Conference Proceedings

Innovation without Borders: Uniting Ideas, Technologies, and Communities

2024 Summer Biomechanics, Bioengineering, and Biotransport Conference

June 11–14, Lake Geneva, Wisconsin

This conference was supported by the National Science Foundation's Civil, Mechanical, and Manufacturing Innovation Division (Biomechanics and Mechanobiology) under award number 2413182, and by award number R13EB033191A from the National Institute of Biomedical Imaging and Bioengineering. The views expressed in written conference materials or publications and by speakers and moderators do not necessarily reflect the official policies of National Science Foundation nor those of the Department of Health and Human Services; nor does mention of trade names, commercial practices, or organizations imply endorsement by the U.S. Government.

Congratulations to the 2023 Cover Art Contest Winner:

Catherine M. Porter and Alex J. Hughes, University of Pennsylvania
Title: Highly Parallel Production of Designer Organoids by Mosaic Patterning of Progenitors

Description: Proximal-to-distal segmentation in an immunostained human kidney organoid. The midplane from a confocal z-stack of an induced pluripotent stem cell-derived kidney organoid shows nephron segmentation. Nephrin (yellow) marks the boundaries of podocytes, the cells in glomeruli that initially filter blood in vivo. Lotus tetragonolobus lectin (cyan) delineates proximal tubule cells, and membranous E-cadherin (bright pink) outlines distal tubule cells. This kidney organoid was grown in suspension using a novel culture device, which integrates transient 2D cell patterning technology with microwell arrays.

ISBN 978-1-7351808-6-1

SB^{3}C 2024 Meeting Scientific Podium Sessions

Tuesday, June 11	4:15PM–5:45PM CDT

AI & Machine Learning in Biofluids

Session Chairs: **Amir Arzani**, *University of Utah*
Hoda Hatoum, *Michigan Technological University*

Loramoor C

4:15PM **Generative Modeling of Congenital Heart Defect Anatomies for Surrogate Cardiac Flow Simulations**
Fanwei Kong, Alison Marsden
Stanford University

4:30PM **Towards 3D-3C Velocity Maps From Single Camera 2D-2C PTV Using Physics-Informed Neural Networks**
Amin Pashai Kalajahi, Zayeed Bin Mamun, Forouzan Naderi, Sangeeta Yadav, Roshan D'Souza
University of Wisconsin-Milwaukee

4:45PM **Modeling Pharyngeal Airway Pressure Distributions With Neural Networks**
Jun Tao Cui[1], Kok Ren Choy[1], Sanghun Sin[2], Mark E. Wagshul[3], Jayaram K. Udupa[4], Raanan Arens[2], David M. Wootton[1]
[1]Cooper Union, [2]Children's Hospital at Montefiore, [3]Albert Einstein College of Medicine, [4]University of Pennsylvania

5:00PM **Automated Bladder Segmentation of 3D Dynamic MRI for Urodynamic Analysis Using Deep Learning**
Labib Shahid, Juan Pablo Gonzalez-Pereira, Jennifer Franck, Alejandro Roldán-Alzate
University of Wisconsin-Madison

5:15PM **Synthesizing Multi-Branch Aortic Vessels Using Diffusion Model**
Pan Du, Xiaozhi Zhu, Jian-xun Wang
University of Notre Dame

5:30PM **Accuracy of Physics-Informed Neural Networks Under Laminar and Turbulent-Like Aortic Flow Conditions**
Arman Aghaee, M. Owais Khan
Toronto Metropolitan University

Tuesday, June 11	4:15PM–5:45PM CDT

Cartilage Structure, Lubrication & Mechanics

Session Chairs: **Corinne Henak**, *University of Wisconsin-Madison*
Matthew Fisher, *NC State and UNC Chapel Hill*

Maple Lawn B

4:15PM **Distinct Molecular and Structural Traits of Permanent Versus Transient Cartilage in Early Development**

Jiaqi Xiang[1], Bryan Kwok[1], Mingyue Fan[1], Meghan Kupratis[2], Sara Tufa[3], Douglas Keene[3], Robert Mauck[2], Nathaniel Dyment[2], Eiki Koyama[4], Lin Han[1]

[1]Drexel University, [2]University of Pennsylvania, [3]Shriners Hospital for Children, [4]Children's Hospital of Philadelphia

4:30PM **Sustained Structural and Functional Deficits in the Porcine Knee Six Months Following Meniscus Destabilization**

Brendan Stoeckl[1,2], Stephen Ching[1], Veridiana Nadruz[1], Kyle Meadows[3], John Peloquin[3], Owen McGroary[1], Madeline Boyes[1], Lorielle Laforest[1,2], Tim Teinturier[1], Miltiadis Zgonis[1,2], Dawn Elliott[3], Robert Mauck[1,2], Michael Hast[1], Thomas Schaer[1], David Steinberg[1,2]

[1]University of Pennsylvania, [2]CMC VA Medical Center, [3]University of Delaware

4:45PM **Impact of Lubricant Properties on the Synergistic Lubrication of Articular Cartilage**

Emily Lambeth, Brooklyn Tyndall, Sean Farrington, David Burris, Norman Wagner, Christopher Price

University of Delaware

5:00PM **The Protective Effect of Synovial Fluid Against Cartilage Fatigue Wear Is Concentration Dependent**

C.V. Sise, Courtney Petersen, Anna Ashford, Sinisa Vukelic, Clark Hung, Gerard Ateshian

Columbia University

5:15PM **Cartilage Strain Predicts Patient-Reported Outcomes Six Months Post-ACL Reconstruction**

Emily Miller[1], Timothy Lowe[1], Hongtian Zhu[1], Woowon Lee[1], Daniel Stokes[2], Rachel Frank[2], Jonathan Bravman[2], Eric McCarty[2], Nancy Emery[1], Corey Neu[1] *[1]University of Colorado, Boulder, [2]University of Colorado, Anschutz*

5:30PM **Influence of Labrum Size and Material Parameters on Cartilage Mechanics in Hips With Cam FAIS**

Luke Hudson[1,2], Travis Maak[1], Andrew Anderson[1,2], Gerard Ateshian[3], Jeffrey Weiss[1,2]

[1]University of Utah, [2]Scientific Computing and Imaging Institute, [3]Columbia University

Tuesday, June 11	4:15PM–5:45PM CDT

Fiber Mechanics Symposium

Session Chairs: Ian Sigal, *University of Pittsburgh* **Maple Lawn C**
Jason Hua, *University of Mississippi*

4:15PM **Displacement Propagation in Prestressed Two-Dimensional Fibrous Networks**
Ashutosh Mishra, Hamed Hatami-Marbini
University of Illinois at Chicago

4:30PM **A Continuum Model May Artefactually Homogenize Local Strains While Also Artefactually Disrupting Long Distance Strain Transmission**
Xuehuan He[1], Mohammad Islam[2], Bingrui Wang[1], Ian Sigal[1]
[1]University of Pittsburgh, [2]University of Texas Rio at Grande Valley

4:45PM **Effect of Collagen Fiber Tortuosity Distribution on the Mechanical Response of Arterial Tissue**
Yamnesh Agrawal, Ronald N Fortunato, Alireza Asadbeygi, Mehdi Ramezanpour, Michael R Hill, Anne M. Robertson, Spandan Maiti
University of Pittsburgh

5:00PM **Physics Based Machine Learned Constitutive Models for Fibrous Materials**
Jacob Merson, Nishan Parvez
Rensselaer Polytechnic Institute

5:15PM **An Interpenetrating-Network Theory of the Cytoskeletal Networks in Living Cells**
Haiqian Yang, Ming Guo
Massachusetts Institute of Technology

5:30PM **Fiber Alignment and Tortuosity Influence the Load-Carrying Performance of the Lamina Cribrosa Collagen Beams**
Yi Hua[1], Lindee Wilson[1], Ian Sigal[2]
[1]University of Mississippi, [2]University of Pittsburgh

Tuesday, June 11	4:15PM–5:45PM CDT

Mechanobiology in Cancer

Session Chairs: **Alisa Morss Clyne**, *University of Maryland*
M. K. Sewell-Loftin, *University of Alabama at Birmingham*

Maple Lawn A

4:15PM **YAP/TAZ Activity Regulates a Mechano-Metabolic Crosstalk During 3D Breast Cancer Invasion**
Haider Ali[1], Hrishika Rai[1], Adil Khan[1], Jacopo Ferruzzi[1,2]
[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center

4:30PM **Mechanical Stimulation and Hyaluronic Acid Alter Ovarian Cancer Cell Behaviors**
Maranda Kramer, Allyson Criswell, Kamari Marzette, M.K. Sewell-Loftin
University of Alabama at Birmingham

4:45PM **A Cell-Based and AI-Accelerated Computational Framework for the Prediction of Mechanosensitive Tumour Growth**
Irish Senthilkumar, Enda Howley, Eoin McEvoy
University of Galway

5:00PM **Decoding the Quantitative Relationship Between Mechanical Forces on Cell Nucleus and YAP Protein Translocation**
Miao Huang[1,2], Maedeh Lotfi[1], Kevin Connell[1], Malisa Sarntinoranont[1], Xin Tang[1,2]
[1]University of Florida, [2]UF Health Cancer Center

5:15PM **Intratumoral Compression Promotes Proneural to Mesenchymal Transitions in Glioblastoma**
Allison McKenzie Johnson, Lylah Cox, Joseph Chen
University of Louisville

Tuesday, June 11	4:15PM–5:45PM CDT

Modeling Cardiac and Coronary Artery Flow and Physiology

Session Chairs: Hannah Cebull, *Emory University*
Vitaliy Rayz, *Purdue University*

Loramoor A

4:15PM **Synthesis of Coronary Arterial Networks From Myocardial Blood Volume Maps**
Mostafa Mahmoudi[1,2], Amirhossein Arzani[3,4], Kim-Lien Nguyen[1,2]
[1]University of California, Los Angeles, [2]VA Greater Los Angeles Healthcare System, [3]University of Utah, [4]Scientific Computing and Imaging Institute

4:30PM **Hemodynamic Assessment of Coronary Atherosclerotic Lesions in Elderly Patients With Myocardial Infarction: a Longitudinal Study**
Diego Gallo[1], Maurizio Lodi Rizzini[1], Alessandro Candreva[1,2], Jean Paul Aben[3], Claudio Chiastra[1], Barbara Stähli[2], Simone Biscaglia[4], Gianluca Campo[4], Umberto Morbiducci[1]
[1]Politecnico di Torino, [2]University Hospital Zurich, [3]Pie Medical Imaging, [4]University of Ferrara

4:45PM **A Multi-Physics Model of Contrast Injection in the Coronary Arteries to Assess Index of Microcirculatory Resistance**
Haizhou Yang[1], Jiyang Zhang[2], Ismael Assi[3], Brahmajee Nallamothu[1], Krishna Garikipati[4], C. Alberto Figueroa[1]
[1]University of Michigan, [2]Sichuan University, [3]University of Cincinnati, [4]University of Southern California

5:00PM **Personalized and Uncertainty-Aware Virtual Planning for Coronary Artery Bypass Graft Surgery Informed by CT Myocardial Perfusion Imaging**
Karthik Menon[1], Zachary Sexton[1], Owais Khan[2], Daniele Schiavazzi[3], Koen Nieman[1], Alison Marsden[1]
[1]Stanford University, [2]Toronto Metropolitan University, [3]University of Notre Dame

5:15PM **The Importance of the Left Atrial Appendage on the Flow in the Atrium** Ahmad Bshennaty[1], Brennan Vogl[1], Alessandra Bravo[2], Agata Sularz[3], Anders Kramer[4], Jens Nielsen-Kudsk[4], Yuheng Jia[5], Ole De Backer[5], Matthieu De Beule[2], Mohamad Alkhouli[3], Hoda Hatoum[1]
[1]Michigan Technological University, [2]FEops, [3]Mayo Clinic, [4]Aarhus University Hospital, [5]Copenhagen University Hospital

5:30PM **Evaluation of Flow Dynamics in the Left Atrium After Hybrid Ablation for Atrial Fibrillation**
Brennan Vogl[1], Grace Hoeppner[1], Hailey LaBonte[1], Emily Vitale[1], Agata Sularz[2], Alejandra Chavez-Ponce[2], Ammar Killu[2], Mohamad Alkhouli[2], Hoda Hatoum[1]
[1]Michigan Technological University, [2]Mayo Clinic

Spine & Disc

Session Chairs: **Deva Chan**, *Purdue University* **Linwood**
Daniel Cortes, *Pennsylvania State University*

4:15PM **Low Back Pain Treatment Options Based on Statistical Shape Models: Spinal Decompression Surgery Versus Non-Operative**
Mary Foltz, Alexandra Seidenstein, Amit Jain, Jill Middendorf
Johns Hopkins University

4:30PM **A Novel Approach to Create the Mean Lumbar Spine Model Using Statistical Shape Modeling for Finite Element Analysis**
Faris Almalki[1,2], Daniel Cortes[2]
[1]University of Jeddah, [2]Penn State University

4:45PM **Correlation of Pain Symptoms in Military Fighter Pilots With Spinal Morphology Obtained Using Supine and Upright MRI Scans**
Rachel Cutlan[1], Vaibhav Porwal[2], Riley McCarty[2], Cory Everts[2,3], Alok Shah[2], Amy Nader[2], Keeley Hamill[2], Narayan Yoganandan[2,4], Keri Hainsworth[2], L. Tugan Muftuler[2], Timothy Meier[2], Hershel Raff[2], Peter Le[5], Chris Dooley[5], Benjamin Gerds[3], Brian Stemper[1,2,4]
[1]Marquette University and Medical College of Wisconsin, [2]Medical College of Wisconsin, [3]115th Fighter Wing, Wisconsin Air National Guard, [4]Zablocki Veterans Affairs Medical Center, [5]Air Force Research Laboratory

5:00PM **In Vivo Lumbar Intervertebral Disc Strain in Flexion, Extension, and Diurnal Motions: Variation With Age in Healthy Adults**
John Peloquin, Harrah Newman, Edward Vresilovic, Dawn Elliott
University of Delaware

5:15PM **Mechanical and Structural Changes to the Annulus Fibrosus in Response to Cyclic Loading: an I-PREDICT Study**
Jack Seifert[1,2,3], Lance Frazer[4], Dennis Maiman[2], Alok Shah[2,3], Narayan Yoganandan[2,3], Keith King[5], James Sheehy[5], Glenn Paskoff[5], Timothy Bentley[6], Daniel Nicolella[4], Brian Stemper[1,2,3]
[1]Marquette University, [2]Medical College of Wisconsin, [3]Zablocki Veterans Affairs Medical Center, [4]Southwest Research Institute, [5]Naval Air Warfare Center, [6]Office of Naval Research

5:30PM **Biomechanicnal Comparison of Commonly Used Three Different Material Composition Used in Cervical Disc Arthroplasty**
Yuvaraj Purushothaman[1], Resetar Ethan[2], Hoon Choi[1], Abdulbaki Kozan[1], Narayan Yoganandan[3]
[1]Cleveland Clinic Florida, [2]University Of Michigan, [3]Medical College Of Wisconsin

Tuesday, June 11	4:15PM–5:45PM CDT

Valvular Biomechanics

Session Chairs: **Rana Zakerzadeh**, *Duquesne University*
Rouzbeh Amini, *Northeastern University*

Loramoor B

4:15PM **Patient-Specific Long-Term Prediction of Transcatheter Edge-to-Edge Mitral Valve Repair**
Natalie Simonian[1], Sneha Vakamudi[2], Mark Pirwitz[2], Michael Sacks[1]
[1]University of Texas at Austin, [2]Ascension Texas Cardiovascular

4:30PM **The Impact of Sex and Hormone-Differences on Heart Valve Disease**
Colton Kostelnik[1], Chien-Yu Lin[1], Magda Piekarska[2], Gaweda Boguslaw[2], Austin Goodyke[2], Tomasz Timek[2], Manuel Rausch[1]
[1]University of Texas at Austin, [2]Corewell Health

4:45PM **Device Deployment and the Onset of Structural Valve Degeneration: Simulation of Transcatheter Aortic Valve Implantation In Vitro**
Sam Boxwell[1], Dylan Armfield[2], William Hickey[3], Scott Cook[3], Patricia Kelly[3], Philip Cardiff[2], Laoise McNamara[1]
[1]University of Galway, [2]University College Dublin, [3]Boston Scientific Corporation

5:00PM **A Parametric Analysis of Chordae Tendineae Density and Branching in Finite Element Simulations of Mitral Valve Closure**
Nicolas Mangine[1], Patricia Sabin[1], Devin Laurance[1], Wensi Wu[1], Christian Herz[1], Christopher Zelonis[1], Csaba Pinter[2], Andras Lasso[3], Stephen Ching[1], Steve Maas[4], Jeff Weiss[4], Metthew Joley[1]
[1]Children's Hospital of Philadelphia, [2]EBATINCA, [3]Queens University, [4]University of Utah

5:15PM **Biomechanical Impact of Neochordoplasty and Leaflet Resection for Mitral Valve Prolapse Repair**
Gediminas Gaidulis[1], Muralidhar Padala[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Nyra Medical Inc.

5:30PM **A Neural-Network Finite-Element Approach to Modeling of Multibody Contact of Trileaflet Heart Valves**
Kenneth Meyer, Christian Goodbrake, Shruti Motiwale, Michael Sacks
Oden Institute for Computational Engineering and Sciences

Biomedical Devices and Materials for Global Health Solutions

Session Chairs: **Byron D. Erath**, *Clarkson University*
Mahsa Dabagh, *University of Wisconsin-Milwaukee*

Maple Lawn C

8:00AM **A Soft 3D Microarchitected Pressure Sensor for Urethral Monitoring**
Nakhiah Goulbourne
University of Michigan

8:15AM **Development and In-Vitro Validation of a Simple 1D Mechanical Model for Pediatric Vascular Patch Planning**
Shannen Kizilski[1,2], Dominic Recco[1,2], Jocelyn Davee[1], Patrick Earley[1], Nicholas Kneier[1], Lauren Marshall[1], Peter Hammer[1,2], David Hoganson[1,2]
[1]Boston Children's Hospital, [2]Harvard Medical School

8:30AM **Machining Living Osteochondral Allografts for Joint ResurfacingIn A Canine Patellofemoral Joint Model**
Katherine Spack[1], Chantelle Bozynski[2], Courtney Petersen[1], Joseph Viola[1], Peter Shyu[1], Edward Guo[1], Clark Hung[1], James Cook[2], Gerard Ateshian[1]
[1]Columbia University, [2]University of Missouri

8:45AM **Detecting Cardiac States With Photoplethysmography Wearables: Implications for Out-of-Hospital Cardiac Arrest Detection**
Mahsa Khalili, Saud Lingawi, Jacob Hutton, Babak Shadgan, Jim Christenson, Brian Grunau, Calvin Kuo
University of British Columbia

9:00AM **Refined Endovascular Solutions: Leveraging 3D Printing in Shape Memory Polymer-Based Embolization for Intracranial Aneurysm Rupture Prevention**
Tanner Cabaniss[1], Yingtao Liu[1], Bradley Bohnstedt[2], Chung-Hao Lee[3]
[1]University of Oklahoma, [2]Indiana University School of Medicine, [3]University of California, Riverside

9:15AM **Assessment of Clot Adhesion Strength on Endothelial Cells and Biocompatible Materials**
Vikas Kannojiya[1], Sara Almasy[1], Ian Goetz[1], Jose Monclova[1], Francesco Costanzo[1], Keefe Manning[1,2]
[1]Pennsylvania State University, [2]Penn State Hershey Medical Center

Cancer Mechanics I

Session Chairs: **Meenal Datta**, *University of Notre Dame*
Jacopo Ferruzzi, *University of Texas at Dallas*

Loramoor A

8:00AM **Towards Cancer Mechano-Therapy: Yap as an Emerging Mechanical Target to Eradicate Tumors**
Miao Huang[1,2], Mu Yu[1,2], Chase Stallings[1], HeYang Wang[3], Lu Li[1], Conner Traugot[1], Mingyi Xie[1,2], Youhua Tan[4], Franziska Haderk[5], Juan Guan[6], Lizi Wu[1,2], Xin Tang[1,2]
[1]University of Florida, [2]UF Health Cancer Center (UFHCC), [3]Northwestern University, [4]Hong Kong Polytechnic University, [5]University of California, San Francisco, [6]University of Texas at Austin

8:15AM **Multiscale Mechanoimmunology: From Molecular Mechanisms to Precision Therapies**
Kolade Adebowale
Harvard University

8:30AM **Reverse-Engineering Cancer Mechanics: Piezo Regulates Epithelial Topology and Promotes Precision in Organ Size Control**
Nilay Kumar, Mayesha Mim, Megan Levis, Maria Unger, Gabriel Miranda, Trent Robinett, Jeremiah Zartman
University of Notre Dame

8:45AM **Development of a High-Throughput Drug Screening Platform Via Pipetting Gel Droplet Micro-Organoids Models**
Daniel Montes Pinzon, Angela Taglione, Fei Fan, Liao Chen, Xin Lu, Sharon Stack, Donny Hanjaya-Putra, Hsueh-Chia Chang
University of Notre Dame

9:00AM **A 3D Model for the Study of Macrophage-Induced Solid Stress**
Alice Burchett, Saeed Siri, Meenal Datta
University of Notre Dame

9:15AM **Chronic Off-Target Cardiotoxicity of Doxorubicin Is Mediated by Pathological Changes in Paracrine Signaling and miRNA Prevalence**
George Ronan[1], Frank Ketchum[1], Nicole Kowalczyk[1], Noor Behnam[1], Lara Çelebi[1], Pinar Zorlutuna[1,2]
[1]University of Notre Dame, [2]Harper Cancer Research Institute

Cardiovascular Devices and Design

Session Chairs: **Noelia Grande Gutiérrez**, *Carnegie Mellon University*
David Bark, *Washington University in St. Louis*

Loramoor C

8:00AM **Digital Twin Development and Fatigue Optimization of Novel Polymeric TAVR Devices Tailored for Patient-Specific Needs**
Brandon Kovarovic[1], Kyle Baylous[1], Ryan Helbock[1], Oren Rotman[1], Marvin Slepian[2], Danny Bluestein[1]
[1]Stony Brook University, [2]University of Arizona

8:15AM **Stent Retriever Removal Forces in an Experimental Stroke Model With Porcine Carotid Arteries**
Demitria Poulos[1], Michael Froehler[2], Bryan Good[1]
[1]University of Tennessee, [2]Vanderbilt University Medical Center

8:30AM **TomoPINNs: Computed Tomography Enriched Physics-Informed Neural Networks for Hemodynamic Descriptors**
Sangeeta Yadav[1,2], Forouzan Naderi[1], Amin Pashaei Kalajahi[1], Zayeed Bin Mamun[1], Roshan M. Dsouza[1]
[1]University of Wisconsin, [2]Indian Institute of Science

8:45AM **Efficient Shape Optimization of the Total Cavopulmonary Connection Via Hyper-Reduced Order Models and Free Form Deformation**
Imran Shah[1,2], Francesco Ballarin[3], Lakshmi Dasi[1], Alessandro Veneziani[2]
[1]Georgia Institute of Technology, [2]Emory University, [3]Università Cattolica del Sacro Cuore

9:00AM **Impacts of Tears Size and Location on Blood Flow Dynamics in Type-B Aortic Dissection**
Khalil Khanafer, Shaun Scofield, Yasser Aboelkassem
University of Michigan

9:15AM **Dynamic Patient-Specific Computer Simulation of Transcatheter Aortic Valve Replacement Using the Evolut R and SApien3**
Masod Sadipour[1], Jordan Brown[2,3], David Wells[2], Boyce Eugene Griffith[1,2]
[1]University of North Carolina, [2]University of North Carolina, Chapel Hill, University of North Carolina, [3]College of Sciences and Mathematics, Belmont University

Wednesday, June 12	8:00AM–9:30AM CDT

Emerging Topics in Biomechanics and Mechanobiology

Session Chairs: **Arina Korneva**, *Virginia Tech*
Lei Shi, *Kennesaw State University*

Maple Lawn A

8:00AM **Human Airway Tissue Biaxial Tensile Mechanics**
Crystal Mariano, Mona Eskandari
University of California, Riverside

8:15AM ***WITHDRAWN*** **Non-Injurious Impact Loading to Explanted Cartilage Results in DNA Damage Within Chondrocytes**
Katie Gallagher[1], Stephanie Schnieder[1], David Pierce[2], Corey Neu[1]
[1]University of Colorado, Boulder, [2]University of Connecticut

8:30AM **Investigating the Range of Cell Cluster Biomechanical Behavior With Cluster Size**
Sara Ghanbarpour Mamaghani, Ethan Wagner, Jonathan P. Celli, Joanna B. Dahl
University of Massachusetts Boston

8:45AM **Dietary Cholesterol Stiffens the Steatotic Liver**
David Li, Abigail Loneker, Paul Janmey, Rebecca Wells
University of Pennsylvania

9:00AM **The Role of Early Life (Psychological) Stress on Central Artery Aging and Remodeling**
Brooks Lane[1], Nazli Gharraee[1], Gabrielle Lohrenz[1], Abigail Polter[2], Paul Marvar[2], John Eberth[1]
[1]Drexel University, [2]George Washington University, Pharmacology and Physiology

9:15AM **Stiffening or Softening? Deciphering the Role of Multiple Contracting Inclusions in Modulating the Stiffness of a Fibrous Matrix**
Mainak Sarkar, Brian M. Burkel, Suzanne M. Ponik, Jacob Notbohm
University of Wisconsin-Madison

Engineered In Vitro Models

Session Chairs: Spencer Szczesny, *Pennsylvania State University*
Yubing Sun, *University of Massachusetts Amherst*

Loramoor B

8:00AM **Development and Analysis of Scaffold-Free Adipose Spheroids**
Jesse Liszewski, Riley Behan-Bush, Michael Schrodt, Aloysius Klingelhutz, Ed Sander, James Ankrum
University of Iowa

8:15AM **A Bioreactor Platform Designed to Estimate Cell Generated Stresses Within Uniaxially Constrained Tissue Equivalents**
Andrew V. Glick[1], Daniel Paukner[2], Christian J. Cyron[2], Jacopo Ferruzzi[1,3]
[1]University of Texas at Dallas, [2]Institute for Continuum and Material Mechanics, Hamburg University of Technology, [3]University of Texas Southwestern Medical Center

8:30AM **Development of Engineered Tendon Tissue Micro-Gauges (TENTUGS) for Investigating Tendon Organization and Mechanobiology**
Stephanie Steltzer, Seung-Ho Bae, Nicole Migotsky, Henry Yu, Charlie Mentzer, Syeda Lamia, Brendon Baker, Megan Killian, Adam Abraham
University of Michigan

8:45AM **A Novel Millifluidic Dual-Flow Bioreactor for Recapitulating Shear Stress In Vitro**
Fariha Ahmad, Katrina Cao, Jane Grande-Allen
Rice University

9:00AM **A 3D In-Vitro Neuro-Vascular Human Brain Model With Meningeal Lymphatics for Studying Alzheimer's Disease**
Xun Wang[1], Seunggyu Kim[1], Maria Proestaki[1], Shun Zhang[1], Georgios Pavlou[1], Se Hoon Choi[2,3], Rudolph Tanzi[2,3], Roger Kamm[1]
[1]Massachusetts Institute of Technology, [2]Massachusetts General Hospital, [3]Harvard Medical School

9:15AM **Strain, Stiffness, and Composition Effects on Lung Fibroblasts and Their Implications in Pulmonary Fibrosis**
Qi Wang, Kristan Worthington, Ed Sander
University of Iowa

Ligament & Tendon Mechanics & Imaging

Session Chairs: **Stephanie Cone**, *University of Delaware* **Linwood**

Zachary G. Davis, *DoD-VA Extremity Trauma and Amputation Center of Excellence*

8:00AM **Connexin-43 Positive Cell Ratio Is Not Modulated by Severity of Damage or Change in Cycle Number in Tendon Fatigue Injury Model**
Benjamin Johnston[1], Nelly Andarawis-Puri[1,2]
[1]Cornell University, [2]Hospital for Special Surgery

8:15AM **Elastin Alters Fatigue Mechanics of Functionally Distinct Tendon Fascicles in Murine Model of Elastin Knockdown**
Shawn Pavey, Nathan Xu, Spencer Lake
Washington University in St. Louis

8:30AM **Tendon Impingement Produces Differential Regional Profiles of Intact and Fragmented Aggrecan**
Brian Wise, Whasil Lee, Mark Buckley
University of Rochester

8:45AM **Aged Tendons Have a Higher Strain Threshold for Stimulation From Dynamic Compression Than Young Tendons**
Samuel Mlawer, Brianne Connizzo
Boston University

9:00AM **Estrogen Receptor Expression Is Greater Than Progesterone Receptor Expression in the Porcine Anterior Cruciate Ligament and Varies Across Age and Animal**
Jacob D. Thompson[1], Matthew B. Fisher[1,2]
[1]North Carolina State University and University of North Carolina at Chapel Hill, [2]University of North Carolina at Chapel Hill

9:15AM **Effects of Soaking Solution on Anterior Cruciate Ligament Hydration, Mechanics, and Magnetic Resonance Imaging**
Charlotte Andreasen[1], Peter Kuetzing[1], Hassan Siddiqui[2], Audrey McManus[1], Ulrich Scheven[1], Ellen Arruda[1]
[1]University of Michigan, [2]Pennsylvania State University

Nano, Micro, Tissue & Multiscale Mechanics

Session Chairs: **Camilo Duarte Cordon**, *Columbia University*
Kristin Myers, *Columbia University*

Maple Lawn B

8:00AM **Does Tissue Composition Alter Strain-Based or Stress-Based Susceptibility to Injury?**
Callan Luetkemeyer
University of Illinois Urbana-Champaign

8:15AM **Anisotropic Mechanical Properties in Scaled Lattice Composites Estimated by Magnetic Resonance Elastography**
Kevin Eckstein[1], Daniel Yoon[1], Margrethe Ruding[1], Ramin Balouchzadeh[1], Aaliyah Thompson-Mazzeo[1], Ruth Okamoto[1], Curtis Johnson[2], Matthew McGarry[3], Philip Bayly[1]
[1]Washington University in St. Louis, [2]University of Delaware, [3]Dartmouth College

8:30AM **Influence of Glenohumeral Joint Angle on in Situ Supraspinatus Strain Behavior**
Aaron Hellem, John Liffrig, Allison Rao, Matthew MacEwen, Victor Barocas, Paula Ludewig, Arin Ellingson
University of Minnesota

8:45AM **A Tale of Two Tissues: Effects of Collagen III Dysyfunction on Determinants of Mechanical Properties in Tendon and Cervix**
Amir Moghaddam[1], Matthew Confer[2], Roberto Pineda Guzman[3], Kelechi Uhegbu[4], Rohit Bhargava[2], Bruce Damon[3,2], Sanmi Koyejo[4], Christina Laukaitis[3,2], Amy Wagoner Johnson[2], Mariana Kersh[2]
[1]University of Nebraska-Lincoln, [2]University of Illinois at Urbana-Champaign, [3]Carle Health, [4]Stanford University

9:00AM **Flexible Carbon Nanotubes (CNT)-Polydimethylsiloxane (PDMS) Force Sensors for the Rate-Dependent Characterization of Compliant Biomaterials** Sinan Candan, Vanessa Barton, Joseph Andrewas, Jacob Notbohm, Christian Franck
University of Wisconsin-Madison

9:15AM **Evaluating Adaptation of Amputee Skin Due to Prosthesis Use**
Jack Hayes[1], Jennifer Andrews[2], Tomas Andriuskevicius[1], Omar Abdelwahab[3], Ralph Gordon[3], Tom Briggs[1], Peter Worsley[3], Claire Higgins[1], Marc Masen[1] *[1]Imperial College London, [2]University of Salford, [3]University of Southampton*

Cancer Mechanics II

Session Chairs: Meenal Datta, *University of Notre Dame* **Loramoor A**
Jacopo Ferruzzi, *University of Texas at Dallas*

11:30AM **Structural and Biomechanical Hallmarks of Early-Onset Colorectal Cancer**
Nicole Huning[1], Munir Buhaya[2], Adil Khan[1], Haider Ali[1], Sara Roccabianca[3], Emina Huang[2], Jacopo Ferruzzi[1,2]
[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center, [3]Michigan State University

11:45AM **Interplay Between Interstitial Flow and Extracellular Matrix Physical Properties in the Initiation and Control of Angiogenesis and Lymphangiogenesis**
Jonathan W. Song, Jacob C. Holter, Shashwat S. Agarwal, Joseph W Tinapple, Marcos G. Cortes-Medina, Travis H. Jones, Joseph Barlage
Ohio State University

12:00PM **Quantifying Enzymatic Small Extracellular Vesicles (SEVs) for Cancer Companion Diagnostics Using Magnetic Nanoporous Membrane (MNM)-Based Activity Assay**
Tiger Shi[1], Chenguang Zhang[1], Youwen Zhang[1], Xuemin Lu[1], Gaeun Kim[1], Sonu Kumar[1], Ceming Wang[2], Nan Su[2], Yichun Wang[1], Xin Lu[1], Satyajyoti Senapati[1], Hsueh-Chia Chang[1,2]
[1]University of Notre Dame, [2]Aopia Biosciences, Inc.

12:15PM **Investigating the Paracrine Effects of Breast Cancer Cells on Osteoblast Differentiation, Proliferation, and Mineral Deposition**
Sarah Nano[1], Laurie Littlepage[1], Laoise McNamara[2], Glen Niebur[1]
[1]University of Notre Dame, [2]University of Galway

12:30PM **Investigating the Effects of an Increased Adipocyte Density on A 3D Human Breast Tumor Spheroid Model**
Jensen Amens, Gokhan Bacecioglu, Pinar Zorlutuna
University of Notre Dame

12:45PM **Oscillatory Shear Stress Modulates Lymphatic Progenitor Cells Maturation Into Lymphatic Vessels With Anti-Cancer Phenotypes**
Nancy Keilany Lightsey, Eva Hall, Sanjoy Saha, Donghyun Paul Jeong, Donny Hanjaya-Putra
University of Notre Dame

Wednesday, June 12	11:30AM–1:00PM CDT

Cardiovascular Patient-Specific Modeling in the Setting of Disease

Session Chairs: Stephanie George, *East Carolina University* **Loramoor C**
Noelia Grande Gutiérrez, *Carnegie Mellon University*

11:30AM **Computational Modeling of a Human Placentone**
Armita Najmi, Noelia Grande Gutiérrez
Carnegie Mellon University

11:45AM **In Situ Robotic Mechanical Testing of Rat Tibiofemoral Joints**
Karol Calò[1], Andrea Guala[2], Valentina Mazzi[1], Maurizio Lodi Rizzini[1], Lydia Dux-Santoy[2], Jose Rodriguez-Palomares[2], Stefania Scarsoglio[1], Luca Ridolfi[1], Diego Gallo[1], Umberto Morbiducci[1]
[1]Politecnico di Torino, [2]Vall d'Hebron Institut de recerca

12:00PM **Wall Shear Stress in Intracranial Aneurysms Computed From CFD and 4D Flow MRI Augmented With Flow Physics Principles**
Farshid Goudarzian, Mohammadreza Balouchestani Asl, Neal Patel, Abhishek Singh, Jiacheng Zhang, Pavlos Vlachos, Vitaliy Rayz
Purdue University

12:15PM **Analysis of Regional Hemodynamic Changes in Type A Aortic Dissection Repair Using 4D Flow MRI**
Hannah Cebull[1], Hai Dong[2], Minliang Liu[2], Rudy Gleason[2], John Elefteriades[3], John Oshinski[1,2], Marina Piccinelli[1], Bradley Leshnower[1]
[1]Emory University, [2]Georgia Institute of Technology, [3]Yale University

12:30PM **A Case Study: Computational Modeling of Hemodynamics in a Patient With End Stage Renal Disease Under Hemodialysis Via Arteriovenous Fistula With Pulmonary Hypertension**
Fatemeh Bahmani, Kaitlin Southern, Alex Vadati, Veeranna Maddipati, Stephanie George
East Carolina University

12:45PM **Patient-Specific Modeling of Hemodynamics During Splenic Artery Embolization**
Younes Tatari[1], Tyler Andrew Smith[1], Jingjie Hu[2], Amirhossein Arzani[1]
[1]University of Utah, [2]North Carolina State University

Wednesday, June 12	11:30AM–1:00PM CDT

Digital Health and Computational Modeling to Improve Health Outcomes

Session Chairs: **Antonis P. Stylianou**, *University of Missouri-Kansas City*
Lyndia C. Wu, *University of British Columbia*

Maple Lawn C

11:30AM **Real-Time Segmentation, Virtual Image Modification, Surgical Intervention Modeling and 3D Printing (REVISIT-3D): A Treatment Planning Workflow for Congenital Heart Disease**
Robert McCarthy[1], Kasey Chaszczewski[2,3], John LaDisa[1,2,3,4]
[1]Marquette University and the Medical College of Wisconsin, [2]Pediatric Cardiology, Medical College of Wisconsin, [3]Herma Heart Institute, Children's Wisconsin, [4]Cardiovascular Medicine

11:45AM **Vascular Model Generation With the Space Colonization Algorithm**
Daniel Emerson, Yoed Rabin, Levent Burak Kara
Carnegie Mellon University

12:00PM **Optimal Lattice Geometry for Implementation in Scoliotic Braces**
Robert Rizza[1], Xue-Cheng Liu[2], Vince Anewenter[1]
[1]Milwaukee School of Engineering, [2]Medical College of Wisconsin

12:15PM **Virtual Prostate Cancer Biopsies Using Adc Targeted Lesions Shows Superior Performance Than T2 and Non-Mr Guided Surgical Sampling**
Savannah Duenweg[1], Samuel Bobholz[1], Allison Lowman[1], Aleksandra Winiarz[1], Biprojit Nath[1], Kenneth Iczkowski[2], Kenneth Jacobsohn[1], Peter LaViolette[1]
[1]Medical College of Wisconsin, [2]University of California, Davis

12:30PM **Perfusion Optimization in Engineered Microvessel Network Design**
Elbert Heng, Lazaros Papamanolis, Alyssa Garrison, Daniel Alnasir, Weiguang Yang, Zachary Sexton, Aravind Krishnan, Alison Marsden, John MacArthur
Stanford University

12:45PM **Comparison of Computational Models for Predicting Leaching From Implanted Medical Devices**
Martin L. Tanaka[1], David M. Saylor[2], Robert M. Elder[2]
[1]Western Carolina University, [2]US Food and Drug Administration

Emerging Topics in Soft Tissue Mechanics

Session Chairs: **Sara Roccabianca**, *Michigan State University*
Mona Eskandari, *University of California*

Maple Lawn B

11:30AM **High-Speed Cardiac Pressure Volume Simulations Using A Novel Neural Network Finite Element Approach**
Shruti Motiwale, Michael Sacks
University of Texas at Austin

11:45AM **Mouse Lung Emphysematous Mechanical Strains Under Positive Versus Negative Pressure Ventilation**
Talyah Nelson, Kathrine Quiros, Mona Eskandari
University of California, Riverside

12:00PM **Artificial Intelligence Assisted Multiscale Lung Modeling to Predict Alveolar Septal Wall Stress**
Sunder Neelakantan[1], Raza Mehdi[1], Bradford Smith[2], Kyle Myers[1], Rahim Rizi[3], Reza Avazmohmammadi[1]
[1]Texas A&M University, [2]University of Colorado Denver, [3]University of Pennsylvania

12:15PM **Concentric Contraction During Unloading Prevents Strain Softening in the Mouse Urinary Bladder**
Tyler Tuttle[1], Daniel Deuel[1], Sara Roccabianca[2], Sarah Calve[1]
[1]University of Colorado, [2]Michigan State University

12:30PM **Employing Micro-Computed Tomography to Elucidate Hypoxanthine-Induced Alterations in Bladder Wall Geometry**
Fatemeh Azari[1], Lori Ann Birder[2,^], Amanda Sue Wolf-Johnston[2], Ricardo Cardozo[1], Anne M. Robertson[1,*]
[1]University of Pittsburgh, [2]University of Pittsburgh,

12:45PM **Infants Sucking Patterns Identification Using Machine Learning**
Abdullahi Olapojoye, Fatemeh Hassanipour, Abishek Pratap Singh
University of Texas at Dallas

Wednesday, June 12	11:30AM–1:00PM CDT

Emerging Topics in Tissue & Cellular Engineering

Session Chairs: **Victor Varner**, *University of Texas at Dallas*
Soham Ghosh, *Colorado State University*

Loramoor B

11:30AM **Characterization of Biomaterial Interfaces for Cranial Phantoms to Investigate Traumatic Brain Injury**
Anthony Baker[1], Natalie Smith[2], Suhas Vidhate[3], Ricardo Mejia-Alvarez[3], Zane Lybrand[2], Tony Yuan[4], Adam Willis[3,5], Michaelann Tartis[1]
[1]New Mexico Institute of Mining and Technology, [2]Texas Woman's University, [3]Michigan State University, [4]Uniformed Services University of Health Sciences, [5]59th Medical Wing

11:45AM **Assessment of DNA Motility Within Local Nuclear Area Through Telomere Motion Analysis**
Masashi Yamazaki[1,2], Bansei Andoshiro[2], Hiromi Miyoshi[1,2], Satoshi Ii[1,2], Naoya Sakamoto[1,2]
[1]Faculty of Systems Design, Tokyo Metropolitan University, [2]Tokyo Metropolitan University

12:00PM **Characteristics of Resolvable Polymers Used for Developing in Utero Fetal Valve Replacements**
Sanchita Bhat, Julia Toma, Lakshmi Prasad Dasi
Georgia Institute of Technology

12:15PM **Lympho-Vascularized Breast-Skin Platform for Modeling Lymphovascular Space Invasion in Advanced Breast Cancer**
Melika Mehrabi Dehdezi, Marissa Nichole Rylander
University of Texas at Austin

12:30PM **Profibrotic and Myofibroblast Activation Gene Expression in Right Ventricular Cardiac Fibroblasts in Pulmonary Arterial Hypertension**
Giuditta Monti, Yufan Lin, Daniela Valdez-Jasso
University of California San Diego

12:45PM **Incubation in Physiologically Relevant Oxygen Conditions Changes Lymphatic Endothelial Cell Gene Expression and Vessel Morphology**
Ellie Johandes, Donny Hanjaya-Putra
University of Notre Dame

Growth, Remodeling, and Repair

Session Chairs: **Pat Alford**, *University of Minnesota*
Adrian Buganza Tepole, *Purdue University*

Maple Lawn A

11:30AM **Multiscale Model Predicts Modulation of Cardiac Remodeling by Intrinsic Ventricular Contractility Before and After Mitral Valve Repair**
Johane Bracamonte[1], Lamario Williams[1], Brett Cooke[1], Rongbing Xie[1], Panayotis Vardas[1], Betty Pat[1], Louis Dell'Italia[1], Lionel Watkins[2], Jeffrey Saucerman[2], Jeffrey Holmes[1]
[1]University of Alabama at Birmingham, [2]University of Virginia

11:45AM **Biomechanical and Compositional Changes in the Murine Uterus With Age**
Mari Domingo[1], Triniti Vanoven[1,2], Raffaella De Vita[3], Maria Florian-Rodriguez[2], Isaac Pence[1,2], Kristin Miller[1,2]
[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center, [3]Virginia Tech

12:00PM **Micromechanics and Mechanoresponsivity of the Developing Porcine Meniscus**
Meghan E. Kupratis[1], Yuqi Zhang[1], Jiaqi Xiang[2], Byan Kwok[1], Elisabeth A. Lemmon[1], Karen Xu[1], Nathaniel A. Dyment[1], Lin Han[2], Eiki Koyama[3], Robert L. Mauck[1]
[1]University of Pennsylvania, [2]Drexel University, [3]Children's Hospital of Philadelphia

12:15PM **Localized Growth Rate Analysis on a Global Ensemble Averaging of Abdominal Aortic Aneurysm Growth**
Pratik Mitra[1], Juan C. Restrepo[1], Merjulah Roby[1], Satish C. Muluk[2], Mark K. Eskandari[3], Seungik Baek[4], Ender A. Finol[1]
[1]University of Texas at San Antonio, [2]Allegheny Health Network, [3]Northwestern University School of Medicine, [4]Michigan State University

12:30PM **Coupling Systems Biology and Kinematic Growth in Open-Source Finite Element Software**
Steven LaBelle[1], Mohammadreza Sadrabadi[2], Seungik Baek[3], Mohammad Mofrad[4,5], Jeffrey Weiss[1], Amirhossein Arzani[1]
[1]University of Utah, [2]Northern Arizona University, [3]Michigan State University, [4]University of California, Berkley, [5]University of California, Riverside

12:45PM **Influence of In-Vitro Tissue Culturing Conditions on the Properties of Tissue-Engineered Heart Valves - A Computational Analysis**
Elmer Middendorp[1], Justina Ghebryal[1], Valery Visser[2], Polina Zaytseva[2], Sarah Motta[2], Simon Hoerstrup[2,3], Max Emmert[2,3,4], Frank Baaijens[1], Sandra Loerakker[1]
[1]Eindhoven University, [2]Institute for Regenerative Medicine (IREM), University of Zurich, [3]ETH Zurich, [4]German Heart Center Berlin

Wednesday, June 12	11:30AM–1:00PM CDT

Novel Approaches to Bioengineering Education and Outreach

Session Chairs: **Alan Eberhardt**, *University of Alabama at Birmingham*
Jifu Tan, *Northern Illinois University*

Linwood

11:30AM **Students' Perceptions on Using Generative Artificial Intelligence (GAI) in Engineering Courses**
Victor Lai
University of Minnesota - Duluth

11:45AM **Increasing Students' Exposure to Research Via Applied Homework Problems Integrated in Research Manuscripts**
Sean Harrington, Turner Jennings, Ana Vargas, Frederick Sebastian, Rouzbeh Amini
Northeastern University

12:00PM **Fostering STEM Engagement: Building a Collaborative Partnership Between a Research University and Local High School**
Ryan Castile[1], Jamie Jobe[2], Leanne Iannucci[1], Rebecca Reals[1], Shawn Pavey[1], Jon Fitzgerald[2], Spencer Lake[1]
[1]Washington University, [2]Pattonville High School

12:15PM **Immersion, Innovation, Design & Development (I2D2): A 9-Week Summer Experience in Biomedical Bngineering**
Alan Eberhardt
University of Alabama at Birmingham

12:30PM **A 'Dinner Party' Themed Approach to Constructing Equitable and Exciting Literature Reviews**
Daniel Pearce, Corinne Henak
University of Wisconsin-Madison

12:45PM **Establishing a Comprehensive Collection of Ethics Resources for BMES at the Online Ethics Center: Assessing and Structuring Mentoring Resources**
Anjelyka Fasci[1], Sanjana Prashanth[2], Andrew Brightman[2], Lyle Hood[1]
[1]University of Texas at San Antonio, [2]Purdue University

Wednesday, June 12	3:45PM–5:00PM CDT

Translational Technology Pitch Competition

Session Chair: Lyle Hood, *University of Texas, San Antonio* **Maple Lawn C**

3:45PM **A Rapid Novel Assay for Measuring Hemoglobin-Oxygen Affinity**
Rucha Natu[1], Zoe Sekyonda[1], Yuxuan Du[1], John Hinshaw[2], Peter Galen[2], Umut Gurkan[1,2]
[1]Case Western Reserve University, [2]Hemex Health Inc

4:00PM **From Light to Relief: Revolutionizing Pain Management With Optical Blood-Spinal Cord Barrier Modulation**
Harsh Dave[1], Tiffany Leong[1], Eric David[1], Theodore Price[1,1], Zhenpeng Qin[1,1]
[1]University of Texas at Dallas

4:15PM **YoungHeartValve - Next Generation Heart Valve Technology**
Lakshmi Dasi[1], Srujana Joshi[1], Justin Gangwish[2], Nipa Khair[2], Susan James[2]
[1]Georgia Institute of Technology, [2]Colorado State University

4:30PM **Pulse Electric Field Treatment Induced Angiogenesis as a Promising Therapy for Diabetic Foot Ulcers**
Neeraj Raghuraman Rajagopalan, Govindarajan Srimathveeravalli
University of Massachusetts Amherst

4:45PM **Tapping Into Ligament Tension With Our Ligament Tensiometer to Enhance Outcomes Following Total Knee Arthroplasty**
Lesley Arant, Josh Roth
University of Wisconsin - Madison

Emerging Topics in Computational Modeling and Imaging in Soft Tissue Mechanics

Session Chairs: **Maria Holland**, *University of Notre Dame*
Emma Lejeune, *Boston University*

Linwood

8:00AM **The Mechanical Loading of the Murine Uterus and Cervix in Early Pregnancy**
Abigail Laughlin[1], Joy Vink[2], Steven Abramowitch[3], Kristin Miller[4], Raffaella De Vita[5], Kristin Myers[1]
[1]Columbia University, [2]University of Hawaii, [3]University of Pittsburgh, [4]University of Texas at Dallas, [5]Virginia Tech

8:15AM **Automated Full-Field Mechanical Analysis of Cardiac Microbundles**
Hiba Kobeissi, Emma Lejeune
Boston University

8:30AM **Low-Energy Impact Induced Damage in Cartilage: A Multiscale Modeling Study Using FE2M**
Kosar Safari, Ashkan Almasi, Phoebe Szarek, David M. Pierce
University of Connecticut

8:45AM **Lamina Cribrosa Vascular Network Analysis: Associations Between Structural and Functional Parameters**
Yuankai Lu[1], Hua Yi[2], Ruhani Gill[1], Andrew Theophanous[1], Po-Yi Lee[1], Ian Sigal[1,1]
[1]University of Pittsburgh, [2]University of Mississippi

9:00AM **Image-Based Patient-Specific Modeling of Human Stomach Electromechanics**
Lei Shi[1], Qi Zhao[2], Yurui Chen[3]
[1]Kennesaw State University, [2]Shandong Provincial Hospital, [3]Columbia University

Joint Biomechanics

Session Chairs: **Brianne Connizzo**, *Boston University*
Ken Fischer, *University of Kansas*

Maple Lawn B

8:00AM **Functional-Aggregate Method for Objective Determination of Vertebral Coordinate Systems**
Tara Nagle, Jeremy Loss, Rob Colbrunn
Cleveland Clinic Foundation

8:15AM **Sensor Fusion Algorithm to Improve Accuracy of Robotic Superposition Testing Using a 6-DOF Position Sensor**
Callan Gillespie[1], Lesley Arant[2], Tara Nagle[1], Joshua Roth[2], Robb Colbrunn[1]
[1]Cleveland Clinic, [2]University of Wisconsin-Madison

8:30AM **Characterization of the Mechanical and Compositional Effects of MMP-9 Exposure on Neuron-Collagen Constructs: Implications for Joint Degeneration**
Chang Wang, Michelle Meyers, Prabesh Ghimire, Mistica Lozano Perez, Beth Winkelstein
University of Pennsylvania

8:45AM **A Biomechanical Evaluation of Two Internal Fixation Methods With Different Screw Directions for Capitellum Fractures**
Hui Zhang, Justin Hellwinkel, Kiran Agarwal-Harding, Thomas Gardner, Susanne Roberts
Columbia University

9:00AM **Biomechanical Analysis of Dual Mobility Intraprosthetic Dissociation**
Joshua Bland, Alexander Hooke, Allison Tanner, Katherine Mallett, Sergio Gaurin-Perez, James Fitzsimmons, Chunfeng Zhao, Michael Taunton, Rafael Sierra
Mayo Clinic

9:15AM **In Situ Robotic Mechanical Testing of Rat Tibiofemoral Joints**
Olivia Dyer, Stephanie Cone
University of Delaware

Machine Learning: Computational Modeling & Predicting Patient Outcomes

Session Chairs: **Luke Mattar**, *University of Pittsburgh*
Jeremy Warren, *University of Texas at Dallas*

Maple Lawn C

8:00AM **Machine Learning Mediated Prognosis of Major Adverse Cardiac Event (MACE) for Patients With Coronary Artery Dysfunction Using Pressure Drop Coefficient**
Israel Ajiboye, Rao Marepalli, Rupak Banerjee
University of Cincinnati

8:15AM **A Novel Diffusion Tensor Myocardial Material Model Using Neural Networks for Form Determination**
Benjamin Thomas, Christian Goodbrake, Michael Sacks
Oden Institute for Computational Engineering and Sciences

8:30AM **Advancing 3D Organ Geometric Reconstruction From MRI: A Hybird Framework With Deep Learning and Iterative Optimization**
Hui Wang[1,2], Xiaowei Li[3], Chenxin Zhang[1,2], Jianwei Zuo[1,2], Xiuli Sun[3], Jianliu Wang[3], Jiajia Luo[1,2]
[1]Peking University Health Science Center, [2]Peking University, [3]Peking University People's Hospital

8:45AM **Computational Modeling and Machine Learning Methods to Predict Patient-Specific Healing Following Breast-Conserving Surgery**
Zachary Harbin[1], Alexander Argyros[1], Carla Fisher[2], Sherry Voytik-Harbin[1], Adrian Buganza Tepole[1]
[1]Purdue University, [2]Indiana University

9:00AM **Role of Physics-Informed Constraints in Real-Time Assessment of 3D Vascular Fluid Dynamics Via Multi-Case Deep Learning Neural Network**
Wei Xuan Chan, Wenhao Ding, Binghuan Li, Hong Shen Wong, Choon Hwai Yap
Imperial College London

9:15AM **Super-Resolving and Denoising 4D Flow MRI of CSF Using a Physics-Guided Temporally Coherent Neural Network**
Neal Patel, Sriram Baireddy, A.J. Schwichtenberg, Edward Delp, Vitaliy Rayz
Purdue University

Mechanobiology and Engineering of Musculoskeletal Soft Tissues

Session Chairs: **Deva Chan**, *Purdue University*
Ed Sander, *University of Iowa*

Maple Lawn A

8:00AM **Effects of Spontaneous Calcium Signaling on Cartilage Anabolic Activities**
Ying Peng, Annie Porter, Steven DiStefano, X. Lucas Lu
University of Delaware

8:15AM **Female Anterior Cruciate Ligaments Exhibit A Minimal Mechanobiological Response to Mechanical Loading**
Lauren Paschall, Maxwell Konnaris, Aman Dhawan, Erdem Tabdanov, Ilias Georgakopoulos-Soares, Spencer Szczesny
Pennsylvania State University

8:30AM **In Vitro Assessment of Metformin Treatments for Cartilage Injury**
Hessam Noori-Dokht[1,2], Taylor Williams[1], Sogol Younesi[2], Diane Wagner[1]
[1]Indiana University, [2]Purdue University

8:45AM **The Effect of Hyaluronic Acid and Proteoglycan on the Centrifugally Compressed Cell-Collagen Combined Construct (C6)**
Kazuki Moribe, Xu Ye, Masashi Yamazaki, Hiromichi Fujie
Tokyo Metropolitan University

9:00AM **An Engineered In VitroModel of the Human Myotendinous Junction** Mitchell Josvai, Erzsebet Polyak, Meghana Kalluri, Samantha Robertson, Wendy Crone, Masatoshi Suzuki
University of Wisconsin-Madison

9:15AM **Neocartilage Cellular Morphology and Strain Profiles Are Improved by Physiologic TGF-β Doses**
Yifan Peng, Tianbai Wang, Sedat Dogru, Celina Maldonado, Michael Albro
Boston University

Thursday, June 13	8:00AM–9:30AM CDT

Mechanobiology and Fluid Mechanics in the Setting of Disease

Session Chairs: **Ruihang (Rita) Zhang**, *University of Minnesota*
Colleen Witzenburg, *University of Wisconsin-Madison*

Loramoor C

8:00AM **Uniform Growth Laws Recapitulate Some Aspects of Ascending Aortic Aneurysm Progression in the FbInSMKO Mouse**
Marisa Bazzi, Hadi Wiputra, Victor Barocas
University of Minnesota

8:15AM **Morphological and Hemodynamic Changes to the Right Ventricular Microvascular Network in Response to Chronic Pressure Overload**
Ilham Essafri[1], Kenzo Ichimura[2], Kurt Stenmark[1], Edda Spiekerkoetter[2], Vitaly Kheyfets[1]
[1]University of Colorado, Anschutz Medical Campus, [2]Stanford University

8:30AM **Co-Mapping of Smooth Muscle Cell Actin and Hemodynamics in Intact Human Intracranial Aneurysm**
Yasutaka Tobe[1], Anne Robertson[1], Mehdi Ramezanpour[1], Juan Cebral[2], Simon Watkins[1], Fady Charbel[3], Sepideh Amin-Hanjani[4], Alexander Yu[5], Boyle Cheng[6], Henry Woo[7]
[1]University of Pittsburgh, [2]George Mason University, [3]University of Illinois at Chicago, [4]University Hospital Cleveland Medical Center, [5]Allegheny Health Network, [6]Director of Translational Research, Neuroscience and Orthopedic Institutes, Allegheny Health Network, [7]Donald and Barbara Zucker School of Medicine at Hofstra Northwell

8:45AM **Elevated VWF Levels Drive Thrombus Instability**
Ava Obenaus[1], Dang Truong[1], Derek Macatangay[1], Annie Ke[1], Junmei Chen[2], José López[2], Nathan Sniadecki[1]
[1]University of Washington, [2]Bloodworks Northwest Research Institute

9:00AM **Presence of Red Blood Cells Promotes Stretching and Cleavage of Von Willebrand Factor in Whole Blood Under High Shear**
Rukiye Tuna[1], Alice Liu[2], David Bark[2], Z. Leonardo Liu[1]
[1]FAMU-FSU College of Engineering, [2]Washington University School of Medicine

9:15AM **Coronary Height and Peak Systolic Velocity as Main Predictors of Post-TAVR Thrombosis**
Fateme Esmailie[1], Aniket Venkatesh[2], Hoda Hatoum[3], Huang Chen[4], Breandan Yeats[2], BeomJun Lee[2], Philipp Ruile[5], Franz-Josef Neumann[5], Lakshmi Prasad Dasi[2]
[1]University of North Texas, Denton, [2]Georgia Institute of Technology, [3]Michigan Technological University, [4]University of Nevada, [5]Medical Center - University of Freiburg

Mineralized & Soft Tissue Mechanics & Modeling

Session Chairs: **Jacqueline Cole**, *NC State and UNC Chapel Hill*
Megan Killian, *University of Michigan*

Loramoor A

8:00AM **Probable Relation Between Structure & Composition of the Dentin-Enamel Junction (DEJ) & Dentinogenesis Imperfecta (DGI)**
Sobhan Katebifar[1,1], Kai Clark[1], Bradley Rosenberg[1], Michael Truhlar[1], Alix Deymier[1,1]
[1]UConn Health

8:15AM **Ovine Fracture Healing Is Robust to High Gap Strain: A Virtual Mechanical Testing and Image Colocalization Analysis**
Maham Tanveer, Hannah Dailey
Lehigh University

8:30AM **Cam Morphology and Sex-Based Differences in the Proximal Femur Anatomy of Collegiate Athletes Without Hip Pain: A Three-Dimensional Statistical Shape Modeling Analysis**
Bergen Braun, Andrew Anderson
University of Utah

8:45AM **Medial Iliofemoral Ligament Strain and Orientation Following THA Implantation Correlate With Its Ability to Contribute to Hip Stability**
Clarisse Zigan, Jennifer Bido, Kathleen Meyers, Jose Rodriguez, Timothy Wright, Fernando Quevedo Gonazalez
Hospital for Special Surgery

9:00AM **Physeal-Sparing ACL Reconstruction Provides Better Initial Joint Stability and Function Than Complete Transphyseal ACL Reconstruction in an Early Adolescent Porcine Model**
Yukun Zhang[1], Kaan Gurbuz[2], Jeffrey Spang[3], Matthew Fisher[1,3]
[1]North Carolina State University and University of North Carolina at Chapel Hill, [2]Kayseri State Education & Research Hospital, [3]University of North Carolina at Chapel Hill

9:15AM **Investigating Nonlinear Intrinsic Viscoelasticity of Collagen Type II in Immature Bovine Articular Cartilage**
Kimberly Kroupa[1], Jeffrey Weiss[2], Gerard Ateshian[1]
[1]Columbia University, [2]University of Utah

Thrombosis, Hemolysis & Mechanical Circulatory Support

Session Chairs: Bryan Good, *University of Tennessee* **Loramoor B**
John LaDisa, *Marquette University and the Medical College of Wisconsin*

8:00AM **In Vitro Fluid Mechanics and Blood Study to Evaluate Catheter-Related Thrombosis**
Hannah Palahnuk[1], Boyang Su[1], Thaddeus Harbaugh[2], Elias Rizk[2], Sprague Hazard[2], Jonathan Bernstein[3], Keefe Manning[1,2]
[1]Pennsylvania State University, [2]Penn State Hershey Medical Center, [3]Penn State Hershey Children's Hospital

8:15AM **Micro-Channels Maintain Endothelial Cell Adhesion Under Physiologic Wall Shear Stress**
Alexander Armstrong[1], Patrick McCarthy[1,2], Alexander Raskin[1], John LaDisa[1,2,3], Brandon Tefft[1]
[1]Medical College of Wisconsin, [2]Marquette University, [3]Herma Heart Institute, Children's Wisconsin

8:30AM **Plaque Length and Stenosis Influence Instantaneous Wave-Free Ratio and Wall Shear Stress**
Arnav Garcha, Noelia Grande Gutiérrez
Carnegie Mellon University

8:45AM **The Balance of Von Willebrand Factor and Platelet Activation in Causing Bleeding in an Aortic Stenosis**
Alice Liu, Katrina Ashworth, Nina Lasky, Yi Qiao, Kimsey Platten, Jorge Di Paola, David Bark
Washington University in St. Louis

9:00AM **Post-TAVR Thrombogenic Risk Comparisons for Bicuspid Aortic Valve Patients Using Novel Fluid-Structure Interaction Approach**
Kyle Baylous[1], Brandon Kovarovic[1], Salwa Anam[1], Ryan Helbock[1], Marvin Slepian[2], Danny Bluestein[1]
[1]Stony Brook University, [2]University of Arizona

9:15AM **Flow and Turbulence Quantification Using 4D Flow Magnetic Resonance Imaging in a Pulsatile Total Artificial Heart**
Twan Bakker[1], Azad Najar[1,2], Thomas Finocchiaro[3], Ina Laura Perkins[3], Jonas Lantz[1], Tino Ebbers[1]
[1]Linköping University, [2]Scandinavian Real Heart AB, [3]Scandinavian Realheart AB

Thursday, June 13	11:00AM–12:30PM CDT

PhD SPC: Biotransport, Human Motion, Reproductive, and Other Emerging Topics

Session Chairs: **Ottman Teruliano**, *University of Pennsylvania*
Alix Deymier, *UConn Health*

Loramoor A

11:00AM **Enzyme- and Compartment-Free Single Protein Detection by Digital Plasmonic Nanobubble**
Tingting Zhang[1], Ye Gao[1], Yaning Liu[1], Zhenpeng Qin[1,2]
[1]University of Texas at Dallas, [2]University of Texas at Southwestern Medical Center

11:15AM **The Fate of Ultrasmall Fluorescent Silica Nanoparticles as Drug Delivery Vehicles in Cartilage Explants: Differential Retention Kinetics Between Matrix and Chondrocytes**
Aiyana Fortin, Antonio Garces, Ulrich Wiesner, Lawrence Bonassar
Cornell University

11:30AM **Generic Versus Personalized Foot-Ground Contact Models- Is Personalization Worth the Effort?**
Spencer Williams, Kayla Pariser, Claire Hammond, Benjamin Fregly
Rice University

11:45AM **Ex Vivo Minoxidil Treatment Increases Elastic Fiber Deposition in the Murine Vaginal Wall**
Niyousha Karbasion[1], John Caleb Snider[1], Savannah Chatman[1], Kristin Miller[2], Matthew Bersi[1]
[1]Washington University in St. Louis, [2]University of Texas at Dallas

12:00PM **Mechanistic Model of Biochemical-Biomechanical Crosstalk in Vascular Endothelial Cell Alignment**
Shannon Flanary, Victor Barocas
University of Minnesota

12:15PM **Deep Learning-Based Biomechanical Characterization of Infarcted Myocardium From Strain Imaging**
Rana Raza Mehdi, Tanmay Mukherjee, Emilio Agustin Mendiola, Sunder Neelakantan, Reza Avazmohammadi
Texas A&M University

Thursday, June 13	11:00AM–12:30PM CDT

PhD SPC: Heart Valves, Devices, and Computational Fluid Mechanics

Session Chairs: **Alejandro Roldán-Alzate**, *University of Wisconsin-Madison*
Marisa Bazzi, *University of Minnesota*

Loramoor C

11:00AM **Changes in Gene Spatial Expression, Structure, and Function in Response to Altered Mechanical Stress in a Murine Model of Bicuspid Aortic Valve**
Hail Kazik, Julie Kessler, Carol Mattern, Joy Lincoln, John LaDisa
Medical College of Wisconsin

11:15AM **Feasibility and Post-Procedural Risk Analysis of Redo-Transcatheter Aortic Valve Replacement: A Patient-Specific Fluid-Structure Interaction Based Study**
Symon Reza, Brandon Kovarovic, Danny Bluestein
Stony Brook University

11:30AM **Assessment of Aortic Valve Stenosis Using a Novel Functional Index: a Pilot Prospective Study for Trans-Catheter Aortic Valve Replacement Patients**
Shreyash M. Manegaonkar[1], Mohamed A. Effat[1], Marepalli Rao[2], Rishi Sukhija[1], Rupak K. Banerjee[3]
[1]University of Cincinnati, [2]Environmental & Public Health Sciences, University of Cincinnati, [3]University of Cincinnati, Veterans Affairs Medical Center

11:45AM **Parametric Investigation of a Bioprinted Pulsatile Fontan Conduit**
Zinan Hu[1], Jessica Herrmann[1], Erica Schwarz[2], Fannie Gerosa[1], Nir Emuna[2], Jay Humphrey[2], Tain-Yen Hsia[3], Mark Skylar-Scott[1], Alison Marsden[1]
[1]Stanford University, [2]Yale University, [3]Arnold Palmer Hospital for Children

12:00PM **Prediction of Pressure Drop Across Aortic Coarctation During Exercise Using a Hybrid Mock Circulatory Loop**
Priya Nair[1], Emanuele Perra[2], Doff McElhinney[1], Alison Marsden[1], Daniel Ennis[1], Seraina Dual[2]
[1]Stanford University, [2]KTH Royal Institute of Technology

12:15PM **Enhancing 4D-Flow MRI With Input-Parametrized Physics-Informed Neural Network (IP-PINN)**
Amin Pashaei Kalajahi[1], Omid Amili[2], Amirhossein Arzani[3], Roshan D'Souza[1]
[1]University of Wisconsin-Milwaukee, [2]University of Toledo, [3]University of Utah

PhD SPC: Musculoskeletal, Joint, and Spine Solid Mechanics

Session Chairs: **Daniel Cortes**, *Penn State University*
Caitlyn Collins, *Virginia Tech*

Maple Lawn B

11:00AM **Benefits of Using Functional Joint Coordinate Systems in In Vitro Knee Testing**
Tara Nagle[1,2], Jeremy Loss[1], Callan Gillespie[1,2], Robb Colbrunn[1,2]
[1]Cleveland Clinic Foundation, [2]Cleveland State University

11:15AM **Direct Quantification of Errors in Bone Positions and Ligament Tensions Using the Superposition Technique With a Robotic Testing System**
Lesley Arant, Joshua Roth
University of Wisconsin - Madison

11:30AM **Raman Arthrotomy for IN Vivo Quantitative Monitoring of Cartilage Defect Repair in Equine Stifle Joint**
Erik Ersland[1], Madeline Boyes[2], Keming Yan[1], Li-Hsin Han[3], J. Todd Lawrence[4], Thomas Schaer[2], Mark Grinstaff[1], Brian Snyder[5], Mads Bergholt[6], Michael Albro[1]
[1]Boston University, [2]University of Pennsylvania, [3]Drexel University, [4]Children's Hospital of Philadelphia, [5]Beth Israel Deaconess Medical Center, [6]King's College London

11:45AM **Immobilization and Soft Tissue Injury Are Necessary to Cause Persistent Disability in a Rat Model of Elbow Contracture**
Rebecca Reals[1], Alex Reiter[1,2], Ryan Castile[1], Sophia Miller[1], Spencer Lake[1]
[1]Washington University in St. Louis, [2]Saint Louis University

12:00PM **Loss of Decorin Accelerates Cartilage Surface Damage and Aberrant Fibrous Remodeling During Aging**
Mingyue Fan[1], Bryan Kwok[1], Aanya Mohan[2], Michael Newton[2], Jiaqi Xiang[1], Yuchen Liu[1], Ling Qin[3], David Birk[4], Renato Iozzo[5], Tristan Maerz[2], Robert Mauck[3], Lin Han[1]
[1]Drexel University, [2]University of Michigan, [3]University of Pennsylvania, [4]University of South Florida, [5]Thomas Jefferson University

12:15PM **Influence of Sex and Sex Hormones on Skeletal Responses to Intermittent Parathyroid Hormone (PTH) Treatment and Discontinuation**
Y. Vincent Jin, Wonsae Lee, Tala Azar, Xiaoyu Xu, Kruti Desai, Wei-Ju Tseng, X. Sherry Liu
University of Pennsylvania

PhD SPC: Platelets and Cardiovascular Biomechanics

Session Chairs: **Noelia Gutierrez**, *Carnegie Mellon University*
Bryan Good, *University of Tennessee*

Loramoor B

11:00AM **Shear-Induced Platelet Aggregation Is Mediated by vWF-Binding Receptors in A Stenotic Model**
Connor Watson[1], Christopher Siedlecki[1,2], Keefe Manning[1,2]
[1]Pennsylvania State University, [2]Penn State Hershey Medical Center

11:15AM **A Micromechanics Based Multiscale Model for Platelet-Driven Clot Contraction**
Chayut Teeraratkul, Debanjan Mukherjee
University of Colorado, Boulder

11:30AM **The Biomechanics of Radiation-Induced Cardiotoxicity in Mice**
Tanmay Mukherjee[1], Sarah Elliott[2], Prasanna Alluri[2], Reza Avazmohammadi[1]
[1]Texas A&M University, [2]University of Texas Southwestern Medical Center

11:45AM **Investigating the Influence of Lactation on Murine Heart Growth Through Ultrasound and Computational Analysis**
Molly Kaissar[1], Arden Shen[2], Jennifer Anderson[2,3], Elnaz Ghajar-Rahimi[2], Adalyn Meeks[2], Craig Goergen[2], Kyoko Yoshida[1]
[1]University of Minnesota, [2]Purdue University, [3]University of Vermont

12:00PM **Dynamic Imaging of the Collagenous Myocardial Extracellular Matrix During Post-Infarction Inflammation**
Daniel Pearce, Colleen Witzenburg
University of Wisconsin-Madison

12:15PM **Microstructural Alterations in the Murine Thoracic Aorta: Unveiling a Mechanism for Biomechanical Remodeling in Late-Gestation Pregnancy**
Ana Vargas, Turner Jennings, Rouzbeh Amini, Chiara Bellini
Northeastern University

PhD SPC: Tissue Engineering, Development, Mechanobiology, and Other Emerging Topics

Session Chairs: **Meghan Kupratis**, *University of Pennsylvania*
Jason Szafron, *Carnegie Mellon University*

Linwood

11:00AM **Rhythmic Nephron Progenitor Renewal and Differentiation Informs Kidney Tissue Engineering Strategies**
Samuel Grindel, Sachin Davis, John Viola, Grace Liu, Jiageng Liu, Grace Qian, Catherine Porter, Alex Hughes
University of Pennsylvania

11:15AM **Tailored Delivery of A Small Molecule Agonist for Hedgehog Signaling Activation in Tendon-to-Bone Integration**
Jonathan Marcelin, Rashad Madi, Timur Kamalitdinov, Xi Jiang, Dong Hwa Kim, Robert Mauck, Andrew Kuntz, Nathaniel Dyment
University of Pennsylvania

11:30AM **Scleraxis-Targeted Deletion of Non-Muscle Myosin Leads to Tendon Degeneration**
Mary Kate Evans[1], Ellie Bernstein[1], Tonia Tsinman[1], Ellie Ferguson[1], Xi Jiang[1], Joel Boerckel[1], Lin Han[2], Eiki Koyama[3], Robert Mauck[1], Nathaniel Dyment[1]
[1]University of Pennsylvania, [2]Drexel University, [3]Orthopaedic Biomedical Research, Children's Hospital of Philadelphia

11:45AM **Reduced Loading After Sciatic Nerve Resection Impairs Hindlimb Growth and Maturation**
Talayah Johnson[1], Natalie Fogarty[1], Alisia Lin[1], Xi Jiang[1], Eiki Koyama[2], Lin Han[3], Josh Baxter[1], Joel Boerckel[1], Robert Mauck[1], Nathaniel Dyment[1]
[1]University of Pennsylvania, [2]Children Hospital of Philadelphia, [3]Drexel University

12:00PM **Cell-Extracellular Matrix Feedback Results in Spontaneous Cellular Orientation and Contact Guidance Behavior in 3D Discrete Fiber Models of Cell Compaction**
Adam Ley, Lauren Bersie-Larson, Ryan Collanton, Sabin Adhikari, Robert Tranquillo, Kevin Dorfman, Victor Barocas
University of Minnesota, Twin Cities

12:15PM **Logic-Based Cell Signaling Model for Predicting Vascular Smooth Muscle Cell Contractility During Pregnancy**
Paige Nielsen, Yusheng Wu, Kyoko Yoshida
University of Minnesota

Thursday, June 13	11:00AM–12:30PM CDT

PhD SPC: Neural, Lung, and Developmental Solid Mechanics

Session Chairs: **Sara Moshage**, *University of Illinois at Urbana-Champaign*
Ryan Pedrigi, *University of Nebraska-Lincoln*

Maple Lawn A

11:00AM **Cross-Correlation of Biomechanical, Connectomic, and Pathologic Markers in Neurodegeneration at 7T MRI**
Em Triolo[1], Mackenzie Langan[2], Oleksandr Khegai[2], Sarah Binder[2], Trey Hedden[2], Priti Balchandani[2], Mehmet Kurt[1,2]
[1]University of Washington, [2]Icahn School of Medicine at Mount Sinai

11:15AM **Comparison of Head Impact Biomechanics Across Multiple Sports**
Zaryan Masood, David Luke, Rebecca Kenny, Daniel Bondi, Adam Clansey, Lyndia Wu
University of British Columbia

11:30AM **Associations Between Cerebrovascular Remodeling and Neuropathological Changes in the Brain During Alzheimer's Disease Progression**
Samuel Halvorsen[1], Raymond Nicks[2], Thor Stein[2,3], Katherine Zhang[1]
[1]Boston University, [2]Boston University School of Medicine, [3]US Department of Veterans Affairs

11:45AM **Surfactant Depleted Rat Lungs: A Global to Local Study of the Impact of Positive Versus Negative Pressure Ventilation**
Matthew Shankel, Mona Eskandari
University of California, Riverside

12:00PM **Towards Improved Surgical Sealants by Investigating Human Visceral Pleura Mechanics**
Gustavo Ramirez, Mona Eskandari
University of California, Riverside

12:15PM **Lung Lobar Sliding Reduces Parenchymal Distortion in the Left and Right Lungs**
Adam Galloy, Joseph Reinhardt, Suresh M. L. Raghavan
University of Iowa

Friday, June 14	10:00AM–11:30AM CDT

Undergraduate Design Competition

Session Chair: Anita Singh, *Temple University* **Maple Lawn B**

10:00AM **Soft Robotics for Progressive Vertebrae Rehabilitation**
Rachel Yu, Charmaine Tan, Michelle Haung, Thomas Ho, Jesse Kimie-Brylka, Nathan Ou, Amber Kashay, Ian Morales, Allison Cheng, Sina Ghadimi, Carissa Ott, Evan Zhao
University of California, Los Angeles

10:15AM **Preventing and Detecting Nasogastric Tube Dislodgement in Infant Patients**
Jeffrey Huang, Katherine Han, Stephanie Yoon, Dahin Song
University of Pennsylvania

10:30AM **Reinforcing Safe Walker Use: A Universal 2-Wheel Walker Monitoring Device**
Ashwin Gadiraju, Pradnesh Kolluru, Cecelia Rodriguez, Nick Tsintolas
Duke University

10:45AM **LAPPI: Lip and Palate Prosthetic Interface**
Camilla Whitesel, Serena Carson, Andrea Urdaneta, Ryan Lim, Ravikiran Ramjee
University of Pennsylvania

11:00AM **Sistance: A Two-Way Base Communication System for Deaf-Blind Students**
Mackenzie Hunt, Maxim Hansen, Souleymane Cissokho, Timothy Johnson
Rose-Hulman Institute of Technology

11:15AM **Adaptive Sport Solutions: Assistive Kayak Mount Device for Mobility Impaired Users**
Alex Britton, Megan Parker, Douglas Wingert, Christine Walck
Embry-Riddle Aeronautical University

Friday, June 14	12:45PM–2:15PM CDT

Cardiac Biomechanics

Session Chairs: Lei Fan, *Marquette University*
Colleen Witzenburg, *University of Wisconsin-Madison*

Evergreen I

12:45PM **Right Ventricular Myocardium Remodeling in Pulmonary Arterial Hypertension Is Sex-Specific and Ovarian-Hormone Dependent**
Becky Hardie, Jessica Huberts, Daniela Valdez-Jasso
University of California San Diego

1:00PM **Estrogen, Testosterone, and Mechanics : Modeling Sex-Specific Left Ventricular Remodeling in Heart Failure**
Adhithi Lakshmikanthan[1], Minnie Kay[1], Kenneth Bilchick[2], Anya Grosberg[1], Pim Oomen[1]
[1]University of California, Irvine, [2]University of Virginia

1:15PM **Identifying the Role of the Septum Wall in Right Ventricular Remodeling**
Kristen Garcia, Becky Hardie, Jessica Huberts, Daniela Valdez-Jasso
University of California San Diego

1:30PM **Comparative Analysis of Myocardial Wall Thickness: Insights From MRI-Derived Models and Biomechanical Simulations Across the Cardiac Cycle**
Mohsen Darayi[1], Mary Robakowski[1,2], Yiling Fan[3], Danielle Kara[1], Ojas Potdar[4], Christopher Nguyen[1], Debkalpa Goswami[1]
[1]Cleveland Clinic, [2]Cleveland State University, [3]Massachusetts Institute of Technology, [4]Case Western Reserve University

1:45PM **Patient-Specific Modeling of Left Atrial Electromechanics**
Lei Shi[1], Aaron Brown[2], Fanwei Kong[2], Chen Zhang[3], Hannah Haider[3], Vijay Vedula[3]
[1]Kennesaw State University, [2]Stanford University, [3]Columbia University

2:00PM **A Personalized Multiscale Model of Biventricular Cardiac Electromechanics**
Aaron Brown[1,2], Lei Shi[3], Matteo Salvador[1,2], Fanwei Kong[1,2], Vijay Vedula[4], Alison Marsden[1,2]
[1]Stanford University, [2]Stanford Cardiovascular Institute, [3]Kennesaw State University, [4]Columbia University

Emerging In Vitro, Experimental, and Computational Methods in Fluid Mechanics I

Session Chairs: Grace McIlvain, *Emory University*
Melissa Brindise, *Pennsylvania State University*

Maple Lawn A

12:45PM **Eulerian-Lagrangian Framework for Simulations of Particle-Laden Biological Flows in Complex Geometries**
Abhilash Reddy Malipeddi, Jesse Capecelatro, C. Alberto Figueroa
University of Michigan

1:00PM **Computational Analysis of the Effect of Type B Aortic Dissection on Pulse Wave Velocity and Pulse Waveform Shape**
Marisa Bazzi[1], Hadi Wiputra[2], Rumi Faizer[3], Victor Barocas[2]
[1], University of Minnesota, [2]University of Minnesota, [3]UP Medical

1:15PM **Experimental Validation of 3D Dynamic MRI Using an Ex-Vivo Porcine Model of the Bladder**
James Rice, Michael Stellon, Wade Bushman, Alejandro Roldán-Alzate
University of Wisconsin-Madison

1:30PM **Biphasic Modeling of 9L Glioma: Radiation Treated Versus Untreated**
Isabel Rivera Santiago[1], Malisa Sarntinoranont[1], James R. Ewing[2,3,4,5], Prabhu Acharya[2,4], Glauber Cabral[2], Tavarekere N. Nagaraja[2,3], Stephen L. Brown[3,2]
[1]University of Florida, [2]Henry Ford Hospital, [3]Michigan State University, [4]Oakland University, [5]Wayne State University

1:45PM **Experimental and Computational Modeling of Brain Shunt Performance**
Bryan Good, Ashley Handy, Alyson Matushek, Stephanie TerMaath
University of Tennessee

2:00PM **Spatiotemporal Variations in Blood Velocity and Hematocrit in A Microfluidic Capillary Network**
Solomon Oshabaheebwa, Christopher Delianides, Michael Suster, Pedram Mohseni, Umut Gurkan
Case Western Reserve University

Friday, June 14	12:45PM–2:15PM CDT

Head & Injury Mechanics I

Session Chairs: **Maria Holland**, *University of Notre Dame*
Ken Monson, *University of Utah*

Loramoor C

12:45PM **Strain-Based Cellular Injury Thresholds in a 3D In Vitro Model of Traumatic Brain Injury**
Jessica Park, Annalise Daul, Jing Zhang, Christian Franck
UW-Madison

1:00PM **A Human Organoid Model of Traumatic Brain Injury**
Shahrzad Shiravi[1], Alexandra Yufa[2], Maria Jose Quezada Valladares[3], Colin Franz[3], John Finan[2]
[1]Chicago, [2]University of Illinois at Chicago, [3]Northwestern University

1:15PM **Bridging Gaps in Traumatic Brain Injury Modeling: A Multiscale Approach to Unifying Global and Axonal Injury Models**
Chaokai Zhang[1], Lara Bartels[2], Adam Clansey[2], Julian Kloiber[2], Daniel Bondi[2], Paul van Donkelaar[2], Lyndia Wu[2], Alexander Rauscher[2], Songbai Ji[1]
[1]Worcester Polytechnic Institute, [2]University of British Columbia

1:30PM **Mapping Nonlinear Mechanical Properties of Ex VivoBrain Tissue Using MR Elastography With Applied Pre-Strain**
Olivia Bailey, Alexa Diano, Ali Lateef, Elise Corbin, Curtis Johnson
University of Delaware

1:45PM **Improving Glioma Segmentation Fairness in Low-Resolution Domains With Transfer Learning**
Juampablo Heras Rivera[1], Tianyi Ren[1], Ethan Honey[1], Harshitha Rebala[2], Abhishek Sharma[1], Mehmet Kurt[1]
[1]University of Washington, [2]Computer Science- University of Washington

2:00PM **Exploring the Potential Role of Sex-Based Brain Structural Variations in Susceptibility to Traumatic Brain Injury From a Biomechanics Perspective**
Bahram Jafari, Marzieh Memar
University of Texas at San Antonio

Friday, June 14	12:45PM–2:15PM CDT

Knee Biomechanics

Session Chairs: **Jacob Merson**, *Rensselaer Polytechnic Institute*
Tara Nagle, *Cleveland Clinic Foundation*

Maple Lawn C

12:45PM **Study of the Structures That Limit Combined Abnormal Hyperextension and Abnormal Varus of the Knee**
Rebekah Deardurff[1,2,3], Edward Grood[1,2], Frank Noyes[2,3,4]
[1]University of Cincinnati, [2]Cincinnati SportsMedicine Research and Education Foundation, [3]Cincinnati Sports Medicine and Orthopedic Research, The Jewish Hospital, Mercy Health, [4]Noyes Knee Institute

1:00PM **Towards Validation of Knee-Specific Finite Element Models in A Loaded MRI Condition**
Sean Letendre[1], Kalle Chastain[1], Joshua Leadem[2], Manuela Montes de Oca[2], Lila Pender[2], Madison Lang[2], Erin Leatherman[3], Thomas Santner[4], Kate Lindsey[2], Erin Argentieri[1], Amanda Wach[1], Ashley Pekmezian[1], Sara Sacher[1], Matthew Koff[1], Amy Lerner[2], Scott Rodeo[1], Suzanne Maher[1], Brett Steineman[1]
[1]Hospital for Special Surgery, [2]University of Rochester, [3]Kenyon College, [4]Ohio State University

1:15PM **Longitudinal MRI Analysis of Intratissue Cartilage Strain and Relaxometry in the ACL Reconstructed Knee: A Case Study**
Hongtian Zhu[1], Emily Miller[2], Woowon Lee[1], Timothy Lowe[1], Corey Neu[1,2]
[1]Paul M. Rady University of Colorado, Boulder, [2]University of Colorado, Boulder

1:30PM **Tibial Slope Affects ACL Force and Coupled Internal Tibial Rotation Under A Simulated Clinical Pivot Shift Exam: A Computational Study**
Reza Pourmodheji[1], Mitchell Wheatley[1], Julien Lulec[2], Jacob Hirth[1], Mark Amirtharaj[1], Thomas Wickiewicz[1], Matthieu Olivier[2], Andrew Pearle[1], Danyal Nawabi[1], Carl Imhauser[1]
[1]Hospital for Special Surgery, [2]Aix-Marseille University

1:45PM **Higher Percent Load Through the Intact Meniscus Results in Higher Reduction in Meniscal Loading After Partial Meniscectomy at Heel Strike in Simulated Gait**
Kalle Chastain, Sean Letendre, Heath Gould, Ian Hutchinson, Joshua Wright-Chisem, Arden Wach, Anil Ranawat, Scott Rodeo, Suzanne Maher
Hospital for Special Surgery

2:00PM **Biomechanical Consequences of Ligament Releases During Total Knee Arthroplasty**
Matthew Blomquist, Dylan Schmitz, Joshua Roth
University of Wisconsin-Madison

Friday, June 14	12:45PM–2:15PM CDT

Mechanobiology in Tissue & Cellular Engineering

Session Chairs: **Eno Ebong**, *Northeastern University*
Daniela Valdez-Jasso, *University of California, San Diego*

Maple Lawn B

12:45PM **An Optogenetic Platform for Controlled Release of Nucleocytoplasmic Shuttling Proteins**
Erin Berlew, Paula Camacho Sierra, Joel Boerckel
University of Pennsylvania

1:00PM **TRPV4 Integrates Matrix Mechanosensing to Modulate Calcium Signaling and Mechanobiology in Schlemm'S Canal Cells**
Haiyan Li[1], Seyed Siadat[2], Kristin Perkumas[3], Jacques Bertrand[4], Darryl Overby[4], Todd Sulchek[5], W. Daniel Stamer[3], C.Ross Ethier[1]
[1]Georgia Institute of Technology/Emory University, [2]Northeastern University, [3]Duke University, [4]Imperial College London, [5]Georgia Institute of Technology

1:15PM **Functional Expression of Mechanosensitive Ion Channels in Regenerating Axolotl Limbs**
Vineel Kondiboyina, Melissa Miller, James Monaghan, Sandra Shefelbine
Northeastern University

1:30PM **Pharmaceutical Interrogation of Podocyte Biomechanics Through Kinome Screening**
Jonathan Haydak[1], Anika Hudson[1], Stefanie DeFronzo[2], Yibang Chen[1], Nanditha Anandakrishnan[1], Alan Stern[1], Evren Azeloglu[1]
[1]Icahn School of Medicine at Mount Sinai, [2]Northeastern University

1:45PM **Interaction With Endothelial Cells Induces Vascular Smooth Muscle Cell Orientation Under Wall Shear Stress Condition**
Kaoru Sawasaki[1], Masanori Nakamura[2], Naoyuki Kimura[3], Koji Kawahito[3], Masashi Yamazaki[1], Hiromichi Fujie[1], Naoya Sakamoto[1]
[1]Tokyo Metropolitan University, [2]Nagoya Institute of Technology, [3]Jichi Medical University

2:00PM **Collagen Type-Dependent Extracellular Defect Sensing Driven by Actin Protrusions and Membrane Tension**
Hannah Zmuda, Christopher Walter, Amit Pathak
Washington University in St. Louis

Special Session Honoring Ken Diller

Session Chairs: **Sihong Wang**, *City College of New York*
Chris Rylander, *University of Texas at Austin*

Loramoor A

12:45PM **Thermal Control of Circadian Function for Enhanced Sleep Onset and Blood Pressure Modulation**
Kenneth Diller, Laura Namisnak, Sepideh Khoshnevis
University of Texas

1:00PM **Professor Ken Diller's Impact in Cryobiology and Biomedical Engineering**
Mehmet Toner
Massachusetts General Hospital

1:15PM **Ken Diller and Bioheat Transfer**
John Bischof
University of Minnesota

1:30PM **In Vitro Platforms to Assess the Spatial Response to Burn Injury and Thermoembolization**
S. Brocklehurst, A. Sabaghan, M.N. Rylander
University of Texas, Austin

1:45PM **Rapid Thermal Control of Liquids (RealCooL): Development of a Four-Compartment Transient Heat Transfer Model**
Nadia Hannon, Marissa Rylander, Chris Rylander
University of Texas at Austin

2:00PM **Synergistic Effects of Periodically Mild Hyperthermia and Ultrasound Treatment on Osteogenesis in Aged Human Mesenchymal Stem Cells**
D. Dawkins, Sihong Wong
City College of New York

Friday, June 14	12:45PM–2:15PM CDT

Speech Biomechanics

Session Chairs: **Rana Zakerzadeh**, *Duquesne University*
Byron Erath, *Clarkson University*

Loramoor B

12:45PM **The Influence of Blunt Force Laryngeal Trauma on Phonation: Aerodynamic, Kinematic, and Acoustic Effects**
Md Roknujjaman, Molly E. Stewart, Byron D. Erath
Clarkson University

1:00PM **Insights Into Curved and Incomplete Glottal Closure Patterns: an Euler-Bernoulli Approach**
Mohamed Serry[1], Gabriel Alzamendi[2], Matias Zanartu[3], Sean Peterson[1]
[1]University of Waterloo, [2]CONICET-UNER, [3]Universidad Tecnica Federico Santa Maria

1:15PM **Effect of Type I Thyroplasty Implant Location and Stiffness on Voice Production**
Weili Jiang[1], Mahdi Sangbori[1], Liran Oren[2], Charles de Luzan[2], Ephraim Gutmark[2], Xudong Zheng[1], Qian Xue[1]
[1]Rochester Institute of Technology, [2]University of Cincinnati

1:30PM **Building a Numerical Framework for Energy Budget Analysis of Phonation**
Lucy Zhang
National Science Foundataion

1:45PM **Effects of Semi-Occluded Vocal Tract Exercise on Vocal Fold Biomechanics as Observed During High-Speed Videoendoscopy**
David Ford[1], Dimitar Deliyski[2]
[1]Duquesne University, [2]Michigan State University

2:00PM **Multiphysics Simulation of Flow and Oxygen Transport in a Poroelastic Vocal Fold Model**
Isabella McCollum, Manoela Neves, Rana Zakerzadeh
Duquesne University

Friday, June 14	2:30PM–4:00PM CDT

Biotech and Drug Delivery

Session Chairs: **Marissa Rylander**, *University of Texas at Austin*
Lyle Hood, *University of Texas at San Antonio*

Loramoor A

2:30PM **Evaluation of the Effects of PFAS on Pancreatic Cancer Using A Microfluidic Pancreas Model**
Tarun Singh[1], Sae Choi[1], Barbara Hocevar[2], Lisa Kamendulis[2], Bumsoo Han[1]
[1]Purdue University, [2]Indiana University

2:45PM **Compensating for the Simulated Foreign Body Response to Medical Implants Using Local Fluid Flow**
Lesley Trask[1], Niamh A. Ward[1], Ruth Tarpey[1], Rachel Beatty[1,2], Eimear Wallace[1], Joanne O'Dwyer[1], William Ronan[1], Garry P. Duffy[1,2], Eimear B. Dolan[1]
[1]University of Galway, [2]Trinity College Dublin

3:00PM **A Multiphasic Model for Determination of Mouse Ascending Thoracic Aorta Mass Transport Properties With and Without Aneurysms**
Keshav Kailash, Jessica Wagenseil
Washington University in St. Louis

3:15PM **Pulse-Driven Microfluidic Infusion Pumps With Constant and Heart Rate-Sensitive Flow Rates**
Shuyu Zhang[1], Rafael Davalos[2], Anne Staples[1]
[1]Virginia Tech, [2]Georgia Institute of Technology

3:30PM **Sex Differences in Placenta Villous Structure in Low- and High-Risk Pregnancies**
Adrienne Scott, Patrick Yang, Abigail Arter, Caroline Fosher, Ulugbek Kamilov, Anthony Odibo, Michelle Oyen
Washington University in St. Louis

3:45PM **Characterization of a Polymeric Device for Localized and Controlled Drug Delivery to Cervical Cancer**
Jacob Provencio[1], Monica Elbjorn[1], Paige Phillips[1], David Di Rocco[1], Lyle Hood[1,2]
[1]University of Texas at San Antonio, [2]University of Texas Health Science Center at San Antonio

Friday, June 14	2:30PM–4:00PM CDT

Bone and Cartilage Mechanobiology & Tissue Engineering

Session Chairs: **Alejandro Almarza**, *University of Pittsburgh*
Arun Nair, *University of Arkansas*

Loramoor B

2:30PM **Wnt-11 and SOST Are Regulated by Different Mechanical Stimuli in Loaded Bone**
Meghana Machireddy, Sara Cole, Lucas DeBiase, Jun Li, Glen Niebur
University of Notre Dame

2:45PM **Dynamic Micromechanical Characterization of 3D Printed Bone In Vitro Models Manufactured Via Vat Photopolymerization**
Elizabeth Hunt, Sera Choi, Edward Shangin, Emma Nguyen, Abby Whittington, Caitlyn Collins
Virginia Tech

3:00PM **Magnetic Actuation of Piezo1 Functionalized Superparamagnetic Iron Oxide-Gold Nanoparticles: A Novel Dual Acting Osteogenesis and Anti-Osteopenia Nanomedicine**
Elias Georgas[1], Muzhaozi Yuan[2], Ya Wang[2], Yi-Xian Qin[1]
[1]Stony Brook University, [2]Texas A&M University

3:15PM **Bone Formation Dependance on Microsphere Size in 3D Printed PLGA Microsphere Scaffolds**
Roland Klar, James Cox, Naren Raja, Stefan Lohfeld
University of Missouri-Kansas City

3:30PM **Raman Monitoring of Engineered Cartilage Development Across Different Hydrogel Scaffolds**
Dev Mehrotra[1], Carolina Cordova[1], Erik Ersland[1], Thomas Schaer[2], Mark Grinstaff[1], Brian Snyder[3], Mads Bergholt[4], Michael Albro[1]
[1]Boston University, [2]New Bolton Center, [3]Beth Israel Deaconess Medical Center, [4]King's College London

3:45PM **Investigating Dynamic Loading-Induced Fluid Effects on Bone Cells in 3D**
Kailin Chen[1], Alessandro Maggi[2], Alexander Bolanos-Campos[1], Mistica Perez[1], Michael Abrams[2], Julia Greer[2], Ottman Tertuliano[1]
[1]University of Pennsylvania, [2]California Institute of Technology

Emerging In Vitro, Experimental, and Computational Methods in Fluid Mechanics II

Session Chairs: **Anne Staples**, *Virginia Tech*
Alejandro Roldán-Alzate, *University of Wisconsin-Madison*

Maple Lawn A

2:30PM **Development and Implementation of Novel Framework for Thermofluid Analyses in FEBio**
Raphael Kepecs[1], Steve Maas[2], Jeffrey Weiss[2], Gerard Ateshian[1]
[1]Columbia University, [2]University of Utah

2:45PM **SeqSeg: Automatic Image-Based Vascular Model Construction Using Sequential Segmentations**
Numi Sveinsson Cepero, Shawn C. Shadden
University of California Berkeley

3:00PM **Pre-Surgical Assessments of CSF Flow and Brain Motion Are Indicative of Improved Cerebral Dynamics Following Surgery in Chiari Malformation I**
Grace McIlvain[1], Saeed Mohsenian[2], Mohamad Motaz Al Samman[2], Brice Williams[1], Daniel Barrow[1], Francis Loth[2], John Oshinski[1]
[1]Emory University, [2]Northeastern University

3:15PM **Negative Effort Dependence in Obstructive Sleep Apnea: Insights From a Mathematical Model**
Guilherme Garcia[1,2], B. Tucker Woodson[1]
[1]Medical College of Wisconsin, [2]Marquette University

3:30PM **Temperature Effect on In-Vitro Sinus Flow After Aortic Valve Replacement**
Ahmad Bshennaty[1], Brennan Vogl[1], Agata Sularz[2], Mohamad Alkhouli[2], Hoda Hatoum[1,1]
[1]Michigan Technological University, [2]Mayo Clinic

3:45PM **In Vitro Flow Study of the Penn State Pediatric Total Artificial Heart**
Cody Kubicki[1], Emma Raich[1], Peter Selinsky[1], Sailahari Ponnaluri[1], Steven Deutsch[1], William Weiss[2], Keefe Manning[1,2]
[1]Penn State University, [2]Penn State College of Medicine

Friday, June 14	2:30PM–4:00PM CDT

Emerging Tools for Cell Mechanics

Session Chairs: **Guy Genin**, *Washington University in St. Louis*
Ming Guo, *Massachusetts Institute of Technology*

Maple Lawn C

2:30PM **Myosin-Free Molecular Clutch Model Predicting Myosin-Independent Stiffness Sensing**
Sangyoon Han, Nikhil Mittal
Michigan Technological University

2:45PM **Optimal Design of Experiments for Nuclear Membrane Stiffness Estimation**
Emilio Mendiola[1], Rana Raza Mehdi[1], Jacques Ohayon[2,3], Roderic Pettigrew[1,3], Reza Avazmohammadi[1,3]
[1]Texas A&M University, [2]Savoie Mont-Blanc University, [3]Houston Methodist Research Institute

3:00PM **FRET Measurement of Cellular Tension in Tissues Using Conventional Confocal Microscopy in Newly Established Transgenic Mice Expressing Actinin Tension Sensor**
Takeo Matsumoto[1], Junfeng Wang[1], Eijiro Maeda[1], Yuki Tsujimura[2], Takaya Abe[3], Hiroshi Kiyonari[3], Hideo Yokota[2], Tetsuya Kitaguchi[4]
[1]Nagoya University, [2]RIKEN Center for Advanced Photonics, [3]RIKEN Center for Biosystems Dynamics Research, [4]Tokyo Institute of Technology

3:15PM ***WITHDRAWN*** **Uncovering Electro-Mechano-Physiological Rules of Life: A New 2D/3D All-Optical Interrogation Technology**
Chenyu Liang[1], Erica Hengartner[2], Abygale Cochrane[3], Bruna Balbino de Paula[4], Basak Ayaz[4], Robert Caudle[5], Allison Campbell[6], Eleana Manousiouthakis[6], Christine Schmidt[6], Tian He[7], Christopher Werley[8], Xin Tang[1,6,9]
[1]Mechanical and Aerospace Engineering, University of Florida, [2]Biochemistry, University of Florida, [3]Physics, University of Florida, [4]Neuroscience, University of Florida, [5]Dentistry, University of Florida, [6]University of Florida, [7]BioNTech SE, [8]Vertex Pharmaceuticals, [9]UF Health Cancer Center

3:30PM **Non-Contact Biomechanical Imaging of Cell and Tissue Using Optical Brillouin Microscopy**
Jitao Zhang
Wayne State University

3:45PM **Controlling Cellular Rearrangements in an Epithelial Monolayer Through Micropatterning Techniques**
Molly McCord, Jacob Notbohm
University of Wisconsin - Madison

Friday, June 14	2:30PM–4:00PM CDT

Head & Injury Mechanics II

Session Chairs: **Lyndia Wu**, *University of British Columbia*
Mehmet Kurt, *University of Washington*

Loramoor C

2:30PM **Population-Specific Biomechanical Response of the Brain by Age and Sex**
Ahmed A. Alshareef[1], Aaron Carass[2], Yuan-Chiao Lu[3], Joy Mojumder[4], Ruth J. Okamoto[5], Alexa M. Diano[6], Curtis L. Johnson[6], Dzung L. Pham[3,7], Jerry L. Prince[2], Philip V. Bayly[5]
[1]University of South Carolina, [2]Johns Hopkins University, [3]Henry M. Jackson Foundation, [4]National Institutes of Health (NIH), [5]Washington University in St. Louis, [6]University of Delaware, [7]Uniformed Services University

2:45PM **Sex-Related Variations in Head Impact Kinematics During Controlled Soccer Heading**
Alireza Abbasi Ghiri, Morteza Seidi, Kelly Cheever, Marzieh Memar
University of Texas at San Antonio

3:00PM **A Computational Modeling Approach for the Forensic Analysis of Infant Short Height Falls**
Keith Button, Yun Cai, Luis Nolasco, Brian Weaver
Explico

3:15PM **Detection of Intracranial Cavitation in Polyacrylamide Brain Phantoms Under Blunt Impacts Using Shadowgraph and Acoustic Plane Wave Imaging**
Eric Galindo[1], Ricardo Mejia-Alvarez[2], Michaelann Tartis[1], Adam Willis[2,3]
[1]New Mexico Institute of Mining and Technology, [2]Michigan State University, [3](3) 59th Medical Wing, Office of the Chief Scientist, Lackland AFB

3:30PM **Liver Injuries in Porcine Due to Behind Armor Blunt Trauma**
Parker Berthelson[1], Justin McMahon[1], Alexander Stotka[1], Barney McEntire[2], Robert Salzar[1]
[1]University of Virginia, [2]U.S. Army Aeromedical Laboratory

3:45PM **The Structural and Mechanical Behavior of Skin During Puncture for Different Impactor Sizes and Loading Rates**
Joseph LeSueur[1,2], Carolyn Hampton[3], Jared Koser[1], William Dzwierzynski[1], Michael Kleinberger[3], Frank Pintar[1,2]
[1]Medical College of Wisconsin, [2]Marquette University, [3]Army Research Laboratory

Friday, June 14	2:30PM–4:00PM CDT

Reproductive Biomechanics

Session Chairs: **Matthew Bersi**, *Washington University in St. Louis*
Kyoko Yoshida, *University of Minnesota*

Evergreen I

2:30PM **Impact of Novel Elastomeric Membrane on Vaginal Smooth Muscle Structure and Function**
Sophya Breedlove[1], Gabrielle King[2], Pamela Moalli[1,2], Katrina Knight[1]
[1]University of Pittsburgh, [2]Magee-Womens Research Institute

2:45PM **Evaluating Mechanical Properties and Extracellular Matrix Composition of Anterior and Posterior Murine Vaginal Walls**
Qinhan Zhou[1], Triniti Vanoven[2,3], Maria Florian-Rodriguez[3], Isaac Pence[3,2], Kristin Miller[2,3]
[1]Univerity of Texas at Dallas, [2]University of Texas at Dallas, [3]University of Texas Southwestern Medical Center

3:00PM **Finite Deformations of the Entire Murine Reproductive Tract Under Inflation**
Aileen Suarez[1], Steven Abramowitch[2], Kristin Myers[3], Kristin Miller[4], Raffaella De Vita[1]
[1]Virginia Tech, [2]University of Pittsburgh, [3]Columbia University, [4]University of Texas Dallas

3:15PM **Three-Dimensional Shape Analysis of the Pelvic Floor: Identifying Defects in Cystocele Development**
Liam Martin[1], Alireza Hadizadeh[2], Henry Chill[2], Ghazaleh Rostaminia[2], Steven Abramowitch[1]
[1]University of Pittsburgh, [2]University of Chicago

3:30PM **The Effects of Growth and Remodeling on the Contractile Function of the Pregnant Murine Uterus**
Emily Hoffmann, Kyoko Yoshida
University of Minnesota

3:45PM **A Reactive Viscoelastic Model of the Macaque Rhesus Cervix to Quantify Cervical Remodeling**
Camilo Duarte-Cordon[1], Shuyang Fang[2], Ivan Rosado-Mendez[3], Timothy Hall[3], Helen Feltovich[4], Kristin Myers[2]
[1]New York, [2]Columbia University, [3]University of Wisconsin-Madison, [4]Mount Sinai

Friday, June 14	2:30PM–4:00PM CDT

Vascular Biomechanics & Pathology I

Session Chairs: **Jacopo Ferruzzi**, *University of Texas at Dallas*
Rebecca Vanderpool, *University of Arizona*

Maple Lawn B

2:30PM **Numerical Analysis of Pulmonary Artery Behavior: Investigating the Effects of Wall Complexity, Model Parameters, and Prestrain**
Seda Aslan[1], Tianyi Xu[1], Enze Chen[1], Miya Mese-Jones[2], Xiaolong Liu[3], Bryan Gonzalez[4], Ryan O'Hara[4], Yue-Hin Loke[4], Narutoshi Hibino[5], Laura Olivieri[6], Axel Krieger[1], Thao Nguyen[1]
[1]Johns Hopkins University, [2]Baltimore Polytechnic Institute, [3]Texas Tech University, [4]Children's National Hospital, [5]University of Chicago, [6]University of Pittsburgh Medical Center

2:45PM **Comparing Regional Variations in Radiodensity With Stiffness in an Atherosclerotic Human Aorta**
Carly Donahue, Victor Barocas
University of Minnesota

3:00PM **Alterations of the Mechanical and Failure Properties of Aging Human Descending Thoracic Aorta With Type-II Diabetes**
Ruizhi Wang, Katherine Zhang
Boston University

3:15PM **A Sex-Based Biomechanical Analysis and Normalization for Improved Prediction of Abdominal Aortic Aneurysm Rupture**
Katherine Kerr[1], Pete Gueldner[1], Indrani Sen[2], Tiziano Tallarita[2], Joseph Wildenberg[2], Nathan Liang[3], David Vorp[1], Timothy Chung[1]
[1]University of Pittsburgh, [2]Mayo Clinic Health Systems, [3]University of Pittsburgh Medical Center

3:30PM **Impact of Elastin Fragmentation on the Mechanical Dissection Properties of the Human Descending Thoracic Aorta**
Ramin Shahbad, Majid Jadidi, Sayed Ahmadreza Razian, Anastasia Desyatova
University of Nebraska Omaha

3:45PM **The Stiffness of False Lumen Wall Increased in Chronic Type B Aortic Dissection Vs. Normal Tissue Based on the Unified-Fiber-Distribution (UFD) Model**
Hai Dong[1,2], Minliang Liu[3,2], Hannah Cebull[1], Marina Piccinelli[1], John Oshinski[1], John Elefteriades[4], Rudolph Gleason[2], Bradley Leshnower[1]
[1]Emory University, [2]Georgia Institute of Technology, [3]Texas Tech University, [4]Yale University

Friday, June 14	4:15PM–5:45PM CDT

Cell-Microstructure Interactions in Cardiovascular Mechanics

Session Chairs: **Chiara Bellini**, *Northeastern University*
Matthew Bersi, *Washington University in St. Louis*

Evergreen I

4:15PM **Cellular Micro-Biaxial Stretching for Characterizing Stress-Strain Relations for Single Cardiomyocytes Exposed to Complex Deformations**
Taylor Rothermel[1], Anna Grosberg[2], Patrick Alford[1]
[1]University of Minnesota, [2]University of California, Irvine

4:30PM **Mechanical Characterization of Calcified Clot Analogs**
Jose Jose Monclova[1], Daniel Walsh[1], Vikas Kannojiya[1], Scott Simon[2], Francesco Costanzo[1,1], Keefe Manning[1,2]
[1]Pennsylvania State University, [2]Penn State Hershey Medical Center

4:45PM **Adipose-Driven Hypertension Impacts 3rd Order Mesenteric Artery Contractile Behavior in a Sex-Dependent Manner**
Dillon McClintock, Osvaldo Vega Rodríguez, Nathan Tykocki, Sara Roccabianca
Michigan State University

5:00PM **Mechanical Heterogeneity in Human Cerebral Aneurysms: Exploring the Role of Tissue Microstructure and Inflammation**
Sergio A. Pineda-Castillo, Elizabeth D. Shih, Andrew W. Grande, Patrick W. Alford
University of Minnesota

5:15PM **Effects of Mechanical Dyssynchrony on Myocardial Contractility**
Lei Fan[1], Jenny Choy[2], Chenghan Cai[1], Ghassan Kassab[2], Lik Chuan Lee[3]
[1]Marquette University and Medical College of Wisconsin, [2]California Medical Innovations Institute, [3]Michigan State University

5:30PM **Smooth Muscle Cell Mechanoadaptation Is Chronically Disrupted by High-Velocity Stretching**
Samuel Boland, Patrick Alford
University of Minnesota

Friday, June 14	4:15PM–5:45PM CDT

Emerging Topics in Extracellular Matrix Adaption, Alterations, and Therapy in Soft Tissue Mechanics

Session Chairs: **Michelle Oyen**, *Washington University in St. Louis*
Xun Wang, *Massachusetts Institute of Technology*

Maple Lawn C

4:15PM ***WITHDRAWN***

Evidence of Highly Localized Mechanical Adaptation in the Lamina Cribrosa: Within Beam Regional Variations in Collagen Crimp and Stretch-Induced Uncrimping

Qi Tian, Po-Yi Lee, Juana Yang, Ian Sigal

[1]*University of Pittsburgh*

4:30PM

Differentiating Between the Effect of Damage to Tenocytes and Extracellular Matrix Using Precise Laser Ablation

Diane Stonestreet[1], Robert Hawkins[1], Nozomi Nishimura[1], Nelly Andarawis-Puri[1,2]

[1]*Cornell University,* [2]*Hospital for Special Surgery*

4:45PM

Photosensitizer-Mediated Low-Level Light Exposure Alters the Stiffness of Nonpregnant and Pregnant Human Cervix Tissue

Daniella Fodera[1], Jiashuai Fan[1], Aidan Therien[1], Serena Russell[1], Christine Hendon[1], Joy Vink[2], Kristin Myers[1]

[1]*Columbia University,* [2]*University of Hawaii*

5:00PM

Impact of GAGs Removal and CXL Therapy on Corneal Stromal Properties

Hamed Hatami-Marbini, M.E Emu

University of Illinois Chicago

5:15PM

Exploring the Possible Relationship Between Lost Elastin Integrity and Glycosaminoglycan Buildup in Elastic Arteries Using Computational Modelling

Yousof Abdel-Raouf[1], Lauranne Maes[2], Mathias Peirlinck[3], Nele Famaey[2], Patrick Sips[1], Julie De Backer[1,4], Patrick Segers[1], Jay Humphrey[5,6]

[1]*Ghent University,* [2]*KU Leuven,* [3]*Delft University of Technology,* [4]*Ghent University Hospital,* [5]*Yale University,* [6]*Yale School of Medicine*

5:30PM

The Influence of Pectinate Ligaments on the Patency of the Murine Aqueous Humor Outflow Pathway: a Finite Element Study

Babak N. Safa[1,2], Nina Sara Fraticelli Guzmán[1,2], Guorong Li[3], W. Daniel Stamer[3], Andrew J. Feola[1,2,4], C. Ross Ethier[1,2]

[1]*Georgia Institute of Technology,* [2]*Emory University,* [3]*Duke University,* [4]*Atlanta VA Center for Visual and Noncognitive Rehabilitation*

Engineering Tissue Regeneration and Wound Healing

Session Chairs: **Kristan Worthington**, *University of Iowa*
Kyoko Yoshida, *University of Minnesota*

Loramoor B

4:15PM **The Effects of Preeclamptic Milieu on Cord Blood Derived Endothelial Colony-Forming Cells**
Eva Hall[1], Laura Alderfer[1], Sanjoy Saha[1], Ellie Johandes[1], Laura Haneline[2], Donny Hanjaya-Putra[1]
[1]University of Notre Dame, [2]Indiana University School of Medicine

4:30PM **Injectable Synthetic Platelet-Based Therapy Enhances Clot Formation in Synovial Fluid Joint Injury Model**
Melika Osareh, Grant Scull, Jacob D. Thompson, Ashley C. Brown, Matthew B. Fisher
North Carolina State University and University of North Carolina at Chapel Hill

4:45PM **Can Pattern Recognition Receptor Agonists Modulate Tendon Healing In Vitro?**
Sam Winston, Amelia Stoner, Jade Kurihara, Lyndah Chow, Lynn Pezzanite, Steven Dow, Kirk McGilvray
Colorado State University

5:00PM **IL-1β Increases Mitochondrial Transfer From Mesenchymal Stromal Cells to Annulus Fibrosus Cells**
Ashley Cardenas, Lawrence Bonassar
Cornell University

5:15PM **Optimization of iPSC Differentiation to Lymphatic Endothelial Cells Through Metabolites and Machine Learning**
Donghyun Jeong, Sanjoy Saha, Maksym Zarodniuk, Donny Hanjaya-Putra
University of Notre Dame

5:30PM **Fibroblast-Adipocyte Interactions Alter Extracellular Matrix Production**
Ed Sander[1], Mariam El-Hattab[1], Kathryn Jacobson[2]
[1]University of Iowa, [2]University of Colorado

Friday, June 14	4:15PM–5:45PM CDT

Head & Injury Mechanics III

Session Chairs: **John Finan**, *University of Illinois at Chicago*
Corinne Henak, *University of Wisconsin-Madison*

Loramoor C

4:15PM **Mechanical Covariance Networks of the Cortex Regions as Identified by Magnetic Resonance Elastography**
Kyra Twohy, Alexa Diano, Olivia Bailey, Mary Kramer, Curtis Johnson
University of Delaware

4:30PM **Effect of Cortical Folds on Head Acceleration-Induced Brain Deformation: A Computational Study**
Anu Tripathi[1], Jose Gonzalez[2], Peter Ferrazzano[2], Christian Franck[2], Rika Carlsen[1]
[1]Robert Morris University, [2]University of Wisconsin Madison

4:45PM **Regional Correlation of Stiffness and Perfusion in the Human Brain at 7T MRI Through MR Elastography and Arterial Spin Labeling Techniques**
Caitlin Neher, Em Triolo, Mehmet Kurt
University of Washington

5:00PM **Incremental Overstretch Increases Failure Values of Cerebral Blood Vessels**
Farshid Shojaeianforoud, Brittany Coats, Ken Monson
University of Utah

5:15PM **Microstructural Damage Progression in the Pia-Arachnoid Complex**
Leonardo Marin, Tim Dixon, Brittany Coats
University of Utah

5:30PM **Novel MRI Phantoms for Investigating Skull-Brain Mechanics Using Magnetic Resonance Elastography**
Joy Mojumder[1], Suhas Vidhate[2], Yuan-Chiao Lu[1,3], Alexa Diano[4], Ahmed Alshareef[5], Curtis Johnson[4], Michaelann Tartis[6], John Butman[1], Dzung Pham[1,7]
[1]National Institutes of Health, [2]Intuitive Surgical Inc, [3]The Henry M. Jackson Foundation, [4]University of Delaware, [5]University of South Carolina, [6]New Mexico Institute of Mining and Technology, [7]Uniformed Services University

Friday, June 14	4:15PM–5:45PM CDT

Heart Valve and Ventricular Fluid Mechanics

Session Chairs: Hoda Hatoum, *Michigan Technological University* **Maple Lawn A**
John LaDisa, *Marquette University and the Medical College of Wisconsin*

4:15PM **Post-Transcatheter Edge-to-Edge Repair Pressure Gradient Prediction After Mitraclip in Functional Mitral Regurgitation Patients**
Shelley Gooden[1], Mani Vannan[2], Konstantinos Boudoulas[3], Vinod Thourani[2], Pradeep Yadav[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Piedmont Heart Institute, [3]Wexner Medical Center

4:30PM **Computational Construction and Optimization of A Novel Tri-Tube Heart Valve Design**
Jirong Li, Yijiang Yu, Robert Tranquillo
University of Minnesota, Twin Cities

4:45PM **Patient-Specific Fluid-Structure Interaction Simulations of Young Bicuspid Aortic Valve Patients**
Hail Kazik[1,2], Harkamaljot Kandail[3], Joy Lincoln[1,4], John LaDisa[1,2,4]
[1]Medical College of Wisconsin, [2]Marquette University, [3]Medtronic Neurovascular, [4]Children's Wisconsin

5:00PM **Intraventricular Fluid Dynamics Study Using an In VitroModel of Mitral Valve Regurgitation and Edge-to-Edge Therapy**
Cody Kubicki[1], Michael Sacks[2], Keefe Manning[1,3]
[1]Pennsylvania State University, [2]University of Texas, [3]Penn State College of Medicine

5:15PM **Analysis of Energy and Pressure in the Sinus Under Different Blood Pressures After Aortic Valve Replacement**
Brennan Vogl[1], Agata Sularz[2], Scott Lilly[3], Vinod Thourani[4], Mohamad Alkhouli[2], Hoda Hatoum[1]
[1]Michigan Technological University, [2]Mayo Clinic, [3]Ohio State University, [4]Piedmont Heart Institute

5:30PM **Effect of Patient-Specific Ascending Aortic Curvature on Flow in the Vicinity of TAVR**
Jae Hyun Kim[1], Vahid Sadri[1], Huang Chen[1], Sanchita Bhat[1], Keshav Kohli[1], Raj Makkar[2], Vasilis Babaliaros[3], Rahul Sharma[4], Ajit Yoganathan[1]
[1]Georgia Institute of Technology, [2]Smidt Heart Institute, [3]Emory University Hospital, [4]Stanford University

Nanotechnology and Microfluidics

Session Chairs: **Jing Fan**, *City College of New York*
Khalil Khanafer, *University of Michigan*

Loramoor A

4:15PM **On the Margination of White Blood Cells**
Tam Nguyen, Trung Le
North Dakota State University

4:30PM **Development of a Microfluidic Dual-Gel Cell Culture Model**
Malgorzata Dwulat, Sihong Wang, Jing Fan
City College of New York

4:45PM **Design of a µ-Fluidic Chip for in Situ Quantification of Traumatic Brain Injury Biomarker Release**
Mauricio Araiza Canizales[1], Alexander McGhee[2], Rafael González-Cruz[3], Diane Hoffman-Kim[3], Christian Franck[1]
[1]University of Wisconsin-Madison, [2]University of Arizona, [3]Brown University

5:00PM **Prototyping of a Microfluidic Mechanochemical Gradient Chip by 3D Printed Molding for In Vitro Drug Testing**
Milad Fathi, Ali Mehrasa, Altuğ Özçelikkale
Middle East Technical University

5:15PM **Enhancing the Target Efficacy of Endothelial Colony Forming Cells for Renal Regeneration Via Kidney-Targeted Liposomal Nanoparticles**
Brenda Cruz Gonzalez[1], Fei Fan[2], Eva Hall[1], Sanjoy Saha[1]
[1]University of Notre Dame, [2]Michigan State University

5:30PM **Radiofrequency Ablation Facilitated by Microchannel Jetting**
Bo Cao, Hongying Wang, Ruizhe Hou, Shiqing Zhao, Aili Zhang
Shanghai Jiao Tong University

Friday, June 14	4:15PM–5:45PM CDT

Vascular Biomechanics & Pathology II

Session Chairs: **Abhay Ramachandra**, *Iowa State University* **Maple Lawn B**
Luke Timmins, *Texas A&M University*

4:15PM **Relation Between Cyclic Convection Fluid Filtration (CCFF) and Atherosclerosis**
Bruce Simon[1], Paul Rigby[2], Paul Howard[3], Jonathan Vande Geest[4]
[1]University of Arizona, [2]Raytheon Technologies, [3]Midwest Cardiovascular Specialists Indiana University, [4]University of Pittsburgh

4:30PM **Differential Effects of Hypertension on the Morphological, Mechanical, and Physiologic Characteristics of Male and Female Human Femoropopliteal Arteries**
Sayed Ahmadreza Razian, Majid Jadidi, Alexey Kamenskiy
University of Nebraska at Omaha

4:45PM **Effects of the Loading Rate on the Mechanical Behavior of Proximal Superficial Femoral Artery**
Ali Zolfaghari Sichani, Majid Jadidi
University of Nebraska at Omaha

5:00PM **Age and Sex Specific Biomechanics and Extracellular Matrix Remodeling of the Ascending Aorta in A Mouse Model of Marfan Syndrome**
Krashn Dwivedi, Jacob Rother, Jessica E. Wagenseil
Washington University in St. Louis

5:15PM **Effect of Collagen Accumulation on Right Ventricular Passive Viscoelasticity With Pulmonary Hypertension Development**
Yuecheng Wang, Kristen LeBar, Zhijie Wang
Colorado State University

5:30PM **Accelerated Stent Deployment Simulations Via Model Order Reduction for Predictive Modeling of Transcatheter Aortic Valve Replacement**
Imran Shah[1,2], Sri Krishna Sivakumar[1], Francesco Ballarin[3], Vinod Thourani[4], Alessandro Veneziani[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Emory University, [3]Università Cattolica del Sacro Cuore, [4]Piedmont Heart Institute

Poster Sessions

Posters will be presented in two sessions as listed below. See the Instructions for Poster Presenters section on page 8 for additional information. All poster sessions will take place in the **Forum** exhibition hall.

Poster Session I	**Wednesday, June 12, 1:00 - 2:30 PM CDT**
Poster Session II	**Thursday, June 13, 12:30 - 2:00 PM CDT**

Poster Session I

BS SPC: Experimental Methods in Biomechanics and Mechanobiology

P1 **Building ASGR1-Overexpressed Fluorescent Reporter Cell Model for Optimization of CRISPR Delivery**
Yun-I Sang, Morgan Clay, Chun-Wei Chi, Yeh-Hsing Lao
University at Buffalo

P2 **Impact of a Cognitive Dual Task on Older Adult Motor Performance and Strategies**
Erin Kreis, Mitchell Tillman, Jun Liu, Zahava Hirsch, Antonia Zaferiou
Stevens Institute of Technology

P3 **Measuring Limb Loads Using A Novel Prosthetic Pylon Force Sensor**
Hanna Armstrong, Kaleb Burch, Amit Chaudhari, Sagar Doshi, Erik Thostenson, Jill Higginson
University of Delaware

P4 **Comprehensive Assessment of Community Mobility and Participation of Wheelchair Users Using Wearables.**
Madisyn R. Adelman[1], Maja Goršič[1,2], Grace Fasipe[1], Jacob R. Rammer[1]
[1]University of Wisconsin-Milwaukee, [2]Marquette University

P5 **Collaborative Pathways: Empowering Pregnant and Parenting Teens Through STEM Engagement**
Oluwatomisin Ajayi[1], Emily Hoffmann[1], Paige Nielsen[1], Lauren Tolbert[2], Kyoko Yoshida[1]
[1]University of Minnesota, [2]Longfellow Alternative High School

P6 **Development of a Benchtop Model for Cerebral Collateral Circulation**
Argudit Chauhan, Alena Tucker, Debanjan Mukherjee
University of Colorado Boulder

P7 **Full-Field Comparison of Porcine Pulmonary and Aortic Valve Leaflet Collagenous Architecture Using Quantitative Polarized Light Imaging**
Shreya Sreedhar, Daniel Pearce, Connor Link, Colleen Witzenburg
University of Wisconsin-Madison

P8 **Mechanical and Damage Properties of Preterm and Adult Sheep Middle Cerebral Arteries Following Mechanical Damage**
Kerrigan Denham, Joseph Bail, Andrew Rebentisch, Kurt Albertine, Kenneth Monson
University of Utah

P9 **In Vitro Stretch Injury Affects Mitochondrial Membrane Potential, Calcium Concentration, and Nuclear Morphology in Rat Astrocytes**
Citlally Santacruz, Shahrzad Shiravi, Alexandra Yufa, John Finan
University of Illinois Chicago

P10 **Design and Optimization of a 3D-Printed Testing Platform for Evaluating the Effects of Voluntary Wheel Running on the Biomechanical Properties of Murine Achilles Tendons**
Elsa Lecaj, Samantha Muscat, Nolan Sparks, Mark Buckley, Anne Nichols
University of Rochester

P11 **Regional Mechanical Properties on the Macroscale and Microscale Are Not Associated for the Equine Superficial Digital Flexor Tendon**
Samantha Watson[1], Zachary Davis[1,2], Shannon Connard[2], Lauren Schnabel[2], Matthew Fisher[1,2,3]
[1]NC State and UNC Chapel Hill, [2]North Carolina State University, [3]University of North Carolina - Chapel Hill

P12 **Effect of Intermolecular Crosslinking on the Multiscale Mechanical Behavior of Tendons**
Madeline Wagner[1], Rachel Klink[1], Steven Eppell[2], Allen Lin[3], Jeffrey Weiss[1]
[1]University of Utah, [2]Case Western Reserve University, [3]Revvity

P13 **Mechanical Response to Compression of the Pig Optic Nerve**
Katherine Metrey, Arina Korneva
Virginia Tech

P14 **Combined Effects of Proteoglycan and Collagen on the Lubrication Properties of a Polyvinyl Alcohol Hydrogel**
Monika Maeda, Heitaro Chiba, Hiromichi Fujie
Tokyo Metropolitan University

P15 **Controlling Neural Culture Density and Orientation for Enhanced Analysis of Traumatic Brain Injury Electrophysiology**
Griffin Radtke, Jamie Sergay, Jessica Park, Jing Zhang, Christian Franck
University of Wisconsin-Madison

P16 **Investigating the Effects of Surface Stiffness and Viscoelasticity on Human Mesenchymal Stem Cell Immunomodulation**
Sara Olsen, Rose Leader, Bethany Almeida
Clarkson University

P17 **Effects of Detrusor Contraction on Urinary Bladder Extracellular Matrix Organization**
Daniel Deuel[1,2], Tyler Tuttle[3], Sara Roccabianca[4], Sarah Calve[3]
[1]University of Colorado, Boulder, [2]University of Colorado Boulder, [3]Paul M. Rady University of Colorado Boulder, [4]Michigan State University

P18 **Biomedical Applications of Novel Magnetostrictive Composite**
Aaron Brandner[1], Chui Law[2], Rani Elhajjar[2], Priyatha Premnath[2]
[1]University of Wisconsin-Madison, [2]University of Wisconsin-Milwaukee

P19 **Compliance Matching A Polyurethane and PLCL Biohybrid Tissue Engineered Vascular Graft**
Trin Murphy[1,2], David Maestas[1,2], Katarina Martinet[1,2], William Wagner[1,2], Sang-Ho Ye[1,2], Jonathan Vande Geest[1,2,3]
[1]University of Pittsburgh, [2]McGowan Institute for Regenerative Medicine, [3]Vascular Medicine Insitute

BS SPC: Image-Based Measurement, Analysis, and Modeling

P20 **Kinematic Sensitivity Study of Total Knee Replacement FEA Model to Ligament Attachment Site**
Elizabeth Wynn[1,2], Takayuki Koya[1,3], Markus Wimmer[1], Hannah Lundberg[1], Steven Mell[1]
[1]Rush University, [2]University of Illinois at Chicago, [3]Showa University Koto Toyosu Hospital

P21 **VIGOR4D: Vascular Idealized Geometry Open-Source Repository for 4D Flow MRI Denoising and Super-Resolution**
Moses Hamm, Neal Patel, Vitaliy Rayz
Purdue University

P22 **A Machine Learning Approach to Mining Hemodynamics Data From Pulmonary Arterial Hypertension Rats**
Jingwen Hui, Ethan Kwan, Daniela Valdez-Jasso
University of California, San Diego

P23 **4D Flow MRI Reveals That Carotid Artery Bifurcation Geometry Impacts Hemodynamics Associated With Atherosclerosis**
Carissa Lucas[1], Brennen Anderson[2], Retta El Sayed[1,3], Jason Allen[3,4], John Oshinski[1,3]
[1]Georgia Institute of Technology, [2]Augusta University, [3]Emory University, [4]Indiana University

P24 **Advancing Cardiac Metrics: Computational CMR Methods for Ejection Fraction Evaluation**
Ella Lyon[1,2], Ilham Essafri[2], Mengqian Zhang[2], Melissa Lucero[2], Kenzo Ichimura[3], Kurt Stenmark[2], Edda Spiekerkoetter[3], Vitaly Kheyfets[2]
[1]Colorado School of Mines, [2]University of Colorado Anschutz Medical Campus, [3]Stanford University

P25 **Comparative Study of Image-Based Modeling Using a Novel Medical-Image-to-Reduced-Order-Simulation Framework**
Boyang Gan, Numi Sveinsson, Shawn Shadden
University of California, Berkeley

P26 **Multimodal Study of Ischemic Cardiac Remodeling: Murine 4D Ultrasound and Mass Spectrometry Imaging**

WITHDRAWN

Amelya Fox[1], Luke Schepers[2], Conner Earl[2], Craig Goergen[2], Colleen Crouch[1]
[1]University of Tennessee, Knoxville, [2]Purdue University

P27 **MRI-Based Measurements of Strain in the Aorta: Does Cardiac Disease Impact Aortic Deformation?**

Petra Alsahwi, Alice Guest, Rylan Marianchuk, Dina Labib, James White, Elena Di Martino
University of Calgary

P28 **Personalized Finite Element Models of Tissue Expansion for Breast Reconstruction After Mastectomy**

Joel Laudo[1], Tianhong Han[1], Ariel Figueroa Baker[2], Arun Gosain[2], Taeksang Lee[3], Adrian Buganza Tepole[1]
[1]Purdue University, [2]Northwestern University, [3]Myongji University

P29 **Development of Tailored Finite Element Head Models for Free Vibrational Analysis Across Subject Specific Geometry**

Diego Acosta, Turner Jennings, Sinan Müftü, Rouzbeh Amini
Northeastern University

P30 **Optimization of Objective Measurements for Evaluating Sagittal Synostosis Detection and Treatment Efficacy**

Tim Dixon[1], Jason Ramsey[2], Philip Stevens[2], Brittany Coats[1]
[1]University of Utah, [2]Hanger Clinic

P31 **Toward the Detection of Cerebral Vessel Softening Using Magnetic Resonance Elastography**

Lucas Bolster, Henrik Odeen, Allison Payne, Ken Monson
University of Utah

P32 **A Framework for Slice-Wise Motion Correction in Magnetic Resonance Elastography of the Human Brain**

Tyson Lam, Emily Triolo, Mehmet Kurt
University of Washington

P33 **Sensitivity of Contact Mechanics to FE Model Generation Decisions Compared to Variations Between Knees and Due to Partial Meniscectomy**

Joshua Leadem
University of Rochester

P34 **3D Geometric Reconstruction of Electrospun Fibers**

Evan He, Shruti Motiwale, Elizabeth Cosgriff-Hernandez, Michael Sacks
University of Texas at Austin

P35 Sex Differences in Iris Stiffness With a History of Angle-Closure Glaucoma: An In-Vivo Image-Based Inverse Modeling Analysis
Hayden DelCiello[1], Frederick Sebastian[2], Anup Pant[3], Vanita Pathak-Ray[4], Syril Dorairaj[5], Rouzbeh Amini[2,2]
[1]Khoury Northeastern University, [2]Northeastern University, [3]University of Akron, [4]LV Prasad Eye Institute, [5]Mayo Clinic

P36 In-Silico Models of In-Vivo Cervical Stiffness Measurements for Improving Preterm Birth Prediction
Adriana Delagarza[1], Erin Louwagie[1], Abigail Laughlin[1], Jacqueline Hairston[1], Mirella Mourad[1], Michael House[2], Kristin Myers[1]
[1]Columbia University, [2]Tufts University

P37 Development of In-Silico Model of Cancerous Tissue
Nathanael Sovitzky
University of Wisconsin-Milwaukee

P38 Assessment of a Tumor's Malignancy Using In Silico Model of Breast Tumor Tissue
Hannah Vincent[1], Morgan Connaughton[1], Kianoush Falahkheirkhah[2], Erik Robert Hansen[1], Rohit Bhargava[2], Mahsa Dabagh[1]
[1]University of Wisconsin Milwaukee, [2]University of Illinois at Urbana-Champaign

Design, Dynamics, Rehabilitation, and Regulations

P80 Exploration of the Full-Field Biomechanics of the Human Spine
Emma C. Coltoff, Benjamin S. Hezrony, Philip J. Brown
Wake Forest School of Medicine

P81 Comparison of OpenSim and AnyBody Modeling System Predictions in Biomechanical Modeling of Upper Extremities
kamal Gautam, Mohamed Samir Hefzy, Abdul A Mustapha, Behrens Kyle
University of Toledo

P82 Stability of the C2-C3/C3-C4 Level During C4-C6 Laminoplasty With and Without C3 Laminectomy in Cadaveric Biomechanical Models
John Francis[1], Jeremy Loss[2], Derrick Obiri-Yeboah[3], Orlando Martinez[1], Bilal Butt[2], Michael Steinmetz[2]
[1]Case Western Reserve University School of Medicine, [2]Cleveland Clinic Foundation, [3]Cleveland Clinic Lerner College of Medicine

P83 Evaluating the Performance of Extended Kalman Filter Vs. Unscented Kalman Filter for Displacement Estimation
Nafiseh Mohammadianaftah[1], Sara Wilson[1], Neena Sharma[2]
[1]University of Kansas, [2]University of Kansas Medical Center

P84 Novel Stent Design and Prototyping Method
Kaitlyn Elmer[1], Barry Uretsky[2], Adib Chaus[3], Morten Jensen[1]
[1]University of Arkansas, [2]University of Arkansas for Medical Sciences, [3]Lutheran General Hospital

P85 In Vitro Clot Trapping Efficiency of the FDA Generic Inferior Vena Cava Filter in the Supine Position
Ian Goetz[1], Ryan Frasca[1], Garrett Campbell[1], Terrell Barraclough[1], Kenneth Aycock[2], Brent Craven[2], Keefe Manning[1,3]
[1]Pennsylvania State University, [2]US Food and Drug Administration, [3]Penn State College of Medicine

P86 Bubbler System Design for Removal of Oxygen From Media in an Open Testing Environment
Margaret Capalbo, Spencer Szczesny
Pennsylvania State University

P87 Uncovering Electro-Mechano-Physiological Rules of Life: A New 2D/3D All-Optical Interrogation Technology
Chenyu Liang[1], Erica Hengartner[1], Abygale Cochrane[1], Bruna Balbino de Paula[1], Basak Ayaz[1], Robert Caudle[1], Allison Campbell[1], Eleana Manousiouthakis[1], Christine Schmidt[1], Tian He[2], Christopher Werley[3], Xin Tang[1]
[1]University of Florida, [2]Harvard University, [3]Q-State Biosciences

P88 Ocular Hypothermia, In-Vitro Validation of A Novel Therapeutic Apparatus Using Non Perfused Porcine Eye Model
Luigi Mecacci, Yukinari Nakamura, John R. Hetling
University of Illinois at Chicago

P89 The Pomelo Peel as Impact Protection From Fall-Related Femur Fracture: Mechanical and Biological Property Investigation
Stacey Zeigler, Benjamin Ellis, Daniel Fuller, Laurel Kuxhaus
Clarkson University

P90 Validation of FEA Models for Design of Engineered Foam for Scoliotic Braces
Robert Rizza[1], Xue-Cheng Liu[2], Vince Anewenter[1]
[1]Milwaukee School of Engineering, [2]medical College of Wisconsin

Fluid Mechanics

P91 Geometry and Physics-Informed Neural Network Modeling of Flows Inside Y-Shaped Bifurcated Ducts
Abdullahi Olapojoye, Fatemeh Hassanipour
University of Texas at Dallas

P92 Enhancing Predictive Accuracy in Cerebral Aneurysm Hemodynamics: Insights From Machine-Learning Evaluation and Parameter Influence Analysis
Narges Kamaei Asl[1], Mahkame Sharbatdar[2]
[1]University of Tehran, [2]K. N. Toosi University of Technology

P93 Automatic Segmentation of Abdominal Aortic Aneurysm From Computed Tomography Angiography Using A Patch-Based Dilated U-Net Model
Merjulah Roby[1], Juan Restrepo[1], Haehwan Park[1], Satish Muluk[2], Mark Eskandari[3], Ender Finol[1]
[1]University of Texas at San Antonio, [2]Allegheny Health Network, [3]Northwestern University School of Medicine

P94 Experimental Evaluation of the 'Plunger Technique' for Manual Cyclic Aspiration Treatment of Acute Ischemic Stroke
Demitria Poulos[1], James Keith[1], Michael Froehler[2], Bryan Good[1]
[1]University of Tennessee, [2]Vanderbilt University Medical Center

P95 Impact of Particle Seeding on the Rheological Characteristics of Blood Analog Fluid Used in Laser Doppler Velocimetry
Shreyash M Manegaonkar[1], Israel Ajiboye[1], Gavin A. D'Souza[2], Rupak K Banerjee[1]
[1]University of Cincinnati, [2]US Food and Drug Administration

P96 Clinical Validation of the PSCOPE Hybrid Framework for Cardiovascular Predictive Modeling
Abraham Umo[1], Brett Welch[2], Armand Kilic[2], Ethan Kung[1]
[1]Clemson University, [2]Medical University of South Carolina

P97 A 3D Tissue Model of the Endothelial Glycocalyx Post-Pneumonectomy
Camden Holm, Jacob Elliot, Mia Long, Solomon Mensah
Worcester Polytechnic Institute

P98 A Computational Model to Simulate the Roughness of Narrowed Coronary and Cerebral Arteries in Diabetes Mellitus Patients and to Design Effective Treatment Strategies
Senol Piskin
Istinye University

P99 A Simple Model of Angiotensin Converting Enzyme Hub Capacity on Peptide Flux and Renin Influence
Brian Westwood, Mark Chappell
Wake Forest School of Medicine

P100 Comparison of Lumped, Distributive and 1D Navier-Stokes Model of Coronary Blood Flow
Chenghan Cai[1], Lik Chuan Lee[2], Lei Fan[3]
[1]Medical College of Wisconsin, [2]Michigan State University, [3]Marquette University

P101 Development and Application of On-Site Velocity Boundary
Reza Bozorgpour, Mahsa Dabaghmeshin
University of Wisconsin-Milwaukee

P102 Numerical Simulation of Multi-Frequency Ventilation Within the Central Airways of a Porcine Lung
Bing Han[1,2], Emmanuel A. Akor[3], Mingchao Cai[4], David W. Kaczka[2,3,2]
[1]University of North Carolina, Chapel Hill and Morgan State University, [2]University of Iowa, [3]Roy J. Carver University of Iowa, [4]University of North Carolina, Chapel Hill, Morgan State University

P103 Modeling Heat Sink Effects of Cerebrospinal Fluid (CSF) During Thermal Therapies for Treatment of Glioblastoma (GBM)
Yash Lad, Omar Abdulqader, Shreeniket Pawar, Anilchandra Attaluri
Pennsylvania State University

P104 Proportional Integral Derivative (PID) Controller Applied to Magnetic Nanoparticle Hyperthermia Therapy (MNHT)
Nageshwar Arepally, Yash Lad, Shreeniket Pawar, Ma'Moun Abu-Ayyad, Anilchandra Attaluri
Pennsylvania State University

P105 Heat Sink Effects of Large Blood Vessel During Thermal Therapies
Shreeniket Pawar, Naveen Kondreddy, Yash Lad, Anilchandra Attaluri
Pennsylvania State University Harrisburg

P106 Computational Analysis of Stroke Risk During Cardiopulmonary Bypass in Adult and Pediatric Anatomies
Nafis Arefin, Bryan Good
University of Tennessee

P107 Flow Dynamic Factors Correlated With Device-Related Thrombosis After Left Atrial Appendage Occlusion
Brennan Vogl[1], Agata Sularz[2], Alessandra Bavo[3], Matthieu De Beule[3], Jens Erik Nielsen-Kudsk[4], Ole De Backer[5], Mohamad Alkhouli[2], Hoda Hatoum[1]
[1]Michigan Technological University, [2]Mayo Clinic, [3]FEops, [4]Aarhus University Hospital, [5]Copenhagen Univerrsity Hospital

P108 Computational Modeling of Carotid Artery Stenosis and Fibromuscular Dysplasia for Prediction of Biomechanical Platelet Activation
J. Scott Malloy[1], Suman Guntupalli[2], Scott Cameron[2], Vitaliy Rayz[1]
[1]Purdue University, [2]Cleveland Clinic

P109 Flexible Rotor Blades in LVADs: Investigating Implications for Hemocompatibility
Shweta Karnik, Shobana Santhanam, Charles Federico, Huang Chen, Lakshmi Prasad Dasi
Georgia Institute of Technology

P110 Simulation of the Viscoelasticity of Clots Considering Red Blood Cells and Fibrin Network
Ryan Mueller, Jifu Tan
Northern Illinois University

P111 Hemodynamic Evaluation of the Sensitivity of Graft Morphology on Direct Vascular Surgery for Moyamoya Disease: An In Vitro and In Silico Study
Cheng Peng[1], Ephraim Church[2], Melissa Brindise[1]
[1]Pennsylvania State University, [2]Hershey Medical Center

P112 The Influence of Echocardiographic and Computed Tomography Phases on the Resulting Flow Dynamics in the Left Atrium
Ahmad Bshennaty[1], Brennan Vogl[1], Agata Sularz[2], Mohamad Alkhouli[2], Hoda Hatoum[1]
[1]Michigan Technological University, [2]Mayo Clinic

Solid Mechanics

P127 Anisotropic Porous Hydroxyapatite/Gelatin Implants for Trabecular Structure Reconstruction
Anton Pavlov, Jimmy Johnson, Ben Gadomski
Colorado State University

P128 Radiation Induces Fibrosis in Skin, but This Injury Is Mitigated in Expanded Skin
Laura Nunez[1], Joanna Ledwon[2], Vahid Tac[1], Arun Gosain[2], Adrian Buganza[1]
[1]Purdue University, [2]Northwestern University

P129 Creation of a Multi-Scale Model of Skin Growth to Understand the Effect of Microstructure and Tissue Heterogeneities on Skin Mechanobiology
Omar Moreno Flores[1], Maria Holland[2], Adrian Buganza Tepole[1]
[1]Purdue University, [2]University of Notre Dame

P130 Selection of Loading Conditions for Reliable Virtual Mechanical Testing of Bone Fracture Healing in Sheep and Humans
Mehran Bahrami, Kylie Frew, Hannah Dailey
Mechanical Engineering & Mechanics, Lehigh University

P131 Automatic Boundary Detection and Meshing for Virtual Mechanical Testing of Tibial Fracture Healing
Alireza Ariyanfar, Mehran Bahrami, Hannah Dailey
Lehigh University

P132 Modelling Vascularization in the Healing Callus After Fracture
Joseph Soldenwagner, Priyatha Premnath, Mahsa Dabagh
University of Wisconsin Milwaukee

P133 Adaptation of a Multiscale Model of Heart Growth in Pregnancy for Use in Canines
Tiffany Corlin, Molly Kaissar, Kyoko Yoshida
University of Minnesota

P134 Measurement of the Population Distribution of Helmet-to-Head Contact Forces
Turner Jennings, Aidan Tillman, D'Mitra Mukasa, Michael Marchev, Rouzbeh Amini, Sinan Müftü
Northeastern University

P135 Is Synthetic Clear Gelatin a Validated Surrogate for Biological Tissue in Low-Velocity Penetrating Impacts?
Joseph LeSueur[1,2], Jared Koser[1], Stephen Hargarten[1], Frank Pintar[1,2]
[1]Medical College of Wisconsin, [2]Marquette University

P136 Infant Skull Anatomical Standards for Use in Head Trauma Modeling
Yousef Alsanea, Tagrid Ruiz-Maldonado, Brittany Coats
University of Utah

P137 A Numerical Study on the Effect of Cortical Diffusivity on Brain Tissue Gyrification
Karan Taneja, Maria Holland
University of Notre Dame

P138 Effect of Impact Magnitude and Direction on the Injury Risk of Neural Cells
Raisa Akhtaruzzaman, Arthur Koster, Kamal Awad, Venu Varanasi, Marco Brotto, Ashfaq Adnan
University of Texas at Arlington

P139 Method for Extracting Intact Skull-Brain Samples for Ex-Vivo Mechanical Testing
Brandon Chelstrom, Corinne Henak
University of Wisconsin-Madison

P140 Numerical Modelling of Low-Level Blast Scenarios to Quantify Likelihood of Cavitation-Induced Traumatic Brain Injury
Manik Bansal[1], Baudouin Fonkwa[2], Eric Johnsen[2], Christian Franck[3], Rika Carlsen[1]
[1]Robert Morris University, [2]University of Michigan, [3]University of Wisconsin-Madison

P141 Modification of Polyacrylamide Using Dextran and Linear Acrylamide Chains to Mimic Human Brain Tissue
James Angelos[1], Adam Willis[2,3], Michaelann Tartis[1]
[1]New Mexico Institute of Mining and Technology, [2]Michigan State University, [3]59th Medical Wing

P142 Re-DiffiNet: Modeling Discrepancy in Tumor Segmentation Using Diffusion Models
Tianyi Ren, Abhishek Sharma, Juampablo Heras Rivera, Harshitha Rebala, Agamdeep Chopra, Ethan Honey, Mehmet Kurt
University of Washington

P143 Estimating Severe Injury Risk to Human Cervical Spine Using Scaled Head Kinematic Response From Non-Human Primate
Jesse Gerringer, Karthik Somasundaram, Frank Pintar
Medical College of Wisconsin and Marquette University

P144 Effect of Rear Impact on the Instrumented Spine: A Finite Element Study
Balaji Harinathan[1,2], Karthik Devaraj[3], Aditya Vedantam[3], Narayan Yoganandan[3]
[1]Medical College of Wisconsin, [2]Vellore Institute of Technology, [3]Medical College Wisconsin

P145 Cervical Neck Muscle Morphology Under Load-Bearing Conditions and Its Impact on Spinal Alignment: An Upright Magnetic Resonance Imaging Study
Mahmudur Rahman[1], Ali Warraich[2], Vicky Varghese[3], Aditya Vedantam[1], Narayan Yoganandan[1]
[1]Medical College of Wisconsin, [2]University of Chicago, [3]American International University

P146 Neck Strength and Endurance After 1-Hour Exposure to Vertical Whole-Body Vibration
Ana I. Lorente, Robert S. Salzar
University of Virginia

P147 Quantitative Analysis of the Compressive Force Applied to the ACL Tibial Enthesis
Daichi Ishii, Shiho Sato, Hiromichi Fujie
Tokyo Metropolitan University

P148 The Effect of Cam Morphology of the Hip on Sacroiliac Motion During Functional Hip Biomechanics
Alexander Hooke, Mason Uvodich, Joshua Bland, Allison Tanner, Zachary Braig, Micah Nieboer, Evan Dugdale, William Cross, Chunfeng Zhao, Aaron Krych, Mario Hevesi
Mayo Clinic

P149 The Importance of the Meniscus Inner Segment on the Mechanical Function of the Meniscus
Satoshi Yamakawa, Toshitaka Tsunematsu, Issei Ogasawara, Tomoki Ohori, Akira Tsujii, Shoji Kondo, Seira Sato, Takashi Kanamoto, Ken Nakata
Osaka University

P150 Compression Stability of Three Fixation Modes for Intraoperative Femoral Condyle Fractures During Knee Replacement
Timothy Eastep[1], Brady Killham[1], Yi Hong[1], Cheng-Jen Chuong[1], Dane Wukich[2], Jun Liao[1], Senthil Sambandam[3]
[1]University of Texas at Arlington, [2]University of Texas Southwestern Medical Center, [3]Dallas VA Medical Center

P151 Biomechanical Variability in Composite Lumbar Spine Surrogates During Multi-Laboratory Collaborative Testing
Emma Coltoff[1], Jeremy Loss[2], Siril Dukkipati[3], Jenna Wahbeh[4], Kalle Chastain[5], Matthew Pelletier[6], Tian Wang[6], Philip Brown[1], Mark Driscoll[7], Sophia Sangiorgio[4], Edward Ebramzadeh[4], Kathleen Meyers[5], William Walsh[6], Bryan Cornwall[6,8], Brian Kelly[9], Robb Colbrunn[2]
[1]Wake Forest School of Medicine, [2]Cleveland Clinic, [3]McGill University, [4]University of California, Los Angeles, [5]Hospital for Special Surgery, [6]University of New South Wales, [7]McGill University,, [8]University of San Diego, [9]Barrow Neurological Institute

P152 Temporal Variability in Composite Lumbar Spine Surrogates During Multi-Laboratory Collaborative Testing

Emma Coltoff[1], Jeremy Loss[2], Siril Dukkipati[3], Jenna Wahbeh[4], Kalle Chastain[5], Matthew Pelletier[6], Tian Wang[6], Philip Brown[1], Mark Driscoll[3], Sophia Sangiorgio[4], Edward Ebramzadeh[4], Kathleen Meyers[5], William Walsh[6], Bryan Cornwall[6,7], Brian Kelly[8], Robb Colbrunn[2]

[1]Wake Forest School of Medicine, [2]Cleveland Clinic, [3]McGill University, [4]University of California, Los Angeles, [5]Hospital for Special Surgery, [6]University of New South Wales, [7]University of San Diego, [8]Barrow Neurological Institute

P153 Walking Recovers Cartilage Strain: An Analysis of Measurement Repeatability

JiYeon Hong[1], Tejus Surendran[1], Shu-Jin Kust[2], Dana Voinier[3], Kyle Meadows[3], Dawn Elliott[3], Daniel White[3], Axel Moore[1]

[1]Carnegie Mellon University, [2]Temple University, [3]University of Delaware

P154 Rotary Pivot Shift: A New Loading Profile for Quantifying Rotational Stability in the Knee

Elizabeth Pace, Robb Colbrunn, Vincent Lizzio, Paul Saluan, Tara Nagle

Cleveland Clinic Foundation

P155 Evaluation of Spine Biomechanics Using Micro-Computed Tomography

Hutomo Tanoto, Yuxiao Zhou

Texas A&M University

P156 Extent of Vascular Damage at Varying Degrees of Stretch in Hypoxic Neonatal Brachial Plexus

Sanjna Srinivasan[1], Virginia Orozco[1], Smriti Nair[2], Mitali Sahni[3], Sriram Balasubramanian[1], Anita Singh[2]

[1]Drexel University, [2]Temple University, [3]Sunrise Children's Hospital

P157 Collagen Denaturation Quantification in Bone Using Collagen Hybridizing Peptide.

William Woolley[1], Katy Martin[2], Seungju Yu[2], Claire Acevedo[1,2]

[1]University of California, San Diego, [2]University of Utah

P158 Resolving Nanoscale Deformations of Mineralized Collagen Fibrils in 3D

Riti Sharma, Luc Capaldi, Kailin Chen, Ottman A. Tertuliano

University of Pennsylvania

P159 Investigating the Effect of Co and Cr Substitutions on Biomimetic Apatite Maturation

Kennedy Drake[1], Julianna DeSantis-Raymond[2], Stephanie Wong[1], Alix Deymier[1]

[1]University of Connecticut Health Center, [2]University of Connecticut

P160 Osteotomy Has Variable Effects on Construct Stiffness of Cadaveric Tibiae: Implications for Functional Evaluations

Luke Mattar[1], M. Enes Kayaalp[2], Tianyu Chen[1], Ron Curelaru[1], Volker Musahl[1], Richard Debski[1]

[1]University of Pittsburgh, [2]Istanbul Kartal Dr. Lutfi Kirdar Training and Research Hospital

P161 Mechanics of Cobalt Substitution in Biommetic Apatites
Abigail Eaton[1], Stephanie Wong[2], Kennedy Drake[2], Arun Nair[1]
[1]University of Arkansas, [2]University of Connecticut

P162 Correlation Between Loading-Induced Changes in Optical Redox Metrics and Mitochondrial Depolarization Varies by Strain Rate and Cartilage Zone
Jingyi Wang, Greta Scheidt, Corinne Henak
University of Wisconsin-Madison

P163 Quantifying Soleus Muscle Structure Through Diffuse Tensor Imaging (DTI) in Individuals With Achilles Tendon Rupture
Shabnam Rahimnezhad Baghche Jooghi[1], Xiaoxiao Bai[1], Tanzil Arefin[1], Thomas Neuberger[1], Morgan Voulo[2], Daniel Cortes[1]
[1]Pennsylvania State University, [2]Milton Hershey Medical Center

P164 Investigating the Mechanisms of Patella Osteochondral Allograft Transplant Failure Using Finite Element Methods
Michael Hernández Lamberty, John Grant, Rhima Coleman, Ellen Arruda
University of Michigan

P165 Postural Stability in Helicopter Aircrew With and Without Neck and Back Pain: the Medical College of Wisconsin Military Aircrew Neck and Back Pain Study
Rachel Cutlan[1], Cory Everts[2,3], Alok Shah[2], Amy Nader[2], Keeley Hamill[2], Narayan Yoganandan[2,4], Lance Frazer[5], Barry Shender[6], James Sheehy[6], Glenn Paskoff[6], Daniel Nicolella[5], Timothy Bentley[7], Brian Stemper[1,2,4]
[1]Marquette University and Medical College of Wisconsin, [2]Medical College of Wisconsin, [3]115th Fighter Wing, Wisconsin Air National Guard, [4]Zablocki Veterans Affairs Medical Center, [5]Southwest Research Institute, [6]Naval Air Warfare Center Aircraft Division, [7]Office of Naval Research

P166 Multiscale Correlations Between, Joint and Tissue Biomechanics and Morphology in Ovine Stifles
Aritra Chatterjee[1,2], Zachary Davis[2], Timothy Lescun[2], Deva Chan[2]
[1]Birla Institute of Science and Technology, [2]Purdue University

P167 Selective Bundle ACL Reconstruction Does Not Initially Restore the Normal ACL Force Distribution in an Adolescent Porcine Model: Implications for Treatment of Partial ACL Injuries
Yukun Zhang[1], Kaan Gurbuz[2], Jeffrey Spang[3], Matthew Fisher[1,3]
[1]NC State and UNC Chapel Hill, [2]Kayseri State Education & Research Hospital, [3]University of North Carolina at Chapel Hill

P168 Tackling Heterogeneity in Canine Osteosarcoma- A Biomechanical Analysis of Histotripsy-Treated and Untreated Bone
Preeya Achari[1], Elliana Vickers[1], Lauren Ruger[1], Eli Vslaisavljevich[1], Joanne Tuohy[2], Caitlyn Collins[1]
[1]Virginia Tech, [2]Virginia-Maryland College of Veterinary Medicine

P169 Growth Plate and Its Role in Pediatric ACL Injuries
Isaac Woodward, Antonis Stylianou
University of Missouri-Kansas City

Special Session: Cancer Mechanics

P66 Single Cell Mechanical Analysis Reveals Viscoelastic Similarities Between Astrocytes and Glioblastoma Cells
Julian Najera, Killian Onwudiwe, Luke Holen, Alice Burchett, Dorielis Rodriguez, Maksym Zarodniuk, Saeed Siri, Meenal Datta
University of Notre Dame

P67 Long-Distance Symphony Among Human Cancer Cells: an Underappreciated Mechano-Regulated Process in Tumor Progression
Chenyu Liang[1,2], Mai Tanaka[2], Dietmar Siemann[2], Bo Zeng[3], Xin Tang[1,2]
[1]University of Florida, [2]UF Health Cancer Center, [3]Southwest Medical University

P68 Perivascular CNS Fibroblasts Are Associated With Increased Tumor Stiffness and Poor Immunotherapy Response in Glioblastoma Patients
Maksym Zarodniuk, Megna Panchbhavi, Alexander Steele, Xin Lu, Jun Li, Meenal Datta
University of Notre Dame

P69 Simulating the Impact of Tumor Mechanical Forces on Glymphatic Networks in the Brain Parenchyma
Saeed Siri, Alice Burchett, Meenal Datta
University of Notre Dame

P70 Biophysical Characterization of Increased Prostate Cancer Cell Survival in Muscle Tissue
Jonah Spencer[1], Anne Cress[2], Jacob Notbohm[1]
[1]University of Wisconsin-Madison, [2]University of Arizona

P71 Direct Quantification of Cancer-Associated Exosomes in Plasma Enables Rapid Identification of Cancer Using Rotational Diffusometry of Janus Particles
John Sinclair[1], Sonu Kumar[1], Tiger Shi[1], Satyajyoti Senapati[1], Han-Sheng Chuang[2], Chia Chang[1]
[1]Notre Dame, [2]National Cheng Kung University

P72 Towards the Estimation of Tumor Stiffness Using B-Mode Ultrasound Imaging
Tanmay Mukherjee, Adarsh Shree, Reza Avazmohammadi
Texas A&M University

Special Session: Emerging Tools for Cell Mechanics

P73 A Novel Method for Studying Mechanotransduction: Complex Force Frequency Application Using Magnetic Vortex Microdiscs
Matthew Holler[1], Elena Rozhkova[2], Valentine Novosad[2], Scott Wood[1]
[1]South Dakota School of Mines, [2]Argonne National Laboratory

P74 Building Homemade Optical Tweezers to Study the Mechanical Forces of the Chondrocyte Cytoskeleton in the Context of Osteoarthritis
Samantha Smith, Scott Wood
South Dakota School of Mines

Special Session: Fiber Mechanics

P75 3D Printing Patient-Specific Left-Heart Models for Surgical Planning
Jakari Harris, Scott Hollister, Lakshmi Dasi
Georgia Institute of Technology

P76 Assessing the Impact of Hyaluronic Acid on the Rheological Properties of Collagen Hydrogels
Nicholas Gigliotti, Vivian Su, Mitra Taheri
Johns Hopkins University

P77 Femtosecond Laser Generated Micro-Cuts in Partially Recruited Collagen Fibers Show Micro-Forces Relevant on the Microscale
Miriam Bohlmann Kunz, Hannah Schilpp, Po-Yi Lee, Ian Sigal
University of Pittsburgh

P78 Using Fiber Modeling to Understand the Effects of Modulating Tissue Mechanical Properties as A Preventative Treatment for Glaucoma
Yingzhe Han, Bingrui Wang, Xuehuan He, Yuankai Lu, Ian Sigal
University of Pittsburgh

P79 Low Strain Rate Cyclic Loading and Recovery Effect on the Fatigue Properties of the Anterior Cruciate Ligament
Peter Kuetzing, Ulrich Scheven, Ellen Arruda
University of Michigan

Tissue & Cellular Engineering

P113 Developing a Scaffold With Gradient Mechanical Properties for Rotator Cuff Repair: A Parametric Finite Element Study
Sam Winston[1], Lynn Pezzanite[1], Ted Schlegel[2], Anthony Romeo[3], Steven Dow[1], Kirk McGilvray[1]
[1]Colorado State University, [2]University of Colorado School of Medicine, [3]Rothman Orthopedic Institute

P114 Role of Obese-Like Adipocytes in the Pathophysiology of Atrial Fibrillation Using 3D Bioprinted Models
Lara Celebi, Pinar Zorlutuna
University of Notre Dame

P115 Shining Light on Calcium-Mediated Morphogenesis: Forward Engineering Organ Development With Optogenetics and Mechanosensation
David Gazzo, Mayesha Sahir Mim, Nilay Kumar, Megan Levis, Maria Unger, Gabriel Miranda, Jeremiah Zartman
University of Notre Dame

P116 In Vitro Regionalization of Early Midbrain and Hindbrain Tissues Derived From Micropatterned Human Pluripotent Stem Cells
Tianfa Xie, Han Jiang, Lauren Brown, ChangHui Pak, Yubing Sun
University of Massachusetts Amherst

P117 Balancing Competing Effects of Epithelial Tissue Growth and Cytoskeletal Regulation During Organogenesis
Nilay Kumar[1], Jennifer Ambriz[2], Kevin Tsai[2], Mayesha Mim[1], Marycruz Flores-Flores[1], Weitao Chen[2], Mark Alber[2], Jeremiah Zartman[1]
[1]University of Notre Dame, [2]University of California

P118 Spatiotemporal Analysis for Hypertrophic Chondrocyte Differentiation in Spheroid Culture
Jeonghyun Kim[1], Kosei Tomida[1], Eijiro Maeda[1], Taiji Adachi[2], Takeo Matsumoto[1]
[1]Nagoya University, [2]Kyoto University

P119 Developing Mouse-Tumor Model for High Intensity Foucsed Ultrasound (HIFU) Ablation Procedures
Nabin Khanal[1], Victoria Summey[2], Jeffrey Bailey[2], Xin Duan[2], Rupak K. Banerjee[1]
[1]University of Cincinnati, [2]Cincinnati Children's Hospital Medical Center

P120 A Click Chemistry Method to Evaluate Glycosaminoglycan Composition and Metabolism in Articular Cartilage
Annie Porter, Steven DiStefano, Emily Newcomb, Michael Axe, X. Lucas Lu
University of Delaware

P121 Polychlorinated Biphenyls Alter Macrophage Polarization and Plasticity
Riley Behan-Bush, Jesse Liszewski, Michael Schrodt, Aloysius Klingelhutz, James Ankrum
University of Iowa

P122 A Novel Explant-in-A-Chip Perfusion Platform for Ex Vivo Preservation of Tissue Viability Applied to Both Healthy and Cancerous Tissues
WITHDRAWN
Eva Zeringa[1], Saverio Charalambous[1,2], Kinga Suba[1], Avirup Chowdhury[1,2], Ester Reina-Torres[1], Larry O'Connell[1], Foivos Chatzidimitriou[1], Joseph van Batenburg-Sherwood[1], Olivier Pardo[1], Alan Melcher[1,2], Paul Huang[2], Darryl Overby[1]
[1]Imperial College, [2]Institute of Cancer Research

P123 p21 Suppression to Improve Osteogenic Capacity of MSCs
Sina Jafari, Aaron Brandner, Julie Sandria, Priyatha Premnath
University of Wisconsin Milwaukee

P124 Assessing Pattern Recognition Receptor Agonist Loaded Hydrogels as A Potential Rotator Cuff Repair Augment
Sam Winston, Devin von Stade, Cody Plaisance, Renata Impastato, Lynn Pezzanite, Steven Dow, Kirk McGilvray
Colorado State University

P125 The Effect of Tissue Engineered Heart Valve Design on Remodeling: Optimizing Valve Functionality and Collagen Organization
Valery Visser[1], Sarah Motta[1], Simon Hoerstrup[1,2], Frank Baaijens[3,4], Sandra Loerakker[3,4], Maximilian Emmert[1,2,5,6]
[1]Institute for Regenerative Medicine, [2]Wyss Translational Center, [3]Eindhoven University of Technology, [4]Institute for Complex Molecular Systems, [5]German Heart Center, [6]Charité Universitätsmedizin

P126 Synthetic Hyaluronic Acid Coating Preserves the Phenotypes of Lymphatic Endothelial Cells
Sanjoy Saha, Fei Fan, Laura Alderfer, Francine Graham, Eva Hall, Donny Hanjaya-Putra
University of Notre Dame

Translational Technology Pitch Competition

P64 Integrating Autopsy-Based Radio-Pathomic Maps of Tumor Probability for Guiding Surgical Biopsies in Glioblastoma
Samuel Bobholz, Allison Lowman, Aleksandra Winiarz, Savannah Duenweg, Michael Flatley, Biprojit Nath, Jennifer Connelly, Dylan Coss, Max Krucoff, Anjishnu Banerjee, Peter LaViolette
Medical College of Wisconsin

P65 Delta Cuff
Cyrus Darvish[1], Pete Gueldner[1], Rabih Chaer[2], David Vorp[1], Timothy Chung[1]
[1]University of Pittsburgh, [2]University of Pittsburgh Medical Center

Poster Session II — Biotransport

P64 Hydrogel Wound Healing in Palliative Care
Tre Welch, Jamie Wright, Vanini Pimpalwar, Kelley Newcomer, Matteo Ligorio
University of Texas Southwestern Medical Center of Dallas

P65 Characterization of Microstructural Changes on Biglycan/Decorin Induced Mouse Bone by Low-Field NMR
Qingwen Ni
Texas A&M International University

P66 Comparative Liquid Flow Analysis in Battery-Powered Suction Devices for Advanced Airway Management
Maria J. Londono[1], Saketh R. Peri[1,2], Zach Fallon[1], David DiRocco[1], David Restrepo[1], Robert A. De Lorenzo[2,1], R. Lyle Hood[1,2]
[1]University of Texas at San Antonio, [2]University of Texas Health Science Center at San Antonio

P67 **Significantly Amplified Photoacoustic Effect for Silica-Coated Gold Nanoparticles by Interface Heat Transfer Mechanisms**
Chen Xie[1], Peiyuan Kang[1], Jonghae Youn[1], Blake Wilson[1], Lokesh Basavarajappa[1], Qingxiao Wang[1,2], Moon Kim[1], Kenneth Hoyt[1], Zhenpeng Qin[1,3]
[1]University of Texas at Dallas, [2]King Abdullah University of Science and Technology, [3]University of Texas at Southwestern Medical Center

P68 **Development of a Non-Invasive Imaging Approach for Assessing Radiation-Induced Changes in Intestinal Barrier Function**
Austen Nissen, Christopher Hansen, Guru Sharma, Brian Fish, Dana Veley, Amit Joshi, Heather Himburg
Medical College of Wisconsin

P69 **Effect of Breathing Technique for Targeted Laryngopharyngeal Drug Delivery**
Shamudra Dey[1], Guilherme J.M. Garcia[1,2]
[1]Marquette University and Medical College of Wisconsin, [2]Medical College of Wisconsin

P70 **A New Strategy to Enhance Radiofrequency Ablation Within the Low Electrical Conductivity Region of Atherosclerotic Plaque: A Mathematical Modeling**
Ruizhe Hou, Hongying Wang, Shiqing Zhao, Aili Zhang
Shanghai JiaoTong University

P71 **Enhancing Fluid Infusion via Introduction and Enlargement of Microcracks in Tumors – Theoretical Simulations**
Md Jawed Naseem, Ronghui Ma, Liang Zhu
University of Maryland Baltimore County

P72 **Accelerating Hydrodynamic Fabrication of Microstructure Using Deep Neural Networks**
WITHDRAWN
Nicholus Clinkinbeard, Reza Montazami, Nicole Hashemi
Iowa State University

P73 **Measuring Flow Resistivity in Microfluidic-Based Medical Devices**
Ali Bozorgnezhad, Luke Herbertson, Suvajyoti Guha
US Food and Drug Administration

P74 **Computational Analysis of the Contribution of Paracrine Chemotaxis to Spatial Distribution of Leukocytes in Cerebral Aneurysms**
Ruskin Shi, Hadi Wiputra, Victor Barocas
University of Minnesota-Twin Cities

Fluid Mechanics

P75 **The Hemodynamics of Mechanical Heart Valves: A Comparison of Numerical Simulations Against Experimental Measurements**
Syed Samar Abbas[1], Lorenzo Ferrari[2], Dominik Obrist[2], Iman Borazjani[1]
[1]Texas A&M University, [2]University of Bern

P76 A Parametric Model of the Mitral Valve From Multimodal Imaging Data
André Da Luz Moreira, Anders Persson, Farkas Vanky, Matts Karlsson, Jonas Lantz, Tino Ebbers
Linköping University

P77 Non-Newtonian Effects on Sinus Flow After Aortic Valve Replacement
Ahmad Bshennaty[1], Brennan Vogl[1], Zhongtian Zhang[1], Agata Sularz[2], Bruce Lee[1], Mohamad Alkhouli[2], Hoda Hatoum[1,1]
[1]Michigan Technological University, [2]Mayo Clinic

P78 Image-Based 3D Reconstruction Analysis of Regional Thrombosis After Transcatheter Aortic Valve Replacement
Katelynne Berland[1], Breandan Yeats[1], Taylor Becker[2], Marco Moscarelli[3], Khalil Fattouch[3], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Ohio State University, [3]Maria Eleonora Hospital

P79 Transcatheter Aortic Valve Hemodynamics in HALT Positive and Negative Patient Cohorts: An FSI Study
Thangam Natarajan[1], Aniket Venkatesh[1], Stephanie Sellers[2], Janarthanan Sathananthan[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]University of British Columbia

P80 Virtual Stenting of Patient-Specific Vascular Stenoses
Jonathan Pham, Fanwei Kong, Doug James, Jeffrey Feinstein, Alison Marsden
Stanford University

P81 Impact of Boundary Conditions and Blood Rheology on Indices of Wall Shear Stress From IVUS-Based Patient-Specific Stented Coronary Artery Simulations
Robert McCarthy[1], Peter Mason[2], David Marks[3], John LaDisa[1,3,4,5]
[1]Marquette University and the Medical College of Wisconsin, [2]Medical College of Wisconsin, [3]Cardiovascular Medicine, Medical College of Wisconsin, [4]Pediatric Cardiology, Medical College of Wisconsin, [5]Children's Wisconsin

P82 Fluid-Structure Interaction Model of the Human Heart With a Closed-Loop Model of the Circulation
Masod Sadipour[1], Marshall Davey[2], David Wells[3], Charles Puelz[4], Boyce Griffith[1,5]
[1]University of North Carolina, [2]Curriculum in Bioinformatics and Computational Biology,University of North Carolina, [3]University of North Carolina at Chapel Hill, [4]Baylor College of Medicine and Texas Children's Hospital, [5]University of North Carolina, Chapel Hill

P83 Cardiac-Induced Brain Tissue Motion in Chiari Malformation Type 1 and Its Relationship to: Surgery, Crowding, and Symptomatology
Mahsa Karamzadeh[1], Mohamad Motaz Al Samman[1], Christopher Maclellan[2,3], Rafeeque Bhadelia[2,3], Amir Ebrahimzadeh[2,3], John Oshinski[4], Francis Loth[1]
[1]Northeastern University, [2]Beth Israel Deaconess Medical Center, [3]Harvard Medical School, [4]Emory University School of Medicine

P84 Characterization of Failure in Cerebral Aneurysm Stenting

Reza Bozorgpour[1], Pilhwan Kim[1], Peter Tze Man Kan[2], Mahsa Dabaghmeshin[1]
[1]University of Wisconsin-Milwaukee, [2]University of Texas Medical Branch

P85 Using CFD to Assess Tracheal Work of Breathing in Neonates With Tracheoesophageal Defects Pre and Post Surgical Repair

Christopher Boles[1,2], Chamindu Gunatilaka[1], Qiwei Xiao[1], Jason Woods[1], Paul Kingma[1], Alister Bates[1,2]
[1]Cincinnati Children's Hospital Medical Center, [2]University of Cincinnati

P86 Multiscale Modeling of Blood Flow in Aortic Root Aneurysm

Yurui Chen[1], Hannah Zhai[1], Hiroo Takayama[2], Vijay Vedula[1]
[1]Columbia University, [2]Columbia University Irving Medical Center

P87 Bladder Biomechanics and Shape Characterization: Comparison Study of Healthy vs BPH Using Uro-Dynamic MRI

Juan P. Gonzalez-Pereira, Shane Wells, Matthew Grimes, Wade Bushman, Alejandro Roldan-Alzate
University of Wisconsin-Madison

P88 Extension of Murray's Law to Three Dimensions With Multiple Daughter Vessels

Seth Street[1], David Dierker[1], Mark Johnson[1], Samer Hoz[2], James Castiglione[3], Charles Prestigiacomo[1]
[1]University of Cincinnati College of Medicine, [2]University of Pittsburgh, [3]Thomas Jefferson University

P89 Comparison Between Vessel Wall Models to Estimate Hemodynamics in Coronary Artery Bypass Graft Patients

Nhien Tran-Nguyen[1], Andrew Yan[1,2], Stephen Fremes[1,3,4], Laura Jimenez-Juan[1,2,4], Piero Triverio[1]
[1]University of Toronto, [2]St. Michael's Hospital, [3]Sunnybrook Health Sciences Centre, [4]Sunnybrook Research Institute

P90 Longitudinal Changes in Mechanical Properties of Aorta From Angiotensin-II Infused Mice Obtained by an Inverse Finite Element Method

Hadi Wiputra[1], Sydney Clark[2], Craig Goergen[2], Victor Barocas[1], Matthew Bersi[3]
[1]University of Minnesota, [2]Purdue University, [3]Washington University in St. Louis

P91 Differences in Flow Dynamics Between Coronary Artery Aneurysms and Ectasia

Brennan Vogl[1], Emily Vitale[1], Simon Lee[2], John Kovalchin[3], Hoda Hatoum[1]
[1]Michigan Technological University, [2]Lurie Children's Hospital of Chicago, [3]Nationwide Children's Hospital

P92 Medical Imaging Based Patient-Specific Blood Flow Modelling of Cerebrovasculature

Amar Shrivastava[1], Ashish Suri[2], Sitikantha Roy[1]
[1]Indian Institute of Technology Delhi, [2]AIIMS New Delhi

P93 **Revisiting Murray's Law Pulmonary Arteries: Exploring Branching Patterns and Principles**
Sofia Altieri Correa, Amirreza Kachabi, Mitchel J. Colebank, Naomi C. Chesler
University of California, Irvine

P94 **Hemodynamic Analysis of Sinotubular Junction Plication Techniques During Ascending Aortic Replacement**
Hannah Zhai[1], Yurui Chen[1], Yu Hohri[2], Hiroo Takayama[2], Vijay Vedula[1]
[1]Columbia University, [2]Columbia University Medical Center

P95 **A Thermodynamics-Based Approach for Estimating Ventricular Efficiency: Application in Patients With Single Ventricle Physiology**
Sanjib Gurung, Arutyun Pogosyan, Gregory S. Perens, Kim-Lien Nguyen, John Paul Finn
University of California, Los Angeles

MS SPC: Cardiovascular

P39 **Development of Coarctation of the Aorta Software to Combat Hypertension**
Shahd Sawalhi[1], Arash Ghorbannia[1,2,3], Andrew Spearman[2], Robert Cooper[1], John LaDisa[1,2,4]
[1]Marquette University and the Medical College of Wisconsin, [2]Children's Wisconsin and the Medical College of Wisconsin, [3]Duke University, [4]Medical College of Wisconsin

P40 **Computational Study on the Hemodynamics of Bioprosthetic Pulmonary Valves in Patients With Repaired Tetralogy of Fallot**
Kwang-Bem Ko[1], Jung-Hee Seo[1], Ashish Doshi[2], Danielle Gottlieb-Sen[2], Rajat Mittal[1]
[1]Johns Hopkins University, [2]Johns Hopkins Medicine

P41 **Estimation of Flow Rates From Clinical Pressure Measurements for Individualized CFD of Cerebral Venous Stenotic Disease**
Gurnish Sidora[1], Anna Haley[1], Nicole Cancelliere[2], Vitor Pereirav[2,1], David Steinman[1]
[1]University of Toronto, [2]St. Michael's Hospital

P42 **The Impact of Natural Estrogen and Progesterone Cycling on Cardiac Function in Mice**
Thaotho Nguyen, Cassandra Conway-O'Donnell, Naomi Chesler
University of California, Irvine

P43 **Computational Modeling of Left Ventricular Flow Using MRI-Derived Four-Dimensional Wall Motion**
Seyed Babak Peighambari[1], Tanmay Mukherjee[1], Amr Darwish[2], Roderic Pettigrew[1,3], Dipan Shah[2], Reza Avazmohammadi[1,3]
[1]Texas A&M University, [2]Houston Methodist DeBakey Heart & Vascular Center, [3]School of Engineering Medicine

P44 **Marginal Chordae Force Data in a Physiological In Vitro Mitral Valve Setup**
Mads Ancker[1], Sam Stephens[1], Neil Ingels[1], Jonathan Wenk[2], Morten Jensen[1]
[1]University of Arkansas, [2]University of Kentucky

P45 **Structural and Mechanical Analysis of Treated and Untreated Aortic Coarctation**
Matt Culver, Colleen Witzenburg, Alejandro Roldan-Alzate, Luke Lamers, Michael Stellon, Leah Gober
University of Wisconsin-Madison

P46 **Porcine Thoracic Aortic Tissue Failure Strength Is Associated With Bulk Density Which May Be Detectable From Diffusion Tensor Imaging**
Pete Gueldner[1], Cyrus Darvish[1], Timothy Chung[1], Chandler Benjamin[2], Keshava Rajagopal[3], Kevin Hitchens[1], Spandan Maiti[1], Kumbakonam Rajagopal[2], David Vorp[1]
[1]University of Pittsburgh, [2]Texas A&M University, [3]Thomas Jefferson University

MS SPC: Solid Mechanics

P47 **The Mechanicalization of Locomotor Training for Gait Rehabilitation Due to Damage Caused by Partial Spinal Injuries: Defing Parameter of Knee Jerk Relex Stimulation Device.**
Hannah Khelfa, Mohammed Sbai, Sanford Meek
University of Utah

P48 **A Finite Element Model for Simulating Closed-Head Impact Injury in a Mouse Model: Implications for Tau Pathology in Traumatic Brain Injury**
Ruiyuan Chi, Patrick Alford
University of Minnesota Twin Cities

P49 **The Material Tuning of Annealing PVA Hydrogels for the Application of TMJ Disc Replacement**
Hassan Mahmoud, Christian Puttlitz, Kevin Labus
Colorado State University

P50 **3D Assessment of Rat Knee Joint Anatomy Using High Field MRI**
Olivia Dyer, Mackenzie Conner, Stephanie Cone
University of Delaware

P51 **Microscale Shear Wave Tensiometry Tracks Axial Stress in Tendon Fascicles**
Shreya Kotha[1], Samantha Kahr[1], Darryl Thelen[1], Jonathon Blank[2], Alex Reiter[3]
[1]University of Wisconsin-Madison, [2]University of Pennsylvania, [3]St. Louis University

P52 **A Systematic Analysis Confirmed That Mechanical and Structural Anisotropies Do Not Concur in 37 percent of Equatorial Sclera Samples**
Bangquan Liao[1], Yi Hua[2], Fengting Ji[1], Frederick Sebastian[3], Rouzbeh Amini[3], Ian Sigal[1]
[1]University of Pittsburgh, [2]University of Mississippi, [3]Northeastern University

P53 **Development and Validation of a Vehicle Front Profile Finite Element Model to Evaluate Pedestrian Impacts**
James Wolf, Karthik Somasundaram, Frank Pintar
Marquette University and Medical College of Wisconsin

P54 Pregnancy and Age Differentially Affect Stiffness, Collagen Microdamage Susceptibility, and Composition of Uterosacral Ligaments
Catalina Bastias[1,2], Lea Savard[2], Kathleen Connell[3], Kathryn Jacobson[2], Sarah Calve[2], Virginia Ferguson[2], Callan Luetkemeyer[1]
[1]University of Illinois Urbana-Champaign, [2]University of Colorado Boulder, [3]University of Colorado Anschutz

P55 Uniaxial Biomechanical Response of Murine Uterine Tissue After Surgery-Induced Scarring
Savannah Chatman, Niyousha Karbasion, Abigail Fisk, Matthew Bersi, Perry Ann Brody
Washington University in St. Louis

MS SPC: Tissue Engineering, Biotransport, Mechanobiology

P56 Functionalized Nanoparticles Mediated High Intensity Focused Ultrasound (HIFU) Ablation in Mice
Nabin Khanal[1], Michael Marciniak[2], Marie-Christine Daniel[2], Liang Zhu[2], Matthew Lanier[3], Charles Dumoulin[3,1], Rupak K. Banerjee[1]
[1]University of Cincinnati, [2]University of Maryland Baltimore County, [3]Cincinnati Children's Hospital Medical Center

P57 Mechanical Characterization of Human Mesenchymal Stem Cell-Derived Osteocytic Spheroids by Uniaxial Compression Testing
Takashi Inagaki, Jeonghyun Kim, Eijiro Maeda, Takeo Matsumoto
Nagoya University

P58 Pressure Overload During Murine Pregnancy and Its Effects on Acute Cardiac Remodeling
Adalyn Meeks[1], Elnaz Ghajar-Rahimi[1], Molly Kaissar[2], Kyoko Yoshida[2], Craig Goergen[1]
[1]Purdue University, [2]University of Minnesota

P59 Evaluating the Biomechanical Response of 3D Printed Synthetic Tissue-Mimicking Materials for Cardiovascular Applications.
Vivian Tan[1], Daniella Eliathamby[2], Craig Simmons[2], Jennifer Chung[3], M. Owais Khan[1]
[1]Toronto Metropolitan University, [2]University of Toronto, [3]University Health Network

P60 Induced Pluripotent Stem-Cell Derived Cardiomyocyte Aged Tissue Model
Hatice Emanet, Frances Dipietro, Sneha Philip, Aylin Acun
Widener University

P61 The Impacts of Estrogen and Progesterone on Extracellular Matrix Remodeling in Female Mice Are Strain-Dependent
Allison Sander, Brianne Connizzo
Boston University

P62 A Pre-Chondrogenic Stem Cell Niche Facilitating Articular Cartilage Formation via Improving Chondrogenic Phenotype via Changing Stiffness and Cell Seeding Density

Yuqian Yang[1], Ruxin Yang[1], Kiera Downey[1], Samuel Oh[1], Erika Noel[2], Cheri Deng[1], Rhima Coleman[1]

[1]University of Michigan, [2]Florida International University

P63 Modulating In Vivo Compliance and Remodeling of a Polyurethane Based, Antithrombogenic Tissue Engineered Vascular Graft via Gelatin Incorporation

Katarina Martinet[1], David Maestas[1], Keishi Kohyama[1], William Wagner[1,2], Jonathan Vande Geest[1,2,3]

[1]University of Pittsburgh, [2]McGowan Institute of Regenerative Medicine, [3]Vascular Medicine Institute

Solid Mechanics

P112 Rapid Estimation of Left Ventricular Contractility With a Physics-Informed Neural Network Inverse Modeling Approach

Ehsan Naghavi[1], Haifeng Wang[1], Lei Fan[2,3], Jenny S. Choy[4], Ghassan Kassab[4], Seungik Baek[1], Lik-Chuan Lee[1]

[1]Michigan State University, [2]Marquette University, [3]Medical College of Wisconsin, [4]California Medical Innovations Institute

P113 iPSC-Derived Endothelial Multi-Cell Networks Synergistically Modify Their Basal Contractility and Extracellular Matrix in 3D

Toni West, Jiwan Han, Gabriel Peery, Robin Tuscher, Janet Zoldan, Michael Sacks

University of Texas

P114 Unravelling the Structural Mechanisms Underlying Aging-Augmented Risk of Aortic Dissection

Ruizhi Wang, Xunjie Yu, Bela Suki, Katherine Zhang

Boston University

P115 Deciphering Cardiac Allograft Vasculopathy: A Multiscale Computational Approach to Improve Heart Transplant Outcomes

Elisa Serafini[1,2], Anna Corti[3], Enrico Sangiorgio[4], Maddalena Bovetti[4], Diego Gallo[4], Carly S. Filgueira[1], Xian C. Li[1,5], Claudio Chiastra[4], Stefano Casarin[1,2,5]

[1]Houston Methodist Research Institute, [2]La Rochelle University, [3]Politecnico di Milano, [4]Politecnico di Torino, [5]Houston Methodist Hospital

P116 Mechanism of the Developed Pressure – Preload Relationship in Ex-Vivo Beating Heart

Lei Fan[1], Vahid Ziaei-Rad[2], Jason Bazil[2], Lik Chuan Lee[2]

[1]Marquette University and Medical College of Wisconsin, [2]Michigan State University

P117 Mechanical Stress in Atherosclerotic Coronary Arteries Are Associated With Plaque Growth

Jeremy Warren, Clark Meyer, Heather Hayenga

University of Texas at Dallas

P118 AI-Based Quantification of Vascular Calcifications for Enhanced Risk Evaluation
Mehdi Ramezanpour[1], Anne M. Robertson[1], Xiaowei Jia[1], Juan R. Cebral[2]
[1]University of Pittsburgh, [2]George Mason University

P119 Biomechanics Parameter Predicts Outcome of Fetal Heart Intervention Better Than Clinical Scan Parameters
Laura Green[1], Wei Xuan Chan[1], Andreas Tulzer[2], Gerald Tulzer[2], Choon Hwai Yap[1]
[1]Imperial College London, [2]Children's Heart Center Linz

P120 Multiscale Cardiac Modeling of Preterm Neonates
Salla Kim[1], Mitchel Colebank[1], Filip Jezek[2], Kara Goss[3], Pim Oomen[1], Dan Beard[2], Naomi Chesler[1]
[1]University of California, Irvine, [2]University of Michigan, [3]University of Texas Southwestern Medical Center

P121 A Random Forest Classification Method to Estimate Rupture Risk of Abdominal Aortic Aneurysms Based on Biomechanical and Geometric Surrogates
Juan C. Restrepo[1], Merjulah Roby[1], Pratik Mitra[1], Satish C. Muluk[2], Mark Eskandari[3], Ender A. Finol[1]
[1]University of Texas at San Antonio, [2]Allegheny Health Network, [3]Northwestern University School of Medicine

P122 Computational Insights on the Correlation of Myofiber Contractility With the Developed Pressure-Preload Dynamics in Ex-Vivo Beating Hearts
Vahid Ziaei-Rad[1], Lei Fan[2], Jason Bazil[1], Lik Chuan Lee[1]
[1]Michigan State University, [2]Marquette University and Medical College of Wisconsin

P123 Computational Modeling of the Aorta in a Mouse Model of Marfan Syndrome to Determine Temporal Changes in Geometric Biomarkers and Wall Shear Stress
Yufan Wu, Krashn Dwivedi, Jessica Wagenseil
Washington University in St. Louis

P124 Investigating the Role of Wall Stress in Aortic Growth of Acute Uncomplicated Type B Aortic Dissection Using Fluid-Structure Interaction Analysis
Minliang Liu[1], Yuxuan Wu[2], Adam Mazlout[2], Yuhang Du[1], Rishika Agarwal[2], Hannah Cebull[3], Marina Piccinelli[3], John Elefteriades[4], Rudolph Gleason[2], Bradley Leshnower[3]
[1]Texas Tech University, [2]Georgia Institute of Technology, [3]Emory University, [4]Yale University

P125 Microstructural Abnormalities in Human Hypertrophic Septal Tissues
Duc Khang Chung[1], Milad Almasian[2], Houjia Chen[1], Katherine Copeland[1], Kytai Nguyen[1], Matthias Peltz[3], Pietro Bajona[3], Yi Hong[1], Yichen Ding[2], Jun Liao[1]
[1]University of Texas at Arlington, [2]University of Texas at Dallas, [3]University of Texas Southwestern Medical Center

P126 Finite Element Simulations of Heart Valve Function With Shape Enforcement in FEBio
Devin Laurence[1], Patricia Sabin[1], Steve Maas[2], Jeffrey Weiss[2], Matthew Jolley[1]
[1]Children's Hospital of Philadelphia, [2]University of Utah

P127 The Impact of Right Ventricular Fiber Re-Orientation on Left Ventricular Contraction: A Numerical Studay
Mengqian Zhang[1], Kenzo Ichimura[2], Kurt Stenmark[1], Edda Spiekerkoetter[2], Vitaly Kheyfets[1]
[1]University of Colorado Anschutz Medical Campus, [2]Stanford University

P128 Novel Computational Model for Planning Patent Ductus Arteriosus Stenting Procedure
Luis René Mata Quiñonez[1,2], Srujana Joshi[1,2], Shweta Karnik[1,2], Leon Cheng[1,2], Andrew Marini[1,2], Shobana Santhanam[1,2], Rahav Kothuri[1], Charles Federico[1,2], Suhaas Bonkur[1,2], Lakshmi Dasi[1,2], Holly Bauser-Heaton[1,2,3]
[1]Georgia Institute of Technology, [2]Emory University, [3]Children's Healthcare of Atlanta

P129 Structure and Function of the Murine Greater Thoracic Vessels
Abhay Ramachandra[1], Cristina Cavinato[2], Jay Humphrey[3]
[1]Iowa State University, [2]Université Montpellier, [3]Yale University

P130 Evaluation of Transcatheter Edge-to-Edge Repair Clip Selection via an Open-Source Finite Element Simulation Framework
Patricia Sabin[1], Devin Laurence[1], Wensi Wu[1], Christian Herz[1], Steve Maas[2], Jeffrey Weiss[2], Matthew Jolley[1]
[1]Children's Hospital of Philadelphia, [2]University of Utah

P131 Fiber Shortening and Laminar Thickening Strain Attributes Reveal Greater Transmural Heterogeneity in Myocardial Deformation than Green Strains via DENSE MRI
Tawfik Hussein, John Oshinski
Georgia Institute of Technology

P132 Effects of Residual Stress on the Buckling and Twisting Behavior of Arteries
Qin Liu[1,2], Alejandro Cisneros[1], Hai-Chao Han[1]
[1]University of Texas at San Antonio, [2]New York Institute of Technology

P133 Simulated TAVR Lifetime Management to Assess Coronary Obstruction Risk for Varied Deployments of Balloon-Expandable and Self-Expanding Valves
Courtney Ream[1], Taylor Becker[2], Venkateshwar Polsani[3], Pradeep Yadav[3], Vinod Thourani[3], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Ohio State University, [3]Piedmont Hospital

P134 Simulation of Self-Expanding Transcatheter Pulmonary Valve Deployment in the Right Ventricular Outflow Tract
Christopher Zelonis[1], Nicolas Mangine[1], Kyle Sunderland[2], Steve Maas[3], Stephen Ching[1], Yuval Barak-Corren[1], Devin Laurence[1], Wensi Wu[1], Patricia Sabin[1], Andras Lasso[2], Matthew Gillespie[1], Jeff Weiss[3], Matthew Jolley[1]
[1]Children's Hospital of Philadelphia, [2]Queen's University, [3]University of Utah

P135 Aortic Location and Sex Specific Alterations in Mechanics and Wall Remodeling in a Mouse Model of Marfan Syndrome
Krashn Dwivedi, Jacob Rother, Jessica E Wagenseil
Washington University in St. Louis

P136 Developing an Experimentally Informed Structurally Representative Human Lung Model
Arif Badrou, Crystal Mariano, Gustavo Ramirez, Matthew Shankel, Talyah Nelson, Mona Eskandari
University of California, Riverside

P137 In Vivo Pulmonary and Thoracic Wall Injury Risk From Behind Armor Blunt Trauma
Justin McMahon[1], Parker Berthelson[1], Alexander Stotka[1], Barney McEntire[2], Robert Salzar[1]
[1]University of Virginia, [2]US Army Aeromedical Laboratory

P138 Mechanical Characterization of the Fibrosed Lung Surface via Spherical Indentation
Kathrine Quiros[1], Talyah Nelson[1], Mona Eskandari[2,1]
[1]University of California, [2]University of California, Riverside

P139 Shear Strains as a Tear Growth Mechanism for High-Grade Partial-Thickness Rotator Cuff Tendon Tears
Carla Nathaly Villacis Nunez[1], Ulrich Scheven[1], Asheesh Bedi[2], Ellen Arruda[1]
[1]University of Michigan, [2]NorthShore Orthopedic and Spine Institute

P140 Microscale Remodeling of Arterial Wall Leads to Macroscopic Pressure-Independent Axial Force
Ruturaj Badal, Ryan Mahutga, Patrick Alford, Victor Barocas
University of Minnesota

P141 Determining High Strain Rate Porcine Brain Material Properties Using Inertial Microcavitation
Elizabeth Bremer-Sai[1], Anastasia Tzoumaka[2], Surya Kolluri[2], David Henann[2], Christian Franck[1]
[1]University of Wisconsin-Madison, [2]Brown University

P142 In-Situ and In-Vitro Heterogeneity of Porcine Meninges: Insights From 2-Photon Microscopy and Correlated Micro-Indentation
Seyed Mohammad Tabatabaei, Lakiesha N. Williams
J. Crayton Pruitt Family University of Florida

P143 Functions of Prolyl Hydroxylation in Elastin
Chengeng Yang, Anna Tarakanova
University of Connecticut

P144 Validation of a Platform to Quantify Corneal Endothelial Cell Damage Due to Indentation
Alex J. McMullen[1], Aldo Tecse[1], Paul D. Funkenbusch[1], Naveen Mysore[2], Yousuf M. Khalifa[3], Mark R. Buckley[1]
[1]University of Rochester, [2]University of Rochester Medical Center, [3]Emory University School of Medicine

P145 IOP-Induced Lamina Cribrosa Astrocyte Deformations Measured Directly From the Astrocytes Are Larger Than Those Estimated From the Deformations of the Collagen Beams
Bingrui Wang, Susannah Waxman, Sofia Lusvardi, Hannah Schilpp, Ashley Linton, Yuankai Lu, Ian Sigal
[1]*University of Pittsburgh*

P146 Investigating the Influence of GAG Digestion and Corneal Crosslinking on Collagen Fibril Organization
M.E. Emu, H. Hatami-Marbini
University of Illinois Chicago

P147 Preconditioning Impact on Porcine Corneal Biomechanics
Md Esharuzzaman Emu, Hamed Hatami-Marbini
University of Illinois Chicago

P148 Predicting Failure Locations in Heterogeneous Soft Materials
Catherine Eberman, Colleen Witzenburg
University of Wisconsin Madison

P149 A Multiscale and Multimodal Computational Framework Towards Understanding Mechanotransduction in the Distal Colon and Rectum
Amirhossein Shokrani, Bin Feng, David M. Pierce
University of Connecticut

P150 AI in B3: Artificial Intelligence in Biomechanics, Bioengineering, and Biotransport
Chester Jar, Lindsey Westover, Gail Thornton
University of Alberta

P151 Probing the Rat Urinary Bladder During Isotonic Active Contraction Using Multiphoton Microscopy
Alireza Asadbeygi[1], Yasutaka Tobe[1], Sean Stocker[1], Simon Watkins[1], Paul Watton[1,2], Christopher Hardin[3], Naoki Yoshimura[1], Anne Robertson[1]
[1]*University of Pittsburgh,* [2]*University of Sheffield,* [3]*University of Missouri*

P152 Y-Shaped Cutting of Soft Solids: Potential for Soft Biological Material Characterization
Shaobo Zhan, Amy Wagoner Johnson, Shelby Hutchens
University of Illinois at Urbana-Champaign

P153 Finite Element Modeling of Behind Armor Blunt Trauma From Indentor Impacts to the Lung and Liver
Karthik Banurekha Devaraj[1,2], Balaji Harinathan[1,2], Alok Shah[2], Jared Koser[2], Karthik Somasundaram[2], Brian Stemper[2], Narayan Yoganandan[2]
[1]*Vellore Institute of Technology,* [2]*Medical College of Wisconsin*

P154 Computational and Multi-Scale Mechanical Analysis of Soy Gel Extrusion Process
Marco Fielder, Arun Nair
University of Arkansas

P155 Optical Coherence Elastography Measurement of Cerebral Artery Stiffness
Mykyta Ananchenko[1], Xu Feng[2], Samuel Halvorsen[1], Guoyang Li[3], Seok-Hyun Yun[2,4], Yanhang Zhang[1]
[1]Boston University, [2]Massachusetts General Hospital, [3]Peking University, [4]Harvard University

P156 Development of an Acoustically Augmented Uniaxial Extension Testing Apparatus to Detect the Proportional Limit in Biological Soft Tissues
Cyrus Darvish[1], Peter Jacobs[2], Elias Mignonga[2], Yuqi Cai[2], Pete Gueldner[2], David Vorp[2], Timothy Chung[2]
[1]Univeristy of Pittsburgh, [2]University of Pittsburgh

P157 Morphological Analysis of Hindfoot Osteoarthritis via Statistical Shape Modeling of the Foot and Ankle
Elana Renae Lapins[1,1], Shireen Elhabian[1,1], Charles Saltzman[1], Amy Lenz[1,1]
[1]University of Utah

P158 Propylparaben Exposure Alters Uterine Microstructure and Indentation Modulus
Mahmuda Arshee, Indrani Bagchi, Ayelet Ziv-Gal, Amy Wagoner Johnson
University of Illinois at Urbana-Champaign

P159 Hydrogel Phantom System as Mechanical Placental Tissue Mimics
Samyuktha Kolluru[1], Adrienne Scott[2], Patrick Yang[2], Michelle Oyen[1,2]
[1]Washington University in St. Louis, [2]Washington University in St Louis

P160 Umbilical Arterial Development and Mechanics in Gestational Diabetes Mellitus
Kara Peak, Sarah Wernimont, Victor Barocas
University of Minnesota

P161 MRC2 Is Necessary for Typical Cervical Remodeling in Rodent Pregnancy
Serena Russell[1], Bex Pendrak[1], Mariano Colon-Caraballo[2], Mala Mahendroo[2], Kristin Myers[1]
[1]Columbia University, [2]University of Texas Southwestern Medical Center

P162 Prediction of Tearing in Vaginal Tissue Using Machine Learning
Mostafa Zakeri, William Snyder, Justin Krometis, Traian Iliescu, Raffaella De Vita
Virginia Tech

P163 Characterizing the Influence of Proteoglycans on Passive and Viscoelastic Material Properties of Female Pelvic Floor Skeletal Muscles
Megan Routzong[1], Francesca Sesillo[1], John Rudell[1], Marianna Alperin[1,2]
[1]University of California, San Diego, [2]Sanford Consortium for Regenerative Medicine

P164 Spatially Mapping the Time-Dependent Material Properties of the Nonhuman Primate Cervix Through Gestation
Echo Xu[1], Camilo Duarte-Cordon[1], Daniella Fodera[1], Shuyang Fang[1], Ivan Rosado-Mendez[2], Timothy Hall[2], Helen Feltovich[3], Kristin Myers[1]
[1]Columbia University, [2]University of Wisconsin-Madison, [3]Mount Sinai

Tissue & Cellular Engineering

P96 3D Age-Related Breast Cancer Model With Aged and Young Collagen Extracts for Drug Screening
Jun Yang, Gokhan Bahcecioglu, Aktar Ali, Brian Blagg, Pinar Zorlutuna
University of Notre Dame

P97 Spatial Heterogeneity in Engineered Heart Tissue Mechanics Following In Vitro Infarction
Michael Potter[1], Samuel Coeyman[1], Jonathan Heywood[1], William Richardson[2]
[1]Clemson University, [2]University of Arkansas

P98 Development of Hormonally Responsive Tunable Hydrogel
Vivian Su[1], Nicholas Gigliotti[1], Juan Diego Carrizo[2], Mitra Taheri[1]
[1]Johns Hopkins University, [2]University of Pennsylvania

P99 Microfluidic Dual-Gel Cell Culture Model: Studying Cell Migration Under Controlled Interstitial Flow
Rossana Iturbide, Alimohammad Anbari, Jing Fan, Sihong Wang
City College of New York

P100 Role of Sex and Sex Hormones in Pulmonary Artery Adventitial Fibroblast Mechanosignaling
Yufan Lin, Giuditta Monti, Daniela Valdez-Jasso
University of California, San Diego

P101 Engineering Mesenchymal Stromal/Stem Cells Into an Anti-Oxidative Agent by a Mechanically Dynamic Hydrogel System Sensitive to Oxidative Stress
Nicholas Serio, Thomas Leahman, Sing-Wan Wong
Colorado State University

P102 Quantifying Changes in Morphological and Biochemical Properties of Senescent Cells
Amarnath Singam[1], Kimberly Ramirez[1], Deok-Ho Kim[2], Jingchun Chen[1], Seungman Park[1]
[1]University of Nevada, Las Vegas, [2]Johns Hopkins University

P103 The Compound Stimulation of Matrix Stiffness and Collagen Concentration on Tumor Organoid Migration
Bo-Jiang Lin, Hiromichi Fujie, Masashi Yamazaki, Koji Takahashi, Naoya Sakamoto
Tokyo Metropolitan University

P104 Alterations in Microglia Morphology and Viability Following In Vitro Traumatic Brain Injury
Emily Blick, Christian Franck, Aviad Hai
University of Wisconsin-Madison

P105 Role of Calcium in Regulating Mechanical Phenotype of Cells in A 3D Microtissue
Vaishali Bala, M.K. Sewell-Loftin
University of Alabama at Birmingham

P106 In Vitro, Network-Wide Excitotoxic Disruption Following Traumatic Brain Injury Model to Assess Critical Injury Thresholds
Jamie Sergay[1], Natalie Schick[2], Emily Blick[1], Aviad Hai[1], Christian Franck[1]
[1]University of Wisconsin Madison, [2]Rutgers

P107 Endothelial Cells Exhibit a Similar Temporal Response to Ultrasound as Normal Flow
Ian McCue, Adam Johnson, Joseph Turner, Ryan Pedrigi
University of Nebraska-Lincoln

P108 Characterization of the Basal Endothelial Glycocalyx
Zoe Vittum, Solomon Mensah
Worcester Polytechnic Institute

P109 Dissecting YAP/TAZ Mechanotransductive Mechanisms in Vascular Morphogenesis
Paula Camacho[1], Brendan Tobin[2], Devon Mason[1], Jason Burdick[3], Amber Stratman[4], Levi Wood[2], Joel Boerckel[1]
[1]University of Pennsylvania, [2]Georgia Institute of Technology, [3]University of Colorado Boulder, [4]Washington University in St. Louis

P110 LIM-Nebulette Regulates Podocyte Mechanoresponse and Focal Adhesion Remodeling
Jacob Wright[1], Yixin Hu[1], Anthony Mendoza[1], Nanditha Anandakrishnan[1], Anika Hudson[1], Alan Stern[1], Eric Lima[2], Evren Azeloglu[1]
[1]Icahn School of Medicine at Mount Sinai, [2]Cooper Union

P111 Assessing the Effect of Dimethyl Sulfoxide on the Properties of Regulatory Enzyme Fructose 1,6-Bisphosphatase in Gluconeogenesis Conditions
Amin Sabaghan, Neda Ghousifam, Mahboobeh Rezaeeyazdi, Christopher Riley, Dwight Romanovicz, Marissa Nichole Rylander, Matthew Uden
University of Texas at Austin

Undergraduate Design Competition

P165 Exoskeleton for Surgery Training
Moved to Poster Session I: P170
Jeremy Varughese, Andres Miramontes, Jesse Gomez, Andrew Gonzales Alayo, Anissa Cantu, Luis Morales
University of Texas at Dallas

P166 Epilog: Rapid EEG Detection of Status Epilepticus
Rohan Chhaya, Carly Flynn, Elena Grajales, Priya Shah, Dori Xu
University of Pennsylvania

P167 Erias: A Bluetooth Cardiac Monitoring System for Pediatric Inpatient Use Erias: A Bluetooth Cardiac Monitoring System for Pediatric Inpatient Use
Alexandra Dumas, Angela Song, Samir Maarouf, Daphne Nie, Georgia Georgostathi
University of Pennsylvania

P168 Region Adjustable Prosthetic Socket
Camilo Rodriguez Rozas, Kristin Bindas, Katie LeClaire, Maddi Viteri, Savannah Waymer
University of Pittsburgh

P169 Easy-O: Low-Cost Oxygen Therapy Unit
Emma Kim, Kaito Hara-Lee, Alina Gammage, Darien Gaw, Sabrina Packer, Michael Jones, Amanda Donoso, Xian Wang
Queen's University

P170 See-Rynge: A Visually Accessible Liquid Measurement Device
Chiadika Eleh, Liam Pharr, Venkatesh Shenoy, Joey Wei, Isaac Kim
University of Pennsylvania

P171 IV Tutor: IV Insertion Training Module
Kaito Hara-Lee, Maya Goodman, Nathan Duncan, Andrew Kim, Gavin Nyhof, Rebecca Hisey, Xian Wang
Queen's University

P172 Non-Invasive, Quantitative Anterior Cruciate Ligament Integrity Measurement System
Lindsay Phillips, Daniel Lounsbery, Jake Ritchie, Alex Ropars
Binghamton University

P173 SmartSleeve+: A Post-Operation Solution for Detecting Infections Underneath Casts for Patients With Open Fractures
Jamie Moni, Gautham Nair, Ajit Saran, Pavan Raghupathy
University of Pennsylvania

P174 Home Unweighting Exercise Device for Patients With Diabetic Foot Ulcers
MOVED TO SESSION I, POSTER 171
Victoria Moore, Miles Yoshinobu, Mirabella Herrera, Tanveer Ahmed, Rachel Porter
University of Texas at Dallas

P175 KneeVive: At-Home Osteoarthritis Symptom Mitigation
Aaryan Chaudhary, Anitez Gautam, Yennifer Lemus, Devan Yarberry, Zeeshan Haque, Anna Maria Kuraszkiewicz, Aryan Kulkarni, Ian Miller, Anna Lin, Benjamin Goldblatt, Brooke Oberlee, Caroline Gerety, Diya Asawa, Dylan Yee, Juliette Tao, Kavyon Touserkani, Kush Gami, Liam Morrison, Michael Leacoma, Nare Parseghian, Shafeena Uddin, Sofia Goryachev, Victoria Villalonga, Wesley Hanson, Zainab Khalil
University of Massachusetts Amherst

P176 Enhancing Labor Comfort: Development of an Adaptive Pressure Clamp for Double Hip Squeeze
Connor Beck[1], Noah Kibler[2], Sheryl Korah[1], Osman Sayginer[1]
[1]Temple University, [2]Drexel University

P177 CARDIOFORECASTER - An AI-Driven Cardiovascular Disease Forecasting Platform
Valerie Balas, Krysta Bernold, Mathieu Colon, James Evangelisto III, Kylie Herbert, Daniel Roozbahani, Ria Mazumder
Widener University

P178 TrueDose, An Adolescent Medication Compliance iOS Application
Nicolette Cilenti, Matthew Jester, Skylar Ford, Elle Ferguson
University of Pennsylvania

P179 Neuragame: Integrating App-Based & Physical Therapy for at Home Stroke Rehabilitation
Jishnu Basu, Samarth Kabbur, Arnav Nair, Deeya Kaneria, Ryan Virkar, Reshmitha Muppala
University of Texas at Austin

P180 OASIS: Oxygen Auto-Titrating System for Increased Sustainability
WITHDRAWN
Srish Chenna, Kira Lu, Sylvia Mihailescu, Karan Shah, Kalen Truong
University of Pennsylvania

P181 Engineering Mesenchymal Stromal Cells to Facilitate Muscle Regeneration by Correcting Oxidative Stress
Ali Eldeiry, Sing-Wan Wong
Colorado State University

P182 Universal Hitch Attachment for Blind Veteran
Alexa Warren, Anna Sasse, Joshua Perry, Bailey Erickson, Marvin Aguilera, Christopher Luliucci, Erik Brewer
Rowan University

P183 VITAFLOW - The Future of Heart Preservation
Jimin Jung, Nigel Newby, Spencer Tuohy, Tyler McGoldrick
University of Pennsylvania

P184 Tracheostomy Humidification Device
Estefania Enciso Pelayo, Jonathan Balsano, Michael Fong
University of California, San Diego

IMMERSION, INNOVATION, DESIGN & DEVELOPMENT (I2D2): A 9-WEEK SUMMER EXPERIENCE IN BIOMEDICAL ENGINEERING

Alan W. Eberhardt

Department of Biomedical Engineering
University of Alabama at Birmingham
Birmingham, Alabama, USA

INTRODUCTION

The past fifty years has seen tremendous growth in the healthcare industry, constituting 20% of the gross domestic product of the United States (U.S.) by 2020 [1]. With a medical device market size of $155 billion in 2017, the U.S. was considered the largest market in the world [2]. Engineered solutions produced game-changing medical innovations including MRI/CT scanning, angioplasty and stents, hip and knee replacement [3]. Clinical and rehabilitation needs present golden opportunities for biomedical engineering (BME) students to be trained in medical device design and commercialization.

The National Institute for Biomedical Imaging and Bioengineering (NIBIB) has long been a strong advocate for interdisciplinary approaches to STEM education that apply knowledge and employ innovative technologies. Interdisciplinary education that brings together biomedical engineering and business/entrepreneurship is key to bolstering innovation. The present abstract describes an 8-week summer program aimed at providing rising juniors in biomedical engineering at the University of Alabama at Birmingham (UAB) an opportunity to gain an introductory experience in clinical immersion, innovation, design, and development (I2D2).

METHODS

This program was designed to provide rising juniors from the UAB BME undergraduate program an opportunity to engage in an 8-week innovation experience based on clinical immersion. Six Summer Innovation Fellowships of $3,000 were awarded competitively that were intended to defray expenses incurred by students living on campus during the summer. An additional $250 was available for prototyping expenses. As a recipient of the award, students were expected to invest at least 30 hours per week to their project, performing background research, engaging in design and prototyping, and interacting extensively with clinicians and other project mentors. Projects emphasized improving outcomes for hospitalized patients and patients living with disabilities. No outside employment was permitted for the duration of the fellowship.

The program began with discussions on empathy, where students familiarized themselves with the areas they would encounter during their clinical rotations (advanced endoscopy, minimally invasive surgery, endovascular/vascular surgery, colo/rectal/GI surgery, endocrine surgery, and melanoma surgery). Shadowing was completed over one week, including clinicians from the UAB School of Medicine. Two additional days of shadowing were done at Lakeshore Foundation (a fitness facility and hospital for people with disabilities, where students were exposed to rehab engineering and various needs for assistive technologies. The students returned to the classroom and defined the problem(s) and articulated the challenges clinicians faced with respect to a particular process or device for treating a specific disorder.

The next two weeks were spent on classroom lectures, provided by the author, on the following topics:

1. Disease State Fundamentals, Existing Solutions
2. Working in teams – DISC, Need Statements
3. From Need Specs to Design Constraints
4. Stakeholder & Market Analyses
5. Intellectual Property & Regulatory Pathways
6. Best Design Practices, User-centered Design
7. Ideation & Evaluation
8. Early- and Late-Stage Prototyping

To better prepare students to be successful with their early design planning, lectures on “Best Practices in Design” were presented using excerpts from Biodesign [4]. A lecture was given on Design for Manufacture/Assembly (DFMA), where students were instructed to minimize and standardize parts and subassemblies, and determine what is commercially available (e.g., motors, bearings) vs. custom-made components. The ideation portion of the class tasked the students with generating multiple ideas. A Pugh matrix approach was used to identify

the leading solution candidate based upon the established design requirements. Prototyping of leading design candidates was enabled through multiple fabricating facilities for conventional machining, forming, and 3D printing of prototypes. Solutions were expressed in written and oral form through team-based reports and presentations. Highlights are shown in Figure 1.

At the completion of the I2D2 program, students were asked to

Figure 1. (left) early prototyping; (center) machine shop work; (right) final presentation day with surgeons.

rank the following concepts with a 1 (no knowledge/skill) to 5 (knowledgeable/ skilled), according to their experiences (before vs. after completing I2D2.

1. How to perform clinical needs finding
2. Ability to formulate design constraints
3. How to determine a medical device class
4. How to determine the market associated with a device
5. How to use machine shop tools to build a device
6. How to perform a Risk Analysis

They were also asked to provide comments concerning the time spent performing clinical rotations; in the classroom; and building and testing prototypes (too short, too long, just about right), as well as what recommendations would you provide to make the overall experience better for the students next summer?

RESULTS

All students agreed that the time spent in the classroom was too long, while the time spent prototyping was too short. Time spent shadowing clinicians/therapists was about right, though the students reported feeling a bit lost.

Figure 2 shows the survey results comparing the students' opinions of their own knowledge/skill levels regarding the lecture portion of the course. There are clear increases across the board – the experience was valuable in helping students to work with clinicians to identify needs and to establish the relevant design constraints. The identification of medical device class was a topic where students were initially very ignorant but learned easily how to use the FDA website to identify relevant predicate devices to establish the likely device class of their design. Interesting, students felt the most confident and there was the least change in knowledge/skill related to market analysis. The experience gained in the UAB Design & Fabrication Facility proved invaluable to the students and the topic of Risk Analysis was one that they had never seen and after the experience, still felt a bit uncertain.

Students were encouraged to submit their work to the 2023 BMES Annual Meeting. One student did so and traveled to Seattle where her work was accepted for the undergraduate student poster session.

DISCUSSION

Improvements planned for Summer, 2024 include reducing the overall number of days in the classroom by increasing the hours/day during the initial lectures. The mix of hospital/rehab projects was good. Overall, the complexities of the hospital projects, along with the regulatory hurdles involved in bringing a device into the clinic, preclude most hospital projects from making it beyond initial prototypes. Rehab/assistive technologies, on the other hand, commonly result in devices that can be delivered to the client, which increases the overall satisfaction of both client and the students. Prototyping will be extended allowing the students more time to iterate on designs based on feedback from clients.

One addition will be to have the students better familiarize themselves with the problem and disease state through a review of peer-reviewed journal articles related to the clinical problems.

COMPARISON OF COMPUTATIONAL MODELS FOR PREDICTING LEACHING FROM IMPLANTED MEDICAL DEVICES

Martin L. Tanaka (1), David M. Saylor (2), Robert M. Elder (2)

(1) College of Engineering and Technology, Western Carolina University, Cullowhee, NC, USA
(2) US Food and Drug Administration (DBCMS – OSEL – CDRH), Silver Spring, MD, USA

INTRODUCTION

Utilization of computational modeling and simulation in medical device development can enable faster development of new products, lower research and development costs, and decrease animal usage. The engineering standard ASME V&V40, "Assessing Credibility of Computational Modeling through Verification and Validation: Application to Medical Devices" released in 2018 has made the use of computational modeling more accessible for companies seeking approval or clearance from the US Food and Drug Administration (FDA). Moreover, Regulatory Science Tools (RSTs) and Medical Device Development Tools (MDDTs) approved by the FDA include new computational approaches to aid with submissions that did not exist only a few years ago.

An important aspect of any implanted medical device is biocompatibility, an attribute of which is the need for a device not to release hazardous materials into the body at a level above the safe limit (toxicological threshold). The rate that polymeric components within medical devices leach potentially hazardous materials can be estimated using computational modeling.

In this research, two computational models are developed and compared. The first is a one-component model that predicts the rate that materials are leached from an implanted polymeric medical device using Fickian diffusion equations and a sink boundary condition at the polymer tissue interface. The second model contains two components and adds complexity and clinical relevance by accounting for migration across the polymer tissue interface and diffusion through peri-implant tissue. Differences in the modeling results are compared and the advantages of each approach are identified.

METHODS

Physics based models were developed to calculate the diffusion rate of leachables using Fick's law [1],

$$\frac{\partial C(x,t)}{\partial t} = D_p \nabla^2 C(x,t) \tag{1}$$

where, the concentration of the leachable substance, C, is a function of the position within the polymer, x, and time, t. D_p is the effective (macroscopic) diffusion coefficient of the leachable in the polymer. D_p is scalar and independent of C, x, and t.

The one-component model for the mass release $M(\tau)$ as a fraction of the initial mass of leachable contained within the device M_0 is given by,

$$\frac{M(\tau)}{M_0} = \begin{cases} 2\sqrt{\frac{\tau}{\pi}} & \tau \le 0.2 \\ 1 - \frac{8}{\pi^2} exp\left(-\frac{\tau \pi^2}{4}\right) & \tau > 0.2 \end{cases} \tag{2}$$

$$\tau = \frac{D_p\, t}{L^2} \tag{3}$$

where τ, is a dimensionless time parameter that is scaled by D_p, and half the implant thickness, L.

Leaching from the two-component model is characterized by the equation below [2],

$$\frac{M(\tau,\beta)}{M_0} = \left(\frac{\beta}{1+\beta}\right) 2\sqrt{\tau}\left(\frac{1}{\sqrt{\pi}} - \left(\frac{\beta}{1+\beta}\right) 2 \sum_{n=1}^{\infty}\left[\left(\frac{1-\beta}{1+\beta}\right)^{n-1} ierfc\left(\frac{n}{\sqrt{\tau}}\right)\right]\right) \tag{4}$$

$$\beta = \frac{1}{K_{p:t}} \sqrt{\frac{D_t}{D_p}} \tag{5}$$

where, β, is a dimensionless parameter associated with migration across the polymer-tissue interface and the relative migration rate within the polymer, $K_{p:t}$, is the polymer tissue partition coefficient, and D_t, is the diffusion rate of the leachable within the tissue.

Numerical solutions were developed using custom MATLAB code to characterize a "general medical device". Thus, the solutions presented are applicable to any implanted device that contains polymeric material. Two cases were used as an example 1) the release of Bisphenol A (BPA) from a silicone device and 2) the release of Irganox 1010 from a device made from high density polyethylene (HDPE). The first case is representative of small molecules diffusing through a high diffusivity polymer where $\log_{10}\beta$ = - 1.27. The second case represents the other extreme, a large molecule diffusing through a low diffusivity polymer where $\log_{10}\beta$ = 2.40.

RESULTS

For BPA in silicone the one-component model estimated complete mass release (M/M_0 = 100%) within about 8 hours, but the more complex two-component model only predicted 35.3% mass release in 24 hours (Figure 1a). For Irganox 1010 in HDPE the one-component model and two-component model have visibly identical results with the first line being totally covered by the second (Figure 1b). Both models predict a mass release of 0.15% of the total mass in the first 24 hours.

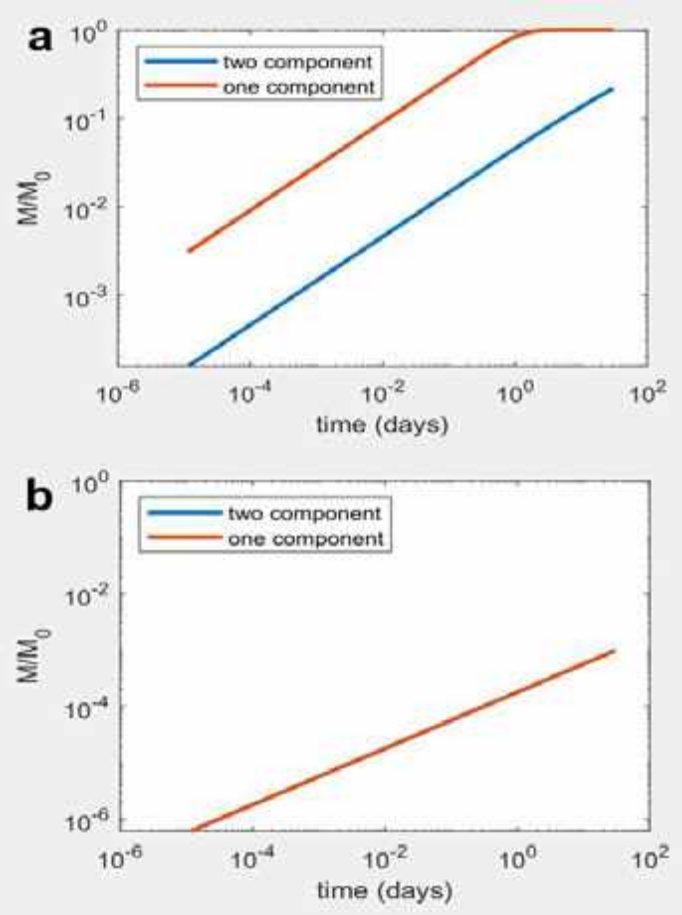

Figure 1: Comparison of model results for cumulative mass release of BPA in silicone (a) and Irganox 1010 in HDPE (b).

Figure 2 shows the difference in predicted mass release using the two models to be indistinguishable over much of the clinically relevant input parameter range (Deep blue area on the top portion). However, when the value of β was small, large differences were observed in the predicted mass release, exceeding four orders of magnitude in some instances.

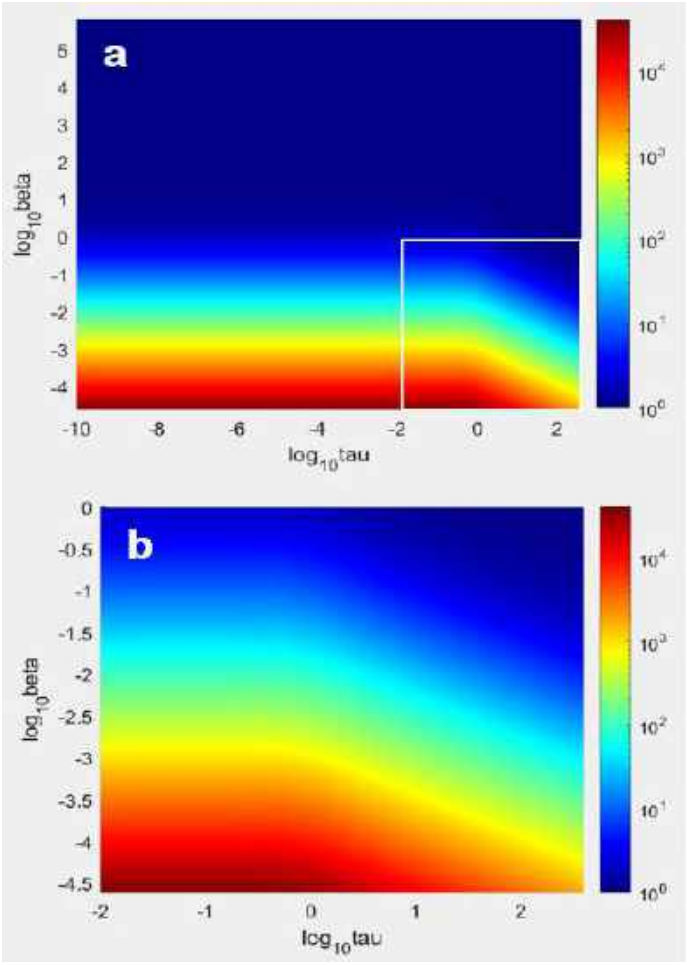

Figure 2: The ratio of predicted mass release (one-component model / two-component model) is shown over the typical range of input parameter values (a) and in a close-up section (b).

DISCUSSION

The findings imply that the one-component model may be sufficient to predict the mass release in cases like Irganox 1010 in HDPE because the two models yield essentially the same result. This effect was also observed in general for other cases where values of β are high. Thus, in these cases, it may not be beneficial to apply the more complex model when the simpler model predicts the same outcome.

However, in the case of BPA in silicone, mass release predicted by the one-component model exceeded the two-component model by an order of magnitude. When clinically relevant predictions of mass release are desired, use of the more complex two-component model may be warranted.

INTRODUCTION

In malignant tumors, the physical attributes of the host organ can significantly affect cancer spread. For tumors outside of the brain, it has been previously reported that cancer cells become softer and more mobile than normal cells in response to local mechanical forces, promoting their migration and metastasis away from the primary tumor [1]. However, these mechanobiological phenomena are vastly unexplored in the brain. In this study, we aimed to compare the viscoelastic properties of human U87 glioblastoma (GBM) cells and their normal counterpart, immortalized human astrocytes (IHAs) using a parallel-plate flow chamber. We also used fluorescence microscopy to quantify actin density and alignment in both cell types given the essential role of actin in cellular mechanical behavior. Indeed, an understanding of GBM cell mechanics may lead to the identification of novel disease mechanisms, biomarkers, and therapeutic strategies to improve treatment outcomes.

METHODS

Cell Culture. IHAs and U87 GBM cells were cultured at 37 °C and 5% CO_2. GBM cells were cultured in DMEM + 10% FBS + 1% penicillin/streptomycin, and IHAs were cultured in SuperCult IHA Media + 1% IHA growth supplement + 2% FBS + 1% penicillin/streptomycin. Both cell types were seeded in 35 mm Petri plates at a density of 5,000 cells/plate.

Shear Assay. The viscoelastic properties of IHAs and U87 cells were evaluated by employing our previously established modified shear assay technique [2]. Briefly, IHAs and U87 cells were exposed to physiological levels of fluid shear stress (FSS) experienced in the brain (4 Pa). The amount of stress applied (σ) was calculated using the formula for a parallel-plate flow chamber (Eqn. 1).

$$\sigma = \frac{6\mu Q}{wh^2} \tag{1}$$

Here, μ is the viscosity of the infused fluid (serum-free DMEM + 0.5 wt% methylcellulose), Q is the volumetric flow rate, and w and h are the width and height of the rubber gasket placed on the flow chamber, respectively. Phase-contrast video recordings were taken of cells while exposed to FSS for subsequent digital image correlation (DIC) analysis.

Digital Image Correlation Analysis. The Davis 10.1.2 software was used to perform DIC analysis on individual cells exposed to FSS using the phase-contrast recordings taken. Nuclear and cytoplasmic deformation within a cell was tracked by adding strain gauges to randomly selected areas of the nucleus and cytoplasm and using the sum of the differential track option. The output of the DIC analysis is a strain-time profile that can be further analyzed for mechanical characterization of the cell's subcellular components.

Modeling and Computation. Strain (ε)-time (t) profiles were fitted with a three-parameter generalized Maxwell model (Eqn. 2 and 3) using MATLAB's curve-fitting tool to quantify the viscoelastic properties (stiffness [E], viscosity [η_1], and stress-relaxation time [τ]) of the nucleus and cytoplasm of individual cells.

$$\varepsilon = \left(\frac{\sigma}{\eta_1}\right)t + \frac{\sigma}{E}\left(1 - \exp\left(\frac{-t}{\tau}\right)\right) \tag{2}$$

$$\tau = \frac{\eta_2}{E} \tag{3}$$

Statistical Analysis. T-tests were performed using the IBM SPSS statistical software. We adopted a 95% confidence level and considered means as being statistically significantly different at $p < 0.05$. Bar plots display the mean ± standard error of the mean (SEM).

Actin Density Quantification and Fiber Alignment Analysis. The actin fibers of IHAs and U87 GBM cells were stained with phalloidin to evaluate actin organization and alignment. The stained cells were imaged using a Keyence BZ-X810 widefield microscope. The Leica

fluorescence image processing software, LAS X, was used to quantify mean actin stain intensity for individual cells from each cell type as a measure of cellular actin density. Fiber alignment analysis was conducted using the MATLAB-based software CT-FIRE. Fiber angles were normalized to the circular mean angle for each cell and combined for statistical analysis.

RESULTS

A total of 84 U87 cells and 96 IHAs were analyzed for mechanical characterization. Our analysis of the strain-time profiles showed that the nuclear and cytoplasmic viscoelastic properties quantified were not statistically significantly different ($p > 0.05$) between U87 cells and IHAs (Fig. 1). Thus, there are no distinct mechanical differences between the normal and malignant brain cells. Comparing nuclear and cytoplasmic viscoelastic properties within each cell type, however, revealed that there are statistically significant differences ($p < 0.05$) in the stiffness and relaxation time in IHAs, but not in U87 GBM cells (Fig. 2). The difference between the nuclear and cytoplasmic viscosity in both cell types was statistically insignificant.

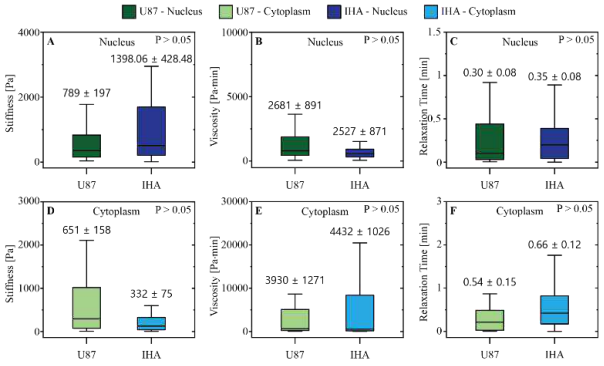

Figure 1: Comparison of the (A) nuclear stiffness, (B) nuclear viscosity, (C) nuclear relaxation time, (D) cytoplasmic stiffness, (E) cytoplasmic viscosity, and (F) cytoplasmic relaxation time between IHAs and U87 GBM cells.

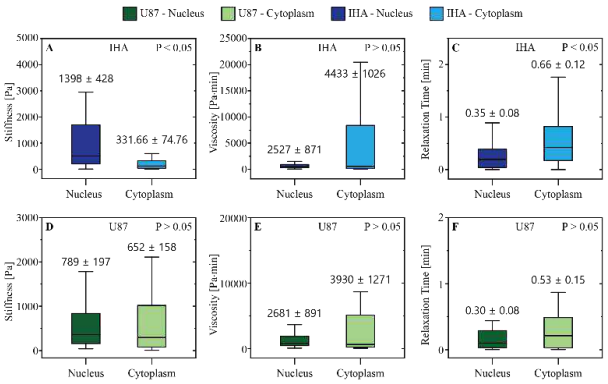

Figure 2: Comparison of nuclear and cytoplasmic stiffness, viscosity, and relaxation time of IHAs (A-C) and of U87 cells (D-F)

The actin density and alignment of 29 U87 cells and 32 IHAs was analyzed via fluorescent microscopy and is presented in Fig. 3. Fluorescent intensity analysis revealed that IHAs and GBM cells have similar levels of actin density as there were no statistically significant differences between the fluorescent intensity per cell area of both cell types. On the other hand, analysis of the actin fibers showed that the actin fibers of IHAs are typically more organized and aligned relative to U87 cells.

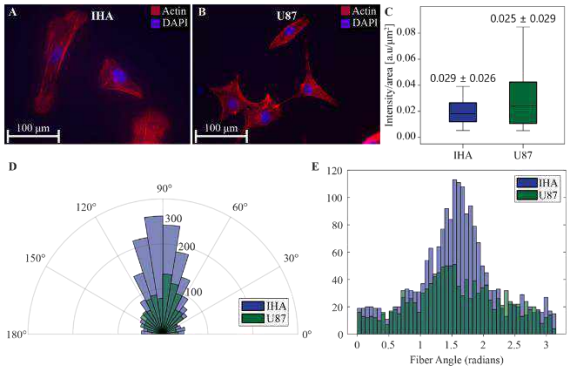

Figure 3: Representative images of phalloidin-stained (A) GBM cells and (B) IHAs. (C) Comparison of actin stain intensity between GBM cells and IHAs. (D) Angular representation of fiber orientation in GBM cells and IHAs. (E) Distribution of fiber angles relative to the average angle in each cell type investigated.

DISCUSSION

Our study sought to compare the mechanical properties between normal astrocytes and malignant brain cancer cells. Surprisingly, our results showed that, contrary to cancer cells originating from outside of the brain [1], the viscoelastic properties of GBM cells are similar to their normal counterpart. Moreover, our findings showed that, unlike the GBM cells, the differences between the stiffness and relaxation time of the nucleus and cytoplasm of IHAs are statistically significant. We also found that the actin density between both cell types did not differ significantly; this aligns with our mechanical analysis of IHAs and GBM cells discussed earlier. However, we did notice that the actin fibers of IHAs were more aligned and organized compared to the U87 cells. This feature may contribute to cell-type specific physiological and mechanical behaviors not captured in this study.

Overall, our results suggest that GBM cells may exhibit unique behaviors not seen in other extracranial cancer cell types. Notably, given the important role cellular mechanics plays in cancer cell migration, as well as the low mechanical demands and high fluid content in the brain [3], malignant cells may adopt unique brain-specific mechanical properties via inherent (genetic) and externally-driven (microenvironmental) mechanisms. This may explain why metastasis in GBM patients is rare [4] and conventional treatment options are unsuccessful [5], although future studies directly evaluating this connection are required. The impact of experimental parameters such as substrate stiffness is also a subject of future studies as tuning them may reveal mechanical differences not captured in this study.

IMPACTS OF TEARS SIZE AND LOCATION ON BLOOD FLOW DYNAMICS IN TYPE-B AORTIC DISSECTION

K. Khanafer (1), S. Scofield (1), Y. Aboelkassem (1)

(1) Engineering/Technology Division, University of Michigan, Flint, Michigan, USA

INTRODUCTION

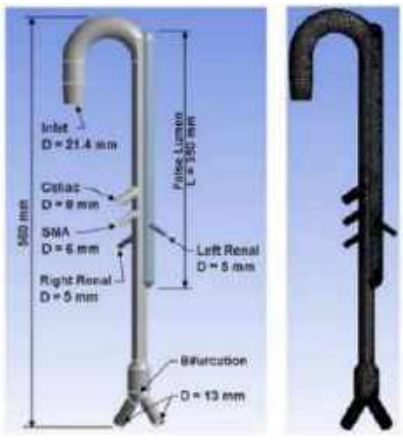
Acute type B aortic dissection (TBAD) is a critical cardiac condition with a high mortality rate that increases by 1-2% per hour after symptom onset [1]. This condition leads to tears in the inner layer of the aorta, resulting in the development of a flap tissue and the separation of aortic wall layers. The thin, weak outer aortic wall and a flexible, curved flap are significant consequences of acute dissection [2, 3]. Clinical interventions, such as grafting methods, surgery, and medications, are employed to restore normal aortic blood flow and prevent complications. Studies have investigated risk factors, including anatomical features (e.g., maximum aorta diameter, false lumen patency) and hemodynamic parameters (e.g., flow velocities through tears, pressure difference across the flap), influencing aortic dilation post-aortic dissection repair to mitigate the risk of complications.

Computational fluid dynamics (CFD) is considered a potential modeling tool to assist clinicians in provide valuable information on the hemodynamics of TBAD. The mechanism of some vascular illnesses, such aortic dissection, can be better understood and their course can be predicted using CFD. Previous research has shown that hemodynamic factors such flow velocity, wall pressure, and wall shear stress (WSS) strongly correlate with rupture. The development of a dissecting aneurysm is subject to a number of phenomena that CFD helps to understand and anticipate. There have been many studies on tears of aortic dissection. However, the majority of these studies assumed rigid wall model [8-11]. For example, Shi et al. [12] studied the effect of hemodynamics on Stanford type-A aortic dissection with various tear sizes and location. Their results illustrated that entry tear can significantly change the hemodynamics of aortic dissection. Further, their numerical results showed that the velocity in the true lumen was lower when the entry tear size was larger, and inversely, the velocity in the false lumen was higher.

The objective of this study is to develop in-silico numerical simulations using fluid structure interaction technique to study the effect of changing tear size and location on false lumen pressure of type-B aortic dissection.

