Therefore the objective of this study is to investigate the hemodynamics in regions around the Transcatheter aortic valve (TAV) using a loosely coupled fluid-structure interaction approach across four patient-specific anatomies with blinded HALT outcomes. The work involves the virtual deployment of a bioprosthetic valve using pre-TAVR CTs, followed by structural simulations for leaflet kinematics and fluid simulations for flow characteristics. First, we seek to establish a methodology where we use pre-TAVR CTs to segment and then deploy a bioprosthetic valve virtually. Then, we initiate a structural simulation to obtain the leaflet kinematics and integrate the displaced leaflets into a fluid simulation to obtain the flow characteristics. We initially validate our methodology against already published experiments and then present the hemodynamics of these four cases aiming to contribute to a deeper understanding of subclinical leaflet thrombosis and its links to hemodynamics in the neo-sinus.

METHODS

Patient anatomies were segmented, smoothed and converted to surface files from pre-TAVR CT scans. A bioprosthetic valve (SAPIEN 3) was deployed in these anatomies virtually using a reduced order method (ROM). This approach simulated the post-TAVR condition. Subsequently, patient-specific pressure waveforms were applied to the deployed valve leaflets, and their displacement and motion were obtained through finite element modeling (FEA) in Abaqus. The leaflet motion data were then integrated into fluid flow simulations under patient-specific conditions, conducted using the Open Field Operation and Manipulation (OpenFOAM) code.

The simulations involved solving the incompressible Navier-Stokes equations, assuming blood as Newtonian with a kinematic viscosity and density of 0.0036 Pa s and 1060 kg/m3, respectively. Aortic flow rate waveform was prescribed at the inlet and a generic pressure waveform was prescribed at the outlet and a no-slip boundary condition was applied to the walls. For each patient, the aortic flow waveform was scaled to match the patient's peak systolic flow rate, obtained from analysis of the left ventricular volume over the cardiac cycle. Parallel processing was implemented through the Message-passing interface (MPI) protocol, with grid partitioning facilitated by the SCOTCH algorithm [6]. Hexahedral control volumes discretized all grids, focusing on clustering cells around thin structures such as leaflets and stents. Each simulation ran for five cycles to mitigate initial transients, and results were extracted from the last cycle for presentation.The simulations were performed on Linux machines equipped with dual Intel Xeon 6226 @ 2.7 GHz CPUs on the PACE Phoenix cluster [7].

RESULTS

In fig. 1, a time-lapse top-down view illustrates leaflet motion from early systole (completely closed) to peak systole (completely open) for

one of the examined cases. The leaflet dynamics obtained from FEA simulations align closely with experimentally observed dynamics, validating our methodology to obtain the displaced leaflets. Figure 2 shows the instantaneous flow fields via velocity magnitude along the center slice of the anatomy at peak systole and late diastole. Inset figures indicate corresponding leaflet displacements. The centerline jet remains well-preserved, breaking down gradually upon impingement on the aortic arch before reaching the descending aorta. Notably, the flow around the sinus region exhibits greater persistence during diastole than the systolic phase. In fig. 3, vortex cores are presented via isosurfaces of Q-criterion (colored by vorticity) during various points in the cardiac cycle. Vortex cores break down, with a more prominent presence in the diastolic phase, particularly clustering around the sinus region.

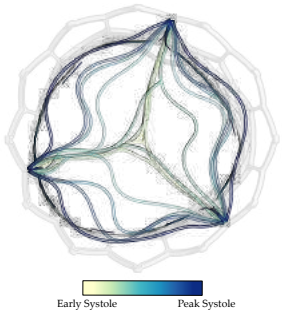

Figure 1: Top view of the bioprosthetic leaflet dynamics overlaid on top of each other from early systole to peak systole

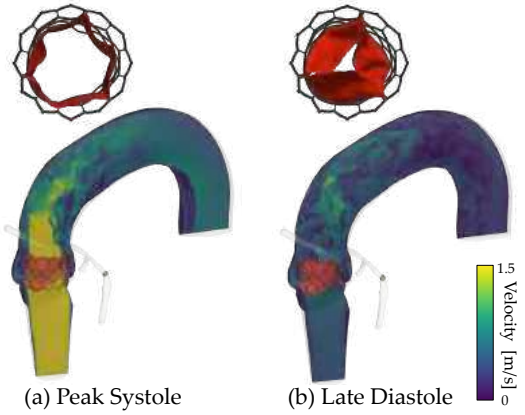

Figure 2: Velocity magnitude along the slice of the anatomy at (a) peak systole and (2) late diastole and the inset figures showing the opening area of the leaflets.

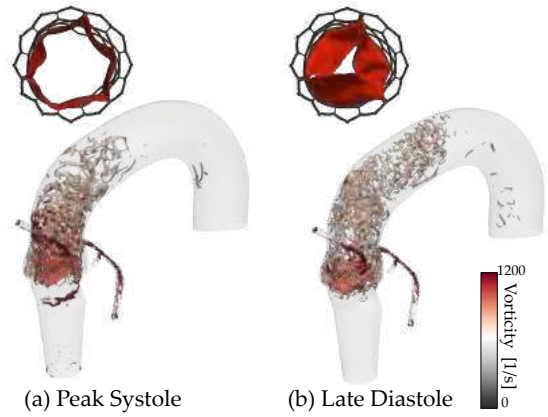

Figure 3: Isosurfaces of Q-criterion visualized at (a) peak systole and (2) late diastole and the inset figures showing the opening area of the leaflets.

DISCUSSION

Qualitative assessment of instantaneous flow fields reveals notable high-frequency flow fluctuations throughout the cardiac cycle. The impact of these fluctuations on degenerative changes, such as endothelial or mural cell remodeling and turnover, is well-documented [8, 9]. To investigate these flow fluctuations, we intend to analyze them spectrally using short-time Fourier transforms (STFT) represented via spectrograms [10].

Studies by Biasetti et al. [11] and Naim et al. [12] emphasize the significance of vortical structures and their interaction with the vessel wall or lumen. As a first step we investigate the evolution and interaction of vortical structures throughout the cardiac cycle by extracting the Q-criterion. Subsequently, given the known association of flow structures, particularly vortex cores, with thrombosis development and progression, we aim to assess the intensity of these vortex cores alongside wall shear stress in the relevant region.

Considering fluid dynamics, the hypothesized contribution of flow stasis to HALT prompts further investigation. We will analyze washout curves and identify flow stagnation regions around the sinus and neosinus, comparing outcomes between HALT-positive and HALT-negative cohorts. Steep washout curves, indicating efficient particle exit from the neo-sinus region in fewer cycles, generally suggest improved flow circulation. This comprehensive analysis aims to enhance our understanding of the hemodynamic factors contributing to HALT and further informs potential implications for patient outcomes.

In summary, our study intends to explore the fluid dynamics of TAVR, focusing on subclinical leaflet thrombosis. Through advanced simulations, we initially validate dynamic leaflet motion, revealing insights into flow fluctuations and vortex cores. Examining washout curves and flow stagnation regions in HALT-positive and HALT-negative cases could provide key perspectives on flow dynamics. These findings may offer valuable insights for better understanding HALT, contributing to improved patient care and informed clinical decisions in TAVR procedures.

INTRODUCTION

Fibromuscular dysplasia (FMD) is a non-inflammatory, non-atherosclerotic blood vessel disorder, most commonly affecting the carotid and renal arteries, that results in alternating regions of narrowed and dilated vasculature [1]. This so-called "string of beads" in multifocal FMD increases the risk of catastrophic vascular events including arterial dissection due to known weaknesses in the blood vessel well as well as platelet action as platelets and mechanically stimulated following exposure to disturbed blood flow (D-flow) in the ectatic artery. Both events increase the risk for thrombotic stroke. [2]. FMD often affects multiple regions of an artery, in contrast to carotid artery stenosis, which can be concentrated in a single location in the vessel. FMD is diagnosed via computed tomography angiography (CTA), MRA, or Carotid Duplex imaging but is not always easily distinguishable from other arterial diseases that cause arterial stenosis. Imaging-based diagnoses also make it challenging to determine which patients are at highest risk for stroke to properly manage medication. The purpose of this study is to analyze the hemodynamic environment in the carotid artery of patients with FMD compared with carotid artery stenosis to quantify the unique mechanical stress environment created from multifocal malformations. Comparisons are to be made against healthy arteries, as well as carotid artery stenosis (CAS) to determine any unique biomechanical patterns that can be found in patients with multifocal FMD for improved diagnostic decision making. Predictions of mechanical platelet activation will also be compared to platelet sensitivity to activation for patients with each respective disease to further characterize the effects of these diseases on platelet activation and clot formation. These findings will serve as the basis for incorporating quantitative metrics of platelet activation risk to clinical management of FMD patients.

METHODS

To quantify the hemodynamic conditions for FMD and stenotic carotid arteries, image-based models of diseased vasculature were imported into an open-source modeling software, Simvascular. Multiple cases, ranging severity of both FMD and CAS were used to characterize the biomechanical impact of each respective disease on blood flow and platelets. The flow was modeled as Newtonian and laminar and the arterial walls were assumed rigid. Generalized boundary conditions for inlet flow rates and outlet Windkessel conditions were assigned to the solver and the transient Navier-Stokes equations were numerically solved to obtain velocity fields. Computed velocity gradients were used to calculate the VonMises-like scalar stress at nodes according to (1):

$$\tau = \frac{1}{6}\left[(\sigma_x - \sigma_y)^2 + (\sigma_y - \sigma_z)^2 + (\sigma_x - \sigma_z)^2\right] + {\tau_{xy}}^2 + {\tau_{yz}}^2 + {\tau_{xz}}^2 \quad (1)$$

where, sigma and tau correspond to components of the rate of strain tensor. This evaluates the level of mechanical stress that the platelets experience as a result of the velocity field and has been used in the past to assess hemodynamic stress for red blood cells and platelets [3].

Biomechanical platelet activation is known to be a function of both platelet surface stress level and exposure time [3]. For each vascular geometry, the computed velocity field was used for Lagrangian particle tracking over multiple cardiac cycles, to represent the trajectories of platelets. This generates a stress history that discerns how long circulating platelets spend in different stress regions. A fourth order Runge-Kutta scheme, in combination with trilinear interpolation was utilized to advect particles as they travel through the vessel. The resulting stress history was then used to assess the levels of mechanical platelet activation, as defined by Soares et al. [4]. This three term model was solved using a fourth-order Runge-Kutta from the ordinary differential equation, shown below.

$$\frac{dPAS(t)}{dt} = [S(PAS, H_\tau) + F(PAS, \tau) + G(PAS, \dot{t})](1 - PAS) \quad (2)$$

In this equation, PAS is the platelet activation state at time t. S corresponds to the stress accumulation, where H is the integral of stress up to a time t. F is the contribution of the current level of stress. G is determined by the rate of stress loading.

$$S(PAS, H_\tau) = S_r * PAS * H_\tau \quad (3)$$

$$H_\tau = \int_0^t \tau(s)ds \quad (4)$$

$$F(PAS, \tau) = C^{\frac{1}{\beta}} * \beta * PAS^{\frac{\beta-1}{\beta}} * \tau^{\frac{\alpha}{\beta}} \quad (5)$$

$$G(PAS, \dot{\tau}) = C_r^{\frac{1}{\delta}} * PAS^{\frac{\delta-1}{\delta}} * |\dot{\tau}|^{\frac{\gamma}{\delta}} \quad (6)$$

The threshold for platelet activation which would increase the risk for stroke is also assessed in experiments, using platelets isolated from patients with FMD and CAS. These platelets are subjected to mechanical loading in rotating flow cones designed to produce varying levels of mechanical stress, especially resembling D-flow conditions. Platelet activation is then assessed via the appearance of surface biomarkers, such as CD62P (p-selectin), which is a widely accepted method to demonstrate increased expression in activated platelets [5].

RESULTS

Shown in Figure 1 is one representative case of FMD (1A), healthy (1B), and CAS (1C). Direct comparisons of hemodynamics within a single case of FMD in comparison to healthy vasculature, identified small regions of increased VonMises stress in multiple regions of the FMD patient, where there are noticeable beading patterns (1A). In contrast to this, the healthy case, has relatively uniform stress across straight segments of the artery (1B). The CAS model showed concentrated regions of elevated stress near to the stenosis (1C).

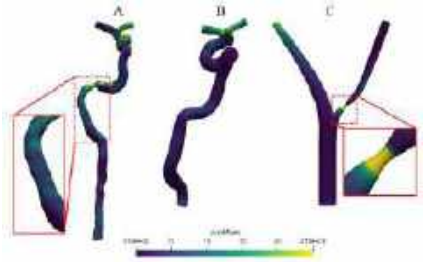

Figure 1: Stress Distribution in FMD, Healthy, and CAS Carotid

Initial results comparing single cases of FMD, and healthy arteries show increased levels of PAS in the left and right carotid of the FMD in comparison to the left and right healthy carotid artery respectively (2).

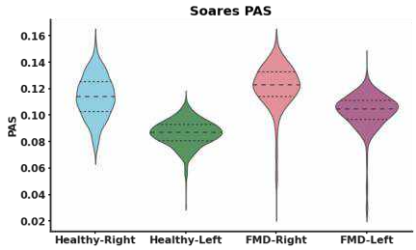

Figure 2: Predicted platelet activation in Healthy vs FMD Carotid

Platelets from FMD patients, healthy patients, and CAS patients showed differences in p-selectin expression after exposure to mechanical stress via rotating flow cones. Platelets isolated from FMD patients exhibited the highest amounts of p-selectin, demonstrating their increased reactivity to mechanical stress environments.

DISCUSSION

Stress distributions within the healthy, CAS, and FMD arteries show differences in the variations that may be seen in the stress history of platelets traveling through these patients. The major difference is the continuous pattern of elevated stresses along the wall of FMD patients. This continuous exposure to elevated levels of stress has the potential to induce activation, known to be a function of both stress and exposure time. This is a pattern that is unique to FMD and may present in a characteristic phenotype that can be used for more targeted diagnostic and therapeutic approaches to FMD. In comparison, CAS models show a focal region of higher shear, where platelets would likely reside in for a short period of time. The subsequent relaxation may create differences in activation characteristics of platelets highlighted in platelet activation state modeling and surface biomarker studies.

Initial comparisons identified minor elevation in PAS for the FMD patient carotid arteries compared to the healthy patient carotids. These results may be exemplified in further analysis of different arterial geometries and the platelet pathways. The initial results show promise in differentiating a case that does not have substantial regions of disturbed and recirculating flow or tortuous beading patterns observed in more severe cases of FMD. As such, looking at a broader range of FMD severity may lead to increased differences observed between the healthy and diseased cases. Additionally, the inclusion of patient outcomes will further validate findings by comparing numerically predicted activation levels to experimentally measured sensitivity of platelets to mechanical activation observed for the same patients.

Future analysis of stenotic in comparison to FMD and healthy vessels will provide confirmation of expected differences in stress history based on the stress distributions shown. The continuation of this calculation to platelet activation state will assess how effects of focal stenosis on platelets vary from multifocal FMD. The corresponding biomarker data from these cases will validate numerical predictions to determine characteristic phenotypes associated with FMD.

Large recirculating regions commonly observed distal to stenosis could also induce stroke due to increased flow residence time and reduced shear stresses which promote coagulation. Clots resulting from this phenomenon are rich in red-blood cells, distinguishable from the platelet-rich clots considered in this study.

This study aims to further understand how biomechanical environment in various arteriopathies affect platelet activation and risk of thrombosis. A quantifiable hemodynamic metric associated with the risk of stroke in FMD can help in creating patient-specific management plans for these patients.

INTRODUCTION

In living tissues, cells mechanically interact with the surrounding fibrous extracellular matrix [1, 2]. Prior studies showed that the forces produced by a solitary contractile cell stiffens the matrix at the scale of tens of microns [3]. However, in many tissues, cells can interspersed within the same matrix. Owing to nonlinearity and complex force transmission within the matrix, it remains elusive how the collective contraction of many cells would alter the stiffness of the matrix and the subsequent effect on the cell sensing and response. To address this gap, we used mechanics-based models and experiments to quantify the stiffness of random fibrous matrices embedded with multiple contracting inclusions (which mimicked contracting cells) [4]. We also verified that the changes in the matrix stiffness due to contraction of inclusions were sufficient for the cells to sense and respond.

METHODS

We began by preparing models of random fibrous matrices embedded with multiple contracting inclusions, each of diameter $D = 2L_\mathrm{f}$ (L_f being the average fiber length in the matrix). The fibers in the matrix were modelled as beams highly susceptible to bending, similar to type I collagen fibers. Finite element simulations were performed with two load steps, wherein first load step induced contraction of the inclusions and a second load step was used to measure the stiffness of the matrix. While inducing contraction of the inclusions, free external boundaries were considered in the matrix which ensured global shrinkage of the matrix. To measure the stiffness of the matrix at cell scales, contracting dipoles of varying orientations were used.

To experimentally validate the simulation findings, we polymerized matrices of collagen type I and embedded contracting inclusions inside the matrices. These inclusions were active thermosensitive microspheres of poly(N-isopropylacrylamide) (PNIPAAm) [5], whose controlled contraction induced localized tension inside the matrix similarly to contracting cells. For matrices with free external boundaries, contraction of PNIPAAm microspheres induced global contraction of the matrices. The stiffness of these matrices was measured at the length scale of tens of microns using microscopic indentation experiments. To understand if the changes in the matrix stiffness due to the contraction of inclusions were sufficient for cells to sense, we seeded breast carcinoma cells (MDA-MB-231) on these matrices. Cell morphologies at 18 hr post-seeding were evaluated by analyzing microscopic images of cells.

RESULTS

To determine the effect of multiple contracting cells on the matrix stiffness, we used the computational model of fibrous matrix with contracting inclusions. Keeping the external matrix boundaries free, the embedded inclusions were radially contracted by 40% to induce localized tension in the matrix similar to the cell-generated forces (Fig. 1a,b), which also triggered global contraction of the matrix (Fig. 1b). The stiffness of the matrix was measured using contracting dipoles of length $2L_\mathrm{f}$ at various locations inside the matrix. Based on the prior literature [6, 7], the expectation was for the cell-induced local tension to stiffen the matrix. But, to our surprise, we noticed the stiffness of the matrix decreased due to the contraction of inclusions. For several independent random matrices, the ratio of the values of stiffness after and before the contraction of inclusions, k_s and $k_\mathrm{s,ref}$ respectively, were consistently less than one indicating softening in the matrix at all locations and in all directions (Fig. 1c).

To explain what might have caused this softening, we studied the evolving microstructure of the matrix due to the contraction of the inclusions. In the close vicinity of the contracting dipoles used to measure the stiffness of the matrix, we noticed the fibers to buckle strongly in response to the contraction of inclusions, as depicted in Fig. 2a, where fibers are color coded based on the extent of buckling. The extent of matrix softening measured by independent dipoles was correlated to the average buckling of fibers in the neighborhood of those dipoles (Fig. 2b), meaning that more fiber buckling corresponded to more softening in the matrix.

We experimentally validated these model predictions of softening using microscopic indentation tests on matrices of fibrous collagen embedded

with contracting PNIPAAm microspheres. With the outer boundaries of these matrices free, we induced contraction of the embedded microspheres and measured the stiffness of the matrix by indenting its surface with glass microspheres. Results showed that the matrices with contracted PNIPAAm microspheres softened in contrast to the control matrices with no microspheres, verifying model predictions (Fig. 3a). Lastly, in another series of experiments, we observed that cells could sense this buckling-induced softening in the matrix by altering their morphologies from being elongated to more rounded (Fig. 3b,c).

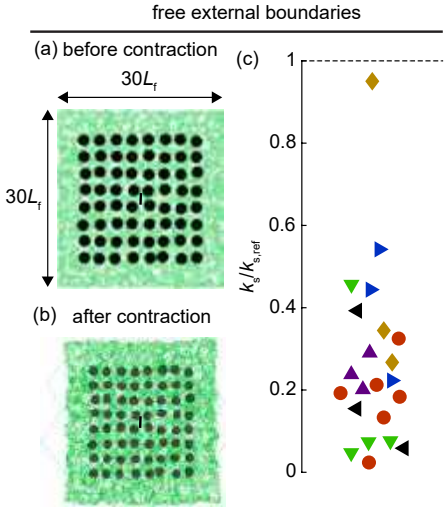

Figure 1: Contracting inclusions soften the matrix. (a) Undeformed matrix. (b) Deformed matrix (globally shrunk) after contraction of inclusions. Dipole used to measure the matrix stiffness is depicted by a black line in panels a and b. (c) For differently aligned dipoles and six independent matrices, $k_s/k_{s,ref} < 1$ indicates softening. Each marker type indicates a dipole from an independent model. Figure panels are adapted from ref. [4].

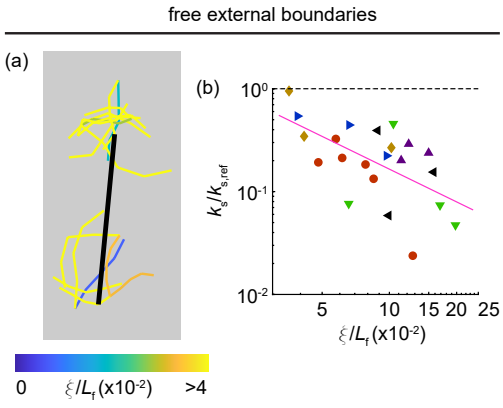

Figure 2: Fiber buckling is mapped to matrix softening. (a) Depiction of buckled fibers in the vicinity of contracting dipole, after the contraction of embedded inclusions. The extent of buckling of fibers were colored by measuring the difference between the contour length and the end-to-end distance of fibers (fiber excess length, ξ). (b) Scatter plot of normalized stiffness sensed by each dipole against the average excess length (ξ) in the vicinity of dipole. Each marker type indicates a dipole from an independent model. Figure panels are adapted from ref. [4].

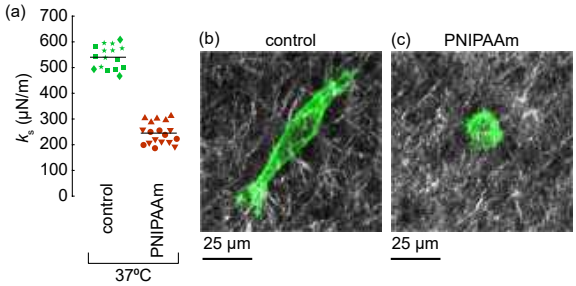

Figure 3: Cells sensed and responded to the changes in the stiffness of the matrix. (a) Stiffness of matrix at cell scales measured by different glass micro-indenters in control collagen matrices, and in globally contracted collagen matrices due to contracted PNIPAAm microspheres. Notice the drop in stiffness by a factor of 2 in the contracted matrices indicating softening by contracted inclusions. Markers with an identical shape and color indicate independent indenters from one sample. (b) Representative elongated morphology of MDA-MB-231 cell in control collagen matrix. (c) Representative rounded morphology of MDA-MB-231 cell in contracted collagen matrix, where contracting PNIPAAm microspheres triggered matrix contraction. Figure panels are adapted from ref. [4].

DISCUSSION

Our simulations and experiments reported softening under the boundary conditions different from prior studies. In contrast to the prior studies which showed softening in matrices under global compression [8], our study depicted a surprising phenomenon of matrix softening driven by the tensile forces generated by many contracting inclusions. Our observation of the occurrence of substantial fiber buckling in an unconstrained matrix with contracting inclusions is novel, and elucidates a new role of fiber buckling in modulating the mechanics of fibrous matrices that has not been reported before.

These findings have the potential to shift the paradigm in the field on how we interpret cell-matrix interactions in experiments on cell-embedded matrices. By revising the common notion that cells only stiffen the matrices, we introduced a new insight that the presence of many contracting cells can induce fiber buckling that triggers substantial mechanical softening in the matrix. For future work, it could be worth investigating to see if contracting myofibroblasts soften the fibrin matrix in wound healing. Such softening mechanism, if exists, can be speculated as a natural remedy against scar formation.

INTRODUCTION

Mechanical forces generated by stromal cells in the perivascular matrix play an essential role in controlling blood vessel growth and function [1]. Despite advances in tissue engineering, the ability to create larger, vascularized tissue scaffolds remains limited, largely due to the poor understanding of how mechanical cues promote and regulate angiogenesis. Our recent studies have provided some evidence suggesting that mechanical forces may drive angiogenesis through the activation of VEGFR-2 [2]. Previous work in our laboratory has enabled the characterization of mechanical fingerprints, or mechanical phenotypes, of various stromal cells by tracking matrix distortions generated by contractility events [3, 4]. Highly contractile cells generate more matrix distortions, and we refer to them as having a mechanically-active phenotype. Moreover, cadherins are recognized as mechanosensors responsible for sensing mechanical stimuli and maintaining cell-cell interactions and blood vessel stability [5]. Neural cadherin (N-Cad) in the vasculature, forming homotypic bonds, is responsible for polarity during cell migration, motility, and endothelial cell proliferation. [6]. Despite this knowledge, the role of mechanical crosstalk through cadherin signaling between different cell types in the perivascular matrix is still poorly understood. It could offer insight into regulating vascular function and growth through mechanical stimulation and whether it can be controlled while fabricating large, vascularized scaffolds.

Studies have indicated that lowering the calcium concentration available to the cells can deplete N-Cad due to reduction in binding affinity through mechanical cues [7]. Based on previous studies, we selected human microvascular endothelial cells (HMECs), normal breast fibroblasts (NBFs), normal human cardiac fibroblasts (NHCFs), and normal human lung fibroblasts (NHLFs) for our studies since they offer a diverse representation for investigation. HMECs, as endothelial cells, have the capability to grow blood vessels. NHLFs and NHCFs are pro-angiogenic fibroblasts, while NBFs are non-angiogenic. Our objective is to investigate the mechanical phenotype of these cells in 3D microtissue models with fluorophore beads. Additionally, we aim to quantify the amount of N-Cad present in these microtissues. Our studies explore whether N-Cad depletion can lead to mechanical phenotype changes, as measured by the ability to generate matrix distortions.

METHODS

HMECs, NBFs, NHCFs, and NHLFs were subjected to a bead displacement assay to track cellular movement and matrix distortions within a 3D microtissue model made of 10mg/mL fibrin using a polydimethylsiloxane ring to hold the tissues [3]. The microtissues received Dulbecco's Modified Eagle's Medium (DMEM) on Day 0. On Day 1, the control samples received DMEM media with physiological levels of Ca^{2+}, while the experimental samples received DMEM media with low Ca^{2+}.

The plates were imaged using live-cell imaging on Day 2 with an Olympus IX83 inverted epifluorescence microscope. A previously developed bead displacement algorithm was utilized to gather the data and analyze the mechanical phenotype of fibroblasts and endothelial cells [4]. The microtissues were then fixed and stained for N-Cad (Abcam, ab19348) at a 1:400 concentration. DAPI was used as a counterstain to calculate the total cell count. The samples were re-imaged after staining. All images collected were 100μm z-stacks with a step-size of 2.

RESULTS

The matrix distortion study was used to investigate the effects of N-Cad depletion on cell matrix distortions as measured by the ability of the cells to distort the matrix. Our data show that the 3D microtissue models with HMECs, NHCFs, and NHLFs showed significantly reduced average matrix distortion magnitudes compared to the control microtissues when cultured in low calcium conditions. At the same time, NBFs showed a significant increase in matrix distortion

magnitudes with low calcium levels (Figure 1). NHCFs displayed the highest matrix distortions, while NHLFs revealed the lowest matrix distortions amongst the cell lines. Staining for N-Cad indicates that HMECs, NHCFs, and NHLFs display a decrease in N-Cad expression levels in low calcium conditions (Figure 2). At the same time, no differences are seen in NBFs.

