of vessel puncture.

VWF generally circulates in a globular form, but can extend when sufficient fluid drag forces are applied. Extension increases the tension along the multimer. If this tension exceeds approximately 20 pN of force at a given region, it will expose key domains for both platelet binding and for ADAMTS13 cleavage [1–3]. It's thought that the high shear associated with an AS is the cause for AVWS due to exposure of the ADAMTS13 cleavage site, as supported by the increasing loss of high molecular weight multimers with increasing AS severity [4]. However, the amount of cleavage seen from high shear is modest and does not account for the substantial loss of HMWMs seen in AS patients [2]. Furthermore, the shear required to cause a tension of 20 pN may be excessively high [1, 5]. Lastly, high shear also leads to shear-induced platelet activation and aggregation (SIPA) and it's not clear whether this occurs in AS.

Recently, our group discovered unprecedented VWF cleavage when exposing it to turbulent flow [6]. However, our studies also involved very high shear stress and we did not study the impact on platelet activation. In this current work, we probe the flow found in AS and evaluate the effects on both VWF and SIPA, combining *in vivo* an *ex vivo* work to better understand bleeding in AS. Results also translate to other cases of non-physiological shear, like in the case of ventricular assist devices.

METHODS

***In Vivo* Transthoracic Aortic Constriction** We create a transthoracic aortic constriction (TAC) in the mouse aorta to recapitulate characteristics of AS in humans, noting that the scale is much smaller. This is done by tying off a needle of set gauge along the aortic arch, and removing to the needle to create a controlled reduction in aortic diameter. We also use VWF-/- and ADAMTS13-/- genetic lines. We quantify flow through computational fluid dynamics (CFD) with computed tomography images, matched with Doppler ultrasound. ***Ex Vivo* Experiments** We recreate flow characteristics of the TAC model using a benchtop vortexer, combined with a 96 well plate, with flow characterized through both CFD and particle imaging velocimetry (PIV). Platelet poor plasma and platelet rich plasma is obtained from centrifugation steps of citrated human blood. **Measurements** We quantify VWF size through multimer gels and function by quantifying binding capacity. We also quantify platelet activation through flow cytometry and through microfluidic collagen-binding assays. Lastly, we quantify overall bleeding in mice through a tail bleeding assay, where the tail is cut.

RESULTS

***In Vivo* Mouse Model** The bleeding time for cut tails in mice increases with increasing stenosis severity, 7 days post-procedure. Excessive bleeding times are found for VWF-/- mice, extending to our maximum time point of 10 minutes, demonstrating the importance of VWF in hemostasis, Fig. 1. Compartively, ADAMTS13-/- mice have no cleavage from ADAMTS13 and we find that bleeding times are the shortest for these mice. HMWMs are reduced with increasing stenosis severity, as early as 24 hours after the TAC procedure, and remain reduced for our maximum time point of 7 days, Fig. 2a. HMWMs are at a normal level for ADAMTS13-/- mice. The percent of platelets activating, based on integrin activation and granule release, increase with increasing stenosis severity at 24 hours post-procedure, whereas the amount of activation significantly decreases at 7 days, Fig. 2b.

VWF-/- mice exhibit no platelet activation, whereas ADAMTS13-/- continue to have high levels of platelet activaiton at 7 days. Lastly, we determined the shear rates and turbulent kinetic energy through CFD so that they can be matched in *ex vivo* experiments.

***Ex Vivo* Vortexer** We use four different speeds on the vortexer, 34, 112, 150, and 230 rad/s to cover a range of shear rates. Furthermore, flow becomes transitional at 150 rad/s and turbulent at 230 rad/s. Thrombus growth in a collagen-coated microfluidic device decreases with increasing rotational speeds. HMWMs decrease for increasing vortexing speed, with a sudden decrease at 150 rad/s. Similarly, VWF function decreases with a dramatic loss in function at 150 rad/s. The percent of platelets activating in this system increase with increasing speeds. Various inhibitors were used and the inhibitor with the greatest effect blocks platelet binding to VWF, where almost no platelet activation is seen. Finally, to determine the relative role of turbulence, we increase the viscosity of our sample by adding dextran, thereby lowering the Reynolds number to convert turbulent flow to laminar flow, while simultaneously increasing shear stress. In these experiments, the amount of VWF cleavage is significantly reduced and the amount of platelet activation is reduced.

DISCUSSION

We demonstrate that an AS leads to VWF cleavage through ADAMTS13, leading to AVWS that becomes more severe with increasing stenosis severity, in agreeement with what has been found in humans [4]. However, we also show that this is greatly enhanced if the AS leads to turbulence, as supported by our earlier work [6]. For the first time, to our knowledge, we show that SIPA in this system can occur when HMWM VWF is present, but that is greatly reduced as plasma VWF size distribution decreases due to cleavage. These results demonstrate a fine balance between VWF size and platelet activation that can tend toward bleeding when VWF size is reduced, or thrombosis, when HMWMs remain in the plasma.

In other cases of nonphysiological flow, like ventricular assist devices, AVWS is prevalent, occuring in almost all patients receiving these devices. However, these patients are not just at risk for bleeding, they are also at risk for thrombosis (or blood clotting that can block blood flow). We believe this can be due to high levels of SIPA where perhaps VWF size remains sufficient to induce SIPA or perhaps the shear stress is so high that it can also lead to VWF extension and 'activation' despite the lack of HMWMs. We also acknowledge that the cause of thrombosis in these patients may also relate to blood-material interactions, as opposed to being purely flow-induced.

INTRODUCTION

Pediatric anterior cruciate ligament (ACL) injuries and subsequent reconstruction surgeries have been rising over the past 20 years. [1,2]. Furthermore, adolescent female athletes are 3 to 4 times more likely to tear their ACL in specific sports [3-5]. As a result of these sex-specific differences in injury rates, female sex hormones have received considerable attention, with several groups drawing associations between ACL injuries, menstrual cycle phases, and corresponding serum sex hormones [6,7]. Furthermore, sex-specific structural differences have been identified in the porcine ACL, with the posterolateral (PL) bundle size plateauing in adolescent female animals near the onset of puberty, while the male PL bundle continues to increase in size [8]. Likewise in humans, the cross-sectional area of the ACL increases more rapidly in males than in females following puberty [9]. However, there is no clear mechanism for these structural changes. Previous work has identified sex hormone receptors within cells throughout the adult ACLs [10]. Additionally, after monolayer culture of adult ACL fibroblasts, only ~5% of the cell population express these receptors [11]. There is currently no understanding of changing hormone receptor expression in the ACL throughout growth, specifically in pre- vs. post-puberty. The objective of this work was to determine native levels of female sex hormone receptors in juvenile and adolescent ACL bundles and determine if hormone receptor expression is retained in-vitro.

METHODS

Twelve female pig hindlimbs were collected at pre-puberty (8 weeks) or post-puberty (>8 months) ages (n=6 animals/age). Animals were sourced from various research projects performed at NC State. The ACL was dissected into the anteromedial (AM) and PL bundles. The bundles were snap frozen in liquid nitrogen and cryosectioned at 10 um section thickness. Prior to immunostaining, sections were washed and warmed to room temperature in 1X PBS for 10 minutes. Sections were then permeabilized for 15 minutes with 0.1% Triton-X in 1X PBS and blocked in a solution of commercial IHC/ICC blocking buffer (45%), 0.1% Triton-X in 1X PBS (45%), and donkey serum (5%) for 1 hour. After blocking, primary antibodies were added for estrogen receptor-alpha (1:400, ERα) and progesterone receptor-beta (1:200, PRβ) in the blocking solution at 4°C overnight. Corresponding rabbit IgG isotypes, no-primary controls, and positive uterine tissue were used to determine the non-specific binding antibodies and to verify positive staining. Slides were washed with 0.1% Tween-20 in 1X PBS, and anti-rabbit secondary antibodies were added for 2 hours at room temperature in the dark. The slides were washed again with 0.1% Tween-20 in 1X PBS mounted with Prolong Gold with DAPI. All images were acquired with a cellSens Olympus LS fluorescent microscope.

ACL fibroblasts were isolated from the AM and PL bundles of the ACL to assess hormone receptor density during monolayer culture. Synovium was aseptically removed from the AM and PL bundles, and cleaned bundles were placed in sterile PBS. The sections were diced and placed in a 2 mg/mL solution of collagenase type I in complete media (10% fetal bovine serum, 1% penicillin/streptomycin/fungizone in DMEM). Tissues were incubated for 6-8 hrs at 37°C. Following incubation, cells were isolated and plated as passage 0, and cultured in complete media at 37°C and 5% CO_2. Tissue explants were also plated to allow cell migration from the tissue. Once the cells reached confluency, they were fixed with 4% paraformaldehyde and washed with PBS. They were then stained for ERα and PRβ.

Immunostaining results were quantified by thresholding images set by the isotype and no primary controls in ImageJ. The area of the signal was then recorded for DAPI and the secondary antibodies. The expression index reported was the area of the signal for ERα and PRβ divided by the DAPI area. Two-way ANOVAs were used to determine overall effects of age and bundle on hormone receptor expression and Hold-Sidak post-hoc tests were used for multiple comparisons. Statistical analyses were performed at a set alpha value of 0.05.

RESULTS

Age had a significant effect on ERα expression (p=0.005), with a 6-fold higher ERα expression in the pre-pubescent group on average (Figure 1). Across bundle, there was only a 1.5-fold higher ERα expression in the AM bundle compared to the PL bundle on average, which was not statistically significant (p=0.27). In the PL bundle, the post-pubescent animals had a 79% lower expression than in the pre-pubescent animals on average, but this was not statistically significant (p=0.09, Figure 1A). For PRβ expression, there was a statistically significantly higher expression in the PL bundle for the pre-pubescent group compared to the AM bundle (p=0.008, Figure 1B). Additionally, there was statistically significantly higher expression of PRβ in the pre-pubescent PL bundle than in the post-pubescent PL bundle (p=0.01). Pooling pre- and post-pubescent animals, ERα expression was significantly higher in both bundles than PRβ expression (AM bundle: p=0.003, PL bundle: p=0.03; Figure 1C).

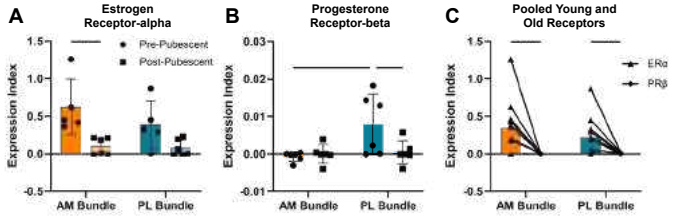

Figure 1: ERα expression decreases after puberty and is significantly higher than PRβ expression. (A) ERα expression (ERα/DAPI) and (B) PRβ expression (PRβ/DAPI) by age group and ACL bundle. (C) Receptor data pooled from pre- and post-pubescent animals. Bars indicate p<0.05.

While there were statistically significant differences across age for ERα, a binary ERα expression was observed across animals in the post-pubescent group (Figure 2). Three of the six animals positively stained for ERα with a similar expression index of 0.20 in the AM bundle, and the other three animals had zero expression (Figure 2). This differs from the pre-pubescent AM bundle group where all animals had some baseline expression of ERα (images not shown). In the post-pubescent group, Pigs 1, 2, and 3 were also known to be 2-3 days before ovulation (based on research studies involving reproductive status).

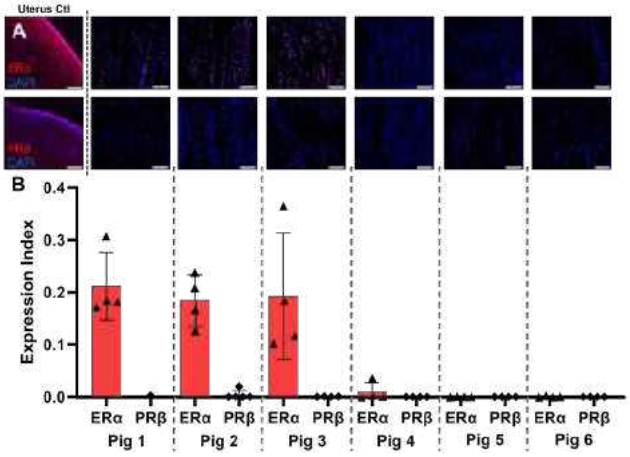

Figure 2: ERα expression dichotomy in post-pubescent animals. (A) Representative images of ERα and PRβ expression in the ACL (AM bundle) by animal, with positive control. (B) Quantification of ERα and PRβ expression by animal. Each point represents one image. Scale bars are 100µm.

To further study the hormone receptor density in-vitro, cells were isolated from the AM and PL bundle of post-pubescent Pig 3 via digestion and explants and stained for hormone receptors. After the initial plating of cells (P0), there was no ERα expression for either Pig 3 AM or PL fibroblasts despite the strong staining in the tissue (Figure 3). This loss was sustained throughout passage 1 and 3.

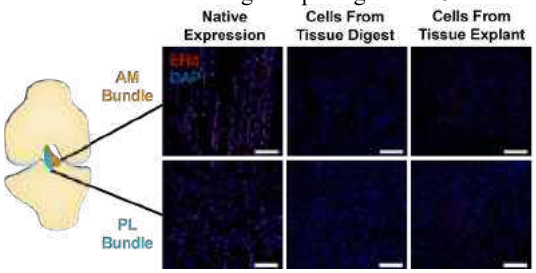

Figure 3: ERα disappears rapidly after AM and PL bundle fibroblast isolation and several days of monolayer culture. Cells were isolated from the same animal. Scale bars are 100µm.

DISCUSSION

There was strong effect of age on ERα expression in the ACL, with higher expression in the pre-pubescent porcine ACL than in the post-pubescent group. Furthermore, there was an interesting binary expression of either strong or no ERα staining in post-pubescent animals. There was relatively little PRβ expression in any of the animals (all groups were not significantly different from 0 (p>0.05; secondary statistical analysis, data not shown). When isolating ACL fibroblasts for subsequent cellular studies from one of the animals with strong ERα staining, the ERα expression was lost rapidly in monolayer culture.

The presence of hormone receptors in healthy pre-pubescent porcine ACLs indicates that there may a be direct hormonal impact on ACL growth and development prior to sexual maturity, an idea that is supported by circulating low levels of estradiol in prepubescent humans [12]. Additionally, the presence of ERα in both ACL bundles may not support the role of estradiol on differences in bundle size during adolescence. The minor staining of PRβ also may indicate a lesser effect of progesterone on the ACL. However, a larger sample size is needed to support these findings, and longitudinal studies across the reproductive cycle may elucidate fluctuations in receptor expression. Finally, the loss of hormone receptors after monolayer culturing regardless of technique indicates early phenotypic drift in ACL fibroblasts from skeletally immature animals in in-vitro culture, which confirms other studies tracking loss of phenotype in primary cell culturing [13]. Overall, the change in receptor density across age and potentially estrus cycle phase reinforces the idea that the ACL is responsive to sex hormones during growth. Future work will identify how sex hormones impact extracellular organization and tissue mechanics.

INTRODUCTION

Shear wave tensiometry is a noninvasive method to gauge axial stress in tendons based on wave propagation. Tensiometry is premised on a tensioned Timoshenko beam model [1], which predicts that shear wave speed will varies in proportion to the square root of axial stress in structures with a low tangential shear modulus. It was previously shown that the tensioned beam model applies to whole tendons subjected to axial loading [1]. However, it is unknown whether this model and measurement system holds across microstructural scales of tendinous tissue, such as in tendon fascicles.

The objective of this study was to investigate microscale shear wave propagation in isolated tendon fascicles. We hypothesized that a tensioned beam model would describe the shear wave speed-stress relationship across fascicles after accounting for differences in morphology. The results of this study can inform tensiometry measurements in whole tendons, while providing an experimental platform for probing how fatigue loading and damage can affect wave propagation in individual fascicles.

METHODS

Specimen Preparation: Tails from two 9-month-old rat tails (F334xBN), were dissected, stored at -20°C, and then thawed before testing. Individual fascicles (n = 6) were extracted from the proximal end of the tail and then immediately tested. Fascicles were immersed in a 1X PBS bath and secured on either end to waveform grips of a custom benchtop loading device (Aerotech PRO165LM, Fig. 1a). One grip was attached to a 10-lb miniature submersible load cell (Futek LSB210) to monitor axial loading. Fascicles were preloaded to 0.1 N. The gauge length of each fascicle in the grips was measured using a vernier caliper.

Wave Speed Measurement: Shear waves were induced using impulsive lateral taps (50 Hz, 0.3 ms pulse) at a fascicle cross-section located 5 mm from a grip. Wave propagation was measured using two laser Doppler vibrometers (Polytec PDV 100) centered on the fascicle at 20 and 50 mm from the tap (Fig. 1a). Wave travel time between vibrometer points was computed using cross-correlation of vibrometer signals within a Kalman filtering routine [2]. Wave speeds, in meters per second, were computed using the known distance between laser vibrometer points (30 mm).

Mechanical Testing: Fascicles underwent 10 cycles (1 Hz) of preconditioning between 0 and 5% strain. Following a 300s rest interval, the fascicles were then harmonically stretched to 5% strain at 0.1, 0.2, and 0.4 Hz. Two 10-second trials at each frequency were performed, with a 60-second rest interval between trials. Laser vibrometer, load cell, and stage displacement were synchronously recorded at 100,000 Hz using an 8-channel AD board (NI USB-6251).

Cross-sectional Area: Fascicle profiles and cross-sectional areas were measured at 3 cross-sections by rotating each fascicle within a laser micrometer (Keyence LS-7010) [3]. Fascicles were kept hydrated throughout the measurement using miniature ultrasonic humidifiers. The maximum cross-sectional area for each fascicle was used to compute axial stress (σ) from the measured force.

Analysis: A tensioned Timoshenko beam model predicts that the shear wave speed, c, is dependent on the tangential shear modulus (μ) of the tissue, the axial stress (σ), a shear correction factor (k'), and the effective density (ρ) of the tissue (Eq. 1):

$$c = \sqrt{\frac{k'\mu + \sigma}{\rho}} \quad (1)$$

We used nonlinear least squares fitting to estimate fascicle shear modulus (μ, *assuming* $k' \cong 1$) and effective density (ρ) given measurements of wave speed and stress. Goodness of fit was assessed by the coefficient of variation R^2, which represents the proportion of the variance in wave speed explained by a tensioned beam model.

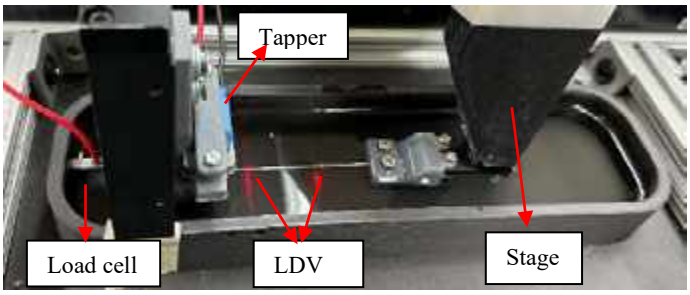

Figure 1: (a) Shear waves were induced by an electrodynamic tapper and tracked via laser Doppler vibrometers while a linear stage cyclically stretched the fascicle.

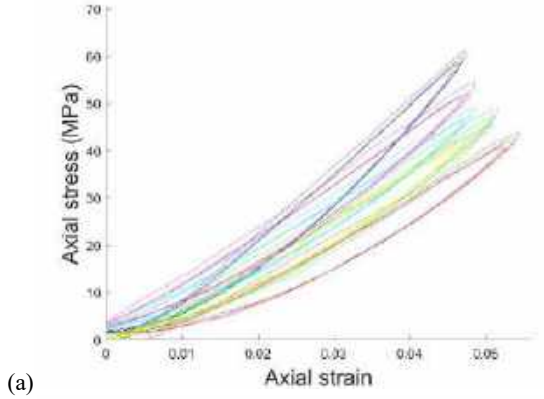
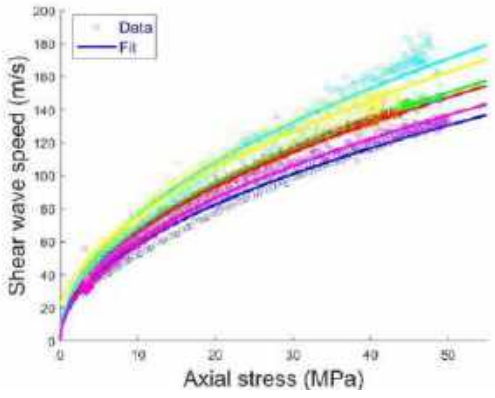
RESULTS

Fascicles exhibited characteristic strain-stiffening behavior and hysteresis in response to cyclic stretch (Fig. 2a). The lack of hysteresis in the wave speed-stress relationship (Fig. 2b) supports the premise that wave speed depends directly on the applied stress. Wave speeds were well described by a tensioned beam model (average R^2=0.99).

At the 0.4 Hz loading rate, estimates of effective density were 2182±537 (mean±1sd) kg/m^3, while shear modulus averaged 0.66±0.78 MPa. These parameters did not vary substantially across the loading rates considered.



(a)



(b)

Figure 2: (a) Fascicles exhibited strain stiffening behavior and hysteresis with cyclic loading. (b) Shear wave speeds increased with the square root of axial stress, as predicted by a tensioned beam model, during both loading and unloading phases. Each color represents a different fascicle tested at a 0.4 Hz cyclic loading rate.

DISCUSSION

This study investigated the wave speed-stress relationship in tendon fascicles. Our results show that fascicle wave speeds depend directly on stress during axial stretch, with the general relationship well described by a tensioned beam model. To our knowledge, this is the first application of shear wave propagation for measuring tissue mechanics at the microscale. To date, shear wave tensiometry and ultrasound elastography studies in tendons have generally focused on measuring shear waves in an entire tendon unit [4]. By studying smaller constituents of tendons, such as fascicles, microscale tensiometry may enable noninvasive investigations of soft tissue structure-function relationships following repetitive loading, microstructural damage, or disease. Such focused study could better inform the use and interpretation of *in vivo* shear wave speed measurements in tendon.

Wave speed varied with the square root of axial stress, as predicted by a tensioned beam model. Estimates of effective density were substantially higher than the tissue itself (1060 kg/m^3), which likely reflects the added inertia effects due to the fascicle vibrating in a water bath. It has been estimated that the added mass effect of the bath can substantially increase the effective density [5], which is consistent with our observations.

Our estimate of fascicle shear modulus μ were <1 MPa, but did exhibit considerable variability across specimens. The inherent shear modulus is the determinant of the unloaded wave speed, which was estimated to be <20 m/s. Unloaded *in vivo* tendon wave speeds are in a similar range, averaging ~15 m/s in the human Achilles tendon [6]. Unfortunately, we were unable to directly assess wave speed in unloaded fascicles, due to lack of laser alignment on the fascicle in a slack condition.

We note that our model fitting approach assumed a constant shear modulus throughout the loading regime. Prior experimental studies would suggest that shear modulus may increase with loading due to strain-stiffening behavior [7]. It is challenging to empirically delineate the increase in wave speed due to axial stress and shear modulus stiffening.

In summary, this study introduces microscale tensiometry, which can be used to noninvasively characterize loading in tendinous substructures. Future studies will ascertain how wave speeds vary across hierarchical scales of a tendon, and will also investigate how fatigue-related damage in fascicles may be evident in wave speed metrics.

INTRODUCTION

Current blood rheology technologies investigate the flow of red blood cells (RBCs) mostly through large-diameter vessels. However, *in vivo*, RBCs flow through a wide range of vessel diameters from 3 cm in the aorta down to 3 μm in the smallest capillaries. Rheology in the capillaries is especially unique due to their intricate topology involving a high degree of winding, bifurcation, and merging. Devices that mimic these complex flow conditions are needed to identify subtle pathological alterations in blood rheology that manifest in the capillaries.

Microfluidics offers the potential to investigate rheology in physiologically relevant geometries. To maximize the utility of such devices, computational modeling can be used to predict flow dynamics and optimize design parameters. Here, we detail a simple computational model designed to reflect spatiotemporal variations in RBC velocity and distribution in a microfluidic capillary network. The modelled microfluidic device was previously used to assess RBC deformability based on the tendency of stiff RBCs to occlude narrow openings [1]. However, abnormal RBCs may pass through narrow capillaries and still alter rheology, leading to chronic pathology. Studying RBC velocity and distribution profiles may reveal rheologic disturbances missed by occlusion measures and other bulk flow rheology assays.