METHODS

The numerical model of the aorta dissection used in this investigation is shown in Figure 1. Blood flow is governed by the incompressible Naiver-Stokes and continuity equations in a moving domain described by an arbitrary Lagrangian-Eulerian (ALE). The Navier–Stokes equations were solved numerically with a commercial finite-volume fluid dynamics solver (ANSYS Fluent 2023R1). Transient analysis was adopted to investigate the pulsatility of blood flow. The SST *k*-ω model was used in this investigation to describe turbulent flow.



(a) (b)

Figure 1: (a) Schematic diagram of the model, (b) Mesh

Time-dependent pressure waveforms and velocities obtained from ex-vitro experiments [13] were applied at the inlet and outlet branches of the fluid domain. Total pressure was applied at the inlet of the numerical model while static pressures were applied at renal, celiac, superior mesenteric artery and iliac arteries. In this work, the false lumen, flap, and branches were assigned an elastic modulus of 9 MPa (PTFE) to mimic the physical model in [13].

RESULTS

In this section, we compare our numerical predictions with the experimental data reported in [13]. To arrive at a periodic solution, simulations for four cardiac cycles were run. The information output from the final cycle served as the foundation for the results shown below. Our numerical model was first validated against the ex-vitro experimental results for 65 mm^2 proximal tear and 20 mm^2 distal tear [13]. Pressure was measured in true and false lumens of the ex-vitro experimental model and was used to validate the values predicted by the numerical model in the same location. An excellent comparison was found between numerical and experimental results as depicted in Figure 2.

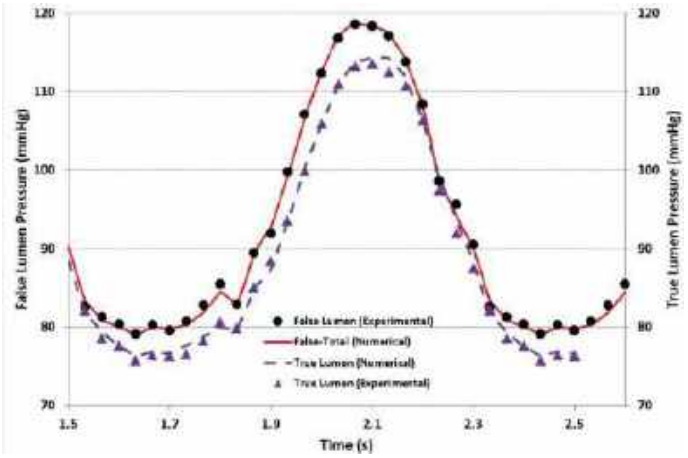


Figure 2: Comparison of the pressures in the true lumen and false lumen between experimental and numerical results (65 mm^2 proximal tear and 20 mm^2 distal tear).

The effect of varying the tear size on the pressure in false and true lumens was analyzed using FSI model. The results indicated that as the size of the distal tear increased, the peak systolic pressure decreased in both true and false lumens (Figure 3). Moreover, the pressure observed in both false and true lumens was significantly higher in the scenario with only a proximal tear compared to a situation involving both proximal and distal tears. In this context, the distal tear serves as a mechanism to diminish the pressure within the false lumen, subsequently lowering the risk of aneurysm development. These findings indicate that enlarging the distal tear size further will lead to a reduction in pressure disparity across the flap, eventually equalizing the pressure.

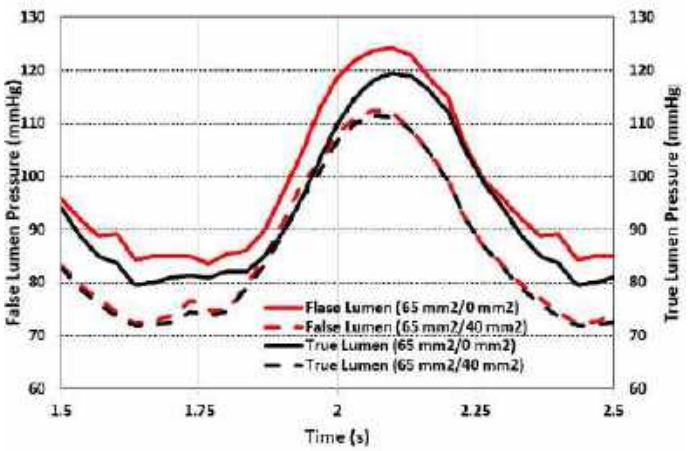

Figure 3: Effect of varying the tear size on the pressure in true lumen and false lumen.

INTRODUCTION

Congenital heart disease (CHD) has an incidence rate of 1.79% worldwide and affects about 40,000 births annually in the United States [1,2]. Approximately 8% of CHD patients have single ventricle anomalies (SVAs), which require surgical palliation or heart transplantation. However, donor scarcity has resulted in high waitlist mortality rates. According to the US Organ Procurement and Transplantation Network (OPTN), 592 infants < 1 year of age and 496 children aged 1-5 years received heart transplants in the US over the last 5 years (2019-2023). Of the 703 new pediatric patients added to the waiting list in 2021, 21.3% were under 1 year of age, and 26.4% were 1-5 years of age. Infants younger than 1 year of age had the highest waitlist mortality in 2021 at 29.8 deaths per 100 patient-years. In addition, biventricular failure, often associated with CHD, is not uncommon in pediatrics. Biventricular assist devices (BiVADs) were used in 37.3% of Berlin Heart EXCOR patients in a review by Rohde *et al.* [3]. However, BiVAD patients had higher overall mortality (45.9%) compared to left ventricular assist device (LVAD) patients (19.6%). Stroke remains one of the prevalent adverse events experienced by pediatric patients receiving biventricular support with the EXCOR device. To address current pediatric mechanical circulatory support device (MCSD) complications and donor scarcity, Penn State is developing a pediatric total artificial heart (pTAH) to support infants and small children with SVAs or biventricular heart failure. The design intends to reduce thromboembolic complication incidence by minimizing regions of flow stasis, increasing high wall shear rate (WSR) exposure, and promoting efficient pump filling and ejection.

In the present study, we characterize flow experimentally within the pTAH using particle image velocimetry (PIV) and identify potential thrombogenic regions of flow stasis and low WSR. Results are compared to the Penn State ventricular assist device (PVAD), which has been studied extensively [4-7].

METHODS

To study the pump fluid mechanics, acrylic models of the right side (RpTAH) and left side (LpTAH) of the Penn State pTAH were manufactured to provide a clear visualization surface and to mimic the internal geometry of the pump sac and blood contacting surface. The LpTAH and RpTAH were studied independently in a mock circulatory loop, which replicated physiological hemodynamic conditions. A non-Newtonian blood analog was created to mimic the viscoelastic behavior of pediatric blood by matching the kinematic viscosity and elasticity of pediatric whole blood [8]. The blood analog was primarily composed of sodium iodide, de-ionized water, glycerin, and Xanthan gum. Pressure transducers (Utah Medical Products, Inc.) and ultrasonic flow probes (Transonic, Inc.) measured pressure and flow rate, respectively.

Two dimensional-planar PIV was used to quantify the flow. The system included a camera (TSI, Inc.) mounted orthogonally to a laser (Quantel, Inc.), which illuminated an ~800 μm thick plane within the acrylic pump model. A frame straddling technique was used to capture images with a frame capture time difference of 200 μs and a laser exposure time of 405 μs. The camera and laser synchronizer (TSI, Inc.) was triggered by the outlet pressure waveform. End of systole and beginning of diastole were defined as the time point of peak outlet pressure. Two hundred image pairs were collected every 50 ms, ranging from 50 to 700 ms into the cardiac cycle. PIV images were masked along the wall using an in-house MATLAB® (The MathWorks, Inc.) code that defined the fluid boundary and improved near-wall image quality. Masked images were processed using Insight 4G™ (TSI, Inc.). Velocity fields at each plane were averaged for each time point, and the vorticity field was calculated using a least squares finite difference approximation approach appropriate for oversampled PIV data [9]. Velocity and vorticity data were postprocessed to generate contour plots using TECPLOT Focus (TECPLOT, Inc.).

WSRs were determined using an in-house MATLAB® code developed by Hochareon *et al.* [10], which calculated the WSR based

on the tangential velocity and distance from the wall. Navitsky *et al.* established a minimum threshold value of 500 s^{-1} for reduction of platelet adhesion and thrombus deposition onto polyurethane materials, such as the material used to make the pTAH pump sac [11]. WSR magnitude and high WSR exposure time were combined into a thrombus susceptibility potential (TSP) metric, given by

$$\mathrm{TSP} = 1 - \sum_0^N \left(\frac{\Delta t \gamma_w}{\gamma_c t_{crit}}\right)\left(\frac{e^{[(\gamma_w-\gamma_p)/(\gamma_c-\gamma_p)]}-1}{e^1-1}\right) \quad (1)$$

Where N was the number of PIV data collection time points, γ_w was the WSR, Δt was the portion of each time step that $\gamma_w > \gamma_{peak}$, γ_{peak} was the threshold for thrombus deposition (500 s^{-1}), γ_{cutoff} was the threshold for platelet deposition inhibition (1000 s^{-1}), and t_{crit} was double the time interval between PIV collection times. TSP ranges from zero (reduced thrombus risk) to one (elevated thrombus risk).

RESULTS

Diastole was characterized by a strong jet through the inlet valve. The jet was observed in all three parallel planes and in the normal inlet planes in the RpTAH (Figure 1). The jets corresponded to the inlet valve major and minor orifice locations and orientations. Rotational flow in the central body of the pump was initiated by the inlet jet during diastole. However, rotational flow fully developed 100 ms later in the LpTAH compared to the RpTAH. The rotation aligned flow near the outlet side in the direction of the outlet port prior to systolic ejection.

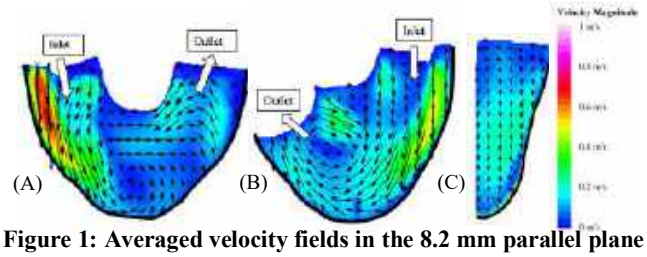

Figure 1: Averaged velocity fields in the 8.2 mm parallel plane of the (A) LpTAH and (B) RpTAH at 400 ms (87% diastole), and (C) RpTAH inlet centerline normal plane.

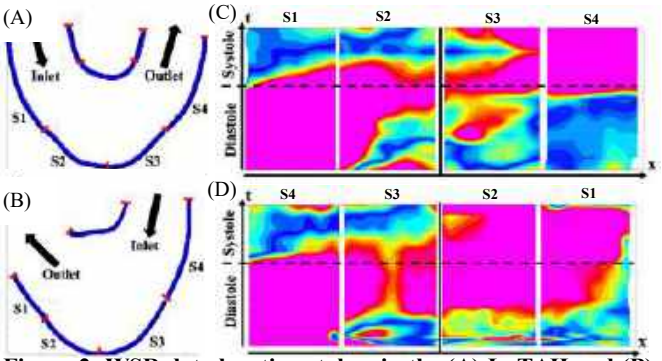

Figure 2: WSR data locations taken in the (A) LpTAH and (B) RpTAH. Normalized WSR contour plots along the bottom wall in the 8.2 mm parallel plane of the (C) LpTAH and (D) RpTAH.

The systolic characteristic flow pattern was the rapid formation of the outlet jet while rotational flow decayed. The RpTAH and LpTAH outlet jets encompassed the entire outlet port diameter and were skewed toward the outer wall of the device, leading to a rapid ejection of fluid. Flow patterns through the RpTAH during systole were more complex than those of the LpTAH due to the three dimensionality of the outlet port. Rotational flow in the RpTAH was maintained longer than in the LpTAH. The outlet jet also began to converge toward the center of the outlet port to orient flow with the outlet valve major orifice.

Most regions near the inlet and outlet had consistently high WSRs (Figure 2) and a low TSP. Some regions near the LpTAH apex failed to sustain WSRs above the threshold for sufficient wall washing, resulting in elevated TSP. Despite increased flow complexity in the RpTAH resulting from the modified geometry, the TSP values were mostly consistent with the LpTAH, showing low TSP near the inlet and outlet and elevated TSP along the apex wall (Figure 3).

The LpTAH and Penn State PVAD had many common flow characteristics and similar WSR trends. However, TSP in the LpTAH was slightly elevated near the pump apex compared to the PVAD due to reduced strength of the rotational flow in the LpTAH.

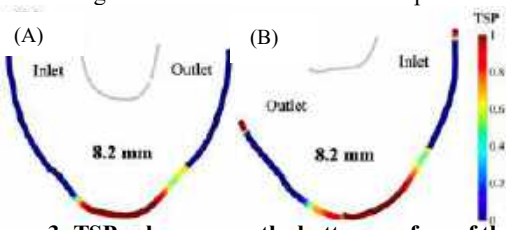

Figure 3: TSP values across the bottom surface of the (A) LpTAH and (B) RpTAH in the 8.2 mm parallel plane.

DISCUSSION

Previous studies show that the flow inside similar pulsatile MCSDs directly impacts thrombus formation on blood contacting surfaces. Scaled down pediatric MCSDs have complex flow compared to larger adult devices due to increased levels of curvature along the surfaces. Currently, no PIV studies exist that assess the fluid mechanics in a pTAH. Flow characterization can identify regions of flow stasis and low WSR, which provides guidance for optimizing device design and operation to reduce the thrombogenic risk potential that plagues similar circulatory support devices. The pTAH design generates three-dimensional flow due to the angling of the inlet and outlet ports, particularly in the RpTAH, compared to the PVAD whose inlet and outlet are aligned on a single plane with the pump body [12]. Overall, this study shows that the Penn State pTAH design experiences low thrombus deposition potential along much of the pump surface, similar to the PVAD. The primary area of concern is in the apical region of the pump, which is consistent with observations in other pulsatile MCSDs. These results suggest the Penn State pTAH may have comparable thrombogenic potential to other available pulsatile MCSDs despite its reduced size. Thus, making this device a viable option to support pediatric patients with severe biventricular failure as a bridge-to-transplant therapy.

A SIMPLE MODEL OF ANGIOTENSIN CONVERTING ENZYME HUB CAPACITY ON PEPTIDE FLUX AND RENIN INFLUENCE

Brian M. Westwood, Mark C. Chappell

Department of Surgery/Hypertension and Vascular Research, Cardiovascular Sciences Center

INTRODUCTION

Under classical physiologic conditions, angiotensin converting enzyme (ACE, EC 3.4.15.1) is a critical hub node for the Renin-Angiotensin-Aldosterone System (RAAS) and the conservation of the precursor angiotensinogen (Ao) consumption for a direct chain of conversions to angiotensin-(1-5) [Ang-(1-5)]. Angiotensin I [Ang-(1-10) or Ang I] is generated by renin [EC 3.4.23.15] from Ao, then ACE yields the first N-terminally intact bioactive peptide (with direct receptor action, B) in this cascade, angiotensin II [Ang-(1-8) or Ang II], which is converted to the next B, angiotensin-(1-7) [Ang-(1-7)], then ACE generates Ang-(1-5) [1] (Fig. 1).

We recently completed a post-hoc analysis of the RAAS in a subset of patients from the VICTAS septic shock trial that revealed a strong association of renin to mortality [2]. However, plasma samples were not collected with a renin inhibitor, so Ang I or intact Ao levels were not assessed in the study. To determine these components, we developed a conservation model that utilized the RAAS data from the VICTAS trial, which may be applied to other situations to calculate an unknown member of the RAAS [3].

METHODS

If we consider ACE and its substrates and products from Fig. 1 as a hub control volume extended (ACE hub, gray arrows) from Ang-(1-7), we can write the conservation equation 1 [this model assumes essentially all Ang I generated by renin is converted to Ang II by ACE, then directly converted to Ang-(1-7) by ACE2 [EC 3.4.17.23] and is acted upon by ACE to generate Ang-(1-5)]. There is an egress construct in the ACE hub linear model for bioactive peptides with rate B* acting on Ang II (encompassing direct receptor binding or conversion to Ang-(1-7) with receptor binding and/or any other non-ACE hub flux), which we modeled as equivalent to that of ACE [Q0, Q1, Q2 and Q3]. Under the pseudo-steady state hypothesis (PSSH), we can set the accumulation term to zero, and solve for Ao (equation 2).

Given the ACE hub (Fig. 1), the conservation of Ang-(1-7) can be described:

$$\frac{dAng-(1-7)}{dt} = Renin[Ao] - ACE[Ang-(1-7)] - B*[Ang\ II] = 0 \quad (1)$$

Enzyme concentrations were used as proxy for rate constants. The PSSH yields the key to estimating intact Ao level:

$$[Ao]_{calc} = \frac{ACE[Ang-(1-7)]+B*[AngII]}{Renin} \quad (2)$$

Calculated Ao values were evaluated to find 'far out' extreme outliers (outer fence) [4]. These 'wild shots' were Winsorized (W) by setting them to the outer fence value [5].

Area under the curve (AUC) for receiver operating characteristic (ROC) curves [6] were calculated by renin concentration percentile divisible by 5 (%ile/5) vs. whether Ao_{calc}, AngII and Ang-(1-7) concentrations were in normal range or not [1] (Fig. 2).

All calculations were performed in Excel (Microsoft Corp., WA), Prism (GraphPad Software, MA) was used for plotting data in figures and statistical analyses.

RESULTS

Using ACE quartiles as a surrogate for B* yielded output values with a correlation matrix for the four sets of calculations with all coefficients being greater than 0.995. The field solution was repeated for 20 control subjects, with $Q1_{ACE}$ yielding an interquartile range of Ao_{ctrl} calculated values matching the range of normal range values for Ao [1]. For all subsequent plots B* = $Q1_{ACE}$. Ao_{calc}, Ang II and Ang-(1-7) [r^2= (0.64, 0.04 and 0.24) log-log line (with 95% CI bands), respectively; n=84; Ao_{ctrl}, r^2=0.59, n=20; Fig. 3] concentrations were

plotted against renin. W signal clipping only effected the uppermost [Ao] values ($r^2_{noW\text{-}Ao}$ = 0.67).

ROC curves were plotted relative to renin %ile/5 for Ao_{calc}, Ang II and Ang-(1-7) in Fig. 4. W had no effect on ROC analysis.

The three AUC values were 0.65±0.032 ($\bar{x}$ ±SD). To achieve an FP rate = 0 and TP rate = 1 would result in an AUC = 1 yielding a perfect positive performance [6].

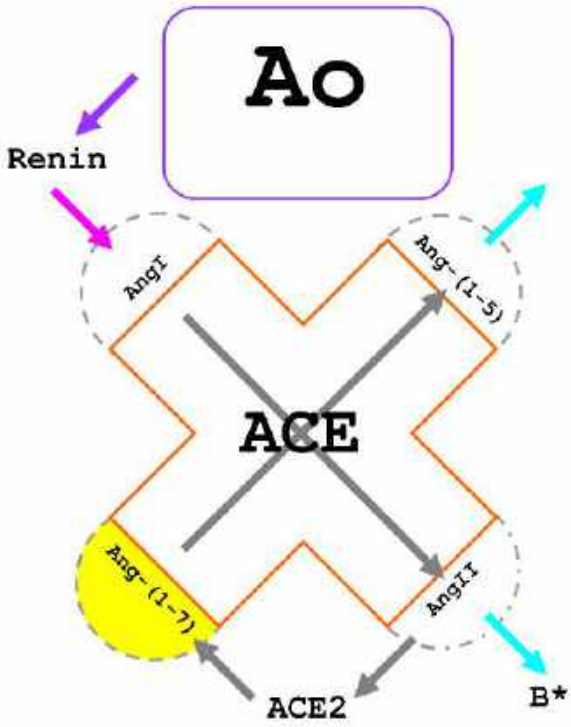

Figure 1: Simple model for ACE hub with the control volume extended to substrates and products, for development of conservation equation mathematical model for RAAS components. Graphic shows the mostly linear path of major angiotensin peptides under classical physiologic conditions.

For each **[renin]** %ile/5	Are **[Ao]**, **[AngII]** and **[Ang-(1-7)]** in normal range?		
		Yes	No
[renin] %ile	below	TP	FP
	above	FN	TN

Figure 2: Receiver operating characteristics for renin, relative to the two major bioactive RAS peptides and the system precursor protein. Contingency used to analyze data shown in Figure 4.

DISCUSSION

While the correlations between renin concentrations vs. Ao_{calc}, Ang-(1-7) and Ang II concentrations denote rank logarithmic decay {[Ao_{calc}, Ang-(1-7), Ang II], [0.64, 0.24, 0.04]; r^2 = 1}, the receiver operating characteristic AUC values have a small rank slope {[Ang-(1-7), Ao_{calc}, Ang II], [0.69,0.64,0.63]; equation 3, r^2 = 0.87}.

$$AUC = -0.03(rank) + 0.71 \qquad (3)$$

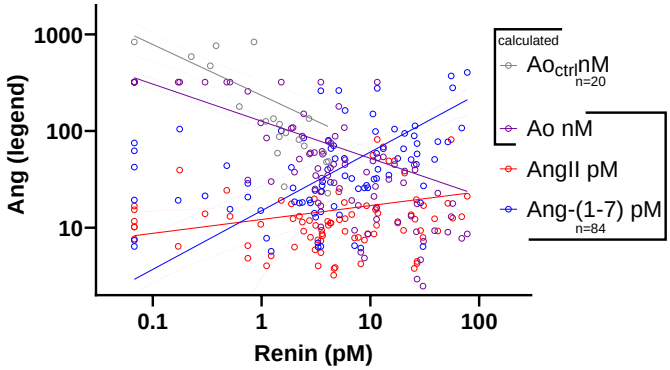

Figure 3: Log-log plot of Ao_{ctrl}, Ao_{calc}, Ang II and Ang-(1-7) concentrations vs. renin concentration.

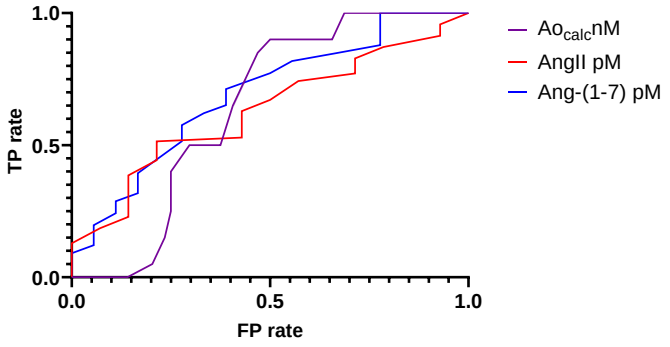

Figure 4: ROC curves for Ao_{calc}, Ang II and Ang-(1-7) concentration contingency with renin concentration as described in Figure 2.

This model may represent a seed method for the description of the complex interplay between not only this select catalog of RAAS components, but also may be generalized as a paradigm to explore greater utility in more complex systems.

IMMOBILIZATION AND SOFT TISSUE INJURY ARE NECESSARY TO CAUSE PERSISTENT DISABILITY IN A RAT MODEL OF ELBOW CONTRACTURE

INTRODUCTION

Post-traumatic joint contracture (PTJC) is a debilitating condition that occurs in up to 50% of elbow injuries, causing pain, stiffness, and reduced range of motion (ROM) [1]. Physical therapy is a common nonsurgical treatment strategy, and early joint use limits ROM loss and tissue pathology [2]. Immobilization (IM) is known to contribute to joint stiffness and reduced ROM, but clinical practice typically requires a period of joint IM after injury to prevent re-injury and limit joint instability [2]. Thus, identifying the contribution of IM to stiffness and decreased ROM will help to optimize physical therapy protocols to maximize ROM while sufficiently stabilizing the joint.

Other groups have investigated animal models of IM in the shoulder [3-5], hip [6], knee [7-15], and ankle [16,17], reporting muscle atrophy, joint contracture, capsule fibrosis, and inflammatory cell infiltration. However, to our knowledge the effect of IM without injury in the elbow joint has not yet been evaluated.

Previously, our group established the first animal model of elbow contracture [18], wherein we replicate soft tissue injuries seen in a simple elbow dislocation through anterior capsule puncture and lateral collateral ligament transection, which when combined with IM of the injured limb results in characteristic traits of PTJC such as persistent motion loss and anterior capsule fibrosis [2,18]. Past studies using this model have shown that early motion initiated soon after injury improves ROM in the joint [2]. Here, we investigated the contributors to PTJC to determine if IM without injury is sufficient for persistent ROM loss or whether soft tissue damage is also necessary to produce contracture. We hypothesized that animals receiving IM only in the absence of soft tissue injury would develop joint contracture, but that it would be less severe than the contracture seen in animals with both IM and soft tissue injury.

METHODS

In this IACUC approved study, male Long-Evans rats underwent unilateral IM of one forelimb with stretch netting and Vetrap bandages as previously described [18] (IM-Only group, n=6). IM limbs received no injury or surgical procedure, and contralateral (CL) limbs received neither injury nor IM. After 21 days of IM, bandages were removed and animals were allowed 21 days of free mobilization (FM) via unrestricted cage activity (Figure 1). Animals were sacrificed at the end of the FM period. Past data from an injured group with 21 days IM and 21 days FM [2] (Injury+IM; n=8 for mechanics; n=2 for functional testing) were included for comparison.

Functional testing was performed during the FM period. Forelimb strength was measured weekly beginning on day 21 using a custom-built device as previously described [19] to obtain maximum left and right forelimb strength measurements simultaneously. Gait analysis was performed weekly beginning on day 28 as previously described [19] using an open source, fully automated rodent gait system.

After sacrifice, both forelimbs were prepared as previously described [18] and mechanically tested in flexion-extension. Torque vs. angular position curves were analyzed to obtain total ROM, maximum extension/flexion, and extension/flexion stiffness.

Past data from a group with no injury or IM [19] (Control, n=9-10), which had functional testing at six different time points and mechanical testing after sacrifice were included for comparison. Mechanical testing parameters from all three groups were compared using one-way ANOVA with post-hoc Bonferroni correction. Forelimb strength and gait parameters from IM-Only group were compared to Injury+IM group using linear mixed models as previously described [19]. Control functional testing data were averaged and included as a reference line for comparison, but not statistically evaluated.

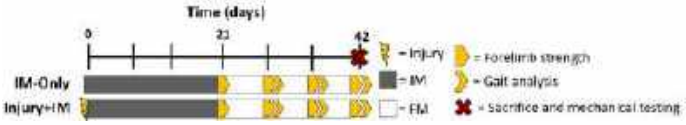

Figure 1: Timeline for immobilized groups. Control group with no injury or immobilization was also included from past data.

RESULTS

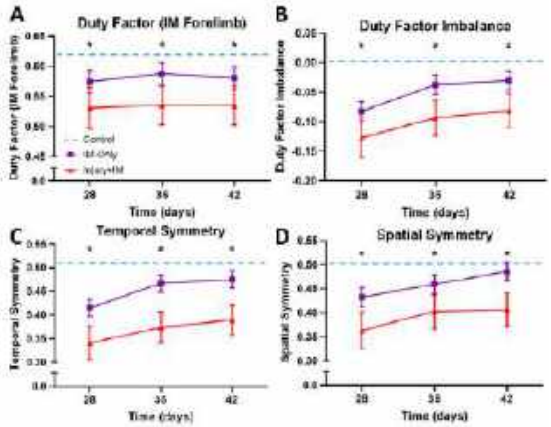

Figure 2: Gait analysis: (A) IM duty factor, (B) duty factor imbalance between forelimbs, (C) temporal symmetry, and (D) spatial symmetry were significantly different between IM-Only and Injury+IM (* for $p<0.05$); while IM-Only values approximated Control levels (dashed lines) over time, Injury+IM values remained decreased compared to Control (data are model predictions for rats of average weight/velocity with 95% CI).

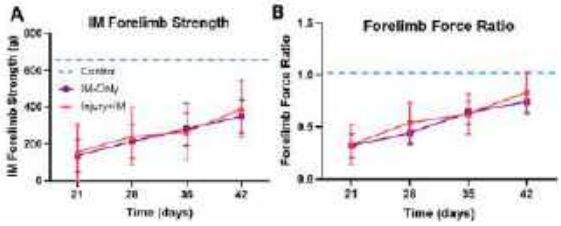

Figure 3: (A) IM forelimb strength and (B) force ratio between forelimbs increased towards Control levels (dashed lines) over time but were not different between groups (data are model predictions for rats of average weight with 95% CI).

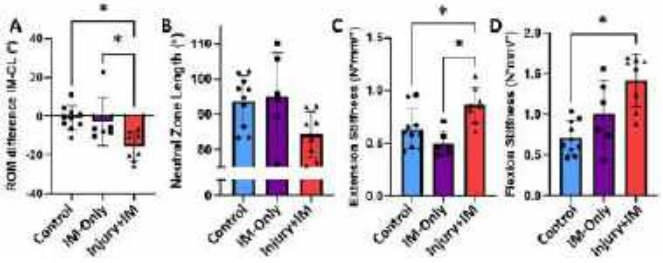

Figure 4: Joint mechanics: (A) ROM difference between forelimbs, (B) neutral zone length, (C) extension stiffness, and (D) flexion stiffness showed some differences between IM-Only and Injury+IM, but only Injury+IM values were different from Control (mean ± std; * for $p < 0.05$).

Gait analysis showed that duty factor (i.e., percent stance time) in the IM forelimb (Fig. 2A), duty factor imbalance between forelimbs (Fig. 2B), temporal symmetry between forelimbs (Fig. 2C), and spatial symmetry between forelimbs (Fig. 2D) were all significantly reduced for Injury+IM compared to IM-Only at all time points.

Forelimb strength in the IM forelimb (Fig. 3A) and the ratio between IM forelimb and CL forelimb (Fig. 3B) were not significantly different between IM-Only and Injury+IM at any time point. Both parameters increased over time in both groups.

Joint ROM difference (Fig. 4A) was significantly different in Injury+IM versus both IM-Only and Control; however, IM-Only ROM was not different from control. Neutral zone length (Fig. 4B) was not significantly different between groups. Extension stiffness (Fig. 4C) for Injury+IM was significantly different than Control and IM-Only, while Control values were not different from IM-Only. Flexion stiffness (Fig. 4D) was only significantly different between Control and Injury+IM.

DISCUSSION

Results show that IM alone in the rat elbow induces some features of PTJC (reduced forelimb strength, altered gait parameters, slightly reduced ROM, and slightly increased flexion stiffness compared to Control). However, most parameters were not as severe as Injury+IM and many functional outcomes returned to Control levels after FM.

Gait analysis demonstrated that the IM-Only group exhibited a lower magnitude than Control at the beginning of the FM period, but these differences were less severe than the differences between Control and Injury+IM. All gait parameters in the IM-Only group were significantly different from Injury+IM at all time points, but duty factor imbalance and spatial symmetry of IM-Only nearly returned to Control levels at later time points. Data at time points beyond 42 days would show whether all IM-Only gait parameters eventually return to Control.

Forelimb strength measurements in both IM-Only and Injury+IM exhibited a lower magnitude than control, which may be due to muscle atrophy caused by IM affecting both groups equally. However, forelimb strength improved during FM and previous work showed muscle does not play a significant role in contracture in this preclinical model [20].

No metrics of joint mechanics were significantly different between IM-Only and Control. Conversely, several measures were significantly different between Injury+IM and IM-Only (ROM difference, extension stiffness) and between Injury+IM and Control (ROM difference, extension/flexion stiffness).

Taken together, these results confirm in the elbow what has been demonstrated in other joints, specifically that IM alone causes some stiffness and contracture without injury. The method of IM may affect results; whereas some studies use external methods such as casting [4,13,15,16,17,21-23] or the bandages described here, other studies use surgical IM via Kirschner wires, plates, screws, and/or sutures that are drilled into the bone adjacent to the joint [3,5-12,14]. Although not designed to injure the joint tissues directly, such surgical methods of IM likely cause an inflammatory or foreign body response that could aggravate stiffness and contracture beyond the effect of IM alone.

In conclusion, this work demonstrates that IM alone induces some deficits in forelimb strength and gait parameters, but FM allows these parameters to recover and nearly return to Control levels. Both injury and IM are necessary to replicate the persistent effects of PTJC seen clinically. Future work will assess histological markers of PTJC such as anterior capsule thickness, adhesions, cellularity, and vascularity to investigate the cell and tissue level effects of elbow IM.

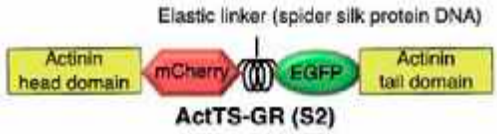
INTRODUCTION

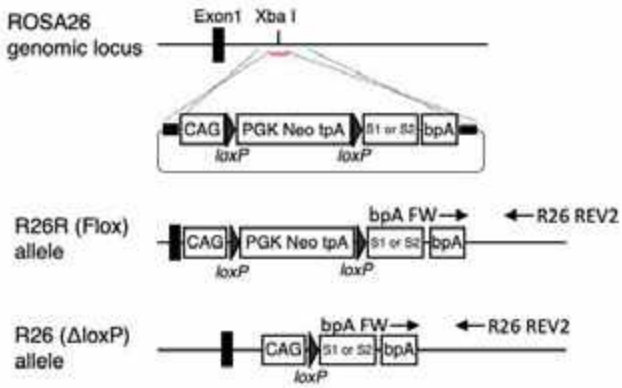
Mechanical forces play crucial roles in many biological phenomena such as embryonic development and etiology of critical diseases. Many research groups study how cells sense and respond to extrinsic mechanical loading, and how cells generate mechanical force to regulate the extracellular environment. To monitor the intracellular mechanical environment, several tension sensors using Förster resonance energy transfer (FRET) have been developed to visualize intracellular forces [1-2]. However, it is extremely difficult to introduce these sensors into tissues using conventional methods such as electrophoresis, and thus visualization of tension in biological tissues at cellular level was practically impossible. Recently, Tao *et al*. [3] developed transgenic mice expressing a tension sensor to visualize forces at the tissue level. Their results were obtained with a high-cost FLIM (Fluorescence Lifetime Imaging Microscopy) but not with a widely-used CLSM (confocal laser scanning microscope), possibly because the response of their sensor to tension is not clear enough. Furthermore, the combination of the fluorophores used in their sensor, mTFP1 and Venus, cannot be observed with the widely used 488-nm laser system. In a previous study, a group including one of the co-authors developed a tension sensor by inserting a FRET cassette made of two fluorophores, EGFP and mCherry, connected with spider flagelliform silk protein into actinin [4]. The response of this sensor to tension can be evaluated with a FRET ratio that is the ratio of the acceptor (mCherry) to the donor (EGFP) fluorescence using a conventional 488 nm CLSM system. In this study, we introduced the gene of this sensor into C57BL/6N mice to obtain mice expressing the tension sensor [5].

METHODS

We introduced our tension sensor gene engineered with the Cre/loxP system into the ROSA26 locus of C57BL/6N mice (Figure 1) and crossbred them with Cre mice to obtain animals expressing the tension sensor. We excised various tissues including the aorta, tail tendon, heart, and skin, and isolated cells from the tissues with enzymes. The isolated tissues and cells were stretched with a tensile tester (STB 150W NK, Strex, Japan) under a conventional CLSM (LSM880, Carl Zeiss, Germany) with a 63× oil immersion objective at room temperature in phosphate-buffered saline (PBS) (Figure 2). The fluorescence signals of EGFP and mCherry were obtained under excitation with a 488 nm wavelength laser at each stretch step to calculate the FRET ratio.



(a) Basic structure of actinin FRET tension sensor



(b) Strategy for the expression of the sensor

Figure 1: Structure of the tension sensor ActTS-GR[5].

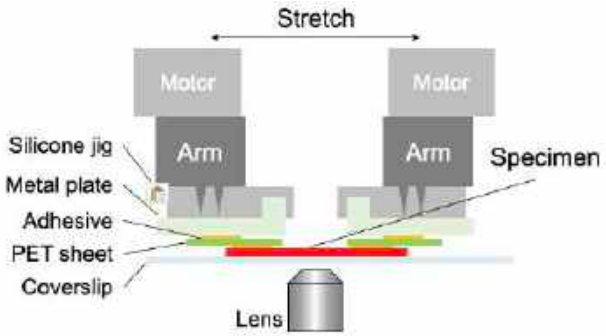


Figure 2: Tensile stretching apparatus and custom-made jigs for application of tensile strain to tissue explants and isolated cells.

RESULTS

The expression of the sensor was clearly observed in all excised tissues (Figure 3) and cells. The fluorescence intensity was high enough to observe the change in the FRET ratio with the confocal microscope. We performed tensile tests of the aortic tissues, tail tendons, and smooth muscle cells (SMCs) isolated from the aortic tissue and confirmed that the FRET ratio decreased in response to stretch, as expected (Figure 4). The FRET ratio decreased linearly in aortic tissues and SMCs. For tendons, it did not change until collagen fibers became straight, and then began to decrease beyond this point. The sensitivity of the FRET sensor was dependent on tissue types and cells. It was -0.63, -1.39, and -2.78 (%FRET/%strain) for aortic tissues, SMCs, and tendons, respectively.

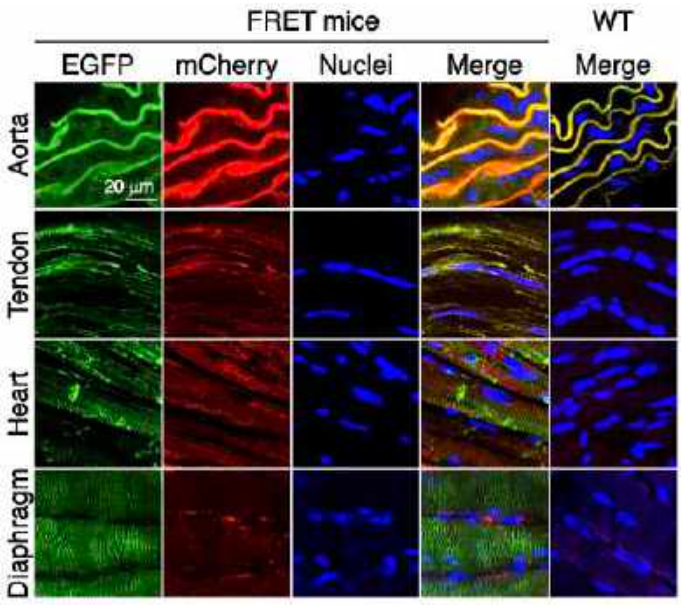

Figure 3: FRET sensors expressed in various tissues [5].

DISCUSSION

Sugita *et al.* have reported that strain in actin stress fibers in SMCs in the direction of the fiber axis was half of the strain in the smooth muscle layers in the circumferential direction of the aorta [6]. The relatively low FRET ratio variation in aortic tissues than SMCs observed in this study may support this observation.

We have developed a transgenic mouse line expressing an actinin tension sensor. The present mouse may become a powerful tool in mechanobiology.

INTRODUCTION

Von Willebrand factor (VWF) is a mechanosensitive plasma glycoprotein that controls hemostasis and thrombosis, with its hemostatic capacity/function directly related to the multimer size/length. Excessive high molecular weight multimer (HMWM) VWF can lead to harmful thrombosis, while the opposite can cause bleeding. The latter occurs in acquired von Willebrand syndrome (aVWS). To maintain healthy hemostasis/homeostasis, HMWM VWF needs to be cleaved by ADAMTS13 in circulation, which requires unfolding of the A2 subdomain on VWF, occurring through stretching beyond a critical tension threshold (∼20 pN) [1]. Although studies have demonstrated VWF cleavage through fluid shear, the loss of HMWM is modest from shear applied to plasma or to recombinant VWF in the presence of ADAMTS13, whereas aVWS involves excessive cleavage and substantial loss of HMWM, creating a gap in knowledge for how aVWS occurs in patients [2]. Combining the state-of-the-art computational and experimental rheometry approaches, we show that the presence of red blood cells (RBCs) creates a complex flow environment leading to elevated instantaneous stretching and tension on VWF in shear that promotes cleavage, elucidating a potential key cofactor to ADMAMTS13 and shear, causing excessive cleavage in aVWS.

METHODS

The study synergistically employs *in vitro* and *in silico* rheometer techniques (Figure 1) to unravel the biophysical mechanisms of shear-mediated activation and cleavage of VWF multimers. **Experiment** Citrated blood was centrifuged in two steps to collect platelet-poor plasma (PPP), which was then resupsended with 3x washed RBCs to a chosen hematocrit. Samples were exposed to a constant shear rate in a Rheostress 1 cone-and-plate rheometer with passivated surfaces. Sodium dodecyl sulphate-agarose discontinuous gel electrophoresis was performed on PPP separated from the RBCs in a western blot. **Computation** A multiscale computational method for simulating cellular and molecular blood flow has been developed to simulate VWF multimer conformation dynamics in concentrated RBC suspensions. The method has been validated to capture realistic hemorheology, cell mechanics and VWF multimer biophysics [3–5].

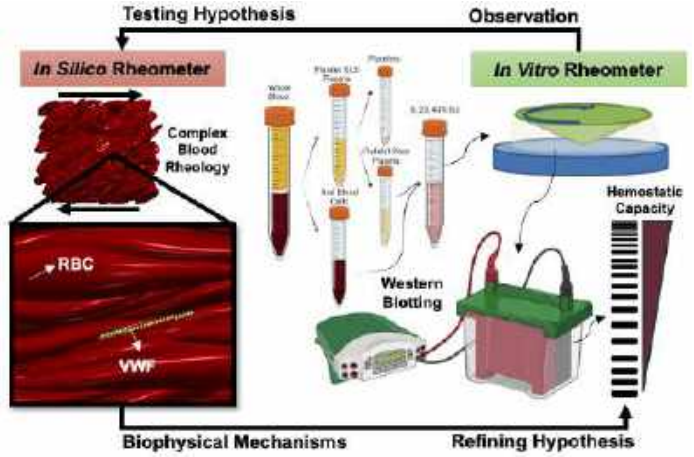

Figure 1: A research engine combining multiscale computational modelling with experimental multimer analysis for understanding the shear-mediated stretching and cleavage of VWF in whole blood.

RESULTS

In vitro exposure of PPP to a constant shear rate of 5000 1/s leads to little or no VWF cleavage, yet when combined with RBCs, there is a loss of HMWM, as seen in Figure 2. Band density in the figure is indicative of the amount of protein found at a specific size, with each band essentially adding another dimer of VWF from the bottom to the top of the gel. A physiological Hct of 40% leads to the most cleavage. Comparatively little to no cleavage is seen at other Hcts, even when samples are supplemented with dextran to increase viscosity of the sample to the levels expected for 40% Hct blood. These results indicate that increasing Hct, increases the potential for VWF cleavage at a specific shear rate through a mechanism related to the RBCs, themselves, as opposed to changes in bulk viscosity (and shear stress).

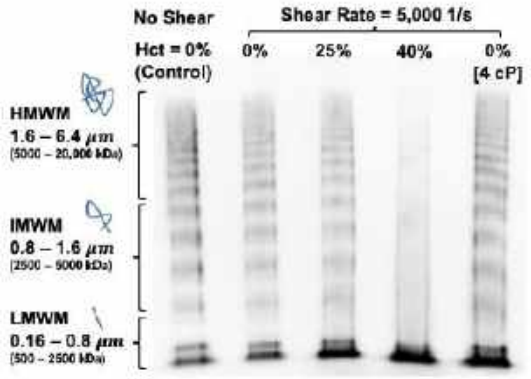

Figure 2: VWF length (molecular weight) distribution demonstrated through Western Blotting. The bands span from low molecular weight multimer (LMWM) through intermediate MWM (IMWM), up to HMWM. The left column is a sample not exposed to shear, while other columns were samples exposed to a shear of 5000 1/s with different amounts of Hct or with the addition of Dextran to elevate viscosity.

In parallel, *in silico* rheometry tests (Figure 1) are performed in a Lees-Edwards shear cell [3] under the same conditions as Figure 2 to investigate the potential biophysical mechanism leading to VWF conformational stretching and subdomain unfolding. Figure 3 shows representative time-lapse snapshots of VWF conformation over a complete folding-elongation cycle. Both of the Hct = 0% cases (with or without elevated bulk viscosity) show typical multimer coil-stretch conformational change under high shear, where the local tensile force on the multimer strand remains consistently below 5 pN. In contrast, the Hct = 40% case under high shear shows much-extended conformation during unfolding, where the instantaneous tensile force can significantly surpass the 20 pN threshold for A2 unfolding, particularly at the middle of the multimer strand.

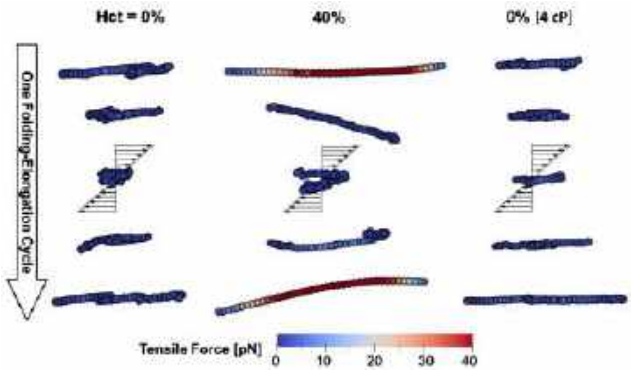

Figure 3: Time-lapse snapshots of VWF folding-elongation cycle with (Hct > 0%) or without (Hct = 0%) added RBCs. During stretching, the 40% Hct case features elevated tensile force (> 40 pN) along the VWF strand. The 0% Hct case consistently shows low tensile force (< 10 pN), even when the plasma viscosity is elevated to the bulk viscosity of whole blood or the 40% Hct RBC suspension (4 cP). The multimer has a contour length 6.4 μm. The shear rate is set to 5000 1/s.

Figure 4 shows the time change of VWF elongation (a), VWF average tension (b) and their statistics corresponding to the HMWM% (c, d, and e). Adding RBCs (25–40% Hct) leads to more frequent and severe VWF elongation than cases without RBCs (Figure 4a), while the 0% Hct with 4 cP viscosity does not significantly enhance VWF elongation. Correspondingly, VWF tension evolution shows that adding Hct to 25–40% can elevate the peak VWF tension by 1–2 orders of magnitude, surpassing the A2 unfolding threshold, even though the bulk viscosity has only been elevated by up to 4×. In addition, increasing the bulk viscosity to 4 cP without adding RBCs only linearly increases the VWF tension. Overall, the presence of RBCs seems to enhance VWF stretching through RBC-VWF micro-hydrodynamic interactions, not through linear increase of macroscopic viscosity. Box plots in Figure 4c confirm that elongation is enhanced significantly in the presence of RBCs. Figure 4d shows that 25-40% Hct leads to ultra-high tension beyond 20 pN (A2 unfolding threshold), making VWF susceptible to cleavage. In contrast, VWF tension with 0% Hct remains well below the A2 unfolding threshold, suggesting cleavage is unlikely. Both VWF stretching and tension statistics predicted *in silico* show strong inverse correlation with the HMWM% data quantified from the *in vitro* western blotting data (Figure 2), suggesting the elevated VWF stretching in the presence of RBCs under shear is likely the mechanistic reason for excessive VWF cleavage.

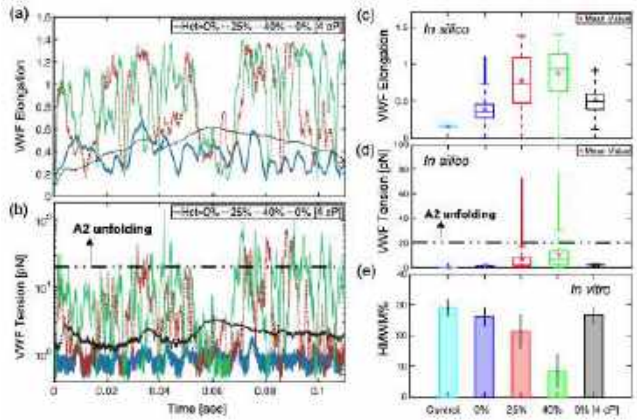

Figure 4: Instantaneous (ab) and average (cd) behavior of VWF elongation and tension. With RBCs (Hct > 0%), VWF tensile force can reach 10–100 pN levels, 1–2 orders of magnitude higher than those without RBCs. Presence of such high-tension events correlates well with the loss of HMWMs% (e). The shear rate is set to 5000 1/s.

DISCUSSION

The presence of RBCs promotes stretching and tension-dependent cleavage of VWF in whole blood under high shear through instantaneous RBC-VWF microhydrodynamic interactions. RBC is found to be a co-factor to high shear to cause VWF cleavage, providing a potential resolution to the controversy that pathological high shear-alone is insufficient to cause excessive VWF cleavage seen in aVWS. Furthermore, this work aligns with previous studies that show turbulence can enhance VWF cleavage, where turbulence also features instantaneous changes in microscale stresses [6]. This work also appears to provide a clue to the natural multimer distributions in circulation, which reaches only a peak shear of 3000 1/s and may allow us to identify better treatment for patients at-risk of aVWS, especially for abnormal hematocrit in high shear situations, e.g. aortic stenosis and patients on mechanical circulatory support.

ACCURACY OF PHYSICS-INFORMED NEURAL NETWORKS UNDER LAMINAR AND TURBULENT-LIKE AORTIC FLOW CONDITIONS

Arman Aghaee(1), M. Owais Khan (1)

(1) Department of Electrical, Computer and Biomedical Engineering, Toronto Metropolitan University, Toronto, Ontario, Canada

INTRODUCTION

Physics-informed neural networks (PINNs) have emerged as a powerful approach to encode governing partial differential equations (PDEs) and training data to model complex engineering problems. One potential application of PINNs includes inverse solutions to the Navier-Stokes equations, with important implications for modelling blood flow in the cardiovascular system. Given the flexibility of PINNs, additional losses from the training data, such as those obtained experimentally or from in-vivo imaging, can be added to the loss function to further regularize the minimization process during the training.

While PINNs has shown tremendous potential, the utility of PINNs in cardiovascular biofluids is still debatable. One of the primary reasons is that the accuracy and convergence of PINNs is dependent on the complexity of the flow due to "spectral bias" that is inherent in neural networks [1]. Due to spectral bias, neural networks can learn low-frequency data much more easily while high-frequency data may be challenging or, in some cases, impossible to learn. Although recent studies have proposed methodological advancements to reduce spectral bias in benchmark problems [2,3], their utility for practical and real-world applications remain unknown. In particular, there is a lack of data available that shows systematically the accuracy of PINNs under physiological and pathological blood flow conditions in patient-specific geometries. Hence, the primary goal of this work was to establish the accuracy of PINNs under a range of a range of patient-specific blood flow conditions using our previously-developed Fourier-based PINNs architecture that has shown higher performance compared to traditional activation functions (e.g., *tanh, swish*) [4].

METHODS

PINNs Model: The solution $u(\boldsymbol{x}, t)$ was approximated with a deep learning network $f(\boldsymbol{x}, t; \theta)$, where θ represents the trainable parameters of the neural network. The loss function is defined as:

$$\mathcal{L}_{\text{total}}(\theta) = \mathcal{L}_{PDE} + \lambda_{BC}\mathcal{L}_{BC} + \lambda_{data}\mathcal{L}_{data} \quad (1)$$

where $\mathcal{L}_{PDE}$, $\mathcal{L}_{BC}$ and $\mathcal{L}_{data}$ correspond to the loss term for the Navier-Stokes equation, boundary conditions, and known sensor data, respectively. The parameters λ_{BC} and λ_{data} aim to balance the interplay of the different terms in the loss function. The training parameter θ is optimized by minimizing the total training loss, $\mathcal{L}_{\text{total}}(\theta)$ via a standard gradient descent optimization (i.e., ADAM).

The weighting coefficients in the loss function, λ_{BC} and λ_{data}, are problem-specific and tedious to choose for complex flow cases. Hence, we applied the strategy of dynamic weights that adaptively update the coefficients by utilizing the back-propagated gradient statistics during training. The iterative formulation for the adaptive weight is:

$$\theta^{k+1} = \theta^{k} - \eta\,\nabla_\theta\mathcal{L}_{PDE} - \eta\lambda_{BC}\nabla_\theta\mathcal{L}_{BC} - \eta\lambda_{data}\nabla_\theta\mathcal{L}_{data} \quad (2)$$

where k is the iteration step, and η is the learning rate. The coefficients λ_{BC} and λ_{data} can be estimated using the following relation [2]:

$$\lambda_{BC} = \frac{max_\theta(|\nabla_\theta\mathcal{L}_{PDE}(\theta_n)|)}{\overline{(|\nabla_\theta\mathcal{L}_{BC}(\theta_n)|)}}, \lambda_{data} = \frac{max_\theta(|\nabla_\theta\mathcal{L}_{PDE}(\theta_n)|)}{\overline{(|\nabla_\theta\mathcal{L}_{data}(\theta_n)|)}} \quad (3)$$

A Fourier-based, ω_o-scaled *sine* activation function (SIREN [5]) was used due to better convergence and differentiability for high-frequency signals. The PINNs architecture consisted of 4 layers with 128 neurons/layer. Boundary conditions and the velocity field at the mesh nodes were treated as unknown quantities. A total of 1600 sensor data points, corresponding to sensor point density of 360 L/D were used.

CFD Simulations: A 3D patient-specific aortic geometry was obtained from a public repository (www.vascularmodel.com, patient ID: 01750000). The patient had a flow rate of 108mL/s, corresponding to a cardiac-averaged Reynolds number of 823. In order to systematically vary the flow complexity, a stenosis was virtually introduced into the thoracic segment of the aorta and varied from 0%-70% severity in increments of 5% (i.e., total 15 cases) (code: https://github.com/Owais-Khan/ImageAnalysisTools). Boundary conditions were assigned such that 25% of the flow was fed to the head and neck vessels while 75% of the flow was fed to the descending aorta.

The model was meshed into ~7 million tetrahedral elements. CFD simulations were performed using the SimVascular package (www.simvascular.github.io) with 10,000 time-steps for four cardiac cycles. The last cycle was used for in all subsequent analyses.

Data Processing: Spectral Power Index (SPI), a normalized parameter that quantifies the power >25 Hz in the velocity signal, was computed for all time-velocity signals to highlight the extent and intensity of turbulent-like flow features. L_2 errors of the velocity magnitude for CFD vs. PINNs was computed using the equation below:

$$L_2 - error = \sqrt{\frac{\sum_{i=1}^{N} |u_{PINNs}(x_i, t_i) - U_{CFD}(x_i, t_i)|^2}{\sum_{i=1}^{N} |U_{CFD}(x_i, t_i)|^2}} \quad (4)$$

where $u_{PINNs}(x,t)$ is the trained approximation, $U_{CFD}(x,t)$ is the ground-truth obtained from CFD, and N is the number of mesh points.

RESULTS

Flow Complexity with Increasing Stenosis Severity: Figure 1 highlights the intensity of turbulent-like flow with increasing stenosis severity in 8 (out of 15) cases simulated. Low-frequency fluctuations are present in 0% stenosis (i.e., healthy) case which increases in intensity with increasing stenosis severity, ultimately covering the entire post-stenotic descending aorta in the 70% stenosis case.

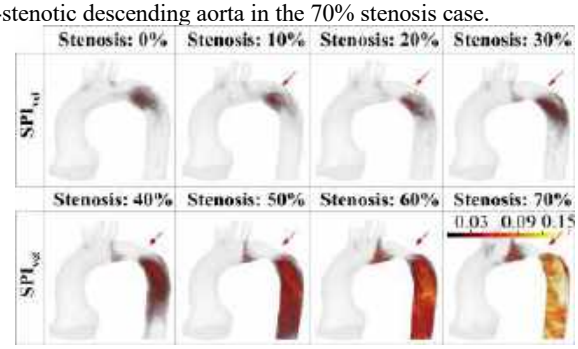

Figure 1: Spectral Power Index (SPI) intensity with increasing stenosis severity. Red arrow: stenosis location

PINNs Errors: Figure 2A shows qualitative comparison of the velocity maps for CFD vs. PINNs in two representative cases. In the highest stenosis severity case of 70%, notable differences are observed within and distal to the stenosis, such as limited penetration and intensity of the stenosis jet. For an intermediate stenosis severity of 40%, the gross velocity patterns predicted by PINNs are similar to those of CFD. Figure 2B shows qualitative contour maps of L_2 errors over the length of the aorta and for all stenosis severities. Errors were limited to 0.1-0.2 within the ascending aorta and increased to 0.2-0.3 in the stenosis region. The highest variability was found in the post-stenotic region. For stenosis severity <30%, errors were ~0.2. However, with increase in stenosis severity, ranging from 30% to 70%, the errors increased from ~0.3 to a maximum of 0.55.

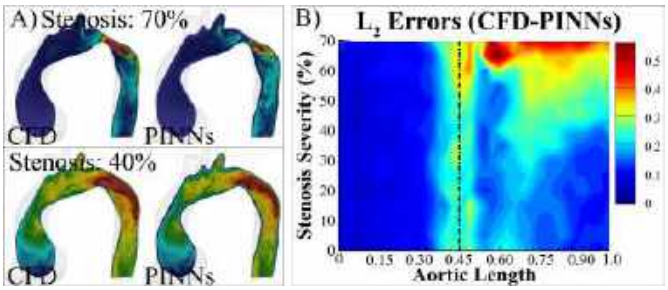

Figure 2: A) Time-averaged CFD vs. PINNs velocity magnitude for two representative cases. Color range is from min to max velocity. B) L_2 errors along the centerline of the Aorta for all 15 cases. The dashed-dotted line corresponds to the location of the stenosis.

POD Eigen-spectra: Figure 3 shows POD eigen-spectra of CFD vs. PINNs for three representative cases. For modes <20, both CFD and PINNs had similar eigen-spectra but deviated beyond >20 modes. More specifically, CFD eigen-spectra contained more kinetic energy in higher modes while PINNs showed reduced kinetic energy, indicating lack of high frequency spatial features in the learned velocity field.

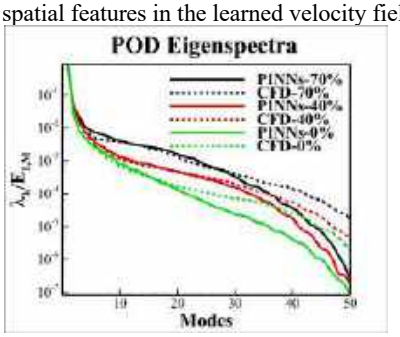

Figure 3: POD Eigen-spectra of CFD vs. PINNs for three representative cases.

DISCUSSION

By systematically increasing stenosis severity and consequently, flow complexity in a 3D patient-specific aorta, we have demonstrated that the accuracy of PINNs is highly dependent on the flow regime. Interestingly, the errors were limited to 0.1-0.2 in models with no stenosis or with stenosis of low severity but increased substantially in cases with pathological flow conditions, such as in patients with intermediate to high stenosis severity (>30%). In addition, we have demonstrated that PINNs was able to capture the kinetic energy within the lower modes, which represents large-scale gross flow features, but deviated substantially at higher modes, which represent high-frequency spatial features.

Our findings highlight that fully-connected neural networks – such as the ones used in PINNs – suffer from spectral bias, which make it incapable of learning functions with high-frequencies both in theory and practice. Our previous work has demonstrated that using Fourier-based activation functions, such as the ones used in this study, compared to conventional activation functions (e.g., *swish*, *tanh*) showed improved accuracy across a range of physical problems [4]. Despite such approaches, no method has shown to completely eliminate spectral bias. Recent findings, such as the use of neural tangent kernel to adaptively calibrate the weights of the neural network, has shown to reduce spectral bias in benchmark test cases; however, the practical utility of such techniques, for example in patient-specific blood flow applications, remain unknown. Future studies should focus on adopting approaches that can reduce such errors in cardiovascular flow applications.

BIOMECHANICS PARAMETER PREDICTS OUTCOME OF FETAL HEART INTERVENTION BETTER THAN CLINICAL SCAN PARAMETERS

L. Green (1), W. X. Chan (1), I. Prakash (1), A. Tulzer (2), G. Tulzer (2), C. H. Yap (1)

(1) Department of Bioengineering, Imperial College London, London, UK
(2) Department of Pediatric Cardiology, Children's Heart Center Linz, Kepler University Hospital, Linz, Austria

INTRODUCTION

Some mid-gestational cardiac abnormalities can progress in severity, causing irreversible damage or hypoplasia to the heart, leading to malformations at birth. Catheter-based fetal heart interventions showed promise in resolving abnormalities preventing the progression.

We study one such intervention: fetal aortic valvuloplasty (FAV), which is performed on fetal hearts with critical aortic stenosis and evolving hypoplastic left heart syndrome (CAS-eHLHS). During CAS-eHLHS, outflow obstruction causes high left ventricular (LV) pressure, diminished LV strains and stroke volume (SV), and mitral regurgitation (MR), leading to underdevelopment of the LV. Most such cases (~73%) progress to hypoplastic left heart syndrome (HLHS) at birth [1], but FAV can reduce the likelihood of a HLHS outcome, to 27-45% [2,3].

However, a considerable number of cases do continue to a HLHS birth outcome despite FAV, suggesting that current selection criteria based on clinical scans alone lacks sufficient predictive capabilities and cannot accurately select suitable patients for the intervention. This exposes inappropriately chosen fetal patients to unnecessary procedural risks, and some who are suitable but not chosen may miss the benefits.

Since the fetal heart is known to respond and develop to mechanical forces, and both CAS disease and FAV involves significant changes to cardiac biomechanics, we hypothesize that biomechanical parameters can indicate how strong the heart is and whether it will respond well to the intervention. We investigate this hypothesis via image-based, patient-specific cardiac finite element (FE) modelling.

METHODS

4D STIC fetal echocardiography is obtained for 9 CAS-eHLHS cases (4 with univentricular (UV) outcomes and 5 with biventricular (BV) outcomes) and 6 healthy cases, with ethics approvals and informed consent. Image-based LV Finite Element (FE) simulations are performed using our previous methods [4] (codes available at [5]), coupled with an age scalable lumped parameter model [6]. FE is iteratively performed while adjusting contractility and valve flow resistances to ensure patient-specific match with imaged data in terms of stroke volume, valve velocities, and expected LV pressures (literature values for healthy hearts and Doppler gradients for diseased cases). The biomechanics parameters are compared to a wide range of echo image measurements to investigate which parameters can best distinguish between UV and BV outcomes in the diseased cohort.

To enable rapid computations of myocardial stress, we derive a simple empirical equation to calculate stress from echo parameters best correlated to it (LV dimensions, volumes, and valve velocities), via principal component analysis (PCA). Myocardial stress calculated this way from pre-FAV data is compared to various pre-FAV echo image parameters, for their ability to predict UV versus BV birth outcomes, via receiver operating characteristic (ROC) analysis, using a cohort of 37 CAS-eHLHS patients undergoing FAV.

RESULTS

Echocardiography measurements show that CAS-eHLHS results in high aortic valve (AV) velocities, reduced circumferential and longitudinal strains and stroke volume, and the presence ofMR. Pre-FAV echo parameters such as valvular velocities, morphometrics, myocardial strain, stroke volume and end diastolic volume (EDV) do not statistically distinguish between cases with UV or BV outcomes (sample plots in Figure 1 top row), although LV inner diameter (LVID) and LV longitudinal length Z score have mild statistical differences between UV and BV ($p=0.0635$). On the other hand, several biomechanics parameters from FE modelling distinguish BV versus UV outcomes well. Cases with BV outcomes showed significantly elevated LV work done ($p=0.0635$), peak systolic myofiber stress (stress in the myofiber direction, $p=0.0159$) and the back-computed myocardial contractility ($p=0.0317$), compared to those with UV outcomes (Figure 1 bottom row). All FE biomechanics parameters are normalized to age-variations.

Using Cohen's D to compare the effect size of all these parameters (in terms of how different they are in BV versus UV groups), we find that peak systolic myocardial stress had an exceptionally high effect size (Figure 2), suggesting that it could distinguish BV versus UV cases much better than all other parameters.

From PCA analysis, the equation for calculating peak systolic myofiber stress is:

$$Stress = -24.924 + 0.9550V_1 + 4.2687V_2 - 0.1952V_3 + 1.1530V_4 + 0.1677V_5 - 1.4611V_6 - 0.004771V_7 + 4.8968V_8$$

Where V1 is aortic valve velocity, V2 is MR velocity, V3 and V4 are LV and RV longitudinal lengths, V5 is LV internal diameter, V6 is relative wall thickness, V7 is LV end-diastolic volume and V8 is LV stroke volume.

ROC analysis showed that myofiber stress has the largest area under the curve (AUC) of 0.91, while the next best performing parameters were LV longitudinal length Z Score (AUC=0.84), and EDV Z score (AUC=0.83).

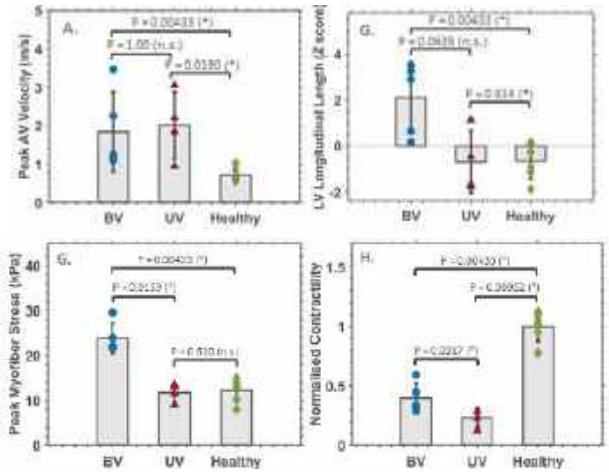

Figure 1: Bar charts (mean±std) of some examples of (top row) clinical echo measurements and (bottom row) FE biomechanics parameters that we investigated, for CAS diseased feal hearts with BV or UV birth outcomes and normal healthy fetal hearts.

DISCUSSION

In our study, we find that biomechanics parameters such as backcomputed active tension magnitude and peak myofiber stress, computed before FAV, have robust abilities to distinguish between UV and BV intervention outcomes, and can do so better than a wide range of echo measured parameters. Our ROC analysis confirms that myofiber stress has stronger predictive power than echo parameters. Our results thus suggest that biomechanics analysis is useful for predicting outcomes of FAV and can be used to improve patient selection, such as by incorporating them into clinical scoring system [2].

On our results that high myofiber stress of CAS-eHLHS diseased hearts can predict BV outcomes, we interpret this to suggest that CAS-eHLHS hearts that respond well to intervention with the ability to develop into functionally BV hearts at birth (as opposed to being UV) tend to be the ones that are biomechanically "stronger". This is where the heart has a stronger contractility to cause higher myocardial stresses, and at the same time, has an ability to withstand the higher myocardial stresses without becoming hypertrophic (which reduces stress).

To achieve clinical adoption, tests on a larger prospective cohort will be necessary. In this sense, our proposed approach to use the empirical equation to compute myocardial stress is useful, as it is fast and can be easily applied to a large cohort, while FE simulations are time consuming and therefore difficult to use on a large cohort.

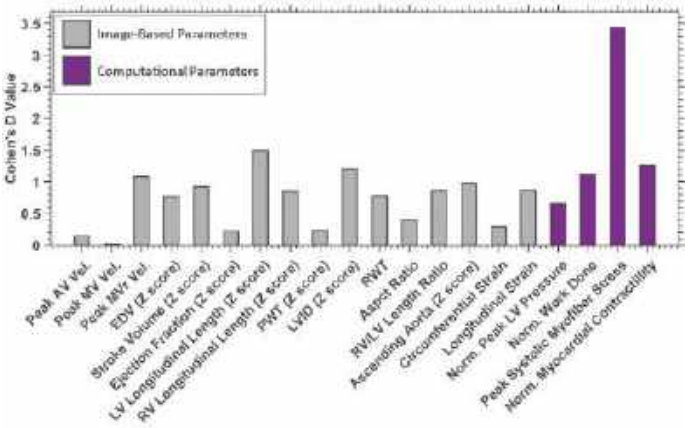

Figure 2: Cohen's D value showing the effect size of various echo (gray) and biomechanics (purple) parameters in their ability to distinguish between UV and BV outcomes for CAS hearts undergoing FAV.

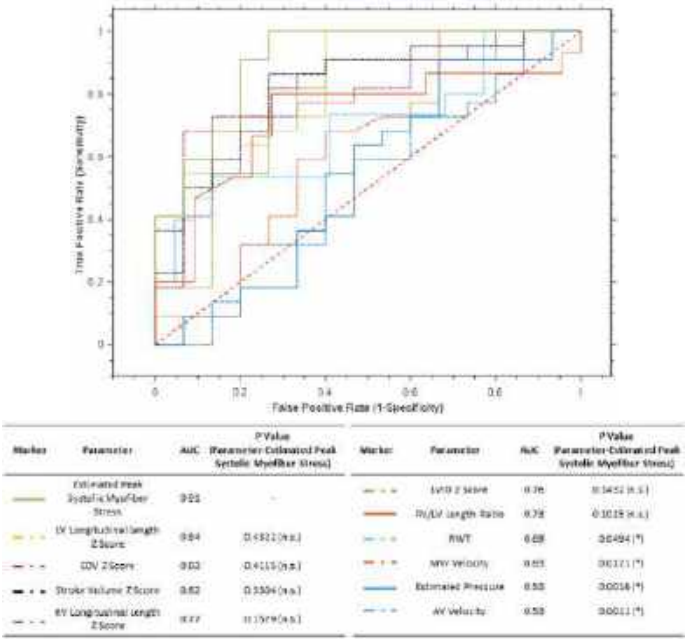

Figure 3: ROC analysis showing that peak systolic myofiber stress, estimated via empirical equation from routine clinical measurements, is the best for predicting UV versus BV outcomes.

DEVELOPING A SCAFFOLD WITH GRADIENT MECHANICAL PROPERTIES FOR ROTATOR CUFF REPAIR: A PARAMETRIC FINITE ELEMENT STUDY

S. Winston (1), L. Pezzanite (2), T. Schlegal (3), A. Romeo (4), S. Dow (2), K. McGilvray (1)

INTRODUCTION

In the United States, >250,000 rotator cuff repair surgeries occur annually. These repairs are currently failing at high rates, typically around 20-94% [1,2], resulting in socioeconomic costs to the US population of roughly $3.44B [3]. Current clinical approaches in rotator cuff repair typically use "patches" that attempt first to augment the acute strength of the repair and second result in a strengthening at the bone-tendon junction following healing to make it stronger. However, retrospective examinations of these repaired tissues indicate that the native biomechanical transition between bone and tendon, the enthesis, is not regenerated using current surgical interventions [4]. Instead, scar tissue forms over the enthesis, leading to a weaker junction and higher retear rates. The poor clinical performance of current devices is thought to stem from the fact that these patches still struggle to recapitulate the native transition from bone to mineralized fibrocartilage to the tendon at the enthesis.

Advances in additive manufacturing have created a potential avenue to create patches that are more effective. Melt electrowriting (MEW) specifically can print precise structure with highly tunable mechanical properties with 'cellularly instructive' fiber diameters. MEW has allowed our group to fabricate a novel scaffold geometry that demonstrates a gradient in the local stiffness across the length of the scaffold using a single material on a length scale similar to those observed across the enthesis.

With this novel structure, little is known about how the critical print parameters play a role in the graded mechanics, so our group aims to probe how the central radius of curvature, the fiber spacing, and the fiber diameter of our scaffold affect the local biomechanical properties of these scaffold geometries (Figure 1) using parametric finite element analysis (FEA). **We hypothesize that our novel architecture will recapitulate the biomimetic gradient of stiffness seen across the rotator cuff enthesis, resulting in a biomechanically robust enthesis formation at the repair site.**

METHODS

Using a custom-built MEW printer, scaffold architectures were printed with 45 kDa polycaprolactone (PCL) (Polysciences) at 5.5 kV, 100 °C, 2.2 psi, and at a 4 mm collector distance. Printed scaffolds (N=4) were loaded to 4% global tensile strain at 0.1% strain • s^{-1}. Regional strain during the test was calculated using digital image correlation (MATLAB 2022b). The mechanical testing data was then utilized to validate a fully converged 2D, linear elastic, beam FEA model of the scaffold geometry (Abaqus 2021). Models were validated based on regional-specific strain levels in the "bony region" and "tendon region" of the scaffolds.

These validated and converged models then underwent a parametric study where the radius of curvature (R), fiber spacing (FS), and fiber diameter (FD) were varied across the printability spectrum of our MEW printer (Figure 1). For each simulation, the ratio between the tendon region and the bony region of the scaffold was calculated and dubbed the "Strain Gradient Factor" (SGF). The SGF gives a unitless metric to how much the geometry parameters affect the regional-specific mechanical properties. Spearman rank correlations were run to determine the

correlation between the varied geometric parameters and the SGF.

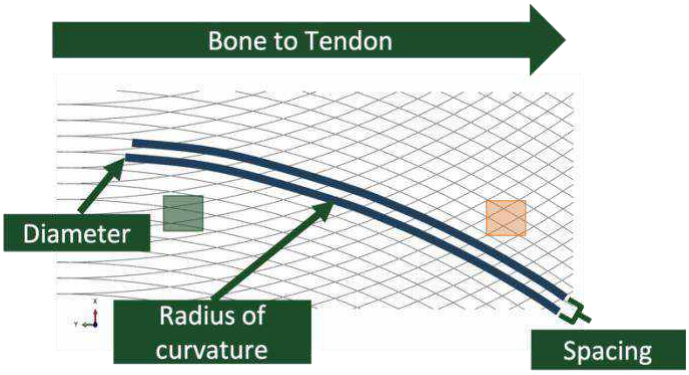

Figure 1: FEA model displaying parameters perturbed in study

RESULTS

The SGF was most correlated with alterations in the scaffold's radius of curvature. For R, FD, and FS The spearman correlation coefficients were -0.12, -0.25, and -0.85 respectively (Figure 2). This indicates that there is a slight inverse relationship between SGF and fiber spacing, a moderate inverse relationship with fiber diameter, and a strong inverse relationship with radius of curvature (figure 2).

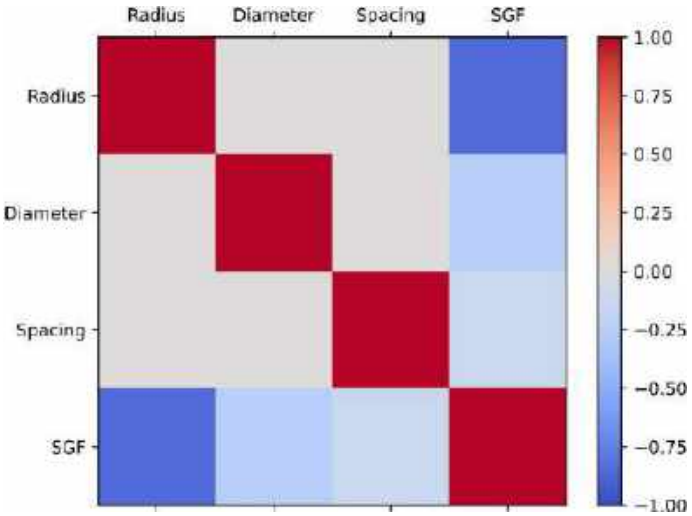

Figure 2: Spearman correlation matrix of each parameter

At R = 50mm and FS = 200 µm, SGF ranged from 48.9 to 8.78 as diameter ranged from 15 µm to 70 µm, and at FS = 200µm and FD = 15 µm SGF ranged from 48.9 to 1.7 as R ranged from 50 to 150 mm. These data clearly illustrate that the SGF can be tuned by selecting specific MEW scaffold geometries.

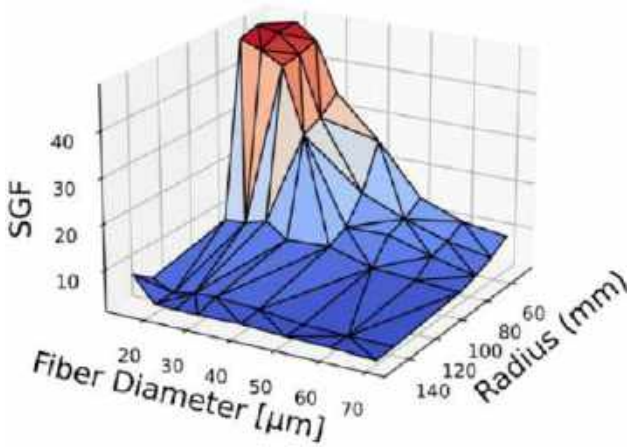

Figure 3: Representative 3D plot of SGF with respect to radius and fiber diameter at fiber spacing = 200 µm

DISCUSSION

The SGF of the scaffold varied the most as the radius of curvature and fiber diameter were parameterized. As the radius of curvature is increased, the rate at which the fiber angle changed decreased leading to a decreased change in local mechanics. As diameter decreased, the SGF increased moderately due to the decreased bending stability of curved fibers loading in bending.

This novel geometry has created a tunable, single material, fibrous scaffold with gradation levels approaching that of the human enthesis (50-100x). Future work will be focused on creating a predictive tissue healing finite element model to determine the optimal scaffold geometry that provides the strain levels that best caters to both bone and tendon regeneration on either side of these scaffolds.

INTRODUCTION

Elastin is a key extracellular matrix protein responsible for elasticity, resilience, and mechanical strength in connective tissues. During elastogenesis, the hierarchical elastic fiber assembly process, elastin is subject to an understudied post-translational modification, prolyl hydroxylation, where, mediated by prolyl-4-hydroxylase, a hydroxyl group replaces one of the hydrogen atoms at the C-γ position in proline residues. While prolyl hydroxylation is known to mediate the structural stability in collagen, a related structural connective tissue protein, the role of prolyl hydroxylation in native elastin remains vague at the molecular scale. According to recent experimental studies, elastin-like peptides with hydroxyproline modifications are more resistant to enzymatic digestion, and subject to abnormal elastogenesis. We hypothesize that hydroxylation alters elastin behavior by modulating protein-solvent interactions. To substantiate our hypothesis, we use existing mass spectrometry data of human elastin samples to build representative molecular models with naturally occurring prolyl hydroxylation patterns and perform extensive molecular dynamics simulations. As a starting point, we employ our recently developed fully atomistic model of the elastin precursor, tropoelastin. Our findings suggest that compared to proline, hydroxyproline increases hydrogen bonding with water and thereby supports adjacent hydrophilic hydration. Such enhanced protein-solvent interactions reduce the number of a residue's local configurations, thereby negatively impacting elastin's global dynamics required for essential biological processes, potentially act to shield the molecule from targeted degradation and modulate canonical hierarchical assembly. Overall, our study results provide insights into the role of hydroxylation in native elastin structure, function, and the process of elastogenesis, as well as offer design consideration for subtle tuning of engineered elastin-based materials.

METHODS

We propose three elastin-based models to study how prolyl hydroxylation impacts elastin function at different scales. We begin with short representative motifs where prolyl hydroxylation often occurs natively to study the fundamental mechanism of how prolyl hydroxylation alters the protein's activity at the scale of unit building blocks. We also consider domain 18 because of its intrinsic flexibility and the high occurrence of prolyl hydroxylation associated with this domain. Finally, we study the full-length tropoelastin molecule as it is the fundamental monomeric building block of elastic fibers.

We employ the hydroxylation degree of a Pro site as one of the criteria to select hydroxylation positions, using mass spectrometry data as our guide to select residues for modification [1]. For example, among 20 hydroxylation sites, Pro 190 and Pro 360 are determined to be hydroxylated in over 70% of the elastin samples, so these two positions are always hydroxylated in the models. In addition, Pro 615 is found 50% hydroxylated among all elastin samples, so half of our models exhibit this position in the unchanged state and half exhibit this position in the hydroxylated state. The hydroxylation degree of the remaining potential sites, however, remains unavailable from experimental studies. Therefore, we select the remaining hydroxylation positions randomly from all the potential sites. We also include a non-hydroxylated native model without any prolyl hydroxylation and an overhydroxylated model that includes all potential hydroxylated sites.

We use the Gromacs simulation package version 2018 for our simulations, with the CHARMM36m protein parameter set for topology and force field parameters for elastin, and TIP3P for water molecules. We implement the Particle Mesh Ewald method to compute electrostatic forces with grid spacing of 1.6 Å. We set the cut-off radius as 12 Å for short-range electrostatic interactions and Lennard-Jones interactions. We first restrain the bonding connecting hydrogen with protein backbone and apply the steepest descent algorithm to minimize the energy of the system for at most 50,000 steps. We then equilibrate the

system for 100 ps respectively in NVT and NPT ensembles. For temperature equilibration, we adopt the V-rescale thermostat to couple protein and non-protein groups to separate temperature baths of 300 K with 0.1 ps as the time constant. We use the Parrinello Rahman barostat for pressure coupling, with 2 ps as the time constant for isotropic pressure coupling, 1 bar as the reference pressure, and 4.5e-5 bar-1 as compressibility. Upon the end of equilibration stages, we remove position restraints and initiate 1000 ns production runs using the NPT ensemble. Across the stages of equilibration and MD production run, we harness the LINCS algorithm to constrain covalent bonds with hydrogen atoms and the leap-frog algorithm for integration every 1 fs during equilibration and every 2 fs during MD production runs. Tropoelastin models are based on our original model in [2]. All measurements are performed as an average over the last 500 ns of the production runs from all replicates. The statistical significance of analysis results is indicated in all figures as, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

RESULTS

We find that the introduction of hydroxyproline results in dissimilar structural ensembles in the models. The full-length tropoelastin models reveal remarkable variations in their representative structural ensembles, some of which adopt an elongated structure with a longer end-to-end length, such as model 5hyp-2, 8hyp-2, 9hyp-1 and 17hyp-1, while some favor a wider molecular shape with a shorter end-to-end length, as model 17hyp-2. Owing to the high number of degrees of freedom in highly disordered molecules as tropoelastin, Hyp-containing models undergo substantial conformational changes and consequently display distinct structural ensembles at equilibrium, where localized changes propagate widely across the whole molecule (Fig 1).

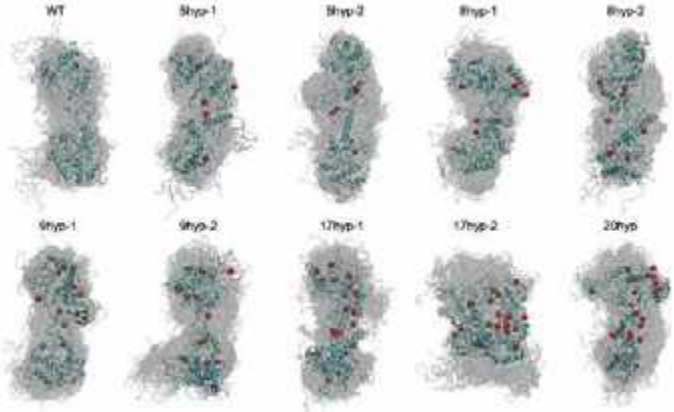

Figure 1: Tropoelastin ensembles with different hydroxylation patters. Hyp shown in red. Peptides and domains not shown.

Comparing the number of hydrogen bonds formed between proline and hydroxyproline residues and their surrounding water molecules, our results indicate that hydroxyproline residues have a greater propensity to form hydrogen bonds with water than proline residues (Fig 2). In the motif models, hydroxyproline forms two more hydrogen bonds with water on average compared to proline. Analogously, hydroxyproline residues in the domain 18 models and the full-length tropoelastin models form twice as many hydrogen bonds with water as proline residues do. Fig 2D shows representative snapshots of the hydrogen bond network within a cut-off distance of 5 Å of Pro vs. Hyp.

We also evaluate the water distribution locally and globally. The local water density around the modification site across different sequence lengths reveals a sharper peak in the first hydration shell (~ 2 Å) of Hyp compared to that of Pro, corresponding to enhanced hydrophilic hydration (not shown). In addition, locally, we observe more hydration waters surrounding Hyp residues compared to Pro residues in the motif models. This finding can be attributed to a higher proportion of hydrophilic hydration in relation to total hydration for Hyp as compared to Pro. We observe similar trends in the domain 18 models and the full-length tropoelastin models. We observe similar global hydration water distribution patterns in the motifs, and domain 18 models; for the full-length tropoelastin models, however, no clear trends are apparent. For each mutation site, Hyp still manifests its affinity to water, as evidenced by a rise in hydrophilic hydration. Based on the close proximity among Hyp sites in the ensembles, we infer that these Hyp residues may form a hydrogen bonding network during structural rearrangement, which is consistent with tropoelastin's flexible nature. Such rearrangement may thereby result in shared hydration waters, leading to a decrease in total hydration water content.

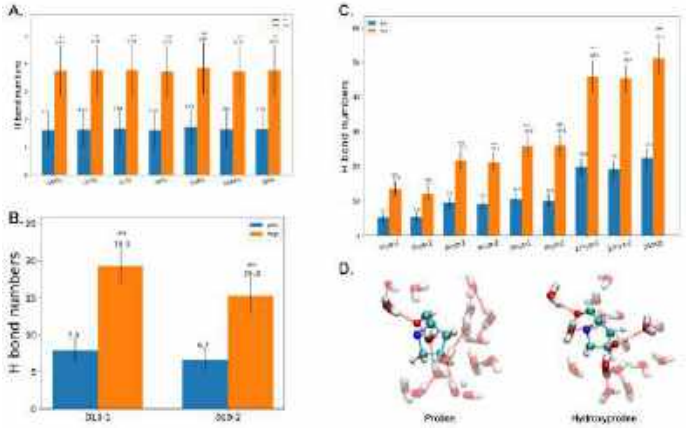

Figure 2: Local hydrogen bonding patterns in (A) motifs, (B) domain 18, (C) tropoelastin, and (D) cartoon representations.

DISCUSSION

We perform molecular dynamics simulations on elastin models of different length, originating from the tropoelastin monomer, namely, short elastin motifs, domain 18, and full-length tropoelastin, in the presence of various combinations of hydroxyproline in place of proline residues, to study the effects of hydroxylation in elastin. We find that prolyl hydroxylation strengthens local hydration effects, specifically, by enhancing protein-water hydrogen bonding, which gives rise to local rigidity characterized by reduced accessible conformational states and reduced local fluctuations. Consequently, the structural ensembles of the elastin molecules are altered, and the protein dynamics are dampened, which together serves as a possible mechanism for reduced enzymatic degradation and abnormal assembly and crosslinking behavior of elastin-like proteins, as observed in experimental studies. These findings shed light on native elastin assembly, and contribute insights into the possible role of hydroxylation in the degeneration of elastin in aging and disease. On this basis, we further propose that strategically placed hydroxyproline residues may be useful for engineering elastin-based materials with desired properties.

A CLICK CHEMISTRY METHOD TO EVALUATE GLYCOSAMINOGLYCAN COMPOSITION AND METABOLISM IN ARTICULAR CARTILAGE

Annie Porter, Steven DiStefano, Emily Newcomb, Michael Axe, X. Lucas Lu

Mechanical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

Proteoglycan is a primary component of cartilage extracellular matrix (ECM). Quantity and composition of proteoglycan plays an essential role in cartilage's mechanical function and the pathology of osteoarthritis [1]. The most abundant proteoglycan in cartilage is aggrecan, on which glycosaminoglycan (GAG) chains covalently attach along a protein core. The two dominant GAG chains are chondroitin sulfate (CS) and keratan sulfate (KS) [2]. Aggrecans can bind to another GAG chain, hyaluronan (HA), to form aggrecan aggregates (Fig. 1a) [3]. GAG chains are composed of repeating disaccharide units. CS chains contain N-acetylgalactosamine (GalNAc) as part of the repeating unit, whereas both KS&HA chains contain N-acetylglucosamine (GlcNAc) (Fig. 1b left) [4]. This study developed a novel click chemistry-based technique to quantify the synthesis and degradation of CS and KS&HA GAG chains separately in articular cartilage.

METHODS

Cartilage samples were harvested either from healthy juvenile bovine (1-2 months) knees or from regions of osteoarthritic senior human (average age 62 yrs) knees which lacked visible degeneration.

GAG Labeling via Click Chemistry. Newly synthesized CS or KS&HA GAG chains in cartilage were labeled using a copper-free click chemistry-based technique [5]. Cartilage was cultured in media supplemented with either GalNAz or GlcNAz, azide modified GalNAc and GlcNAc, respectively. Chondrocyte biosynthetic pathways can incorporate GalNAz into CS chains, and GlcNAz into KS&HA chains. New GAG chains were fluorescently labeled by "clicking" a fluorophore onto the azide groups (Fig. 1b Right). GAG synthesis was quantified by reading the fluorescent intensity of enzymatically digested samples on a plate reader. The click chemistry labelled cartilage can also be cultured afterwards, and the loss of fluorescent GAGs from cartilage into the culture media was longitudinally tracked by reading the fluorescent intensity of culture medium every other day.

GAG Composition by Anatomic Region. The ratio of newly synthesized KS&HA to CS was evaluated in cartilage from four regions of bovine knees: medial and lateral condyles (MC and LC), patellar groove (PG), and tibial plateau (TP) (n=10) (Fig. 2a).

Synthesis Response to Inflammation. The synthesis of CS and KS&HA was quantified after an inflammatory challenge. Bovine cartilage was treated for 72 hrs with IL-1β (10 ng/ml). Senior human

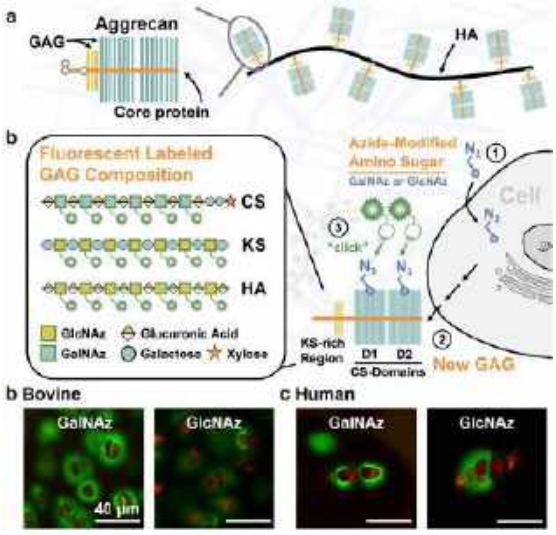

Figure 1. Glycosaminoglycan (GAG) synthesis. (a) Proteoglycan structure. (b) Click chemistry method to label CS (GalNAz) or KS&HA (GlcNAz) GAG chains. Newly synthesized GalNAz or GlcNAz labeled GAGs (green) surrounding (c) juvenile bovine or (d) senior human chondrocytes (red).

cartilage was treated for 96 hrs with a pro-inflammatory cytokine cocktail (5 ng/ml IL-1α, 5 ng/ml IL-1β, 50 ng/ml IL-6, and 20 ng/ml TNF-α) (n=10) (Fig. 3a).

Degradative Response to Inflammation. New CS or KS&HA synthesis was labeled in juvenile bovine (48 hrs) and senior human cartilage (96 hrs). Samples were then treated with pro-inflammatory cytokines as above, and the longitudinal loss of CS or KS&HA was tracked during a 10-day (bovine) or 18-day (human) culture (n=10). The total amount of GAG lost in each group was normalized to the amount of GalNAz lost from control samples.

RESULTS

Newly synthesized CS and KS&HA chains were both localized around the chondrocytes (red), forming a cell halo (green). Chondrocytes from juvenile bovine cartilage synthesized more GAGs in 48 hrs (Fig. 1c) than senior human chondrocytes in 96 hrs (Fig. 1d).

GAG Composition by Anatomic Region. The amount of newly synthesized CS chains (GalNAz) did not vary by anatomic region, but KS&HA synthesis was significantly lower in the medial condyle compared to the lateral condyle and patellar groove ($p<0.05$) (Fig. 2b). The total amount of GAG synthesis (CS+KS&HA) did not vary between regions (Fig. 2c). The ratio of KS&HA to CS was significantly lower in the medial condyle compared to the lateral condyle ($p<0.001$), patellar groove ($p=0.006$) and tibial plateau ($p=0.015$) (Fig. 2d).

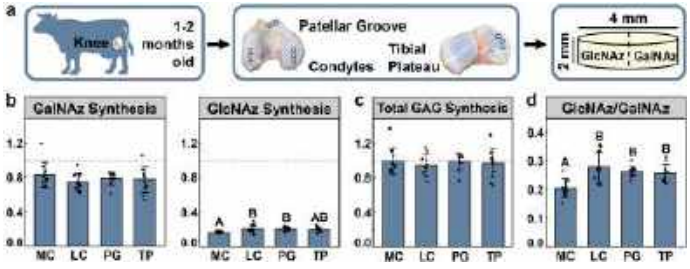

Figure 2. GAG composition by anatomic region. (a) Experimental design. (b) Separately quantified CS (GalNAz) and KS&HA (GlcNAz) GAG chain synthesis. (c) Total GAG (CS+KS&HA) synthesis. (d) Ratio of KS&HA to CS GAG chain synthesis. Different letters indicate significant differences ($p < 0.05$).

Synthesis Response to Inflammation. The ratio of new KS&HA to CS chains was much higher in senior human cartilage (0.42±0.11) than in juvenile bovine cartilage (0.16±0.04, $p<0.001$). In juvenile bovine cartilage, inflammation significantly reduced both CS and KS&HA chain synthesis. However, CS chain synthesis was reduced by a greater amount, increasing the KS&HA to CS ratio (0.22±0.05, $p=0.003$) (Fig. 3b). In senior human cartilage, inflammation only reduced CS chain synthesis, not KS&HA. KS&HA to CS ratio was increased to 0.69±0.10 ($p<0.001$) (Fig. 3c).

Degradative Response to Inflammation. In untreated cartilage, GAG loss in senior human samples had a higher ratio of KS&HA to CS chains (0.63±0.13) compared to juvenile bovine samples (0.50±0.13, $p=0.025$). In juvenile bovine cartilage, inflammation induced seven times more CS chain loss compared to untreated cartilage (7.09±2.96 vs 1.00±0.19, $p<0.001$). Inflammation also increased KS&HA chain loss, although not as drastically (1.32±0.44 vs 0.49±0.10, $p<0.001$), reducing the ratio of KS&HA to CS chains lost (0.19±0.03, $p<0.001$) (Fig. 4a). In senior human cartilage, inflammation increased both CS and KS&HA chain loss, but in lesser amounts compared to healthy bovine cartilage. The loss of CS chains doubled (1.96±0.53 vs 1.00±0.16, $p<0.001$), whereas the loss of KS&HA only increased by ~50% (0.95±0.31 vs 0.62±0.11, $p=0.001$). Thus, the ratio of lost KS&HA to CS chains decreased (0.49±0.13, $p=0.004$) (Fig. 4b).

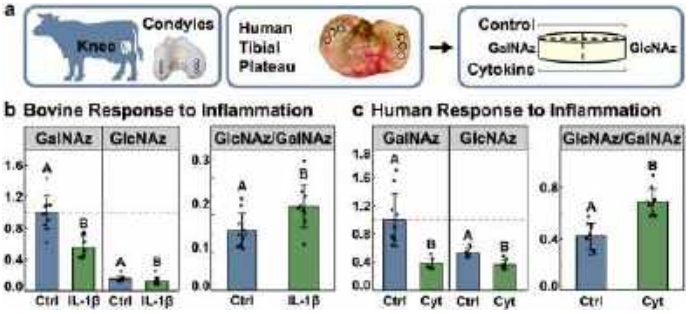

Figure 3. GAG synthesis under inflammation. (a) Experimental design. Separately quantified CS (GalNAz) and KS&HA (GlcNAz) chain synthesis and the ratio of KS&HA to CS chain synthesis for (b) juvenile bovine and (c) senior human cartilage. Different letters indicate significant differences ($p < 0.05$).

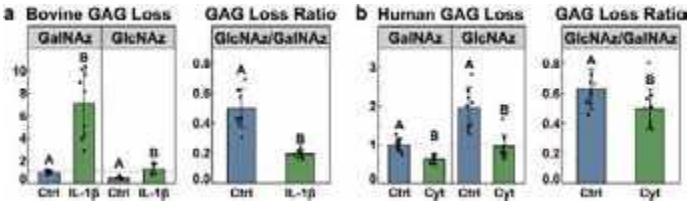

Figure 4. Degradative response to inflammation. Separately quantified CS (GalNAz) and KS&HA (GlcNAz) GAG loss and the ratio of KS&HA to CS chain loss from (a) juvenile bovine and (b) senior human cartilage under inflammation. Different letters indicate significant differences ($p < 0.05$).

DISCUSSION

We presented a novel technique to conveniently quantify the synthesis and degradation of different GAG chains in articular cartilage. The method detected differences in CS and KS&HA synthesis in different species of cartilage, different anatomic regions, and cartilage with/without inflammatory challenge. In confocal images, both GalNAz and GlcNAz labeled GAGs had similar spatial distributions around chondrocytes but differed in fluorescent intensity. This distribution is consistent with aggrecan having attachment domains for both CS and KS along its protein core (Fig. 1a,b bottom).

Inflammation is known to inhibit chondrocyte anabolic activities. For the first time, we showed that it also caused juvenile cartilage to transition to a more aged state, in which the percentage of keratan sulfate increased [6]. Mechanical environment may also regulate GAG composition. The medial femoral condyle, which undergoes the highest loading in the knee, had the lowest KS&HA:CS ratio. Little is known about the function of keratan sulfate in cartilage, or how changes in GAG composition are related to the development of osteoarthritis. Our new technique can help to further our understanding of proteoglycan metabolism in cartilage and its role in osteoarthritis processes.

INTRODUCTION

Degenerative mitral valve disease is one of the most common cardiac valvulopathies, with an estimated 24.2 million cases resulting in over 34,000 deaths globally in 2019 [1]. Mitral valve disease is associated with mitral regurgitation (MR), which is attributed to excess heart failure and mortality in all subsets of patients experiencing MR [2]. The prevalence of this pathology and its increasing global burden due to an aging population has driven recent advances in surgical repair strategies and technologies. Recently, focus has shifted toward minimally invasive catheter-based interventions due to the risks associated with surgery in elderly patients [3]. Of these burgeoning treatment options, edge-to-edge repair is the most common, with more than 200,000 patients treated globally over the past 20 years as reported by Abbott, the manufacturer of the clinical standard MitraClip for edge-to-edge repair. Despite its prevalence, there have been no publications related to quantifying the impacts of clipped valve edge-to-edge repair on intraventricular hemodynamics. This therapy creates a two-orifice inlet to the left ventricle (LV), which is anticipated to drastically change the fluid dynamics. Change from native, healthy flow could result in previously unforeseen comorbidities in patients with edge-to-edge repair and worsen patient long-term outcomes.

In the present study, we construct a LV duplicator with flow visualization capabilities and characterize flow experimentally within the LV experiencing MR using particle image velocimetry (PIV). The study explores how flow is impacted by edge-to-edge repair of the mitral valve using a MitraClip compared to complete valve replacement with a mechanical valve. The goal is to better understand how edge-to-edge mitral valve repair impacts blood flow within the LV.

METHODS

An optically transparent ventricle duplicator was used to perform intraventricular flow visualization studies. The duplicator consisted of an external hydraulic pressure chamber attached to a pulsatile pump (Vivitro Labs, Inc.) and a silicone ventricle model placed inside the hydraulic chamber. The silicone ventricle was attached to a flow loop with a reservoir and resistance clamp (see Fig. 1A). Piston head motion in the pulsatile pump controlled pressure in the hydraulic chamber, which drove flow through the loop by causing ventricle compression. The pump operated at a beat rate of 75 bpm with a 35% systolic duration, producing an average flow rate of roughly 3 L/min through the ventricle. The aortic valve in the system was a Bjork-Shiley monostrut (BSM) tilting disk valve and the mitral valve was either another BSM valve or a custom bileaflet tissue valve.

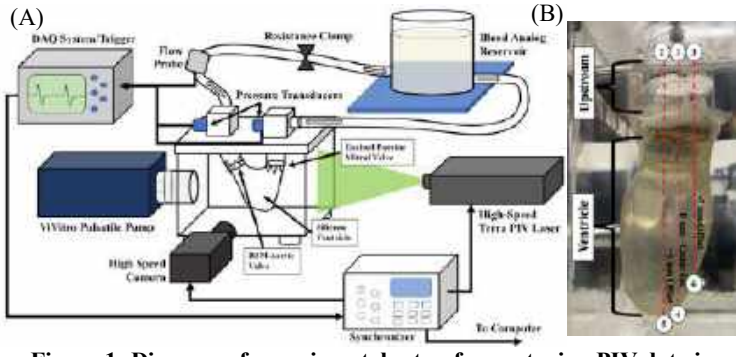

Figure 1: Diagram of experimental setup for capturing PIV data in the ventricle duplicator.

Bileaflet tissue valves were created by extracting the mitral valve from porcine hearts ordered from Lampire Biologics (Lampire Biological Labs, Inc.) and sewing the excised leaflet tissue onto a stent. The valve was secured into the mitral location in the silicone ventricle using internal retaining rings and gaskets. Two conditions were observed in the flow visualization studies: first with no MR treatment and second simulating edge-to-edge repair using a MitraClip (Abbott).

High-speed 2D planar particle image velocimetry (HSPIV) was

used to quantify flow in the silicone ventricle duplicator for the clipped and unclipped mitral valve conditions. The HSPIV setup included a high-speed camera (Vision Research, Inc.) and a high-speed PIV laser (Continuum, Inc.) coupled to lenses to produce a 1 mm thick light sheet mounted orthogonally (see Fig. 1A). The laser sheet was adjusted to image the centerline of the mitral valve stent and two positions offset ±5 mm from the centerline position (see Fig. 1B). Camera position and magnification were adjusted to collect images inside the ventricle and upstream of the mitral valve. Images were collected at 25 Hz to collect images at 21 time points across the 800 ms cardiac cycle for 200 cycles. A blood analog composed of saline and glycerin was made to match the kinematic viscosity of whole blood (3.5 cSt) and seeded with 7 µm fluorescent polymer microspheres (Thermo Fisher Scientific, Inc.). Fluorescent PIV particles coupled with a 546/612 nm camera lens filter reduced reflections from the ventricle, MitraClip, and valve housing. PIV data were processed in Insight4G (TSI, Inc.). Intraventricular viscous energy dissipation (VED) was calculated by (1). VED was used as a metric to quantify reduced pumping efficiency in the LV because of suboptimal flow in the presence of MR [4].

$$VED = \frac{\mu}{2}\int_A \sum_{\forall\, i,j}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)^2 dA \qquad (1)$$

Where μ was the fluid dynamic viscosity and u_i was the velocity in the i^{th} direction. Equation (1) was integrated over the ventricle plane where PIV data were collected. Spatial derivatives were calculated from the discrete PIV data using a least squares finite difference approach for oversampled data [5]. Velocity and vorticity fields and contour plots were generated in post-processing using Tecplot 360 (Tecplot, Inc.).

RESULTS

Each of the three cases had unique intraventricular flow characteristics (see Fig. 2). The MR case did not produce any significant rotational flow during the cardiac cycle. The case with the BSM valve implanted in the mitral location had a major and minor orifice jet that combined directly beneath the valve occluder to form a single coherent inlet jet. This inlet jet produced fully developed rotational flow through the central body of the ventricle. The valve simulating edge-to-edge mitral repair with the MitraClip produced two distinct inlet jets from the two orifices created by the clipped valve. Unlike the major and minor orifice jets in the BSM case, these jets did not combine and remained separate through the ventricle body. These parallel jets produced multiple vortical structures in the ventricle.

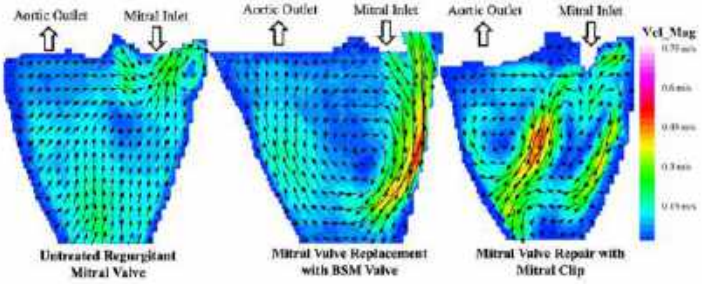

Figure 2: Intraventricular velocity fields from PIV data taken during late diastole for all three mitral valve types in this study.

The flow structures for the three valve types resulted in different levels of VED during the cardiac cycle (see Fig. 3). The VED increased at the beginning of diastole as the LV filled and the inlet jet generated viscous forces. The VED was lower in the BSM case compared to both the clipped and unclipped porcine valve cases. The clipped case had the highest peak and total VED, but the unclipped regurgitant case had a higher sustained VED during late diastole into systole.

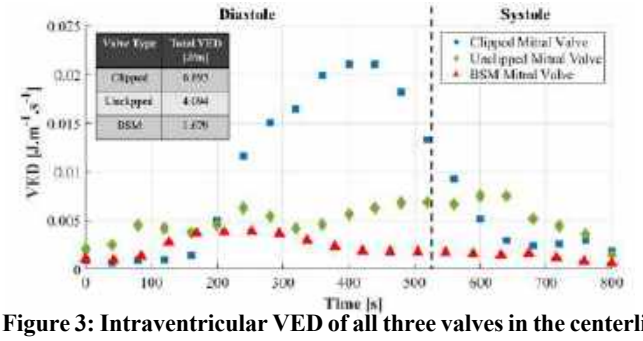

Figure 3: Intraventricular VED of all three valves in the centerline plane integrated over the cardiac cycle in overlapped table.

MR was observed upstream of the mitral valve in both the clipped and unclipped mitral valves (see Fig. 4). The unclipped case produced regurgitant flow that encompassed the entire valve diameter. The clipped case produced two small regurgitant jets at the locations of the two valve orifices created by the attached MitraClip.

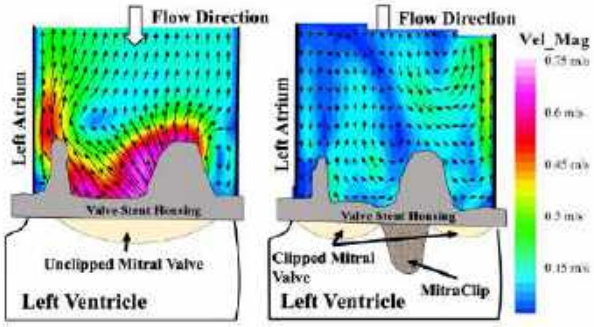

Figure 4: Velocity fields upstream of the valve in the unclipped (left) versus clipped (right) custom bioprosthetic mitral valve.

DISCUSSION

The rising prevalence of transcatheter percutaneous edge-to-edge mitral valve repair as a treatment for MR has increased the importance of improving our understanding of its impact on LV hemodynamics. Characterizing flow changes can help elucidate potential comorbidities associated with edge-to-edge valve repair, advance the development of new surgical therapies, and improve future MR patient outcomes. Currently, no studies exist that have quantified flow in the LV following mitral valve clipping. This study showed that the dual-orifice mitral valve post-treatment resulted in suboptimal flow for efficient ventricle filling and ejection. The two jets resulted in multiple interacting vortices and produced a less coherent diastolic rotational flow structure that is a characteristic of healthy ventricular flow. These changes caused elevated VED, which indicates less efficient intraventricular flow and an elevated workload on the ventricle to maintain healthy cardiac output. These results may indicate the development of comorbidities such as ventricular hypertrophy or reduced ejection fraction resulting in heart failure in patients receiving edge-to-edge repair as a long-term treatment option for MR.

INTRODUCTION

A pressing need exists for a clinical tool capable of rapid assessing and closely monitoring alterations in heart function through the cardiovascular blood circulation. To address this need, we developed a neural network model [1] that encodes the physics of a closed-loop blood circulation system embedding a left ventricle (LV). The physics-informed neural network (PINN) model is trained to satisfy a system of ordinary differential equations (ODEs) associated with a lumped parameter description of the circulatory system [2]. Then, we enhanced and implemented an inverse modeling approach utilizing the trained PINN model, enabling rapid estimation of key model parameters from single-beat LV pressure and volume waveforms, including the end-systolic elastance (E_{es}). This framework was tested with an in vivo animal model where we show that it can potentially be used in the clinic to simultaneously estimate LV contractility and other physiological parameters from single-beat measurements.

METHODS

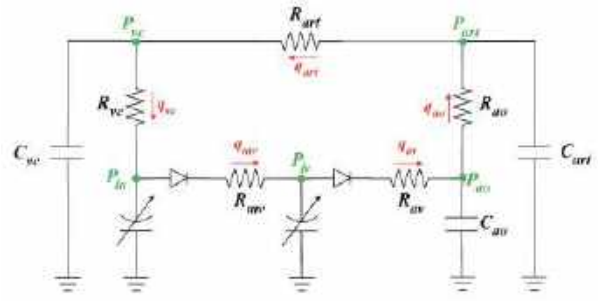

Figure 1: The electrical equivalent diagram of the closed-loop blood circulation. lv, left ventricle; ao, aorta; art, peripheral artery; vc, vena cava; la, left atrium; av, aortic valve; mv, mitral valve.

The closed-loop circulatory model is comprised of five compartments (Fig. 1). The volume change of each compartment is governed by inflow and outflow rates as described by the following system of ODEs

$$\frac{dV_{lv}}{dt} = q_{mv} - q_{av}, \quad \frac{dV_{ao}}{dt} = q_{av} - q_{ao}, \quad \frac{dV_{art}}{dt} = q_{ao} - q_{art}, \quad \frac{dV_{vc}}{dt} = q_{art} - q_{vc}, \quad \frac{dV_{la}}{dt} = q_{vc} - q_{mv}, \tag{1}$$

Flow rates q_{ao}, q_{art}, q_{vc}, q_{mv}, q_{av} are determined by corresponding resistances and pressure differences. Pressure in the blood vessels is governed based on the vessel's volume and compliance. Left ventricle and atrium contraction is modeled using a time-varying elastance model.

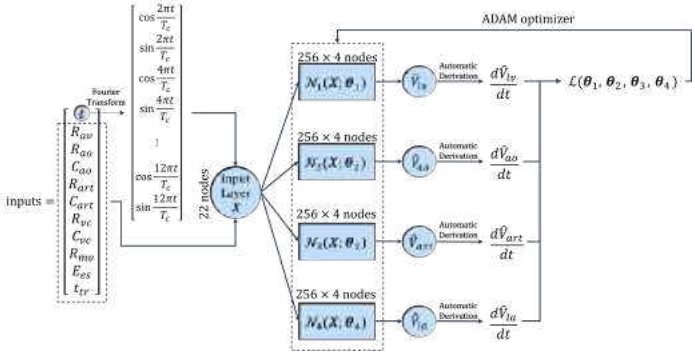

Figure 2: Model architecture: Input layer size is 22, comprising 12 Fourier terms and 10 input parameters. Four separate neural networks, each characterized by its set of weights and biases (θ_i).

The PINN model uses time t and 10 physiological parameters, including E_{es}, as inputs. Volume waveforms are represented by the first twelve terms of the Fourier series of time t to enforce the periodic boundary conditions. Four neural networks (Fig. 2) represent the volume of each indi-

vidual compartments in the system (Fig. 1). The volume of the fifth component (vena cava) is calculated using mass conservation, i.e.,

$$\hat{V}_{vc} = V_{total} - (\hat{V}_{lv} + \hat{V}_{ao} + \hat{V}_{art} + \hat{V}_{la}). \quad (2)$$

A dataset comprising 100 000 cases was generated for the training using Latin Hypercube Sampling (LHS) to sample the parameter space. Each case has 400 timepoints. In total, we have 40 000 000 collocation points for training. The loss function is defined as the mean square error of the sum of the residuals (of Eq. 1) computed at all the collocation points.

The trained PINN model is used to estimate parameters from experimental measurements of 11 Yorkshire swine, including 3 with administration of an inotropic drug (Dobutamine). The goal here is to use given left ventricle pressure and volume waveforms to estimate an optimal combination of input parameters that maximizes the coefficient of determination R^2 between the PINN model predicted waveforms and the given waveforms. Optimization is performed using the differential evolution method. Parameter estimation is also performed on synthetic waveforms generated by the PINN model for 100 cases with distinct parameters to determine whether the same parameters used for generating the waveforms are recovered with inverse modeling.

RESULTS

To assess the trained PINN model's accuracy relative to the numerical solution, the relative mean absolute error (RMAE) for the volume state variables (Eq. 1) was calculated in 1000 cases, with a maximum error below 5%. In inverse modeling, RMAE between parameters estimated based on the synthetic waveforms and their ground truth was below 1% for all parameters in the 100 cases (Fig. 3).

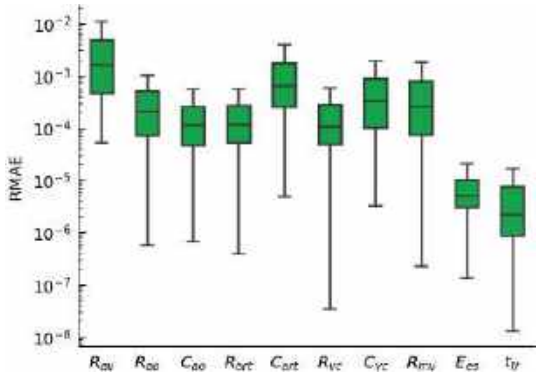

Figure 3: RMAE between the estimated input parameters and their ground truth for 100 synthetic cases

Results of inverse modeling performed using measurements of the swine subjects is shown in Fig. 4. Table 1 shows some of the estimated parameters. For the 3 animal data in which measurements before and after dobutamine administration were available, the inverse modeling is able to predict an increase in contractility (E_{es}). The fitted LV pressure and volume waveforms agree well with the experimental measurements, as reflected by the large R^2 value.

DISCUSSION

We have developed and trained a PINN model that is based on the mathematical ODE formulation of a closed-loop lumped parameter model of the cardiovascular system. The trained PINN model can be used for inverse modeling to estimate parameters reflecting the heart function in less than 3 minutes, which could take up to 6 hours if numerical methods were used. Inverse modeling performed on synthetic LV volume and pressure waveforms successfully recovered the original model inputs, which implies the uniqueness of these parameters (Fig. 3). Correspondingly, parameters estimated from inverse modeling using experimental measurements of the volume and pressure waveforms are likely to be also unique (Fig. 4 and Table 1). We also validated the inverse PINN modeling approach using experimental measurements acquired from a swine model with and without the administration of an inotropic agent. These results suggest that the PINN model can potentially be further developed as a clinical tool to simultaneously estimate ventricular contractility and other physiological parameters using single-beat measurements from patients.

INTRODUCTION

Mechanotransduction, i.e., living cells sense and transduce mechanical forces into intracellular biochemical signaling and gene expression, is ubiquitous across diverse organisms. Increasing evidence suggests that mechanotransduction significantly influences cell functions and its mis-regulation is at the heart of various pathologies. A quantitative characterization of the relationship between mechanical forces and resulted mechanotransduction is pivotal in understanding the rules of life and innovating new therapeutic strategies [1][2][3]. However, while such relationship on the cell surface membrane and cytoskeleton have been well studied, little is known about whether/how mechanical forces applied on the cell interior nucleus ("headquarter of the cell") quantitatively trigger mechanotransduction. This is because conventional techniques cannot simultaneously access, manipulate, and record the mechano-chemo-genetic dynamics inside the cell nucleus. In this presentation, we will present our new results on (1) the experimental characterization of the translocation of YAP (Yes-associated protein) induced by quantitative force applied directly on the nucleus; and (2) computation-guided quantification of applied mechanical forces.

As a critical mechano-sensitive transcription coactivator, YAP regulates downstream gene transcription to promote tumor progression at different key stages of cancer development: neoplasm initiation, growth, metastasis, and drug-resistance [4][5]. Overexpression and nuclear translocation of YAP are observed in multiple tumor types [6]. Independent of conventional Hippo pathway, physiological mechanical force can also induce nuclear translocation of YAP in parallel. In solid tumors, abnormal microenvironment applies elevated mechanical stimuli (tissue stiffness, solid stress, interstitial fluid stress, etc.) to tumor cells, which also show abnormal mechanosensing mechanisms [7]. Therefore, understanding of the YAP-associated mechanism of tumor mechanotransduction is needed for the development of new mechanotherapy.

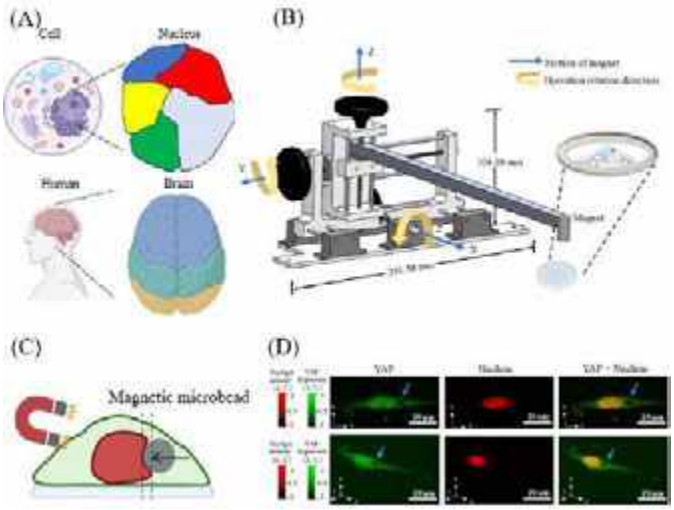

Figure 1: Direct manipulation of nucleus by magnetic microbeads. (A) Nucleus as the central control system of cell. (B) Three-dimensional schematic of device implemented to hold the magnet and move it in x, y, and z directions. The magnet will be lowered to the dish to apply magnetic on magnetic microbeads (C) Schematic of magnetic microbead applying indentation on the nucleus. (D) Representative images showing magnetic microbead (black hollow pointed by blue arrow) is internalized into the cell (indicated by YAP) and outside the nucleus. Top: X-Y cross-section of cell of YAP (green), nucleus (red) and bright-field. Bottom: 3D reconstruction of the cell.

Similar to the function-compartmentalized brain in the human body, the nucleus also has compartmentalized functional regions to perform both central control and multi-task coordination in the cell **(Fig.**

1A). Recent results show that extracellular mechanical signals need to be transmitted through cytoskeleton to the nucleus to induce translocation of YAP. Despite the emerging evidence of LINC complex and nuclear Lamins are involved in nuclear mechanotransduction, multiple critical knowledge gaps remain [8][9][10]. First, how the YAP translocation changes with respect to the magnitude and direction of the force applied to the nucleus remains unclear. Second, how to directly apply the force to the nucleus to regulate YAP translocation without interrupting the normal function of cytoskeleton. To our knowledge, our result is the first to bypass cell membrane and cytoskeleton and directly manipulate cell nucleus to regulate YAP translocation.

METHODS

To quantify the real-time translocation of YAP, we use CRISPR/Cas9-engineered human normal Beas-2B (B2B) cells that highlight endogenous YAP tagged by fluorescence protein mNeonGreen21-10/11. B2B cells are cultured in 35-mm glass-bottom petri dish with RPMI 1640 culture medium and 10% fetal bovine serum for confocal fluorescence imaging. 0.2 g of 7-μm mean diameter carbonyl iron microbeads are cultured with B2B cells for 12 hours to allow internalization of the microbeads into the cytoplasm. An XYZ-manipulator **(Fig. 1B)** is used to move the magnet to attract the intracellular microbeads and apply indentation on the cell nucleus **(Fig. 1C)** [11]. Nuclear/cytoplasmic translocation of YAP is quantified by high-resolution confocal fluorescence imaging throughout the manipulation of the nucleus. Cells are treated with CytoD (2.5 μM; 1 hour) to dissolve the actin cytoskeleton. Nucleus is stained by incubating with 1X NucSpot live-cell nuclear stain for 2 hours.

RESULTS

First, we directly manipulate the nucleus and confirm that nuclear indentation can induce YAP translocation. A set of representative images of increased YAP fluorescence images and corresponding YAP N/C ratio quantification are shown in **Fig. 2A and B**. We observed both increase and decrease of the YAP nucleus to cytoplasm (N/C) ratio when the force is applied to the nucleus because of variance of force magnitude and direction.

Next, we confirm that the force is applied directly to the nucleus. To make sure the magnetic microbead can indent the nucleus from the cytoplasm side, we confirm that the microbeads are internalized by the B2B cells into the cytoplasm while outside the nucleus (after 12 hours of culturing) shown by fluorescence imaging of whole-cell YAP and cell nucleus (**Fig. 1D**). To exclude the possibility that the indentation is induced by deformation of cytoskeleton, we manipulate the nucleus with dissolved actin cytoskeleton (**Fig. 2C**) and observe similar nuclear deformation.

To quantify the force directly applied to the nucleus, we use atomic force microscopy (AFM) to indent cell nucleus with deformation similar to the magnetic indentation. 3D fluorescence imaging shows a representative image that nucleus is indented by 1.5 μm (**Fig. 2D**) and 0.8 μm with two force magnitude. The force magnitude of a single microbead is calibrated as 0.8 nN and 1.4 nN, respectively, when the magnet is 13 mm and 120 mm above the bottom of the petri dish.

Finally, based on the AFM-calibrated force, we develop a finite element model of the cell nucleus to simulate the force magnitude and direction for each cell during the manipulation. The YAP N/C ratio is quantified and recorded during the nuclear manipulation process of each cell. We map the change of the YAP N/C ratio and force applied to the nucleus to generate a mathematical model of how direct manipulation of nucleus induces YAP translocation.

DISCUSSION

To our knowledge, this research is the first attempt to directly manipulate cell nucleus to induce YAP translocation without force transmission through cell membrane or cytoskeleton.

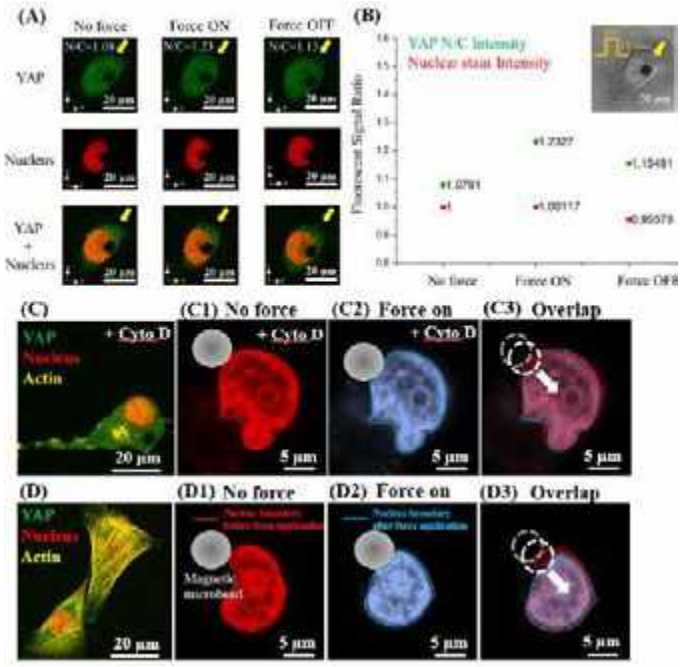

Figure 2: Direct manipulation of nucleus induces translocation of YAP. (A) X-Y cross-section of YAP (green) and nucleus (red) fluorescent image of the cell at no force, force on, and force off. (B) YAP N/C ratio increases when force on (from 1.0791 to 1.2327) and decreases when force off (from 1.2327 to 1.1548). Normalized nuclear stain intensity shows minor change with force application (1.00117) and releasing (0.95578). (C) Cells show disrupted actin filaments (yellow) after Cyto D treatment (2.5 μM, 1 h). Nucleus is indented by magnetic microbead. (D) Nucleus is indented by 1.5 μm with 1.4 nN force.

Our results suggest that magnetic microbeads can regulate the YAP translocation and downstream gene transcription while avoiding the interruption of cytoskeleton and corresponding important cell functions. Our results advance the understanding of the mechanisms of nuclear mechanotransduction and potentially contribute to the development of new therapies for tumor suppression targeting YAP.

INTRODUCTION

Electrically excitable cells such as neurons and cardiomyocytes transmit long-distance calcium (Ca^{2+}) or electrical signals to regulate their physiological functions.[1–3] While the molecular underpinnings and down-stream effects of these intercellular communications in electrically excitable cells have been well appreciated, little is known about whether and how electrically non-excitable cancer cells spontaneously initiate and transmit long-distance intercellular signals.[4–6] Recently we discovered that human cancer cells from different organs, e.g., colon and prostate, can initiate and transmit previously "invisible" long-distance (~100s μm) biochemical Ca^{2+} waves in a substrate-mechanics-regulated manner (**Fig. 1**).[7,8] In this presentation, we will present our new results on (1) the characterization of the long-distance and the intra-/inter-cellular Ca^{2+} signals; (2) the functional influences of mechanical microenvironment on the spatial-temporal properties of Ca^{2+} symphony; and (3) the molecular mechanisms and biological consequences of the Ca^{2+} dynamics during tumor progression *in vivo*.

Ca^{2+} signals offer regulatory functions at different key cancer development stages: tumor initiation, growth, angiogenesis, and metastasis, highlighting their critical role in tumor progression.[5,9] In human colorectal cancer cells, expression of Ca^{2+} channels and transporters has been either abnormally elevated or reduced, which remodels the network of Ca^{2+} signaling and functionally suppress or promote tumor progression.[10,11]

Despite of the significance of Ca^{2+} signals in cancer development, multiple critical knowledge gaps remain. First, spontaneous intercellular Ca^{2+} waves have never been identified in non-excitable tumor cells from organs other than brain and heart. To our knowledge, only one publication to date specifically reported the existence of spontaneous Ca^{2+} transients (not wave) in colon cancer cells.[12] Second, how the physiologically relevant microenvironmental mechanics mechanistically influences the intra-/inter-cellular Ca^{2+} signals in cancer cells remains unclear.

METHODS

GCaMP5G (a genetically-encoded Ca^{2+} sensor)-expressing HCT-8 human colon cancer cells and DU145 human prostate cancer cells, respectively, were cultured on two types of two-dimensional (2D) substrates with different mechanical properties: (1) polyacrylamide (PAA) hydrogels that have elastic Young's moduli of 250 Pa, 10 kPa, 20 kPa, and 40 kPa; and (2) polystyrene (PS) substrates in tissue-culture petri dishes that have an elastic Young's modulus of 3 GPa (**Fig. 1A**).

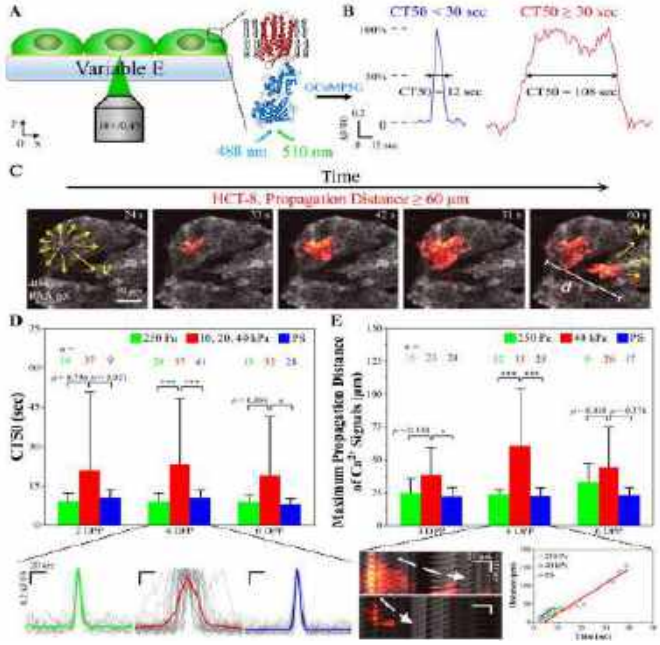

Figure 1: Substrate-stiffness-dependent spatial-temporal characteristics of spontaneous Ca^{2+} signals in HCT-8 cells. (A)

Experimental setup for Ca^{2+} imaging of cancer cells cultured on mechanical-stiffness-variable substrates. (B) Time traces of GCaMP5G fluorescence intensity ($\Delta F/F_0$) for short-duration (left) and long-lasting (right) Ca^{2+} transients. (C) Long-distance propagation of Ca^{2+} waves (hot map) among HCT-8 cells on 40-kPa PAA gels. (D) Top: Mean+SD data for the CT50 of HCT-8 cells cultured on 2D substrates with different Young's moduli. Bottom: Averaged time traces of GCaMP5G fluorescence intensity showing the waveform differences of Ca^{2+} transients in HCT-8 cells on different substrates. (E) Top: Mean+SD data for the propagation distance of Ca^{2+} signals in HCT-8 cells cultured on 2D substrates with different moduli. Bottom left: Kymographs of representative Ca^{2+} wave propagations among HCT-8 cells on 40-kPa (upper) and 250-Pa (lower) PAA gels. Bottom right: Distances of Ca^{2+} wave propagations vs. time in HCT-8 cells on the different substrates.

Time-lapse fluorescent imaging recorded the spatial-temporal dynamics of $[Ca^{2+}]_{cyt}$ daily from the 1st to the 6th day post-plating (DPP). Xenograft model and *ex vivo* Ca^{2+} imaging were performed to investigate Ca^{2+} dynamics in tissues. The spatial-temporal properties of the $[Ca^{2+}]_{cyt}$ signals, including (1) the lasting duration of Ca^{2+} transients at 50% of peak intensity (CT50; **Fig. 1B**) and (2) the maximum spatial propagation distance of Ca^{2+} waves (**Fig. 1C**), were analyzed using customized MATLAB algorithms. Patch-clamp electrophysiology, high-resolution imaging, and pharmacological modulation were integrated to dissect the molecular mechanisms of the Ca^{2+} transient. IP_3 sponges that inhibit Ca^{2+} signals and xenograft model were integrated to elucidate the *in vivo* Ca^{2+} functions on tumor progression.

RESULTS

We found that, starting from the 1st DPP on, non-excitable HCT-8 cells constitutively showed spontaneous intracellular Ca^{2+} transients on both PS substrates and 40-kPa PAA gels (**Fig. 1B–C**). Of note, HCT-8 cells showed a myriad of long-distance, radial intercellular propagations of Ca^{2+} waves in multiple regions of cell colonies cultured on 40-kPa PAA gels (**Fig. 1C**). DU145 human prostate cancer cells also showed spontaneous Ca^{2+} transients and Ca^{2+} waves. Moreover, evident $[Ca^{2+}]_{cyt}$ transients and waves occur in HCT-8 tumor slices *ex vivo*.

Interestingly, regarding to the temporal characteristics, on 10–40-kPa PAA gels, a sub-group of the HCT-8 cells constitutively generated Ca^{2+} transients with CT50 higher than 30 s from the 1st DPP on (**Fig. 1B&D**). In contrast, on 250-Pa PAA gels and 3-GPa PS substrates, all the CT50s of the same batch of HCT-8 cells were less than 30 s (**Fig. 1B&D**). Regarding the spatial characteristics, on 40-kPa PAA gels, the HCT-8 cells constitutively generated radial intercellular Ca^{2+} waves with propagation distance longer than 60 μm at a propagation speed of 6.98 ± 2.45 μm/s in multiple regions of large cell colonies from the 3rd DPP on (**Fig. 1C&E**). In contrast, on 250-Pa PAA gels and 3-GPa PS substrates, all the propagation distances of Ca^{2+} signals were less than 60 μm (**Fig. 1E**). The results suggest that the spatial-temporal characteristics of Ca^{2+} waves can be tuned by the mechanical stiffnesses of culture substrates.

Our mechanistic dissections suggest that the spontaneous Ca^{2+} transient initiation in HCT-8 cells is caused by inositol trisphosphate receptor (IP_3R)-regulated Ca^{2+} release from endoplasmic reticulum (ER), with the G_q-PLC-IP_3R pathway be the upstream signaling. We applied IP_3 sponge, a hyper-affinity IP_3 absorbent that deactivates IP_3R,[13] to inhibit Ca^{2+} transients in HCT-8 cells *in vitro* (**Fig. 2A**) and *ex vivo* (**Fig. 2B–C**). In a xenograft model, the tumors grown from IP_3-sponge-transduced HCT-8 cells possessed 1.6 times lower weight compared to those from control cells, whereas the body weights of the tumor-bearing mice were similar between the two groups (**Fig. 2D–E**). These data suggest that the inhibition of Ca^{2+} signals in HCT-8 cells suppresses *in vivo* tumor growth.

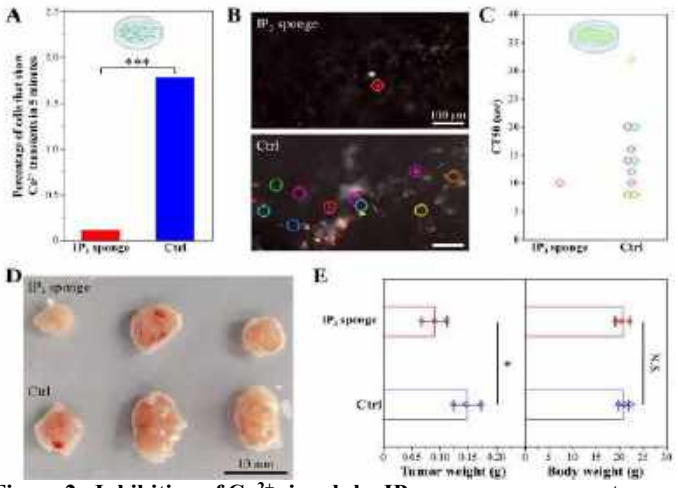

Figure 2: Inhibition of Ca^{2+} signals by IP_3 sponge suppresses tumor growth *in vivo*. (A) The percentages of IP_3-sponge-transduced and control (Ctrl) HCT-8 cells that showed spontaneous Ca^{2+} transients when cultured in petri dishes. (B) Spontaneous Ca^{2+} transients in the tumor slices of the IP_3 sponge and control groups. Ca^{2+} flashing spots during the 5-min recording are circled. (C) The CT50 of Ca^{2+} flashing spots circled in (B). (D) Dissected tumors two weeks after inoculation. (E) The effect of IP_3 sponge on the weight of tumors and the body weight of tumor-bearing mice.

DISCUSSION

To our knowledge, this research is the first attempt to fill several knowledge gaps in the field. Our results suggest that IP_3R-induced Ca^{2+} transients in human colon cancer cells could be regulated by the mechanical microenvironment. These results indicate a possible crosstalk between the G_q-PLC-IP_3R pathway[14,15] and the mechanotransduction process.[16,17] We hypothesize that substrate stiffness could influence the spatial-temporal characteristics of Ca^{2+} signals in HCT-8 cells possibly via regulation of (1) mechanosensitive GPCRs,[18,19] (2) interaction between PIP2 and PLC,[20,21] and (3) IP_3R activities[22,23] in a cytoskeleton-dependent manner. Although we found that HCT-8 cells uniquely show the IP_3 signaling and ER Ca^{2+}-release-based mechanism in comparison to other reported colon cancer cell lines,[12] this mechanism is widely found in many other cell types.[14,15]

This study is the 1st report that shows the long-distance Ca^{2+} waves in human cancer cells (**Fig. 1C**) and tumors derived from xenografts (**Fig. 2B**). Our results advance the understanding of the mechano-regulated functions/mechanisms of Ca^{2+} signals in cancer and potentially contribute to the development of new therapies for tumor suppression.

INTRODUCTION

Biological systems can modulate their electrical membrane potential and apply mechanical forces simultaneously to regulate key physiological functions including proliferation, communication, computation, and migration.[1–4] However, the 4D spatial-temporal dynamics of the electro-mechano-physiological signals in most multi-cellular systems remains unknown, mainly because of the limitation of current technologies to elucidate the coupled signals. To fill this gap and reveal the general rules of life, we created a wide-area 2D/3D optical interrogation system to visualize and control the electro-mechano-physiological signals in > 50 cells simultaneously within 5 min across conditions of *in vitro*, *ex vivo*, and *in vivo*. Our new technologies enable mechanistic study of both electrical and mechanobiological nature of biological systems in a high-throughput, non-invasive, high-speed (> 1 kHz), high signal-to-noise ratio (SNR), cell-type-specific, and long-term (from milli-seconds to months) manner.

Neurological diseases remain a significant unmet societal need today, affecting millions of patients worldwide.[5–7] However, due to the low throughput of traditional drug screening approaches (e.g., up to 200 cells per day for automated patch-clamp)[8,9] and the complexity of the human nervous system (e.g., 100s of neuronal cell types and 100 billion nerve cells),[10,11] neurological drugs have a much longer development time than other-organ-targeting drugs. Hence, we are in dire need of innovative approaches that can improve the throughput to discover new drugs and advance integrative understanding of neurological diseases.

Electrical activities are the "finger-printer" and "regulator" of cell states, especially in neurons.[12,13] In parallel, mechanical stimuli including substrates' mechanical stiffness,[14–17] compression,[18,19] and tension[20,21] are demonstrated to regulate the electrical properties of neurons. However, existing publications show opposite influence of mechanics on the electrical behavior of neurons,[14,17] partially due to the inconsistent methods of the measurement and control for the coupled signals. Moreover, the causal links, i.e., molecular mechanisms, among electrical, mechanical, and physiological signals in neurons are not clear, triggering the development of multidimensional systems to acquire the omics data.

METHODS

Optopatch (optical patch-clamp) imaging was performed via a customized all-optical electrophysiology interrogation (AOEI) system (**Fig. 1A−B**).

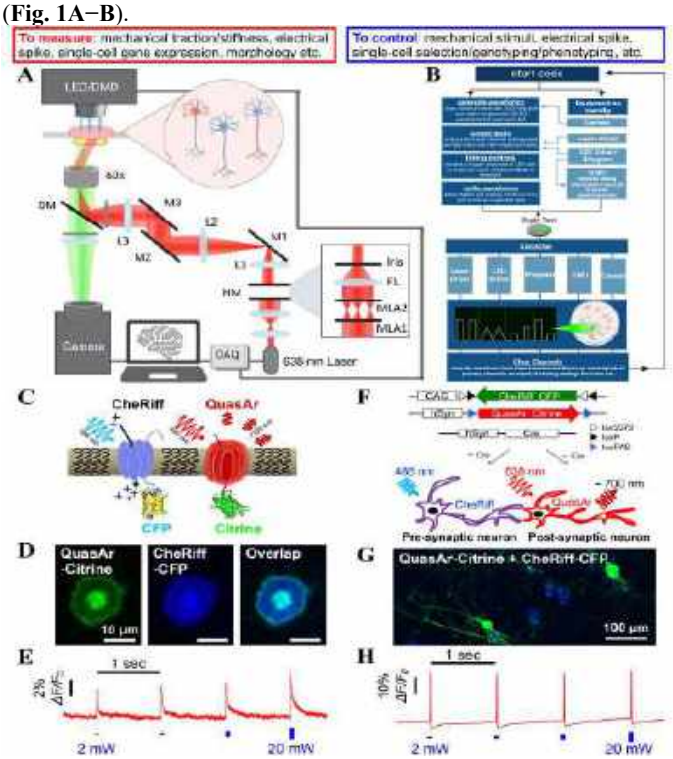

Figure 1: All-optical electrophysiology interrogation (AOEI) system enabling optical recording and control of single action potential (Optopatch) and synaptic transmission (SynOptopatch). (A) Optical path diagram. (B) Synchronization of hardware via precise signals produced by our LabVIEW code. (C) Optopatch molecular tools (QuasAr + CheRiff) in the same neuron. (D) Expression and distribution of QuasAr-Citrine and CheRiff-CFP. (E) Single spike readout (Red) under optogenetic stimulation (Blue) in a single neuron. (F) SynOptopatch molecular tools: Cre-recombinase-mediated exclusive expression of CheRiff and QuasAr. (G) Pre-synaptic neurons expressing CheRiff-CFP and post-synaptic neurons expressing QuasAr-Citrine. (H) Post-synaptic potential readout (Red) under optogenetic stimulation (Blue) including both inhibition and excitation.

For large field-of-view (FOV) voltage imaging, a 4X objective (NA 0.28) and a 0.5-kHz camera sampling rate were used. For high-resolution voltage imaging, a 60X objective (NA 1.5) and a 1-kHz sampling rate were used. The rat primary trigeminal ganglion (TG) and dorsal root ganglion (DRG) neurons were cultured on: (1) polyacrylamide (PAA) hydrogels with elastic Young's moduli of 0.1 kPa and 100 kPa; and (2) glass substrates with a Young's modulus of 70 GPa. The raw data were post-processed and analyzed using ImageJ software and custom MATLAB programs.

RESULTS

To investigate intrinsic neuronal excitability using our AOEI system, we expressed the Optopatch molecular tools (QuasAr for voltage readout[22] + CheRiff for voltage actuation) in the same neuron using lentivirus (**Fig. 1C**). The expression and membrane trafficking of QuasAr and CheRiff were confirmed by confocal imaging of their tagged proteins, Citrine and cyan fluorescent protein (CFP), respectively (**Fig. 1D**). 5-msec stimuli of blue (488 nm) light triggered single action potentials (APs) in multiple Optopatch-expressing primary TG and DRG neurons (**Fig. 1E**). The blue light with increasing intensities triggered APs with increasing peak voltage.

To investigate synaptic transmission using our AOEI system, we expressed the synaptic Optopatch (SynOptopatch) molecular tools,[23] i.e., CheRiff and QuasAr exclusively in the pre-synaptic and post-synaptic neurons using a Cre-recombinase-mediated system (**Fig. 1F**). A multiplicity of infection (MOI) of 1 for AAV-Cre was applied to have approximately equal numbers of neurons expressed CheRiff or QuasAr (**Fig. 1G**). We found that, 5-msec stimuli of blue LED light at the whole FOV triggered post-synaptic potentials in multiple QuasAr-expressing primary TG and DRG neurons (**Fig. 1H**). The post-synaptic potentials reveal both inhibition and excitation in the same post-synaptic neuron.

To increase the FOV of the imaging system for high-throughput AOEI, we expanded the QuasAr illumination area to 4.6×0.7 mm^2 while maintaining the illumination power density at 1 W/mm^2 to compensate for the short exposure time.[24–26] To examine the imaging capability of the whole illumination area, we located the same group of neurons at the middle, right edge, and left edge of the FOV and performed Optopatch imaging in sequence (**Fig. 2A**). We found that, our AOEI system recorded single-spike-resolved AP firing from neurons at all three locations under multiple 500-msec optogenetic stimulation trials (**Fig. 2A**). The blue light with increasing intensities triggered APs with increasing firing frequency in a subgroup of neurons.

To investigate the influence of mechanical microenvironment on the AP firing patterns of neurons, we cultured the rat primary TG neurons on 0.1-kPa PAA, 100-kPa PAA and glass substrates and performed Optopatch imaging (**Fig. 2B**). We found that, primary TG neurons cultured on soft PAA gels started to fire multiple APs at lower intensities of the 500-msec optogenetic stimuli than those cultured on stiff glass (**Fig. 2B**).

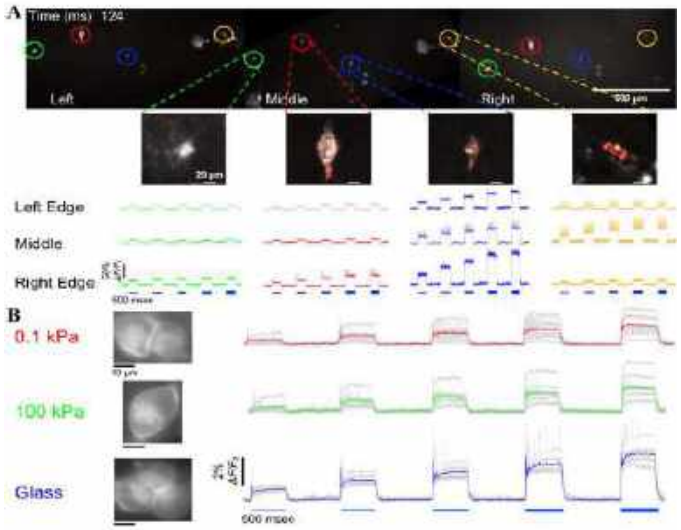

Figure 2: (A) Wide-FOV (4.6×0.7 mm^2, 4X) excitability recordings of primary TG neurons. Top: QuasAr fluorescence (hot map) image of Optopatch-expressing neurons. Middle: Magnified views of spiking neurons circled in the top image. Bottom: AP readout under optogenetic stimulation in neurons at different locations of the whole FOV. (B) High-resolution (60X) excitability recordings of primary TG neurons cultured on mechanical-stiffness-variable substrates. Left: QuasAr expression in spiking neurons. Right: Averaged AP waveforms of neurons under optogenetic stimulation on different substrates.

DISCUSSION

To our knowledge, this research is the first attempt to fill several knowledge gaps in the field, by recruiting 2D substrates with tunable mechanical properties and all-optical interrogation to study the mechano-electrophysiology of primary neurons (**Fig. 2**). Our results suggest that neurons cultured on physiologically relevant soft substrates could be more easily excited compared to those cultured on glass-bottom petri dishes. These data are in the same trend with several previous publications.[16,17] However, those previous results were measured by conventional patch-clamp in a cell-by-cell manner, and our wide-area AOEI system could increase the throughput by > 500-fold.

Our AOEI technologies enable high-throughput investigation of intrinsic neuronal excitability and synaptic transmission under different mechanical microenvironments. More functions are to be added, including compressive/tensile stimuli, traction force measurement, and single-cell-resolved selection/genotyping/phenotyping. The integrated multidimensional system potentially contributes to the mechanistic studies of the omics among electrical/mechanical/physiological signals in neurons and to the drug screening for neurological diseases.

INTRODUCTION

The role of mechanics in skeletal development is pivotal, with extensive research elucidating the significance of mechanical factors in this process[1–3]. Stem cells, which are fundamental for skeletal development, perceive their mechanical surroundings through cell–cell and cell–extracellular matrix adhesion, mechanosensitive ion channels, and primary cilia[4]. The role of mechanosensitive ion channels, TRPV4 and PIEZO are pivotal to mesenchymal stem cell behavior. Volume expansion mediated by TRPV4 activation, has been shown to regulate osteogenesis in stem cells embedded in 3D hydrogels[5]. Similarly, PIEZO1 has been shown to regulate osteoblast differentiation in mesenchymal stem cells[6]. While the in-vitro manipulation of stem cell differentiation by mechanical cues holds promise in tissue engineering and regenerative medicine[4], the specific impact of stresses and strains during regeneration in-vivo remains relatively unexplored.

Even though the gene expression and pattern formation between regeneration and embryonic development are similar[7], there are a few critical differences. Notably, regenerating tissues source their cells from pre-existing mature structures, in contrast to the de novo formation of tissues during development[8]. The blastema, a heterogeneous pool of restricted progenitor cells, is the initial stage of regeneration[9]. Mechanosensitive channels are important in the context of cellular movement during limb regeneration in axolotls.

While several studies have elucidated the critical role of calcium dynamics in skeletal development and maintenance[10], such studies are limited in the context of regeneration. A recent study showed that inhibiting L, N, and T-type calcium channels in regenerating axolotl tail, inhibits regeneration, emphasizing the significance of calcium ion kinetics in regeneration[11]. However, the functional expression of mechanosensitive calcium ion channels, particularly TRPV4 and PIEZO channels, in blastemal cells during axolotl limb regeneration has yet to be studied.

This study aims to bridge this knowledge gap by employing single nuclear RNA sequencing and immunofluorescence to delineate the expression patterns of TRPV4 and PIEZO channels at different stages of axolotl limb regeneration. This will enable us to further elucidate the roles of the channels in blastemal cells, shedding light on their contributions to the regenerative capabilities of axolotl limbs.

METHODS

Single Nuclear RNA Sequencing: Limb tissues from 4 different animals at early and late blastema stage of regeneration were pooled and dissociated for single nuclear RNA sequencing on a Chromium platform. Reads were aligned to the axolotl v6 genome, counted, and normalized using 10X Genomics Cellranger software. Counts matrices were filtered for high quality cells and re-clustered using the 10X Genomics Loupe browser to produce UMAP visualizations with broad tissue type annotation.

Immunostaining: Both forelimbs of fully developed axolotls were amputated mid-humerus. Amputated, fully grown limbs served as the fully-grown time point as well as the positive controls since TRPV4 and PIEZO1/2 ion channels are known to be expressed in skeletal tissues[12]. Tissue from regenerating forelimbs were harvested at early and late blastema stages of regeneration, (3 limbs at each time point). The samples were fixed in 4% paraformaldehyde over night at 4˚C, cryopreserved in Optimal Cutting Temperature Solution and stored at -80˚C. The samples were cryosectioned and baked at 65˚C. The slides were blocked with goat serum and incubated with 1:200 Rabbit Anti-TRPV4 polyclonal antibodies and 1:300 Rabbit Anti- PIEZO2 polyclonal antibodies, followed by staining with 1:400 Goat Anti-Rabbit Alexa Fluor® 647 secondary antibodies. Negative controls were incubated with just the secondary antibodies. The sections were washed and then stained with 1:5000 DAPI nuclear stain. The samples were washed and then mounted with coverslips. The sections were imaged using a confocal microscope.

RESULTS

TRPV4, PIEZO1 and PIEZO2 mechanosensitive ion channel genes are expressed at early and late stages of blastemal growth but with higher expression occurring in the later stage. PIEZO1 has fairly nonspecific expression in both early and late blastema, but moderately increases in the late-blastema stage. PIEZO2 is highly upregulated in fibroblasts at both timepoints. It is also the most highly expressed out of these three genes. TRPV4 is expressed at both stages but appears upregulated in the late-blastema stage and shows moderately higher expression in epithelial populations and macrophages (Figure 1).

Immunofluorescence study confirmed the presence of TRPV4 and PIEZO2 ion channels in early and late stage blastema and as well as in the fully grown cartilage samples as expected (Figure 2).

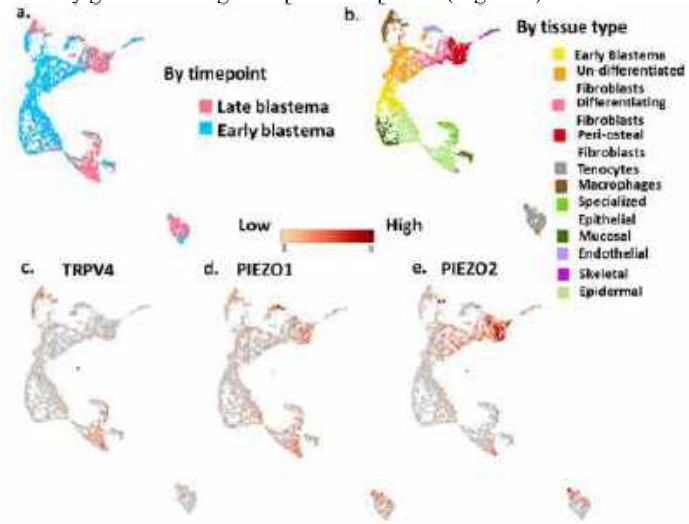

Figure 1: Single Nuclear RNA data (a) Clusters organized by regeneration timepoint (b) Clusters organized by tissue type (c) TRPV4 expression (d) PIEZO1 expression (e) PIEZO2 expression

DISCUSSION

In this study, we have shown that regenerating limb blastemas express mechanosensitive ion channels TRPV4 and PIEZO2 beginning in the early stages of regeneration using immunostaining. Further we showed the differential gene expression of the ion channels in the different populations of the blastemal cells during regeneration using single nuclear RNA sequencing.

Expression of TRPV4 and PIEZO channels in mature chondrocytes align well with published literature[12]. Further, it confirms that the primary antibodies have good target specificity to axolotl tissues.

In our study, we showed that macrophages in the limb blastema highly express TRPV4 genes along with epithelial cells. This is consistent with previous studies that showed the transcriptional presence of TRPV4 in macrophages[13]. Macrophages are known to be pivotal for limb regeneration. Depletion of macrophages results in failure of limb regeneration[14]. Further, activation of PIEZO1 ion channel in macrophages has been shown to inhibit wound healing in-vitro[15]. However, the functional role of TRPV4 channels on macrophage activity in limb blastema is yet to be studied.

We further show that the mesenchyme begins to condense in a proximo-distal direction which aligns well with our previous results where we showed that the stiffness of late stage blastema has a proximo-distal gradient in stiffness with proximal parts having a higher stiffness compared to the distal tissue[16]. The robust expression of TRPV4 and PIEZO channels in the condensate aligns well with studies on limb development that show that cartilage differentiation and proliferation are mediated via the mechanosensitive channels[5].

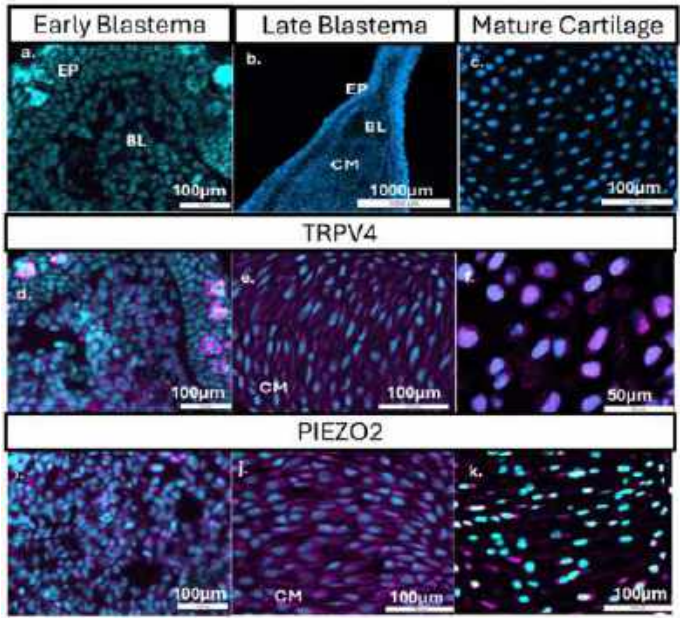

Figure 2: (a-c). Negative controls (d-f) TRPV4 expression (g-i) PIEZO2 expression in early and late blastema, and mature axolotl cartilage. Cyan stains for the nucleus and magenta stains for the presence of TRPV4/ PIEZO2 ion channels. EP: Epithelium, BL : De-differentiated Blastemal cells, CM: Condensed Mesenchyme

Our data shows that blastemal fibroblasts express PIEZO genes. PIEZO1 activation is known to suppress migration of dermal fibroblasts in-vitro[17]. Its role in cell migration and recruitment in blastemal cells needs further investigation.

Future studies will study calcium signaling response mediated by TRPV4 and PIEZO mechanosensitive ion channels in regenerating limbs to evaluate the functionality of the channels in mechanotransduction.

DYNAMIC IMAGING OF THE COLLAGENOUS MYOCARDIAL EXTRACELLULAR MATRIX DURING POST-INFARCTION INFLAMMATION

Daniel P. Pearce (1) and Colleen M. Witzenburg (1)

(1) Cardiovascular Biomechanics Lab, Department of Biomedical Engineering, UW-Madison, Madison, WI, USA

INTRODUCTION

Coronary artery occlusion leads to myocardial infarction (MI), irreparable cardiomyocyte damage, and impaired left ventricle (LV) function for nearly a million Americans each year.[1] During the first week post-MI, an intense inflammatory response occurs in the myocardium that contributes to notable extracellular matrix (ECM) degradation.[2–4] While the destruction of the innate ECM is necessary for the removal of necrotic cardiomyocytes and long-term healing, it weakens the myocardium, leaving it vulnerable to rising volumes and pressures, and raising the risk of ventricular rupture and death.[5,6] While some prior descriptions of the inflammatory post-MI environment have been reported, they relied on one-dimensional measures of stiffness and collagen content.[3,7,8] There remains a need for full-field quantifications of the myocardium's mechanical properties, as well as depictions of the fibrous ECM architecture giving rise to these complex properties during this critical healing phase.

Quantitative polarized light imaging (QPLI) is a novel and affordable imaging modality enabling macroscopic, full-field descriptions of collagen fiber alignment in thin soft tissues. QPLI has been used to examine fiber rotation/alignment in mouse skin,[9] bovine flexor tendons,[10] human ulnar collateral liagments,[11] and pulmonary valve leaflets.[12] To our knowledge, however, it has not been applied to the myocardium. When combined with our Generalized Anisotropic Inverse Mechanics (GAIM) method, these two approaches can capture a soft tissue's dynamic mechanical and structural behavior.[13]

The objective of our study was to leverage both QPLI and GAIM to quantify the full-field anisotropy and stiffness of healthy and infarcted rodent myocardium at one day post-MI, an important, but woefully understudied timepoint in the MI healing process. We hypothesized that post-MI inflammation[2,3,14] would lead to depressed stiffnesses and levels of anisotropy in the affected myocardium,[3,7,8] resulting in a stark borderzone between the infarcted and remote myocardium.

METHODS

Animal Model. Adult male Sprague Dawley rats underwent either permanent occlusion (PO) of their left anterior descending coronary artery through ligation or sham surgery, where their chest was opened but the heart was not disturbed. MI was confirmed by blanching of myocardium downstream of the suture, which remained present until hearts were harvested 1 day after the PO or sham surgery.

Decellularization. Hearts were decellularized by retrograde perfusion of sodium dodecyl sulfate (SDS) and Triton X-100 (Figure 1).[13,15] Briefly, the heart was perfused with SDS via constant pressure, then constant flow at 2 mL/min. Next, it was perfused with deionized water and Triton-X 100 for 30 minutes at constant pressure, followed by PBS for 72 hours. Isolation of the ECM results in thinning of the LV wall enabling plane stress characterizations of the myocardium's passive mechanics.

Figure 1. (Top) Native rodent heart with a clear MI (arrow). **(Bottom)** Decellularized rodent heart with MI (arrow).

Laser Micrometry. Decellularized myocardium samples were trimmed to a cruciform shape[16] and scanned by a LJ-V7080 class II laser micrometer (Keyence; Itasca, IL) operating at 200 Hz to capture their full-field thickness. A custom MATLAB script (shared in our previous publication) generated 3D profiles from the raw CSV files.[17]

Biaxial Testing. Samples were then clamped and secured to a biaxial testing machine using a custom clamping system.[17] After preloading,[18] samples were preconditioned via ten rounds of equibiaxial extension at 20% strain. Each sample was then subjected twice to a series of unique and asymmetric planar biaxial loading patterns to generate a broad strain space, aiding detection of mechanical

heterogeneity.[17] QPLI was captured during the first series, then a speckle pattern was applied to the sample and standard imaging was conducted for GAIM.

GAIM. Images from each extension were exported for digital image correlation (DIC), generating a series of full-field displacements for each test. GAIM combines these displacements with corresponding normal and shear arm forces to estimate the full-field stiffness of each sample[13,19] by assuming a linear relationship between the second Piola-Kirchoff stress and the Green-Lagrange strain. Thickness profiles were also incorporated into GAIM, a step we and others have found crucial for determining mechanics of complex soft tissues.[17,20]

DQPLI. QPLI capitalizes on the birefringent properties of collagen fibers. Full-field QPLI results include *AoP*, the angle of linear polarization which is a measure of preferred collagen fiber angle, and *DoLP*, the degree of linear polarization which is a measure of strength of fiber alignment. DoLP ranges from 0 (indicating no alignment) to 1 (indicating total alignment). QPLI results were then mapped to the GAIM mesh using the location of the grips in each image. Successful mapping allowed for the inference of full-field displacements during polarized light imaging and subsequent determination of full-field QPLI parameters in a particular region of the tissue as that region deforms – i.e., mapping captured the DoLP of the top boundary throughout the test as it moved upwards (Figure 2).

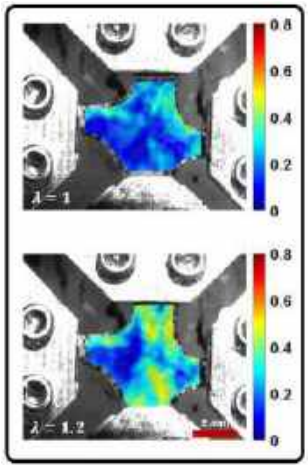

Figure 2. Strength of fiber alignment in an unloaded (**top**) and fully loaded (**bottom**) PO sample during an equibiaxial stretch (λ = 1.2).

Data Analysis. Visual comparisons were made between sham and PO groups and summary statistics were computed. Unpaired, one-sided T-tests were used to detect statistically significant group differences.

RESULTS

Figure 3 depicts the geometrical (thickness), mechanical (stiffness), and structural (DoLP) differences between representative sham and infarcted myocardium samples. The infarct region of two PO samples exhibited much larger thickness than the periphery or sham sample. Despite this notably higher thickness, the infarct regions of both PO samples also exhibited depressed stiffness and low collagen fiber alignment. The sham sample had a remarkably homogeneous thickness (SHAM1: 0.91 ± 0.07 mm, CoV = 0.08) compared to the two PO samples (PO1: 1.56 ± 0.37 mm, CoV = 0.24; PO2: 1.71 ± 0.26 mm, CoV = 0.15, not shown). A similar trend was observed in stiffness (SHAM1: 371 ± 98.4 kPa, CoV = 0.27; PO1: 378 ± 181 kPa, CoV = 0.48; PO2: 155 ± 66.1 kPa, CoV = 0.43). However, DoLP distributions were comparable between the two groups (SHAM1: 0.237 ± 0.12, CoV = 0.52; PO1: 0.245 ± 0.12, CoV = 0.48; PO2: 0.281 ± 0.11, CoV = 0.37).

DISCUSSION

In this study, we applied QPLI, an imaging approach that offers insight into collagen fiber alignment, and GAIM, an inverse method for measuring heterogeneous soft tissue mechanics, to infarcted myocardium at one day post-MI. Although traditionally understudied compared to long-term scar formation, the inflammatory phase of the post-MI healing response is associated with drastic ECM degradation, stiffness reduction, and increased rates of rupture.[2–4] PO samples exhibited high thickness but low stiffness in the infarct region. The thickness and stiffness distributions were also much more heterogeneous (~140% and ~69% increase in CoVs, respectively, compared to sham). Similar DoLP distributions were observed between groups. However, both PO samples exhibited strong collagen fiber alignment at the border surrounding the less aligned infarct core, suggesting a sudden transition in structure that could accentuate stress concentrations in the vulnerable myocardium. Additional samples are necessary to confirm these observations. In the future, we will also include a reperfusion therapy group, which is a more clinically relevant model of MI. We anticipate this work will highlight mechanical and structural properties altered during post-MI inflammation, allowing for the development of therapies to further safeguard the heart against catastrophic ventricular rupture.

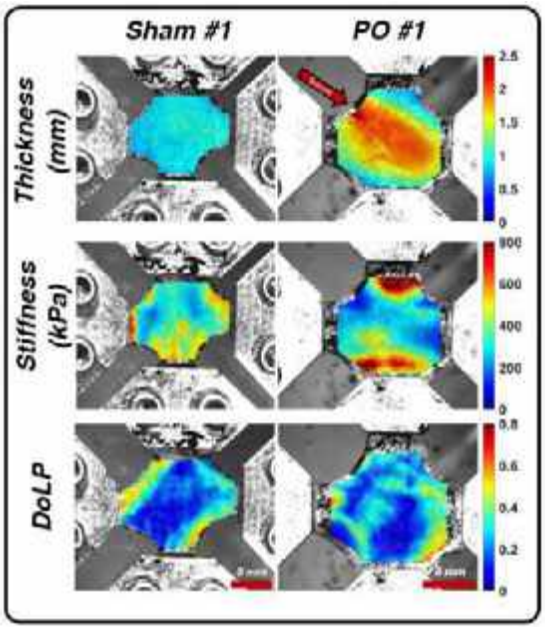

Figure 3. Representative sham (**left**) and PO (**right**; arrow: suture) samples showing full-field thickness from laser micrometry (**top**), stiffness from GAIM (**middle**), and DoLP from QPLI (**bottom**).

INTRODUCTION

With the heart's poor capability of self-regeneration [1], any damage to the heart muscle is not only irreversible but can lead to debilitating effects on the organ's overall function. Cardiac tissue engineering, in particular human induced pluripotent stem cell derived cardiomyocyte (hiPSC-CM) based technology [2], offers a promising approach to understanding heart disease and alleviating its fatal consequences via disease modeling, drug discovery, and regenerative tissue engineering [1, 3]. However, a key limitation of hiPSC-CM technology is that these induced cardiomyocytes resemble fetal CMs and are morphologically and functionally distinct from the cells in mature cardiac tissue [4].

At present, there are multiple techniques to promote maturity of hiPSC-CMs including different physical platform designs (Fig 1) and cell culture protocols. With this variability in the applied techniques, performing quantitative comparisons of functional behavior between different systems becomes a major challenge, especially because there are limited available options for reliably and reproducibly extracting mechanics-based quantitative information from these platforms. Furthermore, available tools to obtain such metrics from time-lapse images of cardiac microbundles mainly provide averaged results, such as post forces and average tissue stress, that lump the spatially heterogeneous tissue behavior into a single value per frame [5–7]. On the other hand, available tools that can output full-field results, such as full-field tissue displacements and strains [8, 9], lack automation and are not readily adaptable to function on new platform designs out of the box.

In this context, we present here our work on "MicroBundleCompute," a computational framework for automatic quantification of morphology-based mechanical metrics from movies of cardiac microbundles subjected to extensive validation against synthetic examples. We further showcase the adaptability of the software to a diverse pool of input examples and highlight the valuable insight about the heterogeneous mechanical behavior of cardiac tissue gained from the extracted full-field metrics such as full-field displacements, subdomain-averaged strains, and displacement and strain-derived outputs. Finally, we make our software available under open-source MIT License on GitHub (https://github.com/HibaKob/MicroBundleCompute).

METHODS

We briefly describe here the underlying code behind "MicroBundleCompute" workflow as well as the data used for testing and validating the software.

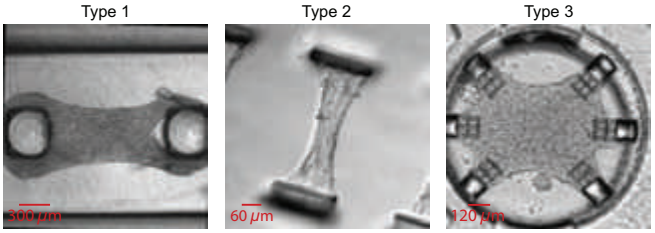

Figure 1: Examples of 3 different microbundle experimental testbeds.

Code. "MicroBundleCompute" is mainly built on OpenCV's implementation of the Lucas-Kanade sparse optical flow algorithm [15]. In our implementation, the tracking points are Shi-Tomasi corner points (points at which a slight shift in location leads to "large" changes in intensity along both main horizontal and vertical axes) [16] computed on the first frame. Notably, our approach relies solely on the natural contrast of brightfield microbundle textures and the resulting intensity gradients which makes it straightforward to implement in the experimental setting. From tracking these points across consecutive frames, we can compute full-field displacement, strain, and strain derived metrics to quantitatively capture mechanical function. Critically, for strain outputs, we avoid differentiating the displacements. Instead, we automatically perform subdomain spatial segmentation and compute a mean deformation gradient, and likewise, an average strain within each subdomain. We mainly adopt this approach to reduce the influence of imaging artifacts and noise on strain results.

Data. Our complete dataset is comprised of two general categories: 1) experimental data comprising of time-lapse videos of brightfield and phase contrast movies of cardiac microbundles and 2) synthetic data with a known ground truth for software validation.

The experimental dataset can be divided into 3 different types (Fig 1).

"Type 1" includes movies obtained from standard experimental microbundle strain gauge devices where cardiac microbundles are seeded between two poly(dimethylsiloxane) (PDMS) pillars, as described in more detail in [10]. "Type 2" is comprised of data collected from non-standard platforms termed FibroTUGs [11]. In these systems, differentiated iPSC-CMs are seeded onto electrospun dextran vinyl sulfone (DVS) fiber matrices suspended between a pair of PDMS cantilevers. As for "Type 3," they represent data obtained from highly versatile PDMS devices with embedded microfluidic channels and deformable seeding wells [12]. A more detailed description of the 3 data types can be found in [13]. We share the whole dataset on Dryad [14] under Creative Commons Zero (CC0) waiver.

Realistic synthetic data of beating cardiac microbundles were generated based on examples from "Type 1." Briefly, we first isolate the microbundle component of a real frame and use the extracted region to obtain both microbundle geometry and image texture. We then run simplified Finite Element (FE) simulations where the microbundle model is defined as nearly-incompressible transversely isotropic hyperelastic material with periodic activation and extract displacement and Green-Lagrange strain results. Based on the obtained FE displacements, we estimate projective transformations and warp the image texture accordingly. Finally, to render this data more challenging, we add Perlin noise of different magnitudes and number of octaves. A more detailed description of the synthetic data generation pipeline can be found in [13] and on GitHub (https://github.com/HibaKob/SyntheticMicroBundle).

RESULTS

We test our computational pipeline on a total of 416 synthetic validation examples and showcase its performance and versatility on 24 experimental time-lapse images of beating cardiac microbundles. A major advantage of "MicroBundleCompute" over similar tools [8, 9] that are available lies in the fact that we can run all 440 examples without the need for any parameter tuning. Furthermore, all software functionality is implemented in a test-driven development framework with 100% code coverage and automatic testing on ubuntu, windows, and macOS platforms.

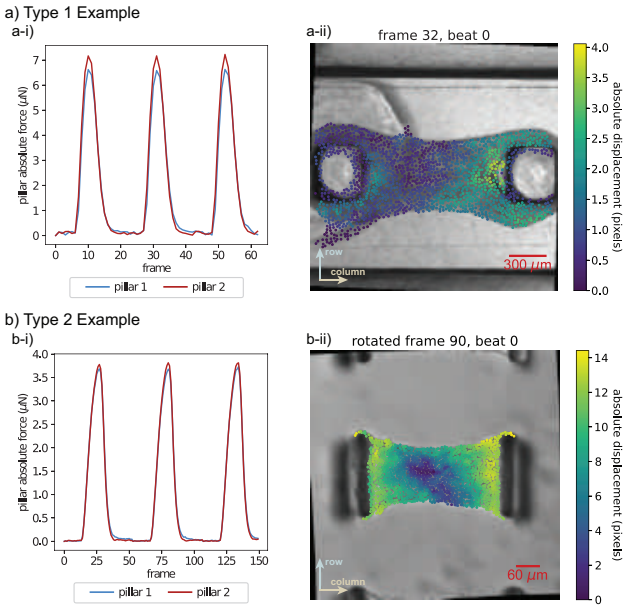

Figure 2: Direct comparison of pillar tracking and tissue tracking.

Experimental Data Examples. In Fig. 2, we show, side by side, the outputs obtained via pillar tracking (a-i and b-i) and via tracking the entire tissue domain (a-ii and b-ii) for an example from "Type 1" and "Type 2" data respectively. While pillar tracking enables the calculation of an average pillar displacement-based tissue force or stress given approximate tissue width and thickness, tissue tracking reveals abundant information regarding the inherent heterogeneous nature of microbundle beating, where for example, full-field displacement fields show regions where maximum or minimum tissue contractions are taking place. Furthermore, subdomain-averaged strains also underline the spatial heterogeneity of the tissue contractions (Fig 3a), and visualizing them with respect to time (or frame number) (Fig 3b) reveals the nature of temporal synchrony across the different subdivisions of the beating microbundle. For the particular example of "Type 3" shown in Fig. 3, the column-column direction (i.e., horizontal) Green-Lagrange strain (E_{cc}) clearly indicates that the microbundle is experiencing positive strains at the center, suggesting that a necking instability is forming on this tissue over time. This observation is further supported by the thinning tissue width at the center. Accordingly, the ability to extract and examine full-field strains enables further investigations into understanding and determining the factors, such as pillar stiffness and ECM density, that play a major role in influencing the behavior of microbundles.

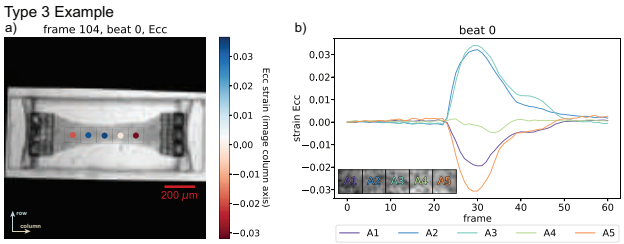

Figure 3: Example strain outputs of "MicroBundleCompute."

Synthetic Data Examples. Validation studies reveal that our software is quite robust to all tested cases with super-pixel displacements and Perlin noise of realistic parameters that result in artifacts found in experimental settings. In these cases, errors on displacements are below 10%.

DISCUSSION

Based on the results, we have demonstrated that complementing conventional metrics (i.e. pillar force and tissue stress) obtained via basic pillar tracking with reliable and reproducible full-field data, such as displacement distributions and subdomain-averaged strains, obtained via "MicroBundleCompute" allows for a better assessment of highly heterogeneous cardiac tissue behavior and a better understanding of the complex underlying mechanisms driving this behavior. Looking forward, our plan is to grow our dataset and build on this approach to develop appropriate statistical models of these tissue.

EFFECTS OF SPONTANEOUS CALCIUM SIGNALING ON CARTILAGE ANABOLIC ACTIVITIES

Ying Peng, Annie Porter, Steven DiStefano, X. Lucas Lu

Department of Mechanical Engineering, University of Delaware, Newark, Delaware, USA

INTRODUCTION

Intracellular calcium, $[Ca^{2+}]_i$, signaling is a crucial mechano-transduction response in chondrocytes and regulates cartilage metabolism [1]. We discovered that chondrocytes in cartilage exhibit spontaneous $[Ca^{2+}]_i$ signaling, similar to active cells such as neurons and cardiomyocytes. A spontaneous $[Ca^{2+}]_i$ peak is initiated by the influx of extracellular Ca^{2+} and can be amplified by the release of Ca^{2+} stored in the endoplasmic reticulum (ER). Additional Ca^{2+} influx may occur through the gap junctions connecting adjacent cells [2]. The roles of spontaneous $[Ca^{2+}]_i$ signaling in chondrocyte metabolism are not well understood. In this study, we investigate: (1) the roles of extracellular Ca^{2+} source, PLC-IP_3 pathway, ER Ca^{2+} store, and gap junctions in spontaneous $[Ca^{2+}]_i$ signaling in human cartilage, and 2) the effects of these pathways on the synthesis rates of proteoglycan and collagen using a novel click chemistry technique.

METHODS

Tissue preparation and treatment: Cylindrical cartilage samples (diameter = 3 mm, thickness = 2 mm) were harvested from human knee joints (n = 5, avg. age = 60 years old) from total knee arthroplasty (Fig. 1a) or from the femoral condyles of calf knees (n = 5, 1 to 2 months old) (Fig. 1d). Cartilage samples were incubated in chondrogenic medium for two days before experiments [2]. Samples were bisected axially into two halves and dyed with 5 μM Calbryte-520 (AAT Bioquest) to label $[Ca^{2+}]_i$. One half of each sample was used as the control; the other half was treated with one of the following antagonists for 30 min (n ≥ 3/group): 1) 10 mM EGTA to chelate all extracellular Ca^{2+}, 2) 11 μM neomycin to inhibit the phospholipase C (PLC) activity that is required for the Ca^{2+} release of ER store, 3) 1 μM thapsigargin (TG) to deplete ER store, or 4) 75 μM 18α-glycyrrhetinic acid (18α-GA) to block the gap junctions (Fig. 3).

Calcium signaling imaging and analysis: Cartilage was imaged on a confocal microscope (Zeiss LSM 510) for 30 min at a frequency of 2 s/frame (Fig. 1b). Calcium videos were processed with an established protocol to extract the $[Ca^{2+}]_i$ transient of each cell. The responsive rate was defined as the ratio of the number of cells with ≥ 1 $[Ca^{2+}]_i$ peak to the total number of cells. Spatiotemporal parameters of the $[Ca^{2+}]_i$ peaks, including the number of multiple peaks, time to reach a peak, time for a peak to relax, magnitude of peaks, and time between two neighboring peaks, were obtained from a custom-built software (Fig. 1c).

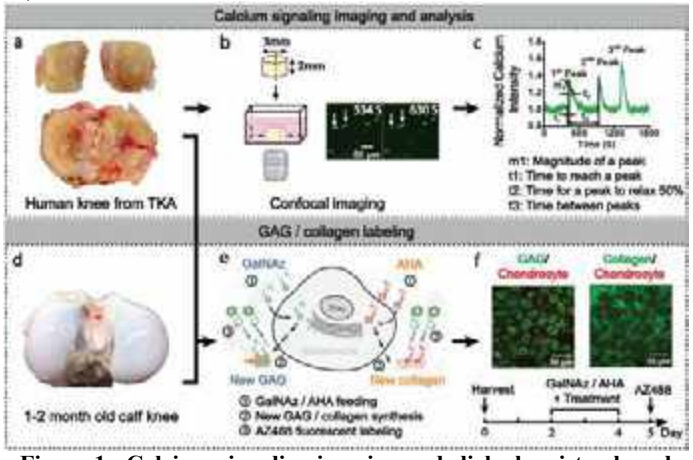

Figure 1: Calcium signaling imaging and click chemistry-based GAG and Collagen labeling.

Fluorescent labeling of new GAG/collagen with click chemistry technique: Samples (n = 12/group) were first cultured in medium containing an azide-modified monosaccharide (GalNAz) or azide-modified analog of methionine (AHA), building blocks for the GAG disaccharide units and collagen molecules, respectively. During the 24-hour incubation for bovine cartilage or 48-hour incubation for human

cartilage, GalNAz was taken up by chondrocytes and incorporated into the newly synthesized chondroitin sulfate in GAG. Similarly, AHA was incorporated into newly synthesized collagen molecules. The antagonists for the pathway study were added to the GalNAz or AHA incubation medium. Afterwards, a fluorescent dye, AZ488, was "clicked" to the azide groups on the new GAG chains and new collagen fibrils (Fig. 1e,f).

Quantification of GAG and collagen content: To quantify the newly synthesized GAG and collagen content, click chemistry labeled cartilage was enzymatically digested, and the fluorescent intensity of the digestion medium was read with a plate reader.

RESULTS

In senior human cartilage, the $[Ca^{2+}]_i$ responsive rate and number of calcium peaks of chondrocytes in cartilage explants decreased with the treatment of EGTA (Ca^{2+} chelator), neomycin (PLC inhibitor), and thapsigargin (ER Ca^{2+} remover) (Fig. 2a,d,g). No differences in responsive rate or number of calcium peaks were observed under 18α-GA (gap junction blocker) treatment (Fig. 2j). The results are consistent with our previous study on juvenile bovine cartilage [2]. $[Ca^{2+}]_i$ peaks took longer to reach apex and to return to the baseline with the treatment of EGTA, neomycin, thapsigargin, and 18α-GA. The magnitude of $[Ca^{2+}]_i$ peaks was reduced in all four treated groups compared to the control (figures not shown).

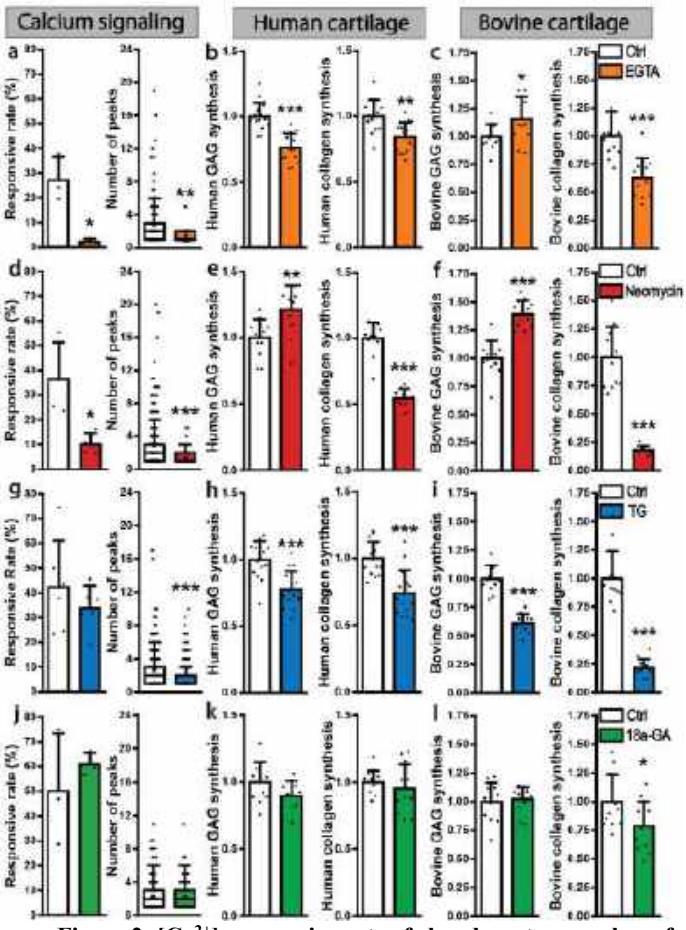

Figure 2: $[Ca^{2+}]_i$ responsive rate of chondrocytes, number of peaks, human GAG and collagen synthesis, bovine GAG and collagen synthesis with the treatment of (a,b,c) EGTA, (d,e,f) neomycin, (g,h,i) thapsigargin, and (j,k,l) 18α-GA.

For the anabolic activities of senior human cartilage, full depletion of extracellular Ca^{2+} with EGTA and emptying of the ER Ca^{2+} store with thapsigargin suppressed both GAG and collagen synthesis (Fig. 2b,h). Inhibition of the PLC-IP_3 pathway with neomycin promoted GAG synthesis but diminished collagen synthesis (Fig. 2e). No differences were noted in GAG and collagen synthesis with the block of gap junctions (Fig. 2k).

In young bovine cartilage, depletion of extracellular Ca^{2+} and blockage of the PLC-IP_3 pathway increased GAG synthesis, but decreased collagen synthesis (Fig. 2c,f). Depletion of the ER Ca^{2+} store inhibited both GAG and collagen synthesis (Fig. 2i). Blocking gap junctions showed no significant impact on GAG synthesis but inhibited collagen synthesis (Fig. 2l).

DISCUSSION

In this study, we have revealed that spontaneous calcium signaling is important for proteoglycan and collagen synthesis rates in both young bovine and senior human cartilage. The blockage of the extracellular Ca^{2+} source, PLC-IP_3 pathway, ER Ca^{2+} store, and gap junctions all inhibited the synthesis of collagen, indicating the necessity of spontaneous calcium signaling for collagen synthesis. This is consistent with the previous study, in which the blockage of Ca^{2+} influx and ER Ca^{2+} release inhibited collagen synthesis in porcine chondrocytes, measured by immunofluorescent staining [3]. In contrast, the synthesis of proteoglycan was regulated in a different manner by calcium signaling. The clearance of extracellular Ca^{2+} source increased GAG synthesis in bovine cartilage but inhibited it in senior human cartilage. The different trends could be related to the difference between young bovine cartilage and senior human cartilage [4]. Inhibition of the PLC-IP_3 pathway promoted GAG synthesis, but removal of the ER Ca^{2+} store impeded GAG synthesis. Blocking gap junctions showed no effect on GAG synthesis in both bovine and human cartilage. Our data brings new insights into the connections between spontaneous calcium signaling in chondrocytes and cartilage metabolism.

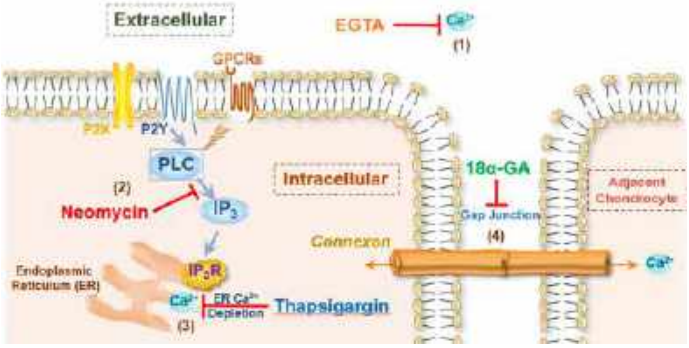

Figure 3: Calcium signaling pathways. (1) Extracellular $[Ca^{2+}]_i$ chelator, EGTA; (2) PLC-IP_3 inhibitor, neomycin; (3) ER $[Ca^{2+}]_i$ remover, thapsigargin; (4) Gap junction blocker, 18α-GA.

INTRODUCTION

Approximately 87% of all strokes in the United States are classified as acute ischemic strokes (AIS), the result of sudden blood loss to areas of the brain [1]. The standard treatment for AIS is a mechanical thrombectomy (MT), which requires the use of either an aspiration or stent retriever (SR) technique. Some studies indicate that aspiration MT leads to faster reperfusion, which correlates to improved patient outcomes [2], when compared to SR MT [3]. Attempts to optimize aspiration MT so that complete reperfusion is achieved on the first aspiration pass have been made by incorporating cyclic aspiration into MT protocols [4-6]. In these cases, cyclic aspiration was shown to outperform static aspiration in terms of overall MT success. However, these results have only been demonstrated using electromechanical vacuum pumps, which are not always used by neuro interventionalists. A manual method to apply cyclic aspiration is needed, therefore the *'plunger technique'* [7] for direct aspiration thrombectomy is evaluated in this study. The 'plunger technique' generates cyclic aspiration using a large syringe and will be compared to manual static aspiration within an experimental benchtop model of AIS. Both aspiration techniques will be applied to embolus analogs (EAs) of varying hematocrit, and the rate of complete clot digestion and/or the percent of partial clot ingestion for each method will be analyzed. We hypothesize that the plunger technique will result in greater clot ingestion compared to static aspiration.

METHODS

Whole bovine blood (Lampire Biologic) was obtained in CPDA-1 anticoagulated bags and centrifuged to separate red blood cells (RBCs) and platelet rich plasma (PRP). The blood was reconstituted to 0% and 50% hematocrits, and recalcified with calcium chloride to promote coagulation. The reconstituted and recalcified blood was then injected into 5.5 mm diameter tubes and placed in a Chandler loop system, where they rotated at 30 RPM for approximately 2 hours while submerged in a 37ºC water bath to mimic *in vivo* conditions. After the clotting period, the EAs were removed from the Chandler loop and stored in PBS at 4 ºC until testing.

A benchtop circulatory flow loop (**Fig. 1**) consisting of a peristaltic pump, fluid reservoir, pressure transducers, and an arterial model was developed to mimic AIS and experimentally study MT techniques. The arterial model was tapered from 5.5 to 3.3mm in diameter to represent a constricting cerebral artery and to ensure the EA lodged within this segment of the flow loop.

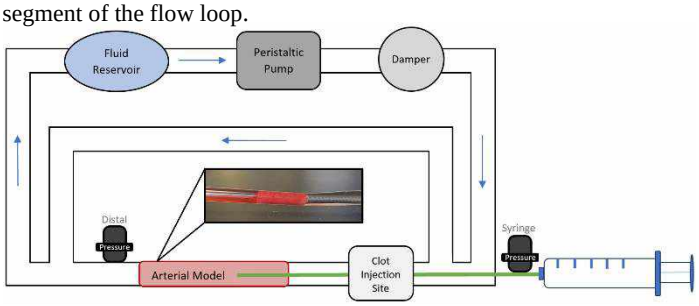

Figure 1: Schematic of benchtop AIS flow loop.

To mimic AIS, an EA was injected upstream into the flow loop and was allowed to lodge downstream within the arterial model for 5 minutes. After this waiting period, a React 71 (Medtronic) large bore catheter connected to a 60 mL VacLock syringe was passed through a hemostatic valve into the flow loop and guided to the proximal face of the EA. Static or plunger technique protocols were then performed to dislodge the EA.

For manual static aspiration, the syringe was fully opened to 60 mL and the plunger was locked so that a constant vacuum was applied to the EA for 60 seconds. For cyclic aspiration, the syringe was opened to 60 mL and then carefully released back to 0 mL. This oscillation between 0 and 60 mL was repeated for 30 seconds, after which the syringe was locked in the fully open position at 60 mL for an additional 30 seconds. Following each aspiration period, the catheter with the

attached EA was removed from the flow loop, and the length of the EA remaining outside the catheter lumen was measured and normalized by the initial EA length, resulting in a % clot ingestion measurement.

RESULTS

Examples of the pressures measured during both static (**Fig. 2A**) and plunger (**Fig. 2B**) aspiration are shown below. An immediate drop in pressure to approximately -670 mmHg is observed during static aspiration and is held constant after the syringe is locked. For cyclic aspiration, a similar drop in pressure is observed as the syringe is opened, followed by oscillations in pressure (between -400 and -710 mmHg) as cyclic aspiration is applied. After the final cycle the syringe is locked, and a constant vacuum is maintained.

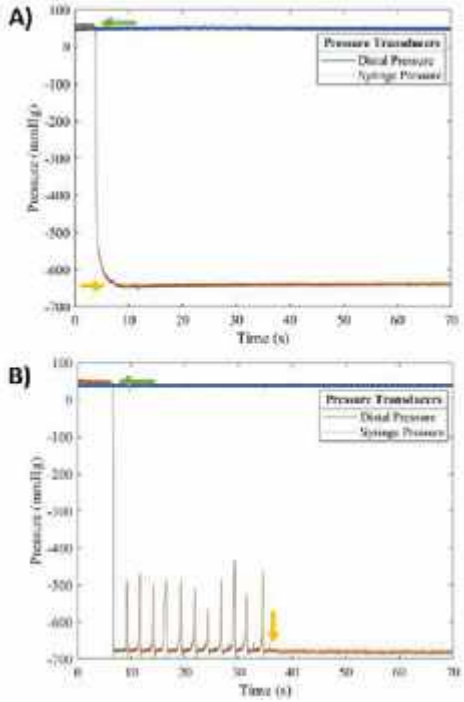

Figure 2. Examples of A) static and B) cyclic aspiration pressure measurements. Green arrows indicate opening and yellow arrows indicate closing of the syringe.

The plunger technique resulted in higher rates of complete clot ingestion (10% of the static and 30% of the plunger cases for 50% hematocrit EAs), as well as greater %'s of partial ingestion for both 0% and 50% hematocrit EAs (examples of EA ingestion shown in **Fig.3**).

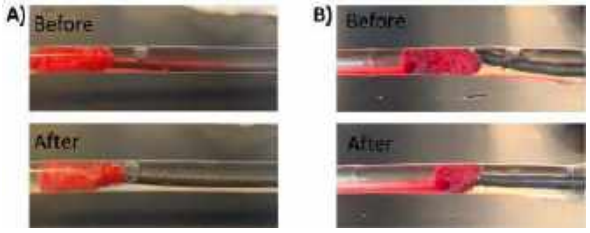

Figure 3. Before and after ingestion images of A) static and B) cyclic aspiration for 50% hematocrit EAs.

The average % ingestion (**Fig. 4**) for the 50% hematocrit EAs was measured to be 15.1±10.0% in the static cases and 34.4±19.5% in the plunger technique cases. An increase in average % ingestion was also observed for the 0% hematocrit EAs, 12.8± 4.6% for static compared to 15.8±7.3% for cyclic aspiration. A one-way ANOVA indicated a statistical difference between the two aspiration techniques for the 50% hematocrit EAs ($p=0.048$). A Tukey-Kramer post hoc test performed on the 50% hematocrit data excluding the complete ingestion cases also indicated significance.

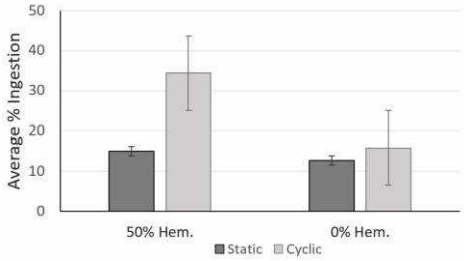

Figure 4. Comparison of average % ingestion (excluding complete ingestion cases) for static and cyclic aspiration techniques.

DISCUSSION

Using Newton's 2nd Law, force equals mass times acceleration, the effect of cyclic aspiration can be predicted. In addition, 'jerk', the time derivative of acceleration, is associated with a change in force with respect to time, and can lead to the deformation of an elastic material. Therefore, by varying the vacuum pressure through cyclic aspiration on the clot, the applied force is altered over time and jerk is generated.

The results of this study indicated that the plunger technique for manual cyclic aspiration, when compared to static aspiration, yielded overall greater levels of ingestion for both 0% and 50% hematocrit EAs (**Fig. 4**). A greater ingestion can minimize the risk of clot detachment from the catheter during the retrieval process, and thus limit the likelihood of multiple aspiration attempts. **Figure 2B** highlights that a negative vacuum pressure is maintained throughout the duration of the cyclic aspiration procedure and confirms that positive pressure does not occur. This suggests that the EA is no more likely to detach from the catheter during this procedure compared to standard techniques and will not lead to an increased risk of embolization. A comparison of the pressures in **Figs. 2A, B** indicate that an increase in maximum vacuum pressure can also be achieved through manual cyclic aspiration (-710 mmHg using plunger compared to -670 mm Hg using static).

Cyclic aspiration takes advantage of the mechanical properties of the clot and an increase in % ingestion may be due to initial clot softening under dynamic loading. A greater % ingestion for the 50% hematocrit EAs (34.4±19.5%) was found compared to the 0% EAs (15.8±7.3%) during cyclic aspiration. RBC-rich EAs exhibit decreased stiffness under compression [8], which may lead to their incremental ingestion through each aspiration cycle. Fibrin-rich EAs exhibit stiffening under cycles of compression and decompression [8], which leads us to the hypothesis that cyclic aspiration may result in a stronger cork (i.e., occlusion of the catheter tip) with fibrin-rich clots. Future work will focus on quantifying the 'corking' of the catheter tip by measuring the force needed to remove the EA from the catheter following both cyclic and static aspiration removal. Plunger technique parameters, including cyclic frequency and duration, will also be the focus of future studies to optimize this technique for a range of clinical scenarios.

EXPLORATION OF THE FULL-FIELD BIOMECHANICS OF THE HUMAN SPINE

Emma C. Coltoff (1), Benjamin S. Hezrony (1), Philip J. Brown, PhD (1)

(1) Department of Biomedical Engineering, Wake Forest School of Medicine, Winston-Salem, North Carolina, USA

INTRODUCTION

Finite element models of the spine have significantly contributed to the study of the spinal biomechanics and the effects of implants and surgical procedures on patient wellness. Yet these models are often based solely on ligamentous behavior in uniplanar loading, in part due to the computational cost of musculoskeletal modeling, but also as a result of available experimental data on which to base the simulation. The biomechanics of the spine is understood to be naturally multidimensional, yet standard single bending moment characterizations developed from the seminal work of Panjabi et al[1] leave motion-loading space in-between planes untested and unknown, leading to incomplete validation of spinal finite element models. Accurate simulation of *in vivo* spinal loads is best supported by experimental loading that is sensitive to 1) the multiplanar behavior of the spine itself[2] and 2) the multidimensional spinal stiffness response and its dependency on the directionality of the loading path. To address this gap, we developed a novel testing protocol using six-degree-of-freedom trajectories to produce complex motion paths which map the spine's multiplanar behavior and visualize its multidimensional bending stiffness in all directions within its physiological limits.

METHODS

One L2-L5 synthetic lumbar surrogate specimen from Sawbones (Washington, USA) was mounted to custom fixtures on a 6 DOF KR 300 R2500 Ultra Robot (KUKA Robotics, Germany). The specimen's moment-displacement behavior was captured by a Delta IP68 SI-330-30 (ATI Industrial Automation Inc, USA) load cell, Optotrak (Northern Digital Inc, Canada) sensors, and simVITRO (Cleveland Clinic BioRobotics, USA) software. A geometric combined FE and LB loading scheme (**Figure 1a**) was designed as a combination of three different loading trajectories which can be run clockwise/counter-clockwise about the craniocaudal axis: circles, angled "petals", and medially/distally moving "rays" which pass through the spine's neutral zone. This pattern is designed with a scalable quantity of intersection points within the spine's physiologic space at which the three trajectories overlap. This series of experiments resulted in 930 distinct intersection points (**Figure 1b**) at each of the three trajectories and their two variants (clockwise/counterclockwise), resulting in eight distinct angles at which the intersection point can be approached during a specimen loading trajectory. The specimen was first tested in moment-controlled loading of combined Flexion-Extension (FE) and Lateral Bending (LB) circles with no axial preload in increasing combined moments up to 7.5 Nm, the standard maximum loading for the lumbar spine[2]. This testing captured the organic shape of the spine's physiologic boundary under maximal combined FE and LB loading. The geometric trajectory was then cropped to match the output of the boundary capture testing, but to maintain the spacing between intersection points. The specimen was then loaded by the cropped trajectory in displacement-controlled loading, to maintain the spacing of the intersection points.

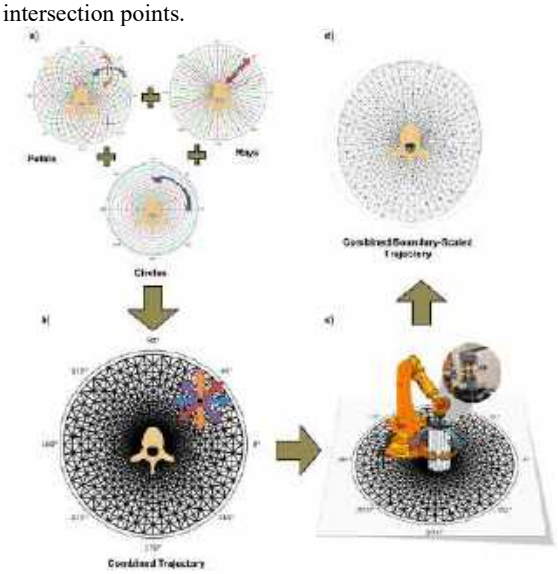

Figure 1: Combination of the ray, petal, and circle trajectories (a,b), test setup (c), and the boundary-scaled output (d).

RESULTS

Displacement measurements from the Optotrak system were transformed through simVITRO into anatomical bending measures in Anterior, Lateral, and Superior translations (mm) and Flexion-Extension, Lateral Bending, and Axial Rotation bending (deg) relative to the joint coordinate system of the spine. The ATI load cell measures were processed through simVITRO to determine the Anterior, Lateral, and Superior forces (N) and Flexion-Extension, Lateral Bending, and Axial Rotation bending moments (Nm) on the spine segment in response to the loading trajectory. The displacements and loads were combined into a resultant stiffness value of the spine throughout the loading trajectory. The data were then sliced to visualize the corresponding FE and LB planar and 45° off-axis stiffness behaviors for each trajectory type in response to the multiplanar loading.

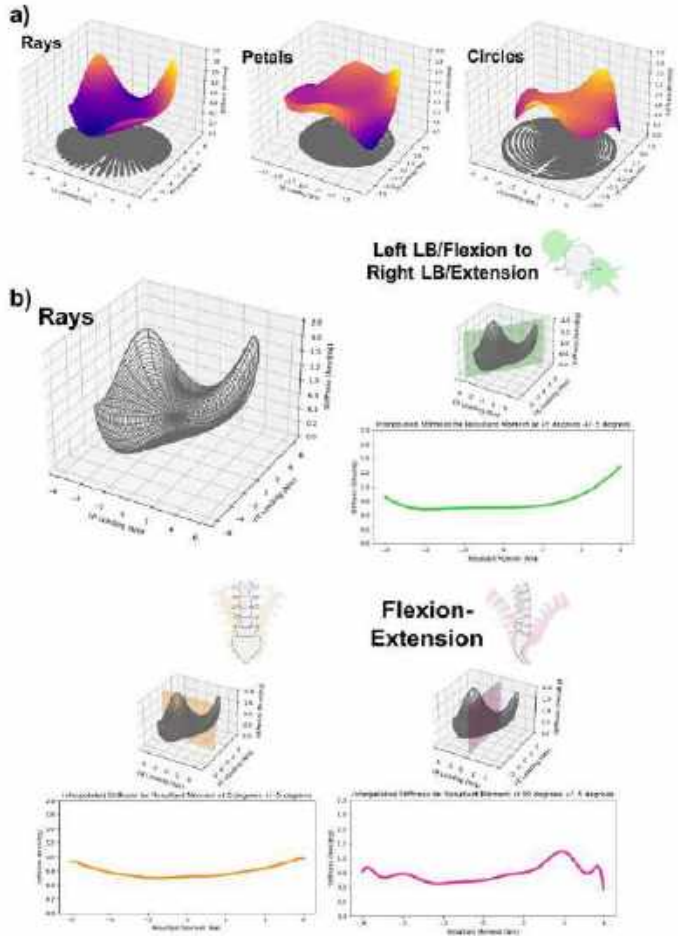

Figure 2. (a) Stiffness surfaces for three trajectories. (b) Slices through stiffness surface for rays trajectory in planar Lateral-Bending and Flexion-Extension and Negative 45° (Left LB/Flexion to Right LB/Extension).

The spinal surrogate stiffness creates vastly different surface shapes shown in the 3D plots in **Figure 2a**. Peak stiffness (1.4 Nm/deg) in the circular trajectory was 0.35 Nm/deg lower than in the petals or rays trajectories (1.75 Nm/deg). The circular trajectory produces peak stiffness measures where LB is minimized and FE is maximized. By contrast, the rays trajectory enables visualization of peak stiffness at the maximum combination of left and right LB and extension. The planar slices (**Figure 2b**) facilitate visualization of distinct behaviors of the spine's stiffness in planar FE and LB for comparison to uniplanar behaviors. The spine had similar peak LB planar stiffness measures (1.09 Nm/deg) under the petal and circle trajectories but a peak of only 0.95 Nm/deg under the rays trajectory.

This testing is unique in that it enables assessment of stiffness of the spine as it passes from combined full Flexion and left LB through the neutral zone to full Extension and right LB (**Figure 3, green**), during which it sees a peak stiffnesses of 0.6-1.2 Nm/deg and 0.9-1.5 Nm/deg at the extrema of the path, respectively, depending on trajectory. The complementary path from full Flexion and right LB through the neutral zone to full Extension and right LB (**Figure 3, blue**), saw different peaks in stiffness values of 1.0-1.1 Nm/deg and 0.75-1.2 Nm/deg. These paths can be compared with a moving average of the stiffness in planar LB and FE (**Figure 3, black dashed**) across the same range of resultant moment values. Focusing just on the circular trajectory, this was calculated to be 1.25 Nm/deg and 1.15 Nm/deg at the extrema. The differences in behavior between the two off-axis slices and the calculated average planar stiffness suggests that multiplanar spinal stiffness cannot be inferred exclusively from planar testing.

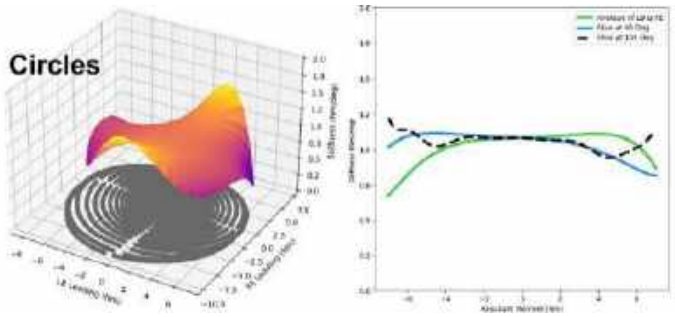

Figure 3: Left LB/Flexion to Right LB/Extension & Right LB/Flexion to Left LB/Extension compared to average planar LB & FE stiffness.

DISCUSSION

Comparing the slice behaviors by their peak and range values helps to establish a range of expected values of spinal stiffness during experimental loading. Integrating the intersection points into the trajectory design affords an opportunity to determine a range of potential stiffness measures of the spine at a specific location in its physiologic space and consequently, to parameterize the expected stiffness behavior of the spine depending on the applied loading behavior. This information can be incorporated into spine finite element models to produce more accurate predictions.

The interpretation of this data is in and of itself, a part of the objective of this study. Mapping the changes in stiffness of the spine across its physiologic spaces enables improved visualization of healthy and injurious spinal behavior. This in turn, informs more nuanced diagnosis, assessment of treatment modalities, and differentiation between movement patterns which may otherwise not be visible in uniplanar testing. Future work will explore the spine's response in various surgical states to inform treatment predictions for patients based on pre-surgical and desired post-surgical biomechanics of the spine.

INTRODUCTION

When measuring knee joint kinematics to assess the effects surgical/pathological conditions have on knee biomechanics, coordinate systems (CS) must be assigned to the tibia and femur. Typically, this step is executed by selecting anatomical landmarks on the knee and using standard definitions for defining Anatomical CS based on landmark locations [1]. Variability in landmark selection can result in varying CS definitions and subsequent representation or interpretation of kinematic responses [2,3].

A previous work [4] utilized a generalized framework incorporating a Linear-Least-Square optimization to redefine the tibia and femur origins, the femur flexion (FE) axis, and the tibia internal rotation (IR) axis based on low-resistance motion profiles. The authors found this approach for establishing Functional CS to significantly reduce CS variability and resulting off-axis translations and rotations during passive motion [4].

In this study, we aimed to quantify the effects landmark selection variability can have on reported kinematic response during loaded states. We hypothesize that regardless of anatomical landmark selection, compared to Anatomical CS, the use of Functional CS will reduce kinematic cross-talk (coupling of DOFs where loads in one direction generate motion in a different direction), which will reduce the variation in kinematic response throughout various loading conditions and flexion angles. Ultimately, use of Functional CS will result in more similar kinematic responses between knee specimens than what has been observed historically, enabling higher fidelity 6 DOF kinematic characterization of knee populations within studies and across different laboratories.

METHODS

Seven (7) fresh-frozen, cadaveric leg specimens were utilized in this study. Specimens were tested using a simVITRO® Universal Musculoskeletal Simulator (Cleveland Clinic, Cleveland, OH) and a 6-axis force/torque sensor (Omega160, ATI, Apex, NC). Each specimen was mounted to the robot and positioned in full extension. A single observer digitized anatomical landmarks to establish Anatomical local CS. Spatial relationships between the specimen, robot, and force/torque sensor were established. Kinematics were calculated based on spatial relationships and robot positions. Kinetics were calculated at the joint coordinate system based on spatial relationships, kinematic measurements, and force/torque sensor measurements. Functional CS were obtained by optimizing the Anatomical CS using the passive motion methodology outlined previously [4].

Quasistatic laxity loading was performed across Anatomical and Functional CS sets at 45° flexion with 20 N compression and all remaining loads minimized, unless specified (Table 1). Kinematic cross-talk was evaluated by performing a paired t-test comparing off-axis range of motion during Anterior-Posterior (AP), Varus-Valgus (VV) and Internal-External Rotation (IRER) laxity loading between Anatomical and Functional CS.

Table 1: Laxity Loading Profiles

Loading Profile	Anterior Force (N)	Valgus Torque (Nm)	IR Torque (Nm)
Anterior	100	0	0
Posterior	-100	0	0
Valgus	0	5	0
Varus	0	-5	0
IR	0	0	5
ER	0	0	-5

A dynamic ISO gait profile (ISO 14243-3) was executed across Anatomical and Functional CS sets with loads scaled to 25% over a 120 second duration. Kinematic response was resampled to 100 data points and the standard deviation of kinematic response was calculated for each data point across Anatomical and Functional CS. Inter-Knee

kinematic variation was evaluated by performing a paired t-test comparing the standard deviation between Anatomical and Functional CS throughout the ISO gait profile.

RESULTS

During laxity loading, significant reductions in off-axis translations and rotations (i.e. kinematic cross-talk) were observed for Functional CS compared to Anatomical. During AP laxity tests, superior, valgus, and IR motion were significantly reduced by 1.38 ± 0.91 mm (P=0.007), 1.04 ± 1.05° (P=0.039), and 12.41 ± 10.99° (P=0.024), respectively (Figure 1a). During IRER laxity tests, medial, posterior, and valgus motion were significantly reduced by 12.48 ± 4.23 mm (P<0.001), 4.59 ± 4.81 mm (P=0.045), and 3.12 ± 2.11° (P=0.008), respectively (Figure 1b). During VV laxity tests, medial, superior, and IR motion were significantly reduced by 3.43 ± 2.97 mm (P=0.022), 0.90 ± 0.65 mm (P=0.011), and 7.40 ± 7.48° (P=0.040), respectively (Figure 1c).

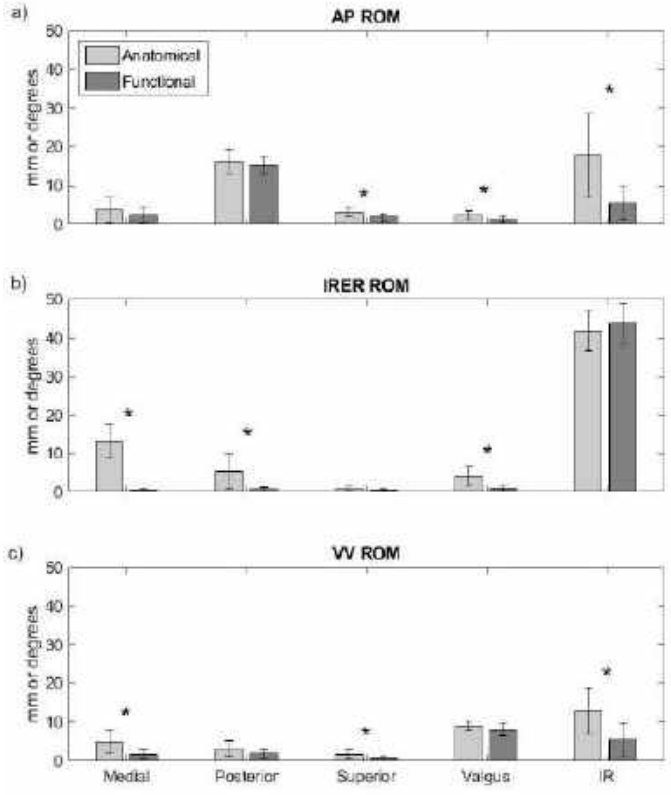

Figure 1: Off-Axis Range of Motion during Laxity Style Loading, *Significance determined for p-value < 0.05

The average and standard deviation of the kinematic responses (and extension torque response) over the 100 resampled points in the ISO Gait profile were calculated using Anatomical and Functional CS. Figure 2 displays the results with the average values represented as lines, and the shaded regions as standard deviation ranges. Significant overall reductions in the standard deviation range were observed using Functional CS compared to Anatomical for each DOF throughout the ISO Gait profile. Average reductions were 0.94 ± 0.67 mm (P<0.001) in medial translation, 0.84 ± 1.07 mm (P<0.001) in posterior translation, 1.94 ± 1.50 mm (P<0.001) in superior translation, 1.14 ± 0.98 Nm (P<0.001) in extension torque, 1.15 ± 1.05° (P<0.001) in valgus rotation and 0.78 ± 1.20° (P<0.001) in internal rotation.

DISCUSSION

Joint kinematics are a common outcome measurement from *in vitro* studies where *in situ* loads are controlled and applied to a joint. It is important that these measurements are objective and minimally influenced by observer decisions, like anatomical landmark selection. If the measurements are objective, then testing the same specimen should generate similar output data, regardless of the operator. Data in Figure 2 compares the kinematic response of the *same* seven knee specimens undergoing the *same* loading profile, with the only difference being how CS systems are defined, which is an experimental setup variable. This data demonstrates that with Anatomical CS, variation in kinematic response throughout a common loading profile is significantly greater compared to Functional CS. Large kinematic variation observed with Anatomical CS makes it difficult to characterize the kinematic response of a population of knees undergoing a complex loading profile. However, kinematic responses with Functional CS yield trending motion paths common to all included specimens.

The reduction in kinematic response variation with Functional CS is, in part, attributed to the significant reduction in kinematic cross-talk compared to Anatomical CS (Figure 1). Functional CS are designed to minimize kinematic cross-talk by optimizing the axes of the joint to be better aligned with the joint's natural passive motion path. If kinematic cross-talk is successfully reduced, then the joint's motion should predominantly be in the direction loads are applied and reduced in all other DOFs (i.e. an applied IR torque would produce an IR rotation with minimal motion in other DOF), which is demonstrated for Functional CS in Figure 1.

In this study, we have demonstrated that using Functional CS significantly reduces kinematic response variation across multiple loading conditions and flexion angles. For this reason, we recommend that Functional CS be used in *in vitro* knee testing.

IMPACT OF ELASTIN FRAGMENTATION ON THE MECHANICAL DISSECTION PROPERTIES OF THE HUMAN DESCENDING THORACIC AORTA

Ramin Shahbad (1), Majid Jadidi (1), Sayed Ahmadreza Razian (1), Anastasia Desyatova (1)

(1) Department of Biomechanics, University of Nebraska Omaha, Omaha, Nebraska, USA

INTRODUCTION

Aortic dissection is a severe and life-threatening condition that involves delamination of the aortic wall layers and primarily occurs in the thoracic segment of the aorta [1]. Aging, aortic aneurysm and atherosclerosis induce significant arterial remodeling, weakening the aortic wall and elevating the risk of dissection up to three-fold when exposed to pulsatile pressure during the cardiac cycle[2]. Understanding the interplay between the wall's structure and mechanical strength is crucial for comprehending dissection onset and progression.

While numerous studies have explored the delamination strength of the arterial wall to unravel the link between heightened aortic dissection risk and structural irregularities [3], quantitative analyses of the impact of elastin fragmentation on the mechanisms underlying aortic dissection in the human population of sufficient age range remain insufficiently understood. Furthermore, current research has not thoroughly addressed the influence of aging on aortic dissections. Therefore, through peeling tests and microstructural analysis, this study aims to address these gaps by investigating how aging and elastin fragmentation contribute to the underlying damage behavior in the context of aortic dissections.

METHODS

Specimen Preparation. Human aorta samples from 35 tissue donors aged 13-76 (average age 38 ±15 years, 31% female) were acquired after the consent of the next of kin. Tubular segments from the descending thoracic aorta were excised and cut lengthwise into flat rectangular sheets. Multiple samples were obtained from each sheet, both longitudinally and circumferentially. An initial incision in the medial layer was created with a scalpel.

Peeling Test Procedure. Peeling tests were conducted utilizing the CellScale biaxial testing device. The two tongues of the sample were securely mounted on custom-designed 3D-printed clamps, which moved in opposite directions while maintaining the sample's center in a fixed position. Aorta samples were fully immersed in a 0.9% phosphate-buffered saline solution at a controlled temperature of 37±1°C throughout the testing process. The peeling force, representing the force required to delaminate the two tongues along the longer side of the sample, was recorded continuously. As shown in Figure 1, the delamination strength of the aorta's media was characterized as Force/Width (F/W), computed by dividing the average force recorded during the stable plateau phase of the force-displacement curve by the sample width.

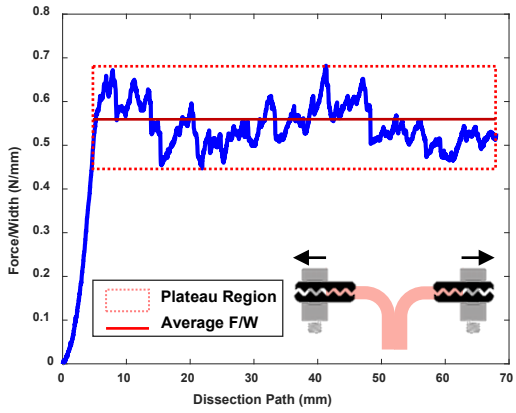

Figure 1. A schematic illustration of the peeling test procedure and the changes in force/width with dissection growth.

Structural Analysis. Structural analysis was conducted using bidirectional histology on the same aorta samples utilized for the peeling tests immediately following the mechanical testing phase. Aorta samples were subjected to Verhoeff-Van Gieson (VVG), which stained the elastin fibers black. A semi-automated, custom-built software was

developed in Visual Studio C# utilizing the .Net 4.6.2 framework, which enabled us to select distinct layers of the arterial wall and perform RGB thresholding to quantify elastin density within each arterial layer individually.

RESULTS

Changes in dissection properties and structural characteristics with aging are presented in Figure 2. As individuals age, delamination strength exhibited a statistically significant decline in both directions (r=-0.7 for longitudinal, r=-0.629 for circumferential, p<0.001). Delamination strength was higher in the longitudinal direction (49.95±17.66 N/mm) than in the circumferential direction (35.13±9.51 N/mm), p < 0.001. The rate of strength decline was more pronounced in the longitudinal direction (-7.744 N/mm per decade) than in the circumferential direction (-3.898 N/mm per decade).

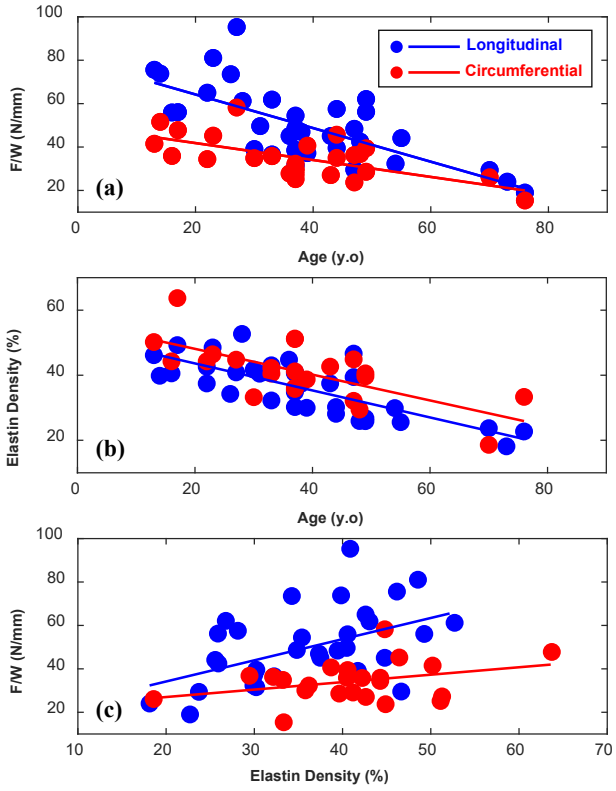

Figure 2. Changes in dissection properties and structural characteristic of descending thoracic aorta with aging.

Quantitative measurements indicated a significant reduction in the density of the media's elastin with aging in both directions (r=-0.762 for axial, r=-0.681 for circumferential, both p<0.001). The elastin density was shown to be significantly higher in the circumferential direction (41.09±9.00) compared to the axial direction (36.54±8.07), p=0.009. Figure 3 demonstrates a comparison of histological images of the aorta's media between young and elderly individuals, illustrating that older arteries tend to exhibit more degraded and fragmented elastin fibers.

Our results demonstrate that samples with higher elastin density exhibit better delamination resistance. The correlation between the strength and elastin density is statistically significant in the longitudinal direction (r=0.487 and p=0.003). However, this correlation is not statistically significant in the circumferential direction (r=0.340 and p=0.112).

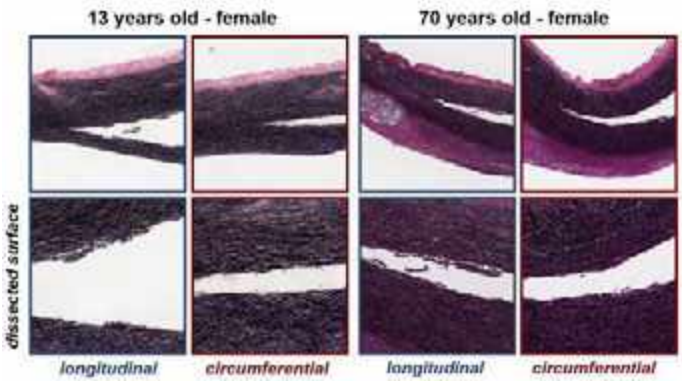

Figure 3. Longitudinal and circumferential VVG-stained images of the descending thoracic aorta in 16-year-old and 76-year-old subjects, highlighting elastin (black) content differences.

DISCUSSION

Quantitative analysis and histology observations revealed an elevated breakdown and fragmentation of interlaminar fibers attributed to aging. The pronounced loss of the framework-like structure is particularly notable in components such as elastin struts, which function as critical connections between laminae within the arterial wall. This breakdown disrupts architectural integrity between laminae, leading to weakened connective fibers and lower resistance to microstructural layer delamination. This explanation bolsters our current findings and aligns with previous research [4], further substantiating the heightened susceptibility of elderly patients to aortic dissection.

The aorta's delamination strength significantly differs when the tear propagates longitudinally versus circumferentially, which is consistent with prior studies indicating strength anisotropies in arterial tissues [5]. This observation is supported by smoother dissection surfaces in the circumferential direction seen in the histology images. These differences seem to be linked to the unique orientation and alignment of fibers in these two distinct directions. In the circumferential direction, both collagen fibers and smooth muscle cells (SMCs) tend to align preferentially in the circumferential orientation. Given that interlamellar connections serve as the link between SMCs and the extracellular matrix, they also exhibit a preference for circumferential alignment. This partial tendency of the fibers to align in the circumferential direction facilitates a smoother and more favorable trajectory for crack propagation. In contrast, the fibers responsible for withstanding delamination forces are predominantly radially oriented in the axial direction. These radial fibers can offer superior resistance to peeling compared with the obliquely oriented bonds in the circumferential direction. This observation aligns with computational findings that indicate fewer interlamellar connections are engaged in processes related to circumferential stretching resistance [6].

INTRODUCTION

Cardiovascular diseases such as aneurysms and arteriovenous malformations present significant health challenges, where understanding hemodynamics is key for effective diagnosis and treatment. 4D-Flow MRI (Magnetic Resonance Imaging) [1], a non-invasive imaging technique, providing in-vivo volumetric time-resolved 3D velocity maps plays a crucial role for estimating hemodynamic parameters but faces limitations like low spatio-temporal resolution, velocity aliasing, acquisition noise, and phase offset errors.

Recent advancements in Computational Fluid Dynamics (CFD) simulations, along with data assimilation techniques and deep learning frameworks have aimed to enhance the resolution and accuracy of hemodynamic estimations. Despite these advancements, challenges remain in accurately representing anatomical characteristics and flow parameters, geometry segmentation, image registration, and processing time [2–4].

Addressing the limitations of 4D-Flow MRI data processing, we introduce the Input Parameterized Physics-Informed Neural Network (IP-PINN), tailored for time-resolved phase-contrast MRI. This novel framework merges Convolutional Neural Networks (CNN)-based method's generalizability with PINNs' continuous field representation, effectively tackling challenges such as low spatio-temporal resolution, noise, phase offset errors, and velocity aliasing. The IP-PINN enhances both the velocity maps reconstruction accuracy and processing time, with experimental validations showing significant improvements over current methods.

PROPOSED METHOD

Our study introduces an algorithm to enhance 4D Flow MRI processing, using 3-directional velocity-encoded complex Cartesian images which is selected from the larger domain of 4D Flow MRI velocity-encoded complex Cartesian scans. At its core, the algorithm employs a hybrid neural network that combines CNNs and Multi layer perceptrons (MLPs). It encodes features from input images into a latent vector $\mathbf{C}$ and then generates high-resolution images using MLPs.

As shown in fig. 1, the CNN component processes the input data to extract pivotal features. This encoder encodes essential information from the input images into a latent vector. The MLPs then use this latent vector, along with normalized spatio-temporal coordinates, to produce high-resolution velocity and magnitude images. IP-PINN approximates two continuous functions: $\mathbf{f}$ and $\mathbf{\Phi}$. Function $\mathbf{f}$ maps the 4D spatio-temporal velocity-encoded complex Cartesian data to the normalized velocities, relative pressure, and image magnitude. Meanwhile, $\mathbf{\Phi}$ predicts phase offset errors in three dimensions. These functions are expressed as:

$$\mathbf{f}(\mathcal{U}^\dagger, \mathbf{x}^\dagger, t^\dagger) = \begin{bmatrix} u^\dagger(\mathbf{x}^\dagger, t^\dagger) \\ v^\dagger(\mathbf{x}^\dagger, t^\dagger) \\ w^\dagger(\mathbf{x}^\dagger, t^\dagger) \\ p^\dagger(\mathbf{x}^\dagger, t^\dagger) \\ |M_o(\mathbf{x}^\dagger, t^\dagger)| \end{bmatrix}, \mathbf{\Phi}_B(\mathcal{U}^\dagger, \mathbf{x}^\dagger, t^\dagger) = \begin{bmatrix} \phi_B^x(\mathbf{x}^\dagger, t^\dagger) \\ \phi_B^y(\mathbf{x}^\dagger, t^\dagger) \\ \phi_B^z(\mathbf{x}^\dagger, t^\dagger) \end{bmatrix} \tag{1}$$

Here, $u^\dagger(\cdot)$, $v^\dagger(\cdot)$, $w^\dagger(\cdot)$, $p^\dagger(\cdot)$, and $|M_o(\cdot)|$ are the dimensionless normalized velocities in the x, y and z directions, relative pressure, and magnitude of the image, respectively and $\phi_B^x(\cdot)$, $\phi_B^y(\cdot)$, and $\phi_B^z(\cdot)$ are the predicted composite phase along the the x, y and z directions, respectively. These functions are approximated using the latent vector $\mathbf{C}$, generated by the CNN from processing $\mathcal{U}^\dagger$, the velocity-encoded scans of the region of interest (ROI). This is further combined with normalized spatio-temporal coordinates, processed by the MLPs, to generate the final outputs:

$$\mathbf{f}^* = \mathcal{M}_{\Theta_2}(\mathbf{C}, \mathbf{x}^\dagger, t^\dagger) = \mathcal{M}_{\Theta_2}(\mathcal{G}_{\Theta_1}(\mathcal{U}^\dagger), \mathbf{x}^\dagger, t^\dagger) \tag{2}$$

$$\mathbf{\Phi}^* = \mathcal{M}_{\Theta_3}(\mathbf{C}, \mathbf{x}^\dagger, t^\dagger) = \mathcal{M}_{\Theta_3}(\mathcal{G}_{\Theta_1}(\mathcal{U}^\dagger), \mathbf{x}^\dagger, t^\dagger) \tag{3}$$

Our training methodology employs a composite loss function, comprising of a data fidelity and physics regularization term. Data fidelity is done with respect to the complex Cartesian image data of the three velocity-encoding scans.

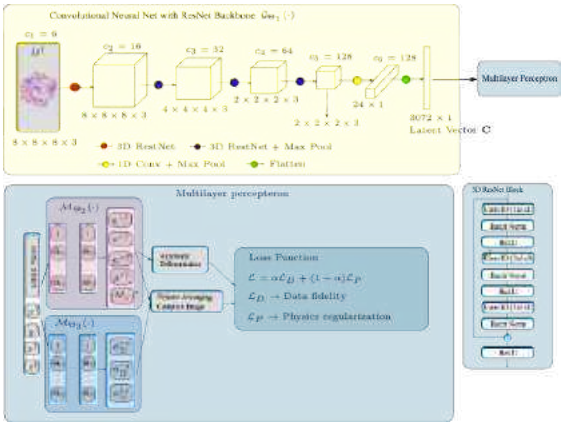

Figure 1: Schematic representation of the proposed IP-PINN architecture.

RESULTS

We tested the IP-PINN algorithm using synthetic 4D-Flow MRI datasets derived from two patient-specific 3D CFD simulations: a posterior cerebral artery (PCA) aneurysm for pre-training and a middle cerebral artery (MCA) aneurysm for testing. Both datasets were downsampled and modified with phase offset errors, using first-order and second-order polynomials for the PCA and MCA simulations, respectively. After pre-training, we fine-tuned IP-PINN for an unseen ROI in the MCA dataset. Figures 2 and 3 show the predicted velocity maps for ROIs at 40 dB and 20 dB noise levels, respectively, for a specific y-direction slice at a given temporal snapshot.

We compared the performance of IP-PINN with a physics-informed neural network (PINN) [3] in terms of accuracy and processing time. By using a pre-trained IP-PINN model on a new dataset, we significantly reduced processing time to 1.5 minutes, compared to 30 minutes with the PINN model. For a fair comparison, both models were trained on the same region of interest. Table 1 summarizes their performance, listing accuracy metrics including root mean squared error (RMSE), coefficient of determination (R^2), and median absolute percentage error for u^*, v^*, and w^*. These results demonstrate the enhanced efficacy of the IP-PINN algorithm over the conventional PINN in terms of both accuracy and processing time.

Our approach uniquely predicts high-resolution velocity and magnitude images from time-resolved phase contrast MRI velocity-encoded images, removing the need for separate MRI reference scans. Figure 4 illustrates this, displaying the luminal boundary in a selected ROI and the corresponding ground truth. It also shows low-resolution MRI magnitude images, generated from overlapping blocks of flow-encoded scan data, demonstrating the IP-PINN model's effective boundary delineation.

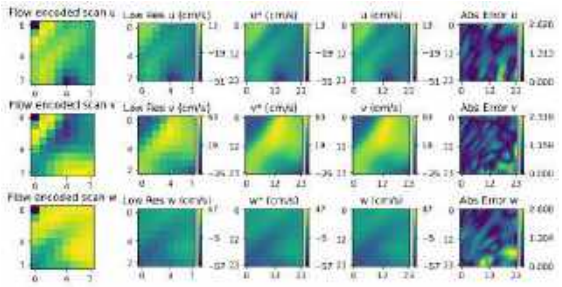

Figure 2: Predicted velocity maps from IP-PINN for a ROI in the MCA aneurysm dataset with a noise level of 40 dB.

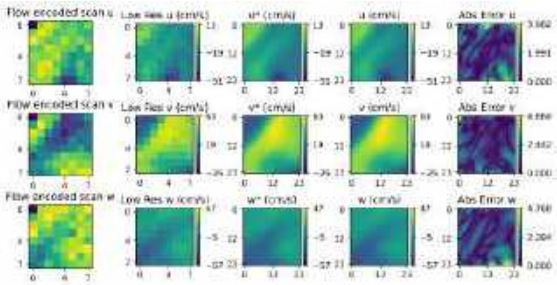

Figure 3: Predicted velocity maps from IP-PINN for a ROI in the MCA aneurysm dataset with a noise level of 20 dB.

Table 1: A comparison of error metrics attained by the PINN models and the proposed IP-PINN model when processing noisy input data.

Method	SNR	RMSE	R^2	MDAPE$_u$	MDAPE$_v$	MDAPE$_w$
IP-PINN	40 dB	1.064	0.997	3.747	1.222	6.522
	20 dB	1.818	0.992	6.178	2.267	8.360
PINN	40 dB	4.508	0.947	12.622	7.604	20.035
	20 dB	5.789	0.913	13.066	8.626	21.144

Figure 4: Luminal boundary prediction.

DISCUSSION

We introduced a novel deep learning method, Input-Parameterized Physics-informed Neural Network (IP-PINN), for enhancing 4D-Flow MRI data, including super-resolution, phase offset corrections, and noise reduction. IP-PINN merges the fast execution and generalizability of traditional image super-resolution frameworks with PINNs' continuous representation capability. It employs a CNN to encode an MRI region of interest into parameters and an MLP for generating high-resolution images. Notably, IP-PINN eliminates the need for ground truth labeling, allows for ongoing training with new data, and significantly reduces processing time – a twentyfold decrease compared to traditional PINNs. This makes IP-PINN a valuable tool for hemodynamic analysis in clinical settings, potentially reducing 4D-Flow MRI scan time by 25% and improving lumen boundary segmentation. While currently validated only on simulated datasets, future work involves in-vitro validation and incorporating actual 4D-Flow MRI acquisition mechanics for further refinement.

INTRODUCTION

Saccular intracranial aneurysms (ICAs), affecting an estimated 4% of the American populace, manifest as protuberances resulting from localized arterial wall attenuation [1]. The primary concern with ICAs revolves around their propensity to rupture (an estimated annual rate of 2.1-7.2% [2]). This rupture often triggers a chain of severe and life-threatening conditions such as subarachnoid hemorrhage (SAH) that bears a daunting 50% fatality rate, with only 6-17% of survivors regaining full cognitive function [3].

Efforts to reduce the risk of aneurysm rupture have driven the development of therapeutic options. While surgical clipping remains effective, advancements have been made in endovascular methods. However, widely used techniques, such as Guglielmi Detachable Coils (GDCs) introduced in 1991, still face limitations including incomplete occlusion rates of ~40% that induces subsequent rebleeding, diminishing its efficacy [4]. Arterial stents, integrated into endovascular therapeutics, pose risks of delayed occlusion post-intervention due to their deployment location [5]. The WEB devices represent a modern alternative addressing limitations of GDCs and stents. However, the challenge lies in inadequate conformity to irregular patient's aneurysm geometries, potentially leading to protrusion complications [6], elevating the risk of rupture by 3-fold compared to regular shapes [2].

Recognizing these limitations, this study aims to address critical shortcomings in current endovascular approaches for treating ICAs. Our focus centers on *three pivotal aspects*: (i) mitigating compaction via anisotropic materials, (ii) enhancing occlusion speed through a dense internal scaffolding network, and (iii) ensuring adaptability to intricate geometries via additive manufacturing technologies.

METHODS

SMP Foam Fabrication: First, sacrificial polyvinyl alcohol (PVA) templates were fabricated via FDM additive manufacturing (Ender 5 printer). Next, polyurethane-based shape memory polymer (SMP) solution comprised of hexamethylene isocyanate (HDI), N,N,N0,N0-tetrakis (hydroxypropyl) ethylenediamine (HPED), and triethanolamine (TEA) in a molar ratio of 1:0.18:0.42, was prepared as previously reported [7]. The PVA templates were coated with the liquidous SMP solution, followed by meticulous removal of excess SMP employing a drying mat. Then, the coated templates underwent a three-stage curing procedure within a vacuum oven: 3 h at 45°C, followed by 1 h at 70°C, and finally, 1 h at 130°C. Dissolution of the foam construct occurred within a circulating water bath, leaving the porous SMP foam.