DISCUSSION

The perivascular matrix mechanics should regulate the formation, permeability, sustained growth of the vasculature since it is located in close proximity to the blood vessel network. Understanding the specific biomechanical cues, such as stromal cell mechanical phenotype in isolation from cytokine signaling, is difficult in *in vivo* models. Specifically, the link between stromal matrix distortion behaviors and cadherin signaling has been previously underexplored, prompting our studies to clarify how mechanical phenotype and cadherin levels regulate angiogenesis/vasculogenesis in 3D microtissue models. This pilot study was critical for identifying changes in mechanical phenotype and N-Cad in single cell cultures before future studies use co-cultures of HMECs with the stromal cells to investigate angiogenesis.

Our matrix distortion results suggest that even highly contractile cells are influenced by N-Cad depletion (Figure 1). These matrix distortions represent the movement of an individual bead caused by cell contracting events embedded within the fibrin matrices. The results also highlighted the heterogeneous nature of mechanical phenotype within a single cell line, as the magnitude of matrix distortion distributions varied in shape and range. While our prior work suggested that fibroblasts with higher matrix distortions can promote blood vessel growth, it is worth noting that NHLFs have long been recognized as pro-angiogenic stromal cells in various studies. Under normal cellular conditions, myosin, a motor protein that interacts with actin filaments to generate contraction, is activated by calcium ions. When calcium levels are reduced, this activation process is impeded, resulting in decreased matrix distortions. Conversely, high calcium conditions can relieve this inhibition, thereby allowing the contractile machinery to become more active, leading to an increase in matrix distortions. This phenomenon could partially explain the decreased matrix distortions in addition to the depletion of N-Cad. Furthermore, matrix distortions also vary depending on cell type as illustrated. Further studies are required to examine the direct influence of N-Cad on mechanical phenotype.

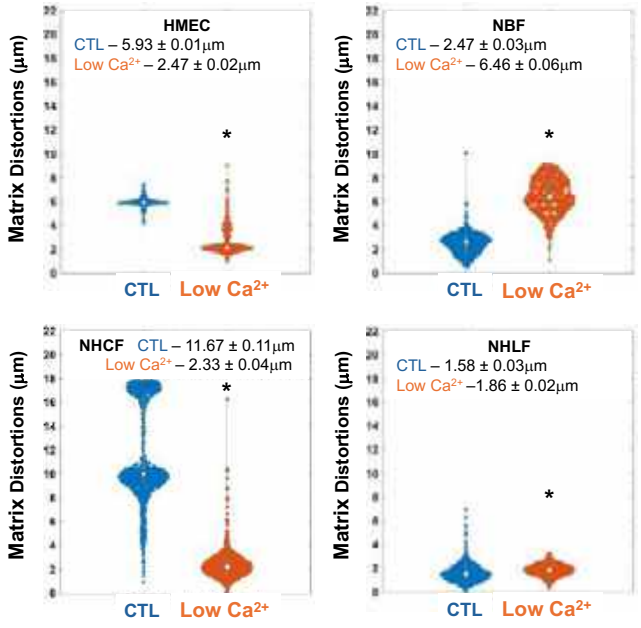

Figure 1 – Low Calcium Alters Fibroblast Generated Matrix Distortions. Violin plots representing bead displacement data from 3D cell cultures with different cell types. CTL is control media. Data is reported as magnitude of matrix distortions measured by bead tracing. Insets show average ± SEM. N = 3 microtissues per cell line with >500 beads per plot. Samples were compared using Student's t-tests with unequal variances. * p<0.0001.

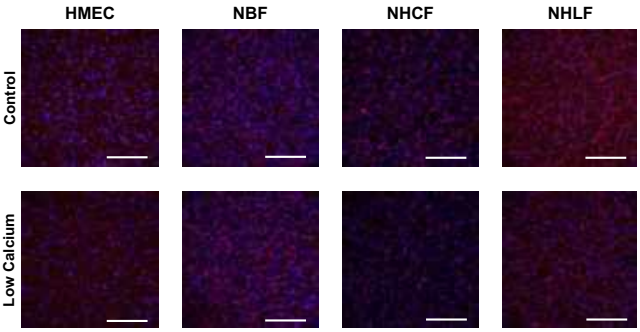

Figure 2 – Expression of N-Cad in 3D Microtissue Models. Representative immunofluorescence images of N-Cad in 3D microtissues cultured in normal (control) vs low calcium media for 24 hours. Scale bar = 200μm.

Upon visual inspection, it appears that the low calcium samples exhibit reduced N-Cad expression (Figure 2). HMECs do not exhibit spindle-like morphology when embedded in a microtissue; they are punctuated. The fibroblasts in 3D culture result in a spindle-like mesh network. The distinct response of NBFs compared to other cell types raises questions about the cell-type-specific regulation of N-Cad in relation to the ability of cells to generate matrix distortions. Such regulation may be influenced by the distinct functional roles of these cells and their particular interactions within the tissue microenvironment.

Together, this suggests that alterations in N-Cad in 3D *in vitro* systems may control how stromal cells interact with neighboring cells and the matrix partially through changes in mechanical phenotype. However, more work is needed to define the precise mechanism of these interactions. In the context of tissue engineering, mechanical forces promoted by cellular populations are a separate feature to include when developing vascularized scaffolds.

INTRODUCTION

Traumatic brain injuries (TBIs) are a serious medical condition in military and civilian populations that can occur after a cranial impact. Long-term TBI effects are established, but damage mechanisms are less understood due to limited brain access during impacts. Thus, tissue surrogates model impact mechanics, and need to be characterized at the micro- and macroscale. In this study, Digital Image Correlation (DIC) characterizes tissue interfaces with embedded organoids, while Atomic Force Microscopy (AFM) probes microscale properties.

Fabricated tissue mimetics represent human brain components in cranial models [1,2]. Polyacrylamide (PAA) gels are employed for their transparency and easily tunable mechanical properties. Using PAA, a human-sized phantom, the Anthropomorphic Neurologic Gyrencephalic Unified Standard (ANGUS), was designed to mimic the bulk tissue deformation mechanics of TBIs [2]. Simplified models are established, but lack neural tissue. Neural organoids incorporate features that allow cellular-scale observations. Microscale characterization of features will show how varying mechanical properties affect neural organoid properties and how microscale and bulk properties relate.

Figure 1: Cranial phantom outline (a), 3D-printed skull (b), cranial phantom in skull (c), adapted from Knutsen, et al., 2023.

Gel-gel interfaces, where each gel has different mechanical properties, may capture properties similar to gray-white matter interfaces. Including these into the ANGUS phantom is crucial to understand shear transfer through an interface to study deformation in a living model. In the ANGUS phantom, blunt impact waves propagate through the gel. Therefore, shear transfer through a multi-layer gel with an embedded organoid needs to be characterized. To visualize shear transfer, DIC tracks unique subsets within an image to identify deformation and calculate strain.

AFM utilizes nanoindentation to obtain force-relaxation data to characterize soft materials, which after frequency analysis, can be compared to bulk rheological measurements, a comparison that is ambiguous [3]. This analysis is also performed on embedded neural organoids as substrate shape and stiffness are known to influence organoid and cell development [4,5]. Measuring neural organoids in physiological conditions is difficult with bulk rheology; however, physiologically favorable conditions are maintained in AFM

In this work, AFM characterizes the mechanical properties of hydrogels and how organoids adapt to them. Shear deformation measurements show shear transfer through gels to an organoid. This study aims to characterize these interfaces as a first step in introducing structural complexity and biological components into the ANGUS phantom to acquire changes in neural organoids after a blunt impact.

METHODS

Three PAA hydrogel formulations, 10% (w/v) 60-1, 7% (w/v) 60-1, and 7% (w/v) 15-1, are used to create various gel structures. The protocol for these gels is detailed in Baker, et al., 2023 [1]. The w/v percentage corresponds to the monomer content based on water volume followed by the monomer-to-crosslinker ratio. 10% (w/v) 60-1 and 7% (w/v) 60-1 gels were characterized and represent white and gray matter tissue [2]. A single layer gel is made for each formulation **Figure 2A**, the 60-1 formulations create double-layer gels **Figure 2B**, and the organoid chip consists of two 60-1 gels with a 15-1 gel microwell mimicking a neural organoid as those have not been embedded in this work **Figure 2C**.

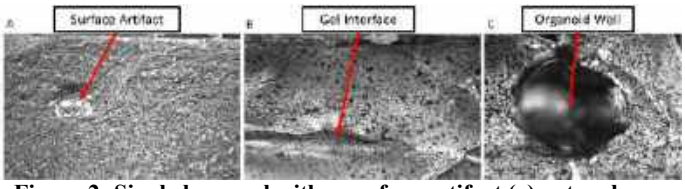

Figure 2: Single layer gel with a surface artifact (a), a two-layer gel (b), and a multi-layer organoid chip with an organoid well (c).

In AFM, super glue (Loctite Super Glue Ultra Gel Control) secures a 5 mm thick hydrogel to a 60 mm diameter x 15 mm deep petri dish (Kigley). The gel is covered with a 1% Pluronic F-127 solution (Sigma-Aldrich) to minimize adhesive interactions. A MLCT-SPH-10UM (Bruker) probe equilibrates in the solution and is then brought into contact with the gel and indented into the sample where that position is held for 30 to 60 seconds to obtain relaxation data.

Frequency analysis is performed on force-relaxation data with methods proposed by Chim, et al., 2018 [3]. The material instantaneous deformation value is calculated from the Hertz model in **Equation 1**, where R is the probe radius, ν is the Poisson ratio, estimated to be 0.5 for PAA, δ is probe displacement, and t is time. The material instantaneous deformation and force data are Fourier transformed and divided to obtain the complex shear modulus (G*) in **Equation 2**. Data is separated into real and imaginary components to exhibit the elastic (G') and loss (G") modulus of the material.

$$\Lambda\big(\delta(t)\big) = \frac{8}{3} * \frac{\sqrt{R}}{1-\nu} * \delta^{\frac{3}{2}}(t) \quad (1)$$

$$G^*(\omega) = \frac{\hat{F}}{\hat{\Lambda}} \quad (2)$$

A shear device developed in Vidhate, et al., 2021 is employed for shear transfer studies [6]. After the hydrogel samples equilibrate, the surface is dried with a Kimwipe to apply a speckle pattern of diluted black acrylic paint using a Master Performance Model 30 airbrush. Hydrogels (25 mm length and 8 mm height) are placed on a stage while a dynamic plate is lowered with enough force to prevent slipping. The dynamic plate is operated at shear rates of 10, 30, 50, and 70 Hz. High-speed images are captured with a Photron Fastcam SA-Z at 4000 FPS for 10 and 30 Hz and 5000 FPS for 50 and 70 Hz, with shutter speeds of 250 μsec and 198 μsec.

Images are analyzed in the VIC-2D (Correlated Solutions) software. Subsets from 25-45 px, step sizes from 5-7 px, and strain filters from 11-15 px are applied depending on speckle pattern quality. For single-layer gels, one area of interest (AOI) is placed from the top to the bottom of the gel. For multi-layer gels, one AOI is placed approximately equal distances from the gel interface and shear source for each gel. Strain values from the max applied shear were averaged in multi-layer gels to compare strain in two gels making up the interface.

RESULTS

Preliminary AFM data displays G' and G" values lower than expected due to measurements being on the surface where polymerization is suboptimal. Deeper indentations reveal a more representative crosslinking density, thus, probing deeper into the gel provides data closer to bulk measurements which will be performed [1].

DIC analysis of the starting versus max shear point are in **Figure 3**. Analysis shows when a two or one-layer gel is deformed, the softer gel experiences higher strain independent of its contact with the shear source. **Table 1** quantifies max shear strain at 30 and 50 Hz where condition one represents 7% (w/v) 60-1 in contact with the shear source, and condition two represents 10% (w/v) 60-1 in contact. **Table 2** quantifies max shear strain in single-layer gels at 30 and 50 Hz.

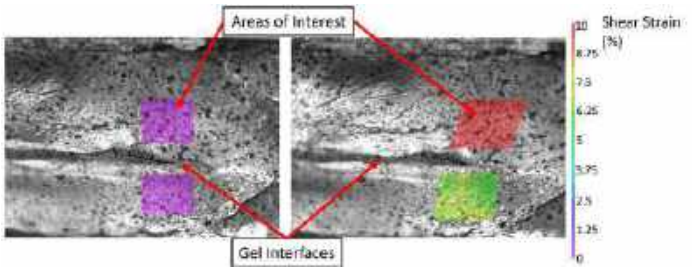

Figure 3: Starting frame (left) and max shear frame (right) of a 2-layer hydrogel from condition 1.

Table 1: Max shear strain in two-layer gels. Significance is shown between different gel formulations, *p<0.05.

	Condition 1		Condition 2	
PAA Gels	**30 Hz (n=6)**	**50 Hz (n=6)**	**30 Hz (n=5)**	**50 Hz (n=5)**
10% (w/v) 60-1	10 ± 0.3	7 ± 0.7	7 ± 0.1	6 ± 0.3
7% (w/v) 60-1	27 ± 0.8*	17 ± 1.8*	26 ± 0.2	27 ± 0.8*

Table 2: Max shear strain values in single-layer gels.

PAA Gels	30 Hz (n=6)	50 Hz (n=6)
10% (w/v) 60-1	7 ± 0.6	7 ± 0.9
7% (w/v) 60-1	11 ± 0.8	10 ± 1.0

DISCUSSION

AFM techniques will need to be optimized to compare bulk and local rheological measurements. Optimizing these measurements allows for force mapping across gel interfaces with a neural organoid. This data may present how organoids adapt to brain tissue mimetics.

DIC analysis shows softer gels experience more strain in shear deformation as expected. While 10% (w/v) 60-1 gels do not have a noticeable change in strain between single and double-layer conditions 7% (w/v) 60-1 gels do, supporting the claim that softer gels experience more shear strain in double-layer gels. Shear transfer will be further characterized to include a mimetic gray-white matter interface in the ANGUS phantom. The present experiments display shear transfer at gel interfaces and allow for correlation of applied shear force to neural organoid damage. This information will inform blunt impact parameters for the ANGUS phantom to induce trauma in embedded organoids.

DIC observations make it apparent that gel interfaces change the shear properties of the bulk material which could affect behavior of brain tissue mimetics. Characterizing these interfaces and neural organoids will help create a more accurate brain model for TBI research.

INTRODUCTION

Fluid mechanics plays a crucial role in numerous physiological processes related to health and disease. Advances in medical imaging, computational power, and mathematical algorithms have made it possible to perform real-time, patient-specific computational fluid dynamics analyses. However, many problems involve complex interactions between fluids and particles of varying mass and size, which presents challenges in understanding and modeling their dynamics. Most of the development around particle-laden flows has been in the context of industrial applications such as gas-solid flows in fluidized beds using structured grids or process/industry applications for gas-solid flows[1, 2]. In contrast, biological flow applications often involve complex geometries and unstructured grids. The goal of this work is to develop a computationally efficient, scalable, physics-based framework for particle-laden biological flows in complex subject-specific geometries to enable the next generation of methods for computer-aided diagnostics and disease research. The present implementation is done within the `CRIMSON` framework [3] which specializes in simulation of blood flow within image-based geometries.

METHODS

The equation for the fluid phase are obtained by applying a spatial filtering operator on the incompressible Navier-Stokes equations, taking into account the volume occupied by the particles and the momentum exchange between the particles and fluid phase[4, 5]. Figure 1 illustrates the filtering procedure on a system of particles suspended in a fluid. The resulting continuity equation after filtering reads

$$\frac{\partial \phi_f}{\partial t} + \frac{\partial}{\partial x_i}\left(\phi_f u_i\right) = 0 \tag{1}$$

and the momentum equation is

$$\rho_f \phi_f \frac{\partial u_i}{\partial t} + \rho_f \phi_f u_j \frac{\partial u_i}{\partial x_j} = -\phi_f \frac{\partial p}{\partial x_i} + \phi_f \frac{\partial \tau_{ij}}{\partial x_j} + \phi_f \rho_f g_i + f_i^p \tag{2}$$

where $\tau_{ij} = \mu\left(u_{i,j} + u_{j,i}\right)$, μ is the fluid viscosity, ρ_f is the fluid density, g_i is the body force. The term f_i^p is the momentum feedback force from the particles acting on the fluid. ϕ_f is the volume fraction of the fluid phase.

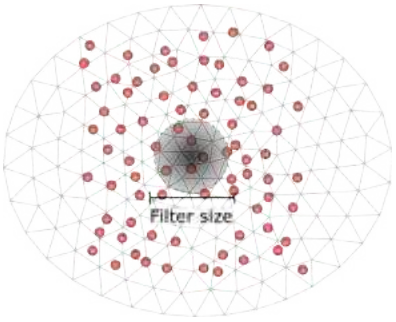

Figure 1: Schematic of Lagrangian particles inside a discretized fluid domain along with a representation of the filtering kernel

The particles are modeled as rigid spheres. Their motion is calculated according to Newtons second law for translation and rotation. The translational motion for particle p is given by

$$m_p \frac{\mathrm{d}v_i}{\mathrm{d}t} = f_i^h + f_i^{col} + (\rho_p - \rho_f) V_p g_i \tag{3}$$

where m_p, V_p and ρ_p are the mass, volume and density of the particle, f_i^h is the hydrodynamic force exerted on the particle by the fluid, which includes drag, added mass effects, Saffman lift forces, and f_i^{col} is the force due to particle-particle and particle-wall collisions.

RESULTS

Our method is applied to two particle-laden flow problems: pressure-driven flow in a pipe accounting for gravity, and flow in a bifurcation.

Pressure driven flow in a pipe: The first case considered is pressure driven flow in a cylindrical vessel (Figure 2). The Reynolds number based on the vessel diameter (5 mm) is 100. There are 10,000 particles ($d_p = 0.1$mm), which are initialized as a spherical bolus near the inlet boundary with a particle volume fraction $\phi_f = 0.3$. The domain is discretized using 25,000 linear tetrahedral elements. The inlet velocity is specified as parabolic flow profile. The outlet is a zero pressure boundary condition and the walls are no-slip boundaries. The particle are denser than the carrier fluid, $\rho_p = 5\rho_f$ and the effects of gravity are included.

Figure 2: In each frame, the figure on the left shows contour plots of the volume fraction of the particles on a vertical slice through the center of the cylinder. The figure on the right shows contour plots of the magnitude of the velocity field along with the particles themselves.

In Figure 2 we see that the particles are transported down the vessel by the fluid. The fully-coupled nature of the simulation is evident from the blocking effect of the particles, apparent in the velocity contours. Initially, the particles are at rest and block the fluid, which accelerates around the particles. This delays the development of the parabolic profile downstream of the particles. The particles slowly accelerate due to the fluid, gradually pick up speed and are carried out of the cylinder through the outlet. Due to the gravity effects, particles also settle along the bottom.

Flow in bifurcation: We present a comparison of particle-laden flows through two different bifurcating vessel geometries –one healthy and one stenosed, as shown in Figure 3. Each geometry is discretized using 220K tetrahedral elements. We initialize a bolus of 100,000 particles in the inlet with a mean volume fraction of 0.35. The particles and fluid are initially at rest. The inlet velocity is specified with a parabolic profile corresponding to a Reynolds number of 250 based on the inlet flowrate and vessel diameter. There is no gravity and the particles density is twice that of the fluid. The outlet vessels are coupled to three-element Windkessel models to represent the downstream vasculature.

Within each panel in Figure 3, the healthy geometry is on the right and the stenosed geometry is on the left. Up until $t = 15s$, the the particle distribution is largely similar for both cases. As the particles flow past the bifurcation (Figure 3(b), $t = 19s$) they split into both downstream vessels following complex trajectories. In figure 3(c) we see that the particles are accelerated through the constriction and reach the outlet much quicker than in the unconstricted case. Furthermore, in the stenosed case we see particles forming a spur-like shape and flowing backwards. This is due to a recirculation zone, a well-known feature of flow through stenosed vessels.

These examples are primarily meant to showcase the capabilities of our method. In the future, this work will be followed up with validation, performance evaluation, and scaling studies. We will also apply this method to larger and complex geometries derived from patient-specific medical images.

Figure 3: Comparison of particles flowing through a bifurcation with and without a stenosis. In (d) the particles can be seen to be flowing back away from the outlet in the stenosed branch. This is due to the formation of a circulating streamline topology caused by the stenosis.

DISCUSSION

We have presented a computational framework for modeling large scale particle-laden flows in complex geometries that enables subject-specific analysis. The framework is based on a volume-filtered Euler-Lagrange approach that uses a finite element method for the fluid phase and a discrete element method for the particle phase. The fluid phase is solved on a three-dimensional unstructured grid using a stabilized finite element method. The particle phase is modeled as rigid spheres and their motion is calculated according to Newton's second law for translation and rotation. The hydrodynamic force on the particles is calculated using a recently developed correlation for freely evolving suspensions of particles. The method is applied to a few different particle-laden flow cases. The results are of a qualitative nature and are not meant to be quantitative. The results demonstrate the capabilities of the implementation and the potential of the method for simulating large-scale particle-laden flows in complex geometries.

DEVICE DEPLOYMENT AND THE ONSET OF STRUCTURAL VALVE DEGENERATION: SIMULATION OF TRANSCATHETER AORTIC VALVE IMPLANTATION IN VITRO

INTRODUCTION:

Despite the rapid growth of transcatheter aortic valve implantation (TAVI) for the treatment of aortic stenosis, devices are prone to early failure due to structural valve degeneration (SVD). Recent standards define SVD as an acquired intrinsic bioprosthetic heart valve (BHV) abnormality, which may be identified as a change in device hemodynamics post-intervention [1]. Although SVD most commonly presents as leaflet calcification and tearing, other mechanisms have been identified including device asymmetry and stent fatigue [1,2]. It is suspected that TAVI deployment factors, including oversizing and eccentricity, may predispose TAVI devices to increased SVD when compared to surgical aortic valve replacements (SAVRs) [1,3,4]. TAVI devices are often oversized relative to the native annulus (between 5-35%) to prevent complications such as paravalvular leakage [5]. However, severe oversizing may result in device underexpansion. Recent clinical studies report optimal oversizing varies across self-expanding and balloon-expanding devices [5], yet the impact of such strategies on long-term device durability is unknown. Additionally, device and native anatomy interaction often results in severe device eccentricity upon deployment, which may impact device kinematics and physiological flow patterns [4,6]. Despite such concerns, recent clinical studies have reported a significantly lower rate of SVD at 8 years following TAVI when compared to SAVR, although TAVI cases of SVD were still substantial (13.9%) [2].

The mechanisms of SVD are intrinsically linked to biomechanical stresses experienced by devices in vivo [1,3]. Thus, computational approaches have been applied to assess and optimize the biomechanics of TAVI devices. Previous finite element (FE) studies report that underexpansion and eccentric deployment of TAVI devices results in increased leaflet stress [4,7], which may impact long-term durability. In a recent study, using a fluid-structure interaction (FSI) approach, Tsolaki et al. correlated biomechanical indicators to BHV calcification under idealized circular deployment, showing excellent agreement with calcification distribution across a sample of explanted SAVRs [8]. Yet due to complexities in simulating valve closure using FSI, this study excluded diastolic loading. Further, this study did not investigate the relationship between TAVI-specific deployment factors, including oversizing and eccentricity, and the onset of SVD, which remains poorly understood.

The objectives of this study are to (1) develop FE and CFD models of a commercial, self-expanding TAVI device, (2) validate the structural and hemodynamic performance of in silico models against in vitro testing, and (3) apply these models to investigate the occurrence of SVD across a range of clinically-relevant degrees of oversizing and eccentricity indices.

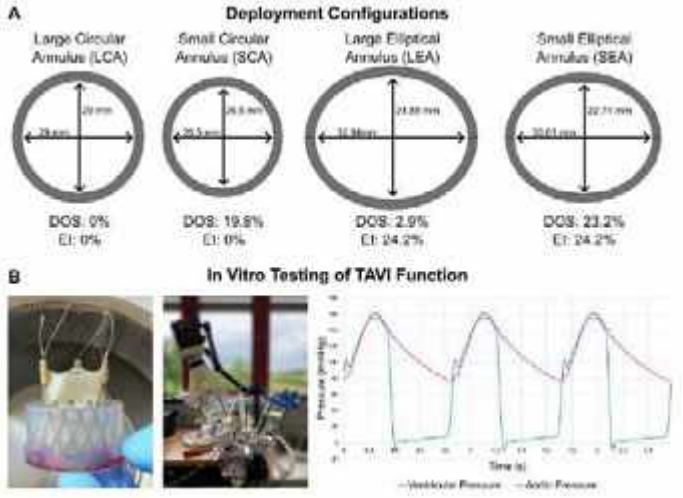

Figure 1: (A) Idealized Aortic Annulus Geometries with Degree of Oversizing (DOS) and Eccentricity Index (EI) and (B) In Vitro Testing Set-up with Moderate Hypertensive Pressure Waveform

METHODS:

The basis for this study was the self-expanding ACURATE Prime XL (Boston Scientific, USA), recommended for aortic annuli perimeter derived diameters ranging from 26.5 mm – 29 mm. This study sought to characterize the influence of annulus geometry by deploying the TAVI device within different annuli as shown in Fig. 1(A), which were characterized by degree of oversizing (DOS) and ellipticity index (EI), as given by [5,9] respectively.

In vitro testing of the TAVI device was performed using a ViVitro Pulse Duplicator (ViVitro Labs Inc., Canada). Briefly, the device was crimped, deployed within annuli geometries (Fig. 1(A)) and subject to moderate hypertensive pressure conditions (Fig. 1(B) – peak transvalvular pressure of 140 ± 3 mmHg at 70 BPM). Structural performance was assessed using a high-speed camera, mounted above the aortic chamber, which captured device dynamics during the cardiac cycle. Specifically, we measured the stent deflection (calculated as a function of the radial distance between the commissures posts at systole and diastole), the geometric orifice area (GOA) and the pinwheeling index (PI). Similarly, hemodynamic assessment captured peak velocities, effective orifice area (EOA) and transvalvular gradients across the various deployment configurations.

Computational models were developed to assess the structural and hemodynamic performance of the TAVI device across the various annuli geometries. FE models of the ACURATE Prime XL were developed using Abaqus/Explicit (Dassault Systemes, USA), with representative material properties for porcine pericardium and nitinol. We completed a parameter variation study examining the impact of various hyperelastic, isotropic leaflet tissue properties [7,11] on associated stent deflections. The FE framework simulated (1) crimping of the device (to numerical stability - 14 mm) using 12 rigid plates and (2) deployment of the complete TAVI device into the annulus. Deployment was simulated by unsheathing a rigid upper and lower catheter respectively, replicating the unique 'top-down' deployment mechanism of the ACURATE Prime XL. To simulate the cardiac cycle, moderate hypertensive pressure conditions were applied, whilst contact definitions comprised "hard" contact with a friction coefficient of 0.20. We validated the models by comparing device dynamics, GOA and PI to in vitro testing results. Following validation, we investigated the impact of both oversizing and eccentric deployment on the von Mises stress distribution throughout the device, a key biomechanical indicator of SVD. CFD simulations are in development, which will be validated using in vitro testing and used to obtain a prediction of shear stress, another biomechanical indicator of SVD [9].

RESULTS:

Fig. 2(B1) shows the deployed TAVI device at peak diastole in circular and elliptical annuli. Upon device deployment in the large circular annulus, the FE model predicts similar GOA (4.51 cm^2 vs 4.27 cm^2), PI (8.5% vs 3.6%) and TAVI stent deflections (1.92 mm vs 1.763 ± 0.275 mm) to in vitro testing data. Similar alignment was noted across the small circular and large elliptical annuli. Table 1 shows the stent deflection across each of the deployment configurations.