METHODS

The microfluidic device model was developed in COMSOL Multiphysics 6.0 and comprised a 155 μm × 350 μm rectangular channel containing 20 μm × 10 μm micropillars arranged to create 4-μm inter-pillar openings with 20-μm separation between rows (Fig. 1). 12-μm-wide side passages were incorporated to mimic arterio-venous anastomoses. The channel height was set to 12 μm. A no-slip condition was assumed on all walls. For each simulation, blood was perfused at a constant inlet pressure of 5 mbar, with the outlet maintained at atmospheric pressure. Blood was modelled as a non-Newtonian fluid governed by the Carreau-Yasuda model as previously published [2].

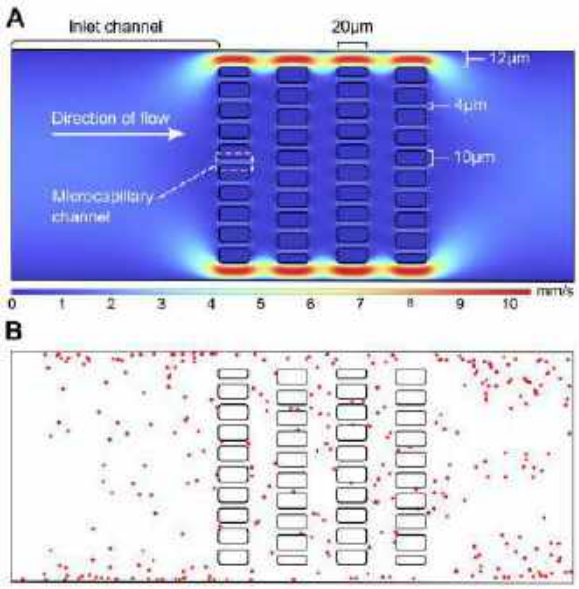

Figure 1: Velocity and RBC distribution profiles in the microfluidic device. (A) Model-predicted high velocity and stagnation regions based on channel geometry. (B) Distribution profile shows a higher density of RBCs in low-velocity regions. RBC size was reduced for this image to aid in visualization.

A particle tracing module within COMSOL was used to predict the distribution of RBCs in the device. The RBCs were modelled as particles of 8-μm diameter with a density of 1,060 kg/m^3. Particles were released at the inlet with a random starting distribution and zero initial velocity. They were subsequently transported by the viscous drag force due to bulk flow (1).

$$F = \frac{18\,\mu}{\rho d^2} m(u - v)\,, \qquad (1)$$

where F is the drag force, μ is viscosity of the bulk fluid, ρ, d, and m are the particle density, diameter, and mass, respectively, u is the fluid velocity at the particle's position, and v is the velocity of the particle.

Particles were left to flow for 500 msec to reach quasi-steady state, after which data was collected at 25 msec intervals over 1 sec. As shown in (2), the hematocrit was measured as the ratio of the total volume of RBCs in a channel to the total channel volume (2).

$$H = \frac{N\,V_c}{l \cdot w \cdot h} \times 100\%, \qquad (2)$$

where H is hematocrit, V_c is the volume of one RBC (set to 90 fL), N is the number of RBCs in the channel, and l, w, and h are the channel length, width, and height, respectively. Results are reported as mean ± standard deviation (SD).

RESULTS

Figure 1A displays the bulk flow velocity distribution profile, reflecting the spatial variation in velocity resulting from channel geometry. Velocity was highest in the side passages given their increased width (12 μm) relative to the capillary openings (4 μm). Anatomically, anastomoses are known to dilate or constrict to regulate the velocity and volume of blood flowing through a capillary network. RBC distribution was spatially non-uniform, with RBCs accumulating in low-velocity regions near channel edges and inter-pillar spaces (Fig. 1B). These variations in distribution profiles point to non-uniformity in rheological properties within the channel since the rheology of blood is known to be significantly modulated by hematocrit.

We analyzed the velocity of individual RBCs in both the inlet channel and the capillary network. The mean velocity of RBCs was lower in the microcapillary network (0.39 ± 0.05 mm/s) than in the inlet channel (0.83 ± 0.26 mm/s) due to interactions with micropillar walls. Additionally, the shape of the velocity distribution differed between the two regions, with inlet channel velocities skewed to the right and microcapillary channel velocities skewed to the left (Fig. 2).

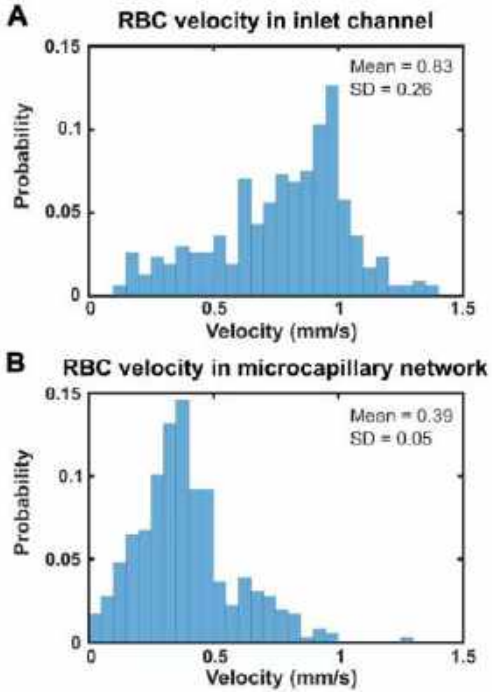

Figure 2: Velocity distribution of RBCs in (A) the inlet channel and (B) the microcapillary network.

The hematocrit within the inlet channel and a 4 μm-wide microcapillary channel (Fig 1A) was sampled every 25 msec over a simulation period of 1 sec. The hematocrit within the inlet channel was 6.5% ± 0.6%, compared to 10.1% ± 10.6% within the microcapillary channel. Importantly, hematocrit within the microcapillary channel showed far higher variability over time, with values ranging from 0% to 38% (Fig. 3).

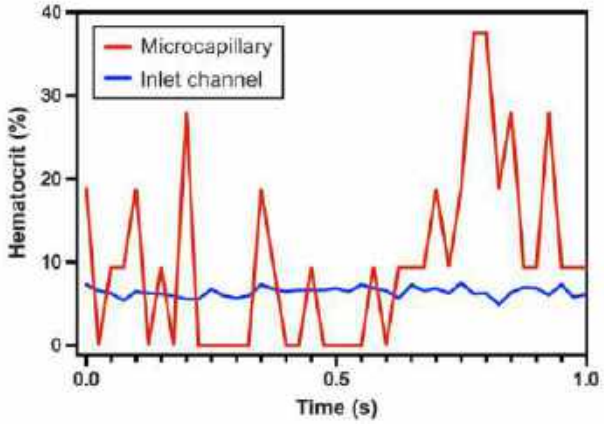

Figure 3: Temporal variation in hematocrit in the inlet channel and a 4 μm-wide microcapillary channel.

DISCUSSION

The models detailed above demonstrate the spatiotemporal variation in RBC velocity and distribution resulting from intricate microcapillary geometry. However, only particles with uniform physical properties were utilized, and cellular deformation was ignored. RBCs, especially in disease, often have heterogenous physical properties and deformability that may alter their rheology. The extension of this work to include variations in RBC physical properties may provide a new method to differentiate RBC subpopulations based on their transit times or spatial distributions. Additionally, localized hematocrit spikes in small capillaries can greatly increase blood viscosity and flow resistance, altering cellular interactions and rheology in ways unobserved in larger vessels. This has important implications for monitoring conditions such as sickle cell trait in which a small population of abnormal RBCs can cause chronic organ damage [3] and yet are undetectable by conventional techniques such as bulk ektacytometry [4]. Microfluidic models such as the one presented here can support the development of novel devices to address present limitations in rheologic monitoring leading to improved patient care. We are currently conducting experimental studies to validate the results obtained from these models and to characterize the velocity and distribution profiles of healthy and diseased RBCs.

INTRODUCTION

Neural connections allow for signals to pass between physically disparate regions of the brain to create behaviors, movement, and memories. Because signal transfer requires a physical connection, they also makeup part of the structure of the brain [1]. In the cortex, particular interest is placed in categorizing which disparate regions are used together during specific tasks as functional networks, which are often characterized through functional MRI (fMRI) [1]. In a physical sense, functionally correlated regions require increased connections of neurons to seamlessly coordinate actions, something that can be quantitatively assessed through diffusion MRI [1].

Additional imaging studies have been done to investigate how the structural integrity of cortex regions, measured via regional morphometry, compare across established functional networks and how this impacts network health [2,3]. Original studies in structural covariance and graph theory showed that similarities in the cortex shape were found both in neighboring regions and more distant ones [4]. This "structural covariance network" showed small world properties and short mean distance between neighboring regions. More recent applications of this work compared the network structures between patient populations and cognitively normal controls, identifying variations in the structure that could contribute to cognitive differences [3]. However, volumetric studies fail to capture the microstructural nuances that more sensitively reflect tissue integrity. Magnetic resonance elastography (MRE) measures are sensitive to changes in the microstructure and have been shown to vary across the regions of the cortex [5]. Previous MRE research has not looked at covariance because property recovery was limited to larger regions that would not provide enough complexity to study the area as a network.

The goal of this study was to identify "mechanical covariance networks" through MRE measure of shear stiffness for the first time utilizing improved cortical property recovery techniques. We hypothesize that shear stiffness will vary together across cortical regions, establishing a network. We also hypothesize that highly connected cortical regions of the network will overlap with already established functional hubs.

METHODS

This study comprised of 61 subjects (37.7 ± 20.5 years, 28M/33F) with ages ranging from 14 to 80. Each participant underwent an MRI scan consisting of both MRE and standard structural scans on a Siemens 3T scanner. For the MRE portion of the protocol, a custom high-resolution 3D multiband, multishot spiral sequence (resolution: 1.5 mm^3 isotropic) was used with 50Hz vibrations delivered to the posterior of the head to induce shear displacements. A T_1-weighted MPRAGE (resolution: 0.9 mm^3 isotropic) was also acquired and used to segment all 60 unilateral cortex regions in Freesurfer. Displacement data collected from the MRE scan was converted to shear stiffness using a nonlinear inversion algorithm (NLI) [6]. To reliably capture the mechanical properties in the small cortex regions, soft prior regularization and reduced spatial filtering were added to NLI following procedures documented in Hiscox et al. [6]. These techniques work to eliminate the influence of surrounding tissue on the property estimates by minimizing divergence of the properties within the anatomical regions as defined by the Freesurfer segmentations and decreasing filtering over the thin structure. Complex shear modulus (G) is calculated using the storage (G') and loss (G'') moduli. From complex shear modulus, shear stiffness (μ) can be calculated using Equation 1.

$$\mu = 2\,|G|^2/(G' + |G|) \quad (1)$$

For each subject, the shear stiffness for all 60 cortical regions was calculated. Correlation matrices were created to show how the properties of regions varied together by running partial correlations for shear stiffness between each region, controlling for age and sex. Nonsignificant correlations ($p>0.05$) were set to 0, as well as the correlations between a region and itself to integrate into the Brain Connectivity Toolbox in MATLAB [7]. This toolbox was used to generate the network backbone based on a minimum-spanning-tree

based algorithm (Figure 1). BrainNet Viewer in MATLAB was used to visualize the network backbone anatomically [8].

RESULTS

Examination of cortical stiffness showed regions that strongly varied together across individuals. The covariance matrix for shear stiffness and the simplified backbone matrix are shown in Figure 1. The backbone matrix highlights the dominant connections of the original matrix. Pairs of regions appear down the diagonal of this matrix, indicating strong connections between the bilateral pairs of a given cortical region thus connecting the two hemispheres. This backbone matrix also highlights regional modules of the network, i.e. the upper left corner of the backbone matrix shows connections between frontal lobe regions. Most of these connections are within a given hemisphere. The same pattern is also seen in the bottom right corner with the parietal and occipital cortical regions. Hub nodes that connect the lobe modules can be seen in the upper right and bottom left corners.

This information can also be seen anatomically in Figure 2. Here the pairing of the left and right regions can be seen on the coronal and transverse views with the connections that are horizontal. The regional modules are visible with more connections spanning within the lobe than between lobes. The between lobe connections rely on the hub regions, indicated with the larger size, particularly the precentral region, which had the highest number of connections at 6.

DISCUSSION

This study presents preliminary findings from an examination of mechanical covariance networks in the brain from MRE measures. 60 subregions of the cortex were used as nodes of the generative network. High covariance across the cortex was seen when using shear stiffness. Centrally located regions including multiple regions in the temporal lobe and the precentral cortex were the hub nodes of the network connecting to multiple regions and connecting the larger modules to each other.

Another hallmark of our findings was the reliance of paired right and left regions of the cortex, creating connections that spanned the hemispheres. This occurred for midline regions, like the precentral cortex, as well as more lateral regions like the superior temporal cortex. This analysis also created two distinct modules that aligned on lobe boundaries. One module was composed of frontal regions, while the second module was composed of the parietal and occipital regions combined.

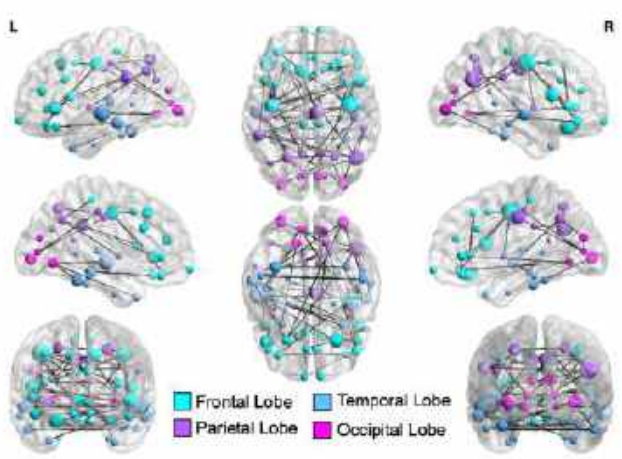

Figure 2: Anatomical visualizations of the network backbone, where each region is represented as a node and the color indicates the lobe. Larger nodes show an increased number of connections.

Structural covariance and graph theory are promising tools to use with MRE in future studies, especially in the identification of structural differences between cognitively normal and patient populations. In this application, graph theory will benefit from the increased sensitivity to structural changes that MRE provides to create tools for understanding the structure of the brain.

INTRODUCTION

Accurate measurements of forces in highly compliant and rate-dependent biomaterials including hydrogels remain challenging. First, most hydrogels are extremely soft (Young's Modulus E~1-100 kPa) such that for most sample geometries force sensors need to be able to measure 10s to 100s of μNs. Second, hydrogels often require complete hydration, which challenges existing miniature force sensing modalities due to the operation within a liquid environment. Third, for microstructurally complex hydrogels, mechanical characterization often requires in situ imaging of the microstructure. Therefore, sensors with customizable form factors are optimal for integrating optical imaging or microscope setups. Finally, hydrogels are rate-dependent materials and often demonstrate distinct mechanical characteristics such as elevated stiffness and hysteresis with increasing strain rates. Unfortunately, high-rate (1-100 s^{-1}) constitutive tensile data and experimental methods for determining those have remained scarce in the literature. This hinders the development of accurate constitutive models for soft biomaterials under impact like loading conditions. Thus, in addition to providing micronewton force resolution, the force sensor should also feature a high temporal response in the order of 0.1-1 ms to accurately resolve forces at strain rates of 1-100 s^{-1}. Several past studies have explored methods for measuring forces in soft hydrogels. One notable approach involves a micro electromechanical system (MEMS) [1] offering sensitivity of 5-50 μN. However, this method is incompatible with in situ aqueous sample testing, requiring an interlink between the sensor and the sample which induces unwanted moments on the hydrogel. In another application specific for cell cultures, forces were being measured by monitoring the deflection of PDMS beams attached to the cell culture [2]. This method could be extended to hydrogel testing, but for samples larger than ~500 μm, simultaneous optical tracking of PDMS beam deflections and microstructural imaging of the sample becomes intractable, necessitating a more complex, multi-camera setup. To address the above-mentioned challenges within a single force sensor, we designed soft piezoelectric force sensors composed of Polydimethylsiloxane (PDMS) and carbon nanotubes (CNTs). In this composite material, the CNTs are dispersed within the PDMS matrix and form a percolation network [3] permitting electrical conduction and produce resistivity changes proportional to the applied material strain. PDMS-CNT composites can be injection molded, water sealed, and made flexible. They demonstrate high temporal response rate, capable of following cyclic deformation at 1 Hz, across a broad range of strains [4]. Thus, these materials hold significant potential for deployment in various scenarios, particularly for accurately measuring forces in soft hydrogels, biomaterials, and tissues at high strain rates.

METHODS

Due to lack of tensile constitutive data, we aim to characterize hydrogels under uniaxial tension by using PDMS-CNT force sensors. We use a previously custom built tensile test setup that is compatible with in-situ imaging of the microstructure [5]. Dogbone shaped hydrogel and PDMS-CNT samples are connected in series, ensuring that the force applied to the hydrogel is equal to the force being transmitted to the PDMS-CNT. During loading, we monitor the electrical resistance changes in the PDMS-CNT, using a source measurement unit (SMU, Keysight B2902A) which has a baseline signal-to-noise ratio of 40 dB. To correlate change of resistance with the applied force, we use a separate calibration setup where the PDMS-CNT is linked with a dog bone shaped PDMS sample of known material properties in series. We employ the PDMS itself as a tool to calibrate our sensors. Because there is a lack of commercially available force sensors capable of detecting low force magnitudes in the range ~100-1000 μN, at varying strain rates (0.1–100 s^{-1}) with low latency and featuring low form factors. The force is calculated by measuring the PDMS strain via digital image correlation (DIC). We use the known material and geometric properties of the PDMS sample to convert the obtained strain information into stress and force. Once validated, we integrate our force sensor into our

Figure 1 – Steps for PDMS-CNT manufacturing, sensor calibration, and Collagen–I test protocol.

existing tension test platform to simultaneously collect microstructural images of the deforming collagen gel. PDMS-CNT composites are prepared according to a protocol presented in literature [3]. We use mixture of Sylgard 527, 70% by weight, and Sylgard 184, 30% by weight, mixture for both CNT matrix and calibration sample. CNT weight percentage is chosen to be 2% to optimize the baseline resistance for achieving a high signal-to-noise ratio. PDMS-CNT sensors are covered with a PDMS layer to generate a waterproof seal. Further manufacturing and sample details are summarized in Figure 1.

RESULTS

Before calibrating the PDMS-CNT force sensor and using it to measure stresses developed in collagen-I gels, we measured just the PDMS-CNT strain-resistance response under deformation. These initial tests mimic the eventual collagen-I testing conditions which consist of uniaxial tension load-unload cycles at different strain rates up to 50% maximum strain. It is important to note that our current loading profile enforces displacement control upon loading and force control under unloading (future experiments will also enforce displacement control during the unloading phase). Separate experiments have shown collagen gels to reach a peak stress of up to ~3 kPa at 50% strain, and PDMS-CNT samples have Young's Modulus E~0.3 MPa under quasi-static loading. As the PDMS-CNT sensors are stiffer, the sensors will undergo less strain than the collagen-I gel, estimated to be around ~10%. To mimic this condition, PDMS-CNT sensors are individually tested up to 12.5% maximum tensile strain. To examine our sensors temporal response, we repeated the tests at different strain rates of 0.125, 1.25, and 12.5 s^{-1} as seen in Figure 2 (a-c). At all rates, the sensor provides excellent temporal response during the loading (displacement control) phase with almost no delay. However, we observe significant latency during the unloading phase (force control) such that the resistance does not come back to its starting value within the timescale of loading. This is a well appreciated phenomenon for carbon-silicone composite strain sensors under creep [6]. These observations should be considered while fitting resistance-force calibration curves to the data before hydrogel testing, or strictly enforce displacement control during the loading and unloading phase. To estimate the smallest force PDMS-CNT sensors can detect, we manufactured a PDMS-CNT strip with 1 mm^2 area and applied quasi-static 0.25% strain to the sensors. Resistance change was measured around 1 Ohm with ~500 Ohm base resistance. Omitting the viscoelastic effects, and observing that E~0.3 MPa, estimated force is 350 μN. These preliminary experiments provide an idea about expected force-resistance calibration curves at varying strain rates.

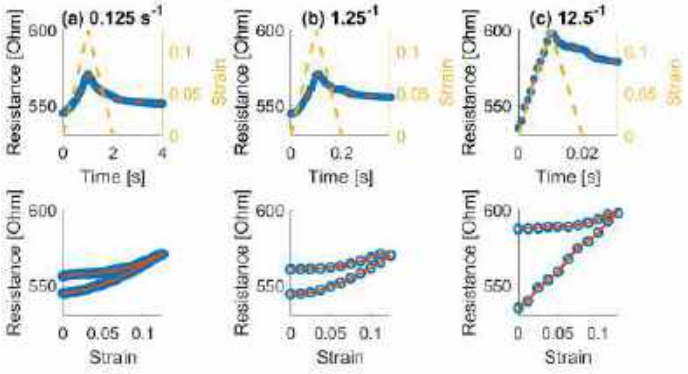

Figure 2 – Load-Unload cycles at (a) 0.125 s^{-1}, (b) 1.25 s^{-1}, and (c) 12.5 s^{-1} rates

DISCUSSION

This study presents the development of a flexible force sensor that features both excellent sensitivity and temporal response albeit showing high latency during the unloading phase when creeping. We show the sensor's potential for measuring small forces even for large strain rates up to 12.5 s^{-1}, while its flexibility, and low footprint allows for simultaneous in-situ imaging of millimeter-sized soft and fully submersed hydrogels. That is, the sensor can record the full stress-strain response of highly compliant collagen I hydrogel over the full finite deformation range (up to 50% strain) and decades of strain rate to provide a more accurate constitutive characterization of these hydrogels and tissues. We will explore these sensors to even higher strain rates (up to 100 s^{-1}) to characterize the complete, finite-deformation, rate-dependent response while also resolving microstructural changes that occur during the loading and unloading process with micron to submicron resolution. Additionally, we will use the sensor for constitutive characterization of other biopolymer gels used for in vitro models, ex vivo tissues, and in vivo tissues which will enlighten the gap of higher rates and concurrent microstructure evolution.

INTRODUCTION

Ductal-dependent cyanotic congenital heart disease is a condition where circulatory equilibrium relies on a patent ductus arteriosus (PDA), a fetal connection from the aorta and pulmonary artery. While this conduit normally closes after birth, its patency is crucial for proper pulmonary blood flow supply in affected patients. Palliative interventions, such as PDA stenting, are employed to maintain continuous pulmonary blood flow ensuring the patient gain weight and stability until definitive surgical repair can be performed[1,2]. Although stenting has shown advantages over its surgical alternative, the Blalock-Taussig-Thomas shunt (BTTS), including reduced operative risks and hospital length of stay, it comes with an increased rate of reinterventions and procedure-related complications[1].

The challenges arise from the complex and tortuous anatomy of the PDA, making successful stent deployment dependent on medical expertise[2]. A critical consideration in procedural planning is the selection of the most appropriate stent length and diameter to ensure complete PDA coverage[1]. Failure to do so could result in incomplete stenting, hindering pulmonary blood flow and pulmonary artery growth, as uncovered segments may undergo natural obliterative processes, leading to constriction.

We hypothesize that enhancing preprocedural planning, leading to the optimal selection of stenting parameters, can mitigate the risk of partial stent coverage. To achieve this, we propose the development of a patient-specific computational framework based on finite element analysis (FEA). This pipeline aims to study the mechanical interactions of medical devices involved in the procedure (angioplasty balloon, stent, and guidewire) with the patient's PDA anatomy. The model could serve as a valuable tool for interventional cardiology teams, aiding in the selection of stenting parameters, predicting the extent of PDA stenting coverage, and providing insights into the patient's candidacy for this procedure.

METHODS

We established a computational simulation FEA-based pipeline for the stenting of PDA with relatively straight anatomies, categorized as Qureshi's type I PDA[1,2]. The methodology involves the following key steps:

1. **DA Segmentation**: Utilizing Mimics software, we segmented the region of interest, including the Ductus arteriosus and adjacent sections of the aorta and pulmonary arteries. Meshing and refinement processes were then carried out using 3-Matic software.
2. **CAD Modeling and Meshing**: We created CAD models for the stent, guidewire, and angioplasty balloon in Solidworks, incorporating data from MicroCT scans obtained through the MicroCT50 equipment (Scanco medical). Following this, hexahedral meshing in Hypermesh was performed, setting the stage for subsequent FEA simulations executed in Abaqus.
3. **Balloon Compression and Stent Crimping**: We simulated radial compression on the stent and angioplasty balloon to obtain the pre-deployment configurations.
4. **Guidewire Modeling**: Using wire elements and displacement boundary conditions, we modeled the PDA straightening in the pre-stenting phase by simulating the advancement of the guidewire through the PDA.
5. **Stent Deployment Simulation**: We conducted simulations involving the angioplasty balloon inflation-deflation processes, incorporating fluid cavity and exchange interactions. We captured the dynamic aspects of stent deployment through amplitude changes. Default configurations of the stent and PDA anatomy were utilized to study their interaction.