Scaffold Characterization: PVA templates and SMP foams were acquired, featuring three distinct line distances between rectilinear internal scaffolds (2.0, 1.5, 1.0 mm). Utilizing an ultramicroscope (Keyence VHX-7000), images were captured for PVA templates and SMP foams (n=3 for each of the rectilinear internal scaffolds and analyzed via ImageJ software to quantify the pore size/facet diameter and porosity. Further, the SMP scaffold thickness was assessed using scanning electron microscopy (Quattro S ESEM), followed by quantitative analysis in ImageJ.

Porous Media Quantification & Patient-Specific CFD Analysis: CAD models representing the internal scaffolds were crafted using SolidWorks. These scaffolds were subsequently positioned within a hollow cylinder (10 mm in diameter and 40 mm in length). The evaluation process involved subjecting the three experimental samples, alongside a control, to a spectrum of inlet velocities and measuring the respective outlet pressure drop using CFD analysis in ANSYS Fluent. The inertial and viscous resistances were determined by:

$$\Delta p = C_0 v^2 + C_1 v\,, \frac{1}{\alpha} = \frac{C_1}{\mu \Delta n}, C_2 = \frac{2C_0}{\rho \Delta n} \quad (1)$$

where Δp is the pressure drop for the velocity, v, and C_0/C_1 are the coefficients of the 2nd order polynomial trendline, μ is the dynamic viscosity, $1/\alpha$ is the viscous resistance, Δn is the thickness of the scaffold section, C_2 is the inertial resistance, and ρ is the fluid density.

Next, a personalized 3D model was constructed in Amira software and finite element mesh was generated via Meshmixer (Autodesk).

Boundary conditions were prescribed to mimic standard hemodynamics observed in the middle cerebral artery [8], with fluid properties configured to match established specifications for intracranial blood. Specifically, the aneurysm sac was designated as a porous zone, its properties determined via porous media evaluation. Post-processing was performed in ParaView software for comprehensive analysis.

Thermal and Mechanical Characterizations: Differential scanning calorimetry (DSC) was employed to analyze solid and porous SMP specimens (n=3) for quantifying the glass transition temperature (T_g) of the specimens. In addition, uniaxial compression within a controlled heated chamber (T_g + 20°C) was performed on the SMP samples (n=3) along both the *X*- and *Z*-axes, with a compression rate of 5 mm/min.

Shape Recovery Evaluation: The shape recovery (SR) properties of dry and wet samples were assessed as follows. Briefly, the samples (10x10x 10 mm) were subjected to 80% compressive strain at T_g+20°C. Next, the samples were placed in a -20°C freezer to set in this reprogrammed configuration and the samples were heated to restore their to original shape. For the wet samples, following saturation in a water bath, samples underwent a 15-minute air-drying period before radial compression and determination of volumetric compression limit.

RESULTS

Scaffold Characterization: The deliberate removal of surplus SMP during the fabrication process enhanced the precision in replicating the structures from PVA templates to SMP foams (**Fig. 1a-f**). The consistency in facet pore diameter translation from PVA templates to SMP foams was observed, and a marginal improvement in precision was noted in 1.5 and 1.0 mm infill line distances (ILDs), **Fig. 1g**.

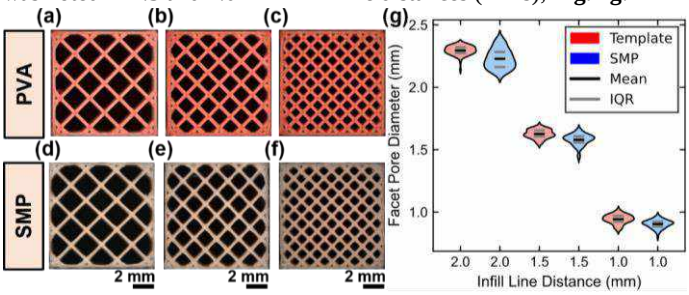

Figure 1: Top view of **(a,b,c)** PVA templates and **(d,e,f)** SMP specimens for 2.0, 1.5, and 1.0 mm infill line distance (ILD), with the corresponding facet pore diameter in **(g)**. Representative scale bars are given at the bottom of each column of images.

Porous Media Quantification & Patient-Specific CFD: Noticeable increases were observed in the porous media as the densities of internal scaffolds increased: 462.8, 724.7, and 1575.0 for the 2.0 mm, 1.5 mm, and 1.0 mm ILDs, respectively. Similarly, the calculated viscous resistances were 9.01×10^6, 1.46×10^7, and 3.22×10^7, respectively. Application of the device yielded noteworthy reductions in both the wall shear stress and the fluid velocities within the aneurysm sac (CFD plots not shown here). These reductions were particularly pronounced in regions distanced farther from the arterial interface (**Fig. 2**), indicating that the impact was more pronounced deeper within the aneurysm sac.

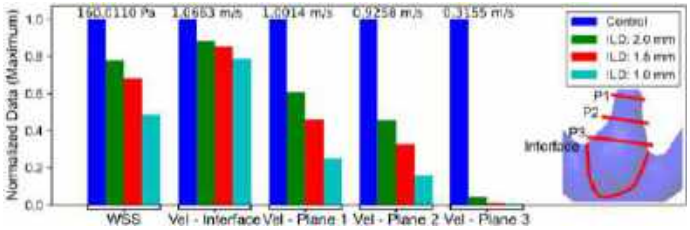

Figure 2: Comparison of the normalized maximum wall shear stress and fluid velocity across surfaces denoted by inscribed image.

Thermal & Mechanical Characterizations: DSC revealed a T_g of 41°C for the porous SMP samples composed of the 1:0.18:0.42 (HDI:HPED:TEA) molar ratio utilized for successively reported tests. In addition, the stress-strain analyses displayed minimal cyclic reduction along the *X*-axis, while the *Z*-axis testing exhibited noticeable effects of cyclic deformation and stress reduction (**Fig. 3a,b**). Uniaxial compression tests unveiled the anisotropic nature of the SMP foams, showcasing up to a 40% increase in maximum stresses for the *Z*-axis compared to the *X*-axis compression evaluations (**Fig. 3c,d**).

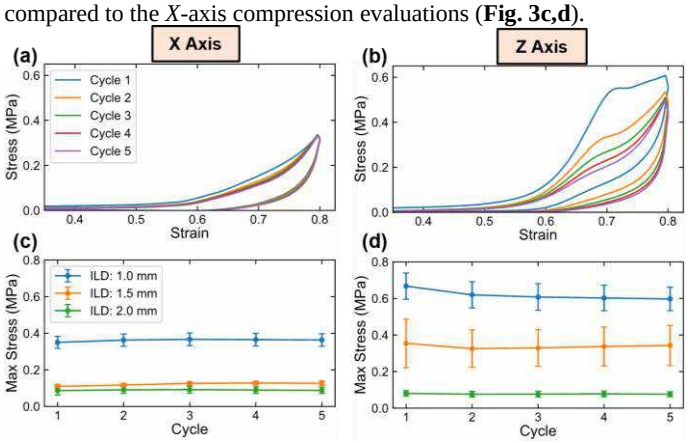

Figure 3: (a,b) Representative stress-strain behaviors of 1.5 mm ILD samples, and **(c,d)** cyclic maximum stress (MPa) for SMP foams under uniaxial compression along the *X*- and *Z*-axes.

Shape Recovery Evaluation: The assessment of shape recovery (SR) under dry conditions demonstrated no substantial variance in SR rate or completeness across the evaluated groups with all groups achieving greater than 95% SR. Under wet conditions, an immediate SR response was observed, accompanied by volumetric compression ratios of 9.61, 7.59, and 5.91 for the three experimental groups, respectively.

DISCUSSION

This study aims to enhance endovascular embolization techniques for ICAs by addressing three key clinical and technological challenges: (i) mitigating compaction tendencies, (ii) improving the occlusion rates, and (iii) optimizing device fitment. Anisotropic mechanical behavior reveals a promising avenue to reduce material displacement within embolized aneurysms, potentially lowering reoccurrence rates. Our CFD findings highlight a localized reduction in blood flow within the aneurysm cavity, suggesting more effective treatment outcomes without impeding essential intracranial/arterial circulation. In addition, the improved precision in replicating patient's 3D geometry is expected to minimize procedural complications. Yet, limitations include porosity constraints for larger aneurysms and a time-intensive fabrication process. Future studies involve refining our 3D printing for larger ICAs, exploring alternative scaffolding patterns, and incorporating carbon nanotubes to enhance conductivity and structural integrity. Collectively, these efforts render a transformative shift in ICA therapeutic paradigms.

INTRODUCTION

Patients with advanced foot and ankle osteoarthritis (OA) experience limited function, severe pain, and reduced quality of life [1,2]. There is no direct cause of foot and ankle OA, however, 75-80% of cases arise secondary to a traumatic event, such as an ankle bone fracture [3]. Isolated subtalar OA (STOA) and isolated tibiotalar OA (TTOA) affect the talocalcaneal and tibiotalar joints, respectively. These joints in the ankle play crucial roles in the movement and biomechanics of the human foot and affect younger populations [1,3,4]. The connection between foot deformities and these two types of OA has not been thoroughly investigated, and a comprehensive understanding could potentially lead to more targeted interventions, enhanced patient care, and informed preventative measures. This gap in knowledge is because foot and ankle OA diagnoses have historically only been used with 2D radiographs. However, with the introduction of three-dimensional weightbearing computed tomography (WBCT), we are now able to capture a complete anatomical view of the foot from a single scan. Morphological analysis can be performed on weightbearing computed tomography (WBCT) data via statistical shape modeling (SSM) to quantify and compare foot shape models between different patient groups [5]. The objective of this study was to create a 19-bone SSM project to investigate the morphology of patients experiencing STOA and TTOA and compare them with healthy control models. We hypothesized that multi-bone SSM would indicate significant and unique morphological differences between the two OA groups and the healthy controls – encompassing significant variation not only within the subtalar and tibiotalar joints, but also in other bones.

METHODS

In this study, WBCT (0.37x0.37x0.37 mm voxel) data from 45 total participants (15 healthy, 15 STOA, 15 TTOA) was acquired with IRB approval. Patients were grouped as STOA or TTOA based on evaluations from a musculoskeletal radiologist and an orthopaedic surgeon. Semi-automatic segmentation software (DISIOR v2, *Bonelogic*) was used to generate preliminary bone segmentations for 19 bones in the ankle: tibia, fibula, talus, calcaneus, navicular, cuboid, cuneiforms (medial, intermediate, lateral), metatarsals, and proximal phalanges. These initial segmentations were verified and revised, if necessary, using Mimics 24.0 (*Materilise*). 3-Matic (*Materialise*) was used to smooth and decimate all segmented bones, then a global plane cut was performed across all patient models based on the shortest tibia and fibula. All 19 bones from each patient were used to create a multidomain SSM project in ShapeWorks 6.4.2 (*SCI Institute*) to determine the mean shape and quantify morphological differences between STOA, TTOA, and healthy patients [5]. Principal Component Analysis (PCA) was utilized to assess the modes of variation from the SSM model, and MATLAB R2023a (*MathWorks Inc.*) parallel analysis determined significant PCA modes. To identify localized regions with notable disparities in both overall morphology and alignment, a Hotelling's T^2 test was employed with a false discovery rate p-value correction. Additionally, PCA scores from each mode were exported from ShapeWorks and compared to another using a t-test or Wilcoxon rank sum test with a Holm-Sidak correction (α=0.05). ShapeWorks 6.4.2 built-in Linear Discriminant Analysis (LDA) was also applied to investigate shape variation between the healthy and OA groups [5].

RESULTS

Figure 1 illustrates the results from Hotelling's T^2 test comparing the healthy, STOA, and TTOA groups. Blue indicates areas that have significantly different morphology and alignment (α=0.05). The two types of OA compared to the healthy controls (top and middle rows) show expected results, where the subtalar or tibiotalar joints are visually different from the healthy group, as areas around those affected joints are blue. Additionally, the p-values suggest that bones distal from the cuneiforms experience less deformity than more proximal bones. The bottom row shows several blue areas in the tibia, fibula, and talus that

indicate variation in morphology and alignment between the two OA groups. Parallel analysis of the PCA scores indicated 7 significant modes of variation among the 3 groups, where 26 total modes accounted for 95% of the overall variation. An ANOVA test of the 3 groups determined two modes that were significantly different (α=0.05) from another: mode 1 of STOA vs. Healthy and mode 1 of TTOA vs. Healthy. PCA mode results are shown in Figure 2 for the first three significant modes comparing all three groups. Mode 1 distributions indicate that STOA appears to align more closely with minus two standard deviation results, and TTOA similarly with plus two standard deviations. Mode 1 contains 30.8% variation and presents cuneiform movement in the radial direction, tibia/fibula movement from posterior to anterior, and subtalar joint movement in the anterior direction. Additionally, this mode appears to represent variants in the specific foot type, ranging from planus to cavus (while standing). Mode 2 accounts for 17.8% of the cumulative variance and demonstrates apparent twisting of the lamina pedis in the direction opposite of the subtalar joint rotation. Lastly, the third mode (10.6% explained variance) represents midfoot bending in the sagittal plane, which alters the subtalar, calcaneal, and talonavicular orientations.

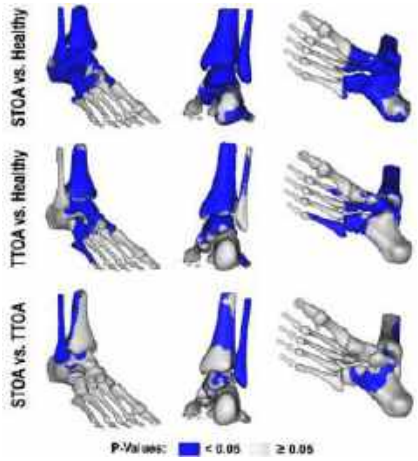

Figure 1: Dorsolateral, posterior, and ventrolateral views of the mean foot shape obtained from SSM. The data illustrates Hotelling's T^2 test with false discovery rate correction that compares the STOA group with the healthy group (Row 1), the TTOA group with the healthy group (Row 2), and the STOA group with the TTOA group (Row 3). Blue indicates significantly different areas with p-values less than α=0.05. Grey areas show non-significant differences in morphology and alignment.

DISCUSSION

The 19-bone SSM model indicated significant differences between the morphology and alignment of patients with STOA, TTOA, and the healthy control group. This type of model is the first three-dimensional 19-bone model that investigates different presentations of hindfoot OA based on patient WBCT data. Information from this type of modeling will have a great impact on clinical diagnoses and treatment planning for patients experiencing hindfoot OA. As mentioned, the SSM model identified 7 significant PCA modes of variation out of the 26. These modes, capturing substantial variability, provide valuable insights into the distinct patterns and trends of joint deformity and structural changes associated with STOA and TTOA. Specifically, information in Figure 2 may be useful for physicians to identify associated deformities such as planus/cavus in Mode 1 (30.7% variance) or anticipate potential restoration of the lamina pedis in cases of midfoot twisting opposing the direction of the subtalar joint rotation seen in Mode 2 (17.8% variance). The persistence of specific foot types (planus/cavus) in patients over time raises questions about the attainability of a neutral position through surgical intervention in affected joints. Addressing solely the affected joint may limit the overall improvement of the foot, as the entire foot structure is not being considered. An isolated focus on realigning a single joint disregards the potential impact of its prolonged diseased state of

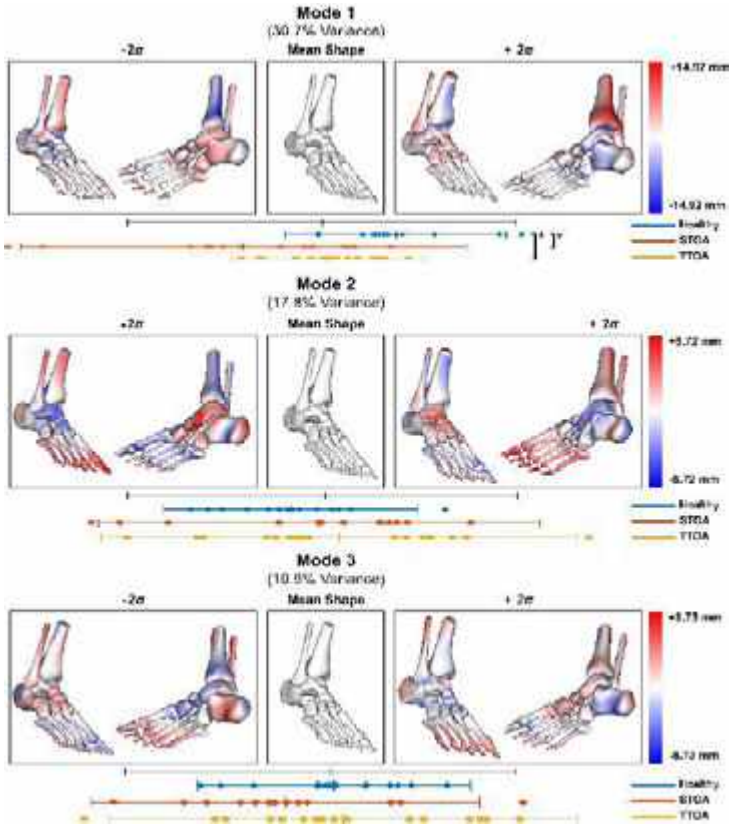

Figure 2: PCA mode analysis across all three subgroups: Healthy, STOA, and TTOA. The top row indicates changes through mode 1 and includes two statistically significant differences in morphology and alignment between the healthy group and both types of OA. The middle and bottom rows show modes 2 and 3, respectively. The left and right columns represent two different views of two standard deviations below and above the mean shape. Blue regions are smaller than the mean, and red regions are larger.

the surrounding structures, potentially triggering further changes in the foot. Understanding these adaptations through three-dimensional modeling highlights the importance of holistic foot joint treatments to attain the most favorable clinical results for patients with hindfoot OA. This work serves as a valuable guide for identifying necessary foot adjustments that are essential for the restoration of normal foot alignment and treatment of pain associated with OA.

Ultimately, the comprehensive understanding gained from SSM and WBCT enables surgeons to make well-informed decisions about full-foot treatment options. The potential impact of this work is vast, offering orthopaedic physicians and surgeons advanced knowledge about different presentations of OA in the foot and ankle. Armed with this depth of understanding, clinicians can formulate patient-specific treatment plans and treat OA in the foot and ankle before the deformities become too severe for intervention.

SURFACTANT DEPLETED RAT LUNGS: A GLOBAL TO LOCAL STUDY OF THE IMPACT OF POSITIVE VERSUS NEGATIVE PRESSURE VENTILATION

INTRODUCTION

Lung diseases can necessitate mechanical ventilation and are often linked to insufficient surfactant levels, resulting in greater surface tension and therefore, increased work of breathing [1]. Ultimately, surfactant loss can lead to atelectasis (partial lung collapse), which increases the risk and severity of ventilator induced lung injury (VILI) due to excessive distension of the remaining aerated lung regions [2]. Prior work utilizing magnetic resonance imaging (MRI) confirms surfactant depletion results in increasing lung distension and finds that improved alveolar recruitment reduces this local overdistension [3]. Furthermore, recent work reports mechanical differences between lungs subjected to negative pressure ventilation (NPV) and positive pressure ventilation (PPV), where NPV results in decreased hysteresis (work of breathing), suggesting that NPV may provide more homogeneous alveolar recruitment [4]. However, past surfactant studies have been limited by the extended imaging acquisition times, where the highly viscoelastic nature of the lung is greatly affected by such time lapses; and the overinflation and heterogeneity due to surfactant depletion has yet to be characterized over the continuous breathing cycle to understand the role of PPV and NPV in surfactant depleted lungs.

To address these knowledge gaps, this current study analyzes the mechanics of surfactant-depleted lungs under both NPV and PPV using a custom-designed apparatus in conjunction with high spatiotemporal digital image correlation (DIC) techniques to facilitate simultaneously linked global inflation behavior and local surface strain patterns characterization [4,5]. We hypothesize NPV results in decreased hysteresis, strains, and heterogeneity compared to PPV in surfactant depleted lungs, indicative of more homogenously recruited alveoli.

METHODS

Eight male Sprague-Dawley rats, weighing 250-320g, were anesthetized and sacrificed, where the lungs were excised and cannulated according to approved IACUC protocol (KUALI #132). Four lungs were established as the control group, while the remaining four underwent a warm internal saline wash via the trachea (37°C, 30mL/kg) three times to remove the native surfactant according to prior methods [2,3]. Subsequently, lungs were prepared for DIC measurements and speckled, as established previously [5]. The lungs were placed in an airtight chamber and attached to our previously validated custom-designed dual piston electro-mechanical ventilation system adapted for rat lungs to acquire the global pressure and volume measurements [4].

To establish a common volume history before the test inflation cycle, lungs were subjected to a driving pressure of 20 cmH_2O with stepwise increments of 3 cmH_2O positive-end expiratory pressure for 30 s each up to 15 cmH_2O, performed at 60 BPM, as used in similar rat studies [3]. Tests applied 6mL of air either by direct inflation via the trachea (PPV) or by removing air from the tank (NPV), where the resulting change in lung volume was matched within 10%. Sequential PPV/NPV tests were applied at 10BPM, enabling quasi-static tissue assessments and DIC measurements, and where the sequence has been demonstrated to not impact the lung response [6,7].

Pressure-volume curves and DIC major strain contour maps were generated (Figure 1-i and 1-ii), where the reduced Jacobian confirmed similar DIC surface areas analyzed across all specimens [4]. Hysteresis was measured as the area between the loading and unloading curve of the pressure-volume cycle (Figure 2-i) [6]. Distributions of the major strain across each lung specimen were analyzed as an average kernel density plot with standard deviation, where the strain distribution peaks represent an increase in the surface fraction exhibiting the measured tissue strains. (Figure 2-ii) [8]. The average major strain and 75th percentile major strain values were calculated (Figure 2-iii and iv).

Statistical analysis between groups was compared using a paired and unpaired t-test, for PPV versus NPV and control versus surfactant

depleted groups respectively, with normality verified via the Shapiro-Wilk test and a significance threshold of $p<0.05$ [9].

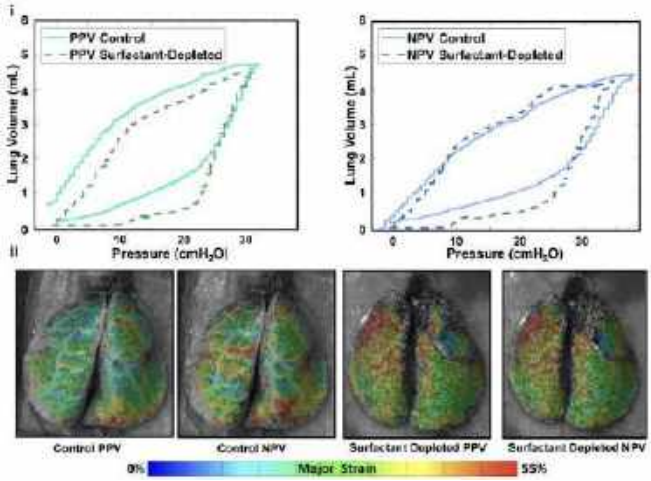

Figure 1: Representative (i) pressure-volume hysteresis curves, and (ii) DIC contour maps of major strain over the pleural surface for contrasted PPV/NPV control/surfactant groups.

RESULTS

Pressure-volume curves exhibited varying hysteresis between groups (Figure 1-i). DIC qualitatively saw an increase in control NPV strains compared to PPV, and similar strain contours for PPV and NPV surfactant depleted groups, where blue indicates 0% strain and red as high as 55% strain (Figure 1-ii). Surfactant depleted groups tended to result in increased hysteresis compared to control PPV and NPV (significant for NPV, Figure 2-i), where NPV trended lower than PPV group counterparts. The relative local strain behavior of PPV to NPV appears to alternate depending on control or surfactant depleted groups: for the control groups, NPV tended to show an increase in strain distribution peak compared to PPV (Figure 2-ii). Contrarily, for the surfactant depleted groups, NPV shifted towards decreased strains compared to the PPV counterpart (Figure 2-ii). The average strain and 75th percentile strain trended higher for the surfactant depleted group compared to the control group, (significant for PPV, Figures 2-iii, 2-iv).

DISCUSSION

In this study, we observe that surfactant depletion leads to increased hysteresis and increased lung surface strains, indicating greater work of breathing and localized overdistension, respectively, confirming prior studies [3-5,10]. Hysteresis is associated with the collapse/re-opening of alveolar groups and with surfactant molecules, where surfactant depletion increases surface tension, thus explaining our findings of greater hysteresis with surfactant depletion; further, the reduced hysteresis in NPV suggests NPV recruitment of alveolar groups may occur more homogeneously than PPV; however, exact mechanisms are unknown currently and warrant further study [4,10].

Although prior work with MRI utilizes longer image acquisition times, and thus cannot capture the mechanics before viscoelastic effects set in, they find increasing distension from surfactant loss [3]. Our study, conducted with high-speed and high-resolution imaging, allows us to substantiate these claims of surfactant loss resulting in increased distension, indicated here by increased regional strains [5]. In the surfactant depletion group, NPV results in notably (albeit insignificantly) lower surface strains compared to PPV, these lower strains may indicate NPV to be a useful method for decreasing overdistension to improve aeration and recruitment in surfactant depleted lungs [3]. Further, we find NPV strains to vary insignificantly

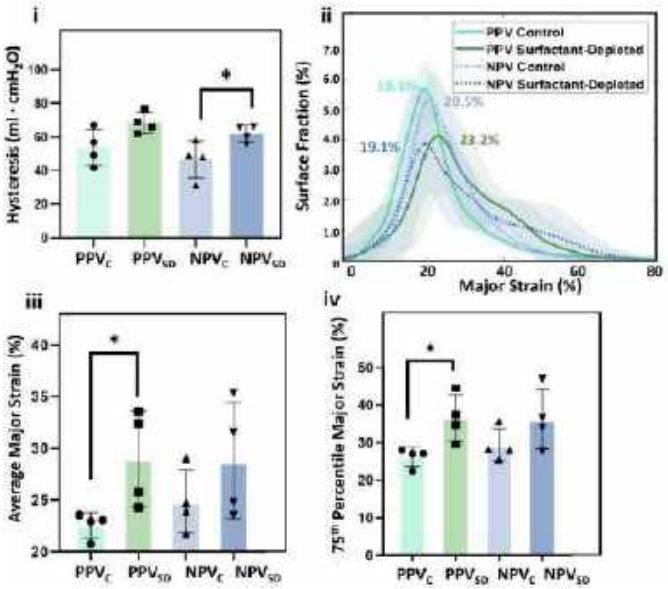

Figure 2: (i) Reported values and significance for hysteresis, (C, control; SD, surfactant depletion). (ii) Kernel density plot demonstrated major strain distribution over the pleural surface. (iii, iv) Reported values and significance for the average and 75th percentile major strain values.

between its surfactant depletion and control groups, in contrast to significant differences in PPV; this is an intriguing implication given ventilators utilize PPV and the compromised surfactant may cause greater overdistension in comparison to NPV. Notably, the non-significant average strain increase between the control NPV compared to PPV contradicts previous findings for pig lungs [4]; this may be attributable to differences in species (e.g., collateral ventilation effects observed in mice rodents but not pigs [11]).

While this study provides evidence of the local effect of surfactant depletion and the impact of NPV, quantified analysis throughout the inflation and deflation cycle will enable improved insights regarding the differences between PPV and NPV. Furthermore, this study was performed ex-vivo, and therefore without the presence of the chest cavity; however, recent studies have suggested surface strains to represent internal strains [12]. Despite these limitations, this study is the first of its kind to evaluate the adverse effect of severe lung disease and injury in the form of surfactant depletion on localized PPV/NPV tissue strains in order to help better probe the mechanics in recruiting damaged lungs and understanding VILI.

INTRODUCTION

Elastin-based elastic fibers are the second most abundant fibrous structural material in tendons after collagen fibrils [1], yet their role in dynamic tendon mechanics is poorly understood [1]. Elastin is known to provide fatigue resistance and recoil properties in soft tissues [1], such as seen in the aorta, and may also reduce strains during tendon repair [2]. We hypothesize that elastin may limit damage accumulation and rupture in tendons, especially in the energy-storing Achilles tendon (AT). Studies have shown significant contributions of the dense mesh-like interfascicular elastin matrix to tendon mechanics, as elastase treatment of the interfascicular matrix drastically reduces fatigue life [3]. The mechanical contribution of axially-aligned elastin within fascicles is less understood; however, uni-fascicular mouse tendons are well suited to addressing their role.

Ramp-to-failure testing of functionally distinct tendons from elastin knockdown (*Prx1Cre*$^{+}$*/Eln*$^{fl/fl}$) mice revealed a trending increase in linear modulus in ATs with elastin knockdown, but a decrease in positional tibialis anterior tendon (TBAT) linear modulus values [4]. Tendon-specific mechanical results agreed with dynamic structural changes measured with quantitative polarized light imaging (QPLI). Thus, elastin's role may change with tendon function, perhaps providing a gradual fiber-recruitment function in wild type (WT) ATs which have a lower linear modulus, and a more direct structural function in TBATs where elastin increases the linear modulus instead.

Building upon previous results, the present study sought to determine the role of fascicular elastic fibers in fatigue mechanics of tendon. We hypothesized that elastin knockdown would reduce the fatigue life of tendons, especially in ATs compared to TBATs. We further expected to observe altered peak strain through the three phases of fatigue: (1) initial steep phase, (2) linear region with constant rate of peak strain increase, and (3) exponential strain increase before rupture. Finally, elastin deficient tendons were expected to show more damage accumulation (collagen denaturation and fiber kinking) during testing.

METHODS

Mechanical Testing: ATs and TBATs (n=55/tendon type; WT and *Prx1Cre*$^{+}$*/Eln*$^{fl/fl}$; ~split male/female) were harvested at 20 weeks and stored in PBS-soaked gauze at -20° C until ready for testing. Thawed samples were clamped and stretched until just taut, at which point gauge length and cross-sectional area were measured. Samples were preloaded to 0.1 N then cyclically loaded at 1 Hz to a percentage of previously determined average ultimate stress for each tendon type. ATs were tested between 0.68 and 34 MPa (1-50%), while TBATs were tested between 2.4 and 81 MPa (1-35%). Stress levels were selected to avoid slippage and optimize test duration. While testing, QPLI videos were acquired to determine ROI average degree of linear polarization (i.e., strength of collagen alignment) and standard deviation of the angle of polarization (i.e., spread of collagen distribution).

Data Analysis: Custom MATLAB code was used to analyze and synchronize mechanical and QPLI data. Six points of interest were determined from the three-phase strain-time plot (Fig. 1): (1) first cycle, (2) beginning of linear region (second phase), (3) middle of linear region, (4) end of linear region, (5) transition point in third phase (based on global optimized fitting of peak strains throughout test), and (6) last cycle before failure. QPLI data was analyzed at twelve frames: one for each peak and trough of the six points of interest.

Multiphoton Imaging: Tendons were flash frozen after mechanical testing failure and stored at -20° C. Samples were stained with Alexa Fluor 633 hydrazide and blocked with bovine serum

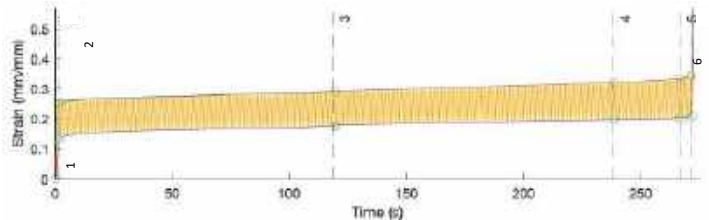

Figure 1: Fatigue curve and calculated points of interest.

albumin and 0.05% Triton-X in 0.1X PBS for two hours, then optically cleared using the SeeDB protocol [5]. Longitudinal image stacks ~150-µm-deep were acquired on an inverted multiphoton microscope with acquisition of SHG/fluorescence for collagen/elastin, respectively. Images were acquired near the break site and mid-substance of the larger fragments post-rupture. Collagen fiber kinking was visualized with a 10x1-µm-deep median Z-projection. Elastic fiber integrity was qualitatively evaluated near break sites and tendon midsubstance.

Statistical Analysis: All statistical outcomes were determined with linear mixed models (JMP, SAS Institute), where genotype, sex, genotype*sex, and a random variable based on mouse of origin were used as model inputs. A standardized effect size parameter, Cohen's *d* [6], was calculated for each parameter, where values of 0.2, 0.5, and 0.8 indicate mild, moderate, and strong effects, respectively. For mechanical testing, exclusion criteria were determined before analysis: any test lasting less than 10 cycles or more than 8000 was excluded. Remaining samples were analyzed in Prism using a ROUT outlier test with Q = 1%. After exclusion, 21 ATs per genotype, 12 *Prx1Cre*$^{+}$*/Eln*$^{fl/fl}$ TBATs and 20 WT TBATs were included (evenly-pooled sex).

RESULTS

Mechanical testing results (Fig.2) show that hysteresis (green) is increased in both *Prx1Cre*$^{+}$*/Eln*$^{fl/fl}$ tendon types early in the fatigue test (roughly time points 1-3), though this difference disappeared by the end of the test. Also, though not significant, the effect sizes for various time points in the test including cycles to failure were substantial (gray), and effect sizes show the range of possibility for the true mean of these effects being mostly negative. The main genotype-specific difference between ATs and TBATs was that only ATs had increased peak and trough strain accumulation (blue) and a decreased dynamic modulus

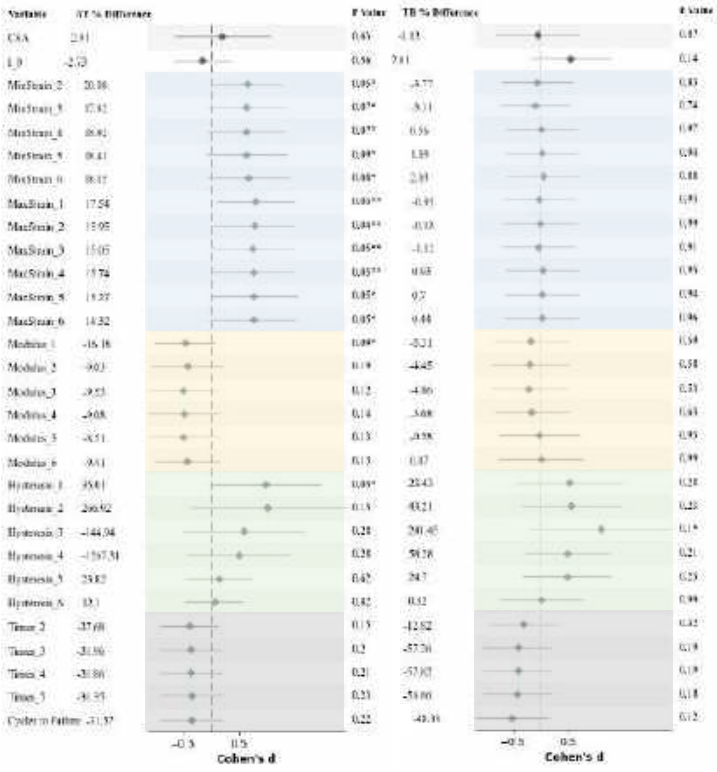

Figure 2: Fatigue mechanical data for ATs (left) and TBATs (right) including percent differences of *Prx1Cre*$^{+}$*/Eln*$^{fl/fl}$ from WT values, *p* values, and Cohen's *d* standardized effect size with 95% CI. Numbers indicate interest points on the fatigue curve.

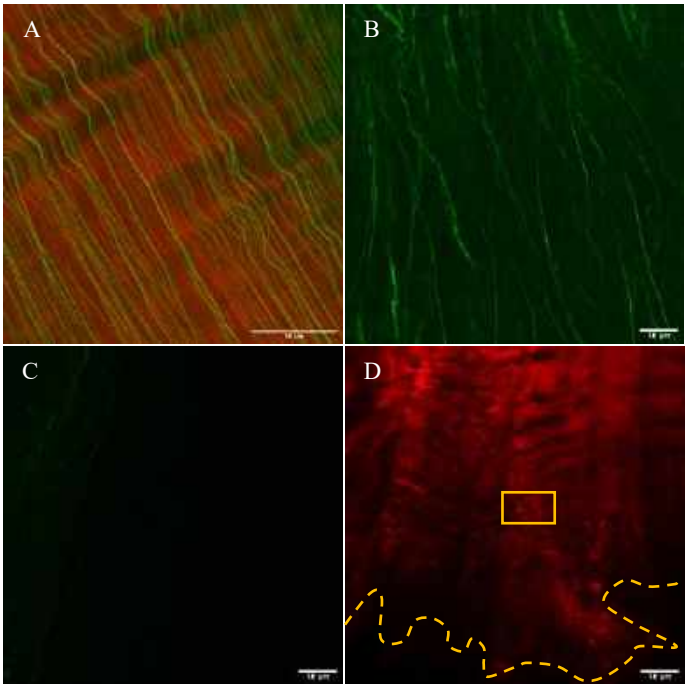

Figure 3: Two photon images of ATs. A: Composite (collagen in red and elastin in green) image of undamaged sample. B: Elastic fibers in damaged WT sample. C: Lack of elastic fibers in damaged Prx1Cre^{+}/Eln$^{fl/fl}$ sample. D: Collagen kinking (rectangle) in WT near fatigue rupture site (dotted line).

(yellow) with elastin knockdown (note this dynamic modulus is different from the linear modulus, it conventionally assumes linearity).

Multiphoton images show uniformly aligned elastic fibers in undamaged WT ATs (Fig.3A) versus frayed, mildly kinked, and less organized fibers after tendon rupture (Fig.3B). There were no visible fibers in *Prx1Cre*$^{+}$*/Eln*$^{fl/fl}$ tendons (Fig.3C). The collagen matrix near the break site was markedly crimped, which seemed to increase in frequency nearer the break site (Fig.3D).

DISCUSSION

Elastic fiber knockdown has significant effects on tendon fatigue dynamics, especially in ATs where increased peak and trough strain values were measured at all time points, potentially pointing to elastin sustained elastic recoil in healthy tendon loading. Though our hypothesis that elastin increases fatigue life was not confirmed by reported p values, Cohen's *d* and confidence intervals for the timing of all points of interest (including cycles to failure) show a possible mild effect of elastin on the timing of the fatigue curve in both tendon types. Multiphoton images unveiled, perhaps for the first time, the morphology of a fascicular elastic fiber networks near a fatigue-induced break site. These fibers are less organized, show mild kinking behavior, and expose branching sites not previously observed. Further quantitative analysis will evaluate elastin and collagen fiber networks farther away from the break site, CHP-based damage assays of collagen denaturation, and analysis of sex dependent. Future work will evaluate pre-failure to determine whether elastin alters damage accumulation kinetics.

INTRODUCTION

Reconstructing 3D organ geometric models from magnetic resonance imaging (MRI) is essential in numerous fields, such as patient-specific solid biomechanical numerical simulations [1], computer-aided diagnosis, treatment and prognosis, and virtual surgical planning. Using high-quality 3D geometric models precisely depicts organ spatial architecture, crucial for finite element analysis. Typically, conventional methods involve either manual or automatic segmentation of 2D MRI slices, followed by several post-processing steps such as reconstructing 3D geometric models, repairing complex geometries, and manually partitioning meshes [2]. The shapes of many organs are complex and diverse, often requiring a significant amount of effort to create high-quality 3D geometric models. The reconstruction process is complicated, tedious, and time-consuming, taking several hours or even days. Furthermore, the consistency of reconstruction results varies with different technicians, limiting its practicality for large-scale analysis.

As an alternative to traditional reconstruction methods, deep learning approaches exhibit great potential in reconstructing 3D geometric models, demonstrating fast execution time and desirable geometric quality. These techniques are categorized into implicit and explicit methods. Implicit methods achieve indirect reconstruction of 3D models by predicting the implicit surface using the signed distance function (SDF) [3], but still necessitate laborious post-processing steps like iso-surface extraction and mesh correction. Explicit methods, which include direct shape prediction and deformable shape modeling, tackle various challenges. The first approach, dependent on loss functions for quality control [4], struggles with training and is limited to simpler geometries. The second, focusing on template geometry deformation to fit the target [5], solves some of these difficulties. However, it presents challenges in designing adaptable templates for different organs and ensuring uniform application across diverse organ reconstructions.

In this work, our aim was to develop a unique hybrid framework for deformable shape modeling. This framework integrates deep learning with iterative optimization to streamline the reconstruction of high-quality 3D organ models from 3D MRI, enabling a flexible tradeoff between reconstruction time and model quality.

METHODS

Figure 1 illustrates our framework's architecture, showcasing inputs and outputs. For instance, 3D MRIs are processed to predict the organ model. Initially, the MRIs undergo segmentation, either manually or automatically. The resulting segmentations are converted into point clouds, which represent the organ boundaries. These points are then normalized within a -1 to 1 range. The deep learning module then processes these point clouds, predicting displacements for spherical template deformation. These displacements serve as initial inputs for the

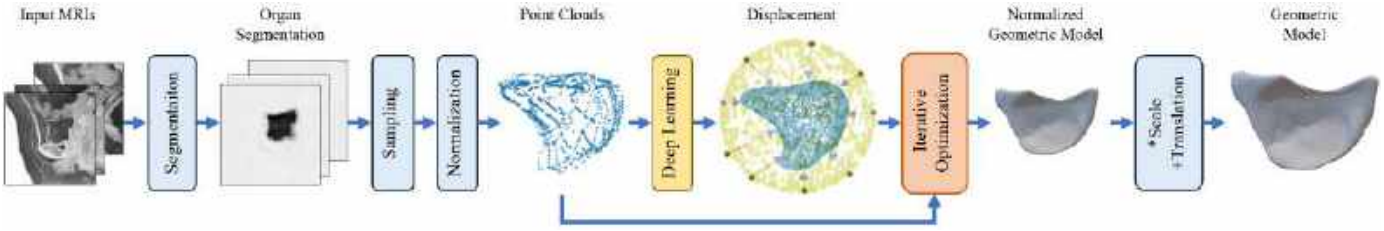

Figure 1: Our framework's architecture

iterative optimization module, refining the organ models. Finally, the resulting model is scaled and positioned by reversing normalization process to form the final 3D organ geometric model.

Input: $Pointcloud_{train}, Mesh_{sphere}$
$Displacement_{train} = 0\ (Zero\ Matrix)$
for $iter = 1 \rightarrow T$ **do**
  $Mesh_{train} = Mesh_{sphere} + Displacement_{train}$
  $Displacement'_{train} = \underset{Displacement_{train}}{\operatorname{argmin}} [Loss_{CD}(Pointcloud_{train}, Mesh_{train}) + Loss_{ENL}(Mesh_{train})]$
end for
$\theta_{train} = \theta_0$
repeat
  $Displacement_{train} = NN_{\theta_{train}}(Pointcloud_{train}, Mesh_{sphere})$
  $\theta'_{train} = \underset{\theta_{train}}{\operatorname{argmin}} [\mathbb{E}_{training\_set}[Loss_{MSE}(Displacement'_{train}, Displacement_{train})]]$
until converged
Output: θ'_{train}

Algorithm 2: Inference

Input: $Pointcloud_{infer}, Mesh_{sphere}, \theta'_{train}$
$\theta_{infer} = \theta'_{train}$
$Displacement_{infer} = NN_{\theta_{infer}}(Pointcloud_{infer}, Mesh_{sphere})$
for $iter = 1 \rightarrow T$ **do**
  $Mesh_{infer} = Mesh_{sphere} + Displacement_{infer}$
  $Displacement'_{infer} = \underset{Displacement_{infer}}{\operatorname{argmin}} [Loss_{CD}(Pointcloud_{infer}, Mesh_{infer}) + Loss_{ENL}(Mesh_{infer})]$
end for
$Mesh_{infer} = Mesh_{sphere} + Displacement'_{infer}$
Output: $Mesh_{infer}$

NN represents the deep learning network. The symbol θ denotes the network's parameters. The minimum value of the variable post-iteration is identified with an asterisk (*). $\mathbb{E}_{training\_set}[]$ signifies the expected outcome of the enclosed expression within the training set.

Figure 2: The algorithm of the training and inference pipeline.

Figure 2 depicts the algorithm of the deep learning and the iterative optimization modules for both training and inference. In training, the iterative optimization module searches for optimal displacement, aiming to minimize the Chamfer Distance (CD) between deformed geometry and input point clouds, augmented with loss function ENL (Edge Loss, Normal Loss, and Laplacian Loss [1]) for geometric model quality. These optimal values are the ground-truth for deep learning training. During inference, the trained deep learning model predicts displacement, initializing the optimization module's further refinement, resulting in the final organ geometric model.

Figure 3 shows the deep learning module's structure. Initially, EdgeConv [6] extracts features from the input point clouds and spherical template individually. These features are combined using a multi-head cross-attention module, followed by spatial feature transformation through EdgeConv. An alternating structure of convolutional neural network (CNN) and self-attention modules is then used for encoding and decoding. Ultimately, EdgeConv is used to perform spatial transformation on the output features, yielding the final displacement values.

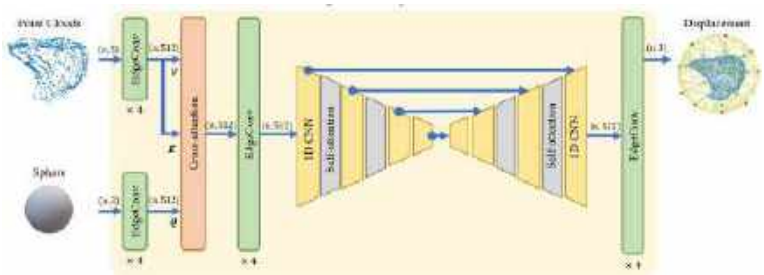

Figure 3: The structure of the deep learning module.

We utilized the Mean Squared Error (MSE) loss function for predicting deep learning displacement. Both CD and Hausdorff Distance (HD) are used as the evaluation metrics.

For training, we adopted the Adam optimizer with a learning rate $1e^{-4}$ and a batch size of 1 across all experiments. The network was implemented using Python 3.8.8, and Pytorch 1.12.0, and executed on an Nvidia Titan RTX graphic card with 24GB of computational memory.

We constructed a 3D MRI dataset of 100 subjects from Peking University People's Hospital. Specifically, the T2 3D sagittal MR data of each subject at rest were used. The MR images had a 2 mm spacing and slice thickness. The dataset was randomly divided into training, validation, and testing sets at a 6:2:2 ratio by subject. During training, we ran 10,000 iterations to ensure optimal reconstruction for each organ. To prove the effectiveness of our approach, we compared it with three other advanced 3D organ reconstruction deep learning methods, including Voxel2mesh [5], MR-net [1], and MeshDeform-Net [7]. To address the significant size discrepancies among individuals and their organs, we adopted a normalized geometric model for quantitative assessments.

RESULTS

Table 1: 3D reconstruction performance on the testing set.

Methods	Bladder		Uterus		Rectum		Levator	
	CD(mm)	HD(mm)	CD(mm)	HD(mm)	CD(mm)	HD(mm)	CD(mm)	HD(mm)
Voxel2mesh	0.0574	0.7469	0.0887	0.8462	0.0356	0.6227	0.0281	0.5936
MR-net	0.0535	0.7609	0.0875	0.8580	0.0383	0.6052	0.0226	0.5869
MeshDeformNet	0.0467	**0.6647**	0.0732	0.8949	0.0348	0.7189	0.0235	0.5364
Ours	**0.0399**	0.7005	**0.0705**	**0.8287**	**0.0263**	**0.5210**	**0.0190**	**0.5036**

The testing results of the 3D reconstruction, along with comparative analysis, are summarized in Table 1, where smaller metrics indicate better results. Additionally, Figure 4 displays the 3D reconstruction and runtime results for four organs (bladder, uterus, rectum, and levator) of a subject from the testing set. These results suggest that our 3D reconstruction closely matches the ground-truth, and the iterative optimization module improves reconstruction quality without the lengthy runtime typical of traditional methods.

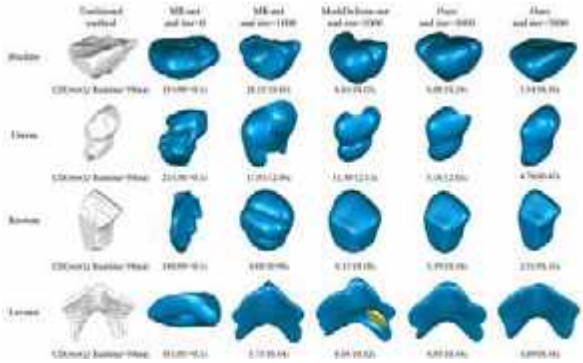

Figure 4: A visual comparison of 3D reconstruction results. The yellow area in the result signifies the bad self-intersection issue.

DISCUSSION

This study introduces a unique hybrid framework for deformable shape modeling, combining deep learning with an iterative optimization module to streamline the reconstruction of high-quality 3D organ models from 3D MRI. The experimental results demonstrate that our framework effectively balances reconstruction speed and quality, proving versatile for various complex organs. Looking ahead, expanding the training dataset is anticipated to further enhance the reconstruction process.

INTRODUCTION

The cellular and extracellular mechanisms underlying tendon disease are not well understood thereby limiting the development of effective therapies.[1,2] The *status quo* as it pertains to *in vitro* tendon biology are monolayer 2D tissue culture plastic or 3D systems with fixed geometry that typically do not provide quantitative biomechanical measures, are relatively large constructs resulting in diffusion gradients, and are incompatible with high-throughput/content microscopy.[3–6] Micro-physiological systems (MPS) have emerged as an invaluable tool for disease modeling and for understanding cell-extracellular matrix (ECM) interactions, which is currently challenging *in vivo*.[7] In this study, we established a tendon-specific MPS to monitor tissue contractility and compared the gene expression of tendon fibroblasts (TFs) in an engineered 3D tendon tissue micro-gauge (tenTμG) to native mouse Achilles and tail tendons.

METHODS

The tenTμG platform was generated by casting polydimethylsiloxane (PDMS) from 3D stereolithography printed resin molds (Phrozen Sonic Mini 8k).[8] Tissue dimensions were 2 mm long x 0.2 mm width tethered between 1 mm long cantilevers with tapered heads (Fig1A). We maintained an aspect ratio of 1:10 for tendon constructs, mimicking the aspect ratio of human Achilles tendon while reducing diffusion gradient issues that arise in larger 3D culture systems.[9] Tail TFs were isolated from N=12 2-month-old C57BL6/J wildtype mice (n=6 male, n=6 female; 2 animals/device). From the same animals, Achilles tendons (AT) and additional tail tendons (TT) were flash frozen for tissue-level RNA isolation. To isolate TFs, tail tendon was embedded in collagen-I hydrogel (PureCol®-S, Millipore) for 10 days. TFs were passaged once to collagen-I-coated tissue culture plastic before being embedded with collagen-I (FibriCol, Advanced BioMatrix) in the tenTμG device. Each device contained 21 micro-gauges (two cylindrical silicone pillars spaced 2-mm apart) in individual wells (Fig1A).

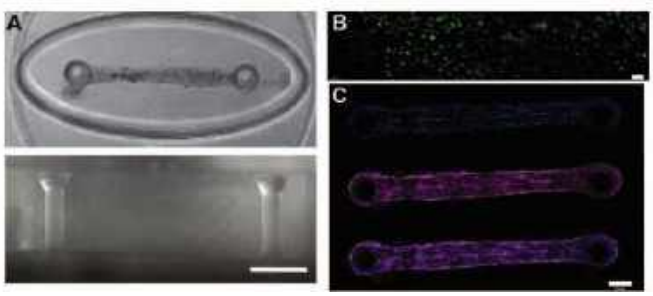

Figure 1: Mouse TFs embedded in tenTμG devices can be maintained for at least 4 weeks. (A) Visualization of the tenTμG molds from top and side. Pillars are 2mm apart (scale bar = 0.5mm). (B) Cell Viability (Live, calcein in green; Dead, ethidium-1 in red) staining shows high cell survival in constructs after 7 days in culture (scale bar = 0.8mm). (C) Nuclear (blue) and phalloidin (purple) staining showed dense, aligned constructs after 4 weeks in culture; scale bar = 0.2mm.

Each tenTμG tissue was formed from 4μL of 2.5mg/mL collagen-I mixed with 1.5 million TFs/mL and cultured in Advanced DMEM/F12 containing 4% FBS, 1% pen/strep. The number of intact gauges, tissue length (distance between the center of the two pillars), and tissue width were assessed on 0-, 1-, 3-, 7- and 10-days using 10x phase contrast imaging (LionHeart, Agilent). Pillar displacement was converted to contractile force using Hooke's law and the pillar's bending stiffness (0.6037 μN/μm, FEBio model simulation; data not shown). Statistical comparisons of tissue survival, force, and width were performed using Prism (GraphPad v10; 2-way ANOVA for time/device). RNA was

isolated from TFs after 10 days in culture or from flash-frozen tissues (AT and TT) for cDNA synthesis for SYBR-based quantitative PCR (qPCR). Expression of matrix-associated genes (*Col1a1, Col1a2, Col3a1, Tnc, Tnmd)* and progenitor markers (*Scx, Mkx)* were quantified from flash frozen tissues and cultured mouse tail TFs and data were normalized to AT from the same animals (Pfaffl-based; $2^{-\Delta\Delta Cq}$; reference = *Rplp0* and *Polr2a*). Statistical comparisons of ΔCqs were made using Prism (GraphPad v10; two-way ANOVA for sex/tissue). Additional devices were treated with either 10ng/mL hTGFβ2 or 0.1% bovine serum albumin (BSA) control at time of seeding (supplemented media was refreshed every 48h) and imaged at 1-, 3-, 7- and 9-days. Treated tenTμGs were imaged on day 9 using brightfield and quantitative polarized light imaging (qPLI, ThorLabs, Inc) on an epifluorescent microscope (Leica).

RESULTS

TFs survived in tenTμG constructs after 1-week in culture (Fig1B). A preliminary study with TFs isolated from 6-month-old female mice (n=2) demonstrated long-term survival (4-week) of TFs in tenTμGs (Fig1C). Over a 10-day period in vitro, tissue tension increased, and tissue width decreased (Fig2A'). The majority of tenTμGs were intact after 1-day in culture and remained intact through the 10-day experiment (Fig2). However, with TGFβ2 treatment, tissue tension increased rapidly and more than half of the tenTμGs failed by 7-days (Fig2B). Prior to failure, collagen alignment increased in TGFβ2-treated tissues as compared to BSA-treated controls (Fig2C).

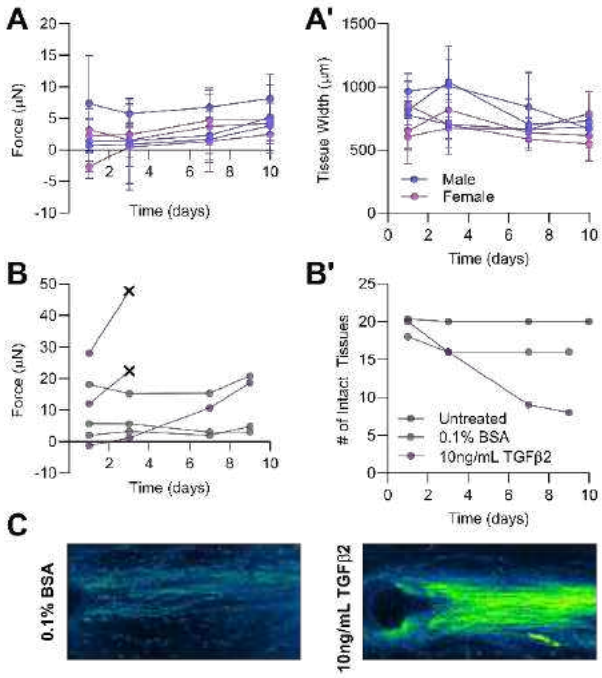

Figure 2: TFs cultured in collagen on tenTμGs devices exhibit mechanical and structural changes including (A) increased tissue force (decreased distance between pillars) and (A') increased compaction (i.e., decreased tissue width) over time in culture. (B) Treatment of tenTμG constructs with TGFβ2 leads to increased contractility and (B') premature construct failure after 3 days in culture compared to untreated or BSA-treated tenTμGs. (C) Collagen organization of remaining intact tenTμGs was increased with TGFβ2 treatment compared to BSA only after 10 days in culture.

In 3D tenTμGs and 2D culture, *Scx* was downregulated compared to native tissues, and *Tnc* was upregulated in 3D tenTμGs compared to 2D culture and native tissue (Fig 3). Additionally, *Col1a1* and *Col3a1* (Fig 3) were upregulated in 3D culture compared to 2D culture and AT (for *Col3a1* only).

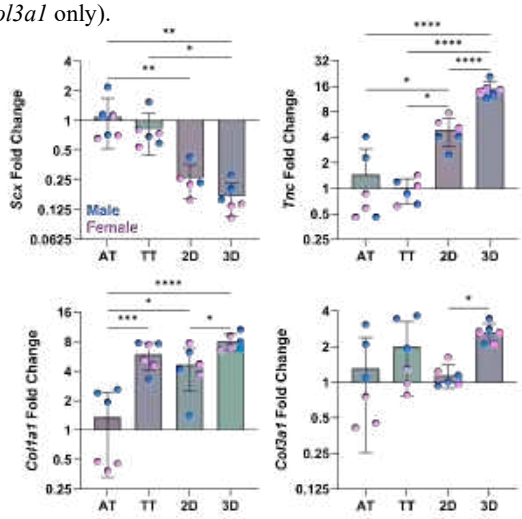

Figure 3: TFs elicit environment-dependent transcriptional responses. Gene expression of native tissues (AT and TT) compared to primary TFs isolated from TT in 2D and 3D tenTμGs culture after 7 days. * p<0.05; **p<0.01; ***p<0.001; ****p<0.0001 (of ΔCq for gene expression). Individual dots represent biological replicates of male (blue) and female (pink) mice.

DISCUSSION

Our findings support the utility of MPS fabrication for developing an *in vitro* platform for measuring TF contractility *in vitro* in 3D. We successfully demonstrated the ability to generate and maintain TF viability and contractility with increased expression of matrix-associated genes in 3D conditions. Previously, TGFβ2 has been shown to enhance tenogenesis (e.g., increase *Scx* expression) in mesenchymal and embryonic stem cells.[4] In agreement, when TGFβ2 was added to tenTμGs, we observed increased contractility and more organized collagen. Although several constructs were lost due to the increased contractility, our pillar geometry can be re-designed to withstand larger contractile forces to prevent failure. Surprisingly, expression of tenogenic transcription factors (e.g., *Scx*) *in vitro* in our tenTμGs did not mimic that of native (adult) tendon. Future studies will compare the expression of genes in developing (e.g., neonatal) tendon. Additionally, this tunable tenTμG platform will allow us examine if and how cellular contractility and pillar stiffness influences nascent matrix deposition. This platform will allow us to investigate mechanisms by which tendon extracellular matrix can be reorganized or regenerated in 3D, as well as test druggable targets that have potential to promote matrix deposition mimicking that of native tendon.

COMPUTATIONAL ANALYSIS OF STROKE RISK DURING CARDIOPULMONARY BYPASS IN ADULT AND PEDIATRIC ANATOMIES

Nafis M. Arefin (1), Bryan C. Good (1)

(1) Department of Mechanical, Aerospace, and Biomedical Engineering, University of Tennessee Knoxville, TN, USA

INTRODUCTION

Neurological complexities resulting from surgery requiring cardiopulmonary bypass (CPB) remain a major concern, encompassing a spectrum of complications including thromboembolic stroke [1]. Surgical manipulation during CPB is considered the primary cause of these neurological complications [2]. This study addresses the overall lack of knowledge concerning CPB hemodynamics within the aorta, employing a combined experimental and computational modeling approach, featuring CFD simulations validated with a realistic *in vitro* CPB circuit [3]. Parametric studies were systematically performed, varying critical CPB parameters including patient-specific aorta anatomy, pump flow rate, hemodiluted blood viscosity, and emboli size and density. This study represents the first comprehensive investigation of the individual and combined effects of these factors on the risk of embolic stroke associated with CPB.

METHODS

For the *in vitro* study, an experimental mock circulatory flow loop (MCFL) (**Fig. 1**) was used to observe emboli distribution through the aorta with varying hemodiluted blood viscosities [3]. This experimental dataset was then used to successfully validate computational simulations of emboli transport in the same patient-specific aorta model of a 26-year-old healthy male [3]. Building upon that work, the study was expanded to investigate the role of emboli density, pump flow rate, and aortic anatomy, specifically focusing on a 7-month-old pediatric patient (acquired from the Vascular Model Repository [4]). Utilizing the Lagrangian particle transport capability of *OpenFOAM*, we observed emboli distribution through the aortic arch branches (**Fig. 3**), replicating the experimental study.

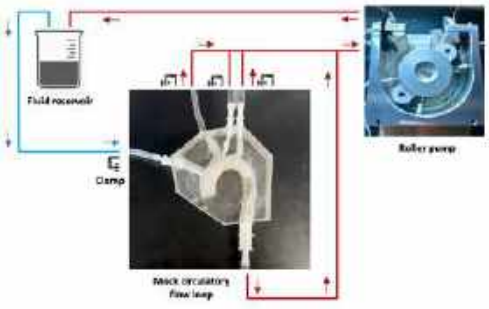

Figure 1: CPB mock flow loop for *in vitro* embolus tracking [3].

Hemodilution: Incorporating hemodilution during CPB is known to improve peripheral perfusion, increase blood flow to tissues, and facilitate venous return [5]. In the CFD simulations, three distinct fluids with viscosities of 1.5, 2.5, and 3.5 cP were used, aligning with the viscosities employed in our *in vitro* study [3].

Pump Flow Rate: Optimal CPB pump flow rate can be determined by calculating the product of an individual's body surface area (BSA) and a constant of 2.2-2.4 [6]. BSA can also be approximated using the Du Bois formula [7]: $BSA[m^2] = Weight\ [kg] \times height\ (cm) \times 0.007184$

This equation was used to estimate BSA, and subsequent pump flow rate and cannula size, for each patient case. For the adult patient, flow rates of 3 LPM and 5 LPM, representing patients with lower BSA and those with higher BSA, respectively, were employed. For the pediatric patient, a pump flow rate of 0.75 LPM was used [7].

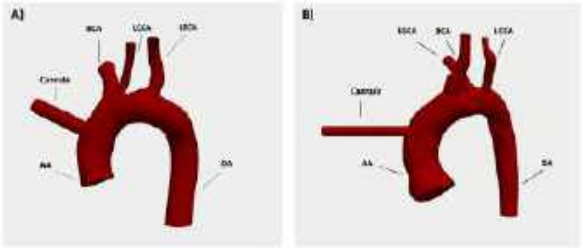

Figure 2: CAD models of patient-specific aorta anatomies: A) 26-year-old male and B) 7-month-old female.

Emboli Size: Prior research established that smaller-sized emboli travel proportionally to the flow, prompting us to exclude micro-emboli from our study. Additionally, it has been found that aortic emboli can range in diameter from 0.3-2.9 mm [8]. Therefore, we chose to employ two emboli sizes in this study: 2.4 mm (1/16 in) and 1.6 mm (3/32 in).

Emboli Density: Simulations were performed using emboli of three different densities: one to match the density of the hemodiluted blood in which they were suspended, one to match the density of whole blood (1092 kg/m³), and one to match the emboli from the *in vitro* study (1134 kg/m³).

RESULTS

In **Fig. 3**, emboli transport is shown over time as the injected particles flow in through the CPB pump cannula and are distributed to one of the aortic outlets. The particles were tracked until they exited through one of the aortic outlets. In phase (i), the injection of the emboli into the aorta model is observed. The particles begin exiting through the outlets of the model in phase (ii) until nearly all have been transported out of the fluid domain by phase (iv).

In **Fig. 4**, the % of emboli exiting through the aortic branches during CPB is shown for two different pump flow rates in the adult aorta model. For all hemodiluted blood viscosities, a marked increase in emboli exit was observed through the aortic branches at the higher 5 LPM flow rate. An increase in emboli transport was also observed, ranging from 12% to 42%, during the transition from 3 to 5 LPM pump flow rate for different blood viscosities.

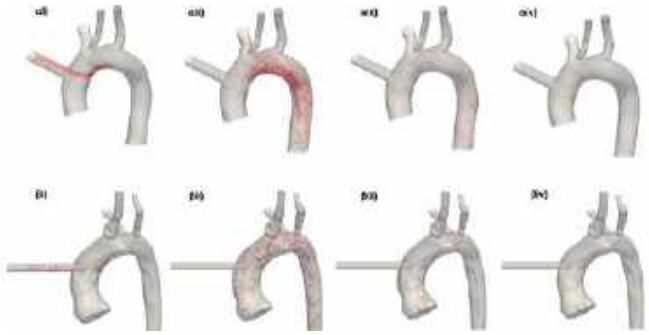

Figure 3: Visualization of emboli trajectories over time in computational simulations in the aortic arch adult (α) and pediatric (β) anatomies.

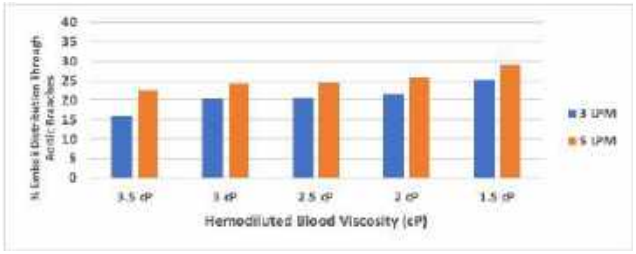

Figure 4: Emboli transport into the aortic branches of the adult anatomy at varying CPB pump flow rates.

Figs. 5 and **6** illustrate the relationship between emboli density and hemodiluted blood viscosity in terms of the % of emboli that exited through the aortic branches for the adult and pediatric anatomies, respectively. It was observed that, across all cases, a higher proportion of emboli exited through the aortic branches as their density decreased. This observation indicates that emboli density plays an important role in their transport in the aorta. Reduced emboli density leads to a notable increase in emboli exiting through the aortic branches, subsequently directing them toward the cerebral vasculature.

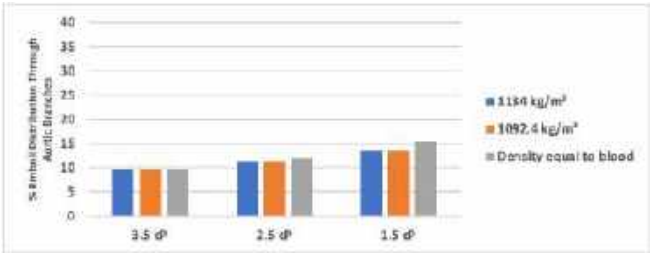

Figure 5: Emboli transport into the aortic branches of the adult anatomy with varying emboli densities.

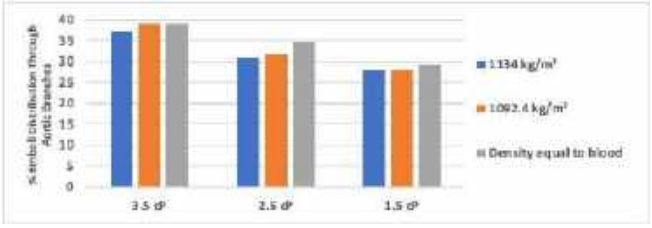

Figure 6: Emboli transport into the aortic branches of the pediatric anatomy with varying emboli densities.

However, with varying blood viscosity, the two aortic models exhibited opposite trends. For the adult case (**Fig. 5**), an inverse relationship was observed, with increased emboli distribution through the aortic branches with decreasing blood viscosity. Conversely, the pediatric case (**Fig. 6**) demonstrated the opposite tendency.

Figure 7 displays the % of large (2.4 mm) and small (1.6 mm) emboli exiting through the aortic branches. It illustrates that, for both patient anatomies, larger emboli exit through the aortic branches at higher rates. Also, the % increase between emboli sizes is similar for both adult (27%) and pediatric (28%) cases.

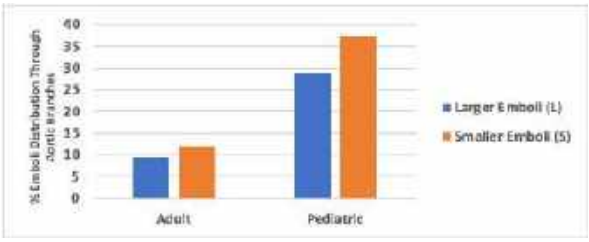

Figure 7: Influence of embolus size on their aortic transport.

DISCUSSION

This study provides critical insights into the interplay of different CPB parameters, employing validated CFD models [3] to compare emboli transport in the human aorta. Further CFD simulations showed that smaller emboli generated during CPB have a higher tendency to exit through the aortic branches compared to larger emboli (**Fig. 7**). Also, irrespective of their size, emboli with lower density have a greater tendency to exit through the aortic branches (**Fig. 6**). Additionally, it was observed that a greater number of emboli exit through the aortic branches at higher pump flow rates. Consequently, emboli tend to follow the fluid streamlines and exit through the descending aorta at lower pump flow rates (**Fig. 4**). This behavior could be attributed to the turbulent nature of the flow exiting the cannula at high pump flow rates, causing emboli to deviate from the streamlines and preferentially exit through the aortic branches. These findings highlight the critical role that high pump flow rate, small emboli size, and lower emboli density play on emboli distribution in the aorta.

The present study has certain limitations, and our future work will involve simulating emboli transport in patient-specific aortas for two additional age groups (adolescent and geriatric). Further, we plan to vary the cannula orientation to comprehensively understand its influence on emboli transport. Through these additional studies, we aim to arrive at a more robust conclusion regarding the reasons behind higher rates of emboli transport to the cerebral vasculature. Additionally, emboli were modeled as rigid spheres. In reality, emboli exhibit irregular shapes, and their viscoelastic mechanical properties may prove critical when simulating larger-sized emboli and their interactions with the vessel walls. Furthermore, the CFD simulations did not account for the pulsatile blood flow, assuming constant CPB pump flow with a cross-clamped ascending aorta.

The computational approach and findings hold significant implications for understanding stroke biomechanics and treatment planning during CPB. This study can make meaningful contributions to the field by reducing the risk of stroke and complications associated with CPB, enhancing the overall safety of cardiovascular surgery.

INTRODUCTION

Skin plays an important role in how we perceive and interface with our environment. Our skin is constantly in mechanical contact with our environment, yet when skin interacts with surfaces or medical devices for long periods of time the contacting skin may break down and develop blisters, ulcers and other lesions. One such group that suffers with persistent skin breakdown is lower limb amputees. Prosthetics have proven to be a very successful medical device, providing users with improved mobility, a factor which is essential for independence and social inclusion, so preventing skin breakdown is critical.

Research into skin injury mechanics has shown that when normal loading is combined with shear, skin breakdown is more severe [1], a common loading scenario in a prosthetic socket. We know that this relationship is site specific, for example the foot can withstand 50 times more loading than skin on the sacrum [2] and foot skin responds positively to mechanical load by forming a thicker stratum corneum [3].

However, it is not well understood what adaptations occur in amputee skin and if they are beneficial to resist mechanical load, despite a clinical belief that the skin of the residuum can be trained to be load bearing [4]. It has not been well explored how the stratum corneum architecture of lower limb amputees is altered compared to the intact contralateral limb and if skin health is altered through inflammatory response to repeated mechanical loading. Previous research has found lower transcutaneous oxygen tension and reduced skin barrier function [5].

Here we address this gap in knowledge by characterizing at multiple scales, the mechanics, microstructure and Raman spectra of amputee and contralateral limb skin. We aim to bridge understanding on how the skin on the residuum adapts to a new role of load bearing skin. We aim to discover how skin barrier composition, cytokine response, morphology, hydration, topography, apparent stiffness and coefficient of friction all vary in the amputated limb compared to the intact contralateral limb. Quantifying these parameters will highlight how changes to residuum skin improve or deteriorate the contact situation and inform adaptations in skin biology from prosthesis use.

METHODS

In this study we analysed the skin of 12 lower limb amputees, results were taken on the surface of the residuum and the contralateral intact limb for comparison. After an initial acclimitisation period (20-minutes), photographs are taken of the skin sites using a Visioscan VC 98 to analyse skin surface roughness. In-vivo skin Raman spectra is then taken using a RiverDiagnostics Gen2-SCA Raman confocal spectroscope. Raman spectra are collected from the skin surface to 53 µm into the tissue. Raman spectra are separated into principal components using the RiverDiagnostics SkinTools software, namely protein, ceramides & fatty acids, cholesterol, natural moisturising factor and water. Depth profiles of each component are then compared between skin sites and tested for statistical significance using the Mann-Whitney test. Raman spectra water depth profiles were used to determine stratum corneum thickness using an indirect method [6]. Sebutapes were applied on both skin sites for 2-minutes and analysed using a recently proposed method [7], with a chemiluminescent multi-analyte V-PLEX kit for inflammatory cytokines (IFN-γ, IL-10, IL-12p70, IL-13, IL-1β, IL-2, IL-4, IL-6, IL-8 and TNF-α).

Coefficient of friction was recorded using a handheld tribometer covered with prosthetic liner material to mimic the contact situation in the prosthetic socket. The tribometer features two load cells perpendicular to measure normal and friction force during motion, the contacting wheel rotates in both directions, friction force is divided by the normal force to calculate coefficient of friction. Here we analyse the middle 50% of the forward motion only. Mechanics in indentation was recorded using a custom-built indenter, that recorded the force applied to a 10 mm steel indenter when applying 5 mm of indentation. Each participant had 5 indentation curves taken from each site. Linear

regression was applied to the indentation portion of the force curve and gradients of the fit were compared as a measure of stiffness.

Results relating to roughness, stratum corneum thickness, coefficient of friction, inflammatory cytokines and stiffness were analysed using a two-tailed unpaired t-test

RESULTS

Stratum corneum thickness was recorded using Raman spectroscopy, the average stratum corneum thickness of the contralateral limb and amputation site was found to be 19.5 (SD = 5.05) µm and 21.1 (SD = 4.96) µm respectively ($p>0.05$).

When analysing the Raman spectra of the epidermis we find lower levels of ceramides and fatty acids, cholesterol and natural moisturising factor content in the stratum corneum of amputee skin compared to intact limbs ($p<0.05$) as a result higher water content is found at superficial layers in amputee skin compared to intact skin ($p<0.05$).

We find that IFN-γ, IL-10, IL-12p70, IL-13, IL-1β, IL-2, IL-4, IL-6, IL-8 and TNF-α levels are all increased in baseline amputee skin than the baseline contralateral control but not significantly ($p>0.05$).

Coefficient of friction is higher ($p<0.05$) at the amputation site at 0.7 (SD = 0.76) compared to 0.6 (SD = 0.58) on the contralateral limb respectively (figure 1A).

We find that the stiffness of the amputation site was significantly lower than the contralateral limb ($p<0.05$) where the stiffness was 0.18 N/mm (SD = 0.13) and 0.49 N/mm (SD = 0.24) respectively (figure 1B).

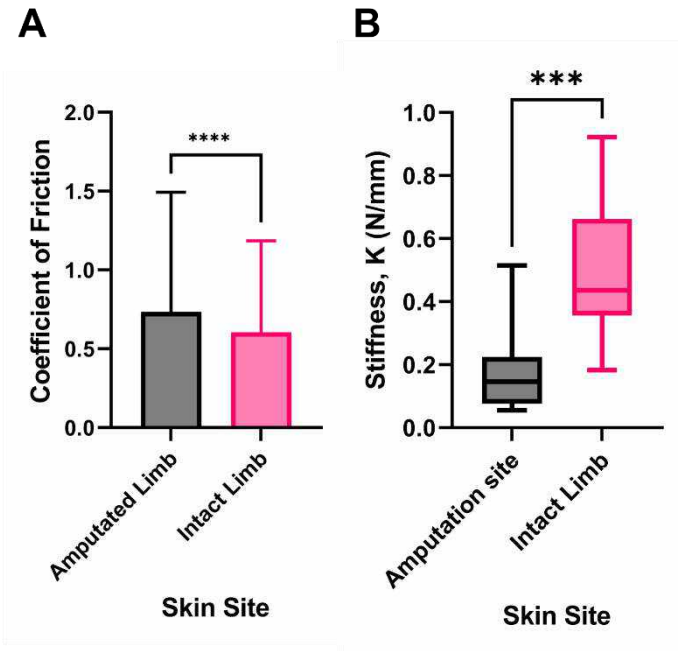

Figure 1: (A) Coefficient of friction in the forward direction for amputated limb (n=9) (black) and intact limb (n=9) (pink), whiskers indicate SD, an asterisk(s) above graph indicates level of significance. (B) Stiffness recorded in indentation only for amputated limb (n=12) (black) and intact limb (n=12) (pink), whiskers indicate min and max data, an asterisk(s) above the graph indicates level of significance.

DISCUSSION

Here we take a multiscale approach to interrogate how skin at the amputation interface has adapted to perform a new load bearing role. We have gained new insights into molecular composition of amputee skin as an outcome of prosthesis use. We found that as a result of prosthesis use, we see adaptation in stratum corneum thickness, allowing amputee skin to mediate mechanical load with a thicker stratum corneum, however these changes are minimal compared to the intact limb. We see adaptation in mechanics as shown by a 64% reduction in stiffness in the amputation limb compared to the contralateral limb (figure 1B). In addition, we record a 17% increase in friction at the amputation site compared to the contralateral limb (figure 1A), suggesting the adapted mechanics of the stump leave skin more susceptible to deformation and friction injuries. Our findings show altered biological function, more specifically, microstructural changes in the skin at the amputation site indicate impaired barrier function, suggesting skin would be more prone to infection, delayed wound healing and impaired desquamation. Altered biological function is also supported by higher baseline inflammatory cytokines at the amputation site compared to the contralateral limb.

While we gained new insights into the in-vivo state of lower limb amputee skin, our recruitment was not exhaustive and would require a larger study population for stronger conclusions.

In conclusion, the work presented shows the adaptation of amputee skin to be minimal. We find reduced stratum corneum thickness and softer contact of the limb, increased friction and reduced skin barrier function. Challenging the notion that amputee skin can be trained to be load bearing. The observations of increased water content and reduced natural moisturising factor content at the superficial layers could lead to higher friction, suggesting a secondary role of a naturally occurring lubricant that protects skin. However, this could be more heavily influenced by the softness of the skin leading to high pile up.

This finding highlights the need for improved therapies as well as product solutions that directly relate to improving load bearing capacity on the skin of the stump.

INTRODUCTION

Research on improving the protective performance of helmets has mainly focused on the development of new and improved materials [1]. However, the effect of helmet ergonomics on protective performance remains understudied. It is well known that in many helmet applications, well-fitting helmets in a reduced risk of brain injury [2-4]. Although we know that good fit is correlated with performance, quantitative descriptions of what constitutes good helmet fit remain scarce. Existing studies on helmet fit in military helmets have not provided sufficient spatial resolution to properly describe the way the helmet rests on the head [5]. Additionally, we hypothesize that helmet fit will vary significantly across the population, and previous work in this area has lacked a representative volunteer population to capture such a distribution [5,6].

A lack of robust data has led to varying assumptions about helmet fit being made. The level of pre-compression in the helmet lining created by the user who wears the helmet, which constitutes the deformed initial condition for any subsequent impact analysis, has not been characterized. As a result, researchers in previous studies of helmet performance have arbitrarily selected initial compression conditions [7,8], or assumed a zero-stress state prior to impact or blast analysis [9]. The wide variety in the assumptions being made demonstrates a *clear need* for a comprehensive description of the appropriate helmet fitting conditions, and how those conditions vary across the population.

In this study, we have developed a method to quantitatively describe helmet fit and addressed the clear need for fit data in the specific case of military helmet systems. We have defined the spatial and population distribution of helmet-to-head contact forces, as well as chinstrap tension, in the Advanced Combat Helmet (ACH) system. We have also evaluated the relationship between head dimensions and the observed force distribution. Finally, we have examined the relationship between population demographics and the resultant helmet fit. We hypothesize that head size and user demographics will change the resultant helmet fit.

METHODS

To evaluate helmet fit, four sizes of the ACH (S, M, L, XL) were fitted with an aftermarket foam padding system. Each pad was instrumented with a force sensitive resistor (FSR), enabling measurement of the contact force between the pads and the head at seven areas around the inside of the helmet, as shown in Figure 1A. Custom mechanical force gauges, shown in Figure 1B, were incorporated into the helmet, replacing the existing tensioning buckles.

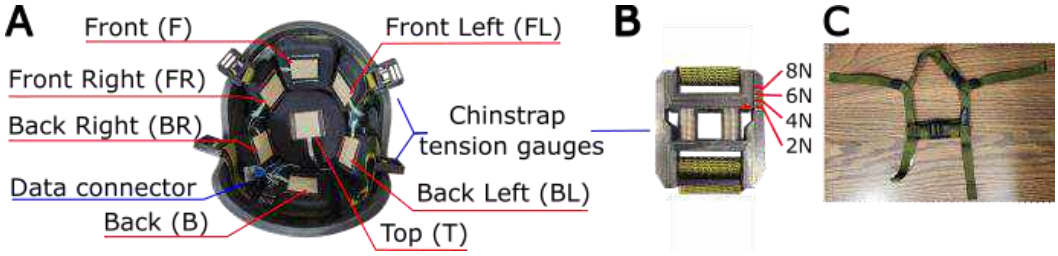

Figure 1. Measurement system diagram. (A) Helmet padding configuration with position notation. (B) Chinstrap tension gauge detail. (C) Helmet chinstrap system.

The force gauges enabled measurement of the chinstrap tension at the four connection points to the helmet, shown in Figure 1A and 1C.

Helmet fit testing was performed on 89 volunteers (25 female, 64 male) with varying levels of prior experience using combat helmet systems. The volunteer study was conducted with official exemption from the Northeastern University Institutional Review Board. The age, biological sex, and experience level of each volunteer were recorded, and their head length, width, and circumference were measured. The correct size helmet was selected for the volunteer based on their head measurements and guidelines prescribed by the helmet manufacturer. Volunteers were asked to wear the helmet in three configurations: Without the chinstrap fastened (No Chinstrap/NC configuration), with the chinstrap tightened to the volunteer's preference (User Comfort/UC configuration), and with the chinstrap tightened to a fixed value by the facilitator (Fixed Tension/FT Configuration). For each configuration, the head/helmet contact force was measured at the seven FSR positions. Chinstrap tension was also recorded for the UC and FT configurations.

RESULTS

We observed contact forces between 0 N and 30 N, with most falling between 0 N and 10 N, as shown in Figure 2. The highest contact forces were found on the front pad and the back left and right pads with some load also carried by the top pad, indicating that the helmet did not sit uniformly on the head. The contact force data followed a skewed distribution with many high outliers.

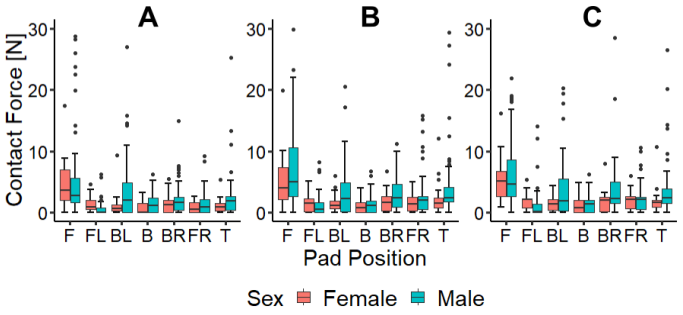

Figure 2. Contact force distribution for (A) NC configuration, (B) UC configuration, (C) FT configuration, measured at each of the seven positions, see Figure 1A for notation.

When the contact force was averaged across the seven interior pads, as shown in Figure 3, most of the outliers disappeared, indicating that high forces in one area of the helmet were compensated by a low force somewhere else and highlighting the role of head shape in the way the helmet sits on the head. We observed a statistically significant difference in contact pressures between male and female volunteers for the two configurations in which they adjusted their own helmet fit, as shown in Figure 3.

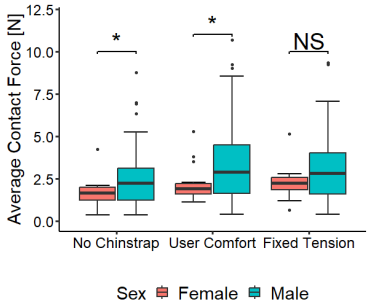

Figure 3. Average contact force in different test configurations comparing male and female volunteers.

Figure 4 shows the relationship between the volunteer head dimensions, normalized as a ratio to the corresponding dimension of the helmet, and the head-to-helmet contact forces observed. We found no correlation between the head dimensions and the resultant contact forces.

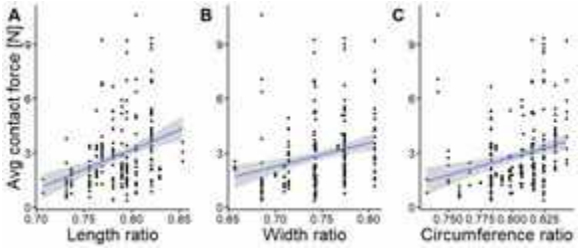

Figure 4. Average contact force vs head / helmet (A) length ratio, R^2=0.10 (B) width ratio, R^2=0.06 (C) circumference ratio, R^2=0.06

DISCUSSION

The experimental fit data shown in Figure 4 highlights the variation in helmet fit between subjects with similar head dimensions. Head length, width, and circumference collected during the study did not show a correlation to the observed contact forces, indicating that head shape, not just size, played a significant role in determining interface forces. The measured head dimensions were selected since they were the measures used to select the correct helmet size. Further evaluation is necessary to determine if there are head dimensions that better correlate with contact forces, and if there may be better dimensions for selecting the appropriate helmet size.

Differences observed between male and female volunteers may be due to different scalp profiles, padding from more hair, different preferences on how to wear the helmet, or some combination of the above. Given that the differences between male and female volunteers became negligible when the study facilitator adjusted the helmet for the volunteer, it is likely that differing comfort levels partially contribute to the observed difference. It is important to note that no conclusions can be drawn from these results as to whether higher or lower contact forces are inherently "better". Additional research is necessary to determine whether the differences observed correspond to a protection difference.

Our study has established—for the first time—a broad, quantitative, and population-inclusive description of the forces at the head/helmet interface for military helmet systems. Although our study focuses on military helmets, the methodology we have established is applicable to a variety of different types of helmets. The framework we have established is critical to establish accurate initial conditions for the evaluation of the protective performance of helmet systems.

INTRODUCTION

Medical implants are being developed to facilitate the delivery of therapy in the form of drugs, proteins, cells, and bioactive agents, to localized sites[1]. Despite having shown some success, many have limited long term performance, in part due to the diffusion barrier they pose which is exacerbated by the foreign body response (FBR) following implantation[2]. This results in the formation of a dense hypo-permeable fibrous capsule (FC) around the device, leading to failure of many implantable technologies[3]. One potential method for overcoming the FBR is to enhance therapy transport through the incorporation of local fluid flow[4-6]. In this work, we used experimental inputs to characterize the change in the FC over time and quantified how it impacts therapy release using computational methods. For this purpose, insulin was used as a representative therapy as encapsulation devices for Type 1 diabetes are among the most-well characterized[7]. We then explored how local fluid flow may be used to counteract the FBR. Achieving continuous flow in a clinically relevant setting may prove challenging as a steady external supply of fluid is required. However, pulsatile flow can be driven by the displacement of interstitial fluid and therefore does not require an external fluid supply. As such, the impacts of both continuous and pulsatile flow were investigated. We aimed to combine computational and experimental methods to better understand the temporally dynamic impacts of the FBR on therapy delivery, and how local fluid flow may be implemented to reduce or eliminate them.

METHODS

The implant modelled in this study was redesigned from previous work[5,6]. The implant consists of a central therapy reservoir with laser cut semi-permeable membranes (0.15 mm thick, 10 µm pores, 3.5 % porosity) on either side. This therapy reservoir (0.5 mm x 10 mm) is surrounded by an actuation reservoir which can be cyclically inflated and deflated to drive interstitial fluid flow (Fig 1A). The implant is made entirely of thermoplastic polyurethane (TPU).

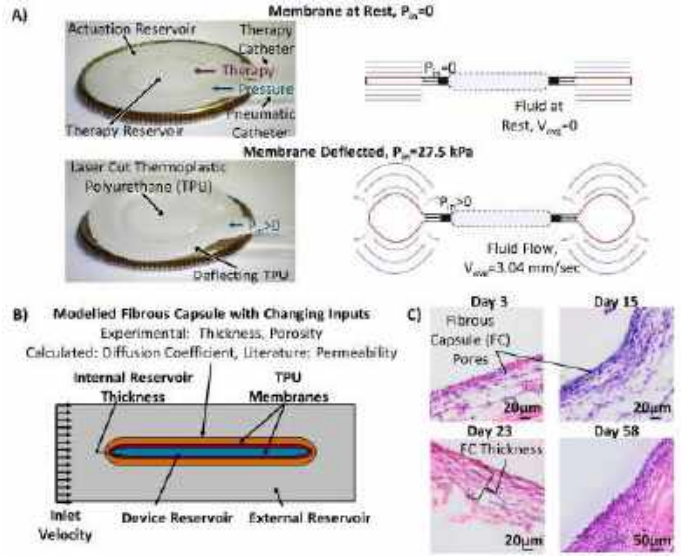

Figure 1: A) Actuating device prototype. B) Model set-up diagram. C) Representative H&E images of the fibrous capsule.

A simplified 2D model of the therapy reservoir and FC at days 15 and 58 post-implantation were constructed in COMSOL Multiphysics® using the Transport of Diluted Species and flow through porous media (Brinkman) modules. The impact of the actuation reservoir on local fluid was captured by idealized flow over the implant (Fig 1B). Two velocities achievable by existing device designs (0.25, 3.04 mm/sec) and two pulsatile regimens (0.1, 1 Hz) were used. The initial therapy reservoir concentration was 9.5×10^{-13} mol/mm^3. Membrane transport properties were obtained using Franz cell apparatus. FC thickness and porosity were taken from previous *in vivo* studies in our group[6,8],

diffusion coefficients were approximated from the porosity (Fig 1C) and a simplified version of Maxwell's model[9], while permeability was taken from literature[8,10].

RESULTS

We first captured the impacts of the FBR on insulin release at days 15 and 58 post-implantation (no flow). This showed reduced therapy diffusion after 15 minutes, the approximate time for first phase insulin secretion (Fig 2A). This is a major contributor to control of postprandial hyperglycaemia and later blood glucose levels in individuals with impaired glucose tolerance[11,12]. This impaired release persisted over 60 minutes with near two-fold reduction by day 58 (Fig 2B). At the clinically relevant 15 minute time point this correlated to drops in area under the curve (AUC) of 35.8% and 64.2% (day 15 and 58) relative to baseline (No FC) (Fig 2C).

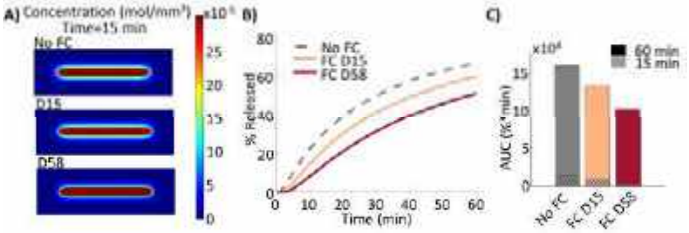

Figure 2: A) Model concentration profiles (15 min). B) Therapy release over 60 min. C) AUC values (15 and 60 min).

Continuous local fluid velocity was incorporated with simulated day 58 FC. There was minimal insulin accumulation outside the implants with fluid flow at 0.25 and 3.04 mm/sec (Fig 3A) and release was restored to baseline levels after 46 and 58 minutes respectively (Fig 3B). However, AUC values did not reach baseline (Fig 3C).

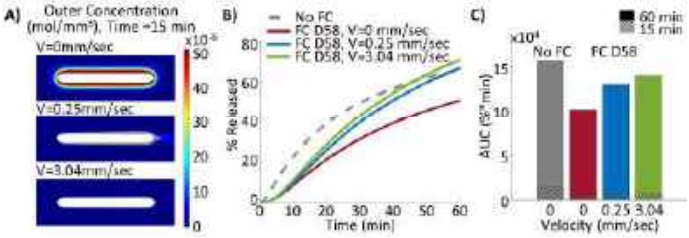

Figure 3: A) Model concentration profiles (15 min). B) Therapy release over 60 min. C) AUC values (15 and 60 min).

Pulsatile flow regimens were then implemented in the model. During the 'pulse' the idealized inlet velocity was cyclically ramped up to the maximum velocity of 3.04 mm/sec (Fig 4A). The resulting release profiles over a 60 minute period showed that a frequency of 1 Hz was sufficient to nearly match that of continuous flow (Fig 4B) with a relative difference in AUC of only 1.8% (Fig 4C).

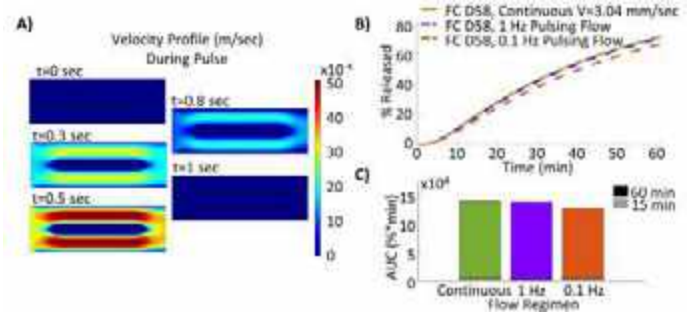

Figure 4: A) Model velocity profiles during pulse. B) Therapy release over 60 min. C) AUC values (15 and 60 min).

DISCUSSION

In this study, we describe a simplified implantable encapsulation device model informed by experimental inputs. It can be used to investigate how therapy release is impacted by the FBR, and the implementation of local continuous and pulsatile fluid flow around the implant. This allows us to evaluate how we expect the implant to perform *in vivo* under a variety of conditions and tune our design accordingly.

Our model is able to capture the expected decrease in therapy release that would result from the FBR at two critical time points, days 15 and 58. Although factors such as glucose uptake by the FC tissue were not considered in this model, the expected deficits in insulin release at days 15 and 58 (35.8% and 64.2% drop in AUC compared to baseline after 15 minutes) correlate reasonably well with the percentage reduction in the maximum percentage blood glucose drop at 3 and 8 weeks seen *in vivo* (43% and 71%, respectively)[5]. Though these values cannot be directly equated, they show a similar trend and magnitude of change, as expected given the intrinsic links between insulin release and circulating blood glucose levels.

We then demonstrate how the implementation of idealized local fluid flow achievable by existing designs may be used to help improve therapy transport and overcome the FBR. We show an improvement in insulin release at the clinically relevant time point of 15 minutes, and a return to baseline (no FC) within 60 minutes using both continuous and more clinically achievable pulsatile flow regimens. Additionally, although not explored herein, previous studies have shown that local mechanical stimuli around implants, such as those induced by fluid flow, can decrease the magnitude of the FBR and resulting FC[,9]. As such, local flow may induce a dual improvement in therapy release through the combined reduction in FBR and advantageous convective transport elements, further improving the 15 minute response captured by the model.

Incorporating local fluid flow may hold the key to overcoming the FBR, which currently leads to consistent implant failure *in vivo*. This model can be used as a method to test and optimize simulated flow regimens readily achievable by existing designs that are suitable for a clinical setting. Although this model was generated using insulin as a representative therapy, these findings are also highly applicable to the delivery of other drugs or cell therapies which rely on timely and accurate transport which can be inhibited by the FBR. Overall, the computational model outlined herein may serve as a valuable means to investigate the impacts of the FBR and how they may be overcome.

INTRODUCTION

Prostate cancer (PCa) is the leading new male cancer diagnosis in the United States, accounting for 1 in 8 new male cancer diagnoses[1]. Improved screening, including multi-parametric magnetic resonance imaging (MP-MRI)-based risk assessment, and treatments have led to a high five-year overall survival rate; however, PCa still accounted for an estimated 35,000 deaths in 2023. Conventionally, PCa diagnosis relies on prostate-specific antigen (PSA) testing and multi-core needle transrectal ultrasound (TRUS)-guided biopsies; however, these biopsies carry risks such as missing significant cancer and infection. The Prostate Imaging Reporting and Data System (PI-RADS) has standardized acquisition, interpretation, and reporting of prostate MRI, as well as aided in the accurate detection of cancerous lesions[2], and recently, MRI-guided biopsies have emerged as a promising alternative, demonstrating the ability to detect higher-risk cancers, requiring fewer biopsy cores, and thus minimizing associated risks. This study, therefore, investigates the potential superiority of simulated MRI-guided biopsies over traditional simulated zone-sampling 12-core needle biopsies using prostate cancer digital twins.

METHODS

This study prospectively recruited 109 patients with pathologically confirmed prostate cancer undergoing radical prostatectomy, whose demographic information can be found in **Table 1**. Patients underwent MP-MRI prior to radical prostatectomy on a 3T MRI scanner using an endorectal coil, including T2 (T2WI) and diffusion weighted imaging (DWI). Apparent diffusion coefficient (ADC) maps calculated from DWI were manually aligned to the T2WI using FreeSurfer's *tkregister2*. After surgery, tissue was sliced using a custom patient-specific, 3D-printed slicing jig modeled after the patient's T2WI. Tissue slices were processed, hematoxylin and eosin (H&E) stained, and digitized at 40x resolution (0.2 microns per pixel) on a sliding stage microscope (**Figure 1**). A board-certified genitourinary pathologist annotated lesions by Gleason patterns on a total of 327 digitized slides (n = 3 per patient). The slides were then nonlinearly aligned to each patient's T2WI using custom in-house control-point based MATLAB software[3, 4].

Table 1: Patient demographic information.

Age, years (mean, SD)	60.1 (6.3)
Preoperative PSA, ng/mL (n, %)	
< 6	57 (52)
≥ 6 – 10	33 (30)
≥ 10 – 20	17 (16)
≥ 20	2 (2)
Grade Group at RP (n, %)	
6	22 (20)
3+4	55 (50)
4+3	15 (14)
8	4 (4)
≥ 9	13 (12)

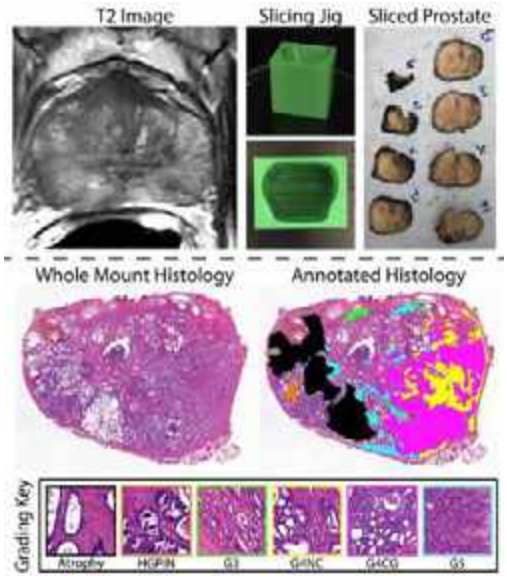

Figure 1: Tissue processing steps (top) and example Gleason pattern annotations (bottom).

Figure 2 illustrates the virtual biopsy simulation process on an example prostate digital twin. Each patient's first aligned slide was divided into twelve equally sized "quadrants" to simulate a 12-core prostate biopsy. Histology within each quadrant was masked and coordinates corresponding to the mask were generated. A random point was selected as the central location of the simulated needle biopsy and was radially expanded by one voxel, for an estimated 1.2mm region (i.e., the standard biopsy needle size). This needle location was translated to the remaining slides and simulated biopsy results (i.e., cancer presence and highest Gleason grade found) were recorded.

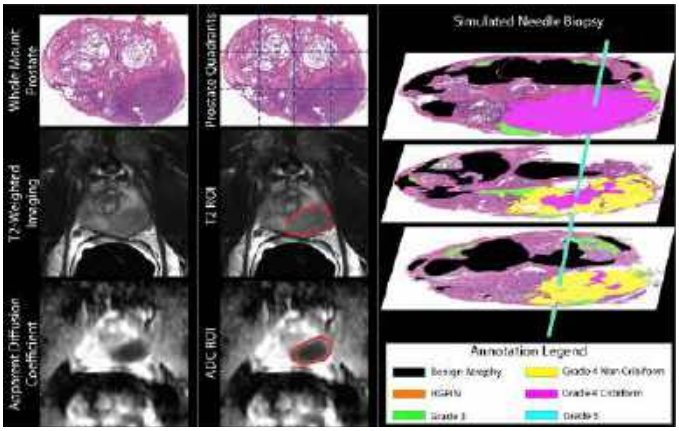

Figure 2: Graphical representation of a virtual biopsy performed on a digital twin.

To test MRI-guided biopsies, a PCa expert annotated 1-3 regions of hypointensity on the T2WI corresponding to the first aligned slide. The coordinates within these regions were translated to histology slides, and four random points were selected as T2-guided needle points. ADC maps were segmented using the 5th percentile of intensity to determine regions of increased hypointensity. Similarly, four randomly selected points within these regions were translated to the histology as ADC-guided needle points. As with the histology-based biopsy needle, the T2 and ADC-derived points were translated into a simulated biopsy needle, and the results were recorded. The entire simulated biopsy process was repeated 100 times per patient for robust predictions. Histograms of biopsies that detected the highest tumor grade present were plotted for each of the simulated procedures, and the average number of successful biopsies were calculated to compare biopsy accuracies.

RESULTS

Simulated ADC-guided prostate biopsies detected the highest tumor grade present on a slide in 81% of simulated biopsies. T2-guided biopsies detected the highest tumor grade in 65% of biopsies, followed by the simulated 12-core histology-based biopsies only capturing the highest tumor grade in 26% of biopsies (**Figure 3**).

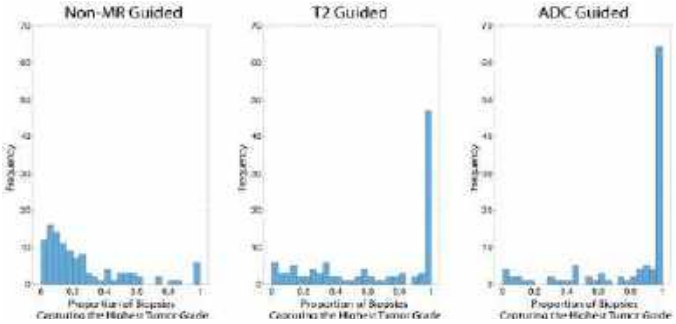

Figure 3: Results of the virtual biopsy analyses. ADC-guided biopsies best captured clinically significant cancers compared to unguided biopsies.

DISCUSSION

While the simulated histology based prostate biopsy used three times as many needles across the entire prostate, simple four needle MRI-guided biopsies more frequently detect high risk cancers. Specifically, ADC-guided biopsy with regions defined by increased hypointensity can detect the highest tumor grade present within patient more frequently with minimal biopsy needles.

SHEAR STRAINS AS A TEAR GROWTH MECHANISM FOR HIGH-GRADE PARTIAL-THICKNESS ROTATOR CUFF TENDON TEARS

INTRODUCTION

Rotator cuff tendon tears are one of the most frequent causes of shoulder dysfunction and pain, with a prevalence between 13% to 32% in the general population and 40% in overhead athletes [1]. Of these, the subset of high-grade partial-thickness rotator cuff tendon tears (type III, 50% of footprint detachment) do not have definite criteria regarding when to surgically repair, as there has been a paucity of biomechanical studies which predict risk of tear progression and the natural history of these tears remains unclear from clinical cases. Consequently, the repair decision is based on anecdotal findings, and not a thorough examination of the likelihood of progression based on the tear's original characteristics.

One of the main metrics to predict tear growth and propagation directions in full-thickness tendon tears has been maximum principal strain concentrations in tear edges [2, 3]. Given that these strains are typically measured with surface probing methods and tear edges are on internal surfaces in partial-thickness tendon tears, examining the strain patterns on these injuries becomes prohibitive with these techniques. Moreover, the effect of the hierarchical and three-dimensional nature of the rotator cuff tendons on strains cannot be evaluated with surface strain measurement methods.

Considering the above, our goal was to obtain full-field displacement and strain patterns in intact and partially torn rotator cuff tendons (type III tear) to evaluate significant changes that could elucidate tear progression mechanisms. Based on our previous studies in type I and II partial-thickness tears, where large shear strains were observed, we hypothesized that delamination (mode II failure) would be a potential tear progression mechanism in type III injuries.

METHODS

The sheep infraspinatus tendon was selected as our animal model to study tear progression, as it has been previously validated as a proxy for the human supraspinatus tendon due to their similar shape and size [4].

The infraspinatus tendon with its intramuscular portion and humeral attachment was isolated from seven fresh ovine shoulders (n=7). Each bony attachment was shaped into a truncated pyramid for fixture fitting, preserving the curved part of the footprint (Figure 1-a). The tendon's intramuscular portion was gripped between interlocked truncated pyramidal teeth, while aligning the sample at a neutral position of $\sim$0 degrees abduction and rotation (Figure 1-a). A wedge was inserted between the anterior part of the bone and the fixture to counteract mechanical moment.

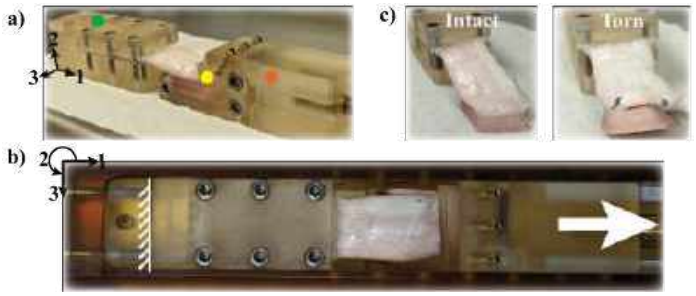

Figure 1: Experimental setup: a) Sample holder with tendon's gripper (green circle), humerus fixture (orange circle), and wedge (yellow circle), b) MRI compatible apparatus with sample holder inside, showing pull direction (white arrow), c) Intact and torn configurations.

Fixtures were mounted to a magnetic resonance imaging (MRI)-compatible apparatus (Figure 1-b) and placed inside a 7 Tesla MRI unit, positioning the region of interest in the center of the magnet. Once in place, samples underwent cyclic uniaxial tension in the main fiber direction. The load-unload cycles were synchronized to a displacement encoding protocol [5], which captured voxel-wise phase variation between loaded and un-

loaded configurations. Full-field displacements, Lagrangian strains, and maximum shear strains were obtained from these phase differences.

We tested two clinically relevant configurations per tendon: i) intact tendon, followed by ii) 75% bursal footprint detachment (type III tear with ∼75% width) with inverted U-shape, surgically cut with a #10 scalpel blade (Figure 1-c). Each configuration underwent two physiologically relevant displacements of 1 mm and 2 mm, which had been shown to represent submaximal and supramaximal human shoulder force ranges in preliminary studies. In total, we ran four experiments per tendon, each with a conditioning cycle of 10 minutes for force stabilization.

Binary masks were obtained from high resolution images of the samples in MATLAB to isolate tendon from bone in the intact and torn configurations. Displacements and strains were evaluated in these regions of interest. Then, each mask was transformed into a smooth high-quality mesh and full-field displacements and strains were interpolated to match these meshes. Quantitative differences were calculated in the interpolated maps.

RESULTS

Non-homogeneous full-field displacement maps in all directions were visualized for both intact and torn tendons (Figures 2-a, 2-b, and 2-c). In the torn configurations, larger displacements in the longitudinal direction were registered in the detached band of fibers (Figure 2-a) as compared to corresponding intact counterparts. In particular, we observed displacements 4 times higher than those of the intact condition close to the detached bursal surface. In the remaining attached portion of fibers in the torn configurations, displacement increases went beyond 1.5 times those of the intact configurations. Lower degree of tendon wrapping around the humeral head appeared to have a lower level of sliding in the detached tissue portion with respect to the attached region, as compared to tendons with higher degree of wrapping (Figure 2-d).

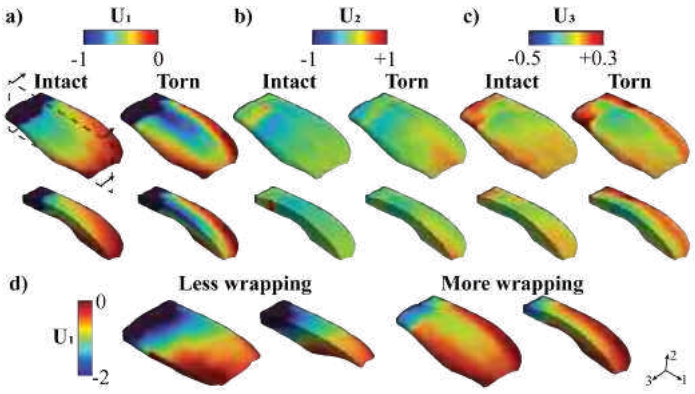

Figure 2: Displacements of intact and torn conditions (representative tendon) in the a) longitudinal, b) vertical, and c) transverse directions. Tendon sections (second row) are obtained from a longitudinal cut, as indicated by the dashed lines and arrows in the first 3D section. d) Displacement in the longitudinal direction for torn tendons with different degrees of wrapping around the bone.

Torn tendons showed absolute shear strain differences larger than 0.10 compared to the intact tendons for all shear strain components. This was a result of the gradient of longitudinal and transverse displacements between the detached band of fibers and the remaining portion of fibers. Shear strain magnitudes were above 0.10 for both the 1-2 and 1-3 components, and 0.05 for the 2-3 component (Figure 3-a, 3-b and 3-c). Maximum shear strain concentrations appeared in the articular surface, the remaining footprint of the tendon, the tendon's mid-substance, and the boundaries between attached and detached tissue bands in torn tendons (Figure 3-d). More than 0.08 maximum shear strains were registered in the regions close to the enthesis, which represented an absolute difference larger than 0.05 compared to the intact configurations. We report values for the 2 mm cyclic displacement; corresponding results for the submaximal force followed a similar trend.

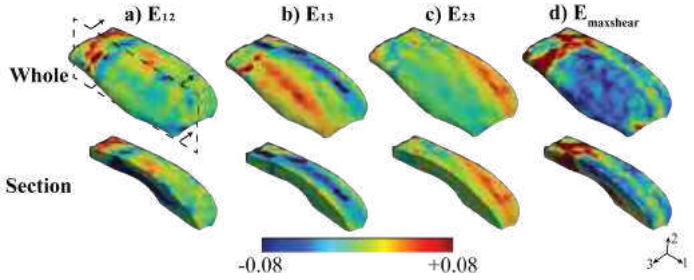

Figure 3: Shear strain maps for a representative torn tendon: a) 1-2 component, b) 1-3 component, c) 2-3 component, d) maximum shear. The dashed lines and arrows indicate the section plane and directions.

DISCUSSION

Our complex displacement maps show material heterogeneity and three-dimensional structure effects in this animal model of the rotator cuff, which implies that surface strain probing methods provide an incomplete picture of the mechanical behavior of the tendon. In high-grade bursal-sided partial-thickness tears, the detached band of tissue appears to slide on top of the remaining portion of fibers, developing larger longitudinal displacements and shear strains as compared to the intact condition. Sliding is a failure mechanism that appears in composite materials with one fiber family and has been visualized in tendons with transverse tears [6]. Hence, a thorough analysis of tendon tear progression should include fiber-matrix debonding or matrix failure mechanisms. Contrary to previous studies [2], we did not observe the largest increase of strain in tear edges, potentially because we examined different tear types. Also, in injured tendons, we observed more than 60% increases for maximum shear strains in the articular-sided region close to the enthesis, suggesting that tear progression could occur in this area even at neutral position with supramaximal forces.

These results support our hypothesis that delamination could be a potential tear growth inducing mechanism in type III bursal-sided tears. However, the progression threshold has not been defined yet, and we could not ascertain tear growth occurrence. Although one of the limitations of our study includes our small sample size, we observed sliding behavior and shear strains larger than 0.10 in all tendons, which should persist in studies with a larger sample size. Also, our animal model of the rotator cuff has a single fiber family and no load sharing as opposed to the human rotator cuff tendons. However, our full-field strain measurement technique is suitable for human cadaveric specimens and could be combined with finite element models for the study of all kinds of tears.

In brief, our full-field data provide quantifiable evidence that high-grade bursal-sided partial-thickness tears produce shear strains between the articular and bursal regions, suggesting that delamination could be a mechanism for tear growth. Accurate measurement of three-dimensional shear strains and damage thresholds in different tear types could inform surgical decisions, tears at high risk of progression, and the natural history of tears.

ROLE OF SEX AND SEX HORMONES IN PULMONARY ARTERY ADVENTITIAL FIBROBLAST MECHANOSIGNALING

Yufan Lin (1), Giuditta Monti (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California, San Diego, La Jolla, California, United States

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a progressive disease driven by pathological activities of mechanosensitive cells in pulmonary arteries (PAs) [1]. PAH is more prevalent in women than men, but pre-menopause females have better outcomes than man and post-menopausal women [2]. As PAH differentially affects men and women, and there is no cure, we are studying the mechanosignaling of pulmonary artery adventitial fibroblasts (PAAFs), the cell type that is attributed for vasculature stiffening in PAH, and how they are regulated by the chromosomal sex and sex hormone in rats. By combining *in-vitro* cell experiments with *in-silico* model simulations, we seek to develop and validate a sex-specific PAAF signaling network model.

METHODS

PAAFs isolated from healthy male, female, and ovariectomized (OVX) female rats are cultured in polyacrylamide gels. These scaffolds are built with different stiffness levels to represent healthy conditions (0.5 kPa), and mild (3 kPa) and severe (10 kPa) disease stages of PAH [3]. To mimic changes in strain due to increase in pulmonary blood pressures, we exposed the gels to 10% biaxial stretch for 24 hours [3]. Cells are then collected and lysed for RNA isolation, which is followed by cDNA synthesis and quantitative PCR (qPCR). qPCR targets were selected to be profibrotic genes shown previously to be upregulated in PAs from animals treated with sugen-hypoxia (SuHx), a well-established animal model of PAH. The gene expressions are normalized against the housekeeping gene *18S*, and analyzed with 2-way ANOVA with the two factors being stretch and stiffness, which is followed by Dunnett's *post-hoc* multiple comparisons test.

The cell signaling model is composed of mechano- and biochemical inputs, receptors, kinases, transcription factors, mRNA, and protein or cell phenotype outputs. The dynamical system is modeled as a logic-based differential equation model, where:

$$\frac{dy_i}{dt} = \frac{1}{\tau_i}\left(\sum_j \omega_j f_j y_i^{max} - y_i\right) \quad (1)$$

where y_i is the activation level of species i, τ_i and y_i^{max} are the time constant and maximal fractional activation, while f_j and ω_j are the associated Hill activation/inhibition functions and corresponding reaction weights, respectively [4].

PAAF signaling model simulations were iteratively conducted with varying mechanical input weight ($\omega_{stiffness}$ and $\omega_{stretch}$) within the normalized interval between 0 and 1 [5]. To recapitulated female signaling, we conducted separate simulations with knockdown of biochemical nodes – including PDGFR, p38 and NFAT - based on literature data [6-7]. In the model, this is implemented by reducing parameters y_{PDGFR}^{max}, y_{p38}^{max}, and y_{NFAT}^{max} to 0.25 from default value of 1.

RESULTS

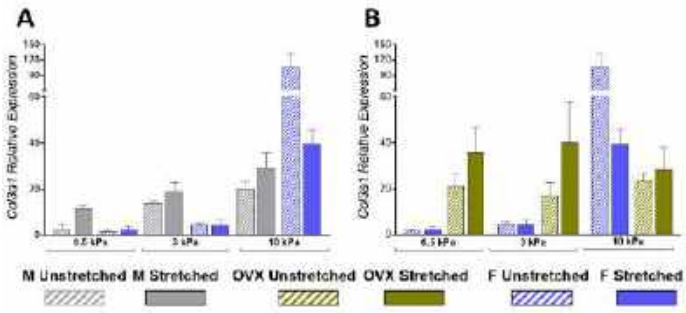

Figure 1: Effect of substrate stiffness and stretch on *Col3a1* expression in PAAFs derived from male rats and female rats (A), and intact vs. OVX female rats (B). Note that female cells have a higher stiffness response threshold than male (A), and OVX cells are more resistant to the up-regulation of substrate stiffness increase compared to intact female (B).

Profibrotic gene expressions in PAAFs derived from male, female, and OVX female animals show an upregulation due to stretch and substrate stiffness (**Figure 1B & D)**. Specifically, intact female-derived PAAFs exhibits a higher substrate stiffness response threshold compared to male **(Figure 1A).** Meanwhile, OVX female-derived cells show higher baseline expression but lower sensitivity to an increase in substrate stiffness when compared to intact female **(Figure 1.B)**.

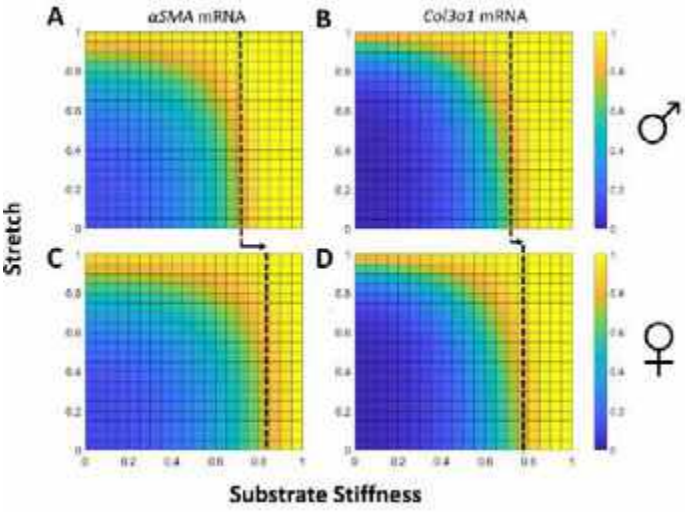

Figure 2: Model simulation ranging from none (0) to fully activated (1) stretch and degrees of substrate stiffness recapitulating male- (A-B) and female-derived (C-D) PAAFs. Dashed lines indicate the stiffness level for expression to reach 0.8 at a low stretch level. In the gene expression of *Acta2* (A, C) and *Col1a1* (B-D), increasing stretch and stiffness levels generally upregulate the expression levels in a non-linear manner. Note that the drastic increase in expression levels occurs at higher stiffness levels in the simulations recapitulating females (C, D).

By simulating the normalized Hill-based computational model of our established PAAF mechanosignaling network iteratively across various mechanical stimuli levels, we obtained the prediction of mechano-induced PAAF profibrotic gene expression dynamics, with parameters tuned to specifically recapitulate male versus female signaling networks (**Figure 2**). Qualitatively, the female-representing simulations – featuring knockdowns of nodes including PDGFR, p38, and NFAT (**Figure 2.C-D**) – show higher stiffness response thresholds for genes including *Acta2* and *Col3a1* than the analogous simulations for male PAAFs (**Figure 2.A-B**).

DISCUSSION

Based on the *in-vitro* cell experiment results, we observe that increased substrate stiffness and stretch generally lead to activation of profibrotic gene expressions. Moreover, the measured levels of these genes - including *Acta2* and *Col3a1* - show differential response patterns between male and female-derive PAAFs; specifically, being female appears to increase the threshold for stiffness-induced response in fibrotic gene expressions, while male cells show a lower threshold when exposed to stretched. In summary, these results demonstrate differential mechanical stimuli thresholds at the cellular level between male and female PAAFs. Similar differences are also observed between intact and OVX female groups. Compared to male, OVX derived cells respond to changes in mechanical stimuli in a similar manner, namely low threshold for stiffness and high sensitivity for stretch, but they also show higher baseline expression levels than male cells. This suggests that the presence of ovarian hormones is also a significant factor to consider during PAH development.

Since our PAAF mechanosignaling model was informed with and validated against exclusively male-derived data, its predictions align well with the male-derived PAAF *in vitro* experiment results. However, the observed sex-dependent phenotype differentiation motivates the incorporation of sex specificity in this network. Studies focusing on cardiac fibroblasts have found key biochemical components to be differentially expressed between cells from male versus female [6-7]. Among these components, the ones involved in profibrotic mechanosignaling activities include PDGFR, p38, and NFAT, all found to be less active in female. Assuming high level similarities between cardiac fibroblasts and PAAF, we conducted simulated knockdowns of these three nodes and thus granted the network female features. Simulating this female-recapitulating network, we observe that mechano-induced activation dynamics for ECM genes (including *Col1a1* and *Col3a1*) and the myofibroblast marker *Acta2* are qualitatively like the male-version simulations, where higher stretch or stiffness levels generally induce greater responses; however, the thresholds for the drastic increase in expression due to substrate stiffness increase are higher in the female simulations. This agrees with the *in vitro* experiment results where female PAAFs are activated only at a relatively high stiffness level. No difference in terms of stretch response thresholds is predicted by the simulations. This network does not yet describe the role of sex hormones, and thus it cannot discriminate OVX versus female-derived cells, while ovarian hormone presence is observed to differentiate PAAF phenotypes *in vitro*. Hence, model expansion and parameter adjustment based on sex hormone presence will be the future direction of the improvement. This computational model will assist in hypothesis generation, response prediction, and results validation for future sex-dependent PAH development studies.

In summary, the *in-vitro* experiments suggest that both chromosomal sex and the presence of ovarian hormones dictate PAAF mechanosignaling by altering the response thresholds and intensities under increasing stretch and substrate stiffness. Upon further expansion and incorporation of sex hormone in the training of the model, we will use this as a tool for signaling mechanism validation, examination target selection, and *in silico* experimentation for more efficient investigation of sex-specific PAAF mechanosignaling activities.

FEMALE ANTERIOR CRUCIATE LIGAMENTS EXHIBIT A MINIMAL MECHANOBIOLOGICAL RESPONSE TO MECHANICAL LOADING

INTRODUCTION

Anterior cruciate ligament (ACL) tears are one of the most common knee injuries affecting over 200,000 people a year. This is particularly true for female athletes, who are 2-8 times more likely to suffer an ACL tear compared to their male counterparts[1,2]. The reason for this phenomenon remains unclear; however, it is possible that exposure to sex hormones make ACLs less capable of repairing tissue damage from repetitive loading. Recent studies suggest that ACL injuries occur from fatigue failure, where repetitive loading causes an accumulation of tissue damage predisposing the ACL to injury[3]. Prevention of ACL fatigue rupture requires successful remodeling of tissue damage, and estrogen has been shown to regulate genes involved in tissue remodeling (collagen, collagen crosslinking, MMPs, and MMP inhibitors)[4,5]. Furthermore, prior data on tendon and bone suggest that estrogen is a key modulator of the biological response of musculoskeletal tissues to mechanical loading[6,7]. Despite these data, the sex-specific response of ACLs to load is unknown. Therefore, the objective of this study was to investigate the sex-specific mechanobiological response of ACLs to cyclic loading. We **hypothesized** that in response to load, female ACLs will exhibit an increased catabolic response and have an impaired activation of mechanotransduction pathways that will be accompanied by activation of the estrogen signaling pathway.

METHODS

Following IACUC approval, ACLs were harvested from both knees of 7 male and 8 female New Zealand white rabbits and placed in a tensile bioreactor with culture media kept at 37°C and 5% CO_2. After 18 h of accumulating the ACLs to explant culture, the bioreactor cyclically loaded the samples to 2, 4, or 8 MPa at 0.5 Hz for 8 h. These stress levels encompass the full range of physiologic ACL loading[8]. Control samples were placed in the bioreactor under the same duration but under a minimal (0.1 MPa) static load. ACLs were immediately removed after loading, rinsed with ice cold RNase-free water and flash frozen in liquid nitrogen. Total RNA was extracted with RNeasy minicolumns, cDNA was synthesized from 10 ng of the total RNA, and real time-PCR was performed using Taqman probes to measure expression of anabolic (*COL1A1, COL1A2, LOX, COL3A1, TGFβ1 ACTA2*), catabolic (*MMP1. MMP2, MMP10, MMP13, TIMP1, TIMP3*), and inflammatory (*IL-1β, PTSG2*) genes with *GAPDH* and *ACTB* as reference genes. Quantification of gene expression was performed via the delta-delta Cq method correcting for primer efficiencies and using the genomic mean of the two reference genes. To determine the effect of mechanical loading on both male and female ACL explants, the male and female cyclically loaded samples were compared to their sex-matched statically loaded control. To determine baseline sex-specific gene expression differences, the statically loaded female samples were compared to male statically loaded samples. Mann-Whitney tests were used to determine differential expression and to compare gene expression response between sexes. Statistical significance was set at $p < 0.05$ with statistical trends set at $p < 0.10$. A subset of the samples was sent to GENEWIZ for RNA-sequencing. Sequence reads were trimmed and mapped to the OryCun 2.0 reference genome. DESeq2 was used to determine differentially expressed genes between the 4 MPa and static load samples for both sexes. The Wald test was used to generate p-values of all the differentially expressed genes. Genes with an adjusted p-value < 0.05 and absolute log2 fold change > 1 were selected as differentially expressed genes. Pathway enrichment analysis was performed using DAVID.

RESULTS

Female ACLs have impaired remodeling response to load: Minimal changes in gene expression were observed at low (2 MPa) and high (8 MPa) loading for both sexes (data not shown). In response to cyclic loading at 4 MPa, male ACLs (n = 5) significantly upregulated anabolic genes (*COL3A1, TIMP1, TIMP3*) ($p < 0.05$) with additional anabolic

genes (*COL1A1, LOX*) trending toward upregulation ($p < 0.1$) (**Fig. 1**). In contrast, when female ACLs were cyclically loaded to 4 MPa (n = 7), there was only significant upregulation of one anabolic gene (*ACTA2*) ($p < 0.05$) (**Fig. 1**). When directly comparing the load-induced gene expression between male and female ACLs, multiple anabolic genes (*COL3A1, TIMP1, TIMP3*) were upregulated in males compared to females, while the anabolic gene *ACTA2* and the catabolic gene *MMP10* were downregulated in male samples ($p < 0.05$) (**Fig. 1**). There was no differential expression of any genes between male and female control samples under static load (data not shown).

Female ACLs have reduced mechanotransduction signaling to load:

In response to 4 MPa load, male ACLs had 760 differentially expressed genes and 80% of those genes were upregulated (**Fig 2A**). In contrast, female ACLs had only 98 differentially expressed genes with 59% of those genes upregulated (**Fig 2A**). In contrast, only 44 genes were differentially expressed between freshly harvested female and male ACLs (**Fig 2A**). Pathway analysis found that male ACLs had 41 signaling pathways enriched in response to load while female ACLs only had 3 enriched pathways (TNF, IL17, PPAR). Of the pathways uniquely enriched in males, 16 of them are mechanotransduction pathways and/or pathways associated with cell-matrix interactions (**Fig. 2B**).

DISCUSSION

This study investigated how female ACLs respond to mechanical loading compared to males in a tissue explant model. Overall, female ACLs had a muted response to mechanical loading. While male ACLs were able to upregulate multiple anabolic genes in response to load, female ACLs were only able to upregulate one. Furthermore, female ACLs had substantially less differentially expressed genes in response to load compared to males (98 and 760 respectively). These differences are despite the fact that there weren't differences in gene expression between male and female ACLs prior to loading. This muted mechanobiological response to load in female ACLs could be partially due to an impaired mechnaotransduction response. While male ACLs had 16 unique pathways enriched associated with mechanotransduction pathways, female ACLs only exhibited one unique pathway associated with mechanotransduction. While we did not observe the estrogen pathway being enriched (as we hypothesized), we did observe pathways involving ERK as/MAPK) and YAP (Hippo) pathways which have been shown to interact with estrogen receptor signaling[9,10]. Together, this study demonstrates that female ACLs have an impaired mechanobiological response to load compared to males, which may help explain the increased rate of ACL tears in women. Future work will directly investigate the role of estrogen in the mechanobiological response of ACLs by treating male ACLs with estrogen and inhibiting estrogen in female studies. Furthermore, future studies will investigate the mechanistic influence of ERK and YAP on ACL tissue remodeling by performing pharmacological perturbations.

IPSC-DERIVED ENDOTHELIAL MULTI-CELL NETWORKS SYNERGISTICALLY MODIFY THEIR BASAL CONTRACTILITY AND EXTRACELLULAR MATRIX IN 3D

INTRODUCTION

Cells modify the local micromechanical environment that they live in. Indeed, we have seen within 3D matrices that newly differentiated endothelial cells (ECs) from induced pluripotent stem cells (iPSCs) migrate towards each other and form networks of connected cells which configure into hollow tubes that resemble capillary networks. [1] Understanding how the mechanical attributes of these cell networks change and affect their microenvironment is key to developing efficacious stem cell therapies for microvascular disease, myocardial infarction repair, and embolism. In our current work, we hypothesize that measurements from 3D traction force microscopy (3D-TFM) experiments can be implemented to develop inverse models to determine how networks of endothelial cells differentially affect their 3D microenvironment (through degradation and collagen deposition) and how their cytoskeletal structure organization is distinct compared to individual cells.

METHODS

We have developed a method for differentiating iPSCs into endothelial cells, which depending on seeding density within 3D gels form into networks composed of single cells, small groups of cells, or large groups of cells that form microvascular-type structures. [2] These cells were seeded into Norbornene-functionalized hyaluronic acid 3D gels at densities that produce single cell distributions and small clusters of cells (Fig 1A). We have previously developed a Gaussian process model to determine how basal cell contractility (the contractile state of the cell when it is in its resting metabolic state) affects displacement of the surrounding 3D gel by implementing traction force microscopy (3D-TFM) [3]. 3D TFM was performed on a Leica laser scanning confocal microscope by imaging cells in their basal state and after treatment with the actin depolymerization agent, cytochalasin-D. In brief, fluorescent microspheres are placed homogenously in the gel and the nearest neighbors principle is applied to track the displacement of the beads, while a live cell stain detects the cell membrane and Hoechst detects the nuclei. This method produced rich 3D displacement fields and cell morphologies.

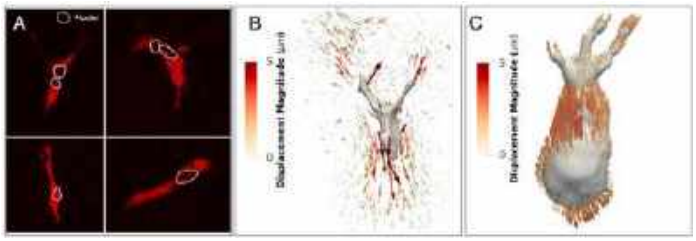

Figure 1: 3D-TFM. A) Maximum intensity for each pixel projected into a flat z-slice. Circles indicate areas of sparse staining at the loci of nuclei. Both single cell and multi-cell networks were analyzed. B) Experimental displacement field of fiducial markers in the local vicinity of the iPSC as measured with FMT. The iPSC surface is reconstructed and shown in white. C) Gaussian-process model interpolation of displacement field onto the cell surface.

To extract the cellular forces, the mechanical properties of the gel need to be accurately known. However, most studies assume the embedded cells do not affect the gel, which is typically not the case. To address this limitation, we have developed an inverse computational model that computes local cell-induced modification of the gel modulus [4]. Using these cell-specific gel mechanical properties, we are then able to utilize an inverse computational continuum model of the internal stress fiber structure of single cells [5] to be able to analyze multi-cell

networks. Eq. 1 delineates our inverse model for extracellular matrix modulus determination:

$$\Psi = \alpha(\boldsymbol{x}_0) * \left[\frac{\mu}{2}(I_1 - 3) - \mu\, ln(J) + \frac{\lambda}{2} ln(J)^2\right] \quad (1)$$

Where $\alpha(\boldsymbol{x}_0)$ is applied to a neo-hookean model, where μ is the homogenous shear modulus, I_1 is the first invariant of the isochoric part of the Right Cauchy Green deformation tensor, J is $det(\mathbf{F})$, and λ is Lame's first parameter. $\alpha(\boldsymbol{x}_0)$ is a scaling parameter that varies spatially over $\boldsymbol{x}_0$ which converges the measured bead displacement to the expected bead displacement if the gel modulus was homogenous. The calculated total strain energy of the system is then divided by the volume of the cell(s) present in the system to determine the amount of strain energy per unit volume.

Eq. 2 defines our inverse continuum model of the internal actin fiber structure of the cell, which accounts for both active and passive contributions of stress fibers:

$$\boldsymbol{T}^{sf} = H(I_4 - 1) * \boldsymbol{T}^p + \boldsymbol{T}^a \quad (2)$$

The Passive stress that arises when fibers are stretched is modeled as

$$\boldsymbol{T}^P = 2\frac{I_4}{J}\frac{\partial \Psi_p^{sf}}{\partial I_4}\boldsymbol{m}\otimes\boldsymbol{m} \quad (3)$$

Where

$$\Psi_p^{sf} = \frac{\mu_{sf}\varphi_{sf}}{2}(I_4 - 1)^2 \quad (4)$$

Application of the Heaviside step function, H, ensures passive stress only from fiber stretch and not compression. The active stress that arises when fibers actively contract is modeled as

$$\boldsymbol{T}^a = f_{sf}\varphi_{sf}\frac{I_4}{J}\boldsymbol{m}\otimes\boldsymbol{m} \quad (5)$$

An objective function combined with the adjoint method is then implemented to fit the model to the data.

Our models therefore account for localized differences in matrix modulus that previous 3D-TFM models assumed were homogenous. Since cells degrade extracellular matrices to grow and move in them while also depositing stiff matrix substances such as collagen, factoring the variation in matrix modulus into our calculations allows us to determine the cell-generated traction forces with much less error. Herein our improved models were implemented to determine the mechanical properties of nuclei, cells, and the microenvironment of 3D multi-cell networks from experimentally measured displacements that occur because of basal contractility (Figure 1B-C).

RESULTS

From our computational models, we found that multi-EC networks, when compared to individual ECs, have roughly four times the strain energy per unit cell volume, an increase in extracellular matrix modification per cell volume, and differing stress fiber orientation that affects basal nuclear shape (Figure 2).

DISCUSSION

These results suggest that networks of iPSC-EC cells work together mechanically in a synergistic manner to form mechanically robust tissues such as capillary beds. The increase in strain energy per unit volume indicates that the cells are more energy dense as clusters. As we have seen here (Fig 3) and previously [1, 2], the number of iPSC-derived ECs in network correlates non-linearly with the amount of matrix modification they produce. In a large enough network, this can even lead to a hollow-space lumen on the inside of the tube of cells, with a high-modulus layer of collagen laid down by the ECs on the exterior of the tube of cells. Further research into the mechanical properties of iPSC-derived ECs will enable us to understand how these cells are able to maintain structural integrity as they highly modify the environment in which they live. This will pave the way for development of stem cell therapies for a variety of diseases where microvascular repair is beneficial.

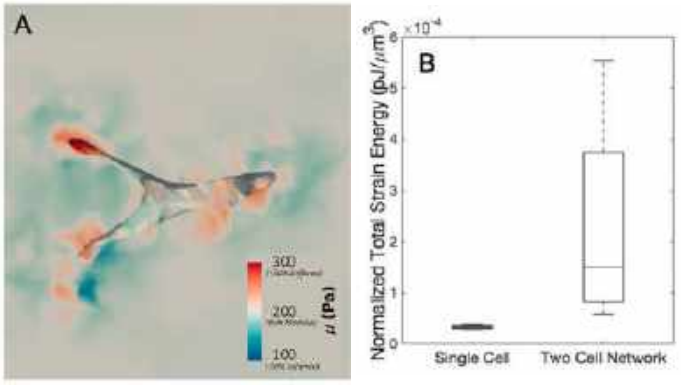

Figure 3: Gel modulus variation and strain energy per unit volume increases greatly in networks of cells. A) Simulated modulus field local to the iPSC. Regions in red are stiffened regions, peaking at around 1.5 times the bulk modulus. Regions in blue show simulated softened hydrogel, which is as soft as 0.5 times the bulk modulus. B) The volume-normalized total strain energy (E_gel) for single and two cell networks increases by a factor of 4 in two-cell networks.

INTRODUCTION

Low back pain (LBP) significantly affects individuals' ability to perform daily life activities [1]. LBP can be caused by facet joint problems [2], [3]. Radiofrequency ablation (RFA) is one of the standard methods to treat this condition [4]. However, the RFA procedure may cause denervation of the multifidus muscle (MF) [5]. In our previous study [6], a musculoskeletal model from AnyBody software was used to evaluate the biomechanics of the spine during different movements. The model simulated the denervation of MF. The results showed that changes occur in the kinematics of the lumbar spine, which may affect the biology of the spine and the strain on the intervertebral disc. This alteration in the mechanobiology can lead to disc degeneration.

To further investigate the effect of the RFA procedure on the intervertebral disc, an anatomical model representing several samples of the lumbar spine would be essential. This model can be provided by statistical shape modeling (SSM), which helps in understanding the spinal mechanics. This investigation aims to create a three-dimensional model that represents the lumbar spine accounting for the average of several samples to be used in finite element analysis (FEA). The purpose of this FEA is to examine the strains of the intervertebral disc under different loads when MF is denervated.

METHODS

In this study, publicly available CT images and 3D lumbar segmentations from the Vertebrae Segmentation Challenge (VerSe) 2020 were utilized [7-9]. A total of 138 lumbar vertebrae from 46 patients were carefully selected. The study ensured a balanced gender representation, with an equal number of male and female patients. The inclusion criteria were centered around CT scans that clearly depicted the L3 to L5 lumbar vertebrae. In contrast, scans were excluded if they showed anomalies such as the lumbar spine terminating at L4 or L6, presence of implants, or inaccuracies in the L5/S1 segmentations.

The VerSe dataset included the original CT scans and the segmented vertebrae (*.nii file type). Using Slicer software and SlicerMorph extension [10], [11], the 3D vertebral segmentations were overlayed onto the corresponding CT scan. This resulted in a combined 3D model containing all the vertebrae as a single object. Using the 'split volume tool' from the 'segmentation editor' module, the model was divided into separate vertebrae and exported (*.nrrd file type).

In the SSM procedure, the segmentations were then processed in ShapeWorks software [12], where they underwent a grooming step to be converted into isotropic meshes (Fig. 1), followed by an optimization step to compute point-based shape models (Fig. 2). These steps were crucial for preparing the data to create the mean of the sample for detailed analysis.

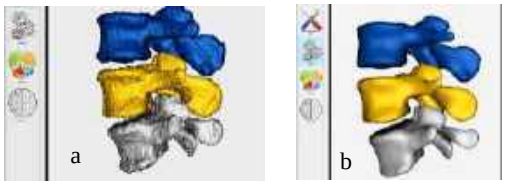

Fig. 1: Lumbar spine model after loading into software (a), and after grooming (b).

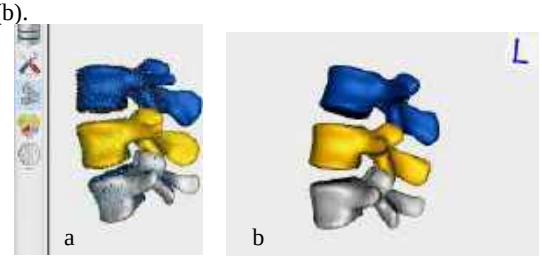

Fig. 2: Optimized lumbar spine model (a), and final mean model (b).

To create the FEA model, the STL files of the vertebrae were imported into a 3D modeling software to create the discs' geometry in between the bones (Fig. 3a). Then, they were imported into Fusion 360 to convert them into BRep models. Next, a 'Boolean cut' operation was performed on the discs to create the interface surface between them and the bone (Fig. 3b). To create the FEA model, Abaqus software was used to partition the discs' internal layers and cartilage endplate inside the disc model and cleaned using 'virtual topology' feature (Fig. 4).

Fig. 3: Creating the disc geometry (a), and performing Boolean cut operation (b)

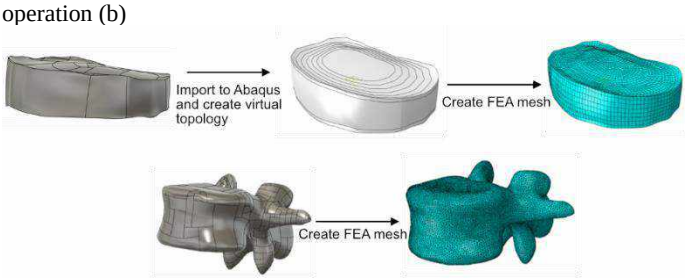

Fig. 4: Generation of FEA mesh in Abaqus

RESULTS

Using this method, 46 statistical shape models (23 per gender) were created for the lumbar spine containing each of the L3, L4, and L5 vertebrae. Each vertebrae represented the mean of the male, female, and combined samples (Fig. 5a). Upon preparing the vertebrae for FEA, two intervertebral discs were created in the joints between each of the L3-L4 and L4-L5 vertebrae. The discs comprised of hexahedral elements. Meanwhile, the vertebrae were made of tetrahedral elements due to their complexity. On the other hand, the resulting endplates were made of shell elements. The final model contained the vertebrae and discs connected by tie constraints. (Fig. 5b)

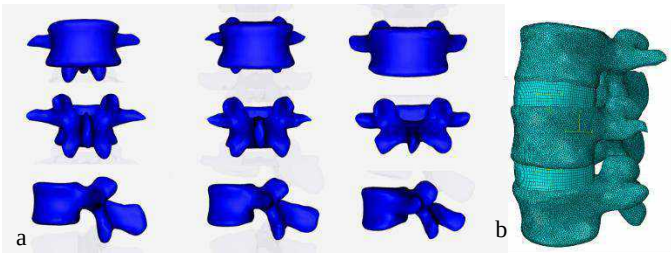

Fig. 5: The lumbar vertebrae SSM of the combined overall sample (a), meshed FEA model of discs and vertebrae.

DISCUSSION

The creation of 3D models representing the spine has been used in several fields. For example, previous research used CT scans and 3D models of the lumbar spine to 3D-print vertebrae [13]. Also, these models were used for visualization of human biomechanical simulations [14]. Moreover, 3D models have been utilized and built for FEA [15]. This study demonstrated how to achieve the average of lumbar vertebrae for usage in applications such as FEA.

The mean of L3L4L5 vertebrae was used to build an FEA model to study the stresses and strains on the intervertebral disc. The advantage of this method, compared to studies that used numerous samples for analysis [16], [17], is the efficiency and simplicity of analyzing a single 3D model. Moreover, the single model represents the average of different samples; thereby, it contains information on the vertebral morphology concisely. The mean model was also visualized clearly to identify the general morphological patterns of the lumbar vertebrae. This method utilized multiple 'domains' analysis so each of the L3L4L5 vertebrae is analyzed separately from other vertebrae. Therefore, the final results do not combine the L3, L4, or L5 vertebrae for more accurate evaluation.

CONCLUSION

This method illustrates the steps to utilize segmentations from CT scans and lumbar vertebrae SSM to create the mean of a sample of L3L4L5 vertebrae for use in FEA. Using this technique can exploit the simplicity and efficiency of 3D software to achieve the best representative average 3D model of other anatomical human parts for further concise yet comprehensive evaluation.

INTRODUCTION

Computational modeling and simulations of patient-specific vascular anatomies are increasingly used to support personalized interventional treatment planning [1]. In angioplasty applications, these tools allow clinicians to non-invasively test different stent and ballooning configurations and simulate the resulting hemodynamics to design optimal treatment strategies [2]. Computational models are not yet routinely used in clinical practice, however, despite these predictive advantages. One of the key bottlenecks preventing routine application is the difficulty of editing the geometry of the anatomical models to reflect the pre-operative and post-operative shapes of the vessels.

In traditional image-based modeling pipelines, a patient-specific vascular anatomical model is created by segmenting 2D contours of the vessels from CT or MRI scans [3]. To perform virtual interventions on the model, segmentations are often edited to produce the post-interventional shape. Segmentation-editing, however, is generally a manual and laborious process, as the segmentations must be carefully updated to prevent intersections between different contours on a single vessel branch, while ensuring that segmentations of daughter branches are fully encapsulated within the segmentations of the parent branch. This makes automated segmentation-editing particularly challenging. In scenarios where multiple stenting configurations need to be explored, such as in treatment planning for patients with multiple peripheral pulmonary stenoses, a common abnormality in patients with Alagille and Williams syndrome, this segmentation-editing procedure must be painstakingly reperformed for each intervention.

We propose a novel framework for automated stenting of virtual vascular anatomies via physics-informed simulations to overcome these challenges. Algorithm 1 shows a high-level overview of our framework. Our framework directly deforms the mesh of the models and enables us to obtain the post-operative vessel shape without segmentation-editing.

METHODS

We morph the stenosed geometry of an input model into its stented shape by simulating the stenting process using Extended Position Based Dynamics (XPBD) [4]. XPBD is a physics-based technique commonly used by the computer graphics community for simulating deformable objects. XPBD represents the objects as particle systems and simulates their motions according to Newton's 2nd law. The vertices of the meshes correspond to the particles in our framework. XPBD begins by applying external forces, such as gravity, to the particles to update their positions (lines 2–3 of Algorithm 1). Internal forces are then applied via an iterative "constraint projection" step (lines 7–8). In XPBD, constraints are functions that govern the material properties of the deformable objects. The velocities of the particles are updated afterwards.

```
(1) For each timestep:
(2)   For all particles:
(3)     Update positions from external forces
(4)   Inflate stent and update SDF
(5)   Find collisions between SDF and vessel mesh
(6)   Add collision constraints
(7)   For each constraint:
(8)     Project constraint and update positions
(9)   For all particles:
(10)    Update velocities from updated positions
```

Algorithm 1: Overview of the virtual stenting framework

We model the internal mechanical behavior of vasculature using geometric constraints. Namely, we use distance and bending constraints, two constraints commonly employed for simulating thin, membranous materials in XPBD [5, 6]. Distance constraints control the amount of stretching of edges in a mesh, while bending constraints govern the degree of bending between adjacent triangle elements.

As stenting is naturally a collision-based process, in which a stent collides with and interacts with a blood vessel, we also include collision

constraints. We model the stent, which has a cylindrical shape, using a signed distance field (SDF). Representing the stent as an SDF, rather than as a mesh, reduces the cost of collision detection. At each time step in the simulation, we radially inflate the stent and search for collisions between the SDF and mesh of the vascular anatomy. Found collisions are then applied using vertex-normal constraints [5].

RESULTS

We illustrate the results of our stenting framework in Figure 1. This figure illustrates stenting in three distinct patient-specific models: an aortic coarctation model and two pulmonary models with peripheral arterial stenoses. The pulmonary models correspond to patients with Alagille syndrome [2]. These models were obtained from the Vascular Model Repository, an open-source collection of patient-specific cardiovascular models [7].

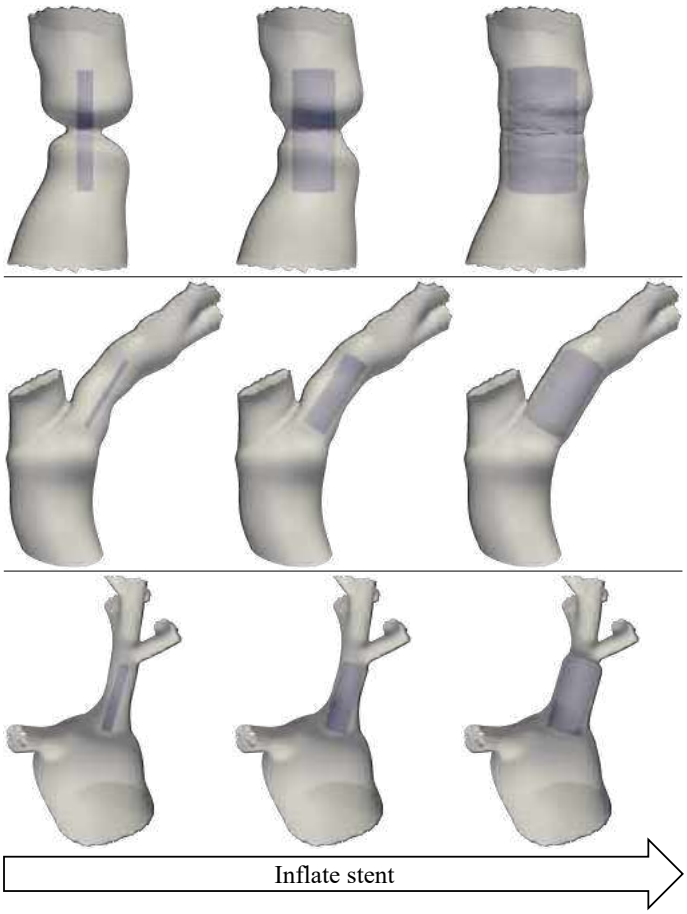

Figure 1: Stents (blue) are placed in the stenosed regions of a patient-specific aortic coarctation model (top) and two pulmonary models (middle and bottom). As the stents inflate to a user-specific diameter, as shown from left to right, they collide with the vascular walls and deform the vessels to relieve the stenoses.

Before applying our framework, we remeshed each model to obtain a uniform mesh resolution, clipped the models to the regions neighboring the stenoses, and applied fixed boundary conditions at the clipped boundaries. We limit our simulations to these sites, which are the regions where the stenting deformations would occur, to reduce their computational expense. With this, each simulation takes only several minutes to run on a standard desktop computer with a single processor.

As we observe Figure 1, the stenosed, pre-operative vessels deform with inflation of the stents and expand to their alleviated, post-operative shapes. We note that the final, deformed meshes do not exhibit any issues with mesh self-intersection.

DISCUSSION

Our methods enable stenting of patient-specific blood vessels using simulation-driven techniques. Such capabilities will enable users to circumvent the need for laborious, manual editing of segmentations. Our framework works well across a wide range of vascular anatomies, as illustrated for the aortic and pulmonary vessels (Figure 1).

One primary advantage of our framework is the ability to parameterize the angle, length, and diameter of the deployed stent. This feature, when coupled with computational fluid dynamics simulations, will allow interventional cardiologists to parametrically and automatically alter stent configurations and quantify the resulting hemodynamic impact. In the example of Alagille and Williams patients with multiple stenoses, such automation will make it significantly easier to create numerous models reflecting different stent designs. This will ultimately help clinicians better optimize treatments for their patients.

The parameterizability of the stent configuration also enables uncertainty-aware planning. By connecting our virtual stenting framework to a robust uncertainty quantification platform [8], uncertainties in the final deployed stent diameter, for example, can be analyzed and used to obtain confidence intervals in the resulting hemodynamics. These confidence intervals will help clinicians assess the viability and success rates of their interventional strategies.

A limitation of our stenting framework, however, is that it can only simulate "rigid" stents, stents that maintain their original orientation and curvature in their fully inflated state. Such rigid mechanical behavior is commonly found in closed-cell stents [9]. Two-way coupled interaction between the stent and the vessel is needed to increase the longitudinal flexibility of the stent and allow it to conform to the curvature of its corresponding vessel, as is commonly characteristic of open-cell stents. To achieve this, we will represent the stent as a mesh and apply collision constraints between vertices and triangle elements of the stent and vessel meshes [5] in future work.

UNRAVELLING THE STRUCTURAL MECHANISMS UNDERLYING AGING-AUGMENTED RISK OF AORTIC DISSECTION

INTRODUCTION

Understanding of the risk factors and underlying mechanisms of aortic dissection (AD) is critical for improved clinical management of the disease. Aging is a prominent risk factor for AD as it increases the incidence and mortality [1] due to impaired aortic interlamellar bonding [2]. However, structural mechanisms of the compromised dissection resistance capabilities in the aging aorta have not been elucidated. Given the dominant role of collagen fibers in maintaining aortic interlamellar integrity [3], we hypothesize that aging-associated structural rearrangement of interlamellar collagen dictates the elevated AD propensity. AD propagates with avalanche-like failure of interlamellar fibers and exhibits a power-law distribution of force drops with an exponent that is closely associated with the mechanical and structural properties of interlamellar fibers [5]. However, quantitative imaging assessment of interlamellar collagen structure is challenging due to the inhomogeneity of interlamellar collagen distribution [3] as well as the obliqueness, dispersion and undulation of collagen orientation [4]. Our previous study using an innovative finite element (FE) model of dissection propagation that captures the rupture of discrete collagen fibers recapitulated the power-law behavior and revealed that the inhomogeneous distribution of interlamellar collagen fibers is the origin of such phenomena [5]. Furthermore, the power-law behavior and exponent could serve as a novel indicator of interlamellar structural characteristics. By recapitulating the power-law behavior observed from experimental testing with FE modeling, this study aims to delineate the structural mechanisms of aging-augmented risk of AD.

METHODS

Human descending thoracic aortas (DTAs) ranging from 24 to 92 years of age were divided into three age groups: <40 years (n=4), 40-60 years (n=6), and >60 years (n=7). Peeling test was performed on samples obtained from each aorta with a rate of 0.2 mm/s in both the circumferential and longitudinal directions. Figure 1a shows a representative curve of peeling force/width versus displacement and the mean peeling force/width (F_m/W). The energy release rate (G_c) was calculated by subtracting the elastic energy stored in each sample from the total work done by the peeling force [6]. Magnitudes of drops of peeling force/width ($\Delta F/W$) were collected. The probability density distribution of $\Delta F/W$ of each age group was analyzed to assess the power-law behavior and corresponding exponent β.

A two-dimensional (2D) FE model in which adjacent elastic lamellae were connected by discrete interlamellar collagen fibers [5], was used to simulate dissection propagation (Figure 1b). The elastic lamellae were meshed with four-node 2D elements and described by a neo-Hookean constitutive law. Interlamellar fibers were modeled with Timoshenko beam elements and followed an exponential stress-strain relation [7] with failure strain uniformly ranging between 0.107 and 0.207 [8]. AD was simulated by prescribing opposite horizontal displacement for the top ends of the lamellae, and the sum of nodal forces at the right top end was taken as the simulated peeling force. For each age group, the interlamellar distance (d) was obtained by dividing the difference between total media thickness [9] and total lamellae thickness by the number of interlamellar spaces [10], while the lamellar stiffness (μ) was obtained by matching the neo-Hookean strain energy density to the elastic energy storage per unit tissue volume during peeling. The density and degree of angular dispersion (θ) of interlamellar collagen fibers were tuned to fit the power-law exponent β from simulations to that of the experimental results. Within each age group, equal number of interlamellar fibers was assumed for the circumferential and longitudinal directions, while θ was independently tuned for each direction.

RESULTS

The mean F_m/W and G_c decreased with aging (Figures 2a and 2b). Power-law behavior was identified in all age groups in both the circumferential and longitudinal directions, as shown by the prominent

linear decrease on a log-log plot of the probability density distribution spanning almost two decades of ΔF/W (Figure 2c). In the circumferential direction, β increased from 1.35 to 1.55 and then to 1.74 for the <40, 40-60, and >60 years groups, respectively. In the longitudinal direction, β decreased from 1.49 to 1.46 and then to 1.17.

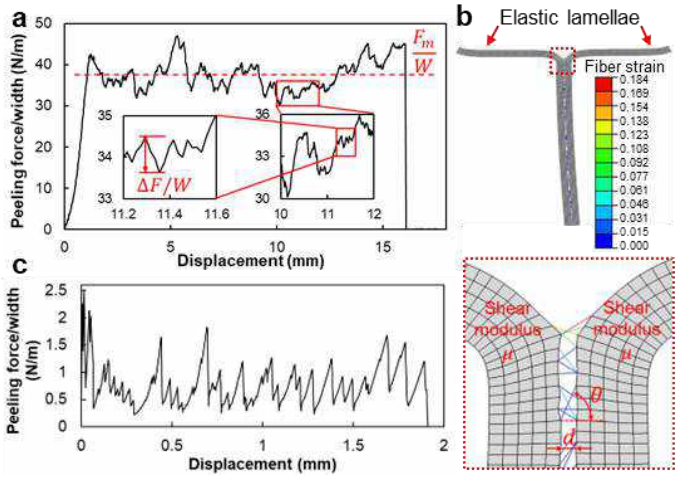

Figure 1: (a) A presentative curve of peeling force/width - displacement and zoom-in graphs showing peeling force oscillation and ΔF/W. (b) FE model of AD with contour plot of fiber strain in the interlamellar fibers. (c) A representative peeling force/width - displacement curve obtained from FE simulation.

The fluctuations of peeling force were reproduced by the FE simulations (Figure 1c), in which both the power-law behavior and associated exponent β of dissection propagation were also recapitulated for all age groups (Figure 2c). The estimated number of interlamellar fibers decreased with aging from 450 to 350 and then to 250 for the <40, 40-60 and >60 years groups, respectively. In the circumferential direction, θ increased from 27° to 56° and then to 68° for the three groups, respectively; in the longitudinal direction, θ remained 27° from the <40 to the 40-60 years groups and increased to 68° for the >60 years group. For both directions, a strong and positive correlation was found between the number of interlamellar fibers and G_c ($p<0.05$), see Figure 2d. No significant correlation was found between θ and G_c.

DISCUSSION

Aging diminishes the dissection resistance capabilities of the lamellar layers within the media of human DTA, in accordance with previous clinical [1] and biomechanical [2] results. The significant decrease of F_m/W and G_c in the >60 years group (Figure 2a and 2b) also agrees well with the mean age of 63 years of AD patients [1]. Therefore, age is a critical factor for AD risk stratification.

Power-law behavior was identified in aortas of all age groups. Interestingly, the corresponding exponents are within the range of avalanche behavior of self-organized criticality [11]. Avalanches occur when a group of fibers at the dissection front transfers accumulated strain energy to subtended fibers which immediately reach their failure strain and break instantaneously. This explains the rapid propagation of AD. The power-law behavior and exponent are a powerful tool toward a quantitative evaluation of interlamellar fiber structure and an in-depth understanding of aortic pathology.

The reduction of interlamellar collagen density in the >60 years group is largely responsible for the higher risk of AD in the elderly population based on the strong correlation between the number of interlamellar fibers and G_c (Figure 2d). Aging-induced extracellular matrix remodeling may impair collagen recruitment to the interlamellar space. The decrease of collagen undulation with aging could reduce the length of radially running segments along a wavy fiber that is oriented in the circumferential-longitudinal plane and thus reduce its chance of being recruited under transmural tension. Also, elastin fragmentation with aging could decrease the connectivity between collagen and elastic lamellae and reduce the number of load bearing interlamellar collagen.

Interlamellar collagen dispersion triggers the power-law behavior in AD propagation [5], which is enhanced by aging. Although such effect has not been demonstrated before, as a major predisposing factor for AD, aneurysm significantly increases interlamellar collagen dispersion [12]. Further investigations into interlamellar fiber dispersion are needed given its fundamental role in AD propagation and a potential marker for aortic health assessment. In conclusion, a prominent aortic interlamellar structural rearrangement of collagen occurs with aging, including lower density and higher dispersion, of which the former diminishes interlamellar bonding while the later is vital in triggering the fast propagating avalanche behavior of AD.

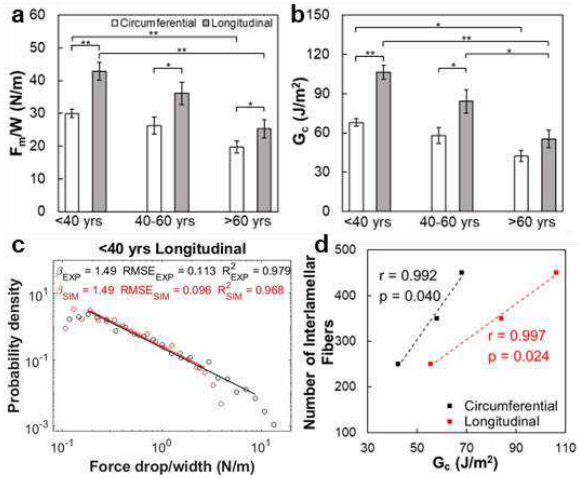

Figure 2: (a) Changes of F_m/W and (b) G_c of DTA media with aging. Error bars represent standard error of the mean ($^{*}p<0.05$, $^{**}p<0.01$). (c) A representative log-log plot (<40 circumferential) of the probability density distribution of ΔF/W from experiment (EXP) and simulation (SIM). The lines represent the power-law fit to the data. The goodness of fit is assessed by the root mean square error (RMSE) and coefficient of determination (R^2). (d) Correlation between the number of interlamellar collagen fibers and G_c. The linear fit is shown with the Pearson's correlation coefficient r and p-value of the correlation.

PRECONDITIONING IMPACT ON PORCINE CORNEAL BIOMECHANICS

M.E. Emu (1), H. Hatami-Marbini (1)

(1) Mechanical and Industrial Engineering, University of Illinois Chicago, Chicago, IL USA
Email: hatami@uic.edu

INTRODUCTION

The eye, an intricately designed organ, undergoes continuous rotational and translational motion within its orbital gimbal suspension, facilitated by multiple extraocular muscles. The cornea, a vital component, maintains structural integrity and optical properties, with its stromal layer constituting 90% of its thickness, comprising collagen fibrils, proteoglycans, and a cellular matrix [1, 2]. Previous studies visualized corneal microstructure, revealing collagen fibril orientations. While uniaxial tensile loading assessed biomechanical properties, biaxial loading and whole-globe inflation offered a more realistic representation of tissue behavior [3].

Preconditioning, releasing residual stress, is essential in biomaterial characterization [4]. Its significance in corneal biomechanics, especially under biaxial loading, is largely unknown. The cornea, associated with the sclera and optic nerve, undergoes deformation and mechanical loading, with repetitive strain injuries and myopia-induced changes [5]. Understanding preconditioning's influence on corneal biomechanics is crucial for managing myopia-related corneal changes.

Our study aims to examine preconditioning's impact on porcine corneal biomechanics using biaxial tests. We seek a comprehensive understanding of how preconditioning influences the cornea's mechanical response in multiple directions, evaluating its anisotropic nature under physiological loading scenarios.

METHODS

Fresh porcine eye globes, obtained from a local abattoir, were carefully transported to the laboratory. After tissue removal, a 2 mm scleral-corneal ring was excised from each globe, resulting in 20 samples. These were divided into preconditioned and nonpreconditioned groups. Using a double-blade cutter, samples were transformed into mm squares for planar biaxial testing (Figure 1). After soaking in a PBS solution to achieve the desired thickness, measured with a pachymeter to ensure similar thickness for preconditioned and non-preconditioned specimens.

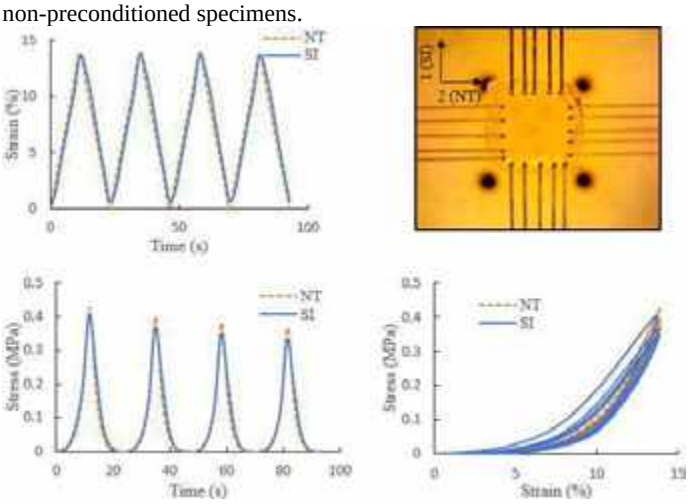

Figure 1: Preconditioning curve and biaxial test setup with Bio-Rakes for secure sample fixation.

Mechanical tests utilized the "ElectroForce TestBench" system, with modified grips for secure fixation of square corneal strips using bio-rakes. These grips, preferred for their speed and moisture preservation, facilitated secure sample attachment. Strain measurement relied on grip position or Digital Image Correlation (DIC), showing comparable results. Displacement control tests were chosen over load control tests, performed at various stretch ratios and displacement rates. Preconditioning involved four loading-unloading cycles, maintaining tissue integrity and reproducible responses. Strain rates and levels, relaxation time, and cycle counts were carefully selected to prevent tissue damage while ensuring accuracy. Samples were pre-stressed at

0.02N and underwent preconditioning cycles before equibiaxial strain at 2 mm/min. Non-preconditioned samples followed a similar process without preconditioning cycles. Continuous hydration using a PBS spray, maintained sample thickness for consistent testing conditions and reliable mechanical property measurements.

Data analysis encompassed meticulous processing in Microsoft Excel and statistical analysis using SAS Analytic Software. Normality of specimen groups was assessed via the Shapiro-Wilk test. Subsequent t-tests and ANOVA tests, with a significance level of α=0.05, determined statistical differences between groups.

RESULTS

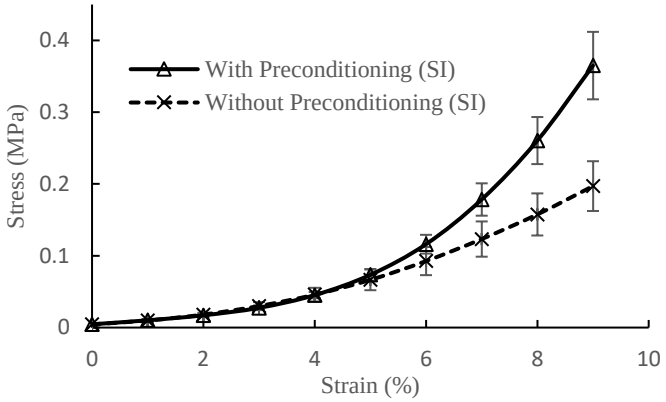

Figure 2: Stress-strain curve comparison of preconditioned and non-preconditioned porcine corneal stroma at equibiaxial strain ratio. The vertical error bars represent the standard deviation.

Our focus was on preconditioning's impact on corneal biomechanics, particularly elasticity and extensibility. Figure 2 showcases stress-strain curves of the porcine cornea in the superior-inferior direction under equibiaxial loading. It was seen that the stress increased nonlinearly with tensile strain in both preconditioned and non-preconditioned corneal specimens. We also observed no directional anisotropy in the tensile behavior of the cornea, and stress-strain behavior in the SI and NT directions was almost similar.

Peak stress values for superior-inferior (SI) and nasal-temporal (NT) directions were determined. For example, with preconditioning, the SI direction had 0.37±0.05 MPa peak stress and without preconditioning, it showed 0.20±0.04 MPa.

The tangent moduli were also determined from Figure 2 across different strain levels. At lower strains (3%), preconditioning showed no significant effect. However, at higher strains (>3%), preconditioning significantly influenced the cornea's mechanical response.

DISCUSSION

Our study aimed to explore how preconditioning affects corneal biomechanics, focusing on elasticity and extensibility. Analyzing stress-strain behavior in equibiaxial-loaded porcine corneas, we found a distinct nonlinear stress increase, revealing no directional anisotropy. Peak stress values for different directions showed significantly higher levels with preconditioning, aligning with previous ocular tissue studies [6]. This consistency underscores preconditioning's crucial role in understanding these tissues' biomechanics. Additionally, our analysis revealed higher stress and modulus due to preconditioning, particularly at higher strain levels. However, at lower strains, the effect on the modulus was not statistically significant. These findings enhance our understanding of corneal biomechanics, emphasizing preconditioning's role in its mechanical response.

Preconditioning ensures consistent results in biological material testing, but its impact on corneal tissue remains unclear. Our study investigated this using equibiaxial testing at varying strain levels. At lower strains, preconditioning didn't significantly affect corneal tissue, but at higher strains, it notably altered the tissue's behavior, potentially impacting overall biomechanics. This aligns with previous research on human sclera [6]. Collagen fiber features, observed in Transmission Electron Microscopy (TEM) images (Figure 3), might explain preconditioning effects. Crimped collagen fibers transitioned to an uncrimped state during loading cycles, impacting strains at higher levels. However, at lower strains, this transition may not occur fully, explaining the lack of significant effect on corneal strength. These findings highlight the intricate relationship between preconditioning, collagen organization, and corneal biomechanics, urging further research for implications in surgeries and biomaterials.

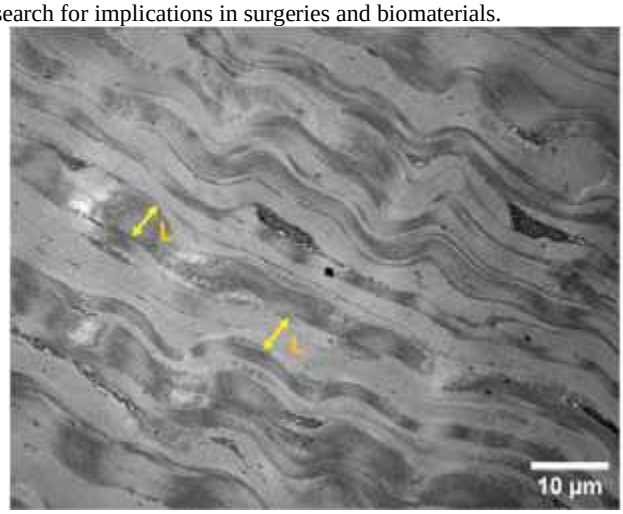

Figure 3: TEM analysis of porcine cornea reveals lamellar (L) structural features in NT (out-of-plane) and SI (in-plane).

While effective, our biaxial loading system has limitations. Unlike studies using digital image correlation (DIC), we prioritized grip position for strain calculation, leveraging a rigid gripping system for comparable results. A limitation includes the lack of control over porcine age and breed, introducing variability. Preload discrepancies due to corneal curvature were addressed by focusing on elastic modulus comparisons in each direction. A large sample size aimed to minimize individual variations. Despite peak strains of 9-11%, considered low for soft tissues, our study captured the corneal stress-strain curve trend. Though limited, our findings offer valuable insights into corneal biomechanics, emphasizing preconditioning's role in ocular tissue characterization.

INTRODUCTION

Mechanical Heart Valves (MHVs) have undergone tremendous design improvements in the past few decades. Their current commercially most preferred designs are termed Bileaflet MHVs (BMHVs), being used in about 20% of the total aortic heart valve replacement surgeries every year [1]. The use of BMHVs has been widely associated with platelet activation [1-2] and thrombotic complications. Consequently, the valve's recipient is necessarily required to undergo life-long anticoagulation therapy [3].

In efforts to reduce the thrombogenic potential of MHVs, several designs of Trileaflet MHVs (TMHVs) have been proposed that offer an inherently improved hemodynamics owing to their design [4]. To the best of our knowledge, however, there are no published studies on the comparison of the cardiac mechanics and hemodynamics of a TMHV and a BMHV, carried out under similar numerical and experimental conditions. Such studies are needed to provide a validation of the employed numerical methodology, so that it could be extended to obtain further highly resolved, unprecedented insights into the cardiac performance of the two MHVs. In this research, we present a comparison of the numerical simulations and experimental measurements of a TMHV and a BMHV under similar conditions.

METHODS

The TRIFLO Valve (Novostia, Switzerland) and the On-X Valve (Cryolife Inc., USA) have been respectively modelled as the TMHV (Figure 1a) and the BMHV (Figure 1b) in this study.

For the numerical assessment, the continuity equation and the Navier Stokes equations constitute the set of governing equations. The Curvilinear Immersed Boundary (CURVIB) method has been used as a flow solver [1,3], strongly coupled to a Fluid-Structure Interaction (FSI) algorithm for calculating the leaflet kinematics of the MHVs. The *In-Vitro* measurements of the MHV flow fields have been performed in a validated pulse duplicator with a multi-view imaging system for Tomographic Particle Image Velocimetry (Tomo-PIV) [5]. The flow is computed as an ensemble-average over 200 consecutive beats. The Refractive Index Matched (RIM) fluid for the Tomo-PIV experiment has been obtained by mixing a water/glycerol/NaCl solution, with a respective weight ratio of 0.494:0.340:0.166. The dynamic viscosity 5.6 of mPa/s and the density of 1200 kg/m^3 in experiments match the fluid parameters in the numerical simulations.

Figure 1: (a) the TMHV (b) the BMHV

RESULTS

Figure 2 compares the projected areas of the TMHV and the BMHV, which is an indicative parameter of their leaflets' kinematics.

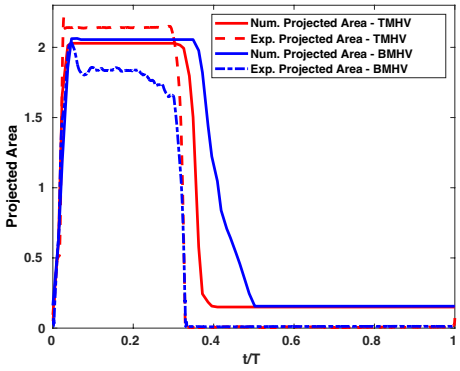

Figure 2: Comparison of the projected areas

An excellent agreement is observed between the numerical and experimental projected areas for the TMHV and BMHV during the valves' opening phase (t/T < 0.05). Numerically, upon fully opening, the TMHV and BMHV demonstrate a constant projected area of 2.0290 cm^2 and 2.0634 cm^2, respectively. Experimentally, while the TMHV has a constant projected area of 2.215 cm^2 after fully opening, a decline in that is observed for the BMHV. The fractional difference between the numerical and experimental maximum projected areas of the TMHV is 8.2945%, whereas that for BMHV is 11.32%. While both valves start to close simultaneously during the forward deceleration phase of the cardiac cycle in experiments, numerically we observe a subtle difference. The TMHV leaflets in numerical simulations start to close during late systole whereas the BMHV leaflets begin their closing excursion at the onset of regurgitation. In addition, the projected areas of the two valves reduce to zero in experiments, while to a minimum of 0.15 cm^2 in the numerical simulations. This difference could be attributed to a limitation of the employed numerical method, i.e., the upstream and downstream regions of the valves must be simply connected for the Pressure Poisson solver to converge. Therefore, a small opening must be provided in the numerical TMHV and BMHV models while they realistically should be 'fully closed'.

Figures 3 and 4 respectively compare the streamwise velocities for the TMHV and BMHV at peak systole, plotted at three different lines (as shown on the contours) to facilitate a quantitative comparison.

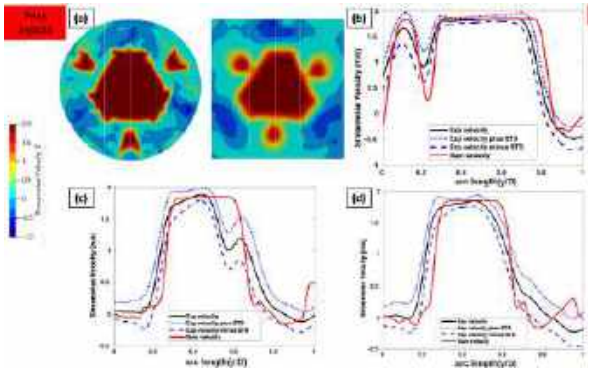

Figure 3: Comparison of velocity profile for the TMHV

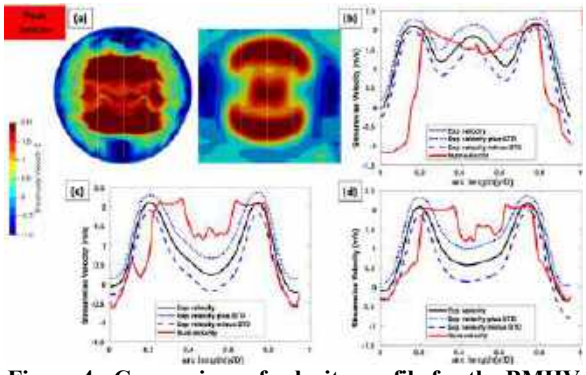

Figure 4: Comparison of velocity profile for the BMHV

The TMHV demonstrates a strong central jet, that dominantly covers the arc lengths of the three lines, alongside three narrower lateral jets. For the central (Figure 3b) and the right line (Figure 3d), we observe that the numerically calculated streamwise velocity is in excellent agreement with the averaged, experimentally measured streamwise velocity for the central jet ($0.25 < y/D < 0.85$), whereas lies mostly within the Root Mean Square (RMS) of the experimental velocity fluctuations for the lateral jet ($y/D < 0.25$ or $y/D > 0.85$). The differences on the left line (Figure 3c) could be attributed to the slight misorientation of TMHV in experiments relative to simulations.

For the BMHV, from the contours at the peak systole (Figure 4a), we numerically observe that the central jet has a diffused shape in comparison to the side jets. Similarly, the central jet seems to be narrower and weaker than the side jets, and only extends to the central lumen region in experiments. For the central line (Figure 4b), both numerical simulations and experimental measurements demonstrate higher streamwise velocities in the side jets relative to the central jet. The numerical simulations also predict higher adverse streamwise velocity compared to experiments in the region encompassing the aortic sinuses as the end points of the central line extend to regions of high adverse velocity. For the left line (Figure 4c) and the right line (Figure 4d), although the numerically predicted maximum streamwise velocities in the side jets are in good agreement with the experimental measurements, the numerical velocities exceed the RMS fluctuations of the experiments in the middle region of the two lines ($0.2 < y/D < 0.7$). This discrepancy could be explained based on the previously discussed lesser/reduced extension of the central jet in the experiments compared to the numerical simulations, not extending to the points covered by the left and the right lines.

DISCUSSION

We compare the numerical simulations and experimental measurements of leaflet kinematics and hemodynamics of a novel TMHV design against a BMHV. While we obtain a good agreement in the numerical and experimental predictions of opening kinematics of the two valves, striking differences exist during the closing phase. Numerically, the TMHV leaflets start to close during forward deceleration while the BMHV leaflets wait for the reversed flow to begin their closing excursion. The delayed closure of BMHV has been previously reported by several studies [1-4] and can have adverse effects on the performance of the heart. Experimentally, both valves start to close simultaneously by late systole, which is in contradiction with previous findings on other BMHVs. The early closure of the TMHV, observed both numerically and experimentally, is a desirable feature.

The flow field of the TMHV is dominated by a strong central jet, resembling that of natural/tissue valve [3]. The magnitudes of the numerical streamwise velocities are either in excellent agreement over the arc lengths or deviate while staying within the RMS fluctuations of experiment. For the BMHV, the qualitative trends look similar in numerical simulations and experiments, such as generation of tri-orifical jets and a weaker extension of central jet compared to side jets. The trends on the streamwise velocities plotted over lines slightly differ between the numerical simulations and experiments for the BMHV, likely due to the misorientation of the valve in two setups. The validated numerical setup could now be employed to quantify parameters that are difficult to be experimentally measured, for instance, clotting potential.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a well-established, minimally invasive treatment for severe aortic stenosis. The number of TAVR procedures has surpassed surgical aortic valve replacement (SAVR). TAVR is now expanding to younger patient cohorts and is being used to treat patients with bicuspid aortic valve (BAV) [1,2]. However, TAVR is associated with several clinical complications, including long-term, life-threatening thrombotic events that may be a consequence of prolonged exposure of platelets to elevated cyclic stresses. These risk factors may be exacerbated in BAV patients due to the complexity of bicuspid anatomy that often leads to improper deployment of TAVR device stent frames and leaflets in an elliptical annulus, as opposed to circular annuli in conventional trileaflet aortic valve (TAV) patients. Under-expansion of the device can cause the leaflets to perform poorly, as the opening orifice area is greatly reduced along with excessive leaflet flutter during systole. During diastole, paravalvular leaks occur due to poor device sealing post-deployment which is largely affected by calcium deposits on the native BAV leaflets. All these factors cause elevated flow velocity profiles and jets that can cause shear stress on platelets, leading to stress accumulation and subsequent activation [3].

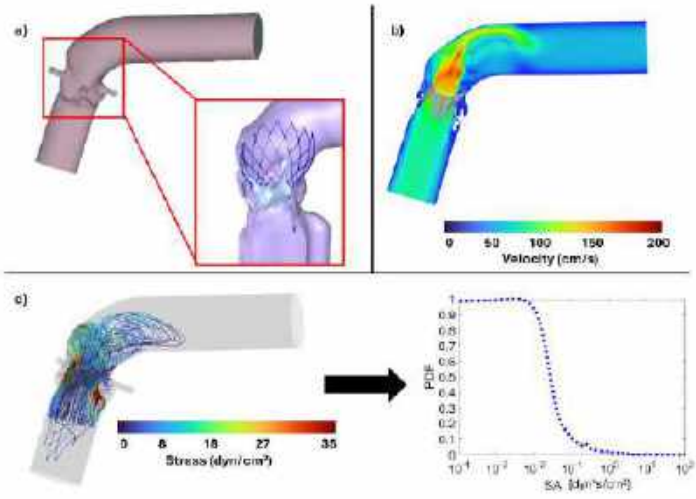

Figure 1. a) Patient-specific FSI geometry with deployed TAVR device shown. b) Flow results showing a contour plot for flow velocity. c) Contours of virtual platelet stresses plotted on the trajectories (left) along with the respective PDF profile (right).

Flow-induced thrombogenicity increases the risk of platelet activation, and microthromboemboli formation can lead to a range of complications, from prosthetic leaflet thrombosis to embolism and stroke [1,2,3]. The rapid expansion of TAVR in BAV patients highlights the importance of developing alternatives to current tissue-based TAVR devices that suffer from structural deterioration and thrombus formation – leading to poor functionality and efficacy for the long-term in these patients, which is evident after just 30 days from reports of significantly higher occurrence of stroke in BAV patients [4]. Here we examine and compare thrombogenicity of a current commercial TAVR device deployed in three BAV patients with varying degrees of eccentricity and anatomical complexity, demonstrating the utility of our novel fluid-structure interaction (FSI) workflow for detecting thrombogenic risk. This also further motivates designing a novel BAV-specific device.

METHODS

The patient-specific *in silico* models used in this study for FSI were reconstructed from three type 1 BAV patients that received a 29-mm self-expandable TAVR [5]. De-identified preoperative CT scans of these patients were obtained from Rabin Medical Center (Petah Tikva, Israel) under Stony Brook IRB approved protocol (522113). ScanIP

(Synopsys, Mountain View, CA) was used for segmentation of the relevant patient geometries (Fig. 1a). To validate the FSI models, a 3D printed replica of one BAV patient was created and the TAVR device was deployed inside following the clinical procedures performed in these patients [6]. Flow data was collected *in vitro* using a left heart simulator (VivitroLabs, Inc., Victoria, BC). The patient-specific TAVR device deployment was then modeled *in silico* (ABAQUS Explicit v2022, Dassault Systèmes, Vélizy-Villacoublay, France) and FSI simulations were created and run using LS-Dyna (ANSYS, Canonsburg, PA) such that the *in vitro* and *in silico* flow rates could be compared. The thrombogenic risk analysis was then conducted by taking the three post-TAVR deployment (29-mm Evolut R) patient models and configuring each with a physiological pressure gradient waveform. Each FSI simulation was conducted for three beat cycles and the flow data was collected (Fig. 1b). Each FSI simulation was then post-processed using EnSight (ANSYS, Canonsburg, PA) in which ~50,000 virtual platelets were seeded in the flow (Fig. 1c). Stress accumulation (SA) was calculated and tracked for all the seeded platelets. Continuous seeding was done to accurately model new platelets introduced into the flow [7]. The probability density function (PDF) of the accumulated stresses of the large population of flowing platelets was then computed for each patient, which represents the unique "thrombogenic footprint" for the TAVR device in the respective patient [7]. To analyze the thrombogenic potential of the device in the different BAV patients, PDFs were compared amongst each other - along with tabulated SA data – with Hellum's criterion considered.

RESULTS

The flow velocity profiles showed peak systolic jet velocities over 200 cm/s. The highest velocities were found near the centerline of the flow in addition to near the wall of the upper aortic arch, where the flow was directed (Fig. 2). Recirculation zones were observed near the

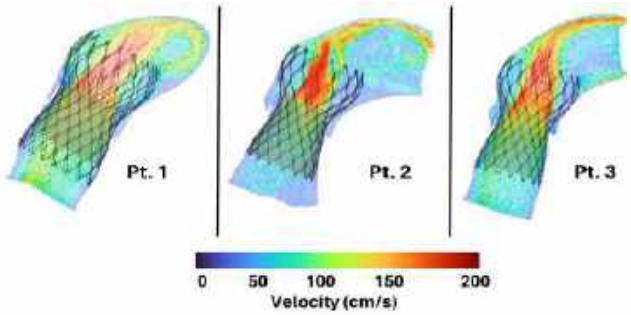

Figure 2. Peak systolic flow velocity in each patient model.

sinuses of the patient models and at the initial bend of the aortic arch. Paravalvular leak (PVL) was observed in all patients, with velocities reaching over 250 cm/s through these gaps. Based on the flow results, thrombogenic risk simulations were then performed. The virtual platelets experienced the largest stress values near the surfaces of the leaflets and while traveling through PVL gaps (Fig. 3). Upon comparison of the PDFs and top 100 stress accumulation platelet trajectories, or "hotspots", in each of the patient models, it was evident that platelet activation thresholds were surpassed in each patient. However, the performance of the Evolut R device varied since patient #1 had the highest median stress accumulation of 1.193 Pa-s (Table 1), while patient #2 showed a much lower median stress accumulation of 0.687 Pa-s. Patients with higher anatomic eccentricity showed higher thrombogenic risk due to excessive leaflet fluttering, irregular GOA shapes and larger PVL gaps.

Table 1. Median SA from top 100 platelet hotspots for patients #1-3.

BAV Patient No.	Pt. 1	Pt. 2	Pt. 3
Median SA (Pa-s)	1.193	0.6870	0.7574

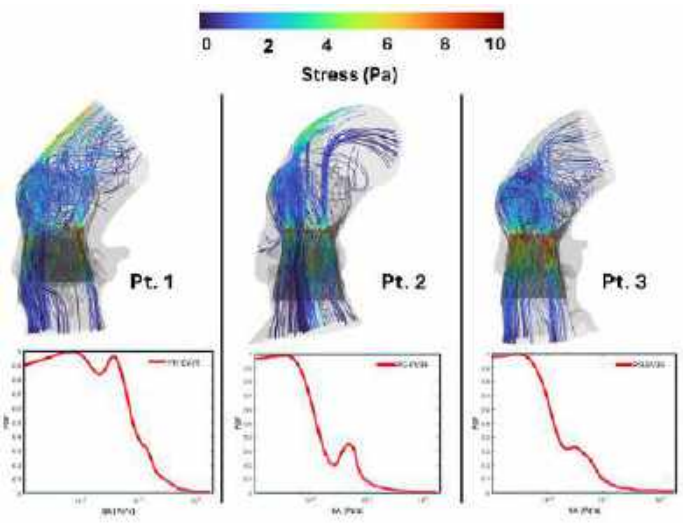

Figure 3. Visualized platelet trajectories with contour plot of stress (top) and respective PDF profiles (bottom) for patients #1-3.

DISCUSSION

This study demonstrates the ability to analyze and compare post-TAVR thrombogenic risk by studying hemodynamics of prosthetic devices via a fully integrated TAVR FSI approach. More specifically, our workflow allows us to take patient CT scans and create fully coupled FSI models for thrombogenic risk analysis where we can analyze the performance of TAVR devices in a patient-specific manner. From this study, we see that more complex and eccentric BAV patient anatomies can lead to poorer TAVR device performance and increased risk of platelet activation. This highlights the importance of developing novel TAVR devices that may outperform current ones on the market with special attention paid to reducing thrombogenicity and enhancing durability for new patient cohorts such as BAV [5]. This analysis can be applied to the optimization of a BAV-specific TAVR device in addition to understanding what specific patients would benefit most from such a device. Limitations of this study include the inability to use patient-specific flow conditions due to the lack of catheterization data. In the future, we wish to compare thrombogenic risk between current TAVR devices and our own BAV-specific design, PolyV-B. Additionally, we plan to perform our own *in vitro* hemodynamics testing with TAVR devices that we are developing.

COMPUTATIONAL ANALYSIS OF THE CONTRIBUTION OF PARACRINE CHEMOTAXIS TO SPATIAL DISTRIBUTION OF LEUKOCYTES IN CEREBRAL ANEURYSMS

Zhitian "Ruskin" Shi (1), Hadi Wiputra (1), Victor H. Barocas (1)

(1) Department of Biomedical Engineering,
University of Minnesota-Twin Cities,
Minneapolis, MN, USA

INTRODUCTION

As much as 3% [1] of the general population is affected by cerebral aneurysms (CAs). CA rupture is rare, but its consequences are severe, with a mortality rate of 25-50% [1]. Surgical repair also carries inherent risk of mortality, ranging from 0.6% to 2% [2]. To improve risk evaluation (rupture vs. surgery risk), there is a need for computational tools to help understand CA growth, remodeling, and rupture.

Leukocyte secretion of matrix metalloproteinases [3] in the aneurysm wall can weaken the wall and increase rupture risk., and leukocyte deposition in aneurysmal wall has been linked experimentally to CA rupture [4]. The reported distribution of leukocytes in CA walls varies widely: leukocytes can concentrate in the apex, neck, or body of CA [4], or they can distribute diffusely [5]. Despite the leukocytes' role in CA remodeling, and despite the many computational models of CAs, to our knowledge, no model of the leukocyte distribution has been proposed. We tested the hypothesis that ***leukocyte chemotaxis and chemokine secretion lead to spontaneous inhomogeneity within the aneurysm wall***. In this study, we hypothesized that non-uniform distributions of leukocytes can arise due to a feedback loop between chemotactic movement and chemokine production and transport. Further, we explored how different magnitudes of chemokine kinetics can lead to different of leukocyte distributions.

METHODS

A bidomain model (Figure 1) of leukocyte distribution was constructed, consisting of a discrete leukocyte domain and a continuous chemokine domain. The discrete domain is described by an agent-based model (ABM) for leukocyte chemotactic movement, informed by the (continuous) chemokine concentration distribution. The continuous domain is described by a partial differential equation for chemokine transport within the vessel wall, treating a subset of leukocytes as discrete chemokine sources. The two model domains are described in more detail below.

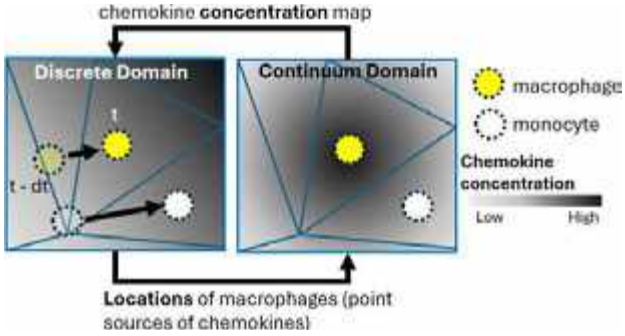

Figure 1: Schematic of the mathematical model.

Discrete (Leukocyte) Domain: Leukocyte recruitment into the vessel wall is a multi-step process that involves a series of phenotypic transitions. Three classes of leukocytes were simulated:

- **Monocytes**, which have been captured by the vessel wall, roll and/or crawl on its luminal surface. Extravasation into the wall and the transition to macrophages are triggered if surrounding chemokine concentration > 0.3 mmol/um^3. Monocytes are highly motile and do not secrete chemokine.
- **Macrophages** are less motile but still motile. They transition into the foamy phenotype if surrounding chemokine concentration > 3 mmol/um^3. Macrophages secrete chemokine at a moderate level.
- **Foamy macrophages** have low motility but secrete larger amounts of chemokine than macrophages.

Leukocyte movement was discretized into steps of uniform length and was made chemotactic via direction control. Specifically, the direction of each leukocyte step was determined as a biased random variable drawn from a Von Mises distribution [6], with the distribution parameters based on the chemokine concentration field around the cell.

Continuum (chemokine) Domain: Because leukocytes' chemotactic movements are significantly slower than chemokine diffusion, the transport of chemokine was assumed to reach steady state at the end of every time step, as given by the equation

$$D\nabla^2 c - kc + p\delta^3\left(\vec{x} - \vec{x}_{secreting\ cell(s)}\right) = 0 \qquad (1)$$

where D is the diffusivity; p is the production rate of chemokine by each leukocyte as point source; and δ^3 is the three-dimensional Dirac delta function. The clearance of chemokine from the aneurysmal tissue was assumed to be first order with rate constant k [7]. Assuming that the surrounding tissue is not inflamed, the chemokine concentration was set to zero at the domain boundary. Chemokine diffusivity was set to 150 um^2/s [8]. The chemokine production rate p was set to 1 mmol/s for macrophages and 3 mmol/s for foamy macrophages. Eq (1) was solved in a custom MATLAB Finite Element code.

The second Damköhler Number (Da_{II}) was introduced to normalize the chemokine clearance rate with respect to diffusivity:

$$Da_{II} = \frac{kL^2}{D} \qquad (2)$$

where k and D are as defined above, and L is a characteristic length.

RESULTS

Leukocyte clustering results fell into four broad, roughly defined regimes, as demonstrated in Figure 2a, which shows final results for four different Damköhler numbers.

$Da_{II} < 1$: Chemokine concentration is high throughout the domain because of rapid diffusion, driving monocytes to differentiate into macrophages and then foamy macrophages quickly upon entering the vessel wall. Macrophages have low motility, leading to minimal clustering. Nearly all macrophages are foamy.

$Da_{II} \in (1, 40]$: Leukocytes form large clusters. Chemokine level is not high enough to trigger the macrophage phenotypic switch to foamy, but the chemokine concentration is high enough to sustain a paracrine chemotactic feedback loop in which macrophages secrete chemokine → more macrophages recruited → more chemokine secretion. No foamy macrophages are present.

$Da_{II} \in (40, 500]$: Leukocytes form small clusters. The same feedback loop exists as previously, but the chemotactic range is smaller as chemokine clearance (k) begins to outweigh diffusion (D). No foamy macrophages are present.

$Da_{II} > 500$: Chemokine clearance is so fast that the chemotactic gradient does not extend significantly out from the cell, so secreting macrophages do not attract monocytes, and thus no clusters form. No foamy macrophages are present, and most cells are monocytes.

These effects can be quantified by plotting the number of clusters, cluster diameter, and % foamy macrophages vs. Da_{II}. As can be seen in Figure 2b and 2c, both the number and the diameter of clusters rises with Da_{II} and then falls, with few clusters forming at either extreme Da_{II} value. Almost all of the macrophages are foamy for small Da_{II}, with a sharp shift to almost no foamy macrophages at about $Da_{II} = 1$.

DISCUSSION

The key conclusion of this work was that there is a window of Damköhler number values for which the combination of phenotypic transitions and chemokine dynamics lead to clusters. For the conditions we studied, this window generally did not include transition to foamy macrophages, although changes in the phenotypic transition parameters or the leukocyte motility parameters could lead to different results.

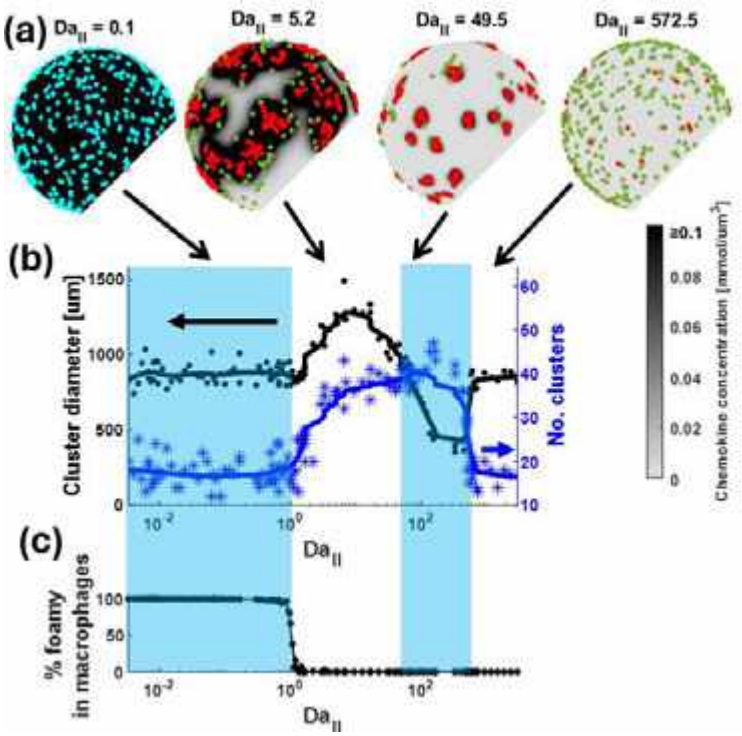

Figure 2: (a, b) Cluster diameter, number of clusters, & percentage of foamy macrophages in all macrophages were used to quantify clustering states. Each dot represents one simulation; solid lines are moving average fits of the dots. (c) one simulation output from each range of Damköhler number. Cyan dot = foamy macrophage, red dot = macrophage, green dot = monocyte.

Both leukocyte and chemokine dynamics were simplified in this model. Leukocyte migration, a complex process that involves many signaling molecules, was represented by a single chemokine, and both chemokinesis or contact guidance were ignored. Similarly, multiple factors were lumped into the chemokine clearance parameter k, including the thickness of vessel wall, chemokine mass transfer to the bloodstream, and natural decay of chemokine. Despite these simplifications, the model showed different clustering regimes and provides a tool to evaluate the interaction among different mechanisms.

Macrophage activation has been identified as a surrogate marker distinguishing between rupture-prone and lower risk aneurysms [9]. In our model, we observed correlated behavior between the leukocyte clustering and phenotype (Fig. 2b,c), which may help guide future studies into the biological difference between the walls of rupture-prone aneurysm and lower risk aneurysm.

INTRODUCTION

Coronary artery disease (CAD) is the leading cause of death globally. While coronary artery bypass graft (CABG) surgery improves mortality in patients with severe CAD, long-term outcomes remain a challenge, with 24% of patients reporting chest pain within a year [1]. This is because revascularization is often guided by anatomical risk, which has worse outcomes than treatment based on hemodynamic severity [2]. To address this, personalized computational fluid dynamics (CFD) simulations can improve CAD treatment outcomes via non-invasive hemodynamic risk assessment and virtual treatment planning.

CFD can non-invasively calculate clinically relevant hemodynamics by simulating blood flow in patient-specific anatomies based on non-invasive clinical imaging. However, while current CFD tools are mostly diagnostic, predictive surgical planning requires personalized and multi-scale models that recapitulate pre-treatment hemodynamics for each patient and link clinical interventions in epicardial vessels with downstream myocardial blood flow. This is a challenge with image-based models because clinical imaging cannot resolve arteries below the image resolution, thus resulting in models that omit small vasculature and do not reflect true patient-specific coronary flow. These image-based models distribute flow among arteries empirically [3], which ignores patient variability, disease and model uncertainty. In addition, while current models are usually deterministic, robust clinical application requires rigorous uncertainty quantification to be incorporated into these virtual diagnosis and treatment planning tools.

To address these issues, we demonstrates a framework for more accurate, personalized and uncertainty-aware coronary hemodynamics models that are informed by clinical data. In particular, the focus is on personalized models for virtual CABG surgical planning that include novel methods to (1) combine conventional image-based models with synthetic vascular trees to represent arteries that are under-resolved in clinical imaging; (2) estimate more accurate and personalized model parameters and boundary conditions based on clinical data; (3) incorporate uncertainty in model parameters as well as clinically relevant hemodynamic metrics. We demonstrate the utility of these data-informed models both in disease diagnosis and CABG treatment planning.

METHODS

We used patient-specific coronary anatomical models based on CT angiography (CTA). The models were constructed using the the open-source *SimVascular* software and 3D flow simulations were performed using the finite element solver *svSolver* within *SimVascular*. We used 0D lumped-parameter models of flow in distal vasculature as well as for parameter estimation.

We augmented the image-based models with synthetic vascular trees generated using Constrained Constructive Optimization (CCO) [4] to represent vessels that are under-resolved in CTA. CCO can generate multiple non-intersecting trees in concave ventricle-like volumes that are constrained by hemodynamics and vascular scaling laws while minimizing vascular volume. This allowed us to create realistic vascular trees beyond the limits of CTA resolution.

We used closed-loop lumped parameter network (LPN) boundary conditions at inlets and outlets of the aorta and coronary arteries in the 3D simulations to capture the coupling with downstream systemic circulation. This included blocks to model each heart chamber, the intramyocardial pressure in coronary arteries, and resistance of vascular beds distal to each coronary artery which determines the distribution of flow amongst coronary arteries [5].

We enforced patient-specific flow distributions in the coronary tree based on clinical dynamic CT myocardial perfusion imaging (MPI_{CT}) [6]. MPI_{CT} is a non-invasive contrast-based imaging modality that quantifies the spatial distribution of blood flow perfusing the left ventricle (LV). From clinical MPI_{CT}, we extracted patient-specific LV volumes and myocardial blood flow (MBF) distributions. Using co-registered 3D models of each patient's coronary anatomy from CTA and the MBF distribution in the LV

from MPI_{CT}, we estimated the LV perfusion regions and MBF corresponding to each coronary artery.

The models described above consisted of several parameters governing the hemodynamics of upstream coronary arteries as well as the distal closed-loop circulation model. Personalized parameters were estimated using MPI_{CT} and measurements of cardiac function for each patient so that the resulting simulations reproduced clinically measured coronary flows, heart rate, aortic pressure, cardiac output and ejection fraction for each patient. This parameter estimation was performed in two ways - (1) using deterministic gradient-free Nelder Mead optimization; (2) using uncertainty-aware Bayesian estimation based on an adaptive Markov Chain Monte Carlo method [7].

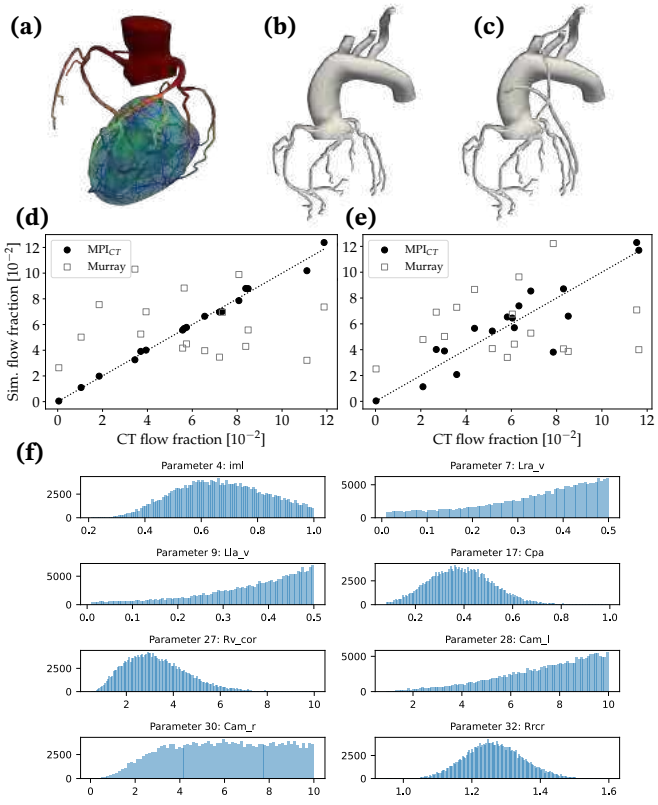

Figure 1: (a) Sample case with synthetic vascular trees. (b) Pre-CABG model (c) Post-CABG model. (d) Simulated pre-CABG flow in each coronary compared with flow from MPI_{CT}. (e) Simulated post-CABG flow in each coronary compared with flow from MPI_{CT}. (f) Posterior distributions for a subset of model paramaters.

RESULTS

We compared the framework proposed here for the estimation of personalized coronary flow distributions with the conventionally used Murray's law method for assigning coronary flow distributions [3] with an exponent of 2.6. We performed this comparison for hemodynamics simulated pre-CABG as well as post-CABG. Figure 1(a) shows a sample image-based anatomical model augmented with synthetic vascular trees that are constrained to grow in the patient-specific LV volume. Figures 1(b)-(c) show the patient's pre-CABG and post-CABG coronary anatomy.

Preliminary results indicate that our automated framework to personalize coronary hemodynamics models accurately recapitulates patient-specific clinical measurements both pre-CABG and post-CABG. Figures 1(d)-(e) compare the clinically measured flow in each branch of the coronary tree, estimated from MPI_{CT}, with simulation results based on the novel MPI_{CT}-informed technique and conventional Murray's law. In the pre-CABG scenario, figure 1(d) shows that the MPI_{CT}-informed model is significantly more accurate in capturing coronary flow fractions than the Murray's law-based model, with errors of 4.04% and 391.23% respectively. Importantly, when these personalized pre-CABG models are used to predict post-CABG outcomes, the models based on MPI_{CT} continue to be more accurate than the models based on Murray's law, with errors of 23.82% and 692.37% respectively. Although not show here, this automated personalization framework also produces good agreement between simulations and clinically measured metrics of cardiac function.

We have also incorporated uncertainty quantification into this parameter estimation framework using Bayesian methods to estimate posterior distributions for model parameters based on physiologically informed priors and patient-specific clinical measurements. Figure 1(f) shows the posterior distribution of a subset of the model parameters for a sample patient.

DISCUSSION

This work presents a novel framework for personalized and uncertainty-aware CABG treatment planning that is informed by non-invasive myocardial perfusion imaging and augmented with synthetic vascular trees. We seek to address three challenges in current coronary hemodynamics CFD models; (1) the exclusion of anatomical features of the coronary tree that cannot be resolved from clinical imaging; (2) the use of empirical flow splits amongst arteries that are not patient-specific; (3) the incorporation of novel uncertainty quantification techniques. Preliminary results indicate good success with the automated framework for tuning simulation parameters to reproduce patient-specific clinical measurements of coronary flow distributions as well as cardiac function. Importantly, our results indicate that such patient-specific flows are beneficial to recapitulate accurate hemodynamics pre-CABG as well as for the prediction of post-CABG outcomes.

Previous work has highlighted the inaccuracies introduced in coronary hemodynamics simulations due to inaccuracies in anatomy as well as outflow boundary conditions [5, 8]. We expect that this model personalization framework will aid in producing more personalized flow distributions as well as provide rigorous uncertainty estimates in pre-treatment disease diagnosis as well as in predictive virtual treatment planning. Moreover, the incorporation of non-invasive perfusion imaging into the tuning of coronary flow boundary conditions is a novel method to obtain personalized flow distributions in the coronary tree, which in turn leads to more accurate estimates of clinically relevant hemodynamic metrics such as fractional flow reserve.

NON-CONTACT BIOMECHANICAL IMAGING OF CELL AND TISSUE USING OPTICAL BRILLOUIN MICROSCOPY

Jitao Zhang

Department of Biomedical Engineering, Wayne State University, Detroit, MI, USA

INTRODUCTION

Biomechanical interactions play crucial roles in regulating many cellular functions and system-level behaviors. To understand the mechanical interplay within cells and tissue, we need tools to identify mechanically related pathways, measure deformations and forces, and quantify the mechanical properties (e.g., elasticity) of materials. Many important techniques have been developed to assess material mechanical properties and can be loosely classified into three categories [1]. The first is contact-based techniques, including atomic force microscopy (AFM) and other cantilever-based indentation methods, micropipette aspiration, parallel-plate rheometer, and stretching substrate. Contact-based techniques can provide direct quantification of elasticity and are considered the gold standard. However, they need to physically touch and apply force to the sample during experiment, making the measurement invasive and mostly limited to the superficial layer of material. The second is bead-based techniques, including optical tweezer, magnetic tweezer, magnetic twisting cytometry, passive microrheology, and microdroplet-based sensors. These techniques have been extensively used to extract the localized mechanical properties of the sample, mostly at the cellular and subcellular scales. However, the injection of beads or droplets is required for experiments. The third is elastography techniques, where the application of an external force is coupled with imaging technologies to measure force-induced deformation and back calculate the strain. These include optical stretching, optical coherence elastography (OCE), and microfluidics-based deformers. OCE is powerful to characterize and map the mechanical properties of biological tissue in large scale, and the microfluidics-based techniques can assess cell biomechanics in medium with high throughput. In short, each of these techniques has strengths and limitations, leading to a specialization of their use for particular applications.

Here, we would like to introduce a new technology named optical Brillouin microscopy [2-4], which utilizes an entirely different approach to probing material mechanical properties. Brillouin microscopy is based on the physical principle of spontaneous Brillouin light scattering, where the incident light undergoes a frequency shift (i.e., Brillouin shift) after interaction with the sample being tested. The Brillouin shift Ω is proportional to the local longitudinal elastic modulus M' of the sample by $M' = K \cdot \Omega^2$, where the coefficient $K = \lambda\rho/(4n^2)$ for backward scattered light. λ is the known laser wavelength in air, ρ and n is the mass density and refractive index of the sample, respectively. With a known value of ρ/n^2, the longitudinal modulus M' can be computed from the Brillouin shift Ω measured by a Brillouin spectrometer. A confocal Brillouin microscope is built by integrating a Brillouin spectrometer and a standard optical confocal microscope [4], allowing the mechanical mapping of material with diffraction-limited resolution in 3D. Brillouin microscopy only uses a laser beam to probe the mechanical modulus, making it a non-contact, non-invasive, and label-free mechanical testing tool.

The unique features of the Brillouin microscopy provide new opportunities for probing cell and tissue biomechanics in physiologically relevant conditions that are not easily accessible to conventional technologies, such as the nuclear mechanics in an intact cell, subcellular mechanics during confined migrations and in 3D *in vitro* microenvironments (e.g., 3D culture, spheroid, and organoid), and tissue mechanics of early-stage embryo. In this work, we will first talk about the innovation and instrumentation of several Brillouin technologies, including confocal Brillouin microscopy [4], line-scanning Brillouin microscopy [5], and Brillouin flow cytometry [6]. We will then show several biomedical research that is enabled by Brillouin technology, with a focus on cancer related research and embryo development.

METHODS

Figure 1a shows the schematic setup of a confocal Brillouin microscope. To excite Brillouin signal, the beam of a laser source

(single mode, continuous wave laser) is guided into a standard optical microscope by several optical components and focused into a spot by an objective lens. The backward-scattered Brillouin signal generated from the beam voxel is collected by the same objective lens and analyzed by a Brillouin spectrometer, which quantifies the optical Brillouin frequency shift by using a specific optical etalon. A single-mode fiber is used for both delivering Brillouin signal and serving as a confocal pinhole. Therefore, the spatial resolution of Brillouin microscope is mainly determined by the size of the focused beam spot, which is usually less than 1μm laterally when using an objective lens with moderate numerical aperture (e.g., 0.6). Therefore, a high-resolution 2D mechanical Brillouin image of a cell can be acquired by scanning the sample using a translational stage. By adding Brillouin microscopy to a fluorescence microscope, the co-registered mechanical and molecular image could allow comprehensive understanding of biological processes (**Figure 1b**).

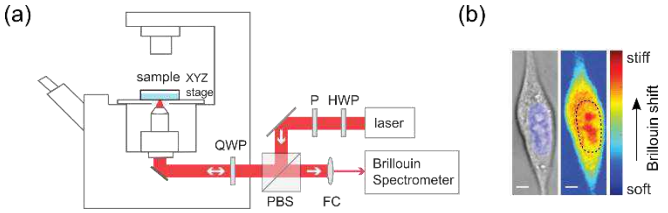

Figure 1: Confocal Brillouin microscopy. (a) Optical setup of a confocal Brillouin microscope. HWP: half-wave plate, P: polarizer, PBS: polarized beam splitter, QWP: quarter-wave plate, FC: fiber coupler. (b) Brightfield/fluorescence and Brillouin image of a NIH 3T3 fibroblast cell. Color map represents Brillouin shift. Dash line indicates the nucleus. Scale bar: 5 μm.

RESULTS

A. Cellular nuclear biomechanics and their role in cancer metastasis.

Cellular nucleus has been identified as a critical mechanosensory and regulates many cell functions including migration, immune cell trafficking and cancer metastasis. However, nucleus in an intact cell is not directly accessible to conventional contact-based technologies because it is enclosed by, and mechanically interacts with, the surrounding cytoplasm. In our recent work [7], we directly quantified intact nuclear mechanics using the non-contact Brillouin microscopy. The technological advantage of Brillouin further enabled us to reveal the role of cytoskeletal modulation in nuclear mechanics (**Figure 2a**), which is confirmed by chemomechanical modeling.

In addition, we employed Brillouin microscopy to probe nuclear modulus of metastatic cancer cells as they are migrating inside the confined microchannel [8]. We observed that cells in vertical confinement have slower migration speed and higher nuclear modulus than their counterpart in lateral confinement (**Figure 2b**). This work leads to the new finding that cancer cells respond to external confinement by adjusting nuclear stiffness regulated via a crosstalk between myosin II and lamin-A.

During the process of cancer metastasis, tumor cells experience substantial changes in shape to pass through the junctions between endothelial cells in blood vessel walls. As the gap is usually narrower than the size of nucleus, the nuclear stiffness could be an important limiting factor for transendothelial migration, yet no studies has been conducted to understand whether cancer cells mediate nuclear stiffness to facilitate this process. Using the Brillouin microscopy, for the first time, we observed that cancer cells soften their body and nuclei upon extravasation (**Figure 2c**) [9]. Collectively, these works suggest that adjusting stiffness could be a common strategy employed by cancer cells during metastasis.

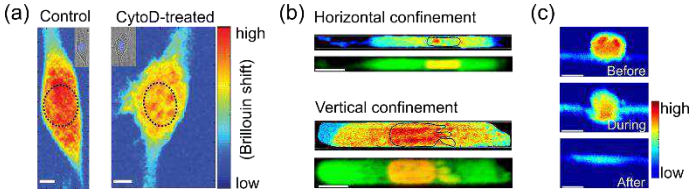

Figure 2: (a) Brillouin shift of nucleus decreases upon disruption of actin filament. Inset: brightfield image. Scale: 5μm. (b) Co-registered Brillouin and fluorescence images. Brillouin shift of nucleus is higher in vertical confinement than in horizontal confinement. (c) Cancer cells show decreased Brillouin shift during transendothelial migration. Scale in (b) and (c) is 10μm. Color bar: Brillouin shift. Dashed line highlights nucleus.

B. Evolution of tissue mechanics during embryo development.

Tissue biomechanics, together with genetic factors and molecular signaling, coordinates morphogenesis in embryonic development. However, mapping tissue mechanics *in situ* is highly challenging because of 3D mechanical interactions inside the embryo body. Using optical coherence tomography-guided Brillouin microscopy, we acquired 2D mechanical maps of mouse embryonic tissue, confirming that the Brillouin technology has cellular spatial resolution and sufficient mechanical sensitivity for early-stage embryo. Very recently, our lab devised a time-lapse Brillouin microscopy that can conduct longitudinal mechanical imaging when a live embryo is developing, enabling real-time quantification of tissue biomechanics during neural tube closure (**Figure 3**).

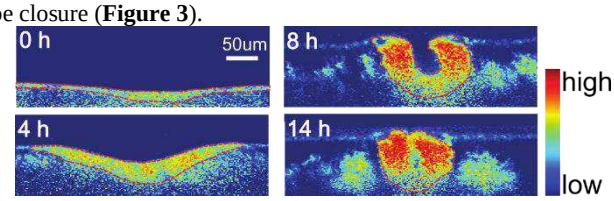

Figure 3: Time-lapse mechanical imaging of neural plate tissue (highlighted by red dashed line) of a live chick embryo.

DISCUSSION

As an emerging technology, Brillouin microscopy is currently far from mature and has limitations and challenges [10], including the acquisition speed, penetration depth, potential phototoxicity, and data interpretation and validation. While the technology itself is rapidly growing to address these challenges, we expect this new technology can serve as a unique complement to existing mechanical testing tools and promote research in a broad range of fields where the understanding of biomechanics is urgently needed but currently remains in accessible, such as cancer metastasis and tumorigenesis, organogenesis, congenital defects, regenerative medicine, tissue engineering, and biomaterials.

p21 SUPPRESSION TO IMPROVE OSTEOGENIC CAPACITY OF MSCS

Sina Jafari (1), Aaron Levi Brandner (1), Julie Sandria (1) Priyatha Premnath (1)

(1) Department of Biomedical Engineering, University of Wisconsin Milwaukee, WI, USA

INTRODUCTION

The recovery process following a fracture is contingent upon several variables, including the nature of the fracture (comminuted or non-comminuted) [1], smoking [2] history, and the presence of diabetes. Generally, individuals who are young and in optimal health often exhibit favorable healing outcomes, particularly with non-comminuted fractures. Conversely, individuals facing more intricate fractures, advanced age [3], or conditions like osteoporosis [4] that disrupt the natural healing process may require external interventions to facilitate a successful recovery. When a bone is fractured, the body naturally recruits mesenchymal stem cells (MSCs) to the fracture site. MSCs then differentiate into bone (osteoblasts) or cartilage cells (chondrocytes), release growth factors, and exhibit anti-inflammatory properties. These actions promote bone healing by supporting tissue repair, angiogenesis, and extracellular matrix production [5]. The immunomodulatory effects of MSCs also contribute to a balanced immune response, enhancing the overall regenerative process.

One way of enhancing bone regeneration after a fracture is through gene therapy, where specific genes can be targeted to improve outcomes [6]. p21, a cyclin-dependent kinase inhibitor (CDKN1A), is a pivotal gene that regulates various aspects of the cell cycle, such as inducing cycle arrest, apoptosis, senescence, and facilitating DNA repair. Studies have demonstrated that inhibiting p21 can enhance bone healing and regeneration following an injury [7]. A small molecule inhibitor of p21 is UC2288. UC2288 is a derivative of Sorafenib, a multikinase inhibitor renowned for its ability to decrease p21 [8]. Sorafenib, an FDA-approved and extensively studied multiple kinase inhibitor, is utilized for treating various cancer types, particularly hepatocellular carcinoma (HCC). Sorafenib can impede angiogenesis, curb tumor cell proliferation, and facilitate apoptosis in HCC [9]. In contrast to Sorafenib, UC2288 does not impact the levels of p-ERK protein or hinder the activity of Raf kinases [8]. Instead, UC2288 diminishes the p21 protein at the transcriptional or post-transcriptional level without involving protein degradation. It significantly reduces cytosolic p21 protein levels while leaving nuclear p21 unaffected and operates independently of p53 [10].

In this research project, our objective is to investigate the efficiency of UC2288 in reducing p21. The underlying hypothesis is that reducing p21 levels will amplify the osteogenic potential within mesenchymal stem cells (MSCs). To investigate this hypothesis, we tested human umbilical cord derived MSCs (HU UCMSCs) with various concentrations of UC2288. The subsequent analysis focused on assessing any discernible improvement in their osteogenic capabilities.

METHODS

Cell viability was assessed via an MTT assay in HU UCMSCs. 2.5 μM, 5 μM, and 10 μM concentrations of UC2288 were tested with 5k cells of HU UCMSCs in a 96-well plate for 24, 48, and 72 hours. To determine transcriptional changes in the osteogenic capacity of the cells, RT-qPCR in a 24-well plate was performed with 30k cells at 2.5 μM, 5 μM, and 10 μM concentrations of UC2288 for 7,14 and 21 days to quantify the expression of osteogenic genes of interest that included Sp7, RUNX2, Bglap, Col1a1, and p21. Data was normalized against endogenous control gene 18s. Results were analyzed using the ΔΔCt method of analysis. Results were analyzed via a 2way ANOVA. Alizarin red staining was performed on a 24-well plate with cells seeded at a density of 30,000 cells per well to visualize the extracellular release of calcium. The cells were treated with UC2288 at concentrations of 2.5 μM, 5 μM, and 10 μM for 21 days.

RESULTS

MTT assay indicates that 2.5 μM and 5 μM UC2288 is not cytotoxic to Hu UCMSCs, while at 72 hours 10 μM decreases cell viability.

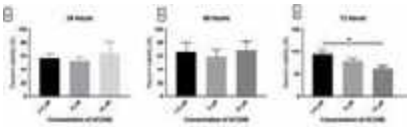

Figure 1: Percent viability of Hu UCMSCs when incubated with UC2288 at 24, 48 and 72 hours. n=3, *p<0.5.

For Alizarin red staining, 2.5 µM resulted in more intense staining of Alizarin red compared to the control (Figures 2(a-b). 10 µM of UC2288 resulted in reduced viability of cells as evidenced by the absence of cells (Figures 2d).

Figure 2. Alizarin red staining of Hu UCMSC incubated with different concentrations of UC2288 for 21 days.

RT-qPCR shows that 2.5µM of UC2288 increased osteogenic expression at transcriptional level when cultured with Hu UCMSCs for 7 and 14 days (figure a, b). At 21 days however there was no significant change between the osteogenic genes expect at concentration of 10µM for Sp7 and Bglap which were significantly higher (figure c).

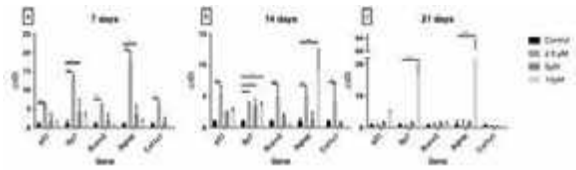

Figure 3. Relative expression of osteogenic genes and p21 after Hu UCMSCs were treated with UC2288.

DISCUSSION

Previous studies in mice showed that inhibition of p21 can increase rate at which bone heals after an injury [8]. It was hypothesized that MSCs were recruited to the site of injury and aided in healing of the fracture by differentiating into bone cells. Therefore, in this study, we focused on MSCs. When Hu UCMSC were treated with UC2288 to decrease p21, a transcriptional increase in osteogenic activity was observed through RT-qPCR at 7 and 14 days compared to control but not at 21 days. At 21 days' time point it could be that the cells are becoming drug tolerant. While we observed overall positive results with HUMSCs, bone marrow MSCs present a more accessible alternative to clinical applications where a patient's own MSCs can be used to increase osteogenic capacity. In this case, either cells can be isolated and cultured ex-vivo with UC2288, or UC2288 can be delivered to the fracture site. Once the nature of UC2288-cell interaction is further understood, a delivery mechanism will be determined to deliver the drug locally to the site of interest. Eventually, the therapeutics targeting p21 could pave new pathways for bone healing. This is especially important in the aging population, and this line of study could ultimately lead to clinical applications.

ACKNOWLEDGEMENTS

This project was partially funded by a UWMRF Catalyst Grant and an NSF I-Corps grant.

HYDROGEL WOUND HEALING IN PALLIATIVE CARE

T. Welch (1), J. Wright (1), V. Pimpalwar(1), K. Newcomer (2), M. Ligorio (3)

INTRODUCTION

Palliative care patients often undergo an aggressive oral regimen for adequate pain management due to cancer dissemination in multiple (non-skin) organs. Chronic wounds affect 5 – 7 million patients and cost more than $30 billion annually in the US. As a result, topical solutions are synergistically added to the oral administrations of other analgesic compounds, which unfortunately limits their pain control in skin and mucosa ulcerated tissues. In addition, high doses of systemic administered opioids can trigger a state of hyperalgesia, worsening the pain from neoplastic ulcers. Moreover, several studies have indicated a decrease in the utilization of oral opiates when topical formulations are co-administered to mitigate the current opioid abuse crisis. In further support of this, the World Health Organization recommends trying adjuvants such as topical analgesics before systemic medications in its Analgesic Ladder. The objective is to develop a topical hydrogel to effectively deliver pharmaceuticals to patients.

METHODS

We developed a hydrogel through a design of experiments to determine concentrations of polyvinyl alcohol and poloxymer and used dexamethasone as a proof-of-principle drug for the experimental work. We analyzed the hydrogels' polymer peak identification by Fourier transform infrared spectroscopy (FTIR), rheological properties, drug release, and thermal properties. The hydrogels were fabricated by placing PVA (10% wt/wt), water and Poloxymer (10% wt/wt), and Dexamethasone (3% wt/wt) at 90 °C bath with continuous mixing for 3 hours. The samples (n=3 per group) were placed into separate circular glass plates and freeze thawed at -80 °C for 12 hours 2 times (2X), 4 times (4X) and 6 times (6X). For drug saturation limit determination, 4 films per drug loading group, 20%, 30%, 40% and 50% were analyzed on differential scanning calorimetry. Fourier Transform Infrared Spectroscopy (FTIR) was used to characterize the presence of specific chemical groups in the materials that were obtained as 1–2 mm thick films and analyzed by FTIR using Transmittance Mode in the range of wavenumber from 4000 to 650 cm^{-1} during 64 scans, with 2 cm^{-1} resolution (Nicolet iS5, Thermoscientific, USA).

Rheological properties such as storage modulus and loss modulus were measured on a parallel plate rheometer (AR G2, TA Instruments, Newcastle, DE) with a gap size of 1000 μm. For strain rate dependence experiments, the temperature was held at room temperature, while the strain rate was varied continuously from 0.1 to 100 s^{-1}. For stress dependence, the temperature was held at room temperature, and the stress was varied from 1 to 1000 (Pa). Next, thermal properties were determined by differential scanning calorimetry (Q20, TA Instruments, Newcastle, DE). Three samples from each group were equilibrated at 20 °C and ramped to 250 C at a rate of 10 °C / min and held constant for 3 minutes and cooled by to 20 °C at 50 °C / min. Heat curves were analyzed for heat of enthalpy, H_m, using TA Universal Analysis Software. The percent crystallinity was determined by equation (1) with H_0 = 138.6 J/g for 100% crystalline PVA measured at the equilibrium point T_m. [1]. The drug saturation limit was determined by linear regression analysis using the measured enthalpy of fusion for each drug loaded hydrogel and graphing the enthalpy of fusion vs the dexamethasone amount loaded per hydrogel.

The last experiment was determining the drug release curve for a 2x freeze thaw cycle and a control of Solosite (S1), a commonly used hydrogel in wound healing, mixed with 3 % (wt/wt) dexamethasone compared to a 2x freeze thaw film (H1). Using three PermeGear Franz Cells fitted with an Ultracel 10 kDa membrane in each one and Phosphate Buffered Saline at 37 °C in the 12 ml receptor chamber with a 37 °C circulating heated water jacket. Drug release was measured each hour up to 12 hours and one at 24, 36, 48, 60, 72 hours with a Dionex Ultimate 3000 HPLC with an acclaim C-30 column. The mobile phase was 50:50 Water / Acetonitrile / 0.001% Trifluoroacetic acid with a pH of 2.0 at a flow rate of 0.5 ml / min. The cumulative drug release was plotted and analyzed using power law equation (2) curve fitting.

All data sets were analyzed using GraphPad Prism version 10.0.0 for Windows, GraphPad Software, Boston, Massachusetts USA. The rheology data was analyzed using One-Way ANOVA per cross-linking group followed by a *post hoc* Bonferroni test ($p < 0.05$). For DSC, all cross-linking groups were analyzed using a One-Way ANOVA followed by a post hoc Bonferroni test ($p < 0.05$). The saturation limit was determined by a linear regression analysis where the y-intercept is the saturation limit.

Equation

$$X\,(\%) = \frac{H_m}{H_0} \times 100 \qquad (1)$$

$$\frac{M_t}{M_\infty} = kt^n \qquad (2)$$

RESULTS

The drug release curve of these films showed a dexamethasone release of approximately 50% in 24 hours and 67% within 72 hours. On the contrary, the hydrogel control, solosite, showed a (linear) dexamethasone release of less than 5% in 24 hours. The hydrogels were fitted to the Korsmeyer-Peppas Power Law, equation (2) [1] since only one equation does not fit the data across the entire time range. The zero-order kinetics model, Higuchi, gave us a correlation coefficient of 0.96; therefore, we fitted the data piecewise to the first 12 hours and then 13–72 hours. The corresponding equations shown have an "n" value of 0.87, which relates closely to a zero-order function where the drug release depends on the polymer relaxation and swelling with a correlation coefficient of 0.99. The second equation, 16–72 hours, has an "n" value of 0.37. The Peppas Power Law equation without piecewise fitting shows the drug release as non-fickian diffusion with an n = 0.53 (**Figure 1A**). Based on this, we believe the piecewise curve fitting better explains the drug release being linear due to polymer swelling and forcing the drug out of the polymer matrix with an n = 0.87 for the first 12 hours and quasi-fickian release with an n = 0.37 for the later times of drug release (**Figure 2B**). This lower value corresponds to a diffusion model where the drug release depends on diffusion.

The FTIR results showed we can make hydrogels with dexamethasone entrapped within the polymer. The dexamethasone aromatic stretches (-C=O) are shown at v1615 cm^{-1}, v1657 cm^{-1} and v1705 cm^{-1}. PVA is shown at (C-H) v2939 cm^{-1}, (-C=O) 1742 cm^{-1}, CH_2 s 1455 cm^{-1}, C-O v1141 cm^{-1}, C-O-C v1057 cm^{-1}, and poloxamer at (C-H) s2877 cm^{-1}, (O-H) b1345 cm^{-1} and (C-O) s1111 cm^{-1} stretches.

The rheology results showed that as the frequency increases, so does the storage modulus and loss modulus up to 100 Hz. No crossover between the storage and loss modulus was observed on the frequency sweep. The storage modulus shows an increasing trend with more freeze-thaw cycles from 5652±629 Pa to 7842±84 Pa, but none was statistically different. The yield stress of the polymer shows an increase from 283±12 kPa to 432±26 kPa with an increase in the number of freeze-thaw cycles, but they are not statistically different. At high oscillating strains above 10% we saw a crossover between the storage and loss modulus. At high oscillating stresses above 100 Pa we observed a crossover between the storage and loss modulus.

The DSC results showed the percent crystallinity increases with degree of freeze thaw cycles from 10% - 17 %. The distinct enthalpy peaks show up for poloxamer at 54.6±0.3 °C, PVA at 190.8±0.3 °C and dexamethasone at 252.6±1.7 °C for 2X group; poloxamer at 51.5 ±0.5 °C, PVA at 190.6±0.2 °C and dexamethasone at 249±0.6 °C for 4X group, 53.4±0.3 °C, PVA at 191.5±0.5 °C and dexamethasone at 253.3±1.1 °C for 6X group. The drug saturation was determined to be 10.06%. The scatter data was plotted for each drug loaded amount of dexamethasone and fit to a linear regression curve with a $R^2 = 0.89$.

DISCUSSION

Using the Korsmeyer-Peppas power law model in a piecewise model fits the drug release profile with higher correlation coefficients of 0.99 compared to other methods, such as Higuchi of 0.96. The synthetic hydrogel we have formulated has a drug release curve that is mostly linear for the first 12 hours at a 35% drug release and then asymptotically changes to plateau around 60% drug release. In comparison to control, solosite, or S1, we showed a higher drug release. Hydrogel formulation usually occurs by cross-linking with UV, physical entanglement, hydrogen bonding, and ion cross-linking. There are several hydrogels, such as chitosan, a natural hydrogel with strong strength and stability. Others have used carboxy methylcellulose and modified the formulation with essential oils to increase their drug release with curcumin. They showed a drug release range of 20% without any modification to 80% using different essential oils to modulate their drug release. Others have used chemical crosslinkers to modulate their drug release, such as glutaraldehyde with PVA, creating a sustained drug release over 35 days. In comparison, our model showed that we could achieve a high release of the drug within 24 hours without chemical crosslinking or the use of other oils or ointments. The limitations of the study show a one-way diffusion model for topical treatment and the use of a membrane instead of skin as a filter. The implications of this work are to advance treatment options for patients in palliative care for wound management.

Although much progress has been made in early diagnostic and therapeutics, many cancer remain a deadly disease. Virtually all patients with uncurable metastatic conditions undergo palliate treatments, including oral or intravenous (IV) administration of opioids. Recent studies showed that a better control of cancer-related pain and discomfort for cancer patients with skin or mucosal lesions can be achieved by using the local administration of pain-control compounds. Local vs. systemic drug administration has several benefits, spanning from fewer drugs needed to superior control of the local pain/discomfort to largely limit systemic side effects. Our hydrogel has the potential to outperform all the current topical-delivery methodologies as shown herein by a 50% drug released compared to 5% of a commonly used hydrogel, solosite, in current palliative care practice. This 10-fold enrichment in drug release has also the potential, if it proved efficacious in prospective clinical trials, to mitigate the current opioid crisis determined by an abuse of the systemic administration (e.g., oral or IV) of opioids, which our society has experienced in the last decade.

INTRODUCTION

Violent crimes using knives or other sharp objects account for 22% of all global homicides [1] in addition to thousands of non-fatal sharp force injuries treated daily in the United States [2]. In court, forensic experts have assessed the alleged assailant's level of intent by comparing it to force thresholds. However, blunter instruments with varying tip radii and geometry, such as screwdrivers, glass shards, scissors, and sharpened metal rods [2], lack quantified force data and are more difficult to determine when excessive force is used [3,4].

Forensic studies have investigated the high-rate, traumatic failure of skin during puncture and stabbings from screwdrivers and knives [3,5]. However, many studies have used skin simulants rather than biological tissue to reduce variability [3–5], but synthetic materials do not account for anisotropy and viscoelasticity of skin with natural pre-tension. Based on impactor size and geometry, sharp and blunt punctures have differences in failure mechanisms [6], but damage to the microstructure of skin from puncture has not been examined.

To account for the multivariate nature of puncture incidents, finite element models have been developed to simulate puncture of fruit [7] and skin simulants [8]. Mechanical behavior of skin may be validated with experimental surface deformations measured using 3D digital image correlation (DIC). 3D-DIC also allows analysis of localized strains during puncture to validate anisotropy of strain distribution.

The purpose of this study was to investigate the structure and mechanical behavior of skin in isolated puncture through histological analyses, strain distribution using 3D-DIC, and statistical effects of skin thickness, loading rate, and impactor diameter. Experimental results may be used to develop a computational model of puncture, capable of predicting failure thresholds for various impactor sizes and geometries.