Table 1: In Silico TAVI Stent Deflections

Annulus	Commissure	Deflections (mm)
Large Circular	P1, P2, P3	1.92
Small Circular	P1, P2, P3	0.86
Large Elliptical	P1	2.63
	P2, P3	1.88

We predict that peak leaflet stress occurs at the commissure region across all deployment configurations. These magnitudes were decreased in the small circular deployment configuration, when compared to the large circular annulus (2.58 MPa vs. 3.36 MPa). Further, small circular deployment decreased pinwheeling (PI - 6.3% vs 8.5%), resulting in reduced von Mises stress on leaflet contact surfaces (0.20 vs 0.32 MPa). Coaptation mismatch and severe pinwheeling of non-dominant leaflets was observed in the elliptical deployment configuration, which was accompanied by increased von Mises stress on contact surfaces (3.40 MPa) and commissure region of non-dominant leaflets (2.91 MPa vs 3.42 MPa). As evident in Table 1 and Fig. 2(B2), leaflet deformation induced noticeable stent deflections (up to 2.63 mm). Despite this, stent maximum alternating strains were largely below adjusted alternating strain limits (0.215% vs 0.525% for large circular deployment).

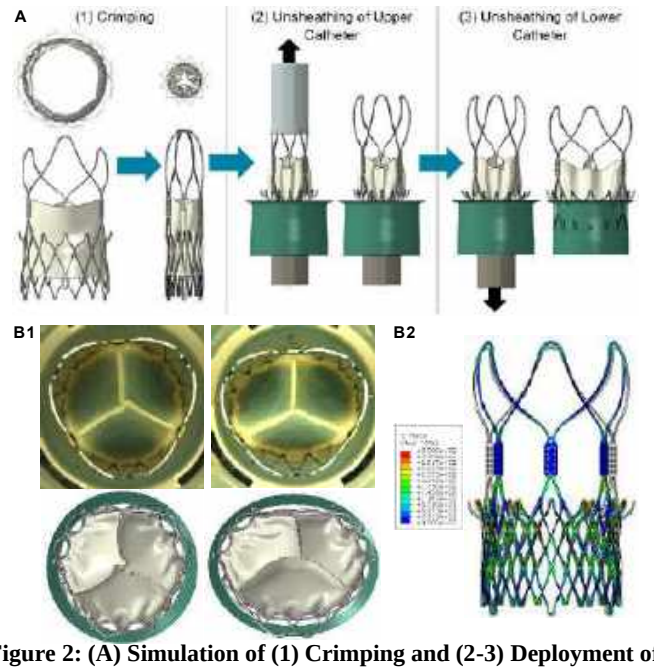

Figure 2: (A) Simulation of (1) Crimping and (2-3) Deployment of TAVI Device, (B1) Comparison of In Vitro and In Silico Circular and Elliptical Model at Peak Diastole, (B2) TAVI Stent Deflection between Systole and Diastole showing Von Mises Stress

DISCUSSION:

In this study, we investigated the influence of annulus geometry on TAVI deployment and function. We predicted that TAVI oversizing (up to 20%) is associated with reduced leaflet stress in regions prone to device failure in vivo [1]. Our ongoing work is assessing the impact of oversizing across a wider range of indices to capture oversizing ranges observed in vivo (5 – 35%) [5]. We also predicted that TAVI elliptical deployment resulted in coaptation mismatch, severe localized pinwheeling and altered device kinematics, which aligns with findings from previously published studies [4,7]. Our ongoing studies are developing CFD models to assess the impact of both oversizing and eccentricity on bulk flow and shear stress, to further investigate how valve oversizing may mitigate the occurrence of SVD in vivo.

INTRODUCTION

Unlike other diseases, cancer's intrinsic use of healthy cells allows it to grow and develop using pathways established within the human body. Perversion of the body's systems allows tumors to grow largely unchecked and without the knowledge of the individual. The disease only becomes apparent when the afflicted experiences signs of illness, typically indications of systemic toxicity. Naturally, this results in ~50% of cancers diagnosed in advanced stages and ~90% of cancer deaths caused ultimately by metastasis [1, 2]. An early diagnosis allows for more treatments and a more optimistic prognosis, with a number of cancers having 5-year survival rates of >80% and even >90% [2]. Exosomes, small lipid-bound extracellular vesicles, have shown diagnostic prowess in identifying cancer in a non-invasive screening manner [3-5].

Exosomes provide a communication highway for cells; their cargos contains a plethora of peptides, proteins, and RNA [6]. The cargos mediate roles including intercellular communication, immune modulation, cargo transportation, and communication across the blood brain barrier [6]. When a tumor develops, it has access to these powerful communication pathways, and abuses them for the survival of the tumor. This typically means exosomes induce immunosuppression, tumorigenesis, angiogenesis, and eventually metastasis [7].

While it is widely established that these exosomes are a good indicator of the presence of cancer, current isolation and purification methods prohibit the use of these techniques in high-throughput, sensitive detection methods. Ultracentrifugation (UC), the gold-standard in exosome isolation, can take 6 hours to extract unpurified exosomes from blood, and 2-3 days to extract purified exosomes from blood [8, 9]. Our lab has developed a technique to bypass this purification process and accurately quantify cancer-associated exosomes using a rapid, novel interference-resistant Janus Particle Technology[10].

METHODS

Our lab has developed a technique for quantifying plasma exosomes that employs rotational Brownian motion. The technology utilizes Janus Particles (JPs), one-micron fluorescent beads coated with a thin layer of gold on a singular hemisphere. Fundamental rotational Brownian motion produces a spin on the spheres with a frequency inversely proportional to the cubed particle diameter. The JPs appear to blink on account of the dissimilar halves, and any increase in the effective size, i.e. via exosome coupling, will slow the rotation with great sensitivity. These beads provide rapid (<60 minute) detection of exosomes due to a small ~100 um average separation of the JPs and exosomes in solution.

The JPs utilizes gold-conjugation to adhere antibodies onto the surface which will dock exosomes upon incubation. Our selected anti-active epidermal growth receptor (aEGFR), anti-carcinoembryonic antigen (CEA), and anti-glypican-1 (GPC1) antibodies due to their presence and upregulation in glioblastoma multiforme (GBM), Colorectal cancer (CRC), and pancreatic ductal adenocarcinoma (PDAC)[3-5].

We have developed a single particle tracking algorithm capable of decoupling translational Brownian motion from the rotational Brownian motion. The tracking records the brightness fluctuations of a JP across the duration of a video and applies a wavelet function to the signal in order to isolate the rotational frequency. The average value is calculated for the ensemble of JPs and compared against a sample where there are no exosomes present. The shift in rotational frequency can then be extrapolated to quantity the number of exosomes in solution.

RESULTS

To develop Janus Particles as a reliable nanoparticle biosensor, we first validated the platform using UC purified exosomes derived from healthy patients and quantified with Nanosight (Figure 1). Exosomes were serially diluted and incubated with Janus Particles that were

functionalized to detect exosomes containing the characteristic tetraspanin, CD63.

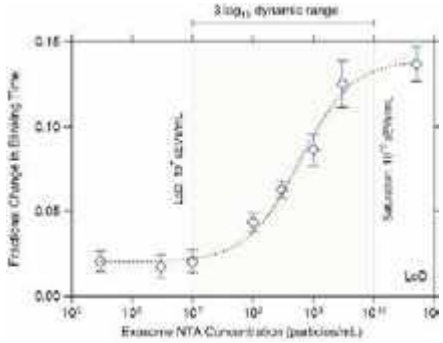

Figure 1: Janus Particle Calibration Curve using NTA benchmark

The first figure shows that they JPs have an impressive 3-log dynamic range and can detect as low as 1E7 exosomes/mL of plasma, which makes it ideal for quantifying low concentrations of exosomes. The initial experiment shows the potential to detect exosomes after purification, but our goal is to detect exosomes in complex media, such as plasma. We separated exosomes from the remainder of the plasma (flowthrough) using a tangential flow technique and recombined them in various ratios to see how well JPs respond to interference. JPs were then functionalized with an isotype antibody and subjected to the same exosome samples before being recorded. Both can be seen in Figure 2, below.

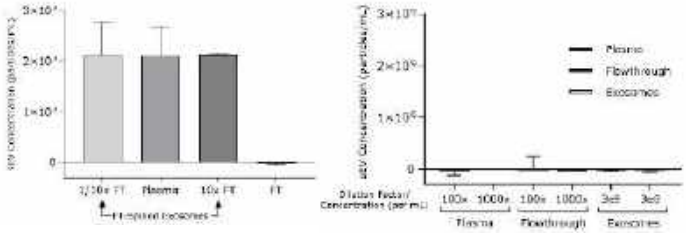

Figure 2: Janus Particle spiked protein incubation (left) and isotype control experiment (right)

Certain exosome characterization techniques respond poorly to the presence of interfering proteins. However, The Janus Particle response reveals it is sensitive only to exosomes containing the protein it is functionalized to detect and will not respond to non-target exosomes or soluble forms of protein in solution. This led us to believe that the JP platform would be ideal for selecting for cancer-associated exosomes while selecting against healthy exosomes which is tested in Figure 3.

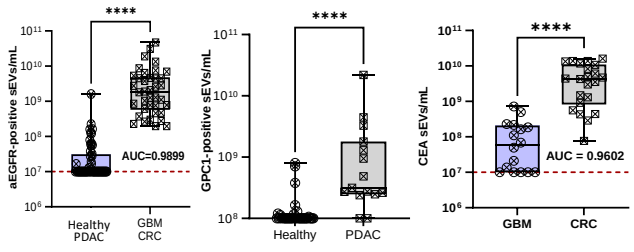

Figure 3: Glioblastoma, colorectal cancer, pancreatic cancer study using aEGFR, GPC1, and CEA functionalized Janus Particles.

The figure above represents the results acquired from our cancer trial. GBM and CRC to overexpress active EGFR while allows us to separate them from the healthy groups and those with pancreatic cancer. In the second graph, we are able to differentiate pancreatic cancer patients due to their upregulation of GPC-1 on their exosomes. In the final graph, we distinguish between the colorectal cancer patients from the glioblastoma patients due to the upregulation of CEA. Each individual point is a separate biological replicate with three technical replicates each.

DISCUSSION

Our results support our initial presumptions that the Janus Particle platform would be an ideal method for determing not just the presence of cancer, but the type of cancer as well. Previous screening techniques are isolated primarily to superficial organs of the body and are full of limitations. The rotational Brownian motion of Janus particles shows not only are we able to effectively able to screen for being positive or negative for cancer, but we are able to determine the origin of the exosomes and thus the type of cancer the patient likely has. This shows a potential for efficacious methods for screening complex, well-hidden cancers that would otherwise go completely unnoticed. The results of these experiments can be extrapolated to other cancers as well, if appropriate exosomal surface markers are readily detectable.

INTRODUCTION

Nonunion or delayed fracture healing is a prevalent clinical complication with a devastating impact on patient quality of life, leading to significant financial burden for patients[1]. Despite knowledge of the mechanobiology behind bone healing, we lack the ability to discern bone healing capacity in individual patients. Existing biomarkers for healing progression and clinical imaging modalities fail to discern which patients experience delayed fracture healing or proceed to nonunion. Current preclinical models for bone fracture healing rely on 2D cell culture and animal experiments, each with their own limitations regarding translation to patients[2]. Additionally, current detection strategies such as radiolucency in planar x-rays and reported pain by the patients do not account for the *in vivo* mechanical environment[3,4] though studies have shown a positive relationship between loading and bone healing[5]. 3D culture systems such as organoids provide an *in vitro* tissue culture platform that allow for the prolonged study of human cells in an environment that mimics *in vivo*[6]. To develop such a platform for assessing individual patient risk factors for non-union, this study aims to manufacture porous 3D scaffold geometries using a novel, osteoconductive resin via vat photopolymerization (VP) and analyze their ability to mimic the *in vivo* bone micromechanical environment.

METHODS

Resin Formulation: A mixture of 50 wt% epoxidized soybean oil acrylate (ESOA, Sigma-Aldrich) and 50 wt% polyethylene glycol diacrylate (PEGDA, Sigma-Aldrich, MW = 575) was used to formulate the resin for printing. To promote curing, 1 wt% diphenyl(2,4,6-trimethylbenzoyl)phosphine oxide photoinitiator (Sigma-Aldrich) and 0.20 wt% 2,5-bis(5-tert-butyl-benzoxazol-2-yl)thiophene UV absorber (TCI Chemicals) was added.

*Scaffold Printing & Sterilization***:** Three scaffold geometries (Voronoi, IsoTruss, and Truncated Octahedron (TO)) were designed (nTopology, Figure 1) with 489, 476, and 554 μm average pore diameters, respectively, and printed using a VP bottom-up platform (Autodesk Ember). Five burn-in layers underwent UV exposure (5 W, λ = 405 nm) for 25 s per layer, and the rest of the model layers were exposed for 2.5 s per layer. Every layer was 0.1 mm thick for a total of 10 mm for the entire scaffold. After printing, the burn-in layers were removed and the scaffolds were washed in 70% isopropyl alcohol (IPA) and UV cured for one minute.

Prior to cell seeding, scaffolds underwent sterilization using 70% ethanol for 1 hr, followed by 3 washes with phosphate buffered saline (PBS) and a final wash using media made of αMEM and supplemented with 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin-amphotericin (Thermo-Fisher).

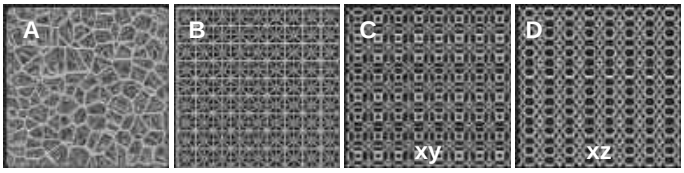

Figure 1: Voronoi (A), IsoTruss (B), and TO (C & D) lattices.

*Cell Seeding & Analysis***:** Murine fibroblasts (1 x 10^5 NIH 3T3) were seeded on each scaffold (n = 6/geometry) and cultured in media under static conditions for 4 and 7 days, with media exchange every 2-3 days. Subsequently, each sample was immersed for 5 minutes in 1 mL 10% formalin fixation solution, rinsed with PBS, and immersed in 1 mL of a post-fixation solution of 10% formalin. Scaffolds were then rinsed in PBS for 1 minute and stained with DAPI and Rhodamine Phalloidin dyes (Thermo-Fisher) for 1 hr in the dark before storage in deionized water at 4°C.

For assessment of the structural fidelity and biocompatibility, the scaffolds were cut in half and examined using a laser scanning confocal fluorescence microscope (Zeiss Axio Observer.Z1) with 10x objective (Plan-Apochromat 10x/0.45 M27, Zeiss) and 60 μm diameter pinhole.

Consistent processing and analysis of image stacks (voxel size 0.85x0.85x5.4 μm) were employed to assess cell nuclei spatial distribution within the scaffolds and the pore distribution within the scaffolds following image segmentation (ImageJ).

Dynamic Mechanical Analysis: Dynamic mechanical analysis (DMA, ElectroForce 3200) was performed on the seeded (n=6/geometry/day culture) and unseeded (n=1/geometry) scaffolds via cyclic compression using a strain sweep to analyze how microstructure impacts the organoid elastic modulus (E', storage modulus), viscous modulus (loss modulus), and damping coefficient (tanδ). The strain sweep was conducted at a frequency of 0.1 Hz starting with a dynamic amplitude of 0.2 mm (4% strain) and increasing by 0.1 mm until reaching 1 mm dynamic amplitude (10% strain). All testing was performed submerged in a 1x concentrated phosphate-buffered saline (PBS, pH 7.4) solution at 37 °C.

Statistical Analysis: Mechanical data was analyzed for descriptive statistics (python) using paired t-tests to determine significant differences between the 4-day and 7-day cultured scaffolds (α=0.05).

RESULTS

After 4 and 7 days of seeding, confocal microscopy confirmed successful cell adhesion and proliferation, with cells well distributed throughout all three scaffold geometries (Figure 2). Average pore diameters were 579, 397, 662 μm for the Voronoi, IsoTruss, and TO scaffolds, respectively, within range of the targeted print size.

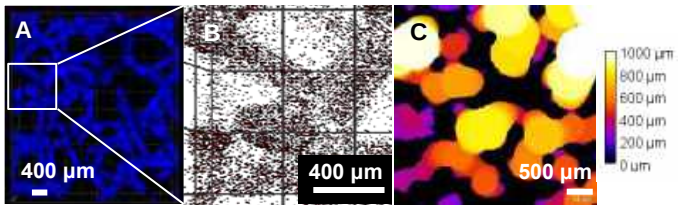

Figure 2: Voronoi structure (A, DAPI), cell nuclei distribution (B, Rhodamine), and pore thickness distribution map (C).

Some of the IsoTruss scaffolds (n=2) failed prematurely during the DMA testing due to inconsistencies in the printing, these were excluded from further analyses. For the remaining scaffolds, average storage modulus increased from day 4 to 7 of static culture (Table 1). The stiffest storage modulus achieved overall was reached by a 7-day cultured IsoTruss scaffold (2.70 MPa) Note, variation in the storage modulus for the 7-day IsoTruss scaffolds was the highest. The Voronoi scaffolds had the only significant and consistent increase in storage modulus between 4- and 7-day cultures (p=0.0293).

Table 1: Storage modulus (MPa) of the three scaffold geometries for 4- and 7-day cultures (mean ± SD).

Day	n	IsoTruss	TO	Voronoi
0	1	1.08	0.46	0.91
4	6	0.80±0.53*	0.64±0.40	0.55±0.25
7	6	0.81±1.27*	0.69±0.35	1.19±0.57
*n=4 for IsoTruss 4- and 7-day culture mechanical testing				

The peak storage modulus for the Voronoi 7-day cultured scaffolds is 2.26 MPa. Both of these peaks for IsoTruss and Voronoi are reached at the first strain sweep condition of 2% strain, or a dynamic amplitude of 2 mm. The peak storage modulus is achieved by a 4-day cultured scaffold for the TO geometry at 1.28 MPa at 2.14 % oscillation strain. Trends in loss modulus were consistent among the Voronoi and TO scaffolds, with a general increase with increased oscillation strain (Figure 3). On average, the loss modulus of IsoTruss scaffolds decreased at higher oscillation strains, leading to a tanδ of 0.0613, which is over 2x greater than Voronoi (0.0227) and TO (0.0297) at 2% strain.

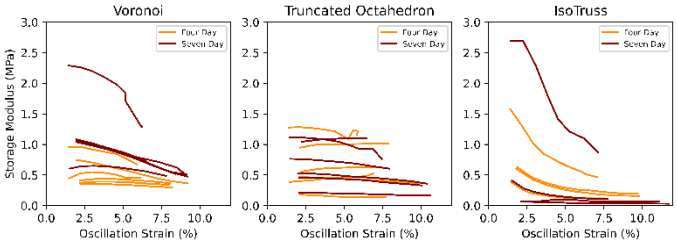

Figure 3: Storage modulus (MPa) vs. oscillation strain (%) for Voronoi, TO, and IsoTruss scaffolds.

DISCUSSION

Scaffold stiffness varied, with storage moduli on the order of soft fracture callus tissue after seeding (fracture callus moduli: 0.5-1000 MPa)[7]. Despite the limited number of samples available for testing, trends were observed on how seeding impacted scaffold stiffness. IsoTruss scaffolds achieved the maximum storage modulus of all 7-day seeded scaffolds; however, the rest of the 7-day IsoTruss seeded samples were significantly softer than the average TO and Voronoi scaffolds. Voronoi scaffolds had more consistent mechanical properties, while still achieving the second highest value for storage modulus. Further, Voronoi scaffolds had the most consistent increase in modulus with longer culture times, which may suggest the more consistent formation of extracellular matrix. Note, however, the range between 4- and 7-day seeded Voronoi scaffold storage moduli is limited. A portion of the IsoTruss scaffolds were too soft to perform DMA testing on, which could be due to inconsistencies in either the printing parameters or the curing process. As such, the remaining IsoTruss samples may have also been impacted by the same inconsistencies that prevented testing of the rest of the samples, contributing to the significantly higher damping detected in the IsoTruss specimens. Further spatial analysis of the cell distribution may also provide insight into the differences observed between scaffold geometries and culture time. The results of this study represent a successful first step at generating an organoid that recapitulates the micromechanical environment of healing bone. The investigated scaffold geometries 3DP via VP using the novel ESOA and PEGDA resin resulted in successful cell adhesion, proliferation, and extracellular matrix deposition, providing valuable insight into the structure/function relationship of pore shape and bone organoid mechanical properties.

INTRODUCTION

Cervical cancer ranks as the fourth most common cancer among women internationally, with 604,127 new cases reported annually (*1*). In 2020, over 300,000 deaths were attributed to this malignancy, making cervical cancer the fourth deadliest cancer among women (*2*). Individualized treatment plans depend on factors such as the patient's age, medical history, and stage of cancer. Traditionally, chemotherapy is administered either intravenously or through an ingestible pill. These forms of drug administration are suboptimal as they rely on systemic circulation, resulting in only a minor fraction reaching the malignant site (*3*). Consequently, higher dosages are required, leading to increased side effects and complications. A more effective form of administration would involve delivering medication locally to the target site, minimizing circulation elsewhere (*4*).

This work focused on an innovative localized implantable drug delivery system aimed to reduce the side effects and complications that arise from cervical cancer chemotherapy. The primary objective was to demonstrate loading and maintenance dosing protocol *in vitro*. A polymer injection mold was developed for manufacturing test implants. Implants produced from two different polymers and with four different geometries were loaded with Rhodamine B, acting as a drug analog. Subsequently, the implants underwent release testing over a 21-day period.

METHODS

Polycaprolactone (PCL) was chosen for this study due to its hydrophobicity and biocompatibility. Polylactic Acid (PLA) was selected for its versatility as a biopolymer, thermoplastic behavior, and biocompatibility (*5*). These polymers were combined with Rhodamine B, serving as a tracer dye and drug analog for cisplatin, a commonly used chemotherapeutic agent for localized cervical cancer treatment (*6*). Phosphate Buffered Saline (PBS) was chosen as a physiologically mimicking solvent due to its pH and isotonic nature.

Figure 1. shows the 12-bead injection mold which allowed for the mass production of polymeric devices, streamlining the creation through a highly repeatable batch process. Devices were manufactured using 2.00 grams of either PCL or PLA and 0.02 grams of Rhodamine B (1% of the mixture). The polymers were heated on a hot plate to their melting point, combined with Rhodamine B, and stirred for thorough mixing. The resulting mixture was then pressed into a hopper, leading into the 12-bead aluminum mold with interlocking channels to create the test devices. A post processing phase yielded four distinct devices: a Sphere, Sphere with a Through Hole, a Rod, and a Tube.

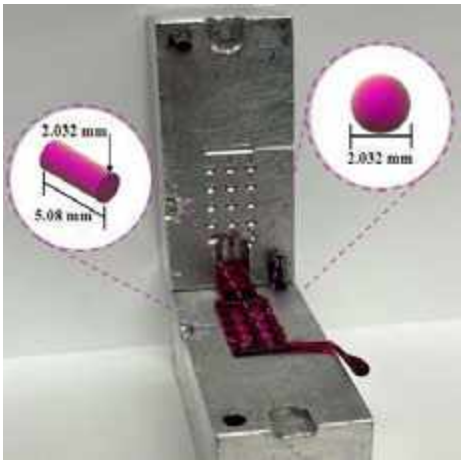

Figure 1. Mold for 12 Beads and Depiction of Polymeric Based Device Measurements

A 21-day release experiment assessed the release rate of the Rhodamine B devices. Batch produced devices were measured with

calipers to ensure that all selected test samples fell under a tolerance of ± 0.020 mm. Four implants were submerged in separate beakers, each containing 150 ml of PBS. A magnetic stir bar was added to maintain a well-mixed sink condition. A volume of 2.5 ml was withdrawn from the 150 ml sink solution and replaced with fresh PBS daily. The extracted sample was then pipetted into a cuvette for analysis using a UV-Vis Spectrophotometer. The sampling and analysis process was maintained for 21 days, with the final spectrophotometer analysis conducted at the conclusion of the experimentation period.

A secondary experiment aimed to ascertain the proper distribution of Rhodamine B within each individual implant during the batch-making process. Distribution was determined by splitting an implant into four equal pieces, with each piece then immersed in a 150 ml volume of PBS, sampled for 21-days, and analyzed as previously described. An additional split device was evaluated for homogeneity using the Scanning Electron Microscope (SEM) at resolutions of 300 µm, 10 µm, 5 µm, and 2 µm.

A third experiment was conducted to determine how varying the implant's geometry and surface area (SA) would impact the release rate. Four distinct geometries were tested: a Sphere (SA 12.97 mm^2), a Sphere with a Though Hole (SA 34.84 mm^2), a Rod (SA38.90 mm^2), and a Tube (SA 48.40 mm^2). Various geometrical patterns, including inner diameters of 0.635 mm, were achieved through post processing following the injection process. Each device was placed into a 150 ml volume of PBS, sampled, and analyzed as previously described.

RESULTS

Results exhibited a biphasic linear release pattern from PCL, characterized by an initial burst on the first day followed by a consistent linear release for the next 20 days. In contrast, PLA did not demonstrate any release in any of the experiments. For PCL, there was an initial surge of Rhodamine B release measuring 2.295 ± 0.40 µg on the first day of testing. The tracer dye continued to release incrementally at approximately 0.11 µg/ml daily throughout the 21-day experimentation period. After the initial week of testing, the average mass release form the PCL based devices were approximately 2.8 ± 0.3 µg. The initial burst of Rhodamine B accounted for 0.04% of the total release of tracer dye in a singular device. For the duration of the experimentation period, 3.8 µg was released from the device, representing 0.12% of the total amount of Rhodamine B per implant. After the initial burst, the incremental release of Rhodamine B exhibited an R^2 value of 0.9847 for the remaining days.

The experiment evaluating PCL implants being split into four pieces demonstrated similar biphasic linear release profiles with a percentage different of 4.2 ± 0.5%, establishing the fabrication process produced implants with Rhodamine B consistently mixed throughout the device. The images obtained using the SEM identified a smooth combination between Rhodamine B and PCL, with no clumping of tracer dye throughout the mixture.

The final experiment, shown in Figure 2., compared geometrical variability between each of the polymeric devices. The cylindrical tube achieved the highest initial and overall mass release of Rhodamine B, measuring 13.02 µg and 31.08 µg, respectively. The standard shaped sphere exhibited the least initial and final mass release, 3.68 µg and 8.02 µg, respectively. Changing the geometry of the sphere into a cylindrical rod increased the mass release by 22.48% ± 2%. Introducing a hole through the center of the cylindrical rod (tube), resulted in further increase in mass release by 35.064% ± 2%. As the surface area of the devices increased, the percentage of the total mass release increased congruently.

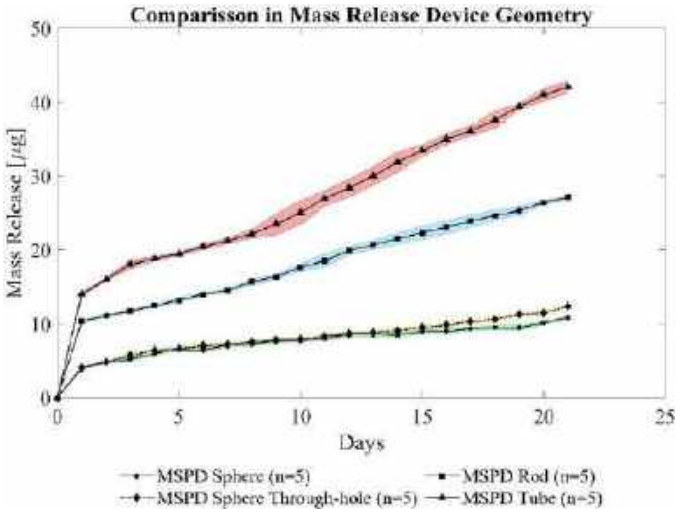

Figure 2. Mass Release profile comparison between a Sphere, Sphere with a Through Hole, Rod, and Tube

DISCUSSION

The implementation of a 12-bead polymer injection mold reduced the time needed for manufacturing experimental devices, ensuring consistent ratios of Rhodamine B to PCL and PLA. Results demonstrated that PLA was a poor choice as a drug release medium but may serve as a capping layer that could be leveraged in future composite geometries. Evaluation of four distinct geometries revealed a correlation between release rate and surface area, providing a tuning parameter for future dosage control. Future work is focused on controlling the initial burst release and refining dosage control through geometry and surface area. This study provides a foundation for future development of polymeric implantable for chemotherapeutic treatments.