Figure 1 is a diagram of the steps involved in our methodology.

RESULTS

In our study, we applied our FEA-based framework to simulate the stenting of a PDA in a patient with a moderately straight anatomy

(Qureshi's type I) who underwent the stenting procedure at the Children's Healthcare of Atlanta (CHOA). The segmentation of the PDA and adjacent vascular structures was performed using pre-procedural CT scans. Centerline analysis revealed a PDA dimension of 13.95 mm, a minimal diameter of 3.65 mm (located at the aortic origin), and a maximal diameter of 4.10 mm on the pulmonary side. Considering the recommended aortic protrusion of ~2 mm and a pulmonary protrusion of 2-4 mm, a Promus Premier stent (Boston Scientific) of dimensions 4x20 was employed for the simulations. In the pre-stenting simulation, which included guidewire modeling, we observed a straightening of the PDA primarily on the left pulmonary end, a preferred location for stenting due to a more straightforward path and the avoidance of excessive stent deformation, given the presence of an elbow configuration. Given the vertical PDA configuration, we positioned the guidewire to simulate carotid vascular access and aligned with the longitudinal axis of the PDA (Figure 2a).

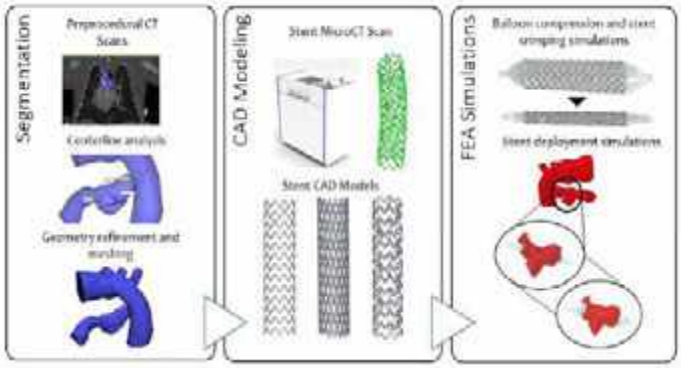

Figure 1: Methodology of FEA-based simulation pipeline for PDA stenting procedure.

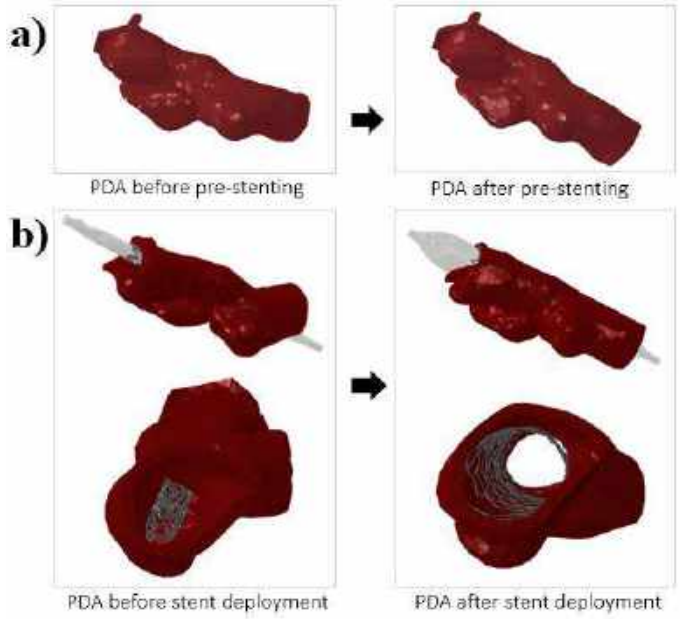

Figure 2: a) Results of pre-stenting simulation before and after positioning of the guidewire. b) Stent deployment simulation results showing the pre and post deployment configurations of the stent, angioplasty balloon and stent. The angioplasty balloon was removed in the pictures at the bottom for improved visualization of the stented PDA.

Concerning the stent deployment simulation, minimal stent recoil was noted at the end of the inflation step where we incorporated a slight deflation equivalent to 5% of the balloon volume. The stent conformed to the tortuous PDA geometry, exhibiting flare at the fixation on the aortic side where the minimal diameter is present. On the pronounced curves in the PDA, located immediately after the aortic origin, we observed significant straightening of the stent rings. In general, there was a distinctive straightening of the PDA morphology caused by the inherent rigidity and tubular configuration of the stent. Also, tissue bulges after the original connection of the PDA with the left pulmonary artery were formed; however, no stenosis was formed (Figure 2b).

Analysis of Von Mises stress distribution showed accentuated stress on the stent fixation at the aortic side due to the tight tolerance between the stent and PDA on the minimal diameter section. Additionally, stress concentration within the stent was predominantly present on the straight sections of the struts (Figure 3).

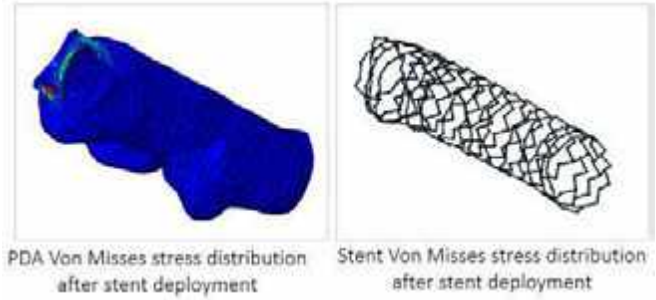

Figure 3: Von Misses stress distribution on the PDA and stent after stent deployment.

DISCUSSION

The simulation results present several noteworthy observations with implications for the stenting procedure in patients with moderately straight PDA anatomies (Qureshi's type I)[1,2]. The stent model in our simulations exhibits multiple deformation zones, including flares and strut straightening, which raises concerns about potential stress concentration. This could pose risks such as vascular spasm and in-stent restenosis over the long term. It is crucial to acknowledge the role of aortic and pulmonary protrusions in ensuring complete stenting coverage and proper fixation points, even though it comes with the drawback of increased stress concentration. Moreover, the simulations enable us to evaluate the potential extent of stenosis caused by tissue bulges, which holds clinical relevance for anticipating the need for reinterventions. In such cases, additional stents may need to be telescopically implanted to improve pulmonary blood flow.

Looking ahead, our future work will involve applying this simulation pipeline to a broader range of patient-specific geometries. We plan to introduce additional steps to model stent deployment in more complex PDA geometries, such as Qureshi's types II and III[1,2], accompanied by a rigorous validation process to enhance the accuracy and reliability of our simulations.

INTRODUCTION

Conducting *in vitro* experiments with real blood presents various challenges including coagulation complexities, storage, and procedural handling concerns. To overcome these challenges, blood analog fluid (BAF), typically comprised of water, glycerin, and Xanthan gum, is often used to characterize the hemodynamic performance of blood-contacting medical devices and novel diagnostic indices. The BAF composition enables a close approximation of the shear-thinning behavior of real blood [1]. Occasionally, the BAF composition also includes microsphere particles to facilitate flow visualization studies using Laser Doppler Velocimetry (LDV). Flow visualization studies are important to characterize the flow field within the cardiovascular system and in medical devices (such as blood pumps, valves, grafts), and thereby evaluate adverse flow regions that pose hemolytic and thrombotic risks. Additionally, flow visualization is also used to validate computational models.

Blood viscosity is influenced by multiple factors, such as blood composition (e.g., hematocrit level), temperature, shear rate, vessel diameter leading to Fähraeus-Lindqvist effect, cell aggregation, shape, deformation, orientation, and plasma viscosity [2]. Thus, it is hypothesized that the addition of particles in the form of polymer microspheres in BAF solution affects the rheological properties of the fluid.

Therefore, this research aims to characterize the effect of polymer microspheres on BAF viscosity, and thereby facilitate *in vitro* flow visualization using LDV under relevant physiologic conditions observed *in vivo*. The outcomes of this work are expected to enhance the clinical relevance of *in vitro* hemodynamic evaluations of medical devices and diagnostic indices.

METHODS

Formulation of BAF. In the current composition of BAF, glycerin controls the viscosity at infinite shear rates, whereas Xanthan gum is introduced to modulate the non-Newtonian behavior, particularly at low shear rates [3]. An optimal ratio of glycerin, water, and Xanthan gum must be achieved in order to create a BAF that accurately mimics the rheological characteristics of actual blood [4, 5].

Incorporation of Microspheres in BAF. Microspheres induced in BAF have an important role, particularly in generating the scattering signal essential for LDV measurements. The selection of the type and size of microspheres significantly influences the precision of LDV measurements. In the current study, solid polymer microspheres with a diameter of 8 $\boldsymbol{\mu}$m were utilized.

Three different test fluids comprising of 16 ml BAF solution with the following varying concentrations of polymer microspheres were created: 1% (weight/volume; w/v) and 2% w/v represent test samples, whereas 0% w/v represents a control sample. Three experiments (n = 3) were performed for each test fluid. Each experiment was carried according to an identical approach. For each test fluid, the recorded viscosities from the three measurements were averaged. This methodology of three experiments and a subsequent averaging, provides robust and reliable viscosity data for comparisons of variable microsphere seeding compositions.

To measure the viscosity of BAF with and without polymer microspheres, a concentric cylinder viscometer (Brookfield Engineering Laboratories Inc.) was used. The recorded viscosity data was then fitted to the Carreau model using the equation [1] below:

$$\mu = \mu_\infty + (\mu_0 - \mu_\infty) \times (1 + (\lambda\dot{\gamma})^2)^{\frac{n-1}{2}} \quad (1)$$

where λ = time constant, n = power law index, μ_0 = zero shear viscosity (cP), μ_∞ = infinite shear viscosity (cP), and $\dot{\gamma}$ = shear rate (1/s).

RESULTS

Figure 1 presents a visual comparison of viscosities among BAF with different polymer microsphere concentrations of 0%, 1%, and 2%. Table 1 outlines the Carreau model coefficients for BAFs with and without polymer microspheres. The subsequent section demonstrates differences in viscosity profiles between real blood (solid line) [6] and the various BAF compositions.

BAF for 0% microspheres (base line), comprising 80% (volume/volume; v/v) distilled water, 20% (v/v) glycerol and 0.027% (w/v) Xanthan gum, had a viscosity profile that is similar to real blood over shear rates ranging from 1 s^{-1} to 100 s^{-1}. The Carreau model coefficients for BAF with 0% microspheres were obtained as λ = 3.1, n = 0.4, μ_0 = 42.3 cP, μ_∞ = 5.4 cP. These values were found comparable with the Carreau model coefficients of blood [6].

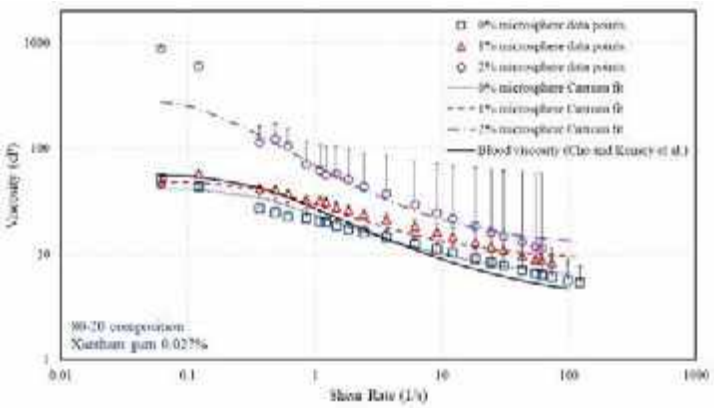

Figure 1: BAF viscosity with a) 0%, b) 1%, and c) 2% (w/v) polymer microsphere in 80/20 composition.

	μ_∞	μ_0	λ	n
0% microspheres	5.4	42.3	3.1	0.4
1% microspheres	8.5	49	2.5	0.35
2% microspheres	12	300	7.5	0.21

Table 1: Carreau coefficients comparison between a) 0%, b) 1%, and c) 2% (w/v) polymer microsphere in BAF 80/20 composition.

For the 1% microspheres, an absolute increase of 3.1 cP in μ_∞ and a 6.7 cP increase in μ_0 (Figure 3) were observed in comparison to the baseline (0% microspheres) values of BAF. The Carreau model coefficients for BAF, incorporating 1% microspheres, were determined as λ = 2.5, n = 0.35, μ_0 = 49 cP, and μ_∞ = 8.5 cP (Figure 1 and Table 1).

Similarly, with 2% microspheres, there was an increase in the absolute value of μ_∞ by 6.6 cP and a 264.3 cP increase in μ_0 (Figure 3) in comparison to the baseline (0% microspheres) BAF values. The Carreau model coefficients for BAF with 2% microspheres were reported as λ = 7.5, n = 0.21, μ_0 = 300 cP, and μ_∞ = 12 cP (Figure 1 and Table 1).

DISCUSSION

BAF plays an important role in many flow visualization experiments, enabling controlled velocity measurements for testing cardiovascular devices such as blood pumps, valves, stents, grafts etc. As observed in Figure 1, a relatively small % of microsphere seeding significantly influences BAF viscosity. Sensitivity of microsphere-seeding concentration in BAF suggests improved optimization is required for accurate mimicking of physiological conditions during LDV measurements.

In conclusion, incorporation of polymer microspheres results in significant changes in non-Newtonian viscosity, both μ_0 and μ_∞, of BAF in relation to viscosity of human blood. Therefore, accounting for the effects of microspheres is essential for better quantification of hemodynamics in medical devices during LDV experiments.

INTRODUCTION

There has been an increase in the occurrence of anterior cruciate ligament (ACL) injuries among children and adolescents, with approximately 25% of these being partial tears [1]. Partial injury typically happens to either the anteromedial (AM) or posterolateral (PL) bundles of the ACL, which share in providing overall ACL function. When only one bundle is disrupted, reconstruction surgery may be performed on the injured bundle while preserving the healthy bundle [2]. Clinical studies have shown that selective bundle ACL reconstruction preserves the intact ACL fibers and enhances vascularization of the graft, as well as significantly reduces the differential joint laxity relative to the healthy side at 1-3 years follow-up [3,4,9], with similar values after AM or PL bundle reconstruction [5,6]. Yet, there is a lack of research comparing the relative forces within the graft and remaining intact bundle, which may impact re-injury risk and long-term degenerative outcomes. In the porcine model, the ACL bundles undergo changes in size and function throughout skeletal growth [7], thus age-specific bundle function should be controlled for in experimental studies, which is difficult in clinical studies. Therefore, the objective of this study was to evaluate the initial joint stability and bundle function following selective AM and PL bundle ACL reconstruction within an adolescent porcine model.

METHODS

A total of 8 pairs of deep digital flexor tendons and 8 pairs of normal hindlimbs were collected from adolescent (6 months old) pigs from separate studies. The specimens were divided into two groups for AM bundle reconstruction (n=8) and PL bundle reconstruction (n=8). A 6-degree-of-freedom robotic testing system with a universal force-moment sensor was used to test joint function (Kuka, simVITRO) (Figure 1A). The intact joint was separately subjected to a 100 N anterior-posterior (AP) load, a 150 N compression, and a 5 N·m varus-valgus (VV) torque at 60° of flexion. Kinematics were recorded, then repeated while recording forces for the intact joint and after capsule removal. The same loading conditions were then applied after AM bundle transection (AMT) or PL bundle transection (PLT) while recording the kinematics, which was then repeated with forces/moments recorded. Selective bundle reconstruction was then performed for AM and PL groups: 1) AM bundle reconstruction (AMR) while preserving the remaining intact PL bundle; 2) PL bundle reconstruction (PLR) while preserving the remaining intact AM bundle. Deep digital flexor tendon grafts were used for both AMR and PLR. A complete transphyseal technique was performed with tunnels drilled through the footprints of the transected bundle. Femoral fixation was achieved with a #2 FiberWire (Arthrex) and an ABS button (Arthrex), followed by 5 cycles of passive flexion-extension preconditioning at 22 N of tension. Tibial fixation was then accomplished by a staple (Arthrex) with 100 N pretension applied to the graft at maximum posterior translation at 40° of knee flexion. The same AP, compression, and VV loads were applied following AMR and PLR. The recorded kinematics from intact, AMT or PLT, and AMR or PLR states were repeated after removing the AM or PL bundle graft, followed by removal of the remaining intact PL or AM bundle.

AP tibial translation (APTT) under applied AP load, anterior tibial translation (ATT) under applied compression, and VV rotation under applied VV torques were calculated. Tissue forces were calculated using the principle of superposition. The difference in anterior load and varus/valgus resultant force contribution between the AM and PL bundle was calculated by (AM-PL)/(AM+PL). Joint laxity and tissue force contributions were compared between different states using one-way repeated measures ANOVA with Tukey's HSD. Paired t-test were utilized to compare differential joint laxity relative to intact state from different groups. Significance was set at 0.05.

RESULTS

AMT and PLT resulted in minor destabilization in the joint under AP drawer (Figure 1B). Both PL bundle injured and reconstructed joint showed AP joint laxity within 1 mm of intact state, which was more

stable than AM bundle injured and reconstructed joint (within 3 mm) (Figure 1C).

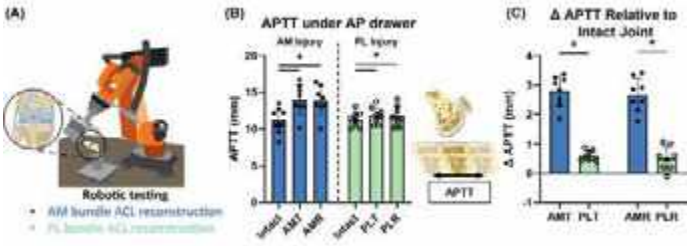

Figure 1: (A) Robotic testing system to assess selective ACL reconstruction. (B) Selective bundle reconstruction (AMR, PLR) did not significantly restore anterior-posterior tibial translation (APTT) relative to the bundle transected state (AMT, PLT). (C) PL bundle transected (PLT) and reconstructed (PLR) states showed better AP stability relative to the respective AM bundle groups. Data points presented with mean and 95% CI. Statistical significance ($p<0.05$) between states indicated (*).

AMT and AMR increased anterior instability under compression (ATT increased by 3.3 and 2.6 mm, respectively), while both PLT and PLR showed similar ATT as the intact joint (ΔATT relative to intact state was 0.5 and -0.7 mm, respectively) (Figure 2A). AMT and PLT resulted in joint destabilization under VV torque (VV increased by 1.1° and 0.4°, respectively) (Figure 2B). Varus-valgus stability was restored to intact state after both AM and PL bundle reconstruction (ΔVV relative to intact state was 0.3° and -0.3°, respectively) (Figure 2B).

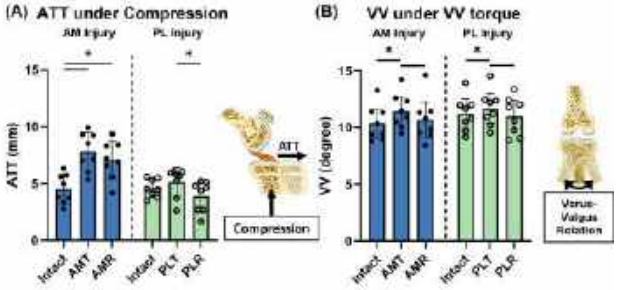

Figure 2: (A) Under compressive loading, both PL bundle transected (PLT) and reconstructed (PLR) states had similar anterior tibial translation (ATT) as the intact joint, but the AMT and AMR groups had increased ATT. (B) Varus-valgus rotation increased after AMT or PLT and was restored to levels similar to the intact state after AMR or PLR. Data points presented with mean and 95% CI. Statistical significance ($p<0.05$) between states indicated (*).

After AM bundle injury, the PL bundle bore higher forces under anterior tibial loading and varus-valgus moments (Figure 3). AM bundle reconstruction was able to restore the normal force distribution under varus-valgus loading (Figure 3B) but not anterior loading (Figure 3A). After PL bundle injury, the AM bundle also bore higher forces, though the forces in the intact state were already high (Figure 3). PLR partially returned these forces under anterior loading (Figure 3A). Under varus and valgus loading, PLR showed a dramatic shift such that the graft carried more force than the intact AM bundle (AM% - PL% = -47% and -25%, respectively) (Figure 3B).

DISCUSSION

In this study, selective bundle reconstruction showed the ability to partially restore the minor changes in joint laxity after partial ACL injury, but the force distribution within the graft and remaining ACL bundle did not fully restore the normal distribution within the intact

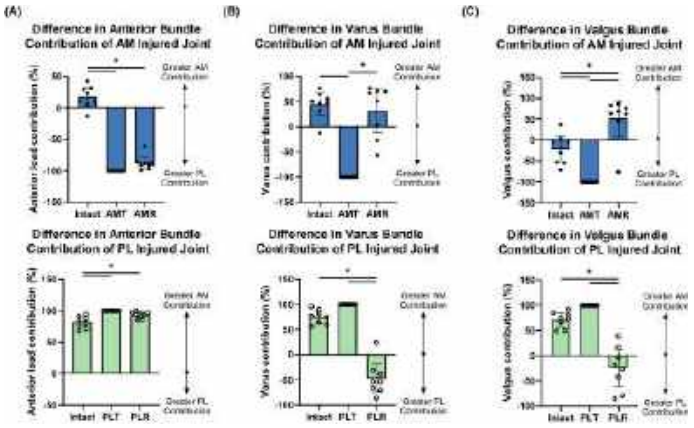

Figure 3: (A) The relative anterior force contribution of the bundles under anterior drawer shifted to PL bundle after AM bundle transection (AMT) and reconstruction (AMR), while stayed in the AM bundle after PLT and PLR in the PL groups. (B,C) The differences between groups in varus (B) and valgus (C) resultant force contribution were similar for both AM and PL groups. AMR restored VV resultant force back toward the AM bundle graft while PLR resulted in more VV resultant force in PL bundle graft relative to the intact PL bundle. Data points presented with mean and 95% CI. Statistical significance ($p<0.05$) between states indicated (*).

ACL bundles. The APTT kinematic data in the present work aligns with results reported in previous human cadaveric data and clinical data, indicating better initial and long-term joint stability following PL injury [7,8]. Additionally, the restoration of varus-valgus laxity through selective bundle reconstruction may be relevant in preventing secondary meniscus or medial collateral ligament (MCL) injuries. In terms of tissue-level forces, neither AM bundle nor PL bundle reconstruction could restore the normal ACL force distribution under all loading conditions tested. It is unclear how these initial imbalances in force distribution may change once the in-vivo graft remodeling process occurs [8]. Previous data from human patients revealed better ability to reduce anterior joint laxity after AM bundle reconstruction (0.8 mm side-to-side difference) compared to our work (2.7 mm) [9]. This difference may be impacted by the manner of testing: our study performed open surgery on cadaveric porcine joints, while clinical work performed arthroscopic surgery on human patients. Our data advances the understanding of selective bundle reconstruction in pediatric cases by providing biomechanical insights into the roles of AM and PL bundles. Ongoing and future in-vivo work will be needed to compare joint laxity and function after graft and intact bundle remodeling.

Multiscale Model Predicts Modulation of Cardiac Remodeling by Intrinsic Ventricular Contractility Before and After Mitral Valve Repair

INTRODUCTION

Mitral valve repair (MVr) is a highly effective treatment for primary mitral valve regurgitation (MR), with survival rates equivalent to aged matched controls in clinical trials [1]. In some cases, MVr partially reverses hypertrophic remodeling of the left ventricle (LV) [2]. However, the timing of mitral valve surgical repair is critical: once patients develop dyspnea, orthopnea, LV ejection fraction (EF) below 60% or end-systolic ventricular diameter above 40 mm, clinical outcomes are worse [1]. Furthermore, 20% of the patients develop postoperative LV dysfunction even when pre-operative EF>60% [3]. These data suggest that more information is needed to improve the timely management of primary MR towards earlier intervention in some patients, before geometric, hormonal, and signaling changes associated with the gradual progression to heart failure become too entrenched. Recently, LV circumferential strain rate and LV end systolic dimension – both closely related to LV contractility – were identified as important predictors of post-operative ventricular dysfunction [3]. Previously, we developed a multiscale model of cardiovascular mechanics and cardiomyocyte hypertrophy and calibrated it to experimental data from experimental MR and volume overload. Here, we apply the calibrated multiscale model to explore how the ability to compensate for altered hemodynamic loading by increasing intrinsic contractility affects predicted ventricular growth and remodeling following MVr.