METHODS

Frozen porcine tissue was thawed, excised into discs, and subjected to physiological initial tension [9]. Initial tension was quantified by measuring biaxial strain of the sample, and skin thickness was measured at the puncture site after testing using calipers (1-4 mm inclusion).

An electrohydraulic piston actuator (MTS) with an attached uniaxial accelerometer (DTS) loaded the skin and recorded force, displacement, and acceleration at 20 kHz. A steel impactor with a 3, 5, or 8 mm stainless steel sphere was fixed to the load cell. Skin was pre-conditioned while unclamped and sub-failure trials were conducted to a displacement of 15 mm at 50 and 500 mm/s while clamped, allowing the sample to recover between runs. A failure trial was performed at a rate of 5, 50, 500, or 1000 mm/s. Inertial effects were minimized by subtracting forces due to acceleration. Trials were excluded when failure occurred at displacements less than 15 mm or strain energy of sub-failure 2 decreased by more than a conservative 12% from sub-failure 1 determined from sample inspection, however, "damaging" pre-failure loads have shown to not affect ultimate strength of skin [10].

3D digital image correlation (DIC) was performed using two high-speed cameras (NX-Air series, IDT) at sampling rates up to 5250 Hz for failure runs to measure local surface strains during puncture. A speckle pattern was randomly applied to the adipose surface of the specimen. Displacement and major strain were calculated with a median spatial filter of 5 pixels (GOM Correlate Pro, Trilion). DIC data was imported into MATLAB and interpolated to create a continuous surface. For wounds of samples punctured at 5 mm/s, the elliptical area of disrupted tissue was quantified using Image J and statistically compared between the three impactor sizes with ANOVA.

A generalized linear mixed model with random effects (of pig) was used to determine significance of loading rate, skin thickness, and impactor diameter for displacement, stiffness, force, and strain energy at failure (SAS Studio). A generalized linear model with repeated measures and a logit link function was used to predict probability of puncture by normalized force and impactor diameter.

To investigate histological changes, twelve samples from 3 pigs were tested in puncture with the 5 mm impactor. Skin samples were

grossed at the area of impact, fixed, processed, sliced cross-sectionally and parallel to the epidermis about 100 μm deep, and stained with H&E after each step in the puncture protocol (Untested, Pre-Conditioned (PC), Sub 1, Sub 2, and Failure). PC samples were sliced near and away from the impactor site to analyze fiber re-orientation. Quantitative analysis of gaps between collagen bundles, previously reported as damage [11], were determined using the Color Threshold tool on ImageJ for 8 encompassing areas at 10x. Collagen fiber orientation was analyzed using the Distribution tool at 20x to calculate the percentage of fibers aligned with ± 15° of the preferred collagen orientation. ANOVA was used to determine significant differences.

RESULTS

After exclusion of 15 samples, 218 puncture trials were analyzed for 3 impactor diameters impacting at 4 various rates (n>18 for each impactor diameter and rate). Force at failure and skin thickness demonstrated a strong linear correlation and force was normalized by thickness for analysis. Increased impactor diameter resulted in greater normalized force, displacement, and strain energy, whereas increased rate resulted in increased normalized force and stiffness but decreased displacement (**Figure 1**). Normalized force and impactor diameter were significant (p<0.001) in predicting probability of penetration (**Figure 1**), but impact rate between 50 and 500 mm/s was insignificant (p=0.58).

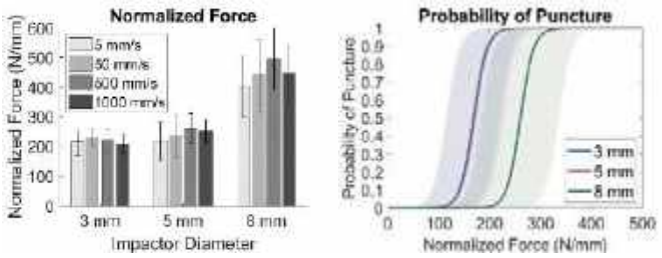

Figure 1: Effect of rate and impactor diameter in normalized force (left) and probability of puncture by normalized force (right)

The generalized linear model resulted in significant dependency of thickness, loading rate, and impactor diameter at failure (**Table 1**).

Table 1: p-values in failure metrics (* indicates significance)

	Displacement	Stiffness	Force	Strain Energy
Rate	<.0001*	<.0001*	.0011*	.1122
Thickness	.0018*	<.0001*	<.0001*	.0019*
Impactor Size	.0329*	.0695	.0164*	.0114*

Prior to puncture, the skin expressed conically distributed displacement (**Figure 2a-b**) but directionally in major (principal) strain (**Figure 2c**), which confirmed the presence of anisotropy at failure. The major strain distribution and resulting wound (**Figure 2d**) formed an ellipse-like shape, assumed parallel to natural skin tension lines and independent of the applied tension direction. The major axis length of wounded tissue was significantly greater from 8 mm punctures (p<0.001) with no differences between 3 mm and 5 mm impactor wounds (p=0.88).

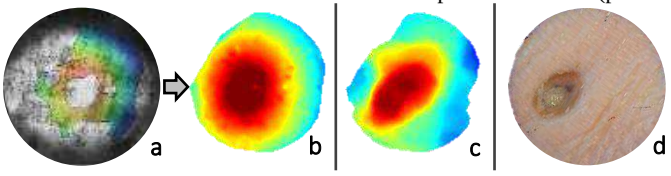

Figure 2: a) 3D-DIC displacement map of skin before failure (subcutaneous view), b) interpolation in MATLAB, c) elliptical strain profile, and d) zoomed-in wound orientation (surface view)

Natural gaps (white area) between collagen fiber families (up to 12%) were observed in untested skin (**Figure 3**). Gaps between collagen fibers significantly increased after Sub 2 and Failure (p<0.01). Collagen fibers were significantly more aligned after PC near center compared to PC away trials (p<0.001). With parallel slices, only Failure resulted in significantly more gaps than Untested, PC, and Sub 1 (p<0.01).

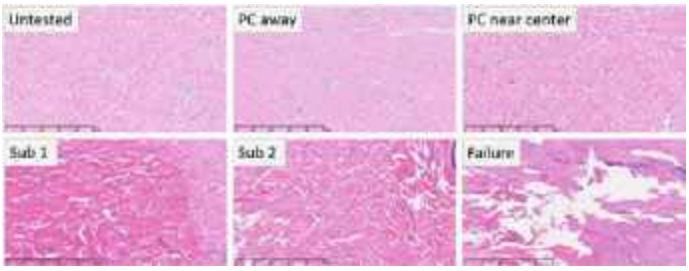

Figure 3: H&E cross-sectional stain of the dermis after Pre-conditioning (PC), Subfailure (Sub 1 and Sub 2), and Failure tests with white area showing gaps between collagen fiber families

DISCUSSION

Rate-dependency was observed in displacement, stiffness, and force during dynamic puncture of skin, which similar trends have been observed in uniaxial tension of skin [12,13]. Significantly greater failure thresholds and wound sizes were observed with the 8 mm impactor, which was also reported with increased screwdriver cross-sectional area [3], due to increased contact area and simultaneous blunt loading of the dermis and epidermis [6]. Expressing probability of puncture based on normalized force and impactor diameter allows forensic experts to quantify the likelihood of puncture with a specific instrument.

From the histological analyses, we can conclude alignment of collagen fibers near the impactor from pre-conditioning, sub-failure trials caused minimal structural damage with consistent mechanical behavior [11], and the failure mechanism of skin during puncture occurred first in the reticular dermis followed by subsequent failure of the papillary dermis and epidermis.

For accurate simulation of puncture, a material model of skin should account for the viscoelastic nature of skin with rate effects. Furthermore, this model should account for the anisotropic behavior of skin with a directionally dependent strain distribution at failure, which was measured with 3D-DIC. Ultimately, this study lays the foundation for development of a finite element model of skin during puncture to quantitatively assess failure thresholds of skin with various impactor sizes, geometries, rates, and skin thicknesses, which may aid in determining level of intent during unique stabbing incidents.

IS SYNTHETIC CLEAR GELATIN A VALIDATED SURROGATE FOR BIOLOGICAL TISSUE IN LOW-VELOCITY PENETRATING IMPACTS?

INTRODUCTION

Biological tissue is variable and difficult to access large sample sizes. Ballistic gelatin provides a repeatable, biofidelic surrogate to simulate the mechanical response of biological tissues in which 10% ordnance gelatin at 4°C has been adopted as the best surrogate for muscle [1]. Historically, calibration tests were conducted by launching a .177 steel BB at 181 meters per second (m/s) and the measured depth of penetration (DoP) must be 85 ± 5 millimeters (mm) in 10% gelatin at 4°C to verify the biofidelity [1,2]. This standard to calibrate gelatin was based on ballistic experiments into *one* porcine leg (n=10) by Dr Fackler in the late 1980s [2,3]. To assess DoP at varying velocities, empirical relationships have also been developed to establish calibration boundaries for 10% ordnance gelatin at varying temperatures [4,5].

Recent studies have compiled substantially larger datasets of DoP measurements into animals and post-mortem human subjects (PMHS) from ballistic impact of spheres and fragment simulating projectiles at velocities up to 1200 m/s [5–7]. Surprisingly, these DoP measurements were substantially less than values reported by Fackler, in which the 10% ordnance gelatin calibration standard was established. Better biofidelity was observed in 20% ordnance gelatin at 10°C. Although the 20% gelatin was adopted as the "NATO standard" for testing of small arms [8], there is no standard to verify its calibration [9,10].

One attempt to calibrate 20% gelatin used the same experimental procedure that was performed on 10% ballistic gelatin and measured the DoP, which a synthetic gelatin manufacturer claimed as 1.50 ± 0.25 inches (38.1 ± 6.35 mm) (Clear Ballistics, Greenville, SC). Since this "NATO standard" was developed based on extrapolation from 10% ordnance gelatin performance rather than biological DoP data, there is no verification that "calibrated" 20% gelatin represents a biofidelic response, especially with larger DoP data sets that contradict early, limited findings of Fackler [5].

Ordnance gelatin has been commonly used for decades but has some limitations including sensitivity to temperature and considerable variability during formation of the gelatin [1,9,10]. Synthetic gelatin has been introduced to overcome these limitations with better temperature-independence, simpler formation, increased transparency for high speed video, and the ability to re-melt multiple times. Several studies have compared the DoP, energy absorption, and cavity mechanics between ordnance and synthetic gelatins [5,11,12]. Most researchers have dismissed the opportunity to utilize synthetic gelatin in ballistic testing due to differences in these metrics. However, very few studies have compared synthetic gelatin to the actual medium researchers are attempting to simulate: biological tissue.

The purpose of this study was to investigate the validity of synthetic clear gelatin as an acceptable surrogate of biological tissue by comparing measured DoP at the low-velocity calibration range.

METHODS

90 whole porcine legs from 30 post-mortem Yorkshire pigs were frozen thawed according to previous studies, shown to not significantly affect impact behavior [13]. Shaved legs were suspended from the most proximal bone and oriented perpendicular from the projectile path. Multiple trials were conducted on each leg, but erroneous impacts to skin with underlying bone and impacts within 4 cm of a previous impact were excluded [13]. The internal and external tissue temperatures were measured at the impact site prior to each trial.

Impact velocities were targeted so that approximately half of the projectiles penetrated the skin; only penetrating impacts were used for analysis in this study. Thirteen spherical ball bearings (BBs) of stainless steel, silicon nitride, or Delrin acetal plastic ranging from 1.59 mm (1/16") to 9.53 mm (3/8") were chosen to create a spectrum of sectional densities from 0.3 to 5 g/cm^2. High-speed videography was captured laterally up to 40 kHz (nac Image Technology, Simi Valley, CA), and projectile motion (velocity and displacement) was quantified using a physics-based video analysis software (Tracker, Aptos, CA). 2D video

analysis was calibrated using the known distance of the test label, which was taped to the barrel in the plane of projectile motion.

Two blocks of 20% synthetic NATO Clear Ballistics gelatin were received from the manufacturer that claimed a calibrated DoP of 1.41 inches. The gelatin block was unbounded on a metal stand and oriented perpendicular to the projectile path at 20°C. Forty-three impacts with .177 (n=10) and 3/16" (n=33) steel BBs were conducted into gelatin spaced at least 4 cm apart. To re-test the manufacture's calibration, .177 steel BBs were launched into two blocks at a range of velocities around 590 fps. The DoP was measured and compared to the NATO "standard" using linear regression to predict the DoP at 590 fps. Additionally, 3/16" stainless steel BBs were launched into the same two gelatin blocks at velocities consistent with penetrating impacts into porcine legs. The gelatin temperature was measured at the impact site prior to each trial.

DoP was measured by inserting a probe into the tissue/gelatin until contacting the BB and adding the diameter of the BB. CT scans of the porcine legs were captured to measure DoP on RadiAnt DICOM Viewer for projectiles that were unable to be located with manual dissection. Measurements of DoP were verified using 2D video analysis.

A literature search was performed to add DoP data for low velocity ($\leq$ 250 m/s) impacts into pigs and post-mortem human subjects (PMHS). To compare DoP between projectiles of different sizes and materials, DoP was normalized by dividing by projectile diameter and material density [5]. Analysis of covariance (ANCOVA) was performed (SPSS, IBM) to determine differences in DoP (dependent variable) over velocity (covariate) between pig, PMHS, and gelatin (categorical independent variables).

RESULTS

A total of 264 penetrating ballistic trials on pig (n=192, 36 from literature), PMHS (n=29 from literature), and synthetic gel (n=43) were used for DoP analysis. At 590 fps (180 m/s) the .177 steel BB was predicted to penetrate 1.50 inches (38.10 mm) with linear regression (**Figure 1**), which was consistent with the manufacturer's calibration of 1.41 inches and the NATO standard between 1.25 in (31.75 mm) and 1.75 in (44.45 mm). Due to a larger diameter, the 3/16" steel BBs resulted in a similar linear regression slope with slightly greater DoP.

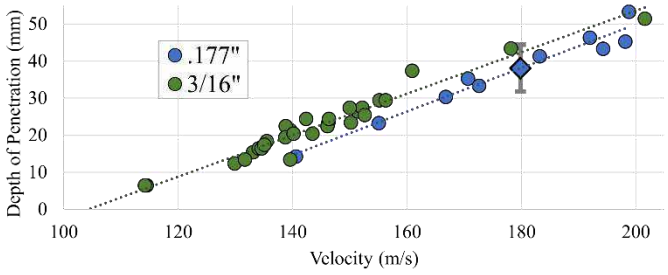

Figure 1: DoP versus velocity into 20% clear synthetic gel at 20°C with a 3/16" and .177 stainless steel BB. The calibration bounds according to the NATO standard (error bar) and the predicted velocity (diamond) at the fixed velocity of 180 m/s are shown.

Linear regression of normalized DoP over density and velocity resulted in similar equations for combined pig ($y = 0.26v - 2.16$, R^2=0.40), PMHS ($y = 0.19v - 1.28$, R^2=0.61), and clear gelatin ($y = 0.36v - 3.88$, R^2=0.96) (**Figure 2**). The synthetic gelatin demonstrated the least variability in DoP and sufficiently achieved a "calibrated" normalized DoP over density at 180 m/s, according to NATO standards. From the One-way ANCOVA, velocity was a significant covariate ($p<0.001$), and there were insignificant differences ($p=0.22$) between medium type (pig, PMHS, and gelatin).

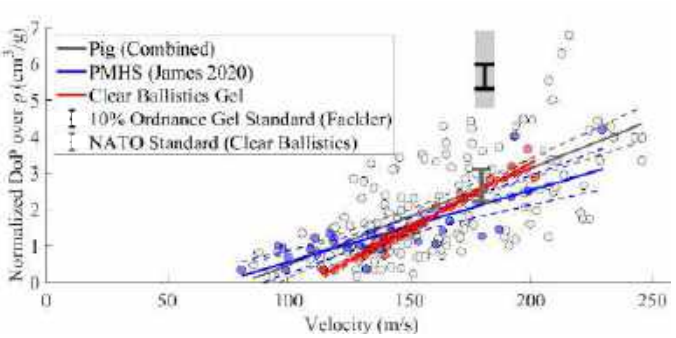

Figure 2: Linear regression of normalized DoP over density and velocity for pig, PMHS, and synthetic gelatin. The original Fackler average DoP and standard deviation into porcine leg that established the 10% ordnance gelatin standard at 4°C is shaded in gray.

DISCUSSION

Previous studies have dismissed the use of synthetic gelatin due to significantly smaller temporary cavities and greater DoP in the Clear Ballistics gel (10%) than 10% ordnance gel [12]. Unsurprisingly, differences in mechanic behavior between ordnance gelatin and synthetic gelatin have been reported. However, a larger dataset of DoP in biological tissue suggests that the original 10% gelatin standard based on experimental work by Fackler [3] may not have been infallible. These discrepancies may be due to limited sample size (1 porcine leg, 10 impacts) and small size and weight (40 kg) of the pig [3].

The results from this study and the doctoral work by James in 2020 suggest that 20% ballistic gelatin (synthetic and organic) is a better surrogate than 10% gelatin at 4°C for biological muscle tissue based on DoP [5]. Furthermore, Humphrey et al found that clear gel (10%) at 16°C was not significantly different in energy loss compared to lung, liver, kidney, heart, and 10% ordnance gel at 4°C for medium velocity impacts of 450 m/s [11], suggesting that 10% gelatin at 4°C better simulates organs rather than muscle tissue.

Ultimately, this study lays the foundation for using synthetic gelatin in ballistic research of firearms. The establishment of ordnance gelatin standards seemed to be blindly accepted based on an underwhelming sample size, but recent studies with abundant sample sizes have contradicted this DoP "standard." The authors of this study recognize the longevity of knowledge from 10% ordnance gelatin and believe the surrogate should not be entirely replaced, but that synthetic gelatin may also be used as a repeatable surrogate of biological tissue.

INTRODUCTION

Low back pain (LBP) is prevalent in military helicopter pilots [1], influenced by the unique combination of high frequency whole body vibration and the duration/frequency of missions. Whole body vibration was shown to increase mechanical loading on the spine [2], which likely contributes to annulus fibrosus (AF) degradation [3], a known contributor to LBP [4]. To prevent or limit AF degradation in these populations, protocols and technologies can be developed to reduce the mechanical burden individual pilots endure. However, to properly design these mitigation strategies it is necessary to understand how the structure and mechanical properties of AF tissue change in response to elevated mechanical loading conditions. Thus, we aimed to quantify how repetitive loads, relevant to the military environment, alter AF mechanics and understand structural changes to the tissue associated with damage. We hypothesized that structural changes would occur in response to elevated mechanical loads and the elastic response, viscoelastic response, and ultimate strength of the AF would degrade relative to the magnitude and duration of applied loads.

METHODS

Fresh porcine cervical spines were acquired from a local abattoir and AF specimens were dissected with a scalpel from the outermost layers of the anterior AF region from C3/4 to C6/7 intervertebral discs (IVDs). Test specimens were oriented in the circumferential direction and hydrated in a bath of physiologic saline for approximately one hour prior to testing to ensure uniform hydration levels. Specimen length, width, and thickness were measured using ImageJ Software (Version 1.53). A fine metal mesh was secured to each end of the specimen to prevent slippage during tensile testing and the specimen was mounted in the load frame (ElectroForce 3200, TA Instruments) using grips with knurled contact surfaces. Specimens were submerged during testing in a saline bath heated to a constant temperature (37°C). Force and displacement were measured via a 45-N loadcell (TA Instruments, New Castle, DE) and a linear variable differential transformer (LVDT) internally within the load frame. Force was converted into stress using the mid-length specimen cross sectional area as measured prior to the initiation of testing. Displacement was converted to strain based on specimen length at the 0.1-N pre-load step in the loading protocol.

Mechanical changes from cyclic loading were assessed with a 3-step experimental protocol: (1) Pre-Damage: (1A) Pre-load specimen to 0.1 N; (1B) Precondition; (1C) Incremental strain step and hold for 20 minutes at four discrete strain magnitudes (4%, 8%, 12%, 16%); and (1D) 100 tensile cycles to 11% strain at 5 Hz. (2) Damage: Specimens were exposed to one damage protocol with a constant strain magnitude (11%, 20%, 28%, 44%) for a set number of loading cycles (400, 1600, 6400, 12800 cycles) tensile loading cycles at 1.3-5 Hz. Sixteen total damage protocols were created, each with n=5, to quantify damage induced by each combination of strains and cycle count. (3) Post-Damage: (3A) Incremental strain step and hold for 20 minutes at four discrete strain magnitudes (4%, 8%, 12%, 16%); (3B) 100 tensile cycles to 11% strain at 5Hz; (3C) Quasi-static distraction to failure. All cyclic loading steps (1D, 2, 3B) were strain rate matched at 1.12 s^{-1}. Specimens were allowed to recover between each loading step. Average change in strain energy density (SED) from pre- to post-damage was calculated to quantify changes in the elastic response of the tissue. Strain energy density for each loading hysteresis was the difference between the area under the loading and unloading stress strain curve for each loading cycle (100 pre-damage, 100 post-damage). Relaxation stress delta (delta = maximum stress – minimum stress) of each incremental strain hold was calculated and compared pre- to post-damage to quantify changes in the viscoelastic response of the tissue. Finally, the linear modulus of each specimen was calculated as the slope of the linear region of the stress-strain curve during quasi-static distraction to failure. The ultimate stress and strain for each specimen were calculated to be the point at which peak stress before failure was reached, and the SED of the failure curve was calculated as the area under the stress-strain curve. To

determine what effects the assigned damage strain magnitude and number of damage loading cycles had on the mechanical properties, two factor ANOVAs were performed using (1) strain magnitude and (2) number of cycles during the damage protocol as factors.

Structural change from cyclic loading was assessed with a 2-step experimental protocol: mechanical loading followed by histologic analysis. Cyclic loading consisted of preloading AF specimens to 0.1N to remove slack from the tissue followed by 6400 cycles of cyclic loading to each of the four strain magnitudes outlined in step (2) of the aforementioned protocol. One control group was created that underwent all the same experimental steps excluding any mechanical loading. Following cyclic loading, specimens were fixed, processed, sliced parallel to the AF lamella, and stained with Verhoeff-van Gieson (VVG) stain.

RESULTS

No changes in SED and relaxation stress delta were present between Steps 1 and 3 in the baseline group, indicating their elastic and viscoelastic properties were not altered by the pre-damage and post-damage loading protocols. Ultimate properties from the baseline group were comparable with findings from our previous study measuring the elastic and ultimate properties in healthy AF tissue. Specimens exposed to damage cycles had dose dependent changes in the elastic and viscoelastic response that were each significantly dependent on strain magnitude ($p<0.001$) and number of damage cycles ($p<0.001$). Interestingly, during quasi-static distraction to failure, the linear modulus (16.6±6.5 MPa) (p strain=0.4, p cycles = 0.6), ultimate stress (5.0±2.1 MPa) (p strain=0.9, p cycles = 0.6), ultimate strain (0.58±0.2) (p strain= 0.5, p cycles = 0.9), and SED to failure (1.2±0.8 MPa) (p strain= 0.3, p cycles = 0.4) were not significantly affected by damage protocol. These findings indicate that the mechanical response during low strain magnitudes is significantly affected, while the high strain mechanical response remains relatively unaffected. This statement is further supported by the stress response in the toe and transition regions (0-30% strain) of the stress-strain curve during quasi-static distraction to failure (Figure 1). It was determined that the SED of the toe and transition regions was significantly dependent on both the strain magnitude ($p<0.001$) and number of damage cycles ($p=0.003$). Specimens exposed to 44% strain for 12800 cycles were affected the most and had a SED of 0.017±0.01 MPa, 95.2% less than the baseline group.

Histologic analysis of the AF tissue following cyclic loading shows cleft formation between collagen bundles as well as uncrimping of individual fibers (Figure 2). Damage to the elastic fiber matrix is under preliminary analysis.

DISCUSSION

This study characterized mechanical and structural changes in AF associated with sub-failure damage from repetitive loading. It was determined that increasing the number and strain magnitude of damage cycles significantly affected the mechanical response at low strain magnitudes (0-30%). However, the linear modulus and ultimate stress and strain were unaffected, regardless of the damage protocol, suggesting the mechanical response at high strain magnitudes is maintained. Prior studies reported similar changes in the low strain regime after cyclic loading. Gregory et al. cyclically loaded porcine functional spinal units at 5hz, finding a diminished toe region in the stress-strain response [5]. They hypothesized this change occurred because of elastin damage, a fiber which influences the low strain response of collagenous tissue [6].

In addition to elastin damage, collagen uncrimping found during histological examination of damaged AF tissue correlate with the mechanical changes reported from cyclic loading. Uncrimped collagen fibers, like damaged elastin fibers, decrease the response of tissues at low strain magnitudes [7]. However, despite the altered toe region mechanics, the collagen fibers are likely intact as the ultimate properties of the AF were not affected by our damage protocol, which was consistent with prior studies [8].

Mechanical and structural changes within the AF would contribute to instability of the IVD after cyclic loading, as shown by the reduced elastic, viscoelastic response, and uncrimping of collagen fibers. Due to segmental load sharing between the disc and facet joints, IVD instability can cause higher stresses in the facet joints that would contribute to accelerated facet arthropathy and may be one contributing factor to the acute back pain many helicopter pilots experience post-flight [9]. Despite these structural and mechanical changes, the overall integrity of the IVD appears to be maintained as the ultimate stress and strain in all damage groups are equivalent to un-damaged tissue. These findings can be used to better inform the design of future technologies and exposure protocols aimed at reducing the mechanical load on the lumbar spine to prevent or limit LBP and AF degeneration.

INFANT SKULL ANATOMICAL STANDARDS FOR USE IN HEAD TRAUMA MODELING

Y. Alsanea (1), T. Ruiz-Maldonado (2), B. Coats (1)

(1) Mechanical Engineering, University of Utah, Salt Lake City, Utah, USA

INTRODUCTION

Child abuse and neglect is a long-standing global problem. Infants under the age of one are particularly vulnerable as they have the highest risk of fatality and recurrence if not detected [1]. Low-height falls are the most common etiology reported in cases of suspected abusive head trauma, but it is also the most common cause of accidental head trauma in the same age group [2]. The paucity of biomechanical data in this vulnerable age group makes it challenging for medical professionals and legal teams to differentiate between accidental and inflicted trauma.

Computational modeling is an effective tool for investigating the mechanics of pediatric head trauma and predicting the likelihood of injury in accidental scenarios [3]. However, many models still face uncertainties and limitations, particularly when it comes to accounting for natural anatomical variability in infants. Typically, computational models of the infant skull are derived from a single infant and used to represent an entire infant population without justification. The objective of this study was to evaluate the similarity of infant skull thickness distribution within data-driven age and sex groups and identify the skull most representative of all infants in each age/sex group.

METHODS

CT images of 273 infants (<15 months of age) without any evidence of abnormality were collected from Primary Children's Hospital with approval from the Institutional Review Boards of Primary Children's Hospital and the University of Utah. Previously, we quantified skull thickness at over 12,000 locations for each infant CT image dataset [4]. In this study, these data were averaged for each infant and used in a Jenks Natural Breaks (JNB) optimization algorithm that identified potential divisions in the skull thickness data by minimizing in-class variance with a specified number of groups. We varied the number of groups from 1 to 10, and the goodness of variance fit was calculated for each number of groups. The appropriate number of groups was chosen to be the point where diminishing returns in goodness of fit were observed.

The JNB optimization does not consider the age dependence of the data. Therefore, a Receiver Operating Characteristic (ROC) analysis was employed after the JNB optimization to identify appropriate age divisions based on the JNB thickness groups. For each thickness group, we systematically examined all possible age ranges containing that thickness group. For each age range, we defined a predicted positive region as the interval between the lower and upper age limit. The true positive region was defined as thickness values in the predicted positive region that belonged to the thickness group being evaluated. Other groups within the predicted positive region were false positive predictions. True and false negatives were evaluated in a similar manner, focused on the predicted negative regions outside of the limits.

For each pair of age limits, a single sensitivity and specificity were calculated based on the true/false positive/negative calculations. The pair of limits associated with the best sensitivity and specificity (i.e. closest Euclidean distance to 0,1 when plotting 1-specificity vs specificity) were chosen as the ideal age limits for that thickness group. Each thickness group was evaluated independently of the limits defined by other thickness groups because this would introduce a bias based on the order in which the groups were evaluated. The independent analysis thus naturally resulted in overlapping upper and lower bounds for the age groups because thickness groups shared age ranges. To remove overlap, we created a variance optimization algorithm that maximized the between-group variance and minimized the sum of the within-group variance. Groups were optimized in consecutive pairs by shifting the lower limit of the subsequent group towards the upper limit of the former group until the variance optimization requirements were met.

Once age groups were found, a similarity metric was developed to identify similar patterns of skull thickness distribution within each age/sex group. For this analysis, the 12,000 thickness data points were divided and averaged across 132 locations on the skull. The similarity

metric calculated and summed distances between rank-ordered thickness at these locations for pairwise comparisons of all subjects. Data were normalized by a spatial weight matrix dictated by a negative exponential function. A similarity score of 1 indicated perfect similarity between regions of high and low thickness across the skull, while a score of 0 indicated no similarity. The subject with the highest similarity metric in each age/sex group was selected to act as the anatomical standard for that group.

RESULTS

The JNB optimization resulted in diminishing returns in goodness of fit after 5 thickness groups (**Fig. 1A**). The 5 thickness groups (**Fig. 1B**) had overlapping age ranges due to natural variability in an infant population. Using these 5 thickness groups in the ROC analysis and subsequent variance optimization, the optimal age divisions for infants under 15 months of age were 0-1.8 months, 1.9-5.4 months, 5.5-8.3 months, 8.4-10.3 months, and 10.4-15 months (**Fig. 2**).

Table 1 provides a summary of similarity metric descriptive statistics for each age and sex group. Infants in the Male 1.9-5.4-month age group had the lowest variability, while infants in the Male 10.4-15-month age group had the highest variability. While some differences are seen in skull thickness between the selected skull standard and other calvaria in the age/sex group (**Fig. 3**), thickness distribution trends are similar

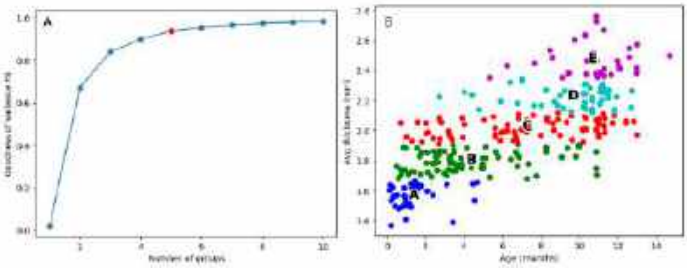

Figure 1. (A) Goodness of variance fits to find the best number of groups based on the Jenks Natural Breaks optimization on skull thickness data. The chosen number of groups was 5, which is shown as a red circle. (B) This resulted in 5 groups represented by blue dots (Group A), green dots (Group B), red dots (Group C), cyan dots (Group D), and magenta dots (Group E).

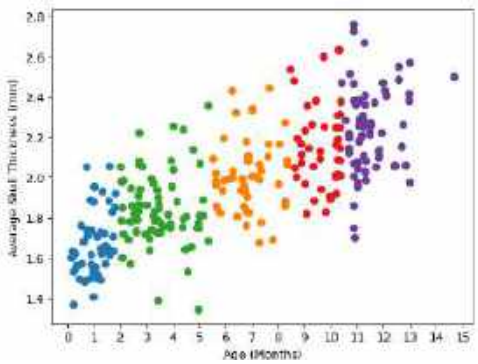

Figure 2. The optimal age groups in the clinical data set were 0-1.8 months (blue), 1.9-5.4 months (green), 5.5-8.3 months (orange), 8.4-10.3 months (red), and 10.4-15 months (purple).

Table 1: Subject pool size and similarity for each age/sex group

Sex	Age group (months)	Count	Max Similarity	Minimum Similarity	Average Similarity
F	0-1.8	22	0.7011	0.6882	0.6947
	1.9-5.4	33	0.7099	0.6871	0.7002
	5.5-8.3	18	0.7089	0.6864	0.6999
	8.4-10.3	12	0.7030	0.6855	0.6947
	10.4-15	35	0.7048	0.6887	0.6961
M	0-1.8	24	0.7085	0.6862	0.6999
	1.9-5.4	39	0.7127	0.6868	0.7037
	5.5-8.3	27	0.7039	0.6870	0.6957
	8.4-10.3	18	0.7036	0.6856	0.6961
	10.4-15	53	0.7001	0.6845	0.6930

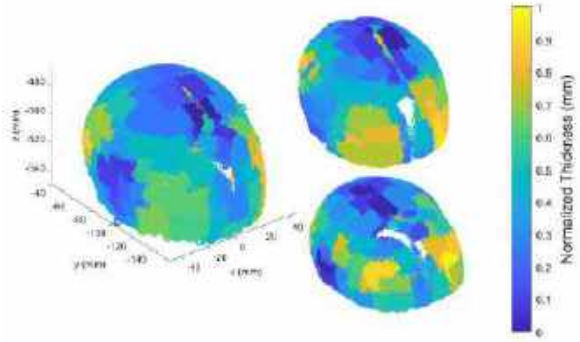

Figure 3. Thickness contour map of most similar male infant skull 1mo (left) and other male infant skulls in age group <1.8 months old (right).

DISCUSSION

Typically, age groups are defined *a priori* for a study and data is binned accordingly. To our knowledge, this study is the first to determine infant age bins based on the data itself. Our findings suggest that splitting up ages less than 15 months into 5 groups is optimal. Other studies have previously split similar age ranges into 2 or 3 groups. Utilization of 5 age groups improves the identification of anatomical changes in the rapidly developing cranium in early infancy.

We then calculated similarity metrics based on pairwise Euclidean distances between ranked thickness locations across each skull. The variation of the similarity metric within each age/sex group was small because groups were defined by minimizing variance, and ideally, they should be small. The anatomical standards for each age/sex group were chosen as the skull with the highest average similarity score. A previous study also created anatomical standards for 0-3, 3-6, and 10–12 month-old infants but only used 24 locations of comparison on each skull and had n=4, 3, and 6 infants per age group, respectively [5]. Our previous work found significant age-dependent differences in skull thickness between males and females that were also not considered in the above study. The developed age- and sex-based anatomical standards and similarity metrics methodology will improve consistency and accuracy for predicting infant head trauma through early development.

INFANTS SUCKING PATTERNS IDENTIFICATION USING MACHINE LEARNING

Abdullahi O. Olapojoye (1), Fatemeh Hassanipour (1), Abishek P. Singh (1)

(1) Department of Mechanical Engineering, University of Texas at Dallas, Richardson, TX, USA

INTRODUCTION

Breastfeeding is a complex process that demands the synchronized coordination of swallowing, breathing, and sucking. The efficiency of nutrient delivery to an infant during breastfeeding depends on the child's sucking proficiency. Evaluating in real-time whether a baby is receiving the required amount of milk is challenging, often leading to the identification of signs of inadequate sucking after the infant has already faced a nutrient deficiency.

Newborns possess primal reflexes, such as grasping, searching, sucking, and swallowing, which enable them to initiate feeding shortly after birth. The intricate sucking mechanism involves the elevation of the jaw, pressing the tongue against the nipple's front tip, and subsequent peristaltic action that effectively extracts milk. This roller-like tongue movement, reminiscent of peristalsis, facilitates the efficient expression of milk from the nipple [1]. However, infants may encounter feeding challenges due to underdeveloped primitive reflexes.

Addressing these challenges necessitates a deep understanding of infant feeding behavior. Various scientific methodologies, including ultrasonic tomography and intraoral video cameras, have been employed in research to comprehend the actions of the tongue during feeding [2–5]. The gradual integration of Machine Learning (ML) techniques into healthcare is evident, with studies focusing on assessing and intervening in various aspects of infant care [6, 7]. This exploration not only enhances our understanding of infant feeding patterns but also opens avenues for tailored interventions to support the unique needs of infants.

Traditionally, assessments of an infant's sucking potential are performed by medical professionals relying on subjective judgments, introducing variability into the evaluation process. Our approach involves the utilization of an artificial nipple-based sensor to capture tongue forces exerted by infants during breastfeeding sessions. We leverage this clinical data to develop a robust system that identifies the sucking potential of an infant. By integrating ML into clinical practice, our goal is to enhance real-time assessments and early identification of unhealthy sucking patterns, enabling timely interventions and proactive healthcare management of infants.

METHODS

To comprehend the intricate dynamics of infant feeding, a specialized measurement sensor device embedded in an artificial nipple was devised to capture the peristaltic-like movement of an infant's tongue during sucking. This innovative device features two sensors attached to a baby bottle nipple, providing insights into the forces generated during the sucking activity [8].

The force sensor integrated into the artificial nipple employs a cantilever structure, utilizing a thin stainless-steel plate as a beam. A strategically affixed strain gauge on its surface enables precise force measurement. The two sensor channels are positioned at the tip and base of the nipple, measuring forces at the root and tip of the tongue, respectively. The workflow for the proposed system is illustrated (Figure 1).

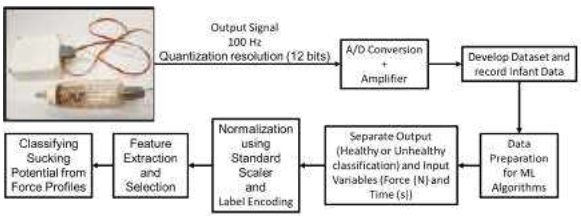

Figure 1: Sucking Pattern Classification Workflow.

During the clinical experiment, each subject was held, and the sensor device was inserted into their oral cavity, simulating the position used during normal breastfeeding. To translate these force measurements into usable data, the output signal undergoes A/D conversion through a bridge circuit and an amplifier before being transmitted to a PC via USB. Operating at a sampling frequency of 100 Hz with a 12 bits quantization resolution, this system ensures a detailed and accurate representation of peristaltic-like tongue movements.

To enhance data quality, a Low-Pass Filter was applied to mitigate noise and emphasize essential signal components in the force data. The force data involved a total of 40 subjects, categorized into unhealthy sucking (18 infants) and healthy sucking (22 infants).

In the present investigation, we developed two traditional ML and two

Deep Learning (DL) models with the aim of identifying infant sucking patterns using time series force data. The four models employed in this study are the Support Vector Classifier (SVC), Gradient Boosting Classifier (GBC), one-dimensional Convolutional Neural Network (1D-CNN), and Long Short-Term Memory (LSTM). We also conducted hyperparameter optimization to enhance the performance of our models.

RESULTS

Ten subjects' data were allocated for testing, while the remaining thirty were designated for training and cross-validation purposes. A summary of the results obtained from the five-fold cross-validation experiment is presented (Table 1). Concerning accuracy, the 1D-CNN model exhibited superior performance with approximately 90% accuracy for training, cross-validation, and testing, surpassing all other models. Following closely, the LSTM model demonstrated commendable accuracy levels of around 80%, 83%, and 90% for training, cross-validation, and testing, respectively. The noteworthy performance of CNNs and LSTM models in uncovering intricate relationships within our data can be attributed to their capability to automatically extract relevant features and capture local patterns and dependencies, and handle noise inherent in clinical data.

Table 1: Cross-Validation(CV) Experiment Results(Accuracy)

Model	Training(%)	CV(%)	Testing(%)
SVC	76.7	60.0	70.4
GBC	100.0	75.6	80.0
LSTM	80.0	83.3	90.0
1D-CNN	90.0	90.0	90.0

Evaluating the performance of a classification model based solely on accuracy may not provide a comprehensive assessment. Consequently, we extended our analysis to include precision, recall, and F1 score, along with the corresponding confusion matrix. The confusion matrix and ROC curve for the best performing model (1D-CNN) is shown (Figure 2).

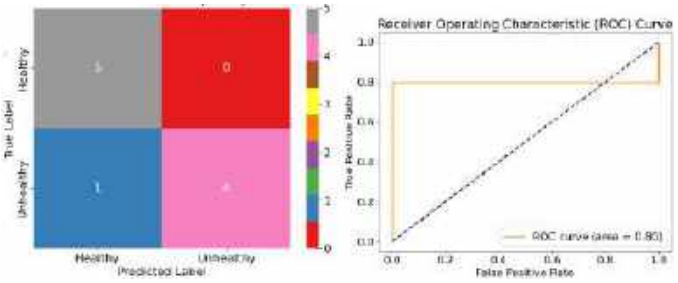

Figure 2: Confusion matrix and ROC curve for 1D-CNN model.

The confusion matrix revealed that all four models achieved a precision score of 100%. A high precision score signifies minimal false positives, implying that when the model predicts an unhealthy sucking pattern, it is typically correct. However, only the CNN and LSTM models attained the highest recall score of 80%. A high recall score indicates few false negatives, suggesting that the models excel at capturing actual positives.

In a medical diagnosis scenario, where false positives and false negatives carry distinct implications, the F1-score serves as a valuable metric to assess the overall effectiveness of the model. A high F1-score, approaching 1, signifies both high precision and high recall, indicating a well-balanced and effective model. In our study, the 1D-CNN and LSTM models shared the top position with an F1-score of 0.90, showcasing a harmonious blend of precision and recall. Following closely, the GBC model achieved an F1-score of 0.79, while the SVC model obtained a score of 0.67. We present comprehensive details regarding recall, precision, and F1-score (Table 2).

Table 2: Classification Report

Model	Recall(%)	Precision(%)	F1-score
SVC	40.0	100.0	0.67
GBC	60.0	100.0	0.79
LSTM	80.0	100.0	0.90
1D-CNN	80.0	100.0	0.90

Additionally, the analysis of Receiver Operating Characteristics (ROC) curves and the computation of the Area Under Curve (AUC) provided valuable insights into the performance of the models at different sensitivity and specificity levels. The AUC ranges from 0 to 1, where 0.5 indicates random guessing and 1 signifies a flawless model. Notably, the AUC values obtained for the SVC (0.84), GBC (0.80), 1D-CNN (0.80), and LSTM (0.80) models indicate the discriminatory power of each model.

Our results highlights the ability of the proposed system to identify infants unhealthy sucking patterns in real-time. As far as our understanding goes, this represents the pioneering application of machine learning to classify infants' sucking potential based on the force exerted by the infant during breastfeeding. This approach is readily applicable to new datasets in a clinical setting, thus serving as a significant decision-support system in infant care.

DISCUSSION

Our study has introduced a robust classification system for infant sucking patterns, leveraging artificial nipple-based sensors to capture tongue forces exerted by infants and generating valuable clinical data. Analyzing the collected time-series data involved the application of machine learning algorithms to extract pertinent features and identify distinctive sucking patterns. The emphasis on identifying unhealthy sucking patterns is paramount for timely intervention. Both LSTM and 1D-CNN models excelled in this aspect, achieving 90% accuracy, 80% recall, a perfect precision score of 100%, a 0.9 f1-score, and an AUC of 0.80.

In practical terms, the high precision score assures us that when the model predicts a sucking pattern to be unhealthy, it is highly likely to be correct, minimizing instances where it falsely identifies an unhealthy pattern when it's not the case. Simultaneously, the recall score assures that the model is adept at capturing the majority of actual unhealthy pattern instances, ensuring a robust performance in identifying the true positives while keeping false negatives at a lower rate.

This classification system, driven by advanced machine learning techniques, holds promise for providing valuable insights into infant health by accurately identifying and distinguishing sucking patterns associated with both health and potential concerns. The findings suggest that leveraging these models in clinical settings could significantly contribute to early detection and intervention, ultimately improving infant care and well-being.

INTRODUCTION

Glioblastoma is a unilaterally lethal form of primary brain tumor expected to affect more than 14,000 persons in the US in 2023. Maximally safe surgical resection is critical to improving patient survival, with gross total resection showing the largest impact on prognosis across disease factors. Following surgery, targeted radiation is used to treat residual tumor. Both critical treatments require precise localization of the tumor to maximize efficacy, which is primarily based on MRI. Contrast-enhanced T1-weighted images show a bright lesion where tumor-associated blood vessel formation is occurring and is typically used to define the surgical margin. It is, however, well known that areas of non-vascular tumor invasion exist well-beyond the enhancing margin, leading to distant areas of tumor ultimately being spared treatment. Radio-pathomic mapping of tumor probability (TPMs) has demonstrated the ability to detect these areas of non-enhancing tumor using current standard clinical imaging merged with autopsy tissue data. The algorithm allows for expanded surgical margins to more fully remove non-enhancing infiltrative tumor. As gross total resection is the primary driving factor for patient survival, it is likely that extending this margin further to encompass both enhancing and non-enhancing tumor portions will further improve survival outcomes. This study presents the first test cases for clinical implementation, where we tested the hypothesis that tumor probability maps identify areas of non-enhancing tumor for biopsy during both first surgery and recurrence.

METHODS

Autopsy tissue and clinical imaging was acquired from 65 patients with a pathologically confirmed glioma diagnosis. A schematic representation of the data collection process and analytic framework is presented in **Figure 1**.

A total of 159 tissue samples were collected across all patients at autopsy, which were then processed and stained for hematoxylin and eosin (H&E). Following staining, slides were digitized using a sliding stage microscope at 40X magnification (0.2 microns per pixel). Images were then segmented to compute cell density, extracellular fluid density (ECF) and cytoplasm density (Cyt) using a color deconvolution algorithm. A subset of 33 tissue samples from 9 patients were also annotated for tumor presence by our pathologist-trained technician. T1,

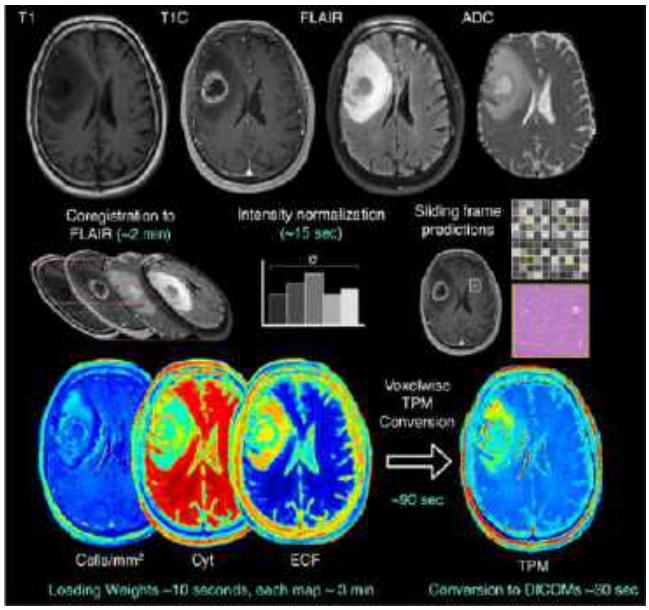

Figure 1: Overview of TPM generation process.

T1C, FLAIR, and ADC images from each patient's last clinical imaging session prior to death were used for this study. All images were aligned to the FLAIR image, and all images (T1, T1C, FLAIR) were intensity normalized. Histology samples were then aligned to the MRI using a custom in-house software that applies a nonlinear transform to match tissue data to the FLAIR image from manually defined control points[8–11]. Separate bootstrap aggregated ("bagged") ensemble algorithms were trained to predict voxel-wise ECF, Cyt, and cell density using 5 by 5 voxel tiles from each MRI. Models were trained on 2/3s of the full data set (43 subjects) and tested on a held out set to assess generalizability (22 subjects). An RUSBoost algorithm was then used to identify tumor presence using the pathological annotations as ground truth and the tissue segmentations for Cell, ECF, and Cyt as input (train size: 6 subjects, test size: 3 subjects). The training and development of this model is presented in full in a previously published study, with an example of the model's potential to identify non-enhancing tumor presented in **Figure 2**[1,2].

For prospective clinical integration, we applied our model to pre-surgical imaging for two patients with a primary glioblastoma, one prior to first surgery and one following radiographic recurrence. Regions of interest were defined based on hotspots of non-enhancing tumor presence on TPM and cellularity radio-pathomic maps, which were then used as biopsy targets prior to surgical resection in addition to standard biopsy procedures. Both surgeries were conducted using 5-aminolevulinic acid (5-ALA) staining for fluorescence-based guidance, as well as compared to our TPM-based predictions for tumor presence. Biopsy tissue was then stained for H&E and immunohistochemical markers, including SOX2 as a measure of pluripotency, and were examined by a board-certified pathologist for tumor presence.

RESULTS

A total of 2 TPM-guided biopsies were taken from prospectively identified regions of interest for each patient **(Figure 3)**. For the first surgery case, both biopsies were collected from 5-ALA negative areas,

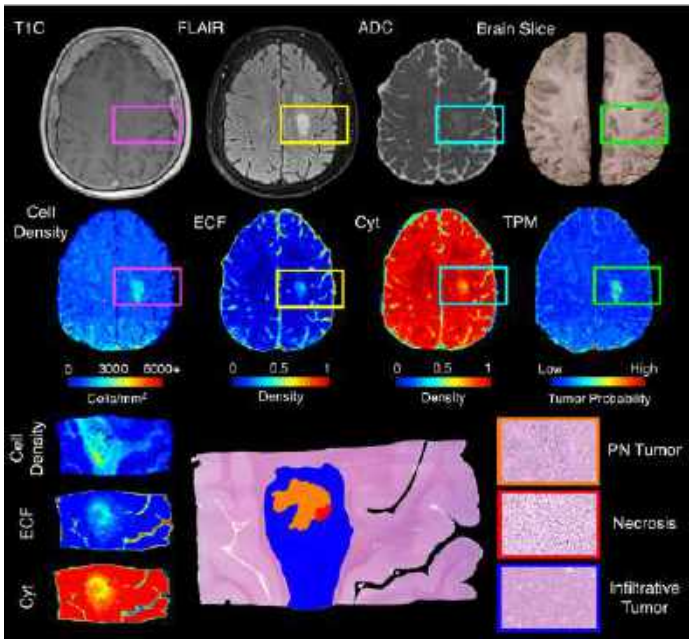

Figure 2: Example TPM accurately identifying an area of non-enhancing tumor, as well as a high ECF area of pseudopalisading necrosis (PN) within the tumor.

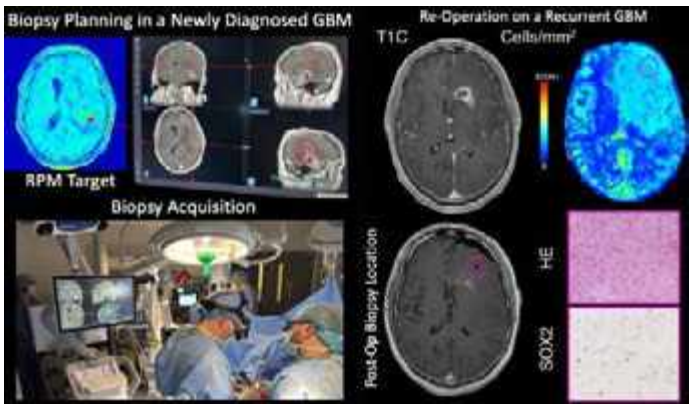

Figure 3: (left) Images from biopsy planning for a prospective newly diagnosed GBM using TPMs to identify non-enhancing tumor areas for sampling. (left) Imaging, TPM, and pathology from a recurrent surgery where TPM-guided biopsy found SOX2-positive tumor from beyond the enhancing region.

indicating an absence of tumor on both radiological and fluorescence-based guidance. Both biopsies were found to contain pathological tumor presence, indicating tumor presence identified by TPMs that failed to present on other visualization methods. For the recurring patient, prior follow-up surgeries had failed to identify tumor presence despite radiographic progression, suggesting pseudoprogression. Both of the TPM-guided samples were 5-ALA positive, potentially indicating tumor presence, and both showed moderately increased cellularity and positive SOX2 staining, supporting tumor presence. No other biopsies collected from this surgery showed signs of tumor presence from traditionally identified regions.

DISCUSSION

This preliminary study provides a framework and initial evidence for the surgical integration of radio-pathomic TPMs to identify occult tumor missed by other forms of surgical guidance, such as traditional MRI and intraoperative fluorescence. These maps are rapidly generated using traditional MRI as input, allowing for non-enhancing tumor identification without impacting scanner time or slowing down clinical workflows. This tool has also been undergoing extensive external validation, where high-quality maps have been generated for over 1000 external cases from publicly available datasets in addition to external studies comparing high tumor probability regions to advanced imaging signatures such as perfusion imaging, APT-CEST based pH-weighted imaging, and MR spectroscopy for measuring tumor metabolism. While this small prospective sample will require a larger sample size to fully validate the use of TPMs for guiding surgery, the results from this study suggest this technique has the potential to non-invasively expand the treatable tumor margin for glial tumors.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is one of the world's most prevalent morbidities, often requiring ventilatory support [1]. However, this may lead to ventilator induced lung injury (VILI), as devices commonly employ non-physiological positive pressure ventilation (PPV) which pushes air directly into the lung [2]. Negative pressure ventilation (NPV) devices are more akin to physiological breathing which induces an external pressure drop, causing an inrush of air to the lung to balance pressure. NPV devices are not widely used, and the deviation from natural breathing in clinical PPV may contribute to VILI [3,4,5]. Specifically, studies link VILI to elevated lung heterogeneity, using this metric to investigate ventilatory methods [6,7]. Yet, most PPV versus NPV literature addresses global pressure-volume measures and cannot explore nuanced local attributes, such as heterogeneity, and how they differ between schemes [3]. While current local studies exist, they are limited to healthy states [5], underscoring the need to examine PPV versus NPV for pathological lungs.

Herein, we examine healthy control versus emphysematous murine local lung strains by pairing digital image correlation (DIC) with interchangeable PPV and NPV loads. DIC allows full-field spatial and temporally continuous deformation quantification; thus, we examine lung expansion over the inflation profile to quantify heterogeneity, anisotropy, and evolution of these strains, which is central to divulging potential pathways to VILI [8,9]. By analyzing elastase exposed lungs, we explore how emphysema, a clinically relevant pathology, affects the local pulmonary response to PPV versus NPV [10]. We hypothesize NPV strains will be less heterogenous and of lower magnitude (i.e., less stretch) than PPV—reducing potential for VILI [4,5].

METHODS

Ten 8-12 week-old male C57BL/6J mice were procured (Jackson Laboratory, Bar Harbor, ME, USA; Institutional Animal Care and Use Committee approved). Five mice were intranasally exposed to porcine pancreatic elastase (single dose, 0.9 ul) to induce emphysematous COPD, while the five healthy controls received 1X phosphate-buffered saline, according to established protocols [10]. After four weeks, mice were anesthetized and sacrificed, then lungs were extracted, cannulated, inflated to 0.5 ml, and speckled for DIC as in previous methods [11].

Lungs were placed in an airtight clear tank attached to our custom electromechanical dual-piston breathing mimicry device, facilitating inflation testing via both PPV and NPV on each specimen consecutively (albeit the response is not PPV/NPV mode sequence dependent [12]). Briefly, a piston either pushed air (PPV) into the lung, or increased tank volume to prompt air entrainment (NPV) into the lung. Simultaneously, a compensatory piston accounted for real-time air compression, and reported resultant global lung pressure [13]. Lungs were tested at 0.7 ml applied volume at 10 breaths/minute, in accordance with past studies [14]. The test sequence included a 5 cmH_2O preload, followed by three inflation-deflation preconditioning cycles, and a fourth test inflation cycle wherein overhead DIC cameras captured surface deformation (Trilion Quality Systems, King of Prussia, PA, USA), as extensively validated in past works [9,11]. Collected DIC data was analyzed for principal strains

Average pressure-strain curves reported the lung local response (analogous to global pressure-volume curves) [9] (Fig. 1). Slopes were fitted (R^2>0.95) to assess bilinear compliance where applicable, (C_1=lower slope associated with initial recruitment, C_2=final steeper slope; Fig. 1b) [5,9,15]. Moreover, correlated surface strain histograms exhibit the evolutionary strain response at select inflation volumes (0.2, 0.5, and 0.7 ml maximum air delivery); averaged mean strain values (ε_{avg}) and interquartile range (IQR, used to assess heterogeneity [16]) are listed with each histogram. The anisotropic ratio (AR, major to minor stretch ratio) was assessed at 0.7 ml, where a value of 1 is isotropic [5,9,11]. Strain metrics were compared between PPV and NPV within control and exposed groups using a paired two-tailed t-test with $p<0.05$ for significance (GraphPad Prism 9 for Windows) [17].

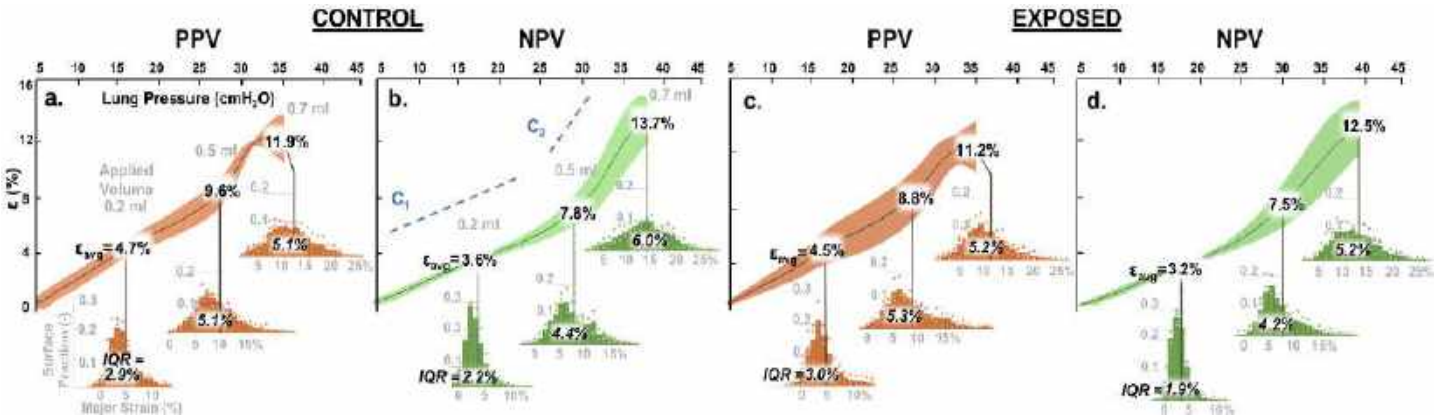

Fig. 1. Murine lung PPV (orange) and NPV (green) pressure-strain curves (average ± standard deviation; shadows) for control (a, b) and elastase-exposed emphysematous (c, d) lungs. Representative compliance slopes are shown (dotted blue lines; b). Histograms of average strain ± standard deviation (dots) are shown at 0.2, 0.5, and 0.7 ml, with averaged mean strain (ε_{avg}) and interquartile range (IQR; italicized).

RESULTS

The local pressure-strain response for PPV curves (orange) were not consistently bilinear, rendering C_2 occasionally immeasurable (Fig. 1); average C_1 slopes were 0.35 and 0.27 %/cmH_2O for control (Fig. 1a) and exposed (Fig. 1c) emphysema groups, respectively. NPV curves (green) were notably bilinear, with average C_1 slopes of 0.25 %/cmH_2O for both control and exposed specimens, and C_2 slopes of 0.81 and 0.65 %/cmH_2O for control (Fig. 1b) and exposed (Fig. 1d), respectively. Thus, PPV tended to yield steeper C_1 slopes than NPV, albeit statistically insignificant.

Histograms associated with low- to mid-volume (i.e., 0.2 and 0.5 ml) tended to show higher ε_{avg} and IQR in PPV compared to NPV. Conversely, ε_{avg} and IQR trended greater for NPV at 0.7 ml (control group IQR: $p<0.05$).

AR values were 0.93 (PPV) and 0.94 (NPV), for both control and exposed lungs. This greater anisotropy for PPV compared to NPV was significant for the exposed group ($p<0.05$).

DISCUSSION

We find strain magnitude trends greater in PPV at 0.2 and 0.5 ml, suggesting greater stretch and therefore more potential for VILI, compared to NPV [2,4,5]; however, we observe decreased strain in PPV compared to NPV at maximum volume in contrast to previous porcine studies, possibly due to physiological discrepancies between species [5,18]. Moreover, elevated mechanical heterogeneity is correlated with injury and disease [6,7], and we find strain heterogeneity increases in PPV (0.2 and 0.5 ml), in agreement with porcine lungs—thus indicative of VILI tendencies.

Anisotropic ratio assesses tissue stretch distortions [5], which can indicate injury or pathologies (e.g., COPD) [19]. We find lungs are generally isotropic, but show more anisotropy with PPV, as in previous studies [5]. Notably, this is significant for exposed lungs, suggesting that VILI induced by PPV may be exacerbated by emphysema.

We also observe disparate pressure-strain inflation profiles between the schemes: C_1 tends to be greater in PPV, and curves are not always bilinear in PPV contrary to NPV. Previous studies claim that the recruitment of secondary peripheral airways (indicated by C_2 [9,15]) may be delayed in PPV [12]. Our findings may also reflect such an altered secondary recruitment phase in PPV.

Elastase-induced emphysema in mice affects centrilobular regions [20]. Thus, highly compliant (fenestrated) central regions, combined with PPV and its lessened ability to distend peripheral secondary airways, may render PPV-emphysematous lungs susceptible to centrally-located regional overdistension. This may be why we observe greater heterogeneity trends (i.e., IQR regional variability) in PPV compared to NPV for exposed lungs (0.2 and 0.5 ml, Fig. 1c and Fig. 1d), while IQR values tend to be more similar between PPV and NPV for controls (0.2 and 0.5 ml, Fig. 1a and Fig. 1b). Interestingly, this behavior does not carry through to maximum inflation at 0.7 ml, which motivates further investigation.

Herein, we assess murine lungs' local mechanical response to PPV versus NPV. DIC methods are used to characterize continuous local strains, which are nascent despite providing nuanced insights that global metrics cannot. Notably, we provide localized comparisons of ventilatory schemes for lungs with induced emphysema, offering new perspectives on how artificial ventilation (PPV) deviates from natural breathing (NPV). Ultimately, this may help reveal how VILI develops in lung states which necessitate ventilatory support. Future work will characterize other pathologies, such as fibrosis, to further catalog clinically relevant lung diseases under the ventilation schemes.

INTRODUCTION

Computational fluid dynamics (CFD) simulations have emerged as a powerful tool in biomedical and clinical applications, for e.g., it is used for determining vascular fractional flow reserves to guide coronary interventions, for sizing bypass grafts, and for identification regions of abnormal flow during atherosclerosis and aneurysms for predicting disease progression. However, traditional simulations are slow, and cannot generate large data to show utility of biomechanics parameters, which is needed before clinical adoption. Here, we investigate the use of deep learning [1] to enable real-time computation of vascular fluid mechanics. We propose to use multi-case networks, which are networks pre-trained across a range of vascular geometries, such that they can give real-time fluid dynamics results. We tested an unsupervised Physics-Informed Neural Network (PINN) [2] and a fully supervised network trained by CFD without physics constraints. We compare these two networks to understand the utility of physics-informed training, and investigate associated strategies to achieve accuracy.

METHODS

We train networks to calculate full 3D flow fields over an arbitrary range of vascular geometries. Geometric variations are controlled by three geometric shape parameters, "S1" and "S2" control the half-sinusoidal curvature in the y- and z-axis respectively, and "A" controls the stenotic extent in the middle of the vessel (Figure 1). The centerline c, defined over $x = [-0.15m, 0.15m]$ follows the equation,

$$c_y = S_1 \sin(x\pi/0.15) - \sin(2x\pi/0.15) \quad (1)$$

$$c_z = S_2 \sin(x\pi/0.15) + \sin(2x\pi/0.15) \quad (2)$$

while the radius of the vessel as a function of x is,

$$r = 0.006\,[1 - A\,exp(-x^2/0.045)] \quad (3)$$

A parabolic profile with max velocity of 0.12m/s at the inlet, zero reference pressure at the outlet via boundary condition loss functions (**BC**). For **PINN**, the incompressibility and steady-state Navier-stokes Equations are applied as loss terms. For the fully supervised network (**SN**), instead of fluid physics equations, constraints enforce a similarity to CFD velocity and pressure results for a range of geometries.

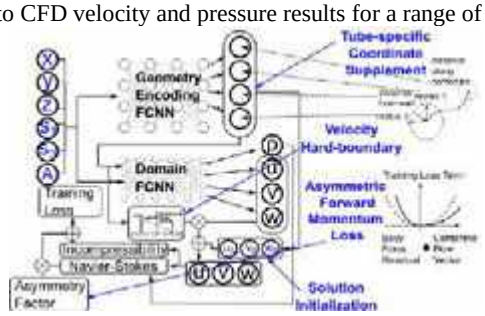

Figure 1: Illustration of Neural network structure with dependent techniques.

WE further tested several ancillary strategies: **(1) Geometric Encoding (GE):** a side network, the GE network is trained separately and used to compute tube-specific coordinates (centerline distance, distance from wall, etc.) of any point in the flow field. These are used as additional input to the main network on top of the cartesian coordinates and geometric shape parameters to improve results (Fig 1). **(2) Hard Wall Boundary Constraint (HB):** The no slip wall boundary conditions better enforced via a hard constraint rather than a loss term, by multiplying network velocity results with a power law function that dips to zero at the walls, guided by the distance to wall parameter. **(3) Volume Flow Rate Constraint (QC):** a loss term enforces the same volume flow rate at the inlet and outlet to mitigate difficulty in spatial propagation of PINN convergence. **(4) Asymmetric loss function (ASYM):** The Navier Stokes momentum equation loss was biased to favor forward flow momentum, to mitigate the optimizer's tendency to move towards the zero-velocity solution. We used NVIDIA Modulus v22.09 with additional codes [3]. Training is performed for 64 geometries, along a regular grid (4 by 4 by 4) of shape parameters.

RESULTS

From training PINN for a single geometry, we find that QC, GE,

HB and ASYM strategies all improved accuracy (Fig 2), with GE being the most important. Our PINN is reasonably optimized with GE, HB and ASYM, having low errors. This is then used for multi-case training. Fig 3 can show that PINN results closely resemble CFD results in 3D.

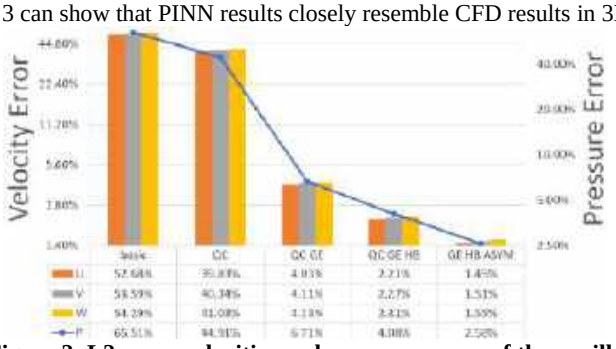

Figure 2: L2 norm velocities and pressure errors of the vanilla PINN and PINN in combinations with various strategies.

Figure 3: Comparison of PINN results to CFD results.

After the multi-case training, both PINN and SN can rapidly produce flow field results in real-time (~15ms inference time per 1000 data points) even for previously unseen geometries. Accuracy testing is conducted using 279 geometries unseen by the networks, spaced regularly across the 3 shape parameters, and errors are quantified by comparing deep learning outputs to CFD outputs. When we compared the accuracy of PINN to SN, surprisingly, SN performed better in terms of velocity and pressure errors (Table 1). We further tested a network that combines PINN and SN, where some CFD results are used to help the training in PINN, at geometries where errors are high (PINN+TC). Results are still not as good as SN. This surprising result suggests that physics-informed training is not as robust as CFD-guided training in the network. However, PINN has lower errors when quantifying wall shear stresses (WSS) than SN (Table 2).

type	BC	HB	GE	Relative L2 error (%) (Average/Maximum value)			
				U	v	w	p
SN	√	√	√	0.55 / 1.61	0.63 / 1.87	0.54 / 1.60	0.64 / 2.51
SN		√	√	0.76 / 2.75	0.90 / 3.05	0.84 / 2.84	1.31 / 5.86
SN			√	0.79 / 2.64	0.88 / 2.80	0.91 / 3.33	1.38 / 3.67
SN				0.72 / 2.14	0.83 / 2.20	0.72 / 2.41	1.16 / 4.50
SN	√			0.75 / 1.44	0.86 / 1.64	0.67 / 1.26	0.57 / 0.92
PINN	√	√	√	2.11 / 8.62	2.43 / 8.88	2.17 / 8.70	2.52 / 12.5
PINN+TC	√	√	√	1.70 / 3.61	2.14 / 4.20	1.75 / 3.85	2.41 / 6.50

Table 1: Errors in u, v, w velocities and pressure (p) when testing the multi-case networks, average or maximum of 279 test cases.

type	BC	HB	GE	Relative L2 error of WSS (%)	
				Average	Maximum
SN	√	√	√	8.29	10.86
SN		√	√	6.86	8.95
SN			√	8.85	12.11
SN				8.71	16.58
PINN	√	√	√	4.61	14.59
PINN+TC	√	√	√	4.32	7.46

Table 2: Average and maximum testing errors of wall shear stress within range of case parametric.

Interestingly, even with SN, the additional strategies of BC, HB and GE are still important, as they can reduce velocity and pressure errors substantially (table 1). For wall shear stress, having HB and GE are helpful but not BC in reducing errors.

DISCUSSION

Our vision is for flow details to be available to clinicians, including flow velocities, pressure drops and wall shear stresses, immediately after scans are performed. Having very fast processing can enable large sample clinical investigations to robustly demonstrate the clinical utility of biomechanics parameters, and can enable adoption into clinical practices. Our study shows that it is feasible to develop networks that can instantaneously yield flow simulation results with low errors, even for geometries that are not yet seen by the network, by pretraining the network over a range of geometric shapes. However, currently, our implementation is limited to steady and laminar flow, and we have only trained for 3 shape parameters. Much future work is thus needed to achieve this vision.

Our results show that to achieve good accuracy, it is important to use tube specific coordinates, obtained via GE network. This is likely because fluid dynamics in a tube is highly dependent on these coordinates, eg., velocities are highly dependent on distance to wall, while pressure is highly dependent on centerline distance. This approach is somewhat similar to Oldenburg et al's Geometric-Aware PINN [4], but we have used tube-specific coordinates rather unidentified shape parameters. On the hard boundary constraint (HB) strategy, our results that HB improves accuracy is in agreement with previous implementations [4]. One challenge that PINN has, is the spatial propagation of convergence through the tube. For example, convergence on the continuity equation is difficult to spread from the inlet to the outlet, resulting in the PINN favoring solutions with lower velocities. For this reason, the QC and ASYM strategies were effective in reducing errors. We believe that this is likely related to PINN's use of the fully connected network structure, and enhancements such as graph network may be able to improve this.

Surprisingly, the CFD supervised network (SN) outperformed PINN in velocity and pressure errors. This suggests that the physics equations constraints in PINN are not effective in enabling a convergence to the truth. Again, this is likely related to the weak ability of PINN in achieving convergence and minimization of losses. On top of accuracy, SN also trains and converges faster than PINN. As such, unless PINN's convergence abilities are enhanced, the CFD-supervised approach seems to be a better way for multi-geometry deep learning fluid mechanics inferences. Although PINN has better WSS accuracy than SN, it is possible to train SN with WSS details, on top of velocity and pressure details, to close the gap.

Thus, Overall, our results unexpectedly suggest that CFD-supervised network is superior to PINN for deep learning vascular fluid mechanics estimations. When using such fully supervised networks, our proposed strategies of geometric encoding (GE), providing boundary conditions (BC), and imposing a hard wall boundary constraint can significantly reduce errors.

CORRELATION BETWEEN LOADING-INDUCED CHANGES IN OPTICAL REDOX METRICS AND MITOCHONDRIAL DEPOLARIZATION VARIES BY STRAIN RATE AND CARTILAGE ZONE

INTRODUCTION

Redox balance, the balance between oxidative and reductive reactions, is crucial for cartilage health. Accumulation of reactive oxygen species (ROS) disrupts redox balance and plays a role in osteoarthritis (OA) progression [1] [2]. Monitoring redox balance is a potential way to evaluate cartilage health and screen therapeutics.

Given that mitochondria are the main site of ROS production, monitoring mitochondrial membrane potential, an indicator of mitochondria function, can indicate redox imbalance. Mitochondrial depolarization in cartilage induced by impact injury has been shown using polarity-sensitive fluorescent dye [3]. Although fluorescent dye is a well-established way to evaluate redox balance, clinical usage and translational potential of exogenous dye are limited.

Optical redox imaging (ORI) is a label-free and real-time method to monitor redox balance in living tissue [4]. It utilizes the autofluorescence of flavin adenine dinucleotide (FAD), nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate (together termed NAD(P)H), which are cofactors in cellular redox reactions. The fluorescence intensity correlates with accumulation of the corresponding compound, and the optical redox ratio (ORR) calculated using their intensities reflects their relative concentration. A previous study from our lab showed that ORI metrics (fluorescent intensity of FAD, fluorescent intensity of NAD(P)H, and ORR) were mechanoresponsive [5].

Although ORI provides a promising way to quantify cellular redox balance, there is a knowledge gap between measured ORI metrics and commonly used ways to monitor redox balance such as mitochondrial depolarization. The objective of this study is to establish correlations between ORI metrics and mitochondrial depolarization in response to mechanical stimuli.

METHODS

Twenty full-thickness cartilage strips were collected from the patella of one 4-5-month-old pig (sex unknown). The dimensions of the strips were at least 10 mm long by 0.65±0.17 mm thick (Figure 1A). Ten randomly selected strips underwent tensile loading at either 10%/s or 100%/s, while the other ten served as unloaded controls. A custom microscope-top loading device (Figure 1B) was manufactured so that loaded and unloaded samples were exposed to the same environment throughout the test.

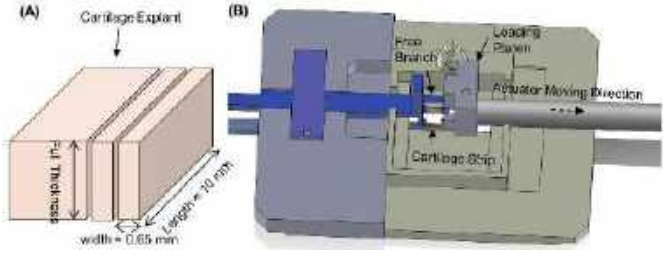

Figure 1: (A) Schematic of cartilage strip collection; (B) Microscope-top loading device.

ORI was performed [5] on 24 regions of interest (ROI) through the superficial, middle, and deep zones (Figure 2). Images in each ROI were taken in green and DAPI channels, corresponding to the spectrum of FAD and NAD(P)H, respectively. Before loading, images were captured in two regions in each zone. At 0 and 30 minutes after loading, images were taken in one region in each zone.

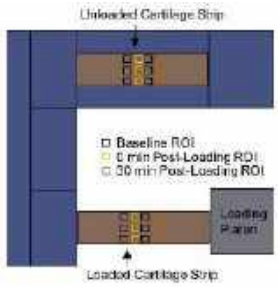

Figure 2: ROIs in microscope view of loading device, articular surface is up.

Five loaded-control pairs were subject to mitochondrial depolarization staining. Both loaded and unloaded samples were removed from the device and incubated with 1x JC-1 mitochondrial membrane potential detection dye (Biotium, Hayward, CA, USA) at 37°C for 15 minutes. Images were then taken in green and red channels, for depolarized and polarized mitochondria, respectively.

Image intensity was measured using Image J. ORR was calculated using equation (1). Post-loading autofluorescent intensity in green channel, post-loading autofluorescent intensity in DAPI channel, and post-loading ORR were normalized to the averaged pre-loading value of each sample in each zone. For JC-1 images, fluorescent intensity in the red channel was divided by that in green channel in the same ROI [6]. Linear regression analysis was conducted on scatter plots between normalized ORI metrics and mitochondrial depolarization (weak correlation at $0.10 < R^2 < 0.20$; no p-values reported because of the small sample size and weak correlations).

$$ORR = \frac{FAD\ intensity}{FAD\ intensity + NAD(P)H\ intensity} \quad (1)$$

RESULTS

When considering all data collected in both loading conditions and all zones together, mitochondrial depolarization was not correlated with either autofluorescent intensity or ORR (Figures 3A). However, weak correlations were observed by loading rate (Figures 3B,C). Also, the superficial zone showed weak correlations (Figure 4A).

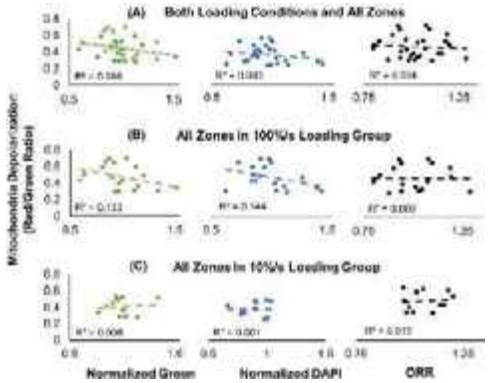

Figure 3: Mitochondrial depolarization versus ORI metrics for (A) all data; (B) 100%/s data; (C) 10%/s data.

Samples loaded at 100%/s and their unloaded counterparts showed a weak correlation between mitochondrial depolarization with normalized autofluorescent intensity in both green and DAPI channels, but there was no correlation between mitochondrial depolarization and ORR (Figure 3B). Mitochondrial depolarization was not correlated with any of the ORI metrics in the 10%/s group (Figure 3C).

For data collected in superficial zone, mitochondrial depolarization correlated with normalized autofluorescent intensity in both green and DAPI channels, but did not correlate with ORR (Figure 4A). There was no correlation between mitochondrial depolarization and any of the ORI metrics in the middle and deep zones (Figure 4B,C).

DISCUSSION

In this study, we induced changes in ORI metrics and mitochondrial membrane potential in cartilage using tensile loading, and showed there were zonal differences in cartilage mechanobiological response. The superficial zone was more responsive than middle or deep zone, demonstrating a weak correlation between post-loading mitochondrial depolarization and ORI metrics. This observation is

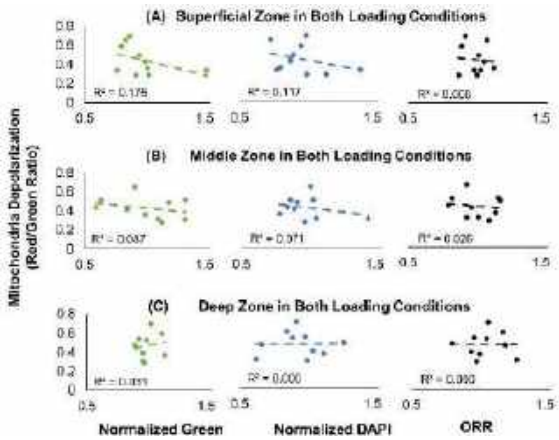

Figure 4: Mitochondrial depolarization versus ORI metrics for (A) superficial zone; (B) middle zone; (C) deep zone.

consistent with the roles of the superficial zone as highly dissipative and compliant [7] and with higher chondrocyte density [8].

Our results also showed that the cartilage mechanobiological response to tensile loading is strain-rate dependent. Samples in 10%/s loading group showed no correlation between post-loading mitochondrial depolarization level and ORI metrics, while samples in 100%/s loading group showed weak correlation between mitochondrial depolarization and autofluorescence in both channels. It is well-known that cartilage is responsive to mechanical stimuli, and its response is dependent on loading parameters such as stress magnitude, frequency, and strain rate. Specifically, a previous study showed the percentage of chondrocytes exhibiting calcium signaling was significantly increased by cyclic compression at a strain rate of 100%/s, but the effect was not observed at 25%/s or 50%/s [9]. Our findings aligned with their observation that cartilage was more responsive to higher strain rates.

The main limitations of this study are the relatively small sample size, the collection from one animal, and the noise inherent in both ORI data and mitochondrial depolarization measures. Only five pairs of samples were subject to JC-1 dye staining (n = 3 for 100%/s loading group, n = 2 for 10%/s loading group). Future research will aim to increase these numbers as well as explore the effects of other stimuli on ORI metrics and mitochondrial depolarization.

Although more data are necessary to complete the story, current findings of the study demonstrated the potential of using autofluorescent intensity to evaluate cartilage redox balance and implied its correlation with mitochondrial depolarization. The variation of correlation by strain rate and zone was consistent with previous knowledge and would be helpful in further study of cartilage redox balance in response to mechanical stimuli.

INTRODUCTION

Oxidative stress is a biochemical stress resulting from the overproduction of reactive oxygen species (ROS)[1]. The accumulation of ROS can damage nucleic acids, proteins, and lipids[2]. It has been reported that oxidative stress has a strong association to some irreversible disease conditions such as fibrosis and cancer[3,4]. Normally, the human body removes ROS by the action of antioxidative enzymes. Unfortunately, there is always redox imbalance in fibrotic or cancerous tissue, as well as post-injury conditions, because the generation of ROS outpaces the removal of it. One logical way to counter excessive oxidative stress is to provide additional antioxidative support to patients. A common way to fulfill the antioxidative demand is to intake antioxidative supplements. But multiple antioxidants are necessary to provide a full spectrum antioxidation because oxidative stress is a result of a collection of varied ROS and different antioxidants are required to neutralize specific ROS. Since consistently taking numerous supplements is not favorable, a solution that can offer multiple antioxidative actions in one shot would be ideal. In this notion, mesenchymal stromal/stem cells (MSCs) can serve as a suitable candidate for this purpose because of their multiaxial regulatory role[5]. Although there has been some success in MSCs therapy, the therapeutic effect of MSCs remains unpredictable in most of the applications[6]. We, therefore, have designed a novel hydrogel system that can control the production of antioxidative enzymes of MSCs through a mechanobiology approach, as it has been shown that the secretome profile of MSCs is sensitive to the mechanical properties of the microenvironment they reside in[7]. Our goal is to develop a mechanically dynamics hydrogel that specifically responds to oxidative stress and then triggers the extra production of antioxidative enzymes from MSCs. We believe the success of this work will offer a new management approach for oxidative stress.

METHODS

To make ROS responsive hydrogels, 3-aminophenylboric acid (PBA) was first conjugated to sodium alginate (Alg) via a reaction with 1-ethyl-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC-HCl) using a 1:1.26:2.73 molar ratio of Alg:PBA:EDC-HCl. The reaction was stirred at room temperature for 24hr, then dialyzed against DI water for 3 days and freeze dried, yielding Alg-PBA (Figure 1)[8].

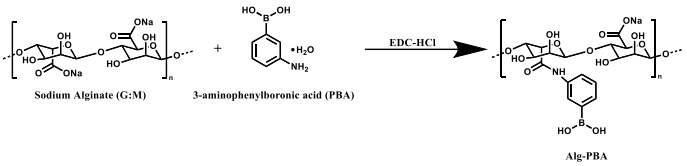

Figure 1: Alg-PBA conjugation.

Dried Alg-PBA was then dissolved in FlouroBrite DMEM (FDMEM) to make a 5%(w/v) solution. The Alg-PBA hydrogel was then formed by a dual crosslinking method: covalent easter bonds between PBA and PVA (polyvinyl alcohol) + ionic bonds between Ca^{2+} ions and the carboxylic groups on the alginate chains that were not conjugated with PBA (Figure 2). The PBA-PVA bonds are expected to cleave in the presence of ROS, while the ionic bonds remain intact. With this partial cleavage of crosslinking bonds, the hydrogel will become mechanically softer in the presence of ROS.

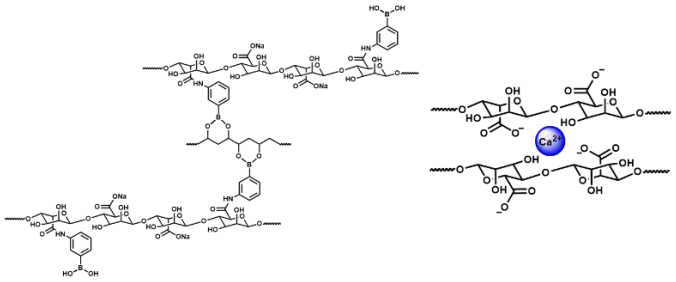

Figure 2: PBA-PVA covalent bonding (left) and ionic bonding between carboxylic groups on the alginate and Ca^{2+} ion (right).

The ROS responsive hydrogels were mechanically characterized using an axial compression test on HR 20 Rheometer (TA Instruments). An 8mm diameter gel disc was compressed with a 25mm diameter indenter. The test was performed in a submerge chamber filled with 10mL of culture media (DMEM +10% fetal bovine serum, +1% GlutaMax, +1% penicillin-streptomycin) and warmed to 37°C. The compression test was conducted with 10% strain, at a 5µm/s strain rate. The Young's Modulus was then calculated by Hertz Model by assuming the Poisson's ratio of the hydrogel was 0.5. To characterize the ROS response of the gel, 2 identical tests were performed on the same gel disc with 1µM H_2O_2 added in between the 2 tests.

Then, to evaluate the effect of the mechanical properties of the culture environment on the anti-oxidative properties of MSCs, one million D1 cells, marine bone marrow derived MSCs, were cultured in the hydrogel, followed by 1µM H_2O_2 treatment for 3 days. The MSC-gel cultures were then digested using alginate lyase and the RNA was extracted and purified from the cells for reverse transcription then qPCR analysis. The expression of antioxidative enzyme genes *sod1*, *gpx1 and cat1* were analyzed and normalized to housekeeping gene *gapdh.*

RESULTS

Rheometer analysis indicates that the Young's modulus of the ROS responsive hydrogel reduced by ~ 43% in the presence of H_2O_2 (Figure 3). This data aligns with our hypothesis that the Alg-PBA-PVA gel will become softer under an oxidative environment. The ROS sensitive hydrogel (+/- H_2O_2) is defined as a "soft gel" and a "stiff gel" respectively onward.

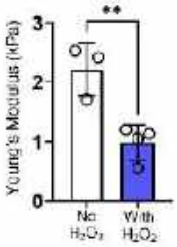

Figure 3: Young's modulus of ROS responsive hydrogel (+/- H_2O_2) where each data point represents one gel disc, **: P <0.01, student T-test

The expression of antioxidative enzymes *sod1*, *gpx1* and *cat1* were analyzed by qPCR (Figure 4). The results reveal there is a significant increase in expression of *sod1* and *gpx1* when the MSCs reside in a softer hydrogel while the expression of *cat1*, in contrast, shows a significant decrease in a softer environment. These data suggest that the anti-oxidative properties of MSCs can be controlled by varying the Young's Modulus of the microenvironment.

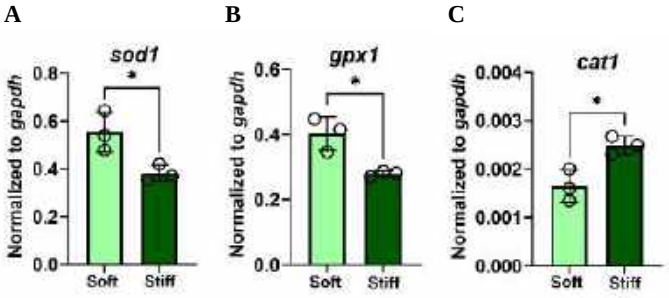

Figure 4. Gene expression of anti-oxidative enzymes (A) *sod1*, (B) *gpx1* and (C) *cat1* as a function of hydrogel stiffness. Technical triplicates, *: P<0.05 in student t-test.

DISCUSSION

With the preliminary data reported here, we developed a novel mechanically dynamic hydrogel system that is sensitive to oxidative stress. We also successfully demonstrated the control of expression of antioxidative enzymes in MSCs with the novel hydrogel. These data reveal the possibility to engineer MSCs, through a mechanobiology approach, to become an antioxidative agent to counteract oxidative stress.

Building on these findings, we will continue to test different compositions of Alg-PBA, the crosslinking protocol, and evaluate the change of mechanical properties of this ROS responsive hydrogel under different strengths of oxidative stress, since oxidative stress is varied between patients depending on their respective disease status.

The central premise of this study is to maximize the dynamic range of mechanical properties of the hydrogel and to investigate the changes in stiffness of the hydrogel as a function of oxidative strength. Followed by the mechanical control of the hydrogel, we will also study the production of anti-oxidative enzymes from MSCs cultured in varied Alg-PBA gels, to provide optimum support to suppress oxidative stress.

We believe this technology can facilitate the personalization of MSCs-based therapy for patients suffering from oxidative stress related diseases such as fibrosis or cancer.

INTRODUCTION

Emerging studies are developing computer-aided tumor detection devices for use in minimally invasive surgery. These devices utilize finger-like indentation to palpate organs and locate stiffer tumors within the healthy tissue [1]. Extraordinarily, the feasibility of this type of device for the lung has already been demonstrated [2]. Baseline mechanical data of healthy lung samples is needed to calibrate detection capabilities and improve the accuracy of these devices. While there is an abundance of tissue characterization studies that utilize tensile tests, results between tensile and compression studies are incongruous [3]; therefore, applying data acquired from tensile experiments does not accurately reflect measures from compressive palpation devices. Currently, data on the compression mechanics of the lung are absent from the literature, particularly for pulmonary tissue and investigations focusing on compressive pulmonary mechanics which are critical to the development of tumor detection, as well as for providing foundational knowledge to advance computational and surgical simulation models.

To address this need, we determine the compressive mechanics of pulmonary tissue using spherical indentation. The Hertz model, as is often used for small strain spherical indentation of biological tissues [4], is employed to calculate the Young's modulus and peak stresses. We perform tests on healthy and fibrotic samples to explore potential effects of known heterogeneous fibrotic stiffening on compressive results. This heterogeneity has recently been demonstrated across the lung surface during inflation testing [5, 6], but is unexplored in indentation studies. We conjecture that demonstrated surface heterogeneity in fibrotic lungs – particularly significant surface stiffening – may interfere with cancerous-tumor detection during robotic palpation. This is important as lung cancer is a common comorbidity of idiopathic pulmonary fibrosis [7]. As such, herein we report baseline compressive data of healthy and fibrosed lungs that can be used for future calibration of tumor-detection devices and used to help develop predictive models (e.g., computational and surgical simulation).

METHODS

Two groups of mice were studied where mice intranasally received 1X phosphate buffered saline (PBS) (n=5) to serve as a control or 12.5% hog dust extract (vol/vol) (n=5) to induce fibrosis, both with an exposure duration of 21 weeks, as previously established for a larger study [3, 5, 8]. Subsequently, animals were sacrificed, and the lungs were removed, inflated, and frozen slowly in PBS to -80 °C to preserve mechanics for this study [9]. Lungs were then thawed at 4 °C on the day of testing. Left lobes were occluded and attached to a metal platform with Cyanoacrylate glue to avoid motion and submerged in PBS (37 °C) for indentation testing. Displacement-controlled micro-indentation was performed on three equidistant regions across the lung's surface using a cantilever indentation apparatus (Figure 1, MicroTester G2, CellScale). A spherical glass tip (diameter = 2 mm) was attached to the tungsten beam (diameter = 0.2032 mm) to probe the sample surface. The indentation protocol included a small (1 μN) preload and four indentation cycles (5% deformation, $0.01\%s^{-1}$). The small strain restriction ($\varepsilon < 0.08$) in this study allowed application of the Hertz model to analyze the fourth cycle [10]. Hertz's theory was used to model the force-displacement and calculate the effective Young's modulus (eqn. 1) and generate stress-strain data (eqn. 2) as follows:

$$F = \frac{4E\sqrt{R}\delta^{3/2}}{3(1-\nu^2)} \quad (1)$$

$$\sigma = \frac{F}{\pi a^2}, \qquad \varepsilon = 0.2\frac{a}{R}, \qquad a = \sqrt{R\delta} \quad (2)$$

where δ is the applied indentation depth, F is the resultant load, E is the calculated Young's modulus, and σ & ε are the calculated indentation stress and strain, respectively. With known values: ν (Poisson's ratio, 0.34, [11]), R (indenter tip radius, 1 mm), and a (contact area) [10]. E & peak σ at all three regions were averaged and analyzed for significance to compare control and exposed groups (student's t-test, $p<0.05$, GraphPad Prism 9), similar to previous analyses [12]. The small

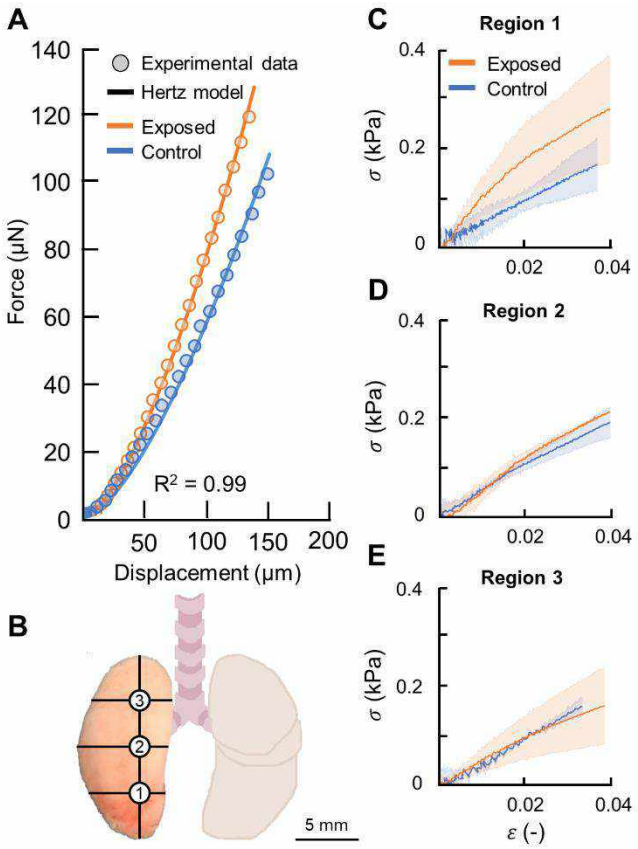

Figure 1: (A) Representative experimental force-displacement loading curves fitted with the Hertz model. Mean ± SD of stress-strain loading curves for control (blue) & fibrotic (orange) specimens. Regional testing performed according to (B). Regional data presented for (C) region 1, (D) region 2, and (E) region 3.

sample size inhibited statistical comparisons between exposed and control groups within each region.

RESULTS

In this study the stiffness associated with fibrosis was evaluated across the lung surface using micro-indentation at three regions. Analysis was completed using the Hertz model which demonstrated an excellent fit of 0.98-0.99 for all tests (Figure 1A).

When tests from all regions were averaged, the Young's modulus (calculated from force-displacement data, eqn. 1) reflected that the exposed group (1.46 ± 0.57 kPa) was slightly stiffer than the control group (1.40 ± 0.24 kPa) but was not statistically significantly stiffer. Stress-strain curves calculated from the force-displacement data were used to analyze the peak stress (Figure 1C-E). Although preliminary, results demonstrated a stiffening of the fibrosis group compared to the control in region 1 alone, the lower region (Figure 1C); neither regions 2 nor 3 (middle and upper regions) exhibited stiffening tendency (Figure 1D & E), albeit regions could not be robustly analyzed for statistical significance.

The peak stress averaged across all test regions reflected no statistical difference between the exposed and control groups despite the potential stiffening seen in region 1 (0.24 ± 0.04 kPa for control versus 0.28 ± 0.08 kPa for exposed groups respectively).

DISCUSSION

In this study, we investigated the compressive mechanics of the surface of the murine left lobe. We find that the heterogenous nature of lung fibrosis results in a single region with seemingly increased stiffness compared to the control, while the average stiffness of the entire surface does not significantly differ between fibrotic and control samples. Specifically, the average mechanics of the total surface – both Young's modulus and peak stress – do not differ between control and fibrotic specimens in this study.

The tendency of region 1 to be stiffer aligns with measurements of low strain from a study employing digital image correlation to analyze the surface of the lung during inflation [5]. This response is anticipated as dense fibrotic tissue manifests in lower and peripheral regions of the lung, as is characteristic of pulmonary fibrosis [6]. This pattern of peripheral and basal scarring is identified on CT scans in the process of diagnosing fibrosis [6]. Interestingly, this study in conjunction with Nelson et al. indicates that dense interior stiffening is also observed in measurements acquired from the lung surface as reported here.

This current pilot study of the lobe heterogeneity suggests that future work should characterize the entire lung surface with finer regional resolution to map fibrotic stiffening with greater accuracy.

As compressive mechanics are sought as baseline data to calibrate tumor detection devices, the probable heterogeneous surface stiffening identified here indicates caution should be taken when characterizing lung tissue of diseased lungs for use in tumor detection. This will be important if fibrosis and tumor stiffnesses are similar as detectable heterogeneous stiffening of the fibrosed lung surface could lead to inaccurate tumor detection. Fortunately, tumors in other organs are known to be ten times stiffer than healthy tissue and if this ratio is similar for the lung, fibrotic regions may be comparably negligible [1].

The limited literature on compressive mechanics reports the Young's modulus of healthy lung tissue to be 1.3-1.4 kPa, which is in excellent agreement with the results of this study [13]. Additionally, the expansive literature reporting the Young's modulus of lung tissue from tensile tests (1.91-7.6 kPa) are greater than that reported here from compressive data [11,13]. Further, as demonstrated here, compressive investigations also allow for the characterization of the intact lung surface heterogeneity unlike destructive tensile tests. Hence, underscoring the pressing need to investigate compressive mechanical parameters to inform accurate surgical probing applications and surgical simulation models.

THE INFLUENCE OF BLUNT FORCE LARYNGEAL TRAUMA ON PHONATION: AERODYNAMIC, KINEMATIC, AND ACOUSTIC EFFECTS

Md. Roknujjaman[1], Molly E. Stewart[1], Byron D. Erath[1]

[1]Department of Mechanical and Aerospace Engineering, Clarkson University, Potsdam, NY, United states

INTRODUCTION

Blunt force laryngeal trauma, while infrequent can pose significant, life-threatening consequences due to the airway being compromised [1]. Common causes of laryngeal trauma include endotracheal intubation, motor vehicle accidents, strangulation, falls, sports activate, etc., The primary injuries resulting from blunt laryngeal trauma are, typically, (1) displaced fractures of the laryngeal cartilage, (2) paralysis affecting at least one vocal fold (VF), and (3) subsequent scar formation in the VF tissue [2]. In addition to the immediate threat posed by airway obstruction, laryngeal trauma also usually results in significantly comprised vocal outcomes due to damage to the larynx and the VFs.

The effect of vertical VF misalignment and vocal fold scarring, as occurs with acute laryngeal trauma, have each been investigated individually [3] [4] [5] [6]. However, it is unclear how VF scarring, in tandem with vertical misalignment, influences phonation. Because most surgical interventions for laryngeal trauma are focused on restoring airway function, restoration of vocal function is a secondary consideration at best. This work aims to address that deficiency by providing insight into how concurrent scarring and vertical displacement of the VFs influence both the kinematics and acoustics of phonation.

EXPERIMENTAL METHOD

An experimental facility with synthetic, self-oscillating VFs was employed for the investigations. The facility consisted of a flow channel representative of the human airway and subglottal tract, which is shown schematically in Figure 1. The geometry of the vocal fold models, and the corresponding layers are shown in Figure 2 (a). Details regarding the facility and VF composition and fabrication are described in previous work [4]. Inferior-superior vertical displacement of the VFs was achieved by inserting 1.0 mm thick shims between the VF mounting bracket and the tracheal flow channel, as shown in Figure 2(b). The vertical displacement (d) was reported as a ratio relative to the length of the VF medial surface in the inferior-superior axis (t_{VF}). The length of the medial surface of the VF models was measured as 2.88 mm. Vocal fold oscillation was initiated by regulating shop air to specify the subglottal pressure, measured via a Dwyer series 1227 flow pressure manometer. The mean flow rate was recorded with a Dwyer RMC 103-SSV flow meter. The VF kinematics were measured from a superior view (see Figure 1) with a Photron AX200 high-speed camera at 20,000 frames per second. Details of the data acquisition can be found in [4].

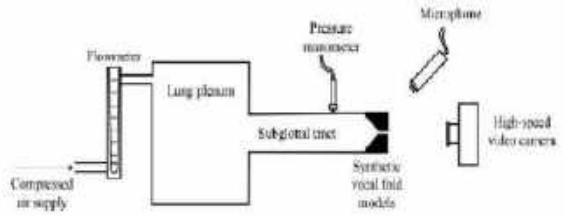

Figure 1. Schematic of the experimental flow facility.

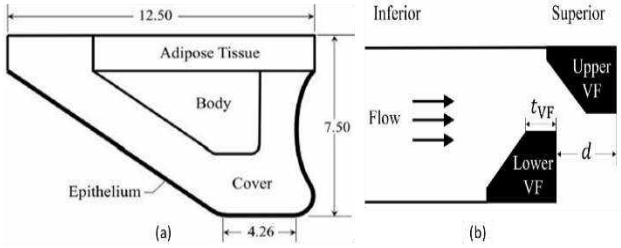

Figure 2. (a) The synthetic VF model geometry. All dimensions are in mm. (b) Inferior-superior thickness of the medial VF surface (t_{VF}) and vertical displacement, d, which was introduced to the upper VF in increments of 1.0 mm.

To mimic VF scarring, three different stiffnesses of the VF cover layer were considered. Table 1 displays the silicone ratios used to fabricate the cover layers and the resultant moduli of elasticity for the three cases of interest. The E_{1x} VF model represented a healthy, unscarred VF and acted as the baseline stiffness model. The E_{3x} and E_{10x} VF models had cover layers that were 3 times and 10 times as stiff as the baseline model, respectively. A stiffness asymmetry between the

opposing VFs was introduced by pairing the E_{1x} VF model with both a E_{3x} and E_{10x} VF model. Vertical displacement in the inferior-superior direction was also introduced to these VF models. A total of four cases were investigated with the two groupings of VF models. The first case was the E_{3x} superior case, denoted as $E_{3x,sup}$ in which the E_{3x} model was displaced superiorly relative to the E_{1x} model. The second case was the E_{3x} inferior case, denoted as $E_{3x,inf}$ where the E_{3x} model was displaced inferiorly with respect to the E_{10x} model. The $E_{10x,sup}$ and $E_{10x,inf}$ cases followed the same approach, but included the $E_{10x,}$ model instead of the E_{3x} model.

Table 1. Modulus of elasticity of the cover layer resulting from different silicone mixtures to achieve three different stiffnesses.

VF model	Silicone ratio	Cover layer stiffness (kPa)
E_{1x}	E1:1:6	1.12
E_{3x}	E1:1:4	3.43
E_{10x}	E1:1:2	10.34

RESULTS AND DISCUSSION

Data were collected at six displacement levels, such that d/t_{VF} = 0.0, 0.35, 0.69, 1.04, 1.39, and 1.74. Figure 3 represents the kymograms for the baseline case of symmetric VF stiffness, with vertical displacement. Figure 4 presents the kymograms for the $E_{3x,sup}$. Even with no vertical displacement, the asymmetric VF cover stiffness resulted in diminished VF closure and an increased open quotient. As the vertical displacement increased, the motion of the stiffer VF model on top also became irregular and began to exhibit an oscillation pattern that was indicative of the emergence of biphonation with period-doubling.; behavior not observed in Figure 3.

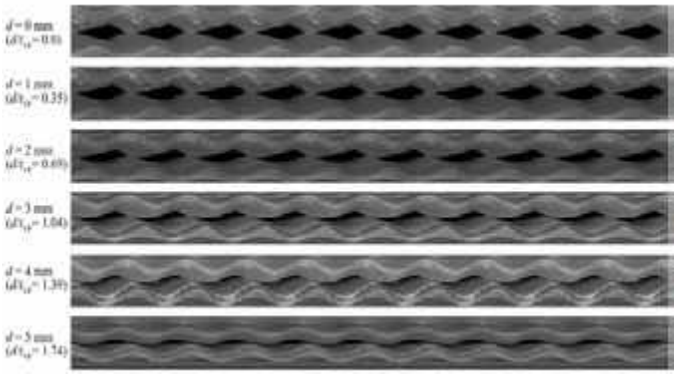

Figure 3. Kymograms consisting of 10 cycles for 6 different displacement levels of d/t_{VF} for symmetric E_{1x} VFs.

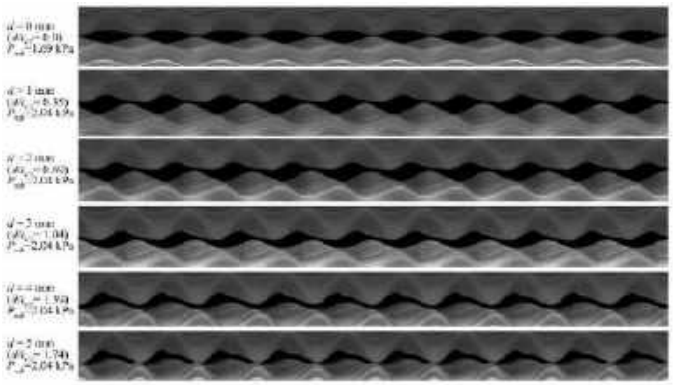

Figure 4. Kymograms consisting of 10 cycles for 6 different displacement levels for the $E_{3x,sup}$ case.

The emergence of higher oscillation modes in asymmetrically tensioned VFs with increasing subglottal pressure is a well-known instability [7]. However, the current results indicate that this instability is more likely to occur as vertical misalignment increases. Interestingly, the E_{3x} case, displacing the stiffer VF in the inferior, as opposed to superior, direction resulted in much more irregular and pathological VF motion, which was also reflected in the acoustic measures of H1-H2, jitter, shimmer, and cepstral peak prominence, which are not reported for brevity. The $E_{10x,inf}$ and $E_{10x,sup}$ investigations exhibited the same, but even more pronounced, behavior. These findings indicate that, importantly, the position of the stiff VF relative to the normal VF influences the emergence of irregular oscillation patterns, and that if the stiffer VF is in a more inferior position, poor phonatory quality is more likely to occur.

CONCLUSION

The effect of blunt force laryngeal trauma to the larynx was modeled by introducing both VF cover stiffness and inferior-posterior positional asymmetries. Kinematic and acoustic measures were more irregular than for vertical misalignment in VFs with symmetric cover stiffnesses. Asymmetric VF cover stiffness produced asymmetric oscillations in both amplitude and phase. These became more pronounced as vertical displacement increased. Positioning a stiffer VF inferior to a normal stiffness model was more likely to result in biphonation and pathological motion.

INTRODUCTION

Coronary artery disease (CAD) often manifests as lesions in the vessel that obstruct blood flow. Invasive treatment for CAD involves balloon angioplasty followed by stent placement. Bifurcation lesions, 20% of all interventions, are notoriously complex to treat [1-2]. The theme of our work is to create stenting devices and methodologies that reduce stent malapposition and other poor procedure outcomes.

A single stent spanning the bifurcation core, with optional second stent placement in distal branches, has been proposed [3-4] (Figure 1).

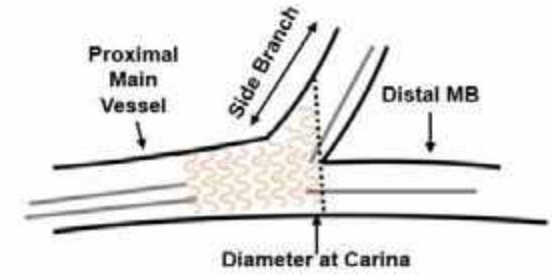

Figure 1: Tapered stent shown within bifurcation core. Carina diameter shown in dashed line.

However, this has not been widely adopted. Recent work has suggested that this 'proximal-to-distal' approach is limited by the change in vessel diameter occurring within the bifurcation core [5]. We propose a tapered stent design, along with novel balloon designs and methodologies, as a solution for proximal-to-distal approaches. Additionally, we anticipate an 'elliptical' shape in the bifurcation core, with chords defined by the diameter at the carina (CD) and proximal main vessel diameter (pMVD). In this study, a tapered stent prototype was designed, constructed, and tested. We also hypothesized that the stents can be expanded into elliptical shapes of equivalent perimeter to the designed distal stent diameter.

METHODS

Design: The stent was designed using a generic stent pattern consisting of sinusoidally-shaped rings connected by connecting struts. The proportions of the sinusoid shape were adapted from commercially-available stents (Xience everolimus-eluting stent; Abbott), in an effort to keep a similar ratio of stent to vessel surface area. The stent was scaled to have a proximal diameter of 16 mm, for ease of prototype creation and handling. The distal diameter was designed to be 21 mm, giving a CD that is 1.3x the pMVD. Amplitude and periodicity of the stent rings were 5.4 mm and 6.5 mm respectively. For the two proximal rings of the stent, 8 periods of the sinusoid shape were used. To create the taper, 9 and 10 periods were used for the distal end, keeping the same sinusoidal shape. Two evenly-spaced connecting struts were placed between each ring, with each row of stents offset between adjacent layers.

Previous work from clinical patient data indicates that most coronary bifurcation have a CD 1.5-2x larger than the pMVD [5]. To approximate an ellipse of 'equivalent expansion' to a 21mm diameter circle, the perimeter of a 21 mm diameter circle was calculated. Using this as the perimeter for an ellipse, with one axis equal to the pMVD (16 mm), the second axis was calculated to be 26 mm.

Ramanujan's Perimeter of Ellipse

$$p = \pi\left\{(a+b) + \frac{3*(a-b)^2}{10*(a+b)\sqrt{a^2+14ab+b^2}}\right\} \quad (1)$$

The long axis (26 mm) was taken as the elliptical carina length (eCD), and is 1.6x the pMVD.

Fabrication: The stent was formed from 0.02" diameter 316L stainless steel wire. The individual layers of the stent were formed into the intended sinusoidal shape. The stent layers were laser-welded to the

connecting struts, forming a flat sheet. The sheet was then wrapped around a mandrel, trimmed, and the seam laser-welded to form the stent.

Testing: The goal of the initial prototype was to determine the feasibility of manufacturing a tapered stent and confirm the stent expands as desired. To show this, the stent was crimped and expanded to the desired shapes (Figure 2).

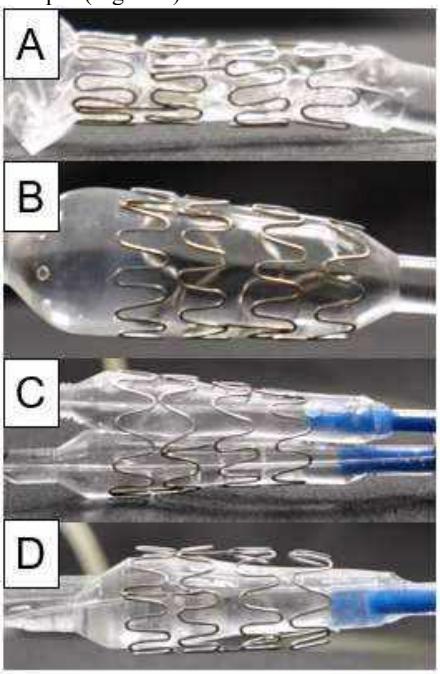

Figure 2: Stent prototype. A) Stent crimped onto deflated balloon. B) Stent expanded on tapered balloon. C) Stent expanded with kissing balloon inflation (KBI) (long axis) D) Stent expanded with KBI (short axis)

Metrics for success were that the stent could be crimped at least 25% without fracture, the stent could be re-expanded to 1.3x pMVD, and then re-expanded again to an ellipse with long axis 1.6x pMVD. Qualitatively, for each test success required no observable stent fracture, particularly at weld points, during each test. For the expansion tests, Percent Elastic Recoil (PER) of the stent should be minimal, ideally ≤10%.

Procedure: For test 1, the stent was crimped onto a deflated tapered balloon. The stent was expanded using the tapered balloon. Tests 2 and 3 used two 'kissing balloons.' Balloon diameters are summarized in Table 1:

Table 1: Balloon Diameters for Inflation Tests

	Proximal Diameter (mm)	Distal Diameter (mm)
Test 1	16	21
Test 2	8	11
Test 3	8	13

All balloons were manufactured using our lab's custom balloon forming machine [6]. The kissing balloons were designed to sum to the desired diameter. For each test, the stents were photographed and measured before and after balloon inflation, and following balloon deflation. The PER was calculated from the after inflation and after deflation measurements.

RESULTS

A prototype stent was designed, fabricated, and tested. The stent was crimped onto a balloon to 11mm, and re-expanded to a 26 mm CD with no observed fracture. The PER of the proximal and distal rings for each expansion of the stent is shown in Table 2. Three additional prototypes are in production to be presented at the conference. PER will be presented as Mean +/- standard deviation.

Table 2: Percent Elastic Recoil for Stent

	Proximal End	Distal End
Test 1: 16-21 mm	11%	10%
Test 2: 8-11 mm KBI		
Long Axis	5%	8%
Short Axis	3%	-5%
Test 3: 8-13 mm KBI		
Long Axis	5%	9%
Short Axis	8%	7%

,During Test 1, the stent was observed to slide proximally along the balloon. Figure 1B shows the distance between the distal end of the balloon and distal end of the stent.

DISCUSSION

This study focused on the feasibility of tapered stent design and expansion capacity. There were no observed fractures in the stent, and it expanded to the desired shape. This indicates that our prototyping methods and tapered stent design are feasible for further study.

The stent expanded to an elliptical distal shape, with the long axis 1.6x the pMVD. This confirms that the stent can expand to elliptical configurations with equivalent perimeter to the circular diameter. This indicates that for use in 'elliptical' bifurcation cores, tapered stents will need to specify the eCD limits for tapered stent sizing. Future work will explore additional tapering ratios. As the change in diameter increases, stent strut location and design may require modification.

The PER for the stent was within reasonable limits, with the recoil decreasing as the stent was expanded to elliptical shapes. The short axis for the first KBI increased slightly (negative recoil), which indicates that the elliptical shape may put stress on the vessel perpendicular to the short axis. Future work will seek to understand and quantify these forces, as well as PER of the stent when under forces that mimic *in-vivo* conditions.

Additional testing will use benchtop bifurcation vessel models in tissue mimicking gel to confirm deliverability and expandability of the stents in environments closer to *in-vivo* conditions. The stent slipping that occurred during the initial stent expansion on a unilaterally tapering balloon may be resolved when the stent is deployed within a blood vessel model.

This study is limited because the stent prototype was scaled up and created using 316L stainless steel rather than alloys such as cobalt chromium. However, we believe that the geometry of the stent design greatly impacts the stent's ability to expand.

INTRODUCTION

Coronary artery disease (CAD) is a cardiovascular disease which has been found to be the leading cause of death in the U.S. Although the development of some clinical indices has helped improve the prognosis of patients suffering from CAD, the underlying mechanisms that cause CAD remain unclear. The lack of understanding of these mechanisms arises largely because of the complicated mechanisms that control blood flow in the coronary vessels, and difficulties/challenges of measuring blood flow and pressures in the coronary vessels embedded in deep layer of the myocardium (**Fig. 1A**). Computational modeling of the coronary vascular system thus provides an alternative approach to understand the pressure-flow relationship in coronary circulation as well as their interaction with cardiac function. The 0D lumped parameter model (LM) and distributive model (DM) based on mass conservation of each vessel, have been applied to predict the pressure and flow rate in coronary vessels. Compared to LM, DM can provide spatial distribution of pressures and blood flow within each vessel, but at a higher computational cost. The 1D Naiver-Stokes (NS) equation based on conservation of both mass and momentum considers the wave propagation in the elastic vessels, and thus provides more physiological predictions of pressure and flow rate. The goal of this work is to develop DM and 1D NS model to predict the spatial distribution of coronary flow and pressure waveform information, which can be potentially applied to understand the mechanisms of CAD.

METHODS

The three-element Windkessel LM has been developed in our previous work [1-2] where each vessel is represented by a proximal resistor (R_1), distal resistor (R_2), and capacitor (C). The mass conservation is imposed as

$$\frac{P_{in}-P_{mid}}{R_1}+\frac{P_{out}-P_{mid}}{R_2}=C\frac{d(P_{mid}-P_T)}{dt} \quad (1)$$

where P_{in} and P_{out} are inlet and outlet pressures, respectively, P_T is intramyocardial pressure (IMP), and P_{mid} is the unknown pressure at the middle of each vessel. Then, the vessel radius, r , is calculated based on P_{mid} as

$$r = = B_P \times \frac{A_P-B_P}{\pi}\left[\frac{\pi}{2}+\arctan\left(\frac{P_{mid}-P_T-\varphi_p}{C_P}\right)\right] \quad (2)$$

where A_P and B_P are the highest and lowest radius, respectively, C_P is the passive response bandwidth of the vessel, φ_p is the transvsacular pressure corresponding to the mean of A_P and B_P. These parameters are the same as used in our previous work [1-2].

In DM, the conservation of mass is given as

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}=0. \quad (3)$$

In Eq (3), A is the cross-sectional area of the vessel, which is a function of unknown vessel radius, and Q is the flow rate which can be written

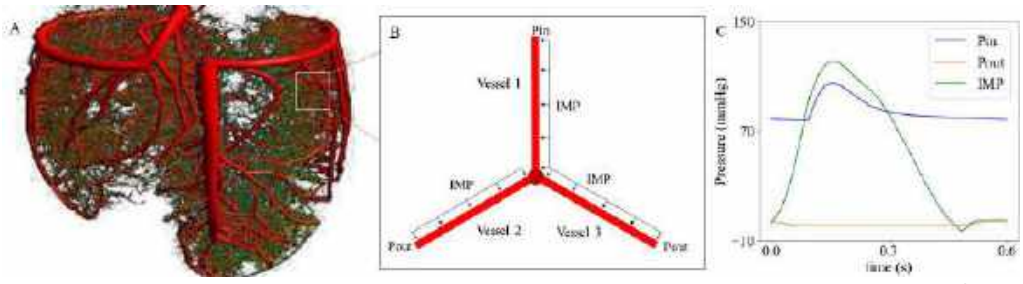

Fig. 1: A. Coronary vessel network; B. Three-vessel network; C. Inlet, outlet pressure waveforms and IMP waveforms used for the three-vessel network.

as a function of unknown vessel radius and pressure as $Q = \frac{\pi r^4}{8\mu}\frac{\partial P}{\partial x}$. The relationship between pressure and radius used in DM is that same as that used in LM (Eq. (2)). Then, Eq. (3) can be rewritten as a function of unknown radius, which will be solved.

The governing equation of 1D NS model based on momentum conservation is given as

$$\rho * \frac{\partial v}{\partial t} + \alpha * \rho * v\nabla v + \nabla P + \beta * \mu\nabla^2 v = 0 \quad (4)$$

where v is the velocity along the vessel direction, μ and ρ are the dynamic viscosity and density of blood inside the vessel, respectively. The parameters α and β are the momentum flux correction factor and viscosity friction coefficient, respectively [3], both of which are affected by the flow velocity in the vessel [4]. The weak form of the governing equation is derived by multiplying a test function (w) as

$$\int \rho * \frac{\partial v}{\partial t} * w * dx + \int \alpha * \rho * v\nabla v * w * dx + \int \nabla P * w * dx + \int \beta * \mu\nabla^2 v * w * dx = 0 \quad (5)$$

where v and P are unknown values. In 1D NS model, the unknown P and v are solved by mass conservation (Eq. (3)), and momentum conservation (Eq. (4)) using a staggered method.

These three methods are used to solve the pressure and coronary flow rate in a three-vessel network (**Fig. 1B**) using hemodynamics measurments of a swine model. Perfusion presssure and IMP in the model are imposed using the difference between arterial and venous pressure waveforms, and the left ventricular pressure, respectively (**Fig. 1C**). LM is implemented in MATLAB to compare agaisnt the developed DM and 1D NS model that are implemented using finite element method in FEniCS. In DM and NS model, each vessel is discretized using 32 elements.

RESULTS

Fig. 2 shows the comparison of model predicted pressure and radius at the middle of each vessel, inlet and outlet flow rate of each vessel, and the flow conservation at the junction of the three-vessel network, using the three methods. It is shown that P_{mid} is smaller in the downstream vessels 2 and 3 compared to vessel 1 in the three models (**Fig. 2A**). Model predicted P_{mid} waveform using DM and 1D NS models shows the similar trend as that predicted by LM. The relative percentage difference is 7% between DM and LM, and 7% between 1D NS model and LM. The largest difference occurs when the IMP gradient is the largest. The model predicted vessel radius shows the same trend using three models and the radius in vessels 2 and 3 reduces are smaller than that in vessel 1 (**Fig. 2B**). The percentage difference is 4% between DM and LM, and 5% between 1D NS model and LM. The model predicted inlet and outlet flow rates shows the same trend using the three models where flow rate reduces during systole as IMP increases to impede flow rate (**Fig. 2C-D**). The diastolic flow rate is higher in vessel 1 than that in vessel 2 and 3 due to the higher perfusion pressure in vessel 1. The percentage difference is 5% between DM and LM, and 6% between LM and 1D NS model for both inlet and outlet flow rates (**Fig. 2C-D**). Three model predictions show that mass conservation is satisfied at the junction of the three-vessel network since the difference between outlet flow rate from vessel 1 and inlet flow rate from vessel 2 and 3 is close to 0 (**Fig. 2E**).

DISCUSSION

In this project, we compared the LM, DM and 1D NS models in a three-vessel coronary network. The model predictions in terms of pressure in the middle of each vessel, radius in the middle of each vessel, inlet flow rate and outlet flow rate using DM and 1D NS are comparable with those predicted by LM. Compared to LM, the DM and 1D NS models can provide pressure and flow rate at any point of the vessel. In the future, we will extend the coronary vessel network and apply the developed model to investigate the pressure and flow rate distribution under physiological and pathological conditions.

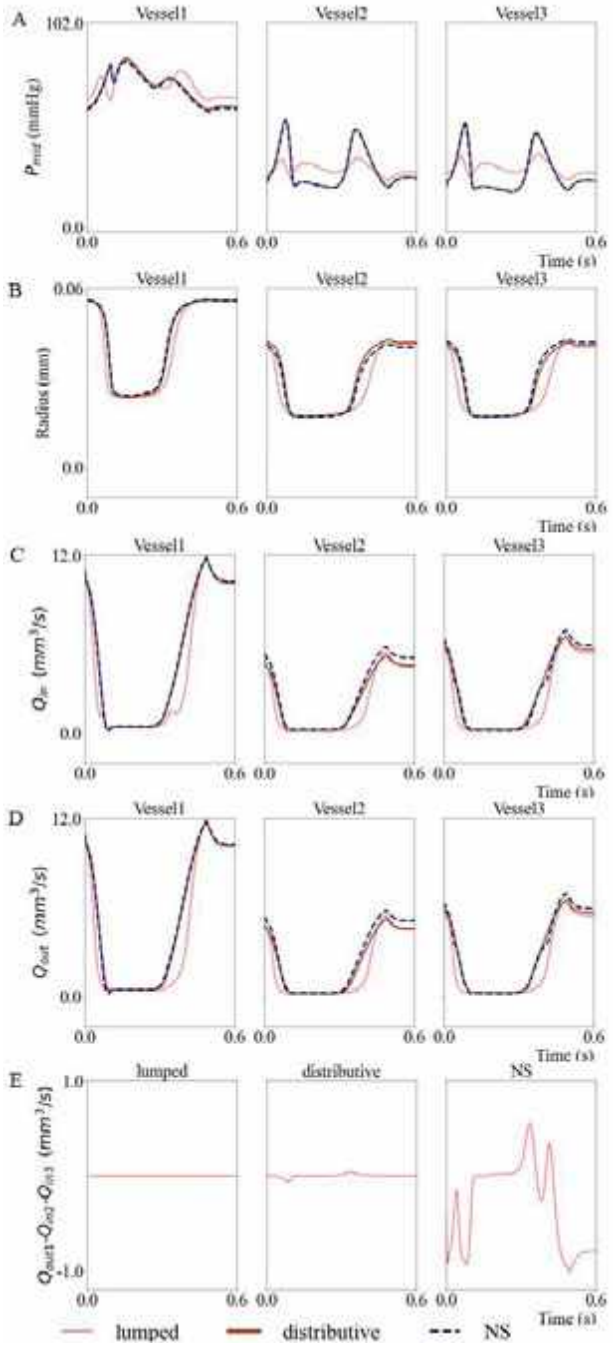

Fig. 2: Comparison of A. pressure in the middle of each vessel; B. radius in the middle of each vessel; C. inlet flow rate; D. outlet flow rate; E. mass conservation at junction, predicted by LM, DM and 1D NS model.

INTRODUCTION

Myocardial infarction (MI), resulting from blockage of the coronary artery, is a leading cause of death in the US and worldwide [1]. The loss of functional cardiac myocytes due to MI induces multiscale remodeling of the myocardium, including alterations in the properties and structure of cellular and extracellular components, degrading the overall heart function in a complex manner [2]. The emerging invasive cardiac interventions for MI patients, such as cardiac sleeves and patches, aim to alleviate post-MI remodeling effects. However, the personalized design of these interventions relies heavily on the basic characteristics of the infarct (scar) regions, including size and stiffness. Late gadolinium enhancement (LGE)-based cardiac magnetic resonance (CMR) imaging remains the state-of-the-art technique to delineate scar regions in MI patients [3]. However, LGE has downsides, including complications with gadolinium injection, safety issues for patients with kidney diseases, reliance on CMR, and prolonged scanning time, which overall limit its scope and safety in time-sensitive clinical applications.

We hypothesize that integrated modeling-strain imaging can accurately predict the heterogeneous tissue stiffness in the MI heart. In this work, we have developed a deep learning (DL)-assisted method that can identify scar regions and their stiffness from cardiac strains attainable from four-dimensional (4D) imaging. We successfully validated the predictions of our model for the size and location of tissue scars against the estimation of cine CMR with LGE. To broaden the applicability of our model and further evaluate its predictions, we sought the validation of our model in rodent models of MI where the rats were imaged by echocardiography (and not CMR), and the infarct regions were characterized using histology and mechanical testing. Our approach thus offers a promising avenue for accurate infarct characterization without subjecting patients to invasive procedures or gadolinium-related concerns and provides an affordable alternative to LGE-CMR by the possibility of needing only echocardiography (echo) instead of CMR.

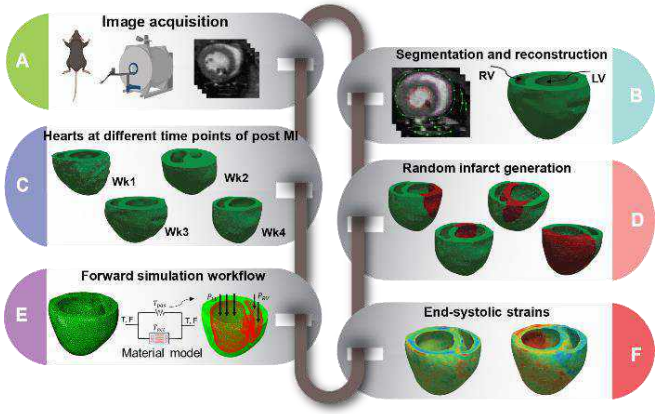

Fig 1: Development of simulated cardiac strains using computational rodent heart models.

METHODS

MI Rodents. The male Wistar-Kyoto rats, aged 8 weeks underwent anteriobasal infarct induction and were sacrificed at four time points post-MI (1-, 2-, 3-, and 4 weeks). *Cardiac simulation.* These subjects were employed for the development of finite-element rodent cardiovascular computational models (Fig. 1). The 3-D biventricular hearts were reconstructed from CMR scans truncated under the valve plane, and a tetrahedral mesh was generated in each heart. We utilized an additive stress decomposition constitutive model [4] to represent the passive and active behaviors of the myocardium, expressed by

$$\mathbf{T} = \underbrace{\frac{1}{J}\bar{\mathbf{F}}\frac{\partial W^{dev}}{\partial \bar{\mathbf{E}}}\bar{\mathbf{F}}^{T} + \frac{\partial W^{vol}}{\partial J}}_{Passive} + \underbrace{\frac{1}{J}\mathbf{F}\mathbf{S}^{\mathbf{act}}\mathbf{F}^{\mathbf{T}}}_{Active}.$$

An inverse problem was set up to estimate the passive material properties and active tension by replicating the biaxial test result and pressure-volume measurements, respectively. The Green Lagrangian strains, including circumferential, radial, and longitudinal (CRL) strains, were obtained for the entire heart, described in detail in [4]. This process was repeated to create 600 examples by infarct sizes, locations, and stiffness levels to obtain a large dataset to train the DL model.

Preprocessing steps of DL. Left ventricle (LV) strain data was translated into standard American Heart Association (AHA) bullseye maps for each CRL strain. These individual CRL maps were then compiled into a single image, followed by rotation for data augmentation. The resulting images were inputs for the UNet DL model, trained with a binary cross-entropy loss function. The evaluation metrics included the dice similarity coefficient metric (DSC), with corresponding binary infarct masks serving as outputs, as illustrated in Fig. 2.

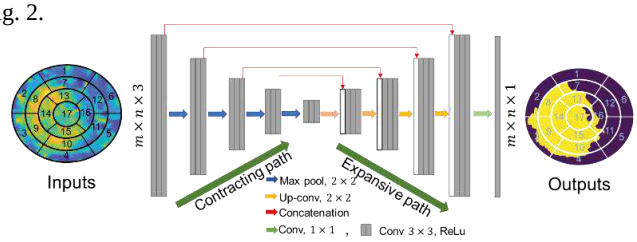

Fig 2: UNet model employing cardiac strains as input and generating the corresponding infarct mask as output.

Validation by human LGE-CMR. Slice deformations were assessed during the end-systole (ES) timeframe, with the end-diastolic frame serving as the reference point using $\mathbf{E} = \frac{1}{2}[\mathbf{F}^{\mathbf{T}}\mathbf{F} - \mathbf{I}]$ expression. The resulting strains were transformed into the widely accepted CRL axes using $\mathbf{E}_{[\mathbf{C},\mathbf{R},\mathbf{L}]} = \mathbf{QEQ}^{\mathbf{T}}$, where **E**, **F**, **I, and Q** represent strain, deformation gradient, identity matrix, and transformation matrix, respectively. *Validation in rodents with echo, biaxial test, and histology*. MI rats were imaged using Vevo 2100 at four timepoints post-MI. LV tissues were mounted on the biaxial tensile machine to obtain a force-displacement plot to measure stiffness. After biaxial testing, LV slices were stained with picrosirius red, and prepared slides were imaged using Olympus VS120 at 20x.

RESULTS

The UNet model predictions for infarct regions in the FE test data examples are illustrated in Fig. 3. The results highlight infarct regions with the highest and lowest DSC metric scores, demonstrating minimal variation between the predicted infarct regions and the ground truth masks even in examples with the lowest DSC scores. The overall performance of the DL model was assessed using the DSC score, resulting in a value of 0.9837. Additionally, we obtained an accuracy of 98.35%, along with sensitivity, precision, and intersection over union-score values of 0.9737, 0.994, and 0.968, respectively.

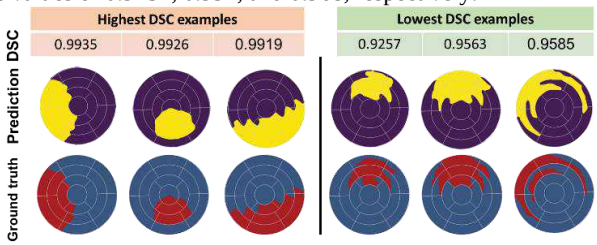

Fig 3: Visual comparison of finite element (FE) ground truth against UNet predictions.

Human LGE-CMR. We validated our proposed model by comparing the DL predictions with measurements by LGE imaging in two MI human patients (Fig. 4). We used our in-house diffeomorphic image registration to calculate 4D strains (3D + time) using only short-axis (SA) slices. End-systolic strains at each segment of AHA segmentation were provided to the DL model to classify the infarcted region. Very good agreement (DSC >0.8) was obtained compared to the estimation by LGE in both patients.

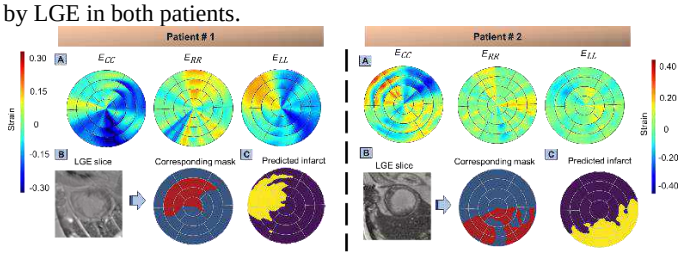

Fig 4: Cardiac CRL strains alongside DL predictions of infarct regions, compared with gadolinium contrast agent. Dice similarity coefficient (DSC) scores for the first and second patients are 0.8084 and 0.8149.

Validation in rodents using echo. The possibility of estimating scar properties from echo strains (Fig. 5a,b) significantly broadens the applicability of our approach due to the ubiquity and affordability of echo compared to CMR. In addition, biaxial testing and histology images in rodents provide the ground truth for the scar tissue stiffness and scar location in contrast to human LGE-CMR (Fig. 5c,d). We have obtained echo strains and infarcted LV myocardium properties (Fig. 5) in 30 rats (6 rats per timepoint plus controls) and are in the process of validating the prediction of our DL model for scar location and stiffness against ex-vivo measurements serving as ground truth.

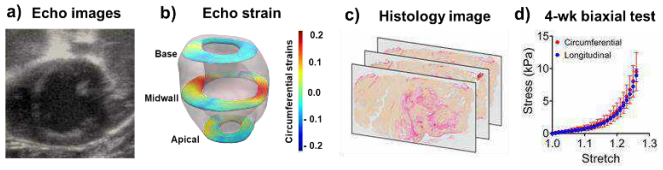

Fig. 5: Integrated validation of infarct characterization in rodent myocardium.

DISCUSSION

In this work, we developed a UNet-based DL model that capitalized exclusively on cardiac strain data as input features. The use of strains eliminated the requirement for pressure values, obviating the need for invasive procedures like catheterization to record patient pressure data. Additionally, our methodology leveraged the concept of impaired deformation at infarct locations. By seamlessly integrating cardiac strain images with DL techniques, we enabled the precise identification of infarct tissue by extracting image features. This innovative framework obviates the need for LGE.

Moreover, our approach used cardiac strains, which can be obtained from more ubiquitous and affordable imaging modalities than CMR, such as echocardiography, reinforcing cardiac strain approach generality in clinical settings. Furthermore, the comprehensive use of strain data enables the characterization of "border" zones with compromised contractility compared to the LGE-CMR approach, which can primarily locate mature scar regions, overall improving the prognostication in MI.

INTRODUCTION

Cardiac Allograft Vasculopathy (CAV) is a coronary artery disease affecting 50% of heart transplant (HTx) recipients, it is the major cause of graft chronic rejection [1], and it is associated with a 30% 5-year mortality [2]. CAV is characterized by a strong inflammatory response triggering a cascade of vascular remodeling processes that ultimately lead to coronary arteries' narrowing, impaired blood flow and graft failure [3]. The poor long-term outcome in CAV management results from an incomplete understanding of the disease initiation mechanisms, making CAV prevention challenging and impairing treatments' effectiveness. The morphology of coronary arteries has been identified as a critical factor influencing vascular response and, consequently, HTx long-term outcome [4]. However, a detailed morphometric characterization of coronary geometry and a comprehensive understanding of how morphology quantitatively affects vessel fate during CAV is lacking. So far, animal studies, mainly based on mouse models, have been extensively used to investigate CAV [2], and have identified inflammation and hemodynamics as the main triggering stimuli. Although informative, *in vivo* studies have limitations such as high time and resource consumption, animal welfare concerns, paucity of investigation time points, and challenges in addressing the pathology multiscale nature. Integrating *in vivo* with *in silico* approaches can overcome these drawbacks and generate more informative models, thus enhancing *in vivo* studies' efficacy. We, therefore, hypothesize that an integrated *in vivo – in silico* approach will optimize anti-chronic rejection research pipeline. Additionally, a thorough morphological measurements' portfolio from mouse model is currently missing in literature, although pivotal to understand how morphology impacts post-transplant follow-up and to feed ad hoc computational models focused on pre-clinical research. Accordingly, we i) generated a portfolio of morphological measurements from mice's coronary artery trees to enrich our understanding of how geometry influences CAV development, and ii) developed a mouse-specific multiscale computational model of CAV formation and progression to study in real time the pathology progression and predict long-term vascular outcome.

METHODS

The project workflow is illustrated in Figure 1. Via *ex vivo* protocol on C57BL/6 mouse models (5-8 weeks, 16.5 g weight), the hearts were perfused with Microfil and fixed in 10% formalin, making the coronary vessels suitable for visualization through µCT-imaging. The µCT technique (SkyScan1276 at 55kV, 200µA, pixel size 10 µm) allowed imaging the hearts (*n = 10*) including both cardiac tissue and microfilled-coronary vessels. The left coronary artery (LCA) was 3D reconstructed through 3 semi-automatic steps: i) segmentation of cardiac tissue in ITK-SNAP software; ii) segmentation of coronary tree via filtering, thresholding and binarization, and iii) retention of the first-K largest volumes in Bruker CTAn Micro-CT software (K spans between 5 and 7 depending on the initial number of volumes). Once reconstructed, LCA geometries were freed from artifacts and smoothened by shrink-wrap technique developed in Ansys SpaceClaim. Subsequently, geometries were subjected to centerline-based morphometric analysis (i.e., branches' and bifurcations' angles, cross-sectional area, curvature, and torsion) and to preliminary simplified CFD simulations. The latter required initialization of mouse-specific blood properties, LCA inlet-velocity profile and the application of intraspecific flow-diameter scaling-laws to properly provide flow partition through the coronary tree [5]. In parallel, an idealized 2D Agent-Based Model (ABM) of CAV [6] was developed to simulate

arterial wall response to inflammation (i.e., leukocyte infiltration, chemoattractant release) and hemodynamic disturbances (i.e., low wall shear stress (WSS)) over 4-weeks of follow-up. Through the implementation of probabilistic rules, these stimuli triggered inflammatory cell activation and exacerbated vascular cell activities. Moreover, an extensive analysis was performed to investigate the ABM sensitivity to the driving parameters (i.e., Latin hypercube sampling based-sensitivity analysis), inputs (i.e., test scenarios with single stimulus, combined stimuli, and stimuli along with main events) and to gain insights into the ABM working mechanisms (i.e., CAV manifestations).

RESULTS

The Microfil perfusion and 3D geometrical reconstruction showed that the same line of mice presents visible different coronary tree structures and degree of complexity. However, the preliminary intra- and inter-sample morphometric analysis reported a consistency in i) branches' angles ([61.9922º ± 11.5532º]) (ii) bifurcation angles ([49.9430º ± 14.0852º]); and iii) decreasing cross-sectional areas from the main inlet toward the outlet's artery (max: 0.0470 ± 0.0050 mm^2, min: 0.0015 ± 0.0002 mm^2) (Figure 2a).

The *solo* 2D ABM was able to effectively replicate a 4-week CAV initiation and progression, characterized by symmetric and non-symmetric lumen area decrease due to progressive intimal thickening in regions exposed to high inflammation and low WSS. Both the scenario testing and CAV manifestations identified three classes of artery response characterized by a slight lumen area decrease (<20%), a moderate lumen area decrease (20%–40%), and a severe lumen area decrease (>50%) (Figure 2b). Moreover, the parameter and input sensitivity analysis highlighted that the inflammatory-related events rather than the WSS predominantly drive CAV, corroborating the inflammatory nature of vasculopathy.

DISCUSSION

The preliminary results of the morphometric analysis performed on mouse coronary tree, along with the ABM insights, fill a fundamental gap of knowledge in CAV literature. Furthermore, these findings pave the way to justify why CAV manifests with different severity in vessels close to each other, since different morphological features (e.g., branches' and bifurcations' angles, or cross-sectional area) can explain different vessel fates. In conclusion, our ABM, scaled-up to a quasi-3D level, and enriched with realistic cross-sectional geometry, mouse-specific blood properties and CFD-derived hemodynamic profiles, represents a versatile tool to elucidate CAV onset and progression on a multiscale perspective, ultimately optimizing preventive pathology research.

INTRODUCTION

Previous study has revealed that water in bone is present in three different conformations; namely freely mobile water in pores; bound water at surfaces and/or within the mineral and collagen phases; and structural water as part of collagen and mineral molecules [1]. Evidence shows that water may also play a major role in viscous response of bone, most likely *via* the so-called sacrificial bonding mechanism. In fact, hydration status significantly affects the toughness of bone, and bound water has been considered as a biomarker for prediction of bone fragility fractures. In addition to the collagen phase, recent evidence shows that glycosaminoglycans (GAGs) of proteoglycans (PGs) in the extracellular matrix also play a pivotal role in regulating the tissue-level hydration status of bone, there by affecting the tissue-level toughness of bone. And biglycan and decorin are two major types of PGs in bone reports. Biglycan/decorin knockout induced changes in GAGs, bound water, as well as bone tissue toughness. Among all subtypes of PGs, biglycan and decorin are identified as a major subtype in the bone mineral matrix [3]. In this study, we used a biglycan/decorin knockout mouse model and the obtained bone samples were measured by low-field nuclear magnetic resonance (NMR) to determine the bone porosity and bound water changes and used to predict if knockout of biglycan/decorin may affect the amount of bound water and subsequently lead to reduce toughness of bone. The technique of low-field pulsed proton NMR spin relaxation is described for assessment of structural changes of normal and disuse (biglycan/decorin knockout) mice bone in situ. This technique involves spin-spin relaxation measurement and inversion spin-spin relaxation spectral analysis methods [2].

METHODS

A total of 24 mouse leg bone specimens with 6 in control (WT), 6 in biglycan knockout, 6 in decorin knockout, and 6 in biglycan/decorin double knockout were obtained from 6 month-old male and the samples were prepared by UTSA/UTHSCSA. The animals were sacrificed at the age of 6 months and the bone soft tissues were dissected and stored in -80 ^{o}C; and prior to NMR measurements, the samples were completely thawed at room temperature. A low-field NMR spectrometer (Bruker 20 MHz) was set up at a proton frequency of 20 MHz for these measurements. ^{1}H spin-spin (T_2) relaxation profiles were obtained by using NMR CPMG $\{90^0 [-\tau- 180^0 -\tau- (\text{echo})]_n - T_R\}$ spin echo method with a 6.5 s wide 90^{o} pulse, τ of 500 μs for mouse bone and T_R (sequences repetition rate) of 15 s. Each T_2 profile, one thousand echoes (one scan with n = 1000) were acquired and sixty-four scans were used. Thus, one scan will have repeated 1000 echoes in the window. For each FID profile, 1000 data points were acquired in one scan (an approximate 2 ms delay window). The data was measured on fresh frozen leg tissues after complete thawing in the room temperature (21 ± 1^{o}C). The full water saturated bone tissues were used for CPMG measurements, and free air dried (mobile water removed) bone tissues were used for FID measurements.

RESULTS

Comparison of disuse mouse leg bone group with control leg bone group, the significant differences are found. For example, in Figure 1, from the inversion NMR CPMG relaxation data spectra (samples are full saturated) the porosity, and the

pore size differences for samples between the control WT and the disuse KO are clearly observed. From the example of inversion FID spectrum, after the mobile water was removed by free air dry, only two water peaks are observed with left first is solid-like component and second is bound water component in Figure 2. From low-field NMR measurement, the relative amount of bound water was then estimated as the ratio of the total intensity of bound water signal with respect to the total intensity of the solid-like from water signal (representative of bone mass because in these sample measurements, the solid form proton signal intensities were correlated with the sample mass weights) of each sample.

The estimated results for ratio of the bound water to solid-like water were calculated. In addition, our previous results showed that the number of GAGs and bound water in bone matrix was significantly reduced in KO mice compared with WT mice [4]. These *in situ* results indicate that coupling with water biglycan/decorin is apparently one of PGs in bone mineral matrix that plays a key role in sustaining the toughness of bone. Our recent study demonstrates that loss of GAGs may significantly reduce the tissue-level toughness of bone and such effects are most likely induced by the associated loss of bound water in bone matrix [5], and the results show the similarity as that among the age-related ultrastructural changes, the loss of bound water in bone matrix with significant reduction of the toughness of bone. Based on the aforementioned evidence, it could be conjectured that changes in matrix GAGs may contribute to the deterioration of bone quality. Studying mice with targeted Bgn/Dcn disruption has revealed the involvement of Bgn/Dec in the regulation of postnatal skeletal growth. Bgn/Dcn deficiency may lead to bone porosity increase, bone bound water decrease and bone biomechanical strength changes.

From these mice groups study, the average of the porosity in control group is 27.27% (±4.64%), the average of the porosity in biglycan knockout group is 33.93% (±8.16%), the average of the porosity in decorin knockout group is 36.36% (±12.3%), the average of the porosity in biglycan/decorin deficient group is 34.46% (±10.6%).

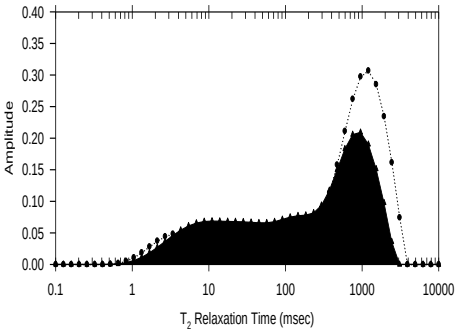

Figure 1. Inversion CPMG T_2 relaxation time spectra for mouse WT and KO leg bones. The high intensity is for KO (●), with porosity 37.7%, and the low intensity (▲) is for WT, with porosity 21.33%, respectively, measured by low-field NMR.

Fig. 2 shows the example of inversion FID spectrum, after the mobile water is removed by free air dry. It is because in mice bone tissues the mobile water signal is overwhelming than the bound water signal, and the mobile water is not the interesting at this moment. Therefore, only two water peaks are observed with left first is solid-like component and second is bound water component. From low-field NMR measurement, the relative amount of bound water is then estimated as the ratio of the total intensity of bound water signal with respect to the total intensity of the solid-like water signal (representative of bone mass because in these sample measurements, the solid form proton signal intensities are correlated with the sample mass weights) of each sample.

As the results, the average of the ratio of bound water to solid-like water in control group is 2.662 (±0.548), the average of bound water to solid-like water in biglycan knockout group is 1.897 (±0.528), the average of bound water to solid-like water in decorin knockout group is 2.005 (±0.324), and the average of the bound water to solid-like water in biglycan/decorin deficient group is 1.883 (±0.476). And the samples mechanical test is planned underway.

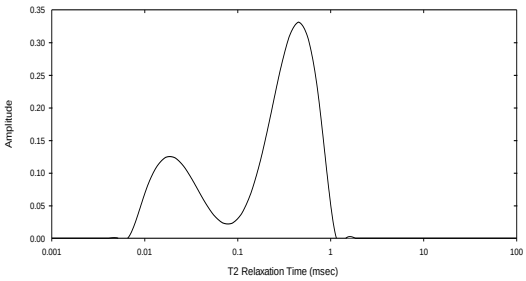

Figure 2. Example of inversion FID T_2 relaxation time spectra for mouse, measured by low-field NMR. The peaks from left to right are solid-like water and bound water, respectively.

INTRODUCTION

Cardiovascular disease emerges as the predominant cause of mortality in the United States reported by AHA [1], and on a global scale reported by WHO [1]. Aortic stenosis (AS) is a form of valvular heart ailment arising from the abnormal constriction of the aortic valve opening. AS is usually caused by gradual degeneration of the aortic valve, leading to an elevated occurrence of calcific aortic disease with advancing age [2]. Therefore, accurate assessment of AS severity is critical. The uncertainties and lack of precision associated with existing diagnostic parameters may lead to less-than-optimal clinical decision-making. This is particularly true for patients with low gradient (LG, $\Delta p < 40$ mmHg) AS, for whom evaluating AS can be challenging.

Benefits and drawbacks of echocardiography and cardiac catheterization has been extensively documented in the literature [3, 4]. Pressure drop across the aortic valve can be exaggerated in elevated circulatory conditions, such as those observed in sepsis, anemia, AV fistula, hyperthyroidism, liver failure and aortic regurgitation, which leads to an overestimation of the degree of stenosis.

In particular, for 'paradoxical low-flow, low-gradient (LFLG) severe AS,' the pressure drop and peak velocities remain low, despite a normal left ventricular ejection fraction (LVEF ≥ 50%). This condition underestimates the true AS severity. The *objective* of this study is to improve the accuracy of AS severity assessment, using a novel functional diagnostic parameter, Aortic Valve Coefficient (AVC: the ratio of the total transvalvular pressure drop (Δp) to the proximal dynamic pressure (1/2×blood density×V_{LVOT}^2;V_{LVOT}: left ventricular outflow peak velocity)). The *hypothesis* is that the AVC, developed from the fundamental fluid dynamics principles, will better delineate the level of AS severity, as it includes square of V_{LVOT} and downstream pressure recovery. This involves assessing the correlation and comparison with established diagnostic parameters aortic valve area (AVA) and transvalvular pressure gradient (Δp).

METHODS

This prospective study consists of 47 patients undergoing transcatheter aortic valve replacement (TAVR) procedure for AS. The study protocol was approved by the Institutional Review Board at University of Cincinnati. The consented patients were aged 65-86 years. The values of jet velocity, V_{LVOT}, and AVA were obtained from the standard Doppler echocardiography reports. Whereas Δp was obtained through catheterization. Pressure-velocity measurements were obtained pre- and post- TAVR, resulting in a total of 78 data points, with 32 of them corresponding to LG AS. The proposed diagnostic index, AVC, was calculated using mean transvalvular Δp and Doppler-derived V_{LVOT} using the following equation [5]:

$$AVC = \frac{\Delta p}{\frac{1}{2}\times\rho\times V_{LVOT}^2}$$, ρ is the density of blood (1050kg/m^3) (1)

A regression analysis was performed on the data set to correlate AVC with AVA. The correlation analysis was carried out for both LG ($\Delta p < 40$ mmHg) and for HG ($\Delta p > 40$ mmHg). Welch 2 sample t-test was performed to compare the mean values of AVC against AVA. A probability value of $p < 0.05$ was considered statistically significant. Statistical data analysis was performed using R markdown software RStudio Team (2022; RStudio: Integrated Development Environment for R. RStudio, PBC, Boston, MA).

RESULTS

Figure 1 shows the linear correlation of AVC with AVA for pre- and post-TAVR data points. The AVC, when correlated with AVA, had a moderately significant correlation ($r = 0.75$, $p < 0.001$), suggesting the feasibility of AVC as a prospective index.

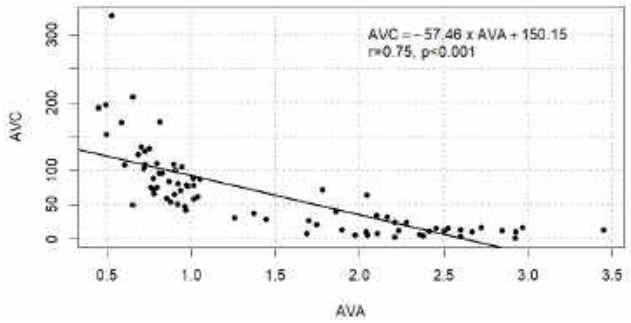

Figure 1: Correlation of AVC with AVA

Figure 2 shows the linear correlation of AVC with AVA for A) low pressure gradient (Δp < 40 mmHg) patients, and B) high pressure gradient (Δp > 40 mmHg) patients. The correlation between AVC and AVA decreased (r = 65, p < 0.001, Fig. 2A) for LG (Δp < 40 mmHg) AS patients, indicating the increased discordancy. However, AVC had a moderately significant correlation (r = 0.74, p < 0.001, Fig. 2B) with AVA for HG (Δp ≥ 40 mmHg) AS patients.

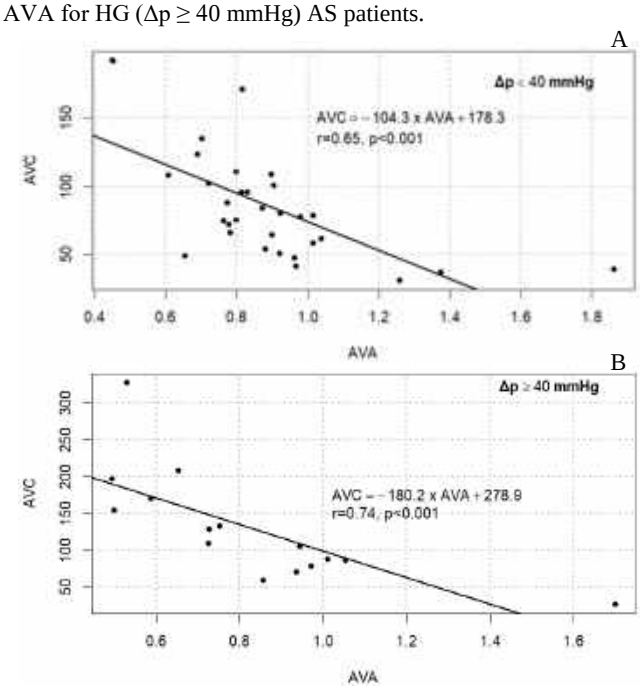

Figure 2: Correlation of AVC with AVA for A) low pressure gradient (Δp < 40 mmHg) cases, and B) high pressure gradient (Δp > 40 mmHg) cases

Comparing AVC and AVA in patients with LGAS with LVEF < 50% and LVEF ≥ 50% (Table 1), the t-test results revealed statistical significance for AVC (*p < 0.05*). In contrast, AVA demonstrated insignificant differences (p = 0.44). The 95% CI for mean values of AVA for LGAS with LVEF < 50% has a *significant overlap* with LVEF ≥ 50%. Therefore, AVC delineates LG AS better than AVA.

DISCUSSION

Misclassification commonly arises due to the pressure-recovery phenomenon in the ascending aorta [3]. The degree of pressure recovery depends on the ratio of *vena contracta area* relative to the cross-sectional area of the ascending aorta. A relatively larger pressure recovery is seen in patients with mild to moderate stenosis and smaller aortas in relation to the overall pressure gradient. Doppler measurements are taken at the *vena contracta* just distal to the aortic valve orifice, neglecting the aortic pressure recovery. In contrast, catheterization measures the pressure difference between the left ventricle and a point in the aorta well beyond the aortic valve, where pressure is generally fully recovered. Consequently, significant disparities exist between Doppler-derived and catheterization-derived pressure gradients. While Δp derived from Doppler often overestimates AS severity, the Δp measured from catheterization is typically recorded after pressure recovery, representing the net pressure drop due to AS. Therefore, AVC derived from Δp measured from catheterization is expected to be superior to AVC obtained from Doppler derived Δp.

	Welch 2 Sample t test			
	LG AS			
	AVC		AVA	
	LVEF < 50%	LVEF >= 50%	LVEF < 50%	LVEF >= 50%
MV ± SD	116.9 ± 11.9	72.2 ± 5.5	0.83 ± 0.06	0.91 ± 0.05
95% CI	93.1 – 140.8	61.2 - 83.2	0.71 - 0.9	0.81 – 1.0
p value	**p* < 0.05**		p = 0.44	

Table 1: Comparison of mean values of AVC and AVA

It is commonly known through the literature that the mean pressure gradient (Δp) and flow rate relationship is non-linear: $\Delta p = A \times V + B \times V^2$ for the flow through constrictions such as arterial lesions and valvular stenosis, Here, A represents the linear coefficient of viscous (frictional) loss, and B is the nonlinear coefficient of pressure loss attributable to momentum change resulting from area reduction [6].The flow becomes transitional (laminar to turbulent) at higher Reynolds number values, ~ 5000, which are frequently observed in the human ascending aorta [7]. When the flow is transitional to turbulent, the nonlinear pressure loss resulting from the aortic stenosis-induced momentum change usually exceeds the linear pressure loss resulting from viscous effects.

Hence, it is important to note that the AVC, a non-dimensional diagnostic parameter, better accounts for the non-linear pressure loss due to having V_{LVOT}^2 in denominator. Furthermore, AVC can enhance assessment of AS severity assessment and aid in clinical decision-making for AS patients.

Study Limitations. The primary limitation of this pilot study was the unavailability of directly measured V_{LVOT} from the cardiac catheterization. Hence, AVC was calculated using Doppler measured V_{LVOT}. Furthermore, the measure of non-linearity can be better evaluated by using the log-transformation; thereby, improving the correlation between AVC and AVA.

INTRODUCTION

A grand challenge in human cancer therapies is to eliminate the drug resistance of cancer cells. To date, even the most effective targeted therapies are not able to completely eradicate the entire tumor, mainly because a subpopulation of cancer cells persistently acquires drug resistance and tirelessly re-develops diseases after the treatments. As a result, high cancer mortality rates have been causing societal burdens worldwide. Hence, we are in dire need of innovative approaches that can eliminate drug resistance. In this talk, I will introduce our recent findings that multiple types of human lung cancer cells, especially EGFR-mutated non-small cell lung cancer (NSCLC) subtypes, dramatically alter their sensitivity and response to mechanical force indicated by Yes-associated protein (YAP) throughout the process of drug treatments. I will discuss our newly developed mechanobiology strategies to apply forces in cancer cells and to promote death of drug-resistant cancer cells.

Human lung cancer contributes to the highest morbidity (22%) within all cancer types, with NSCLC as the most common subtype (85%). EGFR mutation occurs in 50% of Asian NSCLC patients and 10%–16.6% of Caucasian NSCLC patients [1]. Pharmacological targeted therapies including EGFR tyrosine kinase inhibitors (TKI) have been applied in clinical and show enhanced survival (from 29.77 months to 22.97 months) [2]. However, for all generations of EGFR TKI from 1st to 3rd generation, patients gain drug-resistance after a median period of 10–18.9 months [3]. During the acquirement of drug-resistance, YAP nuclear translocation and activation are necessary [4]. Unfortunately, none of the current YAP inhibitors are clinically effective due to their high required dosage and poor selectivity [5]. Therefore, besides pharmacological approach, new methods are needed to reduce YAP-mediated drug-resistance. Independent of conventional Hippo pathway, abnormal tumor microenvironment applies elevated mechanical stimuli to tumor cells and alters YAP nuclear translocation and activities [6,7].

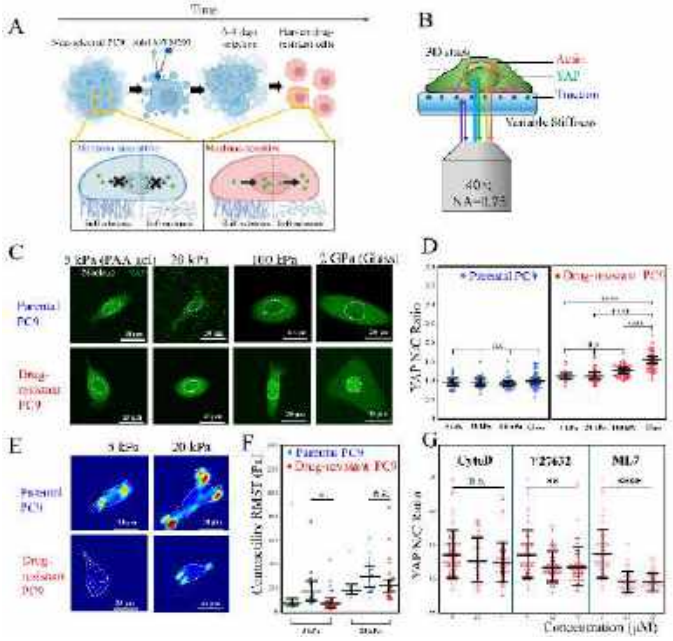

Figure 1: Drug-resistance NSCLC (PC9) cells show increased YAP mechanosensitivity. (A) Schematic of EGFR-TKI selection process and differential YAP mechanosensitivity in drug-resistant cells. (B) Schematic of multi-channel imaging to quantify YAP translocation, actin cytoskeleton structure and contractility. (C) Representative image of YAP translocation in parental and drug-resistant PC9 cells. (D) Quantification of YAP N/C ratio shows no YAP translocation on various substrate stiffness in parental PC9 and significantly increased YAP nuclear translocation in drug-resistant PC9 (YAP N/C ratio = 1.12 on 5 kPa, YAP N/C Ratio = 1.54 on glass,

p = **). (E) Representative image of contractility in parental and drug-resistant PC9 cells. (F) Quantification of root mean square of traction shows decreased (p = *) and similar contractility (p = non-significant) in drug-resistant cells on 5 kPa and 20 kPa substrate, respectively. (G) Pharmacological inhibition of contractility inhibits YAP nuclear translocation in drug-resistant PC9 cells.**

Therefore, mechanical regulation of YAP provides new potential in inhibition of drug-resistance. However, how drug-resistant cancer cells uniquely sense and respond to mechanical signals remains unclear. Our result is the first data that show (1) altered YAP mechanosensitivity of drug-resistant cancer cells; (2) mechanical cyclical stretching can kill 50% of the drug-resistant cancer cells.

METHODS

To quantify the real-time translocation of YAP, we use CRISPR/Cas9-engineered human NSCLC PC9 cells that enable endogenous YAP be tagged by fluorescence protein mNeonGreen21-10/11. PC9 cells are cultured in 35-mm glass-bottom petri dish. Drug-resistant PC9 cells are selected by culturing with 3rd generation of EGFR TKI Osimertinib (AZD9291; 2 μM) for 6–9 days **(Fig. 1A)**. Nuclear/cytoplasmic translocation of YAP is quantified by high-resolution confocal fluorescence imaging throughout the manipulation of the nucleus [8,9,10]. Quantification of mechanical contractility is conducted by traction force microscopy (TFM) on polyacrylamide hydrogels (5 kPa and 20 kPa). YAP imaging with inhibition of contractility is done after 72 hours of application of CytoD, Y27632 and ML7. Uniaxial cyclical stretching of cells is performed on customized PDMS membrane by stretching machine at 0.5 Hz and 13% strain for 20 hours **(Fig. 2A)**. Viability is quantified by flow cytometry with EthD-1 and Propidium Iodide as dead markers.

RESULTS

First, we quantify the mechanosensitivity of YAP in both parental and drug-resistant PC9 cells **(Fig. 1B)**. Different from the conventional findings in most cell types [6,11,12], our results show that, in parental PC9, YAP shows no mechanosensitivity on different substrate stiffness from 5 kPa to glass (~3 GPa). In contrast, drug-resistant PC9 cells show upregulated YAP nuclear translocation on stiffer substrate **(Fig. 1C and D)**. This is the first data showing increased mechanosensitivity of YAP in drug-resistant cancer cells.

Next, to investigate the reason for the increased YAP mechanosensitivity, we measure the cytoskeleton contractility which is considered as an upstream mechanical regulator of YAP **(Fig. 1B)** [11,12,13,14]. On 5 kPa and 20 kPa substrate, drug-resistant PC9 shows significantly lower (p = 0.029) and similar contractility, respectively **(Fig. 1E and F)**. However, in drug-resistant PC9 cells, pharmacological inhibition of contractility (by CytoD, Y27632 and ML7) still can inhibit the YAP translocation **(Fig. 1G)**. This indicates that although contractility is the mechanical regulator of YAP in drug-resistant PC9 cells but is not responsible for the increased YAP mechanosensitivity after AZD9291 treatment.

Finally, based on the increased YAP mechanosensitivity in drug-resistant PC9, we use mechanical cyclical stretching to inhibit YAP and kill the drug-resistant cells. By applying uniaxial cyclical stretching (0.5 Hz, 13% strain) to drug-resistant cells for 20 hours **(Fig. 2A)**, we observe decreased YAP nuclear translocation, decreased viability and a positive correlation (correlation coefficient = 0.82) between YAP N/C ratio and viability **(Fig. 2B)**. Specifically, cell viability and YAP N/C ratio are the lowest with cyclical stretching only **(Fig. 2C–F)**.

DISCUSSION

To our knowledge, this research is the first investigation to show increased YAP mechanosensitivity in drug-resistant cancer cells. Importantly, our data show that the drug-resistant NSCLC cells, which are not sensitive to EGFR TKI, can be mechanical killed up to 50%. Our results suggest that cyclical stretching, and other mechano-based therapies may help eradicate the drug-resistant cancer cells in clinical. Note that whether/which chemotherapy should be applied with mechanotherapy needs to be determined carefully **(Fig. 2D)**.

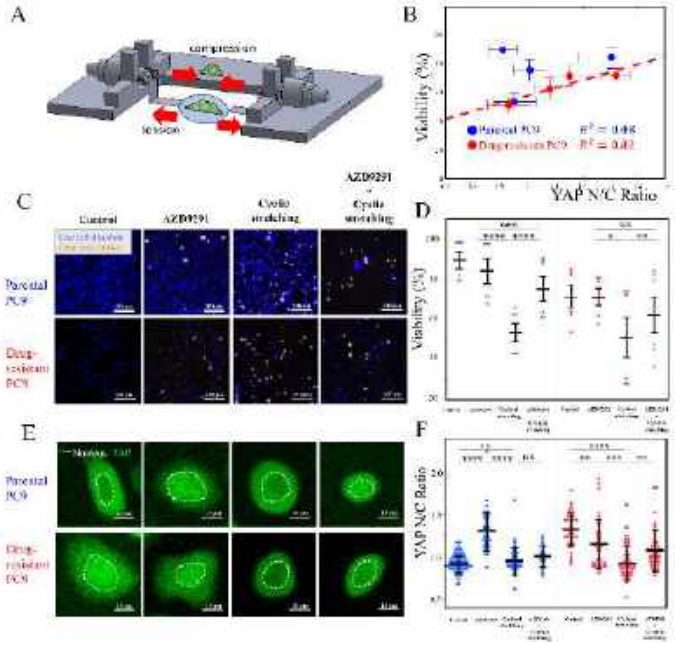

Figure 2: Mechanical cyclical stretching kills drug-resistant NSCLC cells. (A) Customized stretching machine applies uniaxial cyclical stretching on cells. (B) Positive correlation (R^2 = 0.82) between viability and YAP N/C ratio in drug-resistant cells. (C) Viability (51%) is significantly lower with only cyclical stretching applied (p=* compared with AZD9291 only, p= compared with combination of AZD9291 and cyclical stretching). (C) YAP N/C ratio (0.93) is significantly lower with only stretching applied (p=*** compared with AZD9291 only, p=** compared with combination of AZD9291 and cyclical stretching).**

ESTIMATING SEVERE INJURY RISK TO HUMAN CERVICAL SPINE USING SCALED HEAD KINEMATIC RESPONSE FROM NON-HUMAN PRIMATE

INTRODUCTION

Not much is known about the dynamic limits of survivability of humans during frontal impact [1]. However, severe, yet survivable cervical spine injuries are rare, and recovery is extensive [2]. To date, anecdotal cases of survivable, and not survivable, frontal impacts provide only limited information on the potential c-spine dynamics of injury with many variables to consider [3,4]. Historical non-human primate (NHP) frontal impact experiments provide detailed experimental results, spanning from non-injury to severe injury and fatality [5]. It is crucial that the injury risk as a function of head kinematics is assessed, as has been done previously as a function of peak sled acceleration (PSA) and be scaled to a relative human injury risk.

Therefore, the objective of this study was to further develop and validate a ligamentous NHP head-neck model [6] and derive scaling factors from output head kinematics of the NHP model and a previously developed human head-neck model [7]. The scaling factors can then be applied to injury risk curves for respective head kinematic outputs from historical experimental frontal impact data in NHP for an initial estimate of human cervical spine injury risk.

METHODS

The first iteration of the NHP model was developed and described in full in the literature [6], but briefly described below. Model geometry was obtained from CT image data of a NHP skeleton, then meshed, and the head-neck were aligned under the assumption of a neutral head position. Ligaments of the c-spine were attached as 1D elastic spring beam elements with force vs deformation curves imported from a previously developed human head-neck model, the Global Human Body Model Consortium (GHBMC) M50 HN (50th percentile male, head-neck) [7]. These failure curves were scaled to NHP values using the ratio of NHP to human magnitudes at failure [8].

To improve the movement head-neck from the previously published model, 2D discs were constructed between the vertebral bodies from C2-T1. The discs were assigned an estimated Poisson's ratio and Young's modulus adapted from the literature to simplify the discs [9]. Additionally, the cruciate ligament was added as 1D beam elements between the skull-C2 and connected to a 2D shell transverse ligament part allowing the ligaments to interact anatomically. The 2D transverse ligament part was assigned a simplified elastic fabric material type, like the GHBMC model [7].

NHP frontal impact studies from the literature were used to validate the head-neck model [5,10]. In the original NHP experiments, their torsos were restrained to a sled, allowing the head-neck to move freely. Subjects faced the +X lab direction and were fired in the -X direction to simulate an inertial frontal impact. A six-accelerometer package was fixed directly to each subject's skull to record the acceleration in all three planes and calculate the rotational accelerations around each axis. Peak linear and angular accelerations were published publicly [10]. To assess injury threshold risk in NHPs, injury risk as a function of local head kinematics, linear head X (HeadX) and Z (HeadZ) accelerations, was computed using left and right censoring and a weibull statistical fit, as was done previously for injury risk in NHPs as a function of PSA [11]. A total of 40 animal subjects were considered, with 18 total injuries. 12 of these injuries were immediately fatal and 6 ranged from moderate to severe.

For NHP model validation, individual runs were considered for the sample sizes for a total of 57 runs between 10 G and 70 G PSA, at 10 G increments. The NHP model was driven in the -X direction at T1 using a sled pulse from the literature scaled to each PSA [11]. Peak HeadX from the model output was compared to the experimental values since peak HeadX acceleration was the most consistent head kinematic metric. The GHBMC head-neck model was simulated using the same T1 acceleration as for the NHP to replicate the same conditions for theoretical human research volunteers (HRVs). The output peak HeadX and HeadZ from GHBMC were compared to the NHP outputs to obtain

linear scaling equations to then scale the NHP injury risk curves to obtain theoretical HRV injury risk.

RESULTS

Figure 1 demonstrates the model HeadX was close to the experimental measurements for the NHP subjects. Experimental HeadX was the most consistent kinematic metric, with an overall linear behavior and R^2=0.97. For each corridor of PSA, the model output was within the standard deviation or within 15% of the lower bound with respect to the mean, except for 50 G. Model validation was limited to the reported peak kinematic data and would benefit from the full, raw data curves to perform correlative analysis. Additionally, for each corridor, sample sizes are inconsistent and range from n=3 to n=15, with an average of n=8. Nevertheless, for a simplified, ligamentous model the results are sufficient.

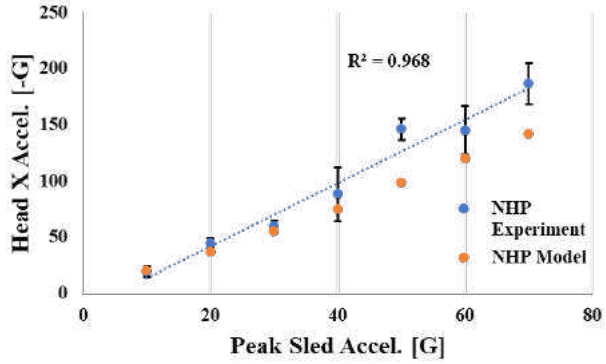

Figure 1: HeadX of the NHP model vs experimental.

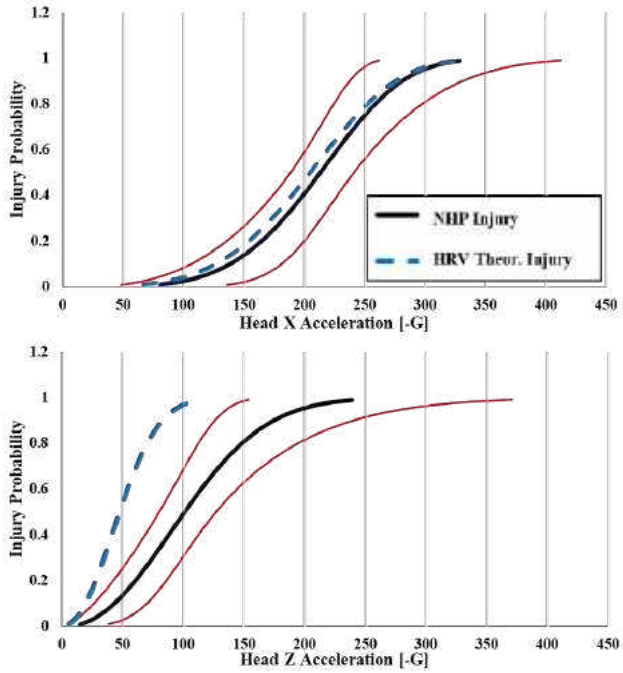

Figure 2: Injury risk probability curves for NHP and theoretical HRV as a function HeadX (top) and HeadZ (bottom).

Injury risk curves with scaled, theoretical human risk are shown in Figure 2 as a function of local head kinematics. For linear HeadX of the NHP, 50% injury risk was at 213 G, ranging from 189 to 241 G. When scaling from NHP to human, the theoretical HRV injury risk as a function of HeadX was almost matching that of the NHP. For HeadZ of the NHP, 50% injury risk was at 101 G, ranging from 80 to 127 G. When scaling from NHP to human, the theoretical HRV injury risk as a function of HeadZ was much lower at 48 G.

DISCUSSION

The scaled injury risk curve demonstrates that for a theoretical HRV subject, the 50% risk of severe injury during frontal impact occurs when the head accelerates at almost half the acceleration of a NHP in the Z direction. Using the head mass of the GHBMC M50 model [7], 4.376 kg, the total load in tension on the neck at 48 G is 2061. N. Yoga et al. reported quasistatic structural failure for isolated head-neck at a load of 1555 N ± 459 and for a human cadaver subject at 3373 N ± 464 [1]. Therefore, the 50% threshold of 48 G for a theoretical HRV injury risk is reasonable as it is between the isolated head-neck and full cadaver maximum tension forces.

A limitation of the scaled results is the lack of raw kinematic data, as stated above and therefore these results should be taken as initial estimates. Raw data would help in fine tuning the material properties to better match the model and experimental kinematic outputs. In particular, the HeadZ is overestimated in the model, ranging between 10-40 G. However, HeadZ had a larger standard deviation for each corridor and the mean peak values were inconsistent with rising PSA, making it difficult to trust the data. If the theoretical HRV simulation results are compared directly the peak HeadZ, the 50% injury risk rises to 69 G, meaning the tension on the neck would be 2962 N, which is just within the standard deviation of the maximum forces a human cadaver neck can withstand [1]. Additionally, the lack of active musculature is a limitation in the NHP ligamentous model. However, the GHBMC model kinematic outputs and ligament strains were almost identical at simulated PSA of 30 G or higher for passive and active musculature indicating the muscles do not dampen the response once the acceleration is higher enough. Muscles were activated in accordance with the authors' previous study on GHBMC muscle activation [12].

The initial scaled injury risk curves shown provide the best estimate of severe injury threshold in humans during frontal impact. With further development of the simplified NHP head-neck model, more analysis on ligament and tissue strains can yield insight into injury mechanisms and help safety system engineers create new injury prevention systems for protection at high acceleration impacts.

ACKNOWLEDGEMENTS

The simulation was completed in part with computational resources and technical support provided by the Research Computing Center at the Medical College of Wisconsin. This work was partially supported by the Department of Veterans Affairs research service and the Dr. Robert D. and Dr. Patricia E. Kern Professorship in Biomedical Engineering.

DIFFERENTIAL EFFECTS OF HYPERTENSION ON THE MORPHOLOGICAL, MECHANICAL, AND PHYSIOLOGIC CHARACTERISTICS OF MALE AND FEMALE HUMAN FEMOROPOPLITEAL ARTERIES

Sayed Ahmadreza Razian (1), Majid Jadidi (1), Alexey Kamenskiy (1)

(1) Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE, USA

INTRODUCTION

Peripheral Artery Disease (PAD) commonly refers to the atherosclerotic blockage of the femoropopliteal artery (FPA) in the lower extremities. It manifests as leg pain, cramping, and numbness during physical exertion, and, in advanced stages, may escalate to critical limb ischemia, potentially leading to limb amputation. Hypertension (HTN) is a primary risk factor for PAD, affecting an estimated 50-90% of individuals with this condition[1].

Both HTN and PAD impact men and women but exhibit notable sex-specific differences in prevalence, pathophysiological development, clinical presentation, and treatment outcomes. Typically, PAD is diagnosed more frequently in younger men, who also tend to experience an earlier onset of HTN, compared to women[2]. Conversely, women often display atypical symptoms or may remain asymptomatic, and they face a higher likelihood of adverse outcomes, including critical limb ischemia or stroke[3].

Despite these epidemiological distinctions between PAD and HTN across sexes, the influence of sex on the morphological, mechanical, and physiologic properties of the FPAs is not well understood. Investigating these aspects could shed light on the varied impacts of HTN on PAD pathogenesis in males and females, but such analysis demands a detailed biomechanical evaluation of FPA tissues, which are seldom available. Our study aimed to compare the biomechanics of the FPA in both healthy and hypertensive conditions across matched male and female subjects, to discern their similarities and differences.

METHODS

The cardiovascular biomechanics research team at the University of Nebraska Omaha, Department of Biomechanics, performed multi-ratio planar biaxial mechanical characterizations of human FPAs from a large group of 463 donors, spanning an age range of 12 to 99 years (average age 51±18 years, 65% males)[4]. Tissues were evaluated fresh within 24 hours of procurement after obtaining consent from their next of kin. Data on age, sex, and risk factors (including HTN) were recorded, and morphological characteristics that included diameter, wall thickness, and circumferential and longitudinal opening angles were measured for each specimen (Figure 1). A total of 176 subjects were devoid of any risk factors, while 82 had only HTN (no diabetes, dyslipidemia, coronary artery disease, or smoking). Constitutive parameters for the invariant-based four-fiber-family model that accurately portrays the behavior of human FPAs in all ages[4], were determined through minimization, and a kinematics framework was used to assess the physiologic arterial characteristics that accounted for the *in situ* longitudinal pre-stretch, circumferential and longitudinal opening angles, and the internal pressures of 120/80 mmHg[5].

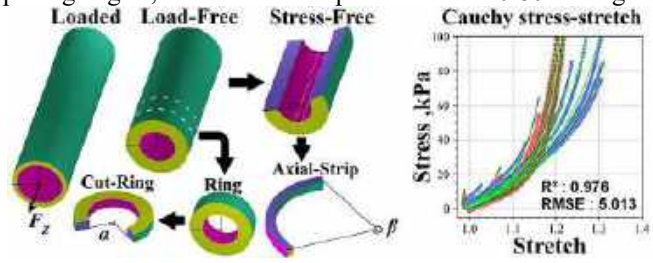

Figure 1. FPA kinematics and biaxial mechanical properties.

The initial phase of the analysis focused on comparing male and female specimens without risk factors. To ensure comparability, male and female arteries were age-matched, with a maximum age difference of 4 years between each pair. In total, 62 pairs were selected for this comparison. The average age in both groups was 36±16 years, indicating no significant age difference (p=0.97). The second phase of the analysis focused on age-matching male and female specimens each presenting a single risk factor – HTN. This process resulted in 28 matched pairs, with an average age of 54±8 years in both groups (p=0.99).

Normality and homogeneity assessments were conducted for all variables. The primary statistical analysis involved conducting an independent t-test for variables that met the normality assumptions. For data not normally distributed, the Mann-Whitney U test was utilized to compare the groups.

RESULTS

In the comparison of healthy pairs (Figure 2), men had arteries that were 12% larger in diameter (6.8mm) compared to women (p<0.01), but there was no significant difference in wall thickness (p=0.05, 1.56mm vs 1.45mm for males and females, respectively). Additionally, no significant differences were noted in either the circumferential or longitudinal opening angles between male and female FPAs (p=0.78 and p=0.85). The intrinsic mechanical properties, assessed as stretches at equibiaxial Cauchy stresses ranging from 40 to 120 kPa in 10kPa increments in both longitudinal and circumferential directions, also showed no notable differences. However, under physiologic conditions, female arteries exhibited a 40% lower axial tethering force associated with the *in situ* pre-stretch (p=0.04). Despite this, there were no differences observed in circumferential stiffness as the artery deformed from diastole to systole (p=0.21), in the elastic strain energy during both systole and diastole (p=0.21 and p=0.22), the *in situ* longitudinal pre-stretch (p=0.44), longitudinal or circumferential physiologic Cauchy stresses (p=0.21, p=0.40), circumferential cardiac cycle stretch (p=0.40), or in the circumferential physiologic stretch between diastole and systole (p=0.49).

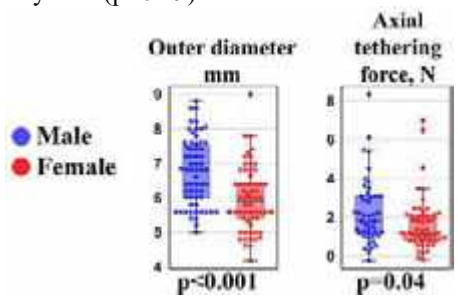

Figure 2. Differences between healthy male and female FPAs.

When comparing male and female subjects with HTN (Figure 3), the arterial diameter was 18% larger in men (7.9mm) than in women (p<0.01), but there were no significant differences in wall thickness (p=0.05), or either circumferential (p=0.24) or longitudinal opening angles (p=0.14). In terms of the intrinsic mechanical properties, FPAs from men with HTN exhibited greater circumferential stiffness compared to those from women with HTN (p<0.02), but there were no differences longitudinally (p>0.43). Physiologically, men with HTN had a 30% higher circumferential arterial stiffness compared to women with HTN (p=0.03). Nevertheless, no significant differences were found in the *in situ* longitudinal pre-stretch (p=0.44), axial tethering force (p=0.97), elastic strain energy at both systole and diastole (p=0.57 and p=0.48), longitudinal or circumferential physiologic Cauchy stresses (p=0.66, p=0.83), circumferential cardiac cycle stretch (p=0.69), or the circumferential stretch across the cardiac cycle (p=0.76).

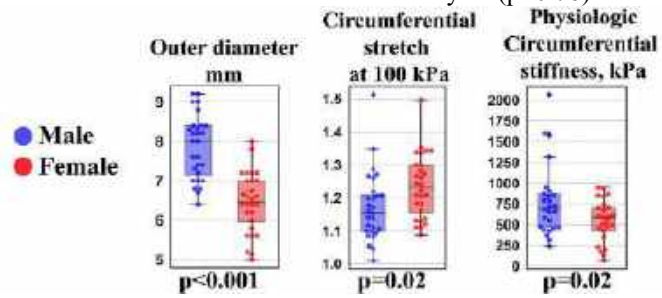

Figure 3. Differences between male and female FPAs with HTN.

DISCUSSION

Healthy males have larger FPAs compared to females, yet most other biomechanical characteristics, including intrinsic mechanical properties and physiologic features, are similar between the sexes. The notable exception is the axial tethering force associated with *in situ* pre-stretch, which is lower in females. HTN impacts male and female FPAs differently, leading to a more pronounced difference in arterial diameter and increased circumferential stiffness in male arteries. This is evident in both intrinsic mechanical properties and physiologic conditions, which take into account axial pre-stretch, opening angles, and internal pressure.

These findings enhance our understanding of the differences and similarities in vascular biomechanics of male and female arteries. This knowledge could be instrumental in developing more effective materials and devices for sex-specific treatment. Furthermore, our data elucidate the distinct effects of HTN on male and female FPAs, which could refine diagnostic methods and improve therapeutic strategies for hypertensive PAD patients of both sexes.

INTRODUCTION

Drug-eluting and bare-metal stents have led to percutaneous coronary intervention (PCI) being the most common form of revascularization. The success of stents is limited by restenosis, resulting in >200,000 repeat PCI procedures in the US annually[1]. Late stent thrombosis (LST) may also lead to morbidity and mortality, but is less common[2]. The factors contributing to restenosis are not fully understood, but wall shear stress (WSS) indices have been implicated since stenting alters artery geometry, which may result in adverse wall shear stress (WSS)[3]. Adverse WSS also correlates with neointimal hyperplasia (NH; the main component of restenosis) and inhibits endothelialization that protects against LST.

Computational fluid dynamics (CFD) has become a valuable tool for assessment of WSS indices due to its noninvasive nature and potential for results with high spatiotemporal resolution. This is particularly important in the setting of stents with local geometric perturbations on the order of ~50 microns. CFD models employ assumptions regarding boundary conditions and rheologic properties that influence WSS indices. It is therefore important to understand the implications of these assumptions and the manner in which they manifest themselves in stent-induced coronary blood flow patterns, and to better interpret the range of WSS results in the literature. The object of this work is to assess differences in WSS indices as a result of assumptions commonly applied with CFD models of stented coronary arteries, focusing on inlet velocity profile, outlet boundary conditions, and the viscosity model.

METHODS

After IRB approval, computed tomography angiography (CTA) and intravascular imaging patient data were acquired after stenting (3.0 x 24.0 mm Synergy, Boston Scientific) of a right coronary artery (RCA) and used to create a patient-specific reconstruction. The workflow described by Ellwein *et al.*[4] for use with optical coherence tomography data was applied to the intravascular ultrasound (IVUS) data obtained in the current case (Fig 1).

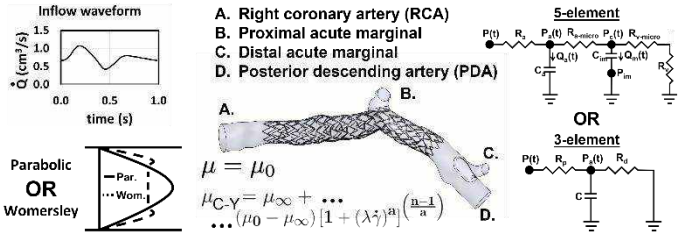

Figure 1: Overview of RCA model and assumptions applied.

Inlet and outlet boundary conditions were individually varied to measure and compare differences in WSS indices. For the inlet, the velocity flow profile was modeled as parabolic or Womersley ($\alpha = 2.5$). The inflow waveform is adopted from healthy RCA flow at rest studied by Ghorbannia *et al.*[5]. For the outlets, lumped parameter networks (LPN) were applied using electrical circuit analogs[6,7]. All outlets for a given simulation were conducted using a 3-element Windkessel model that has been applied for simplicity by ignoring the impact of ventricular contraction[8], or an open loop 5-element coronary model[9]. The resistance and compliance parameters of the 3-element LPN were initially approximated based on patient-specific clinical data and the CTA-derived geometric model, and then iteratively adjusted to yield physiologic outlet pressure and flow waveforms. Parameters for the 5-element LPN were adapted using the approach of Kim *et al.*[6] and Mantero *et al.*[7] while applying the same iterative adjustments employed for the 3-element LPN to achieve physiologic outlet pressure and flow waveforms within the constraints of each approach.

An isometric mesh composed of ~16.8 million elements was created with MeshSim™ (www.simmetrix.com) to resolve complex

flow features around stent struts. Simulations were conducting using SimVascular (simvascular.github.io), where blood was assumed to have a density of 1.06 g/cm^3 and viscosity of 4 cP. Common WSS indices of time-averaged WSS (TAWSS) and oscillatory shear index (OSI) were evaluated for the combination of inlet and outlet boundary conditions studied as shown in Fig 1. To account for the non-Newtonian behavior of blood, results were processed to compare TAWSS from simulations conducted under a Newtonian fluid assumption to those calculated using non-Newtonian viscosity based on the Carreau-Yasuda model[10].

RESULTS

Percent differences in TAWSS between the 3-element and 5-element outlet boundary conditions for a Womersley inlet profile revealed elevated values adjacent to stent struts, often exceeding 5% when coupled with perturbations in the local RCA geometry (Fig 2). This was particularly true in two locations: one along the angled inner portion of the main curve, and one where the stent intersects with the proximal branch. Percent differences in OSI were elevated throughout and proximal to the stented region with values exceeding 100% on ~50% of the lumen surface (Fig 2) with one stented region proximal to the first branch showing values of ~200%.

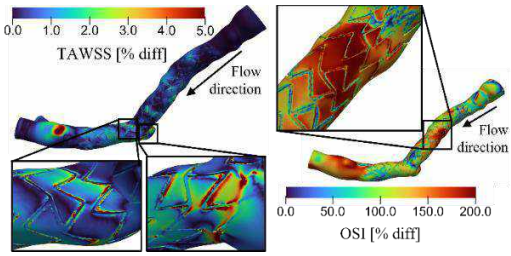

Figure 2: Percent difference in TAWSS (left) and OSI (right) between simulations employing a Womersley inlet flow profile with 3-element vs 5-element outlet boundary conditions.

Local plots of velocity magnitude in these locations shows changes in velocity profiles resulting from different outlet boundary conditions (Fig 3, left). Differences in velocity magnitude between the two inlet velocity profiles employing coronary outlet boundary conditions coincide with the time of greatest pressure difference between the two simulations (Fig 3, right). Cross-sectional slices one and two diameters downstream of the inlet show pronounced differences near the wall. Farther downstream, flow patterns emerge far from the wall distal to the proximal branch, midway into the stented region. Differences in this region persist throughout the entire cardiac cycle.

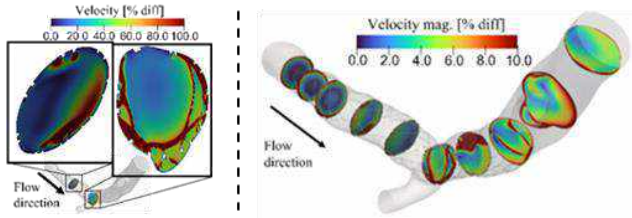

Figure 3: End systolic differences in velocity magnitude due to outlet boundary conditions (left) and inlet velocity profiles (right).

TAWSS calculated using non-Newtonian versus Newtonian viscosities show the greatest percent difference (often exceeding 100%) adjacent to stents struts (Fig 4). Differences at locations greater than one strut width away from the stent rarely exceeded 10%.

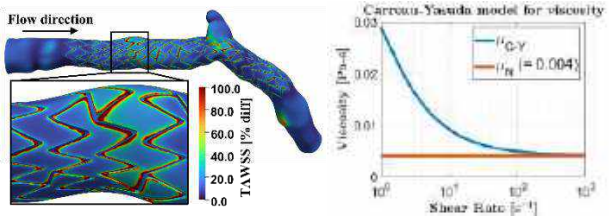

Figure 4: TAWSS percent difference (left) from the viscosity models applied with Womersley inlet flow profile and 5-element outlet boundary conditions.

DISCUSSION

Our IVUS-based patient-specific stented RCA study reveals the importance in choosing appropriate assumptions when conducting CFD simulations of stented coronary arteries. Given the relationship of WSS indices in predicting regions susceptible to restenosis, it is somewhat concerning that model results for TAWSS or OSI can differ by as much as 100-200% from a single assumption. Of note are the differences stemming from the choice of outlet boundary conditions. The 3-element LPN model adapted from literature, although simple to implement, cannot replicate the out-of-phase nature between pressure and flow in the coronary arteries since it ignores intramyocardial pressure. Differences in WSS indices presented in Figure 2 are due to changes in velocity profiles in the model, and are a manifestation of neglecting ventricular contraction, resulting in different pressure gradients during the cardiac cycle. Differences near the inlet due to the prescribed velocity profile were expected and consistent with prior literature[11] since the two types of velocity profiles impose different velocity gradients at the wall thereby resulting in different WSS values. Analysis of differences in velocity between subsequent cycles for a given inlet profile shows that the downstream differences are likely due to turbulent kinetic energy rather than the inlet profile. They can be minimized to some degree with highly resolved meshes and additional cardiac cycles, but are nonetheless an inherent part of flow features developing under complex flow conditions. The choice of viscosity model also affects the WSS indices in the stented region, which agrees with the established literature[12]. This highlights a need for flow solvers to include non-Newtonian models, particularly when characterizing stent-induced differences in WSS indices. Collectively these results suggest that certain assumptions commonly applied for simulations of stented coronary arteries have a greater impact on TAWSS and OSI than others, with outlet boundary conditions being paramount, followed by viscosity model and inlet velocity profile.

GENERIC VERSUS PERSONALIZED FOOT-GROUND CONTACT MODELS- IS PERSONALIZATION WORTH THE EFFORT?

Spencer T. Williams, Kayla M. Pariser, Claire V. Hammond, Benjamin J. Fregly

Mechanical Engineering Department, Rice University, Houston, Texas, United States

INTRODUCTION

Musculoskeletal modeling researchers seek to use predictive simulations to design optimized, personalized treatments for patients with movement impairments [1, 2]. Direct collocation optimal control has become the computational method of choice for developing these predictive simulations [3], ideally using personalized neuromusculoskeletal models of individual subjects [1]. For predictions of post-treatment walking function, an important component in these personalized models is the foot-ground contact (FGC) model. FGC models account for changes in interactions between the subject's feet and the ground as the subject's gait pattern is altered during the optimization, estimating updated ground reaction forces and moments to preserve dynamic consistency.

Despite the goal of designing personalized treatments, nearly all optimal control simulations of walking use generic FGC models that have not been calibrated using experimental ground reaction data collected from the subject being modeled. This study investigated the extent to which personalization of FGC model parameters in a two-segment three-dimensional foot model affects the model's ability to reproduce experimental ground reaction and foot kinematic data collected from a single subject post-stroke. Three different FGC models were investigated: 1) a generic model that uses a sparse non-uniform grid of nonlinear springs [4], 2) a personalized version of this generic model, and 3) a personalized FGC model that uses a dense uniform grid of linear spring contact elements [1, 5].

METHODS

The FGC Model Personalization Tool within the MATLAB-based Neuromusculoskeletal Modeling (NMSM) Pipeline software [6] developed by the authors was used to perform the present study. The software uses two-segment, three-dimensional foot models from full-body OpenSim [2] models and adds viscoelastic frictional contact elements to the bottom of the feet. MATLAB's nonlinear least squares optimization algorithm is used to find FGC model parameter values and minimal kinematic changes such that experimental ground reaction and foot kinematic data are matched as closely as possible. Design variables available within the tool include deviations from spline-fitted hindfoot and toes kinematics, spring stiffness coefficients, a damping coefficient, a dynamic friction coefficient, a viscous friction coefficient, and a spring resting length. The cost function penalizes errors in experimental foot kinematics (four marker positions, four hindfoot and toes orientations) and ground reactions (three forces, three moments). It can also penalize a Gaussian weighted average of each contact element's stiffness deviation relative to its neighbors, designed to prevent discontinuities in the identified stiffness profile. The software can calibrate one foot independently or both feet together using a common set of FGC model parameter values as done in the present study.

The experimental ground reaction and foot kinematic data used for this study were collected from a single subject post-stroke. Two walking trials were included in this analysis; the first involved walking at a self-selected speed of 0.35 m/s, and the second involved walking at a fastest comfortable speed of 0.65 m/s. The 0.35 m/s walking trial was used for calibration and testing, and the 0.65 m/s trial was used only for testing.

Three personalized FGC models were investigated in this study in addition to a generic FGC model used in OpenSim Moco optimal control simulations of walking [4]. The generic model uses a sparse non-uniform grid of six spherical contact elements on each foot, where each contact element exerts a Hertzian nonlinear spring force with Hunt and Crossley nonlinear damping [7] in the vertical direction and dynamic and viscous friction in the horizontal direction. Model 1 was a manually personalized version of the generic model. Since the generic model represents a barefoot subject, Model 1 manual personalization involved changing the vertical location of the contact elements in the feet to account for the height of the subject's shoe. For this model and the generic model, the FGC Model Personalization Tool adjusted only foot kinematics while seeking to reproduce the experimental ground reaction

and foot kinematic data. Model 2 was a fully personalized version of Model 1. For this model, the FGC Model Personalization Tool adjusted stiffness coefficients common to both feet, friction coefficients, and the common radius of the spherical contact elements along with foot kinematics. Model 3 was a personalized FGC model used for GPOPS-II [8] optimal control simulations of walking [1]. This contact model uses a dense uniform grid of 55 contact elements on each foot, where each contact element exerts a linear spring force with linear damping in the vertical direction and dynamic and viscous friction in the horizontal direction. For this model, the FGC Model Personalization Tool adjusted individual stiffness coefficients shared by both feet, common friction coefficients a spring resting length along with foot kinematics.

The three personalized FGC models were calibrated using a single cycle of 0.35 m/s gait data and tested using the 0.35 m/s cycle and a second cycle of 0.65 m/s gait data. Testing involved adjusting only foot kinematics and keeping all model parameter values fixed while seeking to match experimental ground reaction and foot kinematic data.

RESULTS

While the generic model was unable to reproduce experimental ground reactions forces and moments for the 0.35 m/s calibration cycle, all three personalized models reproduced them closely while also reproducing experimental foot kinematics closely (Table 1). When the personalized models were tested using the 0.35 m/s and 0.65 m/s cycles, all three reproduced experimental ground reaction and foot kinematic data with comparable accuracy to the calibration cycle (Tables 2 and 3). Though Model 3 generally had the lowest errors, the differences from Model 1 and 2 results were small.

Table 1: RMS error in matching experimental kinematics and ground reactions for calibration with 0.35 m/s gait trial.

Model	Generic	Model 1	Model 2	Model 3
GRF (N)	311.88	9.95	10.16	8.51
Moment (Nm)	21.06	3.13	2.98	2.50
Rotation (°)	0.35	0.73	0.74	0.50
Trans (mm)	5.44	6.30	5.34	3.02

Table 2: RMS error in matching experimental kinematics and ground reactions for testing with 0.35 m/s gait trial. Model 1 is included again for comparison.

Model	Model 1	Model 2	Model 3
GRF (N)	9.95	10.37	8.51
Moment (Nm)	3.13	3.05	2.49
Rotation (°)	0.73	0.74	0.50
Trans (mm)	6.30	5.30	3.02

Table 3: RMS error in matching experimental kinematics and ground reactions for testing with 0.65 m/s gait trial.

Model	Model 1	Model 2	Model 3
GRF (N)	12.05	13.84	12.63
Moment (Nm)	3.72	3.69	3.12
Rotation (°)	0.73	0.74	0.46
Trans (mm)	5.40	5.15	3.44

DISCUSSION

Our results indicate that FGC models may be sufficiently personalized for walking simulations by simply modifying the vertical locations of the contact elements in the feet, and thus calibrating FGC model parameter values may be unnecessary for generating accurate full-body predictive simulations of walking. Without changing parameter values in the generic FGC model, Model 1 accurately reproduced experimental ground reaction and foot kinematic data, though changing the height of the contact elements in the feet was essential, as shown by the failure of the generic model in Table 1. For full-body predictive simulations of walking, the main potential benefit of Model 3 is the smaller vertical translation error, which may make it easier to produce an initial dynamically consistent walking simulation.

Though model personalization was performed using a single 0.35 m/s calibration cycle, all three personalized models also produced accurate results for 0.35 and 0.65 m/s gait data in testing. Thus, the personalized models remained accurate under new testing conditions despite the facts that model parameter values were the same for both feet and the two feet interacted with the ground in a very different manner due to the subject's stroke. These findings support the generalizability of the personalized FGC models to new simulated walking motions produced during the optimal control solution process.

Despite how well Model 1 reproduced experimental ground reaction data with minimal changes to foot kinematics, other situations may necessitate the more extensive personalization performed for Models 2 and 3. First, movements other than straight level walking at constant speed may require a more personalized FGC model. For example, walking up or down an incline or stairs, turning, running, or squatting may require a more highly personalized model. Second, foot models possessing more than two segments may also require a more personalized FGC model. While two-segment foot models are sufficient for optimal control simulations of walking [1], researchers interested in predicting detailed foot kinematics and kinetics may want to include more segments in their foot models. The limited set of spherical contact elements used in Models 1 and 2 may not work for foot models with more segments, and the denser grid of springs used in Model 3 may be useful. Third, walking simulations intended to predict the pressure distribution under the foot may require the denser grid of contact elements used by Model 3. However, pressure maps predicted by Model 3 have not yet been validated. Fourth, modeling different types of shoes may require more extensive model personalization. The subject in the present study wore Adidas Samba sneakers, which possess a uniform neutral sole. It is unknown whether a higher level of personalization would be needed to model more complex shoe designs, such as those with variable stiffness or thickness soles.

This study was limited by the fact that only one subject was included. Nonetheless, the fact that the three personalized FGC models worked well for different walking speeds and both feet of a subject with an asymmetrical gait pattern suggests that similar results are likely to be found for other subjects.

MATLAB source code for the FGC Model Personalization Tool is available on SimTK.org as a part of the NMSM Pipeline. The data used in this study will also be made available on SimTK.org as part of the first Stroke Grand Challenge Competition.

INTRODUCTION

Vascular endothelial cells (ECs) are highly responsive to mechanical[1] and biochemical[2] stimuli. When exposed to fluid flow *in vitro*, ECs align along the flow direction, mimicking their axial alignment *in vivo*.[3] Seminal work by Nerem and co-workers demonstrated that EC alignment is dependent on magnitude of shear stress stimulus and proper cellular mechanosensing,[3,4] but the exact mechanobiological mechanisms involved remain undetermined.

EC alignment is vital for vascular barrier integrity. In regions with low shear stress or perturbed flow patterns such as arterial bifurcation points, alignment is decreased, and this structural change is paired with alterations in surface protein expression, leading to an increased propensity for atherosclerotic plaque formation.[5]

Diabetes is a major cardiovascular disease risk factor and is strongly associated with endothelial dysfunction.[6] In non-diabetic individuals, atherosclerotic plaques occur mainly in regions of disturbed flow, but diabetic patients also develop diffuse plaques in laminar flow regions.[6] Alterations in endothelial biochemical signaling due to hyperglycemia have been proposed; the interplay between these alterations and cellular mechanics, however, is unknown.[2]

While *in vitro* experiments have provided valuable insight into mechanical[1] and biological[2] regulation of EC alignment, computational modeling techniques can examine the interconnected mechanisms in complementary ways. The objective of this study was to create a model of the structural EC response to mechanical and biochemical stimuli by connecting intracellular signaling to the mechanical stress fiber response and cellular repositioning. We hypothesized that ECs require actin-myosin motor engagement, which is dampened by hyperglycemia, for stress fibers to respond to a flow stimulus and for the cells to align.

METHODS

Model Formulation. The model (Fig. 1) consists of (1) biochemical signaling, (2) single-actin-filament mechanics in response to biochemical activation, (3) cell-substrate mechanical coupling, and (4) a cellular Potts model of EC shape change. Each component is described in turn below.

Biochemical Signaling Model. The signaling network was constructed from published vascular endothelial responses to glucose, mechanical stretch, and shear stress (Fig. 1). Each reaction "edge" was supported by one publication, and each species' response to perturbations in input species (blue nodes) by a minimum of two publications. The species reactions were defined using established methods,[7] with node activations represented by a system of ordinary differential equations and connected by Boolean logic. The hyperglycemic condition was simulated by increasing the "Glucose" node input from 0.4 to 0.9. The "Intracellular Tension" node input was determined by the normalized mean fiber stress.

Actomyosin Contraction. The steady-state level of the "Actomyosin" node within the biochemical network was passed to the fiber-level component, triggering stress fiber activation.[8] The stress fiber activations were converted into an active fiber stress described by

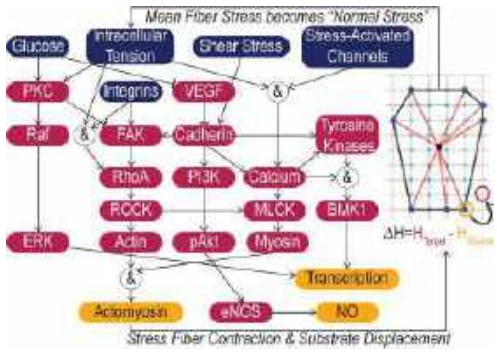

Figure 1: Model Schematic. (a) Signaling model responds to various stimuli and computes an actomyosin activation signal. (b) The cell moves in accordance with that signal.

a Hill-type model that depended on strain rate. The passive fiber stress depended exponentially on fiber strain.[8]

Elastic Substrate Response. The deformation due to focal adhesion-applied traction force was found by assuming that the substrate was an 10 kPa, elastic half-space.[9] Mechanical equilibrium was enforced at each time step to determine each node's position.

Cellular Potts Model (CPM). At each time step, the CPM iteratively attempted a number of moves equal to the number of lattice sites. For each move, a random source and neighboring target were selected (Fig. 1). The pseudo-energy of the system was represented by a Hamiltonian that combined the effects of area and perimeter changes, local substrate strain-stiffening, and fiber stress avoidance. The energy associated with cellular area and perimeter was quantified as

$$H_{Geom} = \sum_{i \in cells} \lambda_A (a_i - A)^8 + \lambda_P \left(p_i - p_{i,0}\right)^4$$

where λ_A and λ_P were weighting parameters for area and perimeter change contributions, a_i and p_i were the cell area and perimeter, A was a target resting area, and $p_{i,0}$ was the target perimeter. Elastic substrate deformation lead to local stiffening,[10] represented in the model as

$$\Delta H_{Strain} = -g(\vec{x}, \vec{x}')\lambda_S \left(h\left(E(\varepsilon_1)\right)(\vec{v}_1 \cdot \vec{v}_m)^2 + h\left(E(\varepsilon_2)\right)(\vec{v}_2 \cdot \vec{v}_m)^2\right)$$

where $g = 1$ for extension and -1 for retraction, λ_S was a weighting parameter, $h\left(E(\varepsilon_1)\right)$ was a sigmoidal focal adhesion maturation function, $\vec{v}_m$ was a unit vector of the movement direction, and $\vec{v}_1$, $\vec{v}_2$, ε_1, and ε_2 were the eigenvectors and eigenvalues of the local substrate strain. The energy associated with fiber shear stress avoidance was quantified as

$$H_{Shear} = \sum_{j \in fibers} \tau_F \eta_j \frac{l_j}{L} \left(\tan^{-1}\left(\frac{\pi^2}{64}\right) - \tan^{-1}\left(\left(\theta_j - \frac{\pi}{2}\right)^2\right)\right)$$

where τ_F was normalized shear stress magnitude, η_j was the fiber activation, l_j/L was the ratio of fiber length to lattice spacing, and θ_j was the angle of the fiber with respect to the fluid flow. The sum of all Hamiltonian components was converted into an acceptance probability to determine whether the proposed move occurred.

Cell Alignment. The alignment tensor was calculated as

$$A_{ij} = \frac{\sum_{k \in fibers} l^k n_i^k n_j^k}{\sum_{k \in fibers} l^k}$$

where for fiber *k*, *l* was the length and *n* was a unit vector of its direction. The degree of cell alignment was defined as the difference between the two eigenvalues of *A* (1 is perfectly aligned, 0 is isotropic). The model was run 10 times with 4 cells per replicate for each condition (shear stress input in increments of 0.1 between 0 and 1, ± hyperglycemia) for 1000 simulated seconds.

RESULTS

ECs respond to many stimuli by altering their structure and preferred alignment. In the absence of exterior stimuli, the simulated ECs were mostly isotropic (Fig. 2a). In response to shear, the cells aligned with the flow (Fig. 2b). With or without flow, stress fibers activated and equilibrated at 91% of max activation (Fig. 2c). When a flow stimulus was present, the fiber activation was conferred into EC realignment parallel to the direction of flow (Fig. 2d).

When the glucose levels were increased to mimic hyperglycemia,

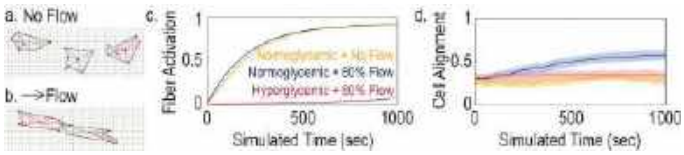

Figure 2. Representative normoglycemic cells without (a) and with (b) flow stimulation. (c) Stress fiber activation and (d) cell alignment in normoglycemic cells with (blue) and without (yellow) flow and hyperglycemic cells with flow (pink). Shaded regions are 95% CI (n=40). Fiber activation error is $\sigma(10^{-3})$.

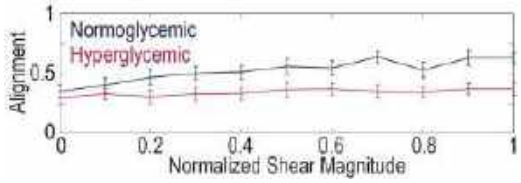

Figure 3. ECs align with increasing shear. Error is 95% CI (n=40).

the flow-mediated cadherin signaling was partially blocked by inhibition of FAK by PKC (Fig. 1), and the stress fibers did not activate beyond 7% of max activation (Fig. 2c), and the cells did not align in response to the flow (Fig. 2d).

The normoglycemic cell response was dependent on the magnitude of shear stress. With increasing normalized shear magnitude, the model endothelial cells achieved greater alignment (Fig. 3). The degree of cell alignment saturated at ~50% normalized shear, with a mean degree of alignment of roughly 0.63.

DISCUSSION

These results demonstrate the capability of our model to describe the complex biochemical and mechanical signaling events that drive EC structural alignment. To our knowledge, this model is the first to connect knowledge of the biochemical signaling of ECs to a structural mechanical response to normal and shear stress. Previous computational models have been employed to predict single fiber[11] and cellular[12] alignment responses to cyclic stretch, but there was no consideration for biochemical signaling events. A more recent model by Hardin *et al*. incorporates the mechanical effects of intercellular communication, but not disease-perturbed behaviors.[13]

Since Nerem's seminal work, numerous *in vitro* studies have observed that ECs respond to both mechanical stimuli, e.g. cyclic stretch or fluid flow, and biochemical stimuli, e.g. changes in glucose levels or pharmacological interventions. The power of our model is demonstrated in its recapitulation of perturbed EC alignment in hyperglycemic systems (Fig. 2, 3). Biochemically, our model connects previous findings[2] of glucose-mediated PKC inhibition of actomyosin (Fig. 1); mechanisms that can now be more fully explored computationally than was previously possible in an *in vitro* system. Our model suggests that the mechanical, stress-avoidant response of stress fibers is prevented in hyperglycemic systems by a lack of actin-myosin activation (Fig. 2).

In its current form, our model employs a simplified fiber network to represent the cytoskeleton, so there is no consideration of actin monomer retrograde flow nor a stiff nuclear body. Actively migrating cells or those undergoing external stretching utilize actin retrograde flow to coordinate stress fiber alignment and cell polarization.[11,14] Even without these features, however, our model offers a tool to quantify and interpret experimentally-observed biophysical mechanisms of EC alignment.

SHEAR-INDUCED PLATELET AGGREGATION IS MEDIATED BY vWF-BINDING RECEPTORS IN A STENOTIC MODEL

INTRODUCTION

Atherosclerosis and mechanical circulatory support (MCS) devices perturb healthy blood flow, demonstrating supraphysiological shear rates (>1-2,000 s^{-1}) [1] that induce platelet activation, amplify unfurling of the von Willebrand factor (vWF), and increase platelet adhesion [2]. vWF is an ultralarge, mechanically sensitive glycoprotein that circulates within plasma as a coiled multimer, acting to temporarily tether platelets prior to firm clot stabilization by other adhesive receptors. These multimers unfurl in response to arterial or supraphysiological shear stresses, upregulating vWF-mediated platelet capture.

MCS devices apply supraphysiological shear stresses, often resulting in device-induced thrombosis. Recent studies have highlighted the vWF-rich composition of these blood clots [3]. Device-induced thrombosis can occur within blood-contacting pumps or the arterial circulation as a result of systemically elevated prothrombotic factors and platelet activity [1]. The physical forces experienced by blood in MCS devices prime vWF and platelets to a hyper adhesive state, driving the incidence of thrombosis in these patients.

Due to the clinical severity of arterial thrombosis-associated pathology, it is crucial that the factors contributing to vWF-mediated platelet adhesion are further mapped to improve predictive modeling and inform the development of novel anticoagulant and antiplatelet agents. Elevated shear rates and shear rate gradients have been demonstrated to play a role in vWF-mediated platelet aggregation [4]. Local shear rates and shear rate gradients induced by flow-perturbing geometries drive an increase in both vWF adhesion and effective platelet capture by the unfurling of adherent vWF multimers [5]. Recent studies highlight vWF-binding GPIb as the major receptor involved in shear-induced platelet aggregation (SIPA) [6] and collagen-binding GPVI as a potential target for antiplatelet therapy [7]. The primary objective of this study was to observe the effect of variable shear rate as a means to understand the contributions of different platelet receptors to platelet deposition in a stenotic model.

METHODS

Using established methods of soft lithography [8], polydimethylsiloxane (PDMS) microchannels were fabricated to act as a testing platform for shear-altered deposition. Four stenotic geometries were fabricated to induce rapid shear rate gradients, with contractions of 0, 25, 50, and 75% **(Figure 1)**. Microchannels had a cross-section of 200 x 50 µm in the upstream region. PDMS chips and glass microslides were cleaned in 70% ethanol and sealed by air-plasma treatment in a plasma cleaner (Harrick Plasma, Ithaca NY). Shear rates were calculated in ANSYS FLUENT (ANSYS, Canonsburg PA) and verified by velocity data using a micro-PIV system (TSI Inc., Shoreview MN).

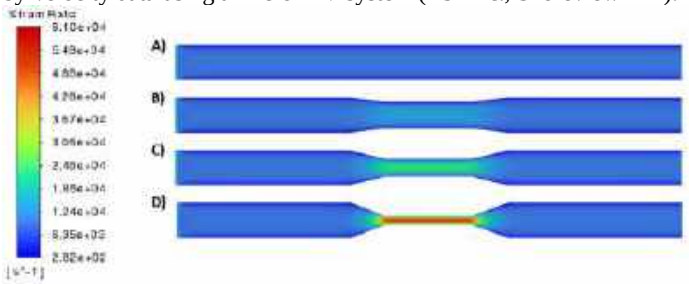

Figure 1: Numerical calculation of shear rates at 50 µL/min flow (upstream shear rate of 10,000 s^{-1}) for A) 0% B) 25% C) 50% and D) 75% stenotic channels with diameters ranging from 50-200 µm. Contour plane is 2 µm from the channel bottom wall.

Prior to experiments, channels were coated with human type I collagen at 100 µg/mL to create an adherent surface. Human blood was acquired via a Penn State IRB approved protocol and anticoagulated with sodium citrate at a final concentration of 0.32%. Blood was centrifuged at 300g for 30 min to obtain separated platelet rich plasma (PRP), which was used to quantify platelet concentration. Platelets were stained with $DiOC_6$ and incubated for 30 min at 37˚C. To determine the

contributions of platelet binding receptors, GPIb and $\alpha_{IIb}\beta_{III}$ function was inhibited by incubation with monoclonal blocking antibodies (Biolegend, San Diego CA), while GPVI was blocked by D-dimer (Abcam, Cambridge UK). Blood was then reconstituted to 40% HCT with PRP, maintaining native platelet concentration (367±93 x 10^6 /mL). Blood was not recalcified to avoid triggering the coagulation cascade. Blood was then perfused for 5 min through microchannels with a Harvard syringe pump (Kd Scientific, MA) at 5, 25, or 50 µL/min to achieve upstream wall shear rates of 1,000, 5,000, and 10,000 s^{-1}, correlating to arteriolar, pathological, and mechanical device-relevant shear rates, respectively. Throat shear rates (up to 40000 s^{-1}) within the stenoses were dependent on both the aforementioned prescribed flow rate and degree of stenotic contraction **(Figure 1).** Real-time immunofluorescence images were acquired at 1 frame per second with an Olympus IX71 inverted microscope and DP74 4MP CMOS camera (Olympus, Tokyo Japan). Pixel resolution was 0.586 µm/pixel. Images were converted to binary and processed in ImageJ (NIH, Bethesda MD) and MATLAB (Mathworks, Natick MA). Significance was assessed by a two-way ANOVA followed by Dunnett's multiple comparisons test.

RESULTS

Control samples exhibited SIPA as a result of increasing shear rate and increasing stenotic contraction **(Figure 2)**. Platelet adhesion (measured by % surface area coverage) and aggregation (measured by mean thrombus area) increased proportionally with increasing shear rate and stenotic contraction. Inhibition of $\alpha_{IIb}\beta_{III}$ and GPIb receptors caused rapid reduction in both platelet adhesion and a loss of aggregation at >1,000 s^{-1}. GPVI inhibition did not notably reduce platelet adhesion at 1,000 s^{-1} but affected microthrombus stability at 5-10,000 s^{-1}. While adhesion and aggregation were modestly reduced, embolization notably occurred as shear rates and stenotic grade increased. At an upstream shear rate of 10,000 s^{-1}, adhesion of unblocked samples (n=6-8) increased as stenotic grade increased, while GPIb-inhibited and $\alpha_{IIb}\beta_{III}$-inhibited samples displayed minimal platelet adhesion, and no shear-induced aggregation. GPVI-inhibited samples (n=6-7) displayed reduced surface area coverage (SAC), but this effect was more pronounced in 50 and 75% stenotic channels.

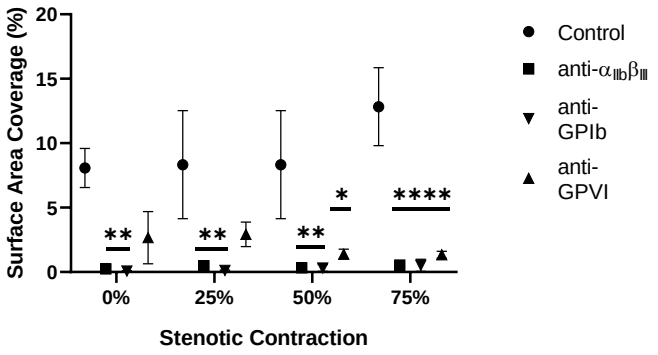

Figure 2: Surface area coverage (SAC) measuring platelet adhesion at 50 µL/min (upstream shear rate of 10,000 s^{-1}) for 0-75% stenoses. Data are presented as mean±SEM. Significance denotes the effect of receptor inhibition vs unblocked (control) samples.

Platelet aggregation followed similar trends to overall adhesion. Mean thrombus area (MTA) was dramatically reduced in $\alpha_{IIb}\beta_{III}$- and GPIb-inhibited samples as throat shear rates exceeded 1-2,000 s^{-1} **(Figure 3)**. GPVI-inhibited samples did not display significantly reduced MTA until throat shear rates exceeded 10,000 s^{-1}. This reduction was not due to a loss of aggregability from GPVI inhibition but frequent embolization of large (>100 µm^2) thrombi as throat shear rates reached 2-40,000 s^{-1} within the 50 and 75% stenotic channels.

DISCUSSION

SIPA of unblocked blood samples was observed at supraphysiological shear rates, influenced by both upstream shear rate and stenotic contraction. Inhibition of the vWF-binding receptors $\alpha_{IIb}\beta_{III}$ and GPIb completely blocked platelet adhesion and aggregation at shear rates exceeding 1-2,000 s^{-1}. The lack of any platelet adhesion at these shear rates further supports the need for an initial vWF-bound platelet layer to facilitate arterial, pathological, or device-mediated thrombosis within the acute time scale investigated here.

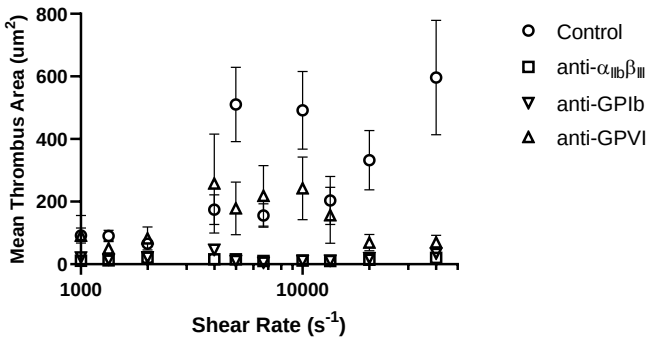

Figure 3: Mean thrombus area (MTA) measuring platelet aggregation for all flow rates (5-50 µL/min). Shear rate is the wall shear rate within the throat of each channel, based on flow rate and stenotic grade (0-75%). Data are presented as mean±SEM.

Alternatively, inhibition of GPVI only modestly decreased platelet adhesion at upstream shear rates of 5-10,000 s^{-1} but made larger microthrombi more susceptible to embolization at 20-40000 s^{-1}. Prior to embolization, larger microthrombi formed as a result of platelet aggregation in GPVI-inhibited samples. This suggests that the collagen-binding function of GPVI serves primarily as a method of stabilization as thrombi grow into the freestream and experience stronger hydrodynamic drag. This does not prohibit SIPA in a thrombogenic geometry such as a severe stenosis and may not be an effective target for the regulation of arterial thrombosis.

This study yields further insight into mechanisms regulating rapid growth of arterial thrombi at supraphysiological shear rates. Three major platelet adhesion receptors were investigated in a study of shear-induced platelet aggregation. Stenotic geometries created shear rate gradients that increased platelet adhesion in unblocked blood samples, yet increased embolization in GPVI-blocked samples. Inhibition of $\alpha_{IIb}\beta_{III}$ and GPIb prohibited platelet adhesion and aggregation, indicating a reliance on vWF-mediated adhesion to precipitate SIPA.

INTRODUCTION

Cardiovascular disease stands as the primary cause of mortality in the United States [1]. Severe valvular heart disease induces pressure or volume overload on the cardiac chambers, impairing myocardial contraction and ultimately impacting the overall function of the heart [2]. The prevailing approaches for in vivo cardiovascular research and diagnosis involve catheterization and imaging. However, these methods present drawbacks–imaging tends to be costly, and catheterization is invasive [3]. To address these limitations, computational modeling, especially fluid structure interaction (FSI) simulations of the whole heart, emerges as a valuable tool for researchers and clinicians. Previous whole-heart fluid-structure interaction models either lack physiologic valves [4] or fail to capture the nuanced stresses and strains within the myocardium [5]. We propose instead to construct a model utilizing the immersed finite element/finite difference (IFED) technique [6], which has been successfully used in previous work to simulate heart chambers and valves [7,8]. This approach is employed to develop a model of the entire heart, serving as a foundation for future studies on valve replacement and repair. Furthermore, it is demonstrated that our model captures the Frank-Starling mechanism, which is a fundamental response of the heart in which increased diastolic filling results in increased systolic ejection.

METHODS

Anatomical structures were derived from cardiac computed tomography (CT) imaging, capturing detailed three-dimensional representations of major cardiac components (Figure 1). Biomechanical models of the heart and its valves were parameterized using experimental tensile test data sourced exclusively from human tissue specimens. These models incorporated established approaches describing the heart's fiber architecture based on prior experimental work. FSI simulations utilized the IFED version [6,9] of the immersed boundary method, enabling automatic handling of contact between structures, including valve leaflets.

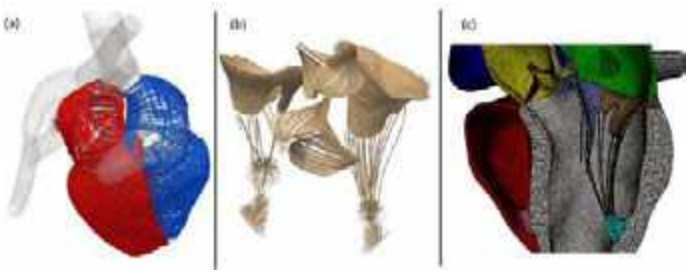

Figure 1. (a) The main myocardial fibers within the right heart and left heart depicted in blue and red, respectively. (b) A visualization of the main fiber orientation on the valve leaflet, chordae, and papillary muscles. (c) A visualization of the heart mesh with a focus on the left side and mitral valve apparatus. The colors denote different subdomains within the mesh [10].

In this study, the circulation model employed is a closed system, where the flows and pressures originating from the left and right sides of the heart are coupled, unlike previous iterations of the model.

RESULTS

Preliminary dynamic simulation results using a decoupled circulation model illustrated crucial aspects of the cardiac cycle for the left heart (Fig. 2). Blood velocity magnitudes and pressures depicted fluid dynamics within the heart, providing insights into blood flow patterns during various phases of the cardiac cycle. These

representations underscore essential dynamics, showcasing the model's ability to simulate key aspects of cardiac function.

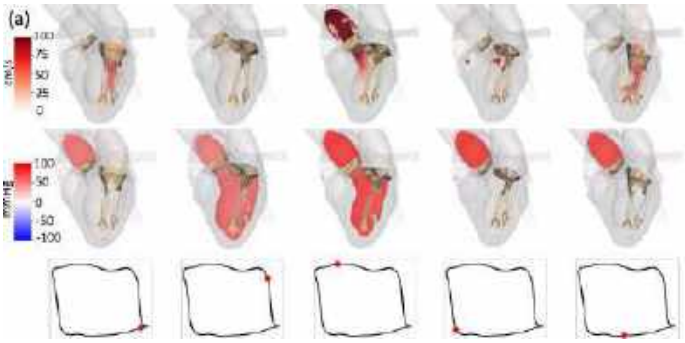

Figure 2. Blood flow dynamics within the heart: Visual representations of both blood velocity magnitude and pressure across a plane dividing the aortic and mitral valves, depicted alongside semi-transparent views of the heart chambers at five distinct time intervals throughout the cardiac cycle. The lowest panels display the pressure-volume loop generated by the model.

To demonstrate the satisfaction of the Frank-Starling mechanism, in Fig. 3(a), our model effectively captures the expected trend, showing that a larger end-diastolic volume (ventricular preload) corresponds to a larger stroke volume. This relationship is quantified in the ventricular function curve depicted in Fig. 3(c). While approaching a non-linear response, as seen in Fig. 3(c) with larger loads [11 -13], additional data points at higher loads will help confirm this observation. Although ventricular preload (end-diastolic volume) is not a perfect indicator of cellular length [12], it remains adequate for capturing overall trends in the Frank-Starling mechanism. The consistency of the end-diastolic filling section of the pressure-volume relation across different loads is highlighted in Fig. 3(b). This observation aligns with in vivo findings [11, 14].

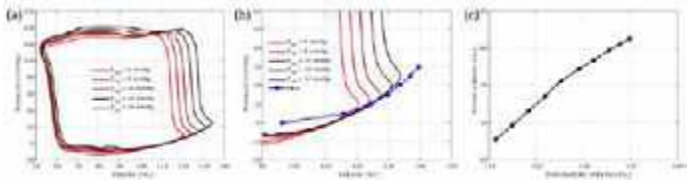

Figure 3. (a) The overlaid pressure-volume relations from multiple cycles (b) Comparison of the diastolic filling portion of the pressure-volume relations to the static end-diastolic pressure-volume relationship [15] (c) Plot of the left ventricular end-diastolic volume load values against the resultant stroke volumes to generate the left ventricular function curve for atrial loading pressures of 6-15 mmHg.

DISCUSSION

Our model showcases nuanced dynamics of the cardiac cycle, capturing distinct features like the mitral valve closing transient and aortic valve closure, aligning qualitatively with clinical and experimental data. While our pressure-volume relationships do not replicate textbook curves or idealized valve models, they mirror clinical measurements, emphasizing the model's realism in representing physiological cardiac function. The discrepancies observed, such as differences in volume losses and left ventricular pressure during isovolumetric contraction compared to in vivo examples, highlight areas for further refinement. However, our model's ability to replicate clinical features, such as regurgitant flow volumes and mitral flow rate waveforms, showcases its potential in simulating and understanding complex cardiac dynamics. These findings underscore the model's strength in capturing realistic pressure-flow relations and its relevance in studying various cardiac dysfunctions, particularly valvular disorders. By providing direct access to crucial metrics like flows and pressures, our model holds promise for advancing simulation-based studies aimed at improving the understanding and treatment of a wide spectrum of cardiac pathologies.

INTRODUCTION

The extracellular matrix (ECM) represents the vast scaffolding and framework of microstructural elements that lend soft tissues their mechanical properties, as well as protein molecules that facilitate signaling and sensing of cells to their environment. A confluence of this physicochemical signaling and sensing provides cells with a myriad of sophisticated adaptive mechanisms to respond to changes in their homeostatic environment, and understanding the ECM as a constantly evolving environment has recontextualized the importance of mechanobiology in the larger scale of biomechanics [1].

More specifically, recent advances in microscopy and imaging have allowed us a closer look at the ECM of elastic arteries, and attention has been drawn to the sensing and remodeling undertaken by the stress sensing smooth muscle cells (SMC) which predominantly occupies the media of these arteries. SMCs are predominantly oriented circumferentially, and reside within elastin lamellae organized concentrically around the axis of flow. There is evidence to suggest that the spacing between these lamellae is conserved in aging [2], which is typically associated with progressive elastin degradation. SMCs differentially deposit glycosaminoglycans (GAGs) -which in turn generates Donnan Swelling- in response to change in their mechanical environment [3, 4]. In a more extreme model for advanced ageing, Murtada and Kawamura et al. [5] shows that SMCs in the media of Hutchinson-Guilford Progeria mice modulate their phenotype to an osteochondrogenic phenotype that produces pathological amounts of GAGs as a response to medial degeneration of elastin in advanced ageing.

Since the correlation between elastin damage, GAG deposition and aortic dilatation is of importance, we seek to describe these relationships in a mathematical framework. To that end, we revisit work presented by Roccabianca et al. [6,7] previously developed to describe the mechanics of swollen arteries. We utilize this framework in an attempt to simulate the behavior of arteries undergoing elastin damage and Donnan Swelling. First, we observe the behavior of the model in the context of elastin integrity loss. Additionally, we attempt to characterize the swelling that would take place during this elastin loss. Since [2] and [4] suggest that interlamellar distance and medial thickness are somewhat conserved with elastin damage and dilatation (to maintain radially sensed stresses by SMCs), we attempt to reflect this in our model. Finally, a simple coupling between damage and swelling is directly imposed, and subsequent biomechanical change is reported.

METHODS

Identical to [7], the framework of the constrained mixture model is used to describe the constitutive behavior of the bilayered modelled arteries. The cylindrically shaped layers are an inner layer (comprising approximately 38% of the total thickness) representing the media, and an outer one representing the adventitia. Relevant to our investigation are two configurations that deviate from homeostatically hydrated (swollen) homeostatic conditions ($\kappa_h{}^*$) conditions previously reported in [7]. These configurations are shown in **Fig. 1**. The first configuration (κ_γ^*) corresponds to the carotid artery dimensions at the homeostatic load but with a compromised elastin integrity, that we implement by multiplying the neo-Hookean constant c^e by a gain parameter ranging between 0 % and 100 % integrity. As elastin degrades, the artery must dilate to accommodate the homeostatic load, leading to a decrease in the interlamellar distance. The second configuration (κ_{γ,ν^*}^*) corresponds to the swelling that takes place in the medial layer due to that elastin loss. While in [7] the swelling was applied onto excised sample tissue, we wish to understand what swelling would take place to satisfy the hypothesis derived from [2] and [4].

The deformation gradient describing the change from a swollen homeostatic configuration to a new configuration with elastin compromise is given by $\mathbf{F}_\gamma{}^* = \mathrm{diag}[\frac{dr_\gamma}{dr_h}, \frac{r_\gamma}{r_h}, \lambda_\gamma]$. The kinematic constraint between configurations is given by the following radius change in cylindrical coordinates $r_\gamma = \sqrt{{r_{\gamma i}}^2 + \frac{{r_h}^2 - {r_{hi}}^2}{\lambda_\gamma}}$. Similarly, the deformation gradient mapping from this damaged configuration to one with damage and swelling adapted to damage is given by $\mathbf{F}_{\nu^*,\gamma}{}^* = \mathrm{diag}[\nu_\gamma^* \frac{dr_{\gamma,\nu}}{dr_\gamma}, \frac{r_{\gamma,\nu}}{r_\gamma}, 1]$ and the radius change is dictated by $r_{\gamma,\nu} = \sqrt{{r_{\gamma,\nu i}}^2 + \frac{\int \nu_\gamma^* r_\gamma \, dr_\gamma}{2}}$. The swelling formulation corresponds to a volume change, and is directly applied axisymmetrically on the domain according to the following scalar analytical relationship to the radius r_γ

$$\nu_\gamma^* = \frac{\nu_a + \nu_i}{2} + \frac{\alpha(r_\gamma - r_{\gamma m})}{\sqrt{1 + \frac{4\alpha^2 (r_\gamma - r_{\gamma m})^2}{(\nu_a - \nu_i)^2}}} \quad (1)$$

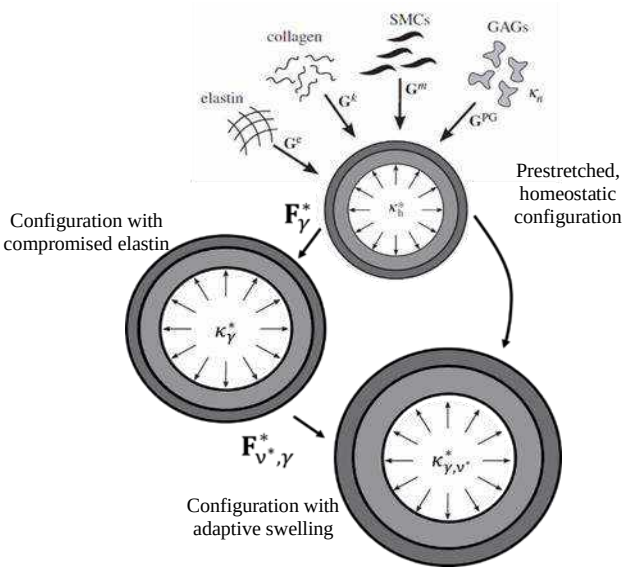

Figure 1 Illustration of configurations of interest

where ν_a and ν_i corresponds to the volume change at the adventitia (outer radius) and the intima (inner radius) respectively. r_{ym} here corresponds to the radial position from the inner radius at the border where the media and adventitia meet. Since this analytical relationship creates a sigmoidal shape, the parameter α enforces the steepness of the sigmoid. In our investigations, we always apply the boundary condition where $\nu_a = 1$ meaning that the volume change at the adventitia does not take place, and a large value of α therefore means that the adventitial volume change can entirely and uniformly be given a value of 1 and the entire volume change of the intima takes a value of $\int_i^a \nu_i dr$. In our effort to investigate swelling as a function of damage, and subsequent modification of the swelling profile, we optimize for the value of ν_i at 93.33 mmHg with the conservation of medial thickness being the objective function to minimize. In other words, loss of medial thickness due to dilatation and elastin loss is counteracted by swelling which aims to maintain medial thickness.