A SYSTEMATIC ANALYSIS CONFIRMED THAT MECHANICAL AND STRUCTURAL ANISOTROPIES DO NOT CONCUR IN 37% OF EQUATORIAL SCLERA SAMPLES

INTRODUCTION

Many soft tissues are mechanically anisotropic, meaning that their stiffness varies by orientation [1]. Collagen fibers are the main load-bearing components of soft tissues, and therefore the macro-scale mechanical anisotropy arises from micro-scale structural anisotropy in the collagen fibers [2,3]. Thus, it is frequently assumed that mechanical and structural anisotropies concur [4]. For instance, it is common to use fiber orientation information obtained from techniques such as polarized light microscopy (PLM) or small angle light scattering to derive constitutive models in which the mechanical anisotropy essentially matches the structural anisotropy [5].

Recently, we measured the mechanical and structural anisotropies of equatorial sclera using standard equibiaxial testing and PLM techniques [2,5]. To our surprise, we found that the mechanical and structural anisotropies did not always concur. Although we only analyzed four samples from one eye, and the mismatch only occurred in half of them, we reasoned that a discrepancy between mechanical and structural anisotropies would be crucial to understand, even if it only occurs sporadically.

Our goal in this study was to systematically replicate our previous study, increasing the number of eyes and carefully checking each and every step to ensure that there were no mistakes or artifacts that could have produced the observed mismatch in anisotropies.

METHODS

Equibiaxial tensile testing. Five pig eyes were dissected to isolate equatorial sclera samples (11mm × 11mm) for each anatomical quadrant: nasal (N), superior(S), temporal (T), and inferior(I). A small cut was made on the top right corner of the samples to indicate the meridional direction. Mechanical anisotropy was measured using equibiaxial tensile testing with loading axes aligned with the equatorial and meridional directions to a maximum stress of 120 kPa.[6] (**Figure 1**) The specimen subjected to ten cycles of loading/unloading, and the data from tenth cycle was used for further analysis. The specimens were immersed in PBS during testing and switched to formalin afterward.

Polarized light microscopy (PLM). The samples were cryosectioned (30μm thick) and all sections imaged by PLM using an MVX 10 microscope [7]. The images were registered into stacks and collagen orientations computed for each pixel and then for the whole tissue (**Figure 2**).

Mechanical anisotropy was quantified by the ratio of the stiffness (the stress-strain curve slope at the point of full fiber recruitment) in the meridional and equatorial directions. Structural anisotropy was quantified from the ratio of areas under the fiber distribution curves.

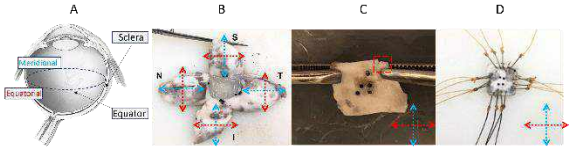

Figure 1: (A) Diagram of the eye with the location of the equator and the meridional and equatorial directions [6]. (B) Eye after dissection. (C) Excised quadrant with orientation mark. (D) Sample set for equibiaxial testing to measure mechanical anisotropy.

RESULTS

The equibiaxial test results show variable mechanical anisotropies between samples. Superior and inferior sectors had stiffer meridional directions (**Figure 3**). Nasal and

inferior sectors were closer to isotropic. The PLM measurements indicate substantial structural anisotropies, with a majority of the samples having the primary fiber alignment close to the meridional direction (**Figure 3**). Example cases with anisotropy match and mismatch are shown in **Figure 4**. One sample had problematic stretch tests and was excluded from further analysis. Overall, 7 of 19 samples (37%) had mismatched results between the mechanical and structural anisotropies (**Figure 5**).

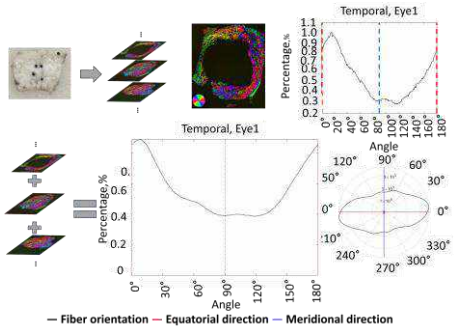

Figure 2: Structural anisotropy was measured from collagen orientation determined using PLM images of tissue cryosections. Shown are example images and orientation maps of a single section (top) and stack (bottom). This sample (T1) had clear anisotropy with fibers preferentially along the equatorial direction.

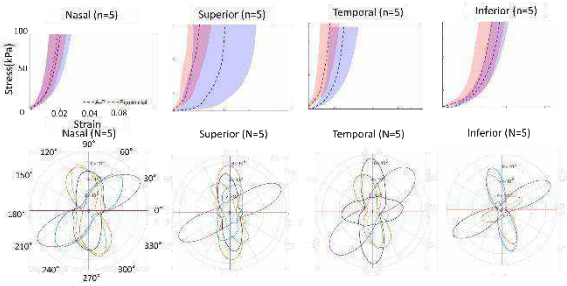

Figure 3: (top row) Arithmetic average (n=5) of 4 quadrants' strain at the same stress. Dashed curves represent the mean value of meridional and equatorial directions. The shaded regions are the standard error of the mean value. (bottom row) Polar plots of fiber orientations for all samples. Both tests show clear anisotropy and wide variations between samples.

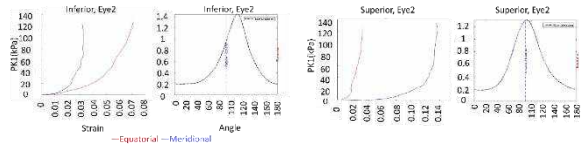

Figure 4: Matching (left pair) and mismatching (right pair) mechanical and structural anisotropies.

DISCUSSION

This study confirmed our previous finding that most equatorial sclera samples are mechanically and structurally anisotropic. Our observation that most equatorial sclera samples had collagen fibers preferentially aligned in the meridional direction is consistent with the literature [8]. Most importantly, our results confirmed that for 37% of the samples the mechanical and structural anisotropies do not concur.

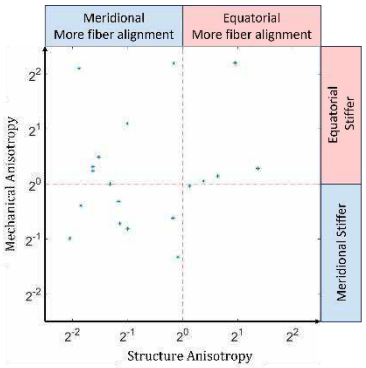

Figure 5. Scatter plot of R_{PLM} vs. R_{Mech}. The dashed line across the figure represents the mechanical and structure isotropic property. 7 samples are in mismatched regions. 12 samples are on the contrary.

The mismatch between anisotropies was not a surprise for this work. As we explained above, this study was motivated by the observation of the mismatch. In addition, in another study carried out independently by our group in collaboration with the Chen and Zhou labs in California we had observed anisotropy mismatches. Specifically, we had reported a mismatch between equatorial sclera mechanical and structural anisotropies. In those studies, however, mechanical anisotropies were not measured directly as we have done in this work. Tissue mechanics were instead inferred from measurements of wave propagation obtained from ultrasound and optical coherence tomography.

The causes underlying the mismatch between mechanical and structural anisotropies are not yet understood. This study cannot provide a definitive explanation for the mismatch phenomenon. But it is possible to speculate on some potential causes. One possible explanation could be differential collagen fiber crimp between orientations. This, however, seems unlikely as it would be discernible in the shape of the recruitment curve. It is also possible that the collagen fibers of the sclera vary in diameter [8], and thus in stiffness. It is also possible that there are directional variations in crosslinking [10], proteoglycan content or collagen type. Note that the PLM measurements are not perfect and do not account for the complex 3D nature of fibers that are interwoven. Fiber interweaving can also affect sample mechanics [11].

INTRODUCTION

Coronary microvascular dysfunction (CMD) is characterized by impaired blood flow and blood regulation in the microcirculation, and is a critical concern in the field of cardiology [1]. CMD encompasses a range of structural maladaptations in vessels and myocardium that disrupt the delicate balance between blood supply and demand, leading to adverse clinical outcomes. The index of microcirculatory resistance (IMR) is regarded as the current gold standard for evaluating coronary microcirculatory function [2]. IMR has reliably predicted myocardial viability after primary angioplasty following myocardial infarction as well as the extent and severity of myocardial infarction in patients [3], [4]. However, IMR assessment remains underused in many medical settings due to its invasive nature as it requires additional placement of a coronary wire in the vessel. Therefore, a non-invasive, data-driven approach for IMR assessment is highly desired. The primary goal of this study is to develop a data-driven framework capable of harnessing information encapsulated within angiography data, the most commonly used modality for coronary artery disease assessment, with multi-physics computational models to quantify IMR. Toward that goal, we have developed and calibrated a multi-physics computational fluid dynamics (CFD) model of contrast injection. This model provides a tool to: 1) interpret the computational angiography data, i.e. the dynamics of the contrast injection and washout within the coronary arteries, and 2) study the correlation between these dynamics and IMR.

METHODS

To provide an interpretation of the parameters that control the different scenarios of the contrast injection and washout, we developed a novel multi-physics CFD model of iodine contrast injection using CRIMSON [5]. Figure 1 shows an anatomical model of the aortic root and the main branches of the right coronary artery (RCA) built from a CT scan of a patient. The model includes the distal end of a catheter that will be used to simulate contrast injection. A key aspect of the model is the lumped parameter models (LPMs) for the left heart, right coronary arteries, and aortic outflow which are used as boundary conditions for the CFD simulation. The left heart model relies on a time-varying elastance function $E_{LV}(t)$, which represents ventricular contractility. The coronary models account for the systolic myocardial compression that produces the characteristic diastolic-dominated coronary flow patterns. The Navier–Stokes equations and the convection-diffusion transport equation are then solved in the 3D geometry to calculate velocity, pressure, and concentration of iodine contrast.

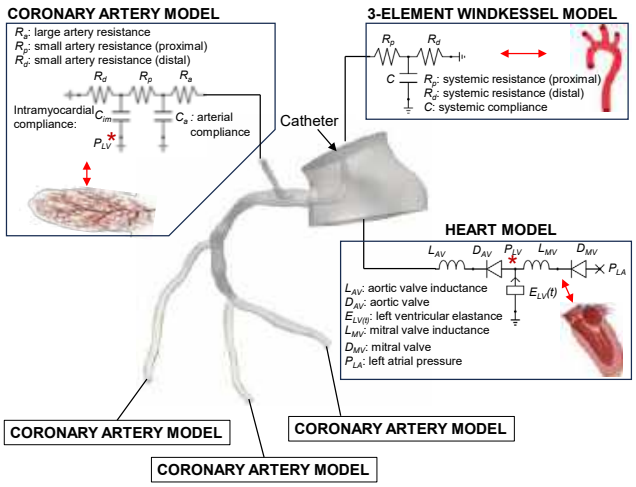

Figure 1: CFD model of contrast injection with LPMs as boundary conditions.

The computation of the transport of contrast within the coronary vessels provides a surrogate of the angiographic data, and the contrast

intensity curve can be extracted, as shown in Figure 2. The computed concentration of contrast within the RCA is projected onto 2D images using similar angles as in clinical X-ray angiograms. Segmentation is then performed via thresholding to generate binary images. Bright pixels for each frame are counted and an intensity curve representing the injection and washout of the contrast is produced. Similarly, AngioNet [6] was deployed to calculate contrast intensity curves through recursive segmentation of clinical angiograms in a cohort of 104 patients after successful percutaneous coronary intervention.

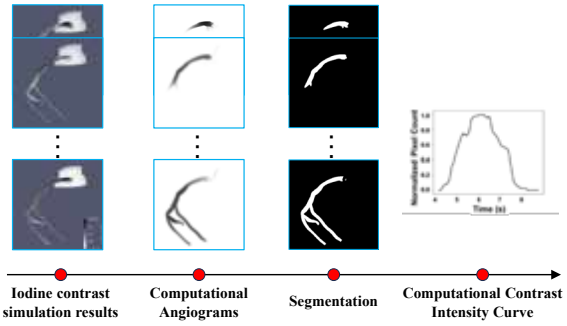

Figure 2: Contrast intensity curve generation from computational results.

RESULTS

Figure 3 depicts flow and pressure waveforms of a multi-physics simulation at aortic inlet, acute marginal and right posterior atrioventricular coronary outlets, as well as the 2-second iodine contrast injection through the catheter (denoted by light blue shade, **panel (b)**). Cardiac output (CO) is 4.88 L/min, and total RCA flow is 0.1 L/min (2% of CO). Coronary outlets present the typical diastolic-dominated profiles. Pressure ranges from 170-100 mmHg, without gradients through the RCA vessels, consistent with a lack of epicardial disease. **Panel (a)** shows a snapshot of pressure, velocity, and contrast agent concentration at time t=5.9 s. These hemodynamic results are therefore physiologically relevant and produce a solid foundation to study hemodynamics in these patients.

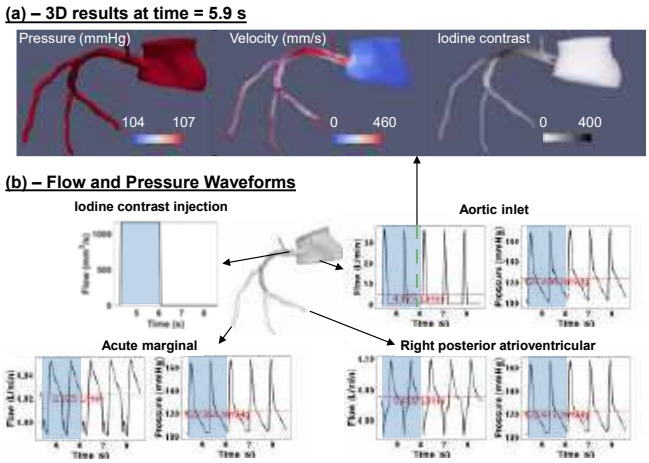

Figure 3: (a): 3D contours of pressure, velocity, and iodine contrast concentration at time t=5.9 s. (b): Representative flow and pressure waveforms.

To demonstrate the impact of altered microvascular resistances in the contrast injection curves, we conducted a study whereby the parameters governing coronary microvascular resistance (R_a, R_p, R_d in Figure 1) were gradually altered to simulate increased degrees of microvascular dysfunction. Figure 4 presents contrast intensity curves corresponding to three simulation scenarios: **1)** a healthy baseline (green line) with a total RCA flow of 0.15 L/min; **2)** a moderate disease (blue line) with a total RCA flow of 0.08 L/min, obtained by uniformly increasing R_a, R_p, R_d by 100% relative to the baseline case; **3)** a severe disease (orange line) with a total RCA flow of 0.05 L/min, obtained by further uniformly increasing R_a, R_p, R_d by 50% relative to the moderate disease case. The simulated contrast intensity curves matched the patterns from the patient cohort depicted in Figure 5, which demonstrates the substantial variability in the rising and falling slopes of the contrast intensity curves in a cohort of 104 patients. Slower rising and emptying patterns in the contrast intensity curves correspond to higher resistance values in the coronary microcirculation.

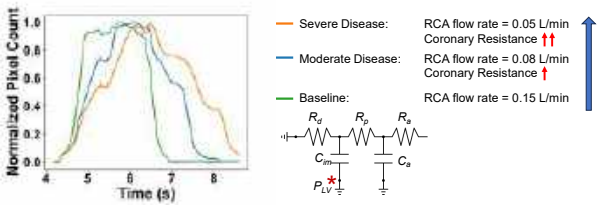

Figure 4: Contrast intensity curves of different simulations with increasing values of coronary resistance, indicative of coronary microvascular disease.

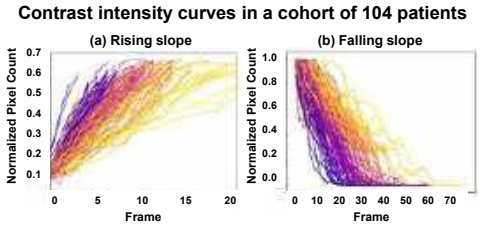

Figure 5: Intensity curves of RCA angiography data from 104 patients (warmer colors indicate greater disease severity).

DISCUSSION

This study developed a multi-physics CFD model to simulate the injection of iodine contrast into the coronary artery. The contract intensity curves are obtained from both computational angiograms and clinical angiograms to investigate the relationship between the dynamics of the contrast and microcirculatory resistance. Results show that the computational CFD model is a feasible surrogate for simulating the process of iodine contrast injection. Furthermore, both computational and clinical results prove that there is a strong correlation between the contrast intensity curve and microcirculatory resistance. Slower rising and emptying patterns in the contrast intensity curves correspond to higher resistance in the coronary microcirculation.

IN VITRO, NETWORK-WIDE EXCITOTOXIC DISRUPTION FOLLOWING TRAUMATIC BRAIN INJURY MODEL TO ASSESS CRITICAL INJURY THRESHOLDS

INTRODUCTION

Traumatic brain injury (TBI) is a mechanically induced trauma to the head known to cause both short-term cognitive deficits and long-term neurodegeneration [1]. Even mild TBIs (mTBIs) present these effects and account for over 80% of TBI cases worldwide [1]. Despite the prevalence of mTBIs among athletes, soldiers, and civilians alike, so much is still unknown about the cellular consequences of the injury and targets for universally effective treatments.

One well-established molecular response is an increase in calcium (Ca^{2+}) ion concentration in neural cells after a TBI. This increased cytoplasmic concentration occurs through mechanosensitive channels, porated membranes, and some internal stores [2, 3]. In addition to the absolute change in internal Ca^{2+}, the Ca^{2+} dynamics associated with neuronal activity are altered [2, 4]. A study by Cramer et al. revealed that the overall functional connectivity of the neuronal network in the mouse dorsal cerebral cortex decreases post mTBI [4]. This study revealed a degradation of overall network health but was unable to calculate dynamics on the individual cell level. TBI literature assessing the effect of mechanical loading on neuronal signaling is scarce and often fails to look at both hyperacute and acute reactions.

Adverse disturbances of electrical activity have been found to impair executive functions at a lower strain threshold than is required to induce cell death [5]. The transmission of signals between individual neurons throughout the central nervous system (CNS) relies on complex causal relationships between ions, proteins, receptors, and other cell structures in the neurons and extracellular matrix. Abnormalities to any of the components can lead to catastrophic disruption to the signal and other secondary events. Excitotoxicity refers to the neurotoxic effects of dysregulated glutamate secretion and hyperactive N-methyl-D-aspartate (NMDA) glutamate receptors [6, 7]. Glutamate is recognized as the primary excitatory neurotransmitter responsible for neuronal depolarization within the mammalian CNS [6]. Excitotoxicity is hypothesized to be responsible for the Ca^{2+} dynamic response to TBI, but literature shows inconsistencies in the event timeline, relevant mechanisms, and biochemical and electrophysiological responses [8–10]. The presented project is needed to simulate cellular injury under controlled mechanical conditions while investigating more physiologically relevant in vitro models to study network activity via calcium dynamics.

METHODS

In vitro 2D cortical neural cell co-cultures are obtained from P0-P1 Sprague-Dawley rats. The dissected and dissociated cells are seeded on a stretchable polydimethylsiloxane dogbone-shaped substrate (SYLGARD 184, 10:1 base to curing agent), as seen in Fig. 1. Cells adhere to the substrate via a poly-d-lysine and laminin treatment before seeding. These cells are maintained for 20 days *in vitro* (DIV) by exchanging media (Neurobasal A Medium, Pen-Strep, DMEM, Glutamax, B-27 Plus) every 2-3 days.

Once a mature neural network has formed, the samples are stretched in a custom uniaxial tension device for precise strain and strain rate application relating to mTBI values [11]. Combinations of strains (0.1, 0.3, 0.5) and strain rates (1 s^{-1} and 50 s^{-1}) are tested as well as controls. The device sits atop the microscope for minimal handling during experiments.

Neural network activity is quantified by optically capturing the calcium dynamics during spontaneous network activities. Cultures are transfected with GCaMP6f at 10 DIV that is only expressed in neurons (AAV-hSyn1-GCaMP6f-P2A-nls-dTomato; from Dr. Jonathan Ting; Addgene plasmid #51085). Timelapse images are acquired at 25 frames per second using widefield microscopy (Nikon TiE; 10X objective NA 0.45; 2x2 bin; 12-bit). Samples are maintained at 37°C during the experiments. Fluorescent traces are extracted, corrected for photobleaching, and normalized via NeuroCa [12]. Two-minute timelapses are recorded immediately before (0^-) and after (0^+) stretch. Samples are incubated at 37°C for 24 hours and recorded one more time.

Cell viability is assessed using 5 μM Calcein UltraBlue in an imaging solution of Hibernate-A, Glutamax, and B-27 Plus. The dye is loaded right before the experiments and again at 24 hours.

Lastly, the role of glutamate is assessed in 20 DIV samples where extracellular glutamate is added in the place of stretching during the experiment. Varying glutamate concentrations are used: 0.5 μM, 1 μM, 5 μM, and 10 μM.

(C) Fully assembled sample with neural cells seeded in the gage region (orange). (D) Gage region at 20 DIV; immunostained for neurons (red: β-III-tubulin) and astrocytes (green: GFAP)

RESULTS

Preliminary data of samples stretched at 50 s^{-1} shows several noteworthy hyperacute post-injury events. Immediately after stretch, there is a global network increase in mean Ca^{2+} intensity and a network hyperexcitation that lasts between 10 to 20 seconds in all strain experimental groups. After this initial period, Ca^{2+} activity decreases compared to the 0^- data. This effect is not seen in sham samples. An example sample showing calcium activity before and after stretch can be seen in Fig. 2.

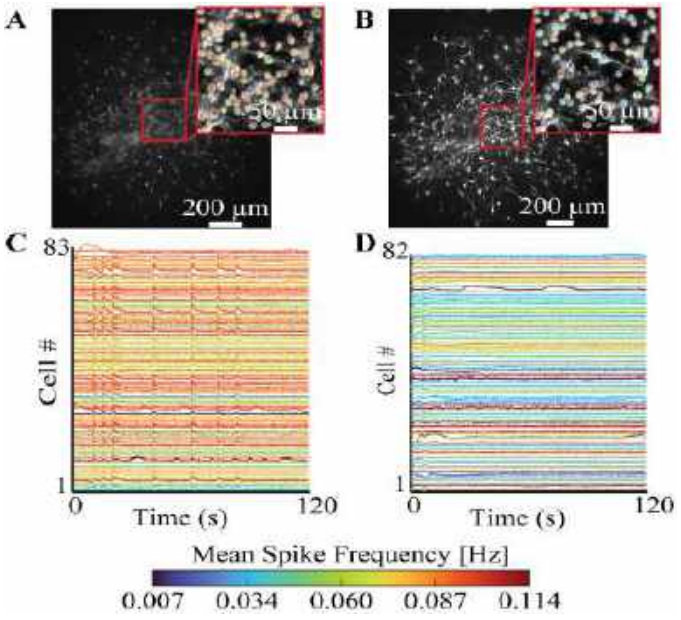

Figure 2: Preliminary data. (A) Neural co-culture stained with calcium probe immediately before applied stretch. (B) Frame of calcium image immediately after stretch (C,D) Normalized fluorescent traces from a subset of cells (respective red box) for the two-minute recording period

There is also an increase in the overall fluorescence after stretch, indicating increased overall intracellular Ca^{2+} concentration. This phenomenon is observed when comparing the unadjusted images in Fig. 2A and 2B.

DISCUSSION

The initial data is consistent with the excitotoxic timeline delineated in literature. After a neuronal stretch injury, studies observed prolonged calcium and sodium influx and potassium efflux into presynaptic neurites and synapses through over-active ion channels or porated membranes [8, 9]. This activates an abnormal depolarization cycle, possibly explaining the hyperpolarization period. This further triggers voltage-activated calcium channels which contributes to prolonged glutamate release [9]. Excitatory neurotransmitter receptors become over-activated, causing further excessive calcium influx into the postsynaptic neuron [8]. This also gives evidence to the overall calcium influx seen in the stretch experiments. The abnormal intracellular calcium levels have been shown to reduce action potentials down the line, lending to the hypo-polarization period [8, 10].

Excitotoxic disruption is believed to occur when extracellular glutamate reaches a concentration of 2 to 5 μM [6]. Blunt impact traumas have been established to release excessive amounts of glutamate into the extracellular space [6]. While the exact concentration is debated, some studies suggest a blunt mTBI may cause a release of up to 10 μM of glutamate [6, 13]. This study's glutamate experiments will clarify the involved mechanisms in the hyperacute network behavior after TBI.

A larger sample size is still needed for statistical analysis of all conditions. If the preliminary findings are consistent, this would indicate that low-level mTBI cases can still show damage to neural network functions even without undergoing significant apoptosis. The ability to collect quantifiable network dynamic measurements from over 200 cells in real time while simultaneously controlling cell deformation mechanics is unique to this experimental setup. The data will serve as the basis for determining a specific critical strain and strain rate threshold for Ca^{2+} signal dysfunction.

VIGOR4D: VASCULAR IDEALIZED GEOMETRY OPEN-SOURCE REPOSITORY FOR 4D FLOW MRI DENOISING AND SUPER-RESOLUTION

Moses J. Hamm (1), Neal M. Patel (1), Vitaliy L. Rayz (1,2)

(1) Biomedical Engineering, Purdue University, West Lafayette, IN, USA

INTRODUCTION

Three-directional phase-contrast magnetic resonance imaging (4D flow MRI) is an emerging imaging technique which provides time-resolved *in vivo* measurements of blood flow velocities. Alterations in velocity-derived hemodynamic parameters such as wall shear stress (WSS) have been implicated in the pathogenesis of several vascular disorders [1]. However, the low resolutions (typically 0.75-3mm^3) and signal-to-noise ratios offered by 4D flow MRI limit accuracy in computation of these metrics, especially in smaller vessels such as the cerebral vasculature. Therefore, super-resolution and denoising of 4D flow MRI will enable more accurate characterization of flow changes in vascular disorders.

Recently, deep learning has become a popular tool to super-resolve and denoise 4D flow MRI data [2, 3]. However, training supervised convolutional neural networks requires large training datasets. While datasets, such as ImageNet [4], exist for many other applications, no such dataset exists for 4D flow MRI due to the prohibitive cost of running a large number of scans. A lack of benchmark data prevents performance comparison between models and forces researchers to curate their own data, negatively impacting sample size, data diversity, and study timelines.

In this work, we make the assumption that subject-specific physiological flows can be broken down into a combination of simpler flow structures. We aim to construct a dataset of these "building blocks" which can allow machine learning models to generalize to more complex subject-specific flow fields measured *in vivo* with 4D flow MRI. Accordingly, we use idealized, physiologically inspired geometries to construct a large dataset of paired high-resolution ground truth and low-resolution synthetic 4D flow MRI in diverse flow geometries and conditions.

METHODS

Idealized Model Generation. Here, we developed a Vascular Idealized Geometry Open-source Repository for 4D flow MRI denoising and super-resolution (VIGOR4D). Five classes of generalized vascular geometries were included in this dataset based on their ubiquity in healthy and diseased blood vessels and the range of secondary flow they cause. These classes include saccular and fusiform aneurysms, stenoses, T-junctions, and multifocal fibromuscular dysplasias (FMD). All geometries were generated in Fusion 360. For each class, nine distinct models were created by manipulating the vessel diameter, centerline curvature, branching pattern, and class-specific features. An example of the geometric variation scheme is shown in Figure 1.