METHODS

Multiscale model

The mechanical model consists of a spherical compartment model of the ventricles with time-varying elastance $\left(E(t)\right)$ proposed by Santamore and Burkhoff, coupled to a lumped-parameter model of the circulation. We adjusted parameters previously calibrated to canine experiments to match human cardiovascular dimensions and dynamics by allometric scaling [4]. We added a mitral valve regurgitation resistance (MVRR) bypassing the one-directional valve element in the circulation model to provide an adjustable level of regurgitant flow. The mechanical model is coupled to a network model consisting of 109 nodes and 144 reactions representing established pathways for cardiac myocyte growth driven by various hormones as well as stretch [5]. The network model represents signaling interactions using a logic-based system of equations with variables normalized between 0 and 1, requiring no interspecies scaling [6].

Coupling of the multiscale model

At each growth step (i), the multicompartmental heart model and lumped-parameter circulation model simulated one cardiac cycle, solving iteratively until reaching steady-state. The calculated end-diastolic strains were passed to the stretch input of the signaling network model along with time-varying, data-driven estimates of circulating hormone levels and used to simulate 12 hours of cellular remodeling, producing a normalized Cell Area between 0 and 1. The Cell Area output was used to prescribe the remodeling of the left ventricle at organ scale. All growth was assumed to occur in the fiber direction [7].

Modeling adrenergic contractile reserve.

End-systolic elastance $\left(E_{sys}\right)$ measured at the chamber level from LV pressures and volumes depends both on the intrinsic contractility of the muscle and the geometry of the chamber. For a thin-walled sphere, these quantities are related by the equation:

$$E_{sys}^{i} = \frac{3}{2\pi}\frac{h_0^i}{\left(r_0^i\right)^4}\, e, \tag{1}$$

Where $\left(r_0^i\right)$ and $\left(h_0^i\right)$ are the radius and wall thickness of the unloaded ventricle at a given growth step, and (e) is the intrinsic contractility [7]. Notably, eccentric growth and dilation (increasing r_0^i) decrease E_{sys} even if (e) remains constant. Nagatsu et al observed that dogs with MR maintained normal pump function for several months but displayed systolic dysfunction under the effects of β blockers, suggesting that adrenergic compensation was preserving overall function by increasing

contractility [8]. To examine the remodeling implications of such compensation, we simulate two scenarios: a fully compensated case, where intrinsic contractility increases as much as needed to hold E_{sys} constant, and systolic dysfunction, where compensatory mechanisms are fully exhausted and contractility never increases above baseline.

Modeling chronic MR and Mitral Valve Repair

Simulation for both cases started from the same baseline, representing a healthy adult human. MR was simulated by setting MVRR to produce a regurgitant fraction of 30%. The neurohormonal response to MR was modeled by increasing the network inputs for ANG2, NE, ET1, ANP and BNP by fold changes of 3, 2, 3, and 10 respectively, based on reports from canine MR [9]. The model reached steady state after 6 simulated months. MVr was then simulated by increasing MVRR to prevent backflow. Following reports of partial normalization of neurohormone concentrations in blood following MVr in dogs and humans, ANG2, NE, ET1, ANP and BNP network inputs were decreased to 20% above the healthy baseline [10] following simulated repair in both simulation cases.

Comparisons to Clinical Data

The simulation results are compared to clinical reports of LV dimensions and function before and following mitral valve repair in primary MR patients with higher or lower pre-operative EF [11–13].

RESULTS

Chronic MR

During simulated MR, both model cases predict large increases in end-diastolic (EDV) and end-systolic (ESV) volumes (Fig. 1), accompanied by a drop in EF (Fig.2). The predicted changes are larger for the systolic dysfunction case, a finding that is consistent with the larger volumes and lower EF reported in primary MR patients with systolic dysfunction [11–13]. In the compensated model, increased contractility allows the LV to operate at lower EDP and EDV, reducing fiber strain and the stretch input to the network compared to the systolic dysfunction case. This results in less predicted dilation at steady state for the compensated model.

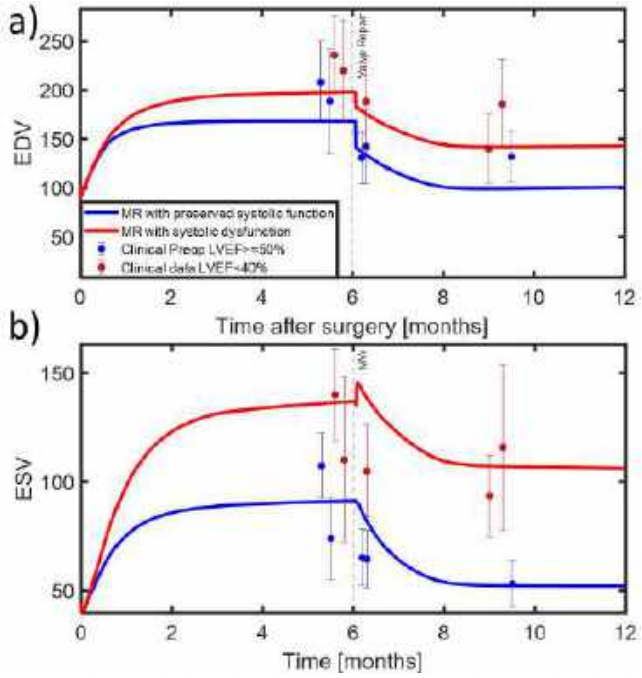

Figure 1. Time evolution of LV dimensions a)EDV, b) ESV for the fully compensated model (blue line), and dysfunctional model (red line) compared to data from patients with pre-op EF>50% (blue dots) and EF<40% (red dots).

Mitral Valve Repair

MVr produces an acute drop in EDV due to the relief of the MR-induced volume overload. The unloading of the LV decreases fiber strain and induces reverse remodeling, leading to further long-term decrease in EDV and ESV (Fig. 1). Without any calibration to the clinical data, the predicted volumes for our generic compensated and dysfunctional models matched reported post-MVr data from patients with higher and lower pre-operative EF (Fig. 1). As expected, simulated MVr initially reduces EF in both model cases, because the LV must eject all blood against the higher resistance of the aorta and systemic circulation (Fig.2) In the compensated model, reverse remodeling gradually restores EF to its preoperative baseline, while in the dysfunctional model EF never fully recovers

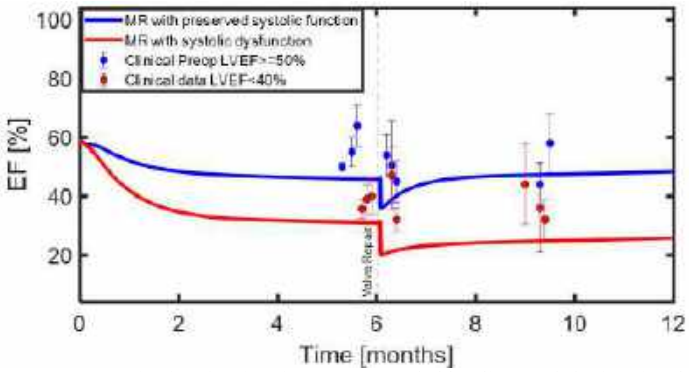

Figure 2. LV ejection fraction for compensated (blue line) and dysfunctional hearts (red line), plotted against clinical data from patients with pre-op EF>50% (blue dots) and EF<40% (red dots).

DISCUSSION

We explored the potential role of compensatory changes in myocardial contractility on ventricular remodeling due to MR and following MVr. Our model predicts that the inability to increase contractility exacerbates dilation in response to chronic MR and impairs reverse remodeling after MVr. This is driven by the higher EDP and EDV required to maintain cardiac output at lower levels of intrinsic contractility, which in turn produces more myocyte stretch and growth mechano-signaling. Systolic dysfunction also prevents the recovery of EF to pre-operatory levels following MVr. The match between reported clinical volumes and this preliminary model is encouraging. Future improvements could include collecting better data on neurohormonal activation post-MVr in patients with different levels of underlying systolic dysfunction and explicitly calibrating models to better match pre-operative states for individual patients or groups of patients.

PHYSEAL-SPARING ACL RECONSTRUCTION PROVIDES BETTER INITIAL JOINT STABILITY AND FUNCTION THAN COMPLETE TRANSPHYSEAL ACL RECONSTRUCTION IN AN EARLY ADOLESCENT PORCINE MODEL

INTRODUCTION

The incidence of pediatric anterior cruciate ligament (ACL) injuries has been increasing [1]. Current pediatric ACL reconstruction (ACLR) techniques include complete transphyseal, partial transphyseal, and physeal-sparing [2]. Complete transphyseal reconstruction is similar to the technique used for skeletally mature patients. Because of the higher risk of growth deformity in the femur, a partial transphyseal technique avoids disturbing the femoral physis for patients with some growth remaining [3, 4]. To further lower the risk of physis disturbance in young patients, physeal-sparing techniques have been developed with both femoral and tibial tunnels in the epiphyses [3]. Patient age is a major factor in technique selection; however, in the pre-adolescent/early adolescent age range (11-14 years old) all three techniques are commonly used [5]. Surgical technique is more associated with the surgeon's fellowship training rather than the joint and ACL function [5]. Yet, the porcine model has shown age-specific joint function during growth [6]. Thus, it is essential to compare ACLR techniques for specific ages using age-specific models. Therefore, the current work aims to compare initial joint stability and function following complete transphyseal, partial transphyseal, and physeal-sparing ACLR within an early adolescent porcine model.

METHODS

A total of 18 deep digital flexor tendons and 18 hindlimbs were collected from early adolescent (4.5 months old) pigs. The specimens were divided into three groups (n=6 each) with different pediatric ACLR techniques: complete transphyseal, partial transphyseal, and physeal-sparing (Figure 1A). A 6-degree-of-freedom robotic testing system with a universal force-moment sensor was used to test joint function (Kuka, simVITRO). The intact joint was first subjected to an 80 N anterior-posterior (AP) load, a 120 N compression, and a 4 N·m varus-valgus (VV) torque at 60° of flexion. Kinematics were recorded, then repeated while recording forces for the intact joint and after capsule removal. The same loading conditions were then applied after ACL transection (ACLT) while recording the kinematics. ACL reconstruction was then performed, using a 4.5-month-old porcine deep digital flexor tendon allograft. For each limb, one reconstruction technique (Fig. 1A) was performed through the tibial and femoral tunnels (8 mm diameter) placed between the anteromedial and posterolateral bundle footprints [6]. Femoral fixation was performed by a #2 FiberWire (Arthrex) with an ABS button (Arthrex), followed by 5 cycles of passive flexion-extension with 22 N pretension for precondition. Tibial fixation was then accomplished by a staple (Arthrex) with 100 N pretension applied to the graft at maximum posterior translation at 40° of knee flexion. The same AP, compression, and VV loads were applied following ACLR. The recorded kinematics were repeated after removing the graft. Then, kinematics from the intact, ACLT, and ACLR states were repeated after removal of the medial collateral ligament (MCL), lateral collateral ligament (LCL), medial meniscus (MMEN), lateral meniscus (LMEN), medial femoral condyle (MCON), and lateral femoral condyle (LCON).

AP tibial translation (APTT) under applied AP load, anterior tibial translation (ATT) under applied compression, and VV rotation under applied VV torques were calculated. Tissue forces were calculated using the principle of superposition. One-way ANOVA with Tukey's HSD was utilized to compare joint laxity between different states as well as tissue force contribution between different surgical techniques. Significance was set at 0.05.

RESULTS

ACL transection (ACLT) resulted in destabilization in the joint under AP drawer (13.4 – 15.1 mm increase). ACLR for all groups partially restored instability, but APTT remained 5.3 – 8.4 mm higher than intact (Figure 1B).

Anterior tibial translation (ATT) under compression increased after ACLT and was restored to intact state after ACLR with partial transphyseal and physeal-sparing (Figure 2A). Change in ATT relative to the intact state was greater in the complete transphyseal group relative to the other two techniques (Figure 2B). Varus-valgus laxity showed similar results, where the partial transphyseal and physeal-sparing

techniques restored the joint laxity to the intact state, but complete transphyseal did not (Figure 2C). No statistically significant difference was observed in the differential VV laxity relative to intact state across techniques, likely due to high variability (Figure 2D).

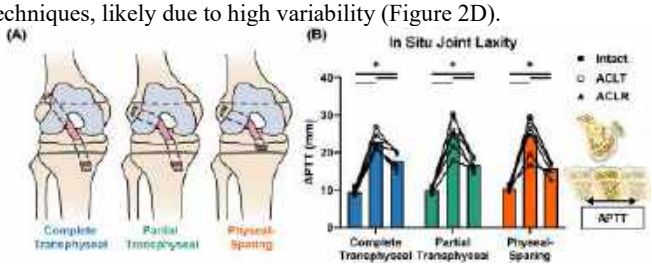

Figure 1: (A) Illustration of pediatric ACL reconstruction surgical techniques. (B) Anterior-posterior tibial translation (APTT) in response to anterior-posterior load was similar between intact, ACL transected (ACLT), and ACLR states. Data points presented with mean and 95% CI. Paired samples were connected. Statistical significance (p<0.05) between states indicated (*).

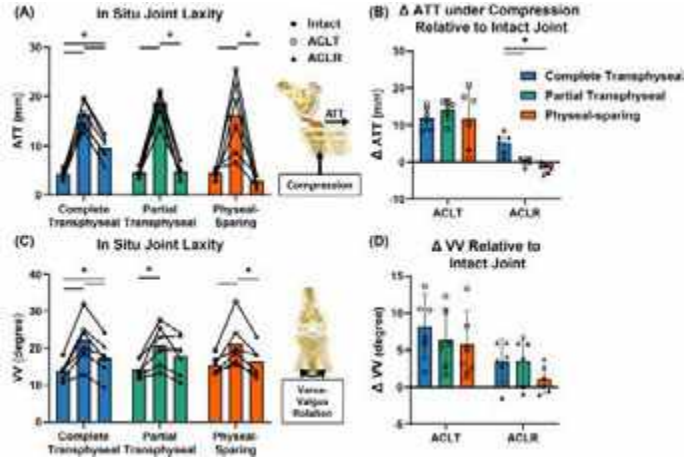

Figure 2: (A) Anterior tibial translation (ATT) under compression following ACLR was comparable to intact state only when using partial transphyseal and physeal-sparing technique. (B) Complete transphyseal led to greater increases in ATT under compression relative to intact state. (C) Varus-valgus (VV) rotation was restored to intact state when using partial transphyseal and physeal-sparing technique but not the complete transphyseal technique. (D) VV increases relative to intact state were variable across techniques. Data points presented with mean and 95% CI. Paired samples were connected. Statistical significance (p<0.05) between states indicated (*).

When performing ACLR with the complete transphyseal technique, the MCL had a greater anterior load contribution (55%) compared to partial transphyseal (33%) and physeal-sparing (28%) (Figure 3A). Under compression, loads shifted from the medial meniscus (MMEN) and medial femoral condyle (MCON) to the lateral structures (Figure 3B). No difference in varus resultant force was found across techniques (Figure 3C). The valgus resultant force taken by MCL increased after all techniques, while physeal-sparing showed the smallest increase in lateral meniscus (LMEN) (Figure 3D).

DISCUSSION

Partial transphyseal and physeal-sparing techniques revealed a superior ability to restore initial joint stability compared to the complete transphyseal technique in an early adolescent porcine joint. The results for anterior stability align with a previous human pediatric study, indicating that physeal-sparing technique resulted in better post-operative anterior joint laxity [7]. Additionally, varus-valgus laxity in

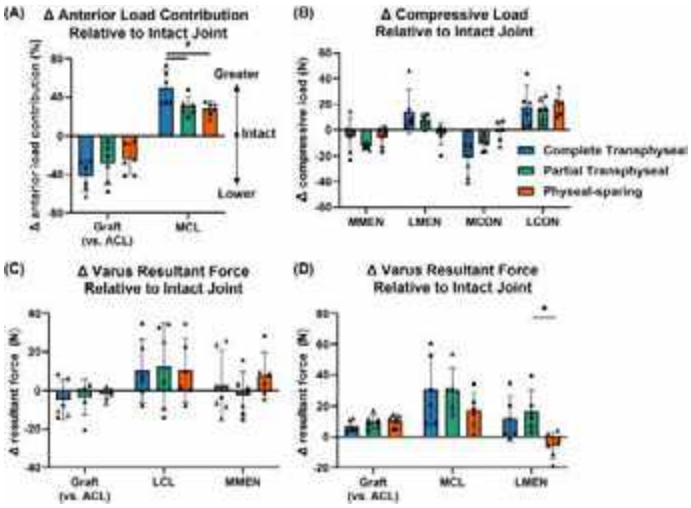

Figure 3: (A) MCL had a higher anterior force contribution under maximum anterior translation when using complete transphyseal technique for ACLR. (B) Compressive load under maximum compression shifted to lateral side following ACLR. (C) No difference in varus resultant force across techniques. (D) Physeal-sparing led to smaller valgus resultant force in the lateral meniscus (LMEN). Data points presented with mean and 95% CI. Statistical significance (p<0.05) between states indicated (*).

the current work was not reduced to the intact level after complete transphyseal ACLR. Tissue-level force data showed that more anterior forces shifted to MCL rather than reconstructed ACL graft following complete transphyseal technique. Femoral tunnel angle could be a factor for the differences between techniques, since the physeal-sparing and partial transphyseal techniques use a sharper angle to avoid crossing the physis. Previous biomechanical work indicated that 10 o'clock position showed better rotatory stability as well as smaller ATT when compared to 11 o'clock position [9]. A limitation of the model is that the differential AP laxity following ACLR ranged from 5.3 mm to 8.4 mm, which was higher than the joint laxity observed from a previous human pediatric patient work (within 2 mm) [5]. Yet, these data were comparable to a porcine biomechanical study with 89 N anterior tibial force after complete transphyseal ACLR (differential laxity of 7.3 mm) [8]. The difference relative to human studies may be due to larger native joint laxity of the porcine joints, along with differences in methods such as cadaveric testing versus clinical exams. A larger sample size may be able to detect additional statistical differences between groups. Identifying the impact of different pediatric ACL reconstruction techniques within age-appropriate joints can lead to a better understanding of operative treatments for ACL injuries in young patients. Future in-vivo work will compare the long-term degenerative outcomes following different pediatric ACLR techniques.

SEX-RELATED VARIATIONS IN HEAD IMPACT KINEMATICS DURING CONTROLLED SOCCER HEADING

INTRODUCTION

In the context of sport-related concussions (SRC), soccer, which is one of the female-male comparable impact sports with high head impact rates, significantly contributes to the increasing incidents of SRC. Epidemiological evidence shows higher rates of SRC, longer recovery periods, and more severe post-concussive symptoms among females compared to males in comparable sports such as soccer [1, 2]; however, literature predominantly has focused on male athletes, creating a data gap in sport-related head impacts in females. Moreover, previous studies indicated that the risk and severity of brain damage are correlated with the severity of head impact kinematics and their characteristics such as magnitudes and directions of linear and angular accelerations, angular velocities and impact durations [3]. Despite these findings, there is limited research on the differences in head kinematics characteristics between male and female soccer athletes heading and their potential contributions to the rate of SRC. Therefore, this study aims to explore these differences and examine the role of head mass and impact location in these distinctions using a controlled laboratory experimental setup. The outcome of this study may inform sex-specific SRC prevention and protective strategies in soccer.

METHODS

Thirty-four healthy collegiate soccer players (18 females, 16 males) with an average of 8.2 years of soccer experience participated in this study. The head masses of participants were estimated as a percentage of their body weight (8.26% for males and 8.2% for females [4]). Participants underwent a soccer heading protocol, executing ten frontal head impacts, one minute apart, which is common in soccer heading practice, with a ball launched at 25 mph from 40 feet away [5]. The head kinematics during heading, including x-y-z direction (frontal-sagittal-transverse plane normal direction) and resultant peak angular accelerations (PAA), peak angular velocities (PAV), and peak linear accelerations (PLA), were accurately measured using validated sensor-embedded mouthguards (Prevent Biometrics, MN). Recorded video was utilized to confirm true impacts and identify the location of impacts on the head, including the front high and top front. Due to the frontal soccer heading protocol, the y-direction and resultant of peak angular accelerations and velocities (PAA-y, PAA-R, PAV-y, PAV-R) and resultant and x-z-direction of peak linear accelerations (PLA-x, PLA-z, PLA-R) were selected for further analyses. The effect of sex and head location of impacts on the kinematics parameters were analyzed using Multivariate Analysis of Variance (MANOVA). The sex, location and their interaction (sex*location) were considered as the main effects in full factorial MANOVA analysis with and without the head mass as a covariate to investigate its effect on the head kinematics. Additionally, pairwise comparison was implemented to explore the effect of the sex factor on each specific level of the location factor. Significance level: 0.05.

RESULTS

Peak Angular Accelerations: Sex had a significant effect on head peak angular accelerations (PAA-y and PAA-R), with greater magnitudes in females, especially for top front locations (Table 1, Figure 1a). However, this effect became insignificant when considering head mass as the covariate. Significant and marginally significant (p-value <0.1) effects of head mass were observed on PAA-R and PAA-y, respectively, in analysis with head mass as the covariate. While the location of impact did not significantly affect PAA-y and PAA-R in both MANOVA analyses, the interaction term (sex*location) showed a significant effect (Table 1).

Peak Angular Velocities: Head peak angular velocities (PAV-y and PAV-R) were not influenced by sex, but were significantly affected by impact location, with a higher magnitude for front high location regardless of adjusting for the head mass as a covariate (Table 1). Also, the interaction of sex and location factors showed a significant effect on PAV-y and a marginally significant effect on PAV-R (Table 1).

Peak Linear Accelerations: Sex did not significantly influence peak linear accelerations (PLA-x, PLA-z, PLA-R) in both MANOVA analyses; however, by including head mass as a covariate, a significant effect of head mass was observed on all three peak linear acceleration

parameters (Table 1, Figure 3a). Also, location and sex*location interaction terms significantly influenced PLA-x and PLA-z, and had no significant influence on PLA-R (Table 1), with or without the head mass as the covariate.

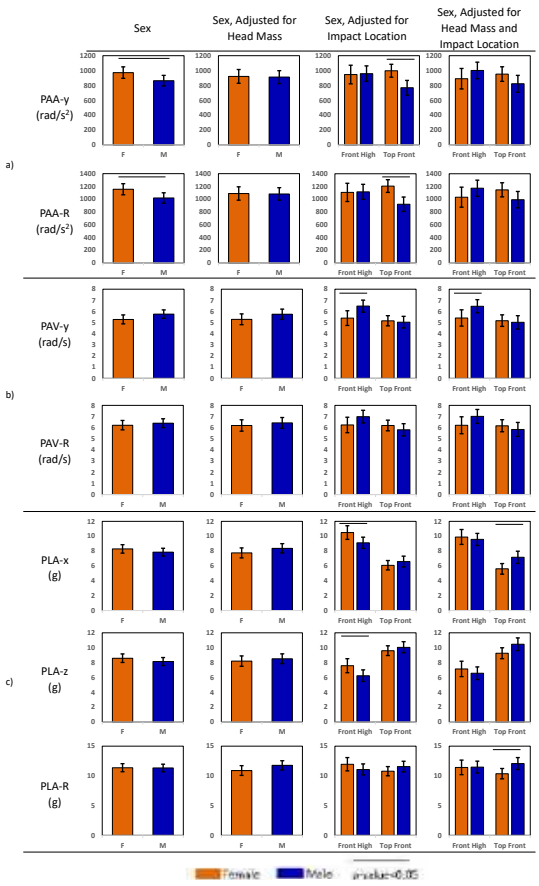

Figure 1: Mean and standard deviation of head kinematic parameters including a) PAA-y and PAA-R, b) PAV-y and PAV-R, and c) PLA-x, PLA-z and PLA-R. MANOVA results with (columns 2 and 4) and without (columns 1 and 3) adjustment for the head mass (as the covariate) are included.

Table 1: Comparison results (p-values) for all head kinematic parameters considering factors including sex, location, and their interactions with (b) and without (a) the head mass as a covariate

		parameter		PAA-y	PAA-R	PAV-y	PAV-R	PLA-x	PLA-z	PLA-R

DISCUSSION

Peak Angular Accelerations: The effect of sex on peak angular accelerations (PAAs) in soccer heading remains a subject of debate in the literature due to variations in the accuracy of head kinematic measuring systems and experimental set-ups employed. While some studies have reported that sex does not significantly affect PAAs [6], the majority of research, including our own, has observed significantly higher PAAs in females compared to males in soccer heading [7, 8]. This observation underscores the role of sex as a determinant in the brain injury outcomes of soccer heading, given the consistent reports of a strong correlation between PAAs and brain tissue deformations, as well as brain pathology [3]. This finding aligns with epidemiological studies indicating a greater incidence of concussions in high school and collegiate female soccer athletes compared to their male counterparts [9, 10]. Our results also indicated that the significant impact of sex on PAAs diminishes when accounting for head mass as a covariate, suggesting head mass serves as a mediating factor. This could explain why females, who typically have lower head mass, experience higher PAAs. This aligns with the previous studies that demonstrated head mass not only exhibits a significant adverse correlation with the peak angular and linear accelerations but also varies between sexes [7, 11].