RESULTS

Our simulation demonstrates that the loss of elastin at differing luminal pressures (and in the absence of compensatory swelling in the media $\mathbf{F}_{\nu^*,\gamma}{}^* = \mathbf{I}$) leads to dilatation (**Fig. 2**). This behavior is asymptotic as elastin loss at different stresses tends to dilate to a diameter at which full collagen and SMC recruitment bear the elastic load, i.e., the model emulates the phenomenon of adventitial rescue. Additionally, we show that the presence of swelling that maintains medial thickness (confirmed in **Fig. 3(a)** solid line) implies logarithmic correlation (**Fig. 3(b)**) between swelling and elastin degradation. The consequence of this adjustment or adaptation on the transmural stress is the decrease of stress attributed to less elastic load bearing and increased fluid (swelling) load-bearing (**Fig. 3(d)**).

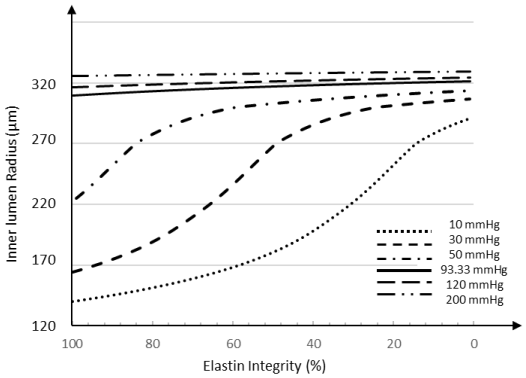

Figure 2 Lumen radius in elastin integrity loss ($\mathbf{F}_{\nu^*,\gamma}{}^* = \mathbf{I}$)

DISCUSSION

Given the importance of incorporating mechanobiological phenomena in soft tissue biomechanics, integrating additional microstructurally and mechanobiologically relevant components of the ECM is significant. We show that the model proposed in [6,7] adopted here can effectively demonstrate adventitial rescue in absence of elastin (**Fig. 2**) which was suggested to explain the absence of dilatation in compromised elastin [8], and why dilatation and excessive GAG production appears when elastin degradation happens in conjunction with adventitial (collagen crosslinking) compromise [9]. Recently published work by Li et al. [10] highlights two forms of failure related to mechanosensing with the first being a linear relationship between elastin loss and tissue damage, and the second being a saturation relationship when mechanosensing is compromised. The latter is heavily correlated with the anchoring of cells in the media, and is sensitive to interlamellar spacing, therefore **Fig. 3(b)** solid line reflects that maintained mechanosensing follows the same trend. We therefore hope to utilize this modelling approach in future numerical studies on evolving GAG content as an adaptive mechanism in response to elastin damage.

NEGATIVE EFFORT DEPENDENCE IN OBSTRUCTIVE SLEEP APNEA: INSIGHTS FROM A MATHEMATICAL MODEL

Guilherme J.M. Garcia (1,2), B. Tucker Woodson (2)

INTRODUCTION

Obstructive sleep apnea (OSA) is a disease characterized by recurrent episodes of airflow limitation during sleep due to upper airway (UA) collapse. OSA pathophysiology is complex, but increased UA collapsibility is a major risk factor [1]. The anatomical and physiological factors that regulate UA collapsibility remain incompletely understood. A better understanding of UA biomechanics may lead to the development of more effective methods to diagnose and treat OSA.

The Starling Resistor (i.e., a collapsible tube between two rigid tubes) has been the archetype model of UA collapse in OSA for the last 35 years as it explains many observations [2]. For example, snoring is similar to oscillations that arise in collapsible tubes during flow limitation [2]. However, the observation of negative effort dependence (NED) in OSA patients led researchers to question if the human UA really behaves like a Starling Resistor [3,4]. NED is a reduction in flowrate with increasing breathing effort. The observation of NED contradicts the leading theory of flow limitation in collapsible tubes (i.e., the wave speed flow limitation theory [5]), which predicts that flowrate remains constant and independent of the downstream pressure after the onset of flow limitation. A mathematical model to explain the occurrence of NED in collapsible tubes is lacking. Here, we present a simple mathematical model to explain NED in OSA. Our model predicts that NED is a consequence of the coupling between the fluid mechanics of airflow in a constricted tube and the solid mechanics of how UA soft tissues respond to negative intraluminal pressure.

METHODS

Our solid mechanics model is the area-pressure relationship (tube law) of the pharynx in OSA patients [6] (**Fig. 1**)

$$A = A_{max}\left[1 - e^{-\frac{C_0}{A_{max}}(P_{pharynx} - P_{close})}\right]$$

where A is the airspace cross-sectional area of the pharyngeal choke point, $P_{pharynx}$ is the air pressure at the choke point, P_{close} is the pharyngeal closing pressure (i.e., $A = 0$ at $P_{pharynx} = P_{close}$), A_{max} is the maximal area of the choke point (observed when $P_{pharynx} \gg P_{close}$), and C_0 is the pharyngeal compliance (slope of the area-pressure relationship) at the closing pressure, namely

$$C_0 = \left(\frac{dA}{dP_{pharynx}}\right)_{P_{pharynx}=P_{close}}$$

The tube law is illustrated in **Fig. 1** for a patient with A_{max} = 1 cm^2, P_{close} = 2 cmH$_2$O, and C_0 = 0.15 cm^2/cmH$_2$O.

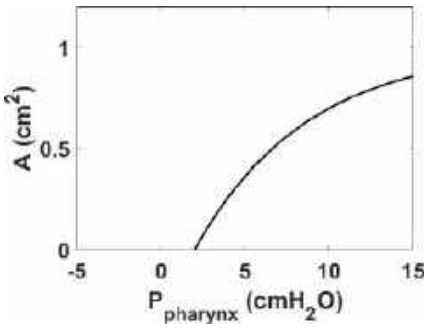

Figure 1: Area-pressure relationship of the human pharynx in an OSA patient with A_{max} = 1 cm^2, P_{close} = 2 cmH$_2$O, and C_0 = 0.15 cm^2/cmH$_2$O.

Our fluid mechanics model consists of equations describing the flow upstream and downstream of the choking point. First, we apply the Bernoulli equation (i.e., conservation of energy) between an upstream point and the pharyngeal choke point to obtain an equation that relates the flowrate (Q) to the choke point cross-sectional area (A)

$$Q = A\sqrt{\frac{2(P_{UP} - P_{pharynx})}{\rho(1-\beta^2)}}$$

where P_{UP} is the upstream pressure, ρ = 1.2 kg/m^3 is air density, and $\beta = A/A_{max}$. Next, we assume that the pressure loss downstream of the choke point is a combination of major losses and minor losses due to a sudden expansion, so that the downstream pressure (P_{DOWN}) is

$$P_{DOWN} = P_{pharynx} - (\Delta P)_{MAJOR} - (\Delta P)_{MINOR}$$

The major losses $(\Delta P)_{MAJOR}$ are computed from the Darcy friction factor in the standard fashion [7] assuming a circular tube with length of 10 cm, while the minor losses are

$$(\Delta P)_{MINOR} = K_L \frac{\rho V^2}{2}$$

where $V = Q/A$ is the air velocity at the pharyngeal choke point and K_L is the loss coefficient of a sudden expansion

$$K_L = \alpha(1-\beta)^2$$

where $\alpha = 1.05$ is the kinetic energy correction factor for turbulent flow [7].

We define negative effort dependence (NED) as the percent reduction in flowrate from the peak flowrate (Q_{max}) to the flowrate Q^* at a downstream pressure of -5 cmH$_2$O (**Fig. 2**)

$$NED = 100\frac{(Q_{max} - Q^*)}{Q_{max}}$$

RESULTS

The model predicts that as the downstream pressure decreases (i.e., breathing effort increases) the flowrate increases, reaches a maximum value (Q_{max}), and then decreases to zero due to UA collapse (**Fig. 2**).

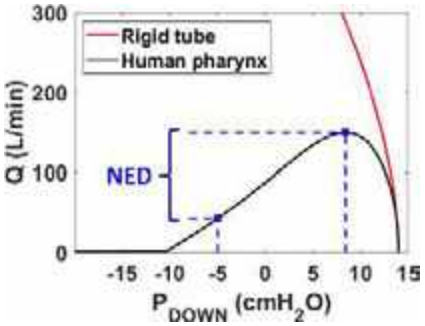

Figure 2: Pressure-flow curve of the human pharynx (A_{max} = 1 cm^2, P_{close} = 2 cmH$_2$O, C_0 = 0.15 cm^2/cmH$_2$O, and P_{UP} = 14 cmH$_2$O) compared to a rigid tube. Abbreviation: NED = negative effort dependence.

For an OSA patient with A_{max} = 1 cm^2, P_{close} = 2 cmH$_2$O, and C_0 = 0.15 cm^2/cmH$_2$O assuming an upstream pressure P_{UP} = 14 cmH$_2$O, the model predicts that NED = 72%, i.e., a 72% reduction in flow from its peak of 149.9 L/min to 42.4 L/min at a downstream pressure of -5 cmH$_2$O (**Fig. 2**). When pharyngeal compliance at the closing pressure was increased from C_0 = 0.05 to 0.25 cm^2/cmH$_2$O while keeping A_{max}, P_{close}, and P_{UP} constant, NED increased from 58.6% to 80.3% (**Fig. 3**). NED depended on the values of A_{max}, P_{close}, and P_{UP}, but higher pharyngeal compliance produced greater NED.

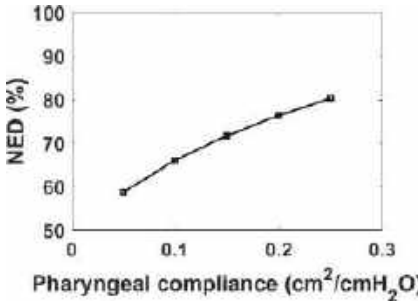

Figure 3: The mathematical model predicts that negative effort dependence (NED) increases as pharyngeal compliance increases.

DISCUSSION

To our knowledge, this is the first biomechanical model to explain the occurrence of NED in OSA patients. Our model predicts that collapsible tubes can also display NED (not shown), which supports the view that the human UA behaves like a Starling Resistor. Importantly, the model predicts that NED increases as pharyngeal compliance increases (**Fig. 3**). This prediction supports the hypothesis by Wellman and collaborators that NED can be used to identify the anatomical structure causing airflow limitation in OSA patients [8]. Specifically, four anatomical structures can cause airflow limitation in OSA, namely the tongue, epiglottis, soft palate, and lateral pharyngeal walls. Our model suggests that the collapse of highly compliant structures that flap quickly (e.g., epiglottis and soft palate) will produce more NED than the collapse of low-compliance structures that move more slowly (e.g., tongue). This prediction is consistent with the in vivo observation that isolated epiglottic collapse and isolated soft palate collapse have greater NED than tongue collapse [8]. We acknowledge that our model is a simplification of the complex fluid-structure interactions involved. Experimental studies are needed to test the validity of our assumptions and to verify our predictions. Future studies will help refine our model and lead to a better understanding of the biomechanics of UA collapse in OSA.

PREDICTING FAILURE LOCATIONS IN HETEROGENEOUS SOFT MATERIALS

Catherine C. Eberman (1), Colleen M. Witzenburg (1,2)

INTRODUCTION

Identifying the risk of rupture in soft tissues, such as aortic or cerebral aneurysms, myocardial infarct tissue, or ligament or tendon following repair, poses a significant clinical challenge [1-4]. Mitigating rupture risk often involves surgical or percutaneous intervention. Current research in failure modeling and prediction often involves complex finite element modeling and damage modeling [5-8], while clinical risk prediction is often limited to geometry (e.g., aneurysms [1]). Predicting failure risk is particularly challenging in pathologic soft tissues since (1) spatial differences in both geometry and material properties contribute to the creation of stress concentration zones and material failure and (2) soft tissues are mechanosensitive and remodel their extracellular matrix in response to disease or injury. The objective of our study was to create an algorithm that predicts failure initiation location from pre-failure biaxial testing data. To test the algorithm, we created spatially variable soft tissue analog samples from PDMS. The algorithm combined full-field deformation, loading direction, and sample geometry from sub failure tests to predict regions at high risk for failure. These locations corresponded well with the actual failure locations in equibiaxial mechanical testing.

METHODS

Sample Preparation and Testing. PDMS (Sylgard) was cast, and silicone sealant or desiccant beads were added to create heterogeneity. Samples were cut into cruciform shapes and speckled using black spray paint (Fig. 1) to enable full-field strain tracking via digital image correlation (DIC). Samples were attached to a biaxial testing machine (574E2, TestResources) and underwent 15 extensions to 10% strain, including equibiaxial, two-arm, three-arm, strip uniaxial, and single arm extension extensions [9]. Samples were then pulled to failure equibiaxially at a rate of 0.15% strain/s. Images of the sample were captured at 4k at a minimum of 24fps for all protocols.

Failure Prediction. DIC was applied to all extensions to determine full-field displacement. Briefly, the tissue boundary was sketched on top of the reference image, meshed with quadrilateral elements, and tracked. The deformation gradient tensor, **F**, was computed at each element edge (i) and compared to the neighboring element (j) [10]:

$$Def = \left(F_{11}^{i} - F_{11}^{j}\right)^2 + \left(F_{12}^{i} - F_{12}^{j}\right)^2 + (F_{21}^{i} - F_{21}^{j})^2 + (F_{22}^{i} - F_{22}^{j})^2 \quad (1)$$

This enables identification of regions with large spatial differences in deformation, *Def*.

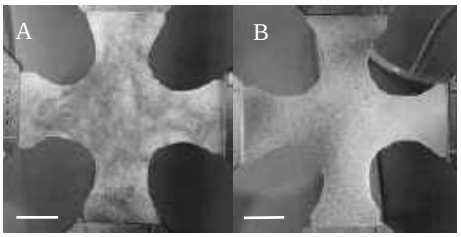

Figure 1: PDMS with silicone sealant (A) or desiccant beads (B) added to produce a heterogeneous sample, scale bar = 0.875 in.

To account for the direction of the deformation, *Dir*, the dot product of the nodal connection direction, N_c, and the local principal strain direction, E_p, from the 10% equibiaxial subfailure test was computed.

$$Dir = \frac{E_p}{|E_p|} \cdot \frac{Nc}{|N_c|} \quad (2)$$

A connectivity matrix, *A*, was generated for the mesh such that if two mesh elements shared an edge, their corresponding centroids were considered connected. The deformation and direction were then used to weight the connectivity matrix.

$$A_w = A * Def * Dir / \max(Dir) \quad (3)$$

The weighted connectivity of shared edges below a certain threshold were reduced to near zero, eliminating the impact of connections with low weight on predicted failure location.

$$A_{threshold} = \begin{matrix} A_w \geq threshold & A_w \\ A_w < threshold & A_w * 10^{-10} \end{matrix} \quad (4)$$

The threshold value was calibrated by fitting the means of the nonzero values of A_w and the effective threshold range for each sample.

$$threshold = -3.40 * mean(A_w) + 3.55 \quad (5)$$

Lastly, following Witzenburg et al. [9] the betweenness of the weighted mesh was computed and the sample was segmented into two distinct regions by removing mesh edges with the largest betweenness.

RESULTS

Fig. 2 shows the spatial variation in *Def* (A), E_p (B), A_w (C) and betweenness (D) for the PDMS sample with silicone sealant. The map of *Def* identifies edges with large differences in the deformation gradient, shown in brighter red, from 15 asymmetric extensions. The map of *Dir* identifies the principal strain directions in the subfailure equibiaxial extension as edges perpendicular to the principal direction are more likely to break. Lastly, betweenness incorporates the geometry of the mesh, favoring more central elements over more remote.

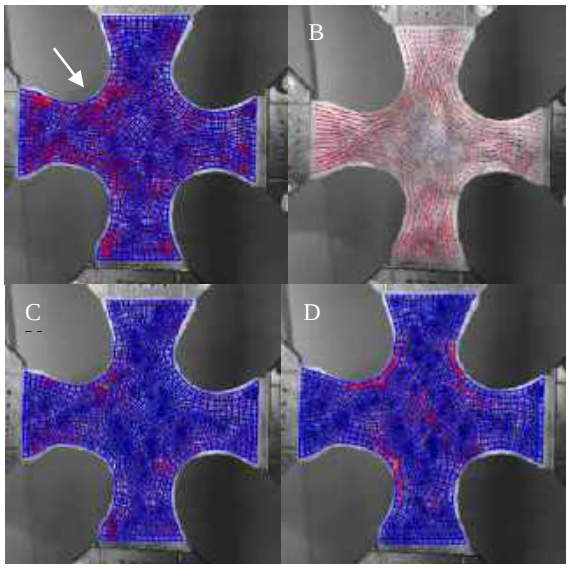

Figure 2: Difference in deformation gradient (A), principal strain for biaxial extension (B), weighted connectivity (C) and betweenness (D) for the heterogeneous PDMS sample with silicone sealant. The arrow in (A) indicates the location where the difference in deformation was largest.

The predicted failure locations for the PDMS samples were very close to the location of experimental failure (Fig. 3). Note that the predicted failure location did not necessarily correspond to the location of largest deformation gradient difference. For the PDMS sample with silicone sealant, *Def* was largest on the interior curve of the sample (arrow in Fig. 2A), while the failure location was across the left arm (Fig. 3C, E).

DISCUSSION

Failure prediction in heterogeneous soft materials is important clinically as disease and damage induces local extracellular matrix variations in tissues and puts them at high rupture risk [1,8]. Unfortunately, local spatial variations in structure can lead to unexpected failure location and mechanics. Our novel algorithm was able to predict failure locations for two heterogeneous PDMS samples, from full field subfailure deformation measurements. In an initial test we were also able to predict the corner where the grip failure initiated in a specimen of decellularized rat myocardium (Fig. 4). Notably this did not require alternation of the algorithm or the threshold value. Thus, this algorithm shows promise for predicting soft tissue failure, however further testing and validation is needed.

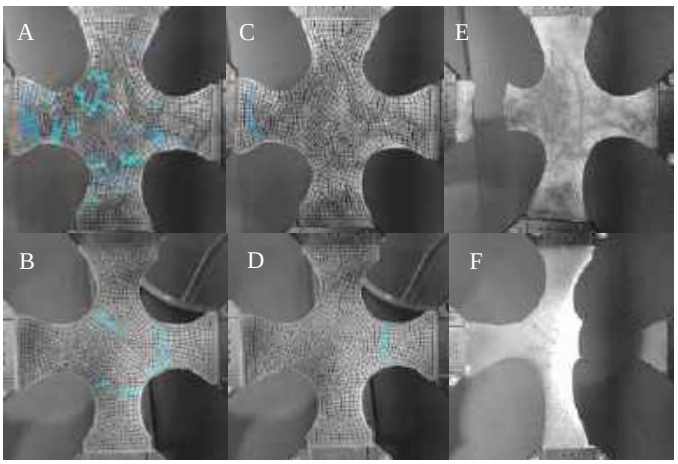

Figure 3: All edges removed prior to predicted failure for the PDMS with silicone sealant (A) or desiccant beads (B). Brighter blue edges were removed first and darker blue were removed later. Edges that were removed corresponding to predicted failure location (C, D). Experimental equibiaxial failure location (E, F).

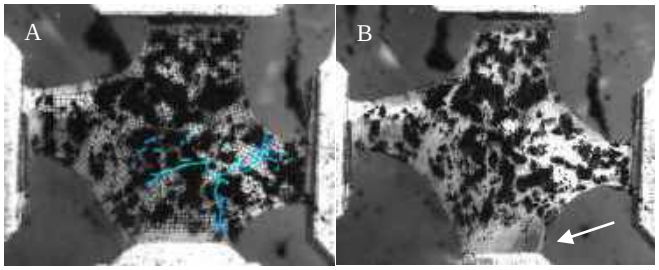

Figure 4: Decellularized myocardial tissue with myocardial infarction showing edges removed prior to predicted failure (A). Grip failure occurred at location of arrow (B).

INFLUENCE OF SEX AND SEX HORMONES ON SKELETAL RESPONSES TO INTERMITTENT PARATHYROID HORMONE (PTH) TREATMENT AND DISCONTINUATION

INTRODUCTION

Intermittent parathyroid hormone (PTH) is an FDA approved treatment for osteoporosis that rapidly elicits new bone formation. Our recent study unexpectedly discovered that intact female and estrogen-deficient female rats had distinct responses to the discontinuation of PTH treatment [1]. No adverse effect was observed in intact female rats, which sustained treatment benefit after PTH discontinuation [1], in contrast to the significant bone loss and bone microarchitecture deterioration observed in estrogen-deficient rats [1-3] and pre-pubertal male rats [4]. However, osteoporosis is a chronic disease that not only affects postmenopausal women, but also aged men. Moreover, though rare, young adults may also suffer from osteoporosis and require treatment. These motivate the objective of the current study to elucidate the influence of sex and gonadal function on skeletal responses to anabolic treatment (such as PTH) and discontinuation. We hypothesized that skeletal responses to PTH treatment and discontinuation are influenced by both sex and sex hormones. To test this hypothesis, ovariectomized (OVX) rats were used to simulate post-menopausal osteoporosis and orchiectomized (ORX) rats were used to simulate hypogonadism in aged men. Age-matched, intact female and male rats were used as young adults with intact gonadal function. Elucidation of the potential sexual dimorphisms associated with PTH treatment and discontinuation may help guide the novel design of anabolic treatment regimens to achieve the greatest treatment benefit by considering patient sex and gonadal function.

METHODS

Animals and treatments: Ten male Sprague-Dawley (SD) rats received bilateral ORX surgery at the age of 4 months and developed osteopenia for 4 weeks before being divided into ORX-PTH (n=5) and ORX-VEH (n=5) groups. Eleven age-matched male, intact SD rats were divided into two groups, Male-PTH (n=5) and Male-VEH (n=6). PTH 1-34 (40 μg/kg/day, 5x/week) was administered for three weeks while saline (VEH) was administered following the same injection plan as in the PTH groups. Data of intact and OVX female rats were from our previously published study [1]. Briefly, 18 female rats received bilateral OVX surgery at the age of 4 months and developed osteopenia for four weeks, before being assigned to groups of OVX-VEH (n=9) and OVX-PTH (n=9). Twelve age-matched female intact rats were divided into Female-PTH (n=6) and Female-VEH (n=6) groups. All animals and procedures were approved by UPenn's IACUC.

In vivo micro computed tomography (μCT) imaging: The right tibiae of male rats were scanned using *in vivo* μCT (Scanco vivaCT80, 11.6 μm voxel size) before ORX surgery (week -4), after osteopenia development (week 0, baseline), after PTH/VEH treatment (week 3), and during treatment discontinuation (weeks 4, 5, 8, 10, and 12). A landmark-initialized mutual information based registration toolkit [5] was employed to identify the corresponding volume of interest (VOI) at different timepoints (Fig. 1A). Bone volume fraction (BV/TV), trabecular thickness (Tb.Th), and trabecular number (Tb.N) were computed in the VOIs. Similar imaging and analysis protocols were used for female rats, with a voxel size of 10.5 μm [1].

Statistics: A two-way ANOVA with repeated measures was performed to compare treatment groups over time with adjustment for baseline. Bonferroni corrections were used for the multiple comparisons. The significance level was set at 0.05.

RESULTS

Skeletal responses in intact and ORX male rats:

Compared to the Male-VEH group (Fig. 1B), BV/TV decreased by 40% in the ORX-VEH group 4 weeks after ORX surgery and then remained stable for 12 weeks (Fig. 1C). In the Male-PTH group, BV/TV improved by 46% after 3-week PTH treatment and continued to increase for one week after the treatment discontinuation, which we defined as the extended anabolic period (EAP), followed by a continuous decrease from weeks 4 to 12 (Fig. 1B). Similarly, in the ORX-PTH group, 3-

week PTH treatment yielded a 97% increase in BV/TV, followed by a 1-week EAP, and decreased continuously after week 4 (Fig. 1C). In both intact and ORX male groups, the benefit in BV/TV from PTH treatment diminished after 9-week treatment discontinuation, as there was no difference in BV/TV between PTH- and VEH-treated bone in either the intact or ORX male groups.

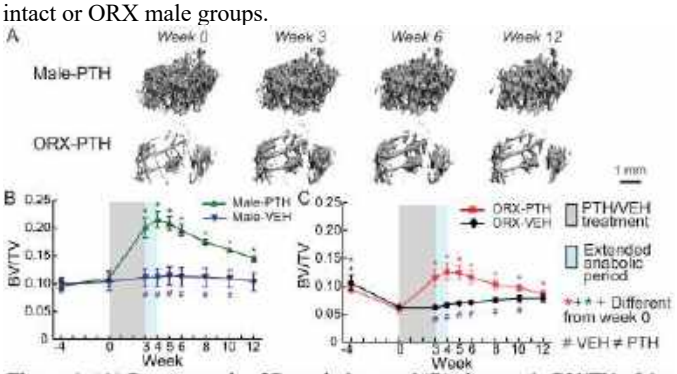

Figure 1. (A) Representative 3D renderings and (B) changes in BV/TV of the registered trabecular bone of the proximal tibiae of Male and ORX groups in response to PTH treatment and discontinuation.

Comparisons between intact male and female rats:

Although VEH treatments had minimal impacts on the BV/TV of intact males and females, there were significant differences between them starting at week 3 (Fig. 2A). These differences were due to the significant trabecular thickening in the males (Fig. 2B). Unexpectedly, there was a similar decline of Tb.N in both intact males and females (Fig. 2C). On the other hand, PTH treatment led to a 2.5-fold greater percentage increase of BV/TV in intact males than in intact females (Fig. 2D). The increased BV/TV in intact females was sustained stably during PTH discontinuation; however, BV/TV continued to decline from weeks 6 to 12 in intact males (Fig. 2D). Significant trabecular thickening occurred in both groups in response to PTH treatment, and the improvement in Tb.Th was maintained during the treatment discontinuation (Fig. 2E). In contrast, while Tb.N stabilized in females, it decreased continuously in males during treatment discontinuation (Fig. 2F).

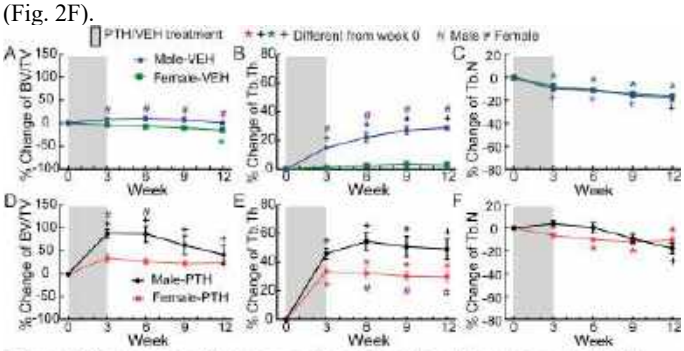

Figure 2. Comparisons between male and female rats in response to (A-C) VEH and (D-F) PTH treatements.

Comparisons between OVX and ORX rats:

There was a significant decline in BV/TV in OVX rats while no change in BV/TV was found in ORX rats (Fig. 3A). Intriguingly, trabecular thickening occurred in both ORX and OVX rats, with a greater extent (58% *vs.* 32%) of thickening in ORX *vs.* OVX rats. (Fig. 3B). Moreover, Tb.N decreased in both groups, but the rate of decrease was greater in OVX *vs.* ORX rats. PTH treatments led to improvements in BV/TV (104% *vs.* 31%) and Tb.Th (55% *vs.* 39%) in both groups, with a greater percent increase in ORX *vs.* OVX rats. Upon treatment discontinuation, BV/TV and Tb.Th continued to increase during the 1-week EAP in both groups. After the EAP, BV/TV started to decline and Tb.Th and Tb.N both reached a plateau in ORX rats (Fig. 3D-E). In contrast, BV/TV, Tb.Th, and Tb.N declined rapidly following the 1-week EAP (Fig. 3D-F).

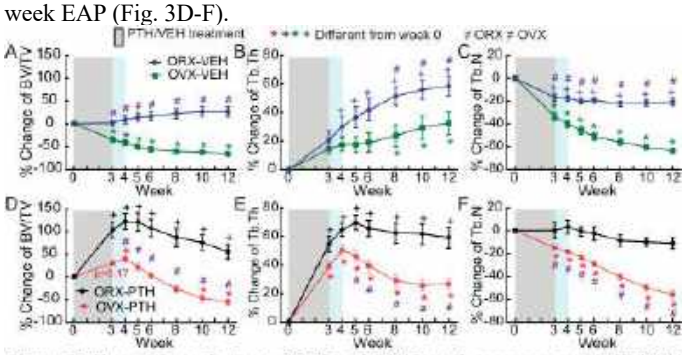

Figure 3. Comparisons between ORX and OVX rats in response to (A-C) VEH and (D-F) PTH treatements.

DISCUSSION

Understanding skeletal responses to the discontinuation of anabolic treatment is crucial to optimize osteoporosis treatment regimens. Significant bone loss after discontinuation of PTH treatment has been reported for postmenopausal women [6-8]. In contrast, there is limited yet conflicting clinical data on premenopausal women [9, 10] and limited data on young men. Similarly, although data are available for estrogen-deficient animals [1, 11], limited data are available regarding the PTH withdrawal effect in intact male or female animals.

Our current study suggested that skeletal responses to the discontinuation of PTH are sex dependent. PTH treatment led to increased bone mass by trabecular thickening in both intact males and females, with greater efficacy in males. However, upon withdrawal from PTH, a reduced number of trabeculae led to a decreased bone mass in male rats, in contrast to female rats, where no adverse effect was found. When comparing ORX and OVX rats that received VEH treatments, surprisingly, no significant bone loss was found in ORX rats, while in contrast, there was substantial bone loss in OVX rats. Our results indicated that trabecular thickening may be an adaptive mechanism to protect excessive bone loss from OVX/ORX conditions, with a greater thickening effect in ORX rats. Similar to intact rats, PTH treatment had greater efficacy in ORX *vs.* OVX rats. However, both ORX and OVX rats showed a significant withdrawal effect in response to PTH discontinuation.

Overall, our current work exhibited a sexual dimorphism in the skeletal responses to PTH treatment and discontinuation in rats. Our results indicated that intact male rats, ORX male rats, and OVX female rats all had significant withdrawal effects in response to PTH discontinuation. In contrast, no adverse effect was observed in intact female rats, which sustained treatment benefit even after 9 weeks of discontinuation. Given that OVX rats, intact male rats, and ORX rats all had substantially lower levels of estradiol than intact female rats, we suspect that skeletal responses to PTH discontinuation may be estradiol level-dependent, which will be a focus of our future studies.

INTRODUCTION

Osteoporosis is a debilitating disease that results in excessive bone loss that can lead to fragility fractures, which can increase mortality, especially in the spine, pelvic, and hip. This disease affects over 200 million patients worldwide and is set to increase further due to the increased life expectancy of the population.[1] Current osteoporosis treatments target osteoclast or osteoblast activity, specifically and very few can simultaneously target both cell types. Treatments that target osteoclasts result in an impairment of osteoblast recruitment, which leads to bone quality reduction and slight improvement in fracture risk.[2] In addition, targeting osteoblast activity has a limited effect over time, which hinders the bone mineral density improvement. Therefore, there is a clear need to develop novel dual-acting osteoporosis treatments.

Nanomaterials, especially nanoparticles that are less than 100 nm, have been attractive in bone and cartilage tissue engineering due to their ability to regulate cell differentiation, maintain tissue stability and promote tissue regeneration. Of the various nanomaterials, gold (Au) and superparamagnetic iron oxide (SPIO) nanoparticles (NPs) have gained significant attention. Au NPs allow for outstanding biocompatibility, high stability and tunable surface function. The ease of surface functionalization makes AuNPs more widely used due to the ability to modify drugs, proteins, peptides and DNA through thiol-Au linkage. SPIO-NPs are easy to synthesize and have good chemical stability, magnetic properties, and biocompatibility, making their use the most promising magnetic nanomaterial in clinical practice.[3] Furthermore, combining the properties of both Au and SPIO by creating Au-SPIO core-shell NPs, can protect the SPIO core and simultaneously enhance both the plasmonic and magnetic properties of Au and SPIO.

Bone is a highly mechanosensitive tissue that requires mechanical stimulation to maintain homeostasis. Localized targeting of mechanosensitive ion channels is a novel approach to enhance the cellular activity of bone cells. Piezo1 (P1), a newly discovered mechanosensitive ion channel, proves to play a critical role in responding to mechanical signals and bone formation. P1 deficiency in osteoblasts leads to loss of bone mass and fractures with increased bone resorption while P1 deficiency in osteoclasts has no effect on bone mass and bone resorption.[4] Interestingly, expression of P1 was significantly upregulated upon exposure to static magnetic field (SMF) in osteoblast cells on SPIO NP doped nanocomposites and only had small changes in expression with no SMF.[5] Our previous research has shown that dynamic magnetic fields (DMF) outperform SMF in enhancing cellular activity and differentiation when combined with SPIO-Au NPs.[6] Therefore, we hypothesized that DMF stimulation of P1 antibody functionalized SPIO-Au NPs will increase activity of P1 and calcium (Ca^{2+}) influx in osteoblasts, which will enhance differentiation and osteogenesis. Furthermore, since Au NPs and magnetic fields mitigate osteoclastogenesis,[7,8] separately, we hypothesized that DMF stimulation of P1-SPIO-Au NPs will also reduce osteoclast formation and function to further mitigate bone loss.

METHODS

The SPIO-Au NPs (20 nm diameter) were synthesized according to our previous work using the seed growth method.[6] P1 antibody was then functionalized to the Au surface using carbodiimide cross linker chemistry. The hydrodynamic diameter and zeta potential of the SPIO-Au NPs were measured after each conjugation step to confirm attachment.

In order to visualize the successful targeting of the P1 ion channel, Alexa Fluor 674 conjugated P1 antibodies were functionalized to SPIO-Au NPs. MC3T3-E1 osteoblast precursor cells were fixed, permeabilized, and stained with either P1-SPIO-Au NPs (20 μg/ml) or P1 antibodies alone. The cells were counterstained with DAPI and visualized using confocal microscopy.

DMF was created by rotating a Halbach array of magnets (0.5T) around a 35-mm petri dish using a DC motor as shown in our previous work.[6] Four groups were evaluated for Ca^{2+} influx: (1) Control, (2)

Control+P1-SPIO-Au NPs, (3) 0.5Hz DMF, (4) 0.5Hz DMF+P1-SPIO-Au NPs. MC3T3-E1 cells were subjected to 30 min of DMF stimulation and Ca^{2+} influx was measured using Fluo-4 3 min following the treatment via confocal microscopy. The baseline fluorescence was determined by averaging the first 10s after stimulation (F_0) and this value was used to normalize the fluorescence for each cell over time ($\Delta F/F_0$). The total fluorescence was determined through area under curve (AUC) analysis using the trapezoidal method.

Pre-osteoclast RAW 264.7 cells were differentiated using receptor activator of nuclear factor κ-β ligand (RANKL) and subjected to the same groups as the Ca^{2+} imaging described previously. DMF treatment was given for 30 min/day for 5 days and then cells were stained for tartrate-resistant acid phosphatase (TRAP) activity. The amount of osteoclasts formed was determined by counting the number of TRAP-positive cells containing ≥3 nuclei (MNCs).

All results were analyzed based on at least 3 independent experiments and differences between groups were compared using one-way ANOVA. Statistical significance was noted for $p<0.05$.

RESULTS

The hydrodynamic diameter and zeta potential of the SPIO-Au NPs were 54.7 ± 0.4 nm and -55.8 ± 0.5 mV, respectively. Attachment of SH-PEG-COOH to the surface increased the hydrodynamic diameter to 68.2 ± 1.8 nm and decreased the zeta potential to -69.15 ± 1.8 mV. The addition of PEG increased the size of the NPs and the addition of COOH created a highly negatively charged surface. After the addition of P1 antibody, the hydrodynamic diameter further increased to 114.7 ± 2.0 nm and the zeta potential increased to -47.9 ± 1.5 mV, indicating the successful conjugation of P1 to SPIO-Au NPs.

The immunofluorescence staining of MC3T3-E1 cells shows that P1 is expressed on the membrane (Fig. 1(a)) and that fluorescently conjugated P1-SPIO-Au NPs were located in the same areas as the antibodies alone (Fig. 1(b)). This demonstrates that P1-SPIO-Au NPs can effectively target P1 in osteoblast cells.

To demonstrate whether DMF can enhance the opening of P1 channels using P1-SPIO-Au NPs, the Ca^{2+} signal in the cell body was visualized using confocal microscopy. Results showed that calcium fluorescence increased 3 min following 30 min of DMF stimulation, but the combination with P1-SPIO-Au NPs resulted in a sustained effect (Fig. 1(c)). Incubation with P1-SPIO-Au NPs alone had no effect on Ca^{2+} fluorescence, while control cells had a decrease in Ca^{2+} fluorescence (Fig. 1(c)). Further quantification using AUC analysis revealed that DMF stimulated P1-SPIO-Au NPs significantly increased Ca^{2+} influx compared to DMF and P1-SPIO-Au NPs alone, and control ($p<0.05$, $p<0.01$, and $p<0.001$, respectively). DMF and P1-SPIO-Au NPs also had significantly greater Ca^{2+} influx compared to control ($p<0.01$), while DMF had a slight more increase in Ca^{2+} influx compared to P1-SPIO-Au NP, but was not significantly different.

To determine the effect of DMF stimulation on osteoclast activity, the amount of osteoclasts, TRAP+ MNCs, were counted. The results showed P1-SPIO-Au NPs, DMF, and DMF + P1-SPIO-Au NPs significantly reduced the formation of osteoclasts compared to the control (Fig. 1(e)) ($p<0.0001$). DMF + P1-SPIO-Au NPs resulted in the greatest inhibition of osteoclast formation, but this reduction was not significant compared to DMF alone.

DISCUSSION

In this work, we demonstrated the ability to magnetically activate P1 functionalized SPIO-Au NPs to enhance the mechanosensitive nature of osteoblasts. Changes in Ca^{2+} intracellular concentration are key secondary messengers in signaling pathways that regulate gene transcription, mRNA translation, and post-translation protein modifications. Here, we show that DMF stimulation of P1-SPIO-Au NPs greatly increases the Ca^{2+} influx in osteoblast cells, which may further regulate proliferation and differentiation. Our previous study investigating DMF stimulated SPIO-Au NPs on neuronal cells found that increased Ca^{2+} influx resulted in enhanced neuronal gene expression, which is in accordance with these results.[6] In addition, magnetic actuation of P1-graphene oxide NPs has been shown to greatly enhance osteogenic gene expression.[9] Further evaluation on osteogenic activity is needed to confirm the potential of DMF stimulated P1-SPIO-Au NPs to increase bone formation, which is ongoing.

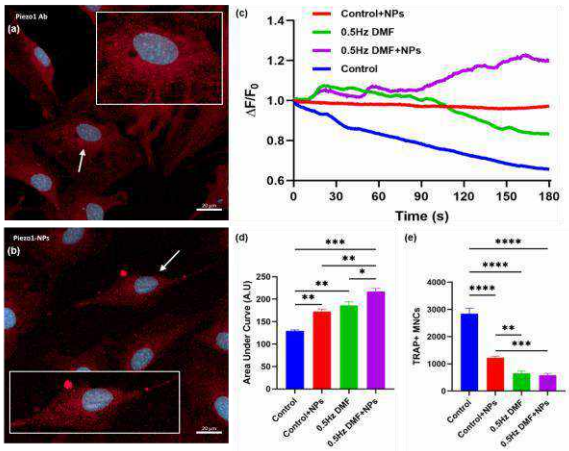

Figure 1: Representative MC3T3-E1 P1 immunofluorescence images after incubation with (a) P1 antibody or (b) P1-SPIO-Au NPs (Red: Piezo1, Blue: Nucleus, Arrow: Zoomed insert, Scale bar: 20 µm). DMF stimulation of P1-SPIO-Au NPs results in an increase in average change in intracellular Ca^{2+} fluorescence (c), and an increase in total intracellular Ca^{2+} fluorescence (d) in osteoblasts, while inhibiting osteoclast formation (e). *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001

Interestingly, we showed that DMF stimulation of P1-SPIO-Au NPs resulted in reduced osteoclast formation. Au NPs have been shown to inhibit osteoclast formation by attenuating reactive oxygen species production, which leads to suppression of osteoclast fusion.[7] Furthermore, SMF attenuates the nuclear factor-κβ pathway in osteoclasts,[8] which may explain the combined effect seen in our results.

In summary, this study demonstrated the potential for a novel non-invasive bone regeneration approach using DMF stimulation integrated with P1-SPIO-Au NPs by simultaneously activating osteoblasts and inhibiting osteoclasts, which may pave the way for future osteoporosis treatments.

INTRODUCTION

Podocytes are highly specialized, terminally differentiated epithelial cells with an arborized morphology that wrap around the glomerular endothelial capillaries and interdigitate with each other to serve as the final component of the glomerular filtration barrier. In proteinuric kidney diseases, such as hypertensive and diabetic nephropathy, podocytes undergo pathologic cytoskeletal rearrangement called foot process effacement (FPE) resulting in a simplification of their morphology and altered biomechanics[1, 2]. Although alterations to the podocyte cytoskeleton and biophysics are a key driver of disease progression, a full mechanistic model driving this phenomenon remains elusive. Here we sought to gain insight into pathways underpinning foot process effacement in podocytes by integrating results from an *in vivo* model of FPE with *in vitro* drug screening. Sprague-Dawley rats injected with puromycin aminonucleoside (PAN), a nephrotoxin, induces temporary and reversible massive proteinuria and FPE in rats [3]. Unbiased proteomics from isolated glomeruli of the PAN-treated rats showed an altered kinome expression that returned to baseline upon resolution of proteinuria. To probe the relative contributions of different kinases on podocyte biomechanics, we performed high content image analysis on iPSC-derived human podocytes treated with various tyrosine kinase inhibitors (TKIs). Although TKIs are clinically used for specific inhibition of one or several kinases, we leveraged their entire inhibition profile obtained from KinomeScans [4, 5] to computationally resolve individual kinase contributions to cytoskeletal and focal adhesion phenotype (Fig. 1). Finally, we identified the Hippo pathway as a key determinant of podocyte biomechanics.

METHODS

6-week-old male Sprague-Dawley rats were injected with 100mg/kg puromycin aminonucleoside (Sigma Aldrich) or phosphate buffered saline (PBS) as control. Rats were euthanized according to approved IACUC protocols, and the kidneys harvested for glomerular isolation using serial sieving at post-injection days 7, 14, 21, and 28. Quantitative isobaric TMT proteomics was then performed on the isolated glomeruli.

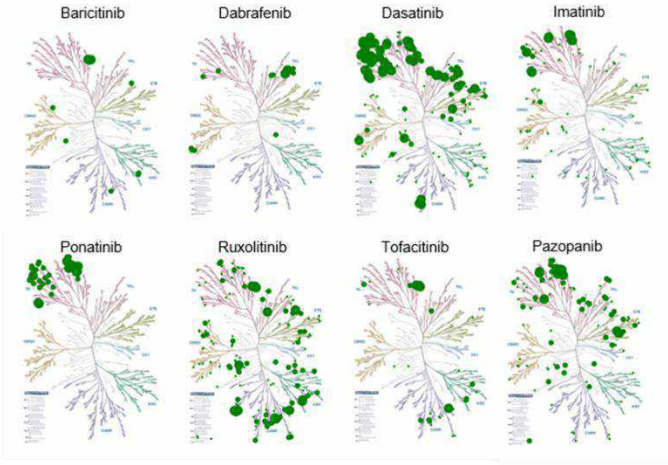

Figure 1: Inhibitory profile of select TKIs used in this study.

For high content imaging, iPSC-derived podocytes were plated onto a 96 well plate (Corning Incorporated) coated with Matrigel. Wells were treated with 12 different TKIs at a concentration of 2 µM for 24 hours and then fixed and stained for nuclei, paxillin, synaptopodin, and YAP. Imaging was performed on an InCell Analyzer 2200 (GE Healthcare) using a 40x air objective. To generate cell and nuclear masks, segmentation with Cellpose was carried out on combined synaptopodin/YAP and the nuclear channel respectively. The raw images and labelled masks were imported into Matlab and run through

an in-house script to generate intensity and morphological based features.

The high content image analysis results and publicly available TKI inhibition profiles from LINCS [5] were run through an in-house SVD-based feature analysis script to calculate individual kinase contributions on cell, focal adhesion, and nuclear morphology and features. Enrichment analysis of top ranking kinases was performed using Enrichr [6] and interconnectivity using Genes2Networks [7].

RESULTS

Male Sprague-Dawley rats (n=3, each group) were injected with a single dose of 100 mg/kg PAN or PBS and monitored for 4 weeks. Rats treated with PAN developed significant albuminuria that peaked at day 7 and achieved near complete resolution by day 28 (Fig. 2A). The rats were euthanized on days 7, 14, 21, and 28 and the kidneys harvested for glomerular isolation. Unbiased isobaric TMT proteomics of the isolated glomeruli revealed significant alterations in kinase expression, correlating with the degree of albuminuria (Fig. 2B).

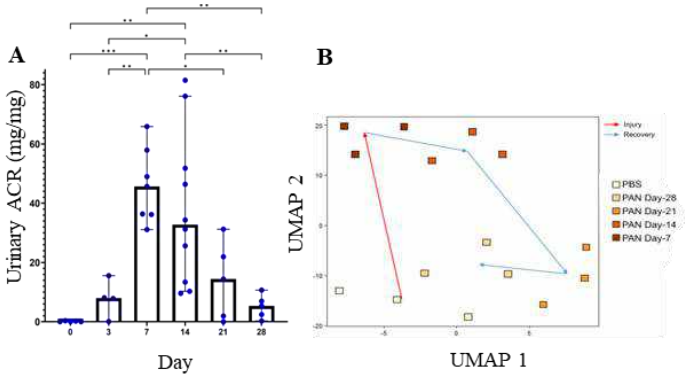

Figure 2: Kidney dysfunction in PAN rats corresponds with altered kinome expression. (A) Urine Albumin-Creatinine ratio over 28 days. (B) UMAP of kinome obtained from proteomics.

We next hypothesized that altered kinase activity is sufficient to drive podocyte cytoskeletal rearrangement and sought to quantify the relative contributions of individual kinases in maintaining podocyte cytoskeletal integrity. To this end, we performed high content image analysis of iPSC-derived human podocytes treated with 12 clinically used TKIs to assess cytoskeletal and focal adhesion organization, obtaining a unique feature signature for each TKI (Fig. 3).

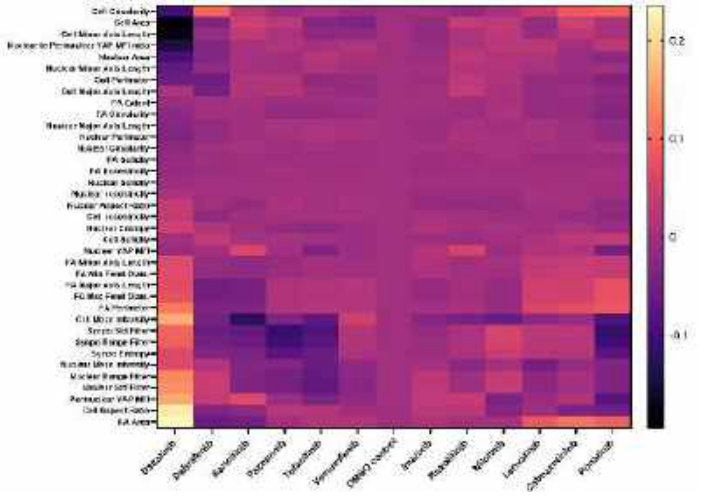

Figure 3: High content image analysis of cytoskeletal and focal adhesion related features of TKI-treated podocytes.

By using the kinome inhibitory profile of each drug (obtained from LINCS), we performed feature analysis to quantify the impact of inhibiting each kinase on each assessed metric. From here, a list of kinases ranked by fold change in the PAN rats at day 7 and a list kinases ranked by cumulative impact on all high content imaging metrics was consolidated to generate a final ranked list of kinases. The top 20 consolidated kinases showed high interconnectivity and overrepresentation analysis identified the Hippo pathway as significantly enriched (adjusted p-value 2.3e-8) (Fig. 4).

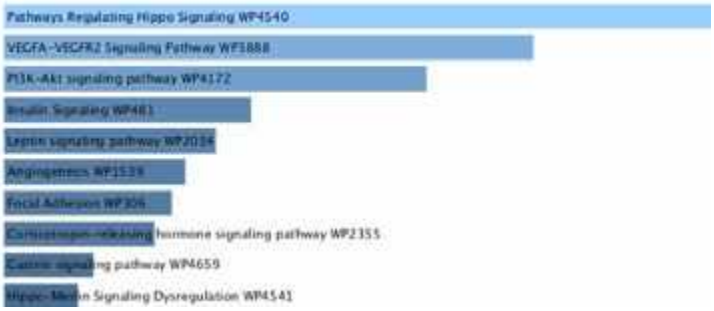

Figure 4: Overrepresentation analysis of the top 20 consolidated kinases on WikiPathways.

DISCUSSION

In this study we integrated proteomics from an *in vivo* kidney disease model to an *in vitro* drug screening assay to identify key kinases that regulate and maintain the podocyte cytoskeleton. The top candidate kinases identify enrich for the Hippo pathway, a signaling pathway whose dysfunction is both sufficient to cause glomerular disease and observed in human kidney disease [8, 9].

In addition to the identification of kinases regulating podocyte biomechanics, this study also provides a means of screening TKIs for potential nephrotoxicity. This framework of using TKIs to deconvolve relative kinase contributions can be applied to virtually cells of any type for any high content metric.

INTRODUCTION

Bladder voiding dysfunction is common among aging men and is often associated with benign prostatic hyperplasia (BPH) and lower urinary tract symptoms (LUTS) [1]. Over 50% of men over 60 years of age suffer from BPH, and 15%-30% of these men have LUTS [2]. Multichannel urodynamic studies are the most common diagnostic method to assess BPH/LUTS [3,4]. These procedures are highly invasive, requiring urethral and rectal catheterization, and provide insufficient information on biomechanical properties, bladder anatomy, and detrusor muscle function [5,6]. Our research group recently published the feasibility of using 3D dynamic MRI to calculate various urodynamic nomograms non-invasively [7]. However, manually segmenting the bladder is a time-consuming step and is a bottleneck for increasing the study cohort. The objective of this study is to implement a deep learning approach that automatically segments the bladder from 3D dynamic images of voiding. This will significantly accelerate our MRI urodynamic workflow.

METHODS

Male subjects were recruited following an IRB-approved HIPAA-compliant protocol. Subjects underwent pelvic MRI on a clinical 3T scanner (Premier, GE Healthcare, Waukesha, WI, USA). The pulse sequence used was either 3D Differential Subsampling with Cartesian Ordering (DISCO) Flex where patients received 1/3 of a single weight-based (0.1 mmol/kg) of gadolinium-based contrast which was slowly hand injected intravenously 15 minutes prior to the start of the imaging session, or balanced steady state free precession (bSSFP) that did not require contrast. Subjects that received contrast were asked to walk around to ensure contrast mixing and homogenous enhancement of the urine in the bladder. Immediately before the scan, the subjects were equipped with a condom catheter to allow micturition and urine collection while scanning. Subjects were scanned in supine position and volumetric dynamic images of the bladder and urethra were acquired throughout the voiding event. The spatial resolution was 1 mm × 1 mm isotropic in the sagittal plane, with a slice thickness of 2 mm.

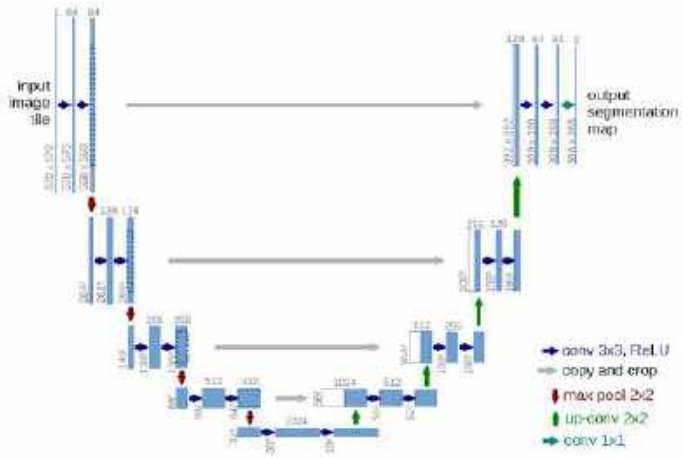

Figure 1: U-Net architecture from Ronneberger et al. [8]

The 3D image datasets were loaded into semiautomatic segmentation software Mimics (Materialise NV, Leuven, Belgium). The bladder was manually segmented such that there were separate 3D masks at each time point of the voiding event. These manually segmented masks served as the ground truth. The U-Net [8] convolutional neural network (CNN) was used to automatically detect the bladder geometry and generate binary masks. The input image undergoes a series of convolutions, rectified linear units, and max pooling operations. The number of channels increase in the contracting path, then decrease in the expansive path. There are 23 convolutional layers in the U-Net architecture. Figure 1 shows the details of the U-Net

architecture that we implemented. We used augmentation (rotations and flips) to quadruple the dataset size. The CNN was implemented using PyTorch (The Linux Foundation, San Francisco, CA, USA) inside a Docker container, and the source code is publicly available (https://github.com/lshahid/Pytorch-UNet). All training and testing were performed on an Intel Core i7-9800X processor and Nvidia Titan RTX GPU on a desktop workstation. Dice score was used to compare manual and automated segmentations.

RESULTS

Five subjects underwent pelvic MR scans and 3D dynamic images were successfully acquired while they voided during scanning. Table 1 provides the subject and scan information. Figure 2 visualizes the bladder for all five subjects. Subject 5's images exhibited significant artifact due to eddy currents that led to poor image quality. 8702 2D sagittal images (256 × 256 pixels) from 3D dynamic MRI were used, with 10% used for validation. After augmentation, the total number of images was 34808. The total training time was 14 hours. The final Dice score was 0.99. Time to manually segment one 3D bladder at one time point was 20 minutes, compared to < 3 minutes using the automated approach.

Table 1: Subject and scan information

Subject	Age	BPH/LUTS?	Pulse Sequence	Temporal Resolution	Void Time
1	29	No	3D DISCO Flex	3.8	111
2	55	No	3D DISCO Flex	4.7	156
3	56	Yes	3D DISCO Flex	4.8	77
4	70	Yes	3D DISCO Flex	5.0	64
5	35	No	bSSFP	1.7	53

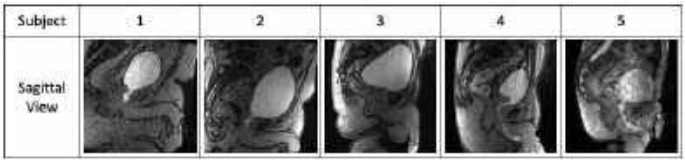

Figure 2: MRI of bladder in the sagittal plane in the middle of voiding

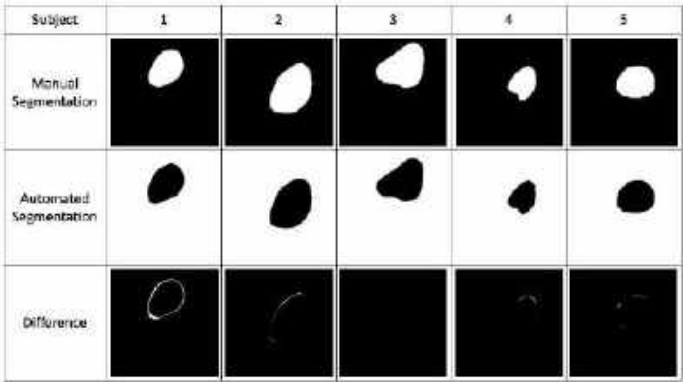

Figure 3: Manual, automated segmentation, and their difference, at the middle of voiding

DISCUSSION

Using 3D dynamic MRI of only five patients, we implemented a deep learning-based automated segmentation of the bladder during voiding. The main findings of the study are that the CNN segments a 3D bladder at one time point in < 3 minutes, produces excellent segmentation, and performs well over a range of subject ages, phenotypes, and two different sequences. Figure 3 shows that the difference in segmentations is about 1-3 pixel wide around the bladder wall, which is in the range of spatial resolution. We chose the U-Net architecture due to its popularity in the image segmentation field. We also prioritized portability of the CNN by using a container which will allow easier scaling to high-performance computing clusters and sharing with the scientific community. The segmented masks can be used to calculate urodynamic metrics including flow rate, post-void residual volume, and bladder neck angle. Future studies would investigate spatio-temporal interconnectivity of the images, increase the number of subjects, explore the effects of interobserver variability and scan parameters, and compare the urodynamic metrics from manual segmentation with automated. We previously introduced MRI urodynamics using 3D dynamic imaging to enhance information from UDS while being non-invasive. Segmentation is the most tedious step in our workflow, and this automated process significantly reduces operator time. This acceleration in the workflow paves the path for MRI urodynamics to increase cohort size including women, diabetes patients, and patients with overactive bladder.

A 'DINNER PARTY' THEMED APPROACH TO CONSTRUCTING EQUITABLE AND EXCITING LITERATURE REVIEWS

D.P. Pearce (1) and C.R. Henak (1,2)

(1) Department of Biomedical Engineering, UW-Madison, Madison, WI, USA
(2) Department of Mechanical Engineering, UW-Madison, Madison, WI, USA

INTRODUCTION

Citations in peer-reviewed articles help solidify the influence and value of the cited studies, but have traditionally contained biases against women and people of color (PoC).[1,2] This results in a lack of citations and recognition for these individuals, and may influence decisions regarding hiring and funding applications. Past work has shown black and Latinx men to be notoriously underrepresented in health and biomedical research, while black, Latinx, and white women were all underrepresented in fields such as engineering and technology, mathematics, and physics.[3] Although citational patterns vary from field to field, many of these biases are still present today despite a growing increase in awareness.[3]

Techniques to visualize and organize citations for a manuscript, such as the *dinner party* strategy,[4] may help promote more equitable citational patterns. The dinner party strategy, first proposed by Kamler and Thomson,[4] transforms the lead author's role to that of a host of a generous and elaborate dinner party, in which each cited author is invited and present at the party. The lead author, or host, then arranges guests based on shared interests, experimental designs, or findings, grouping cited studies in a way that fosters clear connections between studies and promotes a valuable discussion focused on synthesis of ideas and proposed 'next steps' for the field.[4] This technique is employed in literature reviews to promote higher-quality, interwoven narratives, but may also be used as a resource to help reduce student's writing anxiety.[5,6] Additionally, the dinner party technique could be used to promote more equitable citational patterns. By including pictures of cited authors, the lead author is given information regarding the demographics of their bibliography. Should they find their citational patterns to be exclusive, they may go back and add new studies to promote more equitable citational patterns.

Here, we studied graduate student awareness of citational justice in a Tissue Mechanics course at UW-Madison. We hypothesized that students would be generally unaware of citational justice prior to the new instructional material, and that the requirements of this assignment would result in more equitable citational patterns compared to the student's initial submissions. Through this work, we hope to share strategies to aid students learning to write literature reviews and to highlight the importance of being intentionally inclusive when conducting literature searches.

METHODS

Survey Design and Distribution. A survey (MRR IRB 2023-1411) was developed to assess student's awareness of citational justice prior to the delivery of our new lecture material and to help quantify the effectiveness of this material. The survey was distributed digitally to graduate students in BME/ME 615: Tissue Mechanics, a split undergraduate/graduate technical elective course offered at UW-Madison. A total of 8 graduate students were enrolled in the course. The survey, discussed in more detail in the subsequent section, was sent out to students one week prior to the delivery of content material, then one week after the submission of the first draft of their literature review assignment. Responses to the survey, which offered participants the opportunity to use a unique study identifier to log their before-and-after answers, were not accessed until the end of the Fall 2023 semester according to IRB guidelines.

Quantifying Impact of Material and Student Awareness. Our survey first explained the objectives of our study, the accompanying instructional material, and offered participants the chance to grant waived consent. Participants were asked to create a unique identifier using the following scheme: (Birth Month XX) + (First two letters of mother's name) + (First two numbers from current mailing address), taking the form of 12RE72, for example. We then asked participants to select their sex assigned at birth, then the gender with which they identified the most.[7] Next, we asked students a series of questions about their ability to define and explain the concept of citational justice, their perception of its significance and its impact, and strategies for

improving the equitability of citational patterns. For all questions regarding citational justice, participants were presented with multiple-choice answers ranging from Strongly Disagree (-10) to Neither Agree nor Disagree (0) to Strongly Agree (10). These questions were formatted similar to questions presented during end-of-class surveys for ABET accreditation processes.[8,9]

Instructional Material and Delivery. A self-directed literature review assignment is the course project for graduate students in BME/ME 615: Tissue Mechanics. A portion of the assignment is the annotated bibliographies of the studies they plan to use for their literature review. We introduced the dinner party technique and citational justice with a 23-minute asynchronous lecture (available upon request). For their annotated bibliographies, students were required to find pictures of the first and last authors for their cited studies, submit a dinner party for their bibliography, discuss the equitability of their citational patterns, then address any gaps in their citational patterns they may have observed. All assignments were submitted digitally via Canvas.

Quantifying Equitability of Citational Patterns. An example assignment was given to students (and elaborated on during the asynchronous lecture) to demonstrate the dinner party technique. In this example assignment, the most glaring inequities were a lack of women and PoC authors in both first and last author positions. We reported the mean ± st. dev. years for the example assignment, as well as the Man:Woman (M:W) and White:PoC (W:PoC) splits, resulting in similar analyses by many students. For this study, we manually checked the mean year, M:W, and W:PoC splits reported by our students by reviewing headshots, lab webpages, and/or LinkedIn profiles for the first and last authors of each study, and completed this analysis for reviews with different approaches. It is worth noting here that these metrics both reduce identity to a binary state, an inaccurate simplification, but reflects limitations of quantitative tools that may be used in the future to more systematically perform this kind of analysis.[10,11]

Statistical Analysis. Before-and-after survey results, as well as M:W and W:PoC splits before and after our required assignment, were compared statistically using a Wilcoxon signed-rank test. Analyses were performed using GraphPad Prism 10 (Dotmatics; Boston, MA).

RESULTS

M:W and W:PoC splits trended towards a more equitable distribution following the dinner party assignment (Figure 1). For each split, a value of 1 was considered desirable. It is worth nothing that a split of 1 may not be realistic, especially for the W:PoC metric. Following the dinner party assignment, each of these splits displayed a trend towards 1, suggesting improvements in the equitability of the student's citational patterns. Wilcoxon signed-rank tests revealed statistically significant improvements for only the W:PoC split for the first author position, which is likely due to a small sample size and the limited additions (2 – 3 studies) required of students.

We observed positive increases for each survey question, particularly regarding the ability of students to identify strategies to improve the equitability of their citations (Figure 2). These observations were limited by a small number of survey responses and only one true before-after completion (indicated with a *square marker*), so no statistical analysis was included.

DISCUSSION

Despite initial unawareness regarding citational justice, we found that our dinner party assignment and the accompanying lecture promoted more equitable citational patterns and offered students techniques they could use to improve the fairness of their work.

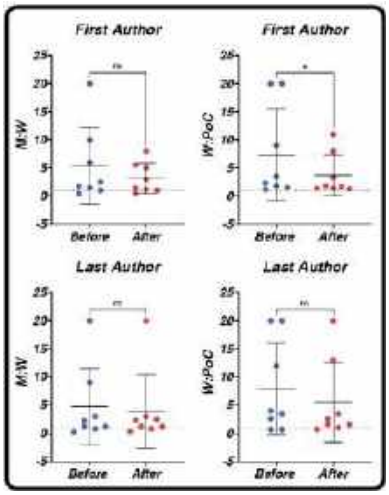

Figure 1. M:W and W:PoC splits for the first and last author positions *before* and *after* the dinner party assignment (*$p < 0.05$).

Citations establish the influence and impact of a study, but are given to women and authors of color at lower rates than men and white authors.[1,2] We found that requiring students to be intentionally inclusive with their references did, in fact, promote more equitable citational patterns. Although we received a limited number of survey responses, we saw encouraging trends in student awareness of citational justice. This was most evident in the ability of students to identify and implement strategies to improve the equitability of their citational patterns. This study was limited by the small sample size and lack of before-after survey responses, which we hope to improve in future iterations of the class. We also hope to compare this semester's citational patterns to those from past semesters to determine the effectiveness of the intervention for promoting more equitable bibliographies. We anticipate this work has improved students' awareness of citational justice, and hope future efforts will be made to actively and intentionally improve the equitability of bibliographies published in peer-reviewed journals.

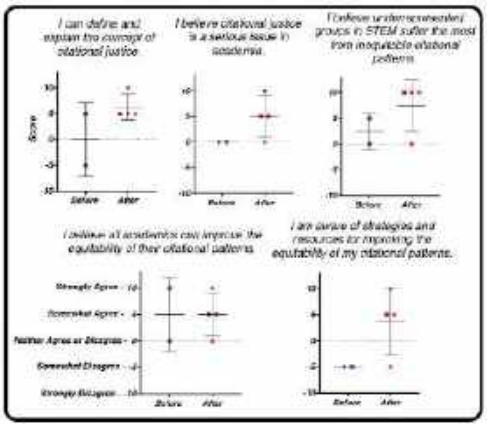

Figure 2. Student opinions of citational justice *before* and *after* delivery of new instructional material.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Alejandro Roldán-Alzate for his help with participant recruitment; Dr. Rouzbeh Amini and Frederick Sebastian for their encouragement and guidance while designing this study; the Delta Program in Research, Teaching, and Learning; and the graduate students who completed our surveys and put together excellent reviews.

INTRODUCTION

Glaucoma is the leading cause of irreversible vision loss worldwide, and elevated intraocular pressure (IOP) is the only modifiable risk factor [1-3]. Elevated IOP results from increased resistance to aqueous humor (AH) outflow in the juxtacanalicular region of the conventional outflow pathway where the trabecular meshwork (TM) and Schlemm's canal (SC) inner wall cells interact [4].

The SC inner wall experiences a basal-to-apical pressure gradient which deforms SC cells to create giant vacuoles and pores that facilitate fluid drainage from the eye [5]. This deformation may also trigger mechanosensitive ion channels, such as transient receptor potential vanilloid 4 (TRPV4). These cationic channels open in response to physical deformation (i.e., cell membrane strain) to allow calcium influx and thus initiate downstream signaling [6]. However, the precise role of TRPV4 in SC cells remains unclear.

The substrate of the SC inner wall, known as the trabecular meshwork (TM), is stiffer in glaucoma [7-9]. Here we investigate how TRPV4 activity and substrate (matrix) stiffness modulate SC cell mechanobiology, with a focus on actin cytoskeletal structure, cell stiffness, and pore formation.

METHODS

Primary SC cells were isolated from healthy and glaucomatous human eyes, and characterized using established protocols [10]. Five normal (nSC) and three glaucomatous (gSC) SC cell strains were used in this study, with donor demographics as follows: nSC75: Male/10-years-old; nSC74: M/0.67; nSC82: na/56; nSC87: M/62; nSC89: M/68; gSC57: M/78; gSC64: M/78; gSC90: F/71. Soft substrates were fabricated by UV crosslinking gelatin methacryloyl (GelMA; 6% + 0.075% (w/v) LAP photoinitiator), whereas stiff substrates incorporated methacrylate-conjugated hyaluronic acid (MA-HA; 0.25%). Substrates were coated with fibronectin (5 μg/cm^2) to mimic the native basal lamina of SC inner wall cells. SC cells were plated on substrates and exposed to the TRPV4 inhibitor HC067047 (10 μM) or activator GSK1016790A (100 nM) for 2 days. TRPV4 transcript levels were assessed by qRT-PCR. F-actin was visualized by phalloidin staining. To assess intracellular Ca^{2+} levels, the SC cells were loaded with Fluo-4 and imaged using a Zeiss LSM 700 confocal microscope. Substrate and cell stiffnesses were measured by atomic force microscopy (AFM) using a 10 μm spherical tip.

Pore formation by SC cells was assessed by a well-developed *in vitro* assay for inducing pores that subjects SC cells to localized cellular stretching [11]. Briefly, carboxyl microspheres (~5 μm dia) were seeded on a biotinylated gelatin substrate, followed by over seeding with SC cells. SC cells were treated +/- ROCK inhibitor (Y27632; 10 μM) for 30 minutes. Subsequently, fluorescently-tagged streptavidin was introduced into the culture medium. The fluorescently-tagged streptavidin traversed the SC cell monolayer at locations where pores or gaps between cells existed, irreversibly adhering to the biotinylated substrate and thereby generating an observable persistent fluorescent signal (**Fig. 1A**). The number of fluorescently-tagged streptavidin spots that associated with microspheres in each well of the plate was quantified. Subsequently, the percentage of pores induced by microspheres was calculated.

RESULTS

The soft and stiff substrates had elastic moduli of 2.36 and 8 kPa, as measured by AFM, similar to the stiffness of the substrate of SC inner wall cells in healthy and glaucomatous eyes, respectively. nSC cells on the stiff substrate exhibited elevated TRPV4 transcript levels (1.31-fold, $p<0.01$), steady-state intracellular Ca^{2+} (1.76-fold, $p<0.001$), and F-actin (2.17-fold, $p<0.0001$) vs. nSC cells on the soft substrate. TRPV4 activation increased F-actin stress fibers in nSC cells grown on the soft substrate (1.85-fold, $p<0.01$) and induced cell stiffening (2.48-fold, $p<0.05$), but not on the stiff substrate. In nSC cells grown on the stiff substrate, TRPV4 inhibition decreased F-actin (0.60-fold, $p<0.0001$)

and cell stiffness ($p<0.05$), but not on the soft substrate. Effects of TRPV4 modulation were damped in gSC cells.

Cellular stretching imparted by microspheres underlying SC cells induced formation of pores (**Fig. 1B**). In normal SC cells, 10.89% of microspheres had an associated pore, which was significantly higher than the frequency observed in glaucomatous cells (7.02%, $p<0.001$; **Fig. 1C**). Importantly, we observed that pore formation in SC cells induced by microspheres correlated strongly with cell stiffness (**Fig. 1D**); softer cells formed more pores and vice versa. Rho-associated kinase (ROCK) inhibitors have been shown to lower IOP, soften SC cells and enhance outflow facility [12]. In our assay, ROCK inhibition of cultured nSC cells for 30 minutes led to a marked increase in pore formation, with noticeable variability between cell strains.

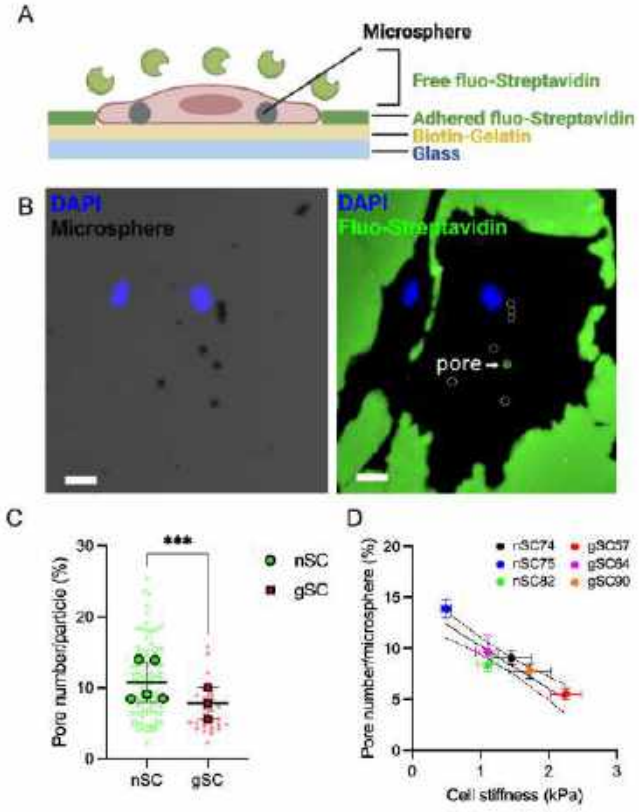

Figure 1. *In vitro* pore induction and detection in SC cells. (A) Schematic showing microspheres for inducing, and fluorescence assay for detecting, pores in SC cells. (B) Fluorescent micrograph showing spots where fluorescently-tagged streptavidin (green) has reacted with biotin substrate under cultured SC cells (at sites of intracellular pores) as well as surrounding regions not covered by cells. White circles outline microspheres. Scale bar: 20 µm. (C) Pore number induced by microspheres in nSC and gSC cell strains (*$p < 0.001$; small symbols = one experimental replicate, large symbols = mean of each cell strain). (D) Correlations (black line) of pore formation rate vs. cell stiffness. Bars = SEM. Light curves = 95% CIs on the linear regression ($p<0.0001$).**

DISCUSSION

SC inner wall cells experience substantial biomechanical stresses and strains, resulting in stretching of the plasma membrane and likely activation of mechanosensitive ion channels (e.g., TRPV4) to induce Ca^{2+} influx. Previous studies have shown that TRPV4 can affect AH outflow facility and IOP [13-16]. However, the detailed mechanisms underlying TRPV4 activity in SC cells under glaucomatous conditions (i.e., increased substrate stiffness) remain to be elucidated. To model this, we used GelMA and HA hydrogels to investigate how TRPV4 integrates matrix mechanosensing to modulate SC cell mechanobiology, including Ca^{2+} signaling. Our data suggest that TRPV4 plays a crucial role in SC cell mechanosensing of substrate stiffness by modulating actin cytoskeletal structure and cell stiffness. This conclusion is supported by the findings that: (i) matrix stiffening upregulated TRPV4 transcript levels, steady-state intracellular Ca^{2+}, and F-actin labeling; (ii) TRPV4 activation in SC cells on the soft substrate increased F-actin and cell stiffness; (iii) TRPV4 inhibition counteracted the effects of matrix stiffening, leading to a decrease in F-actin levels and cell stiffness.

The inner wall of the SC undergoes a basal-to-apical cellular stretch that creates micron-sized pores to regulate AH outflow [5]. To mimic this process, we utilized microspheres to induce a similar basal-to-apical stretch in SC cells, leading to the formation of pores that closely resemble those found naturally. Notably, nSC cells exhibited a higher pore formation rate compared to gSC cells, consistent with previously observed differences in pore formation between normal vs. glaucomatous SC cells, both in native tissues and in an *in vitro* assay inducing pore formation by a membrane stretching device [17, 18].

We observed a strong correlation between the formation of pores induced by microspheres and cell stiffness, with softer cells demonstrating a higher capacity for pore formation. Furthermore, a ROCK inhibitor, a cell-softening agent, increased pore formation, suggesting that SC cell stiffness could be a promising target for IOP reduction. Since we have found a connection between TRPV4 activity and SC cell stiffness, we hypothesize that altering TRPV4 activity may influence SC cell pore formation and thus fluid conductivity via modulating SC cell actin remodeling and cell stiffness.

In conclusion, our findings highlight the importance of TRPV4 in SC cell mechanobiology and suggest that targeting this ion channel could be a promising strategy for the treatment of glaucoma. Future studies are needed to further elucidate the molecular mechanisms underlying TRPV4-mediated cellular responses and to explore the therapeutic potential of TRPV4 in glaucoma treatment.

INTRODUCTION

While the cardiovascular diagnostics is a data-rich area, cardiologists may inadvertently miss important information for predicting, diagnosing and treating coronary artery disease. One of the way this problem can be mitigated is by adopting machine learning-based techniques, which have been employed in different areas of the health care field [1]. Traditionally, doctor's intuition, knowledge, and experience coupled with standard statistical methods have been used for prognosis/prediction of disease risk. However, this practice often leads to unwanted biases, negatively influencing the quality of service provided to patients. With the increasing availability of electronic health data, machine learning has become a more practical approach in the field of disease prediction [2]. Several studies have utilized machine learning algorithms to predict and diagnose diseases such as hepatitis C [1], prostate cancer [3], stroke [4], and diabetes [5]. However, very few studies have applied machine learning techniques to predict % major adverse cardiac events (MACE) such as myocardial infarction, revascularization, and death of patients.

In the field of coronary artery diagnosis, the severity of intermediate epicardial stenosis is determined using the current gold-standard, a pressure-based coronary diagnostic index: fractional flow reverse (FFR, a ratio of distal to proximal pressures across stenosis). It often leads to inaccuracies in the presence of microvascular diseases (MVD). Pressure drop coefficient (CDP), a fundamental fluid dynamics-based combined pressure-flow index, was recently developed to solve this constraint. Specifically, CDP is the ratio of the trans-stenotic pressure drop to the proximal dynamic pressure (1/2 x blood density x APV^2; where APV is average peak velocity). The combined approach of assessing both coronary pressure and flow has been reported as the improved basis to assess coronary physiology [6]. In particular, the CDP was tested *in vitro* [7] as well as *in vivo* in animal studies [8] and was able to delineate between epicardial stenosis and MVD. In addition, CDP has been recognized as possible alternate coronary diagnostic parameters by other researchers [9,10].

The primary *objective* of this study is to use several machine learning algorithms to predict %MACE and survival of patients after five years using FFR and CDP data. The early identification and improved prediction of coronary stenosis prior to the onset of MACE may direct earlier clinical management. The *hypothesis* is that CDP will have a better prognosis of MACE outcome than FFR.

METHODS

Three steps have been employed in this study. First, the description of the datasets, preprocessing, and cleaning of the data by identifying and correcting errors in the dataset, such as missing or inconsistent data, removing duplicates, and handling outliers were conducted. Subsequently, the machine learning algorithms were developed. Lastly, the performance of each algorithm was evaluated, and the best algorithm for the prediction was selected after comparing the performance of each algorithm. The algorithms were developed with Python programming on Google Colab. Figure 1 shows the steps adopted for the study.

Four machine learning algorithms: logistic regression (LGR), support vector machine (SVM), k-nearest neighbors (KNN), and artificial neural networks (ANN) were adopted in this study for training the 5-year MACE outcome data (n = 122). These algorithms were selected based on their proven effectiveness in medical diagnosis. FFR and CDP were used as input, and the outcome was the presence of MACE or survival after five years. The input data was split into 80% training and 20% testing sets. The average accuracy, precision, recall, receiver operating characteristics (ROC), and area under the curve (AUC) for each algorithm was calculated implementing 500 seeding iterations. For the algorithm, this study used solvers 'lbfgs' for Logistic Regression, radial basis kernel function for SVM and n_neighbors being

4 for KNN. Similarly, the activation function 'relu' and hidden layer of 4 for ANN were employed.

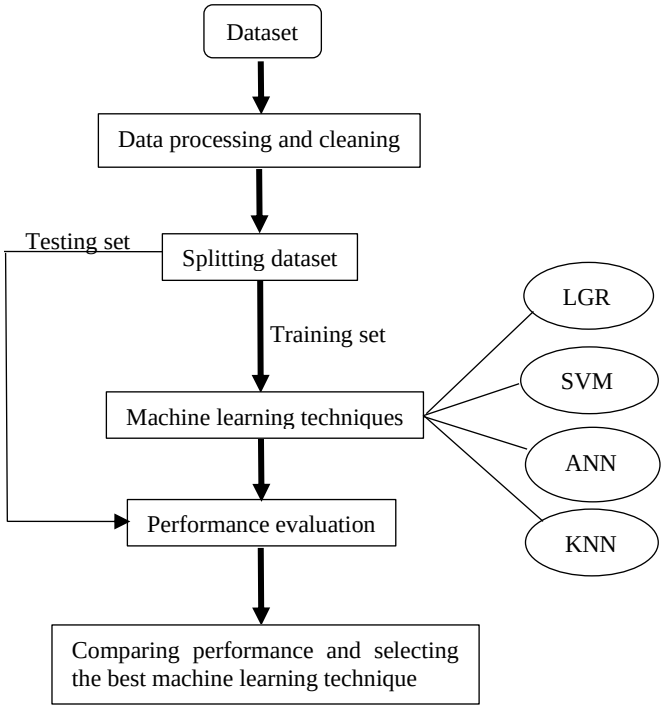

Figure 1: Machine learning steps for prognosis of MACE outcome using FFR and CDP.

RESULTS

Table 1A and 1B below display the output of the algorithms that were used for training the dataset. The SVM had accuracy of 0.50 and precision of 0.51 for FFR whereas accuracy of 0.56 and prediction of 0.57 for CDP. Similarly, the KNN had accuracy of 0.49 and precision of 0.50 for FFR whereas accuracy of 0.55 and prediction of 0.57 for CDP. SVM and KNN provided the best predictions for the two datasets for accuracy and precision. Further, SVM (FFR: recall = 0.65; CDP: recall = 0.62) performed better compared to KNN (FFR: recall = 0.37, CDP: recall = 0.46) for recall value. Importantly, CDP having accuracy = 0.56 and AUC = 0.57 predicts MACE more accurately than FFR having accuracy = 0.50 and AUC = 0.53 for SVM.

DISCUSSION

This study shows that the machine learning-based prognosis of MACE outcome can be better achieved for patients with coronary artery dysfunction using CDP because it incorporates the square of APV in the denominator. This is corroborated by the results of the 5-year outcome (MACE and event-free survival) analysis reported by Banerjee et al [11]. They showed that a clinical decision made on the basis of CDP relative to FFR would reduce MACE and significantly increase event-free survival. The advantages of combining both pressure and flow measurements within a single parameter is well supported by several published studies in the literature.

In particular, results from this study shows that SVM can be an effective tool for medical professionals to predict %MACE and patient survival at five years with the highest accuracy (>50%) and AUC among the test models. This finding is similar to the results of Alizargar et al. [1], where six machine learning algorithms were utilized on NHANES and UCI datasets to predict hepatitis C based on the blood test data of early-stage patients. SVM and XGBoost outperforms other algorithms. SVM has also been reported as the best prediction in some other literatures [12,13] for heart diseases. Nandipati et al. [14] in 2020 reported KNN model as the highest accuracy (51.06 %) in their study using an Egyptian hepatitis C dataset. This present study corroborates this study [14]. One of the strengths of current study is that the data used are for patients whose medical record was followed for 5 years.

It is expected that the accuracy and precision of these algorithms can be improved with larger training datasets of MACE outcomes. This study could serve as a reference for future researchers in the field of machine learning. Furthermore, using current findings patients at risk of MACE can be identified a prior for targeted treatment.

Table 1: Comparative results of the four machine learning algorithms on a) FFR, and b) CDP data.

FFR **A**

	LGR	SVM	ANN	KNN
Accuracy	0.43	**0.50**	0.48	**0.49**
Precision	0.32	**0.51**	0.45	**0.50**
Recall	0.51	**0.65**	0.56	0.37
AUC	0.50	0.53	0.51	0.50

MICROSCALE REMODELING OF ARTERIAL WALL LEADS TO MACROSCOPIC PRESSURE-INDEPENDENT AXIAL FORCE

INTRODUCTION

The aorta, which is the body's largest artery and carries blood flow from the heart, exhibits diverse material properties and dimensions along its length [1]. These variations are influenced by in vivo axial stretch, a crucial factor determining arterial wall behavior and influencing the growth and remodeling processes [2]. A key observation, exemplified by the Pressure-Force experiment [3], is that under healthy conditions, the axial force on the vessel remains remarkably constant despite fluctuating pressure, hinting at a specific optimal in vivo axial stretch. It has been further argued [4] that the flat pressure-axial-force response is energetically advantageous and thus an attractive state for the vessel. Despite its importance, however, there is limited understanding of how an artery reaches the point at which the pressure-axial-force is flat.

This study delves into the microscopic remodeling processes within arterial walls, focusing on how changes in individual fiber dimensions to attain a target fiber stress influence tissue restructuring as a whole. By doing so, this study explores the connection between microscale tissue remodeling and the observed pressure-axial-force behavior. Specifically, we tested the hypothesis that **fiber-level adaptations collectively lead to a consistent axial force response by the tissue in the Pressure-Force experiment at in vivo loading levels**.

METHODS

To investigate this phenomenon, we model the aorta as a thin-walled cylinder, capturing its essential geometric characteristics. Calculations are performed on a single element representing a section of the vessel wall using the Non-affine Fiber Network Solver (NaFNS) plugin for the FEBio software [5]. This approach allows us to employ discrete microstructural fiber networks as a representation of the tissue. The initial network comprises actomyosin (actin), collagen, and elastin fibers, with actin exhibiting an isotropic distribution while elastin and collagen are characterized as transversely isotropic in the axial and circumferential directions. The detailed structure of a representative network element is depicted in (Fig. 1(a)). The properties and governing equations for each fiber type are based on established literature [5-6].

To simulate physiological conditions for remodeling, we apply controlled stretch to the vessel in axial direction and a circumferential stretch representing pressure, while allowing for free expansion in the radial direction. The vessel then undergoes remodeling while maintaining a constant axial stretch and pressure (Fig. 1(b)). Using the NaFNS plugin, we calculate individual fiber stresses. Each fiber in the network then remodels independently based on its specific stress, driven by the core concept of localized tensional homeostasis, under which each fiber seeks to achieve a predefined target stress, ultimately leading to an overall tissue equilibrium state. The remodeling laws and properties in this study are drawn from existing literature [6]. Briefly, elastin does not remodel, but collagen and actin fibers lengthen and thicken if their stress is above the target stress, and they shorten and thin if their stress is below the target stress. The model parameters are the

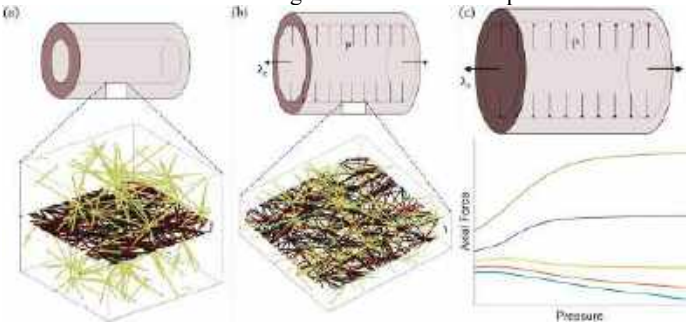

Figure 1: (a) Initial arterial vessel state, with vessel thickness illustrated by a single element in NaFNS plugin. (b) The vessel's remodeled state under the influence of imposed axial stretch (λ_z) of 1.72 and a pressure of 100 mmHg (P), showcasing alterations in the network. (c) Presents a typical outcome from the Pressure-Force test conducted on the sample post-remodeling.

specified target stresses and time constants for collagen and actin. Upon remodeling, the final discrete network representation of the remodeled material is saved for further analysis.

After remodeling, we replace our constraints with free boundaries, and the remodeled tissue moves to an unloaded configuration, thereby defining the growth stretch. Next, we perform a simulated planar biaxial extension test on the remodeled tissue. Finally, we subject the remodeled vessel to a simulated Pressure-Force experiment (Fig. 1(c)). In this experiment, a cylindrical tissue segment that has been subjected to an applied axial stretch is capped at both ends and pressurized. The force at the capped ends is measured for different pressures and axial stretches. On an element level, the axial and circumferential stretch are varied, and the force and pressure are calculated using stresses and stretches. Under the assumption of a thin-walled vessel and the Law of Laplace, the following formulas result:

$$\mathrm{P} = \frac{\mathrm{h}}{\mathrm{r}}\sigma_{\theta\theta} = \frac{\lambda_r h_0 \sigma_{\theta\theta}}{\lambda_\theta R_0} \quad (1)$$

$$\mathrm{F} = 2\pi \mathrm{r h}\left(\sigma_{zz} - \frac{\mathrm{Pr}}{2\mathrm{h}}\right) = \pi R_0 h_0 \lambda_\theta \lambda_r (2\sigma_{zz} - \sigma_{\theta\theta}) \quad (2)$$

where, h_0 is the ex vivo wall thickness, R_0 is the ex vivo radius, λ_θ is circumferential stretch and λ_r is radial stretch. The quantities $\sigma_{\theta\theta}$ and σ_{zz} are circumferential and axial stresses respectively.

We applied the protocol to remodeling at initial in vivo stretches of 1.2 to 1.9 with the remodeling pressure held constant at 100 mmHg. The initial wall thickness and vessel radius were set at 84 μm and 197 μm [7]. For the simulated Pressure-Force test, pressure was varied over the range 0 to 140mmHg, and stretch was varied from 1.1 to 1.95.

RESULTS

In presenting and discussing the results, we employ three different measures of axial stretch. The *imposed* axial stretch (λ_z) is the amount that the vessel is stretched from its initial (unremodeled) configuration. The growth stretch (λ_z^g) is the length of the remodeled vessel relative to that of the initial, and the in vivo stretch (λ_z^*) is the stretch at the in vivo length relative to the remodeled/grown tissue. Thus, $\lambda_z = \lambda_z^* \lambda_z^g$.

As a representative example, we begin with the case of $\lambda_z = 1.72$ and a remodeling pressure of 100 mmHg. For this case, λ_z^g was found to be 1.11. Thus, the in vivo axial stretch λ_z^* using the above formula was found to be 1.72/1.11 = 1.54. Simulated biaxial testing showed the remodeled tissue to be anisotropic, with greater stiffness in the circumferential direction than in the axial (Fig. 2(a)). Under varying pressures, the vessel diameter increased monotonically with applied pressure. At a given pressure, vessel diameter was higher at lower axial stretch (Fig. 2(b)).

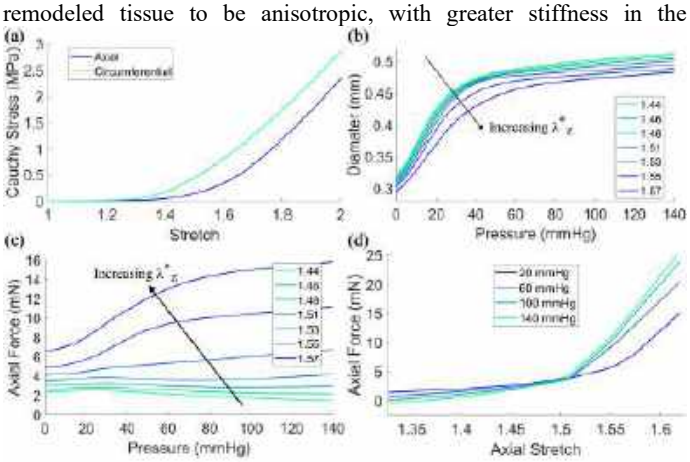

Figure 2: Results for imposed initial axial stretch of 1.72, which resulted in λ_z^g = 1.11 and λ_z^* = 1.54. (a) Biaxial extension test results and (b) alterations in vessel diameter with pressure in the Pressure-Force test. (c) Axial force in a Pressure-Force test decreases for low λ_z^* and increases for high λ_z^*. (d) Axial force rises monotonically with axial stretch, with all curves intersecting at one point.

For axial stretches 1.48 or below, axial force decreased as pressure increased (Fig. 2(c)), meaning that increasing the pressure caused a larger outward force on the end caps. Conversely, for stretches 1.53 or above, the forces exhibited an upward trend with increasing pressure. At an axial stretch of 1.51, the force remained relatively constant over the imposed pressure range, as depicted in Fig. 2(c). Plotting the axial force against the axial stretch across different pressures revealed a compelling trend: all curves converged at a singular point of intersection between 1.5 and 1.55 axial stretch (Fig. 2(d)). These results are all consistent with both classical [4] and recent [7] experimental observations.

Repeating simulations with imposed axial stretch λ_z of 1.2 and 1.9 while maintaining a pressure of 100 mmHg confirmed the observed trends. The λ_z^* for these cases is found to be 1.16 and 1.68 respectively. As in Fig. 2(c), for each case, there was an in vitro stretch ratio for which the pressure-force curve was relatively flat (Fig. 3(a-b)). For all three cases, the stretch associated with the flat pressure-force curve was very close to the in vivo stretch. The effect is illustrated in a plot of the difference in axial force for pressures of 60 and 120 mmHg versus the ratio of the applied axial stretch λ_z^{exp} to the in vivo axial stretch λ_z^* (Fig. 3(c)). For each case, the zero force difference is observed for a ratio close to 1. This finding supports the hypothesis that the force is invariant with pressure at in-vivo axial stretch.

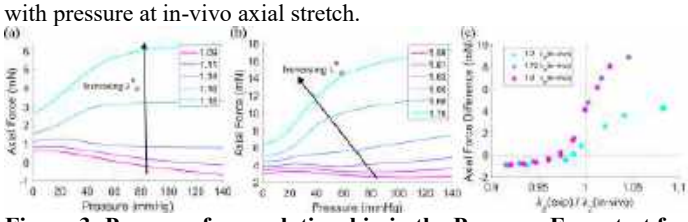

Figure 3: Pressure-force relationship in the Pressure-Force test for λ_z^* of (a) 1.16 and (b) 1.68. (c) Axial force difference between p=60 and p=120 mmHg vs. the ratio of experimental to in vivo axial stretch.

DISCUSSION

We found that the simulated remodeled vessel through the application of local tensional homeostasis had a specific axial stretch at which the force remained roughly invariant with pressure in a pressure-force test, *and that stretch was nearly the same as the in vivo stretch in all cases*. This observation agrees with the experimental observation that the flat pressure-axial-force curve occurs at the in vivo stretch [2,4,7]. The in vivo stretch effect ***arose with no specification of the effect in the model, and without any macroscopic target in the remodeling.*** Rather, the combined effect of all fibers remodeling individually was to produce the flat pressure-axial-force curve at the in vivo remodeling stretch.

INTRODUCTION

The myotendinous junction (MTJ) is a specialized region at the interface of muscle and tendon tissues. The complex architecture forms an integrated mechanical unit capable of transducing forces through the tissue to enable musculoskeletal movement [1]. The MTJ is a common site of injury due to the cyclic nature of tissue loading and the resulting storage and release of energy [2]. While the MTJ represents the transition from muscle to tendon, the microstructure reveals that this is not a discrete boundary between tissues, but rather overlapping interdigitations of the two cell types [3]. At the interface, muscle fibers integrate with tendons through extracellular matrix (ECM) interactions and surface proteins, allowing for functional integration and mechanical transduction without tissue damage [4].

The bidirectional chemical and mechanical crosstalk between myocytes and tenocytes in the developing MTJ occur within a limited spatial and temporal window [5]. However, the architecture and mechanical complexity of the MTJ has made it a difficult tissue to model and study *in vitro* [6]. In this work, we present a novel technique for the spatially restrictive coculture of myocytes and tenocytes for two-dimensional (2D) modeling of the human MTJ.

METHODS

Micropatterned lanes of Cultrex ECM were deposited on 10 kPa polydimethylsiloxane (PDMS) substrates. A 2-well culture chamber defined the initial regions of occupation for each cell line, for a total of approximately 38,500 primary tenocytes (1,750 cells/mm^2) and 67,000 human embryonic stem cell (hESC)-derived myogenic progenitors (3050 cells/mm^2) (**Fig. 1A**). Brightfield live cell imaging for migration and contractile analysis was performed with samples maintained at 37 °C. Samples were immunolabeled to identify proteins of interest and corrected total cell fluorescence was used to quantify their expression [7,8]. On day 24, electrical stimulation (1 Hz, 5 ms, 0.6 – 1.6 V/mm) was provided to induce global full-field contractions for analysis. Digital image correlation (DIC) was used to quantify induced strain behavior [9].

RESULTS

On day 1 after seeding, both lines occupied less than 20% of the initially vacant interstitial zone, referred to henceforth as the junction. Myocyte-tenocyte contact was observed by day 7 when both cell types had undergone a significant increase in area at the junction (**Fig. 1B**).

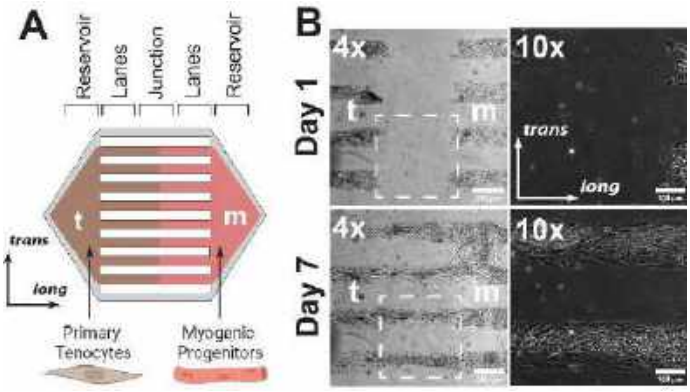

Figure 1: (A) Schematic of the micropatterned design. **(B)** By Day 7, a myocyte-tenocyte interface develops. Scale bars: 250 µm (4x) and 100 µm (10x).

Myocytes within reservoirs exhibit myofibrillar disarray, with fewer myofibers and poor organization in comparison to myocytes within lanes (**Fig. 2A**). By day 24, tenocytes in lanes had secreted an organized network of Collagen Type I (COL1A), while reservoir matrix deposition appears more disorganized (**Fig. 2B**). Tenocytes in lanes

were also found to have increased nuclei area and alignment in the longitudinal orientation in comparison to tenocytes in the reservoir.

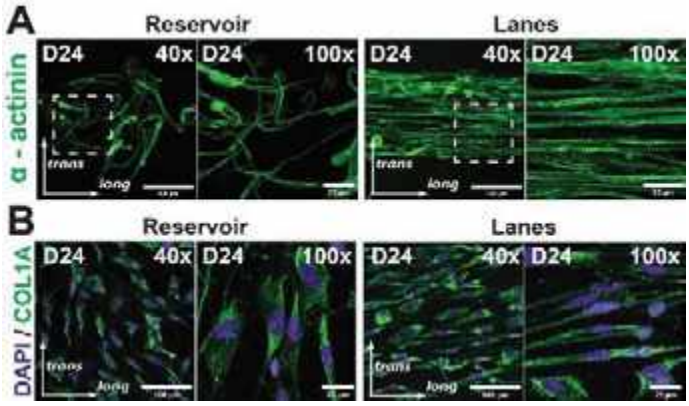

Figure 2: (A) Myofibrillar organization was enhanced in lane regions. **(B)** Tenocytes in lanes orient in the longitudinal direction, parallel to patterned lanes. Scale bars: 100 µm (40x) and 25 µm (100x).

Immunolabeling demonstrated that myocytes and tenocytes at the junction express reported MTJ protein markers and develop integrated structures resembling native MTJ interdigitations. To probe the mechanical integrity of these structures, electric stimulation was provided. Stimulation induced coordinated contractile behavior in the electrically and mechanically active myocytes but did not directly affect the behavior of the passive tenocytes. DIC was used to quantify strains in the longitudinal, transverse, and shear directions relative to the alignment of patterned lanes (**Fig. 3**).

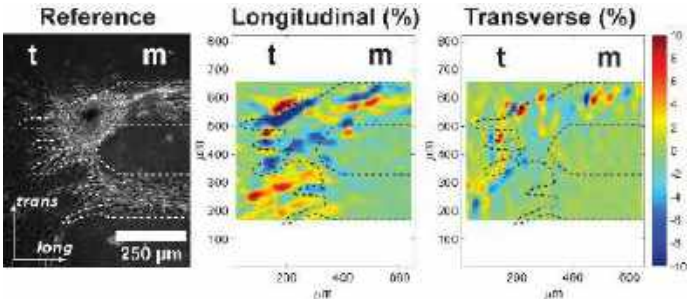

Figure 3: A representative image of the junction in a relaxed state (left), with heat map plots of the same junction in a contracted state, showing the longitudinal (center) and transverse strains (right).

At the junction and within patterned lanes, myocytes demonstrated enhanced contractility and an increased maximum magnitude of strain compared to unpatterned myocytes within the reservoir. No difference existed in the maximum magnitude of strain between myocytes at the junction and myocytes within patterned lanes. The maximum magnitude of tenocyte strain was tensile, or positive, at all regions of interest, and decreased with increased distance from the junction (**Fig. 4**). Tenocytes at the junction experienced the largest magnitude of positive strain in response to the external force of myocyte contraction. Tenocytes within lanes, but not at the junction, experienced significantly decreased magnitudes of strain in comparison to junction cells, as did tenocytes in unpatterned reservoir regions. A positive correlation existed between the maximum magnitude of myocyte strain and the corresponding maximum magnitude of tenocyte strain at the junction (R^2 = .6207). These data demonstrate that the electrically induced myocyte contraction behavior was transferred in part across the phenotypic boundary of the MTJ model, and that myocyte-tenocyte mechanical integrity was achieved.

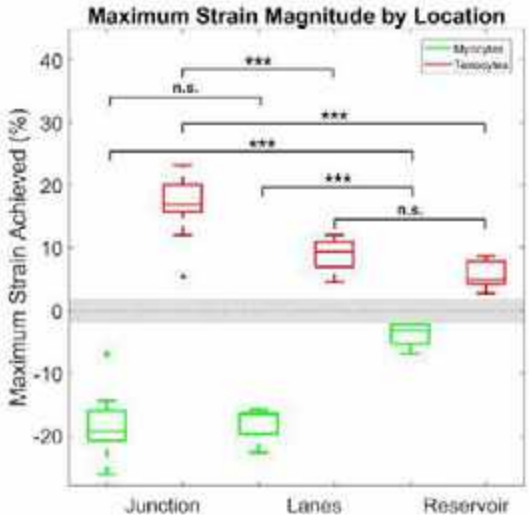

Figure 4: The maximum magnitude of strain in myocytes (green) and tenocytes (red) by region. Dotted line represents zero strain, the shaded area represents the noise limit of DIC detection. ***p < 0.001.

DISCUSSION

Due to the intricate architecture and the necessity that models contain structural and mechanical accuracy, the MTJ has become a difficult area of human anatomy to model *in vitro* [10]. The significance of our study was to engineer a novel 2D micropatterned model of the human MTJ, which aims to mimic cellular structure and mechanics of the native tissue. The model expressed reported MTJ protein markers and developed myocyte-tenocyte integrations capable of transducing forces and strains originating in contracting myocytes across the cell-cell interface to be experienced by tenocytes.

While this system is capable of modeling the 2D architecture and biomechanics of the human MTJ at early developmental timepoints, it also represents a platform capable of investigating injury and disease progression at later stages. We anticipate that the platform will have applications in disease modelling of an assortment of myogenic and tenogenic disorders that manifest at the junction [11, 12].

INTRODUCTION

Hyaline cartilage is a viscoelastic, biphasic, composite material optimized for its mechanical performance, comprised of a type-II collagen (COL) fibril network (5-20% wet weight) that affords structure and tensile strength to constrain a negatively charged sulfated glycosaminoglycan (GAG) hydrogel matrix (<15% wet weight) that retains interstitial water imparting interstitial fluid load support (IFLS). These components act synergistically, bestowing the compressive, rheological and tribological material properties essential to cartilage function. Osteoarthritis (OA) is an incapacitating condition in which hyaline cartilage progressively breaks down as a consequence of mechanical overloading that promulgates structural failure (fissuring/ fibrillation/ superficial zone delamination), tissue swelling, GAG depletion and COL network derangement. GAG depletion reduces IFLS, transferring load to the COL fibril network, which subsequently breaks down, culminating in increased hydraulic permeability, decreased cartilage stiffness and lubricity. Development of disease-modifying OA therapies is impeded by a lack of non-destructive clinical assessments of cartilage composition and mechanical properties germane to tissue function. Quantitative MRI (T1ρ, T2*) and arthroscopic-based cartilage grading (Outerbridge) are only moderately correlated with metrics characterizing cartilage composition and material properties[1]. Raman spectroscopy is an inelastic optical light scattering technique that provides an optical fingerprint of a tissue's molecular building blocks, allowing quantification of the predominant molecular constituents of cartilage (GAG, COL, H_2O) that contribute to the material properties intrinsic to its function. We developed a novel Raman spectroscopy needle probe and real-time spectral analysis platform capable of performing both *ex-vivo* and *in-vivo* measurement of ECM-specific compositional biomarkers for cartilage with a high degree of accuracy[2] (R^2=0.8-0.94). Absolute measures of cartilage content can be derived from the Raman spectra using phantoms comprised of prescribed proportions of GAG, COL and H_2O that serve as biochemical standards.[3] Here we demonstrate that *in-vivo*, real-time Raman spectroscopy performed on the equine stifle joint using a needle probe to measure cartilage composition at discrete anatomical sites along the equine trochlear groove can track changes in cartilage composition after an induced chondral injury and repair (microfracture, autologous chondrocyte implantation).

METHODS

Raman Probe: A custom Raman probe (In Photonics) comprised of a threaded needle tip (2.75mm diam.) with a distal 2mm diam. sapphire ball lens (AWI) was fiber-coupled to a battery powered 785nm laser (100mW output; IPS), and high-performance spectrometer (Eagle; Ibsen), allowing for portability. **Raman Spectra:** High SNR spectra in the fingerprint (800-1800cm^{-1}) and high wavenumber (2700-3800cm^{-1}) ranges were acquired. Spectra were preprocessed by background subtraction and area-under-curve normalization. The cartilage spectra (800-1800cm^{-1}) was fit to a multivariate linear regression model:

$$\mathbf{Cartilage_{spectra}} = GAG_{score}*(\mathbf{GAG_{REF}}) + COL_{score}*(\mathbf{COL_{REF}}) + H_2O_{score}*(\mathbf{H_2O_{REF}}) + Bone_{score}*(\mathbf{Bone_{REF}})$$

where: GAG_{REF}, COL_{REF}, H_2O_{REF}, and $Bone_{REF}$ are reference spectra of purified chemicals comprising each ECM constituent; the "scores" are the "fit" regression coefficients reflecting the relative contribution of each ECM constituent and subchondral bone to the composite spectra (**Fig.1A-C**). The high-wavenumber range spectra (2700-3800cm^{-1}) was used to compute the area under the CH_2 and OH peak, reflecting tissue hydration[4]. Raman spectral analysis was performed in real time, with ECM biomarker scores and quality metrics displayed to the operator via a custom GUI. The fit Raman biomarker scores derived from the cartilage spectra (**Fig1A**) were converted to absolute content measures (%w/v) using tissue phantoms comprised of prescribed ratios of GAG (chondroitin sulfate [0-10%w/v]), COL (gelatin [0-20%w/v]), and H_2O [70-100%w/v] by fitting a 2nd order polynomial to express the known %w/v of the tissue phantoms as a function of the measured Raman scores.[3] ***Ex- Vivo* Validation**: from a 5-y/o equine stifle joint, 3mm full thickness cartilage plugs were harvested at 169 discrete locations over the surface of the femoral trochlear groove. The composition of each

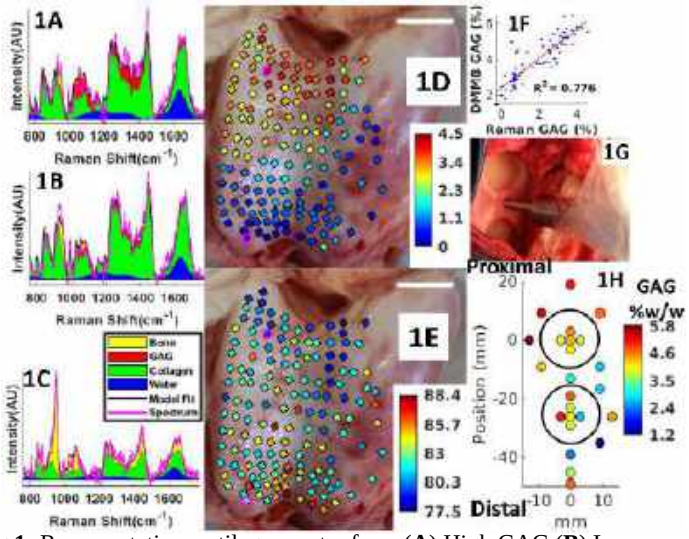

Fig 1: Representative cartilage spectra from (**A**) High GAG (**B**) Low GAG, (**C**) Thin cartilage (high bone signal) specimens. *Ex-vivo* mapping of cartilage composition derived via phantom-corrected Raman measures (%w/v) of (**D**) GAG and (**E**) H_2O. (**F**) Correlation Raman GAG vs. DMMB assay *ex-vivo*. (**G**) Intra-op Raman probe measuring tissue composition adjacent 2 circular excised chondral defects (**H**) *In vivo* phantom corrected Raman GAG content of cartilage prior to chondral defects (represented as circles)

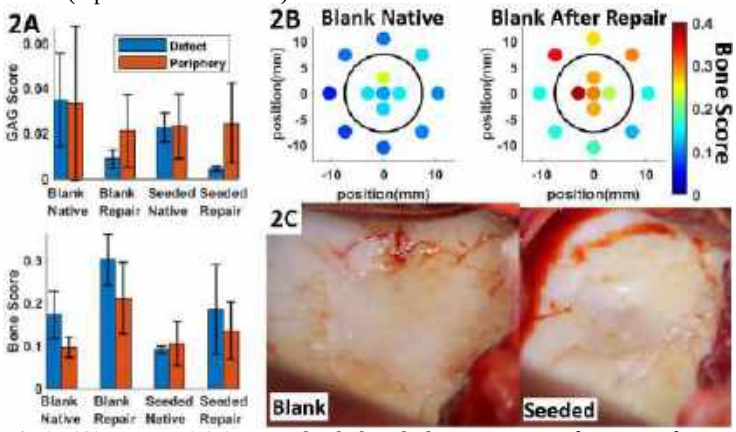

Fig 2: (A) Raman GAG_{score} and subchondral $Bone_{score}$ as a function of location, repair type, and time (before defect or 3month after repair). (**B)** $Bone_{score}$ anatomic site map before defect and 3 months after repair. (**D)** Photographs of neocartilage repair tissue at 3 months

plug was measured by Raman spectral analysis and confirmed by DMMB GAG assay (**Fig 1F**).

***In Vivo* Spectra Analysis**: The needle tip was autoclaved, and optics draped in sterile plastic film. Through a parapatellar arthrotomy between the middle and lateral patellar ligaments, Raman needle probe spectral analysis was performed at multiple sites along the lateral trochlear groove of a 5-year-old thoroughbred horse to measure cartilage composition at defined anatomical sites within the footprint of two planned 15mm diam. focal chondral defects to the subchondral bone (**Fig.1G**) and sites peripheral to the defect (**Fig.1H, 2B**). At each site, the probe lens contacted the surface with minimal force to prevent slipping; spectra were acquired for 5 seconds. **Cartilage Repair:** Defects were repaired by one of two treatments: 1) unseeded collagen scaffold placed on top of micro-fractured subchondral bone (Blank), 2) collagen scaffold seeded with equine chondrocytes (Seeded) covered by a thin collagen membrane sutured to the peripheral cartilage. Raman spectra of the neocartilage repair tissue was performed at the same locations within the defect and peripheral sites 3 months after the defects were created and repaired using a similar surgical approach.

RESULTS

Ex-vivo: Raman derived biochemical estimates accounted for 78% of the variance in DMMB measured GAG content (**Fig.1F**) and depicted a biochemical spatial gradient along the length of the trochlear groove, with GAG content increasing and H_2O content decreasing from distal to proximal (**Fig. 1D,E**). The Raman derived GAG %w/v underestimated the GAG content by ~20%, which is attributable to disparately between the regions of Raman probe interrogation (~300µm depth of penetration) vs. the full thickness cartilage plug used for the DMMB assay. ***In-vivo:*** Using the needle probe, real time Raman analysis achieved high quality spectral acquisition of cartilage, as evidenced by a high SNR and ability of the multivariate regression model to account for 93% of the variation of the "fingerprint" cartilage spectra (R^2=0.93±0.03). *In-vivo* Raman GAG measures of cartilage exhibited a similar range and spatial distribution as the *ex-vivo* phantom converted analysis (**Fig 1H**). For both repair groups, GAG_{score} trended lower in neocartilage, and $Bone_{score}$ was elevated in the neocartilage and peripheral sites around the defect compared to native cartilage (**Fig.2A**).

DISCUSSION

This study establishes the capability of our Raman needle probe spectroscopy platform to achieve accurate quantitative *in-vivo* measures of the biochemical content of native cartilage and neocartilage repair tissue in real time, allowing diagnostic assessments of tissue quality at defined anatomic sites. The accuracy of ECM composition calculated from the *in-vivo* Raman spectral analysis is supported by *ex-vivo* measures of tissue composition at discrete anatomical sites along the trochlea of the equine stifle joint, where Raman derived GAG wt% accounted for 78% of the variation in GAG content. *In-vivo* assessment demonstrated lowered Raman GAG_{score} in the neocartilage for both repair groups at 3 months after repair relative to native cartilage. The higher contribution of subchondral bone to the neocartilage spectra at both the defect + periphery sites, manifest by an elevated Raman $Bone_{score}$, indicates that the repair tissue is thinner than the native cartilage at the same anatomic locations assessed prior to creation of the defect, demonstrating that adjacent cartilage is also degraded as part of the overall inflammatory response to the surgically induced joint trauma. The elevated $Bone_{score}$ also reflects softening of the cartilage, with more compressive tissue strain under the same contact tare force produced by the probe during Raman measures. The elevated $Bone_{score}$ precluded phantom conversion of neocartilage Raman ECM biomarker scores to absolute wt% measures, but we will adopt biochemical phantoms with subchondral bone to allow for fully quantitative Raman-derived biochemical wt% measures of the neocartilage repair tissue.

Significance: This work supports the use of Raman spectroscopy acquired through needle probes as a clinical tool to perform comprehensive diagnostics of the composition of articular cartilage in health and disease and as a non-destructive tool to monitor the tissue response to chondroprotective and chondroregenerative therapies *ex-vivo*, *in-vivo* and clinically using Raman arthrotomy. This is the first longitudinal *in-vivo* Raman assessment of tissue response to a chondroregenerative therapy.

INTRODUCTION

Numerical simulations of the biomechanics of the heart tissue (myocardium) are useful for non-invasive investigations of cardiovascular disease mechanisms and treatments. In such simulations, modeling the circulatory system is essential for capturing physiological cardiac behavior. To reduce the computational cost, blood circulation is typically represented with a zero-dimensional (0D) lumped-parameter network (LPN). Recently, we described a novel scheme to couple three-dimensional (3D) cardiac mechanics models with 0D circulatory models, demonstrating the method with an idealized left ventricle coupled to an open-loop LPN. Here, we extend the coupling scheme to an image-derived, electromechanical model of the left and right ventricles (LV, RV) coupled to a closed-loop LPN. We also present a workflow to personalize the multiscale biventricular model based on clinical measurements of cardiovascular function.

METHODS

We construct a biventricular cardiac model for a healthy adult male. Phase-resolved (3D+t) computerized tomography (CT) images were obtained at 10 time points during the cardiac cycle. We then apply a deep-learning whole-heart mesh reconstruction approach to segment the images [1]. From this, we calculate time-dependent cardiac chamber volumes. Other clinical measurements, including cuff blood pressures and electrocardiogram (ECG) waveforms, were also obtained for this individual (Fig. 1).

The computational model is composed of a 3D biventricular model, obtained from the segmented CT data at end-diastole, coupled to a closed-loop LPN of the circulatory system, borrowed from [2] (see Fig. 2). The LPN contains capacitor-resistance-inductor assemblies to model four basic compartments of the circulatory system – systemic/pulmonary arterial/venous – as well as time-varying elastance elements for the left and right atria (LA, RA). In addition, diodes are used to represent the cardiac valves.

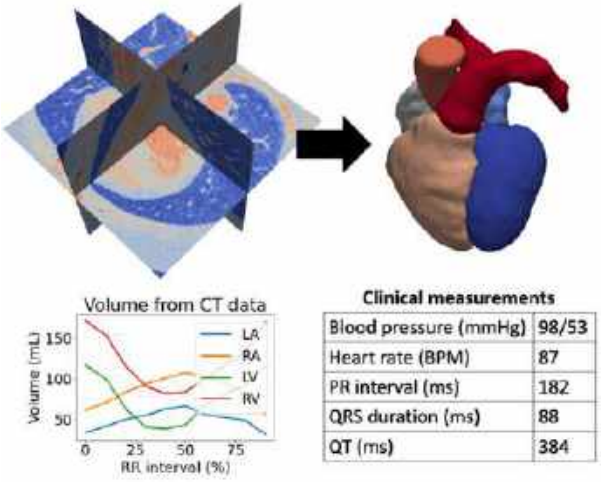

Figure 1: Summary of clinical data used to inform the model. Top: CT image data is automatically segmented using the deep-learning method of [1]. Bottom: Chamber volumes are computed from segmentations, and clinical measurements are obtained.

For the biventricular model, we generate myocardial fiber directions using a rule-based Laplace-Dirichlet method [3]. To model tissue support on epicardial and basal surfaces, we apply Robin boundary conditions, indicated by the spring-dashpot assemblies in Fig. 2. The equations of hyperelastodynamics, with the fiber-based Holzapfel-Ogden material law for myocardium, are solved using a recently developed variational multiscale finite element (FE) method

suitable for incompressible finite deformations [4]. Electrophysiology is simulated using the monodomain equation for the transmembrane potential and the ten Tusscher-Panfilov ionic model [5]. We use a fractal-tree-based Purkinje network [6], crucial for realistic electrical activation patterns and cardiac contraction. Simulations are performed with the open-source multiphysics code *svFSI* [7].

The two submodels – 3D biventricular electromechanics and 0D blood circulation – are coupled using our recently published method [8]. Briefly, in our coupling scheme, flowrate and pressure are passed iteratively between the 3D and 0D solvers, until both are converged in each timestep. In addition, we numerically calculate the resistance experienced by the 3D cardiac model due to the 0D fluid, computed as the derivative of pressure with respect to flowrate. This is used to modify the tangent matrix of the 3D solver, significantly improving the convergence robustness, particularly during the isovolumic cardiac phases.

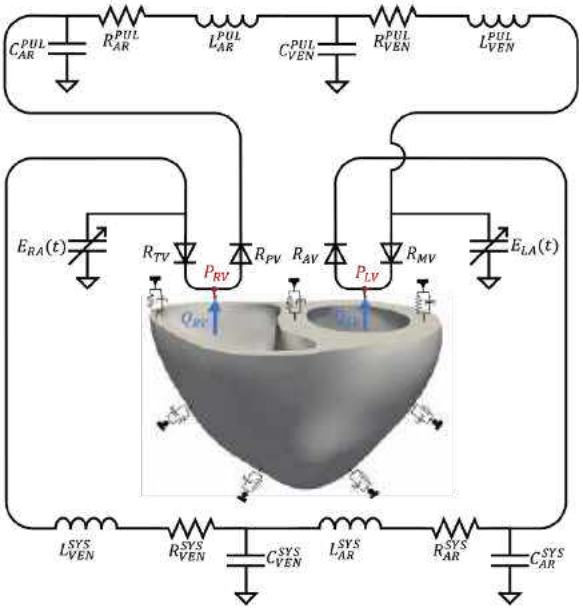

Figure 2: Image-derived biventricular model coupled to closed-loop LPN model of [2].

Our combined 3D-0D model has many parameters that must be tuned to match clinical measurements. This is achieved in multiple steps. First, we employ a full LPN model of the cardiovascular system, in effect replacing the 3D FE model of the ventricles with time-varying elastances. Using a combination of manual tuning and Nelder-Mead optimization, we determine parameters of the LPN that yield the observed patient-specific metrics, within a specified tolerance. Second, we perform an inverse FE analysis to determine the stress-free configuration and passive material parameters of the myocardium using a novel optimization framework [9]. Finally, we again apply Nelder-Mead optimization to determine the parameters of the active cardiac contraction model.

RESULTS

Fig. 3 shows preliminary results, in which we simulate the coupled biventricular model for five cardiac cycles. On the left, we show the biventricular model at end-systole, colored by von Mises stress. Comparing the deformed configuration to the reference configuration, shown in gray and semi-transparent, we see that much of the decrease in volume is obtained by the downward movement of the basal plane. Also, stress is concentrated at the basal plane, owing to stiff Robin boundary conditions imposed here.

On the right, we plot the pressure-volume (PV) loops. For the LV PV loop, we see clear delineation of the four cardiac phases – isovolumic contraction, ejection, isovolumic relaxation, and filling. These phases are less defined for the RV. We also note that LV and RV stroke volumes are initially different but equalize by the fifth cardiac cycle.

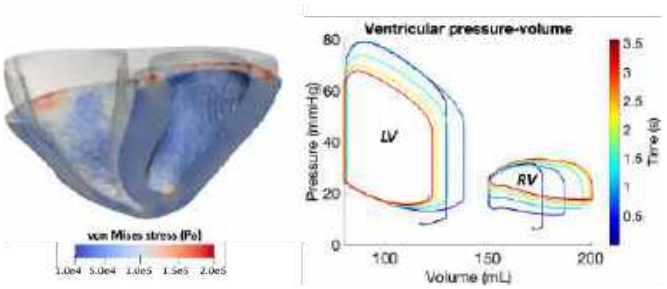

Figure 3: The simulation was run for five cardiac cycles. Left: Biventricular model at end-systole in cut view colored by stress magnitude, with reference configuration in gray and semi-transparent. Right: Pressure volume loops for the LV and RV.

DISCUSSION

This work provides a methodology and a baseline model for simulating personalized biventricular electromechanics, accounting for the entire cardiovascular system. Using a high-fidelity 3D model for the myocardium, but a simplified 0D model for blood circulation, permits a physiological yet computationally tractable simulation of the heart function. Indeed, our preliminary results exhibit important features of physiological cardiovascular behavior, including the downward motion of the basal plane, reasonable PV loops, and equalization of stroke volumes. The isovolumic phases of the cardiac cycle, which traditionally pose numerical challenges, are well captured by our coupling method without any *ad hoc* special treatment [2,8]. One can modify this model to investigate the effect of congenital heart defects (CHDs), including arrhythmia, ventricular dyssynchrony, septal defects, and transposition of the great arteries, as well as surgical interventions to address such diseases. The method may also be extended to four-chamber heart models to simulate whole-heart cardiac electromechanics.

INTRODUCTION

Understanding the motion and geometry of the mitral valve (MV) in a beating heart is a complex and often impractical task with normal medical imaging. Most clinical evaluations of valves are performed using two-dimensional trans-thoracic echocardiography images, which allow for some evaluations of function, lesions and diseases. Some more advanced non-invasive evaluations are performed using transesophageal echocardiography, Cardiac Magnetic Resonance (CMR) and Cardiac Computed Tomography (CCT). These techniques are capable of three-dimensional time-resolved images [1], but still cannot easily produce a clear geometrical representation of the MV. This, however, is of great importance for simulations of cardiac hemodynamics, with blood flow calculated from time-resolved CT using geometrical information of a subject's heart and computational fluid dynamics (CFD) [2]. As detailed valve geometry and their motion cannot be directly extracted from CT data, these simulations utilise approximate open and closed shapes for cardiac valves with motion and dynamics of the valves.

This study presents a method for calculating subject-specific dynamic geometrical models for the mitral valve from either CCT or CMR. The model should be simple enough, while allowing for sufficient agreement with valvular geometries and dynamics. The shapes of the MV annulus and leaflets were parametrised, while the the *chordæ tendinæ* were neglected. The MV geometries included the valve translations and rotations following the cardiac motion.

METHODS

Image data and mitral valve tracking

CT images were obtained from 2 patients with no reported mitral valve disease, subjected to preoperative aortic valve evaluations. Images were obtained either with a 3rd generation energy-integrating dual-source CT scanner (Somatom Force, Siemens Healthineers, Forchheim, Germany) or with a photon-counting detector dual-source CT scanner (NAEOTOM Force, Siemens Healthineers, Forchheim, Germany). Time-resolved images were acquired during an end-inspiration breath hold with full heart beat reconstructed to 20 time instants. Each 3D volume consisted of slices of in-plane resolutions 512×512 pixels, with spacings from 0.309×0.309 mm^2 to 0.391×0.391 mm^2, 0.6 mm thickness, 0.3 mm or 0.4 mm spacing between slices. For MV evaluation, a three-chamber long-axis view was manually defined for each subject using a slice in ParaView v5.11. This cross-sectional view, utilised in clinical echocardiography and CMR, allows for visualisation of cardiac anatomy showing the left atrium, left ventricle and part of the ascending aorta. CT data were interpolated to this plane and to 9 additional evenly rotated planes around an axis from the MV to the ventricular apex, used for mitral valve segmentation.

Cine balanced steady-state free precession (bSSFP) CMR data were obtained from three control subjects in a study investigating MV function and blood flow in postoperative mitral valve repair surgery. The bSSFP images were acquired at end-expiratory breath holds for MV visualisation at a 1.5 T MRI system (Philips Healthcare, Best, the Netherlands). These consisted of a three-chamber view and 7 to 10 additional planes parallel to it. At each of these locations, 40 time frames representing a full cardiac cycle were reconstructed, with slices' in-plane resolutions of 256×256 pixels, spacing of 1.25×1.25 mm^2 and thicknesses and slice spacings of 5 mm. To match the temporal resolution of CCT, only half of the CMR time frames were utilised for tracking.

The studies were approved by the Swedish Ethical Review Authority.

The mitral valve annulus and leaflets, as well and the ventricular apex

and papillary muscles, were manually tracked in the CCT and CMR data, as exemplified in Fig. 1. All steps of data management, interpolation and point tracking were performed using custom developed software implemented in Python 3.11.

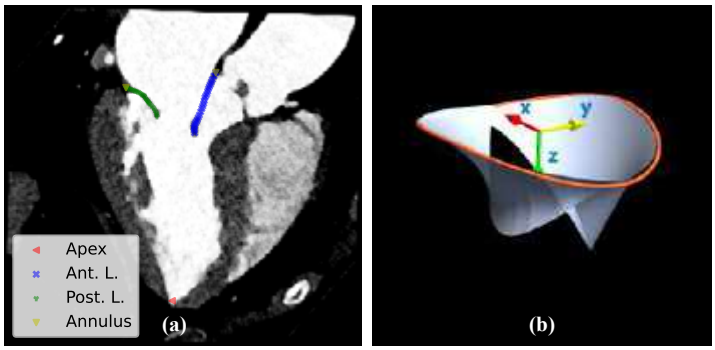

Figure 1: (a) Segmented MV points on three-chamber view from interpolated CCT. (b) Modelled MV geometry in local coordinates.

Mitral valve model

Transformation matrices for the point data were first determined using the MV annulus points at each time step to transform tracked MV points from global coordinates to valve-centric coordinate systems. A translation vector was calculated as the mean coordinate of the annulus points. For standardisation, local coordinate systems' orientations were defined with z-axes from MV to ventricle apex and x-axes lying in a plane perpendicular plane to the three-chamber view in an approximate posteroanterior orientation, as seen in Fig. 2 (a) and (c).

The adoption of a combination of elliptical and hyperbolic paraboloid equations for the mitral annulus has been described extensively in generalised models of the MV geometry [3] , but their use with the tracked points showed poor agreement. To improve the results, the original equations were modified. The two-dimensional elliptical equation in cylindrical coordinates of the MV in local xy-planes was altered with values for the semi-axes depending on each quadrant, while also allowing for displacements in x and y-directions, so the centre of the ellipses may not overlap with the origin of the coordinate system. While the true hyperbolic paraboloid equations have constant parameters, the modified HP used had coefficients changing smoothly as functions of the angle ϕ in cylindrical coordinates. Such changes made it possible to account for asymmetries in the annular shape, improving the agreement between predicted and measure annulus coordinates.

The anterior and posterior MV leaflets were approximated to fourth order polynomial functions in cylindrical coordinates, with the radius ρ as a function of ϕ and z. For each leaflet a displaced coordinate system along the local y-axis was used, to mitigate problems caused by leaflet segments intersecting the coordinate system origin.

The coefficients of the MV annulus and leaflet functions were calculated by minimising the difference from the tracked point coordinates to the outputs of these functions. The transformation displacements and rotations, as well as the coefficients for the annulus and leaflet functions, were smoothed in time to assure continuity between cardiac cycles, used to produce MV geometries at all 20 analysed time steps.

RESULTS

The resulting mitral valve geometries were calculated for the subjects at all analysed time frames using subject-specific input parameters as well as the mean values from the six subjects analysed. Figure 2 shows example MV annulus and leaflet geometries produced using the model approach described, corresponding to the same instant seen in Fig. 1.

Using the parametric model results, the projected annulus area from the modified ellipse equations. The projected leaflet opening area during diastole was also computed using the leaflet parametric models. The results of these area calculations are presented in Figure 3.

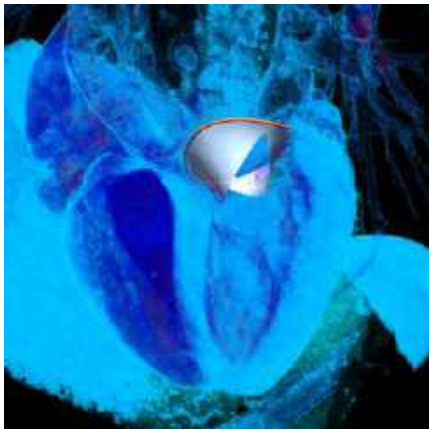

Figure 2: Modelled MV geometry with CCT data.

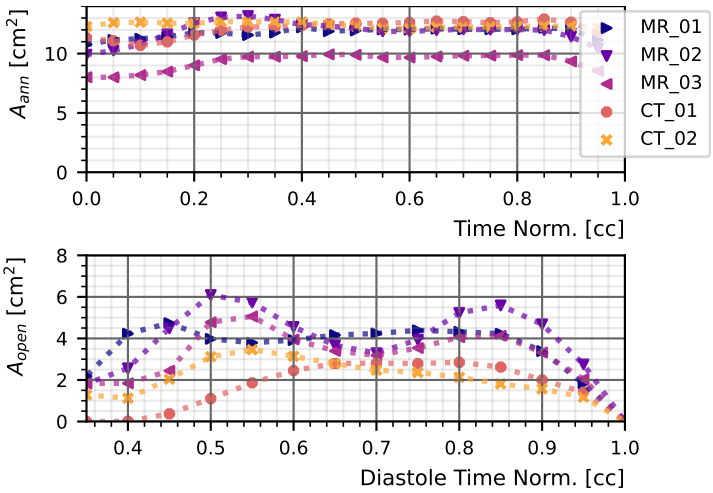

Figure 3: (a) MV annulus projected area and (b) MV opening projected area during diastole.

DISCUSSION

In this study, a method for producing subject-specific geometric models of the mitral valve based on multimodal medical images has been described. The model presents a trade-off between simplicity and accuracy. This method utilises segmentation information for the MV annulus and leaflets, which after data processing produce a parameter-based approach for calculating the valve's position and shape along a cardiac cycle, and the agreement between the calculated geometries and the tracked point coordinates indicates good similarities. As shown in Fig 3, the presented parametric method may potentially be used for assessment of MV annulus and leaflet geometries and function. Additionally, the mitral valve motion is affected by both the left ventricle and atrium, so the the translation and rotations obtained from the transformation parameters may be used for further assessment. This geometrical modelling can also facilitate and increase accuracy of CFD simulation of blood flow, producing dynamic and more realistic representations of the mitral valve geometry.

THE EFFECTS OF GROWTH AND REMODELING ON THE CONTRACTILE FUNCTION OF THE PREGNANT MURINE UTERUS

Emily A. Hoffmann (1), Kyoko Yoshida (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, U.S.A.

INTRODUCTION

The uterus changes dramatically during pregnancy. Significant uterine growth (mass and cavity volume change) and remodeling (mechanical property changes) occur to support a healthy, term pregnancy. Abnormal uterine growth and remodeling (G&R) are implicated in compromised uterine mechanical function, potentially leading to preterm birth (< 37 weeks gestation), a condition that affects over 10% of births worldwide and is the leading cause of newborn mortality [1]. One avenue of preterm birth is a premature increase in uterine contractility [1], but little is known about the mechanical and biological factors that direct the timing and magnitude of contractions.

Soft tissue G&R typically maintains mechanical homeostasis: cells grow or remodel their extracellular matrix to optimize the stress or stretch they experience, helping preserve their function [2]. Unlike in other soft tissues, the mechanical function of the uterus evolves during pregnancy: first remaining relaxed while experiencing large amount of stretch, then increasing its contractility for labor at term [3]. Because stretch determines the active stress that smooth muscle cells (SMCs) generate, we hypothesize that the stretches uterine SMCs experience is an important driver of organ-level uterine function during pregnancy.

Changes in the *in vivo* mechanical environment that uterine SMCs experience, however, are challenging to characterize. Imaging modalities like ultrasound can track changes in total deformation of the tissue, confounding uterine growth (changes in undeformed geometry) with mechanical stretch from the growing fetus. Additionally, uterine tissues are known to remodel, potentially altering *in vivo* stretch or stress [4]. In other soft tissues, the kinematic growth framework has been used to account for growth, remodeling, and mechanical loading in solving for the *in vivo* mechanical environment of muscle cells [5]. Here, we apply the same framework with the goal of elucidating the effects of uterine growth, remodeling, and mechanical loading on the *in vivo* mechanical environment of uterine SMCs. Towards this goal, the objectives of this study were to 1) quantify uterine remodeling by fitting a constitutive model to published passive and active tensile data, and 2) create a finite element (FE) G&R model of the pregnant mouse uterus to investigate the effects of growth, remodeling, and mechanical loading on uterine stress and contractility. We hypothesized that growth would decrease stress in the uterus and that G& R would reduce contractility.

METHODS

Here, we investigate uterine remodeling in mice, a common animal of pregnancy [6]. First, we quantified passive uterine remodeling by fitting a coupled transversely isotropic Mooney-Rivlin (TIMR) constitutive equation (Eq. 1) to published passive uniaxial tensile data from nonpregnant and pregnant mouse uterine tissues on gestation days (d) 7, 13, 15, 17, and 19 of a 19-day gestation [7]. In this constitutive relationship, the strain energy density function (W) depends on fiber stretch (λ), the invariants and Jacobian of the deformation tensor (I_1, I_2, J), material parameters $c_{1\text{-}4}$, and bulk modulus k (Eq. 2).

$$W = c_1(I_1 - 3) + c_2(I_2 - 3) - 2(c_1 + 2c_2)\ln J + F(\lambda) + \frac{1}{2}k(\ln J)^2 \quad (1)$$

$$F(\lambda) = \begin{cases} 0, & \lambda \le 1 \\ c_3\left(e^{-c_4}\left(\mathrm{Ei}(c_4\lambda) - \mathrm{Ei}(c_4)\right) - \ln\lambda\right), & 1 < \lambda \end{cases} \quad (2)$$

where Ei() is the exponential integration function. We determined optimal parameters by simulating the tensile tests with FEBio (v4.0). To prevent overfitting, we set c_2=0 and c_4=1.4 for all gestation days and iterated values of c_1 and c_3 to minimize the R^2 value between the simulated and experimental stretch-stress curves. We incorporated active contraction by prescribing published stretch-active stress curves for each timepoint using the "active fiber stress" model in FEBio [6].

Next, we developed a FE G&R model of the murine uterus (FIG. 1). We idealized the nonpregnant uterus as a thick-walled cylinder based on gross anatomy measurements and modeled a quarter section for computational efficiency. We simulated two myometrial layers to mimic known uterine architecture [7]. Here, we simulated d7 and d13 of pregnancy, each with gestation day specific TIMR and active

contraction parameters. To simulate uterine growth, we assumed constant mass density throughout pregnancy and used the kinematic growth model to prescribe fiber growth ($F_{g,ff}$) based on published uterine weight measurements (d7: $F_{g,ff}$ =1.15[-], d13: $F_{g,ff}$ =1.5[-]) [6]. Fixed boundary conditions enforced symmetry and a coplanar constraint allowed the upper end of the uterus to displace freely in the z-direction (FIG. 1). To simulate mechanical loading, we idealized two pups as spheres (with a sliding facet-on-facet contact between the pups and the inner uterine wall) and used the "cell growth" model to simulate pup growth according to published pup weight data [6,9].

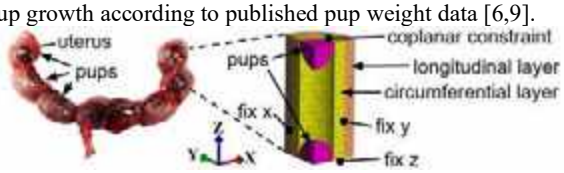

Figure 1: Image of a pregnant mouse uterus with two horns. The FE model simulated a segment with two pups.

We simulated three cases for d7 and d13: 1) remodeling only (R-only), where we changed TIMR properties but not fiber growth ($F_{g,ff}$ =1), 2) growth only (G-only), where we allowed fiber growth but kept TIMR properties unchanged, and 3) growth and remodeling (G+R), where both TIMR parameters and $F_{g,ff}$ changed over time. In each simulation, we allowed the uterus to passively stretch due to pup growth, then simulated contraction. We compared the 1st principal stresses in the three adaptation cases, then before and after contraction, to understand the effects of G&R on uterine stress and contractility.

RESULTS

The TIMR constitutive model successfully captured the passive experimental stretch-stress curves (FIG. 2A). The c_1 and c_3 parameters decreased to capture the elongation and lower slope of the toe region in the experimental stretch-stretch curve (FIG. 2B).

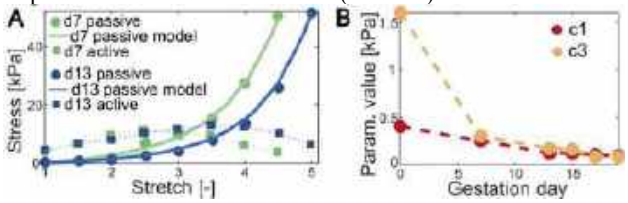

Figure 2: A) Representative material model fits at d7 and d13 demonstrate agreement between model and experimental results. The dotted lines show stretch-dependent active stress curves at d7 and d13. B) TIMR parameters c_1 and c_3 decreased with gestation.

We incorporated these changes in c_1 and c_3 into our organ-level FE models. In the d13 models, the contracted 1st principal stresses were highest when accounting for R-only (av. 1.24kPa, max. 4.97kPa), followed by G-only (0.98, 2.55kPa) then the G+R case (0.53, 1.40kPa) (FIG. 3A). The difference between stress before and after contraction (i.e., the active stress) was highest in the R-only case (0.22kPa) compared to the G-only (0.10kPa) and G+R (0.11kPa) cases.

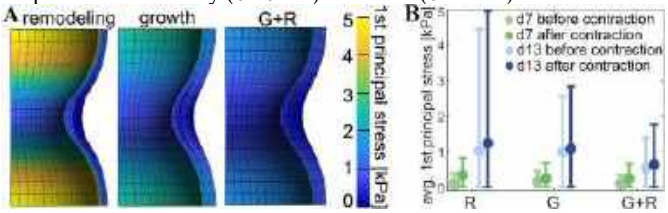

Figure 3: A) 1st principal stresses were different in the three d13 adaptation cases (after contraction). B) Max. and avg. stress were lowest with G+R (error bars: max and min) at both d7 and d13.

The d7 model had similar trends (R: av. 0.10kPa, max. 0.38kPa; G: 0.15, 0.45kPa; G+R: 0.10, 0.32kPa). Comparing across gestation days, stresses were lower at d7 compared to d13, and d7 contractile stresses were similar to those at d13 (R: 0.22, G: 0.08, G+R: 0.14kPa).

DISCUSSION

The objectives of this study were to quantify uterine remodeling during pregnancy and investigate the effects of uterine G&R on stress and contractile function. To this end, we fit a constitutive model to passive tensile data and developed a FE G&R model of the murine uterus, incorporating realistic G&R changes during pregnancy.

By changing the c_1 and c_3 parameters, we were able to capture the elongated toe region and decreased toe region slope in the tensile stress-stretch curve with progressing pregnancy. This result indicates that the TIMR model is appropriate for quantifying uterine remodeling.

In our d13 G&R FE model, passive stresses were highest when accounting for remodeling only, followed closely by the growth-only case. The lowest stresses occurred in the G+R case, indicating that both adaptations are important for maintaining the optimal mechanical environment during pregnancy. R-only and G-only stresses were 94% and 87% higher than stress in the G+R case, respectively. Thus, our simulations demonstrate that the mechanical consequences of G&R, particularly growth, have an important effect on reducing uterine SMC stress during pregnancy. These results support the notion that uterine G&R occurs to help uterine SMCs maintain homeostasis as the fetus grows; this is potentially an important mechanism for protecting uterine SMCs from experiencing too much stretch early in the pregnancy and preventing premature contractions. This idea is also consistent with the higher risk of preterm birth in cases of excess stretch [1].

Interestingly, the ability of the uterus to contract was similar when comparing G-only to G+R. These results suggest that the passive curve can affect the active stress of the uterus. Higher active stress in the R-only case compared to the G-only case agree with literature in which increased substrate stiffness results in higher SMC traction forces [2]. Overall, our results highlight the importance of accounting for mechanical G&R history when developing computational models that simulate pregnancy and labor contractions.

In conclusion, we demonstrate the mechanical consequences of tissue-level uterine G&R on organ-level stress and contractility. Future work will improve model assumptions, including those of identical material properties in the two uterine layers and homogenous properties and growth throughout the tissue. We are currently simulating additional gestation days to understand how the *in vivo* mechanical state of the uterus evolves during pregnancy. In the future, we will integrate this model with biological signaling models to provide a comprehensive multiscale computational platform to elucidate the biological and mechanical interactions that underly preterm birth.

INTRODUCTION

Alzheimer's Disease (AD) is a debilitating neurodegenerative disease and the most common form of dementia, affecting over 6.5 million Americans [1]. AD progression leads to various forms of cognitive decline, most notably memory impairment. Cerebrovascular integrity is essential for proper brain perfusion and metabolism. The ability of cerebral arteries to dampen the pulsatile blood flow is important to prevent damage to the brain. Cerebrovascular remodeling and degradation of artery wall constituents including elastic fibers, collagen, and smooth muscle cells (SMCs) may lead to decreased compliance and impact its ability to remove neurotoxic materials from the brain. This includes amyloid-β (Aβ) deposits and the protein tau in the form of neurofibrillary tangles (NFT), the two proteins established as the primary indicators of preclinical AD [2,3].

In this study, neuropathological AD progression in the form of neuritic Aβ deposition and NFT formation in brain tissue was compared with changes to the mechanical behavior and microstructure of human anterior cerebral arteries (ACAs) from patients diagnosed at various stages of AD. Our findings showed that the presence of NFTs and neuritic Aβ plaques in the regions of the brain supplied by the ACA corresponded with decreased ACA compliance and microstructural changes.

METHODS

Sample Preparation and Mechanical Testing: Human ACAs (n = 49) obtained from the BU Alzheimer Disease Center were delivered to the laboratory on dry ice and stored in a -80°C freezer before experiments. ACA sections roughly 15mm in length and 2mm in diameter were gently cleared of connective tissue and blood was flushed before mechanical testing. ACA samples were mounted on metal cannula in a pressure myograph (DMT 110P, Denmark). Arteries were stretched to their *in vivo* stretch ratio λ_z and inflated to 120mmHg at 2.5mmHg/s for preconditioning and testing. Four inflation-deflation cycles were performed to ensure repeatability. Transmural pressure P, axial force f, and outer radius r_o were measured during the experiment. After testing, an artery ring was carefully excised from the sample to measure the undeformed inner (R_i) and outer (R_o) radii. Circumferential stretch (λ_θ) as well as circumferential (σ_θ) and axial (σ_z) Cauchy stresses were calculated as:

$$\lambda_\theta = \frac{r_o+r_i}{R_o+R_i},\ \sigma_\theta = \frac{Pr_i}{r_o-r_i}, \sigma_z = \frac{f+P\pi r_i^2}{\pi(r_o-r_i)(r_o+r_i)} \qquad (1,2,3)$$

where r_i is the deformed inner radius calculated based on the soft-tissue incompressibility assumption [4]. Circumferential tangent stiffness was calculated as the slope of the stress-stretch curve for the low-pressure region (0-20 mmHg). Mechanical testing data was grouped by age (≤65, 66-79, and ≥80) along with NFT and Aβ pathology levels to study the age dependency and association with brain pathology. AD neuropathological development is quantified by its spread throughout the brain and scored from 0 (control) to 3 (whole brain is afflicted) [5]. In this study, samples were grouped based on NFT (0-1 and 2-3) and Aβ scores (0 and 1-3).

Histology and Multiphoton Microscopy: Sections ~3mm in length were cut from mechanically tested ACAs and fixed in 4% paraformaldehyde overnight. Fixed samples were embedded in paraffin and cut in 5μm thick sections then stained with Movat's pentachrome to view elastic fibers (black), collagen fibers (yellow), cellular material (red), and ground substance (blue). Stained sections were imaged at 40× to examine for structural changes.

ACA microstructures were further examined using multiphoton microscopy using an excitation wavelength of 805 nm with a 20× water immersion objective lens. Signals from elastic fibers (495-540nm) and collagen bundles (390-420nm) were isolated using two-photon excitation and second harmonic generation, respectively. Images of the ACA cross-section and the adventitia were obtained to analyze changes in the abundance and organization of these two structural constituents.

RESULTS

Averaged circumferential stress-stretch responses for the three age groups were plotted in Fig. 1a, with corresponding average tangent stiffness of the low-pressure region in Fig. 1d. The left-ward shift in the curves indicates a progressive stiffening of the ACAs, with a significant decrease in the circumferential stretch and increase in the circumferential stress in the ≥80 age group. A stiffening trend is consistently present in the low-pressure region (Fig. 1d), although the changes are not significant.

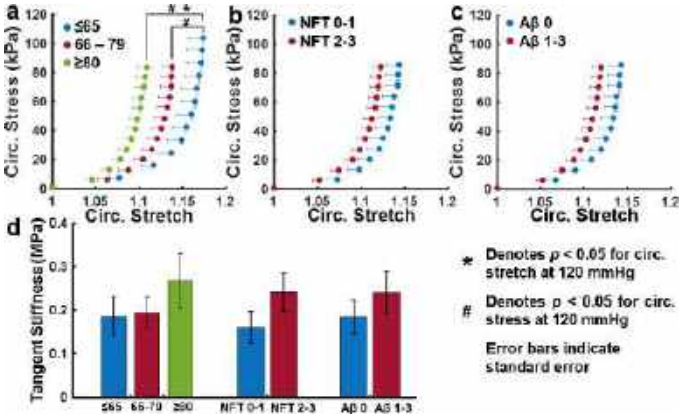

Figure 1. (a)-(c) Circumferential stress-stretch responses of ACAs, grouped by (a) age, (b) NFT formation, and (c) neuritic Aβ deposition. (d) Circumferential tangential stiffness for low-pressure region (0-20mmHg) of the stress-stretch curves in (a)-(c).

To reduce the effects of aging, mechanical testing data for samples above age 65 (n = 31) were grouped by NFT formation (Fig. 1b) and neuritic Aβ deposition (Fig. 1c). In both cases, the presence of NFTs and neuritic Aβ corresponded with decreased maximum circumferential stretch (Figs. 1b,c) and increased tangential stiffness (Fig. 1d).

Representative histological stains of the ACAs with different AD-associated neuropathological stages in Fig. 2 show the multilayered structure of the ACA consisted of the internal elastic lamina (IEL), media, and adventitia. Thinning of the media occurs due to smooth muscle cell atrophy at the media-adventitia interface, and collagen disorganization is present in the adventitia.

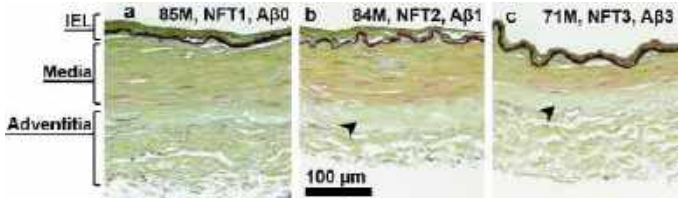

Figure 2. Histological sections of human ACAs from different neuropathological disease stages. Arrow indicates SMC atrophy.

Multiphoton images in Figs. 3a,b show the elastic (green) and collagen (red) fibers in the ACAs from a sample with moderate NFT formation and an older sample with severe deposition of NFTs and Aβ. The IEL (top) exhibits strong elastic signal while the medial elastin content is sparse. Circumferentially oriented elastic fibers populate the media-adventitia border. Adventitial collagen in Figs. 3c,d is primarily aligned in the axial direction with noticeable straightening of the collagen fiber bundles in the old and diseased sample.

DISCUSSION

This study offers new insights into the structure-function relationship of the human cerebrovasculature in neurodegenerative diseases. Our findings suggest the presence of NFTs and Aβ plaques in the frontal cortex corresponds with decreased compliance (Figs. 1b,c) and microstructural changes (Figs. 2,3) in the ACA. Effect of aging on the stiffness of the ACAs (Fig. 1a) should be carefully considered when exploring associations between the progression of AD and cerebrovascular remodeling.

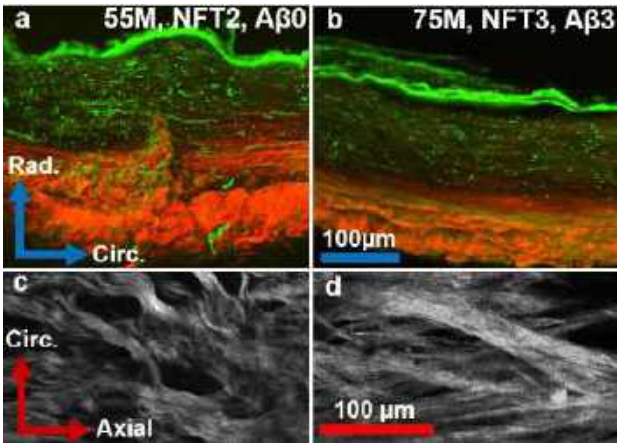

Figure 3. (a)-(b) Max. intensity projections of cross-sectional multiphoton images from ACAs of different age and disease state, showing elastic (green) and collagen (red) fibers. (c)-(d) 1μm thick multiphoton images depicting collagen fiber bundles in the adventitia, matched to samples from (a)-(b), respectively.

The stress-stretch response shows a stiffening trend for ACAs from subjects exhibiting high levels of NFT formation (Figs. 1b,d) or Aβ deposits (Figs. 1c,d). It is important to note that the frontal lobe, in part supplied by the ACA, experiences deposition of Aβ plaques during early AD development (score of 1 out of maximum 3), while NFT formation generally begins in later stages (score of 2). The different deposition patterns of Aβ plaques and NFTs was accounted for when determining the grouping methods for statistical comparisons of mechanical data.

The stiffer circumferential response of the older and diseased samples is evidenced by the shorter toe regions (Figs. 1a-c) and increased stiffness (Fig. 1d). These changes in mechanical properties are corroborated by the straighter collagen fibers seen in the multiphoton images (Fig. 3d), which would be recruited earlier to bear mechanical load than the crimped collagen fibers seen in Fig. 3c.

Changes in the medial thickness due to SMC atrophy (Fig. 2) may also affect the mechanical response of the ACAs. Decreases in perivascular innervation in cerebral arteries has been reported during AD progression [6]. Perivascular innervation provides physiological stimulus for proper blood flow control [7]. Degradation of the neurons and SMC atrophy may be associated with the subsequent microstructural and functional changes in ACA.

The findings of this study provide new insights into the mechanical response of human ACAs and the relationship between their structural remodeling and neuropathological AD development. The complex mechanisms between aging, AD progression, neurodegeneration, and cerebral arterial mechanics requires further investigation.

MECHANISM OF THE DEVELOPED PRESSURE – PRELOAD RELATIONSHIP IN EX-VIVO BEATING HEART

INTRODUCTION

The heart's developed pressure is determined primarily based on the myocardial contractile force that is dependent on the preload (or equivalently the degree of inflation) via the Frank-Starling mechanism. There is a critical transition at which developed pressure starts to decrease with increasing preload. At the myocardial tissue level, this length-dependent property is reflected by an increase in the peak twitch force with increasing muscle stretch [1]. At the cellular level, it is found that modulation of the responsiveness of the cardiac contractile apparatus to activating calcium is largely responsible for the Frank-Starling property, a regulatory mechanism that is termed myofilament length dependent activation [2]. While these studies have demonstrated the pressure-volume or force-sarcomere length relationships across different spatial scales, it still remains unclear whether these observations (at the organ and cell levels) can be directly correlated or connected [3]. This issue largely arises because it is not possible to directly measure forces developed locally by the myocytes in the beating heart. To address this issue, we developed a computational framework consisting of a left ventricular finite element (FE) model based on our previous work [4-6] to connect cellular to organ mechanics found in the *ex-vivo* beating rat heart. *We hypothesis that the saturation of developed pressure at higher preload in the heart at the organ level can be directly connected to the length-dependency of the myocyte contractile force occurring at the cellular level.*

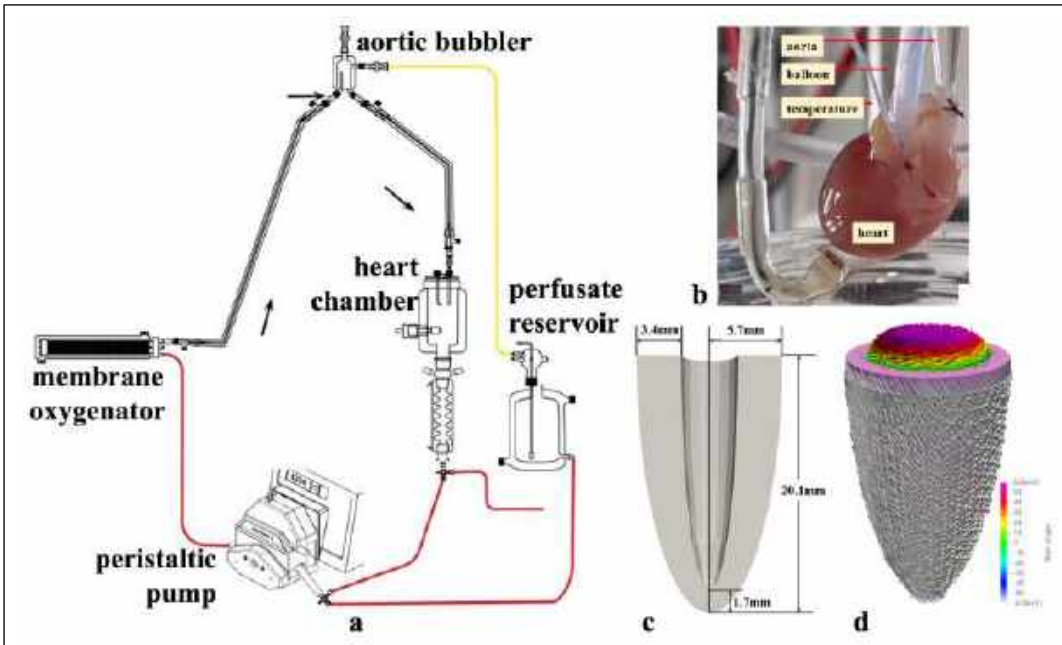

Fig 1: **a**. Schematic of Langendorff perfusion system; **b**. Configuration of the *ex-vivo* beating rat heart experiments; **c.** Idealized left ventricular geometry of a rat with its dimension; **d.** Left ventricular geometry of a rat with myofiber distribution.

METHODS

***Ex-vivo* beating heart experiments**: Approval for conducting the animal experiments using male Sprague-Dawley rat weighting 300-350 g was granted by the Institutional Animal Care and Use Committee of Michigan State University and all animal procedures were conducted in accordance with the Guiding Principles in the Care and Use of Animals.

The animals (n = 5) were first deeply anesthetized with 4-5% isoflurane after 15mins of heparin injection (100 U, i.p.). The animals were then decapitated when they were unresponsive to noxious stimuli, and their chest were opened. The heart was excised immediately from the animals and submerged in cold Krebs-Henseleit bicarbonate (KH) buffer. Then the aorta was rapidly attached to aortic cannula that is connected to an 80mmHg perfusion pressure in Langendorff perfusion system (Radnoti, US) and perfused via the Langendorff constant flow mode at a flow rate of 10 ml/min with oxygenated KH buffer at 37°C with PH 7.14 (**Fig. 1a**). The aorta root was then carefully sutured to the aortic cannula without leaking.

The heart was paced at 4 Hz by a pair of electrodes placed on the surface of the right atrium and connected to an isolated stimulator (AD Instrument). A size 6 latex balloon was inserted into the LV via the pulmonary vein that was exposed to air. A baseline case was established by inflating the balloon until the LVEDP (preload) is between to 5-15 mmHg. The heart was then stabilized for 15-20 mins. Thereafter, the preload was varied by inflating or deflating the balloon. After the heart was stabilized in each preload, the LV pressure and aortic pressure were each continuously recorded by a pressure transducer connected to the isovolumic beating heart (**Fig. 1b**). In addition to these signals, the right pressure product, temperature, and ECG were also continuously recorded in LabChart Pro (AD Instruments).

Computational Modeling: The length, wall thickness, basal inner and outer diameters measured from the rat LV were used to construct a prolate ellipsoid geometry in a finite element (FE) model of the LV (**Fig. 1c**). Myofiber orientation in the LV FE model was prescribed to vary transmurally from -60° at the epicardium to 60° at the endocardium (**Fig. 1d**). The relationship between LV pressure and volume is prescribed as $P_{LV}(t) = f(V_{LV}(t))$, where P_{LV} is decomposed to passive and active components [4]. The LV FE model was applied to simulate the *ex-vivo* beating heart under isovolumic contraction in the Langendorff preparation.

RESULTS

A representative LV pressure waveform measured during isovolumic contraction is shown in **Fig. 2a**. The measured developed pressure (DP) in the LV chamber is greater than 50 mmHg in all the rat hearts. With an increase in preload from 0 to above 65 mmHg, LVESP increases from close to 0 to 118 mmHg at the highest preload. The corresponding LV pressure waveforms were recoreded. By connecting the end-diastolic (ED) and end-systolic (ES) points at different preloads, respectively, the model predicted EDP-t and ESP-t relationships agree with the experimental measurements by increasing the preload that is controlled by inflating the balloon volume in the experiments.

The LV DP, which is the difference between LV ESP and LV EDP, varies non-monotonically with an increase in preload. Specifically, LV DP increases with preload and then decreases with preload beyond a transition point. This transition occurs when the balloon volume is between 280-340 μm (**Fig. 2c**). The computed sarcomere length at the transition point is close to 2.11 μm. The model-predicted contractile force varies similarly with preload as the LV DP with a similar transition point (**Fig. 2d**).

DISCUSSION

The mechanism of this length-tension relationship rests on the degree of overlap between the thick and thin filaments at different sarcomere lengths during cross-bridge cycling. However, it is challenging to directly connect them because of the difficulty in measuring myofiber strain and sarcomere length in the deep myocardial wall in the Langendorff preparation. To circumvent this issue, we developed an LV FE model to simulate isovolumic contraction based on the *ex-vivo* beating rat heart experiments and estimate these two quantities. The model predicted EDPVR and ESPVR at various preloads agree with the measurements from the *ex-vivo* beating rat heart experiments by varying balloon volumes (n = 5). With an increase in preload, DP increases first and then start to decrease at a critical point. At this critical value of preload, the average sarcomere length is 2.11 μm, which is close to the sarcomere length corresponding to the highest force generated by myofiber. With an increase in preload, myocardial contractility increases first and then start to decrease at the same critical point, where DP starts to reduce. This result corroborated that the DP-preload relationship is controlled by the length-tension relationship of the myocytes.

ANISOTROPIC POROUS HYDROXYAPATITE/GELATIN IMPLANTS FOR TRABECULAR STRUCTURE RECONSTRUCTION

A. Pavlov (1), J. Johnson (1), B. Gadomski (1)

(1) Orthopedic Bioengineering Research Laboratory, Colorado State University, Fort Collins, Colorado, USA

INTRODUCTION

Within the United States, it is estimated that 40% of the population suffers from foot related conditions [1]. Specifically, osteoarthritis is one of the most common with more than three million cases reported annually. This condition is most frequently reported in the first metatarsophalangeal (MTP) joint and leads to degenerative joint disease and patient pain and discomfort. In some cases, this can lead to irregularities within the toe orientation (i.e., hallux valgus). Both conditions can lead to loss of mobility [1] and severe discomfort during walking if left unchecked.

For patients who are unresponsive to non-invasive treatments for this condition, the standard of care is arthrodesis. First MTP arthrodesis is a joint fusion approach that entails removal of both articular cartilage surfaces with preparation of the bony surfaces into appropriate opposing geometries (e.g., cup and cone reaming) [2], followed by fixation of the joint using various hardware to eliminate subsequent joint motion. While the removal of cartilage and preparation of the opposing boney surfaces is requisite for successful fusion outcomes [3], it will invariably induce loss of joint length. To maintain anatomical symmetry and unaltered gait, there exists a need for a graft material capable of replacing the lost material and fusing to the bone without significantly lengthening the surgical or recovery process.

To promote cellular infiltration and rapid boney remodeling, a resorbable candidate graft material must be conducive to the design and manufacturing of a tailorable porosity, similar to the trabecular bone underlying these joint/arthrodesis surfaces. Researchers have long investigated hydroxyapatite/collagen for use in bone fusion applications (e.g., coatings for total hip replacements) as collagen has been proven to generate a structurally sound scaffold around which hydroxyapatite crystals can form [4]. These tend to be expensive, however, due to collagen availability and degeneration. Gelatin has emerged as a potential alternative, offering the same ability to create structures of controlled porosity within hydroxyapatite at a fraction of the cost. This allows for a material with mechanical properties comparable with cancellous bone, and anisotropically porous to stimulate quick bone ingrowth for arthrodesis purposes.

This work details the development of a novel biomaterial processing methodology aimed to generate a graft material suitable for use in joint fusion situations such as first MTP arthrodesis. Specifically, this work sought to determine the optimal processing techniques to produce a graft material with similar porosity and mechanical properties to human trabecular bone using a gelatin-hydroxyapatite compound.

METHODS

GEL:HAP Ratio Selection: Commercial hydroxyapatite powder was mixed with a 10% W/V solution of microbiology grade gelatin [5] in decadal concentrations ranging from 30:70 to 70:30 and stirred at 45°C for 20 minutes. After this the slurry was cast into a cylindrical silicon mold with dimensions r=0.5cm, h=0.5cm. The molds were then placed into a freezer at -20°C and left for 24 hours to solidify. From here the samples were immersed in liquid N_2 for 1 minute and lyophilized for 24 hours.

MicroCT Analysis: Micro–computed tomography (microCT) analysis was performed on the specimens using the following parameters: isotropic resolution, 37 µm; voltage, 70 kVp; current, 114 µA; and integration time, 500 ms (Scanco µCT 80; Scanco USA Inc). Following the scans, a bone trabecular morphometry analysis was performed and the density, bone volume/total volume fraction as well as pore size values were recorded.

Gelatin Crosslinking: To crosslink gelatin a solution of 1% Glutaraldehyde was made, and samples were submerged for 24 hours [5]. However, this led to over crosslinking and samples ended up brittle and cracked. To correct for this, 8 test groups of n=5 samples were created. Crosslinking was performed at 2-hour intervals, ranging from 2 to 16 hours with a 24-hour batch being used as a control. After the crosslinking was done, samples were rinsed 3 times in deionized (DI)

water before being fully submerged in DI water. After 10 minutes of soaking a compression test was run to determine mechanical toughness.

Mechanical Testing: Unconfined compression testing was performed using an MTS landmark hydraulic tester at a rate of 1mm/min up to 60% strain. Force-displacement data were utilized to generate stress-strain curves for all samples. Ultimate compressive stress and young's modulus for the 8 different crosslinking times groups were calculated.

Statistical Analysis: A one-way ANOVA with Tukey HSD post hoc test was performed using alpha = 0.05.

RESULTS

MicroCT analysis of samples revealed a linear relationship between Gel:HAp ratio and density and pore size (**Table 1**). In contrast, these data illustrate the logarithmic relationship between Gel:HAp ratio and bone volume fraction (BV/TV) and porosity (**Table 1**). Representative three-dimensional reconstruction images from microCT analysis illustrate the alterations to pore size and distribution at the extreme ends of the tested Gel:HAp ratios (60:40 **Figure 1B**, 30:70 **Figure 1C**). The 60:40 Gel:HAp samples exhibited porosity values of 0.62 most closely replicating porosity noted in human trabecular bone; as such, this group was chosen to proceed to mechanical testing/assessment of crosslinking on mechanical properties.

Mechanical testing of samples revealed a non-monotonic relationship between crosslinking time and ultimate compressive strength, with a maximum at 8-hours (**Figure 3A**). Specifically, the 8-hour group exhibited a 2-fold increase in ultimate compressive strength as compared to the 2-hour time ($p=0.0038$, **Figure 3A**). Compressive modulus was inversely proportional to crosslinking time (**Figure 3B**). A significant decrease in compressive modulus was not found between the 2- and 8-hour groups ($p=0.243$, **Figure 3B**); however, the compressive modulus significantly decreased in all groups with >10-hours crosslinking time ($p\leq0.0001$ **Figure 3B**).

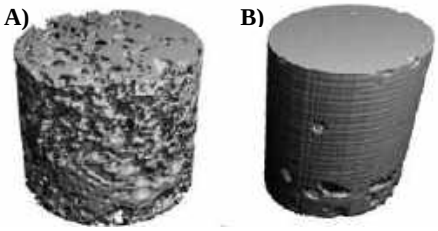

Figure 1: uCT Visualization of Pore distribution. A) 60:40 Gel:HAp ratio. **B)** 30:70 Gel:HAp Ratio

Table 1: Comparison of Gel:HAp ratio to porous properties

Gel:HAp ratio	Density (mg/mL)	BV/TV	Porosity	Pore Size (mm)
30/70	445.6	0.99	0.02	0.08
40/60	430.6	0.96	0.04	0.098
50/50	425.5	0.9	0.1	0.107
60/40	333.5	0.38	0.62	0.205
70/30	320.1	0.2	0.8	0.312

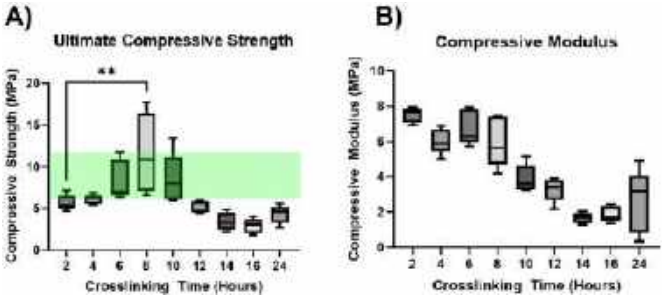

Figure 3: A) Ultimate compressive strength of 60:40 Gel:HAp samples produced with varying crosslinking times. Green band indicates reported compressive strength values of human trabecular bone [5]. **B)** Compressive modulus of 60:40 Gel:HAp samples produced with varying crosslinking times. Boxes indicate lower to upper quartile with mean, whiskers indicate minimum to maximum.

DISCUSSION

These data illustrate that by controlling compound ratio and crosslinking time, a physiologically comparable cancellous bone replacement can be created using a gelatin and hydroxyapatite slurry. This material has porous properties to allow for cellular infiltration possible through the lyophilization of the gelatin solution and crosslinking of the remaining gelatin chains within the hydroxyapatite structure.

Of important consideration is the ratio of Gel:HAp. While a higher concentration of gelatin (≥70%) yielded bigger pores, the pore distribution was uneven. Specifically, pores were located exclusively at the top of the sample and higher concentrations of HAp yielded pores that were too small (<100 μm) and lacked interconnectivity. For these reasons, a ratio of 60:40 Gel:HAp was selected to best mimic human cancellous bone conditions.

To achieve a comparable modulus and ultimate compressive strength to native cancellous bone, a crosslinking time of 8-hours produced peak compressive strength values that fell within the range of reported human cancellous bone [5]. These data also clearly indicate the potential for over-crosslinking, wherein samples became brittle and exhibited decreased strength and modulus values.

In conclusion, the current research delineates a substantial advancement in the synthesis of a Gel:HAp graft material that closely emulates the porosity and mechanical attributes of human trabecular bone. By regulating the Gel:HAp ratio and optimizing crosslinking time, we have successfully engineered a material with potential applicability as a bone surrogate in arthrodesis procedures. This innovation presents a significant step towards enhancing osteoconductivity and mechanical stability in joint fusion procedures, which may ultimately contribute to improved surgical outcomes and patient quality of life. Future explorations are anticipated to refine the fabrication process, augmenting the consistency of the graft material, while further biocompatibility assessments are poised to validate the material's efficacy in promoting osteogenic cell activity and integration within the host tissue.

A SOFT 3D MICROARCHITECTED PRESSURE SENSOR FOR URETHRAL MONITORING

N. C. Goulbourne

Aerospace Engineering, University of Michigan, Ann Arbor, MI, USA

INTRODUCTION

Urethral function in women has received little scientific attention in the past, in part due to the lack of tools to understand its function. Recent studies challenge the long held belief that urethral failure is not clinically important in stress and urge incontinence in women. For decades, urethral pressure and function has been determined using a rigid pressure probe, which fails to isolate urethral closing pressure from kinematic events due to patient-specific movement (for example, coughing). Recent advances in soft materials could enable real-time in situ monitoring of urethral muscle function and move the field forward by providing new approaches where treatment (and success rates) has been stagnant for decades. A soft sensor monitoring urethral wall activity could be the key to achieving real-time, spatially mapped recordings of urethral pressure and muscle function under physiological conditions.

We developed a novel 3D microarchitected dielectric elastomer sensor based on micropillar arrays, which has significant advantages over monolithic sensor designs explored in prior work [1]. The elastomer array is fabricated via soft nanolithography and 3D compliant electrodes are patterned directly via sputter-coating. The sensor generates projected electric fields externally and nonuniform fields within the material itself. Disturbances to these fields as well as deforming the embedded micro-architecture are the two primary mechanisms altering the capacitance of the device. Parasitic capacitance is undesirable and as such the sensor must be designed to eliminate its effects. Design flexibility exists by way of suitable selection of the electrode and dielectric materials, their macroscopic geometry and configuration, and the pillar microarchitecture. A wide range of pillar structures can be designed and fabricated whereby pillar geometry is used to tune the mechanical stiffness of the overall sensor as well as sensor sensitivity. Micropillar structures have been shown to increase response times and reduce viscoelastic effects as compared to monolithic sensors. These are two important aspects in developing soft pressure sensors.

METHODS

We developed micropillar arrays for spatio-temporal pressure sensing over extended contact areas. Our method combines soft elastomeric dielectrics with soft 3D-electrodes to create electromechanical architectures that can be tuned for different sensitivities and mechanical stiffness. Our method is based on existing soft nanolithography processes (Fig. 1) and MEMS electroding techniques making it amenable to a range of soft elastomeric materials and electrodes (from metallic powders to ionic conducting liquids and gels) [2]. The technique creates opportunities for design flexibility in material selection, device geometry, and sensor performance. Previous work on microstructured PDMS has shown its utility for pressure sensing using monolithic flat plate rigid electrodes for pressures above 1 kPa. The current work focuses on a lower pressure regime as would be experienced in evaluating urethral function.

We fabricated soft stretchable sensors based on 3D micro-architected structures of polydimethylsiloxane (PDMS) elastomers with 3D compliant electrodes deposited using a masking technique (Fig. 2). The proof of concept sensor is demonstrated using a 5 x 5 cross-grid array of overlapping 5mm x 5mm gold electrode areas. Different micropillar geometries are fabricated with dimensions on the order of 100 microns.

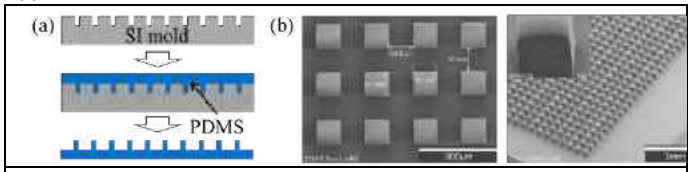

Figure 1: (a) Schematic of the PDMS molding process by replica molding. (b) SEM images of the micropillar array.

The bottom layer of the assembly is a PDMS micropillar array. Buckled metallic electrodes are deposited by sputter coating gold over the individual pillars and between the pillar gaps in a parallel line pattern using a shadow mask on the mm scale. A top monolithic PDMS film is placed on top of the Au micropillar array and is subsequently electroded (lines are orthogonal to the bottom Au layer) using a shadow mask. The electroded lines form a grid pattern.

Micropillars of various designs were fabricated: low aspect ratio pillars, high aspect ratio pillars, C-shaped pillars, and a hybrid design. These structural features influence the deformation mechanisms of the pillars and the overall sensor characteristics. The base design is a square cross-section micropillar array with a 1:1 aspect ratio. The microstructured electrode morphologies locally pattern nonuniform electric fields that amplify electrostatic phenomena. In other words, the pillar geometry can be used to tune sensor sensitivity and mechano-sensitivity. For example, we designed high aspect ratio pillars and exploit their mechanical instabilities to increase sensor sensitivity at low pressures. The integrated microstructures form a network of soft microcapacitor arrays. Future designs can be driven by rational combinations of liquid electronic conductors, ionic conducting gels, ionic conducting liquids, and stretchable metallic films.

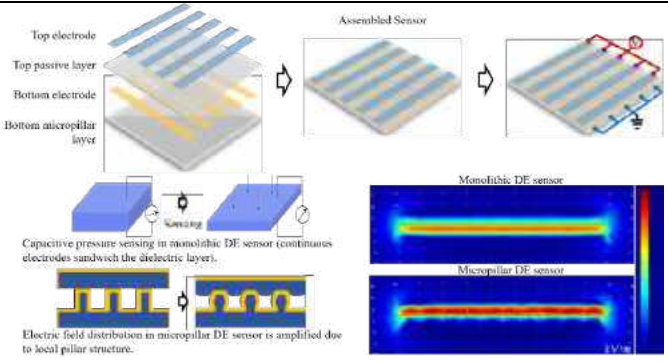

Figure 2: Microarchitected pressure sensor assembly process, capactive sensing mechanism, and electric field simulation using COMSOL.

RESULTS

Sensor performance was evaluated over a range of pressures 100 Pa – 10 kPa for several sensor designs. The base design is a square cross-section micropillar array with a 1:1 aspect ratio. High aspect ratio pillars are designed for bending, C shaped pillars are designed for elastic buckling at low pressures, and a hybrid pillar array composed of multi-level pillars is designed to maximize sensitivity using multiple contact levels through a combination of 3 high aspect ratio pillar designs. The hybrid design has the highest sensitivity over all the pressure ranges tested followed by the high aspect ratio C-shaped pillar arrays.

Precise capacitance measurements were made with a table-top capacitance meter (Model 3000, GLK instruments, 7.4 Hz). The response time of the sensor was measured using a capacitance to digital converter (EVAL-AD7746EBZ, Analog Devices) with a 90 Hz sampling rate. Figure 3 shows the cyclic off and on response of a square cross-section micropillar array due to pressure. Figure 3 shows the typical input/output traces between the applied force and the measured capacitance change. The time scale characteristics of the micropillar array was measured using a digital converter (EVAL-AD7746EBZ, Analog Devices) circuit. For a typical sensor of square geometry and 1:1 aspect ratio, the sensor response time is 60.8 ms. The response time is defined as the time interval between 10% and 90% of the steady state values. We studied the influence of gap distance, cross-section shape, and aspect ratio. Based on these studies, a novel hybrid design was proposed with over 300% increased sensitivity of 0.34 kPa^{-1} and a broad pressure sensing range up to 10kPa with a single sensor platform (i.e. without modifying the structure).

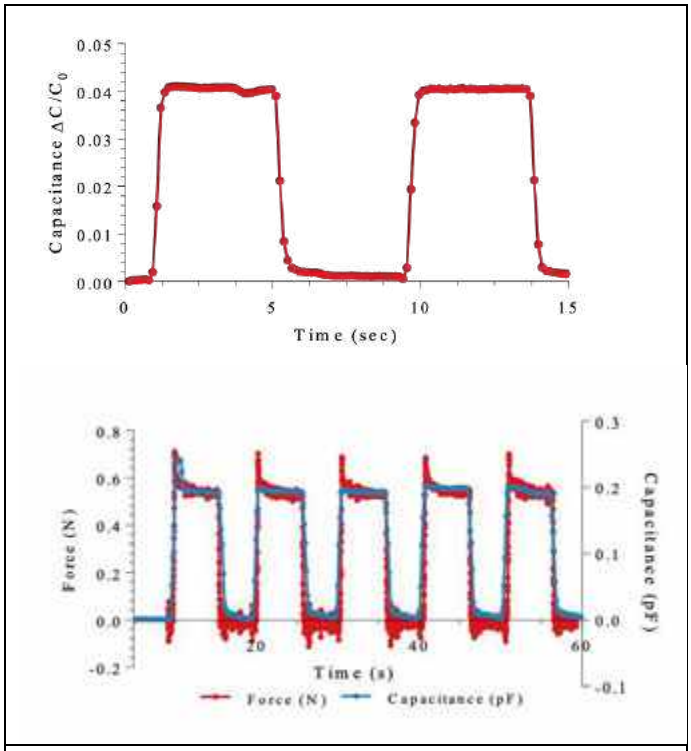

Figure 3: Results for (1:1 aspect ratio, square cross-section, 200µm gap) sensor: (top) Capacitance versus time graph. (bottom) Capacitance and force versus time graph. The response time is 60.8ms.

DISCUSSION

A 3D microarchitected pressure sensor for functional monitoring was developed using well-established fabrication techniques. As a proof of concept, soft Au/PDMS micropillar arrays were fabricated using soft nanolithography and electro-sputtering methods. The sensing response is repeatable and the response time (60.8ms) is comparably fast for capacitive sensors. Also, the resulting system is both flexible and stretchable. These preliminary results highlight this sensor technology as a promising candidate for continuous biomedical monitoring.

INTRODUCTION

Lung injuries such as ventilator-induced lung injury (VILI) and radiation-induced lung injury (RILI) can lead to heterogeneous alterations in the biomechanical behavior of the lungs [1]. For clinical applications, organ-level biomarkers such as X-ray imaging and plethysmography are the most commonly used methods for diagnosing lung injuries and estimating lung function. However, plethysmography measurements represent average metrics across both lungs (global lung function). X-ray imaging may fall short of providing mechanistic and prognostic insights into local lung injuries, especially given their heterogeneous nature. Thus, there remains a need for a regional biomarker to predict the onset and progression of lung injuries due to injury-induced factors such as mechanical ventilation and radiation.

We hypothesize that alveolar septal wall stress (SWS), as a regional biomechanical factor in lung function, plays a key role in the onset and progression of lung injuries. In this study, we aim to estimate SWS from dynamic imaging. Dynamic imaging (or imaging at end-inspiration, EI, and end-expiration, EE) processed by image registration, can provide regional strains at a mesoscale in the lung. Multiscale modeling, incorporating parenchymal microstructure, constitutive tissue models, and mesoscale strains, can estimate SWS accurately [2]. To overcome the challenges of computationally prohibitive multiscale full lung modeling and offer a translational tool for SWS estimation, we propose to use machine learning to both enhance the alveolar architecture databases and estimate SWS directly from strains without the need for finite-element modeling.

METHODS

The lungs of a healthy Sprague-Dawley (SD) rat were fixed, and X-ray microtomography (μCT) imaging was performed to reconstruct the parenchymal microstructure. Cubes of side ~1mm were isolated to serve as the representative tissue element (RTE), for in-silico simulations and training of the ML model. Several RTEs were used for in-silico simulations and to train the ML model. For each simulation, the stretch values were specified on the surface boundaries of the RTE (Fig. 2A). The stretch values were set through Latin hypercube sampling, and 200 simulations were performed for each RTE. The alveolar skeleton in parenchymal tissue was modeled as an incompressible Neo Hookean material.

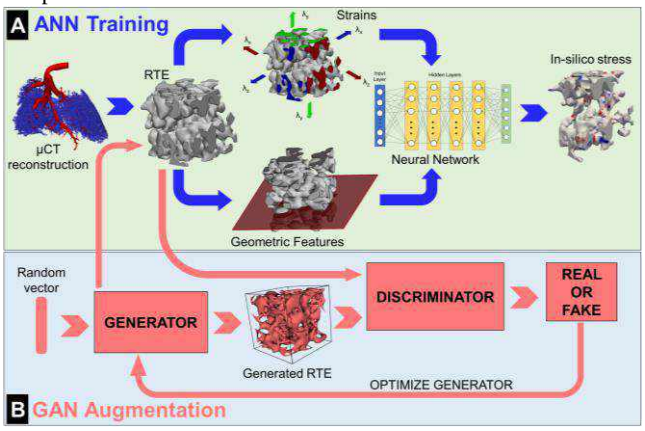

Figure 1: Training of neural network and GAN augmentation of RTE geometry.

Since there is a non-linear relationship between the stresses and strains, we used a multi-layer perceptron (MLP) for this work (Fig. 1A). The input features for the ML model consisted of stretch values and geometric features such as volumetric and cross-sectional area porosity. The output features were the six unique stress values in the stress tensor. The model was trained for 500 epochs with the loss function set to mean absolute error (MAE).

The knowledge of parenchymal microstructure remains a limitation of this approach. To mitigate this limitation, we have used generative networks to create a large synthetic parenchymal microstructure based on realistic inputs. We used a generative

adversarial network (GAN) to generate synthetic RTE geometries based on segmented RTE cubes (Fig. 1B). The components of the GAN were based on a study by Kwon et al [3]. To determine the quality of the RTEs generated by the GAN generator, we performed principal component analysis on the synthetic and actual RTEs.

We used dynamic imaging and image registration from our previous work [4] to calculate strains. Briefly, four-dimensional (4D) computed tomography (CT) scans were obtained for a healthy SD rat placed under isoflurane anesthesia. We used non-linear non-rigid image registration to obtain voxel-based displacement during respiration and, subsequently, the strain. The strains, along with geometric features estimated from voxel intensity, were used as inputs to the trained MLP to estimate SWS across the lungs during inspiration.

RESULTS

The maximum stress occurred in thinner regions and parts of the alveolus prone to stress concentration (Fig. 2B). When training the MLP, the loss function plateaued around 200 epochs (Fig. 2C). The accuracy of the ML was 75.3% for the average normal stress (Fig. 2D). However, training accuracy was increased to 84% when considering only RTE2 and RTE3.

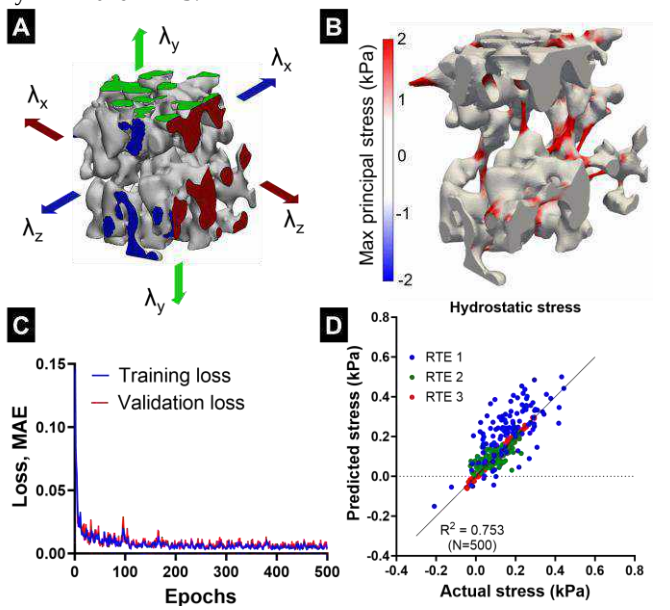

Figure 2: (A) Triaxial stretching of RTE resembling RTE deformation during inspiration. (B) Maximum principal stress in RTE from representative simulation. (C) Training and validation loss during training. (D) Comparison between predicted and actual average normal stress.

When the first two principal components were plotted against each other, the actual and synthetic data occupied the same region (Fig. 3A), indicating that the GAN model can produce RTEs that are quantitatively similar to the actual RTEs obtained from segmentation (Fig. 3B). At end-inspiration, the hydrostatic strain in the lungs was ε=0.15 (Fig. 3C) and the corresponding average stress value was σ=0.32 kPa (Fig. 3D).

DISCUSSION

Through the in-silico simulations, we observed that the maximum stress is two orders of magnitude larger than the average stress in the RTE. This indicates that the parenchymal microstructure is essential to accurately estimate regional SWS in the lungs during respiration. Hence, generating a wide variety of physiologically realistic RTEs becomes a crucial step towards accurately estimating SWS. Towards this end, the GAN method, generating a large number of synthetic but realistic RTEs, serves as a tool to augment the quality and quantity of the training data used in the MLP. This effectively overcomes the difficulty of reconstructing parenchymal microstructure from μCT imaging and potentially increases the quality of generated RTEs.

Lung injuries, such as VILI and RILI, can cause significant heterogeneities in ventilation, leading to additional injuries in the healthy regions. The combination of SWS and kinematic biomarkers, such as strain, can enable an improved understanding of the progression of lung injury. In addition, the method presented in this study has the potential to be applied to optimize mechanical ventilation settings and clinical intervention strategies in humans. We note that while dynamic CT scans are commonly avoided in human patients due to excessive radiation, lung strains can be obtained through static CT scans taken at EE and EI and our method can certainly be extended to accommodate this limitation.

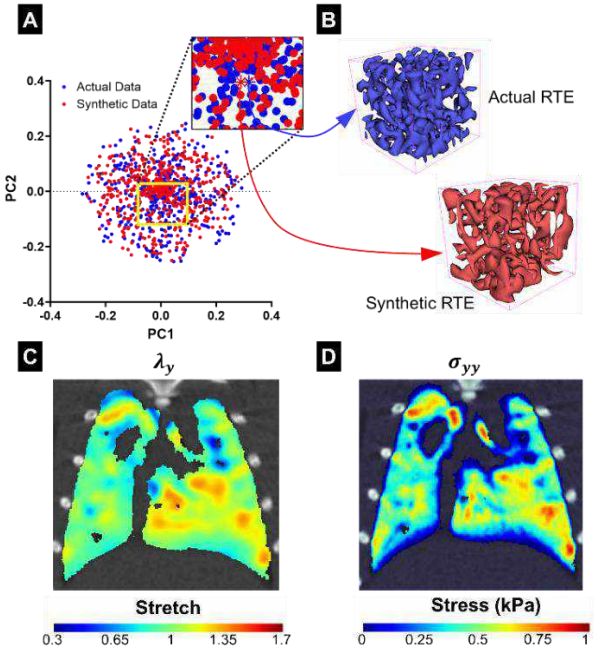

Figure 3: (A) Principal components for segmented and synthetically generated RTEs show excellent agreement. (B) Representative RTEs from each group. (C) Stretch estimated from 4D image registration. (D) Representative stress contour estimated from the MLP model.

In this study, we have presented an integrated ML-imaging-based method to estimate septal wall stress as a critical, but overlooked, regional biomechanical marker to understand and predict the heterogeneous nature of lung injuries. The machine learning model was trained using synthetic data from in-silico simulations of RTEs obtained from μCT imaging. In addition to the RTEs obtained through segmentation and reconstruction, we have presented a method to augment the number of RTE geometries through GAN to enhance the application potential of our ML model. We expect SWS to serve as an important biomarker to identify lung regions at risk of injuries in VILI and RILI.

INTRODUCTION

Denatured collagen is prevalent in various conditions, including age, cancer, osteogenesis imperfecta, osteoarthritis, osteoporosis, and diabetes or mechanical damage [1]. In these conditions, denatured collagen molecules usually result in a local unfolding or unwinding of the collagen triple helix. This unfolding might be caused by breaking a small number of consecutive hydrogen bonds. Collagen denaturation increases the fracture risk and reduces bone's resistance to fracture [2]. The primary approach for determining fracture risk involves evaluating bone mineral density and comparing it to a reference population. However, to thoroughly assess the risk of fractures, it is essential to consider bone mineral density and examine collagen integrity. Ex vivo, collagen denaturation can be measured by a destructive, time-consuming technique called trypsin-hydroxyproline assay. This technique is the gold standard for measuring a quantity but does not allow localization of denatured collagen. This study investigates a novel method to quantify and localize collagen denaturation in bone using collagen hybridizing peptide (CHP). CHP has been used in soft tissues such as tendons, arteries, etc. It is a peptide that specifically binds to denatured collagen and is labeled with a fluorescent head. This study aims to prove that R-CHP can be used in mineralized tissue, such as bone, and that this method can be applied to quantify denatured collagen in a heat treatment model that mimics collagen unfolding in several conditions, such as diabetes or aging.

METHODS

Sample preparation: Bovine bone was cut and polished to 0.5 x 1.5 x 15 mm beams. Samples (n=5/group) were placed in a furnace heated at 150°C for 15 min, 30 min, 1 h, and 2 h to denature mineralized collagen. Samples were rehydrated after the heat treatment.
CHP staining: Samples were stained in 5μM R-CHP solution for 24 h, then rinsed five times for 10 min each.
Confocal imaging: Samples were imaged using a Leica SP8 confocal microscope. Captured images were thresholded using ImageJ to obtain mean pixel intensity values.
CHP microplate assay: After imaging, R-CHP fluorescence was measured in a microplate assay.
Trypsin-hydroxyproline assay: Samples were digested by proteinase K, and the percentage of denatured collagen was measured by absorbance.

RESULTS

Mineralized collagen undergoes denaturation at temperatures around 150°C. The trypsin-hydroxyproline assay revealed that samples subjected to heat treatment at this specific temperature for durations of 15 minutes, 30 minutes, 1 hour, and 2 hours exhibited a statistically significant increase in collagen denaturation (+2495% increase for 2 h vs control) (figure: 1). When employing R-CHP, a peptide that binds to denatured collagen, we observed an increased fluorescence through confocal imaging (+100.8%) (figure: 2). This finding was subsequently validated through a microplate assay that measured the fluorescence of digested samples (+96.3%) (figure: 3). Finally, a calibration curve showing the relationship between trypsin-hydroxyproline collagen denaturation and CHP microplate fluorescence showed a positive correlation (R^2=0.90) (figure: 4).

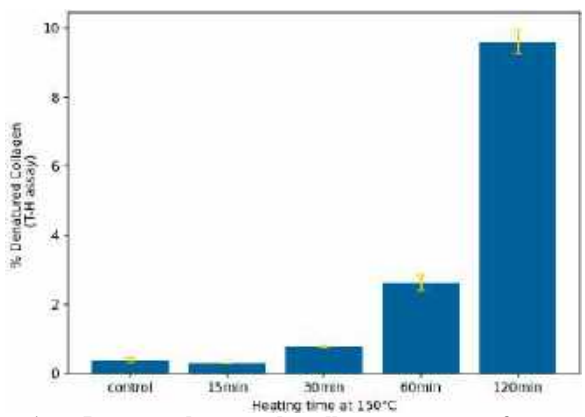

Figure 1: Percent denatured collagen content from trypsin-hydroxyproline assay

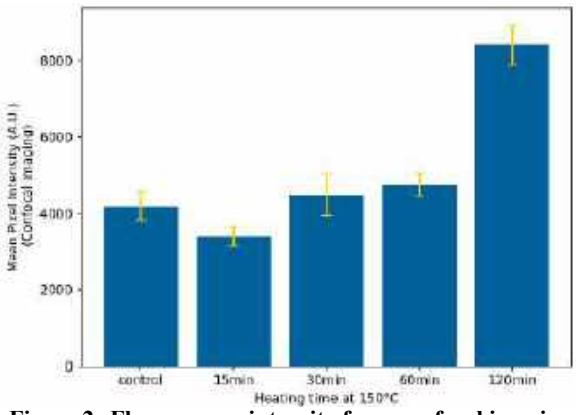

Figure 2: Fluorescence intensity from confocal imaging

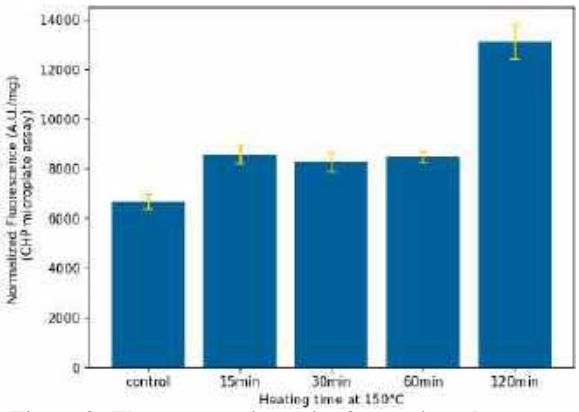

Figure 3: Fluorescence intensity from microplate assay

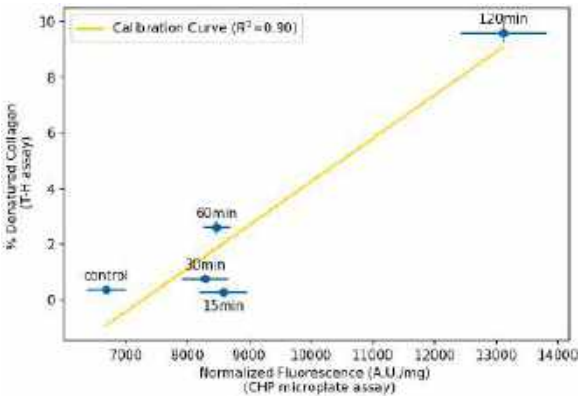

Figure 4: Correlation between percent denatured collagen and fluorescence intensity

DISCUSSION

We showed that R-CHP can be used in mineralized tissues to quantify collagen denaturation. R-CHP was shown to be able to be used in soft tissues such as tendons, ligaments, arteries, etc, but opening this method to hard tissues such as bone is promising for future research. The increase in mineralized collagen denaturation measured by the gold standard, destructive technique – trypsin-hydroxyproline assay – positively correlates with the fluorescence intensity from bone samples stained with R-CHP (R^2=0.90). The heat treatment model used in this study increased the denaturation content in every group except at 15 minutes. This could be due to the time for the oven to stabilize at 150°C after loading the samples and the time for the samples to reach the set temperature. We chose 150°C because denaturation of mineralized collagen in cortical bone has been shown at temperatures between 150°C and 160°C. Having a non-destructive method that can quantify and localize collagen denaturation in bone is an important result. Localizing regions of high denaturation will be compared with other bone quality factors. Studying the effect of diseases, such as diabetes, on collagen denaturation is important for understanding the mechanisms related to reduced toughness in diabetic bones. Future studies will evaluate collagen denaturation under various loading conditions, aiming to uncover the influence of strain on the denaturation process. Finding a non-destructive way to quantify and localize collagen denaturation in bone, and hence an indicator of bone quality, would be beneficial to assess the fracture risk in patients affected by diseases such as diabetes.

ACKNOWLEDGEMENTS

INCREMENTAL OVERSTRETCH INCREASES FAILURE VALUES OF CEREBRAL BLOOD VESSELS

INTRODUCTION

Blood vessels play an important role in maintaining the health of the body, but their function can be compromised by injury. A deeper understanding of vessel damage mechanics is critical to defining mechanisms of injury in and recovery from events like traumatic brain injury and procedures like balloon angioplasty. The development of damage models is particularly important to the prediction of injury processes.

Experiments in our laboratory show that overstretching of cerebral blood vessels results in softening, a persistent change in mechanical properties that likely alters subsequent vessel performance. These experiments show that softening increases with overstretch [1,2]. However, previous experiments also showed that overstretch did not reduce failure properties when samples were stretched to failure following an overstretch [1].

Incremental creep experiments have been used to define the contributions of both discontinuous and continuous softening mechanisms in tendon damage [3]. Using a similar incremental protocol, we subjected cerebral vessels to various amounts of incremental axial overstretch, with the goal of defining how such loading influenced vessel mechanical response, including at failure. Based on our previous research, we expected significant changes in sub-failure stress-stretch behavior but that failure values would be unchanged.

METHODS

Tissue and sample preparation:

Six sections of middle cerebral arteries (MCA) were dissected from 2 adult sheep heads based on the rules established by the Institutional Animal Care and Use Committee at the University of Utah. Immediately after removing the brains from heads, the MCA sections were dissected and placed in phosphate-buffered saline (PBS) until testing. Any side branches were ligated with unwound 6-0 silk suture. Cross-sectional rings cut from the ends of each sample were imaged to provide reference wall dimensions.

Testing apparatus:

The arteries were mounted and attached to two cannulas made of hypodermic needles using 6-0 silk sutures. Cyanoacrylate glue was applied on the distal sides of the sutures to secure the vessels to the cannulas. The specimens were bathed in PBS during testing. One of the cannulas was mounted to a 50-g capacity load cell on the fixed end of the tester, and the other cannula was attached to a voice coil linear actuator with a built-in encoder to monitor displacements. The tester was equipped with a camera mounted on a light microscope to record images during the test. A pressure transducer at each end of the artery monitored the luminal pressure of the vessel. Target pressures were maintained via a syringe pump operating on a closed-loop feedback controller for preconditioning and then changed to a simple PBS column at the desired pressure for the uniaxial tests. Test control and data acquisition were performed with a custom LabVIEW program.

Testing protocol:

Vessels were preconditioned by oscillating the luminal pressure between 6.7 and 20 kPa for five cycles while the vessel length was held constant. Pressure cycles were repeated at gradually increasing lengths until the *in vivo* length (IVL) was identified [4]. The final preconditioning process was conducted at a stretch of 1.05 times IVL.

After preconditioning, vessels were tested using one of two axial-stretch protocols. In Protocol 1, a vessel was cyclically stretched from a slightly buckled configuration to the IVL five times. It was then similarly stretched to 1.05 times IVL for five cycles, then to 1.10 times IVL five times, and so forth, until the vessel ruptured.

In Protocol 2, we applied the same incremental cyclic overstretch procedure described in Protocol 1 but only up to a stretch of 1.2, 1.3, 1.4, 1.5, 1.6, or 1.7. Samples were then stretched to failure.

Data analysis:

Data were collected from the encoders, the load cell, and pressure transducers at a sampling rate of 500 Hz. Load cell data were smoothed using a phaseless, fourth-order Butterworth filter. Stretch was measured using suture-to-suture distances. Reference outer (D_e) and inner diameter (D_i) were measured from cross-section images. The camera mounted on the tester recorded images at a frequency of 3 Hz. The collected data were used to determine stretch – referencing IVL – and first Piola-Kirchhoff stress.

RESULTS

Protocol 1 produced a set of stress-stretch curves with gradually increasing stress and stretch values up to the point of vessel rupture (Figure 1). As is true of our recent findings on vessel softening, the slope of the curve at the IVL consistently decreased with overstretch. However, the maximum slope of the curve increased with overstretch up to 1.65 times IVL and then started to decrease. Also, ultimate failure did not occur until stretch and stress values of 1.9 and 4 MPa, respectively. Previous research characterizing failure values of sheep cerebral arteries [5] reported that the average stretch values at maximum stiffness for juvenile and adult sheep were 1.42 to 1.53, respectively, and that failure stretches and stresses were 1.8 and 1.6, and 3.5 and 2.5 MPa, respectively. Though tested in a single specimen only, these relatively high values led us to revise our hypothesis to state that incremental overstretch increases vessel failure stress and stretch values.

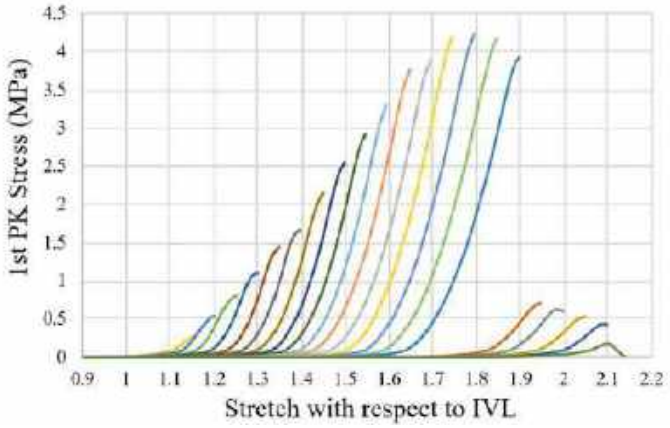

Figure 1: Stress-stretch of the first loading ramp of each set of loading cycles during incremental overstretch in Protocol 1 (stretch is referencing the IVL: 1 on the x-axis shows the IVL).

Protocol 2 resulted in similar sets of stress-stretch curves, though only up to the targeted overstretch values, followed by stretch to failure (only the failure curves are shown in Figure 2). As shown, more extensive incremental overstretch led to larger ultimate stretch values, except for the test with a 1.2 times IVL overstretch. A similar increase in failure stress was also observed in some of the specimens, especially considering that the 1.7 case had been stretched beyond its point of ultimate stress.

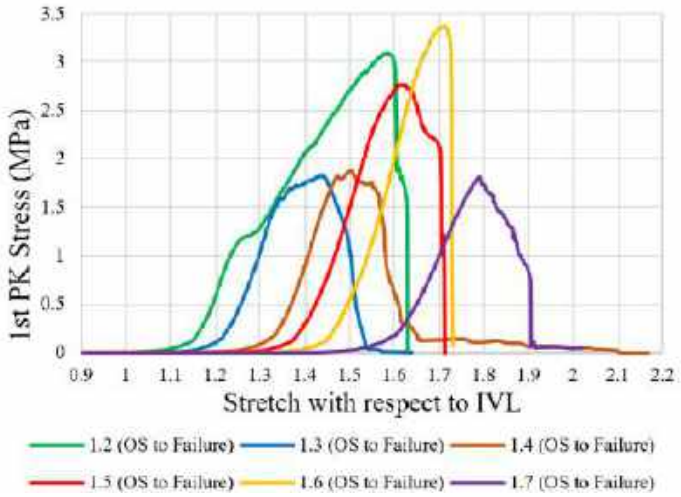

Figure 2: Failure stretch curves following incremental overstretch to 1.2, 1.3, 1.4, 1.5, 1.6, and 1.7 × IVL using Protocol 2

DISCUSSION

This preliminary study aimed to define how incremental loading influences cerebral artery mechanical response. While additional data clearly need to be collected and considered, these preliminary findings suggest that failure values increase with incremental overstretch. This was unexpected, primarily because it seems logical that tissue that has been previously damaged would be more susceptible to further damage and failure, rather than less so. Our previous experiments also showed that a single overstretch did not change failure properties, so we did not expect repeated, and incrementally increasing, overstretch to improve failure properties.

Reasons for this observation are currently unknown, but it seems that repeated, subtle increases in overstretch may serve to reorganize extracellular matrix fibers such that they are more efficiently recruited during loading, perhaps by reducing dispersion of fibers. If this is the case, the mechanical softening observed at lower stretch values may be a manifestation of reorganization rather than structural disruption. As such, this process may be similar to preconditioning, though preconditioning is not typically performed to levels of deformation that significantly exceed typical physiological loads. In any case, these preliminary results provide interesting insights into soft tissue response to overstretch, but additional experiments are clearly needed to confirm these findings and to investigate their associated mechanisms.

AN INTERPENETRATING-NETWORK THEORY OF THE CYTOSKELETAL NETWORKS IN LIVING CELLS

Haiqian Yang (1), Ming Guo (1)

(1) Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

INTRODUCTION

Under many physiological and pathological conditions such as division and migration, cells undergo dramatic deformations, and their mechanical integrity is supported by cytoskeletal networks (i.e. intermediate filaments, F-actin, and microtubules). Recent observations of cytoplasmic microstructure indicate interpenetration among different cytoskeletal networks, and micromechanical experiments have shown evidence of complex characteristics in the mechanical response of the interpenetrating cytoskeletal networks of living cells, including viscoelastic, nonlinear stiffening, microdamage, and healing characteristics [1]. However, a theoretical framework describing such a response is missing, and thus it is not clear how different cytoskeletal components with distinct mechanical properties come together to build the overall complex mechanical features of the cytoskeletal networks.

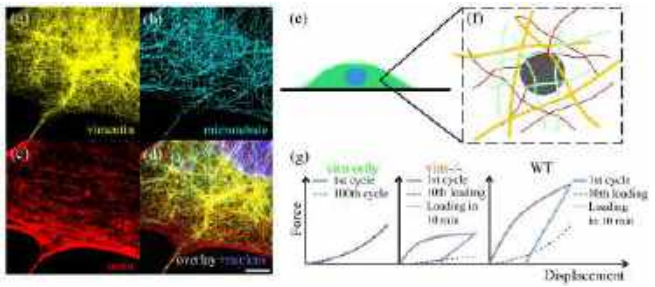

Figure 1: Confocal image of (a) vimentin intermediate filament, (b) microtubule, (c) F-actin, and (d) overlay of a mouse embryonic fibroblast [1]. (Scale bar, $5\,\mu$m). Schematics: (e) A cell. (f) Interpenetrating cytoskeletal fibers. Intermediate filaments (green), F-actin (red), and microtubule (yellow). In an optical-tweezers measurement, a micron-size particle (grey) is perturbed within the cytoplasm. (g) Force-displacement response of vim only, vim-/-, and WT. Multiple cycles are applied. After 10 cycles, the particle stays in its original position for 10 minutes before another loading is applied.

In this work, we address this gap by developing a finite-deformation continuum-mechanical theory with a multi-branch visco-hyperelastic constitutive relation coupled with phase-field damage and healing. The governing equations are derived from the principle of virtual power and free-energy imbalance [2, 3]. Here a summary of the theory is provided.

METHODS

We identify a body B with the region of space it occupies in a fixed reference configuration, and denote by $\mathbf{X}$ an arbitrary material point of B. A motion of B to the deformed body $\mathcal{B}$ is then a smooth one-to-one mapping $\mathbf{x} = \boldsymbol{\chi}(\mathbf{X}, t)$ with the deformation gradient given by $\mathbf{F} = \nabla\boldsymbol{\chi}$. The force balance is

$$\operatorname{Div}\mathbf{P} = \mathbf{0}, \tag{1}$$

where the Piola stress $\mathbf{P}$ is given by $\mathbf{P} = 2\mathbf{F}\frac{\partial\Psi_{\mathrm{R}}}{\partial\mathbf{C}}$, where Ψ_{R} is the free energy per unit reference volume and $\mathbf{C} = \mathbf{F}^{\top}\mathbf{F}$ is the right Cauchy-Green tensor.

To account for the combined effects of nonlinear elasticity, visco-relaxation, damage, and healing in the interpenetrating networks of vimentin intermediate filaments with F-actin and microtubules, we propose the following form of the free energy

$$\Psi_{\mathrm{R}} = \underbrace{\Psi_{\mathrm{R}}^{eq}(\bar{\mathbf{C}})}_{\text{vimentin}} + \underbrace{g(\mathsf{d})}_{\text{damage}}\ \underbrace{\Psi_{\mathrm{R}}^{neq}(\bar{\mathbf{C}}, \{\mathbf{A}^{(i)}\})}_{\text{F-actin/microtubule}} + \Psi_{\mathrm{R}}^{vol}(J) + \Psi_{\mathrm{R}}^{nonlocal}(\nabla\mathsf{d}), \tag{2}$$

with $J = \det\mathbf{F}$ the volumetric deformation, $\bar{\mathbf{C}} = J^{-2/3}\mathbf{C}$ the distortional deformation tensor, $\{\mathbf{A}^{(i)}\}$ $(i = 1, 2)$ two tensorial symmetric and positive definite internal variables that quantify a long-time and a short-time visco-relaxation, d a positive scalar damage variable ($\mathsf{d} = 0$ intact; $\mathsf{d} > 0$ damaged), and $\nabla\mathsf{d}$ the gradient of the damage field. The degradation function $g(\mathsf{d})$ progressively damages the energy-carrying capacity of the F-actin/microtubule networks as the damage variable d increases, and in this work takes the form of an exponential decay function $g(\mathsf{d}) = e^{-\mathsf{d}}$.

The equilibrium energy $\Psi_{\mathrm{R}}^{eq}(\bar{\mathbf{C}})$ accounts for the nonlinear stiffening of the elastic vimentin intermediate filaments, and is given by $\Psi_{\mathrm{R}}^{eq} =$

$\frac{G_{eq}}{2b}\exp\left(b(\bar{I}_1-3)\right)$ [4], with G_{eq} the equilibrium shear modulus b a nonlinear stiffening coefficient, and $\bar{I}_1 = \mathrm{tr}\bar{\mathbf{C}}$.

The non-equilibrium energy $\Psi_{\mathrm{R}}^{neq}(\bar{\mathbf{C}}, \{\mathbf{A}^{(i)}\})$ accounts for the viscoelasticity of F-actin and microtubule, and is given by $\Psi_{\mathrm{R}}^{neq} = \sum_{i=1}^{2} \frac{1}{2} G_{neq}^{(i)} \left(\left(\mathbf{A}^{(i)} : \bar{\mathbf{C}} - 3 \right) - \ln \left(\det \mathbf{A}^{(i)} \right) \right)$ [5], where $G_{neq}^{(i)}$ is the non-equilibrium shear modulus of the ith viscoelastic branch.

The volumetric energy $\Psi_{\mathrm{R}}^{vol}(J)$ accounts for the compressibility of the whole material, and is given by $\Psi_{\mathrm{R}}^{vol} = \frac{1}{2}\kappa(J-1)^2$, with κ the bulk modulus.

The damage gradient energy $\Psi_{\mathrm{R}}^{nonlocal}(\nabla \mathsf{d})$ accounts for energy stored in the process zone of the damaged F-actin and microtubule filaments, and is given by $\Psi_{\mathrm{R}}^{nonlocal} = \frac{1}{2}\psi^* \ell^2 |\nabla \mathsf{d}|^2$ [2], where ψ^* is the energy density stored in the damage process zone and ℓ is the length scale associated with the damage process zone.

The visco-relaxation internal variable $\mathbf{A}^{(i)}$ evolves according to

$$\dot{\mathbf{A}}^{(i)} = \frac{1}{\tau^{(i)}}(\bar{\mathbf{C}}^{-1} - \mathbf{A}^{(i)}), \qquad (i = 1, 2), \tag{3}$$

where $\tau^{(i)}$ is the relaxation time scale of the ith viscoelastic branch.

To account for the damage and healing process of F-actin and microtubule networks, we propose the following form of the evolution equation for the damage variable d

$$\underbrace{\zeta \dot{\mathsf{d}}}_{\text{dissipative}} = \underbrace{e^{-\mathsf{d}} \Psi_{\mathrm{R}}^{neq}(\bar{\mathbf{C}}, \{\mathbf{A}^{(i)}\}) + \psi^* \ell^2 \triangle \mathsf{d}}_{\text{energetic}} - \underbrace{\frac{\zeta}{\tau_H}\mathsf{d}}_{\text{heal}}, \tag{4}$$

where ζ is a material parameter controlling the rate of damage and τ_H is the healing time scale. This evolution equation states that damage d in the non-equilibrium branch increases due to mechanical deformation and gradient effects, and decreases due to healing.

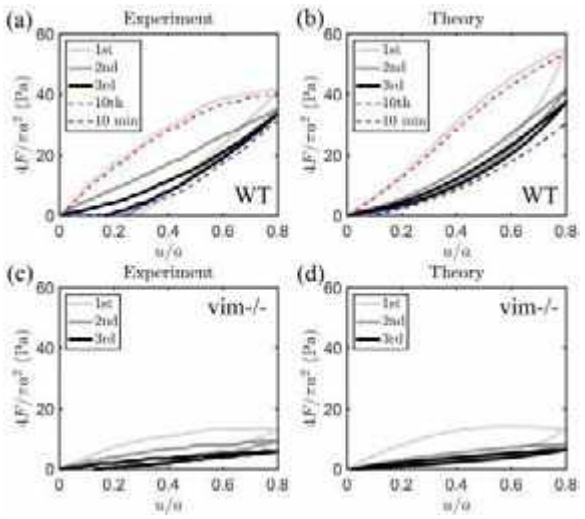

Figure 2: Damage and healing of interpenetrating cytoskeletal networks in the WT cells and the cytoskeletal networks in the vimentin knock-out cells. Cyclic loading damages the viscoelastic network and reveals the elastic-stiffening network, in both (a) experiment and (b) theoretical prediction. The non-equilibrium network is damaged with 10 cycles of loading, while it almost fully heals in 10 minutes, in both (a) experiment and (b) theoretical prediction. 1st, 2nd, 3rd: the first, second, and third loading-unloading cycle; 10th: the tenth loading; 10 min: loading in 10 minutes after the initial ten cycles are finished. Multiple-cycle damage of vim-/- cytoskeletal networks in (c) experiment and (d) theoretical prediction. Experimental data from [1].

We implemented our theory in the finite element program FEniCS [6, 7]. In our simulations, a rigid spherical particle (diameter $a = 1\,\mu\mathrm{m}$) within a cylindrical matrix (diameter and height both $20\,\mu\mathrm{m}$) is displaced in the axial direction to a maximum distance of $0.8\,\mu\mathrm{m}$ at a constant speed $1\,\mu\mathrm{m/s}$, then unloaded at the same speed to the initial position. Multiple-cycle loading-unloading is applied. Our simulations predict the force F on the particle as a function of displacement u, which we then compare with experimental force-displacement data of eukaryotic cytoskeletal networks using optical tweezers in [1].

RESULTS

We explore the damage and healing of WT cells with interpenetrating cytoskeletal networks. We find that the model is capable of describing multiple-cycle hysteresis as well as healing of WT interpenetrating cytoskeletal networks. We demonstrate that cyclic loading-unloading reduces the load-carrying capacity of the cytoskeletal network, and the force-displacement cycle gradually degrades from a viscous-dominated cycle to a hyperelastic-dominated cycle (Fig. 2(b)), consistent with experiments shown in Fig. 2(a). For the healing test, we hold the particle at the initial position for 10 minutes at the end of the 10-cycle loading-unloading, before another loading is applied. Remarkably, the cytoskeletal network restores its load-carrying capacity in 10 minutes, which is captured by the model (Fig. 2(b)) and consistent with the experiment (Fig. 2(a)).

We further test the predictive capabilities of the model by numerically "knocking out" the vimentin intermediate filament network. To do so, we use exactly the same material parameters of the WT and remove the hyperelastic branch. The numerical results nicely capture the behavior of the experimental results measured in vim-/- cells (Fig. 2(c&d)). Consistent with experimental observations, the load-carrying capacity is dramatically reduced after removing the hyperelastic vimentin network (Fig. 2(c&d)).

DISCUSSION

We have idealized the microstructure of the cytoskeletal networks in living cells as an interpenetrating network of intermediate filaments, F-actin, and microtubules. Motivated by this physical picture, we then formulated a finite-deformation continuum-mechanical theory for the cytoskeletal networks which comprises a tough, stretchable, and stiffening primary network in combination with a viscoelastic, damageable, and healable secondary network. We demonstrated that the theory and accompanying numerical implementation capture the micromechanical response, damage and healing of eukaryotic cytoskeletal networks within living cells undergoing mechanical deformation via optical tweezers. These results help to interpret the interactions between the individual networks and explore the contributions from viscous relaxation, elastic stiffening, damage, and healing. The theory and accompanying numerical implementation represent significant advances in understanding and predicting the complex mechanical behavior of the cytoskeletal networks in living cells under large deformations. More generally, the theoretical framework holds great potential for modeling cellular mechanical behaviors under large deformations involved in many other biological processes.

CHANGES IN GENE SPATIAL EXPRESSION, STRUCTURE AND FUNCTION IN RESPONSE TO ALTERED MECHANICAL STRESS IN A MURINE MODEL OF BICUSPID AORTIC VALVE

Hail B. Kazik (1), Julie Kessler (2), Carol Mattern (2), Joy Lincoln (2,3), John F. LaDisa, Jr. (1, 2, 3).

INTRODUCTION

Bicuspid aortic valve (BAV) is the most common congenital cardiovascular defect and is characterized by formation of two, rather than three, leaflets.[1] Approximately 50% of BAV patients prematurely develop calcification and aortic stenosis (AS) by the age of 35, which is more severe with fusion of the right and noncoronary (R/NC) leaflets.[2] This holds true for a cohort of 117 patients with R/NC BAV at the Herma Heart Institute (HHI) where 60% developed AS by age 20. Importantly, not all R/NC BAV patients develop AS since some patients maintain a normal peak gradient into early adulthood (Fig 1).

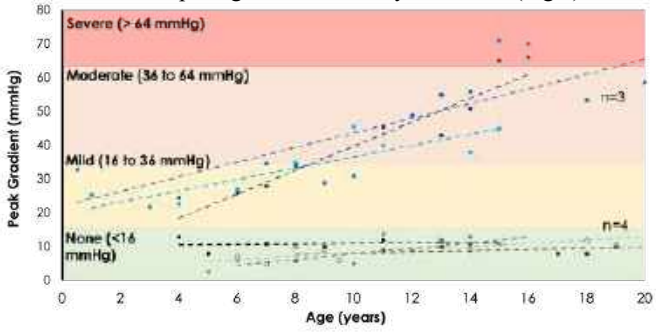

Figure 1. The evolution of peak aortic valve gradients from R/NC BAV patients at our center.

The mechanisms underlying premature AS induced by calcification in BAV patients are unknown, but it has been suggested that abnormal mechanical stimuli induced by the bicuspid anatomy plays a role. While our group is actively conducting computational and ex vivo studies from a BAV patient cohort at the HHI, we are unable to comprehensively study the interplay between changes in gene expression, structure, and function specific to BAV-induced changes in mechanical stress due to limited availability of patient samples preceding the advanced stages of the disease. To address this limitation, we use multi-disciplinary approaches in a murine BAV model that mimics the human disease process and allows us to characterize the anatomical, mechanical, and molecular environment during the progression of calcification in BAV. We hypothesize that in BAV, structure-driven, regionalized adverse mechanical stimuli leads to localized activation of mechanosensitive pro-calcific signaling pathways.

METHODS

Conditional heterozygous knockout of the *exocyst 5* gene (*Nfatc1cre;Exoc5*$^{fl/+}$) leads to formation of the more severely affected configuration (R/NC) of BAV in mice with a penetrance of ~45% in addition to tricuspid aortic valve (TAV) controls.[3] This model was implemented after IACUC approval, resulting in 3 experimental groups: (1) *Cre*+ BAV, (2) *Cre*+ TAV, and (3) *Cre*- TAV. All groups underwent echocardiography at 5 and 10 weeks, followed by valve collection at 10 or 18 weeks. These time points were determined considering the onset of calcification seen in BAV patients in our clinic and murine-to-human age equivalencies.[4] Tissue samples were paraffin-embedded and sectioned at 5 □m. Prior to staining, paraffin sections were serially imaged under autofluorescence using an EVOS M7000 (ThermoFisher). This allowed for 3D reconstruction of the aortic valve leaflets using Amira (ThermoFisher) and subsequent quantification of leaflet thickness and volume. Sections were then stained for Alizarin Red for detection of calcification. Spatial Transcriptomics was performed on *Cre*(+) BAV (n=3), *Cre*(+) TAV (n=3) and *Cre*(-) TAV (n=4) using the Visium Protocol (10X Genomics). Immunofluorescent staining of remaining tissue sections was performed to validate high priority hits from spatial transcriptomics. To conduct fluid-structure interaction (FSI) simulations, subject-informed 3D models were created based on averaged dimensions from echocardiography and Amira 3D leaflet reconstructions of individual mice in each group and time point (Fig 2A, B). Physiologic boundary conditions were implemented

including subject-informed left ventricular pressure at the inlet, a lumped-parameter model of downstream physiology at the aortic outlet, and flow imposed at coronary artery outlets (Fig 2C,D).

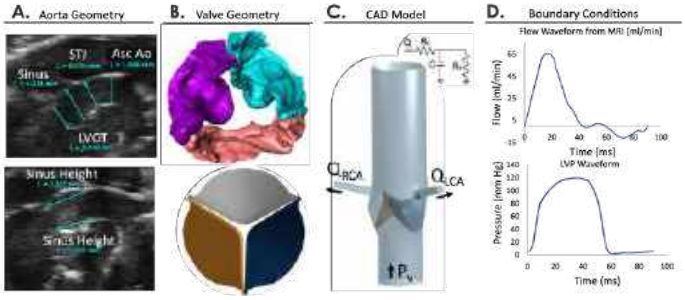

Figure 2. Computational modeling in *Cre*(-) TAV controls.

RESULTS

At 18 weeks, *Cre*(+) BAV mice have structurally different aortic valves, with only two distinct leaflets as opposed to three (Fig 3A). Average leaflet thickness is also significantly increased in *Cre*(+) BAV mice vs *Cre*(+) TAV and *Cre*(-) TAV (Fig 3B; $p < 0.05$, Kruskal-Wallis one-way ANOVA). Alizarin red staining was negative in *Cre*(+) BAV mice at this timepoint, suggesting this is a pre-calcific stage (Fig 3A).

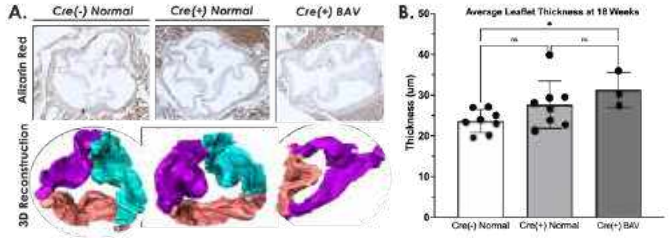

Figure 3. Morphology and Alizarin red staining in *Cre*(+) BAV mice vs. *Cre* (+) TAV and *Cre*(-) TAV controls.

By 5 weeks, *Cre*(+) BAV mice have a significantly higher peak aortic velocity vs *Cre*(+) TAV and *Cre*(-) TAV (Fig 4A; $p<0.05$, repeated measures two-way ANOVA). Between 5 and 10 weeks, *Cre*(+) BAV mice experience a 23% increase in peak aortic velocity vs controls (<10% increase), indicating more rapid progression of peak aortic velocity than that due to physiologic growth over time (Fig 4B).

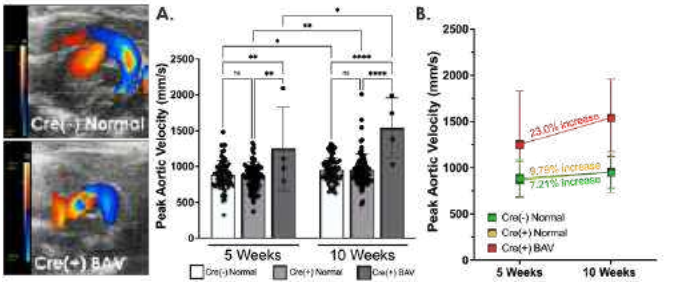

Figure 4. Functional changes in peak aortic velocity in *Cre*(+) BAV mice vs. *Cre* (+) TAV and *Cre*(-) TAV controls.

Despite no Alizarin red positivity, spatial transcriptomics at 18 weeks revealed pathway enrichment for osteogenic processes and mechanosensitive genes. Particularly, there was a 5.4-fold increase in expression of a calcification marker, Secreted Phosphoprotein 1 (*Spp1*) in the attachment and coaptation regions of *Cre*(+) BAV compared to *Cre*(-) TAV (Fig 5B).[5] This was validated through immunostaining of Osteopontin (OPN) which is the protein encoded by *Spp1* (Fig 5C).

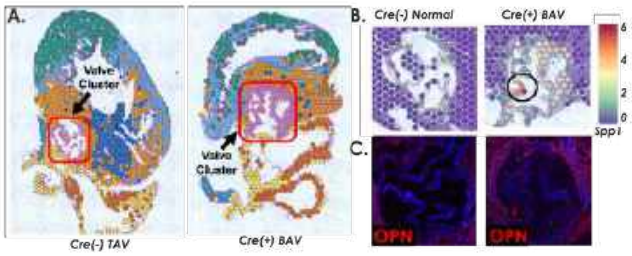

Figure 5. Spatial transcriptomics in *Cre*(+) BAV mice at 18 weeks shows increase in *Spp1* expression in the valve vs. TAV controls.

DISCUSSION

At an early timepoint (5 weeks), *Cre*(+) BAV mice have a significantly higher peak aortic velocity that more rapidly progresses by 10 weeks compared to normal TAV controls. These functional differences contribute to adverse changes in mechanical stress along the valve leaflets and ongoing work to be presented will characterize these changes with fluid structure interaction (FSI) simulations. While there is no detectable calcium deposition at 18 weeks, spatial transcriptomics revealed pre-calcific changes occurring in *Cre*(+) BAV leaflets as evidenced by the increase in *spp1*.[5] Expression of these markers were localized to the attachment and coaptation regions, which are also more likely to develop calcification in the patient population.[6] Additionally, based our group's FSI simulations of BAV in the human population, we expect to see the same increase in mechanical stress indices such as wall shear stress and von Mises stress in those regions in our proposed FSI simulations in the murine model. Our goal is to identify predictive indicators for calcification risk in young BAV patients and determine novel targets for molecular therapies for premature calcification in BAV.

INTRODUCTION

Valvular heart diseases, such as aortic valve stenosis, are becoming more common as the global population's average age rises [1]. Transcatheter aortic valve replacement (TAVR), a less invasive alternative to conventional surgical valve replacement, involves implanting a bioprosthetic valve through arteries. TAVR is now the primary method for aortic valve replacement [2]. Computer modeling can aid in device design, approval, and personalized patient care [3]. This study uses dynamic computer simulations to compare the dynamics of two FDA-approved TAVR devices, the CoreValve Evolut R and the SAPIEN 3. Our models extend prior patient specific TAVR simulations [4] by considering aortic root flexibility, which can have a substantial impact on simulation outcomes [5]. This project, using advanced numerical methods for fluid-structure interaction, incorporates realistic clinical conditions and biomechanics, predicting detailed device performance and interactions within the patient's anatomy.

METHODS

This work utilizes the immersed finite element-difference (IFED) method [6] to simulate the fluid-structure interaction among the transcatheter aortic valve (TAV), native aortic valve, and the aortic root with the surrounding blood. The patient-specific model anatomy (Figure 1(a,c)) is based on pre-procedural CTA images obtained from a female patient scheduled for TAVR using a 26 mm Medtronic CoreValve Evolut R (Figure 1 (b)). As the patient's native valve leaflets weren't clearly visible in the images, idealized representations were created based on measurements from previous research [7].

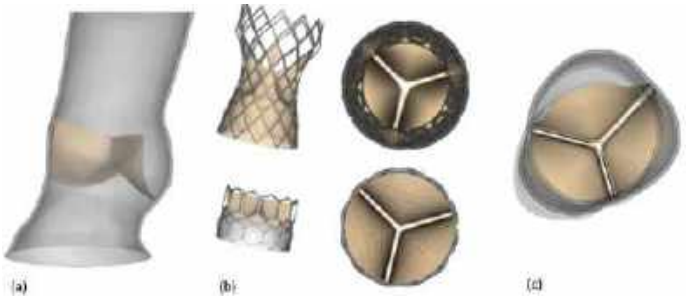

Figure 1: (a) Reconstructed aortic root geometry, (b) Top. CoreValve Evolut R, Bottom. Sapian 3, (c) Native aortic valve geometry.

These artificial valves leaflets were adjusted using SOLIDWORKS to fit the reconstructed anatomy. Both sets of valve leaflets (native valve, porcine and bovine pericardial tissue) and the sealing skirt were modeled as hyperplastic materials. For our leaflets and sealing skirts, we employ the modified Holzapfel–Gasser–Ogden (HGO) model as described by Murdock et al. [8, 9],

$$W = C_{10}\{\exp[C_{01}(\overline{I}_1 - 3)] - 1\} + \frac{k_1}{2k_2}\sum_i\{\exp[k_2(I^*_{4,i} - 1)^2 - 1\} \quad (4)$$

$\overline{I}_1 = \mathrm{tr}(\overline{C})$ is the first invariant of the modified right Cauchy–Green strain tensor $\overline{C}=\overline{F}^{\mathrm{T}}\overline{F}$ and $I^*_{4,i}$= max ($\mathrm{I}_{4,i}$,1) = max ($f_i^0.\overline{C}f_i^0$, 1) where f_i^0 denotes a unit vector aligned with the ith fiber direction, referring to the reference configuration.

Fiber arrangements and model parameters follow those detailed previously [4,8,10]. In addition, we model the vessel wall as a hyperplastic material model based on our vessel wall deformation optimization.

We characterize blood as a viscous incompressible fluid using the Navier-Stokes equations, with density of 1.0 g cm^{-3} and dynamic viscosity $\mu = 3.5$ cP. To set afterload conditions, at the outlet we use a three-element Windkessel model, and at the inlet we employ a time-dependent elastance-based left heart model. The period of the cardiac cycle is T=0.8512s.

RESULTS

Figure 2 displays detailed flow patterns within and downstream of the Evolut R (Fig. 2a) and SAPIEN 3 (Fig. 2b) across the cardiac cycle. The model generates physiological flow rates and yields effective orifice areas that are in good agreement with clinical data. The model can also predict fine-scale flow features. Specifically, in the final frame of Figure 2a, the model captures the nuanced flow dynamics indicative of a minor paravalvular leak, visible behind the native leaflet on the left side of the Evolut R's sealing skirt. Conversely, our intentional over-expansion of the SAPIEN 3 stent frame results in a secure seal within the native leaflets, preventing any occurrence of paravalvular leakage.

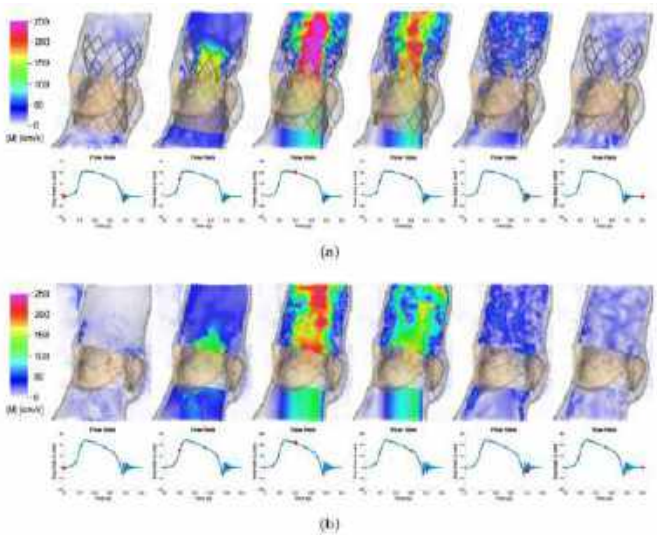

Figure 2: Cross-sectional representations reveal flow patterns for both the (a) Evolut R and (b) SAPIEN models, simulated under driving conditions derived from the time-dependent elastance-based left heart model. Each frame is separated by a time increment of 0.1 seconds.

DISCUSSION

This study introduces a computational modeling framework for fluid-structure interaction in transcatheter aortic valve replacement (TAVR) devices within patient-specific anatomies. It compares two prominent TAVR devices: Medtronic's CoreValve Evolut R and Edwards Lifesciences' SAPIEN 3. Employing a flexible aortic root model and comprehensive three-dimensional representations of the device stent frames, our simulations offer enhanced realism in capturing device interactions with the patient's native anatomy compared to our earlier model. Specifically, our improved model shows a reduction in paravalvular leakage (PVL) compared to a model featuring a stationary aortic root and a discrete device stent frame representation.

INTRODUCTION

The pregnant body adapts to accommodate the growing fetus. For example, the cardiovascular system meets rising physiological demands by expanding blood volume, reducing systemic vascular resistance, and increasing cardiac output.[1] Throughout pregnancy, the left ventricle (LV) grows to support this increased workload.[2] After delivery, these adaptations are thought to reverse. However, whether the heart returns to its pre-pregnant size, shape, and function after delivery is unclear.[2,3] Moreover, postpartum-specific behaviors like lactation are known to affect hemodynamics in rodents, which are common animal models of pregnancy and postpartum. For example, cardiac outputs in lactating rats remain elevated, whereas non-lactating rats return their cardiac outputs to pre-pregnant values.[4] While increased cardiac outputs are implicated in LV growth, direct comparisons of LV growth between lactating and non-lactating animals are lacking.

Thus, the objectives of this study are to (1) measure postpartum changes in LV morphometry, (2) investigate how lactation affects these changes, and (3) use a computational model to analyze the mechanisms driving heart growth after delivery. We hypothesize that LV growth (1) increases to meet the elevated hemodynamic demand of lactation, (2) reverses to its pre-pregnant size, shape, and function without lactation, and (3) that this difference in growth is driven by mechanical loading.

METHODS

Animals: We assessed cardiac hypertrophy longitudinally in mice throughout a 19-day pregnancy and 21-day postpartum period. Female nulliparous C56Bl/6J mice (n = 10) were randomized into Lactating (*L*, n=5) and Non-Lactating (*NL*, n=5) groups to study the effect of nursing on postpartum LV growth. *L* mice were allowed to nurse their pups and *NL* mice were immediately removed from their litter after delivery.

Cardiac ultrasound imaging and processing: To track cardiac growth, we collected four-dimensional cardiac ultrasound (4DUS) images. Baseline measurements were taken before pairing (day 0: D0), and mice were scanned on days 6, 12, 15, and 18 of gestation (GD6, GD12, GD15, GD18) and days 1, 4, 7, 14, and 21 postpartum (PPD1, PPD4, PPD7, PPD14, PPD21) using a high-frequency ultrasound system (Vevo 3100, Fujifilm VisualSonics).[5] Tail cuff blood pressure was monitored throughout the study (CODA, Kent Scientific).