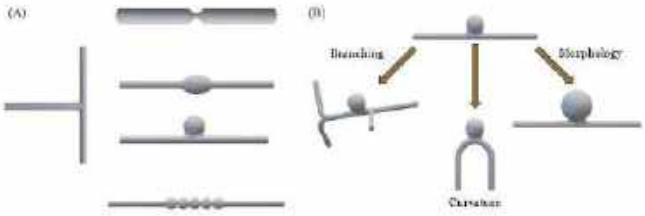

Figure 1: (A) Prototypical models for each class included in VIGOR4D. (B) Examples of additional geometric variations.

Three vessel sizes were represented in this dataset: primary branches of the aorta which typically have a diameter near 10mm, major systemic arteries which have diameters between 4-8mm, and small arteries such as those found near the Circle of Willis, with diameters of 2-4mm. Accordingly, generalized geometries were created with diameters of 3mm, 6.5mm, and 10mm. Models were constructed in straight pipe, semicircle, or 3D spline configurations to capture the interplay between secondary flow structures caused by the vessel's curvature and by the class-specific anatomical features representing vascular disorders. The variation of the branching pattern (e.g., symmetric bifurcations, small side branches, location relative to anatomy of interest) served a dual

purpose. First, it captured the effect of the vascular anatomy on the flow division between the distal branches. Second, it created flow disturbance which affects flow structures in the region of interest. Finally, morphological features such as aneurysm diameter and neck diameter, percent stenosis, and T-junction angle were manipulated to represent the variability among these lesions.

Inflow Waveforms. Because the geometries in this dataset do not correspond to specific arteries, generalized inflow waveforms which reasonably represent flow in any peripheral artery were generated. The reduced-order model presented in Musket et al. was used to generate whole-body population-based inflow boundary conditions [5]. The top three principal components were extracted and used in simulations. Each waveform component was randomly assigned a peak Reynolds number of 600, 1200, or 2000 ±10% considering both the nominal model diameter and any diametric change associated with the relevant pathology (e.g., stenosis).

Simulation. The open-source flow modeling software SimVascular was used to mesh and simulate blood flow in all geometries [6]. Due to the range of vessel sizes, maximum edge lengths were set at $0.1*D_{Nominal}$. A mesh independence study verified that this edge length was sufficient independent of model diameter. Blood was modeled as an incompressible, Newtonian fluid with a density of 1.06 g/mL and a viscosity of 4cP. Three simulations were conducted for each geometry corresponding to different inflow waveforms. Inflow waveforms were prescribed at the inlet using a Womersley velocity profile, and Windkessel RCR boundary conditions were prescribed at the model outlets. Three cardiac cycles were simulated with a time step less than or equal to 1E-4 seconds resulting in CFL << 1. Results from the final cycle were extracted and sampled at 50 time steps per cardiac cycle for further processing.

Synthetic 4D Flow MRI Data. The velocities resulting from simulations performed in SimVascular were used to generate synthetic 4D flow MRI at half the resolution of ground truth velocity fields using algorithms developed in prior work [7, 8]. The velocity fields computed with CFD on unstructured grids were interpolated on two structured isotropic grids with 0.5 mm and 0.33 mm element size respectively. The velocity field (u) over time (t) for all voxels (x_j) on the 0.33 mm isotropic grid is converted to a complex MR signal (ζ).

$$\zeta(x_j, t) = m(x_j) \cdot \exp\left[i \frac{\pi}{venc} u(x_j, t)\right] \quad (1)$$

This MR signal is convolved with a point spread function (h) and resampled Dirac comb function (ш) and a coefficient (c) to model the signal in the downsampled case. Spatial downsampling by a factor of three is performed using a sinc point spread function, and temporally downsampling by a factor of three is performed using a box point spread function. Complex gaussian noise (η) is also added to the complex MR signal:

$$Z = [(\zeta * h) \cdot (c \cdot ш_{4D})] + \eta \quad (2)$$

The complex signal, a reference signal derived by using a zero-vector velocity field, and the velocity encoding parameter (venc) of MRI acquisition are used to reconstruct the low-resolution velocity field (U).

$$U = \frac{venc}{\pi}\left(\angle \frac{Z}{Z_{ref}}\right) \quad (3)$$

Noise generation parameters (e.g., *venc*, noise magnitude, saturation ratio) are varied to simulate diverse data quality, resulting in three low-resolution velocity fields per high-resolution velocity field as shown in Figure 2.

RESULTS

The VIGOR4D dataset includes 135 high-resolution and 405 low-resolution synthetic 4D flow MRI cases in 45 distinct geometries. It is representative of the entire peripheral vasculature and its most common pathologies. In total, ten variables contribute to the overall diversity of the dataset. Geometric variables include the lesion type, diameter, curvature, branching, and morphological features. The boundary condition parameters include the waveform shape and peak Reynolds number. Lastly, simulated 4D flow MRI is generated using variable *vencs*, noise magnitudes, and saturation ratios.

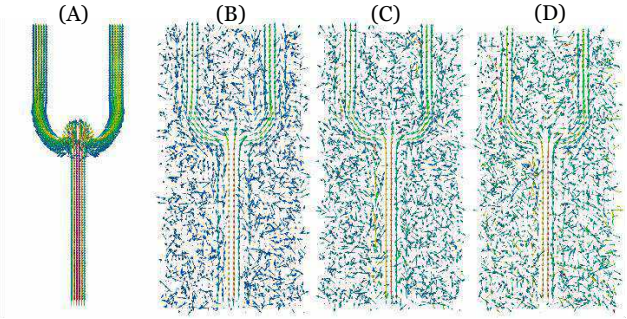

Figure 2: (A) High resolution ground-truth data. (B-D) Synthetic 4D flow MRI data with varied acquisition parameters and increasing noise magnitude.

DISCUSSION

To our knowledge, no training dataset of this scale or diversity has been generated or published in the domain of 4D flow MRI reconstruction. While CFD-derived data cannot fully replicate *in vivo* 4D flow MRI image artifacts and noise distributions, it does offer several benefits. First, the sample size of the dataset is not limited by the cost of imaging studies or difficulty in finding subjects. Second, the use of customized geometries enhances diversity and is assumed to improve generalizability of data-driven reconstruction methods. Finally, synthetic data negates the issue of patient privacy, allowing the dataset to be released publicly. One limitation, however, is that VIGOR4D is not representative of cardiac or aortic flows due to the complexity of turbulence modeling. We hope that VIGOR4D will accelerate development of deep learning algorithms for denoising and super-resolving 4D flow MRI.

MYOSIN-FREE MOLECULAR CLUTCH MODEL PREDICTING MYOSIN-INDEPENDENT STIFFNESS SENSING

Nikhil Mittal (1), Sangyoon Han (1)

(1) Department of Biomedical Engineering
Michigan Technological University
Houghton, MI 49931, USA

INTRODUCTION

A number of studies have shown an increasing traction in response to increasing substrate stiffness (1-3). To explain this stiffness-dependent differential traction, a 'molecular clutch' model has been implemented (4). In the clutch model, F-actin's retrograde flow dynamically 'clutches' with the cell-matrix adhesion that transmits the force to the substrate. Myosin II contractility has been the main source of the retrograde flow where myosin's muscle-like behavior explains the stiffness-dependent differential traction (5, 6). However, evidence shows that even in the absence of myosin activity, cells transmit small but significant traction force with also increasing trend with increasing substrate stiffness (7). Given myosin as a 'result' of mechano-signaling, identifying how cells transmit differential force without myosin would shed light on the very initial stiffness sensing event by a cell without complication by myosin's effect. As an alternative power source, actin assembly at the barbed end of F-actin can contribute to the retrograde flow by pushing the membrane and being pushed by the membrane (8). Actin Related Protein 2/3 complex (Arp2/3) and formin homology protein are the two main actin nucleators (9, 10). In this abstract, we show experimental evidence that myosin-independent tractions are still stiffness-dependent and it comes from the actin retrograde flow powered by actin polymerization and its two main mediators. To predict this behavior, we develop a new molecular-clutch model which considers the role of polymerizing actin and its viscoelasticity in stiffness-dependent differential force transmission in a myosin-independent manner.

METHODS

In this model, the F-actin network unit was modeled as a mesoscale viscoelastic material with a length L with an individual spring constant of k_{actin} and viscosity of η. Rather than being controlled by a constant velocity determined by the force-velocity relationship (eq. 5), the flow in this model is driven by the force equilibrium between the F-actin filament, the clutches, and the substrate. The force generated in the purely elastic spring portion of the actin is generated by the force balance with the elastic clutch, and is found to be:

$$F_{\text{actin-k}} = \frac{N_{\text{n}}L - X_{\text{c}}}{N_{\text{o}} + N_{\text{n}}}\, k_{\text{actin}}, \quad (1)$$

where N_{n} is the number of new actin units added in that time step, and N_0 the number of units in the original filament at the start of the first time-step. N_{n} is modeled to be inversely related to the maximum force in any of the individual clutches denoted as F_{c}:

$$N_{\text{n}} = N_{\text{n,max}}\left(1 - \frac{F_{\text{c}}}{F_{\text{s,actin}}}\right) \quad (2)$$

where $F_{\text{s,actin}}$ is the stall force of actin addition, and $N_{\text{n,max}}$ is the maximum number of actin units that can be added in a single time step. The force in the substrate and clutch are described by following equations:

$$F_{\text{sub}} = k_{\text{s}} * x_{\text{sub}} \quad (3)$$

$$F_{\text{adh}} = N_{\text{c}}K_{\text{c}}(x_{\text{c}} - x_{\text{sub}}) \quad (4)$$

where F_{adh} is the force in the clutch, and N_{c} is the number of bound clutches. As the clutches are attached to the substrate, the force balance between the clutches and the substrate can be used to create the expression for the displacement of the substrate:

$$X_{\text{sub}} = \frac{N_{\text{c}}k_{\text{c}}X_{\text{c}}}{k_{\text{s}} + k_{\text{c}}N_{\text{c}}}. \quad (5)$$

The rate of change of the position of the clutch is derived using following equations:

$$\eta\dot{x}_{\text{c}} = F_{\text{actin-k}} - F_{\text{adh}} \quad (6)$$

$$\dot{x}_{\text{c}} = \frac{1}{\eta}\left(\frac{N_{\text{n}}L - X_{\text{c}}}{N_{\text{o}} + N_{\text{n}}}.\, k_{\text{actin}} - N_{\text{c}}k_{\text{c}}(X_{\text{c}} - X_{\text{sub}})\right). \quad (7)$$

The time derivative of the clutch position is explicitly integrated in the model using the Euler method to find the displacement following each time step of the simulation. The maximum rate of displacement of any of the clutches is considered to be the actin rearward speed. The displacement is used to calculate the force exerted on the substrate using equations (6) and (3), which is used to find the traction exerted on the substrate.

RESULTS

Through a series of experiments using traction force microscopy (TFM), we discovered that the traction of WT NIH 3T3 fibroblasts increases with increasing substrate stiffness, and this stiffness-dependent differential traction is also exhibited by cells treated with blebbistatin, a myosin ATPase inhibitor (11) (Fig. 1A). The myosin-independent, stiffness-dependent traction was significantly reduced with inhibition of either Arp2/3 (Fig. 1A) or formin in addition to myosin activity (11), but the stiffness-dependent differential traction was still observed, even with additional inhibition of actin polymerization itself in addition to myosin contractility (11). Imaging and quantifying F-actin deformation by quantitative fluorescence speckle microscopy (qFSM) revealed that the retrograde F-actin flow speed was differentially regulated by the ECM stiffness in WT cells as well as cells with myosin- or/and Arp2/3 inhibition (Fig. 1A). Such stiffness-dependent flow difference was abolished when formin activity was inhibited in addition to myosin inhibition. These results demonstrate that myosin-independent, stiffness-dependent differential traction depends on actin polymerization-powered actin retrograde flow.

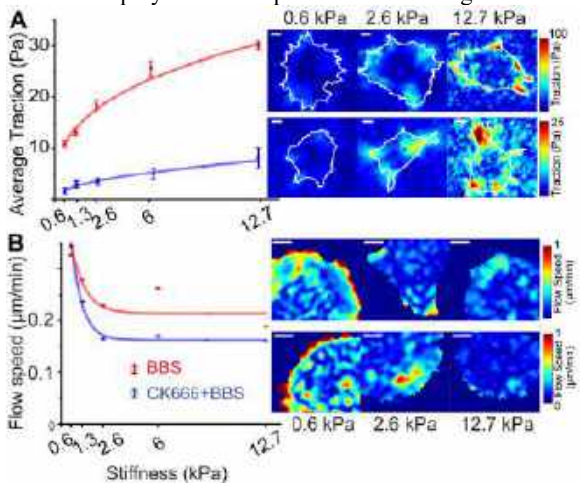

Figure 1: Myosin-independent traction is stiffness-dependent and it depends on the actin polymerization mediated by Arp2/3. (A,B) Average traction (A) and actin flow speed (B) as a function of the substrate stiffness with inhibition of myosin II and Arp2/3 + myosin.

From experiments, we found that Arp2/3 inhibition in addition to myosin reduced traction magnitude by ~4 fold (Fig. 1A) compared to the traction by cells with myosin-only inhibition while minimally reducing the F-actin flow (Fig. 1B). The original molecular clutch model has failed to explain this behavior because the actin filaments were assumed to be rigid (11). To resolve this difficulty, we developed a novel molecular clutch model where F-actin's own viscoelasticity contributes to the transfer of the actin motion to the traction force (Fig. 2). For example, an addition of a new F-actin unit network with higher rigidity (Fig. 2A) can push the clutch molecule harder than those with softer F-actin (Fig. 2B), thus transmitting larger traction while preserving similar actin flow velocity even when cells are on the substrates with the same ECM rigidity. Via collaboration with Dr. Alex Cartagena-Rivera (NIH, NIBIB), we found that indeed Arp2/3 and formin contribute to the elasticity of F-actin network (11). This model was able to explain the elevated traction with Arp2/3 (Fig. 2C) with the small difference in F-actin flow speed compared to myosin-only inhibition (Fig. 2D). Our finding also implies that this stiffness-dependent differential tension could be induced very early to the just-nucleated NAs independently of myosin and other mechano-signaling outputs.

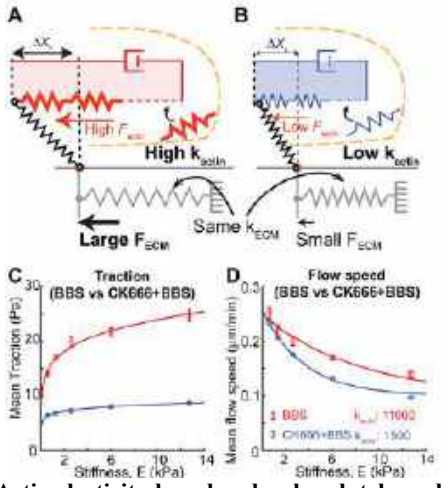

Figure 2: Actin elasticity-based molecular clutch model with high (A) or low (B) actin rigidity, k_{actin}, with the same substrate rigidity, k_{ECM}. Addition of high k_{actin} can push the clutch point more (by larger Dx_c) than the model with low k_{actin}. (C,D) Simulation results of traction (C) and actin flow speed (D) out of 5 independent stochastic simulations.

DISCUSSION

In this study, we provide a stiffness-sensing mechanism for adherent cells when myosin-II, a primary force generator in a cell, is not actively working. Our model suggests that actin nucleators control the sensitivity for stiffness-dependent differential force transmission by modulating the elasticity of the polymerizing actin. Our data demonstrate that the retrograde flow, which still exists in the absence of myosin-II activity via actin polymerization (12, 13), is able to induce the stiffness-dependent differential transmission. Previous molecular clutch models (6, 14) incorporated parameters for actin polymerization, but only they were not considered to be primary source of the retrograde flow and traction forces. Our model, for the first time to the best of our knowledge, uniquely integrates actin polymerization and viscoelasticity, serving as dual contributors to both actin flow and traction forces, which, in conjunction with clutch dynamics, are modulated by substrate stiffness. This approach delineates cellular mechanics without relying on myosin-II-driven forces.

INTRODUCTION

The anterior cruciate ligament (ACL) is a key stabilizing ligament in the human knee. It is also one of the most frequently injured structures by athletes and trauma victims [1]. Ever though ACL reconstruction is able to partially restore knee functionality, the damage to the articular cartilage, including microfracture and macromolecule breakdown, is irreversible, and those damages could eventually lead to post-traumatic osteoarthritis (PTOA) [2,3]. However, the whole picture of this pathological progression is still unknown. Here, with the help of modern magnetic resonance imaging (MRI) techniques, we have a unique opportunity to noninvasively probe the progression of biochemical and biomechanical changes of the tibiofemoral cartilage throughout PTOA pathogenesis.

The primary objective of this case study is to investigate the biochemical and biomechanical alterations of the tibiofemoral cartilage throughout the injury, repair, and recovery processes after ACL reconstruction (ACLR). We were able to collect full MRI analysis of one participant prior to ACL injury, and then again following ACLR and recovery. We were fortunate to acquire relaxometry maps (e.g., T2 [4], T2* [5], and T1ρ [6]), as well as the intratissue displacement and strain of knee cartilage [7] at four different imaging sessions, enabling tracking through time. All MRI metrics were acquired using the same 3 Tesla (T) MRI scanner. As far as we know, this study is the first to report longitudinal biochemical and biomechanical changes prior to injury and throughout the ACLR time course within human tibiofemoral cartilage *in vivo*.

METHODS

Patient recruitment: One 27-year-old Caucasian female with a previously healthy left knee was imaged as a healthy patient in one study [7], but was also enrolled in this continuation study after sustaining a complete ACL tear during a soccer game.

Experimental procedure: The scanning was done using a clinical 3T MRI system (SIEMENS Prisma^{fit} 3T, with QED 15-channel knee coil). For each scanning session, we first collected the proton density-weighted double echo steady state (DESS) images to establish a common plane for multi-contrast image acquisition. After DESS, T2-, T2*-, and T1ρ-weighted images were acquired before the spiral Displacement ENcoded Stimulated Echo MRI (spiral DENSE) sequence, which is capable of capturing the full-field displacement and strain map while the object of interest is under repetitive loading condition. For each set of weighted images, the corresponding relaxivity maps were calculated. Here, the T2 and T2* maps were directly output by the scanner (SIEMENS syngo MapIt; TEs for T2: 13, 26, 39, 52, 65, and 78ms; TEs for T2*: 4.87, 13.46, 22.05, 30.64, 39.23, 47.82, 56.41, and 65ms), while the T1ρ map (TEs: 0, 20, 40, 60, and 80ms) was calculated by fitting a monoexponential decay curve on each voxel of the weighted images using a customized software (MATLAB r2020a). Then, a set of high frame rate (27 frames/s) DENSE images were captured during a 0.5Hz cyclic loading (1s loading, 1s unloading) applied to the patient's ankle in the varus direction via a customized loading device (**Fig. 1A**) [8]. The force applied was equivalent to 0.5× body weight of the patient at the location of medial condyle [9].

To analyze the relaxometry data, the tibial and femoral cartilage areas were manually selected from the first echo of the weighted images as the regions of interest (ROIs), and the relaxivity values were averaged within each ROI. For T2 and T2*, we analyzed both medial and lateral sides, while for T1ρ we only did the medial side due to wrapping artifact. We also investigated cartilage zonal differences by splitting each ROI evenly into a superficial zone and a deep zone (**Fig. 1B**) [10], then averaging the relaxivity value. For the DENSE data, the tibial and femoral cartilage area at the medial condyle side were collectively selected as one ROI, and the displacement and 2D Green-Lagrange strain maps within the ROI were calculated on a pixel-by-pixel basis using customized software (MATLAB r2020a) [11]. The total scanning session was roughly 1.5h, and all images were acquired in the coronal plane.

Longitudinal study plan: This patient already participated in a research-based MRI scanning session before the left knee was injured, and the corresponding metrics were collected. After the injury, the patient returned for three more scans with identical MRI and data analysis protocol. The three scans were one week before the ACLR surgery, four months, and six months after the surgery. The ACLR was done using an autograft quadriceps tendon. The patient went through normal physical training after the surgery.

RESULTS

The average relaxometry data (**Fig. 1C, 1D**) showed a fluctuation in all three metrics throughout time. For T2, the value tended to peak at the before-surgery timepoint and dropped afterwards, while T2* had a similar trend. The lateral femoral cartilage had a maximum T2 value

of 53.25ms before surgery. When looking at the femoral/tibial differences, we noticed that the femur side would have a higher value than its counterpart on the tibia side. We observed the values of the superficial zone were generally higher than the deep zone, while the superficial zone values also peaked at the before-surgery timepoint (maximum 78.88ms at lateral femoral cartilage), then dropped at four-month and six-month timepoints. Meanwhile, the deep zone values gradually increased throughout the recovery process. For T1ρ, we found that the averaged value was lower at the before-surgery timepoint and recovered afterwards, while the femoral cartilage also showed a higher relaxivity value than tibial cartilage. Zonal analysis showed a similar trend except the medial tibial deep zone continued to increase through time. At the six-month timepoint, all three metrics resumed to similar values compared to the healthy timepoint.

The averaged displacement and strain data (**Fig. 2A, 2B**) showed that at before-surgery timepoint, the varus load induced low strains, with minimal *Exx*, *Eyy*, and *Exy* values. At four-month and six-month timepoints, the *x*-displacement would first decrease then increase while the *y*-displacement showed an opposite trend. Meanwhile, *Exx* became lower and *Eyy* became higher, while *Exy* continued to increase.

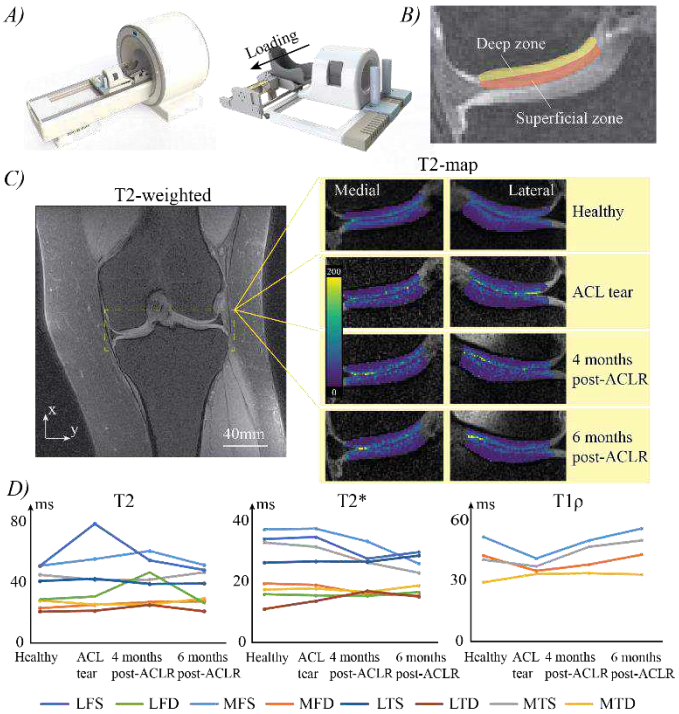

Figure 1: Experimental setup and averaged relaxometry values at 4 timepoints, with one example of the analysis. (A) Loading device in a 3T MRI system, the loading direction indicates varus loading. (B) Demonstration of superficial and deep zone. (C) T2 map at 4 different timepoints. T2* and T1ρ were analyzed similarly. (D) The averaged T2, T2*, and T1ρ values within 8 different ROIs at 4 timepoints. Maximum T2 was found within the lateral femoral cartilage (53.25ms, 78.88ms within its superficial zone) at before-surgery timepoint. Acronyms: LFS – Lateral femoral superficial zone; LFD - Lateral femoral deep zone; MFS – Medial femoral superficial zone; MFD - Medial femoral deep zone; LTS – Lateral tibial superficial zone; LTD - Lateral tibial deep zone; MTS – Medial tibial superficial zone; MTD – Medial tibial deep zone.

DISCUSSION

In this work, we recruited one patient and utilized MRI technology to track the biochemical and biomechanical alternations of the tibiofemoral cartilage at four different timepoints throughout the injury and recovery process of ACLR. The increased T2 and T2* values would suggest that the knee homeostasis had been disrupted and inflammation would occur due to the injury. This would also explain the decreased T1ρ value before surgery [12,13]. The recovery of those values through time would indicate that the restored knee functionality would be helpful to regain homeostasis of the knee and the inflammation was relieved throughout the healing process. Meanwhile, zonal analysis revealed that the superficial zone would be more prone to biochemical and biomechanical interruptions from the injury. The initial alternations will gradually convey through the depth of the cartilage resulting in decreased values of the superficial zone and increased values of the deep zone, and eventually, both zones will reach a new homeostasis. The peaked T2 value at the lateral femoral cartilage could indicate that the missing of the ACL could alternate the dynamics of the knee and would influence the lateral cartilage.

The displacement data demonstrated that the disturbed knee dynamics without ACL and ACLR could partially recover some of the knee functionality. However, the strain data revealed that even though the macroscopic dynamics of the knee was likely to resume back to normal, how the cartilage responded to loading would still be different. The elevated *Exy* could imply that early stage of cartilage degeneration had already occurred even with ACLR [9,14,15].

We believe this work is the first to track biochemical and biomechanical changes of knee cartilage before and after ACL injury in a clinical 3T MRI setup. Further research could involve in *ex vivo* testing of the tissue that collected during the ACLR surgery. Histological tests and omics analysis could be utilized to probe into the compositional alternations at tissue level. By doing so, we would establish a multiscale study which could provide a unique view of the pathogenesis of ACL injuries and lead to a better understanding of the onset of PTOA.

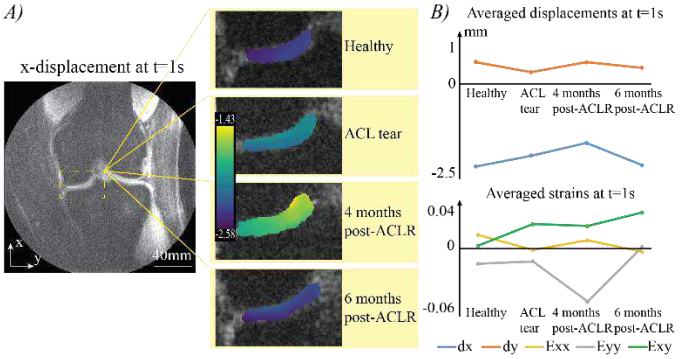

Figure 2: *In vivo* cartilage strain in the medial femoral condyle and tibial plateau was obtained during varus loading of the knee. (A) x-displacement map at 4 timepoints as an example of displacement and strain analysis. Here we only focus on the displacements and strains at t=1s, the raw value ranged from -1.43mm to -2.58mm. (B) The averaged x-displacement, y-displacement, *Exx*, *Eyy*, and *Exy* within ROI at 4 different timepoints.

ENDOTHELIAL CELLS EXHIBIT A SIMILAR TEMPORAL RESPONSE TO ULTRASOUND AS NORMAL FLOW

Ian S. McCue, Adam R. Johnson, Joseph A. Turner, Ryan M. Pedrigi

Department of Mechanical and Materials Engineering, University of Nebraska-Lincoln, Lincoln, NE, USA

INTRODUCTION

Endothelial cells are exquisitely sensitive to flow. Disturbed flow promotes dysfunctional behaviors that can lead to the development of atherosclerosis, while unidirectional flow at a normal magnitude (i.e., normal flow) promotes all primary functions [1]. Importantly, normal flow also protects arteries from atherosclerosis. Moreover, our recent study demonstrated that restoring normal blood flow in atherosclerotic arteries promotes plaque stabilization [2]. This work demonstrates that the mechanobiological effects of normal flow are therapeutic. A remaining challenge is to develop a mechanism to activate the same beneficial mechanosensitive signaling in dysfunctional endothelial cells of diseased arteries in the body as normal flow.