Peak Angular Velocities: This study investigate PAVs of the head during soccer heading, a crucial parameter that is lacking in the literature and is highly correlated with the severity of brain injury [3]. No significant effect of sex and head mass was observed on PAVs. Logically, head mass primarily influences the rate of velocity change (accelerations); explaining why a significant effect of head mass was observed on PAAs and PLAs but not PAVs. Additionally, the higher PAVs for front-high impacts compared to top-front impacts may be attributed to the shorter moment arm in front-high head impacts.

Peak Linear Accelerations: Similar to PAAs and due to different experimental setups and sensor accuracy, literature regarding the effect of sex on the PLAs is inconsistent. While some studies suggested females may experience higher PLAs [8], our findings are in line with the majority of studies that reported no significant effect of sex on PLAs [6, 12, 13]. The significant effect of head mass on PLA parameters aligns with Newton's second law and is in agreement with the literature.

Conclusion: Our findings, showing that females experience higher PAAs, possibly due to their lower head mass, align with epidemiological evidence indicating a greater rate of SRC among female soccer players than males. Future research could investigate other factors such as hormonal dynamic, brain structure, neck stiffness, and heading techniques that contributes to the sex-based variations in the vulnerability, rate, and outcomes of SRC and identify potential interventions to reduce PAAs in female players, such as adjusting ball pressure, employing headgears, and enhancing heading techniques.

TEMPERATURE EFFECT ON IN-VITRO SINUS FLOW AFTER AORTIC VALVE REPLACEMENT

A. Bshennaty (1), B. Vogl (1), A. Sularz (2), M. Alkhouli (2) and H. Hatoum (1,3)

INTRODUCTION

Aortic valve replacement (AVR), whether surgically or percutaneously, is the standard procedure for patients suffering from aortic stenosis (AS) [1]. Leaflet thrombosis and calcification are common complications that arise following AVR due to the changes in the hemodynamics that are imposed by the non-native valve [2]. Therefore, it is imperative that the various commercially available valves are adequately assessed for their impact on the flow dynamics in the sinus and the aorta, which has been primarily performed through in-vitro experimentation based on the ISO standard [3]. Some research studies run their experiments with the blood analog solution at room temperature [4, 5]. Other studies have utilized the blood analog solution at body temperature [6].

It is known that temperature variations can impact the viscosity of fluids [7, 8]. Changes in viscosity may lead to different hemodynamics in the sinus that may impact the translationability of the results to clinical cases. Moreover, in the assessment of self-expanding valves, the complete expansion of the stent is expected to occur at the physiological temperature (37°C). However, Hatoum et al. have shown that the valve geometry exhibited no significant differences when at room temperature and when at body temperature [9]. To date, no comparative study has been performed to assess the impact of temperature in an experimental setting.

The aim of this study is to compare the in-vitro sinus hemodynamics after AVR between a blood analog at room temperature and at body temperature. This study may have implications on the translation of results obtained from experimental valve assessment.

METHODS

The blood analog used in this experiment is a mixture of 37.6% by weight glycerin and water, in line with previous experimental work. The assessment of the flow dynamics in the presence of a bioprosthetic aortic valve was carried out in a left heart simulator. The experimental setup, shown in **Fig.1**, consisted of a reservoir that feeds a bladder pump, which represents the left atrium and left ventricle, respectively.

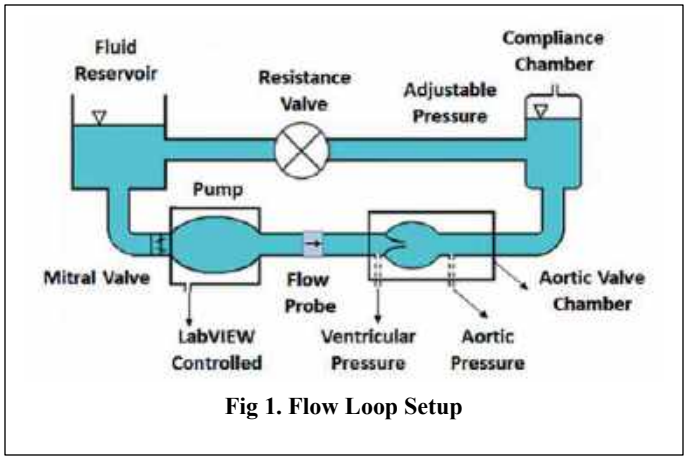

Fig 1. Flow Loop Setup

A mechanical valve is placed between them to prevent reverse flow, and a 23mm Edwards SAPIEN 3 Ultra valve is placed in an acrylic chamber downstream of the pump. The cardiac output was manipulated using a gate valve and a compliance chamber to achieve a flow rate of 5 L/min under a pressure of 120/80 mmHg. The experiment was run once with the solution at room temperature (24°C). Then, the solution was heated to body temperature (37°C), and its temperature was maintained throughout the experiment. In order to perform particle image velocimetry (PIV), the solution in the reservoir was seeded with Rhodamine B particles, which were illuminated using a Single Cavity Diode Pumped Solid State, High Repetition Rate Laser (Photonic Industries, NY, USA). The laser was reflected onto the acrylic chamber along the sinus to be captured by a high-speed CMOS camera (Photron, Inc). The timeseries images were collected at the rate of 4000 frames

per second and introduced to a multi-pass cross-correlation PIV algorithm in order to calculate the velocity field. The vorticity and shear stress data were obtained through the post-processing of the PIV frames.

RESULTS

Fig.2 shows the velocity vectors and vorticity contours in the sinus at peak systole and at deceleration at both temperatures. At peak systole, the sinus seems to exhibit slightly higher vorticities at body temperature. At deceleration, the sinus that is at body temperature seems to exhibit an elevated vorticity when compared with the one that is at body temperature, with no significant differences in the velocities. Overall, the sinus vortex was spotted in both cases rotating counterclockwise.

In order to better quantify the velocity differences, the magnitudes of the velocity and shear stress were extracted, and their probability density functions (PDF) over the full cardiac cycle were plotted in **Fig.3**. The plots indicate the presence of slightly elevated velocities and shear stress values in the sinus at body temperature compared to those at room temperature.

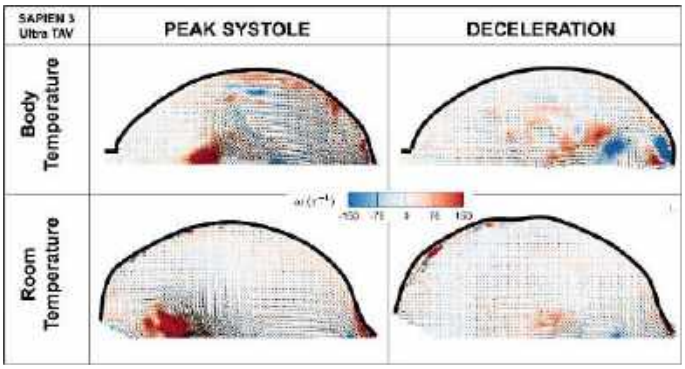

Fig 2. Peak Systole and Deceleration Frames

DISCUSSION

The results of this study have shown that the temperature of the solution has some implications for in-vitro studies assessing sinus flow. In particular, running similar experiments at room temperature may provide an underestimation of velocity and an overestimation of shear stress, albeit slightly. Typically, an increase in temperature correlates with a slight decrease in viscosity which may lead to higher velocities. This seems to be the case for the flow in the sinus, although the difference was not major (1.15 m/s vs. 1 m/s).

While differences are present, it seems that using room temperature in stasis-related diseases assessment such as leaflet thrombosis and calcification presents a more conservative approach compared to using body temperature. This means that an evaluation of blood stasis with a blood analog at room temperature does not necessarily guarantee the same evaluation at body temperature. However, because the difference is minor, studies that use blood analogs without maintaining the body temperature throughout the in-vitro assessment still have valuable information and insight on flow dynamics and disease relationship.

INTRODUCTION

Dual-mobility hip implants were invented in France in the mid 1970's to increase range of motion.[1] Although, dual-mobility (DM) implants have been used in Europe since the 1970's, the adoption of their use in the United States is relatively recent. The FDA approved the use of DM implants in 2009.[1]

Rather than having a single bearing, a DM implant contains two bearing surfaces; a head that rotates within a polyethylene insert which subsequently rotates within an acetabular shell. This unique design reduces the risk of dislocation in total hip arthroplasty.[2-4] Although dislocations are rare for DM implants, there is a specific dislocation unique to DM implants called an intraprosthetic dissociation (IPD). During an IPD, the femoral head comes completely out of the polyethylene insert. While it remains unclear how an IPD happens *in-vivo*, there are documented accounts of IPDs occurring during the treatment of large-head dislocations.[5] A surgical intervention is necessary when an IPD occurs unlike a large-head dislocation which can be treated with manual manipulation.[5]

There is little knowledge on the torques and forces that cause IPDs in dual-mobility implants. The aim of this study was to investigate the forces, torques and energy that cause DM implants from various companies to dissociate.

METHODS

Samples

Polyethylene inserts from the dual mobility hip implants of five different companies were tested for this study.

- DePuy Synthes Pinnacle Dual Mobility, Crosslinked (n=3)
- Link Orthopedics E-Dur Dual Mobility System, Crosslinked (n=3)
- Smith & Nephew Polarcup Dual Mobility, Crosslinked (n=3)
- Stryker Modular Dual Mobility, Crosslinked (n=3)
- Zimmer Biomet G7 Dual Mobility, Crosslinked (n=3)
- Zimmer Biomet G7 Dual Mobility, Vitamin E Infused (n=2)

Testing Setup

All mechanical tests were executed on a servohydraulic test machine (MTS Systems, Eden Prairie, MN). A femoral stem (BioMet, Size 10, 130mm, Type 1 Taper) was attached to a custom fixture for all tests. In addition, a ceramic head (28mm diameter) was epoxied to the neck of the stem. The polyethylene inserts were attached to or resting on the bottom fixture for all tests. Below the bottom fixture was a 15000N capacity load cell that was used to measure loads during the tests.

Mechanical Tests

Three different procedures were used to test the polyethylene inserts (Figure 1). The first procedure was always an assembly force test. During the press-in test, the proximal side of the polyethylene insert rested in a short depression in the bottom fixture plate. The stem moved down at 1mm/s and stopped when the head was completely in the polyethylene insert.

Implants were disassembled using 2 different techniques: a pull-out and a lever-out. The pull-out procedure started with the head already in the polyethylene insert. A ring held the polyethylene insert against the bottom plate. The inner diameter of the ring was 1mm less than the insert's outer diameter. The stem moved up at 1mm/s and stopped when the head was completely out of the polyethylene insert.

The lever out procedure also started with the head already in the polyethylene insert. Similar to the pull-out procedure, a ring held the polyethylene insert against the bottom plate. In addition, the bottom plate was connected to a linear stage to prevent binding. The upper fixture applied a downward force to apply a torque to the stem. The upper fixture lowered at 9.75mm/s, which resulted in around 5 degrees/s of rotation at the impingement point, until the head was completely out of the polyethylene insert.

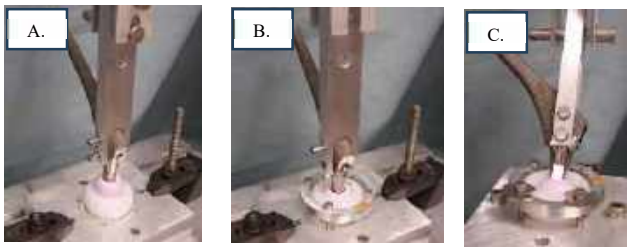

Figure 1: Test configuration for (a) press-in test (b) pull-out test and (c) lever-out tests.

Test Sequence

Each insert underwent a series of 6 total tests, 3 assemblies via press-in and 3 disassemblies via lever- and pull-out. Table 1 shows the testing sequence structure used for the insert models.

Table 1: Test Sequence for each vendor.

Sample #	Test Sequence	Trial # 1	2	3	4	5	6
1	A	Press-In	Lever-Out	Press-In	Pull-out	Press-In	Lever-Out
2	B	Press-In	Pull-Out	Press-In	Lever-Out	Press-In	Pull-Out
3	A	Press-In	Lever-Out	Press-In	Pull-out	Press-In	Lever-Out

*Zimmer Biomet ArCom had 2 samples with sequence B and 1 with sequence A

Data Analysis

For each trial a custom MATLAB script was used to determine the peak force. The component of the peak force normal the stem was used to calculate the dissociation torques for the lever-out trials. The energy values were determined by calculating the area underneath the load-displacement and torque-angle curves.

RESULTS

The maximum assembly force decreased for each repeated assembly (Figure 2). In addition, the maximum assembly force of the first assembly was statistically different between the companies ($p<0.01$). The Link E-Dur Dual Mobility System had the greatest maximum assembly force (1831.9±81.95N), maximum pull-out force (20589.89N), and dissociation torque (38.95±2.79Nm) as seen in Figure 2, Table 2, and Table 3. It should also be noted that when comparing the Zimmer Biomet crosslinked insert with the Zimmer Biomet vitamin E infused insert, the vitamin E infused insert had larger max assembly forces, and pull-out forces.

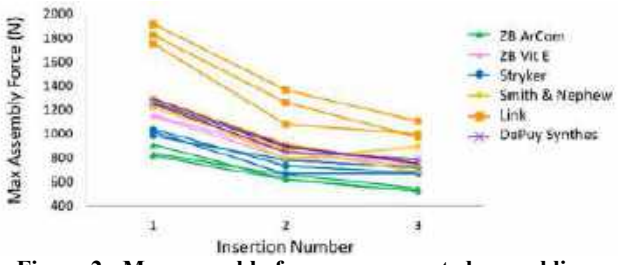

Figure 2: Max assembly force over repeated assemblies.

Table 2: Force and energy data for first pull-out trial.

Vendor	Pull-Out Force (N) Average	Std. Dev.	Sample Size	Pull-Out Energy (J) Average	Std. Dev	Sample Size

DISCUSSION

There is limited published data on assembly and dissociation forces for DM polyethylene inserts. Furthermore, not much is known about the differences in assembly and dissociation forces between DM implants from different companies. This study has shown that there are measurable differences between products lines which has potential implications for creating dissociation based mechanical testing standards. Any testing standards for dissociation should focus on the lever-out procedure as this is a more realistic simulation of *in-vivo* mechanics. This study also showed that the maximum assembly forces decreased after repeated assemblies. This finding indicates that polyethylene inserts should be replaced following dissociations.

The implant with the greatest resistance to dissociation was the Link E-Dur Dual Mobility System. This implant happens to have a vitamin E infused polyethylene liner. Interestingly, the Zimmer Biomet implant with vitamin E infused polyethylene had greater assembly, max pull-out, and max lever-out forces than the Zimmer Biomet crosslinked polyethylene insert. Vitamin E infused polyethylene liners were originally developed for their improved wear characteristics, but it has shown to improve strength as well.[6]

One of the limitations of this study is all testing was done at room temperature. Future studies should also conduct testing at body temperature to better simulate *in-vivo* conditions. Another way to better simulate *in-vivo* conditions would be induce wear of the insert before testing. Additionally, the confined number of samples from each company combined with the order effect of repeated assemblies, limited the number of data points we could use for analysis. The current experimental design makes it difficult to explore the contribution of individual design characteristics to the overall performance of the polyethylene inserts. It would be useful to know how different design and material choices such as diameter, retention ring shape, and polyethylene vitamin E infusion affect the performance independently. Future work should ultimately focus on determining what differences between manufacturers are clinically meaningful to inform minimum dissociation load standards.

COMPUTATIONAL AND MULTI-SCALE MECHANICAL ANALYSIS OF SOY GEL EXTRUSION PROCESS

Marco A. Fielder (1), Arun K. Nair (1)

(1) Mechanical Engineering, University of Arkansas, Fayetteville, AR, United States

INTRODUCTION

Evaluating the mechanical properties of soybean seeds and products derived from soy processed into gel for food applications is important for optimal storage [1]. For example, stress cracking of soybean seeds can occur during harvest, transport, or drying which impacts the quality of subsequent soy products and increases production costs [2]. Additionally, the molecular composition of the soybeans can affect different properties of the processed product. For example, oils with a higher linolenic acid content have improved shelf life [3]. Furthermore, the texture and firmness of food analogs derived from soybean should match that of the foods they substitute such as meats. For example, more cohesive meats like steak will have a different texture and firmness than meats like sausage or nuggets. The texture and firmness of foods can be quantified through measurements of microstructure and mechanical stress. Additionally, soy-based materials are also used in tissue scaffolds for applications in wound healing [4].

Extrusion is one preferred process for developing soy-based meat analogs. At the molecular level during extrusion, shearing promotes the stretching and orientation of unfolded protein along extrusion direction, forming layers like meat's fibrous structure. The shear and pressure expose reactive sites to enable intermolecular crosslinking and promotes protein aggregation. This aggregation forms continuous and dispersed phases that mimic meat texture. At high water levels, hydrogen bonds play a dominant role in extrudates' texture and stabilizing the structure.

This study thus develops a computational multi-scale model to correlate soybean seed composition to soy-based product mechanical properties which would be beneficial to quickly determine the optimal seed type. Furthermore, this study develops a model to understand the biomechanics of soybean and quantify how water content and pressure affect hydrogen bond formation, as well as quantifies the effect of extrusion on soy gel texture and firmness, which would be extremely beneficial in the identifying the optimal processing parameters for tuning the extrudate's texture, as well as tuning matrix texture for cell growth in tissue scaffolds.

METHODS

This study evaluates several experimental studies from literature to develop a regression model of predicted soy gel pore size and seed mechanical properties for different seed types [2, 5-7]. The mechanical properties are input into a finite element model with FEBio software to simulate compression of a soybean seed to quantify seed firmness (maximum stress). The properties are evaluated with machine learning (ML) classification models using Scikit Learn software to correlate different seed types with specific mechanical properties (Figure 1 (a)).

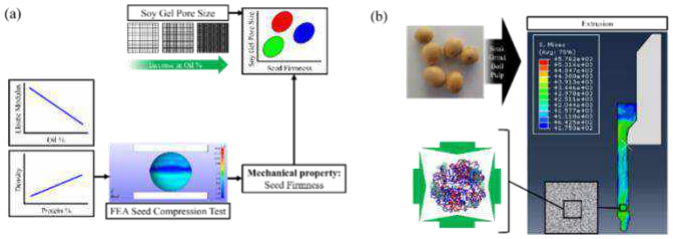

Figure 1: (a) Schematic correlating seed composition to mechanical properties, (b) Schematic of computational evaluation of soy gel micro and molecular structure, and mechanical extrusion tests.

Next, soy gel at the atomic scale is modeled with molecular dynamics (MD) using the 11S soy protein data bank (PDB) with code 3AUP and using OpenMM software and the CHARMM force field to simulate and quantify the formation of hydrogen bonds during compression and with different water contents. Lastly, we use Abaqus software [8] to simulate extrusion of soy gel and quantify the texture (change in dispersed phase aspect ratio), and firmness (maximum stress), as seen in Figure 1 (b) of the observed classes of soy gel for the evaluated seed types (Silken, Soft, and Firm). The gel is modeled as a

viscoelastic plastic material with associated coefficients. The geometry of the gel extrusion is of a cylindrical soy gel sample extruded through a conical steel nozzle. As the gel is extruded, the maximum stress, and overall stress distribution is calculated, and the mechanisms visualized.

RESULTS

From the evaluated mechanical properties of each seed type studied, we find three distinct clusters of seeds: seeds that produce softer gels, seeds that produce firmer gels, and strong seeds that are more resistant to stress cracking (Figure 2). We evaluate these clusters using four ML classification models: Random Forest (RF), Gradient Boost (GB), Support Vector (SV), and Multi-Layer Perceptron (MLP). The GB model was found to be the most accurate at 99%. The three observed classes are used in the soy gel extrusion models to accurately model the extrusion process with three different soy gel types: Silken (soft gels in Cluster A), Soft (strong seeds resistant to fracture in Cluster B), and Firm/Extra Firm (firm gels in Cluster C).

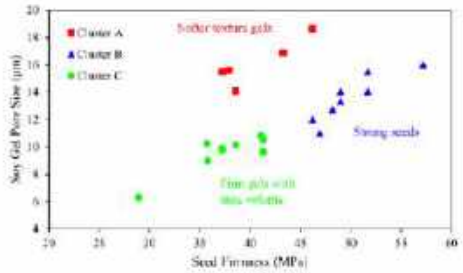

Figure 2: Seed Firmness vs. Soy Gel Pore Size.

Evaluation of the molecular dynamics models shows that hydrogen bonding increases for both increased pressure (1 atm to 1 MPa), and increased water content (6% to 80%) by 1.2% and 556% respectively. For the extrusion of the three soy gel classes, it is observed that the maximum stress increases as the gel elastic modulus increases but reaches a plateau in the Firm class (Figure 3 (a)). The stress also becomes more concentrated as the gel modulus increases (Figure 3 (b)).

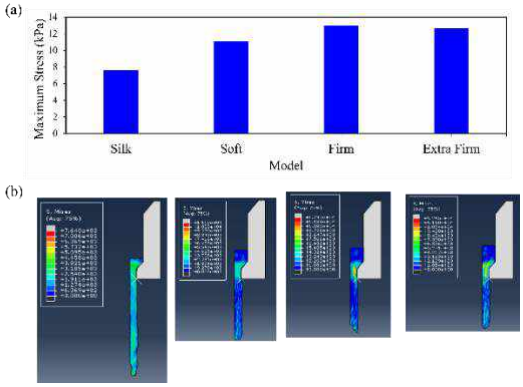

Figure 3: (a) Maximum Stress, and (b) stress distribution for three classes of soy gels

It is observed that as the soy gel becomes firmer, there is a decrease in the percent decrease in the Dispersed Phase Aspect Ratio (DPAR) due to extrusion. In Figure 4 (a) the Soft gel DPAR decreases by ~66%, while the Firm and Extra Firm DPAR decrease by ~33% and ~55% respectively. Figure 4 (b) shows the dispersed phase (not green) geometry before and after extrusion.

DISCUSSION

For the ML model, a higher weight value shows that a variable has a more significant effect on the output. Based on the value of the computed weights the components with the most effect on gel firmness were (in order): oil, linolenic, linoleic, and palmitic percentages. Our results agree with literature that a higher oil content leads to smaller pores (not novel), but linolenic, linoleic, and palmitic acids have the most effect on predicted pore size than the other fatty acids, and a higher percentage of any of these fatty acids results in larger pore sizes compared to the other fatty acids, which is novel. During extrusion, Silken gels extrude more linearly and with less defects, while once the gel is in the Firm class, and there is little change in the maximum stress as the elastic modulus increases.

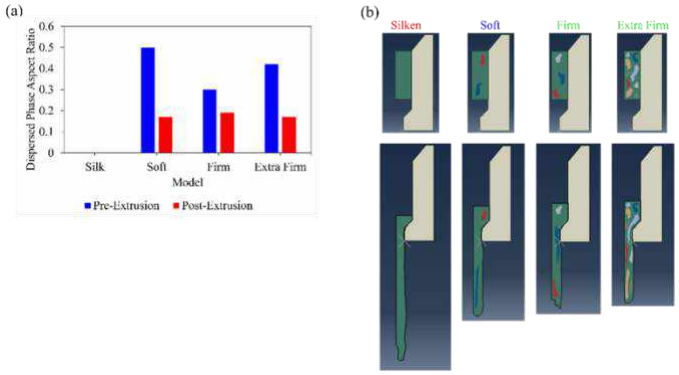

Figure 4: (a) Pre- and (b) post-extrusion dispersed phase aspect ratio for three classes of soy gels

There is also more change in the dispersed phase of softer gels than in firmer gels (66% vs. 33%) due to extrusion. These results are significant for quickly determining the optimal seed types to plant for desired characteristics, as well as for identifying the optimal processing parameters for tuning soy extrudate's texture and firmness for applications such as food analogs and tissue scaffolds for wound healing to match the mechanical properties of the materials they substitute such as meat in food applications, or bone and cartilage for wound healing applications.