Using our previously established methods, we segmented the 4DUS images by outlining the epicardial and endocardial boundaries to trace local wall motion throughout the cardiac cycle.[5] The epicardial and endocardial meshes were used to calculate heart size (LV mass: *LVM*), shape (end-diastolic volume: *EDV*, end-diastolic wall thickness: *WT*), and function (stroke volume: *SV*, ejection fraction: *EF*).

Multiscale model simulations: To test the hypothesis that hemodynamic changes drive postpartum heart growth, we simulated LV growth in *L* and *NL* animals using our previously published multiscale model.[6] This model, which accounts for cell-signaling and hemodynamic interactions during pregnancy, correctly captures heart growth in pregnant rats. We assume the same mechanisms drive pregnancy-induced heart growth across all species; thus, we assume our model can be used to observe relative changes in both rats and mice. To simulate our experiment, we input gestation-appropriate changes in hemodynamics by incorporating relative change in group-averaged systemic vascular resistance (*SVR*) changes based on measured *SV* and mean arterial pressure and optimizing stressed blood volume to match the average changes in *EDV*. We included time-appropriate relative changes in hormones (estrogen, progesterone, angiotensin II) reported in rats. Based on previous research, we assumed that hormonal changes are comparable between rodents during pregnancy and values return to pre-pregnant levels postpartum regardless of lactation status.[7,8]

Statistical Analysis: Metric differences between groups and on selected days (D0, GD18, PPD21) were assessed with a student's t-test ($P < 0.05$ for significance). Raw data are presented as mean ± standard error of the mean (SEM). Relative changes are reported as percent change of the mean ± relative standard deviation (RSD).

RESULTS

Pregnancy induced heart growth: As there were no noteworthy differences in average metrics between the *L* and *NL* groups during pregnancy (Table 1), we compared metrics at D0 and GD18 across all 10 mice. Before pairing (D0), *LVM* measured 68.5±4.4 mg. Throughout gestation, *LVM* grew to 81.7±1.0 mg at GD18 ($P = 0.01$ vs. D0). This growth was facilitated by an increase in *EDV* (D0: 36.3±2.1 µL, GD18: 50.0 ± 2.6 µL, $P = 0.002$) while myocardial *WT* was largely maintained (D0: 1.00±0.04 mm, GD18: 0.99±0.04 mm, $P = 0.60$), suggesting eccentric hypertrophy consistent with volume overload. These changes aligned with increased *SV* (D0: 20.0±2.7 µL, GD18: 30.7±2.7 µL, $P \leq 0.001$) and *EF* (D0: 59.1±2.9%, GD18: 65.3±2.9%, $P = 0.03$), indicating enhanced cardiac function.

Growth continued throughout lactation: *L* mice carried an average litter size of 6.4±0.3 pups, which they nursed for 21 days postpartum. At PPD21, *LVM* increased significantly compared to the end of pregnancy (Table 1, $P = 0.008$ vs. GD18). This additional growth corresponded with further chamber enlargement (*EDV*: $P = 0.02$ vs. GD18) and an upward trend in *SV*, agreeing with reported changes in cardiac output in Wistar rats.[4] However, the average increase in *SV* was not significant compared to the end of pregnancy ($P = 0.12$ vs. GD18). Moreover, *EF* remained consistent with the end of pregnancy ($P = 0.78$ vs. GD18). Together, these results suggest cardiac function was maintained, but not enhanced, during lactation compared to GD18.

Growth partially reversed after pups removed: *NL* mice carried an average litter of 6.8±0.4 pups ($P = 0.62$ vs. *L*), which were removed from the cage after delivery. By PPD21, *LVM* decreased slightly from the end of pregnancy (Table 1, $P = 0.28$ vs. GD18). Interestingly, cavity dilation persisted at the end of the study (*EDV*, $P = 0.04$ vs. D0). While *SV* decreased from the end of pregnancy ($P = 0.02$ vs. GD18), it remained marginally elevated above pre-pregnant levels ($P = 0.06$ vs. D0). Together, these results suggest that the heart does not return to its pre-pregnant shape or function in the first three weeks postpartum.

Lactation status impacted postpartum growth: At PPD21, *L* mice had significantly larger hearts than their *NL* counterparts (*LVM*, Table 1, $P = 0.04$ vs. *NL* at PPD21). Similarly, *L* mice had elevated *SV* ($P = 0.046$ vs. *NL* at PPD21) and *EF* ($P = 0.04$ vs. *NL* at PPD21). As these animals experienced otherwise identical study conditions, these results suggest lactation directly impacts LV growth after delivery.

Table 1: Ultrasound estimations of LV size, shape, and function before pairing (D0), during pregnancy (GD18), and postpartum (PPD21) in *L* and *NL* mice. Values are mean ± SEM. n = 5/group. * $P < 0.05$ vs. D0. $^{+}$ $P < 0.05$ vs. GD18. $^{\$}$ $P < 0.05$ vs. NL.

			D0	*GD18*	*PPD21*

Model predictions differentiate postpartum growth: Since there were no significant differences in *EDV* (Fig 1A) and *SVR* ($\propto 1/SV$, not pictured) between the *L* and *NL* groups during pregnancy, our model predicted similar changes in *LVM* (*L*: +24%, *NL*: +25% vs. D0, Fig 1B) and *WT* (*L*: +5%, *NL*: ±0% vs. D0, Fig 1C) by GD18. These predictions were on par with observed growth in all mice (*LVM*: +19±4% vs. D0, Fig 1B; *WT*: -1±13% vs. D0, Fig 1C).

Postpartum, the higher *EDV* (Fig 1A) and lower *SVR* in the *L* group resulted in the prediction that *LVM* would increase an additional +9% above GD18 by PPD21 (Fig 1B). While this continued growth agreed with the experimental data, our model notably underpredicted the lactation-induced changes in mass (+25±12% vs. GD18, Fig 1B). Yet, the predicted minimal change in *WT* after 21 days of lactation (-5% vs. GD18, Fig 1C) agreed with our experimental results in *L* mice (*WT*: +8±24% vs. GD18, Fig 1C). Given the lower *EDV* (Fig 1A) and higher *SVR* in the *NL* group, our model predicted a slight decrease in *LVM* (-5% vs. GD18, Fig 1B) and *WT* (-5% vs. GD18, Fig 1C), which agrees with our data in the *NL* mice (*LVM*: -5±16% vs. GD18, Fig 1B; *WT*: -3±11% vs. GD18, Fig 1C). Collectively, our predictions suggest that our model can accurately capture organ-level cardiac shape changes.

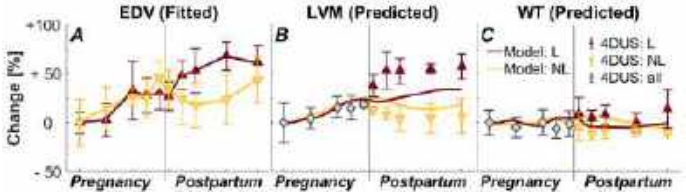

Figure 1: Multiscale model optimized (A) *EDV* to predict (B) *LVM* and (C) *WT*, compared here to relative changes in ultrasound estimations. Symbols are percent change of the mean ± RSD.

DISCUSSION

Here, we explored how the murine heart changes in size, shape, and function following pregnancy-induced hypertrophy. We show that heart growth continued in *L* mice and regressed in *NL* mice after delivery. However, our results suggest the heart does not return completely to its pre-pregnant state in the *NL* mice, disagreeing with our hypothesis. Alternatively, these results imply full recovery may take longer than pregnancy and should be examined in an extended study.

We employed a computational model to interpret our experimentally observed heart growth. We illustrated that changes in postpartum hemodynamics drive continued growth in *L* mice and regression in *NL* mice. However, our model underpredicted *LVM* in the *L* group, suggesting additional (i.e., hormonal) mechanisms may play a role. While these discrepancies may stem from our current model being calibrated to rat anatomy and physiology, it is important to highlight that our rat model successfully captured heart growth during mouse pregnancy. Regardless, we are currently developing a mouse-specific model, which will allow us to simulate animal-specific hemodynamics.

To our knowledge, this murine study is the first to investigate the effects of lactation on LV morphometry following a healthy pregnancy. Our findings demonstrate lactation's significant impact on postpartum heart growth. Unsurprisingly, lactation is integral to transgenic mouse models of new-onset heart failure during pregnancy,[9] which is the leading cause of pregnancy-related deaths after delivery in the United States.[10] Our findings, along with these models, underscore the importance of considering lactation status, which is often not reported, in postpartum-related cardiovascular research.

OCULAR HYPOTHERMIA, IN-VITRO VALIDATION OF A NOVEL THERAPEUTIC APPARATUS USING NON PERFUSED PORCINE EYE MODEL

INTRODUCTION

Hypothermia has been widely used in the heart and brain thanks to its therapeutic effects to people suffering from certain conditions, such as cardiac arrest [1, 2], traumatic brain injury and strokes [3, 4]. Similarly, this technique has been proven to be effective in the ophthalmic field to preserve retinal tissue vitality in the diseased eye [5, 6] and in rat models it prevented adverse effects when applied prior to the onset of an ischemic condition (hypothermic preconditioning) [7, 8].

The physiological effects of hypothermia in the eye, many of which are thought to be neuroprotective, include decrease in the metabolic activity of the cells, reduced release of neurotransmitters, and induce the breakdown of the blood-aqueous barrier as reviewed by Xi [6]. Lactate production levels and glucose utilization levels were lowered in eyes treated with moderate hypothermia when compared to eyes kept at a physiological temperature, while, they also showed a return to normal rates for these two parameters when the hypothermic eyes were brought back to normal temperatures [6].

Current commercially available solutions to deliver therapeutic hypothermia to the eye (i.e. cold packs, cold saline irrigation) present passive heat removal, with an uncontrolled heat removal rate and inconsistent contact areas with the eye decreasing the efficacy of such cooling. As of now, the most used cooling technique is contact cooling using cold packs, in which cooling rate is dependent on the temperature of the pack and the contact area with the eye and surrounding tissues, which changes with time. Thus cooling is not regulated. A second method uses irrigation of the eye with cooled saline which is also not regulated and is only practical in a clinical or laboratory setting. A technology gap exits where the desire is to deliver therapeutic hypothermia to the eye that is regulated and targeted.

METHODS

The Eye Cooler System (ECS) was designed to address the technology gap described above. The ECS is comprised of three main components as shown in Figure 1. An eye contact ring is shaped to conform to the sclera of a typical adult human eye and to be held in place by the eyelids; this ring allows viewing of the cornea and pupil during use. A thermoelectric heat pump actively moves heat from the eye contact ring in a regulated manner (i.e. with feedback). An active convection heat sink (water block) uses chilled fluid to absorb and transport heat away from the heat pump. The viewing port extending through the device is left unobstructed to allow viewing of the cornea and pupil during use. A temperature sensor at the eye surface integrated inside of the eye contact ring provides feedback.

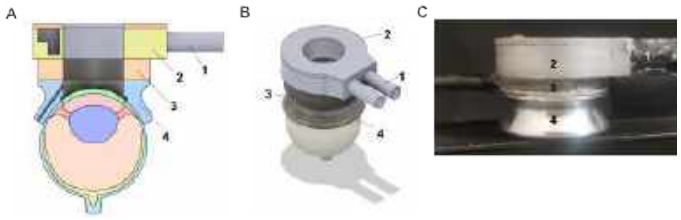

Figure 1: Overall design and components of the Eye Cooler System. (A) Cross-section of the CAD model of the eye cooler set on an eye. The main components of the system are numbered: 1) convection fluid ports, 2) active convection heat sink, 3) thermoelectric heat pump, 4) eye contact ring (B) CAD model of the eye cooler set on an eye, panorama view. The reference numbers are the same as panel A. (C) Side view photograph of the assembled Eye Cooler System; numbered components the same as in panel A.

Fresh pig eyes (n = 5) were obtained and cleaned of extraocular tissue, placed in a custom holder and imaged using MRI to document the gross anatomy.

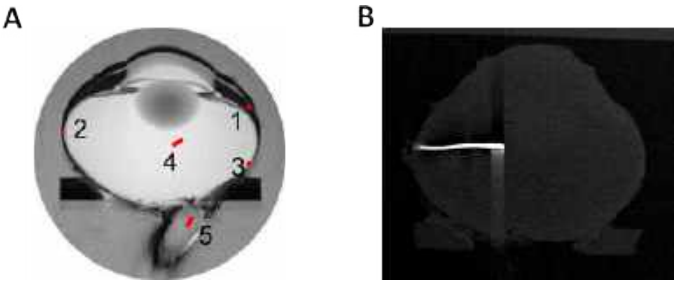

Figure 2: (A) Target position of the implanted thermistors (0.5mm diameter) in the eye, shown in red: 1 anterior sclera, 2 equatorial sclera, 3 posterior sclera, 4 vitreous, 5 optic nerve. (B) CT image showing actual position of an implanted thermistor at Vitreous.

Following MRI imaging, each eye was implanted with temperature sensors (NTC thermistors) at five key locations, as illustrated in Figure 2.

The ECS was then positioned to contact the sclera. The (eye + ECS) was the lowered to the level of the lowest edge of the ECS (approximately 4mm peripheral to the limbus) into a 37°C oil bath (used to simulated naturally found fat tissues surrounding the eye globe) and the eye was allowed to reach equilibrium at typical physiological temperature (34.5°C).
The ECS was turned on, initiating the cooling, and the temperatures monitored as a function of time. The ECS sensor/feedback ensured the sclera was never below 4°C. After 20 minutes of ECS cooling, the device was turned off and the eye was removed from the system. Each eye was then placed back in the custom holder and imaged using micro-CT to document the precise location of each implanted temperature sensor. The position of the sensors was then analysed for consistency across the five eyes.

RESULTS

Each experiment resulted in temperature vs time curves for each of the five sensor positions in the eye plus one curve for the eye contact ring temperature. Temperature vs time curves for each sensors location across the five eyes are summarized in Figure 3.

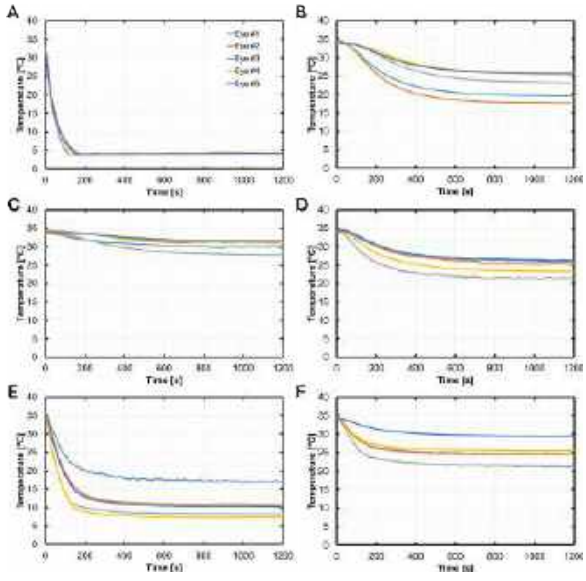

Figure 3: Temperature observed at each thermistor position for all five eyes as a function of time after onset of current through the TEC (at t = 0 s). Each plot shows the temperature data for one of the six sensor locations: (A) eye contact ring, (B) anterior sclera, (C) equatorial sclera, (D) posterior sclera, (E) vitreous, (F) optic nerve. In each plot, the five coloured curves plot the temperatures obtained at that location for the five eyes used in this study.

On average, the temperature at the ECS sensor, located adjacent to the sclera, reached 4°C within three minutes of turning the system on (Figure 4).

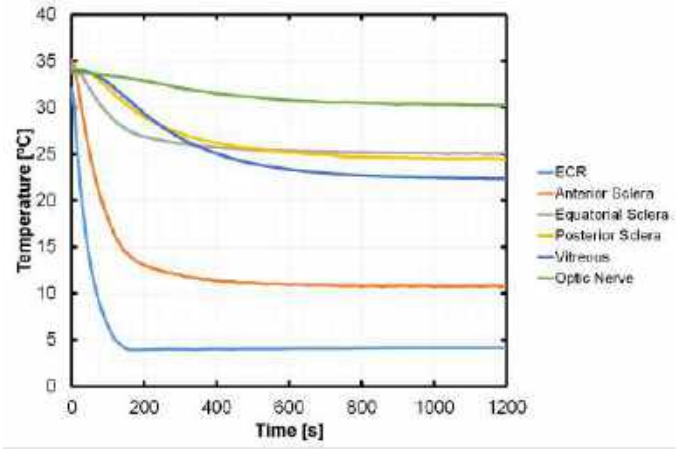

Figure 4: Temperature observed at each of six thermistor positions is plotted versus time following onset of current through the TEC (at t = 0 s). Curves are averages across the five eyes shown in Figure 3

Final equilibrium temperatures, and the times to reach 90% of the final change in temperature at each sensor location (mean across 5 eyes), were: anterior sclera, 10.7°C, 194 sec; equatorial sclera, 25.0°C, 338 sec; posterior sclera, 24.4°C, 532 sec; vitreous, 22.4°C, 569 sec; proximal optic nerve, 30.2°C, 703 sec. Temperature vs time profiles were similar across eyes, with root mean squared differences from the mean profile of 11-29%, depending on sensor location.

DISCUSSION

In the non-perfused eye model, the ECS was able to achieve therapeutically relevant temperatures throughout the eye, including the proximal optic nerve. Equilibrium temperatures could be maintained for as long as the system was powered. Next steps include measuring ECS-induced temperature changes in a human eye model.

INTRODUCTION

The non-proliferative corneal endothelial cells (CEC) located on the posterior side of the cornea are vital for maintaining central corneal transparency by regulating the hydration and thickness of the corneal stroma through a "pump-leak" mechanism [1]. When the endothelial cell density decreases ~80% from healthy adulthood levels, an individual is at risk of developing corneal decompensation [2], which results in blurred vision, pain, and even blindness if untreated [3,4].

A leading etiology for corneal decompensation is CEC damage during intraocular surgeries [2-4]. For instance, CEC losses of 23-42% have been observed at 1 year after corneal transplant surgeries [5,6]. An argument can be made that mechanical loading plays a big role in acute CEC loss, as the mechanical environment CECs experience during corneal transplantation is much different than physiological conditions.

Our lab has previously shown that CECs are highly susceptible to mechanical trauma via indentation [7]. However, further investigation is needed to understand which of the numerous parameters that influence contact mechanics during indentation can be controlled to mitigate acute CEC damage during surgery. Thus, we designed the "CECure Mechanical Testing Platform" (**Fig. 1**).

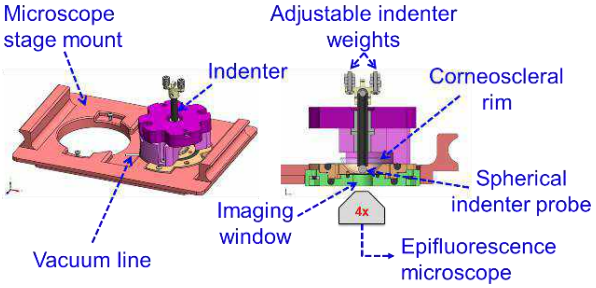

Figure 1: SolidWorks 3-D rendering of the CECure platform, highlighting some important features.

The CECure platform facilitates improved visualization of the endothelium before, during, and after indentation, with less manipulation of the corneal sample to isolate CEC damage as a result of indentation from damage caused by experimental handling.

The objective of this study was to demonstrate the CECure platform's ability to detect differences in CEC viability during different indentation loading conditions. A design of experiments (DOE) approach was used that allowed us to efficiently test the effects of multiple parameters (control factors) simultaneously.

METHODS

Indentation Experiments: Corneoscleral rims were carefully dissected from porcine eyes within 72 hours after euthanasia. For each sample, a solution of PBS and Hexidium Iodide was applied to the endothelium to stain all CEC nuclei. The corneoscleral rim was then rinsed with PBS and placed in the CECure platform endothelial-side-up. A solution of either PBS or ophthalmic viscosurgical device (OVD) and SYTOX Green was placed onto the endothelium, where it remained for the rest of the experiment to stain injured CEC nuclei. Prior to indentation, the baseline z-position was measured and a 3-D z-stack image was acquired of the endothelium using an inverted fluorescence microscope (**Fig. 2A**).

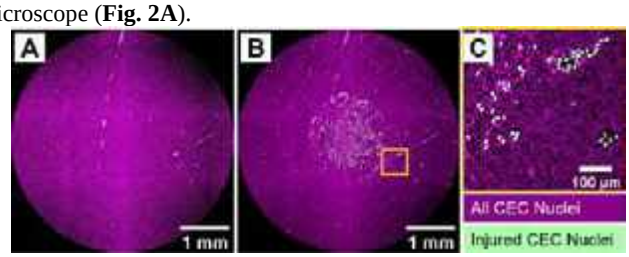

Figure 2: Representative images of the corneal endothelium (A) before and (B) after indentation, as well as a (C) zoomed in view where individual CEC nuclei are visible.

The endothelium was then indented under varying conditions with prescribed values of different control factors, and the z-position of the indenter was measured through the microscope. The indenter was then lifted from the endothelium, and a final fluorescence z-stack image was taken of the endothelium (**Fig. 2B**).

DOE Strategy: A full factorial array design was used to test five different control factors (**Table 1**). This resulted in 32 treatment conditions (TC), or 32 different combinations of control factors.

Table 1: DOE control factors.

Control Factor	Level	
	-1	+1
A. OVD application	Ocu+ 1%	No OVD
B. Indenter diameter	3 mm	4 mm
C. Indent load	~16 mN	~36 mN
D. Indent duration	5 sec	30 min
E. Death-to-Experiment (DTE) time	24-48 hrs	48-72 hrs

Three characteristic responses (outcomes) of CEC damage were measured for each TC: percent CEC injury (PCI), percent CEC detachment (PCD), and total CEC loss (TCL). The effect of each control factor, and their interactions, on each characteristic response was measured using analysis of means (ANOM). Significance of each effect was determined using analysis of variance (ANOVA).

Image Processing & Analysis: Custom image processing/analysis algorithms (ImageJ and MATLAB) were used to flatten and correct the z-stack images, measure indentation depths, and count CEC nuclei to obtain both baseline total and injured CEC counts (TC_1 and IC_1, respectively), and final total and injured CEC counts (TC_2 and IC_2, respectively). These counts were used to calculate PCI and PCD, which were summed together to compute TCL:

$$TCL = PCI + PCD = \left[\left(\frac{IC_2}{TC_2} - \frac{IC_1}{TC_1}\right) \times 100\right] + \left[\frac{TC_1 - TC_2}{TC_1} \times 100\right] \quad (1)$$

RESULTS

As expected, the +1 level for each control factor resulted in more CEC damage than the -1 level, although not all effects were statistically significant (**Fig. 3**). Notice that indent duration had the largest effect on TCL, followed by indent load. There were also several factor interactions that had statistically significant effects (not shown).

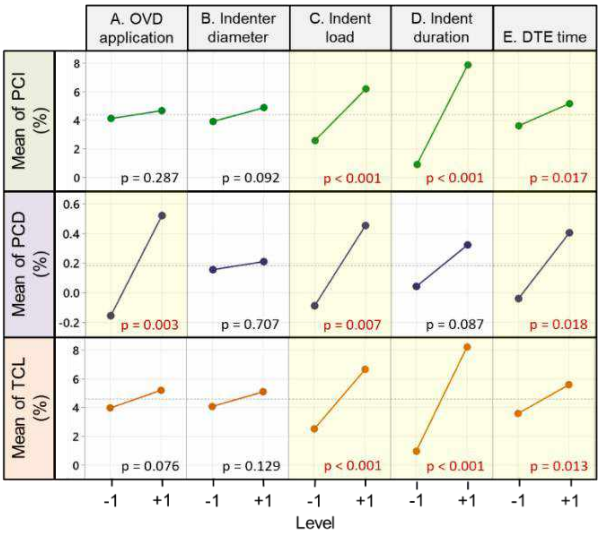

Figure 3: DOE main effects plots from ANOM for PCI (top row), PCD (middle row), and TCL (bottom row), including p-values obtained from ANOVA (significant effects highlighted in yellow).

A linear regression analysis showed that a moderate and significant correlation exists between indentation depth and TCL (**Fig. 4**).

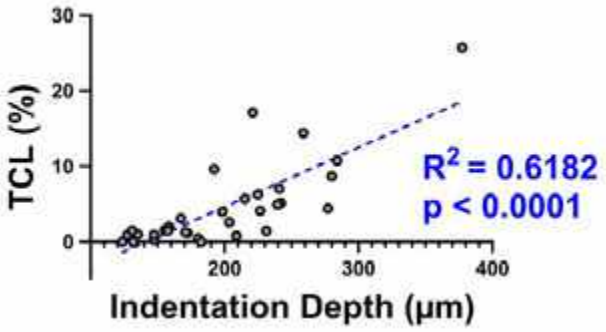

Figure 4: Correlation between indentation depth and TCL.

DISCUSSION

We successfully validated our custom test platform's ability to detect differences in CEC viability under different indentation loading conditions by showing statistically significant effects of multiple parameters that were expected to influence CEC damage. Indent duration had the most notable effect on CEC damage, suggesting that how long CECs are subjected to mechanical loading is just as, if not more, important than the magnitude of the load. More work is needed to better understand if CEC damage at longer durations is due to the poroelastic response of the cornea (time-dependent strain) or a contact surface interaction, such as adhesion.

We also identified an exciting relationship between indentation depth and CEC damage, which suggests corneal mechanical properties could serve as a predictor of CEC loss during surgery. For example, if a surgical maneuver requires application of a given load onto the endothelium of a transplanted corneal graft, our findings suggest a stiff graft will experience less CEC loss than a more compliant graft because it will deform less under the same load.

A limitation of this study was that the levels used for the DOE control factors were meant to test the device rather than represent surgical conditions. However, the CECure platform design is amenable to accommodating more surgically-relevant conditions (e.g. the indenter probe geometry can be changed to match surgical forceps).

Collectively, the findings of this study validate our experimental platform and pave the way for future work investigating how different surgical tools, corneal treatments, and corneal mechanical properties affect the tolerance of CECs to mechanical loading.

INTRODUCTION

Ovarian cancer is both the most common and lethal gynecological cancer[1]. Despite being such a devastating disease, the effects that the tumor microenvironment (TME) play on ovarian cancer cell behavior are not well characterized. Different features of the ovarian TME that can alter cell behaviors include forces such as strains, interstitial flow, or compression; stromal cell interactions; and extracellular matrix (ECM) remodeling[2]. Specifically, this work focuses on tensile strains in the ovarian TME and how strain interacts with changes in ECM composition. Cancer-associated fibroblasts (CAFs) are stromal cells responsible for secreting and remodeling ECM proteins; CAFs also have increased contractility compared to normal fibroblasts[3]. These increases in contractility allow CAFs to exert tensile strains through the matrix components onto the ovarian cancer cells.

Hyaluronic acid (HA) is a matrix component secreted by CAFs commonly found in the ovarian TME, although the role HA plays in the mechanobiology of ovarian cancer is poorly defined. HA can interact with ovarian cancer cells *in vivo* as a stromal or serum component. While stromal HA has been shown to be associated with a worse prognosis and lower 5-year survival rate, serum HA has been shown to not be a predictor of disease stage or progression[4, 5]. HA signals through the cell surface receptor, CD44 which is ubiquitously expressed in a variety of cancers including ovarian, breast, prostate, head, and neck cancers to name a few. The intracellular region of CD44 connects to the cytoskeletal components through ankyrin and ERM proteins (ezrin, radixin, and moesin), which regulate mechanotransduction. There are proteins, including Src and the Rho/ROCK pathway, that associate with CD44 and are known to be mechanosensitive[6]. Through these cytoskeletal proteins, CD44 can alter cancer cell behaviors including proliferation, migration, and drug resistance[7]. However, it is unclear if mechanical stimulation of CD44 alters its signaling pathways. I hypothesize that mechanical stimulation and interaction between HA and CD44 alters downstream signaling and ultimately causes differences in proliferation and migration.

METHODS

All studies utilized the ovarian cancer OVCAR-8 model cell line. A CD44 knock down in the OVCAR-8 line (shCD44) and scramble control (shSCR), both with an RFP reporter, were created using a lentiviral vector. Cells received a No Strain or tensile Strain treatment for 24h at 0.3 Hz and 9% elongation using a FlexCell system before being harvested for use in further experiments. Both 3D disk and 3D microfluidic device models were utilized to elucidate how Strain and HA altered ovarian cancer cell behaviors through CD44 signaling. . OVCAR-8 unmodified (Wild-type, WT), shSCR, and shCD44 cells were used in the disk studies. HA was introduced to the cells either as a matrix component (F+GEL HA) which mimics stromal HA or as a soluble component (F+SOL HA) which mimics serum HA. Fibrin only gels (F only) were used as controls. After Strain treatment, samples were cultured for 48h before being fixed and stained for proliferation marker Ki67 and DAPI. The second model was a microfluidic device that consisted of 3 chambers that were loaded independently to study ovarian cancer cell migration[8]. Cells were loaded into the middle chamber while blank F only gels were loaded into the left side chambers and F+GEL HA were loaded into the right-side chambers. Samples were fed everyday using the outward flow set-up, where media is only provided to the middle chamber and flows equally into the side chambers[8]. Devices were cultured for 7 days before being fixed and stained for DAPI to determine migration between chambers. All images were analyzed using the FIJI Analyze Particle plugin and positive count (Ki67) or positive area (migration) normalized to total cell count or area via DAPI staining was collected for analysis.

RESULTS

Our results show that a Strain pre-treatment followed by F+GEL HA treatment significantly increases the percent of proliferating

cells in the OVCAR-8 WT cells compared to strain F only samples (Figure 1a,b). However, the Strain pre-treatment plus SOL HA does not increase Ki67 staining compared to the F only samples (Figure 1a.b). OVCAR-8 shSCR samples demonstrate a significant increase in proliferation in the F+GEL HA environment with both No Strain and Strain pre-treatment compared to their respective F only samples (Figure 1a,b). The shCD44 cells show no significant changes in proliferation with Strain pre-treatment, F+SOL HA, or F+GEL HA (Figure 1b). After 7 days in the microfluidic devices, our data indicate that the OVCAR-8 WT cells preferentially migrate towards the side chambers containing F+GEL HA compared to the F only side (Figure 2b,c). Pre-treatment with Strain did not influence the ability of the cells to migrate.

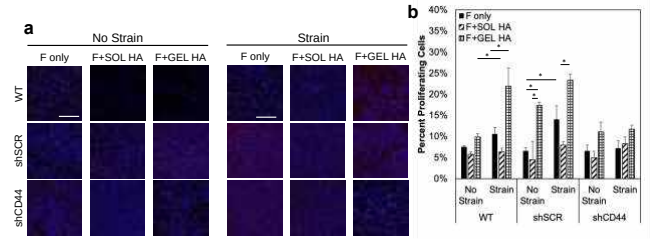

Figure 1: Ovarian Cancer Cell Proliferation is Increased with HA Treatment. (a) Representative images of OVCAR-8 WT, shSCR, and shCD44 cells treated with a 24h Strain pre-treatment before being grown in 3D disk models with F+SOL HA or F+GEL HA Scale bar = 500 µm. (b) Quantification of Ki67 cell count normalized to DAPI cell count in immunofluorescence samples. Data shown as average + SEM, n=3 samples, * p <0.05. Samples were compared using ANOVA followed by post-hoc Tukey HSD.

DISCUSSION

Our studies looked to quantify changes in ovarian cancer behaviors associated with disease progression. Specifically, we looked at proliferation as a stand-in for tumor growth and migration as a model of metastatic potential. HA and CD44 have been associated with both migratory and proliferative behaviors in a variety of cell types, though previous studies have not reported strain-sensitivity of the receptor. The OVCAR-8 WT cells exhibited higher levels of Ki67 positive staining after Strain pre-treatment with the F+GEL HA treatment, while the shSCR cells demonstrated increased proliferation with F+GEL HA treatment both with and without the Strain pre-treatment (Figure 1b). Even without HA, Strain treated OVCAR-8 WT and shSCR cells exhibited some increases in Ki67 staining, indicating that strain can induce proliferation; this was not observed in the shCD44 samples. These results highlight that HA presentations that mimic the stromal HA (F+GEL HA) can increase ovarian cancer cell proliferation while models mimicking serum HA (F+SOL HA) do not. Furthermore, the studies indicate that active tensile strains can enhance the effect of stromal HA on CD44 signaling to increase proliferation of ovarian tumor cells.

Our studies also utilized an advanced 3D TME model to investigate the interactions of strain and HA on ovarian cancer cell migratory behaviors as a readout of metastatic potential. The microfluidic device design was chosen due to the 3 chambers that could be loaded independently, allowing for cellular components to be loaded into the middle while acellular gels with F only or F+HA gels were loaded into the side chambers. The media flow pattern was chosen so that media was fed only into the middle chamber and allowed to diffuse into the side chambers; this resulted in a system where any secreted factors from cells loaded into the middle chamber were equally diffused into the side chambers. This feeding regime creates an equal magnitude of interstitial fluid flows towards the side chambers. Taken together, this means our studies controlled for both secreted factors and shear forces that could affect ovarian cancer cell migration and proliferation in the side chambers, solely focusing the studies on how Strain pre-treatment and HA in the TME drive cell migration. After 7 days, the OVCAR-8 WT cells preferentially migrated into the side chambers containing the F+HA gel regardless of Strain pre-treatment (Figure 2c).

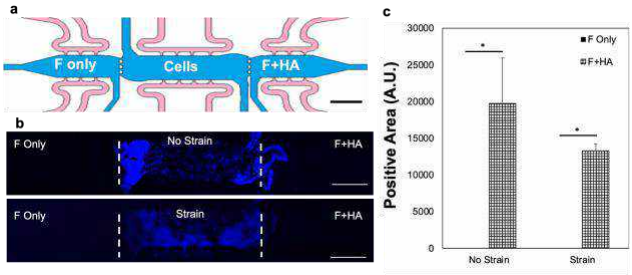

Figure 2: Stromal HA Promotes Migration in 3D Ovarian TME Models. (a) Microfluidic device design showing tissue chambers (blue) connected via communication ports (20µm) and independent fluidic lines (pink). Experimental set up with F-only in left chamber, Cells in F-only in the middle chamber, and F+HA matrix in the right chamber (b) Representative images for DAPI staining of OVCAR-8 WT cells in microfluidic devices. Samples either received Strain pre-treatment (24h) or No Strain prior to loading in F only gels in the middle chamber. Insets indicate side chamber matrix composition. White dashed lines indicate interfaces of adjacent chambers. Scale bars = 500µm. (c) Quantification of DAPI positive area in side chambers. Data presented as average + SEM, n=3 samples, * p < 0.05. Samples were compared using Kruskal-Wallis followed by post-hoc Dunn's tests.

In conclusion, ovarian cancer cells with high levels of CD44 have increased proliferation and migration with HA treatments that model stromal HA but not those that model serum HA. Cells with lower levels of CD44 do not show the same changes in cell behavior. These results suggest a unique interaction between mechanical stimulation and HA-binding that creates mechanosignaling through the CD44 receptor to drive ovarian cancer cell proliferation and migration. With CD44 expression noted in a variety of cancers, these results may translate to other cancers including breast, prostate, head and neck cancers, and glioblastomas. Future studies will focus on uncovering the specific mechanism of mechanosignaling in the CD44 pathway.

THE FATE OF ULTRASMALL FLUORESCENT SILICA NANOPARTICLES AS DRUG DELIVERY VEHICLES IN CARTILAGE EXPLANTS: DIFFERENTIAL RETENTION KINETICS BETWEEN MATRIX AND CHONDROCYTES

INTRODUCTION

The effectiveness of intra-articular (IA) drug delivery approaches for osteoarthritis (OA) is hindered by the dense, avascular extra-cellular matrix (ECM) of cartilage and the rapid synovial fluid clearance time on the order of hours[1]. Due to these diffusion and clearance constraints, there are no available IA-injectable therapeutics that prevent cartilage loss – the hallmark of this irreversible disease[1,2]. Injectable nano- and micro-particle systems have been engineered to deliver therapeutic payloads, yielding modest improvements in cartilage penetration and joint residence time compared to free therapeutics[3,4,5]. However, little is known regarding the fate of these vehicles within joint tissues.

Ultrasmall (d_h ~ 6 nm) fluorescent poly(ethylene glycol) coated core-shell silica nanoparticles (Cornell Prime Dots, or C' Dots) have been used in multiple investigational new drug (IND) FDA-approved diagnostic and therapeutic human clinical trials in oncology[6,7]. Locally or systemically injected C' Dots exhibit favorable biodistribution and pharmacokinetics (PK) in humans due to their small size which enables renal clearance[6]. Our work aims to translate this promising nanotechnology to applications in OA. We have shown previously that C' Dots penetrate the articular surface of healthy cartilage within 2 hours (D_{eff} = 2 μm²/s) to reach tissue-resident chondrocytes *in vitro*[8]. Separately, we characterized the clearance of IA-injected C' Dots in rat knees as a biexponential decay ($t_{1/2,\,1}$ ~ 0.5 days; $t_{1/2,\,2}$ ~ 2 weeks) and observed joint retention for 3+ months after a single injection[9].

Therapeutic nanoparticles are typically characterized for bulk cartilage penetration or biocompatibility and targeting in 2D chondrocyte cultures, but few studies have reported on the role of tissue-resident chondrocytes as part of a delivery strategy[3,4,5]. To our knowledge, there are no data describing the fate of nanoparticles in intra-tissue and intra-cellular compartments in 3D whole tissue. Understanding and leveraging these biological and transport phenomena may inform the design of future OA therapeutics.

The objective of this study was to utilize C' Dots as an ultrabright and photostable fluorescent tracker to probe their processing dynamics and retention kinetics in chondrocytes by assessing whole cartilage explants over 6 days *in vitro*. We hypothesized that internalized C' Dots (e.g. loading explants for 24 hours) would be released from chondrocytes and ECM by 5 days after removal of C' Dots from the media.

METHODS

C' Dot Synthesis: Cyanine 5 fluorophore-encapsulating C' Dots were synthesized following previously established methods[10,11]. *Cellular Internalization:* Cylindrical cartilage plugs (d = 6 mm, h = 2 mm, n = 3 per group) were cut from the patellofemoral groove of 1-3 day old bovine stifle joints and randomly assigned to C' Dot (EXP) or Control (CTRL) groups. C' dots in media (2 μM) passively diffused through the articular surface and radial edges of submerged cartilage plugs[12]. After 24 hours, EXP plugs were moved to fresh media and washed once per day until imaging. *Imaging:* Cartilage plugs were bisected with a lubricated blade for staining (30 minutes Calcein, AM & Sytox Blue nucleic acid stain, 30 minutes lysosome stain, or 24 hours endosome transfection). Tissue penetration and cellular internalization of C' Dots were assessed at the bisected plane using a Zeiss 710 inverted confocal microscope and the following excitation wavelengths: Sytox Blue (405 nm), Calcein, AM (461 nm), Endosome-GFP (488 nm), LysoView 540 (540 nm), tissue reflectance (561 nm), and Cyanine-5 (633 nm). *Image Analysis:* A custom MATLAB code created logical masks for each sample compartment. Sample viability was calculated from Calcein and Sytox Blue cell counts (samples with < 1000 total cells were excluded from further analysis). *Statistical Analysis:* Viabilities and Mean Pixel Intensities were compared using a linear mixed-effects model

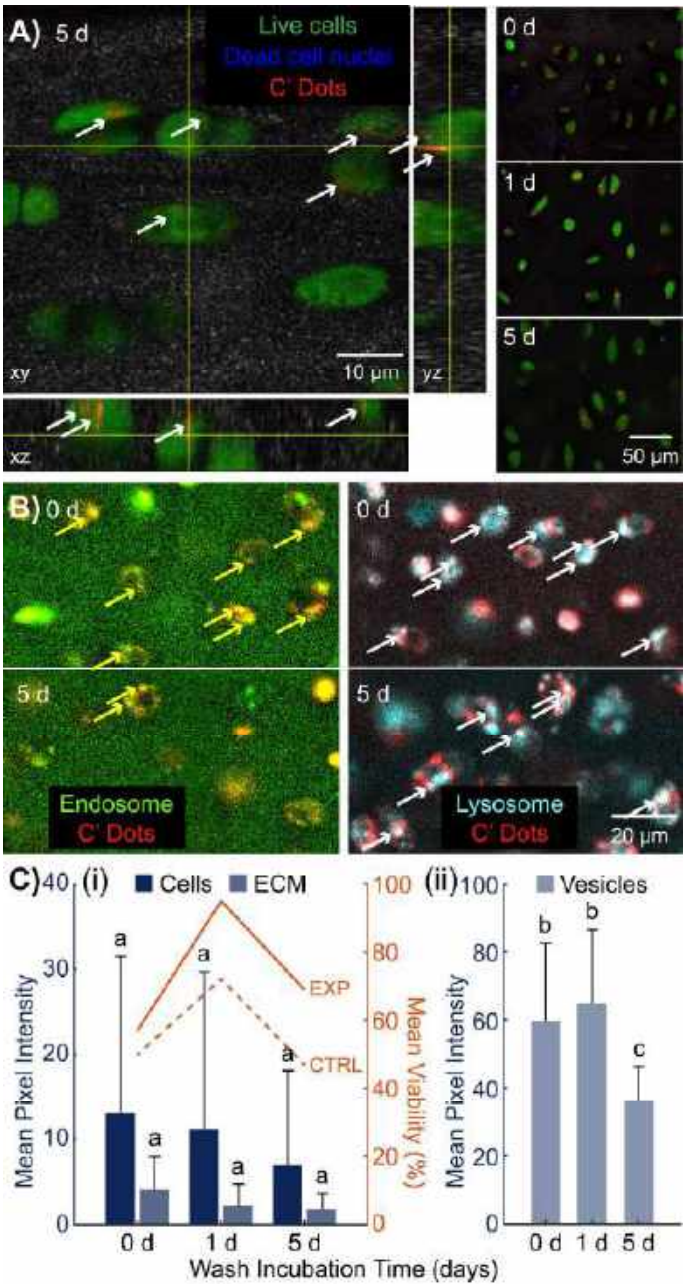

Figure 1. C' Dots are internalized by native chondrocytes in whole cartilage and retained intracellularly for 5 days after removal from the media. A) Merged confocal fluorescence micrographs showing internalized C' Dots (z-stack spans 10 µm; green – Calcein, AM, red – Cyanine 5). Orthogonal views highlight intracellular localization of C' Dots. Arrows indicate C' Dot fluorescence. **B)** Merged confocal micrographs showing internalized C' Dots at 0d (i.e. 24 hours loading) and 5d with co-staining of *(left)* endosomes and *(right)* lysosomes. Arrows indicate colocalized C' Dots & stain. Notably, C' Dots are present in endosomes, lysosomes, and unlabeled vesicular structures. **C) (i)** Quantified mean pixel intensity of C' Dot fluorescence within live cells and within ECM (left axis) and mean viabilities (right axis). **(ii)** Quantified mean pixel intensity of C' Dot fluorescence within vesicular structures (r = 1.5 µm) in live cells. Shared letters denote no significant difference between groups (α = 0.05).

with Kenward-Roger approximation (α = 0.05).

RESULTS

Fluorescent C' Dot puncta were observed within live cell cytoplasm after 24 hours of incubation and 5 subsequent days of washing (**Fig. 1A** *(left)*). C' Dot signal remained detectable intracellularly and in ECM from 0 to 5 days after C' Dots were removed from the media (**Fig. 1A** *(right)*). C' Dot signal was co-localized with endosomal and lysosomal fluorescent markers (arrows), but unlabeled C' Dot-containing vesicular structures were also present (diameter ~ 0.5 – 4 µm) (**Fig. 1B**).

Mean C' Dot signal in the Cell and ECM compartments trended towards decreasing with longer washing, with ~50% reductions observed from 0 d to 5 d (**Fig. 1C (i)**, p = 0.79, p = 0.97, respectively). C' Dot signal is highly heterogeneous within cells; this organization into subcellular vesicular structures contributes to the observed variation in Cell pixel intensity. Vesicle C' Dot signal decreased from 1d to 5d (p = 0.036) and is distinct from total Cell and ECM compartments at 5 d (**Fig. 1C (ii)**, p = 0.037, p = 0.014, respectively). Viabilities were not different between groups (**Fig. 1C (i)**, p > 0.05).

DISCUSSION

C' Dots were internalized within 24 hours by chondrocytes in 3D cartilage explants and remained detectable in Cell, ECM, and Vesicle compartments over 5 days of washing. While we expect that C' Dots will be released from chondrocytes at later timepoints, these processing dynamics and unexpected retention kinetics observed on this timescale offers insight into chondrocyte dynamics for possible applications in drug delivery.

In other studies, chondrocytes in 2D cultures robustly endocytose fluorescent particles as the primary (but not exclusive) uptake mechanism[4,5]. Particles are internalized within 3-6 hours and retained for up to 48 hours[4,5]. To our knowledge, this study is the first to examine compartmental retention of nanoparticles for longer than 48 hours, and the first to use whole tissue explants to investigate chondrocyte processing dynamics.

The role of chondrocytes in processing injected particles may offer a previously unexplored mechanism for increasing joint retention of OA therapeutics. The exceptionally long joint residence of untargeted, unfunctionalized C' Dots observed in our previous *in vivo* study may be due in part to particle interactions with tissue-resident cells[4,5,9]. Further investigation of not only bulk tissue transport kinetics, but complex cell-mediated sink/source modeling on the timescale of days to weeks is necessary to bridge the gap in timescale between *in vitro* studies (e.g. hours-days) and preclinical models (e.g. months-years).

This study highlights the active role of chondrocytes in mediating nanoparticle presence in whole cartilage tissue and yields important insights into chondrocyte-mediated mechanisms to extend particle joint residence and deliver therapeutics with subcellular precision.

LUNG LOBAR SLIDING REDUCES PARENCHYMAL DISTORTION IN THE LEFT AND RIGHT LUNGS

Adam E. Galloy (1), Joseph M. Reinhardt (1), Suresh M. L. Raghavan (1)

(1) Roy J. Carver Department of Biomedical Engineering, University of Iowa, Iowa City, Iowa, United States of America

INTRODUCTION

Lung lobar sliding is an often-overlooked aspect of lung mechanics. Human lungs are typically divided into five lobes (two on the left and three on the right) separated by lobar fissures that allow sliding between lobes. However, some people have incomplete, missing, or auxiliary lobar fissures which may affect lung mechanics through the intermediate mechanism of lobar sliding. During their study of the deformation of dog lungs, Hubmayr et al. [1] hypothesized that lung lobar sliding "provides the means to reduce parenchymal distortion". This hypothesis is difficult to test with controlled in vivo experiments since a method would need to be developed that can prevent sliding between complete lobes without otherwise impacting the deformation of the lung tissue.

The goal of this study was to test the hypothesis that lung lobar sliding reduces parenchymal distortion by performing paired comparisons between subject-specific contact mechanics models of the lung that do and do not allow lobar sliding.

METHODS

Six healthy subjects (ages 22-37) underwent CT scans following a procedure approved by our institutional review board. Scans were obtained with the subjects in the supine position during breath holds at total lung capacity (TLC) and functional residual capacity (FRC). The lobes of the lungs and the left and right thoracic cavities (defined here as the outline of the full lung) were segmented from the images. From the segmentations at TLC, solid meshes representing the lung lobes were generated along with a surface mesh of the thoracic cavity. Left and right lungs were meshed and analyzed separately.

Subject-specific contact mechanics models of lobar sliding were implemented in FEBio using the procedure described in Galloy et al. [2]. Briefly, the lung parenchyma was modeled as a homogenous, hyperelastic solid using the neo-Hookean constitutive law ($\lambda = 1.73$ kPa, $\mu = 1.15$ kPa). Nonzero displacements were prescribed to the thoracic cavity surface to drive deformation of the lobar tissue with frictionless sliding contact constraints between the lung lobes and thoracic cavity. Thoracic cavity displacements were derived by non-rigid registration of the thoracic cavity mask at FRC to the mask at TLC. For the lobe-lobe contact interfaces two different models were made for each subject: a sliding model where frictionless sliding was allowed between lobes, and a non-sliding model where a high Coulomb friction coefficient ($f = 1.5$) effectively eliminated sliding. Boundary conditions for both models are schematically illustrated in Figure 1. Simulations were quasi-static and assumed no viscoelasticity in the lung tissue.

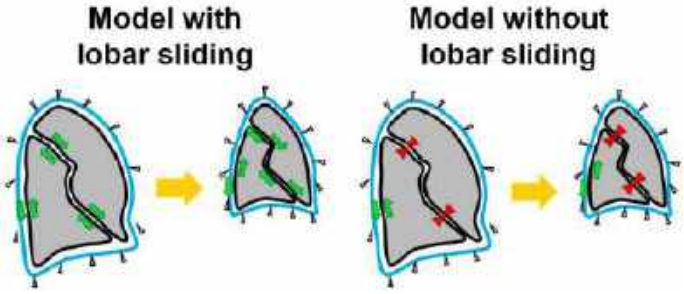

Figure 1: Subject-specific thoracic cavity surface displacements were applied to drive deformation of the lobe volumes through sliding contact constraints. To delineate the effect of lobar sliding a model was made with frictionless sliding between lobes (left) and another with a large friction coefficient to prevent sliding (right).

Parenchymal distortion was quantified by computing the anisotropic deformation index (ADI) in each element of the model [3]:

$$\mathrm{ADI} = \sqrt{\left(\frac{\lambda_1 - \lambda_2}{\lambda_2}\right)^2 + \left(\frac{\lambda_2 - \lambda_3}{\lambda_3}\right)^2} \quad (1)$$

Where λ_i are the principal stretches sorted from greatest to least. The ADI quantifies the anisotropy of deformation independent of volume change making it an appropriate metric for quantifying lung parenchymal distortion. The spatial mean ADI was computed for both the sliding and non-sliding model of each subject for paired intra-subject comparison. Wilcoxon signed rank tests were performed to determine statistical significance ($p < 0.05$).

RESULTS

Mean ADI and its difference between the sliding and non-sliding models for each subject is displayed in Figure 2 to demonstrate the effect of lobar sliding on parenchymal distortion. Results for the left lung are adapted from [4], with the right lung results novel to this work. Examining the lungs in their entirety, the mean ADI was lesser in the sliding models than the non-sliding models with median percent differences across the subjects ($n = 6$) of 3.2% ($p = 0.03$) and 19.6% ($p = 0.03$) for the left and right lung respectively indicating a reduction in distortion with lobar sliding. Notably, lobar sliding had a more pronounced effect on the right lung than the left lung. Examining individual lobes, the reduction in distortion primarily occurred in the left lower, right lower, and right middle lobes with median percent differences of 8.0% ($p = 0.03$), 19.6% ($p = 0.03$), and 40.7% ($p = 0.03$) respectively. On the other hand, in the upper lobes of the lungs the difference in mean ADI between sliding and non-sliding models was insignificant with the median percent difference having the reverse trend of 1.9% ($p = 0.06$) and 1.1% ($p = 0.84$) greater mean ADI in the sliding model for the left and right upper lobes respectively.

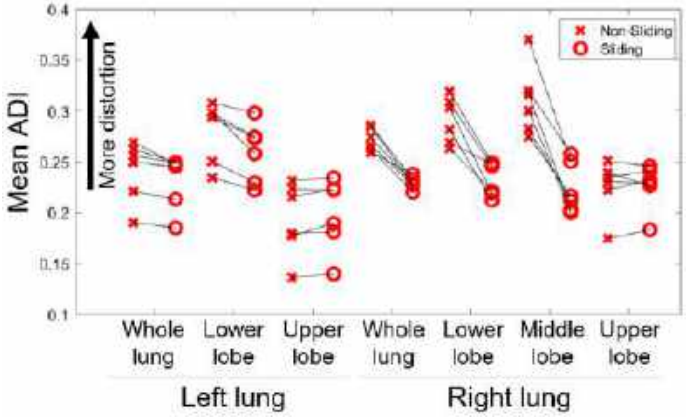

Figure 2: Consistent with the hypothesis that lung lobar sliding reduces parenchymal distortion, the spatial mean ADI for both lungs was lower in simulations that allowed lobar sliding than paired simulations that did not. The difference primarily occurred in the lower and middle lobes with no significant difference in the upper lobe of both lungs.

Contour plots of ADI in a representative subject's right lung (Figure 3a & b) further illustrate the regional differences in lobar sliding's effect on distortion. In the non-sliding model, parenchymal distortion is most densely concentrated towards the base of the lung near the lobar fissure between the left and middle lobes, but this distortion is significantly relieved in the sliding model. The denser concentration of distortion at the base of the lung could explain the greater reduction in distortion with lobar sliding in the lower and middle lobes than the upper lobes. Furthermore, plots of ADI vs. distance from the fissures (Figure 3c) for each right lung lobe in both models demonstrate that the distortion-reducing effect of lobar sliding is most pronounced near the fissure of the lower and middle lobe. The upper lobe is not as affected by lobar sliding regardless of distance from the fissure.

DISCUSSION

The lesser amount of mean ADI in sliding models when compared to non-sliding models is consistent with the hypothesis of Hubmayr et al. [1] that lung lobar sliding reduces parenchymal distortion. This result suggests subjects with incomplete or missing fissures may require more mechanical work to breathe. The need to reduce parenchymal distortion (or the lack of such need) may help explain differences in lobar anatomy between animal species. For example, Hoffman and Ritman noted pronounced lobar fissures in the relatively shape-dynamic lungs of dogs, but fibrosed fissures in the more inert lungs of sloths [5].

The effect of lobar sliding on parenchymal distortion varied with location. The right lung had a significantly larger reduction in distortion with lobar sliding than the left lung did. This is likely because the right lung's three lobes provide more degrees of freedom to reduce the impact of thoracic cavity shape changes on parenchymal distortion. Lobar sliding also had a greater effect on the lower and middle lobes than it did the upper lobes. This seems to be because of the larger amounts of distortion near the base lung where diaphragm motion causes some of the largest shape changes of the thoracic cavity.

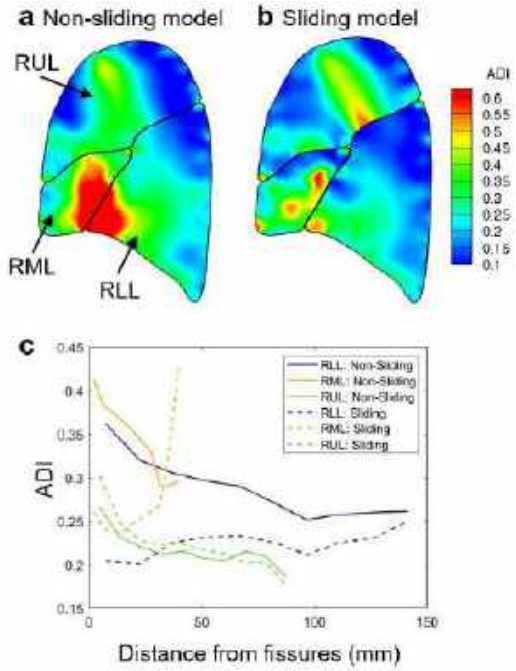

Figure 3: ADI contour plots for both right lung models of a representative subject (a & b) suggest lobar sliding affects the lower and middle lobes more than the upper lobe because of the higher concentration of distortion near the base of the lung. Lobar sliding's effect is greatest near the lobar fissures for the lower and middle lobes, but the upper lobe was largely unaffected by lobar sliding regardless of location as seen in plots of ADI vs. distance from lobar fissures (c).

INTRODUCTION

Glaucoma is the leading cause of irreversible blindness worldwide and is commonly associated with elevated intraocular pressure (IOP). The trabecular meshwork (TM) and Schlemm's canal (SC) – together forming the aqueous outflow pathway – are the primary tissues controlling aqueous humor outflow and IOP. Mice are often used to study these tissues' role in glaucoma; however, mouse eyes have anatomical differences vs. humans that need to be considered. Notably, the murine eye's aqueous humor outflow pathway contains prominent pectinate ligaments (PLs) that connect the iris to the TM (Fig 1). The PLs can exert mechanical traction on the TM, deforming TM and SC, thus affecting aqueous humor outflow [1], which may confound the translation of results obtained in mice to humans. In addition, PLs have developed differentially across species, indicating a potential evolutionary significance [2]. However, much is unknown about the PLs' biomechanics and function, thus motivating this study.

We hypothesized that PL biomechanics directly influences the patency of the murine outflow pathway, including the lumen of SC. We therefore investigated the role of PLs in a common model used in glaucoma research, namely C57BL/6 mice. Specifically, we used image-based finite element (FE) modeling of the murine outflow pathway, based on histomorphometric and optical coherence tomography (OCT) images. We also conducted parametric numerical simulations to elucidate how outflow pathway patency changed with IOP.

METHODS

We summarize experimental procedures described in detail elsewhere [3], [4]. In brief, we conducted OCT imaging of the mouse anterior eye during ocular perfusion tests to capture IOP-induced iris and outflow pathway tissue deformations. Further, we histomorphometrically determined the dimensions of TM region tissues, which are not generally visible in OCT. By combining OCT images and histomorphometric measurements, we then created age-specific finite element (FE) models and evaluated the effects of changing IOP and tissue stiffness on outflow pathway patency, especially SC canal lumen area (SCLA).

Animals: We used wild-type C57BL/6 mice from three age groups: 'young' (2-6 mo), 'middle-aged' (11-16 mo), and 'elderly' (25-32 mo). All procedures received IACUC approval at Duke University.

OCT imaging: Anesthetized mice underwent ocular perfusion at IOP levels of 10, 15, and 20 mmHg [4]. Two types of OCT images were acquired from different mice during perfusions: High resolution (TM-OCT) and low resolution (Iris-OCT), enabling evaluation of SC and iris deformations, respectively.

Histomorphometric analysis: Since the detailed structure of the TM region was not visible by OCT, we augmented OCT images with 0.5 µm

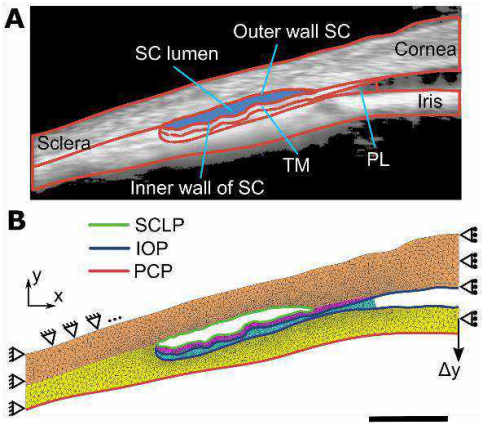

Fig. 1: (A) TM-OCT image used for creating the young model. The boundaries of different regions are shown in red and annotated (SC= Schlemm's canal, TM = trabecular meshwork, and PL = pectinate ligament). (B) The corresponding FE mesh and its associated boundary conditions. SCLP = SC lumenal pressure, IOP= intraocular pressure, PCP = posterior chamber pressure. Scale bar = 100 µm

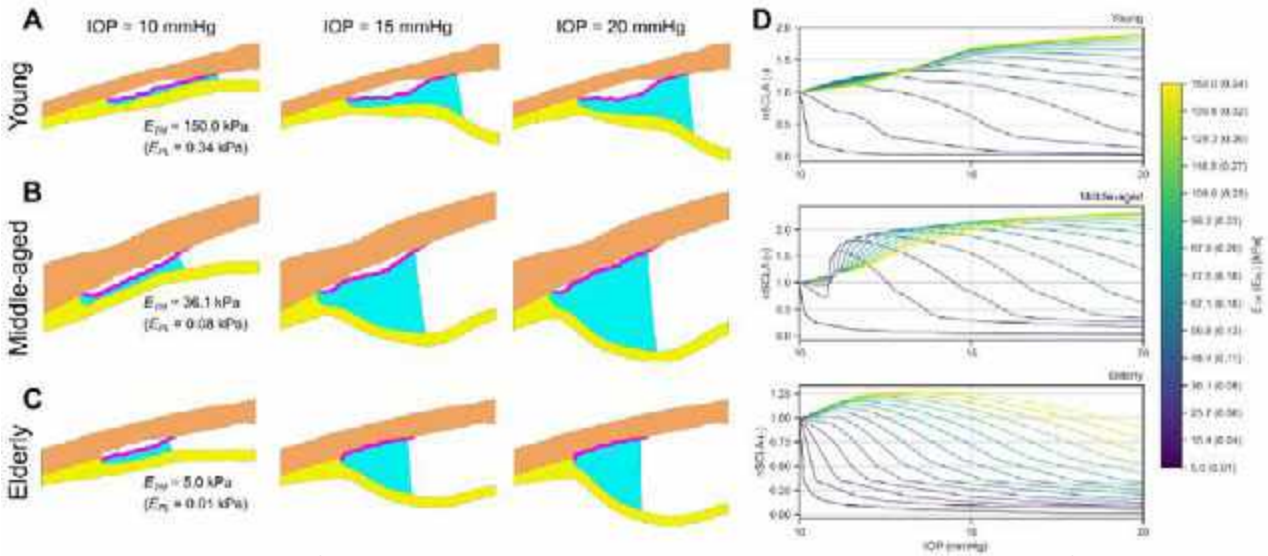

Fig. 2: Representative simulation results from (A) young. (B) middle-aged and (C) elderly models, and (D) detailed graphs of nSCLA dependence to IOP at different TM/PL stiffness (colored lines). Our results indicated that SC collapse was not guaranteed at elevated IOP, where, for instance, in the young models (A and D), the higher TM/PL stiffness case showed expansion of SCLA with elevation of IOP.

thick sagittal histologic sections from age-matched eyes, stained with methylene blue. Key features of the TM region were manually annotated (e.g., TM cross-sectional area and length). These values were used in the creation of age-specific FE meshes.

FE modeling: We used the TM-OCT images to delineate the boundaries of the cornea, sclera, iris, and SC (Fig. 1A). TM and PL regions were added based on the histomorphometric analysis. We then extruded the 2D boundaries by 10 μm to create a plane-strain model, justified based on the small size of the TM region relative to the distance from the eye's axis of symmetry. As a simplifying assumption, the PLs were modeled as a homogenized region. We used TET10 elements for meshing.

The boundary conditions were based on the pressures during the perfusion test ([4]; Fig. 1B), and the deformations of the iris were specified based on the data from the Iris-OCT images (Fig. 1B).

An incompressible, neo-Hookean model was used for all the tissues, except PLs, which were modeled as compressible (Poisson ratio = 0) to account for their fibrous structure. Young's modulus (E) was set to 2700 kPa for cornea/sclera [5] and 96.1 kPa for iris [6]. We varied E_{TM} over a physiological range (5-150 kPa). Finally, we estimated the PL region's effective stiffness as E_{TM} multiplied by a fixed percentage (0.23%), based on the solid fraction of the PL beams.

Data analysis: For each age model, we simulated 15 cases with different TM/PL stiffness using FEBio [7]. We calculated the normalized SC lumen area (nSCLA) as:

$$nSCLA = \frac{SCLA}{SCLA_{@10\ \mathrm{mmHg}}} \quad (1)$$

To quantify SC patency, we defined SC collapse as the nSCLA value becoming less than 33%.

RESULTS

In all age models, we observed SC lumen collapse at elevated IOP (Fig. 2), consistent with experimental observations [4]. Further, SCLA was strongly dependent on TM/PL stiffness, and showed a non-linear dependence on IOP (Fig. 2C). However, SC collapse did not happen in all cases; for example, it only occurred at low TM/PL stiffnesses (lower than E_{TM}/E_{PL}=25.7/0.06 kPa in the young and middle-aged models, and 87.9/0.20 kPa in the elderly model). In all age models, when TM/PL-stiffness was large and IOP was elevated, we were surprised to observe a non-physiological opening of the SC lumen (Fig. 2A). Overall, the elderly model showed a higher susceptibility to IOP-induced SC collapse compared to the younger models.

DISCUSSION

This study provides an analysis of the PLs' role in influencing patency of the outflow pathway, in particular the IOP-induced changes in SC lumen area (SCLA). Our results indicated that the SCLA is sensitive to PLs' biomechanical properties. We also observed that the PLs can exert mechanical traction opposite to that of the physiological trans-TM pressure, thereby inhibiting SC collapse. We also showed age-specific differences in the role of PL in IOP-induced SCLA changes, with younger eyes being less susceptible to SC collapse than older ones.

Our study had some limitations. For instance, since no experimental PL biomechanical properties have been reported, we estimated the PL stiffness from that of TM, an adjacent tissue of similar developmental origin. Further, we modeled the PLs as a homogenized material; in reality, PLs are a complex fibrous structure. Future studies should focus on the characterization of the PL structure and biomechanics to better elucidate the potentially crucial role of PLs in outflow pathway patency and ultimately IOP dynamics in animal models of glaucoma.

INTRODUCTION

Cancer remains a leading source of mortality, with an estimated incidence of 17.5 million cases worldwide. The suggested treatment protocol for many thoracic and breast cancer patients involves radiation therapy (RT), which accounts for significant reduction in malignancy [1]. The risks associated with RT limit its benefits as a long-term therapeutic measure, and are a major health concern. The increasing prevalence of thoracic RT has been associated with the development of radiation-induced cardiotoxicity (RIC). RIC-related myocardial injuries have been identified as precursors to cardiac dysfunction in the form of fibrosis and metabolic impairments that could restrict myocardial contractility. However, despite the benefits of standard functional indices such as the ejection fraction (EF) in diagnosing advanced cases, they fall short in detecting the early-stage development of RIC [2,3]. In contrast to the poor efficacy of functional indices, which are insensitive to subclinical dysfunction, structural indices such as cardiac strains are strong determinants of early-stage cardiac diseases. However, current strain metrics are limited to the anatomical axes, i.e., radial-circumferential-longitudinal (RCL) axes, which may confound the representation of RIC-related myofiber impairment. We propose the investigation of three-dimensional principal strains as an approximation of myofiber contraction to improve the assessment of early-stage RIC.

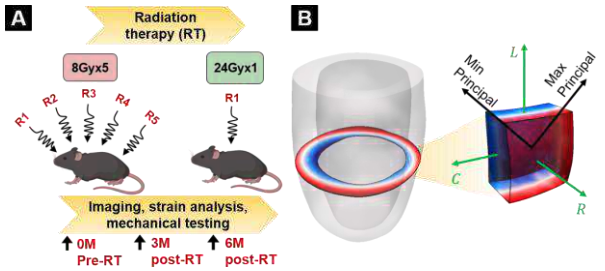

Figure 1: Schematic representation of (A) the longitudinal study to investigate the incidence of radiation-induced cardiotoxicity and (B) strain analysis in the left ventricle (LV)

METHODS

We implemented a longitudinal study in two cohorts of C57BL mice subjected to RT and a pre-RT control group (Control; n = 5; Fig. 1). The first RT group was subjected to five doses of 8 Gy radiation (8Gyx5; n= 5) and the second group was administered a single dose of 24 Gy radiation (24Gyx1; n = 5) via whole heart irradiation using a small animal irradiator (X-RAD 225Cx- Precision X-ray Inc). *In-vivo investigation:* Cardiac magnetic resonance imaging was performed for all mice pre-RT (0M), and three- (3M) and size-months (6M) post-RT. Short-axis (SA) images of the left ventricle (LV) were acquired using a 7T Bruker Avance III HD scanner with a 72 mm quadrature proton volume coil. All mice were anesthetized prior to the procedure, with anesthesia administered via 1-5% isoflurane. An in-house non-rigid image registration framework was used to estimate cardiac motion in terms of cartesian displacements. The resulting displacement vectors and cartesian strain tensor ($\boldsymbol{E}$) were subsequently used to derive strains at end-systole in the RCL axes.

$$\boldsymbol{E}_{RCL} = \boldsymbol{Q}\boldsymbol{E}\boldsymbol{Q}^T = \begin{bmatrix} E_{RR} & E_{RC} & E_{RL} \\ E_{CR} & E_{CC} & E_{CL} \\ E_{LR} & E_{LC} & E_{LL} \end{bmatrix}; \; \boldsymbol{Q} = \begin{bmatrix} cos\theta & -sin\theta & 0 \\ sin\theta & cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

In contrast to the anatomical strains (E_{RR}, E_{CC}, E_{LL}) that ignore all three components of shear and offer confounded measures in describing myofiber contraction, principal strains incorporating both normal and shear strains represent the maximum deformation. The maximum (E_1) and minimum principal (E_3) strains were calculated using an eigenvalue decomposition of $\boldsymbol{E}$. A single global organ-level value averaging the regional distribution of normal or principal strains was calculated to obtain the global circumferential strain (GCS) and the global E_3 strain. *Ex-vivo investigation*: In addition to in-vivo strain analysis, we also

employed ex-vivo mechanical testing to determine the effects of RIC on the biomechanics of the LV myocardium. Hearts were harvested pre-RT and 3M post-RT for five control and 8Gyx5 mice, and the left ventricular free wall (LVFW) was excised. Fresh LVFW specimens were equibiaxially stretched at a rate of 1% per second to a maximum stretch of 30%.

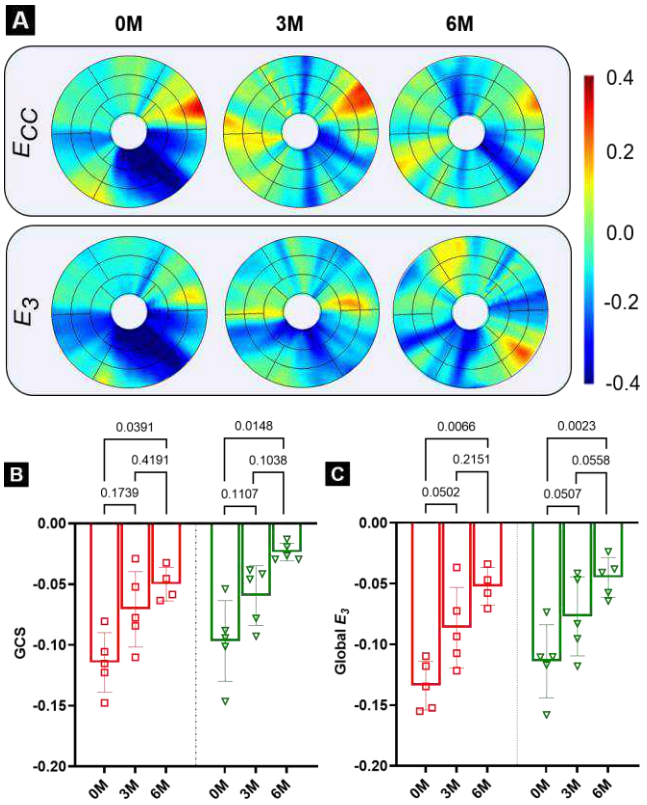

Figure 2: Representative heat maps of end-systolic strain calculations in AHA segmentation plots along the (top) circumferential (E_{CC}) and (bottom) minimum (E_3) principal axes for 8Gyx5 mice. (B) Estimation of the global circumferential (GCS) and minimum principal strains (global E_3) for □ 8Gyx5, and ▽ 24Gyx1 groups at pre-RT (0M, Control), three- (3M) and six-months (6M) post-RT.

RESULTS

Strain analysis showed stark variations in the contractile function of the LV between pre- and post-RT (Fig. 2A). Similar trends in the time-course changes in contractility were noted between GCS and the global E_3 metric (Figs. 2B, C). A near 50% drop in the GCS was observed between 0M and 6M post-RT (-0.09685 ± 0.0332 vs. -0.0594 ± 0.0245). Principal strain markers presented improvements in confidence intervals for both radiation groups, with marked reductions in contractility along the minimum principal axis from 0M to 6M post-RT for all mice in both groups (8Gyx5: -0.1178 ± 0.0252 vs. -0.0506 ± 0.0130; 24Gyx1: -0.1079 ± 0.0337 vs. -0.0450 ± 0.0162 (Fig. 2B). Moreover, the principal strain marker offered improvements in the statistical confidence in the early stages of RIC, with marked reductions between 0M and 3M post-RT. In contrast, measurements of EF at all timepoints presented minimal changes, indicating preserved cardiac function in both groups (Fig. 3A). In addition to the statistical confidence in varying contractile behavior between the control and 8Gyx5 mice evidenced via the in-vivo strains, an increase in the ensemble LVFW stress, measured as the sum of circumferential and longitudinal stresses, was noted at 3M post-RT suggesting RIC-related myocardial stiffening (Fig. 3B).

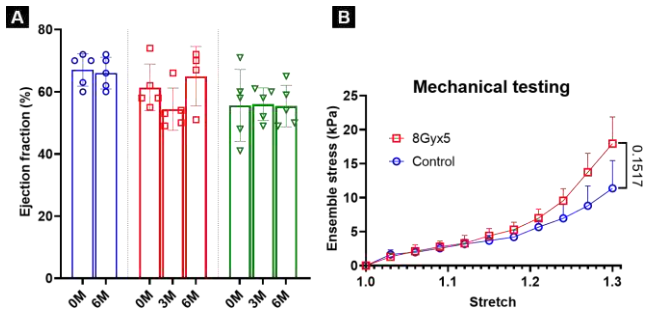

Figure 3: (A) Left ventricular ejection fraction for o Control, □ 8Gyx5, and ▽ 24Gyx1 groups at all timepoints. (D) Ensemble LVFW stress for Control and 8Gyx5 mice at 3M post-RT.

DISCUSSION

Despite the merits of traditional measurements of the EF in advanced-stage RIC, they have shown little promise as an early-stage biomarker. The strain indices proposed in this study aim to provide a more sensitive link between subclinical LV dysfunction and myofiber impairments, thus improving the detection of early-stage RIC. Our findings revealed a rapid decline in LV contractility not evidenced via the EF measurements, suggesting the presence of subclinical LV dysfunction. This is supported by the progressive reduction in both anatomical and principal strain values, with the global E_3 metric offering better delineation of the potential time-course impairments in the LV. Despite comparable magnitudes, E_3 provided a more precise estimation of RIC than GCS while providing greater statistical confidence between all the timepoints. A possible explanation could be the torsional mechanics exhibited by the LV during contraction, and underlying transverse CL shear. Since LV torsion is widely attributed to the helical arrangement of myofibers leading to a counter-rotational twist, principal strain analyses that account for both normal and shear strains may show greater association with the resulting myofiber shortening. Moreover, ex-vivo mechanical testing highlighted potential stiffening of the myocardial tissue, with further investigations required to quantify the associated fiber-level adaptations. A histological examination quantifying the helicity of myofibers will provide further insight into the sensitivity of principal strains to myofiber impairments. Specifically, fiber-level contributors to organ function have been experimentally validated for small animal models [4], and we expect our proposed strain markers to be strong determinants of organ- and fiber-level dysfunction. Additionally, both strain markers provided high levels of statistical significance ($p < 0.05$) 6M post-RT, thus highlighting the utility of structural indices in detecting RIC. Moreover, the alignment of the principal strains with the LV microstructure carries the potential to improve the early-stage diagnostic efficacy of strain analysis. Our findings through a comprehensive strain analysis and mechanical testing offered insight into the debilitating effects of RT on cardiac function. The quantification of contractility and its association with fiber-level dysfunction holds great promise in the characterization of remodeling before the manifestation of LV global decompensation.

PROBABLE RELATION BETWEEN STRUCTURE & COMPOSITION OF THE DENTIN-ENAMEL JUNCTION (DEJ) & DENTINOGENESIS IMPERFECTA (DGI)

Sobhan Katebifar (1), Kai Clark (1), Bradley S. Rosenberg (2), Michael Truhlar (2), Alix C. Deymier (1)

INTRODUCTION

Dentinogenesis Imperfecta (DGI) is an inherited disorder affecting dentin and enamel [1]. DGI type I, associated with COL1A1 or COL1A2 mutations, leads to collagen type I disruption. Individuals with DGI type I exhibit translucent or discolored teeth, rapid enamel loss, and increased tooth wear due to softer dentin [2]. All types of DGI cause tooth discoloration, dentin weaknesses, and enamel defects [3]. Understanding of the structural and mechanical causes of tooth attrition in DGI, particularly at the Dentin-Enamel Junction (DEJ), is limited. The DEJ, the interface which connects dissimilar dentin and enamel tissues, has a graded structural design that minimizes stress concentrations in healthy teeth, making it fracture-resistant [4]. Enamel loss in DGI is suggested to originate from or near the compromised DEJ [5]. This study aims to elucidate the murine DEJ's structure and composition in relation to DGI type I, utilizing Micro-Computed Tomography, high-resolution Raman Spectroscopy mapping and Scanning Electron Microscopy for analysis.

METHODS

Tooth acquisition & Sample Preparation: The Col1a2oim mouse (OIM) was used as a model for Dentinogenesis Imperfecta (DGI). The mice were bred from heterozygous pairs. Genotyping was done through ear notching and DNA extraction, followed by polymerase chain reaction (PCR) and Sanger sequencing. Age-matched Wild type (WT) littermates served as controls. At 12 weeks of age, 20 OIM and 20 WT mice were sacrificed for analysis of their upper and lower incisors through various assessments (Fig. 1). The lower right incisors (n=5 per group) underwent micro-CT scanning without additional preparation. Meanwhile, the left lower incisors (n=5 per group) were embedded, polished for Raman spectroscopy, and coated with Au/Pd for SEM imaging to minimize charging. A subset of embedded samples (n=3 per group) also underwent acid etching before SEM imaging.

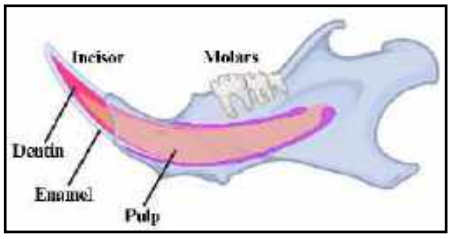

Fig. 1: Schematic of a mouse incisor

Micro-Computed Tomography: The thawed tooth samples were examined with Scanco 50 microcomputed tomography with a resolution of 3.4 µm. Attentuation coefficients across the DEJ of all teeth were determined using CTAn software. Gradients in the attenuation coefficient, which is correlated to tissue density, were fit with a logistic function. The full width half max (FWHM) of the derivative of the logistic function was used to determine the gradient width.

Raman spectroscopy: Raman spectra were acquired over a 15x15 µm area across the DEJ with a 0.5 µm resolution using a Witec Alpha 300 Raman Spectrometer. The 960 cm^{-1} PO_4^{3-} peak FWHM and intensity were determined using Lorentzian fitting and plotted as a function of position. Gradients in peak FWHM, which inversely correlates to crystallinity, and peak intensity, which correlates to mineral content, were fit with logistic functions. Gradients widths and locations were determined from the FWHM and peak center of the logistic function derivative.

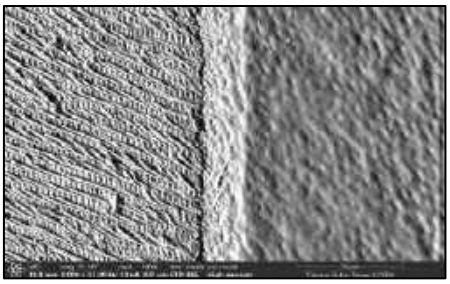

Fig. 2: SEM image from a DGI sample

Scanning electron microscopy (SEM) imaging: After gold sputtering, SEM imaging was conducted on acid-etched (n=3) and unethced samples (n=3) using the

TENEO LVSEM device (Fig. 2). Operating at 15-30 kV, 3.2-13 nA, and high vacuum mode, images were scanned by ETD detector with magnification between ×500 and ×10000. Using ImageJ software, DEJ widths were measured for normal samples, while acid-etched samples were used for mantle dentin width. SEM images were filtered and thresholded for tubule analysis (0.5 to 15 microns) using the ImageJ "Analyze Particle" tool, and porosity was calculated based on tubule count and diameter.

Statistics

For all quantitative data values were compared using 2-way ANOVA followed by Tukey's multiple comparisons test to determine significance using GraphPad Prism software with the factors of condition (DGI and WT) and Sex (male or female). Results are expressed as means ± standard deviation (SD). A value of $p < 0.05$ was considered significant.

RESULTS

Width of the density and compositional gradient across the DEJ: The average density gradient between enamel and dentin was similar for DGI (16.45±3.6 µm) and WT (15.48±2.7 µm) samples, with slight variations between groups. Although DGI females had the widest gradient (17.24±3.4 µm) and WT females the smallest (13.98±2.6 µm), there was no statistical difference overall.

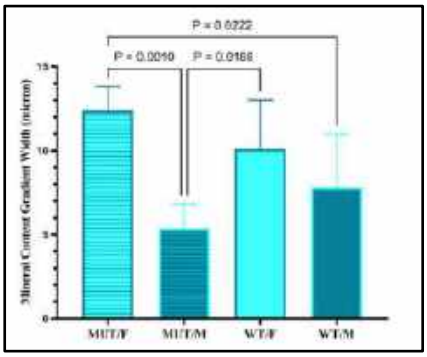

Fig. 3: Mineral content gradient measured by Raman

Raman spectroscopy revealed a larger mineral content gradient in females (11.2±2.5 µm) compared to males (6.6±2.6 µm), irrespective of DGI status. DGI females also exhibited a significantly wider mineral content gradient compared to both DGI and WT males (Fig. 3). The mineral crystallinity gradient (inverse FWHM of PO_4^{3-} ν_1 peak) averaged 9.3±2.7 µm, with no significant differences based on sex or DGI status. The shift in gradient centers between mineral content and mineral crystallinity was similar in DGI and WT mice. However, the mineral content gradient center was significantly shifted towards dentin in females compared to males. The location and width of the PO_4^{3-} ν_1 peak, indicating mineral maturity and crystallinity, remained unchanged in dentin and enamel across sexes and DGI status.

Structural properties (DEJ width, tubule number and size, mantle dentin width) in DGI and WT: In polished samples, the Dentin-Enamel Junction (DEJ) appeared as a single line, but etching revealed a wider zone termed the structural DEJ. DGI mice showed a broader structural DEJ compared to WT, with the widest in DGI females (8± 0.9 µm) and the narrowest in WT males (5±0.7 µm). The DEJ width in female DGI samples is significantly higher than WT males (Fig.4). In SEM examination, DGI mice showed a significant increase in the number of dentinal tubules compared to WT, with mutant females having the highest count (60 per 0.01 mm^2) and WT females having a lower count (30 per 0.01 mm^2). Conversely, the mean diameter of dentinal tubules was significantly smaller in WT compared to DGI, with the largest diameter in WT females and the smallest in DGI females. Despite more tubules in DGI mice, their smaller diameter maintained a consistent total porosity of around 2% to 2.5%. Mantle dentin width significantly decreased in DGI mice compared to WT, with the smallest width in mutant males (43±1.1 µm) and the largest in WT males (around 85 µm).

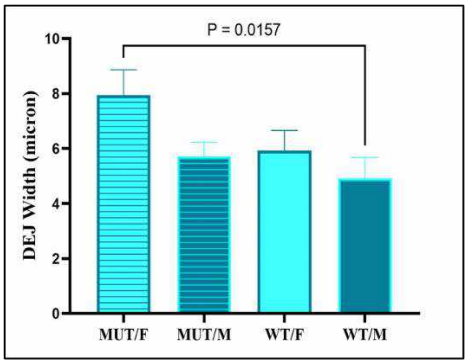

Fig. 4: DEJ width comparison measured by SEM

DISCUSSION

This study shows that the DEJ structure and composition is affected both by DGI and sexual dimorphism. Density gradient widths were unaffected by either factor but agreed with other studies [6]. However, Raman and SEM indicated that the gradients in crystallinity, mineral content, and structural features were significantly smaller, suggesting that the DEJ exhibits multiple overlapping graded structures. The DEJ width as measured by SEM or mineral content was significantly lower in the male mice than the females. This could possibly contribute to the higher occurrence of DGI in men. Although DGI had minimal effects on DEJ width, it had significant effects on the dentin. We found significantly more dentinal tubules in DGI teeth compared to wild types; however, the size of the tubules was reduced in the DGI mice. Although this lead a constant porosity between the DGI and WT enamel, hydrodynamic theory explains that the smaller diameter and greater number of tubules in DGI mice will impact fluid flow and pressure possibly explaining some of the hypersensitivity seen with DGI [7,8]. Finally, the mantle dentin, a thin layer found between the DEJ and the dentin, was significantly thinner in DGI mice compared to WT. This drastic change may be responsible for the higher mechanical failure of DGI teeth; however, little is known about the mechanical role of mantle dentin [9]. This provides an entirely new insight into the compositional and strucutral features that may be critical to controlling tooth mechanics in conditions such as DGI.

MECHANICAL STRESSES IN ATHEROSCLEROTIC CORONARY ARTERIES ARE ASSOCIATED WITH PLAQUE GROWTH

Jeremy L. Warren (1), Clark A. Meyer (1), Heather N. Hayenga (1)

(1) Department of Bioengineering, University of Texas at Dallas, Richardson, TX, United States

INTRODUCTION

Previous research has established that the growth of plaque in atherosclerotic coronary arteries is significantly influenced by low or fluctuating wall shear stress at the luminal surface [1]. However, the role of solid mechanics within the plaque in driving the progression of atherosclerosis remains less understood. To gain insight into this relationship, this study explores how the mechanics of the artery wall affect plaque growth. Using longitudinal patient-specific data and in-silico analyses, we examined correlations between the biomechanics of patient arteries and morphological changes in plaque over a six-month period. The findings from this investigation are expected to enhance our understanding of the mechanical factors influencing plaque growth, offering valuable insights for personalized treatment strategies aimed at slowing disease progression.

METHODS

Our previously published automated meshing algorithm was used to generate volumetric 3D meshes of coronary arteries for finite element analysis (FEA) [2]. A 16-patient dataset of paired VH-IVUS images at baseline (BL) and 6-month follow-up (FU) images were used. Each artery was broken into segments for high fidelity FEA simulations. Volumetric meshes comprised quadratic 10-node tetrahedral elements with a mean edge length of 0.15 mm. A Neo-Hookean material model was utilized for each plaque type [**Table 1**].

Material Type	Young's modulus	Poisson's ratio
Artery	0.3 MPa	0.48
Calcium	10 MPa	0.48
Necrotic Core	0.02 MPa	0.48
Fibrotic	0.6 MPa	0.48
Fibrofatty	0.5 MPa	0.48

Table 1. Neo-Hookean material properties for each plaque type.

Two studies were conducted: (i) an image-to-image comparison study and (ii) a volumetric comparison study.

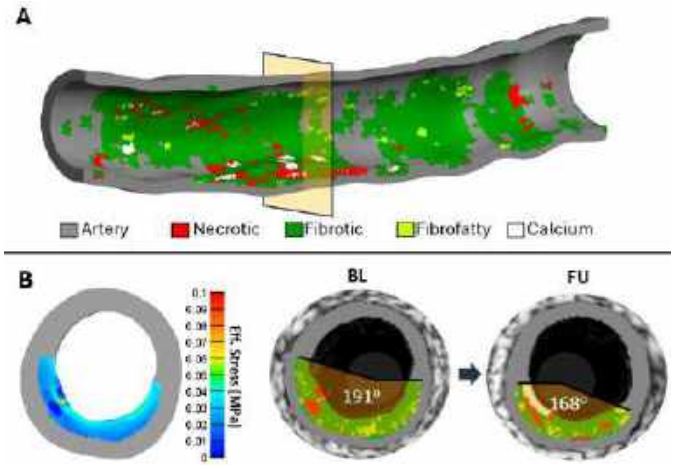

Figure 1. Image-to-image comparison study. A) Volumetric coronary artery mesh. B) FEA analysis and BL to FU images.

Image-to-image Comparison Study. We used our reconstruction algorithm to generate straight meshes of the patient's artery at BL [**Figure 1A**]. Subsequent FEA simulations were performed using the open-source FEBio software [3]. Patient-specific blood pressures were applied to the and the ends of the artery were fixed in space. Heterogenous materials were applied throughout the mesh with literature-derived material properties for each plaque type. Mean elemental effective stress and strain corresponding to each pair of BL and FU VH-IVUS image was calculated from FEA results [**Figure 1B**].

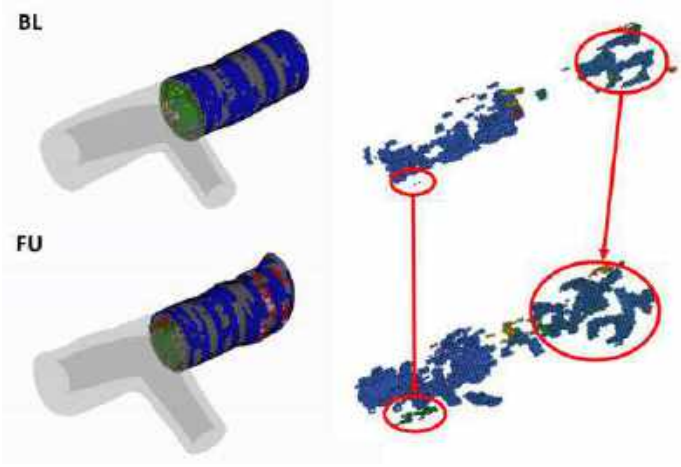

Figure 2. Matching groups of calcium elements in BL to FU volumetric co-registration. Red circles and arrows show co-registered groups of calcium elements.

Volumetric Comparison Study. This study was applied only to severely stenosed, calcified regions of the arteries. The nodes of all calcium elements were combined into a single point cloud. A separate automated script analyzed the point cloud and spatially co-registered groups of calcium elements using a 3D DBSCAN clustering algorithm [**Figure 2**]. Correspondingly, the mean stress of each group of clusters was used to determine correlations between elemental effective stress and changes in calcium volume between BL and FU.

RESULTS

Preliminary results using the 16 patient datasets (1482 total images) showed that larger changes in plaque area between BL and FU occur at low-mid eff. stresses. In the image-to-image study, effective stress was stratified into low (< 35kPa), intermediate (35kPa ≤ σ < 70kPa), and high (>70 kPa) ranges. We saw a high statistical correlation between low stresses and increases in size for calcium and necrotic core plaque types whereas fibrotic and fibrofatty exhibited decreases in size in the same stress range [**Figure 3**]. Similarly in the volumetric comparison study, larger increases in the volume of calcium element clusters corresponded with lower mean effective stresses of those clusters.

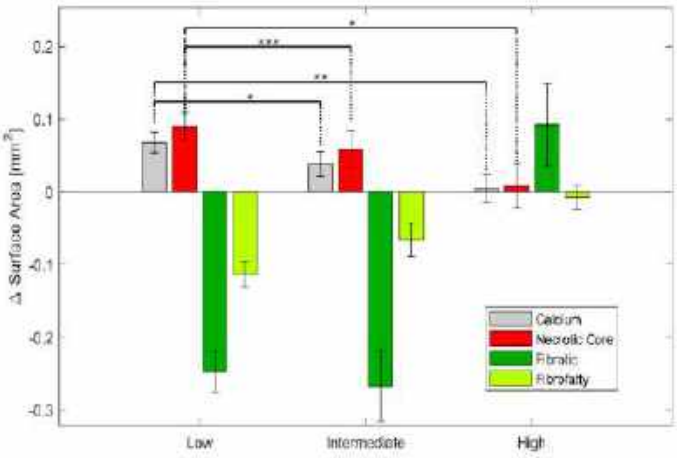

Figure 3. Low stress corresponds with significant increases in plaque size. Calcium and necrotic core exhibit increased size when stratified into low, intermediate, and high stress ranges.

DISCUSSION

Our preliminary results revealed trends similar to those found in the work by Samady et al. which established a correlation between low hemodynamical wall shear stress and increased plaque volume over a 6-month period [1]. Additionally, our results corroborate the work of Tziotziou et. al. which revealed trends that correlated low mechanical wall stress regions with large increase in lipid-rich necrotic core size [4]. The outcomes of our work innovate on both findings, yielding fresh and insightful information regarding the trends of mechanically mediated patient-specific plaque growth in coronary arteries, yet the presented studies are not without limitations. Factors such as mesh resolution, material properties, and boundary conditions can augment stress calculations within the plaque causing discrepancies when comparing results. To this end, both studies utilized the same meshing parameters, material properties, and boundary conditions in the FEA models to ensure comparability of the stress results. We hope the outcomes of these studies set a solid foundation for future research aimed at enhancing our understanding of coronary artery disease.

LOGIC-BASED CELL SIGNALING MODEL FOR PREDICTING VASCULAR SMOOTH MUSCLE CELL CONTRACTILITY DURING PREGNANCY

P. Nielsen (1), Y. Wu (1), K. Yoshida (1)

(1) Department of Biomedical Engineering, University of Minnesota – Twin Cities, Minneapolis, Minnesota, U.S.A.

INTRODUCTION

Adequate flow through maternal arteries is essential for maintaining fetal and maternal health throughout gestation. During normal human pregnancy, uteroplacental blood flow reaches levels near 1 L/min accompanied by an astounding decrease in downstream vascular resistance near the placenta [1]. In response, arteries undergo significant changes in contractile properties and passive mechanics driven by a delicate balance of chemical and mechanical cues. This process is hypothesized to be crucial to prevent adverse pregnancy outcomes such as pre-eclampsia, a leading cause of maternal mortality. Despite our knowledge of the role perturbed artery mechanics plays in hypertensive disorders, little is known about the specific mechanisms that drive mechanical adaptation of arteries during pregnancy. Blood pressure, wall shear stress, and hormonal signaling are all implicated in the growth and remodeling of arteries and vascular smooth muscle cells (VSMCs) [2]. Untangling signal crosstalk during pregnancy is difficult, but important for understanding how a healthy gestation progresses.

Computational modeling is a valuable platform for understanding how chemical and mechanical cues translate through signaling mechanisms to physiologically relevant VSMC function. While pathological arterial signaling and remodeling have been explored extensively using modeling [3], the effects of pregnancy hormones on VSMCs have remained unexplored. Experimentally, researchers are particularly interested in hormonal effects on contractility, but existing work has shown little consistency in contractility measurement and hormonal dose. Importantly, most of these studies are performed at short time scales [C] making it difficult to apply those results to pregnancy. Therefore, the goals of this work are to 1) adapt and validate a signaling network (SN) model of a VSMC from Irons *et al* [3] for pregnancy by incorporating estrogen (E2) and progesterone (P4), and 2) qualitatively compare model predictions to traction force microscopy (TFM) data of VSMCs after long-term exposure to E2 and P4.

METHODS

The model by Irons et al is a generalized arterial VSMC SN model with fibroblast and endothelial signaling, which translates mechanical stresses and biological inputs into matrix production, proliferation, and contractility activation [3]. We added relevant signaling pathways for E2 and P4 through literature review across 23 papers. Our final SN consists of 113 activation/inhibition reactions and 58 species modeled by a system of logic-based normalized Hill differential equations with uniform time constants, EC50, and Hill coefficients (Fig. 1).

Once the reactions were set, we swept for optimal model parameters and baseline inputs for wall shear stress (blood flow), stress (blood pressure), E2, and P4. The parameter combination that yielded the most qualitative agreement of outputs and interior nodes with experimental data from literature was chosen as the optimal parameter set. We validated the model by comparing the absolute difference in baseline and perturbed species to experimental outcomes using separate publications than those used to build the model.

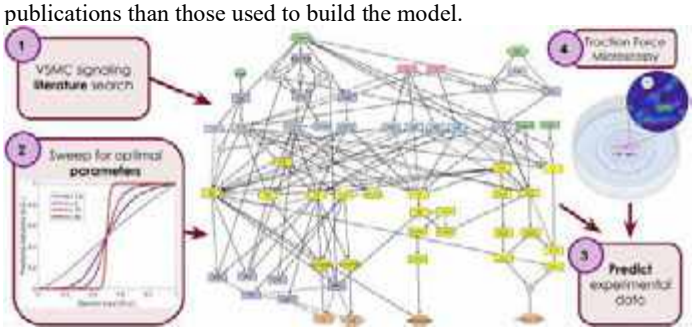

Figure 1: Model structure with mechanical and hormonal inputs.

To simulate an *in vitro* environment, model reactions involving endothelial/nitric oxide signaling were set to zero and stress inputs were decreased to 0.01. E2 and P4 were incrementally increased to evaluate

these dose-dependent hormonal effects on the 'ActomyosinActivity' output. Sensitivity sweeps at high and low integrin inputs were included to evaluate the role of cell adherence on *in vitro* contractility. To validate our model predictions, we conducted TFM experiments by plating human umbilical artery VSMCs on a deformable layer of a 13.5 kPa polyacrylamide gel embedded with fluorescent beads. The cells were incubated with 10 nM E2 and P4, then imaged at 0 and 72 hours to examine long-term traction force. After lysing the cells and comparing the final images with the cell-free state, the tracked displacements were converted to force [4]. The change in the sum of the force magnitudes for a single cell were qualitatively compared to the model output.

RESULTS

The final model parameters chosen correctly predicted 81% of validation paper experimental outcomes; nodes evaluated included interior and output species mediating matrix production, proliferation, and contractility (Fig. 2). Notably, the model failed to predict decrease of the ActomyosinActivity node in response to E2 and P4 increase.

Figure 2: Absolute difference between baseline and perturbed input results and node qualitative agreement with literature data.

In our TFM experiments, treating cells with E2 had no significant effect on traction force (Fig. 3B). This result disagrees with literature (Fig. 2), but agrees with our model (Fig. 3A, left), showing qualitative downregulation but at negligible values, particularly at low integrin activation levels. Treating cells with P4 caused a decrease in traction force, which agrees with literature but disagrees with our model (Fig. 3A, middle). After exposure to the combination of E2+P4, our TFM results show that traction forces are decreased relative to the control; at low doses, our model instead shows contractility upregulation, and at high doses, it shows contractility downregulation (Fig. 3A, right).

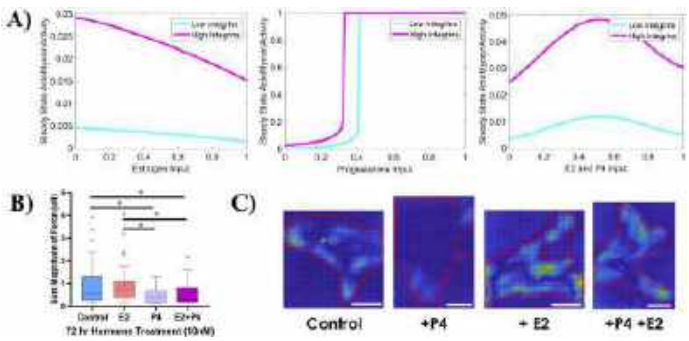

Figure 3: A) SN model results. B) Traction force of VSMCs (* = p < 0.05) exposed to E2 (n = 49), P4 (n = 28), and E2+P4 (n = 46) after 72 hours. C) Representative micrographs of TFM vector fields.

DISCUSSION

The goal of this study was to explore VSMC contractile behavior during pregnancy using modeling and traction force microscopy. While the common consensus is that E2 and P4 relax arteries at the tissue scale [5] and therefore suggest a decrease in VSMC contractility, some tissue myograph studies show no effect of E2 on contraction [6]. Further, our TFM experimental and modeling results show that more information is needed to further elucidate endocrinological effects on contractility.

There are a few possible sources of discrepancies between our modeling results, our TFM data, and literature reports. For example, we did not account for hypertrophy when calculating traction forces; since we define a change in contractility as the sum of the magnitude of the force, 3-D increase in cell volume is lost in translation. We will characterize cell growth in future experiments because pregnancy hormones have been shown to have a hypertrophic effect on other cardiovascular cell types [7]. Additionally, connections in the contraction pathway may still be missing from the model. Research on sex differences has been historically lagging, and information on E2 and P4 pathways is limited. To address this, we'll continue to update the model with new information from our lab or other publications.

An intriguing source of error may be how "contractility" itself is defined. While TFM allows direct force measurements, many studies report indirect measures of VSMC contraction, such as cytoplasmic calcium flux, tissue-scale myograph measurements, and *in vivo* angiographs [6]. Additionally, there is little consistency to the time scales, length scales, and hormonal doses arterial cell and tissue samples are exposed to in these reports. This is particularly important to standardize when modeling active mechanics of cardiovascular cells, as it has been shown that high and low E2/P4 doses have differential effects on cardiomyocyte behavior [7]. While our model failed to capture P4-induced relaxation through the ActomyosinActivity output, it can exhibit time-dependent progesterone-induced dampening of the calcium node (Fig. 4), suggesting that our model can capture short-term, but not long-term, mechanical changes in VSMCs. Long time-scales are crucial for understanding cellular behavior in a pregnancy context, so future work will focus on potential mechanisms of mechanical memory.

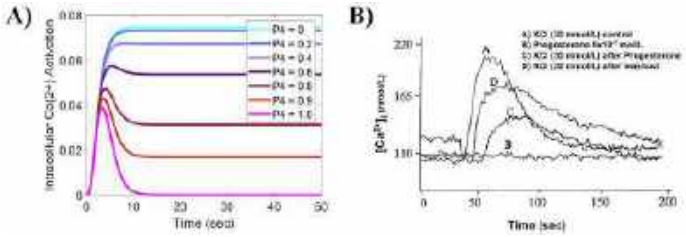

Figure 4: A) Fractional activation of intracellular calcium in response to increasing P4. B) Transient VSMC cytoplasmic calcium dampened by P4 in response to induced contraction [6].

In conclusion, this work uncovers the importance of time-scale, dose, and environment when testing and modeling smooth muscle cell mechanics during pregnancy. In the future, we hope to use this work to develop novel predictive modeling and treatments of pregnancy-induced hypertension and reduce maternal and fetal mortality in the U.S.

LOSS OF DECORIN ACCELERATES CARTILAGE SURFACE DAMAGE AND ABERRANT FIBROUS REMODELING DURING AGING

INTRODUCTION

Aging is the leading risk factor for osteoarthritis (OA), with more than 10% of the adults over 60 years of age presenting with symptomatic disease [1]. While considerable efforts have been made to understand the cellular hallmarks of aging [2], there is limited knowledge on how changes in cartilage extracellular matrix (ECM) contribute to the onset of aging-related spontaneous OA [3]. Our recent studies found that decorin, a small proteoglycan, plays a crucial role in regulating the retention of aggrecan during post-natal growth [4] and in injury-induced OA [5]. In post-traumatic OA, up-regulation of decorin delays loss of fragmented aggrecan and thus attenuates surface fibrillation [5]. Decorin is actively expressed in human cartilage from both young and old donors [6], indicating a potentially active role of decorin in regulating cartilage maintenance during aging. This study sought to investigate how decorin regulates cartilage matrix integrity and associated cell phenotypic changes via evaluating the phenotypic changes of knee cartilage resulted from targeted, cartilage-specific decorin deletion in an aging murine model.

METHODS

Cartilage-specific knockout of *Dcn* was induced by i.p. injection of tamoxifen to $Dcn^{f/f}/AcanCre^{ER}$ (Dcn^{cKO}) mice at 3 months of age [7], and the joints were evaluated at 9 and 18 months (9M and 18M). Safranin-O/Fast Green histology and Picrosirius Red staining were applied to sagittal paraffin sections to assess joint morphology and collagen fiber alignment. RNAscope in situ hybridization of collagen I (*Col1a1*) and decorin (*Dcn*) was applied to evaluate corresponding spatial gene expression profiles and to validate the knockout of *Dcn* gene. Single-cell RNA-sequencing (scRNA-seq, 10X) was applied to 18M femoral condyle cartilage, following pronase and collagenase II enzyme-based cell isolation [8]. High-quality cells were selected with quality control and used for further analysis with the cell numbers of 6,654 for the control and 5,165 for Dcn^{cKO} from 2 mice each. Seurat was used to identify cellular subsets and the PANTHER database to identify biological pathways impacted by *Dcn* deletion via statistical enrichment [9]. SEM was applied to assess the collagen fibril alignment, following established procedures [3]. Distributions of the fibril orientation were plotted after offsetting the mediolateral direction as 0° for each joint.

RESULTS

We validated the reduction of *Dcn* expression as the result of effective knockout in 9M via RNAscope imaging (Fig. 1a). At 9M, Dcn^{cKO} femoral surface already developed highly aligned collagen fibrils, evidencing surface fibrillation (Fig. 2a). At 18M, Dcn^{cKO} femoral cartilage surface formed a layer of highly aligned, thick collagen fibers along the mediolateral direction, which were devoid of sGAGs (Fig. 1b, 2b), highlighting aberrant fibrous remodeling (Fig. 2). In addition to these pronounced matrix phenotypic changes, a new cell group with elongated morphology was noted within this fibrous layer. These cells actively express *Col1a1* (Fig. 1b), indicating the formation of fibrous tissue. They also showed active *Dcn* expression (Fig. 1b), suggesting that these cells were not originated from cartilage, but may have migrated from adjacent tissues that did not express *Acan* at 3M.

In support, scRNA-seq identified a new cell cluster in Dcn^{cKO} cartilage (cluster 2, Fig. 3a,b). These cells were highly metabolic, with high expression of collagens, proteoglycans, lysyl oxidases and MMPs, as well as altered biological pathways (Fig. 3c,d). In contrast, in other cell clusters, including articular chondrocytes (cluster 4), loss of decorin resulted in only mild changes in matrix organization genes, suggesting that decorin may not directly impact chondrocyte biological signaling.

DISCUSSION

This study highlights an unexpected emergent phenotype marked by aberrant fibrous remodeling on the femoral surface of aged cartilage

caused by the loss of decorin. The presence of *Col1a1* and *Dcn*-expressing cells indicates the fibrous character of this surface remodeling and suggests infiltration of cells from adjacent tissues. This fibrous layer consists of thick collagen fibers that are aligned in a mediolateral direction (Fig. 2), and this layer becomes gradually more pronounced from 9M to 18M. The fibrillated cartilage lacks the sGAG-rich hyaline traits, and thus, does not possess the poroelastic energy dissipation functions of cartilage [4]. These changes represent accelerated, severe degradation of femoral condyle cartilage with the deletion of decorin.

Given the observed degenerating of femoral cartilage and aligned fibrils pattern on cartilage surface at 9M (Fig. 2a), it is possible that the continuous physiologic loading on the cartilage with already impaired force dissipation leads to progressive cartilage erosion and cell infiltration. The aligned fibrils on femoral surface formed due to decorin loss at 9M may also facilitate the cell migration and infiltration with the local structural and mechanical environment [10]. These metabolically active cells could originate from adjacent tissues, possibly synovial lining and fat pad, forming this aberrant layer covering the damaged surface by 18M.

As cartilage erosion and fibrillation are common symptoms in advanced OA patients [11], these results point to a crucial role of decorin in inhibiting cartilage damage and OA progression in aged individuals. Notably, such role is primarily manifested through decorin's direct impacts on ECM integrity, rather than chondrocyte signaling, as supported by the mild changes in *Dcn*^{cKO} chondrocyte signaling pathways (cluster 4, Fig. 3c,d). Thus, this study establishes decorin as a novel target for enhancing cartilage maintenance and ameliorating aging-related degeneration.

INTRODUCTION

Vascular calcifications are associated with significant cardiovascular events, such as heart attacks and strokes [1]. These particles exhibit different phenotypes that can significantly influence their effects on diseased tissues. For example, the size of calcifications plays a crucial role, with microcalcifications being reported to contribute to tissue failure, while macrocalcifications may have a protective effect [1]. Another study suggests that macrocalcifications with sharp edges can create stress concentration in tissues, potentially promoting tissue failure [2]. Additionally, the spatial distribution of microcalcifications is highlighted as a factor that can greatly amplify their harmful impact on tissue stability. Specifically, a single microcalcification situated in the fibrous caps of arterial plaques is reported to increase abnormal intramural stresses fourfold [3], and the presence of two closely positioned microcalcifications, regardless of their location within the tissue, can cause substantial elevations in intramural stresses [4]. Furthermore, the impact of calcifications on tissue stresses can be significantly influenced by the surrounding environment in which they are present [2]. For example, it is shown that when calcifications are covered by lipid pools, lipid pools can significantly attenuate stress concentrations caused by calcifications.

Calcifications in an atherosclerotic artery can exhibit various phenotypes whose collective impact on tissue strength is not well understood. Reliable assessment of diseased tissue strength is crucial for enhancing risk evaluation tools for major adverse cardiovascular events (MACE). Current approaches, like calcium scoring (CAC), assume a positive correlation between overall calcification burden and risk, overlooking the protective or deleterious roles of calcification phenotypes in the failure process. This oversight has led to inconsistent outcomes with CAC. Fundamental scientific studies are needed to sophisticate calcium related risk assessment for MACE. Such studies necessarily must include objective and efficient classification of calcification particles in large numbers of arteries (both atherosclerotic and non-atherosclerotic), along with experimental or computational analyses of wall failure in these specimens. Currently lacking are a comprehensive classification system and a high-throughput tool for accurately assessing calcification phenotypes in these tissues.
In this study, we present a novel comprehensive system to classify calcification in vascular tissues based on phenotype and a high-throughput artificial intelligence-based quantification tool capable of performing this classification for thousands of calcification particles in dissected arterial samples in less than seven hours.

METHODS

Figure 1 A depicts the proposed classification system for calcifications in vascular tissues. The 24 identified groups encompass a range of potential phenotypes motivated by prior research. Initially, calcifications are divided by size (micro and macro). Macrocalcifications are then subcategorized by surface topology (sparse or dense), and microcalcifications are grouped by spatial distribution (clustered or isolated). Moving to the next tier, each phenotype is classified based on colocation with lipid pools as atherosclerotic or non-atherosclerotic. Finally, the eight distinct phenotypes are further classified according to their distribution across the wall as innermost, middle, and outermost layers of the wall, denoted as I, M, and O.

Figure 1 B illustrates a semi-automated deep-learning framework. This tool, utilizing transfer learning, accurately segments sample and lipid pools in thousands of high-resolution micro-CT images. Manual annotations are required for less than 1% of the total images. The tool is evaluated on five samples, achieving a mean dice similarity coefficient of 97% and 85% for sample and lipid pool segmentation compared to human expert ground truth.

To create 3D models of calcifications, lipid pools, and samples, we employ an in-house code for segmentation (Figure 2). Subsequently, a

different in-house code is used to calculate the volume of each calcified particle, categorizing them as macro or microcalcifications based on a predefined volume threshold. Microcalcifications are then analyzed for spatial distribution using a density-based clustering algorithm, detecting local elevations in density. This algorithm is then applied to the space occupied by each macrocalcification, classifying them as dense or sparse based on surface topology.

Next, the colocation of each of the calcified particles with lipid pools is determined and applied to classify calcification based on their type as atherosclerotic and non-atherosclerotic. In the final step, to classify calcifications based on their location within arterial walls, an in-house code is applied to the reconstructed 3D model of the samples to split their wall thickness into three distinct layers, including the innermost, middle, and outermost layers. Finally, the colocation of calcifications with each of these layers is determined to classify them based on their location within the tissue wall.

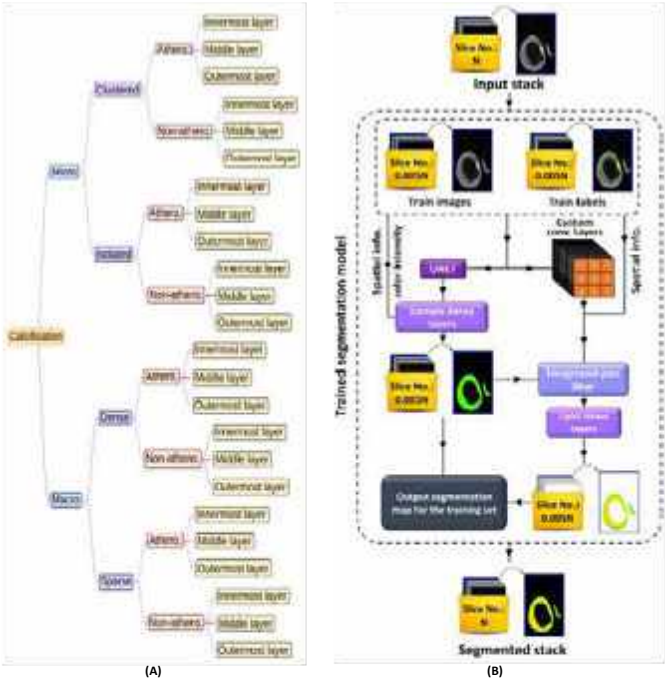

Figure 1: The proposed calcification classification system (A) and the developed semantic segmentation framework.

Figure 2: The reconstructed 3D model for an arterial sample.

RESULTS

The developed quantification tool is applied to a representative dissected sample of atherosclerotic cerebral arteries, and the results are presented in Figure 3. In Figure 3 A, the volumetric ratios of lipid pool to tissue and calcification to tissue are presented, which are measures of atherosclerosis and calcification, respectively. The ratios of atherosclerotic calcification, macrocalcifications, and clustered microcalcifications to overall calcifications are presented, which, based on statistical results, are significant predictors of failure [5].

Figure 3B shows the microcalcification phenotype proportions, crucial for studying correlations between lipid pool presence and microcalcification density, as well as exploring relationships between microcalcification location and spatial distributions. Figure 3C quantifies sparse and dense parts in atherosclerotic and non-atherosclerotic macrocalcifications.

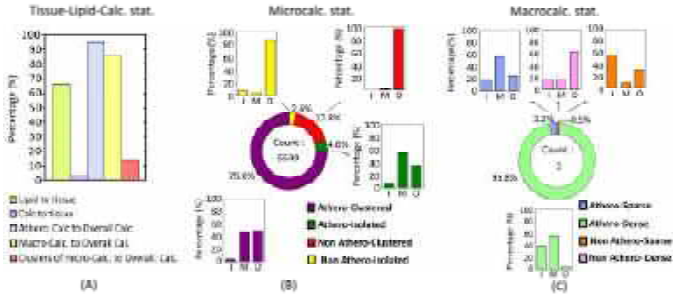

Figure 3: Quantification based on calcification phenotypes.

DISCUSSION

Vascular calcifications are widely acknowledged as a primary contributor to tissue failure in MACE. The impact of calcifications on tissue failure varies depending on their phenotypic characteristics. A thorough understanding of these phenotypes and their intricate interactions is essential for enhancing risk assessment tools for MACE. This study aims to facilitate such understanding by introducing a comprehensive classification system for phenotyping calcification, complemented by a high-throughput quantification tool for assessing samples based on their calcification phenotypes. The evaluation of tissue strength across a sufficiently extensive number of arterial samples, coupled with an exploration of their associations with calcification phenotypes, is pivotal for achieving a more precise risk assessment of MACE.

The classification system includes phenotypes like size, type, spatial distribution, surface topology, and location. Atherosclerotic calcifications are suggested to form in the intima layer, while non-atherosclerotic ones accumulate in the media layer. Our quantification tool allows a detailed investigation of associations between calcification type, location, and tissue origin in various arterial systems. Regarding the size phenotype, studies indicate microcalcifications tend to aggregate into macrocalcifications in locations of fibrous tissues with lower collagen densities [4]. With respect to the surface topology phenotype, it is shown that sharp edges of macrocalcifications can induce stress concentrations, compromising stability [2]. Our tool, equipped with ML-based clustering frameworks, detects local increases in microcalcification distribution and sharp irregularities on macrocalcification surfaces. Understanding the association between microcalcification clusters, macrocalcification surfaces, and the initiation of tissue failure during mechanical testing is crucial for enhancing risk assessment tools that currently overlook these calcification phenotypes.

INTRODUCTION

Sports head impact exposure have been associated with acute and chronic neurological consequences [1]. Wearable head impact sensors have enabled collection of real-world data from multiple sports, with instrumented mouthguards becoming a standard validated technology [2]. Despite increasing application of sensors, most studies focus on investigating single sports, and there has been no quantitative analysis of impact biomechanics across sports using field data. Some studies have introduced potential sport-specific impact characteristics, including American football and rugby, exhibiting high magnitude player-to-player collisions [3], while soccer displaying lower magnitude heading impacts [4]. Since head impact biomechanics have been associated with brain injury risk, further investigation would enable insight into sport-specific injury mechanisms.

Numerous factors contribute to the biomechanical variability in head impacts between sports, including playing style [5], game speed [6], sex differences [7], and the presence of protective equipment, such as helmets [8]. Uniquely, we have gathered head impact data across multiple sports using similar sensors and methodologies that enable comparison of impact biomechanics between ice hockey, American football, soccer, and rugby. With this dataset, we aim to (i) determine biomechanical differences between sports by comparing peak kinematics and impulse duration, and (ii) characterize and compare head impact directionality across sports.

METHODS

A head impact database was curated from previously collected instrumented mouthguard data from university-level men's American football (MF), men's ice hockey (MH), women's rugby (WR), and women's soccer (WS) teams. Both MH and WR teams wore Prevent Biometrics [9] instrumented mouthguards during practices and games. The WS team wore instrumented mouthpieces from Wake Forest Center for Injury Biomechanics [10], while MF wore Stanford University instrumented mouthguards [11]. All instrumented mouthguards were custom-fit and recorded 6 degrees of freedom head linear acceleration and angular velocity. The Prevent and Wake Forest devices had a 5g trigger for recording head impacts while the Stanford mouthguard had a 10g trigger. To account for this difference, we removed all impacts below 10g prior to comparison. Data were sampled at a minimum of 1000Hz, filtered using a low-pass 4th order Butterworth filter at 200Hz for linear accelerations and 180Hz for angular velocity, then transformed to the head center of gravity. Only video-verified head impacts were included in the analysis. Processed signals were used to compute metrics of interest such as peak linear acceleration (PLA), peak angular velocity (PAV), and peak angular acceleration (PAA) in all three planes of motion. Impulse durations were extracted by calculating the width of the impulse at half the maximum value of both linear and angular accelerations. All features were then compared across sports using pairwise Mann-Whitney U test with $\alpha = 0.05$ and Bonferroni correction for multiple comparisons. Dominant planes of head rotation were characterized by determining if PAA in any anatomical plane (coronal - x, sagittal - y, or transverse - z) was greater than 90% of the resultant PAA.

RESULTS

Our database consisted of 1838 video-verified total head impacts, where 463 were from MH, 411 from WR, 1056 from WS, and 275 from MF. Comparing across sports, we observed MF to have the highest median peak linear acceleration (24.6 g), peak angular velocity (11.7 rad/s), and angular acceleration (1996 rad/s^2) compared to MH, WR, WS (Figure 1). We also observed WS to have the lowest median peak kinematics compared to the other sports (14.4 g, 6.9 rad/s, 1269 rad/s^2) (Figure 1). Pairwise comparisons resultant PLA, PAV, and PAA showed statistically significant differences between sports for all combinations except resultant PAA between WR and WS.

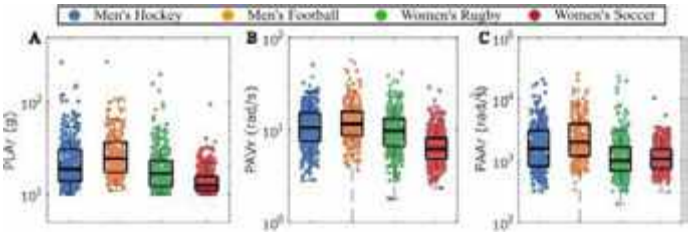

Figure 1: Resultant PLA (A), PAV (B), and PAA (C) for all head impacts across sports.

Figure 2 shows example comparisons of resultant linear acceleration impulse durations, with similar trends observed for each anatomical axis and angular acceleration. While the unhelmeted sports (WR and WS) had slightly higher median impulse durations (11 ms) compared with helmeted sports (MH and MF, 10 ms), pairwise comparisons revealed no significant differences (Figure 2B). Notably, MH and WR show higher variance in impulse duration distributions than MF and WS.

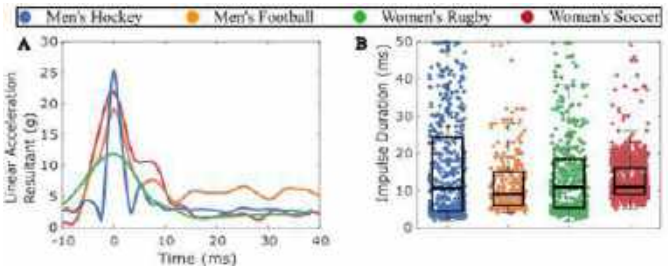

Figure 2: Resultant linear accelerations for one impact used to compute impulse duration (A). Impulse duration across all sports (B).

Examining impact directionality, WS involved more impacts with dominant sagittal plane (y-axis) rotation (50%), MH showed more transverse plane (z-axis) dominance (31%), MF showed more coronal plane (x-axis) dominance (33.4%), while WR involved multi-directional head rotations with no particular directional dominance.

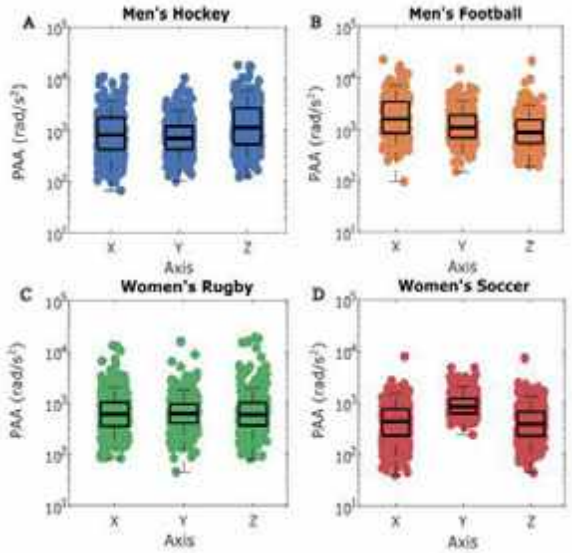

Figure 3: Per axis comparison of PAA for all head impacts.

DISCUSSION

Cross-sport comparisons of peak kinematics highlights MF to exhibit the largest peak linear and angular accelerations, which may be associated with high concussion incidence found in football [3]. MH also exhibited comparable high peak kinematics to MF. Reasons for high kinematics in MF and MH can be multivariable and could be attributed to greater body mass and higher speed collisions [3].

While it was expected that the presence of helmets and padding would attenuate impacts and increase the impact duration, helmeted sports (MH and MF) showed slightly shorter impulse duration than unhelmeted sports (WR and WS), and this duration difference was found to be statistically significant. Contrary to expectations, the helmet does not seem to have any substantial effect on impulse duration based on our findings. Further examination of helmet effects on impact biomechanics may be needed to confirm the effectiveness of helmets.

Furthermore, every sport displayed unique directionality patterns in our study. Most head impacts in soccer occur during frontal heading [4] and indeed our results show sagittal plane linear and angular components to dominate in WS. Past helmet sensor studies have reported inconsistent findings in impact location for American football and ice hockey [12,13], while our study shows preliminary evidence of some dominant planes of head rotation during impact. Animal and modeling studies have shown potential directional-dependence in brain injury risk, with the coronal [14] and transverse [15] planes proposed as more vulnerable.

Given our sample, it is difficult to speculate main factors leading to biomechanical differences between sports, since sex and sport factors cannot be isolated. Previous literature has found sex-differences in impact severity [16]. In the future, we aim to expand our dataset to better match sports for further understanding of the influence of sex, equipment, and playstyle on head impact biomechanics.

In summary, our study is one of the first to compare head impact biomechanics across multiple sports using real-world head impact data. We observed impact magnitude and direction differences between-sports with injury risk implications, as well as unexpected impulse duration findings that call for further investigation of helmet effects on impact biomechanics.

ACKNOWLEDGEMENTS

We would like to thank the CIHR, CFI, and NSERC for funding of this study. We would also like to thank all the Varsity teams involved, along with Prevent Biometrics, Wake Forest Center for Injury Biomechanics, and Stanford CamLab for their support.

SEQSEG: AUTOMATIC IMAGE-BASED VASCULAR MODEL CONSTRUCTION USING SEQUENTIAL SEGMENTATIONS

Numi Sveinsson Cepero (1), Shawn C. Shadden (1)

(1) Department of Mechanical Engineering, University of California Berkeley, Berkeley, California, USA.

INTRODUCTION

Image-based computer modeling of vasculature has become an important aspect of patient care and cardiovascular research [1]. These modeling approaches use medical images to construct an anatomically accurate geometry of patient's blood vessels to be used for simulation-based modeling. Despite its wide range of applications, constructing anatomically correct geometries of blood vessels from medical images remains challenging and involves multiple steps and a combination of approaches, including ones reliant on labour intensive manual inputs.

Segmenting blood vessels from other nearby tissue is challenging because of limited resolution, unclear boundaries and image artifacts. To simplify the task, a "centerline" path is often constructed along vessels of interest, which is then traversed to perform 2D segmentations of the vessel lumen at discrete steps along the path. These 2D segmentations can then be lofted using spline interpolations to form a unified 3D surface representing the blood vessel domain[2]. Until now, these two steps (centerline generation and lumen segmentations) have been viewed as separate, resulting in methods to either accurately construct centerlines [3] or accurately determine lumen boundaries around centerlines [4]. We present a novel method to do both at once automatically, utilizing local deep-learning based segmentation with a tracing algorithm to construct a global vascular segmentation piece-wise while taking steps.

METHODS

Our approach tackles blood vessel segmentation by operating locally around a particular blood vessel segment. Local 3D segmentations are processed to determine vessel direction and size in order to take steps.

Algorithm. Figure 1 shows an overview of the algorithm steps. The algorithm is initialized using a given seed point and radius estimate, which is used to extract the first subvolume. The subvolume is segmented using a 3D U-Net neural network, where pixels are classified in a binary manner; either belonging to blood vessel or not. The segmentation is converted into surface mesh representation using the marching cubes algorithm, and a centerline is extracted using the open-source Vascular Modeling Tool Kit library. The resulting centerline is then post processed to estimate the size of the vessel and choose the next point to move to. If the centerline includes two or more branches, the largest branch is chosen for immediate stepping and the others are stored in a bifurcation queue for subsequent tracing. During step-taking, we save the local segmentations and assemble them in a single global model as the final output.

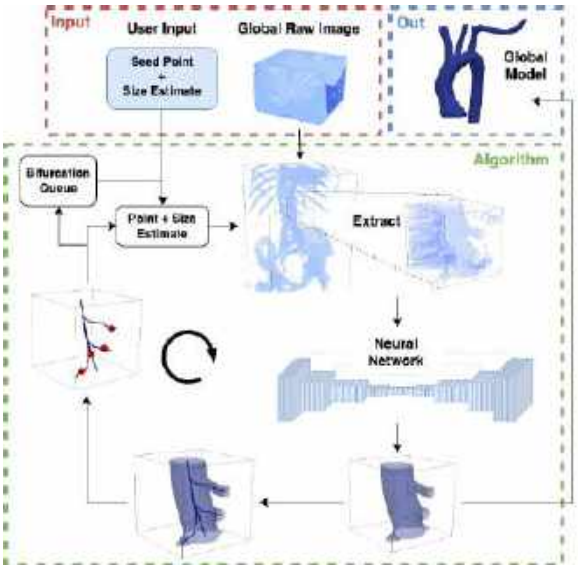

Figure 1: The different steps in the SeqSeg algorithm from initialization with inputs of seed point, radius estimate and global raw image, to subvolume extraction, 3D U-Net segmentation, surface and centerline calculation and stepping. Bifurcation points are saved in queue for subsequent tracing.

Datasets and Sampling. The datasets used are aortic and aortofemoral models from CT, and MR image data, see Table 1, acquired from the open and free Vascular Model Repository, accessible at *vascularmodel.com*[5].

Each case in a dataset has a medical image scan (CT/MR) with corresponding segmentation and centerline, see inputs in Figure 2. For neural network training, the global 3D medical image volume is sampled along the centerline of its corresponding vasculature model, see Fig. 2 for reference. Two subvolumes are extracted at each instance: 1) raw medical image data, and 2) binary segmentation of blood vessel. The samples vary in centering and size; some centered along the centerline while others shifted perpendicular to its tangent, and sizes vary from barely capturing the vessel lumen, to others including more nearby tissue. This variance is purposefully added to represent the variance that the tracing algorithm encounters in practice and is intended to increase the neural network's robustness. Approximately 15% of subvolumes are used for validation and 20% of cases are kept aside for testing, see further details in Table 1.

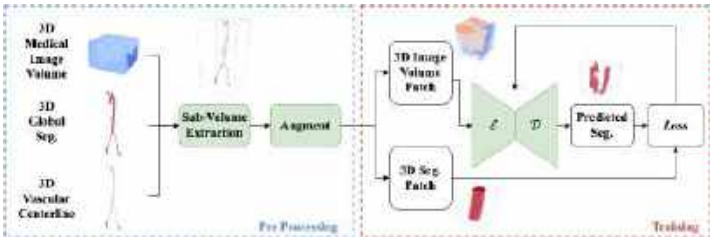

Figure 2: The pre processing of data for neural network training. Samples are extracted along vasculature centerline and augmented, and ground truth segmentations are used for loss calculation.

Table 1: The number of cases used for training and testing.

Dataset	Modality	Train/Val	Test
VMR Aortic / Aortofemoral[5]	CT	33	8
VMR Aortic / Aortofemoral[5]	MR	37	7

Neural Network Architecture and Training. The U-Net architecture is used for the segmentation task, and a 3D-version is chosen. The nnU-Net framework is used for hyperparameter choice and training[6]. The loss function used is a combination of Dice loss and binary cross entropy:

$$l = 1 - \mathcal{D} - \mathcal{CE} \tag{1}$$

where $\mathcal{D}$, $\mathcal{CE}$ are Dice score and binary cross entropy, respectively. Training took place using two GPUs, an NVIDIA k80 dual-GPU, on the Savio High Performance Computing cluster at UC, Berkeley.

Global Assembly. The local segmentations are gathered globally by calculating the mean prediction for each voxel. The final segmentation is then converted to a surface mesh using marching cubes and smoothed to remove voxel artifacts.

RESULTS

We tested our method (SeqSeg) on two different datasets as shown in Table 1, and compare to results from a benchmark model. A global nnU-Net model is chosen as benchmark because of its state-of-the-art performance on medical image segmentation tasks[6]. We compare using Dice score and avg. Hausdorff distance, see Table 2 for the avg. scores across both test datasets. As the results show, SeqSeg, on average, outperforms the benchmark using both metrics. Figure 3 shows a qualitative comparison between the ground truth and predictions from SeqSeg and the benchmark model on six aortic/aortofemoral models, three CT, and three MR. The method, SeqSeg, manages to capture all the branches present in the ground truth model. It also manages to extend the branches further than that was segmented in the ground truth.

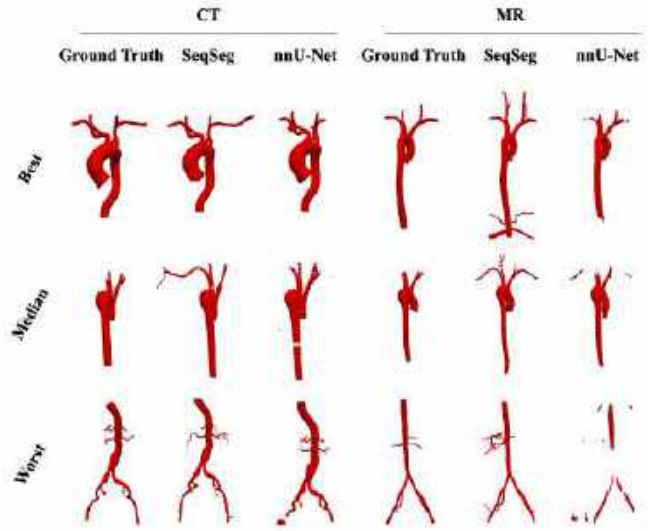

Figure 3: Comparison between ground truth model (left), prediction results from SeqSeg (middle) and nnU-Net benchmark model (right), for CT, and MR data. The cases shown are the best, median, and worst ranking Dice score results for the nnU-Net benchmark model.

Table 2: Avg. Dice score ($\mathcal{D}$) and Avg. Hausdorff distance ($\mathcal{H}$) score results on testing data, comparing SeqSeg (our) and nnU-Net benchmark model.

	$\mathcal{D}\uparrow$		$\mathcal{H}\downarrow$	
Dataset	SeqSeg	nnU-Net	SeqSeg	nnU-Net
CT Aorta VMR	**0.927**	0.901	**0.023**	0.071
MR Aorta VMR	**0.877**	0.844	**0.0335**	0.114

DISCUSSION

We present a novel model construction method, SeqSeg, based on local step taking, which uses deep learning to predict vascular segments instead of the whole vasculature at once. With only a single seed point, SeqSeg is capable of automatically constructing expansive vasculature. As a result of the neural network training strategy, the machine learning model manages to adequately capture bifurcations and generalize to new vessel branches not present in the training data. The results show the method works both for CT, and MR, image data. Additionally, by assembling vascular models piece-wise, the method ensures connectivity of the final segmentation, a necessity if the final purpose is simulation.

INTRODUCTION

Sixty-night million people suffer from traumatic brain injury (TBI) each year [1], with most incidents mild TBI (mTBI) or concussion. It is common to use a global brain model or microscale axonal model to study the mechanisms of TBI. The latter uses strains from the global model as input to study cytoskeletal behaviors to investigate the triggering mechanisms of "traumatic axonal injury (TAI)" [3,4]. Nevertheless, a significant gap exists between a global and a microscale model: a global model provides detailed brain strain responses but the spatial resolution is limited and insufficient to inform damage at the cellular level. While a microscale model is capable of estimating cytoskeletal damage, often it lacks real-world input for simulation.

This study unifies a global model and a microscale axonal injury model in a multimodal analysis pipeline to study the mechanism of TAI. It employs a unique subject-specific multimodal dataset, including on-field head impact kinematics and subject-specific neuroimages to provide anatomy and detailed white matter tractography. The computational pipeline employs a displacement voxelization scheme with adjustable spatial resolution to balancing accuracy and efficiency. The structured data format easily allows multimodal analysis with neuroimages and white matter tractography. The pipeline generates a diverse range of fiber strain profiles, which is important to facilitate future development of a deep learning axonal injury model. This will be critical to allow for large-scale and multiscale biomechanical modeling of TAI to uncover the mechanism of axonal damage at the microscale.

METHODS

The subject-specific multimodal dataset from the University of British Columbia is from a 21-year-old male varsity ice hockey player who suffered a concussion. The study was approved by the Research Ethics Board (ID: H21-00400). Biomechanical data were collected using an instrumented mouthguard. The subject's concussive impact was identified and verified with multi-angle video recordings. Neuroimages were acquired before and after the concussion on a 3T MRI scanner, including 3D T1-weighted scans and diffusion-weighted imaging. A subject specific model [5] was developed based on the anisotropic Worcester Head Injury Model (WHIM) Version 1.0 *via* mesh warping (Figure 1.). The WHIM has been extensively validated for brain responses across a large-range of impact conditions [7].

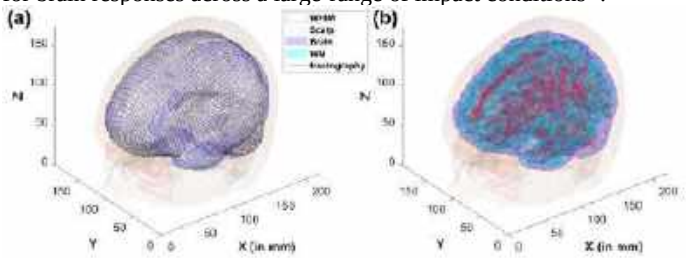

Figure 1: (a) The subject-specific WHIM for the concussed athlete. (b) Randomly selected tractography streamlines overlaid against surface renderings of the white matter.

The subject-specific WHIM model was used to analyze voxel wise strains through a displacement voxelization scheme [6]. Displacement field is utilized to calculate the voxel wise maximum principal strain (MPS) and fiber strain in white matter region. For voxel wise fiber strain, the fiber strain at each white matter fiber sampling point was calculated, and voxel wise weighted averages of peak fiber strains were determined. By resampling impact-induced relative brain-skull displacement at different resolutions, diverse fiber strain profiles in the white matter could be identified. The study's computational pipeline allowed for the processing of simulated biomechanical data at various

spatial resolutions. The ensuing multimodal analysis allows convenient identification of vulnerable brain regions, such as the corpus callosum and gray-white matter interface, to traumatic axonal injury (TAI).

Data analysis includes comparing computational efficiency and accuracy of fiber strains across different displacement resampling resolutions. This also included analyzing representative fiber strain profiles in areas prone to TAI and diverse fiber strain profiles across the white matter. The simulations were conducted in SIMULIA Abaqus with the explicit FEA solver (28 cores, 256GB). While all data analyses were conducted in MATLAB (R2020a; Mathworks, Natick, MA) on a desktop computer (16 cores, 64GB).

RESULTS

Figure 2 shows voxelized relative brain-skull displacement, captured at the moment of peak fiber strain in the corpus callosum. This is illustrated across three neuroimaging planes – coronal, axial, and para-sagittal. Accompanying these are the corresponding voxelwise peak Maximum Principal Strain (MPS) and peak fiber strains.

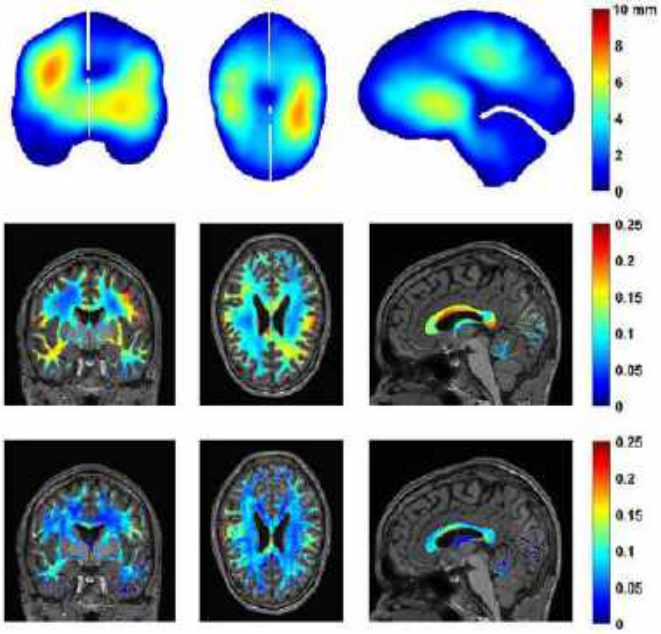

Figure 2: Voxelized magnitude of relative brain-skull displacement from impact simulation (top row) at the time when corpus callosum fiber strain reached its first major peak in coronal (left), axial (middle column) and para-sagittal (right) planes, along with the corresponding voxel wise peak MPS (second row) and fiber strains (bottom row).

In exploring the effects of voxel resampling resolutions on brain-skull displacement and strain measures, we compared fiber train accuracy and efficiency at three different resolutions (1 mm, 2 mm, and 4 mm), using results at the isotropic resolution of 1 mm as the baseline. The results show a direct correlation between the increase of the resampling voxel size and the increase in fiber strain error (6.4% for 2 mm and 14.2% for 4 mm) and the decrease in computational time (83.4% and 96.9% reduction in time for the 2 mm and 4 mm resolutions, respectively). To balance accuracy and efficiency, an isotropic resolution of 2 mm seems to offer an optimal trade-off between response accuracy and computational efficiency.

To illustrate multimodal analysis, representative fiber strain profiles near the gray-white matter interface and in the corpus callosum are shown (Figure 3). They were identified based on subject-specific neuroimage segmentation. It was observed that the left and right hemispherical regions experienced tension and compression in opposite phases, which was expected given the nearly incompressible brain to maintain a nearly constant volume.

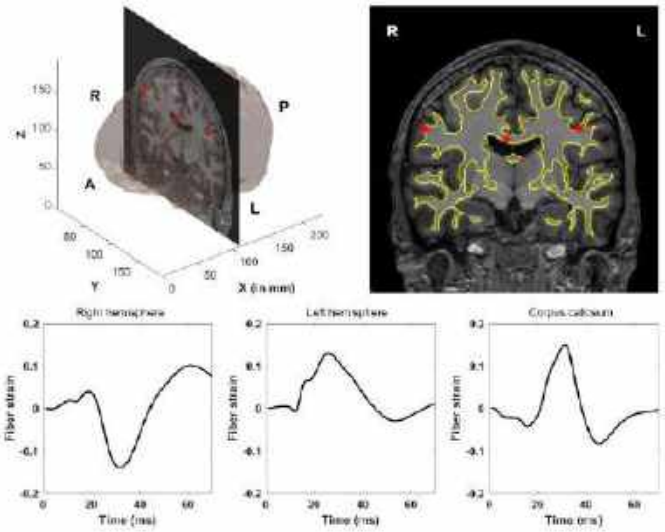

Figure 3: Representative fiber strain profiles near the gray-white matter interface in two contralateral regions and in the corpus callosum for a concussive head impact recorded for a male ice-hockey player.

Finally, the voxelized displacement field over time also enables convenient determination of white matter fiber strains at arbitrary locations. Pearson correlation was calculated between pairs of fiber strain profiles, from which the most diverse set with the lowest Pearson correlation scores were identified. They will be used to develop a deep learning axonal injury model in the future, which will rapidly provide cytoskeletal responses rapidly without a costly direct model simulation, critical for large-scale axonal injury modeling.

DISCUSSION

We have established a computational pipeline to unify a global and a microscale brain injury model. The voxelized displacement field allows accurate and efficient determine voxelwise maximum principal strains and white matter fiber strains. This pipeline is crucial for identifying a diverse set of fiber strain profiles necessary for developing a deep learning model for axonal injury. The framework established in this work is critical for enabling large-scale (i.e., across the entire white matter region, head impacts, and individuals) and multiscale (i.e., from organ to cell length scales) modeling for the investigation of traumatic axonal injury triggering mechanisms. Ultimately, these efforts could enhance the assessment of concussion risks and design of protective headgear. Therefore, this work contributes to improved strategies for concussion detection, mitigation, and prevention.

TENDON IMPINGEMENT PRODUCES DIFFERENTIAL REGIONAL PROFILES OF INTACT AND FRAGMENTED AGGRECAN

Brian C. Wise (1,2), Whasil Lee (1,2,3), Mark R. Buckley (1,2)

(1) Department of Biomedical Engineering, University of Rochester, Rochester, NY, USA

INTRODUCTION

Tendon impingement generates a unique mechanical strain environment distinguished by elevated transverse compressive strains[1] that sustain a localized fibrocartilage phenotype enriched with glycosaminoglycans (GAGs)[2] (**Fig 1A**). While fibrocartilage is a normal feature in impinged regions of healthy tendon, excess GAG content is a hallmark feature of tendinopathy, a degenerative disease that disproportionately affects impinged tendons[3,4]. As such, impingement is clinically recognized as an important extrinsic factor in tendinopathy pathogenesis. Despite this, the cellular and molecular basis of impingement mechanobiology is poorly described, in part due to a lack of experimental models. To fill this void, our lab has developed a novel murine hind limb explant model for studying the mechanobiology of Achilles tendon impingement[5] (**Fig 1B**). By preserving anatomical structures of the impinged region *in situ*, this model allows for controlled prescription of impingement via passive ankle dorsiflexion to reproduce multiaxial strain patterns that are measurable and well-characterized[1] (**Fig 1C**). Moreover, we have demonstrated that impingement produces significant change in GAG staining, consistent with fibrocartilage formation[5] (**Fig 1D**). Here, we utilize this model of impingement to study aggrecan: a large, GAG-rich proteoglycan upregulated in regions of fibrocartilage. Notably, prior studies have explicated dynamic aggrecan turnover in tendon fibrocartilage via constitutive ADAMTS catabolism, with evidence that simple uniaxial compression regulates both aggrecan biosynthesis and turnover[6-9]. Nevertheless, aggrecan turnover within complex, spatially heterogeneous patterns of mechanical strain generated by impingement has yet to be described. We hypothesize that impingement elicits differential regional profiles of intact and fragmented aggrecan across the Achilles tendon insertion.

METHODS

Explant Culture: Hind limbs (C57BL/6, <1 year) were dissected and pretreated in culture media with 100 nM of dexamethasone at 37°C

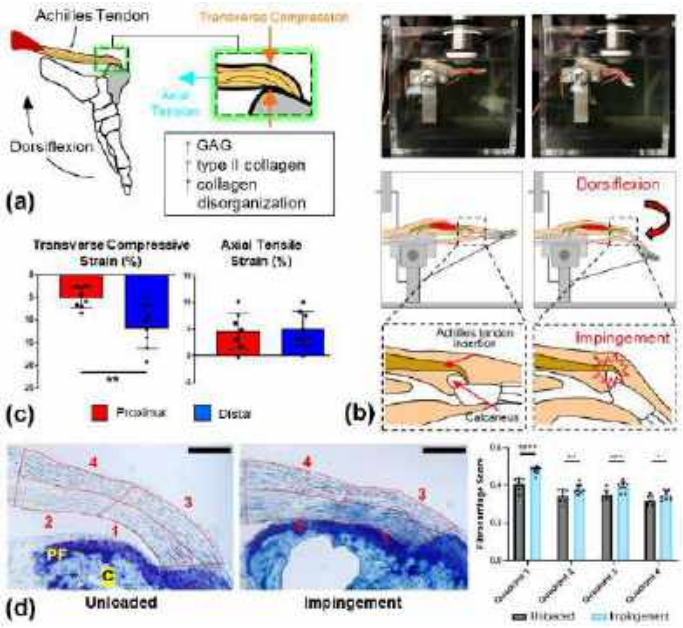

Figure 1: (a) Schematic depicting local fibrocartilage and transverse compressive strains sustained by impingement of the Achilles tendon insertion upon the calcaneus (gray) during ankle dorsiflexion. **(b)** (Top) Hind limb explant in our experimental platform before (left) and after (right) passive dorsiflexion to impinge the Achilles tendon insertion, as shown schematically (bottom)[1]. **(c)** Impingement produces significantly elevated transverse compressive strain (left) at the distal Achilles tendon insertion of hind limb explants measured via ultrasound elastography, but no change in axial tensile strain (right)[1]. **(d)** GAG staining (Toluidine blue) across quadrants dividing the

Achilles tendon insertion after 7 days of impingement (middle) appears enriched in distal quadrant 1 compared to unloaded tendons (left)[5]. (Right) Color image analysis indicates significantly elevated fibrocartilage score (quadrant color normalized to PF color) across all regions[5], most pronounced in distal quadrants 1 and 3. PF: Periosteal fibrocartilage. C: Calcaneus. Scale bar: 200μm.

for 48 hours. After 48 hours, dexamethasone was no longer supplemented in media. From each mouse, one hind limb was cultured for an additional 7 days in the absence of externally applied load, while the contralateral limb was positioned into our experimental platform to place the Achilles tendon insertion under static impingement[5].

Immunofluorescence: Level-matched formalin fixed, paraffin embedded tissue sections (10μm, sagittal) from contralateral pairs of limbs (unloaded vs. static impingement, n=7 pairs) were incubated pairwise (i.e. simultaneously using the same antibody solutions) with rabbit polyclonal anti-Aggrecan antibodies targeting either the G2 domain or the chondroitin sulfate-2 (CS) domain followed by secondary antibodies conjugated with AlexaFluor 555, with DAPI counterstaining. Given the structure of aggrecan and landscape of aggrecan fragments isolated from fresh and cultured tendon tissue[6-9], we expect the G2 antibodies to label intact aggrecan and most prominent fragments, serving as a proxy for total aggrecan content (**Fig 2**). The CS antibodies target a region spanning a high affinity site of ADAMTS-4,5 proteolysis[10] that drives constitutive aggrecan turnover[6-9] and are expected to label only intact aggrecan (**Fig 2**). 60X confocal microscopy images were analyzed to quantify average fluorescence intensity within spatial quadrants subdividing the tendon insertion (**Fig. 3**).

Statistics: Data were compared using repeated measures two-way ANOVA with Šídák's multiple comparison test. *$p \leq 0.05$. **$p \leq 0.01$. ***$p \leq 0.005$. ****$p \leq 0.001$.

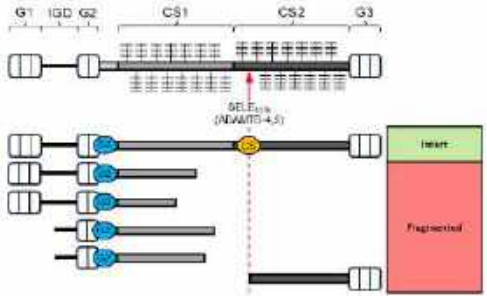

Figure 2: (Top) Schematic of aggrecan structure. Red arrowhead indicates a high affinity site of ADAMTS-4,5 proteolysis[10] that drives constitutive aggrecan turnover in tendon fibrocartilage. (Bottom) Landscape of aggrecan structure in tendon[9]. G2 antibodies serve as a proxy for total aggrecan. CS antibodies label intact aggrecan only.

RESULTS

Significant increases in G2 labeling intensity were detected in quadrant 1 of impinged tendons (**Fig 3A** – insets, data) without any change in CS labeling intensity (**Fig 3B** – insets, data), indicating an increase in total aggrecan with no change in intact aggrecan. This is reflected by a significant decrease in aggrecan integrity score (**Fig 3C**), suggesting lower relative proportions of intact/total aggrecan. Alternatively, no change in G2 labeling intensity was detected in quadrants 2-4 of impinged tendons (**Fig 3A**) despite significantly elevated CS labeling intensity (**Fig 3B**), indicating no change in total aggrecan but an increase in intact aggrecan. This is reflected by significantly elevated aggrecan integrity score in quadrants 3 and 4, suggesting increase in the relative proportions of intact/total aggrecan.

DISCUSSION

The results of this study indicate that impingement produces an

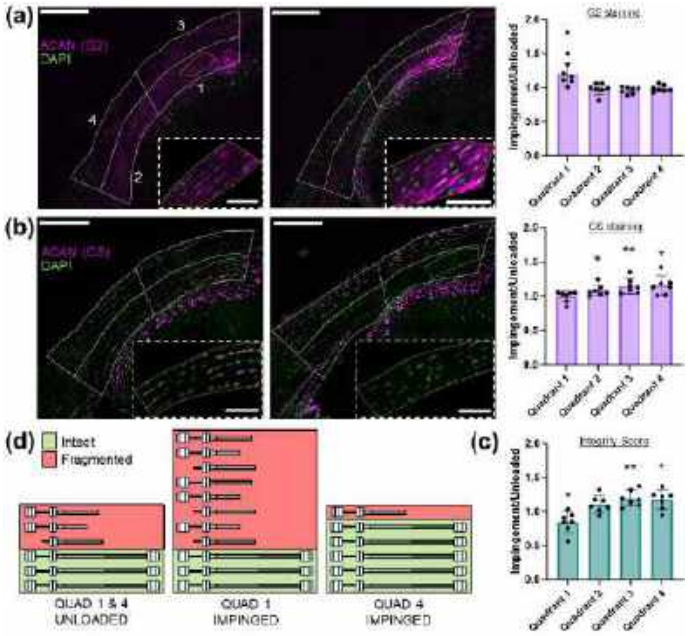

Figure 3: Immunofluorescent labeling of unloaded (left) and impinged (middle) tendons with **(a)** G2 antibodies for total aggrecan and **(b)** CS antibodies for intact aggrecan. (Right) Quadrant intensity data for impinged tendons normalized to contralateral unloaded tendons. Insets highlight change in distal quadrant 1. **(c)** Aggrecan integrity score for impinged tendons normalized to contralateral unloaded tendons, where higher scores represent higher relative proportions of intact/total aggrecan. **(d)** Schematic interpretation of impingement-driven change in aggrecan turnover within compressed (quadrant 1) and tensile (quadrant 4) regions. Scale bars: 200μm (main), 50μm (inset). Significant differences between impinged and unloaded indicated by *$p \leq 0.05$. **$p \leq 0.01$. ***$p \leq 0.005$. ****$p \leq 0.001$.

increase in total aggrecan in quadrant 1 with no change in intact aggrecan, suggesting accumulation of aggrecan fragments (**Fig 3D**). Previously, we measured significantly elevated transverse compressive strain at the distal insertion secondary to impingement despite uniform magnitude of axial tensile strain (**Fig 1C**). Our interpretation of these data is that compressive strains distally drive increased aggrecan turnover in parallel to increased production. Conversely, predominantly tensile strains proximally drive down aggrecan turnover yielding an increase in intact aggrecan with no change in total aggrecan, as described in quadrant 4 (**Fig 3D**). Together, these data support the hypothesis that spatial patterns of mechanical strain elicit differential regional patterns of aggrecan turnover at the impinged Achilles tendon insertion. In the future, we plan to relate these molecular-level changes in aggrecan turnover and structure to microscale change in compressive mechanical properties with atomic force microscopy (AFM).

INTRODUCTION

Glioblastoma (GBM) is the most common type of glioma accounting for more than 60% of all brain tumors in adults. GBM is highly aggressive and carries a profoundly poor prognosis with a median survival (OS) of <2 years [1]. Modern therapies have allowed for a modest increase in average survival time; however, GBM remains a terminal diagnosis with poor outcomes due to resistance to approved treatment modalities. Poor therapeutic response is mediated in part by the tumor microenvironment (TME) that harbors aberrant vasculature that promotes hypoxia and immunosuppression, and limits the entry of drugs and effector immune cells [2]. Although much is known about GBM endothelial cells, pericytes, and perivascular immune cells, it is unknown whether other mural cell types, such as fibroblasts, can be similarly reprogrammed by the tumor to promote its growth and treatment resistance.

Recent studies have uncovered the presence of fibroblasts in the meninges, choroid plexus, and perivascular spaces of the brain. Although the origins and functions of these central nervous system (CNS) fibroblasts are still being elucidated, recent data indicate that these cells play vital roles in fibrotic scarring in the CNS following injury and inflammation. In various CNS malignancies, however, particularly GBM, fibrotic scar formation by fibroblasts has been largely overlooked due to paucity of these cells within the CNS.

In some extracranial cancers, local tissue-resident fibroblasts can be reprogrammed by the tumor into cancer-associated fibroblasts (CAFs) that can remodel extracellular matrix (ECM), thereby accelerating tumor growth and impairing response to immunotherapies [3]. Understanding whether this mechanism is also conserved within the CNS can reveal novel insights into therapeutic resistance and guide the design of new strategies to improve outcomes in brain tumor patients.

To this end, we used publicly available single cell and bulk RNA sequencing (RNA-seq) datasets to identify CNS fibroblasts in glioblastoma and characterize their gene expression profiles, as well as their clinical correlates. In particular, we sought to answer (1) whether CNS fibroblasts may be responsible for ECM remodeling and tumor stiffening (1), and (2) whether CNS fibroblasts may hinder response to immune checkpoint blockade (ICB) immunotherapy in GBM patients.

METHODS

The scRNA-seq data (GSE182109, GSE163577) were obtained from Gene Expression Omnibus [4]. Individual samples were log-normalized and integrated using Seurat's (v4.3.0.1) reciprocal PCA [5]. Doublets were identified and removed using Scrublet (v0.2.3) algorithm [6]. Next, cells were clustered and annotated based on previously reported marker genes [4] as well as copy number alterations (CNAs) inferred using CopyKat (v1.1.0) algorithm [7]. To exclude poor quality cells within each cell type, we applied median absolute deviation (MAD)-based outlier detection approach, as described previously [8]. Clusters characterized by low UMI counts, high fraction of mitochondrial reads, and uninformative marker genes were removed. scRNA-seq datasets were integrated using anchor-based Seurat (v3) integration [9].

Publicly available RNA-seq data were downloaded from TCGA and CGGA databases. Magnetic resonance elastography (MRE) data as well as biopsy-matched RNA-seq data were obtained from GitHub repository (SkabbiVML/stiffR) [10]. TCGA and CGGA datasets were were TMM-normalized (edgeR v3.40.2), and logCPM values were used for all downstream analyses. Signature scoring was performed using ssGSEA (GSVA v1.50.0). Cell type deconvolution was performed using MuSiC (c.1.0.0).

RESULTS

In order to identify CNS fibroblasts as well as other perivascular cell types in scRNA-seq data [4], we first undertook a marker-based approach by subclustering *PDGFRβ+ ACTA2+* mural cells. Based on

previously identified gene expression markers [11], we found distinct clusters of perivascular fibroblasts (P-FB; *FBLN1*, *LAMA2*), meningeal fibroblasts (M-FB; *SLC4A4*, *KCNMA1*), pericytes (PC; *PDGFRB*, *COL4A1*), and smooth muscle cells (SMC; *ACTA2*) (**Fig. 1a**). Integration of GBM mural cells with those from a human brain vascular atlas [11] resulted in alignment of respective subpopulations in the UMAP space (**Fig. 1b**). Notably, the P-FB cluster expressed several classical CAF markers such as *PDGFRA*, *PDGFRB*, *COL1A1*, and *FAP* [12]–[14] (**Fig. 1a**), suggesting that perivascular fibroblasts may assume a CAF-like phenotype in GBM.

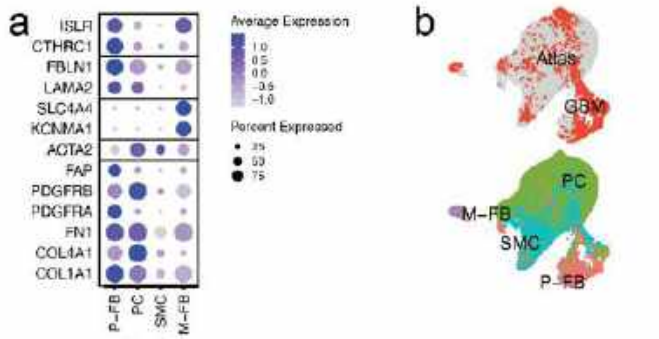

Figure 1: Identification of mural cell populations in GBM. **a** Marker genes identifying subpopulations of mural cells in GBM. P-FB – perivascular fibroblast; PC – pericyte; SMC – smooth muscle cell; M-FB – meningeal fibroblast. **b** Joint UMAP embedding of mural cells from a human brain vascular atlas (grey) and GBM mural cells (red).

Next, we sought to determine whether perivascular fibroblasts may be responsible for deposition of ECM and increased tumor stiffness by analyzing magnetic resonance elastography (MRE) and biopsy-matched RNA-seq data from eight GBM patients [10]. Using single-sample GSEA, we found an enrichment of perivascular fibroblast and pericyte gene signatures in stiff biopsies (**Fig. 2a**). Similarly, we found a higher estimated proportion of perivascular fibroblasts in stiff biopsies using single-cell deconvolution (**Fig. 2b**).

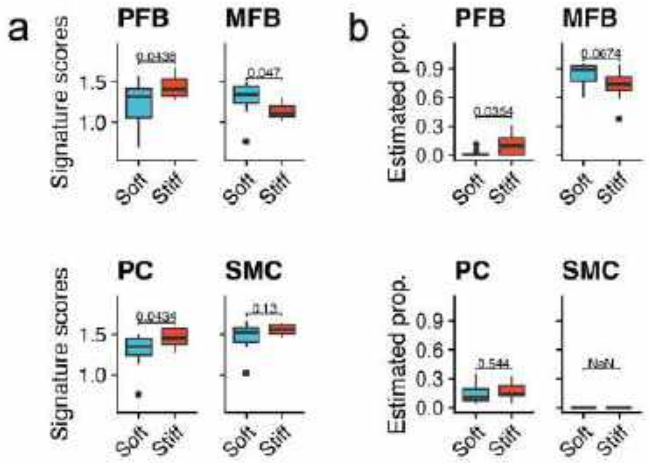

Figure 2: Perivascular fibroblasts are associated with increased GBM stiffness. **a** Marker genes identifying subpopulations of mural cells in GBM. P-FB – perivascular fibroblast; PC – pericyte; SMC – smooth muscle cell; M-FB – meningeal fibroblast. **b** Joint UMAP embedding of mural cells from a human brain vascular atlas (grey) and GBM mural cells (red) (P values were calculated using t-test).

These findings suggest that fibrotic scarring observed in glioblastoma multiforme (GBM) can have common mechanisms with other neuropathologic conditions where fibrogenic cells originate from perivascular fibroblasts in response to inflammatory stimuli.

Next, to determine whether perivascular fibroblasts play a role in response to immunotherapy in GBM, we interrogated retrospective data from two recent anti-PD1 immunotherapy trials [15], [16]. In both cohorts, we found a significant reduction in overall survival for patients whose tumors were enriched in perivascular fibroblasts (**Fig. 3a-b**), suggesting that the presence of perivascular fibroblasts may be prognostic of a poor immunotherapeutic response.

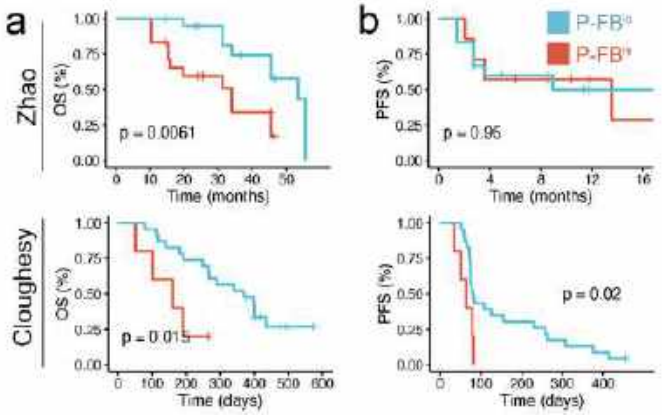

Figure 3: Perivascular fiborblasts predict response to PD-1 immunotherapy. Kaplan–Meier plots of overall (**a**) and progression free (**b**) survival for patients with high (red) or low (blue) presence of perivascular fibroblasts in Cloughesy ($n = 28$) and Zhao ($n = 38$) cohorts treated with anti-PD1 therapy (P values were calculated using log-rank test).

DISCUSSION

A previous study has shown that GBM stiffness is associated with ECM reorganization, particularly fibrillar collagens [10]. However, it was previously unknown which cell type(s) are responsible for this phenomenon. In this study, we used publicly available MRE and gene expression data to show that perivascular fibroblasts are associated with increased tumor stiffness. In contrast, a recent study of human glioblastoma identified pericytes as the cellular source of ECM [17]. However, the reliance of this study on cell surface markers without comprehensive gene expression profiling raises the possibility that the identified cells could represent a different cell type such as fibroblasts or smooth muscle cells, which share overlapping cell surface markers with pericytes [18].

Therapeutically reducing ECM deposition can alleviate immunosuppression across various cancer models, including GBM [19]–[21]. In our study, we further show that perivascular fibroblasts hinder response to PD-1 ICB therapy; however, the mechanisms by which perivascular fibroblasts thwart immunotherapy efficacy remains to be established.

Taken together, our results suggest that perivascular fibroblasts actively remodel ECM, leading to increased tumor stiffness and therapy resistance, and may therefore act as analogs of CAFs in peripheral tumors.

INTRODUCTION

Gold nanoparticles (AuNPs) can efficiently convert laser energy into heat, emitting thermal acoustic waves, making them valuable agents for photoacoustic (PA) signaling in biomedical applications.[1,2] Recently, studies have shown that silica-coated AuNP (SiO_2-AuNP) can enhance the laser-acoustic conversion compared with that of AuNP.[3] However, debate surrounds the mechanism behind this PA enhancement. Hu et al.'s experiments suggest improved thermal transport at the particle-water interface due to silica coating, potentially explaining the enhancement.[4] Conversely, modeling suggests a reduced PA signal due to limited heat conduction through the silica layer.[5] The conflicting results leave the SiO2-AuNP's PA enhancement mechanism uncertain.

Here, we systematically explored the impact of silica coating on PA generation with SiO_2-AuNP under ps and ns pulsed lasers. We observed substantial PA enhancement (up to 400%) with silica coating and ps laser excitation. Our proposed theoretical model highlights two key factors contributing to this amplification: improved interface thermal conductance at the silica-water interface and efficient electron-phonon coupling at the gold-silica interface. This study discovers a regime of large PA amplification and provides a new rationale for plasmonic nanoparticle design to achieve better PA efficiency.

METHODS

Nanoparticle preparation: AuNP was prepared by following the Frens' as previously reported.[6] SiO_2-AuNP preparation were followed by the procedures reported by Luis et al. (**Fig. 1A**).[7]

PA signal reading: Fig. 1B shows the experimental setup: a flow system with dialysis tubing installed in water bath. The laser beam (532 nm) was aligned on tubing. PA signal is detected by a transducer. PA enhancement (%) was calculated from PA signal intensity from sample (P), from bare AuNP (P_{Au}) and from water (P_{H_2O}):

$$PA\ enhancement\ (\%) = \frac{P - P_{Au}}{P_{Au} - P_{H_2O}} \times 100 \quad (1)$$

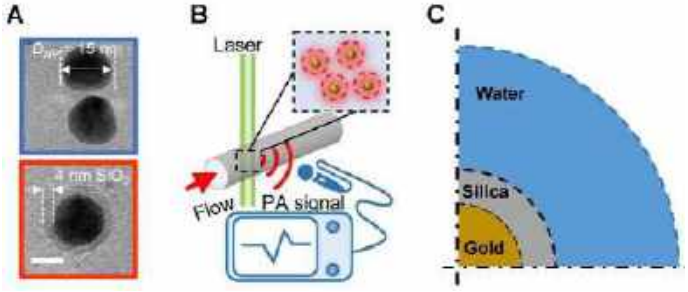

Figure 1. (A) TEM image of AuNP and SiO_2-AuNP, scale bar: 20 nm. (B) Schematic illustration of experimental setup. (C) Schematic illustration of PA modeling setup.

PA modeling: Fig. 1C demonstrates the setup for PA modeling. The plasmonic heating is modeled with two-temperature model:[8]

$$\rho_{Au} C_e \frac{\partial T_e}{\partial t} - \nabla \cdot \mathrm{k}_e \nabla T_e = Q_v(t) - G_{ep}(T_e - T_p) \quad (2)$$

$$\rho_{Au} C_{p\_Au} \frac{\partial T_p}{\partial t} - \nabla \cdot \mathrm{k}_p \nabla T_p = G_{ep}(T_e - T_p) \quad (3)$$

The thermal acoustic emission is estimated with wave function:

$$\frac{1}{\rho_m {c_s}^2} \frac{\partial^2 p_w}{\partial t^2} - \nabla \cdot \left(-\frac{1}{\rho_m} \nabla p_w\right) = \frac{\partial}{\partial t}\left(\beta \frac{\partial T_m}{\partial t}\right) \quad (4)$$

To analyze the laser-acoustic conversion efficiency, we define the PA quantum yield efficiency (Φ_{PA}) as the ratio between acoustic energy ($E_{acoustic}$) and laser energy ($E_{optical}$):

$$\Phi_{PA} = \frac{E_{acoustic}}{E_{optical}} = \frac{4\pi {r_m}^2}{z} \frac{\int p^2 dt}{F C_{abs}} \quad (5)$$

RESULTS

First, we determined the effect of laser pulse duration on the PA signal from AuNP and SiO_2-AuNP (**Fig. 1A**). As shown in **Fig. 2**, upon the ps pulsed laser (28 ps) irradiation, PA signal amplitude from SiO_2-AuNP is larger than that from AuNP. However, no noticeable PA signal enhancement was observed under ns pulsed (6 ns) laser. We further

analyzed the peak-to-peak (P2P) amplitude of PA signal with different laser fluence. With the ps laser excitation, the slope of P2P amplitude for both 15 nm and 45 nm SiO_2-AuNP is significantly higher than that for the bare AuNP (**Fig. 2B&C**), while there is no significant enhancement for the ns laser cases (**Fig. 2E&F**).

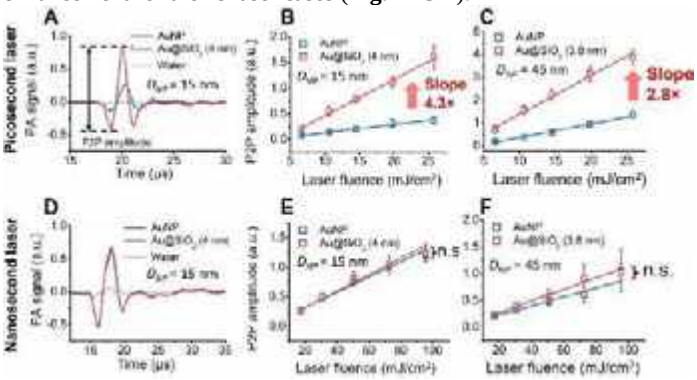

Figure 2. (A) PA wavefunctions of AuNPs and SiO_2-AuNP (15 nm Au core) with ps laser (19.7 mJ/cm^2). Amplitude of PA signals with ps laser (B) 15 nm Au core and (C) 45 nm Au core. (D) PA wavefunctions of AuNPs and SiO_2-AuNP (15 nm Au core) with ns laser (72.5 mJ/cm^2). Amplitude of PA signals with ns laser (E) 15 nm Au core and (F) 45 nm Au core.

Next, we investigated the effect of the thickness of silica coating on PA enhancement with ps laser. SiO_2-AuNP with 2 nm to 16 nm thickness silica coatings are prepared (**Fig. 3A**). As shown in **Fig. 3B**, for the 15 nm Au core, notable PA enhancement (Eq. 1) is observed with thin coatings (2.5 ± 0.5 to 3.9 ± 0.7 nm). Similar for 45 nm Au core (**Fig. 3C**), thin silica coating (2.0 ± 0.4 to 4.9 ± 1.2 nm) leads to PA enhancement. Among these, maximum enhancement around 400% (300%) with 4.6 nm silica (4.9 nm silica) for 15 nm Au core (45 nm Au core) is observed. Additionally, PA enhancement was only observed with a thin silica coating (thickness < 5 nm).

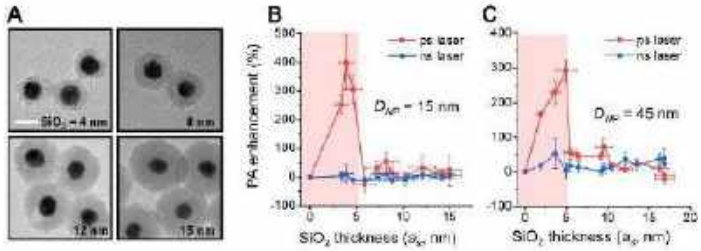

Figure 3. (A) TEM image of SiO_2-AuNP with different thickness of silica coating, scale bar: 20 nm. (B&C) Effects of silica coating thickness (ps laser: 19.8 mJ/cm^2, ns laser: 72.5 mJ/cm^2) on PA signal generation from (B) 15 nm Au core and (C) 45 nm Au core.

Lastly, we proposed a theoretical model for the mechanism of PA enhancement with SiO_2-AuNP. The energy transforms from hot electrons in gold (T_e) to heating in water (T_m) are the key issues in the model. In the traditional two temperature model for AuNP heating (**Fig. 4A**), heat transportation starts from T_e to gold lattice heating (T_p) through electron-phonon (*e-ph*) coupling, and further transfer to T_m through phonon-phonon (*ph-ph*) coupling. In contrary, an extra energy transfer channel from T_e to T_m in the SiO_2-AuNP scenario is considered in our model: 1) Heat transfer from T_e to T_p and then to silica through *ph-ph* coupling (R_{ps}); 2) Energy from T_e directly deposite to silica phonons through *e-ph* coupling at the gold-silica interface (R_{es}, **Fig. 4B**, marked as red). Based on this model, we estimated Φ_{PA} (Eq. 5) and only found Φ_{PA} enhancement with ps laser and thin silica coating (< 5.7 nm) (**Fig. 4C**). This laser duration and silica thickness dependent PA enhancement qualitatively agrees with our experimental findings. Further analysis of the model shows that synergistic heat transfer enhancements on gold-silica interface (*e-ph* coupling) and silica-water interface (h_{sw}) leads to the PA enhancement observed in the experiment (**Fig. 4D**). This study is an important step towards a better understanding of PA signal generation from plasmonic nanoparticles by providing a clear mechanism to account for the PA enhancement by silica coating.

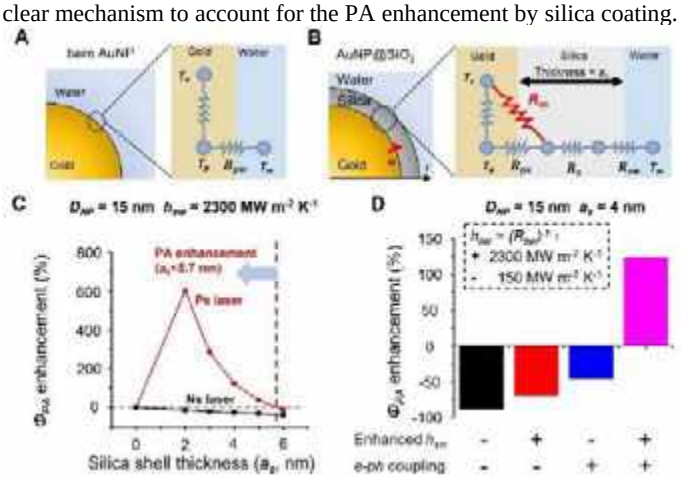

Figure 4. (A&B) Heat transfer model for (A) AuNP and (B) SiO_2-AuNP. (C) The silica shell thickness effect for PA quantum yield efficiency (Φ_{PA}) under ps and ns laser. (D) Enhanced Φ_{PA} is only observed with *e-ph* coupling at gold-silica and enhanced thermal transport at silica-water interface (h_{sw}).

DISCUSSION

In this work, we experimentally investigated the PA enhancement with SiO_2-AuNP and proposed a theoretical model for the mechanism. The theoretical model qualititatively explains the experimental findings. There may be additional factors which can contribute to the observed PA enhancement not captured by the current model, including the silica porosity and the presence of water in silica. Water can decrease silica's thermal conductivity, potentially reducing PA enhancement. However, water confined in narrow nanopores within silica could boost thermal expansion, potentially elevating the PA signal. Further investigation is crucial to unveil the role of silica porosity and the presence of water.

IDENTIFYING THE ROLE OF THE SEPTUM WALL IN RIGHT VENTRICULAR REMODELING

Kristen M. Garcia (1), Becky A. Hardie (1), Jessica Huberts (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California San Diego, La Jolla, CA, US

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a vasculopathy of the arteries of the lungs that is four times more prevalent in women than men. PAH is associated with vasoconstriction, stiffening, and *in-situ* thrombosis, raising the mean pulmonary arterial pressure.[1] This pressure overload induces right ventricle (RV) remodeling. The RV can adapt, however, when left untreated, RV remodeling can become maladaptive and lead to right heart failure and premature death.[2]

Studies of the RV free wall mechanical properties have shown myocardium stiffening and changes in contractility, leading to overall diastolic dysfunction in PAH. However how and what the role of the interventricular septal (IVS) wall has in this remodeling process is understudied.[3] The healthy IVS is softer, with a lower collagen content than the ventricular walls, suggesting a lower stiffness compared to the RV free-wall.[3] It is hypothesized that the increased RV pressures with an unaltered left ventricle can lead to changes in transeptal pressure gradient, increasing septal wall stress, and inducing possible septal flattening. Previous septum studies have included working with slices of canine tissue. Here we seek to characterize the full thickness of the IVS and understand how the properties change during PAH.[4]

METHODS

All protocols were carried out in accordance with the Institutional Animal Care and Use Committee at the University of California San Diego. Septal walls were harvested from 5 male and 4 female Sprague-Dawley rats weighing ~250-300 grams. Rats were anesthetized with 5% isoflurane in 100% oxygen. After exsanguination, the heart is flushed with cold phosphate-buffered saline (PBS) and heparin. Once the heart was harvested, the IVS was isolated from the ventricles, and a rectangle sample region of the tissue was cut with one axis aligned along the apex-to-base (longitudinal direction X_1) and the perpendicular axis aligned circumferentially (X_2) as shown in Figure 1.

PAH was induced in one male rat by a single injection of a vascular endothelial growth factor receptor inhibitor (SU5416,S8442 MilliporeSigma, CAS Number 204005-46-9, PubChemSubstance ID 24278606 Sigma-Aldrich, MO) followed by 3 weeks in hypoxia (10% oxygen levels). The rat was kept in normoxia for an additional 9 weeks. PAH was confirmed by invasive measurements of blood pressure at the inlet of the pulmonary artery with a mean pulmonary arterial pressure of 48 mmHg.

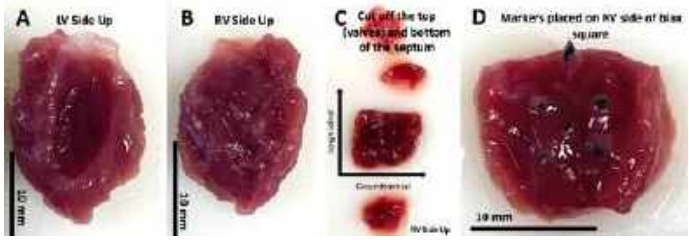

Figure 1. The isolated septum facing the left ventricle (A) and the right ventricle (B). The apical and basal borders of the septum were trimmed to obtain a rectangular sample for biaxial testing (C). Markers were placed on the middle region of the RV side to track displacement during planar biaxial testing.

Planar Biaxial Testing: All protocols for the septum followed the previously used RV planar biaxial protocols described by Vélez-Rendón et al.[5] Sample tissue length along both axes were measured with a digital caliper. Wall thickness was determined by the average of five thickness measurements throughout the sample. Tissue mass was recorded, five graphite markers were placed on the middle region of the RV side of the tissue sample, and the tissue was placed in the Bose Electro Force planar biaxial device attached via hooks placed on a pulley system. The tissue was submersed in temperature-controlled PBS

(37 °C) and the pixel positions of the markers were tracked throughout the test. One preconditioning trial was performed with the tissue being stretched to 8%, 10%, and 12% of the ex-vivo tissue side length. After preconditioning, the sample was preloaded and stretched 10% of the ex vivo side length for multiple trials, following the X_1:X_2 ratios: 1:1, 1:0.5, 1:0.25, 1:1, 0.5:1, 0.25:1, and 1:1.

Constitutive Equations: The septum wall is modeled as a hyperelastic, anisotropic, incompressible material with axes aligned along the longitudinal and circumferential directions (Figure 1). We used a Fung-type exponential strain-energy function to relate stress and strain. The Limited Memory BFGS algorithm is used to optimize the parameters (C, α_1, α_2, and α_3) which are then used to compute the strain-energy surface for each individual animal. The two-dimensional strain-energy density function (per unit area) is described as:

$$W(\boldsymbol{E}) = C(e^{Q(\boldsymbol{E})} - 1) \quad (1)$$
$$\text{where } Q(\boldsymbol{E}) = \alpha_1 \boldsymbol{E}_{11}^2 + \alpha_2 \boldsymbol{E}_{22}^2 + \alpha_3 \boldsymbol{E}_{11}\boldsymbol{E}_{22}$$

where shear strains are negligible. The strain-energy surfaces are averaged across the Green-strain space bounded by experimentally measured strain. The equibiaxial stress-strain curves from the averaged surface +/- standard error curves are plotted to represent a group.

RESULTS

IVS from male and female rats exhibited an isotropic response (Figure 2). When comparing the response between male and female IVS, female tissues are significantly stiffer than the male tissues (Figure 3). Finally, when comparing the normotensive group with a hypertensive male septum, there is a difference in material stiffness (Figure 4).

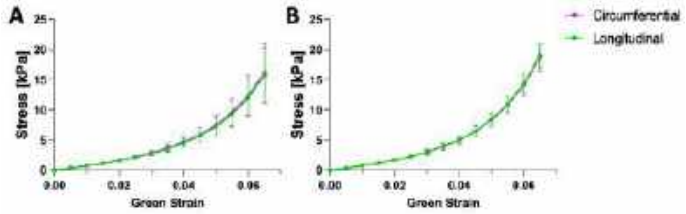

Figure 2. Equibiaxial stress-strain curves of the septum, with RV side facing up exhibit an isotropic tissue response in male (A) and female (B) hearts.

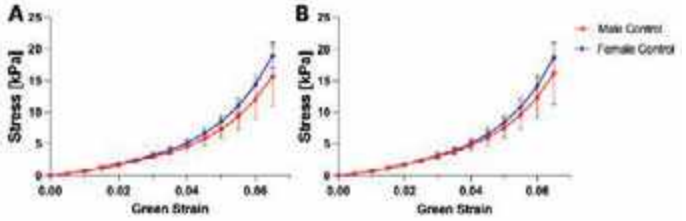

Figure 3. When comparing the male and female control septum tissue responses, we note that female septa are stiffer than the males in both longitudinal (A) and circumferential (B) directions.

DISCUSSION

IVS research with respect to RV remodeling during PAH is limited. Our initial findings indicate feasibility and reproducibility even though the morphology of the septum is more challenging than that of the ventricular walls. Findings of the septum being isotropic has only been found at high strain values in adult sheep hearts by Nguyen-Truong et al.[5] It is noteworthy that at small strains, Nguyen-Truong et al. reported the septum to be anisotropic.[5] Differences in orientation of the tissue and levels of stretch can lead to differences in behavior of the tissue. Some of the discrepancy in these results might be a resultant of testing slices of the septum versus our full-thickness septum samples.

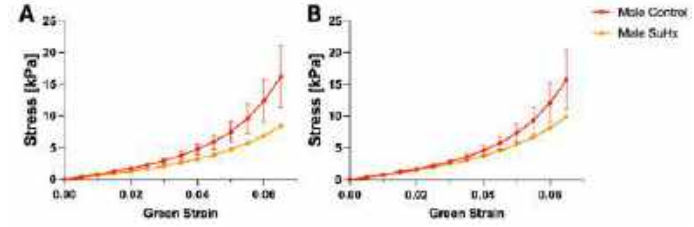

Figure 4. Initial results of comparing the septum from normotensive animals to a pulmonary hypertensive animal septum. We find that in both the circumferential (A) and the longitudinal (B) directions, the male control septa are stiffer.

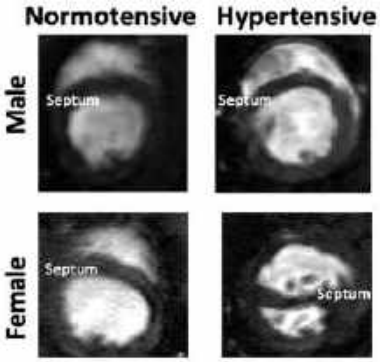

Figure 2. Cardiac magnetic resonance imaging of a female and male rat at the normotensive state and then again at a hypertensive state.

When testing the septa of normotensive male and female animals we found the female septa to be significantly stiffer than the males. When comparing the mechanical properties of male normotensive (n=5) and hypertensive (n=1) septa there appeared to be no significant stiffening from one state to the next. This could explain what we have seen in the cardiac magnetic resonance imaging (Figure 5) of normotensive and hypertensive male rats, where the septum geometry does not change between states. A major limitation of this study is the lack of female hypertensive septum samples. To understand how the female septum responds to progressive pressure overload, future samples are needed. Further investigation is needed for both male and female hypertensive septum. The goal of our work is to understand the mechanics of the IVS and to determine how RV pressure overload changes the properties of the septum wall.

INTRODUCTION

Alzheimer's disease (AD), a progressive neurodegenerative disease thought to be caused by abnormal deposits of amyloid plaques in the cortical gray matter in the brain, is the leading cause of dementia, having an immense impact on the aging population worldwide[1]. Over the progression of AD, damage spreads throughout the brain, shrinking the volume of the overall brain tissue[2]. Early diagnosis of AD is still challenging due to subtle microstructural changes, which is particularly troubling, as most treatments for AD can only be used to slow its progression, not reverse it, and are often far more successful when started early. β-amyloid can be detected through the utility of positron emission tomography (PET) with aid of a radioactive, but this procedure is invasive, leading to a profound need to identify non-invasive correlates of AD pathologies.

MR Elastography (MRE) is a technique for determining the mechanical response of tissues using applied harmonic deformation and motion-sensitive MRI. Performing MRE on human brain can provide information on different structures within brain tissue based on their mechanical properties, and pivotal studies applying MRE have shown a progressive softening of white and gray matter tissue in AD patients in regions in line with the known topography of AD pathology[3,4]. Another potential non-invasive diagnostic tool is diffusion tensor magnetic resonance imaging (DTI), which provides a metric for understanding the integrity of microstructure[5]. In addition to changes in signal intensity in the white matter due to aging, previous DTI studies have also identified changes in DTI signal intensity in gray matter regions[6,7], making it a region of interest to study in aging and neurodegeneration.

Additionally, studies at 3T have found correlations between MR Elastography (MRE) and DTI metrics in small white matter structures in young, healthy individuals[8,9], but low imaging resolution limited the specificity of the results in small regions due to partial volume effects.

Leveraging non-invasive ultra-high field (UHF), 7 Tesla (7T) MRI, with increased signal-to-noise ratio and improved soft tissue contrast afforded by UHF allows us to accurately map tissue microstructure. *In this study we aim to use 7T MRE, 7T DTI, 3T amyloid-PET, and cognitive testing results to determine the relationships between these metrics in a cohort of older individuals with either normal cognition, mild cognitive impairment (MCI), or AD.*

METHODS

Two scanning sessions (7T MRI and 3T PET, Fig 1A) and the Preclinical Alzheimer Cognitive Composite (PACC) test were performed on 14 subjects (Avg. age 70.3±5.2 years) determined to be cognitively normal (CN), and 6 subjects (Avg. age 70.0±9.4 years) determined to have MCI or AD. All MCI/AD patients had a consensus diagnosis of cognitive impairment and a Clinical Dementia Rating >4.0 in the Clinical Dementia Rating Scale Sum of Boxes.

Full brain coverage MRE (using a custom SE-2D-EPI-based sequence[10]) was performed at 1.1mm isotropic resolution and 50Hz vibration frequency[11], using a 32-channel head coil (Nova Medical) on a 7T Siemens Magnetom MRI scanner (TR/slice=140ms, TE=65ms, GRAPPA=3, Partial Fourier 7/8). Raw data were collected and analyzed as described in Triolo, *et al.*[12] to calculate the absolute value of the complex shear modulus (|G*|).

A high-angular-resolved diffusion MRI sequence was acquired with 1.05 mm isotropic resolution (b=1500 s/mm2, reversed-phase encoding in anteroposterior and posteroanterior directions for paired acquisition in 68 directions). The Diffusion pre-processing was performed using the human connectome project (HCP) pipelines, adjusted to account for significant eddy currents.[13]. This allowed us to estimate whole brain maps of mean diffusivity (MD) and fractional anisotropy (FA). Segmentation of brain regions was performed on an MP2RAGE T1scans (0.7mm^3) using Freesurfer[14] and regional masks were co-registered to the MRE space and DTI space using SPM[15]. SPM was also used to estimate the percentage area of CSF for each region.

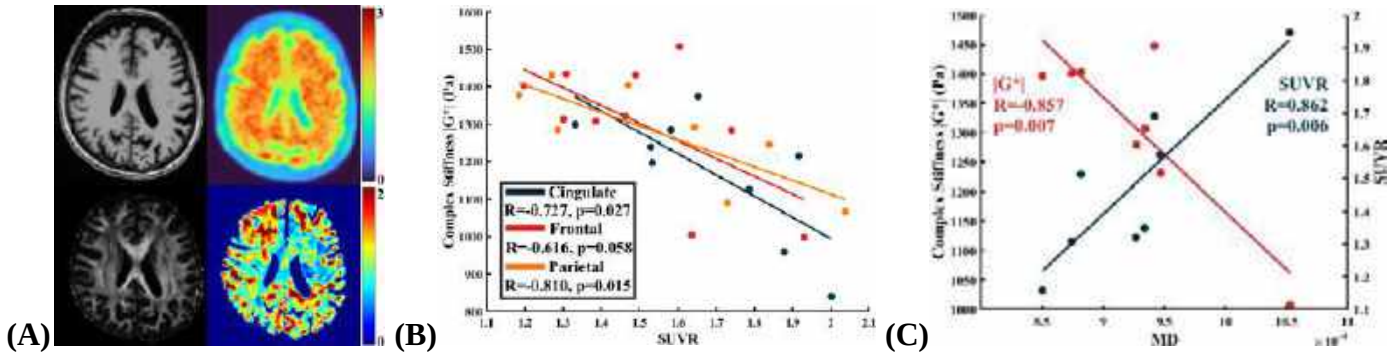

Figure 1: (A) Top: *T1 (left), PET (right), Bottom: FA (left), and |G*| (right) maps for one subject with MCI,* ***(B)*** *Linear correlations between |G*| and SUVR in three cortical brain regions, and* ***(C)*** *The linear correlations between |G*| and MD, and SUVR and MD in the temporal cortex.*

Subjects also underwent a Siemens Biograph mMR simultaneous PET-MR scan to measure Aβ burden using F18-labeled florbetaben using FDA standardize protocols. Average selective uptake value ratio (SUVR), FA, MD, and |G*| were calculated per cortical region of interest as specified in Palmqvist, *et al.*[16]. All MCI/AD subjects and one CN subject were determined to be Aβ-positive. We performed multiple Shapley Regressions in subjects with amyloidosis (subjects whose average SUVR are above the region threshold as described in Bullich, *et al.*)[17] in five PET-relevant brain regions (cingulate, frontal, parietal, temporal, and palmqvist-early)[16] with combinations of the different imaging metrics and PACC that were acquired for each subject.

RESULTS

We found significant differences (one-tailed, unequal variance t-test, $p<0.05$) between the CN and AD/MCI groups in |G*| of the hippocampus and frontal lobe, and SUVR of all brain regions investigated. A significant negative correlation was found between average SUVR and |G*| in the cingulate and parietal cortical regions in the Aβ-positive subjects, with a trending correlation in frontal (Fig 1B). We also found a significant positive correlation between SUVR and MD, and a negative correlation between |G*| and MD in the temporal gray matter (Fig 1C). There was a significant negative correlation between SUVR and PACC, and positive correlation between |G*| and PACC, in all regions.

From the Shapley Regressions (Fig 2 A,B), excluding PACC, |G*| was the best predictor of SUVR in subjects with amyloidosis in all brain regions tested, apart from the temporal and parietal lobes, where MD was a better predictor. Once again, excluding PACC, SUVR was the best predictor of |G*| in subjects in all brain regions tested, apart from the temporal lobe, where MD was a better predictor.

DISCUSSION

The negative correlation between |G*| and SUVR in brain regions initially impacted in MCI/AD progression is consistent with a previous investigation, supporting the hypothesis that tissue degeneration caused by Aβ accumulation results in tissue softening. The Shapley regression analyses demonstrated that SUVR and |G*| were the most important imaging covariates in their corresponding multi-regression analyses for multiple brain regions, which is promising for finding correlates of PET through MRE.

MD being the best predictor of SUVR and G* in the temporal and parietal cortexes is consistent with previous investigations of neurodegenerative and age-related brain changes in gray matter. Specifically, correlations between SUVR or |G*| and MD, but not SUVR and |G*| in the temporal cortex may be indicative of cascades which contribute to Aβ deposition, microstructural damage, and tissue softening and degradation. Additionally, similar correlation coefficients between PACC and |G*|, and PACC and SUVR in all brain regions has interesting implications about use of MRE and DTI instead of PET for diagnosing amyloidosis with cognitive impairment.

One limitation of this study is that a more robust MRE inversion algorithm would benefit the high-resolution allowed by 7T, resulting in even more detail. This study is limited by a small sample size, limiting statistical power, so future studies should look to include larger cohort of subjects diagnosed with MCI/AD. Despite these challenges, our multi-modal biomechanical imaging and analysis framework has promise to determine relationships between a multitude of MRI and PET measures for AD and MCI subjects, providing a physical understanding between tissue mechanics and AD pathophysiology.

INTRODUCTION

Health inequities like sex-differences cost the USA $320 billion today and could reach $1 trillion by 2040 if left unaddressed[1]. In particular, heart failure is a deadly cardiovascular disease that exhibits sex inequities. Women are at lower risk of developing heart failure, with "only" 2.6 million females versus 3.4 million males in the USA suffering from this deadly disease[2]. Premenopausal women are initially at a lower risk of developing heart failure than men, however, after entering menopause the risk for women increases significantly. The phenotype of heart failure is also related to sex: females are predisposed to develop heart failure with preserved ejection fraction (HFpEF) whereas males are more likely to develop heart failure with reduced ejection fraction (HFrEF)[3].

Sex differences in cardiac remodeling play an important role in both the onset and treatment of heart failure[5]. However, the underlying mechanisms are still poorly understood[6]. Estrogen and testosterone are known to strongly affect cardiomyocyte hypertrophy through intracellular signaling pathways[7]. Estrogen has protective effects on the heart (but not on the vasculature), whereas testosterone is considered to be pro-hypertrophic. Since female and male heart failure patients express different levels of sex hormones, we hypothesize that these hormones in combination with changes in mechanics are largely responsible for sex differences in cardiac remodeling.

Our group has previously generated growth models to predict changes in left ventricular structure and function after cardiac resynchronization therapy (CRT), which is implemented through a pacemaker or implantable cardioverter defibrillator to correct electromechanical abnormalities in heart failure. In the present study, we extend these biophysical models to incorporate sex-specific effects of estrogen and testosterone in the prediction of left ventricular growth and remodeling after CRT. Specifically, we develop and validate models of post-CRT remodeling for male sex, female sex in the premenopausal state, and female sex in the postmenopausal state.

METHODS

Multiscale model of Cardiac Growth

We developed a multiscale model of cardiac growth consisting of an organ-level model of cardiac mechanics and cell-level model of cardiomyocyte hypertrophy.

Organ-level cardiac mechanics were modeled using our recently published model[8]. The heart was modeled as three spherical walls using the TriSeg method (Fig 1)[9], where the left ventricular walls were functionally divided into segments according to the 16-segment AHA model to enable modeling of cardiac dyssynchrony. We used a lumped parameter circuit to model the hemodynamic circulation.

Cell-level hypertrophy was modeled using an intracellular signaling network model that we developed using Netflux[10]. The model has 3 inputs: estrogen (E2), testosterone (T), and stretch (Fig 1). The output is captured as a change in cardiomyocyte cell area. The signaling pathways were informed by in-vitro studies and include Calcineurin, CamKII, eNOS, IP3, PI3K and NFkB[7]. Reactions were modeled using normalized Hill-type ordinary differential equations.

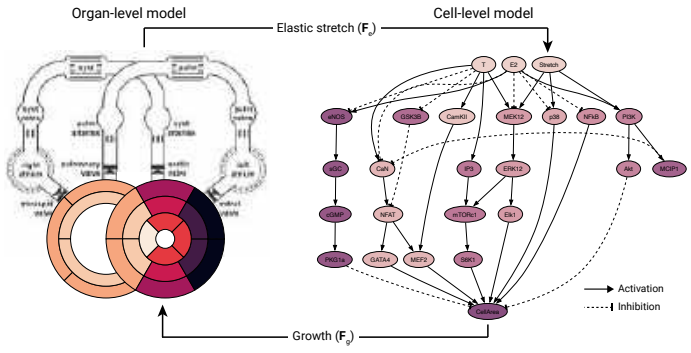

Figure 1: Overview of the multiscale model framework.

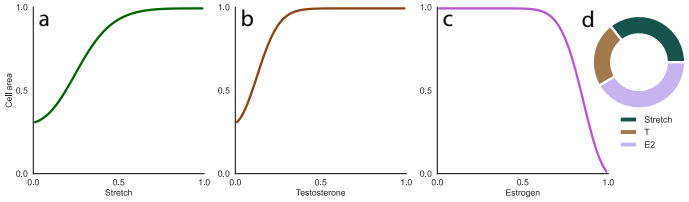

Figure 2: Cell-level model sensitivity to sex hormones and stretch.

The organ-level and cell-level models were coupled using the kinematic growth framework, where the total deformation gradient tensor for each wall segment is decomposed into an elastic and growth part: $\boldsymbol{F} = \boldsymbol{F}_{\mathrm{e}} \cdot \boldsymbol{F}_{\mathrm{g}}$. The growth tensor (we assumed isotropic growth) was determined by the cell-level model's predicted change in cell area. Conversely, the maximum elastic stretch tensor for each wall segment from the organ-level model was used as input into the cell-level model to close the loop (Fig 1).

Sensitivity and response of the signaling network model

Sobol global sensitivity analysis was conducted on the intracellular signaling network to show the impact of inputs on downstream species and cell area change. The model's response to input upregulation and downregulation was tested to compare with literature trends.

Model validation

To test our model's capability of predicting sex-specific cardiac remodeling in patients, we simulated 6 months of remodeling for three individual patients suffering from dyssynchronous heart failure that were treated with CRT. We specifically chose to simulate a premenopausal female, postmenopausal female, and male patient to test different concentrations of sex hormones. We calibrated the organ-level model to match clinical data including blood pressure, wall mass, and ventricular cavity volumes. We then simulated 6 months of post-CRT remodeling. Sex hormone (E2 and T) concentrations were adjusted to match the clinically observed 6-month change in left ventricular end-diastolic volume (LVEDV) and end-systolic volume (LVESV).

RESULTS

The global sensitivity analysis of our cell-level model confirmed that T, E2, as well as stretch significantly influence cell area change (Fig 2d). The signaling model's response to input upregulation and downregulation matches with literature data: a higher concentration of E2 decreased cell area, and higher concentrations of T and stretch increased cell area (Fig 2a-c). For the three patients we simulated, our multiscale model matched post-CRT change in LVESV and LVEDV to within ±2 percent of the measured value (shown for post-menopausal female in Fig 3, dashed lines). We were only able to match the clinically observed 6-month post-CRT remodeling when the hormone concentrations of E2 and T were tuned for each patient. Most excitingly, in each case, the tuned hormone concentrations to match clinically observed remodeling fell within the reported literature range of estrogen and testosterone of each sex and age (Table 1)[11,12]. Higher concentrations of E2 led to better post-CRT remodeling (lower LVESV), while higher concentrations of T exacerbated remodeling for all 3 patients (shown in Fig 3 for the postmenopausal female patient).

DISCUSSION

Purely mechanics-based growth models have in the past successfully predicted changes in ventricular mass or size, however these were unable to discern between outcomes in men and women. We were able to overcome this crucial shortcoming by using a combined mechanics and systems biology approach. To the best of our knowledge, this is the first model that incorporates sex-specific signaling pathways to predict cardiac remodeling.

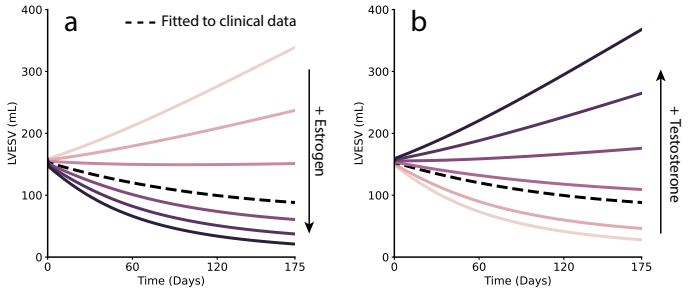

Figure 3: Validation of the multiscale model, predicted cardiac remodeling in postmenopausal female patient.

	Male	Postmenopausal female	Premenopausal female
E2 literature	10-40	0-30	30-400
E2 validated	29.96	**21.09**	314.8
T literature	265-923	2-41	15-70
T validated	278.5	**3.00**	17.00

Table 1: Literature and prediction sex hormone concentrations. E2 in pg/ml, T in ng/dl. Fitted data shown in Fig 3 in bold.

Our multiscale model still has several limitations. Some crosstalk with other connected pathways and feedback loops were not considered in this version of our signaling model. We have currently included hormone concentrations as a fitting parameter because the true concentration in our patients is unknown. Even though all fitted hormone concentrations agreed with literature values, some were towards the outer limits of the reported ranges. However, we here only tested our model for three individual patients; more (female and male) patients will be included in the future.

In conclusion, we developed a multi-scale model and validated cardiac remodeling in response to CRT in three patients: male, postmenopausal and premenopausal females by tuning sex hormones to match measured clinical remodeling volumes (within ±2 percent of measured). As heart failure patients exhibit both mechanical and sex-specific hormonal changes, and receive drugs that alter sex-specific pathways, our multi-scale model has the potential to lead to advancements in heart failure therapies for both women and men.

DEVELOPMENT AND APPLICATION OF ON-SITE VELOCITY BOUNDARY

Reza Bozorgpour (1), Mahsa Dabagh (2)

(1,2) Department of Biomedical Engineering, University of Wisconsin-Milwaukee, WI, Milwaukee, USA

INTRODUCTION

Lattice Boltzmann simulations of fluid flow in complex geometries, like patient-specific cerebro/cardio-vasculature often require on-site boundary conditions. These conditions enable the precise positioning of the boundary, simplifying system analysis independently of other simulation parameters. In practical applications, the ability to freely specify inlet fluid flow direction and easy three-dimensional implementation are crucial. Additionally, for parallelized solvers, locally applicable boundary conditions that involve only the information on the current lattice site offer significant advantages. This study details the adaptation of Zou and He's approach to a D3Q27 lattice, ensuring local application, independence from collision relaxation, and absence of artificial slip. The on-site no-slip boundary condition is seamlessly incorporated. Through various setups, we validate the effectiveness of the proposed boundary condition, demonstrating its accurate modeling of the velocity field up to the second order without any numerical slip.

Simulation Method

The lattice Boltzmann method solves the Boltzmann equation on a discrete lattice, capturing the microscopic dynamics of gas particles, collisions, and momentum exchange. Ideal collisions conserve total momentum and energy. This equation expresses the evolution of the probability function f(x, v, t) over time (t) for finding a particle with velocity v at position x.

$$\boldsymbol{V}.\nabla_x f + \boldsymbol{F}.\nabla_p f + \frac{\partial f}{\partial t} = \hat{\Omega}(f) \quad (1)$$

F is the external force, $\nabla_{x,p}$ is the gradient, and $\hat{\Omega}(f)$ is the collision operator. BGK dynamics, proposed by Bhatnagar, Gross, and Krook [1], uses Ω with a relaxation time τ towards the equilibrium distribution $f^{eq}(v,p)$.

$$\hat{\Omega}(f) = -\frac{1}{\tau}(f - f^{eq}) \quad (2)$$

The lattice Boltzmann method discretizes probability density in space and time for athermal models. Using a D3Q27 lattice in 3D LB simulations, it stores 27 values on each lattice site $f_i(\boldsymbol{X}, t)$, corresponding to lattice vectors c_i. The equilibrium distribution function f^{eq} and discretization depend on the lattice type [2, 3].

$$c_i = \begin{bmatrix} 0 & 1 & -1 & 0 & 0 & 0 & 0 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 0 & 0 & 0 & 0 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 0 & 0 & 0 & 1 & -1 & 0 & 0 & 1 & 1 & -1 & -1 & 0 & 0 & 0 & 0 & 1 & -1 & 1 & -1 & 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 & 0 & 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \end{bmatrix}$$

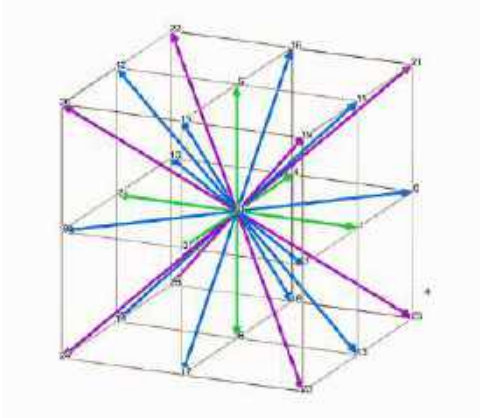

Figure 1. The lattice structure of D3Q27

The sum of all fi yields the local density at a lattice point.

$$\rho(\boldsymbol{X},t) = \sum_1^{27} f_i(\boldsymbol{X},t) \quad (3)$$

The sum of all fi yields the local density at a lattice point.

$$V(\boldsymbol{X},t) = \frac{1}{\rho(\boldsymbol{X},t)} \sum_1^{27} f_i(\boldsymbol{X},t) c_i \quad (4)$$

Discretizing the Boltzmann distribution yields the equilibrium value f^{eq}. We adopt a widely used form involving velocity terms up to the second order, as proposed in various expressions [4-6]

$$f_i^{eq} = \omega_i \rho (1 + 3\frac{c_i.V}{c_s} + \frac{9}{2}\frac{(c_i V)^2}{{c_s}^2} - \frac{3}{2}\frac{V^2}{{c_s}^2}) \quad (5)$$

During each iteration, the lattice Boltzmann method involves two pivotal procedures: streaming and collision. Streaming involves particle movement along discrete velocities to adjacent nodes determined by the lattice discretization. On the other hand, collision entails the relaxation of particle distribution towards the Maxwell-Boltzmann equilibrium distribution, often approximated as f_i^{eq}

$$f_i^{eq} = \omega_i \rho (1 + \frac{\boldsymbol{c_i}.\boldsymbol{u}}{c_s^2} + \frac{\boldsymbol{uu}:(\boldsymbol{c_i c_i} - c_s^2 I)}{2c_s^4}) \quad (6)$$

In our code implementation, we employ a single relaxation time Bhatnagar-Gross-Krook (BGK) collision operator [1] for lattice weights ω_i and a lattice speed of sound $c_s = 1/\sqrt{3}$.

The general on-site velocity boundary condition

Extending Zou and He's [4] boundary condition to a D3Q27 lattice, we provide a detailed derivation for the bottom plane (z = 0). The derivation utilizes the set of equations composed of equation (3) and the components of equation (4).

$$\rho v_x = f_3 + f_7 + f_8 + f_{15} + f_{17} + f_{19} + f_{20} + f_{23} + f_{24} - (f_4 + f_9 + f_{10} + f_{16} + f_{18} + f_{21} + f_{22} + f_{25} + f_{26}) \quad (7)$$

$$\rho v_y = f_1 + f_7 + f_9 + f_{11} + f_{13} + f_{19} + f_{21} + f_{23} + f_{25} - (f_2 + f_8 + f_{10} + f_{12} + f_{14} + f_{20} + f_{22} + f_{24} + f_{26}) \quad (8)$$

$$\rho v_z = f_5 + f_{11} + f_{12} + f_{15} + f_{16} + f_{19} + f_{20} + f_{21} + f_{22} - (f_6 + f_{13} + f_{14} + f_{17} + f_{18} + f_{23} + f_{24} + f_{25} + f_{26}) \quad (9)$$

From (3) and 9

$$v_z = 1 - \frac{1}{\rho}[f_1 + f_2 + f_3 + f_4 + f_7 + f_8 + f_9 + f_{10} + f_{27} + 2(f_{13} + f_{14} + f_{17} + f_{18} + f_{23} + f_{24} + f_{25} + f_{26} + f_{27}) \quad (10)$$

In line with Zou and He's approach, we presume that the bounce-back condition remains valid for the non-equilibrium part f_i^* of the single-particle distribution f_i at the boundary.

$$f_i^* = f_i - f_i^{(eq)} \quad (11)$$

The unknown distribution functions after streaming will be $f_5, f_{11}, f_{12}, f_{15}, f_{16}, f_{19}, f_{20}, f_{21}$ and f_{22}. Using the Zou and He's method,

$$f_5 = f_6 + \frac{2\omega_5}{c_s^2}\rho v_z \quad (12)$$

$$f_{11} = f_{14} + \frac{2\omega_{11}}{c_s^2}\rho(v_y + v_z) \quad (13)$$

$$f_{12} = f_{13} + \frac{2\omega_{12}}{c_s^2}\rho(-v_x + v_z) \quad (14)$$

$$f_{15} = f_{18} + \frac{2\omega_{15}}{c_s^2}\rho(-v_y + v_z) \quad (15)$$

$$f_{16} = f_{17} + \frac{2\omega_{16}}{c_s^2}\rho(v_y + v_z) \quad (16)$$

$$f_{19} = f_{26} + \frac{2\omega_{19}}{c_s^2}\rho(v_x - v_y + v_z) \quad (17)$$

$$f_{20} = f_{25} + \frac{2\omega_{20}}{c_s^2}\rho(-v_x - v_y + v_z) \quad (18)$$

$$f_{21} = f_{24} + \frac{2\omega_{21}}{c_s^2}\rho(v_x + v_y + v_z) \quad (19)$$

$$f_{22} = f_{23} + \frac{2\omega_{22}}{c_s^2}\rho(-v_x + v_y + v_z) \quad (20)$$

Results

In our initial and elementary test case, we replicated the flow dynamics around an elliptic cylinder. We applied the Zou-He boundary condition at the inlet, utilized bounce-back for the wall, and maintained a constant pressure at the outlet. The simulation was conducted for Reynolds numbers of 30, 50, and 60.

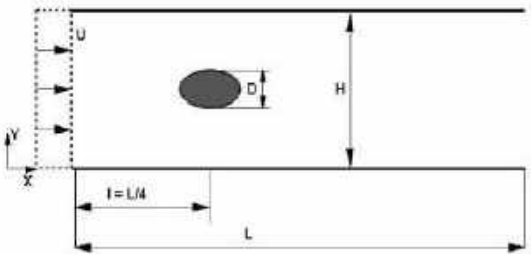

Figure 2. Schematic diagram of the flow past an elliptical cylinder confined in a channel

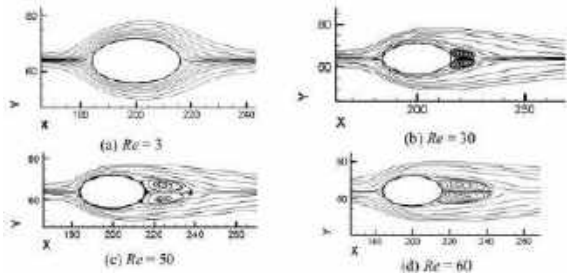

Figure 3. Streamline patterns for steady flows past an elliptical cylinder at different Reynolds

DISCUSSION

An explicit local on-site flux boundary condition was developed for LB simulations on a D3Q27 lattice, integrating velocity terms up to second order to ensure accuracy, validated through numerical tests. Unrestricted influx and outflux velocities in all directions were established. Comparisons between simulation results and theoretical expectations for flow through a tilted channel, specifically a Poiseuille flow, demonstrated numerical accuracy. Testing this boundary condition in Poiseuille flow between planar walls and shear flow revealed exact alignment with analytical solutions, independent of BGK relaxation time and without requiring slip parameters, while incorporating no-slip boundary conditions. Our next step is to simulate flow through different complex vasculatures and validate our results.

INTRODUCTION

An increasing number of medical device manufacturers are integrating microfluidic technologies into their products [1]. However, failure modes such as leakage and bubbles commonly occur for this technology. While flow resistivity information has largely been used in fundamental fluid mechanics research, it can also be used to evaluate the functionality and overall performance of microfluidic medical devices. In the medical device field, flow resistivity measurements can serve two primary purposes for early device developers. Firstly, developers can use flow resisivity measurements to ensure that the device has low flow resistivity, as higher flow resistivity can lead to higher pressures and an increased risk of mechanical integrity issues. High resistivity may also induce higher shear stress on the biological molecules and materials, which can compromise their viability and functionality. Secondly, the flow resistivity of a new design can also be compared to validated benchmark models to confirm that the new system under investigation, along with its flow and pressure controllers and sensors, is adequate over its entire intended operating range.

To date no standard test methods have been developed to accurately measure flow resistivity in a microfluidic device. There are inherent difficulties associated with accurately measuring very low flow rates and pressure differentials in microfluidics. This study presents an experimental protocol to evaluate flow resistivity and a comparison with theoretical predictions. The microfluidics community can use this protocol to measure the flow resistivity of the presented standard geometry as a benchmark to evaluate their capacity to measure the flow resistivity of their flow sensors with acceptable precision.

METHODS

Flow resistivity measurements are made to find the corresponding flow rate of a given pressure difference between the inlet and outlet of the microfluidic device. We used the setup illustrated in Figure 1(a) to conduct the tests. The microchip is made of cyclic olefin copolymer (COC) consisting of a straight microchannel with a 100 µm x 100 µm square cross-section and a length of 17.5 mm. The fluid (ultrapure deionized water) is introduced into the system via the pressure controller, which regulates the pressure within the pressurized reservoir. The 1/16" OD x 1/32" ID PTFE tubings were connected via ¼"-28 Swivel compression fittings to the sensors and the pressurized reservoir. The gas tubing from the pressure controller to the reservoir is reinforced tubing with dimensions of 4 mm OD and 2.4 mm ID, and it was connected to the tank via ¼-28 Swivel to Barbed 3/32" ID Adapter.

The Hagen-Poiseuille equation describes the relationship between the pressure and the flow rate for a laminar steady-state flow in a cross-section where the fluid is incompressible and Newtonian. When rearranged, the following equation can be used to calculate the experimental flow resistivity in a microfluidic channel [3]

$$R_H = \frac{\Delta P}{Q} \tag{1}$$

Where R_H, ΔP and Q are the flow resistivity, pressure difference between the inlet and outlet of the microchip and the flow rate, respectively. The theoretical value of the flow resistivity for a straight microchannel with a rectangular cross-section can be calculated by equation (2) [3]

$$R_{H,sq} = \frac{12\,\mu L}{1-0{,}63\times\left(\frac{h}{w}\right)}\left(\frac{1}{h^3 W}\right) \tag{2}$$

Where the L, w and h are the length, width and height of microchannel, respectively. The μ is the dynamic viscosity which is estimated to be 0.001 Pa·s for water at 23 °C. Given the input parameters above, the theoretical flow resistivity is calculated to be 4.97 x 10^{12} Pa·s/m^3, which is the reference value in this study used for calculating accuracy. Three flow sensors—brand A and B from one manufacturer and brand C from a second manufacturer—were used. Their nominal flow ranges are provided in Figure 1(b). Flow rates were

carefully selected to cover the range of flow rates likely to be encountered for common microfluidic medical device applications [1]. The lower limit for the flow sensor was typically represented as 10% of the maximum labeled flow rate [4].

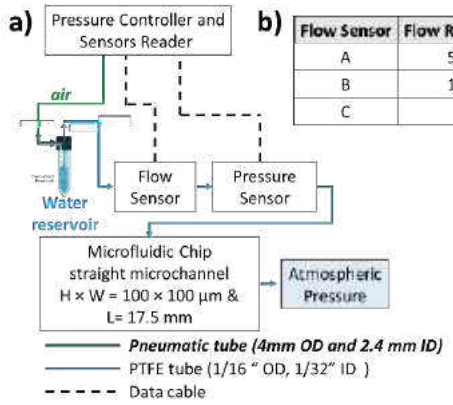

Figure 1: (a) Schematic of the flow resistivity measurement setup (b) Operating ranges for flow sensors.

RESULTS

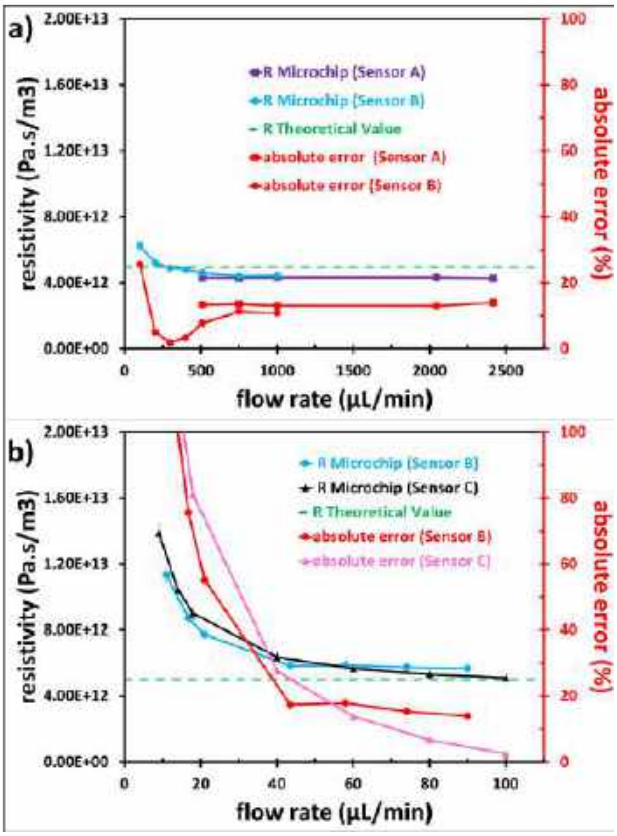

Figure 2: Flow resistivity and absolute error over a range of flow rates for (a) Sensors A and B (≥ 100 µL/min), and, (b) Sensors B and C (≥ 8 µL/min).

Figure 2 reports the flow resistivity for all three sensors. Error bars (not visually apparent) were based on n=3 replicate measurements. We calculated the relative error of resistivity between these experimental data and the theoretical values calculated by Equation 2 and reported the average of the absolute values (used to eliminate the potential of the relative errors with differing positive and negative signs cancelling each other out) of these errors for each flow sensor. The maximum average absolute error of resistivity determined using flow sensor A was ± 13.4 %, using sensor B was +9.54%/-4.54% when in range, and, +46.2%/-60.12% when outside range, and C was ±60.12%.

DISCUSSION

As seen in Figure 2 (a) - (b), sensors A and B had an acceptable performance when used in their nominal flow rate ranges up to 1000 and 2500 µL/min, respectively. While sensor C was used in its nominal flow rate range, sensor B was deliberately used outside its nominal flow rate range to assess sensor measurement errors outside the labeled flow rate range. While the lower limit of the nominal flow rate of sensor B is 100 µL/min, it yielded less than 20% error when used at a flow rate as low as 40 µL/min. However, under 40 µL/min, sensor B reported much higher values of error (55.1% at 21 µL/min, 75.7% at 16 µL/min and 128.3% at 11 µL/min). This underscores the need to operate sensors within their specified, labeled operating ranges. We also observed that although Sensor C was tested within its nominal flow rate range, it generated errors greater than 40%. Therefore, this study shows that while some sensors may provide accurate measurements of resistivity within their nominal range, other sensors may be inaccurate even within nominal range of operation. For device manufacturers embarking on developing a new device that uses microfluidics, this finding emphasizes the need for verifying the flow sensors against a protocol and chip with known resistivity values before using them for complex device development. It can also be used for failure mode studies to assess device performance in presence of bubbles or leakages. Moreover, it is useful for reliability and verification purposes, or as part of quality control process.

Further interlaboratory studies on resistivity based on multiple channel designs may also foster the development of standardized protocols that can be adapted by the community. Our studies were limited to flow rates ≥9 µL/min and ≤2500 µL/min because of limits of our flow and or pressure sensors. The current study was limited to only one design of a simple straight channel with a square cross-sectional area and hence cannot be extraplated to other geometries.

INTRODUCTION

Breast cancer is the one of the most commonly diagnosed cancer in women across the world, with annual reports of new cases estimated at roughly 300,000 in the United States and 2.3 million worldwide [1]. Breast-conserving surgery (BCS; also known as lumpectomy) is now recognized as the preferred treatment for early-stage breast cancer, provided that the surgery maintains adequate breast volume [2]. The goal of BCS is complete removal of the tumor while preserving, as much as possible, healthy breast tissue and breast appearance. The resulting surgical cavity undergoes a healing process resulting in variable levels of tissue contraction, scar tissue formation, and breast deformation. However, the complexity of the breast cavity healing process along with patient-to-patient variability in breast characteristics (e.g., breast and tumor geometry, tumor location, breast density) make it extremely challenging for surgeons to predict post-surgical healing, oncologic, and cosmetic outcomes.

To address this gap, we developed a computational mechanobiology model that simulates breast healing and deformation following BCS. Our previous work focused on the calibration of an initial coupled biochemical-biomechanical model, with model parameters being fit to histopathological data obtained from an experimental porcine study and available human clinical data evaluating cavity contraction [3]. An investigation was also performed to identify how patient-specific characteristics, such as cavity size and breast density, affected breast healing and cosmetic outcomes, with simulation results aligning with clinical findings [3].

Given our initial computational model implemented a generalized human breast geometry, next model iterations aim to use relevant retrospective and prospective human clinical data to obtain a deeper understanding of how patient-specific characteristics affect post-operative healing and deformation outcomes. Here, we utilize the computational mechanobiological model to simulate patient-specific breast and tumor characteristics to predict individual breast healing and deformation outcomes following BCS. Furthermore, these simulations will be applied as training data for machine learning applications, such as Gaussian Process surrogate models, to further understand the complex interplay between patient-specific characteristics and their effect on cavity healing, contraction, and breast deformation. Such patient-specific computational models have potential to assist breast surgeons and their patients in surgical decision-making and treatment planning, addressing the goals for improved predictability of surgical outcomes, reduced complications, and improved patient satisfaction and quality of life.

METHODS

Pre-operative magnetic resonance images (MRIs) of breast cancer patients were obtained through a data repository collected by Duke University Hospital in collaboration with The Cancer Imaging Archive [4]. Patients (n = 103) were randomly selected, with patients with bilateral breast cancer or multiple tumors in one breast excluded. Table 1 summarizes patient and tumor characteristics. Tumor location frequency for the patient population was consistent with other clinical studies, with 41.7% of tumors located in the upper outer quadrant [5].

Table 1: Patient and Tumor Characteristics

Characteristic	Median	Range
Age (years)	51.9	29.3 – 81.6
Breast Density (%)	25.9	4.4 – 71.1
Tumor Volume (mm^3)	1485.3	33.4 – 35096.6
Tumor Major Axis Length (mm)	19.1	2.0 – 59.9
Tumor-to-Breast Volume (%)	0.20	0.0015 – 3.86

Given that MRIs were obtained in the prone position, it was necessary to process images to incorporate gravitational deformation of patient breasts prior to computational model simulations as depicted in Fig. 1. Image tissue segmentation was first performed by applying thresholds in 3D Slicer to approximate volumes of adipose and fibroglandular tissue (depicted as yellow and blue in Fig. 1) [6].

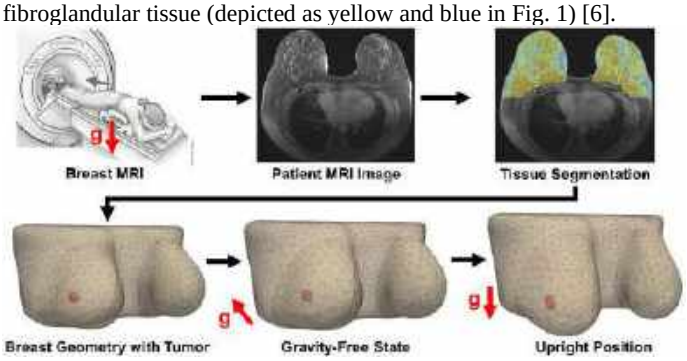

Figure 1: Gravity deformation procedure implemented for each patient MRI. Adapted from [7].

Breast density was then calculated for each patient and used to estimate breast Young's modulus using the rule of mixture. Evaluation of literature [8], along with testing a broad range of values, supported 1.5 kPa and 6 kPa as assumed Young's modulus values for adipose and fibroglandular tissue, respectively.

3D Slicer was used to identify tumor location in MRIs. Tumors were assumed to be ellipsoidal in shape, with patient-specific volumes and dimensions provided in MRI repository datasheets [4]. The BCS cavity was assumed to have the same volume and shape as the tumor. Material properties were assumed to be consistent with the buildup of serous fluid inside the cavity space (low shear modulus; high bulk modulus), which is common after BCS [9].

Patient-specific breast geometries were created and meshed in Slicer 3D based on the MRI acquired in the prone position. Using the established patient-specific characteristics, finite element analysis was performed to simulate breast and cavity deformation due to gravity from the prone position to the upright position (Fig. 1). Simulations were executed in COMSOL (COMSOL Multiphysics, Burlington, MA) with the breast and cavity defined using their respective parameters values as hyperelastic materials under the neo-Hookean model. Processed breast geometries in the upright position were then able to be simulated in the computational mechanobiological model, which is a custom C++ solver used to predict the breast healing response following BCS. The model framework and parameters were established in previous work [3].

RESULTS

MRI segmentation and gravity deformation simulations were performed for all 103 patient MRIs. The mechanobiological model was utilized to predict the breast healing response following BCS over a four-week period for each processed geometry. Exemplary simulation results for two patients are displayed in Fig. 2.

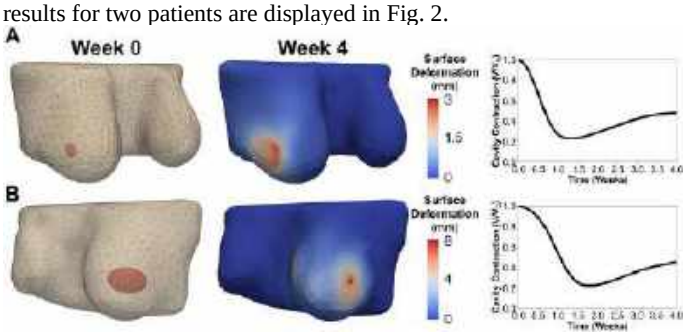

Figure 2: Mechanobiological model outcomes for patient-specific simulations (A and B) displaying post-surgical surface deformation and cavity contraction.

For Patient A, the breast cavity contracted substantially in the first nine days following surgery to 22.8% of its original cavity volume (Fig. 2A). A modest increase in cavity volume was shown by week 4, with the cavity being 48.1% of the excised volume (Fig. 2A). This permanent contracture led to minor deformations visible on the breast surface (Fig. 2A). The maximum point of deformation on the breast surface was found to be 2.71 mm four weeks post-surgery, with an area of 5715 mm^2 being affected by at least 1 mm surface deformation (Fig. 2A).

Patient B saw similar levels of cavity contraction compared to Patient A, as the breast cavity contracted to 22.6% of its original volume 12.5 days after surgery and was 45.3% of the excised volume by week 4 (Fig. 2B). However, Patient B was predicted to have a suboptimal post-surgical cosmetic outcome, as the maximum breast surface deformation was 7.55 mm with an area of 15459 mm^2 being affected by at least 1 mm surface deformation (Fig. 2B). The severity of the deformation led to the formation of a visible divot on the surface of the breast (Fig. 2B). Since breast density and tumor depth were very similar for both patients, the difference in cosmetic result can be attributed to differences in tumor-to-breast volume percentage (TVBP), with values for Patient A and Patient B being 0.36% and 3.86%, respectively. These results, which suggest that TVBP is an important prognostic indicator, are consistent with previous reported clinical outcomes [10].

A summary of the post-operative predictive breast healing and deformation results for the selected patients is shown in Fig. 3. The average patient breast cavity contracted to a minimum of 25.7% of the original excision volume in just nine days post-surgery (Fig. 3A). By week 4, the cavity moderately increased in volume to reach 52.6% of the excised volume (Fig. 3A). Maximum surface deformation range across the patient population was found to be 0.22 – 8.44 mm with an average and median of 1.92 mm and 1.44 mm, respectively (Fig. 3B).

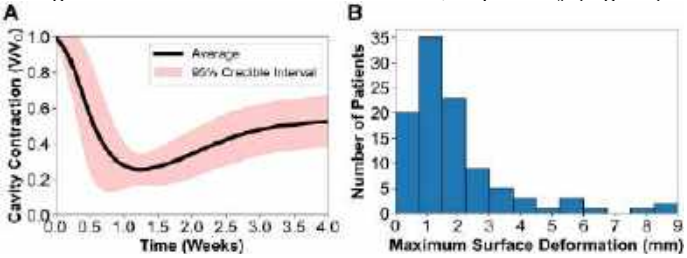

Figure 3: Predicted (A) cavity contraction over time and (B) maximum breast surface deformation for the patient population 4 weeks post-surgery.

DISCUSSION

The accessibility to the breast cancer patient MRI repository allowed for successful acquisition of patient-specific breast and tumor characteristics. This allowed for patient geometries to be utilized for the computational model to simulate breast healing outcomes such as cavity contraction and breast surface deformation following BCS. These simulations will be incorporated as training data for future machine learning applications, replacing the high-fidelity mechanobiological model with inexpensive and accurate surrogate models. Such surrogates can be employed to more efficiently understand the relationship between patient-specific breast characteristics and their effect on BCS outcomes, which will be explored in future work.

The study is not without limitations. The data repository used to obtain patient MRIs does not have additional scans or images following the patient post-surgery, with only pre-operative MRIs being available. Future model iterations will include the necessary data to track individual post-operative outcomes that can be compared to model predictions to further validate the computational mechanobiological model framework and parameters along with any machine learning surrogate models. With this work providing deeper insight into individual healing outcomes, future efforts can be shifted to focus on the addition of radiation therapy effects and the design of therapeutic approaches (e.g., regenerative breast fillers).

RIGHT VENTRICULAR MYOCARDIUM REMODELING IN PULMONARY ARTERIAL HYPERTENSION IS SEX-SPECIFIC AND OVARIAN-HORMONE DEPENDENT

Becky A. Hardie (1), Jessica Huberts (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California San Diego, La Jolla, CA, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a progressive vasculopathy of the pulmonary arteries that frequently results in right-heart failure and death.[1] PAH manifests as sustained elevation of pulmonary arterial pressures exceeding 20 mmHg and irreversible vascular remodeling that leads, and later exacerbates, pressure overload on the right ventricle (RV).[1,2] Previous studies with male animal models have shown that elevated RV pressures are associated with increased myocardial stiffness, tissue fibrosis, and disorganized collagen structure.[2–4] In particular, stiffening of the RV myocardial tissue is thought to be a significant contributor to overall RV chamber stiffness and function, a good prognostic indicator of PAH.[3,4]

PAH is significantly more predominant in women; however, despite the 2-4 times higher incidence in women, pre-menopausal women maintain better cardiac function.[5] Previous studies have shown that administration of 17-β estradiol (E2), the primary female sex hormone in non-pregnant women, improves RV function in rats and that E2 levels correlate with RV function in healthy post-menopausal women undergoing hormone replacement therapy.[5] Due to the less severe phenotype seen in pre-menopausal women, we hypothesize that the RV myocardium remodels in a sex and ovarian-hormone dependent manner in PAH. To investigate the tissue-level properties that may lead to sex or ovarian hormone-dependent remodeling, we designed a study using the well-established sugen-hypoxia (SuHx) rat model of PAH in male, intact female, and ovariectomized female (OVX) rats.

METHODS

Animal model. PAH is induced in male, intact-female, and ovariectomized-female (OVX) Sprague-Dawley rats by a 20 mg/kg injection of Sugen 5416, a vascular endothelial growth factor receptor blocker, followed by 3 weeks of hypoxia at 10% oxygen and a further 1-15 weeks of normoxia. Control animals are kept at normoxia. Hypertension is confirmed by invasive measurements of blood pressure at the inlet of the pulmonary artery. A 1.9Fr admittance pressure-volume catheter is inserted into the RV to obtain pressure-volume time series.

Tissue preparation. Immediately after hemodynamic measurements, the heart is harvested and flushed with saline. The RV free wall is excised and weighed. A square sample aligned along the apex-to-outflow (AOT) direction is cut from the mid-wall. Side lengths and tissue thickness measurements are taken with calipers prior to testing. Five graphite markers are glued on the epicardium in the center of the tissue to track displacement. The sample is attached to a Bose Electro-Force planar biaxial testing device with 4 custom-made hooks on each side and submerged in 37°C phosphate buffered saline.

Mechanical testing. RV samples are pre-stretched with a 3g load to ensure planar motion and preconditioned with two series of an 8%, a 10%, and a 12% *ex vivo* side length stretch at 0.2 Hz. Samples are subjected to displacement-controlled biaxial testing with 7 blocks of 15 loading-unloading cycles at 0.5 Hz. The AOT: circumferential stretch ratios are 1:1, 1:0.5, 1:0.25, 1:1, 0.5:1, 0.25:1, 1:1, with a maximum stretch of 10% of the *ex vivo* side-length. The last 3 cycles of blocks 2-6 are point-wise averaged and used for analysis. Pixel positions of the markers are recorded at 200 Hz throughout the test.

Constitutive equations. The locations of the four outer pixels are used to calculate the deformation gradient tensor $\boldsymbol{F}$ through isoparametric mapping. The Green strain tensor $\boldsymbol{E}$ is defined with respect to the pre-loaded reference configuration β_1, and the second Piola-Kirchhoff stress tensor $\boldsymbol{S}$ is calculated with the deformation gradient tensor. The myocardium is assumed to be a planar hyperelastic material with the loading curve described by a Fung-type exponential strain-energy function.

$$\mathrm{W}(\boldsymbol{E}) = C\left(e^{Q(\boldsymbol{E})} - 1\right) \tag{1}$$

where

$$Q(\boldsymbol{E}) = a_1\boldsymbol{E}_{11}^2 + a_2\boldsymbol{E}_{22}^2 + a_3\boldsymbol{E}_{11}\boldsymbol{E}_{22}. \tag{2}$$

Numerical implementation. Pre-stretch values $\{f_1, f_2\}$ are estimated in terms of the experimental stretches Λ_i as:

$$f_1 = \sqrt{\frac{E_{11}\Lambda_2}{\Lambda_1} + 1},\ f_2 = \sqrt{\frac{E_{22}\Lambda_1}{\Lambda_2} + 1} \quad (3)$$

and used to map from the stress-free reference state β_0 to the pre-loaded configuration β_1 at the beginning of the test. The model equations are fit to the experimental data using the Limited Memory BFGS algorithm by modifying the model parameters {C, a_1, a_2, a_3} in Python. A strain-energy surface is generated for each animal using the optimized set of parameters and within each group, the set of strain-energy surfaces are point-wise averaged over the range of experimentally measured strains. This averaged surface is used to generate a representative set of parameters for each group and the stress and strain relations from an equibiaxial stretch of 8% is computed.

Statistics. All values are presented as mean ± standard error of the mean and the significance level was set at 0.05 for all statistical tests. Two-factor ANOVA is used to compare RV thickness, mass, and hemodynamic measures, with the factors being group and treatment/week, followed by the Tukey *post-hoc* test for group. Stress-strain relations are compared using three-factor analysis of covariance (ANCOVA) with a log transformation in JMP, with the factors being strain, treatment, and group. When the interaction effects are significant, two-factor ANCOVA is performed within each group.