Ultrasound can noninvasively deliver tunable mechanical stimuli into the body in a targeted manner for therapeutic applications such as thrombolysis in treating ischemic stroke [3]. In addition, it has been shown that endothelial cells exhibit angiogenic behaviors to low intensity pulsed ultrasound (LIPUS). An interesting feature of these studies is that cells are only exposed to LIPUS for 2-30 min [4-5]. This duration is much shorter than the 4-24+ h that is typically used in studies of endothelial cells under flow [6]. Short durations of flow have been shown to promote atherogenic behaviors [7-8]. No study has evaluated the endothelial response to longer durations of LIPUS. Therefore, in this study, we hypothesized that endothelial cells exposed to LIPUS for longer durations up to 24 h will exhibit a greater beneficial response than shorter durations (<1 h) and that the temporal response pattern will be similar to that seen under normal flow. We evaluated two well-established mechanosensitive genes related to a healthy endothelium, endothelial nitric oxide synthase (*eNOS*) and Kruppel-like factor 2 (*KLF-2*).

METHODS

Experimental setup. We developed two custom ultrasonic exposure tanks. The acoustic source consisted of 1 MHz unfocused immersion transducers of 13 mm diameter mounted to the bottom of the tanks and driven by a function generator and amplifier at 55 dB gain. 6-well cell culture plates were held within the tank by a mount that positioned the center of each culture well directly above the center of a transducer. The cavity of the bioreactor was filled with sterile degassed distilled water up to the sides of the culture plate.

Acoustic field measurements. We used a custom acoustic field characterization tank with a capsule hydrophone attached to a motorized three-axis gantry system to perform spatial mapping of the peak acoustic pressure field generated by the 1 MHz unfocused transducers in water. Axial mapping (0.5 mm resolution) was performed to determine and characterize the near-field-to-far-field transition. From this map, we set the culture plate position to 73 mm from the transducers. In-plane spatial mapping at this distance from the transducers was also performed (0.25 mm resolution). We also conducted acoustic field measurements within the wells of culture plates to directly evaluate the relationship between peak acoustic pressure versus voltage input to the transducers.

Cell culture. HUVECs pooled from 10 donors were used for all experiments at passages 3 to 7. Cells were seeded at 30,000 cells/cm^2 into 6-well culture plates coated with rat-tail type I collagen 18-24 h prior to the start. Each culture well was provided with 2.41 ml of medium to give a fluid height of 2.5 mm. Cells were visually inspected before and after each experiment to ensure a healthy appearance.

LIPUS experimental protocol. Two hours prior to experiments, the ultrasound exposure tank was sterilized, assembled, filled with degassed and pre-warmed distilled water, and placed in the incubator. Immediately prior to the start, a 1MHz ultrasound transducer (calibrated with the hydrophone) was used to set the acoustic pressure to 217 kPa within each well of a culture plate (without cells). Once set, the endothelial cell-seeded culture plates were placed within the exposure tank and visually inspected to ensure no air bubbles were present at the plate-water interface. A small weight was placed on top of the culture plate lid to prevent floating or other movement during the experiment.

Cell layers in these plates were exposed to a 1 MHz sine wave that was pulsed at 1 Hz (500,000 cycles per burst period) to simulate the cardiac cycle. Control cell layers were seeded into wells of the same culture plate that did not receive direct ultrasound stimulation. An acoustic pressure of 217 kPa was chosen based on preliminary experiments to identify the maximum acoustic pressure that could be applied to endothelial cells in the basal-to-apical direction without causing detachment. Experiments were conducted over five durations: 20 min, 1 h, 6 h, 9 h, and 24 h.

Flow experimental protocol. As a comparator, endothelial cells were exposed to normal flow within the wells of culture plates by using an orbital shaker that moved the plates in a horizontal circular orbit of 5 mm radius at 250 revolutions per minute (RPM) within an incubator. The outer periphery was subjected to unidirectional flow at a normal shear stress (mean of 1.4 Pa) and gene expression was evaluated in this region, following our previous work [1]. Flow experiments were conducted over six durations: 20 min, 1 h, 6 h, 24 h, 48 h, and 72 h.

RT-qPCR. At the end of each experiment, the well plates were removed from the incubator and cells were immediately lysed for total ribonucleic acid (RNA). We used a custom 3D-printed extractor to isolate RNA from the cell layers [1]. For the LIPUS-exposed cell layers, the spatial profile of the acoustic pressure field was used to guide the cell analysis. Therefore, the central 0-6 mm was isolated. For flow-exposed cell layers, the peripheral 11.0-17.4 mm was isolated. RT-qPCR was performed to evaluate *eNOS* and *KLF2* [1]. Data were analyzed with the delta-delta Ct method.

Statistics. Quantities are reported as mean ± standard deviation (SD). For normally distributed data, group comparisons were performed using a Welch's one-way analysis of variance (ANOVA) and pairwise comparisons were performed using an unpaired t-test with equal or unequal variances based on an F-test. Otherwise, a Kruskal-Wallis test and Mann Whitney U test with Levene's test for variances were used. Multiple comparisons were corrected using the Holm-Bonferroni method. A p-value of less than 0.05 was considered significant.

RESULTS

We evaluated the stability of our transducers over 24 h mock experiments (i.e., no cells) at a target peak pressure of 217 kPa (1 Hz pulsing). The mean peak pressure was 218±3 kPa. Thus, the signal deviated from the target by an average of only 0.5%. In-tank temperature measurements showed an increase in temperature from 33.5°C to a steady-state value of 38.2°C, which was achieved in approximately 12 h. Temperature measurements performed without powering the transducers demonstrated an increase from 33.4°C to 36.7°C. Thus, 24 h of pulsed ultrasound (pulsing at 1 Hz) at 217 kPa caused a temperature rise of only 1.5°C. Importantly, both experimental and control cell layers were exposed to this small temperature increase.

We evaluated the time-dependent response of endothelial cells to a peak acoustic pressure of 217 kPa after 20 min, 1 h, 6 h, 9 h, and 24 h of exposure. At 20 min, *eNOS* expression was slightly reduced to 0.77±0.10, in line with the known atherogenic effects of physiologic mechanical stimuli (e.g., normal flow) over short durations. At 1 h, expression increased to 1.14±0.07 and, at 6 h, it peaked with a maximum value of 2.69±0.45 (p<0.01 versus 20 min, 1 h, and 24 h). After, expression dropped off slightly at 9 h (2.24±0.53) and then declined considerably to 1.06±0.30 at 24 h. Similarly, *KLF2* exhibited a negligible response at 20 min (1.13±0.11) that then increased to a peak at 6 h of 1.94±0.35 (p<0.05 versus 20 min and 24 h), followed by a decline to 0.93±0.14 at 24 h. Remarkably, these expression patterns were qualitatively similar to those found for endothelial cell layers exposed to normal flow, but LIPUS induced peak beneficial signaling more rapidly than flow (**Figure 1**). However, peak expression of both genes was substantially higher for cells under flow for 24 h compared to LIPUS for 6 h with values of 6.67±1.78 (p<0.01) and 25.9±2.46 (p<0.001), respectively.

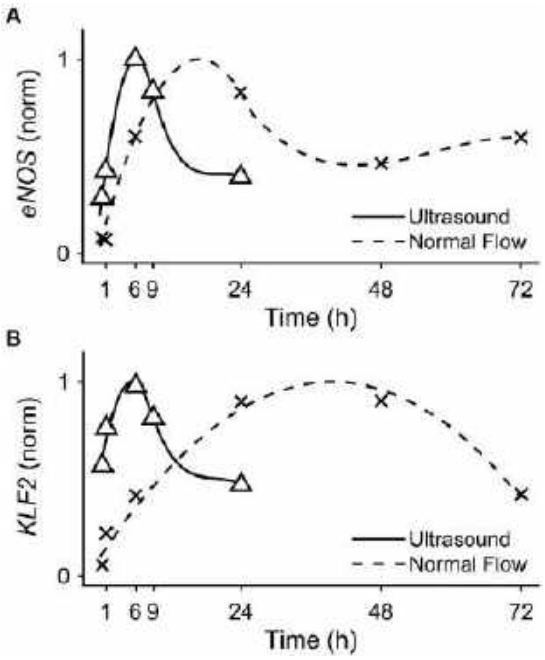

Figure 1. Normalized expression levels of *eNOS* and *KLF2* show qualitatively similar trends over exposure time between low-intensity pulsed ultrasound and normal flow. Normalized (A) *eNOS* and (B) *KLF2*. Points represent the mean expression at each time and lines are polynomial fits to illustrate the trend.

DISCUSSION

The few studies that have characterized the endothelial response to LIPUS have provided little rationale for the choice of parameters used [4-5]. In this study, we reasoned that longer continuous durations of LIPUS than has previously been used may exhibit stronger beneficial biological responses more comparable to those seen under normal flow. Our results demonstrated maximum expression of *eNOS* and *KLF2* after 6 h of LIPUS and similar temporal expression patterns as those seen under normal flow. This suggests that both mechanical stimuli are regulated by the same signaling pathways. However, flow promoted far greater expression of both atheroprotective genes compared to LIPUS, at least for the regimens used herein. Overall, this points to the need for more studies that characterize the endothelial response to the many LIPUS parameters over a broad range of values.

INTRODUCTION

The ability of cells to sense and respond to mechanical forces is critical for various functions, including growth, motility, differentiation, and homeostasis. Recent work has indicated alterations in the mechanical properties of the cell compartments alter mechanosensing, possibly driving disease progression [1]. Thus, the accurate estimation of the mechanical stiffness of cellular components is critical to identifying novel mechanical mechanisms of disease. Currently, atomic force microscopy (AFM) is used to measure the force-displacement relationship and calculate the stiffness of cell compartments. However, many factors can affect the accuracy of AFM measurements, and AFM tests may not provide the most reliable calculation of cell stiffness. There is a need for a robust model-driven approach that can identify the "optimal" locations for AFM measurements, minimizing the effect of factors such as cell geometry and loading conditions on the estimation of the unknown material parameters. In this work, we combined experimental AFM measurements with the development of a cell-specific finite-element (FE) model to estimate the cytoplasmic and nucleus stiffness via an inverse problem approach. The validated FE model was then used to propose an optimal design of experiments approach and identify the locations for force application that provide parameter estimation that is least dependent on confounding factors, thus leading to the robust, unique, and accurate stiffness estimation. This optimal design approach was then used to identify the optimal testing sites and material stiffness for an extended cell model, which includes the nuclear membrane. Results indicated that the optimal design of such cellular experiments can enhance the characterization of the material parameters. This method will ultimately provide a means to reliably predict cell-scale mechanical changes, allowing for the improved investigation of longitudinal mechanical adaptation in the presence of disease.

METHODS

Cell preparation and AFM

Isogenic human umbilical vein endothelial cells (HUVECs) were obtained and cultured as per previously published [1]. Cells were seeded onto glass coverslips, and AFM was performed on the live cells using a Catalyst Biomicroscope (Bruker) with a spherical probe of radius 1.25 μm. Force-indentation measurements were taken at two locations: the cytoplasm and the nucleus. Cells were then fixed and stained. Super-resolution imaging was performed using a Nikon n-SIM Structured Illumination Super-Resolution Microscope System with Z-stack spacing set to 100nm.

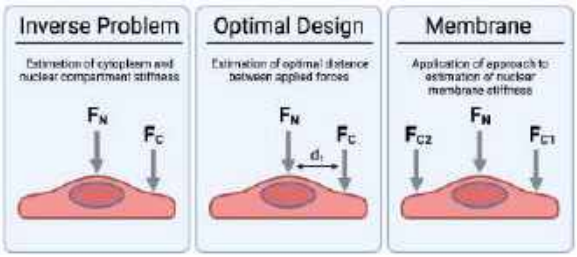

Figure 1: Material parameters were estimated via an inverse problem approach. An optimal design of experiments procedure was used to find the force application sites at which parameter estimation is most robust. The optimal design approach was applied to an extended cell model to accurately estimate the stiffness of the nuclear membrane.

Model development and parameter estimation

The 3-D reconstructed geometries of the cytoplasm and nucleus were used to develop an FE model of the cell. The cytoplasm and nucleus geometries were meshed with linear tetrahedral elements, and the nuclear membrane was modeled using triangular shell elements with a prescribed thickness of

35 nm. The components were modeled as isotropic, hyperelastic, nearly incompressible materials with a constitutive model of the form

$$W(\mathbf{E}) = \frac{a_i}{2b_i} e^{b_i(I_1-3)}; \quad i = c, m, n, \tag{1}$$

where a_c, b_c, a_m, b_m, a_n, and b_n are positive material constants governing the contribution of the cytoplasm (c), nuclear membrane (m), and nucleus (n), respectively. The kinematic variables I_1 is defined as $I_1 = tr\ \mathbf{C}$, where $\mathbf{C}$ is the right Green deformation tensor. The AFM probe was modeled as a thick-walled rigid sphere with an outer radius of 1.25 mm and a thickness of 0.15 mm.

An inverse modeling approach was used to estimate the material parameters. A least-squares optimization routine was used to estimate the material parameters that minimized the squared error between the measured and simulated reaction cellular force at each probe location. The parameter set was estimated simultaneously.

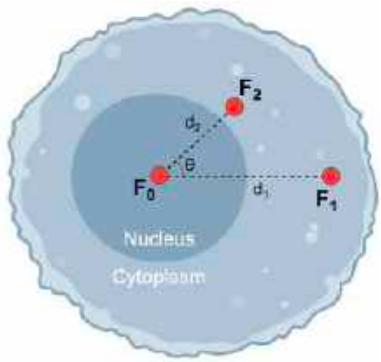

Figure 2: Schematic indicating the variation in locations at which the two cytoplasmic forces will be applied.

Optimal design of experiments

Identifying the optimal locations on the cell surface to conduct the simulated force-indentation measurements results in the best determinability and minimum covariance of the unknown parameters. This identification problem was set up as a parametric optimization of three parameters: d_1, d_2, and θ. The distance d_i is the distance of the applied force from the center of the nucleus, and the angle θ is formed by the two lines connecting the location of the applied cytoplasmic forces to the center of the nucleus (Fig. 2). A set of these parameters was chosen, and the optimal location was determined by minimizing the confidence region of the parameter set, effectively minimizing the covariance of the unknown parameters. This process was accomplished by defining an information matrix $\mathbf{M} = \mathbf{J}^T\mathbf{J}$, where $\mathbf{J}$ is the sensitivity matrix defined as the derivative of the model relative to the parameters. The confidence region was minimized by maximizing the D-optimality of the information matrix $\mathbf{M}$. This optimal design approach is described in detail by Avaz et al. [2].

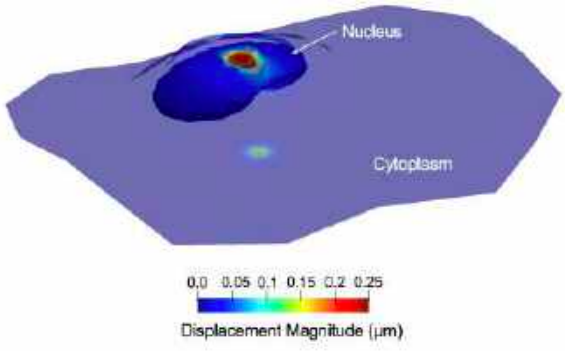

Figure 3: Representative FE simulation results visualizing the displacements in the cell upon application of forces on cytoplasm and nucleus.

RESULTS

Our approach for the optimal design of the experiment was initially conducted with a two-compartment (nucleus and cytoplasm) FE cell model for simplicity. Thus, only one factor was optimized, namely, the distance of the force application from the nucleus.

Table 1: Material parameters estimated by the inverse problem for the cytoplasm and nuclear compartments.

Cytoplasm		Nucleus	
a_c (kPa)	b_c	a_n (kPa)	b_n
7.37	1.08	4.05	1.00

Estimated material parameters

The estimated material parameters for the cytoplasm and nucleus compartments are presented in Table 1. Estimated material parameters indicated the nucleus is softer in comparison to the cytoplasm. The simulated displacement field is presented in Figure 3.

Optimal testing sites

Three locations of force application were compared using the two-compartment model and will be referred to as: near nucleus, middle, and near border. The results of the numerical comparisons between different force application sites are presented in Table 2. Recalling that the maximization of the D-optimality (Δ_D) coincides with the minimization of the confidence region, the results indicate the force application site nearest the cell border (furthest from the nucleus) is the most optimal.

Table 2: The D-optimality criteria for each force application site. Maximizing the D-optimality implies minimization of the confidence region of the parametric optimization.

	Near Nucleus	Middle	Near Border
Δ_D (10^2)	0.317	2.42	5.71

Future work will involve applying our approach to an extended model that includes the nuclear membrane.

DISCUSSION

This study aimed to present a novel integrated experimental-computational method to improve the process of cell-scale mechanical analysis. The accurate estimation of the material behavior of the cell is essential to the improved understanding of diseases that affect cellular mechanobiology.

Our results indicated that, indeed, there exist certain "optimal" sites at which the application of forces for parameter identification improves the identifiability and robustness of the estimation. Previous studies regarding the optimal design of experiments have indicated that the use of optimal sites additionally improves the predictive accuracy of the estimated parameters [2], and we expect to observe a similar improvement in future analysis of our approach. The stiffness of the nuclear membrane, although integral to the mechanical behavior of the cell, is an elusive measurement. The presented pipeline will be applied to similar cells to accurately estimate, for the first time, the stiffness of the nuclear membrane. These results will drive the use of such approaches in the design of cellular AFM experiments and, ultimately, improve the accuracy of the analysis of cellular mechanical properties and the mechanical adaptations of cells in disease.

INTRODUCTION

The incidence of breast cancer is increasing, accounting for 1 in 8 cancer diagnoses globally, with a 20-30% mortality rate associated with metastatic disease [1,2]. Bone is the most common site of breast cancer metastasis, where cancer cells can disseminate to bone even before the primary tumor is diagnosed [3]. Once established, metastatic tumors alter the normal bone physiology, resulting in uncontrolled bone resorption or formation and hyperplasia [4]. Biochemical factors (IL-6, PTHrP, TNFα) produced by cancer cells trigger bone resorption by osteoclasts, which drives the tumor metastatic progression in a vicious cycle.

Mechanical stimulation has been shown to both inhibit tumor progression and prevent bone destruction [5,6,7] and to increase tumor burden in a dose dependent manner [8]. Our group has created an engineered model of bone metastasis showing increased osteoblast-secreted proteins DMP1 and BSP2 in response to mechanical stimulation in mineralized cancer mimetic constructs [9]. Cancer cells have also been shown to induce an osteoblast inflammatory response [10] and disrupt osteoblast arrangement when in physical contact [11]. This indicates a phenotypic change in osteoblasts is partially responsible for the altered bone physiology during metastasis.

Alterations of osteoblast proliferation and viability, differentiation into osteocytes, and mineral deposition in the metastatic environment are not well understood, especially in the presence of mechanical stimulation. Additionally, crosstalk between osteoblasts and osteoclasts in the metastatic environment has not been well characterized. As such, the objectives of this study are to investigate 1) how osteoblast differentiation, proliferation, and mineral deposition is altered in the presence of cancer cells, 2) whether osteoclast resorption alters cancer cell mediated osteoblast activity and 3) if mechanical stimulation mitigates the cancer-induced phenotypic changes of osteoblasts.

METHODS

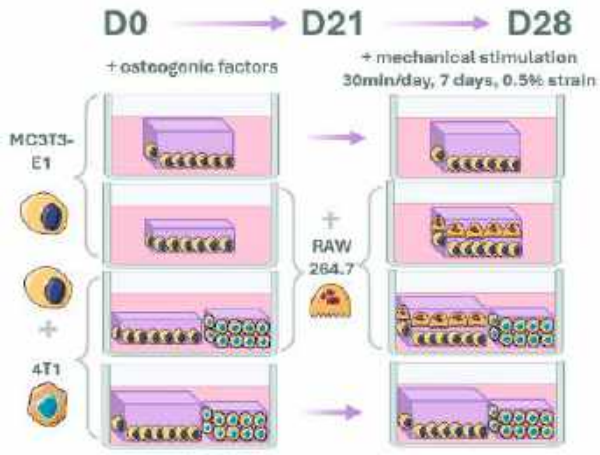

Figure 1: Experimental setup.

We engineered a segregated co-culture hydrogel model to isolate the paracrine effects of cancer cells on osteoblasts (Fig.1). Briefly, MC3T3-E1 murine osteoblastic cells (MC3) are cultured in standard conditions and embedded at 2×10^6 cells/mL in 3% w/v gelatin, 5.5% v/v nano-hydroxyapatite (nHA) and cross-linked with 0.3% w/w microbial transglutaminase. Triple negative murine mammary cancer cells (4T1) are cultured and embedded in a separate hydrogel under the same conditions.

MC3T3 hydrogels are either cultured alone or in the same well as 4T1 hydrogels as segregated co-cultures. All culture conditions are supplemented with osteogenic media (50 μM ascorbic acid, 10 mM β-glycerophosphate, and 100 nM dexamethasone) for 21 days to allow for mineralization of gels. On day 21, RAW264.7 osteoclast precursor cells (RAW) are added to MC3T3 gels in monoculture and co-culture with 4T1 gels. Unloaded controls remain in culture for an additional 7 days. Mechanical stimulation is applied to loaded groups for 30 minutes at 0.5% strain for 7 days. Live-dead staining is performed on day 21 to validate cell viability and quantify apoptotic rates in culture conditions. FITC, DAPI, and DMP1 staining is performed at days 7, 14, 21, and 28 to analyze MC3T3 morphology and differentiation. DNA, calcium, and ALP assays are performed at days 21 and 28 to analyze cell number and bone formation.

RESULTS

Live-dead staining on day 21 confirmed viability of MC3 cells in long-term hydrogel culture (Fig. 2A,E). Cell viability was higher in MC3 monoculture, with a live-dead ratio of 1.47 compared to 0.98 for MC3+4T1 co-culture. There was evidence of increased cell spreading in MC3 monoculture compared to MC3+4T1 coculture in confocal images of actin/nuclear on day 21 (Fig. 2B-C, F-G). Higher levels of visible mineral were found in MC3 monoculture gels (Fig. 2D) compared to MC3+4T1 co-culture (Fig. 2H).

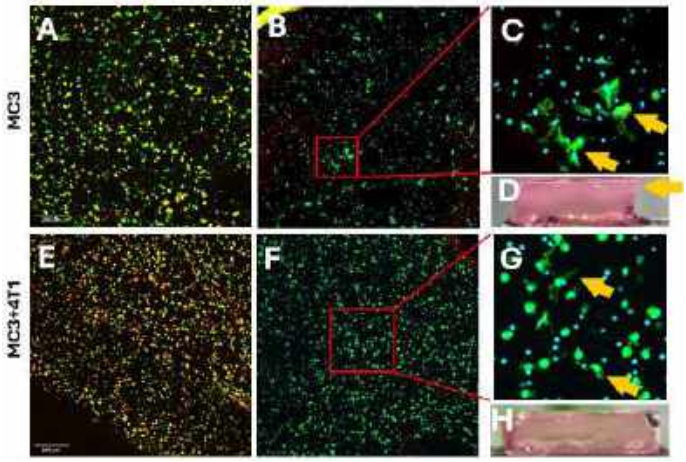

Figure 2: Live dead stain indicated greater cell viability in monoculture (A) than MC3+4T1 coculture (E). More cell spreading was seen in actin/nuclear staining of monoculture (B,C) than co-culture (F,G). Mineral deposition was visually apparent on day 21 in monoculture (D), but not co-culture (H).

DNA assays confirmed similar cell populations in all culture conditions at both time points ($p > 0.05$; not shown). Calcium content was elevated in MC3 monoculture and MC3+RAW co-culture conditions compared to cancer co-cultures, MC3+4T1 and MC3+4T1+RAW, at both 21 and 28 d ($p < 0.0001$; Fig. 3A). Interestingly, calcium content in MC3+RAW co-culture was lower at day 28 compared to day 21 ($p < 0.0001$), but unchanged in MC3+4T1+RAW tri-culture. Extracellular ALP activity was similar between culture conditions at day 21 ($p > 0.05$), except between MC3+RAW and MC3+4T1+RAW co-culture conditions (Fig. 3B). On day 28, the ALP level was highest in MC3+4T1 coculture ($p < 0.005$), and the MC3 monoculture levels were higher than the RAW cell groups ($p < 0.05$). Only the non-loading condition has been analyzed to date.

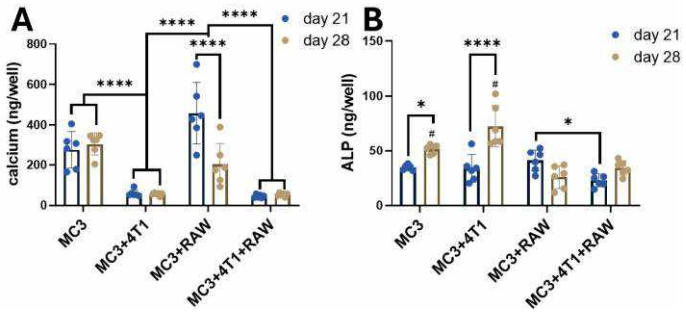

Figure 3: Calcium (A), and extracellular ALP (B) content measured after 21 and 28 d (* $p < 0.05$; **** $p < 0.0001$; # $p < 0.05$ vs +RAW groups at 28 d; N=6; bars are ±1 S.D.).

DISCUSSION

We developed a novel model of the breast cancer metastatic niche in bone to quantify the phenotypic changes of osteoblasts due to paracrine signaling with cancer cells in this environment. Our results demonstrate that osteoblast viability, morphology, mineral deposition and calcium content, and ALP expression are altered through crosstalk with tumor cells in this engineered metastatic niche. Notably, osteoblast mineral deposition and calcium content was greater in the absence of cancer cells. Osteoblasts similarly exhibited a more spread morphology in monoculture compared to co-culture with cancer cells. In contrast, ALP expression was highest in osteoblasts and cancer co-culture, consistent with elevated serum ALP levels in metastatic patients [12], but osteoclasts partially suppress this effect.

Overall, we have shown that triple negative mammary cancer cells alter the morphology of osteoblasts in a 3-D model, suggesting that cancer-associated osteoblasts (CAO) may contribute to altered bone physiology in the presence of metastasis. Future work in this project will further characterize how mechanical stimulation alters osteoblast phenotypic changes in co-culture with breast cancer cells.

INTRODUCTION

During pregnancy, the uterus undergoes structural and mechanical transformations to withstand the demands of a successful delivery [1]. In cases where vaginal birth is not feasible, a Cesarean section (c-section), which involves a transverse abdominal incision, is used to facilitate delivery of the fetus and placenta [2]. Following the procedure, the uterus and abdominal tissue are carefully sutured to support postpartum recovery, leading to uterine scarring at the incision site.

However, women who have undergone a c-section face an increased risk of uterine rupture when attempting vaginal birth in subsequent pregnancies. Uterine rupture is a rare peripartum complication that involves mechanical failure of the uterine wall during gestation or delivery [2]. While a history of vaginal delivery and successful vaginal birth after c-section may reduce the overall risk, factors such as multiple prior c-sections and single-layer uterine closure can elevate the likelihood of uterine rupture [3]. However, the effects of postpartum remodeling and involution on uterine scar integrity and the associated uterine biomechanical properties is not well understood.

Understanding the relationship between uterine scar integrity and biomechanical properties in non-pregnant tissue is a first step toward better understanding the biomechanics of postpartum involution and is essential to predict the risk of uterine rupture during future labor events. To this end, the aim of this project is to utilize ex-vivo mechanical testing to investigate the relationship between uterine scar structure and composition using a surgical model of uterine hysterotomy in nulliparous female mice. This project utilizes mouse uterine ring samples to assess the structural and mechanical properties of the uterus with the goal of quantifying the change in biomechanical properties throughout the healing process. The study will measure the strength of scarred uterus tissue through cyclic loading and extension to failure. Imaging via Optical Coherence Tomography (OCT) will provide insights into tissue structure. Ultimately, this project aims to unveil the connection between uterine scar healing and uterine tensile strength.