INTRODUCTION

One important mechanical property of collagenous soft tissues is their non-linear stress-strain behavior curve (Figure 1). This curve demonstrates that very little force is required to stretch collagen (toe region), up to a certain point after which an increasing amount of force is required to further stretch the tissue and fibers. This nonlinearity is largely attributed to the morphological property crimp, where at the origin of this curve the fibers start crimped and are then straightened by the straining. Straightened fibers require larger forces to stretch, resulting in the increasing stress. This process of crimped fibers straightening is referred to as recruitment.[1] The force required to recruit fibers is small, and thus it is sometimes considered trivial and assumed to be zero.[1] We aim to better understand the process of collagen fiber recruitment. Towards this goal, we need a more refined characterization of the behavior of collagenous tissues in the low stress, high strain toe region of the curve. For this project we aimed to evaluate the effects of using micro-cuts to release the stresses on well-aligned collagen fibers. More specifically, we measured the changes in tortuosity in fibers that were cut compared with non-cut fibers.

METHODS

Chicken tendon was chosen because the collagen fibers are well aligned and uniform. Chicken legs were purchased from a local butcher, and the tendons were removed. A rectangular strip 10 x 2 mm was isolated and cryosectioned into 16 µm thick sections. The 2 mm on both ends of the tendon section were glued with a UV resin between two silicone sheets that were 3 x 3 mm in area and 0.125 mm thick. The ends were clamped with custom 3D printed clamps in a uniaxial micro vice (Micro Vice-Mini, PIKE Technologies). The tissue was immersed in water during testing and imaging. For the large stretch-low stress images, the tendon was stretched to the point that many of the fibers were recruited but stopped before the point of failure. This distance was different for each section.

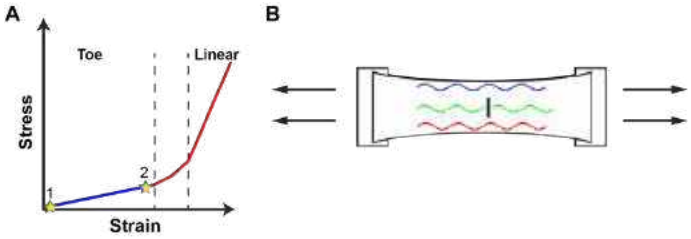

Figure 1. a) Example collagen stress-strain curve with toe region (blue), where little force is required to distort the collagen. Points 1 and 2 are the "no stretch" and "large stretch-low stress" scenarios respectively. b) The sectioned tendon was stretched, and micro-cuts were made (black line). Fiber tortuosities were measured and grouped into three regions relative to the cut: above (blue), within (green), and below (red).

A multiphoton microscope (Nikon) utilizing a femtosecond laser (Coherent) was used to visualize the collagen with second-harmonic generation (SHG) imaging and two-photon autofluorescence (TPF). We used a 25X water immersion objective (NA = 1.1). The femtosecond laser used for the multiphoton microscopy was also used to create the micro-cuts in the tendon sections. The method was adapted from Hovhannisyan et al.[2] The laser is tuned to 800 nm and powers between 25-40 mW are used. The laser continuously scans an area that is 128 x 4 µm. The diffraction limit of the 25X objective at 800 nm is 290 nm, and the laser scanning step-size was 250 nm. The collagen degradation is monitored during the laser exposure by simultaneously measuring the SHG and TPF signals. Photodegradation is marked by a decrease in the SHG signal and an initial increase in the autofluorescence from the creation of photoproducts. Femtosecond laser exposure continued until the SHG signal was zero in the micro-cut area.

Fiber tortuosity is defined as the ratio of the path length to the end-to-end distance. Crimped fibers have tortuosities greater than 1.00. The tortuosity of a perfectly straight fiber would be 1.00. Tortuosity decreases as fibers are recruited, but even when fully recruited the tortuosity can be greater than 1.00.[3] To calculate the tortuosity, the fiber paths were manually traced in the SHG maximum intensity projections, as demonstrated by the green path in Figure 2(c, d).

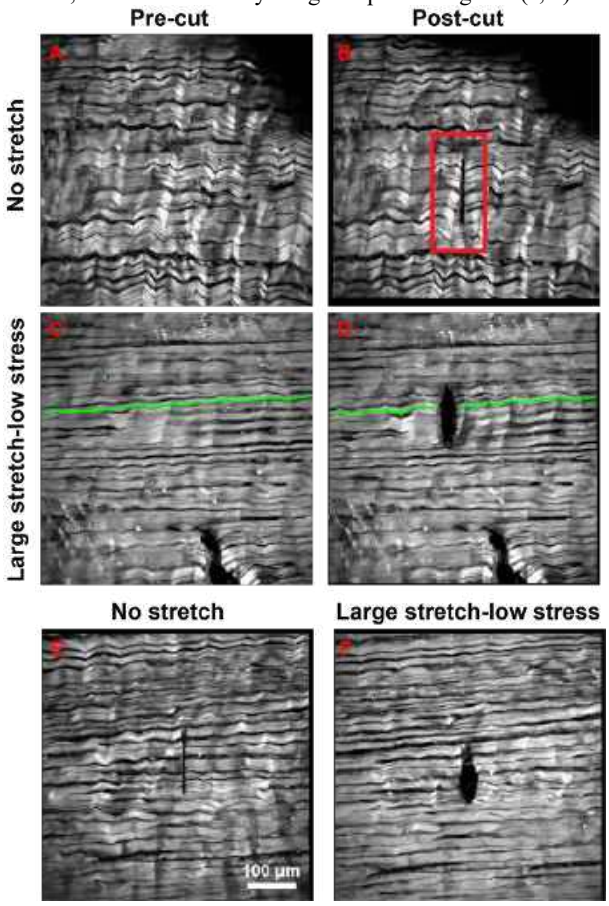

Figure 2. (a-d) show the same tendon section with no stretch (a-b) and with large stretch-low stress (c-d). In both scenarios, a micro-cut was made with a femtosecond laser (red box). The green line illustrates the manual marking to measure tortuosity. (e-f) shows a micro-cut that was made while the section was under no stretch (e), and after the cut was made the section was stretched (f).

RESULTS

We imaged the same tendon section before and after micro-cuts in two different environments: with no stretch, before there is any strain or stress (Fig.2 a-b) and with large stretch-low stress where the collagen fibers are beginning to be recruited (Fig.2 c-d). The "no stretch" corresponds to point 1 in the stress-strain curve, and "large stretch-low stress" corresponds to point 2 in the stress-strain curve. We observe a decrease in the tortuosity from the no stretch to the large stretch-low stress scenarios. The average fiber tortuosities of the section before any stretch or micro-cut was 1.08 and the average fiber tortuosities after stretch was 1.01. After the micro-cut in the no stretch scenario, there was no significant change in tortuosity, as shown by the flat lines in Fig. 3 left column. After the micro-cut while the fibers were in the large stretch-low stress scenario, the tortuosity increased for fibers within the cut (Fig. 3, center column, green lines), but was constant for fibers above and below the cut (Fig. 3, center column, red and blue lines). In addition, there was a greater increase in tortuosity in the center of the micro-cut versus the edges.

In a second tendon section, we made a micro-cut and then stretched the section (Fig. 2e-f). We measured the tortuosity before and after stretching. We observed a tortuosity decrease in fibers that were cut and fibers that were not cut, but observed a smaller decrease in tortuosity for the fibers that were cut (Fig. 3, right column, green lines).

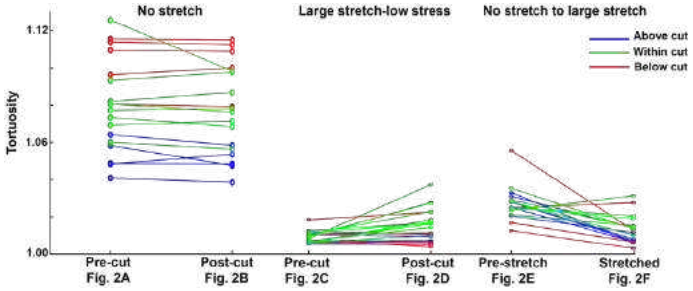

Figure 3. The tortuosity of the fibers in Fig.2 were measured and compared for each pair of images. The points connected by a line show how the tortuosity of a particular fiber changed between the images. The color corresponds to the location of the fiber: above the cut (blue), within the cut (green), or below the cut (red).

DISCUSSION

Our results lead to two points for discussion, the first related to the "toe" region of the stress-strain curve and the second related to the lateral strain in the tendon. The increase in tortuosity after the micro-cut in the large stretch-low stress fibers (Fig. 3 center column, green lines) indicates that there was some stress in the fibers before they were cut. However, we also note that the tortuosity does not increase to the pre-stretch values. These results show that although the stress is small before fibers have been recruited, the stress is not negligible, particularly at the microscale level of our experiments. Therefore, these forces will be important to consider as more research is done to understand the impact of collagen microarchitecture on macroscopic phenomena, as is being done in fiber-based modeling.[4]

For the second point of discussion, we highlight that after stretching the tendon with a micro-cut, even the fibers that were cut have a decrease in tortuosity (Fig. 3 right column, green lines). This is most likely due to the lateral strain in the tendon between the fascicles. The fascicles are connected by the interfascicular matrix leading to the lateral transfer of strain.[5] When the micro-cut is made in the large stretch-low stress scenario, the fiber segments on each side of the cut were pulled away from the cut creating the ellipse shape and an increase in the tortuosity of the cut fibers. This ellipse shape is also an indication of the lateral strain. The method of micro-cuts and uniaxial stretching can be used in the future to determine the spatial extent of the lateral strain and further characterize the contribution of the matrix to the tendon mechanical properties.

INTRODUCTION

Finite element (FE) models have been used to estimate joint contact mechanics in healthy knees and to assess changes in various pathologies or treatment conditions.[1,2,3] Knee models are often developed from cadavers or open-source databases, such as the Open Knee(s) project, with extensive data derived from cadaveric knees, while others have created models based on clinical scans from patients.[4,5] Although models derived from patient scans can be informative, these models are limited since directly measuring and comparing contact mechanics is challenging and invasive. With an interest in developing applicable patient-based FE knee models without calibration, it is important to understand which contact outcomes are reliable. Therefore, the purpose of this study was to quantify the contact mechanics during simulations of a patient loading condition using a cadaver model and uncalibrated knee-specific FE models. We hypothesized that knee-specific FE models accounting for material property variability would exhibit contact area and pressure values similar to those measured by electronic pressure sensors in the simulated patient loading condition.

METHODS

Five cadaver knees (51-76 y.o.; 3M / 2F) were used to develop knee-specific FE models. None of these knees had soft tissue degeneration or prior knee surgery. The knees were dissected at the proximal femur and distal tibia and stripped of soft tissue for potting. Once potted, they were inserted into a loading mechanism designed to emulate a patient's knee position during an MRI equipped with a 6-degree-of-freedom load cell.[6,7] The mechanism was inserted into a clinical 3T MRI scanner (GE Healthcare, Waukeshau, WI) for imaging. Two image sets were acquired for each specimen: a 3D spoiled-gradient echo (SPGR) with frequency selective fat-supression and a 3D CUBE image, as described previously.[7] Images were acquired with the knee in a non-weight-bearing position at full extension to assess the non-deformed geometry of the soft tissue. Next, the gantry was displaced to compress the knee to achieve ½ of the donor's body weight (50-73 kg) to simulate standing in the MRI, similar to previous *in vivo* studies.[6,7] Images were acquired in this loaded configuration to determine the displacement of bones relative to each other for subsequent use in the FE models. Following scanning, the knee was unloaded for at least one hour, and an electronic pressure sensor (Model 4011, Tekscan, Norwood, MA) was inserted into the knee joint and placed across the articular surface of the tibial cartilage below the menisci. The loading protocol was repeated, and images of the loaded configuration were then re-acquired in parallel with data acquisition from the pressure sensor.

The bones and soft tissues were segmented from the unloaded and loaded scans using a combination of MeVisLab (MeVis Medical Solutions AG, Bremen, Germany) and Materialise Mimics (Materialise NV, Leuven, Belgium). The soft tissues were segmented from the unloaded scans. The bones were segmented from both the unloaded and loaded scans. The femoral and tibial cartilage and bones were segmented from the SPGR images, while the menisci were segmented from the CUBE scans due to better meniscal image contrast.

The FE knee models were developed from the scans and segmentations to replicate the loaded condition of each specimen. The soft tissues were meshed with hexahedral elements using TrueGrid (XYZ Scientific Applications, Inc., Pleasant Hill, CA). An iterative closest-point algorithm with Geomagic DesignX (3D Systems, Rock Hill, SC) was used to best-fit align the segmented bones to calculate a transformation matrix of the femur from the unloaded to loaded configuration relative to the tibia. The soft tissue meshes were transformed into the loaded position, and then the femoral cartilage was distracted from the joint to clear the menisci before the simulation. FE simulations were performed in Abaqus (Dassault Systèmes, Simulia Corp., Johnston, RI) by constraining the degrees of freedom of the knee to maintain the loaded orientation of the femur and tibia, except to allow

femoral varus-valgus rotation. A load was applied to mimic the resultant force in the axial direction measured during the loaded scan.

A maximin space-filling approach used ranges of cartilage and meniscal material properties from the literature to provide 70 iterations of material property scenarios. The following material properties were varied: cartilage (isotropic) Young's modulus and Poisson's ratio, menisci (transversely isotropic) circumferential and transverse Young's moduli and Poisson's ratios, and meniscal attachment spring stiffness.

Results, including compartment contact area, peak pressure, and mean pressure on the tibial cartilage, were compiled from the FE model and the electronic pressure sensors. Image intensity from the scans of the loaded knee joint provided an approximate location of the pressure sensor in each knee compartment. The location of the sensors was reconstructed with the FE data (Fig. 1). FE results outside of the sensor boundary were excluded for a more direct comparison.

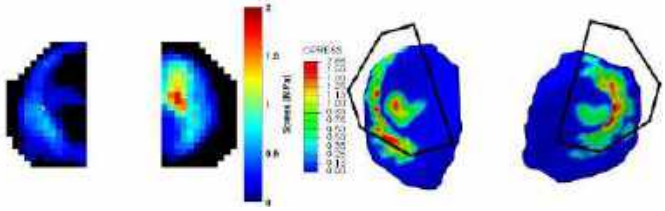

Figure 1: A comparison of pressure sensor data and FE pressure data with pressure sensor boundaries.

RESULTS

The compartment contact area was underestimated in the FE model when compared to the pressure sensor measurements (Fig. 2). In the cadaver models, the contact area varied from 319-563 mm^2 on the medial side and 236-454 mm^2 on the lateral side. The FE results ranged from 26-383 mm^2 on the medial side and 41-352 mm^2 on the lateral side. In the medial compartment, sensor measurements were greater than the FE predicted values by an average of 86±36 mm^2. In the lateral compartment, sensor measurements were greater than the FE model values by an average of 91±75 mm^2. Both models followed similar trends. For example, the knee with the highest contact area estimated by the FE model was also the knee with the highest contact area measured by the electronic pressure sensors in both compartments.

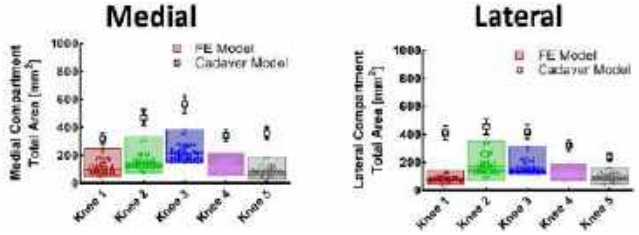

Figure 2: Medial and lateral compartment contact area values. Material property iterations are represented by individual dots with a full range shown by colored bars. Pressure sensor standard deviations were equal to 12% of measured values, based on an assessment of the sensors.

Mean and peak contact pressures measured from the FE knee models either overestimated or fell within the range of FE predictions (Fig. 3). For the mean pressure, sensor measurements fell within the FE model predictions for one of the five knees in the medial compartment and all five knees in the lateral compartment. In the cadaver models, the mean contact pressures varied from 0.19-0.34 MPa on the medial side and 0.34-0.59 MPa on the lateral side. The FE results ranged from 0.27-1.09 MPa on the medial side and 0.31-1.05 MPa on the lateral side. Of the four knees in the medial compartment that did not accurately predict pressure sensor values, the amount of deviation from the range for the mean pressure was 0.1 ± 0.1 MPa.

Peak pressure measurements fell within the FE model predictions for two of the five knees in the medial compartment and all five in the lateral compartment. In the cadaver models, the peak contact pressures varied from 0.6-0.9 MPa on the medial side and 0.8-1.8 MPa on the lateral side. The FE results ranged from 0.4-4.9 MPa on the medial side and 0.5-3.9 MPa on the lateral side. Of the three knees that did not overlap in the medial compartment, the amount of deviation from the range for the peak pressure was also 0.1 ± 0.1 MPa.

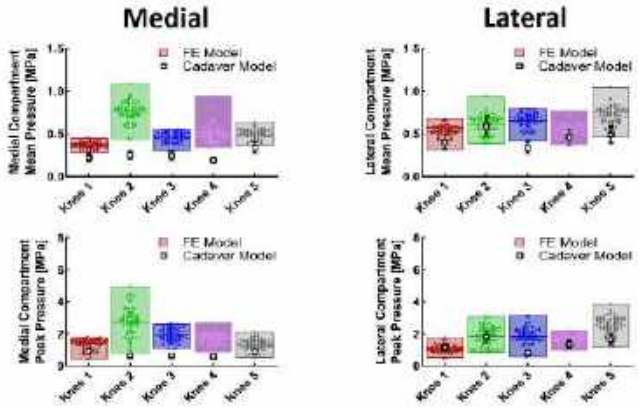

Figure 3: Mean and peak pressure in medial and lateral compartments. Material property iterations are represented by individual dots with a full range shown by colored bars. Pressure sensor standard deviations are equal to 20% of measured values based on an assessment of the sensors.

DISCUSSION

We found that uncalibrated FE knee models simulating a patient loading condition underestimated the compartment contact area but better estimated the mean and peak pressure measured in the physical cadaver model. This study took an uncalibrated modeling approach to evaluate contact mechanics, assuming the inability to obtain any data from patients that may be useful to calibrate the FE models. Future studies utilizing MRI may be used to calibrate the FE models as well as approximate contact area during the loaded portion of scanning by estimating the overlap of the articular soft tissue surfaces.[8] Predicted cartilage overlap maps derived from MR sequences could provide an insightful comparison to FE contact results and warrant investigation. Despite the limitations of uncalibrated FE models, contact pressure outcomes closely approximated values from the simulated loading condition.

INTRODUCTION

With more than 2 in 5 adults in the US currently battling obesity, ongoing research strives to unravel the intricacies of adipose tissue and its role in metabolic syndromes[1], autoimmune diseases[2], cardiovascular diseases[3], and cancers[4]. To fully understand these diseases, it is critical to develop *in vitro* models that not only allow the study of how healthy adipocytes behave but also shed light on how dysfunctional cells may contribute to these pathologies.

Conventional monolayer models of adipogenic differentiation, while convenient, have significant limitations. Cells cultured in monolayers exhibit decreased efficiency in adipogenic differentiation, resulting in a heterogeneous population. Only a minority express the classic mature adipocyte phenotype, characterized by large, unilocular, lipid-rich droplets with substantially increased production of hormones such as adiponectin, along with decreased pro-inflammatory cytokine production [5]. Over the past decade, several 3D models of adipose tissue have been developed, progressively increasing in complexity. Protocols utilizing various scaffolding techniques, such as mechanically tunable 3D environments[6] and microfluidics chips[7] have been created. While these methods are fascinating, they often require specialized resources, expertise, and/or technologies that limit their applicability to a broader group of biomedical researchers.

We have distilled our methods for generating adipose spheroids into two formats that meet a wide range of experimental goals: a 96-well spheroid plate format and agarose micromold format. Both methods are relatively simple allowing their adoption across many biomedical research labs. We compared the two methods for experimental parameter design and use them to highlight the differences between monolayer and spheroid culture and the importance of characterizing donor variability.

METHODS

Adipogenic differentiation of adMSCs in monolayer: To stimulate adipogenesis, adMSCs were plated at 10k/well in a 96-well plate to achieve confluency. Cells were cultured within 150µL Preadipocyte Differentiation Medium (PDM-2) (Lonza) for the first week and changed to 150µL DMEM (25mM D-glucose) with 10% FBS and 1.9µM insulin the following week for achieving maturation. Media was collected for adipokine analysis via LegendPlex Adipokine Panel (BioLegend) according to manufacturer's protocols. Adipogenic differentiation of adMSCs in 96-well spheroid plates: adMSCs were seeded at either 5k, 10k, or 20k cells/well within 150µL PDM-2 (Lonza) for the first week and changed to 150µL DMEM (25mM D-glucose) with 10% FBS and 1.9µM insulin for the following week for adipocyte maturation. Adipogenic differentiation of adMSCs in agarose micromold format: A 4% w/v solution of agarose within PBS -/- was heated to 80°C to achieve a molten state. The solution was then transferred to either a Microtissues© 35-well micromold cast, or in-house printed 10-well micromold cast for 2 minutes until gelled. Micromolds were transferred to a 24-well plate and acclimated within PDM-2 for 1 hour, media was carefully aspirated, and cells were seeded within the cell seeding chamber in 75µL of media at various concentrations to achieve ~1k, 2k, 5k, 10k, or 17.5k cells/spheroid for another hour. Once formed, an additional 1mL of media was added and cells were differentiated as previously described.

Lipid staining and imaging: Cells cultured within monolayer were washed 2x with PBS -/-, fixed for 30 minutes with 10% Formalin, and stained for 30 minutes with 10 µM Hoechst 33342 and 2 µM BODIPY 493/502 within PBS followed by imaging via inverted fluorescent microscopy. Cells cultured within spheroid format followed the same procedure, with increased fixing and staining times of 1hr followed by imaging by confocal microscopy.

RESULTS

Study 1: Spheroid production and function via agarose micromold or spheroid plate. Spheroids formed within agarose micromolds have a greater size variability of 15 - 23 %CV compared to those formed within spheroid plates (Fig. 1C). For the spheroids formed within a 10- or 35-well micromold, increasing the number of cells per spheroids leads to a drastic decrease in adiponectin production, while increasing the overall number of spheroids leads to a further decrease (Fig. 1D).

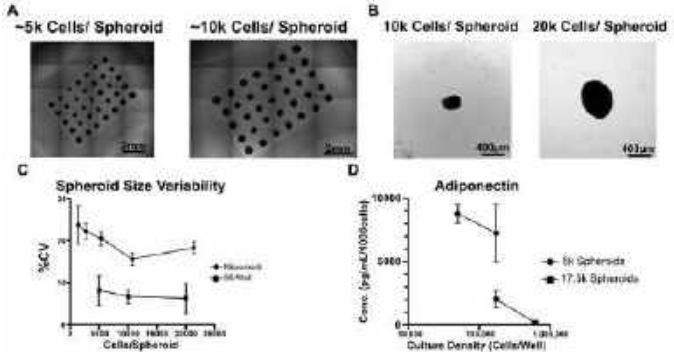

Figure 1: Representative images of spheroid production within (A) agarose micromolds and (B) spheroid plates. Spheroid size variability was compared between the two formats (C). Spheroid size variability depends on method of formation and not cells per spheroid. (D) Quantification of changes in adiponectin output per cell as a function of spheroid size and culture density. N = 3.

Study 2: Adipogenic differentiation in 2D monolayer and 3D spheroid culture formats. Cells differentiated within a 3D spheroid format at 10k cells/spheroid exhibited a 4.6x increase in adiponectin signaling in comparison to cells differentiated in monolayer (Fig. 2A). Pro-inflammatory cytokine production decreased across the board from 2D to 3D culture. Average concentrations decreased 116x for MCP-1 (Fig. 2B), 32x for IL-8 (Fig. 2C), and 65x for IL-6 (Fig. 2D) when switching from monolayer culture to spheroids. Cells differentiated within 3D also illustrated greater lipid droplet production compared to their 2D counterpart (Fig. 2E,F).

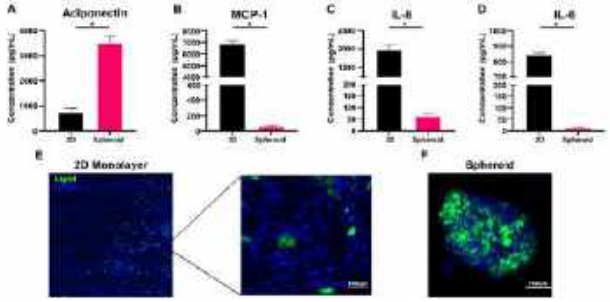

Figure 2: Comparison of adipokine signaling between monolayer- and spheroid differentiated adMSCs for (A) adiponectin, (B) MCP-1, (C) IL-8, and (D) IL-6. N=3 experimental replicates. Unpaired t-test, * designates significant difference of $p<0.05$. Representative fluorescent images of nuclei (blue) and lipid (green) stained cells in monolayer (E) and spheroid (F) formats.