RESULTS

SuHx-treatment significantly increases RV thickness and mass ($p<0.0001$), with intact female RVs significantly thinner than male RVs ($p=0.0097$) and less massive than either male ($p<0.0001$) or OVX ($p=0.0002$) RVs (**Figure 1**). In each individual RV sample, the equibiaxial stress-strain response is isotropic (data not shown), thus only results in the AOT direction are shown.

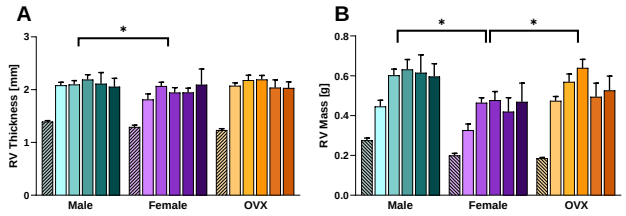

Figure 1: Morphological measurements of normotensive (patterned) and hypertensive (solid) male (green), female (purple), and OVX (orange) rats. RV thickness (A) and mass (B) increase with SuHx treatment in all groups and there is a significant difference between males and females. RV mass is significantly different between intact and OVX females. Data are presented as mean ± standard error and dark colors are later SuHx weeks.

There are significant interaction effects between strain, group, and weeks of treatment on the second Piola-Kirchhoff stress (**Figure 2**), indicating that sex and ovarian hormones impact the RV tissue-level remodeling seen in the SuHx groups. In males, 4 weeks of SuHx-treatment significantly increases RV stiffness (**Figure 2a**). The RV continues to stiffen over the next 4 weeks of treatment, before showing a slight reduction in stiffness at weeks 12 and 15 and a further increase in stiffness at week 18. In intact and ovariectomized females (**Figures 2b and 2c**), RV stiffness increases by week 4, but is then largely maintained at a similar level despite additional weeks of treatment.

DISCUSSION

Detailed studies of RV remodeling in PAH, particularly at the tissue level, have previously been conducted with only male animals. This is despite studies from Frump *et al.* and others that have shown sex-dependent RV remodeling at the organ, cell, and molecular levels and clinical evidence that pre-menopausal women have better cardiac function in PAH.[1,5] This study provides the first reported evidence that sex and ovarian hormones impact tissue-level RV remodeling in PAH.

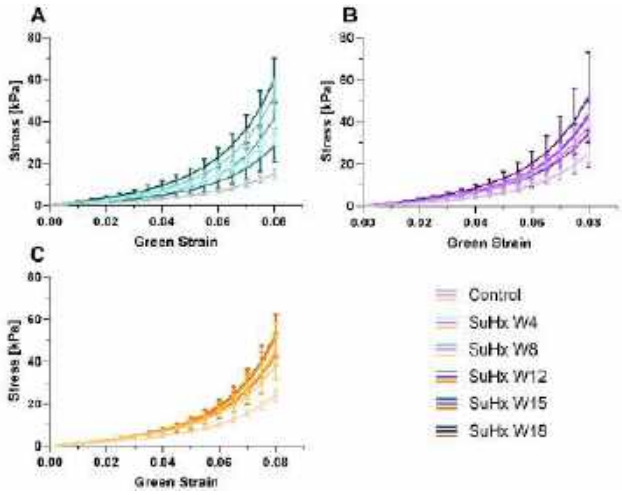

Figure 2: Average AOT stress-strain relations measured during biaxial testing. SuHx treatment increase RV stiffness in male (A), intact female (B), and OVX (C) rats. Data are presented as mean ± standard error and darker colors represent later SuHx weeks.

At baseline, there are significant differences in RV tissue thickness and mass, as well as myocardium stiffness between male and female rats. More specifically, normotensive male RVs are thicker, more massive, and less stiff than female or OVX RVs. SuHx-treatment results in similar pressure-overload in all groups (data not shown), yet the tissue-level response is sex-specific and ovarian hormone dependent. Significant RV myocardial thickening and mass increases with SuHx-treatment in males are consistent with previous studies.[2–4] Female RVs also increase in mass and thickness, but are thinner and less massive than those from males. The lack of ovarian hormones in the OVX rats results in a significant increase in RV mass compared to intact females.

Although the stress-strain relations after SuHx-treatment are show an increase in stiffness in all groups, the significance may lie in the degree of stiffening relative to the groups' normotensive stiffness. After 4 weeks of SuHx-treatment male RVs have approximately doubled in stiffness from control. This compares to the 1.5 times stiffness increase in the female and OVX RVs. By SuHx week 8, the male RV is more than 3.5 times as stiff as the normotensive male RV, whereas the stiffness of the female and OVX RVs still hasn't reached double that of their respective controls. Significant stiffening of the male RV in PAH has been previously reported,[2,4] however, this is the first study reporting a smaller increases in stiffness in female RVs, despite similar overall stiffnesses. In future studies, we will investigate how stiffening of the collagen extracellular matrix contributes to the comparatively large increase in RV stiffness seen in males.

INTRODUCTION

Traumatic brain injuries (TBIs) are a common source of disability and death worldwide, typically however damage mechanisms from an external force vary widely and are still not understood [1]. In civilian life, brain injuries can result from blunt impacts when performing daily activities. Similarly, military personnel encounter TBIs from blunt trauma but in combination with blast waves originating from explosives [2]. Cavitation is a suspected injury mechanism predicted to occur during blunt and blast impacts, where bubbles are expected to rapidly form, grow, and violently collapse in the cerebral spinal fluid (CSF) as a result of the pressure differential [3]. However, whether CSF cavitates during blunt and blast exposure is highly debated because there is no visual evidence due to the inability to monitor *in vivo* brain deformation and pressure profiles during collisions [3].

High-speed optical and acoustic imaging techniques are common approaches to acquire and visualize cavitation and shockwave behavior. Shadowgraph imaging visualizes phase changes through density variances, leading to differences in refractive index [4]. Ultrasound (US) can detect and form cavitation based on pressure differentials, one example being targeted drug delivery applications [5]. Acoustic plane wave imaging (PWI) differs by being able to capture events at high frame rates (max 10,000 FPS), compared to clinical US imaging techniques (10-30 FPS) without a focused transmit wave or varying pressure cycles [6].

This work aims to create a stand-alone tool from acoustic PWI as a unique approach to interpreting intracranial cavitation events at depths during blunt impacts. Therefore, a polyacrylamide (PAA) human head model was fabricated with optical transparency. Also, with similar shear rheological properties and simplified anatomical features present in the human brain. Cavitation was induced in head models under blunt impact via a drop tower setup in different orientations. Lastly, high-speed optical imaging was implemented to visualize and compare cavitation bubble dynamics with acoustic PWI.

METHODS

A drop tower was designed in Autodesk Inventor and fabricated to induce blunt impacts on PAA human head models. The drop tower is composed of aluminum T-slot railings held together by T-slot L-brackets, as presented in **Figure 1**. A 3-D printed impactor has an internal hollow structure that is filled with a mass of 4 kg. A trigger system allows synchronous imaging between acoustic and optical image modalities. The triggering system relies on manually pressing a mechanical button integrated into an Arduino UNO R3 microcontroller. Once pressed, a mechanical actuator retracts and releases the impactor from a height of 60 cm held together by a rope and anchor hook, breaking the continuity of a 36 AWG nichrome wire and sending a trigger voltage to the imaging hardware.

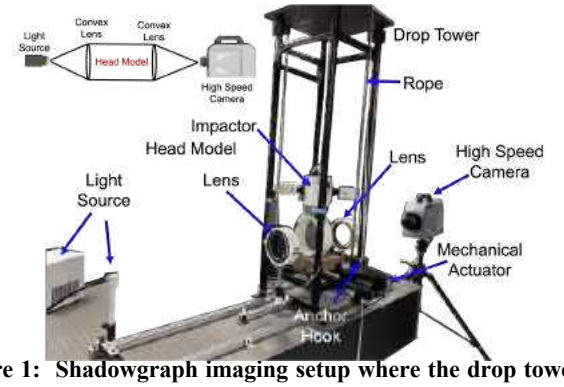

Figure 1: Shadowgraph imaging setup where the drop tower and head model are placed within the parallel light field.

A PAA composition of 10% (w/v) 60:1 (monomer:crosslinker) was chosen to construct a brain phantom. The steps for fabricating a brain phantom are previously reported [7]. Briefly, degassed DI water is mixed with a monomer (acrylamide (purity 98.0%, gas

chromatography)), crosslinker (N'-Methylenebis(acrylamide) (MBA, purity 99%)), initiator (ammonium persulfate (ACS Reagent, 98%)), and catalyst (N,N,N',N'-tetramethylethylenediamine (TEMED, ReagentPlus, 99%)). The homogenized solution is left to polymerize in a mold (**Figure 2a**), and the phantom (**Figure 2b**) is left to swell in an isotonic solution (ISOTON® II Diluent, Beckman Coulter) for 24 hours and is then sealed in a head model (**Figures 2c**) at room temperature (21C). All chemicals were purchased from Sigma-Aldrich, USA. These PAA hydrogels were previously characterized to determine mechanical properties for their applicability to simulate brain tissue [7].

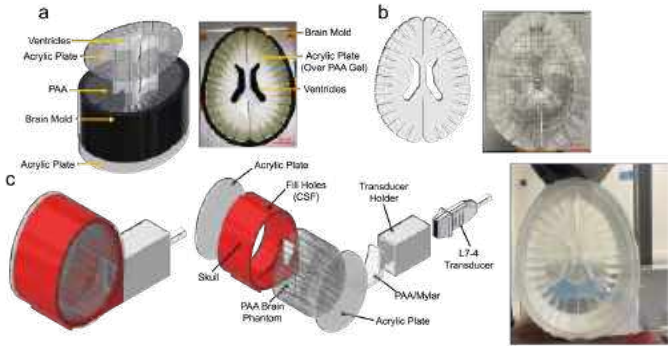

Figure 2: PAA brain phantom (a) fabrication process displaying the creation of the transparent (b) brain phantom. The brain phantom is then extracted from the mold and (c) sealed in a 3-D printed PLA skull to construct a head model. Fabricated head model incorporating a brain phantom with the inclusion of an L7-4 linear array transducer.

Shadowgraph imaging was performed under a parallel light field constructed by two Wollensak MTD telescope objective lenses (D=127 mm, FL =700 mm), as presented in **Figure 1**. A SugarCUBE Ultra LED illuminator light source illuminated the parallel field where the drop tower and head model were placed between both lenses. A Photron SA-Z high-speed camera recording at 100,000 FPS with a 0.16 µsec shutter speed captured events within the parallel light field. A Verasonics (VSX) US research scanner performed acoustic PWI by transmitting a plane wave with all 128 elements and receiving spatial information with the central 64 channels (**Figure 3**). The PWI frames had a 67 x 38 mm axial and lateral resolution, transit voltage of +17 V, and acquisition frame rate of 8620 FPS (Δt =116 µsec).

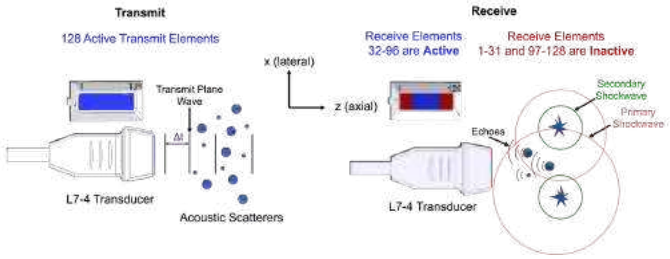

Figure 3: VSX PWI data acquisition sequence.

RESULTS

Shadowgraph imaging illustrated cavitation (yellow arrows) behavior and shockwave (magenta arrows) presence, especially in DI water (**Figures 4 a,e,c, and g**). Brain phantoms (**Figures 4 b,f,d, and h**) showed limited qualitative observations; however, cavitation was observed in the contrecoup region. Rotating the head model 90 degrees prior to impact (**Figure 4 c,g,d, and h**) produced less cavitation but increased material strain. US revealed high contrast regions (**Figure 4i**) during impact and spectra indicative of cavitation growth (**Figure 4j**) and collapse (**Figure 4k**) through broadband and harmonic behavior.

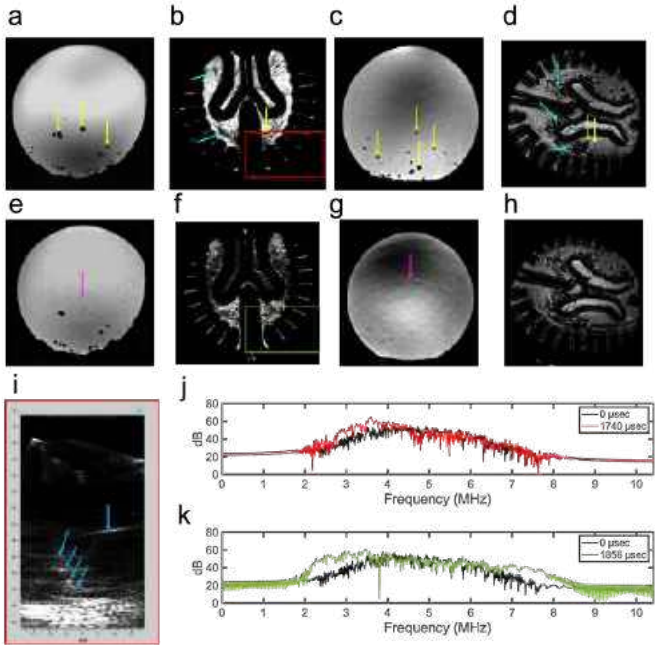

Figure 4: Shadowgraph frames of head models filled with (a,e) DI water and (b,f) brain phantom in the upright orientation. Similarly, head models rotated 90 degrees filled with (c,g) DI water and a (d,h) brain phantom. A representative (i) acoustic frame reveals an area of high contrast (blue arrows) with its corresponding power spectra revealing (j) harmonic and (k) broadband behavior. Yellow, magenta, and cyan-colored arrows reveal cavitation, shockwaves, and surface aberrations in the phantom, respectively.

DISCUSSION

A simplified PAA head model underwent blunt impacts for optical and acoustic data acquisition of cavitation events. Acoustic PWI assisted in detecting intracranial cavitation in the bulk CSF through reconstruction and signal processing techniques but lacks accuracy in spatial location and is the focus of future work. The degree of cavitation is affected by the change in orientation of the head models where the pressure profiles differ. Ultimately, this approach will allow the study of many TBI cases under various impact scenarios.

ACKNOWLEDGEMENTS

We want to thank Kevin Wedeward and the senior NMT electrical engineering student design team for fabricating the acoustic and optical triggering system. INTRODUCTION

The acetabular labrum acts as a mechanical boundary in the hip and a load sharing mechanism with acetabular cartilage. In the presence of cam-type femoroacetabular impingement syndrome (FAIS), secondary labral tears are common and can disrupt these functions, potentially leading to overload of the articular cartilage. Labral tears are often repaired during arthroscopic surgery for FAIS through suture anchor fixation techniques, and labral augmentation and reconstruction are common in cases of hypertrophic and hypotrophic labra[1]. Currently, the role of labrum size in cartilage mechanics and femoroacetabular biomechanics is largely unknown, despite the relatively common use of surgical techniques to address variations in labral size. The objective of this study was to assess the influence of labral size on the mechanical environment of the cam-type hip during walking and squatting using finite element (FE) modeling. We hypothesized that a variation in labral size will not further alter the already deleterious contact stresses and strains in cam-type hips, therefore mechanical indices reflecting the likelihood of cartilage damage would be unchanged.

METHODS

A volunteer diagnosed with cam FAIS was selected from a previous cohort[2]. A FE model was created from closed surfaces of the labrum, cartilage, pelvis, and proximal femur obtained via CT arthrography (CTA). The anatomically normal labrum was modified to reflect a hypotrophic labrum (width $\leq$ 3mm) and a hypertrophic labrum (width $\geq$ 6mm) (Fig. 1)[3,4]. The labrum, cartilage, and pelvis were discretized using quadratic elements.

The acetabular and femoral cartilage were represented as inhomogenous, anisotropic, hyperelastic materials by embedding a continuous ellipsoidal fiber distribution of tension-only collagen fibers within an isotropic matrix[5]. The primary orientation of collagen fibers was varied transmurally to reflect the mechanical contribution and physiological distribution of fibers *in vivo*. The acetabular labrum was represented as transversely isotropic hyperelastic, with collagen fibers oriented circumferentially around the acetabular rim[5]. The pelvis was modeled as a neo-Hookean material with patient-specific material properties derived from the CTA voxel intensity[6].

Patient-specific skin-marker kinematics for both a full gait cycle and deep squat in combination with joint reaction forces from Bergmann et al. were used to drive the FE models[7]. Models analyzed using FEBio (www.febio.org). Modeling outcomes

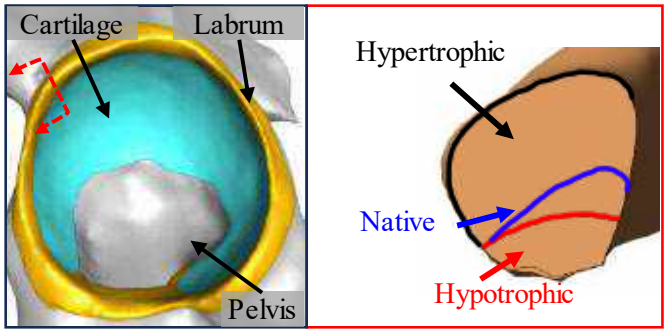

Fig. 1: (Left) Surfaces from a volunteer with cam-type FAIS were used for FE model creation. (Right) The anatomically normal labrum was modified to reflect the hypotrophic and hypertrophic cases.

were analyzed at heel-strike (level walking) and deep flexion (squat), corresponding to the highest amount of hip flexion and peak joint reaction force, where cam impingement traditionally occurs. Labral load support and labrum fiber stretch were evaluated to elucidate potential differences in load transfer and deformation between different sized labra. Contact pressure, 1st principal (tensile) strain on the articular surface, and maximum shear stress at the osteochondral interface (MSS) were also evaluated to compare the distribution of load.

Uncertainty quantification was performed using UncertainSCI[8]. Gamma distributions were defined for cartilage shear modulus, cartilage fiber modulus and labrum fiber modulus, and UncertainSCI generated sampling points in the parameter space. A quasi-static FE model simulating heel-strike was constructed analyzed repeatedly using the sampling points (N=20 models). The results were used in UncertainSCI to generate a statistical emulation model based on a polynomial chaos expansion, facilitating direct quantification of modeling sensitivity.

RESULTS

A larger labrum resulted in greater load transferred to the labrum during the gait cycle (Normal – 5.46%; Hypotrophic – 4.18%; Hypertrophic – 6.68%). Labral load support increased for all three cases during the squat and was greatest for the hypertrophic labrum (7.76%) compared to the hypotrophic (6.21%) and normal (6.93%) labra. Maximum circumferential labrum fiber strain varied from 7.0% to 7.5% during heel-strike, and between 11.0% to 12.6% at deep flexion across the three models. Contact pressure across the articular cartilage was unaffected by labral size (Fig 2). Additionally, there were minimal differences in tensile strain and maximum shear stress during heel-strike and deep flexion across the three labrum morphologies. Sensitivity analysis indicated that the modulus of the cartilage collagen fibers had the greatest contribution to variance in cartilage contact pressure, 1st principal strain, and max shear stress. For the labrum fiber stretch, variations in model outputs were equally sensitive to labrum fiber modulus and cartilage fiber modulus during heel-strike (Fig. 3).

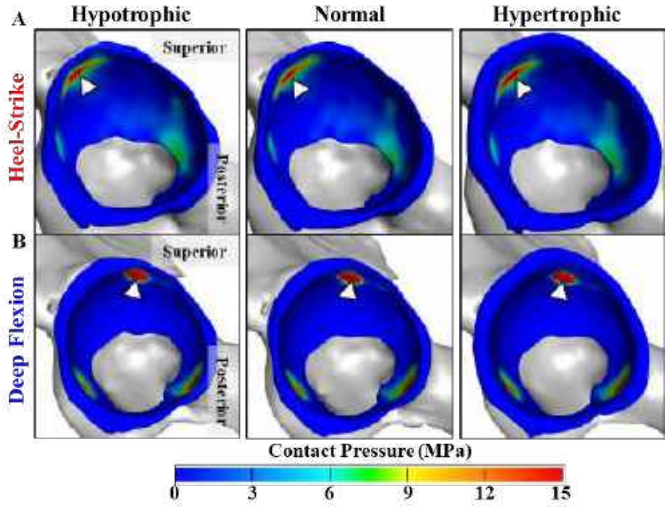

Fig. 2: There was no effect of labrum morphology on contact pressure across the three labrum morphologies during (A) heel-strike for gait or (B) deep flexion for the squat.

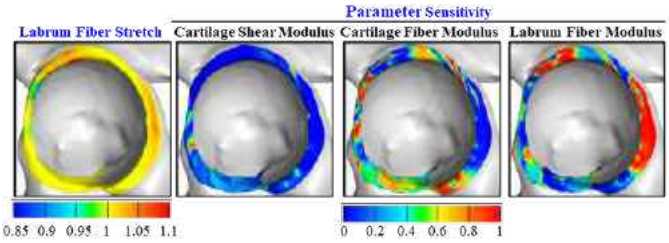

Fig. 3: Variations in the predicted labrum fiber stretch were both primarily sensitive to the cartilage fiber modulus (sensitivity = 0.48) and the labrum fiber modulus (sensitivity = 0.52).

DISCUSSION

The variability in labral load support observed between hypertrophic, normal, and hypotrophic morphologies implies that labral size exerts a discernible influence on load distribution across the joint during walking and squatting. This aligns with existing literature for dysplastic hips, where larger labral dimensions were associated with increased labral load support[9]. Sensitivity analysis revealed that uncertainty in the cartilage fiber modulus parameter directly influences the FE-predicted labral fiber stretch during heel-strike. This observation underscores an important mechanical interplay between the cartilage material properties and labrum deformation.

Despite the differences in labral mechanics among the three labral morphologies, differences in predicted cartilage contact pressure, tensile strain, and maximum shear stress were minimal. These measures fell within previously reported ranges for cam-type hips during both activities[5,10]. These FE results indicate that labrum size does not alter the cartilage stresses and strains in cam-type hips, leaving the cartilage susceptibility to similar levels of damage.

The results of this study likely have implications for surgical management of the labrum during arthroscopic surgery for cam-type FAIS. In particular, if the goal of labrum reconstruction is to reduce cartilage stress and deformation, it may be unnecessary since cartilage stresses and strains did not vary with changes in labrum size. Further, repair of the labrum with native labrum fibers may suffice in restoring hip functionality post-operatively, regardless of patient morphology. Future studies could evaluate the effect of labrum size using more advanced approaches to scale the dimensions of the tissue and incorporate statistical shape modeling to represent anatomical variation in size and shape that occurs across this population.

INTRODUCTION

Over 250,000 rotator cuff (RC) repair surgeries occur annually in the United States. These surgeries are failing at rates ranging from 20-94% [1,2] depending on the age, weight, and other comorbidities of the patient [1,2]. Current estimates suggest that the number of surgeries will only increase subsequently, followed by a larger financial burden and pain on patients. Analysis of tissues after surgery suggests that the healthy transition region from calcified bone to non-calcified tendon vanishes, and the junction becomes scar tissue [4]. Scarring itself in the tendon is a very complex process, but it is known that the immune cell milieu's response to the wound is the primary driver of whether a tissue repairs or scars.

Modulating the immune response to repair tissues has been of significant interest recently. Pattern Recognition Receptor Agonists (PRRAs) are a class of molecules that have been used as vaccine adjuvants and anti-tumor treatment [4,5]. These agonists activate the innate immune response through receptor classes such as nod-like and toll-like receptors (NLRs & TLRs), respectively. **We aim to investigate the effects of NLR-3 and TLR-3 agonist-loaded hydrogels and determine if there are differential effects on an injured tendon healing in a rat model through histopathological means and functional outcomes.**

METHODS

Sprague Dawley Rats (N=32) were injured bilaterally through a partial RC release model and immediately received perilesional injections of a methylcellulose/hyaluronic acid (1.5wt%/0.5wt%) blend hydrogel with NLR3 agonist Aluminum Hydroxide (Invivogen) (ALOH) or TLR3 agonist Poly (I:C) (Invivogen) at concentrations of 50 ng/mL. In addition, select rats also received a melt electrowritten polycaprolactone (PCL) mesh. After surgery, rats voluntarily walked on a Tekscan Rodent Walkway System to analyze gait and weight bearing parameters. Rats were acclimated the week to surgery and were walked 1,2,3,4,6,8,10, and 12 weeks post-surgery.

Rats were euthanized at 1-, 4-, and 12-weeks post-surgery. Shoulders were embedded in paraffin, and 5 µm sections were cut and stained with Hematoxylin and Eosin (H&E). Slides were blindly scored on a 5pt 0-4 scale according to ISO 10993-06, as well as signs for tendon-specific markers such as tenocyte activity, tendon vascularity, and collagen disorganization.

RESULTS

Histology showed that after 4 weeks, the ALOH, ALOH+Mesh, and Poly(I:C) groups had lower levels of collagen disorganization compared to the Injured Control (Figure 1).

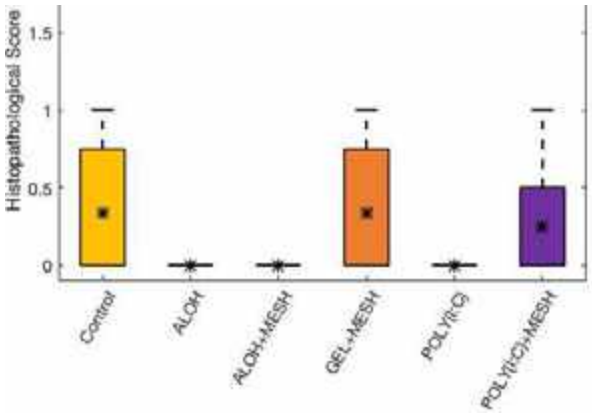

Figure 1: Collagen disorganization levels of each group after 4 weeks. A score of Zero is indicates a more organized, healthier collagen bundle, while a score of 1.5 can be considered to indicate increased disorganization or weaker tendon.

After 4 weeks post-surgery, Poly(I:C) treated rats had significantly higher stride length than ALOH treated rats (Figure 2; p = 0.0021). At 6 weeks, the Poly(I:C) treatment was significantly higher than ALOH+Mesh and ALOH groups (p = 0.0195 and 0.0090, respectively). Poly(I:C) also had markedly higher stride lengths than the injured control at weeks 4 and 6 as well. Finally, at 8 weeks, ALOH was significantly lower than the Injured Control, Poly(I:C), and Poly(I:C)+Mesh groups (p = 0.0460 Injured Control; 0.043 Poly(I:C); and 0.0031 Poly(I:C)+Mesh).

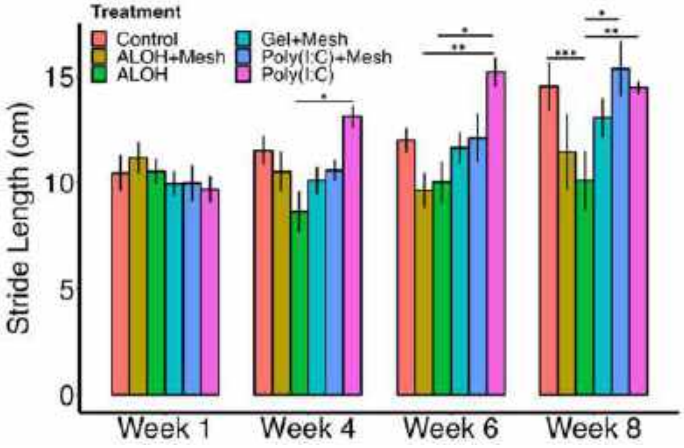

Figure 2: Bar chart of stride length of each rat group in weeks 1, 4, 6, and 8 with significance bars. Significance threshold was set to ($p<0.05$)

DISCUSSION

The Poly(I:C) and ALOH groups had different responses compared to the Control and the Gel+Mesh groups histologically, illustrating that stimulating the immune system through TLR and NLR activation have differential effects on tendon healing, possibly leading the way for a different tendon therapy.

The ALOH group had signs of increased tendon healing histologically, but these signs were not seen in the functional outcome of stride length. ALOH groups did not increase stride length temporally and even fell behind its starting after week 4, indicating less joint function than injured control groups. Poly(I:C) however, had marked increases compared to the injured controls at week 4 and 6, possibly leading to a faster healing response compared to the rat's native healing response. Poly(I:C) also had larger stride lengths compared to the ALOH groups starting at week 4, conveying that Poly(I:C) induced stimulation could be healing the shoulder better than the ALOH stimulated shoulders.

These data serve as an initial investigation of NLR and TLR stimulation in wound healing showing that there are functional level differences in gait after injections of NLR3 and TLR3 agonists ALOH and Poly(I:C) respectively.

INTRODUCTION

The specific signaling events by which tendon cells respond to mechanical cues are largely unknown [1]. Therefore, designing rehabilitation strategies to treat tendon pathologies that produce consistent outcomes is an unmet clinical need. To better understand the cell-intrinsic mechanisms that regulate tendon adaptation to applied loads, we investigated actomyosin contractility, the major force-generating machinery of mesenchymal cells. Actomyosin contractility relies on the fundamental motor protein, non-muscle myosin (NM-II), which binds actin filaments to generate contractile force and transduce signals from applied loads to the nucleus [2]. Prior *ex vivo* studies demonstrated that NM-II mediated contractility can regulate matrix remodeling [3-4] via YAP/TAZ signaling [5]. Yet, the importance of actomyosin contractility in tendon formation and maintenance *in vivo* is unknown. Therefore, we deleted NM-II proteins in tendons throughout growth and development. We hypothesized that NM-II is required to maintain tissue homeostasis.

METHODS

All animal work was IACUC approved. Mouse Model: To preferentially delete NM-II in tendons, we targeted the predominant NM-II isoforms, NM-IIA (*Myh9* gene) and NM-IIB (*Myh10* gene) using the Scleraxis (Scx) Cre driver to generate ScxCre;Myh9$^{f/f}$;Myh10$^{f/f}$ mice (myosin dKO) and Cre-negative littermate controls (WT). Cryohistology: Knees and ankles from P2, P28, and P112 myosin dKO and WT mice were fixed and sectioned in the sagittal plane. *In Situ* Hybridization (ISH): P2 patellar and Achilles tendon sections (n=4/group) were stained for *Myh9* (C1) and *Myh10* (C2) RNA using the BaseScope Duplex Assay. Tendon Morphology: P28 and P112 sections (n=4-7/group) were stained and imaged in two rounds: (1) calcein blue (CB), alkaline phosphatase (ALP), and TO-PRO-3 (nuclei), (2) Toluidine Blue, and were used to determine patellar tendon length and nuclear aspect ratio. Tendon Mechanics: P112 Patellar and Achilles tendon cross-sectional area (CSA) was measured before tendons were subjected to a testing protocol consisting of preconditioning and ramp to failure (0.1%/sec). Cytoskeletal Organization: F-actin (phalloidin staining) and cell nuclei were visualized via confocal z-stacks in P28 patellar tendon sections (n=4/group). Gene Expression: Patellar and Achilles tendon tissue sections (n=4-5/group) were collected for qPCR using a Standard BioTools Dynamic Array for 96 genes of interest. Statistics: Groups were compared via one-way ANOVA with Tukey post-hoc tests (α=0.05).

RESULTS

NM-II deletion in tendons. *Myh9* and *Myh10* expression was deleted from the vast majority of tendon cells. Interestingly, a subset of non-deleted cells in the dKO tendons exhibited elevated expression (**Fig. 1A-B**). Myosin dKO tendons progressively degenerate with age. NM-II deletion caused tendon degeneration by P112, characterized by tendon elongation (**Fig. 2C**), reduced nuclear aspect ratio (**Fig. 2D**), and disorganized matrix with increased proteoglycan staining (**Fig. 2A-B**). In fact, ectopic mineralization was evident in 4/6 patellar and 5/5 Achilles tendons in myosin dKO mice, compared to 0% in WT tendons. When P112 tendons were dissected for mechanical testing, there was a striking visual difference in myosin dKO tendons compared to WT, with patellar tendons presenting with abundant adipose deposits and decreased birefringence, while Achilles tendons appeared significantly smaller (**Fig 3A**). CSA measurements confirmed a decrease in Achilles but not patellar tendon CSA (**Fig 3B**), and both tendons displayed a marked decrease in tissue stiffness (**Fig 3C**). Expression profile of myosin dKO tendons suggest increased tissue remodeling. Gene expression analyses and hierarchical clustering revealed a marked difference in gene expression between WT and myosin dKO mice at both P28 and P112, with increased expression of both anabolic (e.g., *Col1a1*, *Col3a1*, *Lox*) and catabolic markers (e.g., *Mmp13*, *Mmp14*, *Timp1*) in myosin dKO tendons, with these changes being more

pronounced in the patellar tendon than the Achilles (**Fig. 4**). Aberrant cytoskeletal architecture and increased cellularity. Finally, to further probe the events that led to tendon degeneration in the absence of NM-II, we imaged the actin cytoskeletal network in P28 patellar tendons and found regions of disorganized actin cytoarchitecture and increased cellularity in the tendon midsubstance (**Fig. 5**).

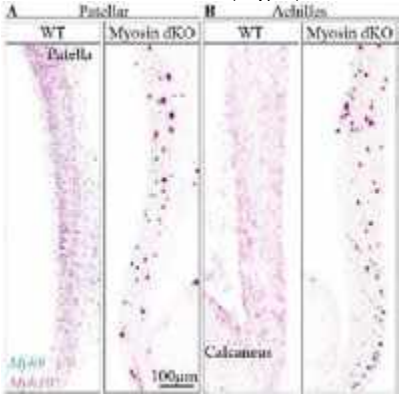

Figure 1: *Myh9* (green) and *Myh10* (red) deletion in (A) Patellar and (B) Achilles tendons of Myosin dKO mice. ISH shows deletion and surprisingly the presence of high-expressing cells in dKO tendons.

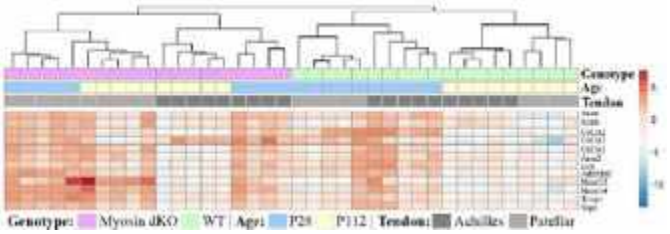

Figure 4: Increased anabolic/catabolic expression in dKO tendons. Heatmap and hierarchical clustering for subset of genes (12 from 91 total) from qPCR array.

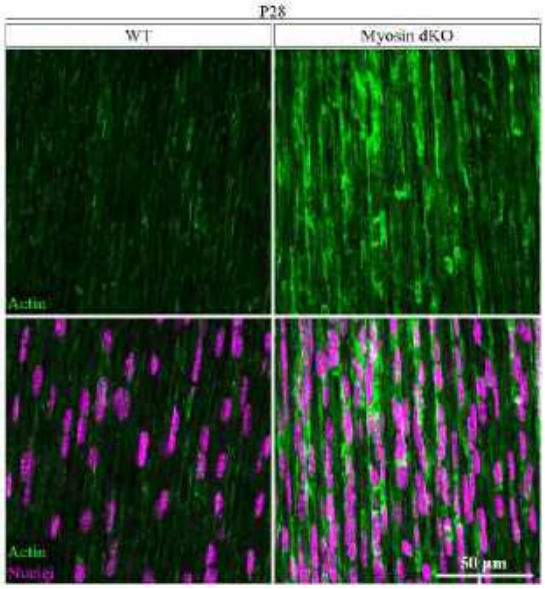

Figure 5: Aberrant actin cyto-architecture and increased cellularity at P28.

DISCUSSION

This study highlights the progressive onset of tendon degeneration following sustained deletion of *Myh9* and *Myh10* throughout tendon growth and development. Although P28 myosin dKO tendons display differences in actin organization and gene expression, they do not yet display the patellar tendon elongation and decreased nuclear aspect ratio present at P112. This progressive onset of tendon degeneration may parallel what has been shown *ex vivo*, where a disruption in tensional homeostasis can trigger a catabolic response and aberrant matrix remodeling [3-5]. Additionally, it is possible that disrupted actomyosin contractility impairs the ability of tenocytes to sustain the increased loading demands leading into adulthood. Alternatively, it may be that, once tendon cells mature and establish a tensional homeostatic set point required for proper tissue maintenance, the cells are less capable of responding appropriately to altered loading. Interestingly, a subset of non-deleted cells in myosin dKO tendons exhibited elevated expression, suggesting compensation. These data highlight the critical importance of NMII-mediated actomyosin contractility in maintaining tendon growth and homeostasis.

A MULTISCALE AND MULTIMODAL COMPUTATIONAL FRAMEWORK TOWARDS UNDERSTANDING MECHANOTRANSDUCTION IN THE DISTAL COLON AND RECTUM

Amirhossein Shokrani (1), Bin Feng (2), David M. Pierce (1,2)

(1) School of Mechanical, Aerospace, and Manufacturing Engineering, University of Connecticut, Storrs, CT, USA

INTRODUCTION

Individuals suffering from irritable bowel syndrome (IBS) report severe chronic discomfort arising from visceral pain, a symptom that impacts their quality of life [1]. Mechanotransduction transforms mechanical stimulation of the colon and rectum (colorectum) into neural action potentials (APs) by sensory afferents and plays a crucial role in bowel pain associated with IBS [2]. Mechanical distension of the colorectum initiates visceral pain in IBS patients. Thus, a broader understanding of colorectal mechanotransduction will likely contribute significantly to the introduction of more effective therapeutic approaches for controlling visceral pain associated with IBS.

Recent experiments on the mouse colorectum have uncovered considerable mechanical heterogeneity across the longitudinal, circumferential, and radial directions [3,4]. Researchers have also captured the responses of sensory afferents to mechanical stimuli using single-fiber recordings to investigate colorectal afferent neural encoding [5]. Molecular-scale characterization also revealed the composition and function of ion channels in afferents of the colorectum, cf. Fig. 1 [6].

In this study, we established a multiscale computational framework to advance our understanding of colorectal mechanotransduction. We designed our multiscale framework to predict neural encoding by individual colorectal afferent endings in response to macroscopic mechanical stimuli applied to the colorectum. First, we model the macroscale biomechanics of the mouse colorectum using an experimentally validated finite element model to predict intra-tissue stresses. We then integrate a neural membrane model, informed by experimental data on the composition of ion channels, to simulate the generation of action potentials in response to local mechanical stress and strain acting on the afferent endings. We aim to apply our computational framework to: (1) evaluate and contrast three hypotheses on mechanical gating of the generation of APs and (2) investigate the effect of orientations of afferent endings on the encoding function.

METHODS

Experimental evidence. We utilized previous evidence from our experiments on mouse colorectums including the biomechanics [3,7], the encoding function [5], and the intra-tissue morphology of colorectal afferents [4] to establish our multiscale computational framework.

Finite element model. We developed a macroscopic FE model that considers mechanical heterogeneity of colorectal tissues in the longitudinal, radial, and circumferential directions using FEBio [8].

Morphology of nerve fibers. We quantified the morphology of nerve fibers within submucosa using our second harmonic generation (SHG) images [9] and custom image processing tools. To study the sensitivity of the generated APs to the orientation of the nerve fibers within the submucosa layer, we employed seven analytical neural afferent endings, each embedded within the colorectum with distinct

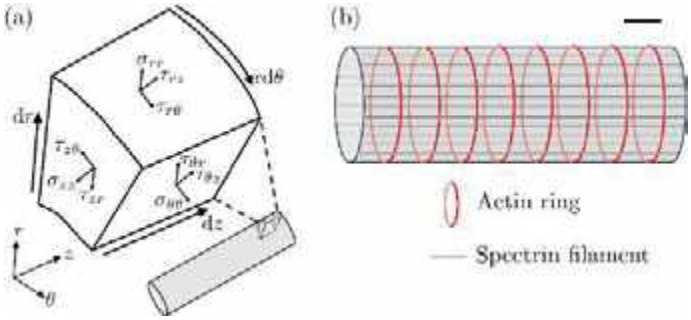

Figure 1: Analysis of afferent membrane tension as the gating parameter for the mechanosensititve (MS) channels. (a) Schematic of the stress components along with the axonal membrane skeleton. (b) Representation of the axon membrane skeleton demonstrating actin rings connected by spectrin filaments that provide structural sustainability of afferent axon. The scale bar is 115 nm.

orientations. For each analytical orientation we calculated the effective stress (in-plane stress) acting on the surface of the embedded fiber to compute the tension applied to the corresponding MS channels.

Micromechanics of nerve fibers. We calculated the local mechanical stress/strain profile along the length of each analytical fiber embedded in the colorectal wall using our custom program [8].

Generation of action potentials. We used our unique, mechanosensitive neural membrane simulation to replicate how local membrane tension along the afferent ending's surface encodes afferent stress/strain into APs. We calibrated our neural membrane simulations to generate results consistent with the experimental data from single fibers recordings considering the rule of NaV1.6 ion channels and mechanosensitive ion channels in spike initiation using NEURON [5,8].

Sensitivity of mechanotransduction using three hypotheses. Recent molecular-level studies have revealed that the cytoskeleton of nerve axons consist of ring-shaped actin filaments evenly spaced by 0.2-0.4 µm, see Fig. 1(b). Thus, we proposed three hypotheses to determine the in-plane stress acting on the membrane of the afferent ending to initiate and propagate the generation of APs: 1) axial stress dictates mechanical gating of mechanosensitive channels, 2) both axial and circumferential stresses contribute, and 3) membrane shear stress dictates, see Fig. 1(a).

RESULTS

In Fig. 2(a) we show the Cauchy stresses at regions surrounding the afferent endings derived from FE analyses. We then derived the stresses along the afferent endings using one of three hypotheses, shown in Figs. 2(b), (c), and (d), respectively.

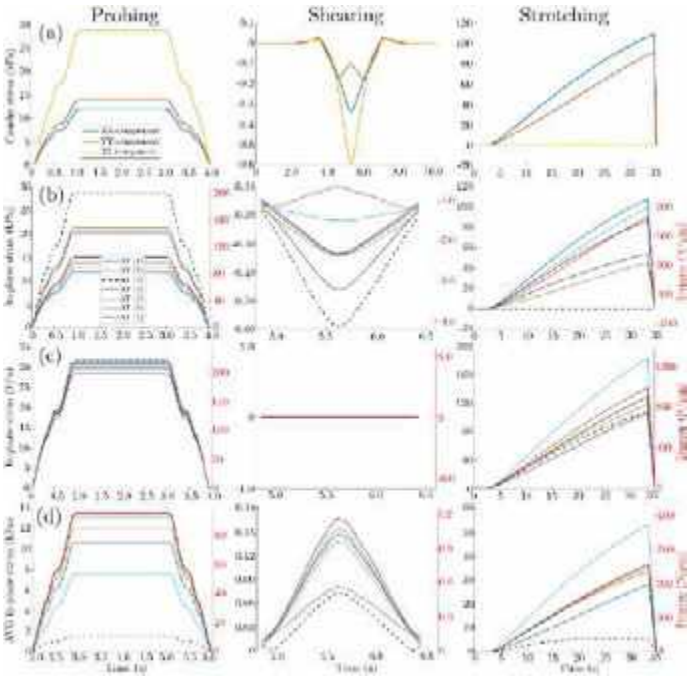

Figure 2: Microscopic stress profiles as a function of time acting on the afferent nerve fibers in response to three different mechanical stimuli to the colorectum: (a) Cauchy stresses at the region of the afferent ending within the colorectum, and membrane stresses and tensions acting on the afferent endings based on the (b) first, (c) second, and (d) third hypotheses.

In Fig. 3 we show APs generated and propagated from analytical fiber 7 (AF(7)) under three hypothesis for the relevant in-plane stresses and due to the three mechanical stimuli to the colorectum.

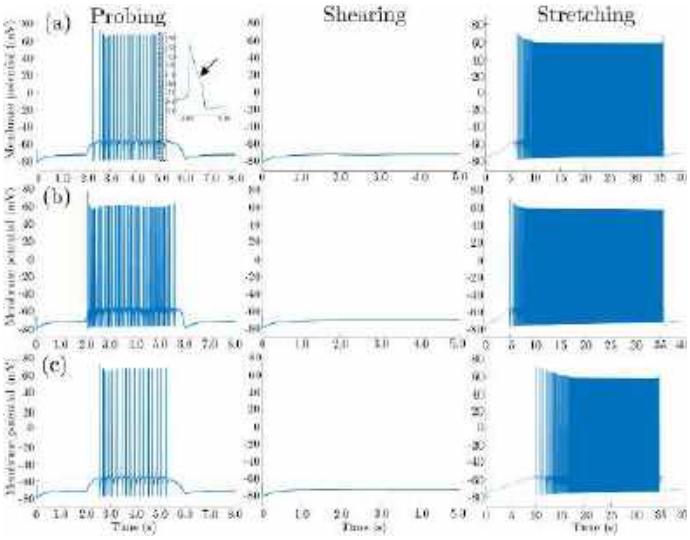

Figure 3: Representative action potentials generated from AF(7) using the membrane tensions calculated using (a) first, (b) second, and (c) third hypotheses for probing, shearing, and stretching.

In Table 1 we demonstrate the responses (or lack thereof) of each of the analytical fibers to each of the mechanical stimulations according to the three hypotheses used for deriving the membrane tension.

Table 1: Activation of action potentials from AF(1) through AF(7) under each stimuli for each of the three hypotheses (Active: A).

Hypothesis	Stimulation	AF(1)	AF(2)	AF(3)	AF(4)	AF(5)	AF(6)	AF(7)
1	Probing	A	A	A	A	A	A	A
	Shearing	-	-	-	-	-	-	-
	Stretching	A	A	-	A	A	A	A
2	Probing	A	A	A	A	A	A	A
	Shearing	-	-	-	-	-	-	-
	Stretching	A	A	A	A	A	A	A
3	Probing	A	A	-	A	A	-	A
	Shearing	-	-	-	-	-	-	-
	Stretching	A	A	-	A	A	A	A

DISCUSSION

We leveraged our experimental results to establish a novel multiscale computational framework enabling us to investigate mechanotransduction in the distal colon and rectum. Each component of our framework is driven by experimental data. Our multiscale modeling framework provides an innovative investigative tool bridging the gap between colorectal biomechanics and sensory afferent neural encoding. This research not only expands our understanding of colorectal mechanonociception but also sheds light on potential non-pharmacological interventions for colorectal diseases.

EX VIVO MINOXIDIL TREATMENT INCREASES ELASTIC FIBER DEPOSITION IN THE MURINE VAGINAL WALL

INTRODUCTION

Female reproductive tissues are a set of dynamic organs, including the uterus, cervix, and vagina. These organs play a crucial role in maintaining hormonal balance and supporting fetal growth. The uterus and vagina undergo significant shape and size changes due to natural processes such as pregnancy, postpartum involution, and aging.

A recent study on the structure of the murine female vaginal wall has indicated that the biochemical composition of the aging vaginal wall, and consequently its mechanical properties such as stiffness, undergo changes due to a decrease in smooth muscle cell contractility and the loss of elastic fibers [1]. The elastin network's role in supporting the proper structure and functionality of vaginal tissues is not only affected by aging but also by different diseases such as pelvic organ prolapse (POP), which is known to be associated with the disruption of the vaginal elastin network in humans [2].

POP is characterized by the gradual descent of the uterus, bladder, or cervix into or through the vaginal canal. Examination of human vaginal samples from patients at different POP severity levels has revealed an inverse relationship between the severity of POP and elastin protein levels [3]. Unfortunately, recent studies have indicated that more than 40 percent of women are diagnosed with some level of POP in their lifetime [4]. Consequently, we hypothesize that strategies for increasing elastin synthesis in vaginal tissue could counteract the disruption of the elastin network resulting from aging and other associated diseases.

Given the significant number of women impacted by POP and the lack of current pharmaceutical intervention, we aimed to use a targeted drug therapy approach. To this end, we investigated the ability of minoxidil sulfate to promote elastic fiber deposition in the vaginal wall. Minoxidil is a potassium channel opener initially developed as an anti-hypertensive drug that has been shown to promote elastic fiber deposition in the cardiovascular system [5,6]. However, the potential for minoxidil to stimulate elastin synthesis in tissues outside of the cardiovascular system has not been explored.

METHODS

Animals. Intact pelvic organs of 10-12 weeks old adult female mice were extracted following anesthetization using isoflurane. The isolated tissues were randomly assigned to untreated control or minoxidil-treated groups. The tissues then were placed in phenol red-free DMEM media containing 10% fetal bovine serum (FBS) and 1% antibiotic-antimycotic solution (100x). The treatment group also received 0.24 mM minoxidil sulfate in the cell culture media. Extracted tissues were incubated at 37°C and 5% CO_2 for 7 days with culture media being replenished every 24 hours.

***Elastin Protein Measurements*.** In order to evaluate the changes in elastic fibers in the vaginal due to ex vivo minoxidil treatment, the total amount of soluble and insoluble elastin protein was measured using a Fastin elastin assay (Biocolor). Measurements were made in both vaginal tissue explants and cell culture media. Changes in the vaginal elastin fiber network were also visualized by sectioning and immuno-fluorescence staining of the tissue. Using an antibody specific to elastin, the stained tissue was imaged and analyzed using ImageJ [7] and CT-Fire (MATLAB) [8] to determine the normalized elastin area in the vaginal wall as well as number, length, and width of elastic fibers.

***Biaxial Mechanical Testing*.** The biaxial mechanical properties of control and minoxidil-treated vaginal tissue were assessed using an established extension-inflation technique [1]. After 7 days of ex vivo treatment, vaginal tissues were cannulated onto 8G and 21G blunt needles, and the unloaded geometry (length and outer diameter) was estimated. Following estimation of an in vivo length based on the axial force-pressure relationship, vaginal tissues were then preconditioned to reduce hysteresis. After preconditioning, the tissues were subjected to 3 cycles of 5-80 mmHg pressurization at the physiological length and ±5% of physiological length. The outer diameter was tracked throughout testing using an in-line camera while axial stretch and force were directly recorded during testing. After testing, vaginal wall

thickness was measured from an Optical Coherence Tomography (OCT) scan of a vaginal ring. Quantification of the wall thickness and average wall stresses were calculated using MATLAB.

Statistical Analysis. Changes in vaginal elastin protein levels (Fastin elastin and immunofluorescence image quantification) were assessed using the nonparametric Mann-Whitney U test. Group comparisons with $p < 0.05$ were considered significantly different.

RESULTS

In order to visualize the elastic fiber network in control and minoxidil-treated vaginas, tissue explants were cryosectioned and stained using an elastin-specific antibody. Interestingly, the number of elastin fibers (**Fig. 1A, B**) and the normalized elastin area fraction (**Fig. 1C)** increased in the minoxidil treated tissues, relative to control. Measuring the amount of insoluble and soluble elastin using a Fastin elastin assay also showed an increase in the amount of elastin in the minoxidil-treated vaginal tissues in comparison to control (**Fig. 1D** and **E**, respectively). We also measured 3.8-fold higher levels of soluble elastin in the culture media of minoxidil-treated samples, suggesting the tissues are producing more elastic fibers following minoxidil treatment.

Biaxial analysis of the untreated and treated tissue indicated changes in tissue geometry and mechanical response. Although the control and minoxidil-treated tissues were subjected to the same range of pressures, the treated tissue exhibited roughly 25 percent greater outer diameter in response to pressurization (**Fig. 2A).** Interestingly**,** the axial stretch of treated tissue was also increased (**Fig. 2B**). Minoxidil treatment not only changed composition and geometry of the tissue, but it also showed marginal increases in the distensibility (circumferential stretch range; **Fig. 2C**) and extensibility (axial stretch range; **Fig. 2D**).

Calculating the tissue stiffness at low (5-20 mmHg) and high pressures (60-80 mmHg) indicated that minoxidil treatment increases vaginal stiffness in both the circumferential and axial directions. Interestingly, the increase in vaginal stiffness was greater in the circumferential direction at both low pressures (89.4% vs. 38.8%) and high pressures (37.6% vs. 9.86%) relative to the axial direction.

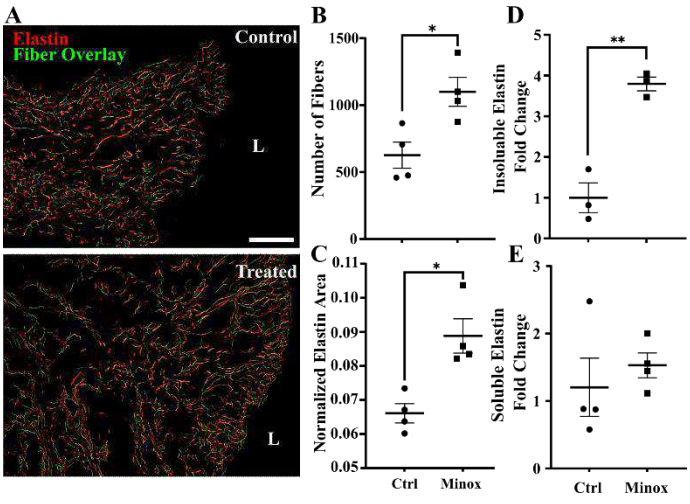

Figure 1: Comparison of elastin protein measurements in response to minoxidil treatment. Representative analysis showing overlaid elastic fibers in control (top) and minoxidil-treated (bottom) vaginal tissue (A). The vaginal lumen is indicated by L and the scale bar indicates 100 µm. Measurement of elastin protein was achieved by immunofluorescence staining (B and C) and a Fastin elastin biochemical assay (D and E). *, ** $p < 0.05, 0.01$; Mann-Whitney U test. n=3-4 biological replicates per group.

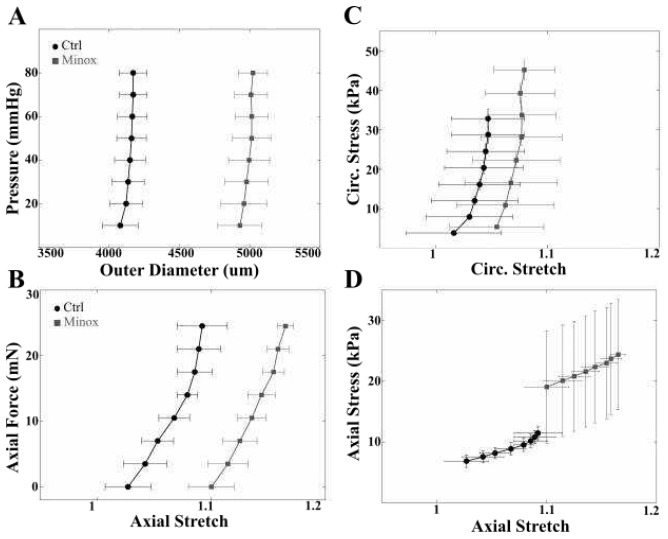

Figure 2: Comparison of tissue geometry and biaxial mechanical response of vaginal tissue following minoxidil treatment. Changes in outer diameter (A) and axial stretch (B) of control (black curves) and minoxidil-treated (gray curves) vaginal tissues exposed to the same range of pressure and force, respectively. Minoxidil treatment resulted in an increase in circumferential (C) and axial stress (D) and stretch. n=2-3 biological replicates per group.

DISCUSSION

In the current study, we have demonstrated for the first time that ex vivo treatment of vaginal tissue with minoxidil sulfate has the potential to alter the elastin network by increasing the number and area fraction of elastic fibers in the tissue. We found that in addition to increasing the amount of elastin in vaginal tissue, minoxidil treatment also led to measurable changes in the tissue geometry as shown by increases in the outer diameter and axial stretch. We also observed a right-ward shift of the biaxial stress-stretch response after minoxidil treatment, as well as increases in tissue stiffness both axially and circumferentially. The increase in elastin content of treated vaginal tissue is significant as it provides evidence for a first pharmaceutical treatment to potentially combat the loss of elastin fiber network associated with aging and other pelvic floor disorders such as POP. Here we have focused on changes in the elastic fiber network of the vaginal wall, however changes in other tissues of the pelvic floor, such as the uterus, cervix, and skeletal muscle, has not been investigated. During the next steps, we will focus on evaluating the potential for minoxidil treatment to effectively induce elastin synthesis in murine vaginal tissue when the drug is administered in an in vivo setting.

EVALUATION OF THE EFFECTS OF PFAS ON PANCREATIC CANCER USING A MICROFLUIDIC PANCREAS MODEL

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal cancer types with a dismal 5-year 12% survival rate [1]. Current therapeutic strategies to treat this ailment have shown minimal improvements in survival rates of patients over the past several years. Previously, most of the scientific research has been conducted around the genetic aspects of the disease and different approaches to target them. However, minimal attention has been given to the role that environmental toxicants might contribute to the promotion and progression of pancreatic cancer.

Per and polyfluoroalkyl substances (PFAS), also referred to as "Forever chemicals", are a hot research topic because of their non-reacting, non-degrading, and biologically interfering nature [2]. Their natural reservoirs include drinking water (several contamination sites have been identified in USA), and in general all surfaces where non-stick properties are necessary. In some human cohorts, the PFAS concentration in blood serum (95th percentile) reach as high as 23.87 ng/ml [3]. One of the family members of PFAS, perfluorooctanoic acid (PFOA, CAS 335-67-1), has previously been under class action lawsuits due to ground water contamination and has since been under investigation [4]. From previous studies conducted on animal models, PFOA has been reported to as a key factor in aggravating testicular, renal and breast cancers [5, 6]. Additionally, it is known to increase endoplasmic reticulum (ER) stress, which is often a characteristic of oncogenic cells [7]. Nevertheless, most research involving PFAS has been conducted on animal models and from human standpoint the data is often sparse.

In this research, we established a microfluidic model which recapitulates human pancreatic acini, and we tested the carcinogenic effects that PFOA has on acinar cells. Acinar cells form the backbone of secretory exocrine pancreas and is a common initiation site of PDAC [8]. Due to their high metabolic rates, acinar cells encounter PFOA dissolved in the serum more often. It is hypothesized that PFOA elevates the ER stress in the healthy acinar cells which in turn activates unfolded protein response (UPR). After persistent insult, cells accumulate oncogenic characteristics and initiate invasion into the surrounding tissue. In this regard, this study visualized the extracellular matrix (ECM) invading characteristics of the pancreas cells and later correlated the genetic changes induced by PFOA. The reported microfluidic model addresses the major knowledge gap of scarcity of human models by mimicking the human physiology and genetic profile, hence gathering the PFOA toxicological data in human subjects. The data presents a previously overlooked aspect of the carcinogenesis of the human pancreas i.e. the contribution of environmental toxicants.

METHODS

Microfluidic model fabrication

The Pancreatic acini-on-a-chip model used in the study was fabricated according to previously published research from our lab [9].

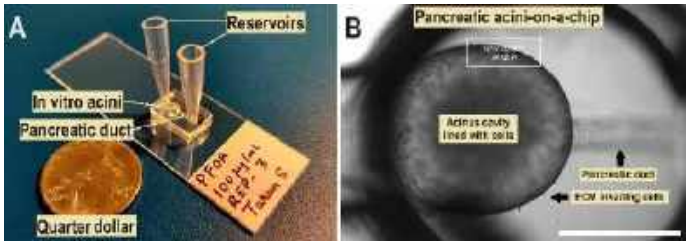

Figure 1: (A) The Pancreatic acini-on-a-chip microfluidic platform and its components (B) The *in vitro* acini with cellular invasion in the ECM. The dimension bar in the image is 500µm.

The theoretical background of the model is a fluid mechanical phenomenon known as viscous fingering, where a low viscosity fluid displaces a higher one to create hollow channel. The hollow channel is later lined with Panc1-Tet-PTF1a inducible cells to create a human acini

analog. Previously, it has been shown that Doxycycline hyclate (1µg/ml) induces PTF1a gene in the cells which creates a more normal like pancreatic cell line [10]. The PTF1a gene has been established as a master regulator of acinar gene program and pathways and keep the cells differentiated.

Toxicant delivery in 2D cultures and microfluidic device

PFOA was added to the cell culture media for the toxicant treatment. The cell culture media was comprised of DMEM supplemented with 10% Tet-free FBS, 1% P/S and 1% Glu. PFOA was tested at concentrations of 1, 10 and 100µg/ml. To reconstitute *in vivo* effects within a short span of days we utilized elevated concentrations. The media was also supplemented with 1µg/ml Dox to induce PTF1a gene expression. The experiment was run for 20 days with culture media changed at 24 hr intervals.

Data acquisition and processing

Images were obtained every 24 hrs using Olympus IX71 under brightfield settings with appropriate exposure times. The data was processed using WEKA segmentation module in ImageJ (NIH). The WEKA was trained over a sample image to identify the translucent cells invading the ECM and the program converted the brightfield image into a binary classified images using thresholding procedure. Once trained machine learning was used to process all the images in the data set. The average invasion was measured by finding the total area WEKA generated and later diving it by the base width. This method gave us an average invasion length. In Figure 1B, the interrogation window is represented by a small white box in which the above data processing procedure was performed.

RESULTS

The hypothesis of the experiment was to test whether PFOA increases invasiveness of the cells and also to verify the findings with molecular tools like PCR. PFOA clearly increased the invasive tendency as depicted in the micrographs (Figure 2A) as shown with marked black arrows.

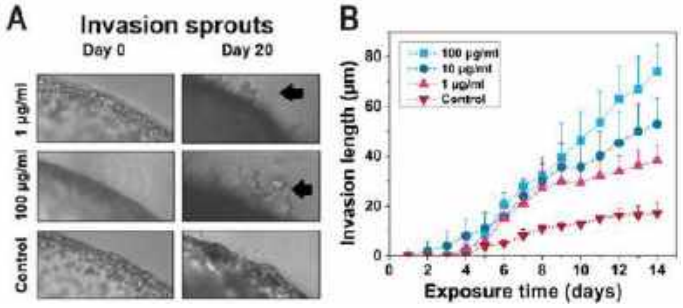

Figure 2: (A) The invasion sprouts seen for multiple PFOA concentrations (B) The average length of invasion for each PFOA treatment case

The protrusions are the group of cells invading the ECM. They were situated on the acini surface at the start and subsequently migrated to ECM compartment upon PFOA treatment. It is evident that upon treatment with PFOA, the average length of invasion increased in a dose dependent manner. The invasion in 1µg/ml was very similar to that of the control in which no PFOA was present. However, for the 100µg/ml PFOA, the invasions were much more prominent. They were both higher in number and thicker compared with those of the other concentrations. This is also reflected as the increase in length in the graph (Figure 1B). This experiment clearly demonstrates the rise in invasive tendency of the cells upon PFOA treatment. It is likely that PFOA could be altering gene expressions associated with higher migratory properties. The data is reported for the first 14 days of the experiment as no appreciable rise was observed in successive days.

To validate our earlier finding of increased invasive of the cells, we performed a set of PCR experiments with gene markers commonly associated cell migration (Epithelial to Mesenchymal Transition- EMT) markers, E-cadherin and vimentin. From Figure 3A , it is evident that E-cadherin expression decreases and vimentin expression increases. E-cadherin is a marker of cells with epithelial lineage and vimentin a marker of mesenchymal lineage.

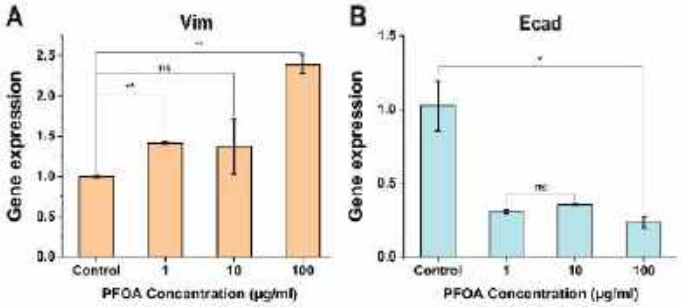

Figure 3: (A) PCR gene expression data for Vimentin (B) Gene expression data for E-cadherin

Taken together, data presented suggest that cell migration characteristics are elevated when exposed to PFOA in a dose dependent manner.

DISCUSSION

Our study establishes a link between pancreatic cancer and exposure to the environmental toxicant, PFOA. Researchers have often overlooked environmental toxicants like PFAS as molecules of concern. Animal studies in this area often use rats and mice which are physiologically and genetically different from humans and hence the translation of PFAS studies into humans are often difficult. Our study provides strong evidence that PFOA is a significant contributor to the progression of pancreatic cancer.

MICROSTRUCTURAL DAMAGE PROGRESSION IN THE PIA-ARACHNOID COMPLEX

L. Marin (1), T. Dixon (1), B. Coats (1)

(1) Mechanical Engineering, University of Utah, Salt Lake City, Utah,

INTRODUCTION

Traumatic brain injury (TBI) affects approximately 1.5 million individuals in the U.S. annually [1]. The majority of TBI research is focused on single-event impacts, neglecting the cumulative biomechanical effects of repeated trauma seen in military, sports, and abusive etiologies. This oversight impedes the development of accurate, comprehensive computational models and analysis, particularly in assessing cumulative strain damage.

When repeated loading has been considered, progressive damage and injury to the brain have been assessed. However, the connections between the brain and skull dictate how force is distributed to the brain. Damage from repeated loading to these connecting structures will alter what the brain experiences and will be critical to characterize before repeated loading to the brain in experimental settings can be defined. This study aims to start filling this knowledge gap by examining the progressive mechanical damage in the pia-arachnoid complex (PAC), a central mechanical interface between the brain and skull.

METHODS

All work in this study was approved by the University of Utah Institutional Animal Care and Use Committee. Sheep brains were extracted from calvaria within 24 hours post-mortem with all dural tissues intact. Following extraction, the dura was gently reflected to expose the PAC. Each brain was positioned in a stereotactic frame for optical coherence tomography (OCT) imaging, employing a Bioptigen R2200 spectral scanner (Leica, USA) with a 12 mm telecentric lens. This system provided a depth resolution of 12.5 µm and a lateral resolution of 6.25 µm.

A 22-gauge needle was inserted through the arachnoid membrane to inflate the subarachnoid space, utilizing a NE-300 New Era syringe pump. A fiber optic micro-catheter pressure transducer (FISO-LS Series, 0.9 Fr tip diameter) was placed in the subarachnoid space in proximity to the imaging location. Inflations were pressure-controlled using an Arduino circuit board to 0.2-0.4 mmHg for low-pressure 'characterization' cycles and 0.8-1.2 mmHg for high-pressure 'injury' cycles. Characterization cycles had low flow rates (0.3 ml/min) to ensure no injury or damage was induced. Injury cycles had higher flow rates (1 ml/min) to create higher strain rates in the system. Maximum pressures were constant within the same test but different across locations. This was because spaces with a greater number of structural connections required more pressure to induce similar amounts of strain. Each location was exposed to 11 inflation cycles, including 3 preconditioning cycles and then 4 injury exposures, which consisted of an injury cycle followed by a characterization cycle (**Fig. 1A**). The last preconditioning cycle was used as the baseline characterization cycle.

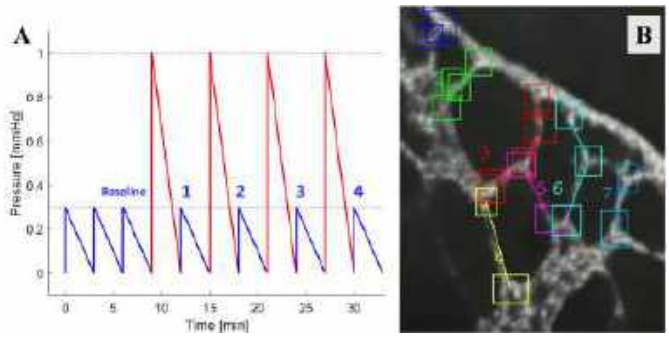

Fig. 1. (A) Ideal test protocol, with low-pressure 'characterization' cycles (blue) and high-pressure 'injury' cycles (red). The third preconditioning cycle (baseline) was used as a reference for damage characterization. (B) Detailed view of the pia-arachnoid space, featuring overlaid polylines for tracking trabeculae length changes during inflation cycles.

Damage to the PAC microstructures was defined by increases in arachnoid membrane displacement and in trabeculae strain. Arachnoid membrane displacement was tracked with a custom Python script and synchronized to pressure data to calculate an equivalent stiffness (peak pressure divided by peak membrane displacement). The lengths of single trabeculae fibers were tracked and quantified throughout all inflation cycles (**Fig. 1B**). Strain for each cycle was calculated as the change in length divided by the fiber length at the beginning of the baseline characterization cycle. Trabeculae that underwent significant shape changes, were excessively short, or moved outside the imaging plane were excluded from the analysis. A linear regression was used to assess progressive damage with each cycle. A Pearson's correlation was used to statistically evaluate the relationship between the magnitude of the injury cycles to the change from baseline in the characterization cycles.

RESULTS

Eight locations in two brains were evaluated. Both membrane equivalent stiffness and trabecular strain experienced progressive softening with each injury cycle, suggesting progressive damage to the microstructures of the PAC (**Fig. 2**). This softening was consistent across all measurements except for one measurement of membrane stiffness in one location which was unchanged (dark red line in **Fig. 2A**), The average decrease in stiffness for the remaining locations was 27.8 ± 19.9% (4.6%-66.6%). There was no significant relationship between the change in membrane stiffness and the magnitude of the injury applied.

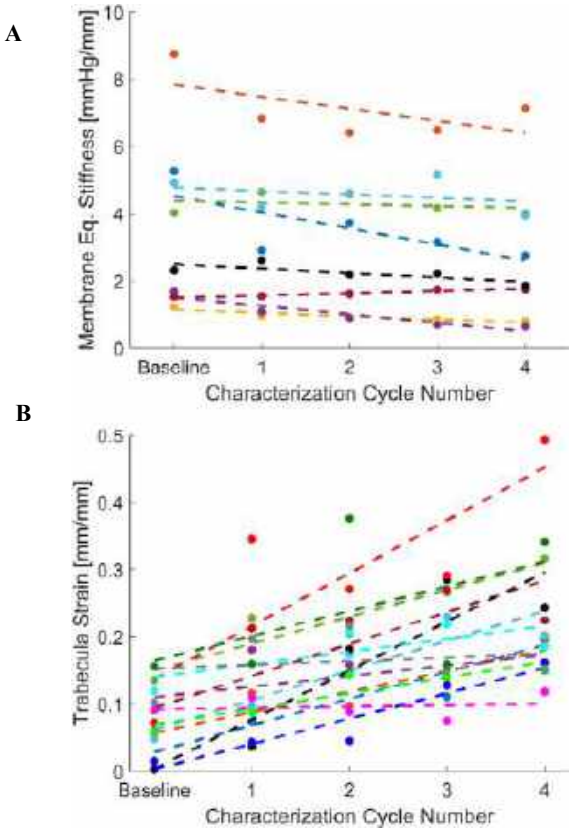

Fig 2. (A) Equivalent stiffness of the arachnoid membrane displays a softening (negative slope) across characterization cycles in 7 out of 8 locations. (B) Trabeculae strain also showed a consistent softening with each cycle (positive slope).

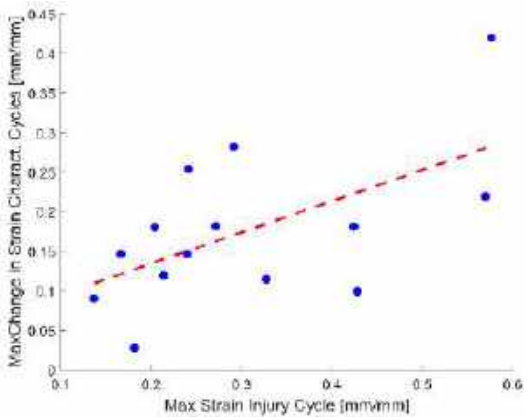

Fig. 3. Maximum change in strain from the baseline cycle to a subsequent characterization cycle was greater for trabeculae experiencing greater strain during the injury cycle.

The same trend was observed when analyzing individual trabeculae (14 trabeculae across the 8 locations, **Fig. 2B**). All trabeculae displayed an increase in strain between the baseline cycle and subsequent characterization cycles. The average increase in strain was 0.17 ± 0.09 (0.03-0.42). A significant correlation (p=0.02) was found between the level of injury and the increase in trabeculae strain (**Fig. 3**). As expected, a higher strain value during injury cycles led to a greater increase in strain during characterization cycles.

DISCUSSION

For the first time, this study demonstrates damage within the subarachnoid space both globally (measurements at the level of the arachnoid membrane) and locally (analysis of individual trabeculae) in an *ex vivo* configuration. This dual-focused approach reveals that global analyses (membrane displacement) may be able to capture overall damage, but they are unable to provide mechanistic correlations to the applied loading. One reason for this may be that we performed a 2D analysis of a single slice of the subarachnoid space in a highly complex 3D structure. Such a simplification may not fully capture the intricacies of spatial relationships and dynamic interactions within the subarachnoid space. Local measurements of trabeculae, however, provided a more direct measurement of deformation and, therefore, better correlated with the applied load. While this analysis was still a 2D analysis, it represents a significant advancement over other approaches in the literature, which have predominantly analyzed the arachnoid space at a macroscopic level [2],[3].

Both metrics in the study identified softening of the PAC microstructures with repeated loading. As a key mechanical connection between the brain and the skull, a reduction in localized structural integrity of the PAC microstructures may alter how force is distributed to the brain. Therefore, characterizing this damage will be paramount to the accuracy of computational simulations investigating repeated loading, and to the prediction of brain injury from repetitive head trauma.

AI IN B3: ARTIFICIAL INTELLIGENCE IN BIOMECHANICS, BIOENGINEERING, AND BIOTRANSPORT

Chester Jar (1), Lindsey Westover (1,2), Gail M. Thornton (1)

(1) Department of Mechanical Engineering, University of Alberta, Edmonton, Alberta, Canada
(2) Department of Biomedical Engineering, University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

The term 'artificial intelligence' (AI) was first coined in 1955 [1], and the significant development of AI-based technology over the recent years has given rise to the consideration of its potential applications in research. As a continuously advancing interdisciplinary field, the growth of biomedical engineering may be further facilitated by implementing AI-based solutions to areas such as data analysis and interpretation, model generation, and imaging analysis [2]. Given that the theme of the 2024 SB³C conference is Innovation without Borders: Uniting Ideas, Technologies, and Communities, how has AI been used over time, which areas have received the most attention, and how widespread is its application in biomedical research? To answer this question, a text analysis of the literature was conducted to identify trends in research involving AI and the "three B's" of SB³C: biomechanics, bioengineering, and biotransport.

METHODS

A total of 97 biomedical engineering journals indexed in the Web of Science were found by filtering Journal Citation Reports from Clarivate for the year 2022 under the category "Engineering, Biomedical" [2]. Of these journals, 96 were listed in MEDLINE (1946-present via Ovid) and were searched for articles containing the specific term of interest "artificial intelligence" with one or more of the three B's of SB³C: "biomechanics OR bioengineering OR biotransport". The search employed multi-purpose (.mp) fields, including the title, abstract, or subject heading, for each search term. The full texts of relevant articles (excluding tables, figures, and their respective captions) were extracted and compiled into an XML file. The file was then imported into Voyant Tools [4], which is an open-source application for text analysis.

To determine how AI has been applied to biomedical engineering research, article texts were analyzed using the built-in functions of Voyant Tools. Text analysis was performed with respect to publication year, article type (original, editorial, review), and topic (biomechanics, bioengineering, biotransport). Common words (e.g. the, a) were omitted using the default stopwords list with additional terms such as "et" and "al". The Terms tool was used to determine keywords with the highest absolute frequencies. For each keyword, the Collocates tool was used to determine terms with the highest frequency in which they appeared within 5 leading or trailing words. The Trends tool was used to determine the overall frequency of each combination of keyword and term identified by the Collocates tool. The results of the Collocates tool are reported as (number of articles categorized as biomechanics/bioengineering/both in which the collocate appears; year(s) with highest article count-number of articles). Correspondence Analysis was also performed using the ScatterPlot tool, using the top 50 terms with the highest relative frequencies.

RESULTS

Current to January 2, 2024, our search retrieved 28 articles from 2004 to 2023 in 16 different journals across 14 countries (of the first corresponding author's or interviewee's institution) (Table 1). This consisted of 17 original articles, 4 editorials, and 7 reviews, where two letters to the editor and one interview were classified as editorials. Over half of the 28 articles were published in the past three years, with 10 being published in 2023 (Figure 1). With respect to topic, 19 articles were related to biomechanics, 8 were related to bioengineering, and one discussed both. However, the search returned no articles containing the term "biotransport" in conjunction with "artificial intelligence".

Across all articles, "model" was the most frequent term (581) when considered together with "models" (388), followed by "data" (821), "gait" (499), and "analysis" (426). The Collocates and Trends tools found that "model*" was commonly associated with terms such as "training" (7/0/0; 2023-3), "emg" (4/0/0; 2004/2017/2020/2021-1), and "biomechanics" (3/1/0; 2011/2017/2020/2021-1). "Data" was associated with "medical" (5/2/1; 2023-3), "learning" (8/1/0,

2021/2023-3), and "classification" (6/0/0; 2023-2). "Gait" was associated with "patterns" (8/1/0; 2023-3), "classification" (6/1/0; 2023-2), and "kinematic(s)" (10/1/0; 2023-4). "Analysis" was associated with terms such as "data" (5/3/1; 2021/2022-2) and "clinical" (10/1/0; 2023-6).

Results of the Correspondence Analysis are shown in Figure 2. "Classification", "knee", "gait", and "musculoskeletal" were common terms in articles applying AI in biomechanics, while bioengineering articles were more general and frequently used terms such as "systems", "human", "models", and "clinical". Articles classified under both categories commonly used terms such as "applications", "medical", "tissue", and "engineering".

Table 1: Article count and country by journal.

DISCUSSION

Despite being coined in 1955 [1], the first occurrence of artificial intelligence detected by our search was in 2004. A larger proportion of original articles being published within the past three years (Figure 1) implies that an increasing number of authors have incorporated AI-based technologies in their research. Additionally, the use of AI appears to be widespread, as the articles are diverse with regards to the country of the first corresponding author/interviewee (Table 1). As an emerging technology however, there are ongoing discussions associated with its implementation, as shown by the three editorial articles published in 2023.

The results of the Correspondence Analysis (Figure 2) and Collocates tool both suggest similar trends in research involving AI in biomechanics and bioengineering. Studies using AI in biomechanics research involved kinetic or kinematic analysis of motion and gait, while bioengineering research comprised a broader, general topic involving artificial models and systems. Although no biotransport articles were found, one article [5] discussed the implementation of AI in lung models for drug development; this was not classified as biotransport since that term was not mentioned anywhere in the text. Across all articles, the most common application of AI was towards gait analysis, such as improving the accuracy of markerless motion capture systems [6-8] and kinematic analysis or algorithms [7-12].

The relatively small number of identified articles was likely, in part, because equivalent search terms were not considered. However, we purposely limited our search terms to (1) look at how the use of the specific term "artificial intelligence" has progressed over time, and (2) adhere to the "three B's" of SB^{3}C (biomechanics, bioengineering, and biotransport). While the reason for the decrease in 2022 remains unclear, part of the increase in 2023 was due to two editorial articles on GPT [2][13]. Overall, the results support the conclusion regarding the growing popularity of AI-based technologies in biomedical research globally, with its current usage mainly revolving around gait analysis, modeling, and data processing/analysis. Further developments in AI should facilitate its application in other areas, in addition to increased discussions surrounding its implementation and use in biomedical research.

RHYTHMIC NEPHRON PROGENITOR RENEWAL AND DIFFERENTIATION INFORMS KIDNEY TISSUE ENGINEERING STRATEGIES

INTRODUCTION

Nephrons are the blood filtering unit of the kidney, removing waste to the ureteric bud (UB)-derived collecting ducts. The kidney has limited endogenous nephron regeneration, leaving millions of people each year prone to pathologies like chronic kidney disease (CKD)[1,2]. However, dialysis and organ transplantation treatments affect quality of life and are associated with adverse health outcomes[3]. Engineering autologous kidney replacement tissue is an emerging alternative strategy, which requires control over nephron induction, maturation, and connection to a urinary collecting duct network. Bioengineering efforts are beginning to meet these demands, but current protocols generate substantially fewer nephrons than are required for tissue replacement.

Nephron organoid protocols currently lack the repeated nephron induction that occurs during kidney organogenesis. *In vitro*, nephrogenesis occurs as a single event leaving remaining NPs with reduced competency for future induction[4]. *In vivo*, nephron progenitor (NP) pools sit in the cap mesenchyme (CM) adjacent to UB tips[5]. A portion of the CM undergoes nephrogenesis approximately every UB tip branching cycle while remaining NPs expand and divide among the daughter UB tips for future nephrogenesis[5]. Cycles of UB branching morphogenesis exponentially duplicate nephrogenic niches and the delicate balance between NP renewal and differentiation is a critical determinant of final nephron number. The mechanisms regulating the balance of NP renewal and differentiation as well as its apparent synchronization with UB branching remain unknown.

Here, we used spatial transcriptomics to evaluate the correlation between NP transcriptional state and UB branching lifecycle. Then, we used human induced pluripotent stem cell (iPSC)-derived nephron organoids to assess how perturbation with phase-specific pathways impacts the balance of nephron progenitor differentiation and renewal. Engineering control over this balance may enable rhythmic nephron production in kidney replacement tissues and devices, finally contributing a third arm to therapy beyond dialysis and transplantation.

METHODS

Spatial transcriptomics: We used the NanoString GeoMx Digital Spatial Profiler (DSP) to profile 47 disparate CM from a mouse embryonic day (E)17 kidney. CM connectedness and UB branch point were used to qualitatively pseudo-aged CM relative to UB lifecycle (pre-, mid-, and post-branching) for comparison. GeoMx data were analyzed in R using code modified from Bioconductor and NanoStringNCTools, GeomxTools, and GeoMxWorkflows libraries.

Organoid culture: Nephron progenitor cells were generated according to a published protocol[4]. Briefly, iPSCs were plated at 5,200 cells/cm^2 in mTeSR plus supplements, then media was switched to TeSR-E6 plus supplements (TeSR-E6+) with 7 uM CHIR99021 from D0 to D5, and finally media was switched to TeSR-E6+ with 1 ug/mL heparin and 200 ng/mL FGF9 from D5 to D10. On D10, NPs were lifted and spotted in 1 µl aliquots (~0.3x10^6 cells/µL) onto 6-well 0.4 µm polyester transwell membranes overlying TeSR-E6+ and 7µM CHIR99021 'pulse' media for 2 hr. This was exchanged for 'chase' media consisting of TeSR-E6+, 1 µg/ml heparin, and 200 ng/ml FGF9 for 2 hr. The pulse or chase media included 0.1 µM TTNPB, 4 µM TRULI, or equivolume DMSO. Following the chase, media was switched to TeSR-E6+ with 1 ug/mL heparin and 200 ng/mL FGF9. Media was switched to TeSRE6+ (basal media) from D12 to D25.

Immunofluorescence: Organoids were fixed with 4% paraformaldehyde, permeabilized with 0.5% Triton-X-100, and blocked with IF Wash (DPBS + 1g/l Bovine Serum Albumin + 0.2% Triton-X-100 + 0.04% Tween-20) + 10% donkey serum. Primary and secondary antibody solutions were incubated overnight at 4°C at appropriate dilution in blocking solution. Following antibody incubations, organoids were washed with IF wash. D12 organoids were counterstained with 1ug/mL DAPI.

Imaging and data analysis: Z-stacks were acquired at 4x,10x, and 20x magnifications on a spinning-disk confocal microscope. Analyses were performed on a single, central z-plane for each organoid. Percent area relative to DAPI area or organoid area (determined by manual annotation of background signal) was determined by thresholding in FIJI. Statistical significance was determined using R to perform one-way ANOVA and Tukey's post-hoc tests.

RESULTS

Using the Nanostring GeoMx DSP (GeoMx), we profiled 47 CM regions of interest (ROI) from an E17 mouse kidney (Fig 1A). Each ROI was pseudo-aged relative to the UB branching lifecycle (pre-, mid-, or post-branching) for differential gene expression analysis. Pre-/mid-branching CM showed GeoMx hits associated with WNT, retinoic acid (RA), JAK-STAT, and TGFβ signaling, while post-branching CM showed GeoMx hits associated with YAP, FGF, and NOTCH signaling. Whole mount immunofluorescence of E17 kidneys showed similar trends at the protein level. Transient elevation in WNT signaling is required for nephron induction, while FGF signaling contributes to NP renewal[6,7]. We turned to a published embryonic whole kidney single cell (sc)RNA-seq datasets to evaluate how the rhythmic NP phases associate with NP and early nephron cell type clusters[8]. Intriguingly, mean normalized expression of post-branching GeoMx hits largely associated with uncommitted and cell cycle associated NP clusters, while pre/mid-branching GeoMx hits associated with committing NP and early nephron clusters. Together, our *in vivo* and scRNA-seq analyses suggest that NPs rhythmically fluctuate between phases of renewal and differentiation synchronized with the UB branching lifecycle (Fig 1B).

We then turned to iPSC-derived NP organoids to determine changes to the nephron formation vs. cell renewal balance conferred by perturbation with phase specific pathways *in vitro*. We promoted nephron induction in NP organoids with transient WNT/β-catenin activation ('pulse') using a GSK3β inhibitor, CHIR99021 (CHIR). CHIR pulses were either overlapped with or followed by ('chased') transient activation of YAP signaling using a LATS kinase inhibitor, TRULI, or RA signaling using an all-trans RA analog, TTNPB (Fig 1C). To evaluate NP balance, we fixed organoids two days after pulse/chase stimulation and performed immunofluorescence for the NP marker SIX2 and early nephron marker JAG1 (Fig 1D). YAP activation overlapped with the CHIR pulse significantly increased the NP population, while overlapping or chasing with YAP activation reduced early nephron populations (Fig 1E). Consistent with reduced early nephron populations, both overlapping or chasing with YAP activation reduced mature nephron area in prolonged culture (Fig 1E). Conversely, both overlapped and chased RA activation significantly reduced NP area but had no change in early nephron area by two days post stimulation (Fig 1E). Similarly, chasing the CHIR pulse with RA activation showed no reduction in mature nephron area in prolonged cultures (Fig 1E). However, RA activation altered nephron morphology in the organoids. Both overlapped and chased conditions showed distinct nephrons with anatomically correct proximal to distal polarization, while control nephrons were largely clustered together with less clear segment connectivity (Fig 1D).

DISCUSSION

How the kidney balances NP renewal and differentiation is an open question in the field with important implications for tissue engineering. We performed spatial transcriptomics with the GeoMx DSP platform, which revealed offset, rhythmic NP phases in synchrony with UB branching. We previously reported that the rate of nephrogenesis in non-uniform during UB branching. Our previous work suggests that UB branching induced mechanical stress in the nephrogenic niche is highest prior to the completion of branching[9], and our current work points to active YAP signaling, a central mechanosensitive pathway, in the post-branching phase. YAP activation also influenced the response of iPSC-derived NPs to WNT signaling. Together, this suggests that cycles of UB branching derived mechanical stress may promote rhythmic YAP signaling in the CM that can reduce NP sensitivity to inductive cues.
Less is known about the role of RA signaling in NPs, but neighboring CM are separated by a stromal progenitor population that actively secrete RA[10]. Here, we found that RA activation increased iPSC-derived NP sensitivity to WNT signaling.

This work provides new insight into the regulation balancing NP renewal and differentiation *in vivo*. Our work points to the potential for rhythmic activation of ancillary pathways to promote iPSC-derived nephron cultures capable of repeated nephron induction and co-existence of nephrons at differing maturities. This would massively increase nephron-forming potential for kidney replacement tissue applications.

INTRODUCTION

To better understand the progression of OA pathology, and to establish a test bed for assessing interventions in the context of an OA phenotype, effective large animal, human scale models of joint injury are necessary. Our previous work developed a porcine destabilization of the medial meniscus (DMM) model, where transection of the anterior horn of the medial meniscus resulted in deleterious changes in the knee at an early time point. However, these changes resolved at later time points, as the anterior attachment scarred back into place and the knee resumed normal biomechanics. [1] In a second iteration of this model, a 6mm portion of the medial meniscus anterior horn was resected en bloc, resulting in more severe joint pathology at a six-week time point [2]. The aim of the current study was to assess the progression of this OA phenotype over a six-month period and to assess changes in gait.

METHODS

Sixteen skeletally mature (12-month-old) Yucatan minipigs underwent mini-arthrotomy of the right stifle, and a 6mm portion of the medial meniscus anterior horn was resected en bloc. Animals were sacrificed at either 6 weeks or 6 months post-operatively (N=8 for both), with contralateral limbs serving as intact controls. Four of the animals in the six-month group were used for gait analysis. Videos of walking pigs were captured at 30 fps both preoperatively and four months post-op. Using DeepLabCut markerless tracking software [3], the hip, knee, ankle, and hind hoof of each pig were tracked across the gait cycle (Fig 3A). Landmark positions were used to compute knee flexion angles. Further analysis was conducted using the GAITFour® walkway system, six months post-operatively. The pigs walked across a sensor-embedded mat, and the contact pressure of each hoof-strike was recorded. A model which normalized by velocity and trial number was used to measure differences between left (intact) and right (DMM) limbs. After sacrifice, stifle joints were dissected, and osteochondral segments of both the medial femoral condyle and medial tibial plateau were isolated. Indentation creep tests were performed, and the resulting deformation

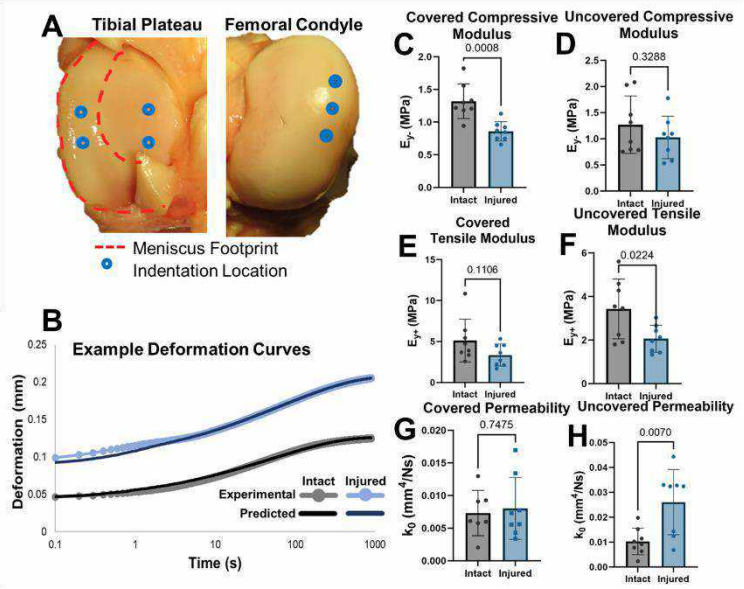

Figure 1: (A) Indentation testing locations on the medial tibial plateau and medial femoral condyle. For each subject, results were averaged for the uncovered and covered tibial plateau, and femoral condyle. (B) Example deformation curves. C-H are all at the 6-month endpoint.

curves fit to a model outputting compressive and tensile moduli and permeability (**Fig 1**). [4] Specimens were then scanned via microCT before and after contrast enhancement with Lugol's solution (I2 and KI

in water). Cylindrical regions of bone were defined superficial and deep to the cartilage interface, and bone volume fraction was calculated for each. For histologic analysis, osteochondral sections were stained with Safranin O/ Fast Green, and synovium sections were stained with Hematoxylin/Eosin. Statistics were performed in Graphpad.

RESULTS

Quantitative tissue analyses were performed at three regions per timepoint—on the medial tibial plateau in areas previously uncovered and covered by the meniscus, and on the medial femoral condyle (**Fig 2**). At 6 weeks, the cartilage was softer across regions of interest, with statistically significant differences in all regions, except for the uncovered tibial plateau. This mechanical weakening persisted at 6 months with statistical differences detected in the compressive modulus in the covered tibia and in the tensile modulus in the uncovered tibia region (**Fig 1)**. Bone volume fraction increased in the covered tibia and superficial femoral condyle regions in DMM knees, but these subchondral changes were attenuated by the 6 month time point. (**Fig 2**). Histologically, osteochondral sections of DMM knees showed some degree of surface fibrillation and roughening at 6 weeks, and mild loss of proteoglycan by 6 months. (**Fig 3A**) At 6 weeks, the synovium of DMM knees showed hyperplasia and signs of fibrosis, but little difference was detectable by 6 months. (**Fig 3B**). For gait analysis, graphical representations of post-op DMM knee flexion revealed a 'double-hump' signature during stance, which was not observed in the other groups (**Fig 4B**). Pigs exhibited greater maximal knee flexion in their post-op intact knee compared to pre-operative and post-op DMM knees (**Fig 4C**). Further, time spent in stance was shorter in both knees post-op compared to preoperatively (**Fig 4D**). When normalized for velocity and trial number, total pressure index percentage was significantly lower on the right hind limb when compared to the left hind limb (model adjusted effect: -0.5 , 95% CI: [-0.9, -0.1], p = 0.005; **Fig 4E**) Similarly, the total scale pressure (the sum of peak pressure values recorded from each activated sensor by a hoof during mat contact) showed significantly less pressure in the right hind limb compared with the left hind limb (model adjusted effect: -1.4, 95% CI: [-2.4, -0.5], p = 0.004; **Fig 4F**).

DISCUSSION

This study showed that a more aggressive medial meniscus destabilization involving a partial anterior horn resection (as opposed to a simple transection) results in a durable osteoarthritic phenotype in a porcine model. We showed persistent cartilage weakening as well as histologic evidence of degenerative changes six months after surgery. Most importantly, functional assays of animal gait showed detectable abnormalities at four and six months after surgery. Animals displayed decreased range of motion during stride in the affected limb, as well as a reduction in time spent in the stance phase, indicating that animals were favoring the unoperated limb. Further, the kinematic parameters assayed during the gait analysis showed a significant and consistent decrease in weight distribution on the affected limb post-surgery. Joint pain alters normal function, particularly locomotion, and is one of the clinical signs of osteoarthritis. The alterations in gait and loadbearing in pigs 6 months postoperatively may reflect painful ambulation secondary to OA changes as a result of DMM. This study developed a clinically relevant large animal model of OA leading to both structural and functional deficits of the knee and changes in pig gait patterns.

A CELL-BASED AND AI-ACCELERATED COMPUTATIONAL FRAMEWORK FOR THE PREDICTION OF MECHANOSENSITIVE TUMOUR GROWTH

INTRODUCTION

Tumour growth is a mechanosensitive process regulated in part by mechanical feedback between cell and the matrix. Sensitivity to mechanical cues can influence tumour progression and ultimately impact disease outcomes. As an example, stresses generated during the expansion of stiff extracellular matrix (ECM) leads to a suppression of proliferation markers [1] and a reduction in tumour spheroid size.

Critically, the underlying biomechanisms by which external loading impacts cellular growth and proliferation have not yet been uncovered. In this study, we propose a novel hydro-mechanical model for tumour cell growth and division, which we implement in a highly scalable agent-based (AB) framework and integrate with a custom neural network (NN) accelerated finite element (FE) solver to simulate stress-dependent growth.

MODEL DEVELOPMENT

Single-Cell Growth

Cell growth is regulated by competition between hydrostatic pressure ΔP arising from active cell stress and external loading, and osmotic pressure $\Delta\Pi$ arising from ion fluxes, such that:

$$dV/dt = -L_{p,m}(\Delta P - \Delta\Pi). \quad (1)$$

This competition is driven by several passive and active biomechanisms including mechanosensitive channels, active ion pumps, leak channels, and cytosolic proteins [2] (Fig. 1A). We consider that cell growth induced electro-osmotic fluxes $d(\phi)/dt$ can be driven by the synthesis of impermeable biomolecules dX/dt during the cell cycle. The osmotic pressure difference across the membrane can then be given by:

$$\Delta\Pi = RT\left(\Sigma\Delta c + \frac{X}{V}\right). \quad (2)$$

Multi-Cellular Simulation

We integrate our cell growth model with PhysiCell, a highly-scalable open-source AB modelling framework [3] which can describe forces associated with contact interactions (F_{ij}^{con}) and adhesion (F_{ij}^{adh}) between discrete cells. Migration is further driven by a motility force F_{ij}^{mot}. As the ECM cannot be explicitly represented within PhysiCell, we developed a custom linear FE solver to simulate continuum-level behavior of the ECM and cell-matrix interactions. Stresses generated from cell deformation are mapped to the matrix nodes through shape functions, and the matrix in turn imposes a point force F_{ij}^{mat} on individual cells. The total force acting on a given cell i is:

$$F_i = \sum_{j\in N(i)} F_{ij}^{adh} - F_{ij}^{con} - F_i^{mat} - F_i^{mot}. \quad (3)$$

We further consider that cell division is subject to a critical volume checkpoint V_{crit} [4]. As division is stochastic in nature, the probability of mitosis for a cell with volume V is then described by:

$$P_d(V) = 1/\left(1 + \exp\left(-k(V/V_{crit} - 1)\right)\right). \quad (4)$$

NN-FE Acceleration

Experimental observations demonstrate that the ECM exhibits nonlinear material behaviour [5]. To efficiently simulate such an anisotropic and hyperelastic matrix response, the deformation of the matrix is predicted using a neural network framework. Synthetic training data for a diverse range of load scenarios is generated using a novel data collection framework for FE software Abaqus. This data is subsequently provided to a fully connected deep neural network, comprised of four layers with 2,500 neurons per layer. This novel NN-FE framework is

extremely computationally efficient, arising from high-speed inference through TensorRT [6].

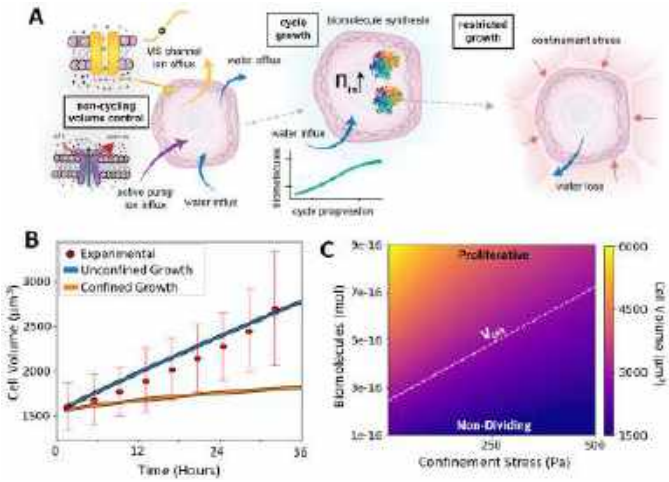

Figure 1: (A) Cell osmolarity and growth is regulated by a complex interplay between active and passive transport phenomena; (B) Cell growth arises from the synthesis of impermeable biomolecules, and mechanical confinement leads to a reduction in cell volume; (C) Phase diagram demonstrating how cell division is driven by high biomolecule concentration and low confinement stress.

RESULTS

At a cellular level, growth is driven by the synthesis of impermeable biomolecules and the associated increase in osmotic pressure. Cell confinement and associated loading can lead to an increase in hydrostatic pressure, which promotes fluid loss (via eqn 1) and ultimately reduces the rate of cell growth (Fig. 1B). This reduction in volume can prevent a cell from surpassing the critical volume checkpoint V_{crit} for division (Fig. 1C). Further, the model suggests that the associated stress to inhibit growth depends on biomolecule and ion concentrations.

Analysis of multicellular growth in a tumour spheroid with deformable matrix contact carries a significant computational cost (203 s per FE increment). Although the one-time up-front computational cost of synthetic training data generation and model training is relatively high, trained NN models can predict highly non-linear anisotropic material behaviour with a negligible computational cost (133 μs per FE increment, Fig. 2A) and near-perfect accuracy (Fig. 2B). Our fully coupled AB-NN-FE model allows for a deep insight into the mechanics of tumour growth at the cellular level (Fig. 2C).

4T1 tumour spheroid growth simulations using our fully coupled model suggests that cells at the tumour core experience greater stresses than cells at the periphery in agreement with data from excised tumours [7]. This promotes a reduction in cell volume at the spheroid core. These cells are also predicted to exhibit higher levels of biomolecule crowding, arising from the combined effects of the growth restriction and suppressed proliferation. Importantly, our simulations indicate that tumour spheroid size reduces with increasing matrix stiffness in a stress-dependent manner (Fig 2D), in agreement with our experimental data (Fig 2E) [8].

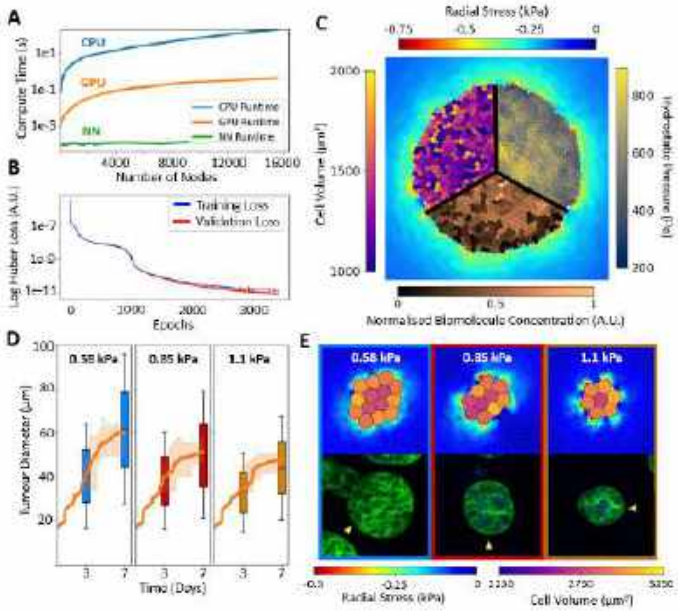

Figure 2: (A) The novel AI-FE framework is 1.5Mx faster than equivalent CPU-based computations, (B) while maintaining 99.95% prediction accuracy; (C) Coupled AB-BP-FE simulations allow for detailed analysis of tumour growth at the cellular level; (D, E) 4T1 spheroid size decreases due to mechanosensitive feedback between the cells and the matrix.

DISCUSSION

Our novel AB-BP-FE model provides a new and fundamental understanding of stress-dependent tissue and tumour growth, which is predicted to arise from a constraint on osmotically-driven growth at the cellular level. Biomolecule synthesis increases the cellular osmolarity, leading to an increase in cell volume and enabling cells to exceed a critical mitotic volume. Conversely, mechanical loading from cell-cell and cell-matrix interactions increases cellular hydrostatic pressure, giving rise to a water and ion efflux. This drives a reduction in cell volume and, subsequently, proliferation. Simulation of multicellular proliferation using NN-accelerated finite element and agent-based models provides critical insight into the evolution of tissue behavior and mechanosensitive growth, with broad applications to patient-specific cancer diagnosis.

ADIPOSE-DRIVEN HYPERTENSION IMPACTS 3RD ORDER MESENTERIC ARTERY CONTRACTILE BEHAVIOR IN A SEX-DEPENDENT MANNER

Dillon McClintock (1), Osvaldo J. Vega Rodríguez (2), Nathan R. Tykocki (2), Sara Roccabianca (1)

INTRODUCTION

Central and peripheral arteries share similar functions, that is to carry oxygenated blood from the heart and lungs to the rest of the body. Despite these common functions, they have many microstructural, biomechanical, and physiological differences. In addition, while aging and hypertension affect all arteries, elastic (central) and muscular (peripheral) arteries are affected in significantly different ways. Previous research has highlighted the importance of remodeling in muscular arteries, particularly mesenteric arteries, within an angiotensin II murine model of hypertension [1]. It is also recognized that mesenteric arteries play a crucial role in regulating peripheral resistance and, consequently, systemic blood pressure [2]. These findings suggest a need to better understand the biomechanical contribution of peripheral arteries to the progression of cardiovascular disease broadly and hypertension specifically. Nevertheless, there is a scarcity of research quantifying the mechanical, physiological, and microstructural changes in muscular arteries in response to hypertension, and especially in an adipose-driven model of hypertension. One single previous paper reported some limited effects of high-fat diet on sympathetic neurotransmission in mesenteric arteries [3]. Furthermore, sex-differences in the biomechanical behavior of muscular arteries remain virtually unexplored, both in health and disease.

In this study, we investigate the contrasting passive and active changes in peripheral arteries, specifically third-order mesenteric arteries, in male and female adult Dahl salt-sensitive rats fed a high fat diet.

METHODS

Experimental methods. The mechanical behavior of third-order mesenteric arteries in male and female Dahl Salt Sensitive (Dahl SS) rats fed a control diet (CD, F=5, M=5) or a high-fat diet (HFD, F=5, M=5) for 24 weeks, was assessed. The Dahl SS rat fed a high fat diet is an established model of adipose-driven hypertension [3]. The systolic arterial pressure of the animals was collected via tail-cuff before sacrifice. Following tissue isolation, the vessels were cannulated in a pressure arteriograph chamber and we estimated the *in-vivo* axial length as that required to prevent buckling at an inner pressure of 60 mmHg was determined (l_{iv}). Pictures were taken of the vessel before and after setting the axial length to measure *in-vivo* axial stretch as

$$\lambda_{iv} = \frac{l_{iv}}{l_o}, \tag{1}$$

where l_o is the axial length of the vessel after cannulation.

The arteries were then exposed to calcium-containing PSS buffer heated to ~37°C, and luminal pressures were incrementally increased from 20 to 120 mmHg in 20 mmHg steps. Luminal pressure was held at 20 mmHg for 20 minutes followed by a KCl contraction to allow for equilibration. At each subsequent step the luminal pressure was held until the vessel diameter plateaued. For each value of pressure, the vessels were subjected to a contraction with phenylephrine (PE). At the end of the experiment, passive diameter was measured at identical decreasing pressure increments from 120 to 20 mmHg in the absence of calcium and at room temperature. Throughout the pressurization protocol, the inner and outer diameter were tracked.

Mechanical metrics. Hoop stress in the arterial wall (σ_h) was calculated at mid-wall using the Laplace law for a thin-walled, cylindrical, pressurized vessel as

$$\sigma_h = \frac{Pd_m}{2h} \quad (2)$$

where d_m and h represent the mid-wall diameter and thickness at a pressure of P, respectively. Percent active diameter change was calculated as

$$\Delta\, diameter = \frac{d_{l,max} - d_l}{d_{l,max}} \times 100 \quad (3)$$

where $d_{l,max}$ is the passive luminal diameter at 120mmHg in and d_l is the active luminal diameter at each pressure P. Finally, wall distensibility at the mid-wall was defined as

$$D_i = \frac{d_{m,i+1} - d_{m,i}}{(P_{i+1} - P_i) d_{m,i}} \quad (4)$$

where i represents a set value of pressure and $i + 1$ the following value in the pressurization protocol (all active diameters). Parameters labelled as active refer to measurements from the portion of the test in calcium containing PSS at ~37°C without PE, while passive refer to absence of calcium.

RESULTS

Table 1. Body weight (mass), systolic blood pressure, in vivo axial stretch, and hoop stress for a pressure of 100 mmHg for all groups. † p<0.05 when comparing between diets. * p<0.05 when comparing between sexes.

	Control Diet	High Fat Diet
Body mass [g]		
Male	461.60±34.63	490.80±22.34
Female	276.60±11.06 *	292.40±19.03 *
Systolic blood pressure [mmHg]		
Male	162.22±10.74	182.98±10.28 †
Female	154.78±14.28	203.02±22.41 †
In vivo axial stretch		
Male	1.49±0.03	1.54±0.01
Female	1.54±0.05	1.61±0.05
Hoop stress [kPa] @100 mmHg		
Male	76.63±10.45	70.61±9.15
Female	74.80±11.25	80.26±9.72

Female animals weighted less when compared to males, independently of diet. Systolic blood pressure was higher in animals fed a high fat diet, independently of sex. We observed no difference in in vivo axial stretch and hoop stress (**Table 1**). Males presented a larger active diameter percent change than females for higher values of pressure on a high-fat diet, but not on a control diet (**Fig. 1**, p=0.0175 at 100 mmHg, and p=0.0113 at 120 mmHg). In addition, the mesenteric arteries of males on a high-fat diet were significantly less distensible than females on in the same pressure range (**Fig. 2**, p=0.0144 at 100-120mmHg).

DISCUSSION

Mean arterial pressure increased as a result of high fat diet in both male and female rats. Somewhat surprisingly, the mean arterial pressure in female animals was significantly higher compared to males fed a high fat diet but not control diet. While most mechanical metrics were unaffected by diet, mesenteric

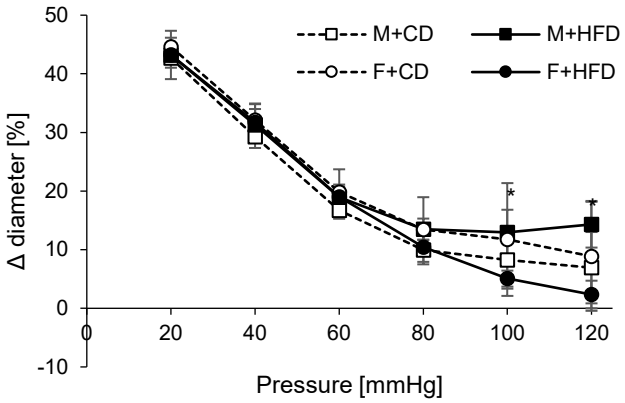

Figure 1: Active percent constriction (Δ *diameter*) of males (squares) vs females (circles) fed a control (open symbols) and high fat (closed symbols) diet. * p<0.05 between sexes in the high fat diet fed groups.

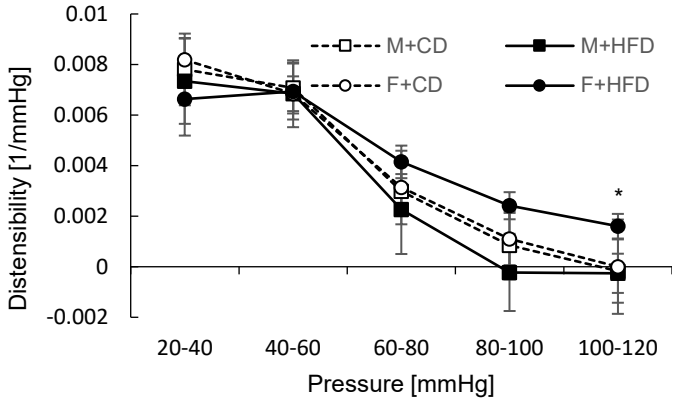

Figure 2: Active distensibility of males (squares) vs females (circles) fed a control (open symbols) and high fat (closed symbols) diet. * p<0.05 between sexes in the high fat diet fed groups.

arteries from high-fat male rats developed significantly more myogenic tone as compared to matched females as shown by the decreased active percent change in males. This resulted in a decreased distensibility in male animals compared to females. In comparison to Murtada [1], we did not see an increase in PE response in the mesenteric artery as a response to hypertension. Notably, the means of hypertension, order of mesenteric artery, and amount of PE used for contraction differed between our experiments. This study suggests, for the first time, that myogenic tone may play a different role in the development of adipose-driven hypertension in male and female animals.

INTRODUCTION

Cells communicate to coordinate cellular processes across tissues, and calcium (Ca^{2+}) ions are second messengers facilitating such multiscale coordination. Ca^{2+} selective cation channels mediate Ca^{2+} influx from the extracellular environment into the cytosol upon activation. However, current understanding of the biological mechanisms precludes direct control of Ca^{2+}-mediated processes. Here, optogenetic[1] and mechanosensitive channels, CsChrimson and Piezo[2], respectively, are utilized as tools to investigate how Ca^{2+} dynamics impact epithelial growth and morphogenesis. *Drosophila melanogaster* was used as an in vivo system whose wing is acutely sensitive to changes in developmental pathways. We outline the phenotypic results of controlled stimulation of CsChrimson and Piezo in *Drosophila*. Optogenetics has emerged as a rapidly expanding solution to better decipher biological processes as it leverages engineered light-sensitive protein constructs to control cells and their governing biomolecular processes and signaling pathways. Hence, an artificial plasma-membrane embedded channelrhodopsin, CsChrimson, was used in transgenic fruit flies. Next, we used an endogenous mechanosensitive channel, Piezo. It can be activated through genetic overexpression, controlled mechanical force, or its specific agonist, Yoda1. We demonstrate that these channels regulate cytosolic Ca^{2+} dynamics, which impacts the activities of downstream proteins and growth-related biological pathways. As a bottom-up approach toward tissue engineering, we used optogenetic and mechanosensitive channels to forward engineer growth control in epithelia. These findings regarding how Ca^{2+} signaling dynamics tune the robustness of organ growth and cellular processes provide scope for future applications related to phenotypic drug screening assays and innovation in treatments of human diseases.

METHODS

GAL4-UAS, a bipartite method of activating gene expression in *Drosophila*, was used to express the genes of interest. To ensure more extended periods of viability during ex vivo imaging and allow the addition of a constant flow of media, a hybrid polyethylene terephthalate laminate (PETL) microfluidic device[3] was used for live imaging. The wing imaginal discs were imaged using a Nikon A1R-MP laser scanning confocal microscope. Wing discs were imaged throughout the entire depth of z-planes with a step size of 0.8 μm, depending on sample thickness, with a 40x and 60x oil objective with 200 ms exposure time, and 50 nW, 405 nm, 488 nm, 561 nm, and 640 nm laser exposure at 44% laser intensity.

For optogenetic experimentation, 1 mM All-Trans-Retinal was supplemented for the functional generation of CsChrimson in *Drosophila* (Fig. 1). The crosses were set up in darkness since white light can desensitize and deactivate the optogenetic channels. The dark condition was maintained by wrapping the vials in aluminum foil. On collecting the embryos in darkness, red light (~600 nm) LED strips were used to activate CsChrimson starting at the 1st instar larval stage. An Arduino microcontroller appended with transistors for amplification and resistors for dimming light was powered by a 9 V DC battery and programmed to manipulate the period of illuminance. A digital illuminance meter was used to measure the level of light in lux.

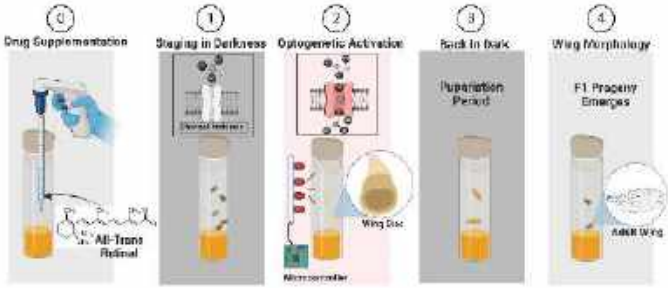

Figure 1: Schematic of Optogenetic Experimental Set-up.

RESULTS

We discovered that CsChrimson and Piezo modulate cellular processes involved in morphogenesis. We first confirmed that these channels transport Ca^{2+} using the GCaMP6f Ca^{2+} indicator in the wing discs and observed increased Ca^{2+} spiking dynamics to activate both channels through light and Yoda1-mediated activations (Fig.2).

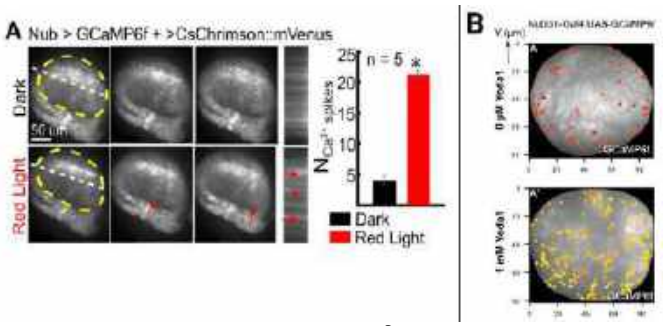

Figure 2: Emergence of elevated Ca^{2+} spiking dynamics on (A) optogenetic and (B) Piezo activation.

This confirmed that CsChrimson or Piezo can regulate Ca^{2+} dynamics in the tissue. Next, to investigate the effect of Ca^{2+} on terminal organ morphology, we discovered severe defects in the final shape and size of the wing for overexpression of CsChrimson or downregulation of Piezo in the wing disc, while overexpression of Piezo also resulted in smaller wings compared to control (Fig.3,4).

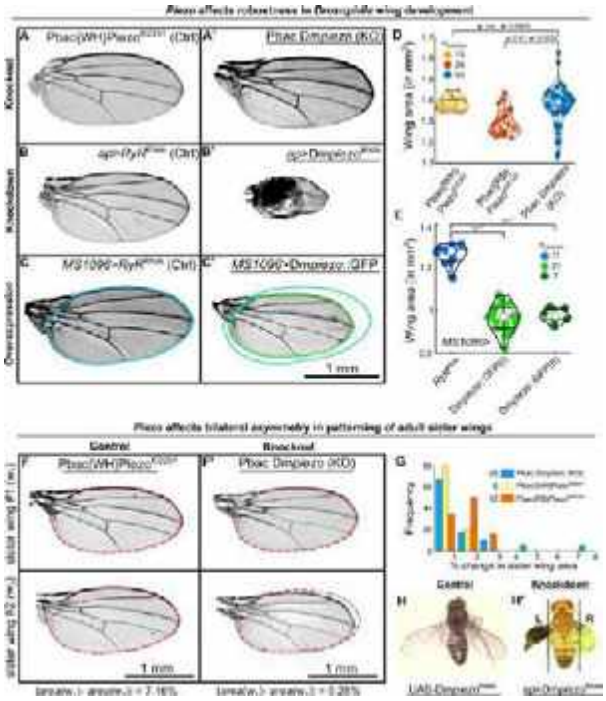

Figure 3: Divergent and spatial effects of Piezo expression in regulating size precision in bilateral organs.

For CsChrimson, the adult wing phenotypes were qualitatively and quantitatively correlated with the gradual increase in the intensity of light (Fig. 4A). Surprisingly, on quantifying the area of wings for different intensities of light activation, we found that at 5 lux of light, the size of the wings was larger compared to other intensities indicating an optimum level of light and Ca^{2+} level that induces growth (Fig. 4B). Different phenotypes for Piezo expression levels also point to similar regulation of morphogenetic processes (Fig. 3).

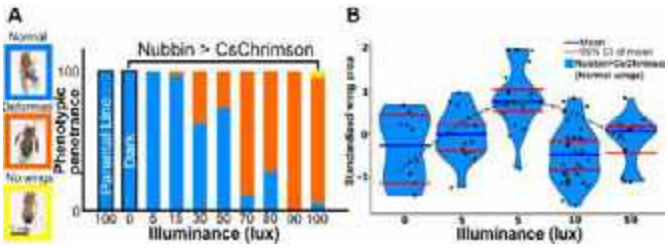

Figure 4: Optogenetic control of Ca^{2+} regulates organ shape and size. (A) Increase in phenotypic severity with the increasing Ca^{2+} levels. (B) Distribution of wing area for different light intensities.

We followed up these results by investigating subcellular processes and found increased cell death in wing discs for long periods of optogenetic activation and genetic misexpression of Piezo. Interestingly, we also observed higher proliferation for overexpression of Piezo or a lower frequency of light activation (1 min on/off period), indicating a probable apoptosis-induced compensatory proliferation phenomenon (Fig.5).

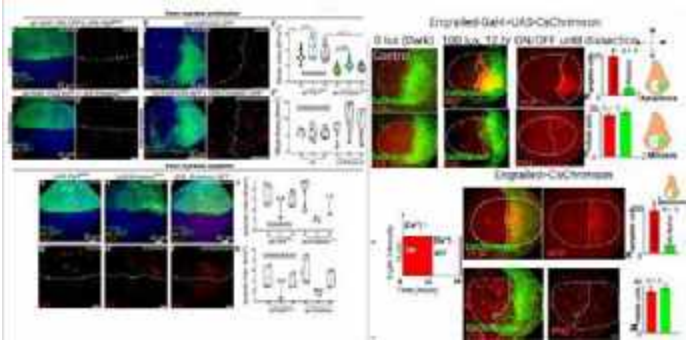

Figure 5: Piezo and Optogenetic mediated control of Ca^{2+} levels regulate cell proliferation and cell death.

Based on our results, we hypothesize that by controlling Ca^{2+}, tissue growth can be directly controlled, and an optimum level of cytosolic Ca^{2+} to promote growth can be established. Systematically varying the width of half max of optogenetic activation, e.g., by using a lower intensity of light or a faster optogenetic activation cycle, or by changing the mechanical activation level of Piezo using a microfluidic device will determine such "Goldilocks zone" of Ca^{2+} level.

DISCUSSION

In this work, we studied Ca^{2+} facilitated cellular communication and its role in shaping the growth of organs. We employed optogenetics and Piezo to program Ca^{2+} to elucidate the multi-layered steps and the general design principles that spatiotemporally govern morphogenesis. Cumulatively, these in vivo and ex vivo findings provide insights into practical applications for improving developmental research.

Through the manipulation of Ca^{2+} channels, we have gained novel insights into Ca^{2+} regulation of organ development and cellular processes while raising new questions regarding downstream growth-regulating pathways. We have also started investigating how these results affect cellular mechanics and developed a vertex model based on our results. Such an in silico model will help us better design our experiment to discover the "Goldilocks Zone" of cytosolic Ca^{2+} and how programming Ca^{2+} signaling may affect subcellular processes, tissue, and organ growth. Eventually, a new avenue of therapeutic discovery can be explored via activation period or activation level-based screening using light or mechanical activation of channels like CsChrimson or Piezo for Ca^{2+} channelopathies.

INTRODUCTION

Recovery from an Achilles tendon rupture (ATR) typically extends over several months. Patients often experience enduring deficits in functional performance. These deficits are characterized by weakness in calf muscle performance[1] and the activation of compensatory mechanisms[2] to overcome the weaknesses of the calf muscle. Functional deficiencies of the lower limb after surgery are intricately tied to the changes in the morphological and mechanical properties that are happening in both calf muscles[3] and the Achilles tendon[4].

Changes in the Achilles tendon include increased length of the free tendon[4], increased cross-sectional area[5], and changes in its mechanical properties [6]. On the other hand, common calf muscle changes include reduced cross-sectional area and volume of the Gastrocnemius and Soleus muscles [7], coupled with increased fat infiltration. Notably, Gastrocnemius muscle atrophy and heightened fat infiltration [7] emphasize the persistent nature of these changes.

Beyond assessing morphological and volume changes in calf muscles, examining alterations at the fascicular level in both the tendon and muscles provides insights into the negative consequences of ATR. Ultrasound, a common imaging modality for studying muscle fascicles [8], can be complemented by other imaging modalities, such as Diffuse Tensor Imaging (DTI)[9]. DTI quantifies tissue properties such as diffusion coefficients and fractional anisotropy [10]. Furthermore, fiber tracking methods using DTI data offer information about fascicle length, pennation angle, and fascicle curvature [11]. Despite investigations into the use of DTI techniques to understand the impact of diseases like Diabetes [12] and anterior interosseous nerve syndrome[13] on muscle structure, there is a noticeable absence of studies considering DTI as a technique for studying post-surgery changes in calf muscles, presenting an opportunity for further exploration and a more comprehensive understanding of the intricate changes occurring at both macro and micro levels in individuals recovering from ATR.

The current study aims to benefit from the DTI technique to comprehensively understand alterations in the Soleus muscle among individuals who have undergone surgical treatment for ATR. By examining the fascicular level changes, particularly in the context of DTI, this research seeks to contribute valuable insights into the intricacies of muscle transformations post-surgery.

METHODS

This study obtained approval and followed the Institutional Review Board (IRB) guidelines at the Pennsylvania State University (Study ID: STUDY00019121). Five participants who recovered from ATR in one leg (2 females and three males, with an average age of 45.6 ± 16.5 years, weight of 85.6 ± 17.6 kg, and height of 174.8 ± 3.4 cm) were included in the study. All participants underwent a 3T MRI system (Siemens Prima Fit) examination to obtain anatomical axial T1 and DTI images of the soleus muscle near the Achilles tendon, utilizing a 15-channel knee coil. For the anatomical scan, the following parameters were applied: coronal T1-weighted, TR/TE=650/8ms, FOV=160x160x144 mm, resolution=320x288x262, scan time= 3 min 35sec. The DTI scans were conducted using the following settings: an axial SE-EPI sequence, TR/TE=6500/70ms,FOV=160x160x144mm, resolution=128x128x192, gradient directions = 64, signal averages = 2, b values ≈ 0 and 600 s/mm^2, scan time = 14 min 26sec. Eddy's current distortions and possible motion during the DTI-EPI scan were corrected using DSI Studio[14]. The ROIEditor in DTI_Studio [15] created a mask for the muscle. Finally, the data was analyzed in MRtrix [16] as described in our former studies[17],[18]. Using MRtrix, we extracted several DTI indices to probe the diffusion integrity in the muscles. However, we have focused on indices, the mean diffusivity (MD) and fractional anisotropy (FA) in soleus. A comparison of each parameter map between the recovered ATR leg and its contralateral healthy counterpart (in the soleus muscle) was conducted to identify the best-suited measure for identifying the effects of the injury.

RESULTS

Key parameters in Diffusion Tensor Imaging (DTI) include the primary eigenvalues (λ_1, λ_2, λ_3), mean diffusivity (MD), and fractional anisotropy (FA). Calf muscle atrophy, involving both the Gastrocnemius and Soleus muscles and increased fat infiltration were

observed in all subjects. Figure 1 illustrates the anatomical, colored fractional anisotropy, and first eigenvalue for subject 2, comparing the right and left legs at the same height. Despite undergoing a total knee replacement on the right knee and Achilles tendon surgery on the left leg, this subject exhibited more pronounced calf muscle atrophy and increased fat infiltration (white tissues in the soleus) in the left leg, which had repaired Achilles tendon rupture. Increased fat filtration was absorbed to some extent in all the subjects.

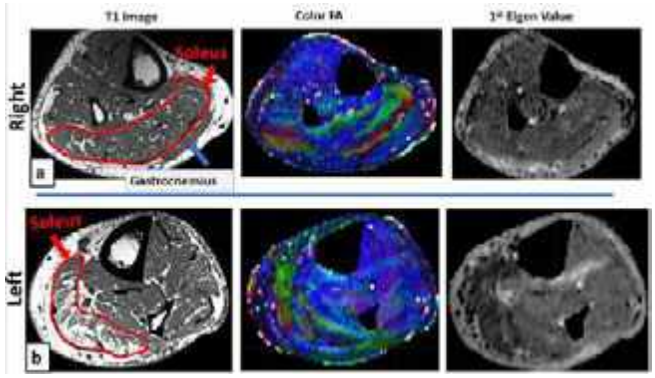

Figure 1: T1 image, color Fa map, 1st Eigenvalue for a) right leg, b) Left Leg

To examine variations in specific parameters (FA, MD, eigenvalues) within the healed leg after an Achilles tendon rupture, we assessed the volume around the musculotendon junction of the Soleus muscle. This analysis will be performed on both the injured and healthy legs, with the chosen volume's height being consistent for both legs. We calculated the mean FA, MD, and eigenvalues in the recovered leg after Achilles tendon rupture and the corresponding contralateral leg for all subjects (Table 2) using statistical analysis of ROIEditor. Figure 2 shows the bar chart of these parameters. Interestingly, the mean values of these parameters across participants do not show consistent trends. However, a compelling observation is the higher standard deviations of measured parameters over the region of interest (ROI) in the injured legs compared to the healthy legs across all subjects. This highlights a discernible alteration in the fascicles and a loss of their arrangement to some extent in the injured legs within the considered ROI. Further statistical analysis, specifically t-test calculations (for example, 0.085 for λ_1 and 0.049 for λ_2**)** underscores that the average standard deviation over the ROI for all participants is a robust indicator of the differences between healthy and injured leg. When contrasted with their healthy counterparts, it effectively demonstrates the inhomogeneity of fascicles in injured legs.

Table 2: Parameters values for different subjects

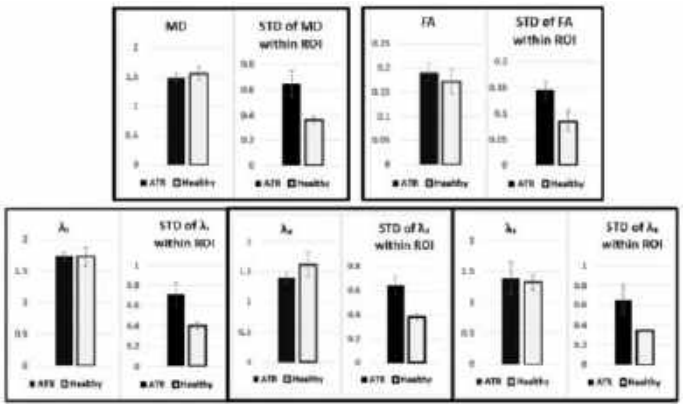

Figure 2. Chart of the changes in the specified parameters (MD, FA, λ_1, λ_2, λ_3)

DISCUSSION

This study utilized the DTI technique's potential to investigate the structural integrity changes in the soleus muscle after ATR and the contralateral healthy legs. From the anatomical images, we observed fat infiltration and muscle atrophy in the soleus muscle of all subjects. DTI results indicated alterations in the fascicle arrangement and inhomogeneity, evidenced by increased standard deviations over ROI of interest in various measured parameters. Despite the higher standard deviation values over ROI in the injured leg, the average values of parameters did not exhibit specific trends between the injured leg and contralateral legs. Given the complexity of the soleus muscle, this study focused on average values over the musculotendon junction volume. Further investigation through tractography-based analysis is recommended to understand the changes in each division of the soleus muscle.

INTRODUCTION

Migrating cell collectives interact with biochemically and mechanically heterogeneous environments. To sense and navigate such an environment, cells bind integrin receptors to extracellular matrix (ECM) proteins to form focal adhesions that connect to actin stress fibers. As epithelial collectives migrate forward and form leading-edge protrusions, the actin network continues to branch out, increasing plasma membrane tension and forming focal adhesions to adherent surfaces. On non-adherent surfaces, cells utilize multicellular actin stress fibers formed along adjacent cells, a purse-string mechanic, to close the gap [1]. However, much of the current work focuses on collagen type-I or fibronectin-laden substrates, or non-adherent substrates. Although classic wound healing assays focus on filling gaps created within epithelia, it remains unclear how cells sense wounds or defects in the ECMs of varying proteins and stiffnesses. Here we investigate how a laser-ablated defect on polyacrylamide gels coated in collagen type-I (col1) or collagen type-IV (col4) can affect collective cell migration.

METHODS

To better understand how collagen type can affect epithelial sensing of ECM defects, human mammary epithelial cells (MCF10A) were seeded on either 0.08, 0.5, or 20kPa polyacrylamide (PA) gels functionalized with either col1 or col4 [2]. After 24hr culture, a portion of the underlying PA gel was ablated perpendicular to the leading edge of the cell cluster using a laser, creating a micro-defect (µ-defect) (Fig. 1A). Subsequently, time-lapse imaging was performed (Zeiss Cell Observer) at 10min intervals for 24hr. Cell migration was measured using Matlab's PIV and manual tracking (ImageJ) of the leading edge on brightfield images. Time spent at the defect was measured by calculating the time difference from when the leading edge was first contacted, and the last leader cell crossed the µ-defect. The following were chemically inhibited or induced (drug): myosin ATPase (10µM Blebbistatin), protein phosphatases PP1 and PP2A (1nM calyculin-A), Arp2/3 (150µM CK666), hyperosmotic (3mM methyl-β-cyclodextrin), and hyposmotic (50% water/50% cell media). For fixed imaging, samples were fixed in 4% PFA after cells contacted the µ-defect. The following antibodies were used: phalloidin, anti-paxillin, and anti-T-plastin. Images were taken on a 63x oil objective on a Zeiss LSM 880 FAST Airyscan confocal. AFM was done with a Bruker Nanoscope Resolve atomic force microscope, and custom silicon nitride cantilever probes (4.5µm-diameter, 0.01N/m polystyrene bead).

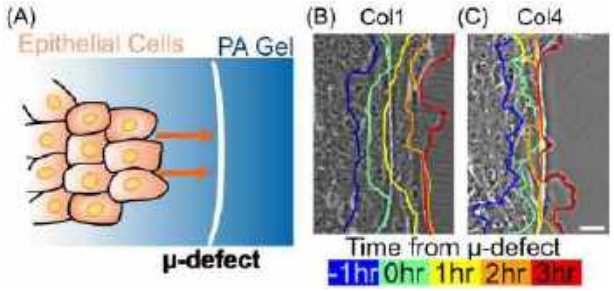

Figure 1. (A) MCF10A are seeded in a cluster on col1 or col4 PA gels. A portion of the PA gel is ablated using a laser (µ-defect). A brightfield image 3hr after the leading edge contacted the µ-defect on (B) col1 and (C) col4. Lines are color-coded based on the time relative to when the leading edge contacted the µ-defect. Scale bar: 25µm

RESULTS

Cells on col1 migrated over the µ-defect (defect) with little effect on migration distance (Fig. 1B). However, cells on col4 gels stalled at the defect site and took longer to migrate over (Fig. 1C). No matter the collagen type, cells migrated over a similar distance in control (non-defect) samples (Fig. 2A). When a defect was introduced, cells on col4 stalled and reduced the distance traveled while the leading edge on col1 traveled at a similar distance to the non-defect samples (Fig. 2A). To

understand whether such defect-sensing is also mechanosensitive, we varied PA stiffness and found that cells on even softer gels (~0.08kPa) sensed defects with both col1 and col4, showing similar times spent at the defect (Fig. 2B). By contrast, on stiffer substrates (~20kPa), cells overcame defects on both col1 and col4, showing negligible stall times in both cases (Fig. 2B).

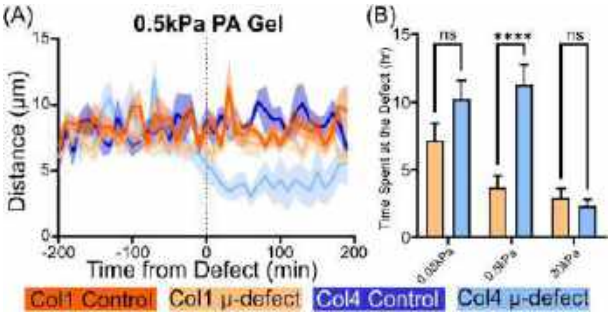

Figure 2. (A) The distance traveled by the leading edge over time. The vertical dashed line represents when the leading edge contacted the defect. (B) The average±SEM of time spent at the defect on different substrate stiffnesses. N≥3; statistical analysis: one-way ANOVA with Tukey's multiple comparisons ****P<0.0001, ns=not significant.

As cells migrate into the defect (Fig. 1C), their protrusions collapse and stall. We wondered if actin branching was critical for col4-dependent stalling. When actin branching was inhibited via CK666, the leading edge further stalled on col4 μ-defect compared to the control, supporting the regulatory function of actin branching of leading edge cells in collagen-dependent defect-sensing. To observe F-actin architecture at the μ-defect, we imaged the leading edge at the defect using Airyscan microscopy. On col1, the leading cell overcame the defect, but the F-actin built up at the μ-defect (Fig. 3Ai). On the other hand, cells on col4 form very short actin fibers at the defect and large actin bundles across adjacent cells parallel with the defect (Fig. 3Bi). Adhesion structures connect the cell cytoskeleton to the ECM. To visualize the adhesions, we imaged for paxillin. Images of paxillin illustrate distinct, individual puncta in the leading cell around the defect on col1 substrates (Fig. 3Aii). However, on col4, there are few distinct paxillin puncta; instead, smaller paxillin fibers at the leading edge and larger paxillin fibers form along the actin fibers (Fig. 3Bii). Cells near the col4 defect exert lower traction forces than those near the col1 defect (data not shown). Along these lines, cells are stiffer (measured via AFM) near col4 compared to col1 defects (data not shown). We also found that myosin activation through calyculin-A and RhoA activation increases defect-based stalling, while myosin inhibition via Blebbistatin allows cells to migrate over the defect (data now shown). These results indicate that leader cells are unable to form protrusions, and instead form long paxillin fibers and exert lower traction forces, all of which cause stalling near col4 defects.

To understand the role of cell protrusions in response to μ-defects, we imaged T-plastin, a calcium-sensitive conserved linker protein for actin branching [3]. We found T-plastin highly expressed in cells on col1 defects (Fig. 3Aiii), indicating a high amount of actin branching, while cells near col4 defects had lower T-plastin expression (Fig. 3Biii). The actin branching on col4 could potentially reduce membrane tension, and thus lower T-plastin in response. We hypothesized that externally lowering membrane tension could enhance protrusions and enable cells to cross the gap. To test this, we pharmacologically created hyperosmotic or hyposmotic media conditions to increase and decrease membrane tension, respectively. Here, cells in hyposmotic conditions were able to reach across the μ-defect more effectively than in hyperosmotic conditions, no matter the collagen type (Fig. 4A, 4B).

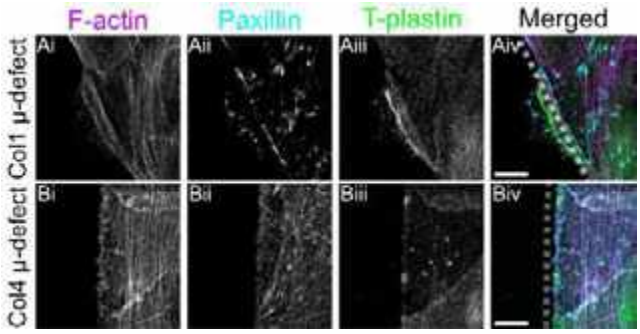

Figure 3. Max z-projection of leader cells at the μ-defect on (A) col1 or (B) col4 coated 0.5kPa PA-gels. (i-iii) Representative grey-scale images of (i) F-actin, (ii) paxillin, and (iii) T-plastin. μ-defects are represented by the gray dashed lines in the merged images. Scale bar: 10μm

DISCUSSION

Collective cells migrate through heterogeneous environments, including ECM gaps, such as wound healing. Much of the previous work utilizes fibronectin as the underlying ECM and focuses on wounds created in the epithelial layers and not the ECM wounds [1,4,5]. Our work reveals that epithelial sensitivities of ECM wounds or defects depend on matrix stiffness and collagen type (col1 vs col4). We further demonstrate that such defect-dependent mechanosensing in epithelia is regulated by actin-based protrusions wherein a rise in cell membrane tension stalls protrusions and slows collective cell migration across ECM defects. One limitation of the study is understanding how collagen structure changes in the presence of defects. Col4 is a dense, sheet-like structure. The fibers may shred during the ablation process while the fibrous col1 fibers remain intact, causing cells to unadhere. Future experiments focus on scanning electron microscopy (SEM) to visualize fiber architecture near the defects. This research helps answer a fundamental question of how differing ECM proteins and their defects can physically and biochemically affect cellular signaling.

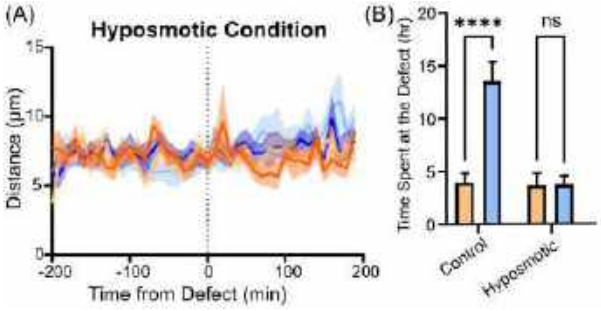

Figure 4. (A) The distance traveled by the leading edge over time in a hyperosmotic condition is similar no matter the collagen type. (B) The average±SEM time spent at the defect is less in hyperosmotic conditions no matter the collagen type. Control represents samples in normal osmotic conditions. . RESOLVING NANOSCALE DEFORMATIONS OF MINERALIZED COLLAGEN FIBRILS IN 3D

Riti Sharma, Luc Capaldi, Kailin Chen, Ottman A. Tertuliano

Mechanical Engineering and Applied Mechanics, University of Pennsylvania, Pennsylvania, USA

INTRODUCTION

Bone is a hierarchical material that exhibits a complex multi-level organizational structure. This hierarchical structure is critical to bone tissue properties and depends on the arrangement and interaction of organic (collagen and proteins) and inorganic (hydroxyapatite) components of the tissue (4). At the nanoscale, the collagen molecules within bone tissue form a twisted and cross-linked structure. These structures have hydroxyapatite mineral crystals embedded in them, thus forming an individual mineralized collagen fibril (~100 nm). Mineralized collagen fibrils are the fundamental building blocks of bone tissue (4).

We have limited knowledge of the fundamental response mechanisms of mineralized collagen fibrils to physiological loads. Especially during cyclic loading, injury, and repair, where the bone tissue is exposed to large strains and dynamic loads presenting a drastic departure from quasi-static and macroscale conditions (5). This necessitates the probing of nanoscale tissue adaptation under dynamic failure processes.

The orientation and arrangement of mineralized collagen fibrils visualized using various imaging techniques have been a matter of interest for some time now (3). However, not all these techniques can be combined with mechanical testing. Electron-based techniques such as in-situ SEM cannot currently provide the spatial resolution to assess the bone's mineralized collagen fibrils and are destructive for 3D imaging (1). X-ray-based in-situ SAXS and WAXS can be useful for measuring strain fields in fibrils but are limited to discrete points in space and cannot provide quantitative data about the 3D orientation of fibrils (6).

Previous work using TEM suggests a reorientation of fibrils near cracks, but fundamental mechanisms remain unclear (Fig. 1) (1). Our overarching aim is to isolate and quantify nanoscale mechanisms facilitating bone fracture and understand how much of the change in mechanical properties of the bone is due to the fundamental building blocks – mineralized collagen fibrils.

Our objectives are to experimentally answer the following: 1. How do mineralized collagen fibrils deform or adapt under cyclic loading in the presence of a crack? 2. What nano and micro-scale mechanisms dictate dynamic fracture in bone?

To answer these questions, we introduce a novel 3D imaging technique using synchrotron X-ray tomography to visualize individual nanoscale mineralized collagen fibrils in bone.

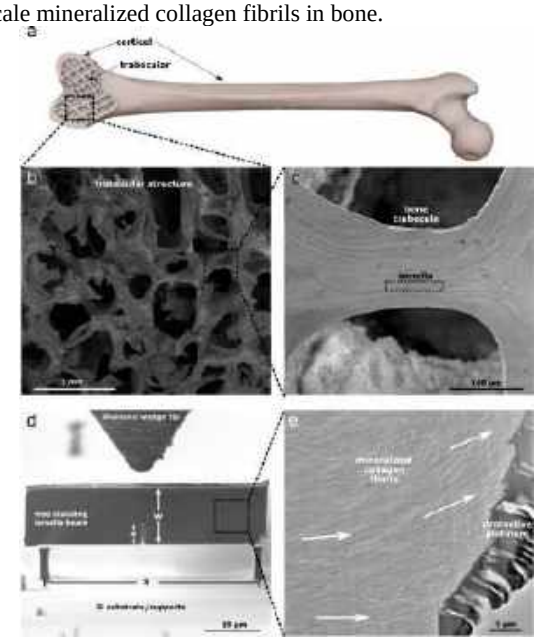

Fig. 1. Preliminary work suggests a reorientation of fibrils along the crack, but mechanisms are still unclear (1)

METHODS

Sample Preparation: Bulk human trabecular bone samples are purchased from healthy human donors with no history of bone disease via a tissue harvesting consortium (Articular Engineering, Inc.). These bulk samples are cleaned, polished, and coated before putting in the Focused Ion Beam – Scanning Electron Microscope (FIB-SEM) at Drexel University. We fabricate microscale (10x10x50 μm^3) beams using the FIB-SEM and introduce a small notch to induce an initial flaw in the bone. These beams are then lifted out and glued onto fabricated silicon supports etched on 2x2 mm^2 wafers. The final setup creates a

microscale three-point bending geometry. This beam setup is ready for X-ray tomography and radiography experiments at the Brookhaven National Laboratory.

In-situ X-ray imaging: First, we perform X-ray tomography of the microscale beams to observe the volumetric arrangement of mineralized collagen fibrils in 3D relative to the introduced notch. After tomography, we perform nanomechanical experiments using an in-situ testing apparatus (KLA NanoFlip) available in our lab at Penn. We use a spherical tip to load the beams to a stress less than 75% of failure stress and then apply a low amplitude cyclic load to propagate a crack. Radiography during this experiment gives us spatial and temporal information about any changes in mineralized collagen fibril arrangement due to applied stresses. After loading, we took another tomography scan to get 3D information about the changes that occurred during the experiment.

Tomography Data Processing: Tomography data was reconstructed using TXM_Sandbox and visualized in Dragonfly. We segmented two regions of interest - mineralized collagen fibrils and nanoscale pores- using histographic segmentation in Dragonfly. This type of segmentation creates a two-dimensional histogram with absorption contrast and domain boundaries. With these two masks, we select clustered data values to create the mentioned regions of interest. 3D orientation of the fibrils in beams with and without cracks can be visualized after segmentation.

Radiography Data Processing Radiography images from nanomechanical experiments were visualized and processed in Fiji. Next, we use Digital Image Correlation (DIC) (2) to quantify the strain and displacement fields of the deformed mineralized collagen fibrils. This processing technique provides full-field information on damage observed using in-situ radiography.

RESULTS

We introduced a novel 3D imaging technique using synchrotron X-ray tomography to visualize individual nanoscale mineralized collagen fibrils in bone with 30 nm voxel resolution (Fig. 2(a)). We found the mineralized collagen fibrils to be of the order of ~100 nm which aligns with previous measurements done using electron microscopy (4). Further, this technique uniquely allows us to capture the crack trajectory in 3D along with nanoscale deformations of fibrils (Fig. 2(b)).

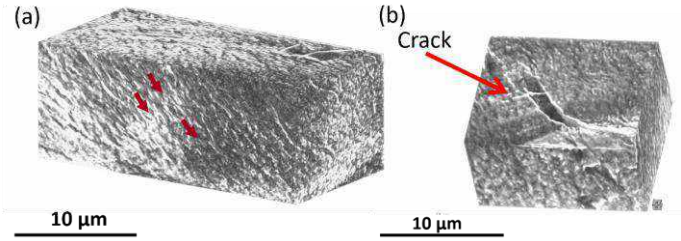

Fig. 2. (a) X-ray tomography reveals individual mineralized collagen fibril alignment and (b) crack trajectory in 3D.

We demonstrate for the first time the ability to successfully conduct in-situ nanomechanical dynamic loading experiments for bone in a synchrotron facility. These experiments have traditionally been done in an SEM to obtain 2D information at micron resolutions (1). Our technique has allowed us unprecedented 30 nm volume resolutions. This method not only gives us information on crack growth but can visualize real-time fibril deformation as well. We found in-situ radiography to be a robust technique for observing real-time nanoscale deformations and adaptation of fibrils under applied loads and near cracks.

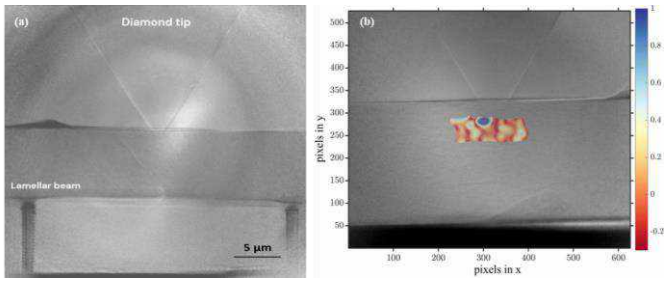

Fig. 3. (a) In-situ x-ray radiography nanomechanical experiments resolve nanoscale fibril deformation. (b) Preliminary data from the use of DIC on in-situ x-ray radiography images.

Data processing techniques like digital image and volume correlation are becoming more prevalent in quantitatively measuring deformation characteristics. This is due to the relative ease and ability to provide full-field displacement and strain fields under applied loads. DIC tracks surface speckle patterns to measure the local heterogeneity of the deforming fibrils using our radiography data. This speckle pattern serves as a marker for deformation information. For cyclic testing, DIC can help monitor the overall strain with loading cycles, along with local damage development of the fibrils. Our ongoing work includes preliminary processing of radiography data and the use of DIC to obtain quantitative information on displacement and strain fields (Fig. 3(b)).

DISCUSSION

The ability to quantitatively analyze the 3D organization and damage of the mineralized collagen fibrils is key to understanding structure-function relationships in bone. Previous attempts at isolating and visualizing deformations experimentally at these small length scales have been using electron microscopes where sample preparation for 3D imaging is destructive. We presented a non-destructive 3D imaging technique that can allow us to tackle these problems and open new paths toward ultrastructure organization investigations of whole sample volumes. Some studies have demonstrated the use of SRµCT to obtain high-resolution (~600 nm) images (7), but this does not allow the resolution of mineralized collagen fibril deformations (~100 nm). We note that the cost of our technique is a higher X-ray dose but generates a vast amount of acquired deformation data per sample (~200 Gb/sample).

Since isolating and quantifying nanoscale mechanisms is critical to understanding disease progression, this technique can help us resolve the changes occurring in bone tissue due to various diseases like osteoarthritis, osteoporosis, etc. We have the opportunity to approach understanding these diseases from a mechanics perspective and fundamentally resolve the role of the building blocks – mineralized collagen fibrils – in disease progression.

BIOMECHANICAL CONSEQUENCES OF LIGAMENT RELEASES DURING TOTAL KNEE ARTHROPLASTY

INTRODUCTION

The traditional alignment goal for total knee arthroplasty (TKA) is to align the femoral and tibial implants to achieve a neutral mechanical alignment. However, altering the native joint alignment often overstuffs the medial and/or lateral compartment [1], which increases the tension in the soft tissue restraints (e.g., ligaments) of the tibiofemoral joint. To reduce excessive tension(s), surgeons routinely perform soft tissue releases [2]. They most often assess whether they have adequately released soft tissue restraints based on the joint gaps and/or varus-valgus (V-V) laxities [3]. Although soft tissue releases reduce tension, they also have been shown to increase the slacklength and decrease the stiffness of the released ligament [4]. Because the ligament properties are key determinants of the biomechanics of the knee, these ligament changes could cause unintended biomechanical changes to the joint (e.g., altered laxity or joint contact forces).

Accordingly, the two objectives of the present study were (1) to characterize the coupled changes in slack length and stiffness due to releases of the superficial medial collateral ligament (sMCL) and lateral collateral ligament (LCL) and (2) to determine how these coupled changes in ligament properties alter important biomechanical variables of knee function (i.e., V-V laxity, contact forces, and ligament tensions).

METHODS

Ex Vivo Mechanical Testing: To characterize the coupled changes in slack length and stiffness due to ligament releases, we isolated five MCLs and five LCLs from a crossbreed of large white, landrace, and red duroc pigs (age: 6 months, weight: 131.8 ± 18.9 kg) for mechanical testing. Following preconditioning, we computed baseline and post-release slacklengths and stiffnesses from the force-deformation data during a loading ramp. On each ligament, we performed ten release iterations consisting of 5 punctures each with a 16-gauge needle. After each release, we cyclically loaded the ligament and then allowed the ligament to recover.

Computational Simulations: To determine how coupled changes in ligament properties alter V-V laxities and tibial forces, we created four sets of TKA models (**Figure 1**). First, we performed 1000 virtual reference TKAs on a validated multi-body model of the knee consisting of 12 degrees of freedom [5]. To account for patient-to-patient variability in the ligament properties, we randomly sampled the stiffness and slacklength of each ligament [5] (*Reference TKA Set*, **Figure 1**).

Second, we created two additional sets of 1000 virtual TKAs with medial or lateral overstuffing by randomly introducing up to 2° of valgus and internal malrotation to the femoral component and up to 2° of valgus malrotation to the tibial component (*Medial Overstuff Set*,

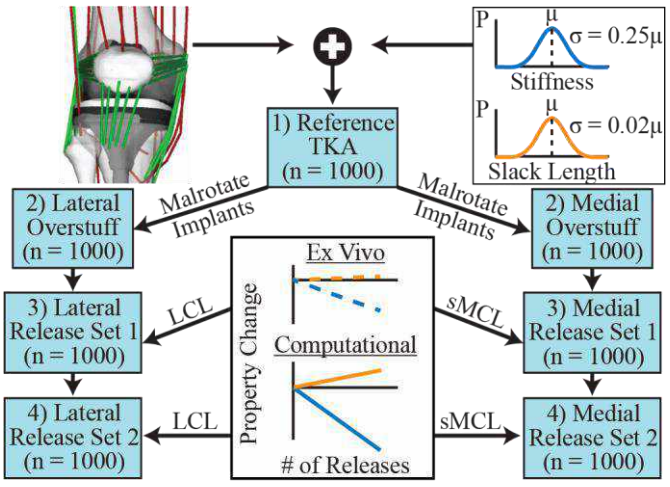

Figure 1: We generated four sets of musculoskeletal models to characterize the effects that implant overstuffing and subsequent releases have on knee biomechanics. In each model, we simulated passive flexion and varus-valgus laxity to compute laxities, contact forces, and ligament tensions.

Figure 1), or by randomly introducing up to 2° of varus and external malrotation to the femoral component and up to 2° of varus malrotation to the tibial component (*Lateral Overstuff Set*, **Figure 1**), respectively.

Third, we performed virtual releases to each overstuffed model by applying coupled reductions in stiffness and increases in slack length to the sMCL and LCL in the medially and laterally overstuffed TKAs, respectively, to reduce the ligament tensions back to those of the *Reference TKA Set* based on the linear regressions of the coupled changes determined in the ex vivo study (*Release Set 1*, **Figure 1**).

Fourth, because the patient-to-patient variability we introduced in the virtual ligament properties lead to different properties than those of the ex vivo ligaments, we performed an additional release set tuned to each of the overstuffed models (*Release Set 2*, **Figure 1**). To tune these releases, we computed the achieved tension change in either the sMCL or LCL between the *Overstuff Set* and *Release Set 1*. We then used the difference between the intended tension changes (*Overstuff Set* - *Reference TKA Set*) and achieved tension changes to inform how many releases iterations *Release Set 2* should have. For example, if an overstuffed model had 60 N of excessive tension and the released model now had 40 N of excessive tension (i.e., 20 N reduction), we determined we would need three times as many releases for *Release Set 2*.

Finally, in each model set, we performed forward dynamic simulations (OpenSim JAM) of passive flexion from 0° to 90° of knee flexion and clinical V-V laxity exams (±10 Nm) at 0°, 45°, and 90° of knee flexion. We computed the differences in compressive contact forces, V-V laxities, and ligament tensions between the four model sets.

RESULTS

In the experimental portion, the slack length of both the MCL and LCL increased linearly with increasing numbers of punctures (0.5 ± 0.2% and 1.0 ± 0.7% after 50 punctures, respectively) (**Figure 2a**). Additionally, the stiffness of both the MCL and LCL decreased linearly with increasing numbers of punctures (-50.4 ± 18.4% and -48.0 ± 28.1% after 50 punctures, respectively) (**Figure 2b**).

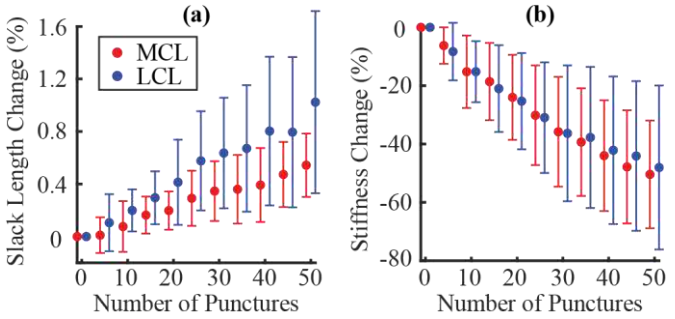

Figure 2: Mean (points) and standard deviation (error bars) show the ex vivo changes in (a) slack length and (b) stiffness.

Computationally, ligament releases decreased the median contact forces by as much as 42% in the medial overstuffed models and 24% in the lateral overstuffed models (**Figure 3a-b**). Additionally, ligament releases increased the median laxity up to 88% in the medial models and 54% in the lateral models (**Figure 3c-d**).

DISCUSSION

The ***key finding of the experimental portion*** of this study was that releases of the MCL and LCL caused coupled increases in slack length and decreases in stiffness. These results agree with a previous study that found similar trends in the MCL of human cadaveric knees [4]. Therefore, these property changes of ligaments should be considered in studies consisting of modeling TKA since releases are routinely performed. In addition, similar to the previous study, we found large

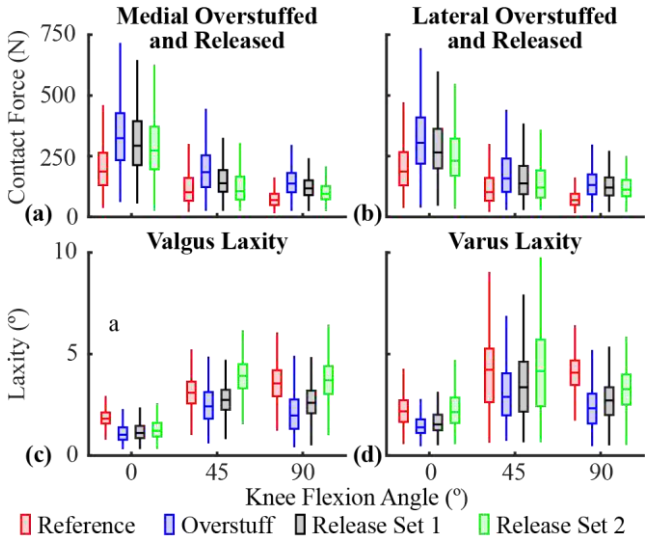

Figure 3: Boxplots show modeling results for (a) medial and (b) lateral contact forces and (c) valgus and (d) varus laxity.

variability in the property changes due to releases. Thus, the number of punctures needed to balance a particular knee is highly patient-specific.

The ***key finding of the computational portion*** of the study was that ligament releases decreased contact forces and increased laxity. However, even though the excessive ligament tension was reduced to approximately zero (median LCL and sMCL tensions were within -6.3 to 10.4 N of reference tensions during passive flexion after *Release Set 2*), contact forces and laxities were not necessarily restored back to the reference values (**Figure 3c-d**). Thus, if surgeons are using laxity assessments to determine the optimal balance of the knee [3], achieving a desired laxity may leave ligament tensions and/or contact forces too high. For example, *Release Set 2* restored varus laxity at 0° of knee flexion (median laxity difference of 0.04° compared to reference), but did not restore the compressive contact force, with a median excess of 44 N. This may lead to residual stiffness or pain in the joint, causing discomfort for the TKA patient. Therefore, laxity assessments alone may not be sufficient to identify overly tight ligaments or elevated contact forces in a TKA knee. Additional measures of biomechanics (e.g., ligament tension measured by a tensiometer [6]) may be necessary to achieve optimal soft tissue balance.

One main limitation of our study is that we did not account for the variability in ligament property changes due to releases (**Figure 2**) in our computational study. However, accounting for this variability was unnecessary to show how coupled changes in the ligament properties due to releases affected laxities, contact forces, and ligament tensions.

In conclusion, this study integrated experimental and computational approaches to show that assessments of ligament balance using V-V laxities might not identify overly tight ligaments and elevated contact forces. Therefore, assessments more specific to the ligaments being released [6] may be necessary to achieve optimal soft tissue balance, and in turn, high patient satisfaction and function.

INTRODUCTION

The Fontan operation has become a standard surgical palliation for patients born with functionally univentricular hearts, enabling them to live with a unique circulatory configuration where systemic and pulmonary circulations are arranged in series [1]. As of 2020, it was estimated that around 50,000 patients worldwide live with a Fontan circulation [2]. While short-term outcomes following the Fontan surgery have improved over time, long-term outcomes remain less favorable, with a survival rate of only 74% over a 20-year period [3]. The absence of a subpulmonary pump in this circulation leads to increased central venous pressures in the range of 10 to 15 mm Hg — up to three times the normal range —and a decrease in cardiac output, which are associated with numerous morbidities including exercise intolerance, protein-losing enteropathy, liver fibrosis, and heart failure [4]. The introduction of an additional power source to the pulmonary circulation may be necessary to alleviate the elevated central venous pressure and improve long-term outcomes for Fontan patients.

With rapid recent advancements in three-dimensional bioprinting technology, we propose a bioprinted pulsatile conduit, constructed from induced pluripotent stem cells, as a promising functional power source. This approach offers significant advantages over traditional mechanical devices, particularly for pediatric patients, as it could potentially grow with the patient and circumvent complications associated with blood-contacting foreign materials. However, bioprinting large-scale tissues remains an expensive and complex process. Computational modeling emerges as a vital tool in this context, providing an efficient pathway for performance evaluation and design space exploration. Using a multiphysics computational framework that integrates active stress and fluid-structure interaction, coupled with a 0D closed-loop Lumped Parameter Network (LPN) representing the Fontan circulation, we evaluate the efficiency of the pulsatile conduit by investigating variations in contraction duration, fiber direction, pumping mechanisms, and valve placement. This approach aims to discern the respective impacts and identify the most favorable design configuration.

METHODS

Based on the standard Gore-Tex graft used in the Fontan surgery, our baseline design is a straight cylinder with a height of 75 mm, an inner radius of 10 mm, and a thickness of 4.4 mm. The fluid-structure interaction simulation of the conduit considers both the structural domain of the cylinder and the fluid domain contained within. All simulations are performed using the svFSI finite element solver provided by the open-source software SimVascular [5].

For the structural wall, Holzapfel's orthotropic material model is used to represent the anisotropic nonlinear material behavior [6] and fiber directions are generated. We approximate the time-resolved active fiber stress function τ (t) along the fiber direction using a linear model [7]. This profile resembles a triangular shape, where the ascending phase encompasses 60% of the total duration time T_d and the descending phase takes up the remaining 40%. The equation for τ (t) is

$$\tau(t) = \begin{cases} \frac{5}{3} \cdot \sigma_{peak} \cdot \frac{t - t_s}{T_d}, & if\ t_s \le t \le t_s + 0.6T_d; \\ \frac{5}{2} \cdot \sigma_{peak} \cdot \frac{t_s + T_d - t}{T_d}, & if\ t_s + 0.6T_d \le t \le t_s + T_d; \\ 0, & otherwise. \end{cases} \quad (1)$$

The parameter σ_{peak} is the maximum active tension and t_s denotes the starting time of contraction. We have set σ_{peak} at 65 kPa to reflect the contractility of an adult left ventricle [7]. At the inlet and outlet of the structural domain, homogeneous Dirichlet boundary conditions are applied, ensuring that the ring-shaped outlets can expand within their planes while being restricted in their axial motion. On the outer wall, a Robin-type boundary condition is employed to simulate the support provided by external tissues.

In the fluid domain, the blood is modeled as an incompressible, Newtonian fluid with density and viscosity given by 1060 kg/m^3 and 0.004Pa · s, respectively. A 0D closed-loop LPN is implicitly coupled to the 3D fluid domain as boundary conditions to model the whole

Fontan circulation [8]. The parameters in the LPN were tuned to match the clinical data from a Fontan patient with elevated central venous pressure elevated of 16.2 mmHg. To promote unidirectional blood flow, we incorporate valves with a 0D resistive immersed surfaces valve model at the outlet and a 0D valve at the inlet.

In this study, our baseline model features fibers with a 30° helix angle, and the contraction duration, T_d, spanning 60% of the cardiac cycle. We then modify this model by shortening the contraction duration to 20% for the fast case, adjusting the helix angles to 0° to simulate a purely circumferential contraction, and varying the starting time spatially, t_s, to create a peristaltic-like compression wave. Additionally, the impact of incorporating valves at both the inlet and outlet is assessed. Through exploring these design parameters, we identify a favorable design that can significantly lower the central venous pressure.

RESULTS

The performance of the conduit was primarily evaluated by the reduction in liver (central venous) pressure obtained from the LPN, and we found this metric to be comprehensive, as a decrease in liver pressure correlates with elevated pulmonary artery pressure, enhanced stroke volume, and improved cardiac output. Table 1 summarizes the simulation results for each design parameter.

Table 1. Simulation results highlighting the hemodynamic of various contraction durations, fiber directions, pumping mechanisms, and valve placements. (Pliver = mean liver pressure [mmHg], Psvc = mean SVC pressure [mmHg], Ppul = mean pulmonary artery pressure [mmHg], SV = Stroke Volume [mL], CO = Cardiac Output [L/min]).

	Pliver	Ppul	Psvc	SV	CO
Contraction Duration					
Normal	7.2	18.4	20.7	13.2	2.9
Fast	5.0	20	22.4	15.8	3.2
Fiber Direction					
Torsional	7.2	18.4	20.7	13.2	2.9
Circumferential	6.2	19.2	21.5	13.5	3.0
Pumping Mechanism					
Peristaltic	10	16.7	18.8	13.5	2.7
Favorable Design					
Fast+Circumferential	3.3	21.2	23.6	14.5	3.4
Valve Placement					
No Inlet Valve	12.2	14.7	12.2	18.2	2.3
No Outlet Valve	14.5	13.6	15.6	29.6	2.3
No Valve	16.5	11.0	13.0	25.6	1.8

Reducing the contraction duration from 60% to 20% of the cardiac cycle, while keeping the shape and contractility constant, significantly lowers the liver pressure to 5.0 mmHg. Since the SVC connects to the pulmonary artery, the SVC pressure is correspondingly increased to 20.7 mmHg. For fiber orientations, the circumferential contraction proves to be more effective, reducing liver pressure by an extra 1 mmHg with a similar stroke volume. Contraction patterns within the conduit can be non-uniform. A common approach is peristalsis, initiating contraction at the bottom and progressing to the top, with other parameters matching the baseline model. Compared to uniform contraction, the peristaltic pump produces a less pronounced pressure gradient, but it exhibits a more gradual increase and sustains over an extended duration. It reduces liver pressure to 10 mmHg, which is less effective than the uniform pumping mechanism.

The results from exploring various design factors indicate that the most favorable conduit design combines a fast contraction profile with circumferential fiber orientation. This configuration notably reduces liver pressure to 3.3 mmHg, increases cardiac output by 59%, raises pulmonary pressure to 21.2 mmHg, and elevates SVC pressure to 23.6 mmHg.

In all valve scenarios, removing valves leads to worsened hemodynamics. Without the inlet valve, significant backflow hinders forward flow. The removal of the outlet valve further reduces performance, dropping liver pressure to just 14.5 mmHg. Removing both valves adversely impacts hemodynamics, causing recirculation near the inlet and outlet, increasing blood volume in the conduit, and significantly enlarging stroke volume.

Overall, our results show a linear inverse relationship between increases in SVC pressure and decreases in liver pressure, primarily influenced by the conduit's geometry. With a consistent geometry, any design changes that keep SVC pressure below 20 mmHg result in a liver pressure around 8.8 mmHg.

DISCUSSION

Using a computational framework, we investigate the impact of different pulsatile conduit designs on Fontan patients' hemodynamics. The favorable design identified can successfully reduce the liver pressure to 3.3 mmHg and increase the cardiac output by 59%. Our study highlights the positive pressure gradient across the conduit as a key indicator of energy transfer efficiency from the structural wall to blood flow. Due to the straight tube design, any pressure increase causes the outlet valve to open, so that blood flows downstream before contraction is fully developed. Shortening contraction duration from 60% to 20% proves beneficial in this context. In this design, the limited time available for a pressure gradient to develop may be attributed to the straight tube geometry; this underscores the importance of exploring alternative geometries in future studies.

The efficiency of pumping is also influenced by the fiber orientation. We found that the conduit with circumferential fiber orientation performs better, which contrasts with the twisting motion seen in the human ventricle. This twist is vital that enables to expel 60-70% of its volume with only 10-20% shortening of myocardial fibers. This difference may stem from boundary conditions that restrict length change. Since torsional motion inherently involves length shortening, our study may not fully capture the associated volume changes. Another important factor is the difference in geometry. The ventricle is cone-shaped, with both inlet and outlet on the same side, necessitating a 180-degree turn of blood flow within the chamber. In contrast, the cylindrical conduit has no angle change between inlet and outlet, making circumferential contraction potentially more efficient. Future studies should include a comprehensive analysis of fiber directions to determine optimal structures.

A potential limitation of the proposed design is the elevation of SVC pressure. While SVC hypertension is generally regarded as more tolerable than central venous hypertension, its long-term clinical implications are yet not fully understood. Our study indicates that using a cylindrical geometry inevitably leads to SVC hypertension. Future research should explore the placement of a valve between the SVC and pulmonary artery, as well as alternative connection configurations, to address this issue.

CARDIAC-INDUCED BRAIN TISSUE MOTION IN CHIARI MALFORMATION TYPE 1 AND ITS RELATIONSHIP TO: SURGERY, CROWDING, AND SYMPTOMATOLOGY

INTRODUCTION

Chiari Malformation type 1 (CMI) is radiologically defined as the decent of the cerebellar tonsil below the McRea line by more than 5mm [1]. The problem with this definition is that it poorly correlates with symptoms and is not predictive posterior fossa decompression (PFD) surgery outcomes [2]. Previous studies have shown that biomechanical parameters such as tissue motion differ between CMI and controls, and that brain tissue motion is more pronounced in CMI compared to healthy controls [3, 4].

In this study, we calculated brain tissue motion during a cardiac cycle for CMI subjects, assessed the displacement of patients after surgery, and compared it with their pre-surgical motion. Furthermore, we examined the relationship between brain tissue motion, specific symptomatology, and tonsillar descent.The goal of this study is to assess the relationship between tissue motion and CMI severity.

METHODS

The study participants, 48 adult CMI subjects (9 males and 39 females), had Phase Contrast Magnetic Resonance Imaging (PCMRI) at Beth Israel Deaconess Medical Center, Boston. 22 out of 48 patients underwent PFD surgery. Among the patients who underwent surgery, only eight had PCMRI scans after the procedure. All patients completed a questionnaire about their symptoms before surgery. These symptoms included cough-associated headache (CAH) (with vs. without = 34:17), neck pain (25:23), paresthesia (26:22), muscle weakness (5:43), dizziness (22:26), vomiting (8:40), problems with coordination and fine motor skills (7:41), hearing problems or tinnitus (6:42), vision problems (14:34), insomnia (5:43), and depression (7:41).

PCMRI scans were conducted using 1.5 or 3T MRI scanner (GE HDxT). These scans provided data about cerebrospinal fluid (CSF) and brain tissue motion during one cardiac cycle, acquired by ensemble averaging over many heartbeats. The images were retrospectively gated with a velocity encoding (VENC) set to 2 cm/s. For each patient, there were 31 phases during the cardiac cycle, with each phase consisting of one-component of velocity (superior-inferior direction) of 512×512 pixels in the midsagittal plane.

A MATLAB-written code was used to analyze the velocity data. Three different brain regions were investigated. These regions are: the cerebellum, the pons, and the medulla (Figure 1).

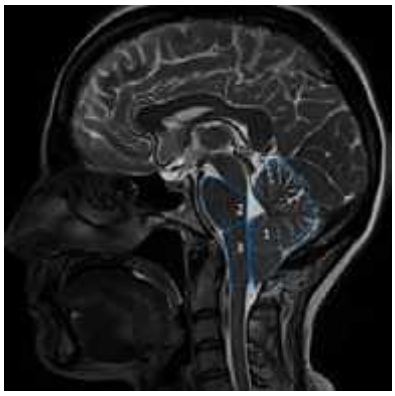

Figure 1. Three regions of interest (ROI) for displacement analysis: 1) cerebellum, 2) pons, 3) medulla

A mask was generated to segment the ROI to include brain tissue only. The velocity over the cardiac cycle for that mask was obtained. Figure 2 is an example of segmentation of the ROI.

By integrating the velocity on each ROI, the spatialy average displacement over the cardiac cycle was derived. Maximum displacement was calculated by subtracting the minimum position from the maximum position. Moreover, the spatially averaged tissue motion within a circle of diameter 5 mm was used to represent the maximum displacement within an ROI of each structure.

Cerebellar tonsillar position (TP) was measured and compared with the motion of the brain tissue. Furthermore, the displacement of the brain tissue was compared with the symptoms of the patients to identify any potential relationship between the motion and the symptoms.

Figure 2. Each region was segmented on the PCMRI image. Cerebellum is shown here

RESULTS

The displacement of brain tissue in eight patients was measured both pre-and post-surgery. There was a significant decrease in the maximum displacement in the cerebellum and medulla after surgery, 337 to 171 µm, p = 0.012 and 363 to 202 µm, p = 0.038, respectively. Figure 2 illustrates the distribution of displacement in the brainstem and cerebellum of one example CMI patient before (a and b) and after (c and d) surgery.

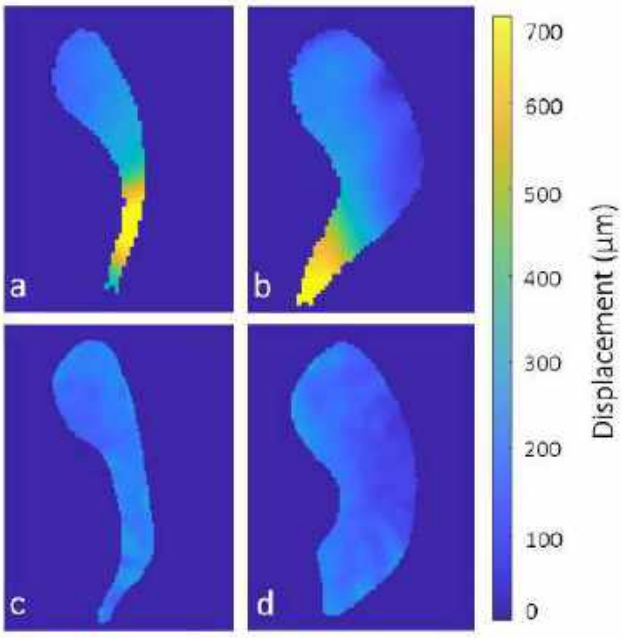

Figure 3. Example of displacement in a CMI subject before and after surgery: (a) brainstem before, (b) cerebellum before, (c) brainstem after, and (d) cerebellum after.

TP for all the patients (n=48) was measured and correlated with the brain tissue motion. TP exhibited a positive correlation with displacement in the cerebellum (r=0.52, p=0.004) and medulla (r=0.49, p=0.009).

No significant relationship was found between any of the examined symptoms. Although the CAH group has a greater motion on average, p-values comparing the two groups were not significant.

The displacement between the group that underwent surgery and the group that did not undergo surgery was compared, but no significant difference was observed.

DISCUSSION

Many researchers have examined brain tissue motion in CMI patients [2, 4-6]. Eppelheimer et al. and Radmanesh et al. demonstrated a significant decrease in tissue displacement in the cerebellum and brainstem after surgery [7, 8]. Eppelheimer et al. use Displacement Encoding with Stimulated Echoes (DENSE) MRI while Radmanesh et al. used trueFISP (fast imaging with steady-state free precession) to measurement brain tissue displacement. Our results demonstrated a similar pattern in decreasing displacement after surgery using PCMRI for the measurement. Our results showed that PCMRI can identify similar trends compared to DENSE and trueFISP which is interesting given the wider accessibility of PCMRI. It should noted that the displacement in the pons did not show statistically signficanant difference after surgery, only the medulla showed this difference. Considering that the increasing herniation of the cerebellar tonsil results in crowdedness at the foramen magnum, cerebellar and medullary motion increases with greater neural crowdedness. This result matching the finding by Mohsenian et al. which showed good correction between resistance to CSF motion and brain tissue displacement [5].

Our results also indicate that there is no relationship between the brain tissue motion and symptoms examined. Similarly, Eppelheimer et al., Al Samman et al., and Dawes et al. did not find a relationship between brain tissue motion and CMI symptomatology [4, 6, 7]. A study by Collin's et al. did find a significant different in tonsillar motion and snoring [9]. Our study did not examine snoring. However, Collin's et al. did not find a significant difference for balance and neck pain which were examined in the present study. Our findings in addition to previous work by others using different methodology and CMI subjects implies that tissue motion is not related to CMI symptomatology which is an important finding towards understanding the pathophysiology of CMI.

No significant difference was observed in the displacement between the surgical and non-surgical groups for any of the examined brain regions. It is important to note that the decision to have surgery or not depends on the patient's choice and factors like pain tolerance which explain the lack of difference between these two groups.

INTRODUCTION

Intracranial aneurysms involve weakened areas of brain blood vessels that can form sacs filled with blood. When these aneurysms rupture, they cause subarachnoid hemorrhages, a life-threatening condition affecting around 30,000 individuals annually in the United States. Common treatments include surgical clipping and endovascular coiling, while flow diversion devices (FDD) offer a newer alternative. FDDs are fine-mesh tubular stents that restrict blood flow into an aneurysm, potentially altering blood flow patterns. Analyzing the blood flow's hemodynamics inside aneurysms can identify specific parameters, aiding in predicting favorable patient responses to stenting and understanding why some aneurysms grow, an undesirable outcome. This research examines eight patients post-stenting, analyzing fluid simulations using Lattice Boltzmann Method (LBM) D3Q27 via C++ programming in conjunction with Paraview software for visual hemodynamic analysis. By comparing hemodynamics and treatment response, crucial parameters such as wall shear stress and blood flow velocity distribution within aneurysms can be identified to predict stenting success in patients. The aim is to establish new criteria by monitoring aneurysm growth over time, distinguishing between stable and growing aneurysms. Approximately 6.5 million Americans have unruptured brain aneurysms, and annually, 30,000 experience rupture. Early detection is challenging due to lack of symptoms, making it difficult for clinicians to anticipate aneurysm stability or growth. Hence, monitoring aneurysm growth becomes vital for preventing rupture. This study involves reconstructing 3D geometries of aneurysms and parent arteries from patient-specific CT-scans. Pulsatile blood flow simulations within these 3D models quantify hemodynamic characteristics.

METHODS

The methodologies employed encompass several key elements:

Lattice Boltzmann Method (LBM)

LBM simulations progress based on the lattice Boltzmann equation [1]. Expressed with the LBM particle distribution function f and employing the single relaxation time (BGK) collision operator, the equation can be formulated separately for each distribution component f_i.

$$f_i(\boldsymbol{X} + \boldsymbol{c}_i, t+1) = f_i(\boldsymbol{X}, t) - \frac{1}{\tau}(f_i(\boldsymbol{X}, t) - f_i^{eq}(\boldsymbol{X}, t)) \quad (1)$$

$$f_i(\boldsymbol{X} + \boldsymbol{c}_i, t+1) = f_i^{eq}(\boldsymbol{X}, t) + (1 - \frac{1}{\tau}) f_i^{neq}(\boldsymbol{X}, t) \quad (2)$$

$$f_i^{neq} = f - f_i^{eq} \quad (3)$$

$$f_i^*(\boldsymbol{X}, t) = f_i^{eq}(\boldsymbol{X}, t) + (1 - \frac{1}{\tau}) f_i^{neq}(\boldsymbol{X}, t) \quad (4)$$

$$f_i(\boldsymbol{X} + \boldsymbol{c}_i, t+1) = f_i^*(\boldsymbol{X}, t) \quad (5)$$

Complex Geometry Handling

Generating uniformly spaced points within complex geometries, as represented by STL files, demands significant time and memory resources due to their intricate nature. The nature of this task entails considerable computational complexity. Additionally, within the LBM, the collision and streaming steps further highlight the need for efficient computational strategies, making MPI (Message Passing Interface) a crucial choice.

In our simulation, the STL file, which serves as a triangulated representation of the complex geometry, is divided across multiple processors to facilitate two distinct yet interrelated processes. Firstly, this distribution aids in efficient collision detection [2] within the

complex geometry. The utilization of MPI optimizes this computation, recognizing the challenge of identifying points within the intricate geometry. To further optimize this process, an Octree [3, 4] data structure is incorporated. This data structure efficiently partitions computations based on spatial hierarchy, significantly improving the collision-detection efficiency within the LBM context.

Post-division, each processor handles its allocated portion of the geometry, conducting collision and streaming operations. The utilization of MPI across various simulation stages, encompassing point generation within complex geometries and the collision and streaming processes in the LBM, yields a unified and highly efficient computational framework. This strategic use of MPI optimizes communication and workload distribution among processors, resulting in enhanced scalability, performance, and overall simulation efficiency. Its application at critical stages significantly accelerates computations while efficiently handling intricate geometries, collision detection, and LBM steps.

Boundary Conditions Implementation

In our simulation, we applied specific boundary conditions to accurately model fluid behavior. The inlet velocity used the Zou-He condition [5], while the walls were set with a bounce-back condition ensuring no-slip behavior. At the outlet, a constant pressure boundary condition was applied. These conditions collectively ensure precise representation of fluid flow dynamics within the computational domain.

Numerical Results

Reconstructed Geometry

In the subsequent section, we implemented the methodology outlined in the preceding section to reconstruct the vasculature and generate the LBM grid points.

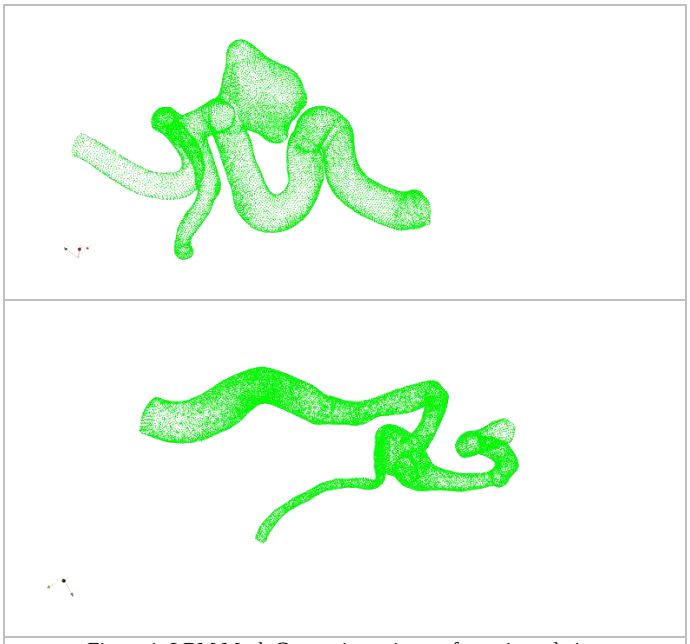

Figure 1. LBM Mesh Generation using surface triangulation

Parabolic Inlet Velocity and Boundary Conditions

In our first test case using cylindrical geometry, we utilized a parabolic velocity profile at the inlet. To accurately represent the inlet flow conditions, we applied the Zou-He boundary condition. This combination enabled precise simulation of fluid flow dynamics within the cylindrical domain.

Pulsatile Flow Simulation

In the subsequent phase, we introduced pulsatile flow within the complex geometry to analyze fluid dynamics. Our focus was on extracting the velocity field and assessing wall shear stress distribution. The aim is to correlate fluctuations in wall shear stress to potential implications for aneurysm growth or post-treatment conditions. This investigation aims to establish connections between fluid-induced mechanical forces, specifically wall shear stress variations, and their possible influence on the progression or alteration of aneurysms, contributing valuable insights into their pathophysiology and treatment outcomes.

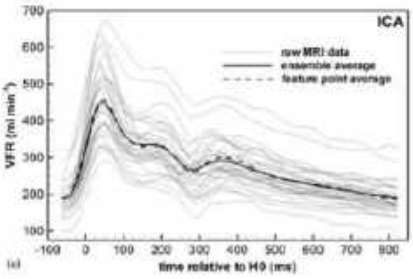

Figure 2. Temporal Profile of Pulsatile Flow: Volumetric flow rate variations over time relative to reference point H0, illustrating the pulsatile nature of fluid dynamics.

Results

In Figure 3, we showcase MPI domain decomposition for collision and streaming steps, with each color denoting a processor. Figure 4 illustrates initial and boundary conditions. Subsequent drafts will feature velocity and WSS distribution.

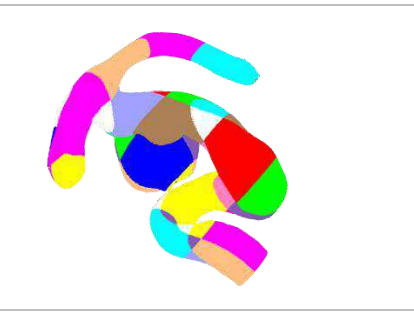

Figure 3. MPI domain decomposition

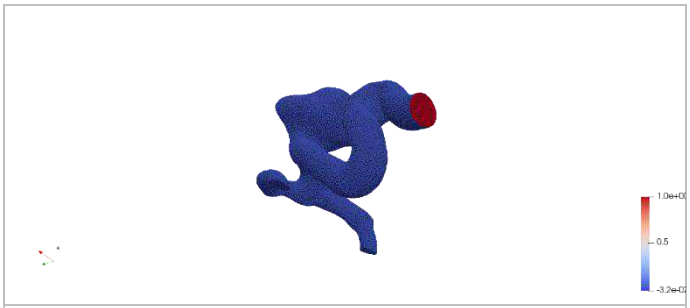

Figure 4: Initial and Boundary Conditions

DISCUSSION

Our study aims to explore the relationship between wall shear stress (WSS) fluctuations and post-stenting aneurysm behavior. Evidence indicates that changes in WSS levels within aneurysms may indicate alterations in their stability or growth after treatment. Elevated or fluctuating WSS has been linked to aneurysm development, while effective treatments seek to reduce WSS by modifying blood flow patterns. Using computational simulations through the Lattice Boltzmann Method (LBM), our objective is to uncover the link between WSS changes and aneurysm response post-stenting. This understanding could assist in predicting treatment outcomes and distinguishing between stable and potentially growing aneurysms. While WSS is crucial, considering other hemodynamic parameters, like flow velocity distribution, will offer a more comprehensive prognosis.

WNT-11 AND SOST ARE REGULATED BY DIFFERENT MECHANICAL STIMULI IN LOADED BONE

INTRODUCTION

Osteoporosis is the most common metabolic bone disease characterized by the degradation of trabecular bone in the spine, proximal femur, and distal radius. Bone adaptation, particularly in response to mechanical loading, is primarily directed by osteocytes, which differentially express several genes in response to mechanical loading [1]. However, the specific mechanical cues osteocytes respond to are unknown. To determine the immediate response of osteocytes to mechanical loading, it is necessary to study the transcriptomic response of osteocytes. We found that SOST is downregulated, and Wnt-11 is upregulated following loading using bulk RNA sequencing [2]. SOST codes for the protein sclerostin which is an antagonist of the Wnt/β-catenin signaling pathway, a major driver of osteoblastogenesis and osteoblast differentiation [3]. Wnt-11 is involved in both canonical and non-canonical Wnt signaling and is necessary for osteoblastogenesis [4]. Trabecular bone is mechanically heterogeneous and there are regions of the bone that experience no strain while other regions experience relatively high strain. Hence, bulk sequencing aggregates the transcriptional response and cannot provide insight into the tissue strains that affect osteocyte gene expression. The goal of this study is to quantify the relationship between gene expression and local tissue strain by spatially mapping expression of Wnt-11 and SOST and finding the strains at the locations of cells that both express and do not express these genes.

METHODS

Cylindrical bone explants (N=8) from the cervical vertebra of mature female pigs were cultured in a bioreactor. Male pigs were excluded because they are typically castrated which could confound result interpretation. After 48h, the explants were subjected to two bouts of 1200 cycles of compressive loading to 196 N with 1 hour between bouts daily for 3 d. In addition, four control samples were cultured without loading. Samples were fixed 6 h after the final load, and were demineralized and embedded in paraffin, and 5 μm thick sections were prepared. The sections were stained using RNAScope Multiplex Kit (ACD, Newark, CA) for SOST and Wnt-11 using custom probes designed by ACD. Random areas covering 15% of the stained sections were imaged at 20x magnification using confocal microscopy (Nikon AXR) (Fig 1A.). Osteocytes were identified using a custom workflow and the intensity of the signal for each probe was measured. Approximately 1000 osteocytes were counted in each sample.

Samples were μ-CT scanned immediately after being removed from the bioreactor and finite element models were created to determine the deviatoric tissue strain corresponding to the measured displacement during loading. The tissue modulus was assigned based on the tissue mineral density [5].

The stained RNAScope labeled sections were aligned to the finite element results (Fig. 1B) to provide a mapping of the locations of the osteocytes and strain at all locations in the bone. We then calculated the mean strain within 10 μm of cells expressing or not expressing each gene in the loaded bone.

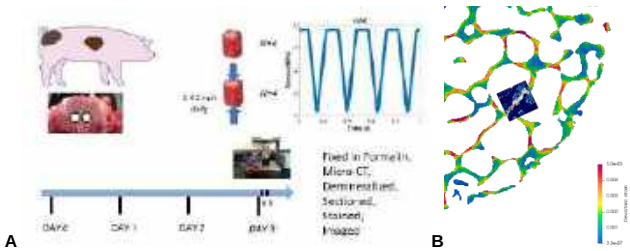

Fig. 1. A) Cervical bone explants were cultured in a bioreactor for 48 h after which samples were compressively loaded to 196 N. 6h after the final load, samples were fixed, μ-CT scanner, demineralized, sectioned, stained, and imaged. B) Histological sections for each gene were aligned to the corresponding location on the finite element model.

RESULTS

Using RNAScope, the intensity of the signal increases with the number of RNA molecules in each cell. The fraction of cells expressing less than

a specified threshold intensity was calculated, and a logistic curve was fit (Fig. 2). More osteocytes expressed SOST at high levels in the unloaded than in the loaded samples. In contrast, more cells expressed Wnt-11 at high levels in the loaded bones (Fig. 2). In order to quantify the difference between the loaded and unloaded groups across all thresholds, we fit a logistic curve to each sample and measured the difference in the characteristics of the curve. For SOST, the symmetric inflection point was significantly different between the loaded and unloaded samples (p=0.017). On the other hand, the threshold decay rate was significantly different for Wnt-11 expression (p=0.042).

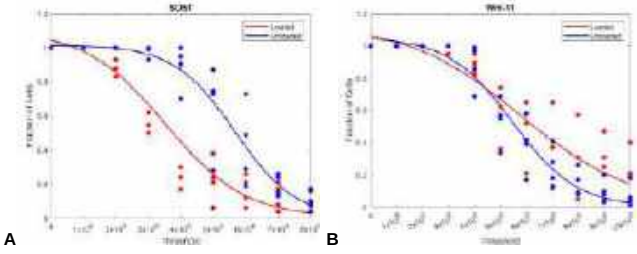

Fig. 2. A) More osteocytes expressed SOST at higher levels in the unloaded compared to loaded samples. B) More osteocytes expressed high levels of Wnt-11 in loaded vs. unloaded samples.

We chose intensity thresholds of $3x10^6$ for SOST and $9x10^6$ for Wnt-11 to differentiate high (+) and low (-) expression. For SOST, this threshold was where the number of cells in the unloaded bone starts to decrease from 100% positive. For Wnt-11, the loaded and unloaded groups did not differ until higher thresholds. We chose a level near the maximum threshold. We first looked at how the expressions of these genes relate to each other. We found that differential expression of Wnt-11 and SOST following loading occurred in different cell populations.

Approximately 80% of the cells that were Wnt-11+ were also SOST+, suggesting that Wnt-11 upregulation is not coincident with SOST suppression. However, 92% and 68% of the SOST+ cells were Wnt11- in the unloaded and loaded bone, respectively (Fig. 3). As such neither upregulated nor downregulated SOST expression implied Wnt-11 upregulation.

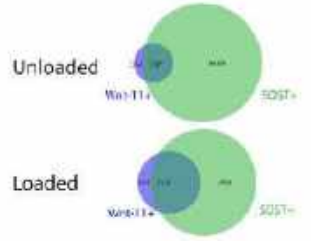

Fig. 3. The Venn diagrams show the fraction of all the cells that highly express Wnt-11 only, SOST only, or both Wnt-11 and SOST.

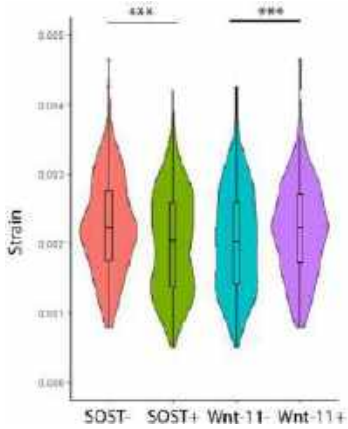

Fig. 4. The average strain near SOST- cells was higher than the strain near SOST+ cells while the average strain near Wnt-11+ cells was higher than the average strain near Wnt-11- cells (*** p<0.0005).

Lastly, we found the mean strain within 10 μm of each osteocyte (Fig. 4). The average strain near SOST- cells was 2254 ±689 με vs. 2009 ±731 με (mean ± S.D.) in SOST+ cells ($p < 0.0005$). In contrast, the average strain near Wnt-11- cells (2037±742 με) was lower than that near Wnt-11+ cells (2181±659 με) ($p < 0.0005$). The strain near SOST- cells was also significantly greater than the strains near Wnt-11+ cells ($p = 0.015$), while there was no difference in the average strain surrounding SOST+ and Wnt-11- cells.

DISCUSSION

The goal of this study was to investigate the spatial heterogeneity of the transcriptional response of osteocytes during mechanical loading. We identified subsets of osteocytes where the differential expression of SOST and Wnt-11 was consistent with bulk sequencing results [2]. However, the differential gene expression was not uniform. We found that most Wnt-11+ cells are also SOST+, but the majority of SOST+ cells are not Wnt-11+. However, the strain associated with Wnt-11+ cells was higher than that surrounding SOST+ osteocytes, on average (p=0.015), yet lower than SOST- osteocytes. This suggests that the conditions for Wnt-11 upregulation in response to mechanical loading differ from those for SOST downregulation. For example, Wnt-11 regulation may depend on the volumetric strain or combinations of strain measures. Indeed, the heterogeneity of the strain surrounding both SOST- and Wnt-11+ cells suggests that deviatoric strain is a weak indicator of osteocyte response.

Our study is unique in that we quantified the range of gene expression in individual cells and identified the strain in the tissue surrounding our cells of interest. This allowed us to capture strain and location dependence of gene expression that cannot be detected by bulk sequencing. However, our results may be sensitive to the threshold chosen for differential expression. RNAscope probes tag individual molecules, resulting in a gradient of fluorescence as the number of transcripts increases. We chose thresholds based on levels that ensured a difference in the fraction of positive cells between the loaded and unloaded bone. For SOST, this occurred at a low threshold and most cells were SOST+ in both loaded and unloaded bone. On the other hand, Wnt-11 expression only differed between loaded and unloaded bone at high thresholds. Further analysis with different thresholds is important to quantify the sensitivity.

Our study complements a recent study that measured the spatial expression of SOST and CTSK in cortical bone [6]. They found that the largest changes in the expression of these genes occurred in the regions of bone with the highest deformation. We similarly found that strain was higher surrounding osteocytes with differential SOST and Wnt-11 expression relative to unloaded bone.

Mechanical loading does not result in a uniform differential expression of all genes in osteocytes. Rather, differential gene expression varies based on the local mechanical environment, which in turn could drive spatially heterogeneous bone adaptation and paracrine effects in the local marrow resident cells.

INTRODUCTION

Traumatic brain injury (TBI) is a major cause of death and disability worldwide. In 2014, 2.53 million emergency visits, 288,000 hospitalizations, and 56,800 deaths related to TBI were documented in the United States by the Center for Disease Control [1]. Even mild TBI increases the risk of neurodegenerative disorders such as Parkinson's [2] and Alzheimer's disease [3]. Some important questions about species-specific and genotype-specific pathology in TBI are difficult to address with conventional rodent models. Human induced pluripotent stem cell (hiPSC) derived brain organoids have the potential to address these questions because they reproduce human pathophysiology and allow precise manipulation of the genotype [4]. Here we mechanically compressed brain organoids at strain magnitudes and rates relevant to clinical TBI and measured the resulting pathology.

METHODS

Cortical organoids were cultured from WTC11 hiPSCs (GM25256, Coriell) for 83 days before injury. Organoids from the same batch were fixed using 4% PFA on day 60 and sectioned for quality control purposes. Sections were mounted on glass slides and stained with MAP2 and S100B to identify mature neurons and glial cells, respectively. The custom injury device includes a stainless-steel indenter mounted on a vertically moving stage driven by a voice coil under closed-loop feedback control (Fig. 1). The injury device was used to measure organoid heights. The zero position was defined as the position at which the indenter was directly in contact with an empty chamber's bottom surface. Organoids were then placed in the chambers and their heights were calculated as the difference between the zero position and the position at which the indenter contacted the organoid. After height measurement, organoids were dynamically compressed between a fixed stage and the indenter. Organoids were compressed by 15, 25, 35 or 45% of their initial height and released in a period of 30 milliseconds. For the sham injury procedure, organoids were contacted but not compressed. Mitochondrial membrane potential was assayed using 3D confocal microscopy and tetramethylrhodamine methyl ester perchlorate (TMRM) staining. TMRM is a cell-permeable, positively charged small molecule stain that accumulates in healthy mitochondria. Injured and sham organoids were stained with 100nM TMRM 3 hours after trauma and incubated at 37°C for 1 hour. A series of fluorescence images were acquired using the 3D Z-stack feature of an Olympus FV3000 confocal microscope. Captured images were projected into a single plane for analysis. Projected images were segmented and analyzed using CellProfiler software to measure the mean intensity of TMRM fluorescence in each organoid.

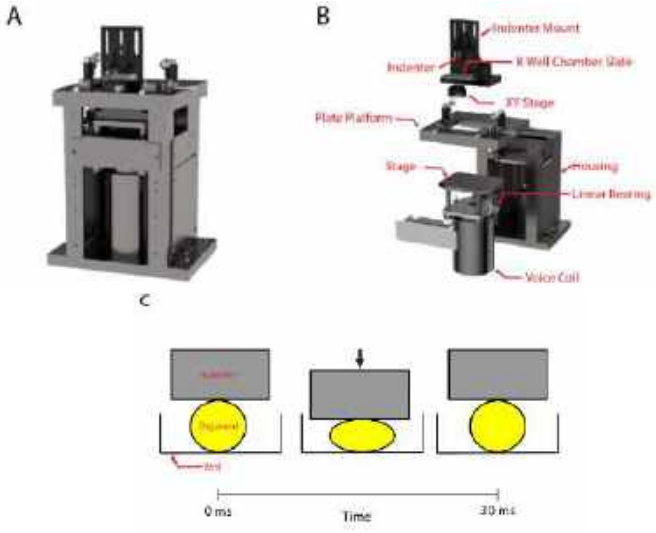

Figure 1: (A) Custom-built injury device. (B) Exploded view of custom-built injury device. (C) Schematic of the sequence of events during injury.

Supernatant was collected from individual organoid-containing wells and NF-L concentration was measured using an ELISA assay.

RESULTS

Organoids stained positive for MAP2 and S100B, indicating the presence of mature neurons and glial cells. (Fig. 2)

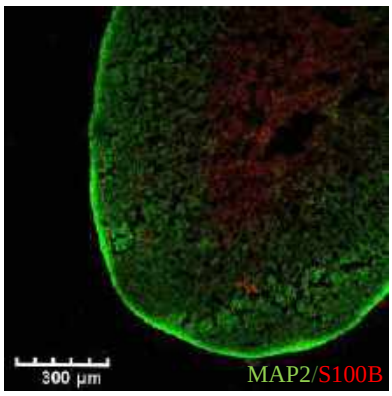

Fig.2: Organoid section stained positive for MAP2 and S100B.

The fluorescent TMRM signal declined steadily with increasing trauma severity (Fig. 3).

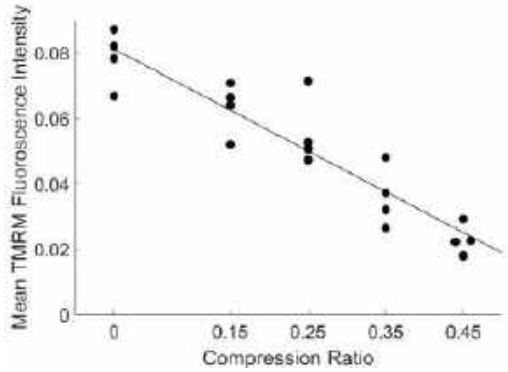

Fig. 3: Linear regression of the effect of various levels of trauma on TMRM fluorescence intensity (R^2=0.856). Compression ratio represents the percentage reduction in the initial height of organoids subjected to compression.

The injury protocol increased the concentration of NF-L in the culture media (Fig. 4). However, there was no clear dependence of NF-L concentration on trauma severity. The absolute concentration of NF-L was low and close to the bottom end of the standard curve used for quantification, suggesting that the volume of cell culture media was greater than the ideal value.

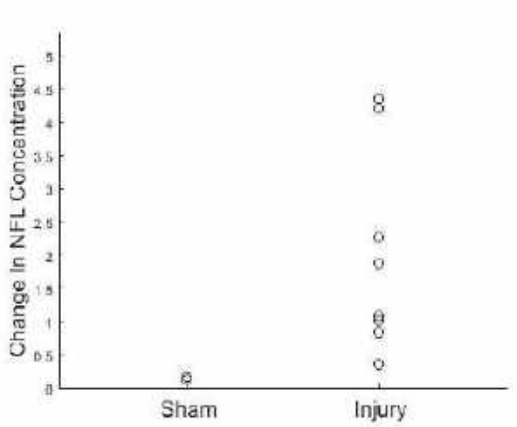

Fig.4: The effect of trauma on NF-L concentration.

DISCUSSION

Dynamic compression of organoids *in vitro* reproduced several important phenotypes of clinical TBI. It disrupted mitochondrial function in a dose-dependent manner (see Fig. 2), consistent with prior studies in other *in vitro* models [5], small animal models [6], and in human subjects [7]. Mitochondrial dysfunction appears to mediate vulnerability to subsequent head impacts after TBI [8]. We also observed post-traumatic mitochondrial dysfunction in an earlier version of the model that did not normalize compression to the initial height of the organoid. However, the data was more variable in that case [4], suggesting that normalizing the compression to the height improves consistency. Although we did not observe a linear relationship between NF-L concentration and trauma severity, the increased NF-L concentration in the trauma group raises the exciting possibility of using clinically validated TBI biomarkers [8, 9] as outcomes in drug discovery studies employing traumatized human cortical organoids.

THE POMELO PEEL AS IMPACT PROTECTION FROM FALL-RELATED FEMUR FRACTURE: MECHANICAL AND BIOLOGICAL PROPERTY INVESTIGATION

INTRODUCTION

Falls from a standing height are the most common mechanisms of injury for the older adult population with hip fracture from fall being a leading cause of morbidity and mortality [1,2]. Wearable hip pad protection has been recommended to prevent fracture from falls [3] but use has been limited due to wearability and efficacy issues [4]. There is a need to do better. Natural materials may offer properties that can overcome the barriers of current hip protection. The pomelo (*citrus maxima*) peel is a naturally available foam-like material that is renowned for its ability to dissipate large amounts of energy from impact [5]. The purpose of our work is to examine natural and synthetic impact resistant materials through cross-disciplinary experimentation to establish material characteristics most valuable for hip fracture prevention from a fall.

METHODS

Testing included two mechanical (drop weight impact testing, compression creep testing) and two biological (scanning electron microscopy, proteomic analysis) assessments of the pomelo peel, with comparison to select market-available hip impact protectors.

Impact testing: A customized Dynatup 8250 Drop Weight Impact Tester was calibrated to meet the Canadian Standards Association Hip Protector Z325:20 testing standard (CSA, 2020) [6], designed to meet the impact force and velocity specifications expected from a sideways ground level fall of an older adult (2500-3000 N, 2.9-3.2 m/s). The assembly was used to test 16 materials (fall-related hip protectors, sport hip protectors, and pomelo peel). The attenuated peak force (APF) was calculated through equation (1) [6]:

$$APF = (1-(Fp/Fb)) \times 100 \quad (1)$$

[Where Fp = average over the three trials in peak recorded force for a given specimen; Fb = average over the two confirmatory trials in the peak recorded force with no specimen]

Creep testing: Uniaxial, direct load compression creep testing was performed utilizing a Bourns Series 3048 linear potentiometer, a flat 7 mm diameter indenter stabilized by linear bearings, and a voice coil actuator applying a 1N constant force at 20 Hz sampling rate. A single exponential model of analysis was applied to the creep testing data to establish the elastic deformation, viscous deformation, and a time constant. From these variables, viscous stiffness (2) and viscosity (3) were calculated:

$$k = f/\delta \quad (2)$$

[Where k = stiffness (N/m); f = force (N); δ = deformation of the test specimen (m)]

$$\eta = \tau \cdot \kappa_2 \quad (3)$$

[Where η = viscosity (Ns/m); τ = time constant (s); κ_2 = viscous stiffness (N/m)]

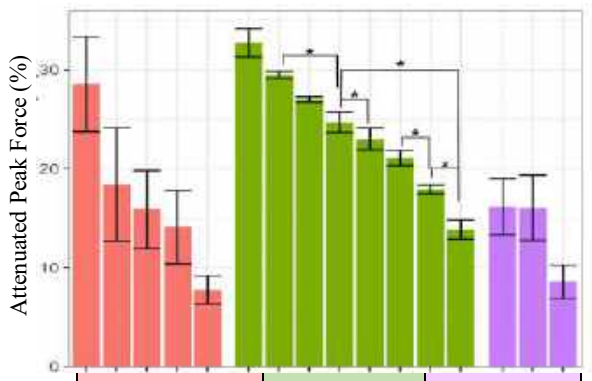
Scanning electron microscopy: Finite element scanning electron microscopy (FESEM) imaging was performed on samples of the surface, internal, and cross sections of each experimental material with a JEOL JSM-7900 FESEM. Pomelo samples were chemically dried prior to imaging. Quantitative comparison of surface and internal cell number fraction with micropores, mean cell size, and cell volume fraction for each material was established with ImageJ software. Correlation analyses and t-tests were performed.

Proteomic analysis: Consistent with a bottom-up proteomics approach [7], protein isolation, gel electrophoresis, and mass spectrometry (MS) were used to isolate and identify proteins in the pomelo peels of two pomelo. These methods established the pomelo proteome, with specific examination for the presence of elastomeric proteins within the peel.

RESULTS

Force Attenuation: Peak force reductions of 32.7%, 28.5%, and 20.1% were achieved by the best performing fall hip pad, sport hip pad, and pomelo peel, respectively. As a biologic material, pomelo peel was

expected to, and did, demonstrate considerable within-category standard deviation, although synthetic material categories of fall and sport hip padding showed variances within the same range as pomelo (Figure 1).



Category	Sport Padding	Fall Padding	Pomelo Peel
Variety (count)	Fig. skate (2), Jr. Hockey(2), Jr. Football(1)	Soft shell hip pads (8)	All red, source (3)
Samples	10	22	9
APF (%)	17.24	24.04	10.78
St. Dev. (%)	7.86	5.77	4.37

Figure 1: Attenuated peak force comparison by category. Error bars indicate APF standard deviation (%). Significance within category materials noted by '*' for $p<0.05$.

As the fall hip padding category had the greatest number of materials with high APF capacity, investigation for viscoelastic properties and cell structure characteristics preceded inclusion of that from other material categories (Table 1).

Table 1: Top APF fall hip padding multiple variable examination. Pearson correlation statistic (r=coefficient; p=significance)

n=6	Stiffness (N/m)	Viscosity (N*s/m)	Cells with micro-pores (%)	Mean cell size (µm)	Cell volume fraction (%)
r	-0.280	0.853	0.708	0.577	0.625
p	0.591	0.031	0.116	0.231	0.185

Stiffness/Viscosity: Viscous stiffness of fall hip padding materials demonstrated a weak inverse correlation to APF but a strong and significant direct correlation with viscosity (Table 1.) Within pomelo peel samples, both viscosity and stiffness have strong and significant correlations to APF (r=-0.99,p=0.04; r=0.99,p=0.05, respectively). Using t-testing to compare the highest APF pomelo peel and fall hip pads, a significantly higher stiffness in the pomelo material is demonstrated ($p<0.001$) while viscosity difference is not significant (p=0.15, power =.84).

Cell Morphology: Internal SEM imaging of synthetic fall hip padding samples demonstrated moderate positive correlations between cell fraction with micropores, mean cell size, and cell volume fractures compared with APF material performance (Table 1). Observational comparison of a pomelo peel with a fall hip pad sample revealed substantial differences in overall morphology and cell variability (Figure 2). The pomelo demonstrates a highly porous, strut laden structure while the hip pad provides a typical image of a compact open cell foam structure with observable micropores.

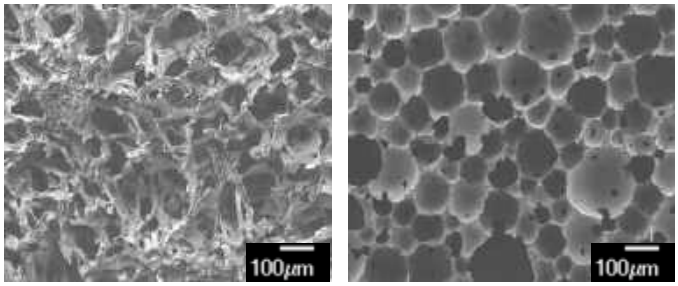


Figure 2: SEM micrographs of internal samples of pomelo peel (*left)* and a fall hip pad (*right)*.

Proteomics: SDS-PAGE gel with Coomassie staining of two domestic (U.S.) pomelo peels yielded generalized visualization of proteins including protein existence in the range for elastomeric proteins (11.5-60 kDa). There was no evidence of elastomeric proteins within the pomelo peel when run against the citrus database nor with specific search for known elastomeric protein sequencing.

DISCUSSION

This work demonstrated that the pomelo peel performs comparably to currently available synthetic hip padding. The biologic and structural reasons for its impact resistance are informative for their differences from existing materials. For example, while viscous stiffness was only very weakly correlated with hip pad APF, it was strongly correlated for pomelo peel. This suggests that there are structures of the pomelo that are designed to manage stiffness for an impact resistance advantage. Further, while all materials examined in this study are porous, pomelo differs substantially demonstrating 'struts' (similar to trabeculae in cancellous bone) suggestive of another potentially advantageous padding advancement.

This work reveals that the differences between biologic and synthetic materials may be the key to a superior material design for impact resistance. The pomelo peel could inform hip fracture prevention from falls and thereby be lifesaving by preventing injury.

Further work includes full analysis of the pomelo peel from SEM imaging, optical microscopy to examine the pomelo peel in its natural, hydrated form, and detailed characterization of the pomelo peel's strut framework.

REDUCED LOADING AFTER SCIATIC NERVE RESECTION IMPAIRS HINDLIMB GROWTH AND MATURATION

INTRODUCTION

Mechanical forces during growth and development are vital for musculoskeletal tissue formation and maturation. Load bearing tissues such as tendons respond to mechanical cues to maintain "tensional homeostasis." For example, tenocytes respond to altered loading by fine tuning the formation and degradation of extracellular matrix proteins [1]. Similarly, reduced loading can increase bone resorption while decreasing formation [2]. Both excessive and insufficient loading are implicated in the disease etiology of musculoskeletal tissue. Manipulation of mechanical loads through implementation of rehabilitative loading exercises promotes repair processes that may culminate in improved restoration of normal structure and function [3]. Understanding the role of mechanical loading on developmental processes of load bearing tissues can improve our understanding the mechanosignaling events that drive tissue formation and maturation while potentially providing insights to guide new therapies.

Growth of load bearing tissues is predominantly governed by cell proliferation and extracellular matrix (ECM) production. For instance, rapid tissue growth occurs in early postnatal stages and this period is when growth can shift from cell proliferation dominant to matrix production dominant, especially in tendons. Here, we performed sciatic nerve resection (SNR) in both neonatal mice (surgery performed on postnatal day 1) and adult mice (surgery performed at 22 weeks of age) (**Fig. 1)** to explore how reduction in loading impacts the growth and maintenance of hindlimb load bearing tissues. Performing SNR in neonates and adults allows us to explore the age-related differences in response to mechanical loads and investigate the mechanisms behind these differences.

We hypothesized that reduced mechanical loading of the hindlimb after SNR would impair both the growth and maintenance of load bearing tissues. The reduced input in neonates will lead to attenuated growth whereas reduced loading in adults will lead to tissue resorption.

METHODS

All animals and procedures were approved by UPenn's IACUC. Unilateral left sciatic nerve resection (SNR) was performed as previously reported by our group [4] in neonate (postnatal day 1, P1) and adult (22-week-old) male and female mice. Gait Analysis. Video gait analysis was used to measure gait parameters at P14 in the neonate group and 14 days after injury (D14) in the adult group. MicroCT. Excised hindlimbs from each group of mice were scanned on a Scanco μCT45 scanner to measure tibial bone parameters. Because of difficulty in measuring bone parameters in P14 mice, limbs from the neonate group were scanned at only P42 whereas adult limbs were scanned at both D14 and D42. Cryohistology. Hindlimbs were harvested, formalin-fixed, embedded in OCT, and cryosectioned (8 μm) in the transverse plane using Cryofilm 2C. Fluorescent imaging with a nuclear counterstain followed by brightfield imaging with toluidine blue staining was performed. Image Analysis. Achilles tendon cross-sectional area and cell density were quantified using Fiji. Statistics. Gait parameters between SNR and control groups were compared via one-way ANOVA with Tukey's HSD post-hoc comparisons ($p<0.05$). SNR limb vs. contralateral limb were compared via paired t-tests for all other assays ($p<0.05$).

RESULTS

Neonatal and Adult SNR impaired gait. Video gait analysis 14 days after SNR (P14 and D14) was used to assess changes in gait parameters that would inform hindlimb loading patterns. SNR limbs exhibited sustained gait perturbations compared to contralateral limbs, including reduced paw print width (a hallmark of sciatic denervation) reduced ankle angle at both paw strike and lift off, and reduced distance from the hock to the ground (hock height) at lift off ($p < 0.01$, **Fig. 2**). These impairments persisted to later time points as well (data not shown).

Neonatal SNR altered Achilles tendon morphometry and mechanical properties. Neonatal SNR significantly decreased Achilles

tendon cross sectional area (CSA) at P14 and P42 ($p<0.05$, $p<0.01$, **Fig. 3A**) with reduced the total number of cells per cross section ($p<0.05$) and an increasing trend in cell density ($p=0.08$). SNR had much less of an effect in adults with only decreasing trends in cells per cross section and cell density at D42 ($p=0.07$, $p=0.09$, **Fig. 3B**).

Neonatal and Adult SNR altered bone morphogenesis. As SNR has been shown previously to affect bone growth, we quantified both trabecular and cortical bone morphometry in the tibia [5]. Neonatal SNR reduced trabecular bone volume fraction (BV/TV) and trabecular thickness ($p<0.05$, **Fig. 4A**) in the proximal metaphysis and reduced cortical polar moment of inertia (**Fig. 4B**) at P42. These data correspond with reduced tibia lengths reported by our group previously [4].

Adult SNR reduced BV/TV, BMD, trabecular number, and trabecular thickness, at both D14 and D42 ($p<0.05$, **Fig. 5A**). Adult SNR did not alter cortical bone parameters at D14, but significantly reduced cortical area and cortical thickness by D42 ($p<0.05$, **Fig. 5B**).

DISCUSSION

Here, we demonstrate that disruption of ambulatory mechanical loading by sciatic nerve resection alters tendon and bone morphogenesis in both neonatal and adult mice. The reduced hindlimb loading affected postnatal growth and adult tissue maintenance in the Achilles tendon and tibia. Neonatal SNR reduced Achilles tendon cross-sectional area and cells per cross section within 14 days, indicating that mechanical loading directs postnatal tendon growth. However, SNR in adults only led to trends in these parameters, suggesting that adult tendons may be less sensitive to the decreased loading from SNR compared to the rapidly growing neonates. As de-tensioning can lead to a catabolic tissue response [6], future work will investigate this mechanism at both ages. The differential effects of loading on tissues were also exemplified in the micro CT data. The reduced trabecular and cortical properties in the Neonate SNR group was likely a result of reduced growth. While the reduced bone volume in the Adult SNR group was likely a result of bone resorption, which we are in the process of analyzing via dynamic histomorphometry. We found differences in the onset of bone loss between trabecular and cortical bone, as trabecular bone is typically more sensitive to altered loading.

Given the results of this study, there are open questions related to the differential response between neonate and adult tissues. The matrix turnover rates are known to be different in both tissues between postnatal growth and adult homeostasis, which may contribute to the ability of these tissues to respond to the altered loading. In addition, the required mechanical inputs required for growth may be quite different than those in homeostasis. Future work will investigate the mechanosignaling events that regulate matrix assembly/turnover in this model system as elucidating these specific mechanisms can provide insights into rehabilitation strategies to treat injuries and disease.

INTRODUCTION

In the US, breast cancer is the most common new cancer diagnosis among women [1], with approximately 50% undergoing mastectomy [1]. Breast reconstruction surgery (BRS) often involves tissue expansion (TE), where a silicon expander is gradually inflated under the skin, promoting tissue growth. However, when combined with radiotherapy (RT), patients may develop radiation-induced fibrosis (RIF), characterized by increased collagen deposition and tissue stiffening [2]. Unfortunately, there is only superficial knowledge of how dermal collagen architecture and skin mechanical properties change in vivo in the presence of RT and TE. Here, we use the preeminent large animal model for human skin, the swine, to measure skin deformation, growth, change in collagen architecture, and change in mechanical properties in three different skin study groups: control (CTRL), radiated (XR) and radiated and expanded (XRTE) skin.

METHODS

Porcine model

We used three 2-month-old Yucatan pigs for the study. Four grids were tattooed on their backs, and then tissue expanders were inserted underneath each grid (Fig.1A). The expanders were filled twice with 45 cc of a saline solution over 10 weeks. Out of the total 12 grids, 8 were exposed to radiation. We analyzed 3 expanded radiated patches (XRTE), 4 control radiated patches (XR), and 4 control non-radiated patches (CTRL). For radiation protocol, 20 Gy was administered on day 14 after the first inflation in the XR and XRTE groups. The experiment concluded at week 10, the expected RIF timeline for human patients [3].

Mechanical characterization

Upon excision, we tested the skin under biaxial stretching in the Biotester (CellScale, Waterloo, Canada). From these tests, we got characteristic stress-stretch curves of hyperelastic materials (Fig. 1B). In these curves, we defined two stages for a simpler analysis: an initial linear response and the non-linear part of the curve in which the stress increases rapidly. The value in the x-axis that divides both phases is termed the transition stretch (l_T). The tangent modulus for the linear response, "low modulus," and an approximate tangent modulus for the nonlinear response, "high modulus," were also quantified on the stress-stretch data.

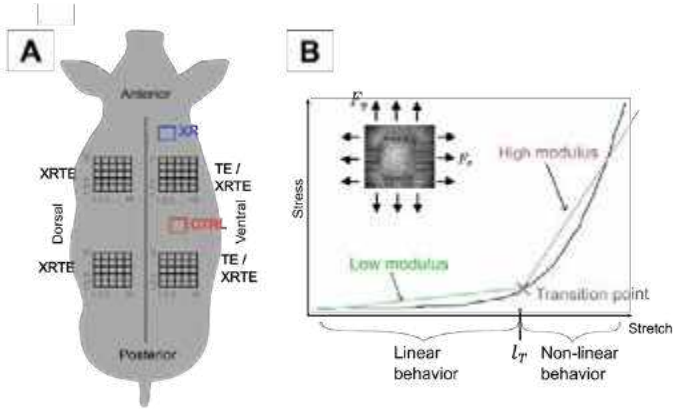

Figure 1: Skin extraction and testing. A) Porcine model. B) Stress-Stretch curve from biaxial mechanical testing.

Image analysis

Histology images of the three different skin groups from two pigs were obtained with Masson's Trichrome technique in which collagen is stained in blue and epithelial cells in red (Fig. 2A). OrientationJ plugin in ImageJ / Fiji software was used to compute orientation distributions of the collagen fibers of each histological image (Fig. 2B). Additionally, we measured coherency with the same plugin, which provided information about the strength of the fiber alignment. Coherency ranges from 0, meaning the fibers are dispersed, to 1, meaning all the fibers nearby follow the same angle [4].

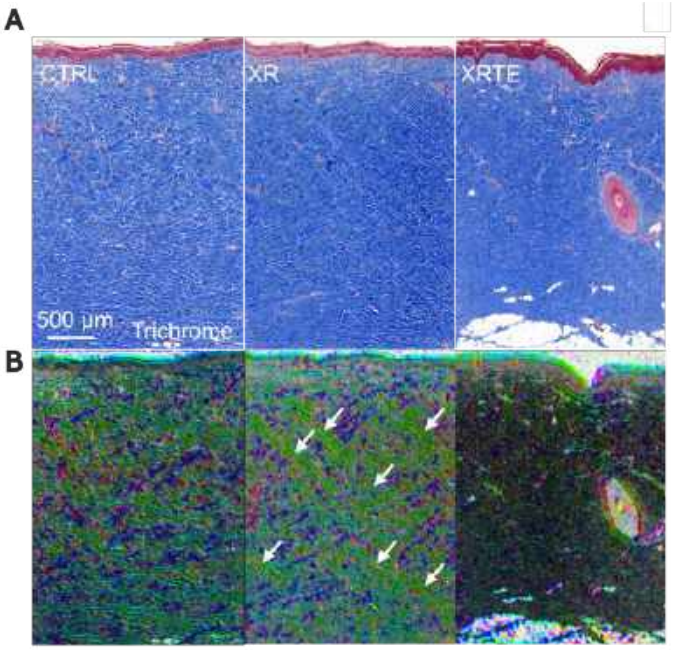

Figure 2: Histological analysis. A) Examples of stained samples with the Masson Trichrome technique. B) Different fiber orientations colored with the OrientationJ plugin of ImageJ / Fiji. Collagen fibers form bundles in XR skin, as shown with arrows.

Model fitting

A hierarchical Bayesian framework was used to estimate the Gasser Ogden Holzapfel (GOH) model parameters [5]. The second Piola Kirchhoff stress fitted was

$$\boldsymbol{S} = -p\boldsymbol{C}^{-1} + \mu\boldsymbol{I} + 2k_{1i}e^{k_{2i}E^2}\boldsymbol{E}[\kappa_i\mathbf{I} + (1-3\kappa_i)\mathbf{M_i}] \quad (1)$$

Where $i = 1,2$, assuming it comprises two groups of fibers distributed in two main orientations. Furthermore, $\mathbf{M_i} = \boldsymbol{a_{Oi}} \otimes \boldsymbol{a_{Oi}}$, with $\boldsymbol{a_{Oi}}$ being the unit vector determined by the angle α_i. Here $\mu, k_{1i}, k_{2i}, \kappa_i$ and α_i were the estimated parameters. We put a prior on the nine parameters and use the experimental stress-stretch data to define a likelihood function. After that, we derive the posteriors of the distributions of the model parameters using Markov-Chain Monte Carlo sampling.

RESULTS

Mechanical characterization

Transition stretch (l_T) was the highest in CTRL skin, considering both test directions (anterior–posterior and dorsal–ventral). In particular, l_T was significantly different between CTRL and both radiated groups, but only in the anterior–posterior direction ($p<0.05$, Dunn test) (Fig. 3A). This means that radiated skin transitions into the nonlinear stiffness regime at smaller stretches in comparison to controls.

Coherency and orientation analysis of histology images

When comparing the mean coherency values between groups, we found a significant difference between CTRL–XR and XR–XRTE ($p<0.05$, ANOVA) (Fig. 3B). When computing the orientation distribution, we found a significant difference between CTRL–XR and XR–XRTE ($p<0.05$, Kolmogorov-Smirnov test). On the other hand, no difference was found between CTRL and XRTE groups (Fig. 3C).

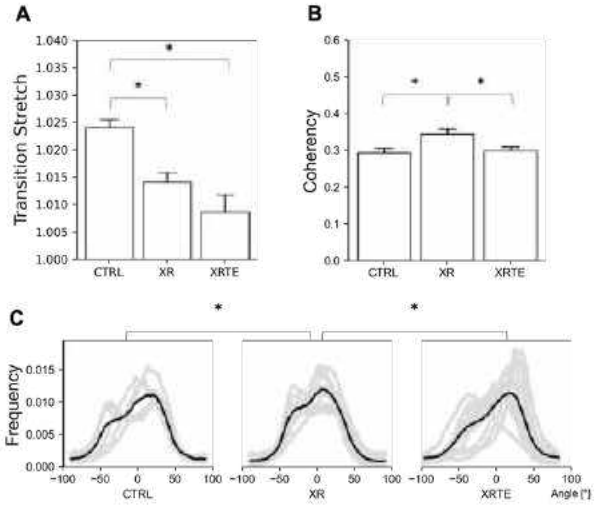

Figure 3: Results from mechanical testing and histological analysis. A) Transition stretch in the anterior-posterior direction (* = $p < 0.05$). B) Coherency (* = $p < 0.05$). C) Orientation distribution of all groups (* = $p < 0.05$).

GOH fitting

We obtained the posterior distribution of the nine parameters for all samples from the Bayesian fitting procedure. The median of each distribution was adjusted to fit the raw data (Fig. 4). The model captures the high modulus with an average error of 5.43%. This is particularly relevant for modeling TE at large stretch values that induce growth.

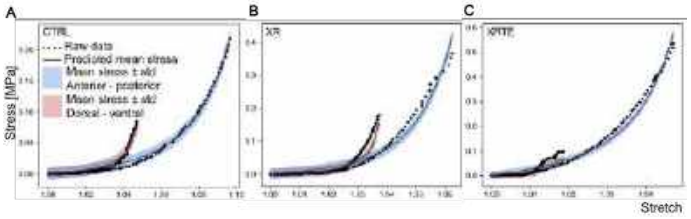

Figure 4: Model fitting for all groups. A) CTRL, B) XR, C) XRTE.

DISCUSSION

Radiated groups XR and XRTE exhibit lower transition stretch l_T, indicating increased skin stiffness due to collagen structural changes, such as bundle formation from cross-linking. This is reflected in high coherency values and less dispersed orientation distributions in radiated skin compared to CTRL and XRTE. Interestingly, CTRL and XRTE show no significant fiber distribution difference, suggesting TE induces fibril disorganization, making collagen structure more akin to normal skin. Unlike previous ones on radiation effects in rats [4], TE-induced changes in porcine models [6], or TE and RT on mouse skin [7], this study uniquely explores the combined effect of TE and RT on an in-vivo model resembling human skin during BRS.

INTRODUCTION

Despite being banned, polychlorinated biphenyl (PCB) mixtures produced before 1979, such as Aroclor 1254, can still be found at high levels in the environment and in building materials such as capacitors, transformers, caulk, and more making PCBs ubiquitous in public spaces. Human exposure to PCBs has been linked to an increased risk of heart disease, stroke, and cancer, as well as the development of metabolic syndromes such as obesity, hyperlipidemia, and type II diabetes [1]. Metabolic syndromes are characterized by insulin resistance, dyslipidemia, increased adiposity, as well as systemic and local inflammation [2]. Adipose tissue is comprised of many cell types including adipocytes, adipose mesenchymal stem cells, endothelial cells, and immune cells such as macrophages. Although adipocytes are often the focus of attention, adipose tissue macrophages (ATMs) play an integral role in regulating the inflammatory state of adipose tissue and influencing adipocyte function. During metabolic disease, ATMs shift from an anti-inflammatory, M2-like phenotype toward an inflammatory, M1-like phenotype. This shift initiates a cascade resulting in local and systemic inflammatory responses that exacerbate metabolic disease [3].

Despite the essential role of ATMs in the regulation of adipocyte function and the known accumulation of PCBs in adipose tissue, little is known about how PCBs directly or indirectly affect macrophages. Previous work suggests PCBs increase adipose tissue inflammation [4]. However, this work only investigated whole adipose tissue cytokines and did not elucidate which cells were responsible. Here, we've expanded on these prior studies to assess the effects of the PCB mixture, Aroclor 1254, on macrophages. Since macrophage phenotype is so vital to the health of adipose tissue, we sought to understand whether PCBs impact the polarization and plasticity of M2 macrophages resulting in shift toward a more inflammatory phenotype.

METHODS

Human Monocyte-Derived Macrophage Isolation and Differentiation All macrophages were derived from human monocytes isolated from peripheral blood mononuclear cells (PBMCs). Briefly, PBMCs were isolated from leukocyte reduction cones (LRCs) using Ficoll-gradient centrifugation. Then, the monocytes were isolated from the PBMCs using a MojoSort negative selection kit. Once monocytes were isolated, they were differentiated into macrophages by culturing them in complete RPMI supplemented with 10 ng/mL M-CSF. After 6 days, monocytes were fully differentiated into naïve macrophages.

Macrophage Polarization Naïve macrophages were polarized toward two different M2 macrophage phenotypes – M(IL-4) or M(dex). To polarize macrophages toward an M(IL-4) phenotype, they were cultured in complete RPMI supplemented with 20 ng/mL IL-4 for 48 hours. To polarize macrophages toward an M(dex) phenotype, they were cultured in complete RPMI supplemented with 100 nM dexamethasone for 48 hours.

Macrophage Exposure to PCBs The PCB mixture, Aroclor 1254, was used for all exposures. Briefly, macrophages were exposed to Aroclor 1254 dissolved in DMSO and mixed with low serum RPMI (0.5% FBS) at a nominal concentration of 10 μM. Macrophages exposed to the vehicle, DMSO (1 μL/mL), were used as a vehicle control (VC).

Surface Marker Analysis Macrophage surface markers CD14, CD16, CD86, CD163, and CD206 were analyzed using flow cytometry. Briefly, the macrophages were lifted using a 5 mM EDTA solution with cells on ice. Once collected, the macrophages were stained for cell death using Zombie B550. After cell death staining, the cells were stained with the following anti-human antibodies: CD14-Alexa Fluor 488, CD16-PE-Fire 640, CD86-PerCP-Cy5.5, CD163-PE-Cy7, CD206-PE-Dazzle. After surface marker staining, the cells were washed and resuspended in cell staining buffer before being analyzed by flow cytometry. Cells were gated based on singlet discrimination and negative cell death stain. The median fluorescent intensity (MFI) for each surface marker was used to compare PCB- vs VC-exposed groups.

ELISA The concentration of IL-8 and IL-10 was analyzed using enzyme-linked immunosorbent assays (ELISA). To perform the assay,

media was collected at the end of each experiment. Analysis was performed with Biolegend ELISA kits as described by manufacturer protocols.

RESULTS

PCBs inhibit M(IL-4) and M(dex) polarization In healthy adipose tissue, newly migrated, naïve macrophages polarize toward M2 phenotypes such as M(IL-4) and M(dex). However, it is unknown whether the accumulation of PCBs in adipose tissue would affect this process. Therefore, we wanted to know whether PCBs disrupt M2 macrophage polarization. To do this, we isolated and differentiated naïve monocyte-derived macrophages. Then, we exposed the naïve macrophages to PCBs for 24 hours. After PCB exposure, we differentiated the PCB-exposed macrophages toward an M(IL-4) or M(dex) phenotype. After 48 hours, the macrophages were collected for flow cytometry and the media was collected for cytokine analysis. We found that PCBs altered both M(IL-4) and M(dex) polarization resulting in more inflammatory macrophages. PCB exposure before M(IL-4) polarization resulted in decreased expression of both anti-inflammatory surface markers, CD163 (Fig 1A) and CD206 (Fig 1B). However, there was no change in the inflammatory marker, CD86 suggesting that PCBs do not globally reduce surface marker expression (Fig 1C). Additionally, there was a small, albeit non-statistically significant increase in the inflammatory cytokine, IL-8 (Fig 1D), as well as a statistically significant decrease in IL-10 (Fig 1E). Exposure of M(dex) macrophages to PCBs resulted in a similar fate. M(dex) macrophages had no change in CD86 (1F) but decreased CD163 (Fig 1G) and CD206 (Fig 1H) expression. Additionally, compared to PCB effects on M(IL-4), PCBs resulted in a much larger increase in IL-8 (Fig 1I) as well as a larger decrease in IL-10 (Fig 1J) for the M(dex) cells. These results suggest that PCBs inhibit M2 polarization resulting in a more inflammatory macrophage niche.

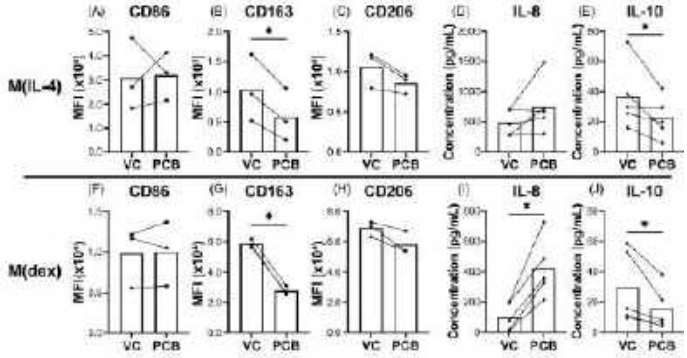

Figure 1: Surface marker and cytokine analysis for PCB exposure before M(IL-4) (A-E) and M(dex) (F-J) polarization. Surface marker analysis: Mean, N=3 donors, paired t-test, * p<0.05. Cytokine analysis: Mean, N=5 donors, paired t-test *p<0.05.