METHODS

Surgical Model of Uterine Scarring. Non-pregnant female wild-type mice (C57BL/6J) were anesthetized using sterile surgical technique prior to midline incision and externalization of one uterine horn. A 3-5 mm longitudinal uterine incision was introduced and subsequently closed with 6/0 absorbable suture prior to sterile washing and closure of the abdominal cavity. After closure of the uterus and abdomen, animals were allowed to recover for either 1, 2, or 3 weeks prior to euthanasia.

Mechanical Testing. Uniaxial loading of murine uterine samples was conducted using an ElectroForce 3200 Series III test instrument (TA Instruments). Figure 1a illustrates the comprehensive experimental setup, including two cameras to track tissue deformation and a saline bath for sample hydration. Figure 1b details the sample mounting fixture and is based on a setup previously published for use in mechanical testing of mouse reproductive tissues [1].

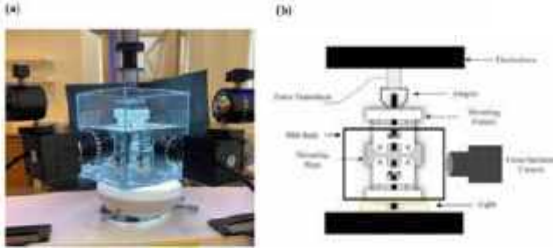

Figure 1: a) Complete experimental setup to test mouse uterine ring samples using the ElectroForce 3200 system. b) Detailed schematic outlining all components needed for proper mounting, imaging, and testing of uterine ring samples.

Uterine horn samples were submerged in PBS, gently cleaned of excess connective tissue, and cut into 2.5-3.5 mm sections (including any scars) to form the ring for mechanical testing. Prepared samples

were then mounted on the fixtures, illustrated in Figure 1b, by threading 2-0 silk suture through the inner lumen of the sample. The sample and mounting plate were then immersed in a PBS bath at 4°C for a minimum of 2 hours before testing to allow for tissue equilibration.

To execute the mechanical test on the ElectroForce 3200 machine, an adapter was added to the top adjustable fixture and secured to the force transducer (max: 45 N). After setting up the sample apparatus in an empty PBS bath and adjusting the actuator height, 400 mL of PBS were added to the bath to submerge the tissue. Finally, two high-resolution cameras were attached to the stage with one camera facing the tissue and the other positioned at a 90° angle from the front.

A preload of 0.01 N was established before testing to set a reference position. Four cyclical loads (0.1 N, 0.3 N, 0.5 N, and 0.7 N) were applied, each with a dwell time of 400 seconds between cycles to allow for tissue recovery toward an equilibrium state. The applied displacement rate was 0.1 mm/s, and each load level was repeated in duplicate. Following completion of the load cycles, samples were ramped until failure. Throughout the testing procedure, the output force-displacement data was recorded in a .csv file. A calibration tool was used to establish video scaling based on the camera lens settings. This allowed for real-time recording of sample geometry during testing for analysis of tissue mechanical properties and the generation of stress-strain curves for each load cycle until failure.

Estimating the geometry of the sample as a rectangular prism, the stress experienced by the uterine ring was calculated using the Cauchy Stress described in Equation (1).

$$\sigma = \frac{F}{A} \quad (1)$$

where F is the experimental force collected by the ElectroForce software and A is the current deformed cross-sectional area measured by the cameras. The cross-sectional area was defined to be that of a rectangular prism, referenced in Equation 2, where W and L are the width and length of the tissue sample as it deformed.

$$A = W \times L \quad (2)$$

To analyze the mechanical behavior of the tissue, the stress was plotted with respect to the stretch described in Equation (3).

$$\lambda = \frac{h}{H} \quad (3)$$

where H is the original height of the sample and h is the current height as measured by via LabView recordings. When testing to failure, the failure point was defined as the maximum stress experienced by the sample prior to a persistent decrease in measured force.

All of the force, geometric behavior, displacement, stress, and strain data was analyzed using Matlab. For statistical comparison, one-way ANOVA was performed with a Dunnett post-hoc comparison to determine differences from control with $p < 0.05$ considered significant.

RESULTS

After a longitudinal scar is introduced to the uterine horn, the uniaxial behavior of the tissue evolves throughout the healing process. Initially, the force required to rupture the tissue, as well as the Cauchy stress and stretch, decreases with respect to un-scarred control tissue ($p < 0.05$ at 1 week post-surgery; **Fig.2A**). The scarred uterine horn samples at each time point, however, can be displaced more prior to rupture than the control with the most prominent increase at 3 weeks after surgery (**Fig.2B**). Over time, the stress-stretch responses begin to resemble that of a normal murine uterine horn. However, the maximum Cauchy stress and stretch at rupture is still less than that of the control, suggesting some persistent tissue remodeling (larger cross-sectional area) that remains at 3 weeks post-surgery ($P< 0.05$, 0.01 at 1 and 3 weeks post-surgery; **Fig.3A,B**). OCT imaging at the location of uterine scarring confirmed the changes in tissue structure and geometry associated with post-surgical healing (**Fig.4**).

DISCUSSION .

The initial findings of this project provide insight into the uniaxial behavior of murine uterine tissue as it recovers from longitudinal scar placement. Despite the maximum rupture force returning to levels similar to the control after three weeks, the Cauchy stress and stretch remained lower than the control for all time points.

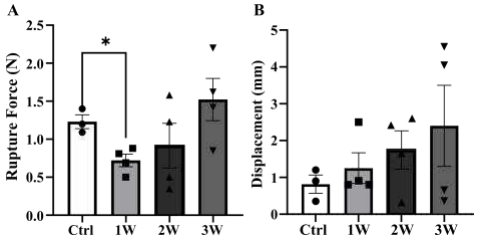

Figure 2: Maximum rupture force (a) and displacement (b) of murine uterine tissue after scar formation. * p < 0.05; one-way ANOVA with post-hoc Dunnett comparison to control.

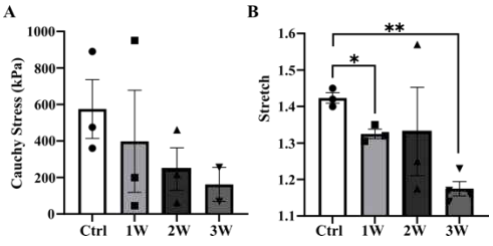

Figure 3: Cauchy stress (a) and strain behavior (b) at failure of murine uterine tissue after scar formation. *, p < 0.05, 0.01; one-way ANOVA with post-hoc Dunnett comparison to control.**

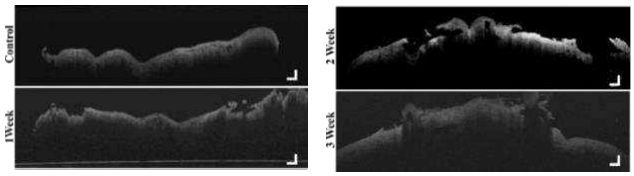

Figure 4: OCT imaging of scarred murine uterine tissue over time

Throughout the healing process, the microstructural composition of the scarred uterine wall must remodel to accommodate the biomechanical demands of the tissue. Thus, it is expected that scarring will affect the uniaxial biomechanical behavior due an increase in scar-related fibrosis. While our findings suggest uterine scar affects the uniaxial behavior of the uterus, additional mechanical testing approaches, such as biaxial testing, could further quantify how scar integrity impacts the likelihood of rupture. Our initial findings show that despite the longitudinal scar changing the tissue composition (see **Fig.4**), the biomechanical response of the uterus begins to return to the baseline values after three weeks of healing. Understanding the mechanobiology of this healing process in non-pregnant animals may also provide insight into the factors regulating c-section scar integrity.

INTRODUCTION

Stem cell engineering has been one of the most promising approaches for precision health nowadays. The Endothelial Colony Forming Cells (ECFCs) have demonstrated to exhibit a high proliferative potential have the unique ability to create *de novo* blood vessels *in-vivo*, indicating a higher angiogenic potential compared to mature endothelial cells like Human Umbilical Vein Endothelial Cells (HUVECs). As a result of these distinctive traits, ECFCs have shown promising therapeutic potential for various vascular disorders [1, 2, 3]. Acute renal failure, also known as AKI (Acute Kidney Injury), is characterized by a sudden decline in renal function primarily caused by ischemia/reperfusion (I/R) injury. This type of injury results in significant vascular damage, leading to capillary loss. Considering these challenges, researchers have explored the administration of exogenous endothelial cells as a potential strategy for treating AKI [4, 5]. Upon immediate injection, ECFCs were detected predominantly in the lungs, with an occasional presence in the kidney, liver, spleen, and heart. However, after 1 hour, ECFC density in the lungs decreased, and their presence in other tissues became scarce. By the 24-hour mark, ECFCs were barely detectable in any tissues [6]. This highlights the need to engineer a solution that can enhance the retention of ECFCs in the kidney, thereby improving their performance in promoting kidney regeneration. In this project, our goal is to utilize Liposome Nanoparticles (LNPs) not as conventional drug carriers but as vehicles to facilitate cell homing and create what it is refereed as the “backpack molecule”. To achieve this, a lipid formulation containing thiol-reactive maleimide headgroups is employed. This reaction is made possible by the presence of free thiol groups on the surface of ECFCs, which readily interact with the maleimide groups in the LNPs [7]. However, it is important to note that this interaction offers specificity.

While LNPs have demonstrated specificity, they lack selectivity, apart from their size, which is a crucial factor to cross organ barriers. To overcome this limitation, it is essential to identify a specific marker capable of target either the kidney or an AKI marker. Kidney-targeted Nanoparticles (NPs) designed for drug delivery have demonstrated great promise as an emerging strategy for AKI therapy. The Kidney Targeting Peptide (KTP) has demonstrated an enhance binding and high accumulation in proximal tubules and vascular endothelium of the kidney. These findings highlight the exceptional renal selectivity of KTP and support the notion that the construct is not species-specific, demonstrating its lack of acute renal toxicity [8]. Therefore, our general hypothesis is that our unique backpack molecule KTP-nanoparticle design will enhance the targeting efficacy of the ECFCs leading to vascular renal regeneration.

METHODS

Synthesis, Conjugation, and Characterization of LNPs with the KTP Peptide.

To facilitate the attachment of KTP to the LNPs, a free thiol group on the KTP peptide, referred to as KTP-SH is introduced. This modification can be achieved using Traut's reagent in a two-pot reaction. Subsequently, the KTP-SH can be attached to the LNPs via a click chemistry reaction, as the LNPs possess a maleimide group that can readily react with free thiol groups. Ellman's assay was employed to detect the successful modification of the KTP peptide after a 24h of incubation period. PEGylation was performed to block possible maleimide groups (MAE) promoting a non-specific interaction in the future with different thiol groups within the cell lines. Dynamic light scattering was performed to show the size distribution and Z-potential of the different sets of LNPs, before and after PEGylation. Absorbance measurements were done in a FITC-SH peptide to show the interaction of the thiol groups with the LNPs.

In-vitro Evaluation of the KTP-nanoparticle design.

The incorporation of the KTP peptide into LNPs (LNPs@KTP) is expected to enhance the selectivity of these nanoparticles for HRPTEpC cells compared to the ECFCs cell line. To establish this selectivity, flow cytometry studies was performed. This was done since a comparison of the behavior of the KTP with different kidney cell lines was previously described [8], therefore the same behavior is expected for our nanoparticle design.

RESULTS & DISCUSSION

The click-chemistry approach is suitable to decorate LNPs.

The modification of the KTP peptide was achieved as described in **Figure 1 A.** Free thiol groups can be detected by Ellman's absorbance assay few minutes after starting the reaction. **Figure 1 B.** Shows the difference between the free thiol groups on the Traut's reagent and the KTP-SH, demonstrating that the KTP after reaction do express free thiol groups which are suitable for the conjugation with the LNPs.

A. B.

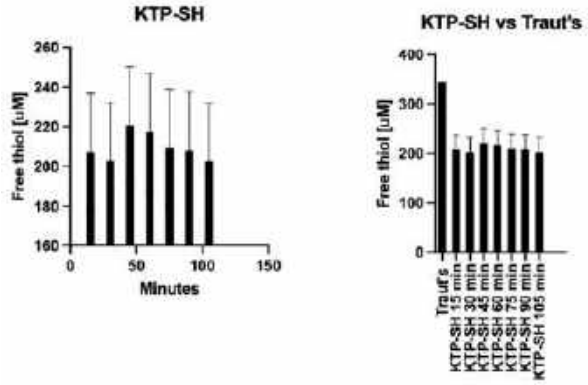

Figure 1. Time Course Analysis of Thiol Group Formation in KTP Peptide (KTP-SH) Reaction and it is a comparison with Traut's reagent. A. Kinetics of thiol group formation on the KTP peptide through a reaction with Traut's reagent. The experiment involves performing Ellman's assay readings at regular intervals (every 15 minutes) for a total of 105 minutes after initiating the KTP-SH reaction. B. Kinetics of thiol group formation on the KTP peptide vs Traut's reagent.

The decoration of the LNPs with the KTP was performed by a click chemistry reaction between the KTP-SH and MAE group on the LNPs (Figures 2, A and B), therefore a change in size and Z-potential is expected. The DLS characterization showed that the size of the LNPs is (141.8±5.6) nm and LNPs@KTP is (164.2±2.9) nm. Moreover, the Z-potential is -28.9 mV and, -30 mV for LNPs and LNPs@KTP respectively. Figure 2C shows the interaction of FITC-SH with the LNPs, where a positive FITC signal suggests that the decoration of the LNPs has been achieved. Those results suggest that the KTP has been successfully attached to the LNPs.

KTP peptide can attach to the preferentially with HRPTEpCs than the ECFCs.

The unique backpack molecule KTP-nanoparticle design showed to provide the expected selectivity for the Human Renal Proximal Tubular Epithelial Cells rather than the control cell line (ECFCs). Figure 4 displays the flow cytometry analysis for the binding studies were in quadrant 2 (Q2) is expected to have positive signal if the binding of the LNPs@KTP@PEG has been achieved, showing that with HRPTEPc (Fig 4A), a 91.3% of the cells are binding to the cell line and ECFCs (Fig. 4B), a 42.0% of cells are being positive for the binding. Those results show that the KTP has demonstrated an enhance binding and high accumulation on the HRPTEPc cell line.

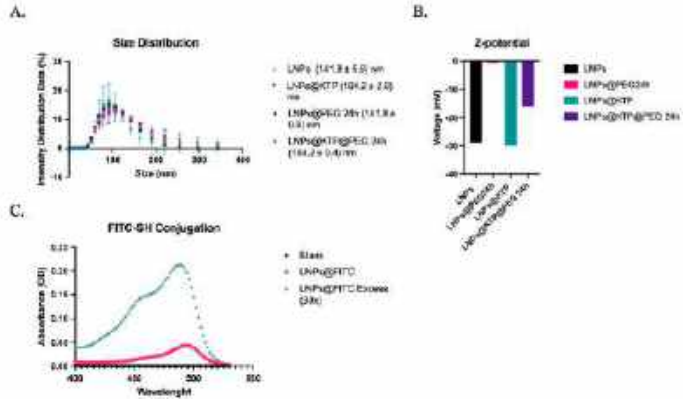

Figure 2. Verification of LNPs@KTP conjugation. A. Size Distribution Analysis for four different sets of LNPs designs. According to our measurements, the size range is (141.8±5.6) nm, (164.2±2.9) nm, (141.8±0.8) nm, and (164.2±0.4) nm for LNPs, LNPs@KTP, LNPs@PEG24h, LNPs@KTP@PEG24h respectively. B. The obtained Z-potential data set is -28.9 mV, -0.635 mV, -30 mV, and -16.1 mV for LNPs, LNPs@PEG24h, LNPs@KTP and LNPs@KTP@PEG24h respectively. C. LNPs showed to be positive for the FITC signal, which suggests that the click chemistry between the FITC-**SH** and the LNPs has been achieved with an excess of the reagent and with our synthesis conditions.

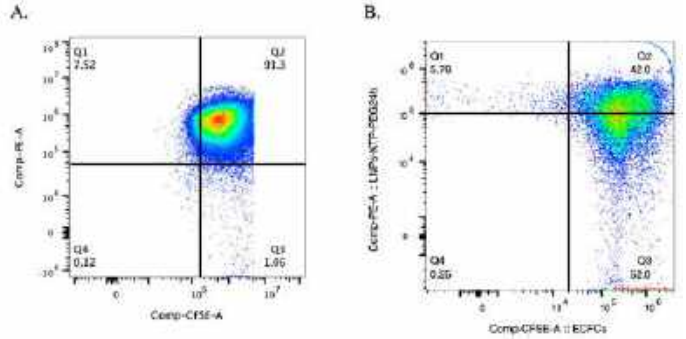

Figure 4. Binding studies for LNPs@KTP@PEG24h on different cell lines. Q4. Displays the double negative staining for PE (LNPs) and CFSE (cell line). Q2. Exhibits the double positive staining for PE and CFSE. Q1. Shows PE positive signal. Q3 Displays CFSE positive signal. A. Flow cytometry assay for the conjugation of HRPTEPc with LNPs@KTP@PEG24h where in Q2 can be appreciated that 91.3% of the cells are successfully binding with the nanoparticle design. B. Conjugation of the ECFCs where Q2 shows that just 42.0% of the cells are attaching to the nanoparticle design.

INTRODUCTION

Knee Osteoarthritis (OA) is a major source of pain for 86 million adults worldwide that lacks both approved therapeutic interventions and disease-modifying treatments. As OA progresses, cartilage composition and material property alterations can contribute to knee pain, joint instability, and biomechanical alterations, ultimately leading to joint destruction and impaired quality of life. Alterations to cartilage can be associated with a traumatic injury such as ligament rupture or can progress over time due to cell- and inflammation-related factors [1]. As nearly one half of individuals with an ACL tear develop post-traumatic OA within 10 years, joint injury cohorts provide an opportunity to study and characterize the development of OA at its earliest stages. Post-traumatic OA may progress from an initial injury in the superficial zone of cartilage to more widespread biochemical and mechanical changes throughout the zonal tissue cartilage, therefore quantifying changes to cartilage mechanical and biochemical properties non-invasively *in vivo* is of substantial interest.

MRI is unique among imaging tools as it can characterize tissues with high contrast and spatial detail and has a deep penetration depth [2]. Recent work supports that quantitative MRI mapping (T2, T2*, T1rho), can discriminate between subjects with mild OA and controls [1]. In other works, dualMRI has been used to calculate pixel level full field displacement maps of cartilage under repetitive motion [2]. In this study, we utilized both dualMRI and qMRI techniques to predict patient outcomes and cartilage function *in vivo* at 6 months post ACL-reconstructive surgery.

METHODS

Participant Recruitment: 32 participants were identified in the orthopedic clinic following unilateral ACL surgery 6±2 months prior to the MRI scan date. Participants ranged from 18 to 40 years of age, having received either a bone-patella tendon-bone autograft or quadriceps tendon autograft at the recommendation of one of three collaborating orthopedic surgeons. All subjects had ligament reconstructive surgery within 3 months of injury. All subjects had no prior history of concomitant, symptomatic knee pathologies on their ACLR knee and no injury or surgery to their contralateral knee. While supervised therapeutic exercise was generally prescribed following ACLR, rehabilitation was not standardized across the cohort. We obtained demographic information on all subjects, including age, sex, body mass index (BMI) and race at the time of recruitment. At the time of the scan, we also collected standardized patient reported outcomes (WOMAC score) to assess pain, knee stiffness, quality of life, and physical activity levels (Figure 1A).

Overview of MRI Method: An MRI-compatible loading apparatus capable of providing a varus load to the tibiofemoral cartilage of the knee, leading to compression of the medial femoral condyle was used to load the cartilage during scanning (Figure 1B) [3-5]. Moment conservation was used to calculate the load applied on the foot to be equivalent to 0.5 times body weight of load applied at the medial condyle. Patients were subjected to a 0.5 Hz cyclic loading regime (i.e., pneumatic, 1s load,1s unload) to mimic a walking cadence. The knee imaging protocol consisted of 3D double echo steady state (DESS) acquisition, quantitative T1ρ, T2 and T2* measurements, and DENSE MRI during cyclic varus loading on the knee joint (Figure 1A). All imaging was performed using a clinical MRI system (3 T; Siemens Prismafit) with a 15-channel quadrature knee coil (Tx/Rx Knee 15 Flare Coil, QED, LLC). For T1ρ images the spin-lock frequency was 500 Hz and the spin-lock durations was 20, 40, 60, 80 ms. T1ρ relaxation maps were calculated by fitting the four MR intensity images to a monoexponential relaxation model using non-linear least squares. T2 measurements were made using a multi-echo spin echo sequence with the following acquisition parameters: TEs = 13, 26, 39, 52, 65, 78 ms, TR = 1290 ms, flip angle = 180°, image average = 2 [3]. Spiral DENSE MRI was collected following preconditioning to a quasi-steady-state

load-displacement response. A steady-state response was achieved by applying 8 minutes of cyclic loading to minimize the viscoelastic response of articular cartilage [4,5]. 10 spiral interleaves were used to collect data on k-space and the temporal resolution was 40ms. Displacement encoding gradient was 0.64cycles/mm.

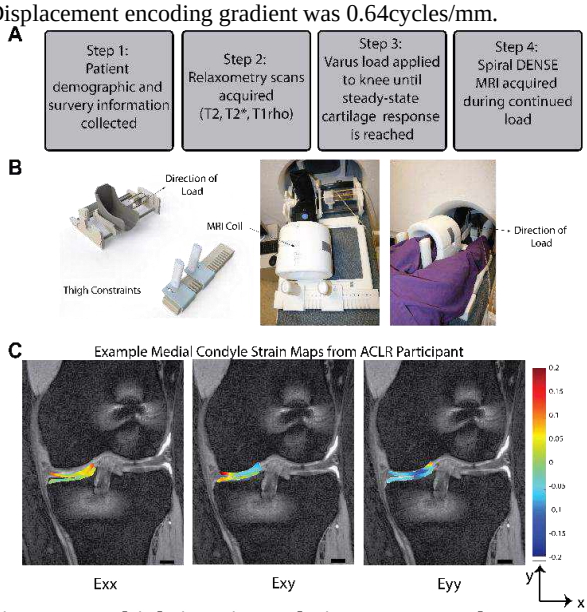

Figure 1: Multiple imaging techniques were used to assess cartilage response to load an ACLR cohort. (A) MRI scanning session workflow. (B) Varus-valgus MRI compatible loading device. (C) Example strain maps from DENSE MRI. Scale bars indicate 10mm.

MRI Data Processing and Statistical Analysis: DENSE MRI Data analysis was processed prior to qMRI processing. The articular cartilage was segmented via a semi-automatic segmentation algorithm into two regions of interest (ROI) based on the anatomical regions of the knee (i.e., medial femur, medial tibia). This was repeated on all 27 time frames. Locally weighted scatterplot smoothing (LOWESS) using a span of 10 and for 30 cycles was applied to raw displacement data to smooth the displacements. In-plane Green-Lagrange strains (Exx, Exy, Eyy) were then calculated on the ROIs from the smoothed displacement using the deformation gradient tensor (Figure 1C) [2]. On the T2, T2*, T1ρ maps, ROIs were selected analogous with the DENSE ROIs. The mean value for each MRI metric within each ROI (femoral and tibial) was then calculated. Correlations were then calculated among MRI metrics and the WOMAC score using a linear mixed-effects model, with patient treated as a random effect and multiple fixed effects accounting for potential covariates (Figure 2). [1]. A mixed effects linear prediction model of patient-reported outcome severity with variable inclusion based upon the previous models was developed (Figure 3).

RESULTS

We found that femoral shear strain best predicted patient-reported outcomes at six months ($p = 0.032$, $R^2=0.41$). We observed that increased shear strains were correlated with worse patient reported outcomes as quantified by higher WOMAC score. This is supported by our previous work demonstrating shear in cartilage explants as a potential biomarker for cartilage degeneration [1]. We also found that axial strain (Exx) was correlated with increased WOMAC score ($p = 0.031$, $R^2=0.42$). No significant correlations were found between WOMAC score and average T2 or T1ρ values. T2* was additionally correlated with WOMAC score with higher T2* indicating a higher WOMAC score, and therefore a worse outcome ($p = 0.005$, $R^2=0.53$).

We also found that the combined use of multiple MRI metrics (multiparametric analysis) may predict patient reported outcomes better than any single MRI metric (Figure 3). The predicted OA scores of a statistical model that contains Exy, T2, T2*, age, surgeon, and graft type were compared to measured scores. This combined model matches the actual data better than either dualMRI or relaxometry individually.

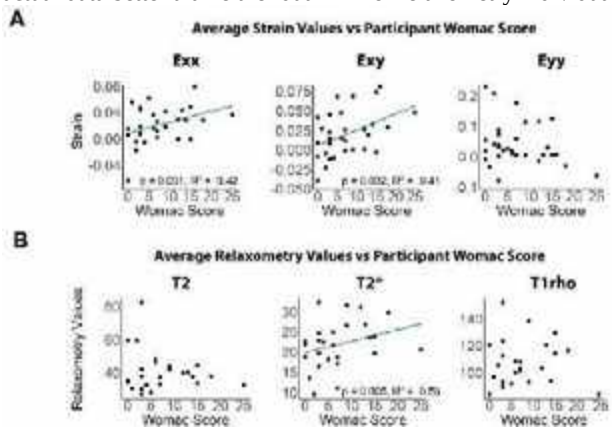

Figure 2: Average strain (A) values and relaxometry (B) values regressed against participant WOMAC score in the medial femoral cartilage region of interest.

DISCUSSION

While previous work has linked macro-scale whole joint mechanical changes post-ACLR, to our knowledge no other studies have quantified tissue level mechanical changes in cartilage *in vivo* in a post-ACLR population. This work provides a small cohort proof-of-concept of an MRI framework to non-invasively determine cartilage strains in a clinical setting. The results support the use of DENSE MRI, in particular shear strain [1,2], as a potential diagnostic tool to evaluate early cartilage degeneration. There is a clinical need for a noninvasive imaging method that can detect and measure articular cartilage changes before cartilage loss occurs. This data demonstrates the potential of dualMRI, particularly in conjunction with other imaging biomarkers, to fulfill that need.

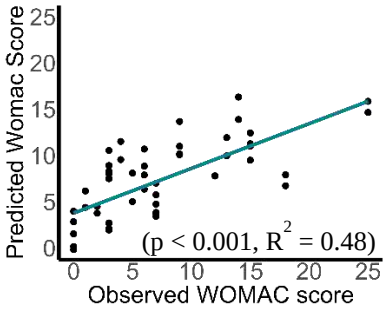

Figure 3: Multicontrast MRI improves results over either dualMRI or qMRI in an ACLR cohort.

INTRODUCTION

Articular cartilage lines the ends of long bones in synovial joints and provides load-bearing and low-friction articulation. These biomechanical functions are largely driven by the poroelastic mechanics of the articular cartilage [1]. Unfortunately, the same poroelastic pressure that leads to load-bearing and lubrication also drives fluid exudation and concurrent tissue consolidation (strain). Static loading in vivo (e.g., standing) produces as much as -30% strain in 60 min. Active loading (e.g., walking, knee bends, cycling, running) in vivo also produces an initial period of fluid exudation and strain (~ -5%) [2]. Interestingly, active loading beyond this initial period leads to a maintenance of tissue hydration and strain unlike static loading [3]. While static and active loading drive fluid exudation and cartilage strain, static unloading (e.g., lying down) provides recovery, and to date, is the only in vivo mechanism that has been shown to restore hydration and strain.

We hypothesize that active loading is actually a hydration and strain recovery mechanism that has yet to be observed. In this study, we investigate whether active loading (walking) is only an exudation and arresting mechanism or whether it is also capable of recovery. We use magnetic resonance (MR) imaging to evaluate the in vivo strain of articular cartilage in human knees following: (1) standing (static loading), (2) lying down (static unloading), and (3) walking (active loading). Furthermore, we evaluate measurement repeatability within and between raters, and with and without blinding.