Study 3: Donor-specific adipogenic variability within 3D culture format. After the 14-day spheroid differentiation at 10k cells/spheroid, Donors 2302 and 2414 had increased average lipid droplet counts of 714-814 compared to Donors 2334, 2220, and 11738 with counts of 174, 159 and 331 respectively (Fig. 3B). When analyzing adiponectin, donors 2414 and 11738 had 11x increased production compared to donors 2334, 2220 and 2302 (Fig. 3C). Donor 2334 had higher pro-inflammatory cytokine production across the board compared to the remaining four (Fig. 3D-F).

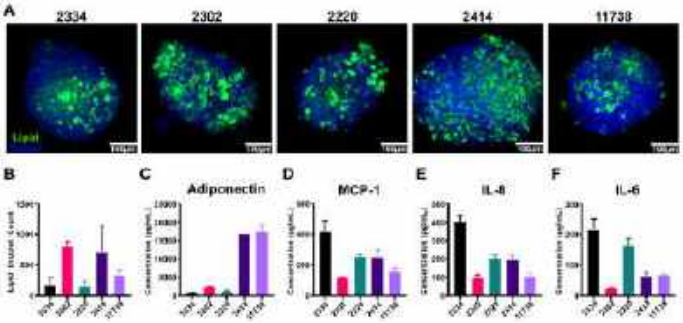

Figure 3: (A) Representative fluorescent confocal images of five separate donors. Total lipid droplet counts were quantified with ImageJ (B). Adiponectin (C), along with inflammatory cytokines: MCP-1 (D), IL-8 (E), and IL-6(F) were quantified via ELISA. n=3 experimental replicates.

DISCUSSION

These findings demonstrate the efficacy of using simple, scaffold-free techniques for adipogenic differentiation without the need for specialized scaffolding, machinery, or materials expertise. Both methods require minimal intervention after initial seeding, reducing user error and enhancing experimental reproducibility. Additionally, they provide full access to the spheroids, facilitating scaling up or increasing complexity. The spheroid plate format allows culturing on an individual spheroid basis, enabling screening experiments without consuming large quantities of reagents while preventing any opportunities for spheroid fusion. Agarose micromolds are well suited for generating spheroids in bulk, allowing experiments requiring 100s to 1000s of spheroids to generate biological material for RNA, conditioned media, or tissue engineering applications. We used these techniques to compare how 3D adipogenic differentiation leads to increased efficiency and decreased pro-inflammatory cytokine production compared to 2D as seen in prior work[5]. This is more in line with the low levels of inflammation expected within adipose tissue. We then directly compare spheroids from the methods showing the benefits and drawbacks of each. Finally, we use the 96-well plate method to highlight reveal donor variability. While all donors are capable of producing lipid droplets, adipokine profiles varied substantially. In conclusion, we have developed a highly reproducible method for generating functional adipose spheroids that is accessible to a broad range of researchers and experimental questions. With these two methods, any biomedical lab is capable of implementing and adapting these cost-effective techniques to achieve their specific goals.

INTRODUCTION

Cardiovascular disease is the most common cause of maternal mortality in the United States [1]. Thus, an understanding of the physiologic cardiovascular changes that occur in pregnancy are paramount to manage the complications that may arise, such as hypertension and heart failure. It is established that there is cardiac growth in pregnancy, as well as changes in systemic vascular resistance and an increase in blood volume throughout gestation [1]. It is important to recognize however, that it is not only mechanical changes that influence the cardiovascular system in pregnancy. The hormonal changes that accompany advancing gestation also play a pivotal role in these physiologic changes [2].

Computational models are a useful tool in predicting the changes that occur during pregnancy, as real-time monitoring is often invasive or not practically feasible. The focus in a prior model was on the left ventricular (LV) mass, which grows, both in mass and in size, by 30% by the end of pregnancy and returns to a non-pregnant baseline within months postpartum [2,3]. These models have been applied to non-human species, such as the rat [2], and are applied here to the canine. Therefore, the aim was to scale the original rat model to a canine as a first step towards the objective of scaling to a human for clinical use.

METHODS

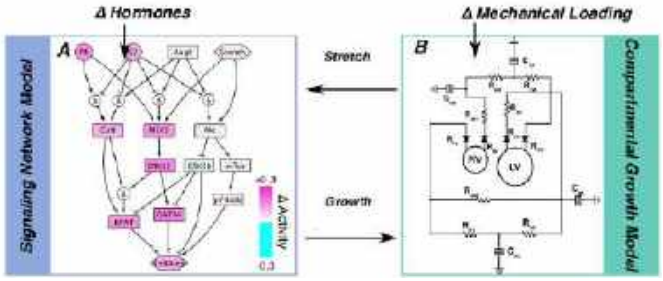
The MATLAB code for the previously developed multiscale model of heart growth in pregnancy in the rat is publicly available and was utilized [2]. The compartmental model was first reparametrized. The compartmental model uses time-varying elastance to simulate the ventricles, which are modeled as thin-walled spheres. The systemic and pulmonary vessels are modeled as capacitors in parallel with resistors. Allometric scaling was used to adapt the rat model's resistors and capacitors (represented by biological variable *Y*) to the canine [2,4-5]. The values were used for a canine based on a mass of 20 kg and a scaling coefficient of b=-3/4 for capacitors and b=1 for resistors [5] (Eq. 1):

$$Y_{canine} = Y_{rat}\left(\frac{M_{canine}}{M_{rat}}\right)^{b} \quad (1)$$

Once the compartmental model was altered to represent the canine hemodynamics, then the multiscale model was applied [2, 4, 6-7]. Hormone levels of estrogen (E2) and progesterone (P4) throughout canine pregnancy were input from published literature [8]. No published data on angiotensin II (AngII) levels in a canine pregnancy were available, thus it was assumed there was a 300% increase throughout pregnancy as is the case in the rat [9].

The relationship between the network and compartmental models involves using a linear transfer function to map the elastic stretch calculated by the compartmental model to the network Stretch input, and a separate transfer function to map the network CellArea output into a growth stretch [2] (Fig. 1). This relationship was not changed for the canine model from the rat model. At each growth step (8-hour increments), heartbeats were simulated until a steady state was reached (compartmental volumes at the start and end of each cardiac cycle differed by < 0.1 mL). We optimized the stressed blood volume at each growth step to match reported changes in end-diastolic diameter (EDD).

Figure 1: Multiscale cardiac growth model for pregnancy. The model couples a cell signaling network model (A) of hormones and stretch acting on the cell to a compartment growth model (B).



RESULTS

Using allometric scaling, the compartmental model demonstrated pressure-volume (PV) loop at baseline for the canine seen in previous studies [4]. From this baseline, we simulated heart growth throughout a 63-day gestation in canines (Fig. 2). The model captures an increase in stroke volume, as well as dropping mean arterial pressure (MAP) secondary to a decrease in peripheral vascular resistance that is known to occur during pregnancy [1] (Fig. 3).

Figure 2: PV loops during pregnancy-induced cardiac growth. Pressure-volume loops throughout 63 days of canine pregnancy. Baseline is in teal and the blue loop is at the end of pregnancy.

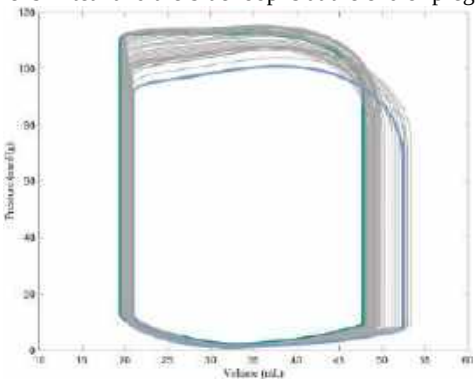


Figure 3: Model predictions for heart growth and hemodynamics. Relative changes in left ventricular mass (A), end-diastolic diameter (B), mean arterial pressure (C), and cardiac output (D) throughout canine pregnancy. Stars represent experimental data [6] and solid lines represent model predictions.

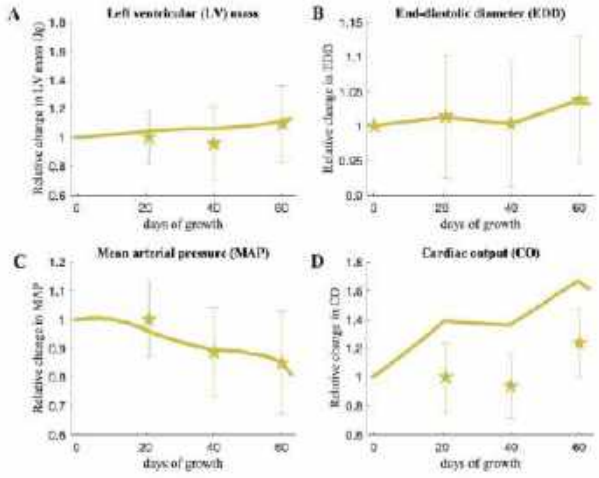
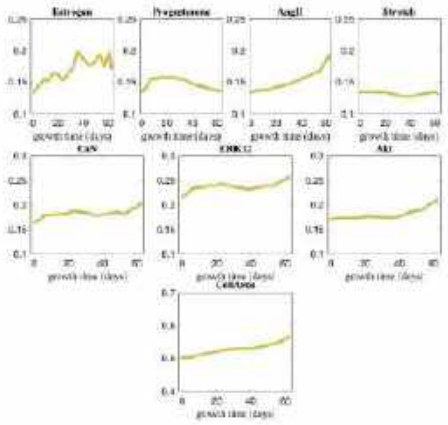


Experimental values of E2 and P4 from the literature demonstrate a slow increase in E2 throughout gestation with an early increase in P4. There were minimal changes in Stretch throughout pregnancy (Fig. 4). There is an increase in CellArea throughout pregnancy, which was primarily driven by the increasing hormones, P4 and AngII. At the organ-level, the model predicted a gradual increase in LV mass throughout pregnancy by nearly 20%, while changes in MAP followed the reported experimental trends (Fig. 4). However, the model overpredicted changes in cardiac output (CO) relative to experimental data [6].

Figure 4: Network model node activity during pregnancy. Values are normalized and range from 0 to 1. Each panel represents nodes in the signaling network.



DISCUSSION

A multiscale model has been scaled from prior work in rats [2] to the hormonal and hemodynamic parameters of a canine, which is the first of its kind to model heart growth during a canine pregnancy. The application of this model to an additional species is novel because it demonstrates the multiscale model's ability to allometrically scale between species without recalibration. This suggests that the coupling framework is not species-specific. The model can predict appropriate growth when only given species-appropriate changes in hormones and hemodynamics, which could be feasibly measured by serum studies, monitoring, or echocardiograms in the clinical setting. Thus, this result has promising implications for real-world application.

We are currently addressing the overprediction of CO in our model by considering alternative hemodynamics measurements for model optimization. For example, we can optimize stressed blood volume to CO, instead of EDD. Understanding which non-invasive measurable hemodynamic parameters are appropriate for predicting growth is also important for future clinical applications.

While the experimental study used here reports no significant increase in LV mass as pregnancy progressed, other studies have reported significant LV growth in canines [6] and with human and rat pregnancies [1,2], thus the model demonstrates what was expected. Next steps will include scaling to the human species with validation from a database of echocardiographic data throughout pregnancy at different gestational ages and into the postpartum period.

In conclusion, we demonstrate that our multiscale model can be easily adapted to a new animal model, suggesting a promising next step towards its clinical application for pregnancy.

INTRODUCTION

Recent studies suggest that neuronal cells change their morphology in response to mechanical stress. These morphological changes include junctions and cytoskeleton remodeling. Yet, the cells' responses to different mechanical loads are to be quantitatively understood [1]. While mechanical loads on cells can come from any directions, most of the lab-based studies are limited to shear-type or stretch-type loading [2, 3]. Here, the aim of this study is to quantify cellular response with application of different magnitudes of acceleration and identify the direction of mechanical loading that leads to a significant cell injury. To study these effects, we first carried out *in-vitro* cell culture studies using human neuronal cells. For the side mechanical load model (SL), we used a spring-loaded cylindrical bar to impart the desired acceleration. While drop tower was used for the top mechanical load model (TL). Cells morphological changes and induced injury were quantified using live-dead fluorescence stain. We tested for accelerations ranging from 5g to 300g as per the healthy to lethal transition range found in the literature [4] and tracked the cellular change over 30 minutes. Fluorescent images were captured and BZ Analyzer as well as ImageJ software were used to assess and quantify the results. The purpose of this study was to understand the biomechanics of brain injury using different mechanical loading mechanisms to fully understand and intervene traumatic brain injury and potentially limit undesirable complications.

METHODS

Human Neuroblastoma SHSY5Y cells were obtained from American Tissue Culture Collection (ATCC). The cells were cultured in DMEM culture medium supplemented with 10% FBS, 100 U/mL penicillin, 100 g/mL streptomycin (GIBCO) and 2 mM l-glutamine and maintained at 37˚C in a 5% CO_2 humidified atmosphere. Upon reaching 80% confluence, the cells were treated with 0.25% trypsin for 3 min to detach the cells. Cells were subsequently resuspended with DMEM culture medium containing 10% FBS. Following, cells were centrifuged at 100 x g for 5 min, the supernatant was removed, and cells were resuspended with fresh culture medium. The cells were counted, then density was adjusted to $5x10^5$ cells for each petri dish coated with Laminin. Subculturing was performed every two or three days, upon the cells reaching 80% confluence. Growth media was replaced every 48 hours. For staining, 10 ml phosphate buffer saline (PBS) containing 5 µL of Calcien AM and 20 µL of Ethidium Homodimer was used. To each 35mm petri dish, 400 µL of prepared stain is added and incubated for 20 minutes while covered with aluminum foil to avoid light exposure. Tri-axis accelerometer attached to the petri dish before impact and the analog signal is converted to digital signal in LabView and the acceleration versus time graph is plotted using MATLAB. A spring-loaded system and a drop tower were used to provide a linear force. In this setup we counted the number of cells and morphological changes (Spindle-like, polygonal, filipodia, etc.,) before and after impact. After impact, time-lapse recording was used for 30 minutes with 3 minutes interval by using BZ analyzer software. Keyence BZ-800X fluorescence microscope was used for imaging, post-processing, and quantification of cellular response.

RESULTS

As indicated in Figure 1, a spring-loaded bar is used to apply acceleration on a 35mm petri-dish and cells were monitored to study the morphological changes over time and with different accelerations. For each acceleration applied, the images after the impact were collected at the exact 3 locations as before and results are shown in figure 2. At accelerations of 30g there is changes in the cell morphology with time but very few or negligible cell death even after 30 minutes of the impact. At 210g, most of the cells are stained with red indicating that the death rate of the cells drastically increased. When impacted with higher acceleration the cells are not able to recover from there injury state. Another preliminary observation was that when insulted from the top by the drop tower for the same acceleration as of side load the injury to

the cells is much higher. Most of the cells were dead when the drop tower was used to insult the cells at a high acceleration (210g).

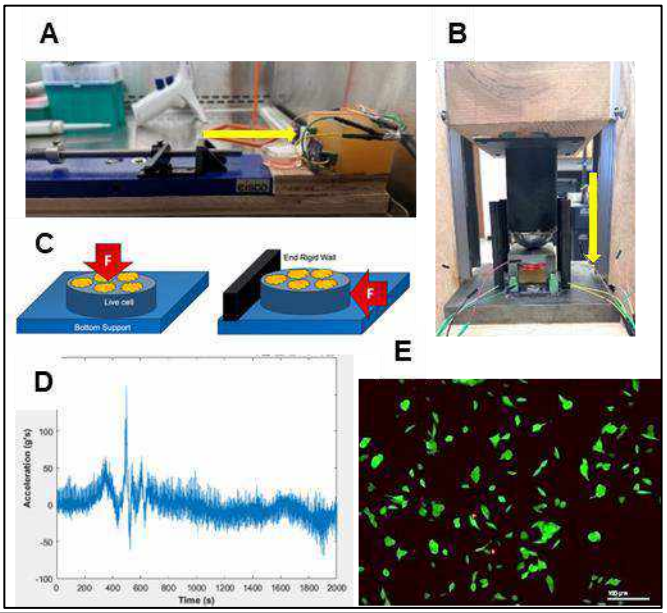

Figure 1: **Illustration of the model**. A) The spring is in compressed form and when release from the slot the bar hits the petri dish attached to the accelerometer. B) the top drop tower is release from a certain height to induce the insult. The line of action of impact is denoted by the yellow arrows in A & B. C) Schematical representation of A & B. D) Raw data display of acceleration response profile. E) Live cells stained with green/red fluorescence stain taken at 20X magnification before and every 3 minutes after the impact for 30 minutes. The red color indicates dead cells, and the green color indicates the live cells. The viability is calculated by dividing the total number of dead cells by the total number of cells.

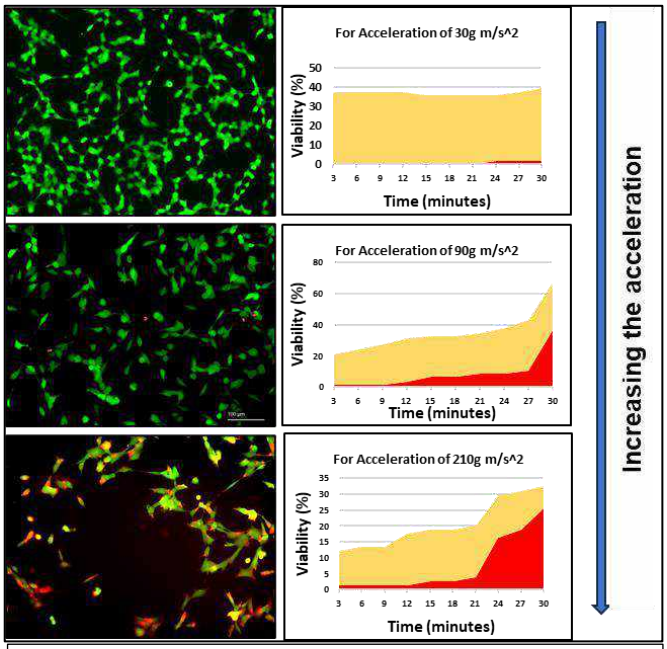

Figure 2: Cells viability at different acceleration. The yellow region in the graph represents unhealthy live cells and the red region represents dead cells. The number of cells is each of the 3 states (Normal cellular morphology, circular, and red) were identified and counted by BZ analyzer software.

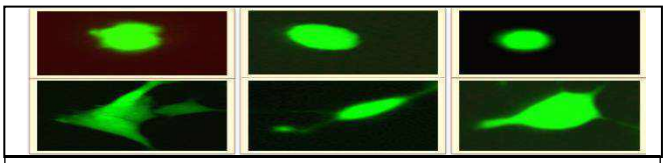

Figure 3: Cell morphology in healthy (top row) and unhealthy (bottom row) state.

DISCUSSION

As indicated in Figure 3, the cellular morphology changes indicate cell-damage as shown by the cells-shrinkage and circular shape. As the cell's stresses, they start to detach from the surface and forming a circular shape with minimal filipodia attachment. We hypothesize that these circular cells are an unhealthy state of the cells and as their concentration increase in the same region, their chances of survival reduce. In addition, in the group where TL is applied, the cell soma seems far more injured and beyond repair whereas for the SL group the cell soma is protected by the arms of the cells the dendrites and axons which when damaged can regrow and recover.

The healthy cells have extended filipodia and spindle-like shape whereas the round cells will either recover after certain amount of time or ultimately die. Axonal injury, loss of dendritic connections, loss of signal passage is known to recover after injury whereas cell soma cannot recover once dead leading to complex mechanical response of each cell. The reason for more dead cells in drop tower model may be due to the fact that cell soma is disrupted directly from surface of attachment with petri dish, whereas when impacted from the sides the axons and dendrites are more disrupted. This finding of directionality together with quantification of extent of cellular death with acceleration are our unique findings. In the case of high acceleration, we see that the whole structure has collapsed. We observe that the morphological change in the cell soma is minimal. But from this experiment we can clearly conclude that accelerations above 180g is fatal. This because some cells experienced spot death, whereas from literature we know it takes time for neuron cells to die due to their complex cellular structure. Thus, further investigation will be performed to fully understand this mechanism.

LIVER INJURIES IN PORCINE DUE TO BEHIND ARMOR BLUNT TRAUMA

INTRODUCTION

Body armor prevents ballistic munitions from penetrating the wearer's torso through the transfer and dissipation of ballistic energy into the deformation of the armor materials. However, this transfer results in a high-rate backface deformation that often leads to blunt injuries to the Warfighter [1-2]. This mechanism is referred to as behind armor blunt trauma (BABT).

The current design assessment methodology uses a clay surrogate (Roma Plastilina #1 [RP1]), clad with armor, to determine the backface deformation following impact loading [3]. A criterion of 44 millimeters (mm) of maximum deformation is then used to determine if the armor is sufficiently protective against BABT injuries [4]. While current armor designs have demonstrated success in BABT protection, there are key limitations to this design assessment criterion and methodology that lead to armors that are overdesigned, cumbersome, and heavy [5].

Primarily, there is limited medical basis for the 44 mm backface deformation criterion. This value was determined through concurrent caprine (clad with soft body armor) and ballistics gelatin testing where 44 mm was the average gelatin deformation [6]. This was later correlated to an overall 10% risk of mortality in the model [7]. Notably, no caprine test resulted in fatality in the original study at less than 44 mm of deformation [6-7]. Further, the current design assessment incorporates the 44 mm testing criterion for all regions of the armor and, in turn, all regions of the torso. It is likely, however, that different regions throughout the body have different levels of susceptibility to these BABT events and, thus, need different amounts of protection.

New criteria must be developed for localized body regions to inform and optimize future armor designs. To accomplish this, the physiological injury associated with impacts to varied body regions must be assessed using live animal surrogates. Previous studies have shown that porcine specimens are an ideal surrogate for the human torso as they have similar thoracic anatomy and physiological response [8-9]. By incorporating physiological injury, more discrete injury risk probabilities may be developed for various body regions that are susceptible to BABT-induced injury, such as the liver, lungs, and heart [10]. These probabilities may then be used to optimize the armor design through the reduction or addition of material depending on the regional injury risk. As such, this study focuses on quantifying the risk of inducing injuries to the liver through BABT.

METHODS

Impact tests were conducted to simulate BABT events using 15 Yorkshire porcine specimens with a target whole-body mass of 40 kilograms (kg) (mass = 45.6 ± 4.6 kg) to approximate the mass of a 50th percentile male human's torso sans extremities [11]. Prior to testing, all animal testing and handling protocols were approved by the University of Virginia (UVA) Animal Care and Use Committee (protocol: 4379-12-21) and the U.S. Army Animal Care and Use Review Office (protocol: MT21006.031.e002).

Upon arrival to the vivarium, each specimen was acclimated within the laboratory space for a minimum of three days prior to testing. On test day, each specimen was initially anesthetized with Telazol and maintained under anesthesia using 2% isoflurane with medical air. Throughout the anesthetized period, each specimen's vitals (blood oxygen, pulse rate, respiration rate, etc.) were monitored and recorded using a veterinary patient monitor (Avante Waveline VS) to ensure physiological stability. Prior to testing, bupivacaine, a local analgesic, was administered to the impact site.

Each impact test was conducted using a pneumatic linear-impactor system that propelled a 3D-printed indenter (mass = 0.245 kg, diameter = 10.2 centimeters [cm], nylon with carbon fiber reinforcement) into the specimen. The indenter's profile was modeled after the backface deformation of rigid body armor to represent a generic armor being impacted by a generic ballistic threat [2]. This indenter was equipped with an onboard single-axis accelerometer (Endevco 7270A) to allow for measurement of acceleration and acceleration-derived measures, such as velocity and displacement, throughout the impact event.

Each specimen was impacted a single time, with impacts conducted to the right side of the ribcage at the location of maximum liver surface area. This impact site was determined using B-Mode ultrasound imaging (Aixplorer Multiwave) to ensure that the liver would be sufficiently contacted by the indenter and to ensure that the more caudal organs, such as the bowels, were not significantly disrupted. Typically, this liver impact location overlapped with right ribs 8 through 12 and the caudal lobe of the right lung.