PCBs induce phenotypic plasticity of M(IL-4) and M(dex) macrophages Healthy adipose tissue contains a high number of M2 macrophages. However, macrophages are incredibly plastic. Therefore, they can alter their phenotype in response to environmental stimuli. PCBs can be liberated from adipocytes during lipolysis where they will then encounter mature adipose macrophages. Thus, we wanted to assess whether PCBs will induce phenotypic plasticity of mature M2 macrophages. To do this, we first polarized our monocyte-derived macrophages toward either an M(IL-4) or M(dex) phenotype for 48 hours. Then, we exposed the pre-polarized macrophages to PCBs for 48 hours. Then, we collected the macrophages for flow cytometry and the media for cytokine analysis. We again found that PCBs pushed the macrophages toward a more inflammatory phenotype. M(IL-4) macrophages exposed to PCBs had limited changes in surface marker expression of CD86 (Fig 2A), CD163 (Fig 2B), and CD206 (Fig 1C). However, PCB exposure resulted in a staggering 400X increase in IL-8 secretion (Fig 2D) as well as a significant decrease in IL-10 (Fig 2E). M(dex) macrophages were even more impacted by PCB exposure. Although M(dex) cells didn't have much change in CD86 (Fig 2F), they had a significant change in CD163 (Fig 2G) and CD206 (Fig 2H). Surprisingly, PCB-exposed M(dex) had an even larger change in cytokines with a 1000x increase in IL-8 (Fig 2I) as well as a significant decrease in IL-10 (Fig 2J). These results show that PCBs induce macrophage plasticity and flip anti-inflammatory M2 cells toward an inflammatory phenotype.

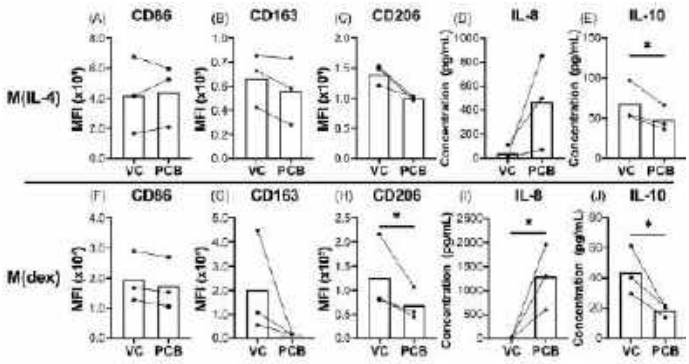

Figure 2: Surface marker and cytokine analysis for M(IL-4) (A-E) and M(dex) (F-J) exposed to PCBs after polarization. Surface marker analysis: Mean, N=3 donors, paired t-test, * p<0.05. Cytokine analysis: Mean, N=5 donors, paired t-test *p<0.05.

DISCUSSION

Our work shows that PCB exposure pushes macrophage toward a more inflammatory phenotype. Previously, Wang et al. showed that PCB 126 induces the polarization of naïve THP-1 macrophages toward an inflammatory, M1-like state [5]. Our results expand on this study to show that PCBs will also inhibit the polarization of anti-inflammatory, M2 macrophages, and more surprisingly, will induce plasticity resulting in a phenotypic switch.

A PCB-induced shift toward more inflammatory macrophages would have profound impacts on adipose tissue. Inflammatory ATMs drive adipocyte dysfunction and insulin resistance by communicating with adipocytes through paracrine signaling [3]. Furthermore, inflammatory macrophages disrupt adipogenesis, leading to improper turnover of mature adipocytes which has been linked to hypertrophic obesity and ectopic lipid accumulation in other tissues [6]. Future work will be needed to understand how PCB exposure alters macrophage-adipocyte crosstalk to influence the development of metabolic syndrome.

HIGH-SPEED CARDIAC PRESSURE-VOLUME SIMULATIONS USING A NOVEL NEURAL NETWORK FINITE ELEMENT APPROACH

INTRODUCTION

With advances in computational modeling as well as imaging techniques, patient-specific cardiovascular modeling for disease modeling and treatment is being widely explored as a means to improve patient outcomes. However, the slow computational speed for accurately simulating the complex physiology of the heart using traditional finite-element based methods still limits their practical clinical application. Moreover, patient-specific clinical applications require rapid evaluation of a large number of clinical scenarios. While reduced order models are commonly used to speed up simulations in many domains at a small loss of accuracy, the associated risk due to this is unacceptable in clinical applications.

We have previously demonstrated the efficacy of the neural network finite element (NNFE) [1] approach for predicting cardiac mechanics of an idealized left ventricle geometry [2] within clinically relevant timeframes without compromising accuracy. In this work, we extend this approach to predict cardiac mechanics using a realistic left ventricle model developed using data obtained from an ovine heart [3].

METHODS

The left-ventricular model utilized in this study is a part of a previously published biventricular ovine model and is described in extensive detail in Liu et al. [3]. Briefly, this model was based on a comprehensive experimental dataset, including ex-vivo MRI data, diffusion tensor MRI imaging data for the local fiber directions as well as in-vivo heart cavity pressures and volumes, all obtained from a single heart (Fig 1). The finite element mesh was created by segmenting the MRI scans and principal myofiber directions were prescribed using DT-MRI data to capture anisotropy and active contraction.

We modeled the passive mechanical properties of the myocardium using an incompressible transversely isotropic Fung-based hyperelastic material model, and the active contraction using an additive stress based on the Hunter-McCulloch-Ter Keurs model with minor modifications

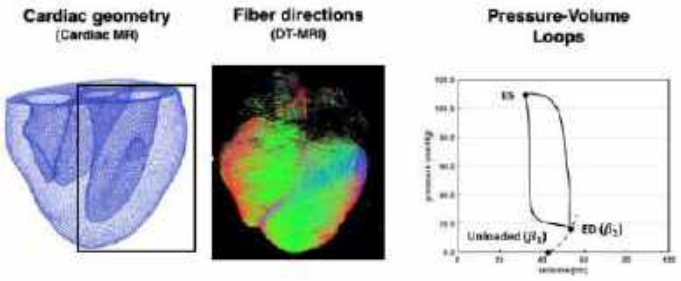

Figure 1: Cardiac geometry, fiber direction and PV loop data collected from a single ovine heart. In this work, we focus on modeling the left ventricle.

with material constants taken from a previous publication [3]. Briefly, the weak form of the governing PDE is

$$\delta W(\boldsymbol{u},\ \delta\boldsymbol{u}) = \int_{\Omega_0} \left(\frac{\partial \Psi}{\partial \mathbf{E}} + \mathbf{S}_{act}\right) : \delta\mathbf{E}\, d\Omega - \int_{\Gamma_0} \mathbf{T}.\,\delta\boldsymbol{u}\, d\Gamma = 0 \qquad (1)$$

where, $\boldsymbol{u} = \mathbf{UN}$ is the displacement field over the domain Ω, **U** are the nodal displacements and **N** are the basis functions, $\delta\boldsymbol{u} = \mathbf{VN}$ is the virtual displacement field and **V** are the virtual nodal displacements, Ψ is the strain energy density function describing the passive behavior of myocardium, **E** is the Green-Lagrange strain tensor, $\mathbf{S}_{act}$ is the 2nd Piola-Kirchhoff active contraction stress and **T** is the traction vector.

The NNFE model utilized a neural network (NN) to represent the nodal displacements, and conventional finite elements (FE) to map the NN output to the problem domain, as well as to specify the boundary conditions and perform numerical integrations (Fig. 2). The NN took pressure p and active contraction T_{Ca} as inputs and predicted nodal displacements **U** in the output layer, from which the myocardial volume (V) was determined.

The NN was trained with a physics-based training scheme by minimizing the residual force vectors of the governing PDE. This

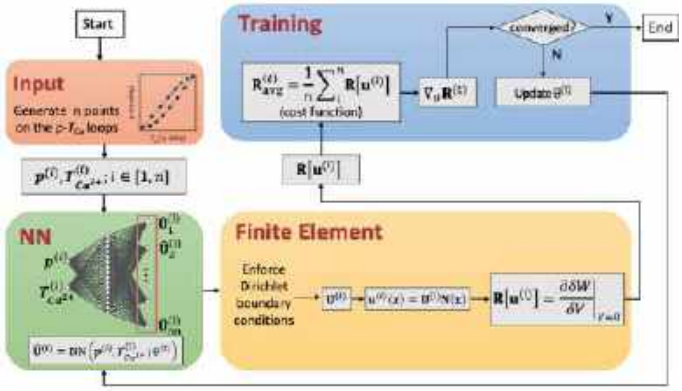

Figure 2: The NN took pressure p and active contraction T_{Ca} as inputs and predicted nodal displacements U in the output layer, from which the myocardial volume (V) was determined. Conventional finite elements were used to map the output on the problem domain. Note that finite element simulations were <u>not</u> run to generate training data for this model. The model was trained by minimizing the residual force vectors of the governing PDE using variational principles.

approach relies on variational principles, and thus, does not rely on the existence of a potential energy formulation of the PDE. The residual of the governing PDE is

$$R = \frac{\partial \delta W}{\partial V} = 0 \qquad (2)$$

where, **V** are the virtual nodal displacements. We designed the NN with five hidden layers and 256 neurons and trained it using the first-order gradient-based optimization algorithm Adam [4] with learning rate scheduling. Unique to this model was that we trained the model over the entire functional training space of pressures, volumes and T_{Ca} at once (Fig. 3). We compared model results against the results of the pre-established model run in Abaqus.

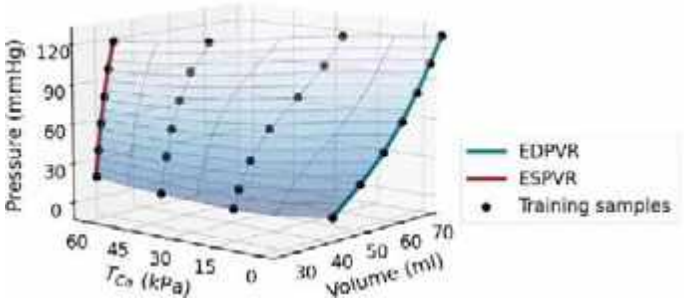

Figure 3: The functional space of the cardiac model is visualized as a 3D space of pressure, volumes and T_{Ca}. The training space consists of the variables p and T_{Ca}, which is space is discretized into a training grid. The model is trained over the entire functional p-T_{Ca} range simultaneously.

RESULTS

The NNFE model predicted the displacement field for any P-V loop in the physiological training space with a max nodal error <1% (Fig. 4). The trained NNFE model could accurately produce the twisting experienced by the left ventricle under active contraction. The NNFE model took 12 hours for training, but a trained NNFE model took 3 seconds for producing the results for any loading, whereas the Abaqus model required ~2.5 hours on average for a single loading path.

Table 1: Comparison of simulation times

Loading path	FEM (Abaqus)	NNFE
Single point	10 min	200 milliseconds
One PV loop	2.5 hours	3 seconds

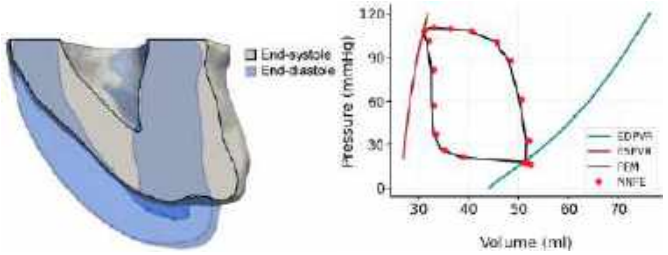

Figure 4: Deformed left ventricle and the pressure-volume loop predicted by the NNFE approach. The NNFE model took 12 hours for training, but a trained NNFE model took 3 seconds for producing the results for any loading path, whereas the Abaqus model required ~2.5 hours on average. Note that the NNFE model is trained only once, and the trained model can predict results for any loading path in the training range.

DISCUSSION

We presented a high-speed NNFE approach to produce the active contractile behavior of a left ventricle for any pressure-volume path within the functional range. Although the NNFE method does take longer to train, this is not a limitation, as the NN only needs to be trained once over a range of boundary conditions. Moreover, the NNFE model was trained over the entire functional space at once and can produce results for any loading path without need for retraining. Consequentially, the NNFE approach is well-suited for many-query problems, such as patient-specific disease modeling and treatment planning, where one needs to solve very similar problems repeatedly with only small changes to the inputs. For such applications, the training can be done in advance, and when presented with the patient-specific data, rapid simulation results can be produced with the trained model.

This approach is different from data-driven machine learning approaches as it does not rely on experimental data or any simulation-generated data for training the model. Instead, it utilizes the weak form of the PDE to train the neural network. However, it is also different from many other physics-based training approaches, as it does not require the existence of a potential energy formulation, and can thus capture a wider range of phenomenon such as non-conservative pressure loading and path-dependent active contraction.

Our results demonstrate the first application of the NNFE approach for a biomedical application at an organ level. We are working on extending this method to study the effects of inotropy on cardiac behavior by varying the slope of the end systolic P-V relationship. Our results represent a small but an important first step towards a digital twin. In the future, geometry and material property variations will be included. While still in its early stages, this approach paves the pathway for high-speed patient-specific clinical simulations.

INTRODUCTION

The structural integrity of arteries is crucial for proper functioning of the cardiovascular system. Vascular diseases such as aneurysms and arteriosclerosis can compromise this integrity, leading to major cardiovascular events and even death. There is a pressing need to understand the structure-biomechanical property-function relationship of the arterial wall tissue in health and disease in order to improve diagnosis and treatment of vascular disease. The primary load-bearing component in the arterial wall is the collagen fiber network. Therefore, the structural role of the diverse features of this network must be elucidated to gain a mechanistic understanding of sources of tissue strength and failure. Previous studies have detailed the influence of fiber density and orientation distribution on the tissue's pre-failure and failure mechanical behavior [1]. While the effect of tortuosity distribution of the collagen fibers on the biomechanical properties of the arterial wall in the elastic regime have been evaluated [2], the impact on failure remains largely unknown.

In this context, we hypothesized that the distribution of collagen fiber tortuosity is a pivotal factor influencing the failure properties of arterial wall tissue. To investigate this hypothesis, we adopted a comprehensive approach combining advanced imaging techniques, experimental testing, and computational modeling to develop a generalized image-based in-silico model of rabbit carotid arterial wall tissue. We refined our tissue model with data from multiphoton microscopy imaging of artery samples and uniaxial tensile tests to characterize the material properties of the tissues. The computational model featured a representative volume element (RVE) that incorporated layer-specific collagen fiber architecture and was validated against experimental data to determine the material properties. Subsequently, a multi-variable parametric study was undertaken, involving finite element analysis on the RVE model and post-processing of simulation data. Our results demonstrated that variations in fiber tortuosity distribution indeed have a significant impact on the biomechanical failure properties of arterial wall tissue, a finding that has the potential to understand the relationship between pathological changes to the arterial wall and deleterious changes to tissue strength.

METHODS

In this study, we utilized the raw experimental data derived from the carotid arteries of six white New Zealand rabbits, obtained from a previous study performed by our research group [2]. The previous study integrated multiphoton microscopy (MPM) with uniaxial tensile (UT) testing to examine the fiber properties at different tissue stretches across the thickness. Moreover, uniaxial tensile test also generated the stress-stretch (SS) curves of each specimen experimentally. These methods are described in detail in [2] and are not repeated here.

To simulate the arterial wall's intricate behavior, we constructed a RVE model of the tissue which encompasses three distinct thickness regions—Adventitia, Media, and the Internal Elastic Lamina (IEL)—with layer dependent composition of the three material components: collagen, elastin, and ground substance. Collagen fibers were modeled as discrete anisotropic elements, while elastin and ground substance were modeled as homogeneous isotropic components. The RVE dimensions were determined based on the MPM scans and the individual layer thicknesses. Densities of elastin and collagen within each layer were quantified using image thresholding techniques applied to MPM scans, and the residual volumetric density was attributed to the ground substance. Collagen fiber diameter and orientation were also obtained from the image analysis of the MPM scans.

The collagen fibers within the arterial tissue demonstrate a crimp behavior, whereby a fiber only begins to bear load after it has been completely straightened. The tissue stretch at which a fiber starts engaging in the load bearing process is termed as the recruitment (or activation) stretch. Due to the natural variability among fibers having different tortuosity, we defined a probability density function of the

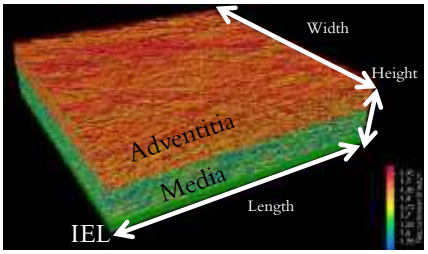

Figure 1: RVE model of the arterial wall tissue

recruitment stretch distribution as shown in Equation 1 where λ_{a1} is the activation stretch of the first recruited fiber. R_a is the range between first and last fiber activation stretches. We have used a Beta probability distribution for defining the shape of the tortuosity distribution function for data from [2]. The distribution function parameter values for the media of each specimen were calculated by obtaining the percentage of recruited fibers at different tissue stretches measured from our combined MPM-UT imaging data.

$$d(\lambda_a) = \lambda_{a1} + R_a \times \text{Beta}(\alpha, \beta) \quad (1)$$

For the adventitial collagen fibers, recruitment stretches were estimated from mapping the tortuous adventitial fibers back to an unloaded configuration, accounting for their angle. Subsequent to the RVE modeling as shown in Figure 1, we performed a finite element (FE) analysis by employing a fiber-reinforced method. In this model, fibers were rendered as 1D tensile rod elements within a 3D continuum, capable of stretching up to 1.2 times before failure [3]. The continuum components were homogeneously modeled using nearly-incompressible neo-Hookean material model. A fixed boundary conditions were applied to one face in the circumferential direction while the displacement load was applied to its opposite face in FE analysis to obtain the SS curve. Material properties of collagen and elastin were calibrated for each specimen by regressing the FE-generated SS curve to align with the experimental UT data. The RVE model for the arterial wall was then validated by comparing the confidence intervals of the material properties obtained from the model calibration and ensuring the SS curve of a random specimen fell within the range of SS curves generated by these intervals. Upon validation, we conducted a parametric study on each of the tortuosity distribution parameters outlined in Equation 1.

RESULTS

A comprehensive parametric study was performed to discern the influence of tortuosity parameters on the stress-stretch behavior of the arterial tissue and the SS curves obtained from the parametric studies of each tortuosity distribution parameter are shown in Figure 2. This investigation focused on key characteristics of the stress-stretch curve: failure stretch and failure stress (or strength). Our study revealed that variations in the value of λ_{a1} significantly affect the tissue's mechanical response. As the value of λ_{a1} increased, there was a notable rise in the tissue's failure stretch from 1.85 ± 0.01 to 2.49 ± 0.005 and strength from 4.64 ± 0.14 to 7.03 ± 0.23 MPa (Figure 2a). Conversely, increasing the range over which fibers were recruited (R_a) led to an increase in failure stretch from 2.035 ± 0.01 to 2.27 ± 0.01 and a slight decrease in failure stress from 5.89 ± 0.15 to 5.61 ± 0.20 MPa, indicating a linear but inverse sensitivity to these parameters (Figure 2b).

Additionally, changing the tortuosity distribution shape function parameters α and β altered the stress-stretch curve's properties in a complex manner, suggesting monotonic and non-monotonic dependencies for failure stretch and stress respectively (Figure 2c-d). An increase in α parameter of the shape function resulted in the increment of failure stretches from 1.96 ± 0.005 to 2.23 ± 0.003. In contrast to α, the parametric study of β displayed an inverse effect: failure stretch decreased from 2.28 ± 0.005 to 2.05 ± 0.006.

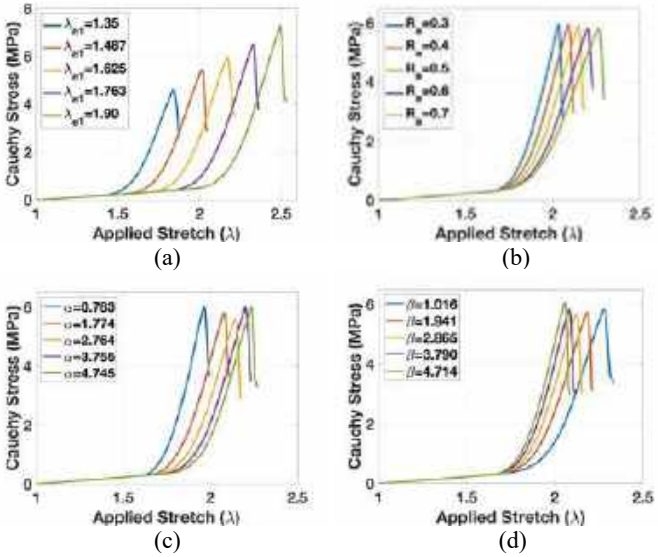

Figure 2: **SS curves generated from parametric study of (a) λ_{a1}, (b) R_a, (c) α and (d) β parameters of Beta probability density function while keeping all other tortuosity distribution parameters fixed.**

DISCUSSION

Our study elucidates the impact of the shape of the tortuosity distribution on the stress-stretch behavior of arterial wall tissue. This relationship is difficult, if not impossible to investigate during physical experiments. Here, we develop a high-fidelity model of a representative multi-layered fiber model of arterial tissue driven by collagen fiber data obtained from multiphoton imaging simultaneous with mechanical testing. The aggregate stress experienced by the tissue arises from the combined stress in both fibers and the surrounding matrix. If the fibers have higher tortuosity, then the overall stress in the tissue will be amplified due to the higher matrix stress. Moreover, if all fibers have identical tortuosity, they all will engage and bear the load simultaneously leading to higher overall stress. Conversely, higher variability in fiber tortuosity in the tissue leads to a scenario where, at any stretch point, some fibers are bearing load while other fibers are either not recruited yet or have already failed, resulting in relatively less overall stress. Taken together, our results suggest that fiber tortuosity plays an important role in failure behavior of the arterial tissues. This knowledge motivates further investigations into fiber distribution in other tissues to provide a better understanding of biomechanical behavior of arterial wall though failure. Ultimately such knowledge will provide a better understanding of how structural changes in arterial pathologies influence tissue failure properties. It is expected that such knowledge will improve treatment of arterial diseases.

INTRODUCTION

The trachea and esophagus begin development as one single tube and separate at about four to eight weeks after conception. If the trachea and esophagus fail to separate, it causes a tracheoesophageal defect/fistula (TED/TEF) and can be life-threatening to neonates. TED/TEF is a connection at one or more places between the trachea and esophagus. As shown in Figure 1, where the esophagus is attached to the bottom of the trachea between the main bronchi. As a result, food or liquids swallowed by a child can be inhaled into their lungs. This rare disease is fixed by a surgical repair that closes the connection. Surgical repair can lead to other complications such as dynamic collapse during breathing, which is known as tracheomalacia and may require further surgical correction. These abnormalities and complications can increase breathing effort. Currently, the effects of TED/TEF and repairs to treat TED/TEF on breathing effort are not known nor whether breathing effort is in the normal range pre and post-surgery.

Computational Fluid Dynamics (CFD) can be used to generate patient specific modeling of respiratory airflow and quantify the effect of TED/TEFs on resistive components of breathing effort. To model patient-specific respiratory aerodynamics, three inputs are needed: respiratory flow rates, airway geometry, and airway motion, including tracheal collapse. These inputs can be captured non-invasively using ultrashort echo time (UTE) MRI. This method of imaging allows reconstruction of respiratory gated images during multiple phases of breathing and is used to create an accurate airway motion model via registration [1,2]. These tracheal component work of breathing (TR-WOB) values are compared to neonates in a healthy population that were previously calculated. We used patient specific CFD simulations to study the effect of TED/TEF on the TR-WOB in neonates. If the TR-WOB calculations are abnormal post-surgery, this would indicate that further surgery and treatment of tracheomalacia is required at the same time as the TED/TEF repair. The purpose of this study was to quantify the pre and post-surgery TR-WOB on the trachea of neonates with TED/TEF and compare it to results previously found in healthy neonates using the same methods.

Figure 1: Coronal slice through an MR image of a neonate with TED/TEF. The slice shows the distal trachea bifurcating at the carina, with a pathological connection to the esophagus occurring at the carina. The esophagus then terminates in a pouch.

METHODS

In this study, three neonatal intensive care unit subjects diagnosed with TED/TEF at Cincinnati Children's Medical Center were imaged using a neonatal MRI scanner before and after surgery. The gestational ages were between 35 and 40 weeks. MR raw k-space data received from the k_0 waveform throughout the breathing cycle were gated into 4 bins representing different respiratory cycles and reconstructed in 4 images [3,4,5]. From the MR Images, 3D segmentations were created from peak expiration, peak inhalation, end inhalation, and end expiration, extending from the nasopharynx to the main bronchi.

Surface registration was used to calculate the airway movement between each of these phases of the respiratory cycle, resulting in a model that moves as the real airway does *in vivo*. The tidal volume was determined from lung segmentations and the k_0 waveform in these MR images was used to calculate the airflow into the left and right bronchi of each subject [3]. For each patient pre- and post-surgery, a CFD simulation was performed utilizing the airway surfaces, motion, and airway flow to model airflow from the upper airway to the main bronchi as shown in figure 2.

CFD package STAR-CCM+ 14.06.012-R8 was utilized for the CFD simulations. Airway motion was included in the simulation by applying prescribed motion obtained from the registration of the airway surface at different timepoints. This technique ensures the CFD airway surface moves as the airway moves *in vivo*, without the necessity for a structural model which would require knowing material properties on the neonatal thorax. The mesh was between 3 million and 5 million polyhedral cells in the airway interior and 9 prism layers on the wall [6] based on previous convergence studies in neonates. The Large-Eddy Simulation turbulence model and no-slip conditions were applied. The CFD simulations for each patient's breathing cycle were unsteady and had a temporal resolution of 0.8 ms [6].

The tracheal component of the resistive TR-WOB was derived from calculating the difference in kinetic energy flux between planes located at the glottis, and carina.

RESULTS

The average tracheal component of the resistive TR-WOB was 1299 J/day in subjects before surgery and 341 J/day in subjects after surgery, as shown in Figure 3. There was a 74% decrease, which demonstrates that surgery aimed at treating TED/TEF significantly reduces the tracheal component of breathing effort.

However, normal values of the TR-WOB range from 24.7 to 96.1 J/day [3]. Therefore, even following the significant decrease due to surgery, patients with TED/TEF have breathing effort approximately 3-fold elevated breathing effort compared with healthy neonates.

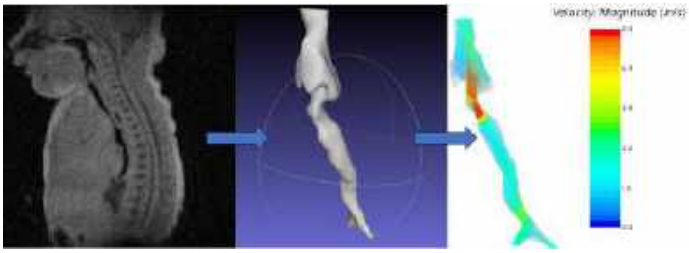

Figure 2: A MR Image is segmented to create a 3D surface of the airway. A surface is created for four timepoints during the respiratory cycle. Surface registration between these surfaces provides the movement of the airway between these timepoints, resulting in a moving airway surface. Using this moving surface, CFD simulations calculate the velocity and pressure fields throughout the airway and duration of the breath.

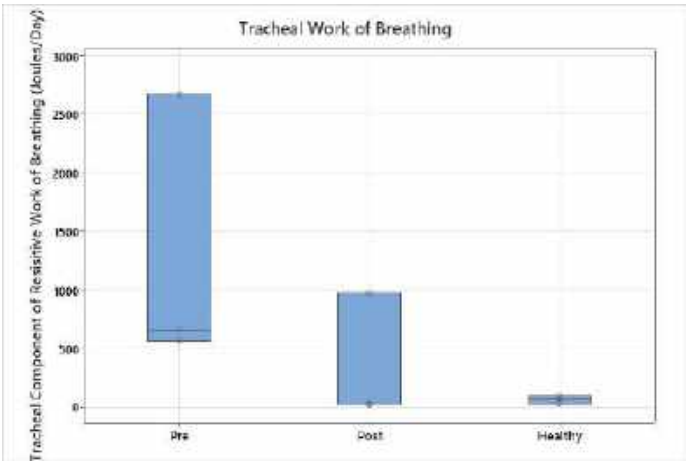

Figure 3: The tracheal component of resistive TR-WOB pre- and post- surgery (left and central boxes, respectively) compared to the normal range, calculated previously [3].

DISCUSSION

This study analyzed how effective surgical repair of TED/TEF is in terms of the reduction in the tracheal component of the TR-WOB due to surgery. Figure 3 indicates that there is a significant 74% decrease in the amount of energy used to breathe post-surgery. This finding demonstrates the positive effect surgery has on respiratory effort, in addition to the primary effect of the surgery which is to correct the tracheoesophageal defect and remove any fistulae between the airway and esophagus. Prior to surgery, the average TR-WOB of a TED patient is 22 times higher than the average for a healthy neonate. While surgery greatly reduces this value, post-surgery, subjects still have a TR-WOB that is 5.5 times higher than the average for controls. Whether this 5.5 higher TR-WOB compared to controls has a significant impact on patients' health will depend on factors outside the scope of this study such as the capacity of the neonate's respiratory system to cope with this increased effort. Patients who are unable to cope with large respiratory effort may require additional surgical interventions, such as aortopexy or tracheopexy to prevent tracheal collapse and further reduce breathing effort. Future studies may be able to predict the post-surgery TR-WOB prior to surgery and therefore, in patients considered unable to support increased respiratory load, will indicate additional surgical repairs to be performed.

Patient-specific simulations of respiratory aerodynamics quantify respiratory effort pre- and post-treatment. This allows the success of surgery to be measured. In neonatal medicine, the ability to quantify respiratory effort is particularly valuable since determining normal respiratory function can be extremely challenging, and the consequence of untreated increased breathing effort is reduced growth and development of the neonate. Therefore, this work demonstrates the value of respiratory CFD in providing an objective assessment of each individual's respiratory health.

PULSE-DRIVEN MICROFLUIDIC INFUSION PUMPS WITH CONSTANT AND HEART RATE-SENSITIVE FLOW RATES

INTRODUCTION

Tethered infusion pumps and syringes have been used nearly as the sole means for the delivery of liquid pharmaceuticals across the skin. These pharmaceuticals include insulin, chemotherapy, analgesia, and vaccines. Tethered infusion pumps pose a wide range of limitations, including pump bulkiness, compromised patient mobility, and technical failures [1-3]. Moreover, both tethered infusion pumps and syringe-driven injections involve the insertion of sharp cannulas and needles, which is reported to be painful and can potentially cause infections, erythema, and fear of needles [4,5]. All these limitations can result in patient non-adherence, which in turn causes morbidity and mortality [6-7].

There is a critical need to develop drug infusion technologies that address these limitations. Here we present a slim, unpowered, minimally invasive alternative to syringes and tethered infusion pumps for the transdermal delivery of liquid drugs. Inspired by the insect respiratory system, we have invented featherweight, *pulse-driven* microfluidic pumps whose flow rate can vary with the driving heart rate and blood pressure. We have evaluated the flow rate of these pumps at different heart rates and blood pressures using a pressurized air-driven pulse simulator and developed device designs with ideal performance profiles.

METHODS

The pulse-driven microfluidic pumps were fabricated using soft lithography and stereolithographic (SLA) 3D printing. Briefly, pump-layer and actuation-layer channels were modified from the tapered channel design (S2) from our previous study [8] and further varied over six design generations. Negative master molds were CAD designed with SOLIDWORKS® and COMSOL Multiphysics® and fabricated with SLA 3D printing using a Formlabs printer. The bottom (pump/flow channel) and top (actuation) device layers were fabricated by cast molding polydimethylsiloxane (PDMS) against the master mold. A flexible membrane was fabricated by spin-coating a thin layer of PDMS onto a silicon wafer. The three PDMS layers were bonded together using a plasma cleaner into a multi-layer device (see Figure 1(a)).

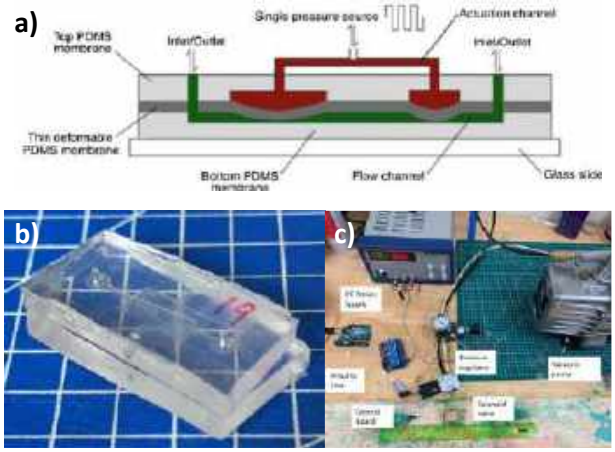

Figure 1: The insect-mimetic, pulse-driven microfluidic pump. (a) Schematic of the original 3-layer insect-mimetic pump from Chatterjee et al. [8]. (b) A prototype 3-layer drug-delivery device. (c) Pulse simulator for device actuation and testing.

To evaluate the performance of the microfluidic pumps, we actuated them using a pressurized air-driven pulse simulator (shown in Figure 1(c)). The pulse simulator was controlled by a solenoid valve that switched periodically between a pressurized air inlet and a vacuum inlet. The modeled heart rate and blood pressure were controlled using an Arduino program and a pressure regulator, respectively. The flow rate was measured by manual video tracking and Elveflow flow sensors.

RESULTS

Testing with the pulse simulator revealed that small changes in device design parameters like the flow channel width could lead to non-continuous changes in the flow rate produced for a given heart rate and sometimes even a change in the sign of the correlation with the driving heart rate. After six generations of device design refinement, we developed families of devices with negative and no correlation with the driving heart rate. The device in Figure 2(a) is in the first category. It is ideal for insulin delivery because it exhibits a sharp, negative correlation between the heart rate and the flow rate. In diabetic patients, elevated heart rates in exercise generally correlates to a reduced need for insulin due to a reduced glucose level in the blood [9]. On the other hand, the three devices in Figure 2(b) are in the second category. They show a constant flow rate across the physiological range of driving heart rates. These devices are ideal for applications other than insulin delivery because the flow rate generated is expected to be unaffected by the heart rate and other patient parameters. For example, Device 18 (teal curve in Figure 2(b)) generated a constant flow rate of 0.5 μL/min (1.8 mL/hr), which is suitable for the delivery of patient-controlled analgesia and chemotherapy [10,11]. Device 21 (magenta curve in Figure 2(b)) generated a flow rate of 2.5 μL/min (9 mL/hr), which is suitable for chemotherapy [11]. Device 25 (black cueve in Figure 2(b)), on the other hand, showed a flow rate of 0.05 μL/min (0.18 mL/hr) and is expected to support insulin delivery without a heart rate-driven feedback loop [12]. Most devices were tested under a simulated blood pressure of 100 mmHg, which approximately corresponds to the blood pressure in the radial artery of a healthy person [13].

We also evaluated the inter-device reproducibility by fabricating three identical replicate prototypes of the devices in the sixth and final design generation. The flow rates exhibited a maximum inter-device variability higher than 100% in each of the two device designs, as shown in Figures 2(c) and 2(d). This indicates that improvements to the device fabrication protocol are needed to reduce the flow rate variability and increase the fidelity of our devices.

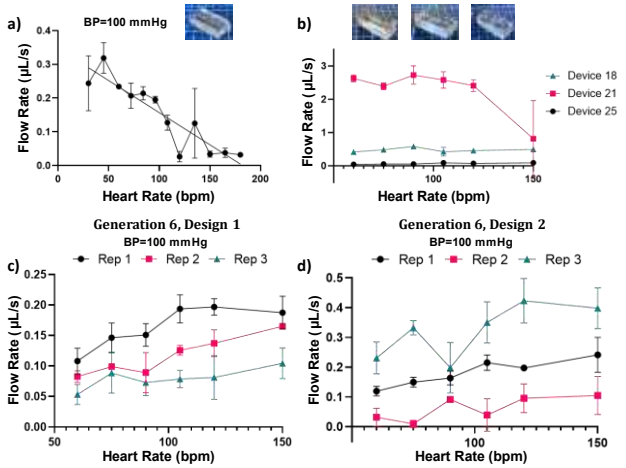

Figure 2: Microfluidic pump performance. (a) Flow rate vs. heart rate data for a prototype Device 19 (fifth design generation). (b) Flow rate vs. heart rate data for three prototype devices from the sixth/final design generation (Devices 18, 21, and 25). (c)(d) Flow rate vs. heart rate data for three replicates for two device prototype devices from the sixth/final design generation.

DISCUSSION

In this study, we have designed and fabricated insect-mimetic, pulse-driven microfluidic pumps for the transdermal infusion of liquid drugs. We evaluated the flow rates generated by more than 100 pump designs over six design generations. We found four ideally behaving prototype pump designs. One of the pumps exhibits a sharply decreasing flow rate with increasing heart rate, which is suitable for insulin delivery, as discussed in the previous section. The other three pumps, in comparison, generate a constant flow rate regardless of the driving heart rate and are suitable for the delivery of chemotherapy, analgesia, and insulin without the closed-loop feedback behavior that the first pump exhibits [10-12]. In the aspect of flow rate variability between prototype pumps of identical design, however, the pumps currently exhibit inconsistent performance compared to commercially available powered infusion pumps. For instance, commercially available insulin pumps typically have a flow rate variation of ±5% [14]. Other infusion pumps, although less stringent on the flow rate accuracy, typically only allow a flow rate variation within ±15% [11,15]. Therefore, it is critical for us to improve upon the device fabrication protocol to improve inter-device flow rate accuracy.

Since our device is intended to deliver liquid drugs across the skin, we are currently working on incorporating hollow microneedle arrays with the devices, which are known to inject drugs across the skin with minimal pain [16]. Other components we are integrating into the system include fluid reservoirs and medical-grade adhesives. Additionally, we plan to use genetic algorithms to optimize each of the four final device designs to provide specific flow rates for a given heart rate, thus tailoring the device designs to the precise needs of a large range of patients.

PREDICTION OF PRESSURE DROP ACROSS AORTIC COARCTATION DURING EXERCISE USING A HYBRID MOCK CIRCULATORY LOOP

INTRODUCTION

Coarctation of the aorta (CoA) is a congenital heart defect characterized by a constriction of the aorta, and with an estimated incidence of 3 per 10,000 births.[1] The narrowing causes a drop in blood pressure (ΔP) across the CoA which can be alleviated using surgical and catheter-based treatments. In the current standard of care, only ΔP at rest (during catheterization) is used when determining whether a patient undergoes a corrective intervention. Since ΔP increases during exercise due to the increased cardiac output (CO), patients with ΔP below the threshold for intervention at rest can develop pathologically high ΔP during exercise, but this varies on a patient-specific basis.[2] In such cases, the catheterization at rest underestimates the actual disease burden. Adrenergic drug (dobutamine) infusion can be used during catheterization to simulate exercise and provoke any exercise-induced gradient, but studies have shown that the hemodynamic response during pharmacological stress does not accurately represent the responses to physical exercise.[3,4]

The aim of this study was to predict ΔP across the CoA in exercise state in a heterogeneous patient cohort (N=5) through *in vitro* measurements acquired in compliant aortic phantoms incorporated in a hybrid mock circulatory loop (HMCL).

METHODS

Acquisition of Patient Data: 4D-Flow MRI datasets (obtained with consent as part of the standard clinical care for CoA patients and approved by the IRB) were acquired from the Lucile Packard Children's Hospital for patients with CoA (N=5, age = 31 ± 16.8 years, 4 male/1 female) prior to their undergoing an invasive catheterization and stent placement. Patients were chosen from a larger patient cohort to represent a variety of CoA anatomies and ΔP at rest. Invasive blood pressure (BP) measurements were obtained via *in vivo* cardiac catheterization in the ascending and descending aorta (AAo and DAo) and in the chambers of the heart. Measurements of CO and heart rate (HR) were available from the catheterization report. Systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) were then calculated.

Anatomic Model Generation: Anatomic images were imported into SimVascular and manually segmented to generate 3D geometries of the aorta and branches arising from the aortic arch. A photopolymerization 3D printer (J735 PolyJet, Stratasys) with novel printing materials (Agilus30 and VeroClear, Stratasys) was used to manufacture compliant wall phantoms of patient-specific geometries with an elastic modulus matching that of a human aorta with CoA (Figure 1).[5] The printed models were coated with a thin conformal coating (DOWSIL 3-1953) to prevent fluid absorption.

Figure 1. 3D-printed patient-specific models of CoA with compliant walls.

Hybrid Mock Circulatory Loop (HMCL): Hemodynamics in the aortic phantoms at rest and exercise were evaluated using an HMCL (Figure 2).[6,7] HMCLs incorporate elements of both *in vitro* and *in silico* modeling allowing for rapid changes in boundary conditions to be mimicked in a closed loop circulation. The compliant aortic phantom was physically integrated into the HMCL *in vitro* while the remainder of the cardiovascular system was represented through a closed-loop lumped parameter numerical model *in silico*. The computer-controlled pressure reservoirs in the HMCL, which are the main hardware parts of the system, form the physical interface between the numerical model and the aortic phantom, by converting the simulated pressure waveforms into controlled actuation with real-time precision. The

parameters of the numerical model were tuned to match patient-specific flows and pressures in the HMCL. The working fluid was a mixture of water and glycerol (volume ratio 5:3) with viscosity matching that of blood. Pressure transducers (SPR-350S, Millar) were used to measure BP in the AAo and DAo (p_{AAo} and p_{DAo}) to determine ΔP during rest and in three different exercise states. An ultrasonic flow probe (Sonoflow CO.55/190, Sonotec GmbH) provided flow measurements at the AAo and DAo. The catheter signals were filtered using a low-pass filter with cutoff frequency between 5 and 10 Hz on a patient-specific basis. Mean pressure drop (ΔP_{mean}) was estimated as the difference in mean p_{AAo} and mean p_{DAo}. The average of the mean pressure drop across 5 cardiac cycles is reported.

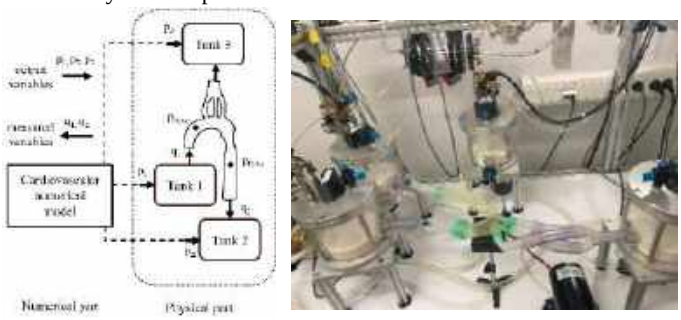

Figure 2. HMCL used for *in vitro* testing.

Simulating Rest and Exercise: *In vitro* pressure measurements were acquired in four patient-specific hemodynamic states: rest (1.00×CO), 1.25×CO, 1.5×CO, and 2×CO. First, for the resting state, the target HR, SVR and PVR were imposed in the numerical model. The simulation's Young's modulus of the systemic and pulmonary artery vessel walls and the maximum elastance of both ventricles were tuned to achieve the target resting CO as well as the target systolic and diastolic blood pressures (SBP, DBP) with a 5 mmHg tolerance. For the exercise states, target HR, SVR and PVR were extrapolated based on literature. For a 50% increase in CO with exercise, HR was increased by 50%, SVR decreased by 20%, and PVR decreased by 15% in accordance with a previous study performed in patients with CoA undergoing MRI-ergometry.[8] Again, Young's modulus of the vessel walls and elastance of the heart chambers were tuned to achieve the target CO, leaving SBP and DBP as dependent variables. For the remaining exercise states, since clinical data was unavailable, the target HR, SVR and PVR were linearly interpolated for 1.25×CO and linearly extrapolated for 2×CO.

RESULTS

Simulated pressures from the patient-specific numerical model were well matched with measured pressures in the HMCL (Figure 3).

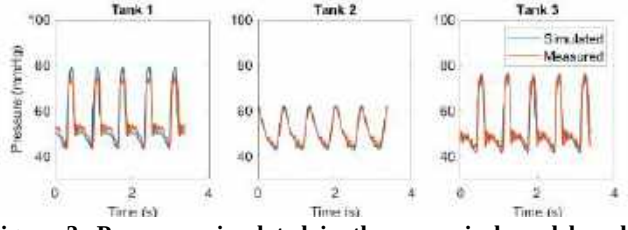

Figure 3. Pressures simulated in the numerical model and measured in the HMCL's reservoirs at rest. Tanks are shown in Figure 2.

simulation and measurement. However, the experimental systolic peak flow differed from the simulated one and did not increase as much as in simulation (Figure 4). As matching of peak systolic flow proved challenging, we report the drop in mean pressure (ΔP_{mean}) between AAo and DAo measured using the catheter (Figure 5).

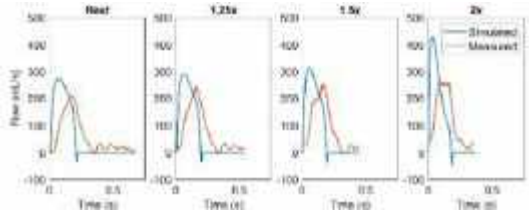

Figure 4. Simulated and measured flow waveforms at different hemodynamic states.

We observe that ΔP_{mean} changes non-linearly with an increase in CO and the changes vary on a patient-specific basis. For example, P2 experiences a linear increase in ΔP_{mean} from rest to 1.5×CO which stabilizes at 2×CO, whereas P4 has a relatively stable ΔP_{mean} from rest to 2×CO.

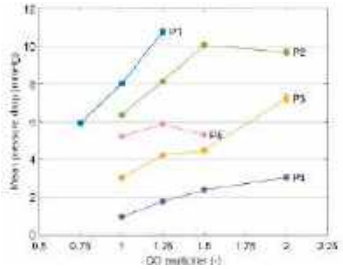

Figure 5. Drop in mean pressure between AAo and DAo at different hemodynamic states in five CoA patients.

DISCUSSION

This study demonstrates the capability of using an HMCL to estimate pressure drops in patients with CoA at rest and states of exercise unattainable in clinical practice. The patient-specific non-linear increase in the mean pressure drop with increasing CO indicates the importance of this study in estimating pressure drops at exercise. These estimates lay the foundation for further research into the factors that influence the non-linearity of pressure drop increase during exercise. The HMCL combined both *in vitro* and *in silico* components, with a numerical representation of the cardiovascular system and incorporation of 3D-printed patient-specific compliant aortic phantoms. The numerical cardiovascular model allowed efficient tuning of the system to achieve patient-specific flows and pressures. Limitations of the current study include mismatched peak flows between simulation and measured aortic flow, and instabilities introduced in the numerical model at high COs. Future studies can validate the findings from this study using CFD simulations in patient-specific CoA models.

MICROSTRUCTURAL ALTERATIONS IN THE MURINE THORACIC AORTA: UNVEILING A MECHANISM FOR BIOMECHANICAL REMODELING IN LATE-GESTATION PREGNANCY

Ana I. Vargas (1), Turner Jennings (2), Rouzbeh Amini (1,2), Chiara Bellini (1)

(1) Department of Bioengineering, Northeastern University, Boston, MA, USA
(2) Department of Mechanical and Industrial Engineering, Northeastern University, Boston, MA, USA

INTRODUCTION

During pregnancy, the maternal body undergoes profound hemodynamic transformations impacting the cardiovascular system. Changes to the maternal body may reveal previously hidden pathologies, leading to ∼4% of global pregnancies complicated by cardiovascular disease (CVD) [1, 2]. In the US, cardiovascular complications account for over one-third of pregnancy-related deaths, making CVD the leading cause of maternal mortality [3]. Despite observing significant changes in the maternal body, the mechanisms of tissue remodeling and mechanical adaptation of elastic arteries in response to pregnancy remain largely unknown.

The aorta plays a crucial role in storing elastic energy and enhancing blood flow throughout the cardiac cycle, while simultaneously maintaining the mechanical strength necessary to withstand hemodynamic forces and prevent structural failure [4]. Its layers, composed of essential extracellular matrix (ECM) components (elastic fibers and fibrillar collagen), are regulated by endothelial cells, smooth muscle cells, and fibroblasts [5]. Our macro-scale functional mechanics data have shown— for the first time—that during pregnancy the aortic wall remodels, becoming thicker and wider but simultaneously experiencing material softening [6]. By imaging the aortic wall under biaxial mechanical loading, we further explored this pregnancy-induced remodeling of the aortic wall, and how the ECM components, specifically collagen fibers, re-orient to account for the macro-scale response of the tissue we previously observed [6]. Therefore, the purpose of this project was to quantify the orientation and distribution of collagen fibers of the descending thoracic aorta (DTA) as a function of mechanical loading. We hypothesized that in the pregnant tissue collagen fibers remodel in response to changes in mechanical loading.

METHODS

Sample Preparation – Segments of the DTA were collected from pregnant C57BL6 mice at gestation day 18 $\pm$ 1 (n=4) and female age-matched control mice (10 $\pm$ 1 weeks of age, n=4). Specimens were cleaned, and stained for the cell nuclei. Tissue samples were then cannulated into our custom-made pressurization device and stretched to group-specific in vivo axial stretch.

Multiphoton Microscopy & Image Analysis – A two-photon microscope was used to image collagen, elastin, and the cell nuclei simultaneously, across the thickness of the aortic wall. Three-dimensional images (z-stack) were acquired at different pressure levels, ranging from 0 - 140 mmHg. After obtaining images for the three signals (collagen, elastin, and cell nuclei), each image underwent post-processing, and z-stacks were transformed to flatten the image and facilitate image in-plane fiber distribution analysis.

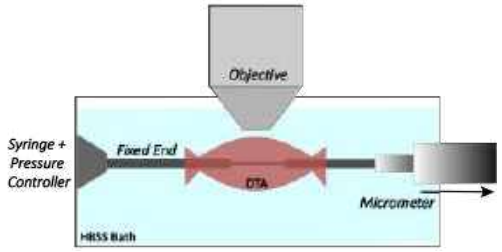

Figure 1: Custom-made pressurization device for ex-vivo multiphoton imaging.

In-plane Collagen Distribution Orientation – Flattened collagen images were post-processed using OrientationJ (ImageJ) to quantify the distribution of the collagen fibers. To model fiber directionality, we assumed our fibers followed a von Mises distribution (Eq. 1) [7]. This distribution function (f) allowed us to quantify the primary orientation angle (μ) and a concentration parameter (κ), of the orientation in circular coordinates (θ).

$$f(\theta \mid \mu, \kappa) = \frac{\exp(\kappa \cos(2\theta - 2\mu))}{\pi I_0(\kappa)} \tag{1}$$

where $I_0(\kappa)$ is a modified Bessel function [8].

Mechanical Behavior Analysis – To get information regarding the mechanical behavior of the aortic tissue and how this compares to the observed structural changes, we analyzed the components of the intrinsic stiffness tensor $\mathscr{C}_{ijkl}$, which was computed using the "small-on-large" theory described by Baek et al. [9] and data collected from passive biaxial mechanical testing [6]:

$$\mathscr{C}ijkl = 2\delta ikF^o_{lA}F^o_{jB}\left.\frac{\partial W}{\partial C_{AB}}\right|_{\mathbf{C}^o} + 2\delta jkF^o_{iA}F^o_{lB}\left.\frac{\partial W}{\partial C_{AB}}\right|_{\mathbf{C}^o} + 4FiA^oF^o_{jB}F^o_{kP}F^o_{lQ}\left.\frac{\partial^2 W}{\partial C_{AB}\partial C_{PQ}}\right|_{\mathbf{C}^o} \quad (2)$$

where $\mathbf{F}^o$ and $\mathbf{C}^o$ represent the deformation gradient tensor and the right Cauchy green tensor at an intermediate loaded condition, respectively. W is a validated strain energy function that models the aortic wall [10]. The ratio of axial to circumferential stiffness ($\mathscr{C}_{zzzz}/\mathscr{C}_{\theta\theta\theta\theta}$) serves as an indicator of the tissue's anisotropy, indicating how its mechanical properties vary in different directions.

RESULTS

The distribution of collagen fiber orientation differed between pregnant and control samples (visualized in Fig. 2). Our Von Mises distribution analysis reveals that pregnant tissue exhibits a less organized collagen structure in contrast to the arrangement observed in the control samples (Fig. 3A), as observed by lower κ values. Both groups share a common trend with κ decreasing, signifying less fiber organization, with higher pressures. The primary orientation of both groups (μ), pregnant and control, suggests that at low pressures, most of the fibers are aligned in the axial direction (Fig. 3B). As pressure increases, the fibers shift more towards the circumferential direction. The pregnant group appears to shift faster towards this direction, reaching values closer to 180 degrees as compared to the control.

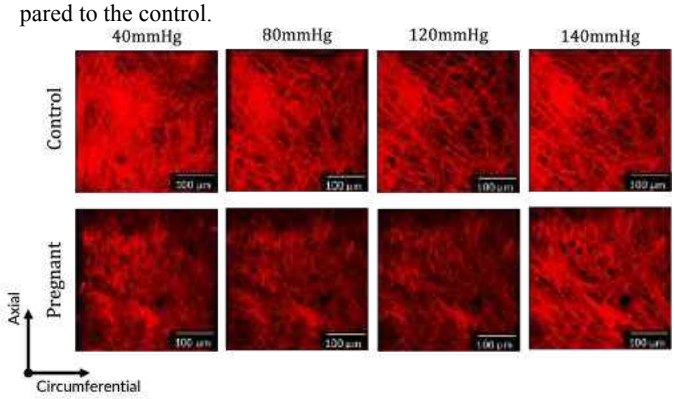

Figure 2: Illustrative projections of 3D images of collagen fibers within the same samples at increasing pressures.

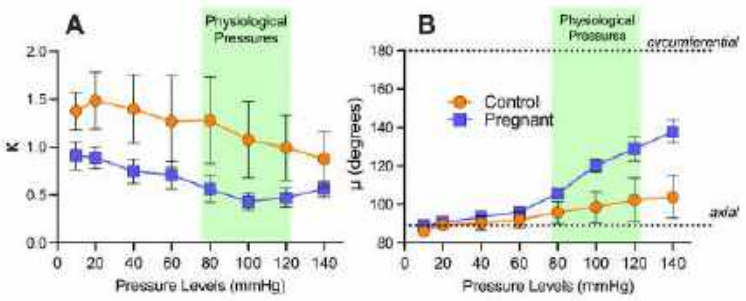

Figure 3: Organization of collagen fibers at in vivo axial stretch. (A) Concentration parameter, κ versus pressure levels. (B) Primary orientation parameter, μ, versus pressure levels. A nonparametric Spearman correlation test indicated a significant p-value for both control (r = -0.90 κ, 1.00 μ) and pregnant (r = -0.83 κ, 1.00 μ) variables.

Our functional mechanics data indicate that, for both groups, axial stiffness surpasses circumferential stiffness (Fig 4). As pressure increases, the increase in circumferential stiffness outpaces the increase in axial stiffness. This phenomenon results in a reduction of our anisotropy ratio ($\mathscr{C}_{zzzz}/\mathscr{C}_{\theta\theta\theta\theta}$), suggesting a shift towards a more isotropic response in the fibers. Notably, in pregnancy, this shift appears to occur more rapidly, with a faster gain in circumferential stiffness and lower anisotropy ratio values reached at equivalent pressure levels compared to the control group. This observation aligns with the faster re-orientation of fibers toward the circumferential direction during pressurization, as illustrated in Fig. 2B.

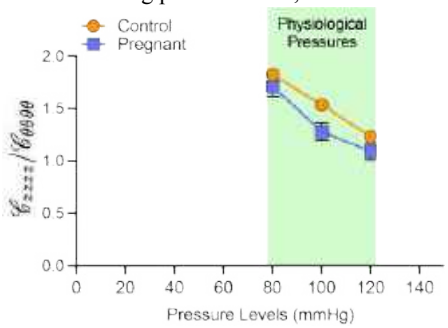

Figure 4: Ratio of circumferential stiffness to axial stiffness versus pressure levels.

DISCUSSION

It is crucial to understand the aortic remodeling process throughout gestation to gain insights into both the immediate and long-term impacts of pregnancy on maternal cardiovascular health. In this study, we present a microstructural assessment of the collagen fibers in the DTA of late-gestation wild-type mice to characterize the remodeling of the tissue at the micro-scale level.

Our functional mechanics data indicate that pregnancy is associated with a more rapid gain in circumferential stiffness under pressurization (Fig. 4), causing a more isotropic mechanical response ($\mathscr{C}_{zzzz}/\mathscr{C}_{\theta\theta\theta\theta} \approx 1$). This dynamic behavior may be attributed to the rapid re-orientation of axially aligned collagen fibers shifting towards the circumferential direction (Fig. 2B). While the shift in mean fiber direction is larger in the pregnant group, it is worth noting that the fibers in are more disorganized than the control group (Fig. 2A).

The changes observed in the microstructure of the tissue may be connected to the macro-scale remodeling we reported in our recent work [6]. Specifically, the pregnant tissue tends to shift in material response towards an isotropic material, which might be connected to the material softening we observed at the macro-scale level. The less uniform organization of collagen fibers in the pregnant group could influence the overall material response, leading to increased distensibility and altered wall stress patterns. These connections indicate that changes at the microstructural level may affect the macro-scale response of the tissue during pregnancy, contributing valuable insights into maternal cardiovascular health. However, to *fully* elucidate how the aortic tissue remodels during pregnancy, a multi-scale computational approach must be employed to relate changes in the micro-environment to macro-scale loading.

Our ongoing research is focused on further analyzing multiphoton microscopy data to include information regarding elastin fiber directionality and lamellae separation, cellular density, and cellular alignment as inputs to our multi-scale computational model.

STRAIN, STIFFNESS, AND COMPOSITION EFFECTS ON LUNG FIBROBLASTS AND THEIR IMPLICATIONS IN PULMONARY FIBROSIS

INTRODUCTION

Pulmonary fibrosis is characterized by abnormal accumulation of fibroblast-secreted extracellular matrix (ECM) in the pulmonary interstitium. This fibroproliferative response appears to proceed through a feedforward loop that is regulated by mechanotransductive and biochemical pathways. Dissecting the relative involvement of each pathway in disease development is difficult because fibrotic lesions are not only stiffer (~2kPa for healthy and ~14 kPa for fibrotic lung tissue) than healthy tissue but they also have altered ECM chemistry, including increased collagen, hyaluronan (HA), and fibronectin.[1,2]

To begin to untangle these factors, we leverage dynamic mechanical loading of photopolymerized hydrogels as a method to mimic mechanical and biochemical signals from three sources: cyclic strain during normal breathing and mechanical ventilation; substrate stiffness; and substrate composition (namely, HA content). This platform provides a means to isolate stiffness, strain magnitude, and biochemical signals as they contribute to expression of genes involved in pulmonary fibrosis. Our long-term goal is to use this platform to help identify the molecular mechanisms involved in initiating lung fibrosis, enabling the identification of potential therapeutic targets.

METHODS

Fabrication of hydrogels: Methacrylated gelatin (*GelMA*), methacrylated hyaluronan (*HAMA*), and non-methacrylated gelatin (*Gel*) were mixed in various concentrations as base materials. Hydrogels were formed via ultraviolet light (0.5W/cm^2) for 90 seconds, with 1%vol Irgacure-2959 as a photoinitiator.

Mechanical testing: Stress-relaxation and compression tests were performed using a Kinexus Ultra+ (Malvern Panalytical) rheometer fitted with an Omnicure S2000 UV light source. Compressive modulus was calculated using the slope of stress-strain curves.

Cyclic Strain: Pre-polymer mixtures were applied to and photopolymerized directly on attachments designed for a force bioreactor (ADMET Inc.), resulting in solid hydrogels attached to the bioreactor. After cell seeding, these hydrogels were then deformed at 0.2 Hz at 5% pre-strain, 25% cyclical strain (Breathing) or 20% pre-strain, 35% cyclical strain (Mechanical Ventilation, MV) conditions.

Cell Culture: Normal human lung fibroblasts (NHLFs) at low passage number (<P7) were cultured in EMEM + 10% FBS. Cells were allowed to attach on hydrogels overnight before mechanical loading.

Gene expression analysis: RNA extraction was performed using TRIzol lysis followed by ethanol precipitation of aqueous phase and Zymo RNA Clean and Concentrator column. cDNA was then synthesized using Superscript VILO cDNA synthesis kit. qPCR for 30 genes related to mechanosensing and fibrogenesis was then performed using Power SYBR green with primer sequences from Primer Bank. Three technical replicates were performed for each condition and expression was normalized to NHLFs of parallel cell seeding on tissue culture plastic.

Statistical analysis: Two-way ANOVA and Tukey's post-hoc analyses were performed using GraphPad Prism. * $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$, **** $p \leq 0.0001$

RESULTS

Compressive moduli were measured after photopolymerization. *Gel* can be added to *GelMA* and *HAMA*, effectively reducing methacrylate group concentration to decrease compressive modulus, thus maintaining similar concentrations of integrin RGD binding sites (**Fig. 1**). The resulting hydrogels with and without *HAMA* had comparable stiffness. However, no proportion of gelatin could be added to *HAMA* mixtures to reduce the compressive modulus to the range of healthy tissue.

Out of the 30 genes investigated with qPCR, expression of MMP1, CTGF, and ROCK1, among others, were significantly impacted by cyclical strain, substrate properties, and their interactive effects (**Fig. 2**). Generally, expression increased substantially with the addition of cyclic strain on *GelMA:Gel* substrates with moderate or fibrotic stiffness.

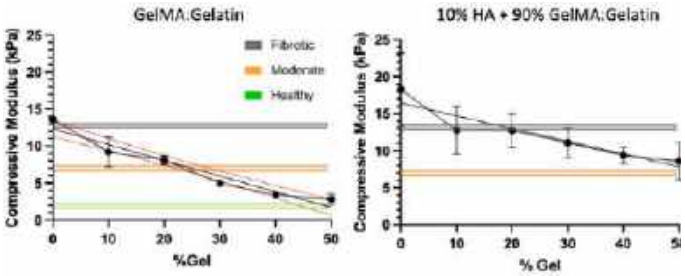

Figure 1. Compressive moduli of hydrogel formulations.

However, the influence of strain was dampened on substrates with healthy stiffness or those containing *HA*. Expression of FN1 was significantly impacted by substrate properties and interactive effects, similar to MMP1 and CTGF, but with more variability when substrates contained *HA*. Surprisingly, strain induced a significant decrease in COL3A1 and DCN expression.

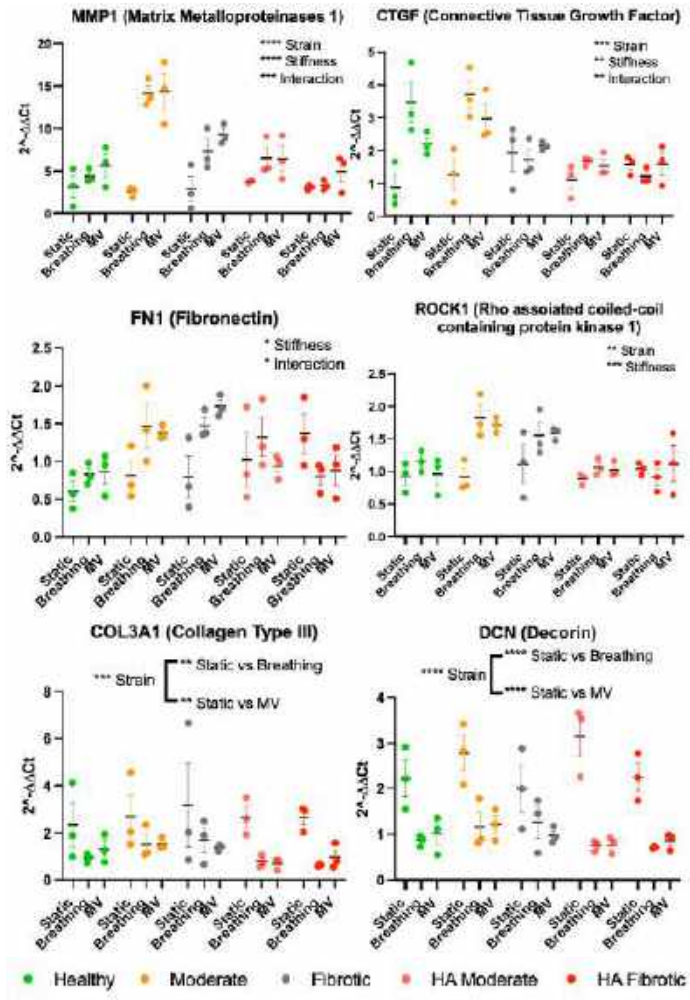

Figure 2: qPCR results of selected genes

DISCUSSION

Various combinations of *GelMA*, *HAMA*, and *Gel* were successfully used to tune the hydrogel compressive modulus within reported ranges of healthy and fibrotic lung tissue. There was a proportional decrease in compressive modulus as the concentration of *Gel* increased. However, the lower limit of compressive modulus for *HAMA* gels is most likely due to the hygroscopic nature and charge interactions associated with HA.

qPCR revealed significant increases in expression of MMP1, CTGF, and ROCK1 due to strain, stiffness, or their interaction. Furthermore, FN1 and several other genes (not shown) had expression patterns similar to MMP1, CTGF, and ROCK1. In general, expression changes in response to strain were only substantial on moderate and fibrotic *GelMA:Gel* hydrogels and not on healthy stiffness, suggesting that the stiffer gel heightened the strain-induced response. However, in several cases, response to strain was dampened when 10% *HAMA* was introduced, even though these hydrogels had comparable stiffness. Overall, these results suggest that the combination of increased stiffness and cyclic strain promote a strong remodeling response, as MMP1, CTGF, FN1 and ROCK1 are elevated in fibrotic pulmonary tissue. Previous studies have shown that CTGF and MMP1 expression increase due to cyclical strain,[3,4] and our results add a new dimension by demonstrating the importance of interactions between dynamic mechanical signals and substrate characteristics. Although additional experiments are needed to further explore the differential responses to strain on *GelMA:Gel* vs. *HAMA* hydrogels, this could be related to cell attachments to HA via CD44. Briefly, more attachments to HA could impact mechanotransduction and alter the effect of integrin binding to RGD.

In contrast to the genes described above, COL3A1 and DCN had decreased expression with cyclical strain. A decrease in COL3A1 expression is unexpected as fibrillar collagens (type I and III) are usually overexpressed in fibrotic disease. However, the ratio of type III to type I is usually lower in stiff scar tissues, which means the decrease observed here could be representative of pro-fibrotic collagen remodeling.[5] DCN regulates ECM assembly and is also an inhibitor of TGF-β1 signaling pathway.[6] The reduction in expression of DCN thus may indicate that strain contributes to fibrosis.

In conclusion, our platform enabled us to use photopolymerizable hydrogels to isolate the effects of dynamic strain, substrate stiffness, and composition on pulmonary fibroblast gene expression. Future work will include characterizing ECM protein production in response to these factors, as gene expression levels are transient and not always indictive of the protein secreted. In the future, we will also leverage the photopolymerizable capabilities of our hydrogel to create finer structures mimicking fibrotic foci to study cell interactions with localized changes in substrates.

EFFECTS OF THE LOADING RATE ON THE MECHANICAL BEHAVIOR OF PROXIMAL SUPERFICIAL FEMORAL ARTERY

A. Zolfaghari Sichani (1), M. Jadidi (1)

(1) Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE, USA

INTRODUCTION

Soft tissues, including blood vessels, are known for their rate-dependent mechanical behavior. Previous researchers have studied the dependency of loading rate on various tissues. The study of Grashow, J. S. et al. [1] demonstrated the effects of strain rate on the biaxial mechanical properties of the mitral valve anterior leaflet (MVAL). Fresh porcine MVAL specimens were subjected to a range of strain-controlled biaxial loading protocols with cycle periods of 15, 1, 0.5, 0.1, and 0.05 s. The researchers reported that the stress–strain behavior of the MVAL was independent of strain rate in both directions over the full range of cycle periods studied. Also, Noble C. et al. [2] found no notable rate-dependent response for porcine aortic heart valve biomaterials. In another study, Anssari-Benam, A. et al. [3] used porcine samples and subjected them to biaxial deformation at different stretch rates. Their analysis showed that the samples exhibited a marked rate-dependency in their deformation behavior, typically stiffening with an increased rate. Delgadillo, J. O. V. et al. [4] found that porcine aorta samples showed reduced loading forces up to 20% when the deformation rate was increased from 10 to 200 $\%s^{-1}$.

The results of these studies have been inconsistent, with some finding that the rate of deformation does not significantly affect stress-strain behavior, while others report the opposite. This inconsistency could arise from different tissue types, loading rates, and testing environments. In this study, our goal was to investigate the loading rate dependency on the mechanical behavior of human superficial femoral arteries (SFA), the main artery in the leg. These properties are crucial to understanding their function and viscoelastic behavior.

METHODS

In this preliminary analysis, we tested proximal SFA (pSFA) samples from 5 deceased male donors (age range: 45 to 55, mean age 48±3 years). This stringent criterion has been imposed to mitigate potential age and sex-related effects on arterial mechanical properties [5]. In the future, this study will be continued by testing female arteries and assessing the role of sex. Each artery was dissected from the surrounding tissues, and subsequently, a 13 mm long tube was cut from the pSFA location. The tube was cut open longitudinally using a scissor and a 10×10 mm square specimen was cut and attached to a CellScale biaxial device, equipped with 2.5 N loadcells. The specimen was attached such that the circumferential direction of the artery aligned with the biaxial device's vertical axis, and the artery's longitudinal direction aligned with the biaxial device's horizontal axis (Figure 1).

The tests were performed in 37°C PBS. After performing 10 preconditioning cycles to obtain repeatable stress-stretch response, these specimens were subjected to load-control tests at five different speed rates: 10, 20, 30, 40, and 50 mN/s at circumferential to longitudinal directions force ratios: 1.0:1.0, 1.0:0.5, 1.0:1.0, 0.5:1.0, and 1.0:1.0. Each speed test was executed sequentially from slow to fast. All samples were stretched to 800 mN load in both directions in equibiaxial protocol. This load was selected based on previous studies [5] that have shown at this level, the human pSFA 45-55 years old will show a nonlinear stress-stretch response while not reaching the plastic domain.

Images and stretch and force data were collected at 5 Hz frequency. We further employed image processing to measure the deformation gradient at the center of the specimen, away from the rakes. We also calculated the experimental Cauchy stress tensor and determined its diagonal components in the circumferential and longitudinal directions, i.e, $T_{\theta\theta}$ and T_{zz}.

In order to compare the samples statistically, we determined the stretches corresponding to the maximum stress level in all samples. In the equibiaxial protocol, we noted that the maximum stress level was 70 kPa in both directions. We selected this stress level for our analysis as it was a consistent measure observed between all samples. We further compared the samples at the stress level of 70 kPa using ANOVA and set the significance level at p-value of 0.05. In addition to the tests of

within-subjects effects, we also conducted pairwise comparisons between different groups.

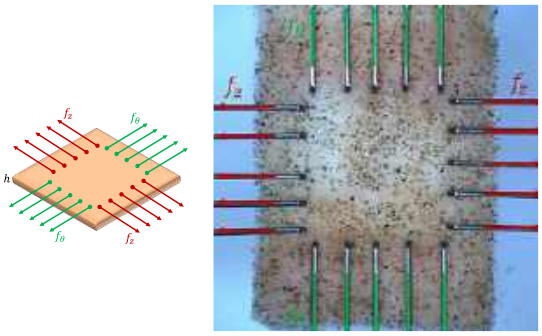

Figure 1. Left: A schematic representation of the planar biaxial test. Right: A view of the experimental setup, showcasing the sample undergoing stretching under applied forces. f_θ and f_z are the applied forces in the circumferential and longitudinal directions of the arterial wall specimen, respectively.

RESULTS

Table 1 provides a detailed overview of the stretch values at 70 kPa equibiaxial protocol for 5 samples. We observed a decrease of approximately 2.5% in the longitudinal direction between the rates of 10 and 50 mN/s for samples 1 and 4. However, we can see an increase of about 1.5% for samples 2 and 3 in the same direction. Similarly, between these rates, there was a decrease of about 2% in the circumferential direction for all samples, with the exception of sample 5.

Table 1. Stretch values of 5 samples at various loading rates, measured at a stress level of 70 kPa.

		Rates (mN/s)					
ID	Age	10	20	30	40	50	Dir.
1	50	1.2619	1.2426	1.2544	1.2246	1.2271	Longitudinal
2	45	1.2484	1.2511	1.2655	1.2636	1.2673	
3	52	1.2536	1.2602	1.2602	1.2620	1.2721	
4	48	1.3270	1.3128	1.3157	1.2979	1.2924	
5	47	1.3900	1.3970	1.4006	1.4008	1.3968	
1	50	1.1202	1.1184	1.1124	1.1174	1.1019	Circumferential
2	45	1.1599	1.1556	1.1420	1.1378	1.1354	
3	52	1.0900	1.0870	1.0768	1.0744	1.0716	
4	48	1.1550	1.1392	1.1283	1.1273	1.1266	
5	47	1.1574	1.1455	1.1469	1.1532	1.1743	

In the statistical analysis of our data, for the circumferential direction, the p-value was 0.057, indicating a trend toward significance. This suggests that the load rate might have an effect on the stretch values in the circumferential direction, although the results did not reach statistical significance at the conventional 0.05 level. For the longitudinal direction, the p-value was 0.690. These results indicate that the load rate does not have a significant effect on the stretch values in the longitudinal direction. The pairwise comparisons revealed significant differences in circumferential stretch values between the groups tested at 10 mN/s and 50 mN/s.

Figure 2 provides a visual representation of the mechanical behavior of a pSFA sample (50-year-old male) under varying loading rates in two directions. The stretch values in the longitudinal direction consistently exceed those in the circumferential direction across all load rates. Moreover, the stretch values vary across different loading rates. This pattern is observed in both the longitudinal and circumferential directions. Furthermore, the difference in stretch values is more noticeable when comparing the rates of 10 mN/s and 50 mN/s. For this sample, we observed a decrease in stretch values from 1.26 to 1.23 in the longitudinal direction, and from 1.12 to 1.10 in the circumferential direction, at the stress level of 70 kPa.

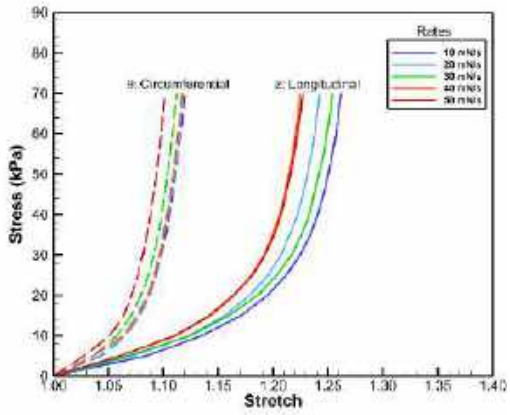

Figure 2. Stress-stretch curves of a 50-year-old sample in both the longitudinal and circumferential directions at different loading rates.

DISCUSSION

Our results indicate a trend toward stiffening of pSFA samples in the circumferential direction with an increase in loading rates, although it did not reach statistical significance. In the longitudinal direction, we showed that the mechanical properties of the samples remain almost unchanged with an increase in loading rates.

While these observations add to the growing body of evidence supporting the rate-dependent mechanical behavior of soft tissues, they should be interpreted within the context of the study's limitations. Firstly, our analysis was preliminary and only included 5 male subjects. To ensure a more robust and meaningful statistical analysis, future studies should aim to include a larger sample size with representation from both sexes. Secondly, our comparison was focused solely on the 70kPa stress level of the equibiaxial protocol. For a more comprehensive understanding, future investigations should compare the loading rates at other stress levels across all protocols.

In conclusion, while our study provides valuable insights into the rate-dependent mechanical behavior of pSFA, further research is needed to fully understand these effects, particularly in different types of tissues and under varying loading conditions.

CREATION OF A MULTI-SCALE MODEL OF SKIN GROWTH TO UNDERSTAND THE EFFECT OF MICROSTRUCTURE AND TISSUE HETEROGENEITIES ON SKIN MECHANOBIOLOGY

O. Moreno Flores (1), Maria Holland (2) A. Buganza Tepole (1,3)

(1) School of Mechanical Engineering, Purdue University, West Lafayette, Indiana, USA
(2) Department of Mechanical and Aerospace Engineering, University of Notre Dame, South Bend, Indiana, USA
(3) Weldon School of Biomedical Engineering, Purdue University, West Lafayette, Indiana, USA

INTRODUCTION

Understanding and correctly simulating the mechanics of skin is crucial for many medical applications, e.g. planning reconstructive surgery or monitoring wound healing. The field of skin biomechanics has often modeled this tissue as a homogeneous material because its response at finite deformations is governed by the dermis due to its collagen content. However, skin consists of two main layers with different mechano-physiology: epidermis at the top and dermis below it. Recently, multi-layer models of skin have been developed to study wrinkling and transport [1]. Still, those models assumed a flat interface between epidermis and dermis when in reality the profile of the interface is sinusoidal, termed *Rete ridges*. We have recently contributed to the modeling of skin mechano-physiology including the effect of this wavy interface [2]. We were interested in the elastic response. However, like all living tissue, a key characteristic of skin is that it grows in response to stretch [3]. This has been used for the reconstructive technique of tissue expansion, in which new skin is grown by over-stretching it via slow inflation of a balloon inserted underneath the skin [3].

The key question we answer here is how is new skin growth able to maintain the Rete ridges [4]. As will be shown later, it is essential to consider two sub-layers within the epidermis: the basal layer, which is the most proliferative, and the rest of the viable epidermis, which is not proliferative and mostly grows from asymmetric cell division in the basal layer pushing cells toward the upper epidermis [5]. Additionally, the existence of different homeostatic pre-strain per layer is needed. Crucially, the skin as a whole remains under tensile pre-stress. We show that different homeostatic stretches for different layers are key to allow buckling of the interface while keeping an overall tensile stress.

METHODS

The 2D multilayered model is made up of three layers which include the epidermis, basal interface, and dermis. Two models, one with a sine wave interface and one with a flat interface are shown in this abstract. The total width and thickness of the model are 0.8002 mm and 1 mm. The interface thickness is h_i =0.0125 mm. The thickness of the dermis is $h_d = 0.9$ mm, whereas the top of the epidermis has a variable thickness $h_e \in [0.1,0.2]$ mm. For the model with the initial sine interface the amplitude is 0.015 mm and the period 0.080 mm, according to physiological values [2]. The three layers are modeled as neo-Hookean with shear moduli μ_e, μ_i, μ_d for epidermis, interface and dermis. The homeostatic pre-stretches are denoted $\lambda_e^{\text{crit}}, \lambda_i^{\text{crit}}, \lambda_d^{\text{crit}}$ and the growth rates k_e^g, k_i^g, k_d^g. To account for the capacity of skin to growth, the total deformation in the x direction, λ, is decomposed into elastic and growth contributions, for each of the layers:

$$\lambda = \lambda_e^e \lambda_e^g = \lambda_i^e \lambda_i^g = \lambda_d^e \lambda_d^g$$

Where the superscript e, g denotes elastic or growth deformation, and the subscript e, i, d denotes epidermis, interface or dermis. The strain energy (and consequently stress) of each layer depends only on the elastic deformation and shear modulus of each layer. The growth deformation obeys the differential equation

$$\dot{\lambda}_*^g = k_*^g(\lambda_*^e - \lambda_*^{\text{crit}})$$

Where $*$ should be substituted for e, i, d for each of the layers.

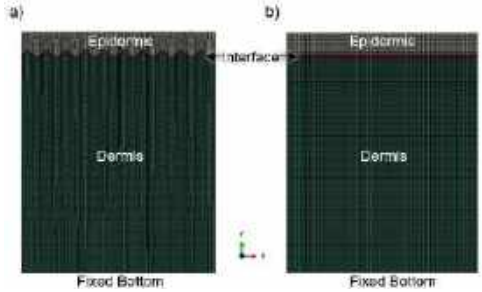

Figure 1: Finite element model with sinusoidal interface (a), and flat interface (b).

RESULTS

Stretching the model with a stress-free sinusoidal interface to twice its original size, in increments similar to what would be done in tissue expansion, triggers growth in all layers such that each layer goes back to its homeostatic pre-stretch. However, the resulting interface, while still sinusoidal, has twice the physiological period. In other words, the interface maintains the initial peaks and valleys, rather than developing new peaks and valleys (Fig 2, left column). The initially flat model, upon initial equilibration to homeostatic value, buckles, leading to a physiological sinusoidal interface. Upon repeated stretching and growth, the different interface points undergo different growth. What was initially the valley grows more compared to what was initially the peak. However, even though growth at the valley is higher, this region is under compression (Fig 3) whereas the initial peaks release some of the compression at each expansion step. As a result, the initial peaks get stretched, leading to valleys separated by flatter interface regions. At some point, however, the growth at the stretched peaks leads to new buckling. What used to be a peak eventually leads to secondary buckling where a valley forms (Fig 2 right column).

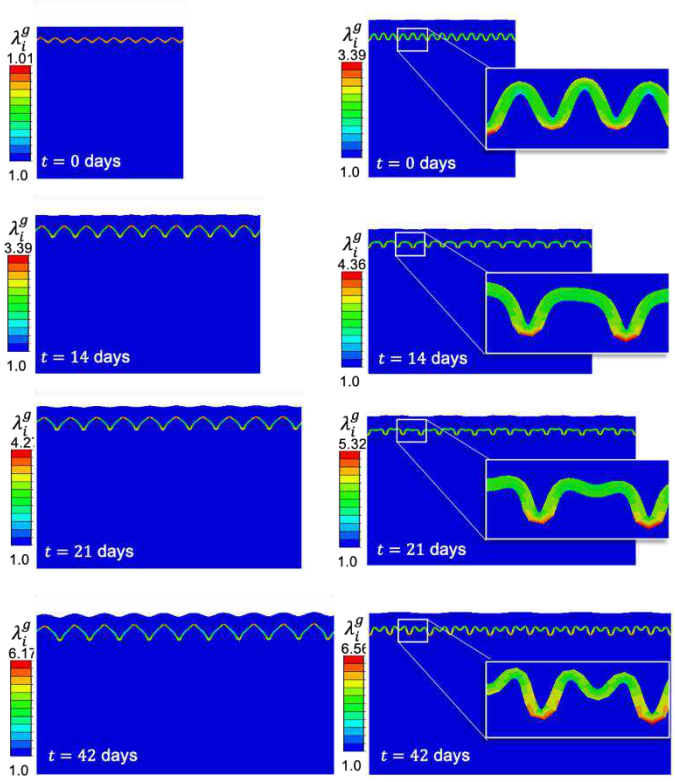

Figure 2: Contour plot of growth at the interface for the model with initial stress-free sinusoidal interface (left) and initially flat interface which by day 0 of tissue expansion already has a sine wave interface due to growth-induced buckling.

Based on work from Colin and Holland [5], who did stability and buckling analysis in bilayer systems, we know that the thickness of the upper layer and contrast of shear modulus between upper and lower layers affects the buckling in bilayer and tri-layer systems. For our case, by changing the epidermis modulus and the homeostatic pre-stretch of the interface we observe the effect on the buckling period and amplitude (fig 4). For softer epidermis (lower shear modulus) is easier to buckle and leads to a higher amplitude and period.

The most important parameter is the homeostatic pre-stretch of the interface, λ_i^{crit}. Note that for the flat interface to buckle, the homeostatic pre-stretch of the interface actually has to be <1 to induce compression and buckling of this middle layer. As λ_i^{crit}>0.8 the buckling disappears and a flat interface remains. As λ_i^{crit}decreased, < 0.8, greater amplitude buckling develops. The period of the sine wave that develops through buckling is also more sensitive to λ_i^{crit}than μ_e, with smaller λ_i^{crit} (greater homeostatic compression) leading to slightly smaller period. However, in our simulations we applied a perturbation to foster the initial buckling, and the perturbation was taken as the physiological period of skin. This perturbation clearly drives the buckling period even as λ_i^{crit}changes. Nevertheless, there is an effect of λ_i^{crit} on the period of the buckling and it is more pronounced than the effect of μ_e.

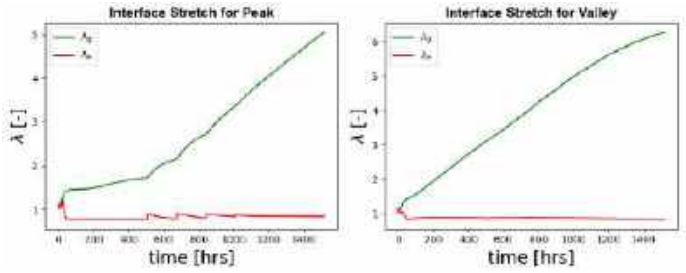

Figure 3: Elastic deformation and growth for the flat interface model at the two locations of interest: peak and valley.

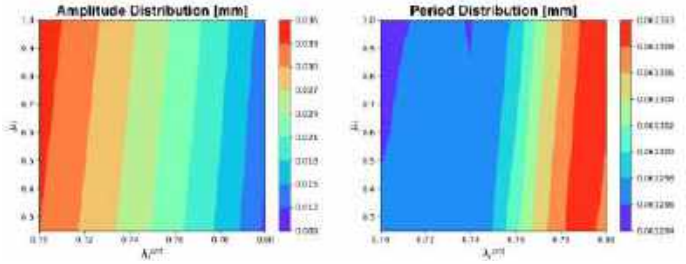

Figure 4: Contour plots of the amplitude and period variation in the flat model with a combined thickness between the epidermis and interface of 0.1 mm.

DISCUSSION

Our analysis shows that considering a stress-free sinusoidal interface does not allow us to recover the subsequent buckling needed to retain physiological Rete ridges during tissue expansion. Instead, an initially flat interface buckles leading to the Rete-ridges, and subsequent buckling during tissue expansion can maintain this physiological feature of skin. The most important parameter is the homeostatic pre-stretch of the interface layer λ_i^{crit}. The pre-stretch needs to be <0.8 to place the layer under enough compression. The compression in the interface layer and the tension in the dermis layer, with a pre-stretch λ_d^{crit}=1.15, allow for buckling of the interface and also physiological pre-tension of skin.

EFFECT OF BREATHING TECHNIQUE FOR TARGETED LARYNGOPHARYNGEAL DRUG DELIVERY

Shamudra Dey (1), Guilherme J.M. Garcia (1,2)

INTRODUCTION

Laryngopharyngeal reflux (LPR) affects approximately 20% of the population in the United States and corresponds to 10% of visits to otolaryngology clinics [1-3]. Like gastroesophageal reflux disease (GERD), LPR is caused by retrograde flow of stomach content, but LPR is associated with symptoms at the larynx and pharynx while GERD causes damage to the esophagus. Currently, there is no gold standard medical therapy to treat LPR. Placebo-controlled trials have shown that acid-suppression therapy (i.e., proton pump inhibitor) that is effective against GERD is not effective against LPR [4]. Therefore, there is an unmet need to develop new pharmaceutical products to treat LPR.

Dry Powder Inhalers (DPIs) were originally developed to treat asthma and chronic obstructive pulmonary disease (COPD). The target site for drug delivery for asthma and COPD is the lungs. The Food and Drug Administration (FDA) specifies that aerodynamic particle size distribution (APSD) and inhalation rates are critical quality attributes of DPIs because these attributes have a major impact on the regional drug distribution in the airways [5]. Currently, the optimal APSD and breathing technique for maximizing drug delivery to the laryngopharynx are unknown. The main objective of this research is to study the effect of breathing techniques (fast, normal, and slow inhalation) for optimized laryngopharyngeal drug delivery using a newly proposed DPI to treat LPR.

METHODS

The 3D model was created using Materialise MIMICS software and is based on the MRI of healthy 49-year-old female (**Fig. 1A**). Poly-hexcore meshes of 2.9 million (coarse), 5.6 million (medium) and 9.2 million (fine) cells and 5 prism layers were created in ANSYS Fluent Meshing. **Fig. 1B** shows a poly-hexcore mesh of 5.6 million cells with 5 prism layers. CFD simulations were performed in ANSYS Fluent using the k−ω SST turbulence model. The transient simulations were implemented with a sinusoidal breathing profile (**Fig. 2**):

$$Q(t) = Q_{max} * \sin(2\pi t/T) \quad (1)$$

where, $\bar{Q}$=30 L/min is the time-averaged inhalation rate and T is the breath duration. We studied three inhalation rates, namely fast (T = 2s), normal (T = 4s), and slow (T = 6s) inhalation.

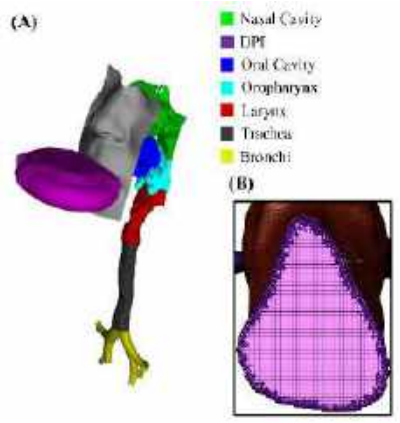

Figure 1: (A) Three-dimensional model of the human respiratory tract. (B) Poly-hexcore mesh with 5.6 million cells and 5 prism layers.

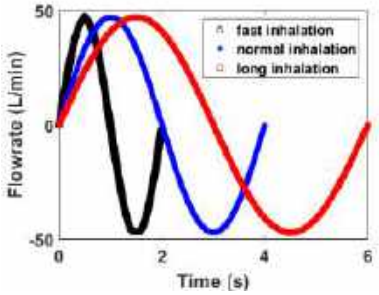

Figure 2: Sinusoidal breathing profiles with fast (T=2s), normal (T=4s) and long (T=6s) inhalation.

To perform discrete phase modeling, 25 log-spaced particle sizes of 1-to-50-micron particles of density $1000\ kgm^{-3}$ were released once the oral inhalation rate reached 15 L/min. The duration of particle release was 0.5 sec, which is the typical emptying time of DPIs based on literature [6]. We assumed a log-normal particle size distribution, where X_{50} = mass median aerodynamic diameter (i.e., half the aerosol mass is in particles smaller than X_{50}) and σ_g = geometric standard deviation (represents the width of the distribution).

RESULTS

The CFD simulations were validated by comparing the CFD-predicted extrathoracic dose (i.e., oral cavity, pharynx, larynx, and trachea) with in vitro experiments by Stahlhofen et al. (1989) [7]. A grid independence study revealed that a mesh with 5.6 million elements provided a nearly mesh independent results for both the air velocity field and particle deposition. **Fig 3** shows both validation of CFD results by comparing them to experimental results and grid independence study of particle deposition.

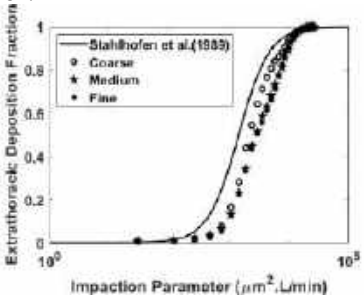

Figure 3: Prediction of Extrathoracic deposition compared to the experimental data of Stahlhofen et al. (1989).

Laryngopharyngeal deposition was predicted to be maximized by an impaction parameter, $IP = d_a^2 Q = 5525$ μm².L/min, where d_a is the particle aerodynamic diameter and Q is the inhalation rate (**Fig. 4**). This suggests that a monodisperse aerosol with d_a = 13.56 μm inhaled with a slow inhalation rate of 30 L/min (corresponding to IP = 5525 μm².L/min) would provide the highest laryngopharyngeal deposition fraction of 0.61 (i.e., 61% of the DPI dose would deposit in the laryngopharynx). However, DPIs are polydisperse. To illustrate the importance of the APSD, we investigated two hypothetical DPIs (DPI-1 & DPI-2) with constant $\sigma_g = 2$ (**Fig. 5**). DPI-1 has an X_{50} = 10 μm, which is hypothesized to be optimal to treat LPR compared to DPI-2, which has X_{50} = 3 μm (representative of current commercial DPIs).

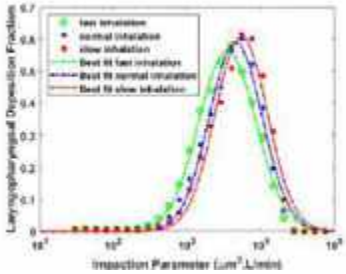

Figure 4: Effect of Breathing techniques on laryngopharyngeal Deposition Fraction for DPI-1 (X_{50} = 10 micron).

Our results suggest that the effect of inhalation rate (breathing technique) is negligible for DPI-1 (30.3 % laryngopharynx DF for normal inhalation and 30.6 % laryngopharynx DF for fast inhalation) (**Fig. 6**). In contrast, the simulations predicted that for DPI-2, a higher laryngopharynx deposition would be achieved with a faster inhalation. However, our simulations predicted that the laryngopharyngeal dose delivered by DPI-1 is significantly higher than the dose delivered by DPI-2 (i.e., 30.6% vs. 9.1% of the total mass for DP1-1 and DPI-2, respectively, for a fast inhalation) (**Fig. 6**).

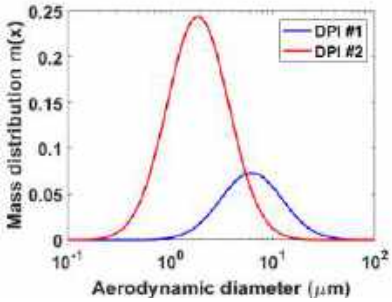

Figure 5: Log-normal particle size distribution of two hypothetical DPIs: DPI-1 (X_{50}= 10 microns and $\sigma_g = 2$) and DPI-2 (X_{50}= 3 microns and $\sigma_g = 2$).

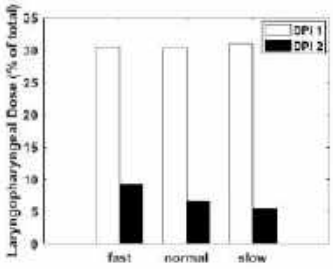

Figure 6: DPI-1 (X_{50} = 10 μm, $\sigma_g = 2$) has significantly higher laryngopharyngeal deposition than DPI-2 (X_{50} = 3 μm, $\sigma_g = 2$).

DISCUSSION

This study investigated the impact of breathing technique (slow vs. fast inhalation) on laryngopharyngeal drug delivery. The study has multiple limitations, including the small sample size (n=1 anatomy). However, this study provides crucial information to design DPIs to treat LPR. For our proposed DPI-1, we observed minimal effect of breathing technique with similar laryngopharyngeal deposition for all three cases. In contrast, for commercially available DPIs ($X_{50} \leq 5$ μm for lung delivery), we observed that faster inhalation led to higher laryngopharynx deposition. However, current DPIs in the market have much smaller laryngopharyngeal deposition compared to our proposed DPI-1. We conclude that DPI-1 (X_{50} = 10 μm) is expected to provide significantly higher laryngopharyngeal deposition compared to DPI-2 (X_{50} = 3 μm).

TAILORED DELIVERY OF A SMALL MOLECULE AGONIST FOR HEDGEHOG SIGNALING ACTIVATION IN TENDON-TO-BONE INTEGRATION

INTRODUCTION

Tendon injuries often occur at the tendon-to-bone junction (i.e., enthesis) and frequently result in disorganized scar tissue formation following injury [1]. The Hedgehog (Hh) signaling pathway plays a vital role in regulating fibrocartilage formation at the enthesis during growth [2-4]. In our prior research, we demonstrated that activating the Hh pathway, either genetically or through systemic Hh agonist administration, promoted tendon-to-bone attachment formation post anterior cruciate ligament reconstruction (ACLR) [5]. Therefore, targeting this pathway shows promise in improving tendon-to-bone repair by encouraging zonal enthesis formation.

Recognizing the importance of Hh signaling in the maintenance of various tissues [6], there is an unmet need to develop localized therapies to leverage this pathway to enhance repair outcomes, while minimizing off target effects. Thus, we developed an electrospun scaffold release system with varying concentrations of SAG, a small-molecule Hh agonist, to locally stimulate Hh signaling in the cells that contribute to tendon-to-bone integration during repair. Thus, this study aimed to incorporate SAG into the scaffold, evaluate scaffold properties post-incorporation, establish the *in vitro* release profile and bioactivity of SAG, and investigate the local activation of the Hh pathway by these scaffolds in promoting tunnel integration in a high throughput bilateral transverse tibial tunnel (TTT) surgical model.

METHODS

Scaffold Fabrication: A PCL solution (35 wt%) was prepared in DMF/THF with the Hh agonist (SAG) at different concentrations (0, 0.001, 0.01, 0.1 mg/ml). The solution (2mL) was spun from an 18G needle at 15kV onto a rotating mandrel (8 m/s, 2.5 ml/hr).

SEM: Fibril alignment and fibril diameter were measured using the OrientationJ plugin and the General Image Fiber Tool (GIFT) in FIJI from images acquired on an FEI Quanta 600 ESEM.

SAG Release Study: All animals and procedures were approved by Institutional IACUC. Blank and SAG-infused scaffolds were placed in culture media in tubes on a shaker at 37ºC (**Fig. 1A**) and conditioned media (CM) was collected over 28 days. CM samples from days 2, 8, 16, or 26 were applied to bone marrow stromal cell (bMSC) cultures for 4 days. Gli1 gene expression was assessed by qPCR.

Tunnel Integration Study: TTT surgeries were performed on 24 mice to test the effect of SAG release on Hh activity and tunnel integration. This procedure was utilized as a simpler, higher throughput model than the ACLR model we used previously [1,5]. Graft tail tendons were harvested from mice and a sterile scaffold was added to the graft bundle. A transverse tibial tunnel was drilled in the metaphysis using a 27G needle. The graft with the scaffold was passed through this tunnel and the samples were assessed on day 14 post-surgery.

Mineralized Cryosectioning, qPCR, and Imaging: Limbs were fixed, embedded, sectioned undecalcified with cryofilm. The medullary canal was microdissected from tissue sections for qPCR. Adjacent sections were stained with Alizarin Complexone (AC) to visualize deposited mineral fluorescently on a Zeiss Axio Scan.Z1. AC area was normalized to the area of the tendon graft and scaffold and quantified.

Statistical Analysis: Fiber diameter, scaffold mechanical properties, and *in vivo* qPCR and AP activity were compared via one-way ANOVA ($p<0.05$). Gli1 expression from *in vitro* release was compared via two-way ANOVA with Sidak's post-hoc tests ($p<0.05$).

RESULTS

SAG incorporation affected fiber alignment but not diameter of electrospun PCL scaffolds: We found that SAG incorporation reduced the overall fiber alignment (SD_{blank} = 15.8º, $SD_{0.01}$ = 19.1º, $SD_{0.001}$ = 25.3º, $SD_{0.1}$ = 26.6º) in the scaffold. However, fiber diameters of the SAG scaffolds were not significantly different from the blank scaffold (0.33+/-0.06, 0.32+/-0.07, 0.35+/-0.05, 0.32+/-0.11 μm; mean+/-SD for 0, 0.001, 0.01, and 0.1mg/ml respectively).

Delivery of conditioned media to bMSCs increased Gli1 expression in

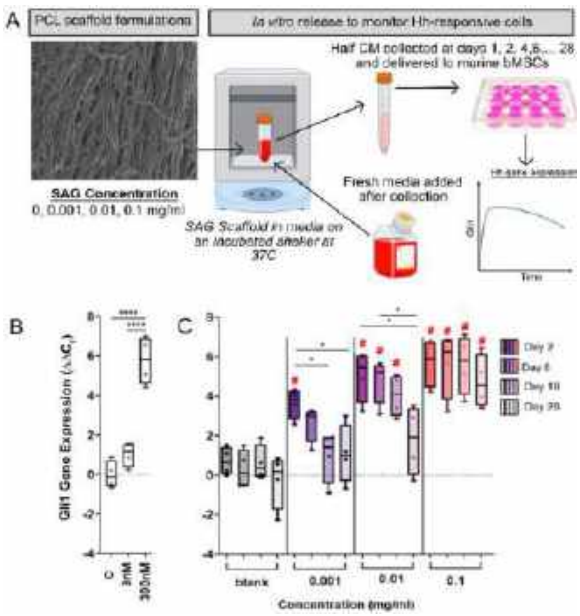

Figure 1: SAG released from scaffolds in dose and time dependent manner. *In vitro* release study design (A). Gli1 ΔΔCq for CM from controls (B) and scaffolds at the four timepoints (C). ****p<0.0001, *p<0.05; # p<0.05 vs. blank.

a dose- and time-dependent manner: As anticipated, we found a significant increase in Gli1 expression with 3nM (2-fold) and 300nM (70-fold) of SAG added directly to the media (p<0.05, **Fig. 1B**) vs control media. CM media from the SAG scaffolds increased Gli1 expression in a dose- and time-dependent manner (p<0.05, **Fig. 1C**). While Gli1 expression did not change over time in the blank scaffolds, it was significantly higher in the SAG scaffolds compared to the blank scaffolds in CM collected on day 2. Interestingly, Gli1 expression remained elevated in the 0.1 mg/ml SAG scaffold for a longer period compared to the other concentrations. The results suggest that the 0.1 mg/ml SAG scaffold released enough SAG to maintain activated Gli1 expression in bMSCs over a 26-day period.

Localized delivery of SAG to the bone tunnels increased Gli1 activity while also promoting mineralized fibrocartilage (MFC) formation in the tendon graft and mineral deposition in the scaffold: To determine the local effect of SAG released from the scaffold on nearby cells in an *in vivo* setting, we microdissected tissue within the medullary canal, including the surgically drilled tunnel (**Fig. 2C**), from cryosections using a needle and performed qPCR. SAG release yielded a dose dependent effect on Gli1 expression, with the 0.1 mg/ml SAG group having ~3-fold higher expression (p=0.009, **Fig. 2D**). To monitor the tunnel integration process, we measured the deposited mineral area in the tendon graft and scaffold (red in **Fig. 3A**). We found that SAG concentration affected AC deposition in a dose-dependent manner, with the 0.1mg/ml group having higher MFC formation in the tendon graft (p=0.044, **Fig. 3C**) and higher mineral deposition in the scaffold region of the 0.01 mg/ml (p=0.048) and 0.1 mg/ml (p=0.047) groups (**Fig. 3D**).

DISCUSSION

Incorporating the Hh signaling agonist, SAG, into electrospun PCL scaffolds enabled controlled release *in vitro* and *in vivo* while maintaining bioactivity. *In vitro*, a dose- and time-dependent release profile revealed sustained Gli1 expression at 0.1 mg/ml, contrasting with reduced levels at other doses over one month. In the *in vivo* TTT model, SAG-treated scaffolds demonstrated a dose-dependent increase in Gli1 expression (**Fig. 2D**) and prompted a dose-dependent augmentation in mineral deposition, notably the 0.1 mg/ml group exhibiting greater MFC formation in the tendon graft and scaffold region (**Fig. 3**). This result is consistent with our previous work using systemic injections of a Hh agonist [5]. The findings support the idea that Hh signaling is a strong regulator of the tendon-to-bone integration process [2-4] and enhance our understanding of Hh pathway dynamics in later stages of zonal attachment formation. Our work suggests that using the Hh pathway for therapy could revolutionize the treatment of tendon and ligament injuries. Delivering agonists within a specific therapeutic window could improve tendon-to-bone repair and recovery times. However, more research is needed to fully understand the Hh pathway and develop new therapies. Therefore**,** future studies will apply the SAG-delivering scaffolds in our more clinically relevant, yet lower throughput, ACLR model to improve the tendon-to-bone integration processes.

INTRODUCTION

Cell-mediated remodeling processes are responsible for tissue organization in developmental biology [1] and tissue reorganization in disease states such as cancer [2]. Thus, a more thorough understanding of how cells interact with and remodel their microenvironment can better inform tissue engineering strategies seeking to mimic or counteract these phenomena. Recent work has investigated how cell-mediated remodeling affects the development of multi-cellular structures, such as angiogenesis [3]. However, a vast majority of the existing body of theoretical work uses a continuum representation of the extracellular matrix (ECM), which does not capture non-affine deformations characteristic of loosely connected fiber networks. While some discrete models of cell-matrix contraction exist [4,5], many simulate the process in 2D or fail to incorporate fiber-fiber interactions, such as entanglement or crosslinking, which result in permanent changes to the ECM structure. This work seeks to address these gaps by using a discrete model of the ECM in a molecular dynamics framework to simulate cell contraction and matrix reorganization. In particular, we explored how feedback between cells and their extracellular matrix can result in spontaneous cellular alignment and directed ECM reorganization. We tested the hypothesis that cell-driven remodeling can induce structural anisotropy in the ECM, in turn leading to preferential cell alignment.

METHODS

ECM Network Generation

Networks were generated to represent a 70x70x70 μm^3 volume of a 4 mg/mL collagen gel. Isotropic ECM networks were generated from periodic 3D Voronoi tessellations on randomly seeded points [6]. Collagen fibrils were modeled as a segmented, bead-spring chains composed of equally spaced beads connected by harmonic bonds (Fig. 1.A-B). To allow for plastic ECM remodeling [7], beads could interact via strong, short-distance Lennard-Jones potentials with a resting length corresponding to a fiber radius of 100 nm (Fig. 1.C).

Cell Model

The cell was modeled as a static ellipsoid at the center of the network. At each time step, the cell was described by its 3 semiaxes and their corresponding unit vectors. During the simulation, the cell volume was kept constant at 1300 μm^3. Pseudopods were generated on a similar ellipsoid 8-times the volume of the cell, modeling pseudopod extension beyond the cell's surface. These pseudopods were bound to the static cell center with a harmonic bond that equilibrated at the cell surface. Pseudopods were able to bind to the ECM via strong Lennard Jones potentials that equilibrated at the radius of the pseudopod, about 7 μm. In this way, ECM beads bound to the pseudopod surface were also retracted towards the cell center during cell contraction.

A model of cell sensing enabled the cell to respond to dynamic changes in the matrix. Prior to pseudopod placement, an ellipsoidal volume of the fiber network centered at the cell and 8-times the cell volume was analyzed. A fiber orientation tensor Ω (Eq. 1) was calculated for fiber segments within this ellipsoid. For each segment,

$$\Omega_{ij} = \frac{1}{l^{f,total}} \sum l^f n_i^f n_j^f \quad (1)$$

the outer product of the normal vector n^f and itself was scaled by the length of the segment l^f. The resulting tensor was then normalized by the total length of fibers within the volume $l^{f,total}$. For isotropic networks, $\Omega_{11}=\Omega_{22}=\Omega_{33}=0.33$. For networks completely aligned in the x-direction, $\Omega_{11}=1$ and $\Omega_{22}=\Omega_{33}=0$. The semiaxes of the cell were updated to match this orientation tensor. Pseudopod locations were randomly generated beyond the surface of the updated morphology, biasing the longer axes to emulate contact guidance behavior [8].

Simulation Procedure

Simulations were conducted using HOOMD [9], a molecular dynamics simulation software (Fig. 1.D). Networks were first allowed to relax before gross network characteristics like density and alignment

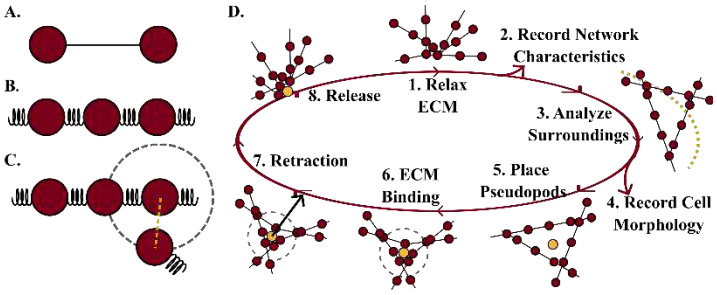

Figure 1: (A, B) Segmented fiber networks were allowed to reorganize (C) and bind neighboring nodes to simulate ECM remodeling during (D) simulations of cell contraction.

were recorded. Spherical cells were then seeded in the center of the network and an orientation tensor was calculated for the network surrounding it. The cell morphology was updated using the orientation tensor, and pseudopods were generated outside the surface of the cell. Pseudopods bonded to the ECM via Lennard Jones potentials before being retracted towards the surface of the cell. Pseudopods were then removed from the simulation, and the network was allowed to relax. This protocol was repeated for each contraction cycle.

Cases Studied

First, a simulated cell contracted within an isotropic network for 40 cycles. After each contraction, spherical subregions of the matrix centered around the cell were analyzed for density, alignment, and strain. This study was a validation of the basic principle and was directly comparable to published experimental work [10].

Next, compaction of 3 different periodic networks was simulated: isotropic, aligned, and narrow. Isotropic gels were created as above. Aligned gels were generated by creating rectangular tessellations that were then morphed into cubes to induce alignment in the x direction with Ω_{xx}=.5. Narrow networks were created by seeding isotropic gels in a unit volume with a 1:3:3 aspect ratio, with the x-direction being the shortest. Since the boundaries are periodic, a narrow domain corresponds to a lattice of cells with smaller spacing in the x direction. Cells were allowed to undergo 6 contractile cycles and cellular Ω_{xx} values were recorded to track cell alignment in the x-direction (Fig.3.A).

RESULTS

Matrix Compaction and Reorganization in Isotropic Networks

Over the course of the simulation, fiber density increased the most in regions close to the cell (Fig. 2.A). Additionally, after many contraction cycles, a plateau in the densification was observed, which is consistent with recent experimental findings [10] (Fig 2. B). In this way, the model suggests that fiber densification varies with both position and time during cell-driven compaction. The shape characteristics of the matrix were recorded. As demonstrated in the insets (Fig. 2.C), repeated contractions resulted in a matrix that was densest around the cell and aligned radially away from the cell center.

Finally, the distribution of fibers' resting strains were recorded at each step. Over the course of the simulation, the proportion of segments in tension (Fig 2.D) and the mean fiber strain increased. Further, the distribution of fiber strains differed from earlier time sequences (P<0.01). These results indicate that not only did the ECM's structure change, but the mechanical properties of the matrix were also changed.

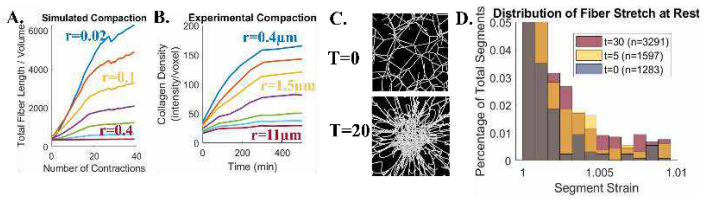

Figure 2: (A) Simulated and (B) experimental [10] densification, (C) matrix reorganization, and (D) resting strain distribution.

Spontaneous Cellular Alignment due to ECM Mechanical Feedback

Cells in isotropic networks did not align in x, whereas cells in aligned networks immediately aligned in the x-direction (Fig. 3.D). Cells in narrow gels started aligning randomly but began aligning in the x-direction with subsequent contractions. By contraction 6, Ω_{xx} for cells in narrow gels differed significantly from that of cells in cubic isotropic gels (P<0.05). In contrast, cells in aligned gels decreased in alignment over the experiment. Despite this, they remained more aligned than cells in the isotropic and narrow gels (P<0.01).

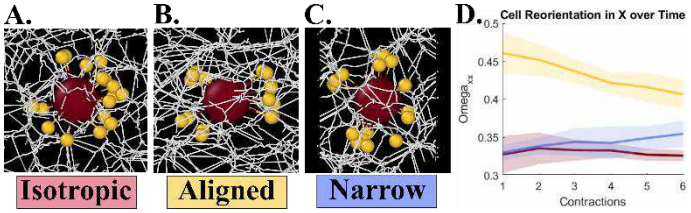

Figure 3: Ω_{xx} indicated that cell orientation remained unaligned in (B) isotropic gels, but aligned in (C) aligned and (D) narrow gels

DISCUSSION

This project sought to create a computational mechanical model of feedback between a contracting cell and its dynamic microenvironment, driving matrix reorganization and cell reorientation. Simulated results of single-cell contraction demonstrate that the model can recapitulate experimental findings like spatiotemporal trends in matrix densification and ECM reorientation. Furthermore, the model incorporates permanent remodeling of the ECM due to cell-mediated fiber rearrangement, as indicated by the distribution of fiber strains at rest. These results appear consistent with findings that cells mechanically remodel their environment, changing ECM density [10] and stiffness [7].

The periodic nature of the simulation presents both an opportunity and a challenge. For one, it enables investigations of cell-ECM-cell interactions, where cells can respond to cues across neighboring unit cells. This was the intention in the narrow simulations, but this phenomenon might also be affecting the other test cases. Thus in order to isolate the effects of one cell, or even two cells, significantly larger unit volume may be needed. Finally, while the model incorporates elements of contact guidance, recent literature suggests that this process is mediated by anisotropic force generation due to structural cues in the network [8,11,12], not just topography. Though this model does not probe for local stiffness anisotropy, the alignment-feedback mechanism coupled with plastic matrix deformation framework allows for more robust investigations into cell-ECM interactions.

INTRODUCTION

Inflammatory Breast Cancer (IBC) stands out as a distinct and aggressive form of breast cancer, accounting for 10% of breast cancer deaths despite its relatively rare occurrence. A significant characteristic of IBC is the invasion of cancer cells into the lymphatic and blood vessels near the skin, leading to the formation of tumor emboli and lymphovascular spread[1]. This phenomenon, known as lymphovascular space invasion (LVSI), plays a crucial role in the clinical manifestations of IBC, making traditional skin-sparing and breast-conserving surgeries ineffective choices. The mechanisms underlying LVSI, particularly its progression from breast tissue into the overlying skin within the lymphatics, termed dermal lymphatic invasion (DLI), remain poorly understood and representative models that account for lymphatics, surrounding metastatic sites, and immune cells do not exist to understand this phenomenon. The goal of this research is to create a Breast-Skin platform with functional blood and lymphatic vessels that can be used for elucidation of LVSI and screening therapeutics.

METHODS

We created physiologically representative breast tumor and skin platforms and integrated them into a multi-tissue Breast-Skin platform with functioning blood and lymphatic vessels. To mimic breast tumor tissue, 1 million MDA-IBC3 cells/mL and THP-1 macrophages were cultured in a matrix of 7 mg/mL collagen type 1 which was polymerized around 22-gauge needles to create the vessels. In order to mimic relevant breast tumor properties that affect drug transport, we characterized tumor porosity using SEM. Vessel permeability was measured by injecting 70 kDa dextran into the channels and imaging its fluorescent intensity that crossed the endothelium in a ROI in images taken every 2 minutes over the course of 30 minutes. After 24 hours, the breast tumor platform was exposed to 5 µm PM37 for 24 hours (end of Day 1). PM37 is a phosphoSTAT6 inhibitor that has been shown to prevent M0 macrophage polarization into the M2 phenotype as well as reverse M2 polarization[2]. For the skin platform the dermis layer of the skin platform was created using a layer of 4 mg/mL collagen solution or 50/50 C/KTN hydrogel solution seeded with 0.1 million cells/mL of primary normal human dermal fibroblasts (NHDFs). A blood vessel was created in the dermis similar to the breast tumor platform. The epidermis layer was created by seeding Ker-CT on top of the platform in the upper compartment in proliferation media at a seeding density of $0.4x10^6$ cells/sample. Vessels were perfused with 1×10^7 cells/mL mKate-labeled tumor microvasculature endothelial(TIME) and 1×10^7 cells/mL Human dermal lymphatic endothelial cells (HDLECs) for blood vessels and lymphatics respectively. We also compared different formulations of matrix materials of collagen solution and 50/50 C/KTN hydrogel solution on the barrier function, epidermal thickness, and vessel permeability of the skin platform. We measured vessel permeability similar to the breast tumor platform, barrier function with Transepithelial electrical resistance (TEER), and characterized epidermal thickness with Hemotoxylin and Eosin staining. By integrating these two platforms we developed Breast-Skin platforms for studying LVSI. Breast-Skin platforms were rotated on all 4 sides for 4 minutes each rotation and then this process was repeated so the endothelial cells could attach on all the surfaces of the hollow channel. All Breast-Skin platforms were then placed in 6 well plates with 1.5-2 mL of complete endothelial cell media in each well surrounding the platform and put back on the rocker for 3 days to allow formation of a confluent vessel.

RESULT S

The presence of THP-1 macrophages is inherent in the IBC tumor microenvironment and resulted in a significantly more permeable

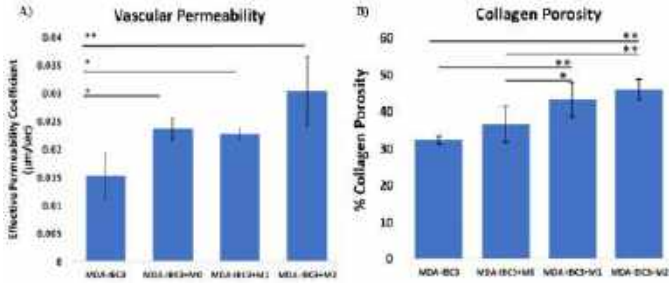

Figure 1: A) Effective permeability of vasculature in breast tumor platform. B) Collagen (ECM) porosity in breast tumor platform.

endothelium compared to platform containing only MDA-IBC3 cells (Fig.1A). We have also shown that incorporating THP-1 macrophages has a significant impact on ECM porosity and vasculature permeability allowing collective tumor cell migration and intravasation. Porosity measurements from SEM processed images revealed the influence of THP-1 macrophages on matrix remodeling. Platforms with the THP-1 M1 or M2 macrophages were significantly more porous than the platforms with THP-1 M0 and the MDA-IBC3 only platforms[3](Fig.1B).

After observing macrophage induced matrix porosity, we perfused the *in vitro* platforms with PM37 to see if we could diminish the increased angiogenic response for therapeutic consideration. Cytokine analyses revealed a transient effect in expression of proangiogenic factors right after treatment, but once PM37 was removed, the expression levels of measured cytokines reverted back to control levels. EGF, bFGF, VEGF-A also decreased following in the MDA-IBC3+M2 platforms on Day 1 right after treatment ended, but these same cytokines were increased in the treatment platforms at the same timepoint in the MDA-IBC3+M1 platform revealing a phenotype dependent response to PM37(Fig.2).

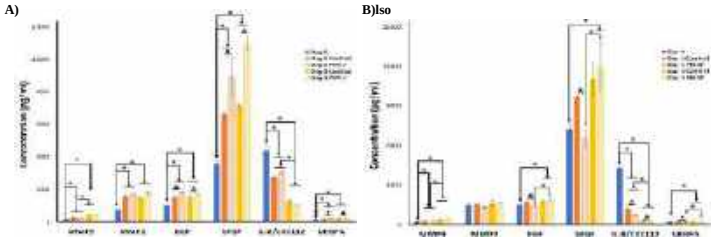

Figure 2: Effect of PM37 on cytokines expression in the A) MDA-IBC3 + M1 *in vitro* platform B) MDA-IBC3 + M2 in vitro platform.

Similarly, we created the first vascularized multi-layer human skin platform (Fig.3) comprised of a collagen dermal layer seeded with normal human dermal fibroblasts (NHDFs, blue, Fig.3A) containing an endothelialized blood vessel with functional endothelial (TIME) cells in red and an epidermal layer above consisting of a unique collagen/keratin blend with keratinocytes that promoted barrier function (green, Fig. 3A). We demonstrated keratinocyte differentiation characteristic of native epidermis with a stratified epidermis (Fig. 3B). TEER measurements showed a significant increase in resistance measured for 50/50 C/KTN hydrogel models compared to collagen hydrogels (Fig. 3C). For permeability measurement, 70 kDa dextran was perfused through the vessel of the vascularized skin platform. Images were taken every 2 minutes to measure the fluorescence intensity over time. The permeability coefficient of the skin layer composed of 100% collagen was significantly higher than that of 50/50 C/KTN hydrogels, indicating a stronger barrier created with the 50/50 C/KTN hydrogel (Fig.3E).

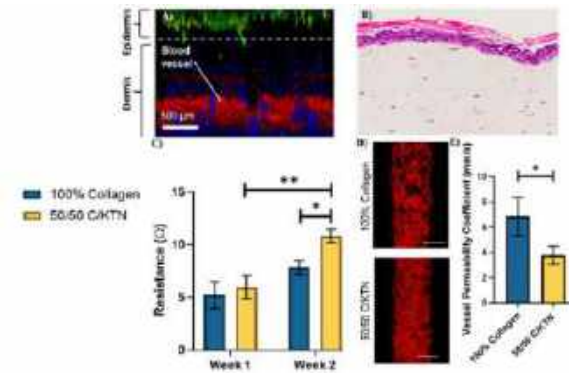

Figure 3: A) Confocal image of longitudinal cross section of multilayer skin platform with endothelial cells (red), fibroblasts(blue) in the dermis, and keratinocytes (green) in the epidermis. B) H&E-stained section of skin platform with stratified epidermis. C) TEER of skin platform at week 1 and 2. D) Confocal images of vessels in 100% collagen and 50/50 C/KTN hydrogel. E) Vessel permeability coefficient in skin platform.

By integrating the breast tumor and skin platforms, we created the first multi-tissue lymphovascularized Breast-Skin platform and generated multiple confluent blood vessels in both the skin and breast tissue, which were subsequently visualized using confocal microscopy (Fig.4). Notably, the channels in the breast tumor tissue appeared brighter than those in the skin, attributed to the increased depth of collagen that the laser had to penetrate to reach the upper layer. As it can be seen in Figure 4B, we also showed IBC cells invading the skin. We also observed the formation of MDA-IBC3 tumor emboli surrounded by newly established vascular vessels and emboli intravasation, a characteristic feature of *in vivo* IBC tumors (Fig. 4C).

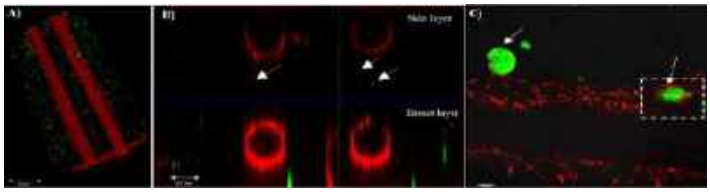

Figure 4: Confocal image of multilayer vascularized Breast-Skin platform. Breast-Skin platform layer seeded with MDA-IBC cells (green) and a vascular endothelium (red) overlaid with skin platform consisting of fibroblasts (unlabeled) around a vascular vessel (red). A) Top view of the Breast-skin platform. B) Cross section of the Breast-Skin platform showing MDA-IBC3 cells in the skin layer (denoted by white arrows). C) Center plane of vascular platform (red) showing tumor emboli (denoted by white arrows) invading vessels.

DISCUSSION

This study demonstrates the creation of the first *in vitro* Breast-Skin platform, with contiguous physiological tissues equipped with functional blood vessels and lymphatics. We have increased the complexity of our existing *in vitro* IBC platform by incorporating macrophages and observed the significance of incorporating different phenotypes of macrophages for studying cancer cells migration. We observed MDA-IBC3 emboli surrounded by these vessels, attempting to intravasate. The observation of vascular endothelium sprouting, and adjacent tumor emboli is solely facilitated by interactions between tumor and endothelial cells, representing the *in vivo* behavior of IBC. Additionally, we utilized the capability of the *in vitro* platforms to study tumor response to therapeutics and revealed a phenotype dependent response. Furthermore, we showed that the presence of KTN in the hydrogel increased barrier function by lowering the permeability of dextran through the developed epidermis and increased the transepithelial electrical resistance. Overall, our platform design enables the evaluation of various functional endpoints, such as intravasation, vessel sprouting, ECM porosity and the presence of stromal emboli. In further studies, we will measure LVSI, DLI, angio/lymphogenesis, vessel permeability, and cytokine expression. This will enable the contribution of metastasis through blood and lymphatic vessels in tumor metastasis.

INTRODUCTION

Protein biomarkers have found widespread use in disease diagnostics such as for cancer and neurodegenerative disorders. The ability to detect and quantify low abundance protein biomarkers is essential for early diagnosis. Digital enzyme-linked immunosorbent assay (dELISA) opens a new era of ultra-low protein concentration detection (attomolar) compared with conventional approaches such as ELISA, mass spectrometry, and Western blotting.[1] dELISA is built upon two fundamental technologies, namely (1) separating the target protein into a large number of fL-pL compartments (microwells or droplets) with each compartment containing no more than one protein molecule, and (2) enzymatic amplification in each compartment to indicate the presence or absence of single molecules. While this method allows single molecule detection and absolute quantification, dELISA is complex, has high cost, and requires sophisticated instrumentation (e.g. Quanaterix SIMOA). [2, 3] Recently, an on-bead amplification using rolling cycle amplification (RCA) removes the need for microscale compartments.[4] but still requires enzyme amplification. Further simplifying dELISA can lead to wider adoption and clinical use.

In this study, we introduce an enzyme- and compartment-free single protein detection platform named Digital Plasmonic Nanobubble Detection for Protein biomarkers (DIAMOND-P). DIAMOND-P is an immunoassay-based platform that involves antibody-coated silica microbead to capture single protein molecules and gold nanoparticle to label the captured proteins. We then applied short laser pulses to generate nanobubbles around the captured gold nanoparticles (AuNPs), allowing instantaneous amplification and detection due to the strong light scattering.[5] Compared with dELISA, DIAMOND-P provides similar attomolar sensitivity while removing the need for slow enzymatic amplification and the use of physical microscale compartments. Moreover, DIAMOND-P can work well at room temperature with small sample volumes (less than 10 µL). Our new DIAMOND-P is a new method for enzyme- and compartment-free digital protein detection at room temperature and can accelerate its wider use in biomarker discovery and diagnostic testing for many disease applications.

METHODS

Plasmonic nanobubble generation and detection:

The generation of plasmonic nanobubbles was using 532 nm pump laser (Ekspla PL2230). Testing sample flowed through a 200 µm micro-capillary. For nanobubble detection, a continuous Red HeNe laser (633 nm, model R-30989, Newport) was used.

Poisson statistic:

The theoretical prediction by Poisson statistics was calculated by:

$$P(x = k; \lambda) = \frac{e^{-\lambda} \cdot \lambda^k}{k!} \qquad (1)$$

where k and λ are the actual and average number of AuNPs per detection zone (pulse laser excitation volume), respectively.

RESULTS

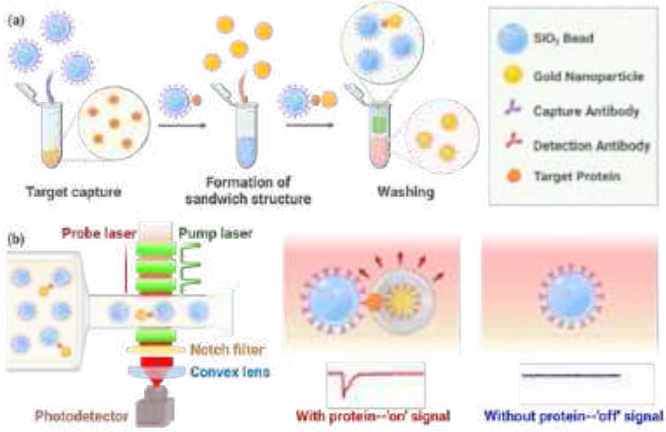

Figure 1: DIAMOND-P assay workflow for protein detection. (a) Bead-based sandwich immunoassay formation. **(b)** Digital counting principle for protein detection.

The detailed schematics for DIAMOND-P, which combines a microbead-based sandwich immunoassay and digital plasmonic nanobubble counting, are illustrated in **Figure 1**. Initially, silica beads coated with specific capture antibodies are introduced to a sample containing target proteins (**Figure 1a**). Gold nanoparticles, modified with detection antibodies, bind to these proteins, forming AuNP-labeled immunocomplexes. A filtration step follows, removing unbound reagents and excess AuNPs, thus isolating the targeted immunocomplexes. **Figure 1b** shows plasmonic nanobubbles (PNBs) generation when gold nanoparticles absorb energy from short laser pulses. These PNBs exhibit strong light scattering, detectable by a second probe laser. This system detects the presence ('on' signal) or absence ('off' signal) of gold nanoparticles that bind to target proteins.

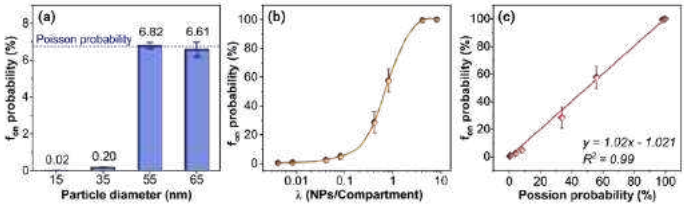

Figure 2: Single Au NPs detection. **(a)** Quantitative analysis of Au NPs of different sizes. **(b)** Quantitative analysis of 65 nm AuNP. **(c)** Linear correlation between experiment and Poisson statistics.

First, we evaluated the ability of the DIAMOND-P to detect single and count AuNP (**Figure 2**). To determine the AuNP size that can be detected by the DIMOND-P platform, we analyzed the probability of nanobubble signals from variously sized AuNP and compared them with the Poisson statistics (**Figure 2a**). The average number of AuNP per detection volume (λ) is 0.07. With 2 J/cm² pulse laser excitation, the result shows that the platform can reliably detect AuNPs larger than 55 nm. We further the ability to count single 65 nm AuNP by varying its concentration (**Figure 2b**). Comparison of the experimental f_{on} and Poisson statistics shows a good linear correlation (**Figure 2c**). These results demonstrate the ability of DIAMOND-P platform in single AuNP detection and quantification.

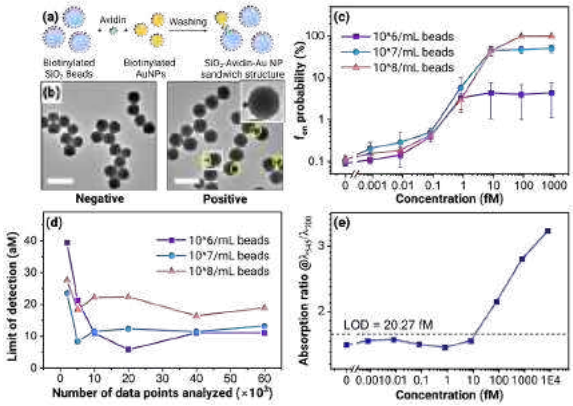

Figure 3: Avidin detection using the DIAMOND-P assay. **(a)** Formation of the SiO_2-Avidin-Au NP sandwich immune structure. **(b)** TEM imaging of post-washing samples with the scale bar of 1 μm, where inset shows the details of single SiO_2-Avidin-Au NP sandwich immune structure. **(c)** Avidin detection calibration curves. **(d)** Data Analysis Impact on Limit of Detection (LOD). **(e)** Colorimetric analog analysis of post-washing samples.

Second, we tested DIMOND-P platform to detect avidin as a model protein (**Figure 3**). We first mixed biotinylated 500 nm SiO_2 beads with avidin for 20 minutes at room temperature, and then incubated with biotinylated AuNPs for 15 minutes. After a filtration washing step to remove unbound reagents and excess AuNPs, we imaged the SiO_2-Avidin-Au NPs complex formation under transmission electron microscopy (TEM). **Figure 3b** shows that AuNPs are captured on SiO_2 beads only in the presence of avidin. **Figure 3c** shows the calibration curves for avidin detection with different SiO_2 bead concentrations (λ = 0.07, 0.7, 7). We further analyzed the limit of detection (LOD) as a function of the number of data points (laser pulses) and the results show that the DIAMOND-P can reach the average detection limit of 12 aM (**Figure 3d**). Compared with the colorimetric analog assay (**Figure 3e**), the LOD of DIAMOND-P is <u>three orders of magnitude lower.</u>

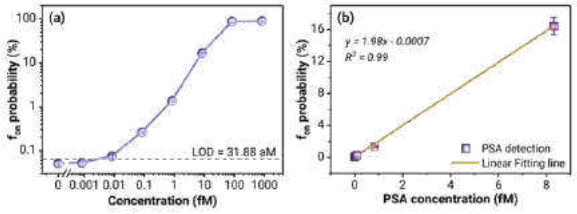

Figure 4: Prostate-Specific Antigen (PSA) detection with the DIAMOND assay. **(a)** Calibration curve for PSA detection. **(b)** Linear correlation analysis of PSA detection.

Lastly, we tested the DIAMOND-P assay's capabilities by detecting prostate-specific antigen (PSA), a crucial biomarker of prostate cancer. First, we established the calibration curve for PSA detection (**Figure 4a**) using SiO_2 beads at a concentration corresponding to λ = 2, where the dashed black line indicates the limit of detection of PSA detection at 31.88 aM. Secondly, we further validated the assay's accuracy through a linear correlation analysis (**Figure 4b**) between the frequency count (f_{on}) obtained experimentally and the PSA concentration. The above results confirm the reliability of the DIAMOND-P assay in quantifying PSA levels, demonstrating its potential in clinical settings.

DISCUSSION

In this study, we introduce a novel enzyme- and compartment-free digital protein detection platform, DIAMOND-P, with attomolar sensitivity. We have demonstrated its capability to count single AuNPs, and detect single protein molecules (avidin, PSA). Future work includes demonstrating the multiplexed detection for a panel of protein biomarkers, which is important in clinical applications for cancer and neurodegenerative diseases. The DIAMOND-P platform has significant potential to simplify the assay complexity of current dELISA platforms and find broader applications in early disease diagnostics.

INTRODUCTION

Respiratory illnesses, a known cause of morbidity and mortality, are a continuously rising concern in the United States linked to cigarette smoking and air pollution [1,2]. Major pulmonary conditions, such as emphysema and asthma impact the structural integrity of airway tissue. While the organ pathways responsible for air delivery to the lungs merits greater research focus, investigations regarding the multidirectional physiological mechanics of human airways remains absent from the literature [3]. Previous studies utilizing equibiaxial tensile tests explore the mechanics of healthy porcine tissues, which may not accurately reflect the variable human tissue mechanics [4], and prior works considering human tissues, solely focus on the trachea while restricted to uniaxial tensile testing [5,6].

In this study, for the first time, we examine the scarce and variable mechanics of healthy human transplant eligible airway tissue. The biaxial tensile mechanics of the human trachea and branching bronchi are quantified, focusing on the non-cartilaginous section allowing extension during breathing. We additionally explore regional heterogeneity and anisotropic features by comparing the understudied primary bronchi regions with the trachea, and by contrasting axial and circumferential material properties. These novel insights can accompany future comparisons of factors such as sex, smoking history, and lung health state, which will be necessary for computational models and early detection of progressive respiratory illnesses.

METHODS

Human airway tissue samples were extracted from three donor lungs (age and sex: 17F, 32F, 48F) within 48 hours after surgical retrieval (IRB exemption approval HS 20-180); these rare specimens were deemed healthy enough to be transplanted but were ultimately rejected and designated for research purposes. 48F had no mentioned history of smoking or pulmonary condition, and while lung transplant eligible, 32F smoked a pack a week and 17F had asthma. The non-cartilaginous smooth muscle section from the airways were carefully dissected from the horseshoe-shaped cartilage tracheal and bronchial segments [7]. Square samples of 5.2x5.2 mm uniform effective testing size were collected from each trachea, left primary bronchus, and right primary bronchus [8]. Specimen collection for each subject was limited to 2-3 samples per region, which resulted in 7-9 samples across each region, and a total of 22 samples tested overall (Figure 1A). Axial and circumferential orientations for each sample were noted upon excision.

Preliminary tests found consistent tearing at 60% strain, and thus, samples were equibiaxally stretched at a rate of 1%/s to a maximum of 50% tensile strain, preceded by 10 preconditioning cycles (CellScale Biomaterials Testing, Waterloo, Canada) [9]. A 10N load cell was used, and specimens were submerged in a temperature controlled 37 ℃ 1X phosphate-buffered saline bath throughout testing [10].

The engineering stress-strain loading curves for each lung region and loading direction were analyzed. The bilinear slopes were calculated based on the initial and ultimate modulus (stiffnesses of the low and high strain regimes, respectively), as in prior studies, with a linear fit of $R^2 > 0.90$ [11]. The initial and ultimate modulus, signifying uncrimping of the microstructural airway fibers, along with the maximum stress value at 50% strain, were compared across regions, loading direction, and subjects. A two-way ANOVA with post-hoc Bonferroni was used to compare regional and directional elasticity characteristics between subjects with defined significance of *$p<0.05$, **$p<0.01$, ***$p<0.001$, and ****$p<0.0001$ [4].

RESULTS

The circumferential and axial stress-strain loading curves were averaged (+/- standard deviation) across each airway region (Figure 1B) or each subject (Figure 1C). For Figure 1B, the axial stresses averaged over all regions appeared greater than circumferential counterparts, more so for increasing strain. The trachea and right primary bronchus stress-strain curves were most comparable and overlapped for the axial

direction. The decreased stiffness at high strains for the left bronchus both axially (134.5 ± 173.3 kPa) and circumferentially (65.2 ± 59.5 kPa) compared to the trachea (334.2 ± 280.4 kPa, 81.0 ± 31.0 kPa) and right bronchus (332.5 ± 367.9 kPa, 100.5 ± 116.6 kPa) was a trend, but statistically insignificant (Figure 1B inset, initial and ultimate moduli).

In Figure 1C, inter-subject comparisons observed 48F showed greater stresses at maximum strains in all regions and directions, except for the circumferential trachea, where 17F had the greatest stresses. Additionally, while 48F and 32F tended to exhibit higher tracheal stresses axially than circumferentially, 17F appeared to show no directional dependence.

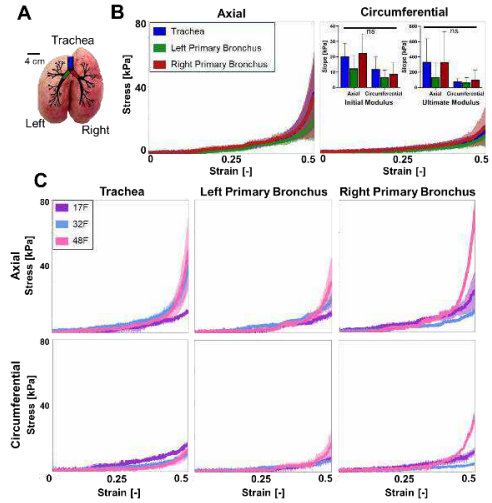

Figure 1: A) Human lung airway regions (trachea, left/right bronchi). The average +/- standard deviation of the stress-strain loading profiles in the circumferential and axial directions B) for each lung region and C) for each human subject.

In Figure 2, the airway smooth muscle stiffness between subjects exhibited shifting and varying regional mechanics. The initial modulus (i.e., low strain regime), showed significantly greater compliance for 48F compared to 17F for the circumferential trachea (4.9 ± 3.8 kPa, 21.2 ± 4.2 kPa, respectively), and greater stiffness (35.0 ± 3.2 kPa) than 32F (11.8 ± 1.1 kPa) for the axial right bronchus. For the ultimate modulus (i.e., high strain regime), the 48F axial right bronchus (872.1 ± 176.5 kPa) was significantly greater across 32F and 17F counterparts (55.3 ± 15.3 kPa, 157.4 ± 137.8 kPa). Maximum stresses in the axial right bronchus for the 48F averaged the greatest across all subjects and regions (73.9 ± 9.6 kPa).

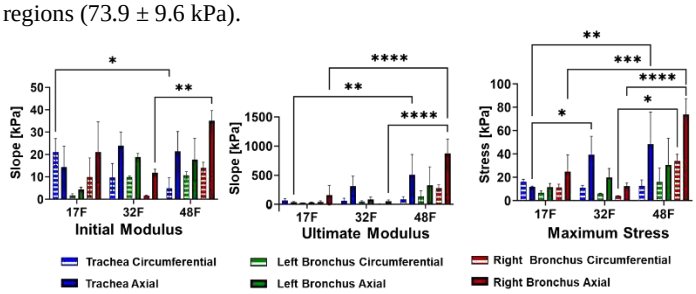

Figure 2: The average +/- standard deviations of the initial and ultimate moduli, and maximum stress of each airway region and orientation.

DISCUSSION

The regional mechanical differences between airway segments observed in our study may be attributable to the micro and macro morphology of human lungs. A recent histological study discovered the majority of tracheal elastic bundles continued distally into the right primary bronchus after initial bifurcation [12], suggesting the shared structural weave of the fiber network. We find our tracheal mechanics values to behave more similar to porcine equibiaxially planar stretched specimens [4] compared to human uniaxial studies, which reported 10x greater stresses at 50% strain [5]; this also indicates that uniaxial versus biaxial mode affects the fiber directional loading response. Furthermore, the trachea and right bronchus share larger airway diameters compared to the left primary bronchus due to the positioning of the heart. These findings substantiate the similar stress-strain curves observed between the trachea and right primary bronchus.

We find human subjects tend to exhibit greater average axial stiffness compared to circumferential direction. This behavior is most prevalent in the high strain regime, likely a result of the structural properties of the airway fiber network, which is predominantly axially oriented [12]. These anisotropic findings concur with prior uniaxial studies on the human trachealis muscle [14,15], as well as tracheal and bronchial porcine airway tissue [9]. However, the tracheal mechanics of one subject (17F) in our study contradicted counterpart trends (32F and 48F) and the established literature. This could be due to its asthmatic nature, since asthma is known for its fibrosis stiffening, which could correlate with the measured stiffer tracheal circumferential behavior [16]; however, the role of age cannot be disregarded given 17F was the youngest subject. Prior studies associate aging with declining lung function, as well as increasing elastic modulus [17,18], and this trend of increasing stiffness with age observed in the oldest subject (48F) is similarly reflected here. The minor smoking history of 32F may also be a factor, since smoking is also known for its stiffening effects [19].

This study's limitations stem from the intrinsic challenges of collecting viable and rare human tissues. The inherent variability of human lung mechanics can be better addressed with additional specimens to adequately substantiate age and conditional effects. Despite these limitations, these novel characterizations of airway mechanics better inform physiologically relevant computational lung models and contribute to our understanding of pulmonary illness.

CAM MORPHOLOGY AND SEX-BASED DIFFERENCES IN THE PROXIMAL FEMUR ANATOMY OF COLLEGIATE ATHLETES WITHOUT HIP PAIN: A THREE-DIMENSIONAL STATISTICAL SHAPE MODELING ANALYSIS

INTRODUCTION

Femoroacetabular impingement syndrome (FAIS) is defined as a painful, motion-related disorder of the hip wherein patients present with cam, pincer, or combined cam/pincer morphology [1]. Cam morphology is described as an aspherical femoral head that causes abnormal contact between the femur and pelvis and commonly occurs in young, active individuals [2]. In athletes, FAIS is known to negatively affect athletic performance from pain and associated degenerative changes to the hip [3,4]. Safran et al. reported that 3% of Division I collegiate athletes are diagnosed with FAIS [3]. Additionally, radiographic studies have reported a high prevalence of cam-type morphology in asymptomatic athletes, suggesting these individuals are at an elevated risk of developing FAIS [5-7].

When diagnosing cam-type FAIS, measurements of plain film radiographs, including the alpha angle and head-neck offset distance, are frequently used to identify abnormal hip morphology. However, more recent research has shown that the two-dimensional measurements used in radiographic studies do not accurately characterize cam deformities [8]. Recent research has also demonstrated that the location of the cam lesion differs between males and females, which may limit the ability of plain film X-rays to distinguish deformities between the sexes [9].

Statistical shape modeling (SSM) is a mathematical method used to quantify 3-D geometric variation within a class of surfaces [10]. SSM provides the ability to define mean group shapes, statistically compare the mean shapes of two or more groups, and identify and isolate the location of regions of morphologic differences. In contrast to radiographic measurements, SSM allows for objective analysis of shape and shape variation across the entire shape of interest, enabling the discovery of anatomic features driving the disease process without the need to predefine specific areas of interest on the shape.

The purpose of this study was to use a three-dimensional statistical shape model of the proximal femur to evaluate how the femur shape of asymptomatic collegiate athletes compares to the shape of radiographically screened controls and cam FAIS patients by (1) quantifying shape variation, (2) establishing sex-based shape differences, and (3) comparing shapes between athletes and cam-type FAIS patients.

METHODS

The study population consisted of three cohorts: athletes (28 M, 23 F), controls (30 M, 17 F), and cam FAIS patients (26 M, 0 F). Double echo steady-state magnetic resonance images were prospectively acquired of the hips of Division I collegiate athletes. An existing dataset of computed tomography scans of cam-type FAIS patients and morphologically screened controls was evaluated. The proximal femur was segmented, reconstructed into a three-dimensional surface, and analyzed to generate a correspondence model using the open-source software, ShapeWorks.

Principal component analysis (PCA) was used to consolidate the dimensionality of the model to a set of linearly uncorrelated modes to describe the dominant shape variations among a given particle set. PCA was performed on the correspondence particles for different groups of femur surfaces, which included Group I - athletes, controls, and patients; Group II - athletes and controls; and Group III – males only. Group II was further broken down into partial cohorts, comparing male and female athletes, female athletes and controls, and male athletes and controls.

Modes containing significant variation were identified via parallel analysis. For groups I and III, PCA component scores were compared between cohorts for significant modes using a one-way ANOVA. When a significant effect of the group was found, the Tukey-Kramer method was applied for multiple comparisons. For group II, PCA component scores between cohorts and partial cohorts for a given mode were compared using two-tailed unpaired t-tests. Given that multiple t-tests were performed for each mode, a Holm-Sidak correction was applied.

Type I error rate was set at 0.05 for all statistical testing. For the group with only males, linear discriminant analysis was performed to distill the high-dimensional particle data to a single numeric "shape score". Shape scores between male cohorts were compared via a one-way ANOVA with a type I error rate set at 0.05, followed by the Tukey-Kramer method for multiple comparisons.

RESULTS

When analyzing the full cohort, significant differences were found between athletes and controls (Mode: VIII, adj. p=0.010), athletes and patients (Modes: I, IV, adj. p=0.002, 0.003), and patients and controls (Modes: IV, VIII, p<0.001). When analyzing only athletes and controls, significant differences were found (Mode: VIII, adj. p=0.040), as well as when analyzing only male and female athletes (Modes: I, II, adj. p=0.006, 0.009). When analyzing only males, significant differences were found between athletes and patients (Mode: IV, adj. p=0.020) and patients and controls (Mode: IV, adj. p=0.003)**.** Shape scores, which represent a generalized value of the entire shape, were significantly different between athletes and patients (adj. p=0.003) and patients and controls (adj. p<0.0001), but there was no difference between athletes and controls (adj. p=0.400) (Figure 1)

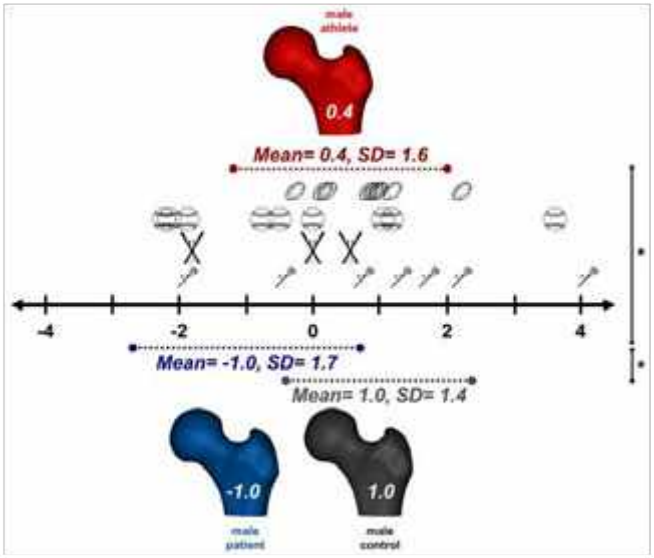

Figure 1. Surface reconstructions representing the mean shape of the male patient (blue), male control (gray), and male athlete (red) proximal femur, as well as sports icons representing each individual athlete's shape score as determined by linear discriminant analysis. Positive shape scores indicate femurs resembling controls, and negative shape scores indicate femurs resembling patients. Horizontal dotted lines represent the standard deviation for each group. Vertical lines indicate a significant difference between athletes and controls and controls and patients.

DISCUSSION

FAIS is a common cause of hip pain and disability in athletes. It is important to recognize that many athletes exhibit cam morphology without symptoms. This study aimed to objectively characterize shape and quantify anatomical variation in proximal femur anatomy of Division I collegiate athletes without hip pain using 3D SSM. A key finding from our analysis is that athletes had proximal femur morphology that more closely resembled that of controls screened for cam morphology.

Previous studies have examined the radiographic prevalence of asymptomatic cam morphology in baseball and football players [5-7]. We found that 66% (6/9) of baseball players had patient-leaning shape scores, which is consistent with the results of a previous study that showed that approximately 70% of baseball players had at least one radiographic sign of cam morphology [7]. However, in our study, the vast majority of football players (90%; 8/9) had a control-leaning shape score, whereas Kapron et al. and Nepple et al. reported that approximately 75% of football players in their studies had at least one radiographic sign of cam morphology [5,6]. The disparities between our study and previous studies examining football players may be due to measurements of plain film X-rays not accurately representing the cam deformity [8], so the deformities seen on radiographs may not be as severe and prevalent as once predicted. Another reason is that we used a higher threshold to define cam morphology (>60°), whereas the aforementioned studies of football players used (>50° or >55°) [5-7]. Still, none of the football players in our study had an alpha angle greater than 55°.

In our study, PCA determined modes I and II (athlete and control group) to exhibit significant differences in shape between male and female athletes. These modes highlighted differences in the shape of the femoral head, concavity of the head-neck junction, and amount of femoral offset. Variability in these regions may point to an increased susceptibility of cam-type FAIS because a decrease in the concavity of the femoral head at the head-neck junction and the femoral offset are a hallmark of cam morphology. SSM enhances our ability to visualize differences in areas of variation that are typically associated with cam morphology.

There is a limitation in this study that warrants consideration. We used an older dataset of patients with FAIS with only four females. Given the small sample, we chose to exclude the female patients from this study. It was previously thought that cam FAIS/morphology was primarily identified in males; however, recent research has shown that cam morphology is just as prevalent in females as it is in males [11]. Future work should include female FAIS patients in the analysis.

In summary, this study used SSM to characterize shape and shape variation in the proximal femur in asymptomatic Division I collegiate athletes. We determined that the athletes in our study had femurs that resemble control femurs, which refutes previously published research. Our results provide further evidence that 2D measurements of the proximal femur are unlikely to provide a complete picture of cam deformities. Utilizing SSM, we can objectively analyze the 3D femur morphology of athletes to identify and better understand morphology that may predispose individuals to FAIS. Future studies should include the pelvis and entire femur as part of the SSM to better understand the role of deformities in the development of FAIS in athletes.

0.1 INTRODUCTION

Cardiovascular diseases (CVDs) encompass a wide range of pathological conditions affecting the human vascular system, including ailments such as aneurysms, arterio-venous malformations, vasospasms, atherosclerosis, peripheral artery disease, and more. Much of the adult US population is affected by CVDs. Preventive surgical and endovascular interventions are increasingly considered as therapeutic options to avert catastrophic conditions such as subarachnoid hemorrhages and stroke. However, these interventions carry significant risks [1, 2]. Clinical decisions currently rely on anatomical measures such as size, location, and the morphology of vascular malformations, assessed through anatomical imaging. These anatomical measures are derived from extensive patient population studies and fail to capture the patient-specific state of diseases. Consequently, decisions based on such anatomical measures can result in unnecessary or incorrect interventions, leading to associated costs and patient morbidities [3, 4]. Recent investigations have revealed that hemodynamic forces, arising from the interaction of blood with vascular walls, play a crucial role in the progression of cardiovascular diseases. This occurs through cell-mediated mechanotransduction and near-wall biochemical transport processes. Hemodynamic flow descriptors, such as pressure gradients, wall shear stresses, and oscillatory shear index derived from blood flow velocity, can potentially indicate the onset of acute life-threatening conditions long before they are observable on anatomical scans. Consequently, these descriptors may offer quantitative data for making objective, patient-specific clinical decisions. Central to hemodynamic descriptor-based patient-specific clinical decision-making is the accurate and reliable estimation of time-resolved blood flow velocities. Currently, there are three leading modalities for estimating blood flow velocities: (a) imaging using three dimensional time-resolved phase contrast magnetic resonance imaging (4D-Flow MRI), (b) patient-specific computational fluid dynamics (CFD), and (c) hybrid methods which combine CFD and 4D-Flow MRI through a process of data-assimilation to improve the fidelity of CFD. The accuracy of estimating blood flow velocities using 4D-Flow MRI is limited by its spatio-temporal resolution, noise, and image artifacts. In addition, 4D-Flow MRI is a new imaging protocol that is currently not used in routine clinical settings. The fidelity of estimating blood flow velocities using patient-specific CFD is limited by modeling assumptions, errors in model parameters, geometry, and boundary conditions. While hybrid methods address some of these issues, they inherit the tedious, error prone, and operator dependent data preparation tasks of patient-specific CFD. Additionally, the accuracy is impacted by errors in image registration across multiple spatio-temporal resolutions that is required to co-locate image and computational domains.

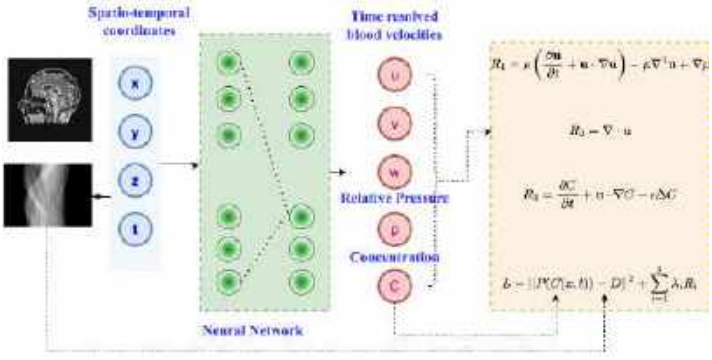

Figure 1: TOMOPinns

0.2 Contributions

We hypothesize that it is possible to estimate time-resolved blood flow velocities and relative pressures from computed tomographic angiography (sCTA) imaging. Nominally, sCTA images are static and highlight vascular structures where contrast is present. By incorporating mass transport and blood flow physics into processing of sCTA sinograms (image precursor X- Ray projection data), we will be able to estimate the underly-

ing spatio-temporally varying blood velocities and relative pressures. We make following contributions through this work:

- Modelled blood flow velocity, contrast concentration, and pressure gradient as functions of spatio-temporal coordinates, demonstrating their learnability from patient-specific CT scan data.
- Developed training data from randomly sampled contrast concentration by applying Radon transform to generate simulated sinograms.
- Demonstrated the efficacy of a CT scans enriched loss function, resulting in better accuracy and faster convergence.

0.3 PROPOSED METHOD

We introduce TOMOPinns, a neural network designed to predict blood flow velocity, contrast concentration, and pressure gradients within a specific region of the human body, utilizing readily available CT scan projections. We considered the transport of a contrast agent with concentration $c(t, x, y, z)$ by the blood flow moving with velocity field $u(t, x, y, z) = [u(t, x, y, z), v(t, x, y, z), w(t, x, y, z)]$, which satisfies the incompressible Navier-Stokes (NS) equations. The contrast agent is advected by the flow and diffused but has no dynamical effect on the fluid motion itself. We sample random spatio-temporal coordinates and concentration values at these points. Additionally, we apply the Radon transform to the concentration data, extracting the ground truth values of sinograms. These sinograms are approximations of synthetic sCTA images. In training the neural network, we align the predicted sinogram with the observed sinogram data, ensuring data fidelity, while simultaneously incorporating object physics through regularization. As illustrated in Fig. 1, we have modeled the spatio-temporal functions for blood flow velocity, relative pressure, and contrast concentration as a deep neural network (DNN).

$$(u, v, w, p, C) = \text{TOMOPinns}_\theta(x, y, z, t) \tag{1}$$

The input to these DNN is the spatio-temporal co-ordinates denoted by $\mathbf{x} = (x, y, z, t)$. Here, $theta$ are the weights of the neural network. We will learn optimal θ^* by backpropagating the loss defined in Eq. 2.The output of the neural network encompasses velocities u, v, w, relative pressure p, and concentration C. Our training process involved aligning the acquired scan data in the projected form and imposing regularization terms that incorporate the physics of fluid flow and contrast transport. Given that the actual scan data is presented as the line integral of the time-varying spatial concentration, we line-integrated the output of the neural network modeling the contrast concentration along the respective beam lines to generate the predicted sinograms. For a given blood density ρ, blood viscosity μ, and contrast diffusivity ϵ, the Navier-Stokes, mass conservation, and advection-diffusion equations, are given as follows:

$$\begin{aligned} R_1 &= \rho\left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) - \mu\nabla^2\mathbf{u} + \nabla p \\ R_2 &= \nabla\cdot\mathbf{u} \\ R_3 &= \frac{\partial C}{\partial t} + \mathbf{u}\cdot\nabla C - \epsilon\Delta C \\ L &= ||P(C(x,t)) - D||^2 + \sum_{i=1}^{3}\lambda_i R_i \end{aligned} \tag{2}$$

In this equation, $P(C(x,t))$ is the line integral of the predicted concentration, D is the observed sCTA sinogram data, λ_i are tuning parameters, and R_i represents the physics regularization terms, which are partial differential equations (PDEs).

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{3}$$

RMSE is a measure of the average deviation between observed values y_i and predicted values $\hat{y}_i$.

0.4 RESULTS

To asses the performance of the proposed network TOMOPinns, we have calculated the RMSE error between the predicted and the ground truth values of u, v, w, p, C.

Table 1: RMSE for time steps 1 to 5 (u, v, w)

Time Step	u	v	w
1	9.7×10^{-4}	7.3×10^{-4}	5.9×10^{-4}
2	8.3×10^{-4}	6.2×10^{-4}	5.1×10^{-4}
3	7.1×10^{-4}	5.4×10^{-4}	4.6×10^{-4}
4	1.2×10^{-4}	3.8×10^{-4}	2.7×10^{-4}
5	1.1×10^{-4}	2.5×10^{-4}	2.3×10^{-4}

Table 2: RMSE for time steps 1 to 5 (p, C)

Time Step	p	C
1	5.6×10^{-2}	8.2×10^{-4}
2	5.2×10^{-2}	7.6×10^{-4}
3	4.8×10^{-2}	6.8×10^{-4}
4	4.2×10^{-2}	5.7×10^{-4}
5	3.9×10^{-2}	5.1×10^{-4}

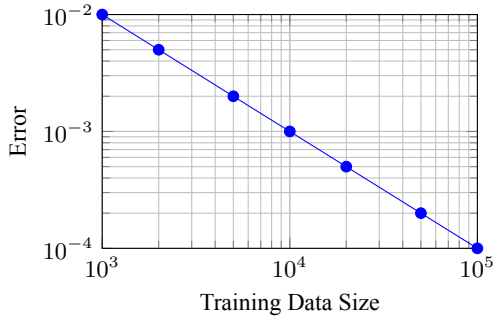

Figure 2: Scaling of TOMOPinns: Error vs Training Data Size

In this section, we discuss the results presented in Tables 1 and 2, which show the RMSE for different variables (u, v, w, p, C) at various time steps (1 to 5). Table 1 presents the RMSE for the velocity components (u, v, w) at each time step. We observe a general trend of decreasing errors as the time steps progress. For example, the error in u decreases from 9.7×10^{-4} at time step 1 to 1.1×10^{-4} at time step 5. Similar trends are observed for v and w. This suggests that the simulation results become more accurate with increasing time steps. Table 2 focuses on the RMSE for pressure (p) and concentration (C) at each time step. The errors in both p and C also exhibit a decreasing trend over the considered time steps. The error in p decreases from 5.6×10^{-4} at time step 1 to 3.9×10^{-4} at time step 5, indicating improved accuracy in pressure prediction. Similarly, the error in C follows a decreasing trend. Overall, the decreasing RMSE across all variables suggest that the simulation model provides more accurate results as the simulation progresses in time. Fig 2, provides insights into the scaling behavior of TOMOPinns concerning the training dataset. As the training data size increases, the error logarithmically decreases, demonstrating the impact of data quantity on the performance of TOMOPinns.

INTRODUCTION

Degenerative cervical myelopathy (DCM) is growing in prevalence as evident from recent epidemiological data.[1] The management of DCM often involves spinal cord decompression with instrumentation. Given the rising incidence of spinal instrumentation in the United States, there is an increasing prevalence of persons living with spinal instrumentation and at risk of sustaining minor trauma. Whiplash injuries, commonly resulting from rear impacts, can lead to various issues, including capsular ligament injury, dama ge to the anterior longitudinal ligament and anterior disc fibers, as well as spinal cord trauma. Such injuries often manifest as neck pain, discogenic pain, and myelopathic trauma, typically without associated vertebral body injuries like compression or burst fractures. While numerous studies have examined rear impact scenarios in Post Mortem Human Subjects (PMHS) and through Finite Element Modeling (FEM), they have primarily focused on the spinal column, often overlooking the spinal cord due to its complexity. This study aims to compare the effect of rear impact on spine and spinal cord responses in three different surgical conditions. The results will highlight the risk of spinal cord injury after minor trauma such as rear impact in humans with spinal instrumentation.

METHODS

In this study, A previously validated finite element model of the human head-neck complex was used.[2] This model encompasses the cervical column from C2 to T1, inclusive of vertebral bodies, posterior elements, disks, ligaments, and the spinal cord, along with the denticulate ligaments, pia mater, dura mater, and CSF. Rear impact acceleration was applied to the constrained T1 vertebra at 2.6 m/s.[3] This model also incorporates active Hill-type muscles. Our study further delved into the biomechanical impacts of three distinct cervical surgical interventions under rear impact. These are anterior cervical discectomy and fusion (ACDF), posterior cervical laminectomy and fusion (PCLF), and laminoplasty (LP). In the ACDF, the intervertebral disk was removed and inserted graft between the vertebral bodies C4-C7. For the PCLF procedure, laminectomy was performed at C4-C6, followed by rod and screw insertion from C3-C7. Laminoplasty was performed at the C4-C6 levels. Used von Mises stress for stress metrics and Maximum principal strain for strain metrics. Measured the biomechanical effects on the spinal column and spinal cord due to these surgeries under rear impact conditions at 2.6m/s. Parameters such as spinal cord stress and strain, range of motion, capsular ligament strain, and anterior longitudinal ligament strain were quantitatively evaluated and compared with laminoplasty intervention.

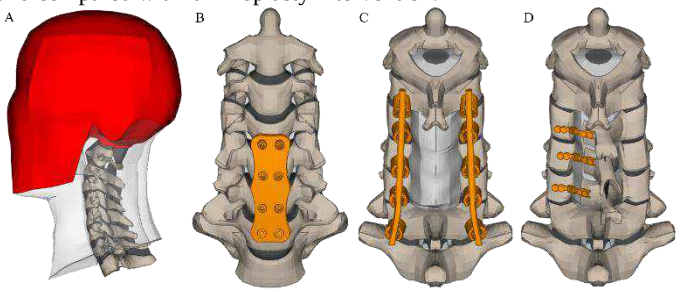

Figure 1: (A) Finite element model of head and neck (B) Anterior cervical discectomy fusion C4-C7 (C) Posterior cervical laminectomy C4-C6 and fusion C3-C7 (D) Laminoplasty C4-C6

RESULTS

In our study, Rear impact was simulated for three different surgical interventions, by applying a linear acceleration corresponding to a change in velocity of 2.6 m/s at T1 vertebrae. Figure 2. demonstrates the variations in neck motion over time due to the impact.

ROM: The mean segmental range of motion at index levels, compared to laminoplasty (LP), decreases to 75% for ACDF and 57.7% for PCLF. LP with its higher ROM, is evidently a motion preservation intervention. At the superior adjacent level, ROM increases by 9% for

ACDF but decreases by 54.7% for PCLF, largely due to PCLF's extended instrumentation at C3-C4. At the inferior adjacent level, ROM decreases by 25.9% for ACDF and increases by 39.2% for PCLF.

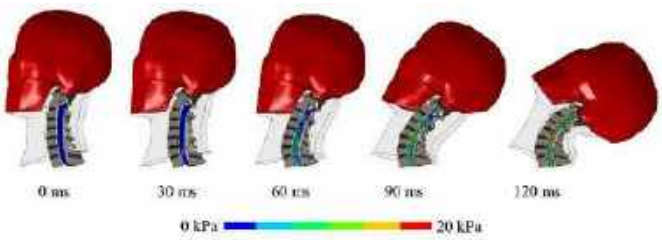

Figure 2: Neck motion and spinal cord stress during the rear impact

Spinal cord stress and strain: In terms of spinal cord stress at index levels, when compared to laminoplasty (LP), ACDF shows a notable increase in spinal cord stress by 105%, whereas PCLF demonstrates a decrease of 60.1%. Notably, ACDF presents higher stress levels despite having a lower range of motion than other surgeries. At the superior adjacent level, stress increases by 65% for ACDF and decreases by 52.6% for PCLF. In contrast, at the inferior adjacent level, stress for ACDF increases by 40.8% while it decreases by 16.2% for PCLF. Regarding spinal cord strain at index levels, compared to LP, ACDF results in a 60% increase in spinal cord strain, whereas PCLF shows a reduction of 31.7%. This trend in ACDF is similar to that observed in stress, where a higher strain is noted despite a lower range of motion relative to other surgical methods. At the superior level, the strain in ACDF increases by 16.3%, and in PCLF, it decreases by 65.6%. Conversely, at the inferior level, ACDF shows an increase in strain by 37.7%, and PCLF also exhibits an increase in strain by 18.1%.

Ligament strain: For the capsular ligament strain at index levels, the strain decreases to 85.7% for ACDF and 27.5% for PCLF compared to LP. Both fusion interventions result in a reduction of strain at the superior level relative to LP. At the inferior level, ACDF shows a reduction in strain to 68.5%, and PCLF decreases further to 22.4%. In the context of the anterior longitudinal ligament (ALL), when comparing PCLF with LP, there is a 13.1% increase in strain for PCLF. In contrast, for ACDF, the ALL is completely severed to facilitate the insertion of the graft from the anterior side. When compared to LP, at the superior level, ACDF shows a slight increase in strain by 0.8%, whereas PCLF shows a more significant increase of 35%. At the inferior level, ACDF exhibits a reduction in strain by 35.8%, whereas PCLF shows a substantial increase of 61.2%.

DISCUSSION

In this study, we conducted simulations on three different cervical surgical interventions: ACDF, PCLF, and LP, Simulated under the rear impact by applying a linear acceleration corresponding to a change in velocity of 2.6 m/s at T1 vertebrae, comparing their biomechanical outcomes with laminoplasty. The FE intact, non-stenotic spine model was validated using range of motion data derived from human cadaver experiments for segments C2–C3 to C7–T1, ensuring the FEM's response under load accurately reflected experimental data.[4] The rationale behind comparing fusion surgical interventions with LP, LP is a motion-preserving procedure compared to ACDF and PCLF, which are fusion surgeries.[5] This comparison allows for an understanding of how fusion surgeries alter spinal biomechanics relative to motion preserving techniques.

For both fusion techniques, ACDF and PCLF, there was a significant reduction in ROM at the index level. In contrast, laminoplasty, as a motion-preserving intervention, showed a higher ROM, as shown in cadaver studies.[5] The ROM at the inferior level was notably higher than at the superior adjacent levels, consistent with previous in vivo and in vitro studies indicating hyperextension in the lower cervical spine during the initial phase of whiplash.[6,7]

The timing of the maximum S-curve, defined as the moment when C2–C3 reaches peak flexion, was observed at 40-45 ms across all surgical interventions, followed by an extension phase.[4]

Regarding spinal cord mechanics, posterior approaches showed lower spinal cord stress and strain compared to the anterior approach after rear impact. This is primarily due to two factors: the ability of posterior approaches to widen the spinal canal and the limited expansion of the spinal canal observed in anterior approaches. During rear impact, which predominantly causes neck extension, a greater portion of the load is transferred to the facet joints. In the case of PCLF, instrumentation in the lateral mass area restricts motion, contributing to its effectiveness in protecting the spinal cord.[8]

In our FE model, muscle activation played a crucial role, as evidenced by a study from Fice et al., which showed a reduction in CL strain from 28% to 13% with active muscles in a 7g rear impact scenario.[9]

Capsular ligaments are particularly critical, given that cervical facet joints are implicated as a primary source of chronic neck pain post-whiplash in 60% of cases. In posterior approaches, notably higher CL strain was observed at inferior adjacent levels, with 163% in PCLF and 133% in LP. findings from Siegmund et al., where maximum principal strain in flexibility tests was significantly lower than in subcatastrophic failures.[10] Posterior approaches demonstrated unfavorable outcomes in CL strain, whereas anterior approaches resulted in only 40% strain.

For the ALL, which is crucial in extension movements, the study by Yoganandan et al. suggests a strain threshold range of 40-45%.[11] In our study, the average ALL strains were below this failure threshold, at under 36%, indicating a lower risk of damage.

In conclusion, this FE study looked at the impact of rear trauma on instrumented spines post-cervical surgeries. Our findings indicate that posterior approaches PCLF and LP exhibit lower spinal stress and strain compared to ACDF, primarily due to the enhanced canal expansion they offer. The study also underscores the importance of muscle activation in reducing capsular ligament strain during rear impacts. Additionally, ALL strains were observed to remain below the failure threshold, suggesting a lower injury risk. These findings offer valuable guidance for clinicians in understanding the biomechanical implications of different cervical surgical techniques, especially in patients who are at risk of sustaining minor trauma post-surgery.

MULTISCALE MODELING OF BLOOD FLOW IN AORTIC ROOT ANEURYSMS

Yurui Chen (1), Hannah Zhai (1), Hiroo Takayama (2), Vijay Vedula (1)

INTRODUCTION

The aortic root at the proximal end of the ascending aorta is frequently prone to diseases such as aortic root aneurysm (ARA) and dissection. These life-threatening conditions have high mortality rates, with no effective pharmacological therapies to prevent rupture. [1] Current risk assessment and surgical planning criteria are based on morphological measurements, often estimated on a 2D slice from medical imaging. Further, the same size-based threshold is applied to all ascending thoracic aortic aneurysms (aTAAs), including the proximally located ARA, and the distally located, mid-aortic aTAA, despite clinical evidence suggesting that ARAs are more malignant than aTAAs in imparting major adverse events (MAEs), such as dissection, rupture, or death. [2] Moreover, it is well-known that the biomechanical environment of an aortic root is substantially different from the mid-aortic segment of the ascending aorta. However, the hemodynamic factors contributing to the growth and severity of ARA compared to a mid-aTAA remain less understood.

Here, we present a workflow to perform multiscale blood flow simulations in ARA patients, coupling the 3D model of the aorta with a closed loop, 0D lumped parameter network (LPN)-based model of blood circulation. The 0D model, with parameters tuned to match the patient data, provides physiological boundary conditions, while the 3D model is constructed from CT data using SimVascular. [3] We then present a novel approach to reconstruct a healthy aorta from the dilated state, and compare hemodynamics by performing blood flow simulations using a validated, stabilized finite element method-based flow solver. Finally, we discuss our plan to extend the framework to perform fluid-structure interaction (FSI) simulations and evaluate hemodynamics in different aTAA phenotypes.

METHODS

We employ SimVascular to perform multiscale blood flow simulations in the ascending aorta of ARA patients, including coronary arteries. [3] We identified an ARA patient in the database at Columbia University Medical Center (CUMC) under an IRB-approved protocol (Fig. 1a). The patient was diagnosed as having a root-only aneurysm, with a cusp to sinus diameter measuring 5cm at the aortic root.

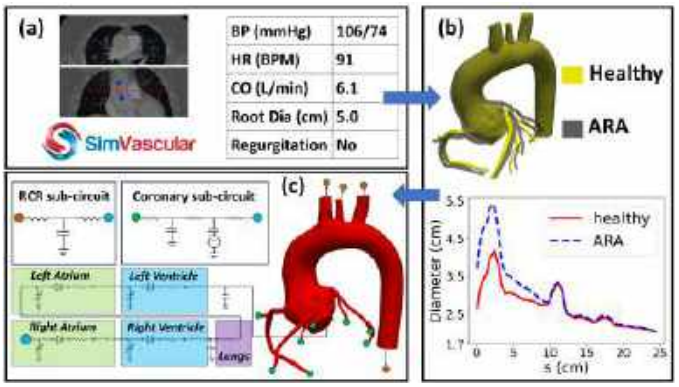

Figure 1: Workflow for patient-specific multiscale blood flow simulations in ARA patients. (a) Model of the ascending aorta constructed using SimVascular; [3] table includes clinical characteristics. (b) (top) Reconstructing a 'healthy' aorta (yellow) from the dilated model (black); (bottom) comparing the centerline diameter between healthy and dilated states. (c) A schematic of the closed-loop 0D/3D model for multiscale blood flow simulations.

We realize that it is pivotal to understand the changes in blood flow and shear forces during aneurysm growth to dissect the hemodynamic factors responsible for disease progression. However, when we measured the growth rate of the ascending aorta in a sample of aTAA patients (N=5) by analyzing their longitudinally acquired CT data for up to 5 years after the initial diagnosis, we found that the aneurysm grew by only a few mm/year. This led to no discernible differences in the dilated ascending aortic morphology, yet these patients were considered clinically at high risk.

Therefore, we developed a novel workflow to reconstruct a 'healthy' pre-dilated aorta from the ARA patient by using morphing techniques (Fig. 1b). The dilated portions of the aortic root and ascending aorta are morphed radially inward toward the vessel centerline, until the dimensions match that of a 'reference' normal subject, appropriately scaled by the BSA (Fig. 1b). This 'reference' subject's dimensions of the ascending aorta are determined from a previously characterized study among 70 normal subjects. [4] At the vessel bifurcations, the diameter scaling factors are smoothly extended through the entire daughter branch from the main parent vessel.

Lastly, any surface irregularities due to morphing are resolved using local smoothing operations in MeshMixer (Autodesk Inc.).

In principle, one could interpolate the healthy and the dilated states of the root aneurysm to create multiple intermediate phases, and assess the hemodynamic changes through a progressing aneurysm. However, in this preliminary analysis, we focus only on the end-states.

We model blood as incompressible and Newtonian, and assume the walls to be rigid. We employ a modular coupling method between the 3D and the 0D domains (Fig. 1c), [5] implemented in the stabilized finite element flow solver, svFSI. [6] A manual tuning is performed to match the LPN model parameters with the clinical data. Because of the proximity of the root with the coronary ostia, we incorporate coronary arteries in our 3D model and add appropriate downstream boundary conditions. [7] Blood flow simulations are performed in healthy and dilated root cases using the bi-partitioned method to solve the Navier-Stokes equations.[8]

RESULTS

Simulated blood flow in the reconstructed healthy aorta is shown in Fig. 2. A volume rendering of the velocity field, colored by its magnitude is shown at peak systole, highlighting the complexity of the flow in the aortic root. Time-dependent flow waveforms are shown at various sections in Fig. 2, including the inlet (A), outlet (RCR, B), left coronary artery (LCA, C), and right coronary artery (RCA, D).

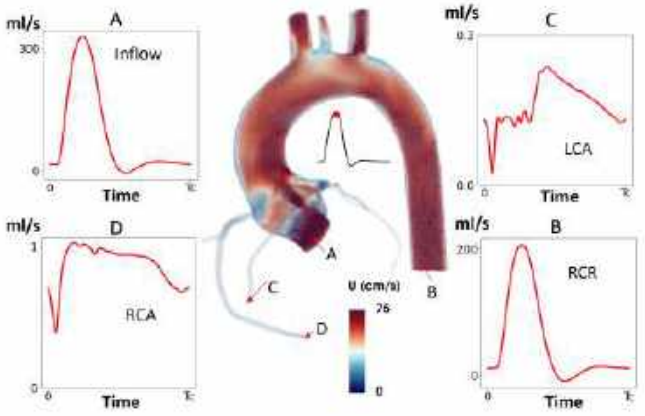

Figure 2: Velocity field at peak systole and time-dependent sectional flow waveforms in the reconstructed healthy aorta.

These simulations were performed using a mesh comprising ∼1.3M linear tetrahedral elements, including boundary layers and locally refined mesh in the coronaries. The simulation takes about 6h for six cardiac cycles on 96 CPU cores.

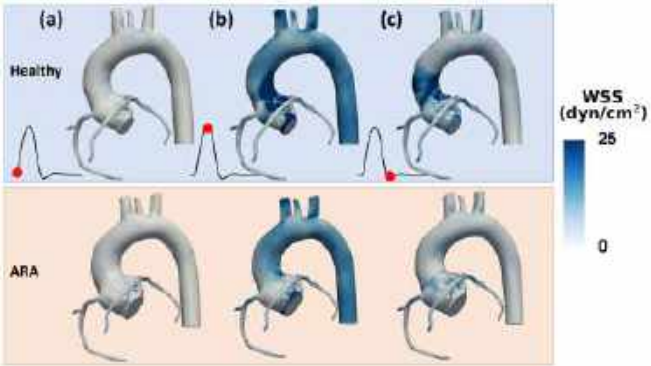

Figure 3: A comparison of spatial variation of wall shear stress (WSS) between healthy (top) and dilated root (ARA, bottom) at (a) onset of systole, (b) peak systole, and (c) end of systole.

Fig. 3 compares the spatial variation of wall shear stress (WSS) between the reconstructed healthy aorta and ARA patient, at three distinct phases of systole, while the time-averaged quantities, including the time-averaged WSS (TAWSS), area-averaged WSS (AWSS), and oscillatory shear index (OSI) are compared in Fig. 4. We note that the WSS and its related indices are generally elevated in the healthy case compared to the dilated root.

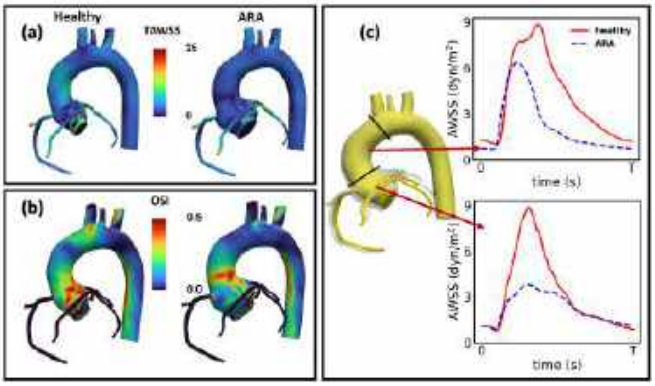

Figure 4: A comparison of WSS-related metrics between healthy and ARA. (a) time-averaged WSS (TAWSS), (b) oscillatory shear index (OSI), and (c) area-averaged WSS (AWSS).

DISCUSSION

Here, we developed a workflow to perform personalized multiscale blood flow simulations in ARA patients. We argued that because the root is already dilated by the time of the first image acquisition, we must reverse engineer a pre-dilated ascending aorta for the patient, with normal dimensions. We demonstrated this approach by radially morphing the dilated segments of the aorta with respect to the vessel centerline. This enables us to evaluate changes in hemodynamics during aneurysm development and dissect factors correlating worsening hemodynamics with changes in morphology, tissue characteristics, and function.

In our preliminary analysis, we showed that WSS is substantially reduced from a healthy state to the dilated aortic root (Fig. 3). Further, we observe a higher level of reduction in the WSS in the aortic root compared to the mid-aortic segments of the ascending aorta (Figs. 3, 4). Likewise, the OSI is markedly high, and uniform across the aortic root sinuses, in the healthy subject compared to the ARA (Fig. 4).

It is important to acknowledge the limitations of this work to plan work ahead. Rigid walls and lack of fluid-structure interaction (FSI) with the aortic valve are two major limitations, and could likely impact the results. For e.g., the asymmetric jet at the inflow (Fig. 2) is likely due to the D-shaped annulus of the ventricular outflow tract during diastole. Including an FSI model of the tissue may, however, lead to a more circular cross-section of the outflow tract, and may not result in the asymmetrically directed jet impingement on the wall of the ascending aorta. We plan to address some of these issues in the near future using our FSI framework.[9] We will also plan to include additional patients to demonstrate statistical significance.

INTRODUCTION

Cystocele is the most prevalent presentation of pelvic organ prolapse, wherein the bladder is displaced into the anterior vaginal wall, causing it to extend near or past the vaginal opening. This uncomfortable and debilitating condition significantly impacts the quality of life for affected women. Approximately 10% of women in the United States undergo surgery for this condition during their lifetime, and the rates of recurrence, resulting in two or more surgeries, are as high as 50% [1].

Part of the reason for the high recurrence rates can be attributed to the repair not addressing the root cause of the cystocele. While it is understood that a cystocele results from a loss of support to the vagina and bladder, the specific tissues responsible are still debated. Some argue that it results from a direct loss of levator muscle function, while others believe that it arises from a defect in the connective tissues supporting the vagina. However, the precise location of the defect, whether at Level I (the more apical uterosacral ligament) or Level II (the paravaginal attachments), remains unclear. Certainly, it is possible that a partial or complete loss of function in all these structures is necessary. This information is critical for accurate diagnoses and the selection of the appropriate repair procedure.

Unfortunately, diagnosis is often limited to an external examination where a clinician measures or estimates the position of the vaginal wall relative to the vaginal opening as a patient strains (increases intra-abdominal pressure) via the pelvic organ prolapse quantification (POP-Q) exam. While this enables the clinician to assess the extent of the prolapse and whether the anterior wall, apex, or posterior wall is more or less affected, they are unable to visualize internally to determine the defect responsible for the prolapse. Cystocele is less commonly measured using bony landmarks on dynamic MR imaging. While this method offers a quantitative assessment of internal structures, the specific defect causing bladder descent cannot be easily observed. Therefore, diagnosis is based on the relative motions of the organs. A rigorous understanding of patient anatomy and normal physiological motions, and how those two differ from anatomy and organ motion consistent with different forms of prolapse, should, in theory, enable a specific defect to be inferred from this type of imaging. However, the diagnosis of cystocele via imaging is frequently inconsistent with findings based on the POP-Q, and the latter is better correlated with patient symptoms. Indeed, dynamic imaging provides the potential to improve diagnoses and repair, but our lack of understanding of the functional anatomy of the female pelvis is limiting. A goal of our laboratory's research is to couple dynamic imaging of the female pelvis with biomechanical analyses to enable the extraction of more clinically useful information from imaging.

Building on our previous work that enhanced radiologic diagnostic criteria for cystocele [2], the goal of the current study is to use three-dimensional statistical shape analysis (SSM) to test the hypothesis that specific defects or functional changes in pelvic floor musculature can be identified in patients who are separated based on these criteria.

METHODS

We conducted a retrospective search for patients diagnosed with radiologic cystocele, determined through dynamic MR imaging based on traditional criteria. To be included in the study, the patient data needed to include complete geometry (entire pelvic floor visible within the MRI volume) for static and dynamic (MR defecography) scans, as well as full demographic data in their patient files. To diagnose cystocele based on our enhanced criteria, we assessed how closely the most inferior bladder point approached the genital hiatus during evacuation in the MR defecography series. Based on these criteria, subjects whose bladder descended within 1 cm of the genital hiatus were classified as having a "clinically relevant cystocele," while subjects whose bladder remained higher than 1 cm were not, independent of the diagnosis based on traditional criteria.

The pelvic floor muscles at rest (excluding the bulbocavernosus, perineal membrane, transverse perinei muscles, and anococcygeal ligament) of all the subject scans were segmented using 3D Slicer (v. 5.2, `https://www.slicer.org/`). Our laboratory's SSM workflow reconstructed the 3D geometries, smoothed, aligned, and scaled them based on correspond-

ing points using Deformetrica, and then performed a principal component analysis on those corresponding points [3]. The individual patient scores (i.e., their position on the axes describing the principal components) were then used to compare shape differences between groups independent of rotation, translation, and scale. Principal components that describe more shape variation than random noise (determined through a parallel analysis) were included in our analyses. Statistical analysis was conducted on both the continuous demographic data and the principal component scores of the shapes for each included principal component using an ANOVA followed by a Benjamini-Hochberg correction post-hoc. Categorical variables were assessed using a Mann-Whitney U Test.

RESULTS

Our database search identified 67 subjects diagnosed with cystocele on MR defecography. The average age of the sample was 56 years-old, with a median parity of 2 (range: $(0-7)$). Based on our enhanced criteria, twenty-eight subjects were identified as having clinically relevant cystocele, while the remainder were not. Subjects in this group were significantly older ($p = 0.001$), had more pregnancies ($p = 0.020$), and more deliveries ($p = 0.010$) compared to those with non-clinically relevant cystocele.

Twelve principal components describe more variance in the data than random noise according to the parallel analysis. After correcting for multiple comparisons, only one principal component (PC 1) was found to be statistically different between the two groups ($p = 0.009$, 24.7% of the shape variation). Figure 1 shows the shape differences described by PC 1, where non-clinically and clinically relevant cystocele are represented by the left and right columns, respectively. PC 1 primarily captured variation laterally and in the distal portion of the pelvic floor, i.e., descent of the perineal body. Subjects with clinically relevant cystocele exhibited greater descent of the pelvic floor muscles away from their attachment to the arcus tendineus fascia pelvis (ATFP). At this level, connective tissues link the obturator internus and the levator ani through the ATFP (Figure 2). This change is particularly evident in the sagittal view (second row). Accompanying this descent, there was a noticeable ballooning of the pelvic floor. When viewed from the top/front (first row), the cystocele group on the right side of the figure appeared to have an increased levator bowl volume, a feature commonly associated with prolapse, compared to the shapes on the left. Because these differences exist on the same principal component, one does not exist without the other in this cohort, implying that the link to the ATFP, descent of the perineal body, and levator bowl volume are all correlated.

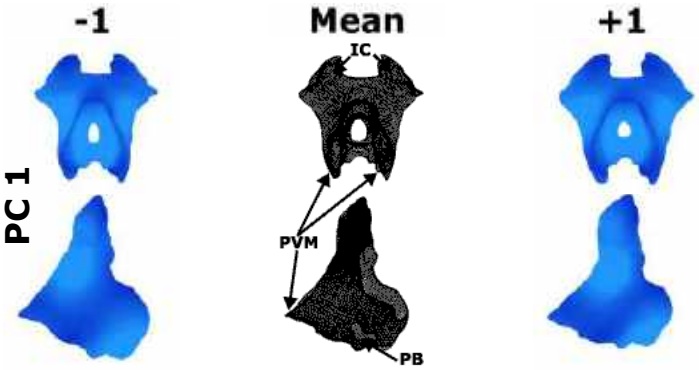

Figure 1: The average shape $\pm$ one standard deviation for pricipal component 1, non-clinically relevant cystocele (left) and clinically relevant cystocele (right). The colormap represents the surface's distance away from the mean (blue = closer, white = further). PVM = pubovisceral muscle, IC = iliococcygeus, and PB = perennial body.

DISCUSSION

Based on enhanced diagnostic criteria, this study identified a specific shape change in the pelvic floor of women associated with the development of cystocele, supporting our hypothesis. It further highlighted the connection of the pelvic floor muscles through the ATFP as a potentially important anatomical defect in these patients. This lends support for theories indicating that a defect within Level II support contributes significantly to the development of cystocele. Moreover, it demonstrates the importance of our enhanced diagnostic criteria in the identification of these patients. While it might be argued that all of these women had a cystocele and we are simply identifying a specific phenotype of cystocele, it should be noted that our previous study demonstrated that the traditional diagnostic criteria often misdiagnosed young, nulliparous, and well-supported women as having a cystocele, suggesting they were not rigorous enough [2].

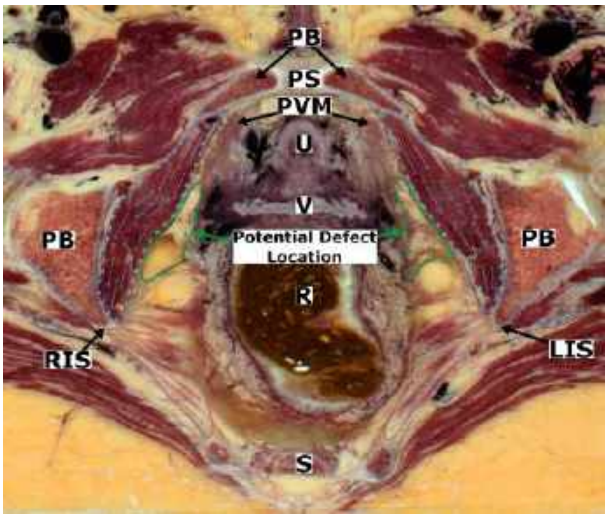

Figure 2: Visualization of the connection of the pelvic floor to the obturator interus muscle, region outlined in green is the area of the potential paravaginal defect leading to cystocele development. Blue, short dashes, obturator internus, red, solid line, iliococcygeus. Estimates of the fiber directions of the muscle in this plane is shown by arrows. PB = pubic bone, PS = pubic symphysis, PVM = pubovisceral muscle, U = urethra, V = vagina, R = rectum and stool, S = sacrum, RIS, LIS = right/left ischial spine.

While this study does not eliminate the possibility of other factors contributing to the development of symptomatic cystocele, it does suggest a potential reason why surgeries that primarily focus on providing support to the vaginal apex are likely to fail in the anterior compartment (i.e., the root cause of the prolapse is not being sufficiently addressed). Our results imply that, to directly treat some forms of cystocele, specifically addressing the defect in Level II support may be necessary, i.e., the area identified in green in Figure 2.

The limitations of this study include its retrospective design and relatively small sample size. Due to the retrospective study design, a POP-Q analysis was not available for all subjects therefore, we chose to replace the assessment in this study with the dynamic MRI-based analog. Our sample of 28 subjects with cystocele is not representative of all types of cystocele and further study is required to include them.

To further understand the functional implications of these findings, our group will aim to perform simulations of defecation using geometries with and without this specific defect.

INTRODUCTION

The superposition or sequential sectioning technique is a ubiquitous method to quantify *in situ* ligament tensions using a robotic testing system.[1] This technique has been used for a range of applications including to ascertain healthy ligament mechanics[2,3], and to determine the effects of injury[4,5] and surgical interventions[6,7] on ligament mechanics. In this technique, the same kinematics are prescribed to a joint with a ligament of interest intact and then resected. The tension in that ligament is computed as the vector difference in the joint reaction forces between the ligament-intact and ligament-deficient states.[1]

In superposition testing to date, joint kinematics have been measured and controlled by applying a rigid transformation from the position of the robot end effector to the position of the joint, referred to herein as robot kinematic control. However, compliance in any structure in the testing system except the ligament of interest (e.g., robot, fixtures, bones) can lead to deflection of the robot and/or the robot-mounted bone between the intact and ligament-deficient states. This deflection can, in turn, introduce errors in joint kinematics leading to errors in superposition-computed tensions. To account for system compliance, joint kinematics can also be measured and controlled using the position of an optical motion capture sensor fixed to the robot-mounted bone, referred to herein as motion capture kinematic control. To date, the superposition technique has not been directly validated in cadaveric joints using either kinematic control mode.

Therefore, the ***objectives of this study*** were to quantify the following errors when using robot kinematic control and motion capture kinematic control: (1) the errors in the positions of the robot-mounted bone between the intact and ligament-deficient joint and (2) the errors in superposition-computed tensions. ***Our overall hypothesis*** was that the motion capture kinematic control mode would result in lower errors in the position of the robot-mounted bone that would, in turn, lower the errors in superposition-computed tensions. We used the lateral collateral ligament (LCL) of the knee as a representative ligament in this study.

METHODS

We prepared five cadaveric knees for robotic testing as previously described (**Figure 1a**).[8] To provide a direct, gold-standard measure of LCL tension, we potted the distal end of the proximal fibula of each knee in an aluminum tube and attached it in-series with a single-axis load cell (Futek LSB210, reported nonlinearity = 0.9 N) to the fixed tibial bone tube (**Figure 1b**). Then, we resected the articular surfaces of the tibiofibular joint to free the fibula from the tibia such that the single-axis load cell directly measured LCL tension.

After fixing a motion capture sensor to the femur, we mounted each knee in our robotic testing system (KR300 2700-2, KUKA) controlled using simVITRO's eXactoPOSE® (**Figure 1a**).[9] After defining a functional coordinate system[10], we prescribed kinetic-control varus (15 Nm) and external rotation (5 Nm) ramp load-unload trajectories. These trajectories were prescribed at 0°, 30°, 60°, and 90° flexion in three specimens and at 0° flexion in the two other specimens. Then, we

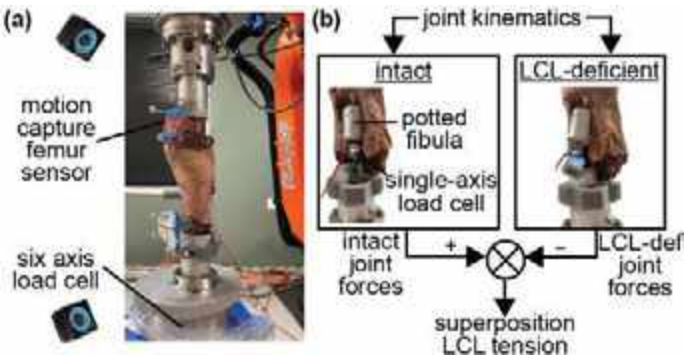

Figure 1: (a) We fixed a motion capture sensor to the femur and mounted each knee in a robotic testing system. (b) We computed superposition tensions using the difference in joint reaction forces between the intact and LCL-deficient states.

prescribed the kinematics measured during these kinetic-control trajectories to the knee using both the robot and motion capture kinematic control modes. We prescribed these kinematics to the intact joint and to the joint with the LCL attachment disconnected (**Figure 1b)**.

We calculated the errors in the motion capture femur sensor position as the magnitude of the difference between the position vectors in the intact and LCL-deficient states for each trajectory and control mode. We used the principle of superposition[1] to compute the *in situ* tension in the LCL for each trajectory and control mode (**Figure 1b**). We calculated the errors between the superposition-computed and load-cell-measured tensions in all specimens. We pooled the errors in the motion capture femur sensor position and superposition tension across specimens and trajectory types (i.e., varus or external rotation) and computed the bias and precision errors.[11] Additionally, we performed paired t-tests (significance level = 0.05) to test the specific null hypotheses that (1) the motion capture femur sensor errors at peak tension are not different between the two control modes and (2) the peak tension errors are not different between the two control modes.

RESULTS

The errors in the motion capture femur sensor position were smaller for the motion capture kinematic control mode than for the robot kinematic control mode ($p < 0.001$) (**Figure 2a**, **Table 1**). For both robot kinematic control and motion capture kinematic control modes, superposition-computed LCL tensions tended to underestimate true LCL tensions. The tension errors were smaller for the motion capture kinematic control mode than for the robot kinematic control mode ($p < 0.001$) (**Figure 2b**, **Table 2**).

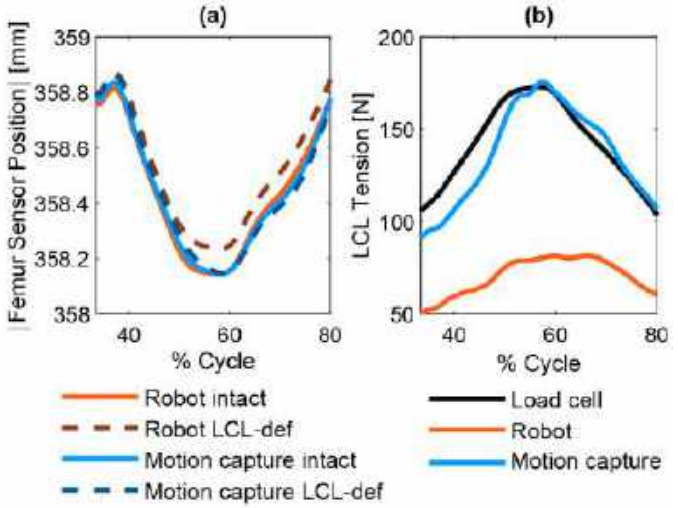

Figure 2: Representative data around peak loading for a varus ramp trajectory at 30° flexion for each control mode depicting (a) the magnitude of the femur motion capture sensor position vectors and (b) the LCL tensions.

Table 1: Errors (bias ± precision) in motion capture femur sensor positions between the LCL-deficient and intact joint states for the robot kinematic control mode and the motion capture (MoCap) kinematic control mode.

	External rotation		Varus	
	Robot	MoCap	Robot	MoCap
Femur sensor error [μm]	117 ± 100	19 ± 15	261 ± 251	41 ± 38
Femur sensor error at peak tension [μm]	178 ± 90	24 ± 21	500 ± 314	47 ± 34

Table 2: Errors (bias ± precision) in LCL tensions between superposition-computed and load cell-measured tensions for the robot kinematic control mode and the motion capture (MoCap) kinematic control mode.

	External rotation		Varus	
	Robot	MoCap	Robot	MoCap
LCL tension error [N]	-17 ± 21	-7 ± 16	-38 ± 35	-3 ± 19
Peak LCL tension error [N]	-35 ± 24	-18 ± 18	-89 ± 24	-10 ± 22

DISCUSSION

Our ***first key finding*** was that the traditional robot kinematic control mode for performing superposition testing can result in large errors in the motion capture femur sensor positions between the intact and ligament-deficient joints (**Table 1**), which violates a key assumption of the principle of superposition.[1] Consequently, we found that the errors in superposition-computed tensions using the robot kinematic control mode were large (**Table 2**). Our ***second key finding*** was that using the motion capture kinematic control mode decreased the errors in the motion capture femur sensor positions (**Table 1**) that in turn lowered the errors in superposition-computed tensions (**Table 2**). Together, ***these key findings support our overall hypothesis*** and indicate that motion capture kinematic control is an attractive alternative to robot kinematic control for determining superposition-computed ligament tensions.

The root cause of the larger errors in superposition-computed tensions using the robot kinematic control mode is deflection of the robot. When a ligament is removed, the loads applied to the robot decrease, resulting in deflection of the robot and robot-mounted bone that can alter joint kinematics (**Figure 2a**). When using robot kinematic control, the robot cannot detect this deflection, and therefore cannot correct for it. In contrast, when using motion capture kinematic control, the motion capture femur sensor measures this deflection, and can correct the prescribed robot motion (**Figure 2a**). We believe that the remaining errors in the superposition-computed tensions for the motion capture kinematic control mode are largely due to noise in our motion capture data. We originally used both the femur and tibia motion capture sensors for control, but found that the motion capture noise outweighed any advantage of accounting for deflection of the tibia. Thus, ongoing work is focused on improving motion capture precision.

Superposition testing has been and will continue to be a valuable experimental approach to quantify ligament tensions. For both control modes, it is necessary to report the errors in superposition-computed tensions to properly interpret the reported ligament tensions, especially because errors will vary with different robotic testing and motion capture systems. Based on our results, we recommend adopting motion capture kinematic control for superposition testing over the traditional robot kinematic control to significantly reduce the errors in superposition-computed ligament tensions.

ACKNOWLEDGEMENTS

We acknowledge the technical support of the simVITRO® team to implement the eXactoPOSE® algorithm.

INTRODUCTION

Cryopreservation of organs has an important role in transplantation and enabling flexible scheduling of surgeries. The major challenge to overcome at low temperatures is the water-to-ice phase transition for cells. In addition, freezing can be extremely fatal to living organisms as both intra- and extracellular ice crystal formation can result in chemical changes in the cells which can lead to extreme mechanical strain on cells [1].

The freezing behavior of cells can be altered in the presence of a cryoprotective agent (also called cryoprotectant), which affects the rates of water transport, nucleation, and ice crystal growth [1,2]. Dimethyl sulfoxide (DMSO) is the most commonly used cryoprotectant that penetrates across lipid bilayers of the cell membrane and prevents intracellular ice formation by reducing the water content inside the cell [1, 2]. However, DMSO can cause concentration-dependent cell toxicity by altering the structure of cell proteins and membrane [3]. The most common DMSO concentration to use in organ cryopreservation has been 30% (v/v) [4].

Previous studies suggest that part of the toxic effect of DMSO on cells is caused by exerting damage to enzyme fructose 1,6-bisphosphatase (FBP1) and ultimately disturbing gluconeogenesis [4]. FBP1 is a rate-limiting enzyme responsible for controlling energy metabolism and glucose in cells through catalyzing gluconeogenesis and glycolysis. It is a complex tetramer and a highly regulated enzyme whose activity is modulated synergistically by the inhibitors 5'-adenosine monophosphate (AMP) and fructose 2,6-bisphosphate (FBP) [5]. In the present study, we aimed to identify whether DMSO exposure modulates FBP1 enzyme properties, which would consequently alter the production mechanism of adenosine triphosphate (ATP) affecting the ultimate cell survival rate. In order to do this, purified pig kidney FBP1 was exposed to DMSO followed by performing a series of characterization techniques to determine whether DMSO is capable of modifying enzyme activity and conformation.

METHODS

FBP1 synthesis: *Bacterial growth*: T7 express lys Y competent E. Coli (BioLabs Inc., C3030J) was mixed with pig FBPase plasmid and cultured on LB agar plates. Bacteria was cultured further in autoclaved TB solution containing glycerol and ampicillin while being shaken at 250 rpm and 30 °C. While induced with Isopropyl-beta-D-thiogalactopyramoside (IPTG) to the final concentration of 120 mM.

FBPase purification: Bacteria were washed with cold phosphate buffer saline (PBS, pH 7.4). The bacteria pellet was then resuspended in 50 mM Tris buffer containing 150 mM sodium chloride, 10% (v/v) glycerol protease phosphate (1:1000), basement membrane extract (BME) (1 mM), Lysozyme (0.1 mg/ml), and RNase/DNase (2.5 units/ml) while keeping the pH at 7.4. The cell suspension was placed on ice and shaken for one hour. The cells were lysed by using a transonic T460/H sonicator (John Morris Scientific Pty Ltd.) for 5 minutes, cycling 5 seconds on and 30 seconds off on ice. The cell debris was removed by centrifugation at 15000×g for 30 min at 4°C. The supernatant containing protein extracts was then mixed with beads at 4°C for one hour. FBP1 stock concentration was measured using the Bradford assay with the absorbance at 595 nm.

Enzymatic activity: Malachite Green Phosphate Assay Kit (Sigma-Aldrich, MAK307) was used to assess the activity of purified FBP1. The activity assay was performed in a Tris buffer pH 7.5 made of 50 mM Tris and 5 mM potassium chloride in DI water. Purified FBP1 stock was desalted against the prepared Tris buffer using Zeba™ Spin Desalting Columns (Thermo Scientific, 89882), and then diluted in Tris buffer to a concentration of 200 nM. Samples containing 200 nM FBP1 in Tris buffer, 200 nM FBP1 in 30% DMSO prepared in Tris buffer, 200 nM FBP1 in 2.4 μM coenzyme A (CoA) prepared in Tris buffer, and 200 nM FBP1 in 30% DMSO and 2.4 μM CoA prepared in Tris buffer were incubated with different concentrations of FBP (0-250 μM).
FBP1 was diluted to a final concentration of 200 nM in Tris buffer containing various amounts of DMSO (0, 0.1, 0.2, 0.5, 1.0, 2.0, 5.0, 10,

20, 30, 40, and 50 % (v/v)) and 250 µM FBP. IC50 and Hill slope were then calculated using Graphpad Prism 9. Tris buffer containing 200 nM FBP1 and various amounts of DMSO (0-50 % (v/v)) were used as control samples for this experiment.

Dynamic light scattering (DLS): Zetasizer Nano ZS-MAL1043824 was used to evaluate the size and size distribution of purified FBP1. In order to study the effect of DMSO on the purified FBP1 protein, DMSO was added to the FBP1 solution to a concentration of 30% (v/v) and incubated at 37°C for an hour before DLS analysis.

RESULTS

The first characterization analysis selected for the purified FBP1 in this study was evaluating the activity of this enzyme using Malachite Green Phosphate activity assay. Results shown in Figure 1 revealed that the activity of purified FBP1 changes with concentration of substrate (FBP). These results indicated that the purified FBP1 in this study is highly active and the activity of FBP1 didn't change upon incubation of the enzyme at 37°C for 24 hours. Incubation with CoA for one hour at 37°C didn't affect the activity of FBP1, while incubation with DMSO inhibited the activity of the enzyme significantly, regardless of incubation time. In addition, CoA didn't repair the oxidation stress that was applied to the FBP1 enzyme by DMSO which resulted in reducing the activity of the enzyme significantly. After 24 hours of incubation with CoA at 37°C, the activity of FBP1 was inhibited.

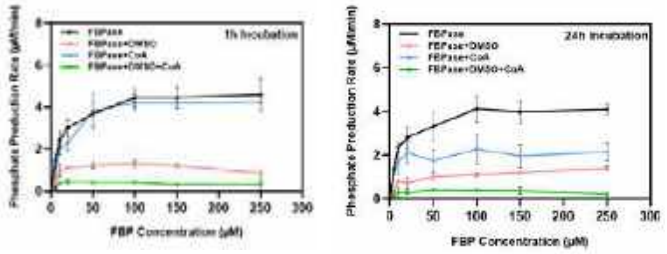

Figure 1. Enzymatic activity of purified FBP1 after incubation with 30% (v/v) DMSO and 2.4 µM CoA for 1 and 24 hours.

In order to assess the inhibition of FBP1 enzyme by DMSO, the IC50 value for FBP1 samples exposed to different concentrations of DMSO was determined using Malachite Green Phosphate activity assay. The IC50 value was calculated to be 2.2 M (20% v/v) with a HillSlope of -2.9 which indicates that at 20% (v/v) DMSO 50% of the FBP1 enzyme's active sites are inhibited.

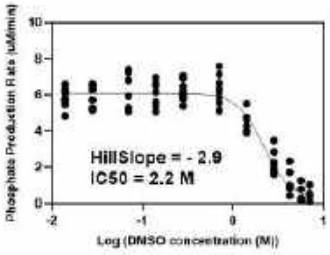

Figure 2. The IC50 value for FBP1 enzyme exposed to different concentrations of DMSO.

Dynamic light scattering (DLS) was used to evaluate the size and size distribution of purified FBP1 enzyme before and after interaction with DMSO. DLS results (Figure 3) showed a homogeneous size distribution of 10 nm for purified FBP1 with minimum aggregation. Upon incubation with DMSO for one hour, a heterogeneous size distribution consisting of two signals were detected for FBP1; one at about 20 nm and the other one at 200 nm which could indicate aggregation of the FBP1 enzyme upon interaction with 30% DMSO.

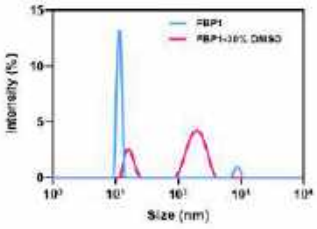

Figure 3. Dynamic light scattering (DLS) analysis of purified FBP1 before and after incubation with 30% DMSO.

DISCUSSION

Understanding the mechanisms of cryoprotectant toxicity could be the means to eliminate toxicity and increase the number of successful organs cryopreserved. Prior research indicates that the detrimental impact of DMSO on cells may arise from its ability to cause damage to FBP1, thereby disrupting gluconeogenesis. It's been shown that high concentrations of DMSO can bind to proteins which can lead to protein unfolding [6]. Furthermore, it's been demonstrated that one of the possible pathways for DMSO cytotoxicity at high concentrations is related to its tendency to aggregate proteins within human cells and pharmaceutical samples [7]. This study aimed to investigate whether exposure to DMSO influences enzyme properties, potentially leading to alterations in ATP production and, consequently, impacting cell survival rates. To this end, the effect of DMSO interactions with FBP1, as the protein responsible for production of ATP and cell survival, was evaluated in this study. The results of DLS measurements (Figure 3) revealed that incubation of FBP1 enzyme with DMSO significantly affects the enzyme's size indicating aggregation of the enzyme which resulted in reduction of its activity and kinetic parameters; these effects worsened over time (1 h vs. 24 h). Furthermore, the enzyme activity, when FBP1 was simultaneously co-incubated with DMSO and CoA, were explored. Coenzyme A is used to protect proteins from irreversible sulfhydryl overoxidation [8]. However, the results in this study (Figure 1) showed no improvement in the activity of FBP1 enzyme upon co-incubation with CoA and DMSO compared to that of DMSO alone. Overal, the data obtained reveals significant changes in FBP1 properties at high concentrations of DMSO, notably a marked inhibition of enzyme activity and consequential alterations in kinetic parameters. These findings provide new insights into DMSO toxicity, suggesting its potential contribution to damage in FBP1 and, consequently, disruptions in glycolysis and gluconeogenesis pathways. The results motivate further investigations to enhance our understanding of the molecular aspects underlying this phenomenon.

INTRODUCTION

The structure of urinary bladder, as a collagenous active tissue comprises several layers, each with specific constituents. The innermost layer or urothelium serves as a protective barrier. Below it, the lamina propria (LP) which contains collagen and elastin fibers, providing flexibility. The key layer for bladder contractile function is the muscularis propria or detrusor smooth muscle layer (DSM), primarily consisting of smooth muscle cells (SMCs), crucial for bladder contraction and relaxation. Collagen fibers are present throughout the wall with different conformations in the different wall layers. In the DSM layer, they are integrated with the SMC bundles [1]. Overall, the collagen fibers contribute the structural stiffness and strength to the bladder wall [2].

The urinary bladder's ability to fill and void is a finely tuned physiological process, integral for normal urinary function. Changes to the aforementioned constituents have been associated with lower urinary tract syndromes (LUTS) including both overactivity and incomplete voiding. Specifically, previous studies have shown that the changes to the structural and physiological response of SMCs as well as their interaction with collagen fibers can lead to micturition issues. Moreover, other studies revealed that the structure of the constituents in the LP and DSM layers and the lumen shape (surface topology) have a significant impact on bladder compliance [1]. Such changes can arise from aging [1] or from diseases such as bladder outlet obstruction (BOO) [3,4]. Therefore, it is essential to study the structure of the constituents and the surface topology simultaneously during active contraction in healthy and diseased tissues.

Previous investigations into bladder wall changes during active contraction primarily relied on 2D histological scans of fixed tissues, providing valuable insights but lacking a comprehensive view of 3D topology during active contraction [5]. A prior study explored active contraction in 3D sections of uterine tissue under isometric loading conditions [6]. However, in such conditions, the tissue cannot contract truly due to the fixed boundaries inherent in isometric loading.

The present study focuses on understanding changes in bladder wall topology during active contraction and imaging the layer-wise constituents, specifically collagen and smooth muscle cells (SMCs), in their contracted state. To achieve this objective, we designed a custom biaxial device for isotonic loading of specimens under multiphoton microscope (MPM). Using this system, for the first time, the in vitro active contraction of bladder under isotonic load is imaged under multiphoton microscope, using our custom designed isotonic biaxial apparatus. This work introduces a protocol for imaging live tissue constituents in both active and passive states under isotonic biaxial loading.

METHODS

Biaxial Isotonic Contraction Apparatus: An important design requirement for the experimental system is physical compatibility with the multiphoton microscope (Nikon A1R MP HD, Tokyo, Japan) considering factors such as chamber size and operational limitations of the lens. Furthermore, the tissue must be firmly clamped without tissue damage and maintained viable for the active contraction during long scanning times. The common commercial isotonic systems are not operational under multiphoton microscopes. Inspired by the simple weight-hanging vertical uniaxial systems, here we designed and fabricated a biaxial isotonic apparatus in which the desired force derives from weights that are hung using a triple-pulley mechanism (Figure 1).

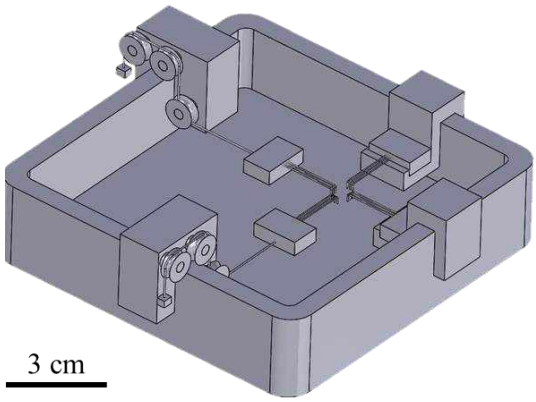

Figure 1. The custom made isotonic apparatus for multiphoton imaging of small tissues. The force is set by hanging weights.

Due to the very small size of the samples (~5mm) and MPM scan area limitations, the previously used commercial rakes [3] could not be used for mounting the bladder samples. Therefore, custom rakes with the appropriate needle diameter and claw length (250 um and 3mm, respectively) were designed with holders fabricated from PLA using 3D printing (an order of magnitude cheaper than the commercial ones). The rake holders were designed to be 90% porous, so they easily float on water within the biaxial tank. The tank with the appropriate size and fixtures was also 3D printed from PLA. Temperature is maintained using a digital temperature controller and a heater located at the base of the tank.

In this study, bladder tissue was obtained from 2 month old male rat bladders which were cut open longitudinally and mounted on the rakes using a custom 3D printed platform with Styrofoam substrate. 1g weights were applied as the isotonic loads. Experiments were performed at 37° C. The tank was filled with KREBS solution [6] aerated with a gas mixture of 95% O_2 and 5% CO_2 to provide physiological environment to ensure cell viability and function.

MPM Scan and Active Contraction of SMCs: The active contraction was induced by addition of KCl to the KREBS solution to achieve 80mM concentration [6]. Two MPM scans were performed before and after contraction, using optimized parameters to make the scan as short as possible (to maintain cell viability). The scanned results were reconstructed and analyzed using IMARIS 10.1.0 (BitPlane AG, Zurich, Switzerland).

Tissue Fixation and staining: The same procedure was performed on another sample. At the end, while the tissue is attached to rakes, the Krebs solution in the tank was replaced with 4% paraformaldehyde in PBS, to fix the tissue in the contracted state under the biaxial loading. The fixed sample was stained with Monoclonal mouse anti-human smooth muscle actin clone 1A4 IgG2a antibody (Dako, Denmark) as the primary antibody and Alexa Fluor 568 goat anti-mouse IgG2a (Invitrogen, USA) for the secondary antibody.

RESULTS

Figure 2a shows a 3D projection of stacks of MPM images from the lumen side of the contracted bladder, while under isotonic loading. The red and green channels correspond to collagen and urothelial cells, respectively. The yellow lines show the location of the in-silico bisection that is visible on the right and bottom of the central square region. Large folds (up to 500 um) form in the upper region which corresponds to the bladder dome (white arrow). These folds are also visible in the vertical bisection (white arrow). These folds are larger in magnitude and wavelength, compared with the trigonal area (bottom, yellow arrow). The smaller amplitude "rugae" in trigonal area are

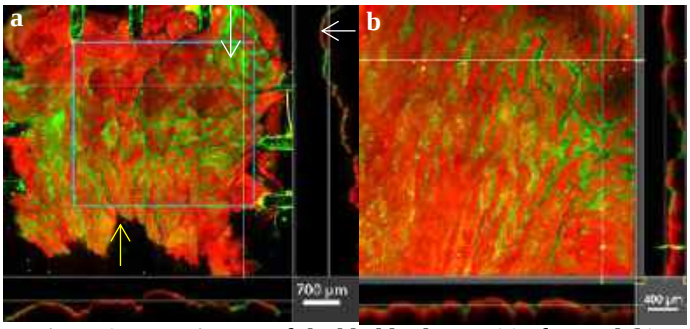

Figure 2. MPM images of the bladder lumen (a) after and (b) before contraction. Large folds can be seen in the contracted tissue, forming convex and concave surfaces on the lumen.

largely oriented longitudinally (vertical in Figure 2), forming a relatively flat surface. The larger folds form convex and concave surfaces after contraction. Although the urothelial cells cover the surface of the lumen, they are folded together in the convex areas, resulting in a higher intensity green signal.

To evaluate changes in surface topology during contraction, a zoomed in area of contracted tissue (blue rectangle in Fig. 2a) is shown in Figure 2b. The surface topology can be seen to change substantially with contraction. In the uncontracted state, the folds uniformly have a smaller amplitude (maximum of 150 µm) than in the contracted state with higher frequency. The orientation of the folds are similar in the contracted and uncontracted states in the trigonal area.

Figure 3 illustrates an orthogonal cross section of bladder with autofluorescent collagen (red), and aSMA stained SMCs (orange) that appear as SMC bundles (blue arrows). The multilayered structure of the bladder wall is seen. It is seen that the SMC bundles have multidirectional orientation. The presence and interaction of collagen fibers between SMC bundles are well illustrated.

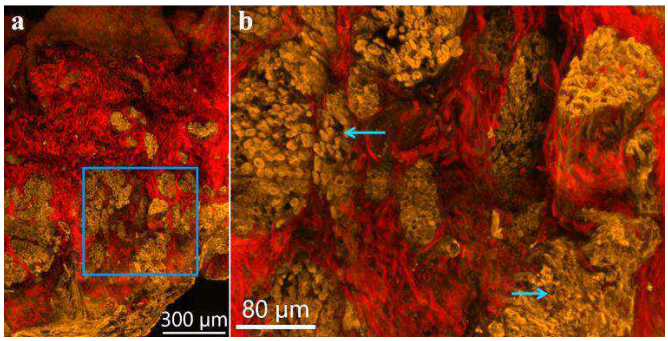

Figure 3. MPM image from a 2D thick-cut section of the contracted bladder, fixed under isotonic loading. Bladder was sectioned orthogonal to the lumen (lumen is up in image). The autofluorescent collagen fibers (red) and SMC bundles (aSMA stained, orange) are illustrated. (a) The whole wall thickness, (b) 4X zoomed in image from blue square in (a).

DISCUSSION

A custom apparatus for biaxial isotonic loading of live tissues is designed and fabricated, that is compatible with multiphoton microscopy. In contrast to the common isometric devices, this isotonic mechanism enables us to image the deformation patterns in active tissues. Using this MPM compatible system, the 3D tissue topology including collagen fibers can be imaged in the same live sample in the uncontracted and contracted state. This is not possible using other imaging modalities like micro-CT or confocal microscopy.

Here we demonstrated the capability of using this system for studying bladder wall constituents and deformation patterns due to active contraction of rat bladder, relevant to the voiding phase. This study identified a spatial heterogeneity even in the qualitative topological features of the contracted bladder. After contraction, the internal layer (LP) buckles in almost all the regions, with larger amplitude in the dome region. These large buckles are three dimensional and are distinct from the small rugae reported in the literature. The heterogenous and multidirectional organization of smooth muscle bundles imaged here in 3D using MPM [7], as the contractile elements of the bladder can justify these heterogenous deformation patterns. Future studies can investigate the observed buckling phenomena, based on the mechanics of multilayer composite sheets.

The proposed methodology enables us to image the deformation patterns and strains in active response of any other live tissues. Of importance, the advanced MPM scanning can image the collagen fibers organization up to single fiber scale (100nm), without any staining. Moreover, following the proposed fixation and staining techniques, the constituents like SMCs can be imaged in their physiological contracted state. This can provide valuable insights for understanding the structure and organization of SMCs in diseased conditions such as BOO bladders, in which hypertrophy and ischemia mechanism results in deficient contractility of SMCs in the voiding function. Although an orthogonal section was stained and imaged in this study, the presented methodology has the potential to image the 3D organization of SMCs throughout the entire bladder in its contracted state. This can be achieved by optically clearing the tissue before staining [7]. Such microstructural information can significantly enhance current computational models, aiding in the development of a high-fidelity digital twin of the bladder, which is the current objective of this research group.

INTRODUCTION

Lowery urinary tract symptoms (LUTS) and changes in bladder function occur with age[1-3]. Patients with LUTS are evaluated with multi-channel urodynamics studies to determine bladder flow and pressure during voiding and filling to assess the presence and severity of symptoms[4]. These tests, however, are invasive and do not provide information about anatomy and flow as the bladder changes shape[5]. Recently, noninvasive techniques based on MRI acquisitions of the bladder during voiding and filling have been developed to paint a broader picture of 3D anatomy and function for lower urinary tract assessment[6]. While this technique provides a more comprehensive picture of bladder function, it largely remains unvalidated.

To combat this, highly controlled experimental validation using an in-vitro, synthetic, bladder mimicking phantom has recently been investigated[7]. While this approach has proved useful, one major limitation is the difficulty in reproducing the tissue-specific behavior of the bladder wall during the flow state. The goal of this study was to perform highly controlled experimental flow validation studies for bSSFP and DISCO Flex-based 3D MRI volumes of the bladder in an ex-vivo porcine model. In doing so, we aimed to better replicate the behavior of urothelium during voiding and filling to more accurately assess the validity of these MRI techniques in obtaining volumetric renderings of the bladder.

METHODS

Porcine bladder tissue was obtained from pigs euthanized for unrelated purposes. To prepare the bladders for flow studies, the ureters were dissected from the renal hilum and the urethra was dissected as distally as possible given anatomical restrictions. The ureters, urethra and bladder were removed *en bloc*. After excision, the ureters and urethra were isolated. Two infusion catheters were placed inside each ureter while a drain catheter was placed in the urethra at the level of the bladder neck. These were sutured in place and connected to a programmable syringe pump to simulate bladder voiding and filling. Two 300cc syringes were utilized, filled to 250cc, and facilitated flow. For all filling and voiding events, 300cc of water was injected through the ureters and withdrawn from the urethra, respectively.

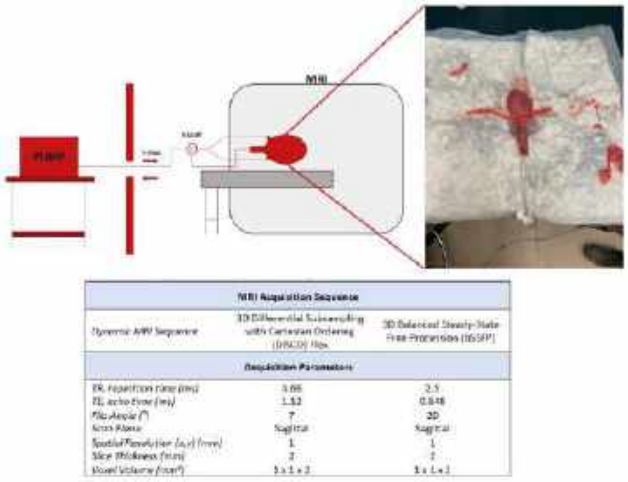
Once air was removed from the system, the porcine bladder was placed in a 3.0T clinical MRI scanner (GE Healthcare) and volumetric data was acquired using two different sequences: (1) 3D Differential Subsampling with Cartesian Ordering (DISCO) Flex and (2) 3D Balanced Steady-State Free Procession (bSSFP). Three different flow rates for both filling and voiding events were simulated in our study – 100, 200 and 300cc/min – resulting in 12 total volumetric acquisitions. bSSFP acquisitions were carried out followed by DISCO Flex due to the requirement of gadolinium-based contrast for signal enhancement during DISCO acquisition. Prior to DISCO acquisitions, 5 ml of gadolinium-based contrast (0.1mmol/kg) was hand-injected into a 1L volume of DI water used to fill the syringes in the flow loop. A summary of acquisition parameters for each sequence are shown in **Figure 1**.

During each MRI acquisition, pressure measurements were acquired by placing an MRI-compatible, fiber-optic pressure transducer (OPP-M200, Opsens Inc) 1cm inside the bladder. Pressure measurements were acquired for the entirety of each flow test at 1000Hz. After acquisitions, pressure and MRI-volumetric data were processed using a custom MATLAB script. A semi-automatic segmentation process was used to determine bladder volume change during and compared to the pump control volume. Changes in successive volumes and the acquisition time were utilized to determine time-resolved volumetric flow rate and compared to imposed flow rates.

RESULTS

Figure 2 depicts typical ex-vivo porcine model volumes over time during a voiding and filling event generated at a flow rate of 300cc/min. MRI-derived flow rates agree within 10% when compared to the known flow rates imposed by the syringe pump with average errors of 8.9% for

total volume error and 8.52% for flow rate error. bSSFP MRI acquisitions led to slightly higher errors in total volume change and flow rate when compared to DISCO Flex for both voiding and filling (9.07% and 10.3% / 8.79% and 6.73 %, respectively).



MRI Acquisition Sequence		
Dynamic MRI Sequence	3D Differential Subsampling with Cartesian Ordering (DISCO) Flex	3D Balanced Steady-State Free Precession (bSSFP)
Acquisition Parameters		
TR: Repetition Time (ms)	3.66	2.5
TE: echo time (ms)	1.52	0.848
Flip Angle (°)	7	20
View Plane	Sagittal	Sagittal
Spatial Resolution (x,y) (mm)	1	1
Slice Thickness (mm)	2	2
Voxel Volume (mm³)	1 x 1 x 2	1 x 1 x 2

Figure 1: (Top) Schematic of experimental ex-vivo MRI setup. (Bottom) Summary of DISCO Flex and bSSFP MRI parameters.

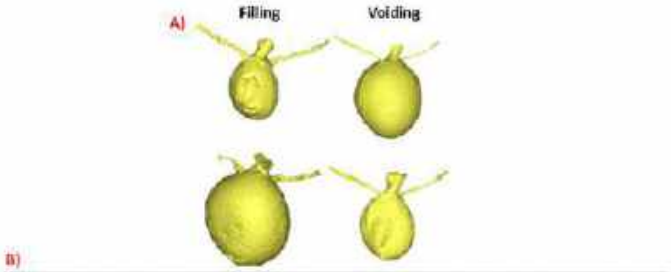


Figure 2: (A) Ex-vivo bladder model renderings obtained from MRI for a 300 cc/min filling and voiding cycle. (B) Total volume change, volumetric flow rate and error analysis for all 12 MRI acquisitions.

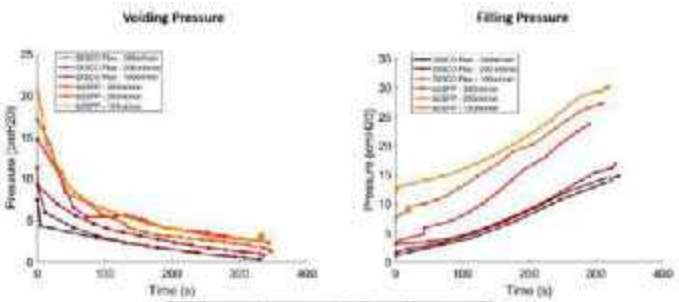
Figure 3 Depicts pressure-volume (PV) loops obtained for each voiding and filling test. A pressure drop is observed for all voiding events while pressure increases are seen during filling. The work associated with bladder emptying and filling is computed as the integral of the PV-loop. More work output was associated with decreased flow rates during voiding and filling. The work done during filling was higher on average than during voiding.

DISCUSSION

Bladder volumes during 12 total voiding and filling tests were successfully calculated from 3D MRI data and used to estimate volumetric flow rate. bSSFP MRI acquisitions yielded slightly larger errors in both total volume change and volumetric flow rate when compared to DISCO Flex. This is likely due to eddy current errors that persist in a few volumes acquired during the bSSFP sequence that render volume segmentations difficult.



Work (mJ)	100 mL/min	200 mL/min	300 mL/min
DISCO Flex Void	57.65	106.08	116.79
bSSFP Void	163.41	113.58	130.42
DISCO Flex Fill	210.88	253.80	267.89
bSSFP Fill	349.47	535.13	611.53

Figure 3: (Top) Voiding and filling pressure traces during ex-vivo MRI acquisitions. (Bottom) Calculation of work for each voiding and filling test from PV-loops obtained during MRI.

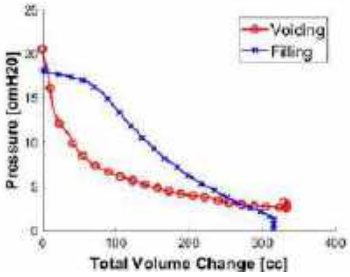


Figure 4: Hysteresis curve generated from the PV loops of the 100 cc/min filling and voiding bSSFP MRI acquisitions.

Both voiding and filling pressure maps were qualitatively similar in profile. Peak pressures in both voiding and filling were higher for lower flow rates. Differences between voiding and filling behavior at the same flow rate are depicted in Figure 4. This represents what can be thought of as a hysteresis curve, displaying the difference in voiding and filling profiles for the same flow rate. This suggests the bladder may deform differently during the emptying compared to filling and more work output is associated with filling events at the same flow rate.

This modeling pipeline represents a novel technique to assess the validity of experimental MRI in the bladder that replicates tissue-specific behavior compared to other modeling methods. Future efforts will focus on analyzing tissue-specific bladder shape changes during experimentation. Visually, it was apparent that the bladder tissue changed during repeated flow tests. We hypothesize that this is a result of the repeated loading and unloading of the tissue outside of the body. Additionally, we would like to better replicate the in-vivo bladder environment in our model (detrusor and abdominal pressures)[8].

INTRODUCTION

Multichannel urodynamic studies (UDS) with or without fluoroscopic imaging and/or urethral pressure profilometry have been the gold standard for assessing the lower urinary tract (LUT) by measuring voiding pressures and urine flow but still provide limited information of LUT anatomy[1]. Pressure-volume analysis is a commonly used technique to analyze cardiac function. This same analysis can be reproduced in the bladder by using UDS-based measurements[6]. Assessment of bladder biomechanics using magnetic resonance imaging (MRI) has been reported in the past[1–3] but lacks detailed analysis of bladder shape as it has only been analyzed using volume-based metrics. Bladder shape during filling has been studied using ultrasound[4]. Similarly, MRI has been used to study bladder shape but not dynamically[5]. The aim of this study is to comprehensively and non-invasively characterize bladder biomechanics in patients with BPH/LUTS and healthy subjects by using pre-existing UDS to analyze bladder energetics, and the recently developed Uro-Dynamic MRI[1] method to analyze anatomy-based biomechanics.

METHODS

Image Acquisition: In this an IRB-approved, HIPAA compliant study. 5 healthy volunteers (37±9 years of age) and 5 subjects diagnosed with BPH (65±6 years of age) were recruited. 15 minutes prior to the MRI scan, 1/3 of a single weight-based dose of gadolinium-based contrast was hand injected for urine enhancement. Subjects were equipped with a condom catheter and instructed to void in the MRI scanner. Urine was collected in a 1L bag attached to the subject's leg. Images were acquired in a 3T MRI scanner (Premier, GE Healthcare, Waukesha, WI) using a high-density flexible array coil (AIR Coil, GE Healthcare) and Uro-dynamic MRI protocol[1].

Bladder Segmentation and Shape Analysis: Images were imported into MIMICS (Materialise, Belgium) where the bladder was segmented and one 3D rendering per time-step was reconstructed within each void (17±4 time-steps). Shape-based metrics, based on the pubic symphysis (PS) and the trigone which are anatomically "static" reference points\, were determined to aid in the characterization of bladder shape throughout the void shown in Fig1A) and Fig1B). Sphericity index, bladder neck angle (BNA) and external BNA (EBNA) were quantified for all subjects throughout the void (Fig1C)[1]. **N** is the distance from the top of the trigone to the PS in black. **LA** is the longest axis long **N** in yellow. **LAN** is the angle between **N** and **LA** in green. **CAS** is the curvature angle in light blue. **DS** is the sagittal curvature length in red. **N**, **LA**, **LAN**, **CAS,** and **DS** are measured in a sagittal plane centered in the PS. **CTB** is the top-bottom distance in blue. **CRL** is the right left distance in purple and **DC** is the coronal curvature distance in red. **CTB**, **CRL**, and **DC** are measured in a coronal plane centered in the PS.

***UDS Analysis*:** A single retrospective UDS was digitized for one of the patients (Healthy 5). Volume measurements were calculated from the constant bladder filling rates and the flow rate for the filling and voiding phases respectively. Detrusor pressure measurements were used for both the filling and the voiding phases. PV curves are shown in Fig2. Work was calculated by integrating over the PV curve of each respective phase.

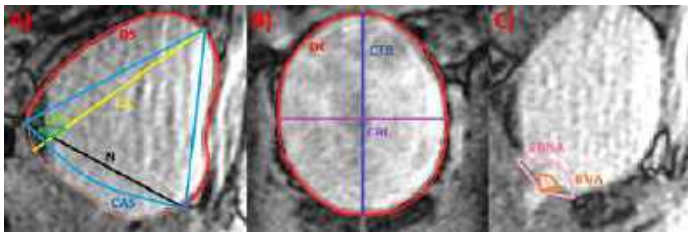

Figure 1: A) Sagittal place displaying the acquired metrics. B) Coronal plane centered in the PS showing acquired metrics. C) Sagittal view showing measurement of BNA and EBNA.

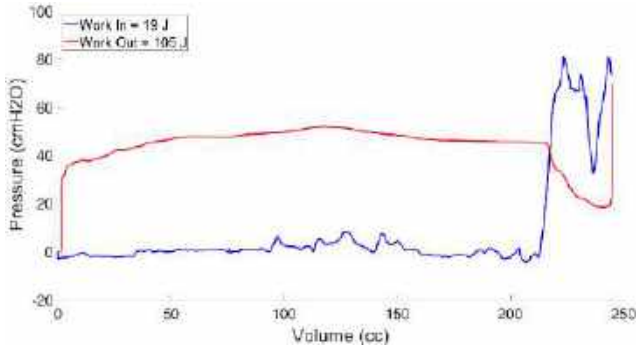

Figure 2: Generated PV curves showing filling (blue) and voiding (red) phases with corresponding work calculations.

RESULTS

Results are summarized in Table 1; Fig.3 contains a complete analysis corresponding to one characteristic subject of each group (highlighted in yellow in Table 1B).

Table 1: A) Maximum and minimum value summary for bladder shape metrics and key metrics highlighted. B) R^2 for all metrics vs flow rate. Characteristic subjects highlighted in yellow.