Following the completion of impact testing, the specimens were closely monitored until medical stability was determined, then they were recovered from anesthesia and returned to their housing area. The specimens were then closely supervised for approximately six hours post-impact (survival = 6.1 ± 0.6 hours) to observe the specimens' well-being over time. Following the survival window, specimens were imaged using computed tomography (CT) with contrast to document any structural or physiological injuries that may have been caused by the impact. Following imaging, the specimens were euthanized using Euthasol and a complete necropsy was conducted to confirm any injuries. The CT scans were then interpreted by a radiologist, who graded the injuries on the American Association for the Surgery of

Trauma (AAST) liver injury scale, which defines injury from grades 1-5 with 5 being the most severe [12].

In addition to the previously discussed measures, test metrics were calculated from the accelerometer data, including indenter velocity, impact energy, backface intrusion, impact force, and impulse. These metrics and injury diagnoses were then incorporated into the development of preliminary injury risk functions (IRF) using survival analysis. Here, data that resulted in induced injuries was considered left censored, while uninjured data was right censored. Predictor metrics and IRF distributions were assessed using the Briar Score (BS) and Akaike information criterion (AIC) [13].

RESULTS

Impact tests that simulate BABT events were conducted to the right side of the liver with resulting impact energies from 37.9 to 276.3 Joules (J). Figure 1 shows the distribution of AAST liver injury grades at each tested impact energy. Figure 2 presents the preliminary injury risk functions derived from this live porcine test data.

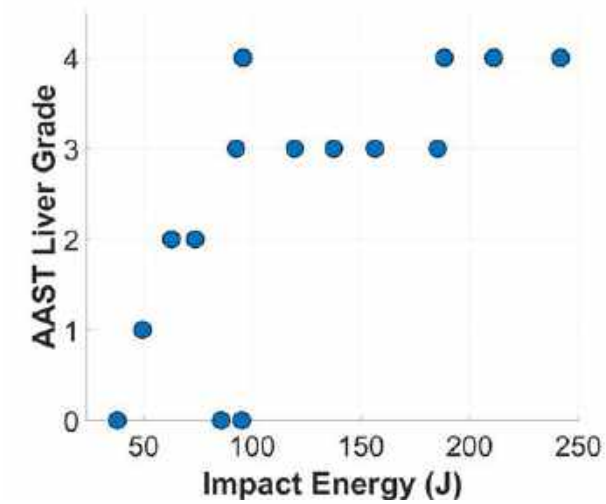

Figure 1: Observed injury outcomes across varied impact energy.

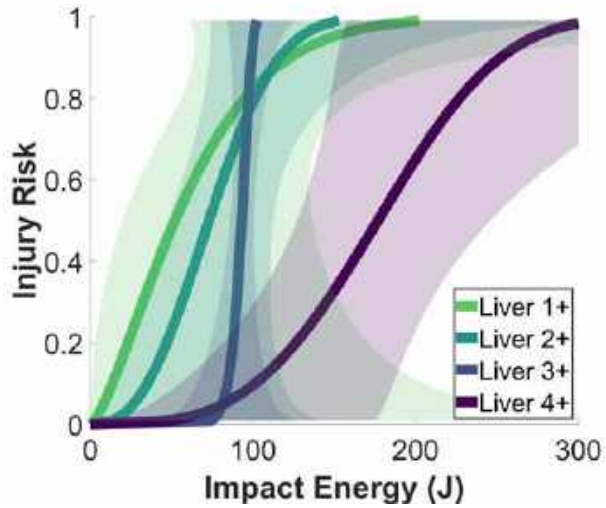

Figure 2: Preliminary injury risk functions that describe AAST grades 1+, 2+, 3+, and 4+ liver injury risk as a function of energy.

A wide array of liver injury severities was observed, ranging from non-injurious at low energies to AAST grade 4+ at high energies, as shown in Figure 1. The most severe of these resulted in large liver lacerations that caused significant active extravasation into the peritoneal cavity over time. In these severe cases, the liver injuries were often accompanied by severe lung contusions, as well as flail chest injuries (i.e., three or more flail rib segments) to the ribcage.

The preliminary IRFs, shown in Figure 2, used the impact energy as the predictor, due to its low BS (range: 0.1-4.5) compared to other metrics (i.e., backface intrusion BS range: 1.5-5.3), and were fit using the Weibull distribution, due to its relatively low AIC (range: 8.7-15.6). Here, the IRFs produced 50% risk levels for inducing AAST grade 1+ liver injuries at 52.0 J, grade 2+ at 72.9 J, grade 3+ at 93.0 J, and grade 4+ at 176.8 J.

DISCUSSION

The goal of this study was to investigate the liver's response to high-rate BABT impacts as a means of quantifying the susceptibility of the lower thoracic region to this injury mechanism. Tests resulted in both non-injurious and injurious outcomes, ranging from minor to very severe. Given the wide array of injury outcomes, IRFs were developed for AAST liver injury severity grades 1+, 2+, 3+, and 4+, illustrating the varied risk probabilities associated with low to high severity liver injuries across different impact energies. Despite current armor standards using backface intrusion as the sole criterion for assessing an armor's protective ability across all thoracic regions, the IRFs in this study produced lower BSs using impact energy as the predictor metric, rather than intrusion. These preliminary risk functions indicate that, generally, the greater severity injuries required increased input energy. However, some variation existed in the higher risk-regime, especially for the liver 3+ injury grades. The steep nature of this IRF was likely due to the data sampling, as only a single test with energy greater than 92.5 J resulted in an injury grade less than AAST level 3+. As testing is currently ongoing, these IRFs are preliminary, and future iterations will seek to improve the prediction at these key injury levels.

INTRODUCTION

The cervix is a collagenous and hydrated tissue that plays a crucial mechanical role in pregnancy. During gestation, the cervix transforms from a rigid and closed structure that sustains the growing load of the fetus in the uterus to a soft and extensible structure that opens to allow birth at term.[1] This process, known as cervical remodeling, involves alterations in the cervix's extracellular matrix (ECM). Within the time scale of acute physiological loading, the cervix exhibits complex time-dependent mechanical behavior, including viscoelasticity, which is believed to be influenced by structural changes in its ECM. A fundamental understanding of the viscoelastic properties of the cervix is essential for developing quantitative ultrasound-based methods to predict cervical pathophysiologies, for instance, cervical insufficiency, which leads to preterm birth. Constitutive material models calibrated with *ex vivo* mechanical testing data from animal and human cervical tissue are valuable tools for quantifying changes in cervical ECM mechanical properties through pregnancy.[2,3] Nevertheless, most studies have focused on the mechanical properties of the cervix under equilibrium conditions. In a few studies examining the time-dependent response of cervical tissue, its viscoelastic properties were obtained only under compressive loading[4] and at two gestational points (pregnant and non-pregnant). Since the cervix exhibits tension–compression asymmetric mechanical response, quantifying the nonlinear time-dependent properties of the cervix under tensile loading will help us understand ECM remodeling, particularly the role of the collagen fiber network. Additionally, pregnancy is a protected environment, which is why studying the cervical viscoelastic response using experimental data from homologous human species, such as rhesus macaques (Fig. 1A), allows us to study the cervix viscoelasticity at multiple and relevant gestational time points.

METHODS

To study the time-dependent mechanical response of the cervix under tensile stress, we implemented a nonlinear viscoelastic model of the rhesus macaque cervical ECM based on the theory of reactive viscoelasticity.[5] In reactive viscoelasticity, biological tissue is modeled as a mixture of strong and weak

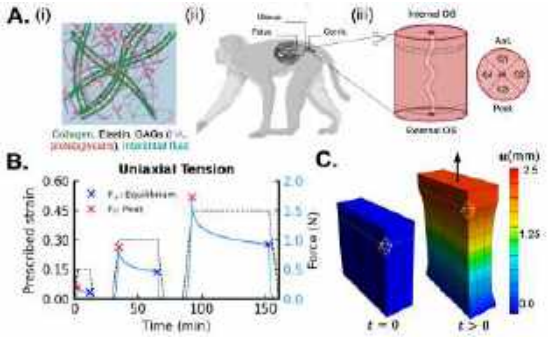

Figure 1: A. (i) Cervical extracellular matrix (ECM), (ii) rhesus macaque anatomy, and (iii) schematic of its cervix, showing the locations and quadrants from where specimens were dissected. B. Representative stress-relaxation curve showing peak F_0 and equilibrium forces F_∞, and C. finite element model built for IFEA.

bonds. Strong and weak bonds are responsible for the equilibrium and transient response of the material, respectively. Furthermore, due to the loading, weak bonds break and reform into a stress-free state. Inspired by the cervical ECM shown in Fig. 1A(i), cervical tissue is modeled as a continuous collagen fiber distribution embedded in a compressible neo-Hookean ground matrix. Only the fibers were assumed to be viscoelastic. The ground substance, which models the mechanical response of glycosaminoglycans (GAGs) and other proteins, only contributes to the equilibrium elastic response of the tissue. We used a continuous fiber distribution model for the strong and weak bonds of the reactive viscoelastic material. The constitutive model parameters were obtained by a three-step inverse finite element analysis (IFEA) using the software packages Dakota and FEBio. In IFEA, the material model parameters are estimated by maximizing the agreement between stress-relaxation curves obtained from simulations and uniaxial tension experiments. We used mechanical testing data from 30 cervical tissue samples collected from four rhesus macaques at the following gestational time points: non-pregnancy (NP), early second trimester (E2), early third trimester (E3), and late third trimester (L3).[6] In brief, cervical tissue samples were dissected from the cervix external os (EO) and internal os (IO) and in differ-

ent quadrants (Fig. 1A(ii) and (iii)). Quadrant 1 (Q1) corresponds to the anterior part of the cervix, quadrant 3 (Q3) is the posterior region, and quadrants 2 and 4 (Q2 and Q4) are the lateral right and left areas of the cervix, respectively. The uniaxial tension test consisted of three load-hold-unload cycles with prescribed displacements of 15%, 30%, and 45% of the grip-to-grip distance (Fig. 1B). A representative finite element (FE) model of the uniaxial tension specimen built for IFEA is shown in Fig. 1C. In total, nine material parameters were estimated from the IFEA, including the Young's modulus and Poisson's ratio of the ground matrix (E, ν), the initial fiber stiffness and stiffening effect constant for the strong (ξ_s, α_s) and weak bonds (ξ_w, α_w), and the exponential distortional relaxation function constants (τ_0, τ_1, α).

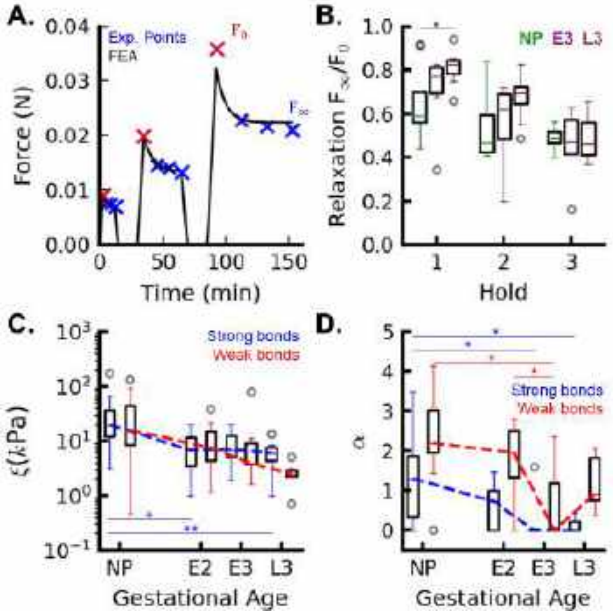

Figure 2: A. Representative force-relaxation curve obtained from finite element simulations (FEA), showing the experimental points used for IFEA. Summary results of material properties showing B. Relaxation ratio F_∞/F_0, C. fiber initial stiffness ξ, and D. stiffening effect constant α for weak and strong bonds (* $p \leq 0.05$, $p \leq 0.01$, and *** $p \leq 0.001$).**

RESULTS

Rhesus macaque cervical tissue exhibits nonlinear viscoelastic mechanical behavior under tensile loading. The reactive viscoelastic material model captures the equilibrium and time-dependent response of rhesus macaque cervical tissue subjected to uniaxial testing, where Fig. 2A shows a representative fitting result of an early second-trimester (E2) specimen dissected from the external os. A comparison of material properties (F_∞/F_0, ξ, and α) for different gestational ages is shown in Fig. 2B, C, and D. The relaxation ratios F_∞/F_0 for E3 and L3 pregnant tissue decrease from hold 1 to 3, with prescribed strains going from 15 % to 45% of the sample length. In contrast, the median value of F_∞/F_0 remains constant for NP. Furthermore, for hold 1 with a prescribed strain of 15%, the relaxation is lower for NP than for L3, suggesting that both samples have similar levels of viscoelasticity. For holds 2 and 3, no significant differences in the relaxation ratios were observed between samples from different gestational age groups. The median initial fiber stiffnesses ξ_s and ξ_w of the strong and weak bonds, respectively, decreased with gestational age, indicating that the cervix became more compliant as pregnancy progresses (Fig. 2C). The stiffening coefficients α_s and α_w also decreased during pregnancy, particularly after the second early trimester (E2), as shown in Fig. 2D. These results suggest that pregnant specimens are more extensible than nonpregnant samples, particularly during late pregnancy. No significant differences were found in other material parameters with the anatomical location and pregnancy status.

DISCUSSION

In this work, we present the implementation of a reactive viscoelastic constitutive model of the rhesus macaque cervix. The model also accounts for the different components of the cervical ECM microstructure, such as the collagen fiber network and ground substance, representing the contribution of GAGs. The model fits well with the multi-ramp uniaxial tension force-relaxation data of rhesus macaque cervical tissue. Notably, the constitutive model allows us to study cervical remodeling in terms of changes in its equilibrium and time-dependent mechanical properties at different gestational time points. We observed that the cervical collagen network plays a significant role in its mechanical response under tensile loading. The initial stiffness of the collagen fibers and stiffening effect coefficient decrease with gestational age, similar to findings from previous studies on cervical remodeling in mice and human tissue. Evidence has shown that this stiffness decrease correlates to a decrease in mature collagen crosslinking in pregnancy. Regarding the time-dependent mechanical properties of the cervix, we observed that the relaxation ratio decreases with prescribed strain for pregnant samples (E3 and L3), whereas for NP, it remains constant. Although the amount of relaxation is similar between pregnant and nonpregnant samples up to a deformation of 45 %, we hypothesize that as deformation increases over this strain value, pregnant samples will decrease their relaxation value and become more viscoelastic.

INTRODUCTION

Anterior cervical discectomy and fusion (ACDF) has traditionally been a widely employed procedure, providing relief from cervical myelopathy and radiculopathy by removing the degenerated disc and promoting fusion between adjacent vertebrae. However, concerns about adjacent segment degeneration and restricted motion have led to the rise of cervical disc arthroplasty (CDA) as an alternative which have been shown to reduce the incidence of adjacent segment disease and need for secondary surgery [1,2]. CDA involves the replacement of degenerated disc with an artificial one aiming to maintain natural spine biomechanics. There are currently several varieties of cervical disc arthroplasty device approved by the FDA and in use by orthopedic and neurosurgical physicians as an alternative to spinal arthrodesis [3]. Each of these devices vary in either material composition, number of moving parts, or both. The different materials composition is most important in their utilization as bearing surfaces which allow for articular motion at the disc space. One issue arising with the variety of CDA devices is a potential for variability in surgical outcomes. It is necessary to investigate how these subtle design and material variations in devices impact spine biomechanics in order to promote positive patient outcomes. The purpose of this study is to investigate the material construction of three different CDA devices (Prestige LP-metal on metal (MOM), Mobi-C- metal on polymer (MOP), Simplify- Polymer on ceramic (POC)) and their impact on cervical spine biomechanics in terms of range of motion (ROM) and facet joint loading.

METHODS

The validated three-dimensional finite element model was used for this study, representing the entire human cervical spinal column spanning from C2 to T1 [4]. The comprehensive intact spine model incorporated all structural components, including bony vertebrae, intervertebral discs, facet joints, and all soft tissue spinal ligaments. Each vertebral body was composed of cortical shell, cancellous bone, and superior and inferior endplates. The intervertebral disc within the model were represented as composite structures of the nucleus pulposus, annulus ground substance and annulus fibers securely attached to the vertebral endplates. The simulated discs were designed to accurately mirror the anteroposterior asymmetry of the human cervical spine. The annular fibers within the disc were structured with a crisscross pattern in the anterior region and oriented vertically in the posterior region to truly capture the nonlinear and orthotropic attributes of the annulus fibrosus. In addition, all ligaments integrated into the model were constructed based on their anatomical attachments and incorporated material properties drawn from well-established literature, aligning with standard practices in finite element modeling studies. The entire model was developed using a mapping block-based hexahedral meshing technique for solid elements and quadrilateral elements were used for soft tissue ligaments.

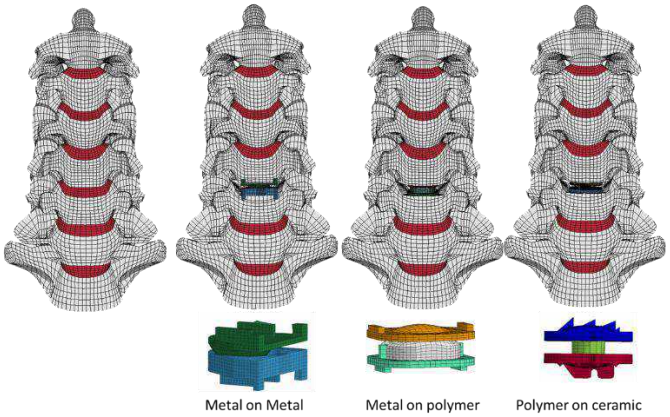

Figure 1: **coronal view of the spinal column (Intact), and the three US FDA approved discs (second (MOM), third (MOP), Fourth (POC) from left).**

The intact spine was modified at the C5-C6 functional spine unit level to simulate the biomechanics of three types of CDAs. The standard surgical procedure was used to simulate CDA at the C5-C6 level (Figure

1). The anterior longitudinal ligament was removed at the surgical level in both cases. In the case of ADR, a cavity was created at the implanted level for the placement of the disc prosthesis. All surgical procedures were executed under the close oversight and expertise of the lead author, a neurosurgeon with extensive clinical experience in cervical disc arthroplasty procedures.

All the finite element models were fixed at the T1 thoracic vertebra in all degrees of freedom, and the load was applied at the C2 superior endplate vertebra. Bending moment (2 Nm) combined with a follower load (75N) magnitude under flexion and extension and lateral bending was applied to the three groups (Prestige LP (MOM), Mobi-C (MOP) and Simplify (POC)). The range of motion was measured at each level and across the C3-C7 levels. The variable moment loading protocol (otherwise known as hybrid loading) was next applied [5]. The bending moment was varied until the MOM, and MOP and POC models displayed the same total range of motion across the C3-C7 levels (although individual segments could have different range of motion). The range of motion and facet force were obtained at the index and adjacent segments under the same loading mode.

RESULTS

FEM testing demonstrated polymer on ceramic to have less ROM, lower index level and both adjacent facet forces in inferior and superior level compared to the metal on metal and metal on polymer CDA's. The metal-on-metal CDA had an 8% inferior and 5% at the superior level decrease in ROM compared to the intact model in adjacent segment flexion. The CDA with metal on polymer had a 5.1% at inferior 13.9% at the superior level decrease compared to the intact. The polymer on ceramic CDA had an 10% inferior and 17.5% at the superior level decrease in ROM compared to the intact model in adjacent segment.

In extension inferior 7.2% and superior 4.5% decrease for MOM, 11.5% and superior 12.5% decrease for MOP and POC CDA at inferior 13% and inferior 16.2% decrease in compared to the intact. Similar decrease was observed in lateral bending with 7.9%, 15.1% and 16.5% in inferior and 5.4%, 15.5% and 12.7% at the superior level for MOM, MOP and POC respectively when compared to intact (Figure 2).

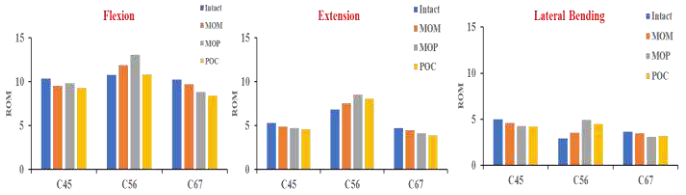

Figure 2: Range of motion at index level and adjacent segments

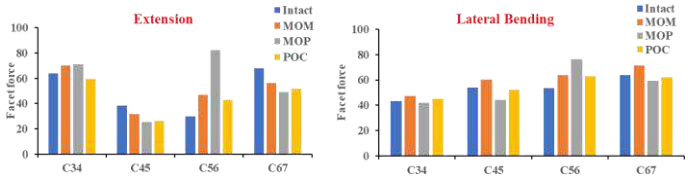

Figure 3: Facet force at index level and adjacent segments

This ROM at adjacent levels results in increased facet forces in MOM by 16.9% and 17% inferior and superior as compared to intact in extension and 11.3% inferior and 12.1% superior in lateral bending. The MOP exhibited 33.9% decrease inferiorly and 27.4% decrease superiorly when compared to intact in extension and 18.4% decrease inferiorly and 6.9 % decrease superiorly in lateral bending. In case of POC facet force decreased by 31.3% and 23.9% inferior and superior as compared to intact in extension and 3.8% Inferior and 2.6% superior in lateral bending. However, at the index level the MOM had a 56.21% and 19.6% increase in facet force at the index level compared to intact spine, similar increase of 174.3% and 43.1% in MOP and POC by 43.3% and 18.1% in extension and lateral bending respectively (Figure 3).

DISCUSSION

The objective of this research is to investigate how variations in the material composition of cervical disc arthroplasty device implanted at the C5-C6 vertebral level impact spinal biomechanics with respect to range of motion and facet joint loading forces. To evaluate this, a finite element (FE) model was used. Cadaveric studies are not as effective for this type of research as the variation of individual vertebral column morphologies lead to confounding variables that can only be overcome by large sample sizes.

The comprehensive biomechanical evaluation of three cervical disc arthroplasty devices- metal on metal (Prestige LP), metal on polymer (Mobi-C), and polymer on ceramic (Simplify)- revealed distinctive performance characteristics with potential clinical implications. Understanding these nuances is critical for informed decision making in spinal surgery. These three devices were compared to a model of an intact disc. It was found that the ceramic on polymer disc most closely matched the degree of spinal flexion seen in an intact model compared to the other material compositions. All three devices demonstrated a similar level of adjacent level flexion compared to the intact model. In extension and lateral bending, it was seen that the MOM most closely mimicked the intact model followed closely by the COP then the MOP device. Facet forces were calculated as a measure of the posterior portion of the vertebral column. During extension the facet forces at the level of implant were increased in all three material compositions with the greatest increases seen in the MOP followed by MOM devices. For the lateral bending the MOM exhibited an increase in force at the adjacent levels while the MOP displayed a large decrease in facet force. The simplify disc most closely mimicked the forces modeled by the intact disc. Adjacent segment disease (ASD) is characterized by degeneration of the intervertebral disc at spine segments that are adjacent to the site of spinal arthrodesis. This is typically accompanied by onset of symptoms reflecting radiculopathy or myelopathy. It has been shown that arthrodesis of a spinal segment leads to increased stress on the adjacent levels [6]. It believed that abnormal disc loading and increased forces on the intervertebral disc are applicable to the occurrence of ASD [7]. While all three of the material types demonstrate some deviation in biomechanical outcomes, the Simplify disc (polymer on ceramic) most closely matched the intact disc in terms of ROM and facet forces. This is important as reducing the strain on adjacent levels could lead to decreased incidence of ASD and necessity of reoperation.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive procedure involving the insertion of a (crimped) bioprosthetic valve via a catheter to replace a stenosed native aortic valve. Positioned as a successful treatment for high-surgical-risk patients with severe symptomatic aortic stenosis, TAVR saw approximately 72,000 procedures in the US in 2019 [1]. The 5-year PARTNER trial indicates comparable results between TAVR and SAVR, making TAVR the preferred treatment for high-risk patients, extending to a younger demographic [2]. However, the trial revealed a significant concern: Subclinical leaflet thrombosis, with up to 30% of patients exhibiting hypoattenuated leaflet thickening (HALT) and reduced leaflet motion (RLM) sometimes within the first year of implantation.

The etiology of leaflet thrombosis can be aligned with the Virchow's triad, where flow dynamics (flow-mediated shear, stasis), mechanical stresses of the TAV itself (over and under-expansion, alignment, and foreign materials), and biological factors (blood chemistry). [3]. Studies suggest that hemodynamics in the neo-sinus, the region between native and bioprosthetic leaflets, may trigger thrombus formation. Flow stasis or sustained low velocity in the neo-sinus could be key contributors [4, 5]. Despite oral anticoagulation (OAC) recommendations for thrombosis risk, it may not consistently benefit patients and can pose risks like thromboembolism and bleeding.