METHODS

Participants. Following IRB approval, we recruited N=8 asymptomatic young adults to participate in the study. Participant age (29 ± 3 years of age, mean ± 95% confidence interval), biological gender (4 male, 4 female), and BMI (23 ± 2) were recorded. Up to 5 days prior to MR scanning, participants were given a wrist worn activity monitor to track the number of steps taken each day (13 ± 5k steps/day). Knee joint health was assessed using the self-reported Knee Injury and Osteoarthritis Outcome Score (KOOS).

MR Scanning. Participants arrived at the MR facility on the day of scanning and were positioned within the scanner (3T MAGNETOM Prisma, Siemens) with a 15 channel Tx/Rx knee coil around their right knee. Participants were scanned in the following fixed order: (1) baseline, and immediately after (2) 30 min of standing, (3) walking for 10 min at 110 steps per min, (4) 30 min of standing, and (5-8) 12, 24, 36, and 48 min of lying down (**Fig 1**). A proton density weighted turbo spin echo (PD-TSE) was used to assess the morphology and thickness of the articular cartilage. The in-plane resolution and slice thickness were 0.3 and 1.5 mm respectively.

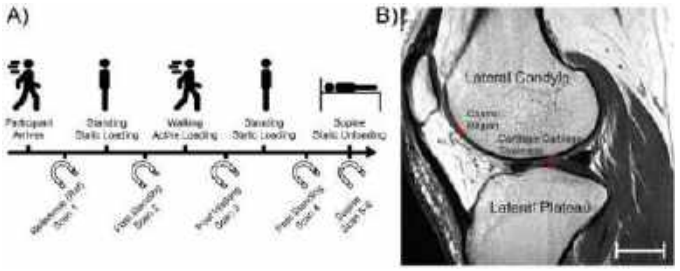

Figure 1: (A) Order of activities. MR scanning is indicated with the magnet symbol, and the numbering corresponds to the scan number, see section *MR Scanning*. (B) Representative measurement locations on a PD-TSE MR image.

Data Analysis. We calculate cartilage thickness as the tibiofemoral bone-to-bone distance within the medial and lateral compartments, measured within the region of contact. MR scans were registered to the baseline scan to ensure the same region was measured. We calculate cartilage strain as the change in cartilage thickness divided

by the baseline thickness. All values are reported as the mean ± 95% confidence interval unless stated otherwise.

Repeatability Analysis. Repeatability was determined through intra-rater and inter-rater assessments. Rater 1 measured the strain in all conditions and then repeated this analysis on a separate day without reference to the original measurement locations. Rater 2 measured the strain in all conditions without reference to Rater 1's measurement locations. In a final test, Rater 2 was blinded to the scan order and performed the same analysis without reference to the original measurement locations.

RESULTS

The average strain in the medial and lateral compartments for 8 participants are shown in **Fig 2 A&B**. The baseline strain is set at 0%. After 30 min of static loading (standing), there is a clear thinning of the articular cartilage to an average -5.0 ± 0.4 and -5.3 ± 0.6% strain in the lateral and medial compartments. Following a 10 min walk (active loading), the cartilage thickness recovers 2.3 ± 0.3 and 2.6 ± 0.6% strain, which directly agrees with our hypothesis that active loading is capable of recovery. Following another bout of static loading to approximately the same strain (-5.4 ± 0.3 lateral and -5.1 ± 0.5% medial) the participant lies supine (static unloading), and the cartilage thickness and strain progressively recover. Following the first scan (12 min post standing), the cartilage recovered 1.5 ± 0.6 and 1.1 ± 1.0% strain in the lateral and medial compartments. Following 48 minutes of unloaded recovery the cartilage recovered 3.8 and 3.6% strain in the lateral and medial compartments.

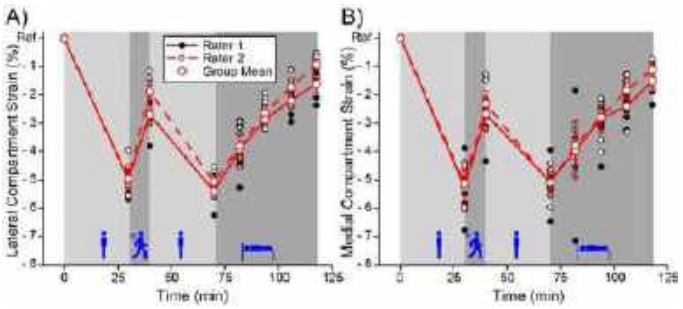

Figure 2: Cartilage strain in the central region of contact for all 8 participants in both the (A) lateral and (B) medial compartments. Individual and mean measures are shown for both Rater 1 and Rater 2.

Repeatability was assessed by quantifying the bias (mean difference) and the ± 95% confidence interval. Intra-rater repeatability was found to be -0.2 ± 0.1% strain. Inter-rater repeatability was found to be -0.3 ± 0.2% strain, see **Fig 2 A&B**.

DISCUSSION

While epidemiological studies have documented the chondroprotective nature of joint activity, we have yet to identify the mechanism that provides chondroprotection. The observation that in vivo active loading recovers cartilage strain, and possibly hydration, opens new opportunities for understanding the long term biomechanical and cellular responses to active loading. Furthermore, the simplicity and repeatability of the analysis method demonstrates methodological robustness and potential for translation.

A COMPUTATIONAL MODELING APPROACH FOR THE FORENSIC ANALYSIS OF INFANT SHORT HEIGHT FALLS

Keith D. Button (1), Yun Cai (1), Luis A. Nolasco (1), Brian T. Weaver (1)

(1) Explico Inc., Novi, MI, USA

INTRODUCTION

Intracranial bleeding, such as subdural and subarachnoid hemorrhaging, represents a serious and potentially life-threatening medical condition. In infants, the presence of intracranial bleeding can potentially be the result of non-accidental trauma. As such, it is especially important to utilize forensic biomechanics techniques to investigate the etiology of infant intracranial bleeding to determine if the scenario presented by the caretaker provides the requisite biomechanical environment to cause these injuries.

Biomechanically, intracranial bleeding occurs as a result of injurious levels of rotational head acceleration [1,2]. Since rotational head acceleration can be imparted as a result of direct impact or inertial loading, biomechanical studies have investigated rotational acceleration induced by both loading environments [3,4]. The first study to investigate this was conducted by Duhaime and colleagues[3]. The authors crafted a model of a 1-month-old infant and exposed it to violent shaking and impact by both male and female experimenters, finding that direct impact produced significantly higher magnitudes of rotational head acceleration. A subsequent study by Prange et al. utilized an anthropomorphic surrogate of a 1.5 month old to simulate falls from short heights (0.3, 0.9, and 1.5 m), vigorous shaking, and inflicted head impact [4]. In a more recent study by Ibrahim et al., the authors developed an updated anthropometric test device and performed drops at 0.3, 0.6, and 0.9 [5]. Results from the Ibrahim and Prange studies showed substantially lower magnitudes of angular acceleration produced by shaking when compared with short-height falls onto both concrete and carpeted surfaces. The next logical step would be to present an approach that allowed for the subject-specific analysis of short-height fall scenarios for the investigation of real-world accidents.

Physical testing has previously been conducted documenting the impact characteristics between the head and various household surfaces. These studies demonstrate that the duration of head impact for more rigid surfaces such as concrete and hardwood typically range between 5 and 7 ms and 7 to 13 ms for more compliant surfaces such as carpet [5–7]. The purpose of the current study was to develop a computational approach to investigate the angular head accelerations experienced during short-height falls allowing for variable drop heights, infant anthropometry, and impact duration for comparison with an applied aggressive shake using MADYMO (MAthematical DYnamic Models). The authors hypothesized that simulated short-height falls would produce greater magnitudes of angular head acceleration than simulated shaking events.

METHODS

Part 1: Simulated Falls/Shakes Using HIII Crash Test Dummy

In order to develop a methodology applicable to the investigation of real-world accidents, it is important to utilize a subject-specific model, scaled to the height and weight of the subject being analyzed. As such, simulations were conducted using the Hybrid III 6-year-old Anthropomorphic Test Device (HIII 6YO ATD), which is a scalable ATD. The HIII 6YO ATD has been validated using component-level tests at the neck, neck/head, and thorax. The HIII 6YO ATD was scaled to the height and weight of a 1 year-old ATD (0.740 m and 9.6 kg).

In MADYMO, the ATD was positioned at heights of 0.3, 0.6, 0.9, and 1.5 m and dropped to the surface (Figure 1). The interaction between the ATD and surface was modulated by adjusting the friction, damping, and impact characterization function to produce impacts with durations of 5, 7, 10, and 13 ms to represent the range of impact characteristics most commonly encountered during household falls. The influence of contact duration and drop height was evaluated using an ANOVA.

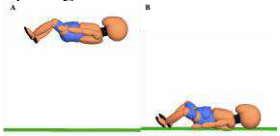

Figure 1: Initial (A) and final positions (B) of drop simulation (0.2 m).

In addition to simulated falls, an aggressive shake was simulated (Figure 2). For this analysis, the ATD was suspended in the air and the torso was accelerated and decelerated based on data provided by Wolfson et al. [8]. In this study, ten volunteers were asked to shake an infant ATD as long and hard as they could. The torso-acceleration trace provided by the authors was applied to the ATD torso and had a maximum linear acceleration of 9 g's.

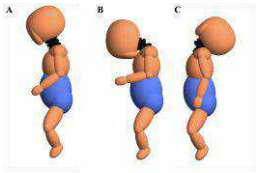

Figure 2: Initial (A), max flexion (B), and max extension of shaking simulations

Part 2: Simulated Falls/Shakes Using HIII 6 Y/O

RESULTS

The maximum linear acceleration and angular head accelerations for the simulated impacts and shakes are depicted in Figure 1 and Figure 2, respectively. Maximum linear (211 g) and angular (46,642 rad/s^2) head accelerations occurred at a drop height of 1.5 m and pulse duration of 5 ms. Minimum linear (22 g) and angular (5,044 rad/s^2) head accelerations occurred at a drop height of 0.3 m and pulse duration of 13 ms. All impacts produced greater linear and angular head accelerations than the shaking simulations (14 g and 1,457 rad/s^2, respectively). A 2-factorial ANOVA (height and duration) found an increase in height and decrease in contact duration to significantly increase the angular ($p < 0.05$) and linear ($p<0.01$) head acceleration.

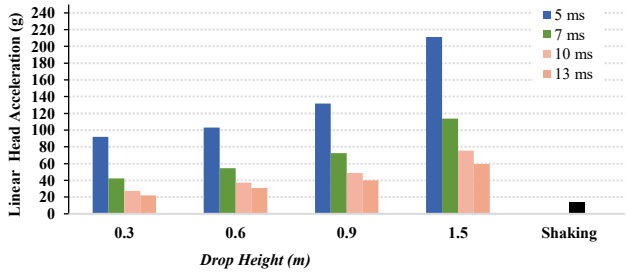

Figure 2: Linear Head Acceleration Resulting from Simulated Short-Height Falls and Shakes

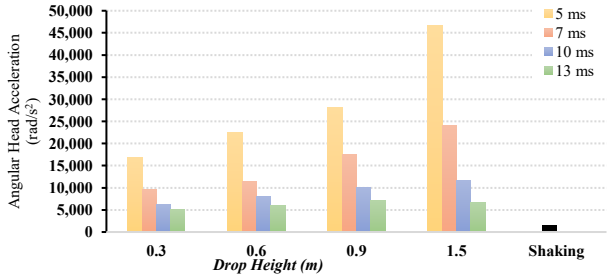

Figure 2: Angular Head Acceleration Resulting from Simulated Short-Height Falls and Shakes

DISCUSSION

Biomechanical work conducted over the last three decades has repeatedly demonstrated the risk of serious and sometimes fatal injuries occurring from short-height falls in infants. The current study presented a computational approach to analyze short height falls with subject-specific inputs for infant anthropometry, fall height, and impact duration.

Results of the simulations were closer to the experimental work done Ibrahim et al. than the work done by Prange et al. [4, 5]. Specially, Ibrahim documented angular head accelerations on carpet (contact durations of 7 ms) of 5,000, 18,000, and 15,000 rad/s^2 at drop heights of 0.3, 0.6, and 0.9 m, respectively. For comparison, the angular head accelerations calculated in the current model at the same heights and duration were 9,536, 11,312, and 17,568 rad/s^2. Prange, however, documented angular head accelerations of between 28,000 and 70,000 rad/s^2 for carpeted drops and between 39,000 and 85,000 rad/s^2 for concrete drops between 0.3 and 1.5 m. It is noteworthy that the Ibrahim neck model was validated based on adult humans and pediatric caprine and primate models, while the Prange neck model utilized a custom-built resistance-free hinge joint. The general agreement between the computational modeling results and the Ibrahim study demonstrates the potential for the use of MADYMO to analyze real-world infant falls using subject-specific modelling. Furthermore, the modeling indicates that short-height falls produce larger head angular head acceleration than aggressive shaking for all impact conditions. These computational results are in agreement with previously-conducted biomechanical studies using various ATDs.

Traumatic acute subdural hemorrhaging occurs as a result of bridging vein rupture. Bridging vein rupture has been produced in adult cadavers at rotational head accelerations between 5,267 and 13,411 rad/ s^2, with a proposed threshold of 10,000 rad/s^2 [1]. All the head accelerations for the 5 ms simulations, the 7 ms simulations at 0.6, 0.9, and 1.5 m, and the 10 ms simulation at 1.5 m exceeded this threshold. While there is currently no accepted threshold to produce bridging vein rupture in infants, the literature reports several videotaped incidents which resulted in bridging vein rupture in infants. One such study documented an incident in which a two-year old child suffered a fall from 71 cm onto a 95 mm thick piece of plush carpet remnant covering a concrete floor, striking first with outstretched hands, then with the right front side of her forehead. The child was diagnosed with a subdural hematoma and bilateral retinal hemorrhaging and the fall was witnessed by the child's grandmother and was videotaped [9]. Another study documented a case in which a 5-month old infant fell from a 5-year old's lap who was seated on an office swivel chair [10]. The infant fell less than 1 m onto a wooden deck and suffered subdural hemorrhages and multilayered retinal hemorrhages. The fall was captured via a home security camera. By utilizing the subject-specific modeling techniques outlined above, there exists the potential to develop thresholds to produce intracranial bleeding in infants based on the information provided by these real-world incidents. These thresholds can be instrumental in the forensic analysis of infant head injury. Additionally, these thresholds could provide valuable information to assist with the design of a safer household environment to protect infants from serious head injury.

FIBER ALIGNMENT AND TORTUOSITY INFLUENCE THE LOAD-CARRYING PERFORMANCE OF THE LAMINA CRIBROSA COLLAGEN BEAMS

INTRODUCTION

The lamina cribrosa (LC) is a trabecular structure consisting of an intricate network of collagen beams that support the delicate retinal ganglion cell axons passing through the pores. [1] The mechanical strength of a beam, vital for its load-carrying performance, is largely determined by its mechanical properties, such as anisotropy (directional stiffness) and nonlinearity (strain-dependent stiffness). [2, 3] Using polarized light microscopy, we observed that collagen fibers align along the beam direction and exhibit a natural crimp with quantifiable tortuosity (path length divided by end-to-end length). [4, 5] However, the influence of fiber alignment and tortuosity on the load-carrying performance of collagen beams remains unclear.

In this study, we developed a specimen-specific model of the LC collagen beams. Following that, we generated three variations of this model by assigning distinct beam mechanical properties: isotropic, anisotropic, and anisotropic with tortuosity. Subsequently, we compared the stress/strain responses of these models under uniaxial stretch to identify the roles of fiber alignment and tortuosity in the load-carrying performance of the collagen beams in the LC.

METHODS

A coronal section of the sheep LC, with a thickness of 16 μm, was imaged using polarized light microscopy (**Figure 1**). The energy information obtained from the image was used to segment the collagen beams in the LC. Based on the segmentation, we reconstructed the model geometry in SolidWorks. We then generated three variations of this model by assigning distinct beam mechanical properties: isotropic, anisotropic, and anisotropic with tortuosity. Specifically, we employed an anisotropic hyperelastic constitutive equation developed in our previous study. [6] This equation allows for incorporating fiber orientations and tortuosities measured by polarized light microscopy. We set the 1st Mooney-Rivlin constant at 150 kPa, and the modulus of straightened fibers at 30 MPa. A concentration parameter, denoted as k, was introduced to regulate the distribution of collagen fibers. For isotropic properties, k was assumed to be zero, while for anisotropic properties, k was set to 2. In addition, we defined a bulk modulus of 0.1 GPa to ensure tissue incompressibility. [7] All models were subjected to uniaxial stretch. Two in-plane loading conditions were considered at the right boundary of the model to simulate a 'pull' from the peripapillary sclera: a pressure of 3 kPa and a displacement of 200 μm (equivalent to 10% stretch). All models were solved in FEBio v2.9.1 with eight-noded hexahedral elements. Convergence tests were performed, and adequate accuracy was achieved with an average element length of 25 μm. We quantified the maximum principal strain (a measure of stretch) and the von Mises stress (a measure of force).

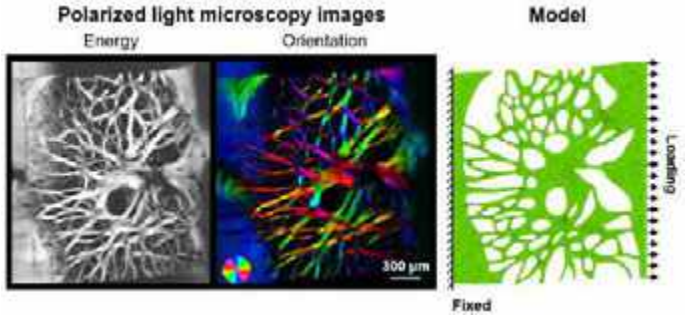

Figure 1. Illustration of the modeling approach. A coronal section (thickness: 16 μm) of the sheep LC was imaged using polarized light microscopy. The energy image represents collagen density, while the orientation image utilizes colors to indicate fiber orientations. The model geometry was reconstructed based on the energy information, and the anisotropic mechanical properties of the model were defined using the orientation information. To simulate uniaxial stretch, full constraint was applied to the left boundary of the model, and in-plane loading was exerted on the right boundary.

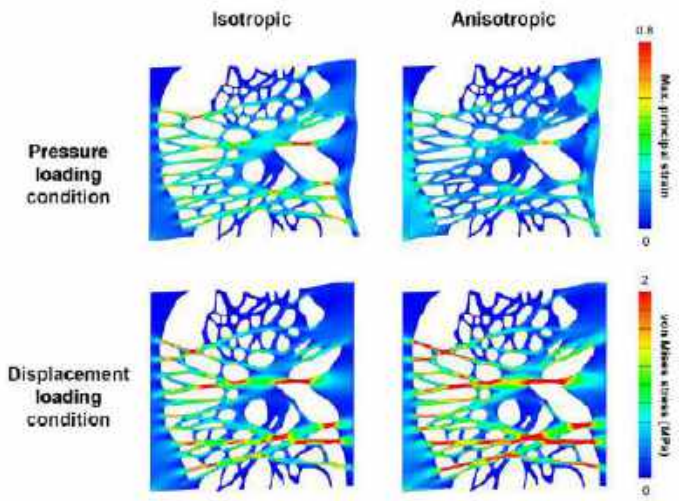

Figure 2. Model-predicted maximum principal strain (top row) and von Mises stress (bottom row) under the pressure and displacement loading conditions, respectively. When subjected to the pressure loading condition, the model with anisotropic mechanical properties demonstrated lower strain compared to the model with isotropic mechanical properties. Conversely, under the displacement loading condition, the model with anisotropic mechanical properties exhibited higher stress than the model with isotropic mechanical properties. These observations collectively indicate that fiber alignment enhances the stiffness and load-carrying performance of the collagen beams.

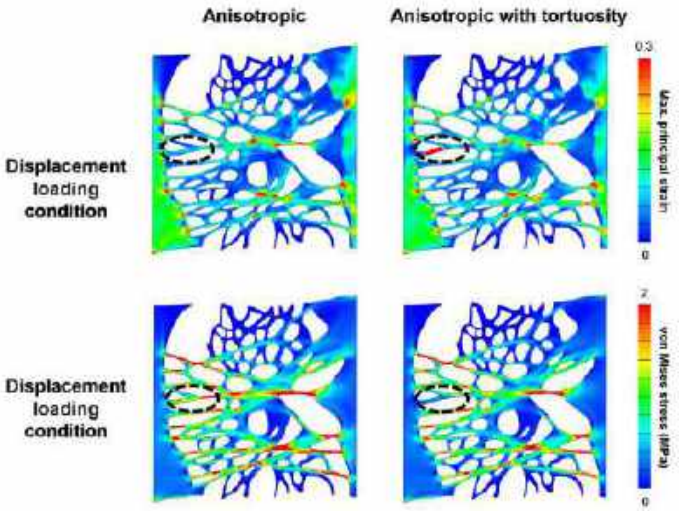

Figure 3. Model-predicted maximum principal strain (top row) and von Mises stress (bottom row) under the displacement loading condition. In the model incorporating anisotropic mechanical properties with tortuosity, the stress of the collagen beams decreases, while the strain increases compared to the model with anisotropic mechanical properties alone. This trend is particularly pronounced in collagen beams exhibiting relatively large tortuosity, as indicated by the dotted ellipse. These results imply that fiber tortuosity reduces the load carried by the collagen beams at the expense of increasing their elongation.

RESULTS

In our analysis, we first examined the impact of fiber alignment by comparing the maximum principal strain and von Mises stress between the models with isotropic and anisotropic mechanical properties (**Figure 2**). Subsequently, we investigated the effects of fiber tortuosity by comparing the maximum principal strain and von Mises stress between the models with anisotropic mechanical properties without and with tortuosity information (**Figure 3**).

DISCUSSION

Our goal was to study the roles of fiber alignment and tortuosity on the load-carrying performance of the LC collagen beams. Two main findings arise from this study: 1) fiber alignment enhances the stiffness and load-carrying performance of the collagen beams, and 2) fiber tortuosity reduces the load carried by the collagen beams at the expense of increasing their elongation. Below we discuss each finding in detail.

In comparison to the model incorporating isotropic mechanical properties, the model incorporating anisotropic mechanical properties exhibited increased stresses during uniaxial stretch. This implies that fiber alignment plays an important role in enhancing the stiffness and load-carrying performance of the LC collagen beams, which is of paramount significance when considering the impact of elevated intraocular pressure. The increased stiffness of collagen beams, resulting from fiber alignment, may serve as a protective mechanism for the delicate neural tissues and intricate vascular network within the LC, by bearing more of the load imposed by increased intraocular pressure.

In the model incorporating anisotropic mechanical properties with tortuosity, the stress of the collagen beams decreases, while the strain increases in comparison to the model with anisotropic mechanical properties alone. This trend is particularly pronounced in collagen beams exhibiting relatively large tortuosity. Our findings indicate that fiber tortuosity acts to reduce the load borne by the collagen beams, albeit at the expense of increasing their elongation. Our earlier study has demonstrated distinctions in fiber tortuosity between thin and thick beams in the LC. [8] Specifically, the thicker beams exhibited greater tortuosity compared to their thinner counterparts, implying that these thicker beams may only stiffen under higher intraocular pressure when subjected to substantial deformation.

In conclusion, our models predict that the load-carrying performance of the LC collagen beams depends on fiber alignment and tortuosity. This understanding of the interplay between fiber alignment, fiber tortuosity, and load-carrying performance offers valuable insights into the biomechanics of the LC, particularly concerning elevated intraocular pressure and its potential implications for retinal ganglion cell axon damage in glaucoma.

INTRODUCTION

Obesity has been reported to increase the risk of breast cancer. Those with obesity who have breast cancer also have a poor prognosis with increased rates of metastasis and decreased rates of cancer-free survival. Current obesity models [1, 2] do not use adipocytes and instead utilize adipose-derived stem cells or are 2D models that don't recapitulate the 3D environment of the human body. Mice are often used to model obesity but lack human physiology. While the impact of obesity on breast cancer risk is clinically clear, the effect of an increased adipocyte density within the breast tissue, which occurs in the case of severe obesity, has not yet been investigated.

METHODS

Adipocytes were detached using trypsin and strained to remove any remaining stem cells. Adipocytes were then mixed into a 6.6 mg/mL solution of human collagen at low (4 million cells/mL) or high (16 million cells/mL) densities, loaded into a bioprinter, and droplet printed into a 96-well plate to form low- or high-density adipocyte stromal compartments.

Tumor spheroids were immediately collected by aspirating with a micropipette, loaded into the bioprinter cartridge, and printed into the stromal compartments (adipocyte-laden collagen). The low- and high-density adipocyte-collagen systems were allowed to gel at 37 °C before being cultured in basal medium (Fig. 1).

Models were then cultured and imaged for live/dead analysis and nile red stained. Alamar blue assays were performed every four days. After two weeks of culture, models were fixed and sectioned and stained for Ki67, MMP-2, MMP-9, ZEB2, and E-Cadherin.

Data were analyzed for statistical significance using GraphPad Prism 6. Welch's t-test was performed to compare the results. Data are presented as the mean ± standard deviation (SD).

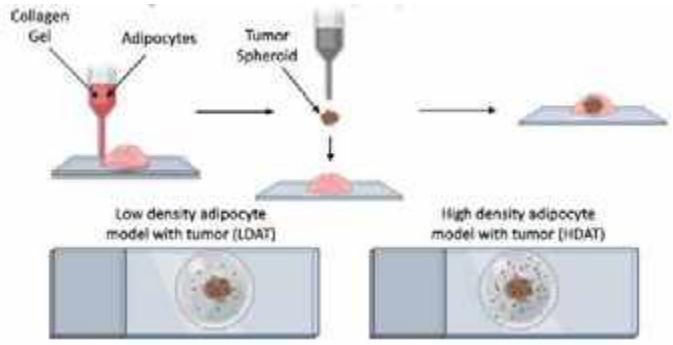

Figure 1: Depiction of 3D model printing schematic and final model configurations.

RESULTS

After 3D bioprinting the models, we first characterized it through brightfield imaging, live/dead staining, and Nile red staining to confirm its viability. We showed through live/dead staining that the bioprinting process did not kill the cells or disintegrate the spheroids and that we had an intact model with cell viability in the range of 66%-88% (mean: 78% ± 9.2%). We also stained the models with Nile red stain to show that the adipocytes were still intact within the gel. The Nile red stain confirmed the presence of two different adipocyte density models.

Next, we wanted to study the effects of the increased adipocyte density within the model on the tumor spheroid. We first investigated its effects on proliferation of the tumor spheroid. We cultured our models for two weeks and performed an Alamar blue assay on days 1, 4, 7, 10, and 14 to study the effect of high adipocyte density on metabolic activity of the tumor cells (Fig. 2A). We found an overall increase in signal, which corresponds to increase in metabolic activity, over the course of the culture time for the high-density adipocyte with

tumor (HDAT) model. Models without tumors were used as negative controls and the unchanged signal with the tumor-free gels over the culture period signifies that the tumor spheroid is what is causing the increase in signal. The HDAT model showed the highest increase in signal, with an increase of 127% over the 14-day period. The increase in signal for the low-density adipocyte with tumor (LDAT) model was lower than that of the HDAT model, with only an increase of 47% over the 14-day period. To confirm that this increase in metabolic activity within the tumor spheroid was due to an increase in proliferation, we stained sections of the tumor models after the culture period with Ki67, which stains for actively dividing cells. We imaged the tumor cells within the model to see if these cells were positive for Ki67. The HDAT model again contained a higher number of Ki67-positive tumor cells (63.0% ± 16.1%) than the LDAT model (21.2% ± 8.2%) (Fig. 2B).

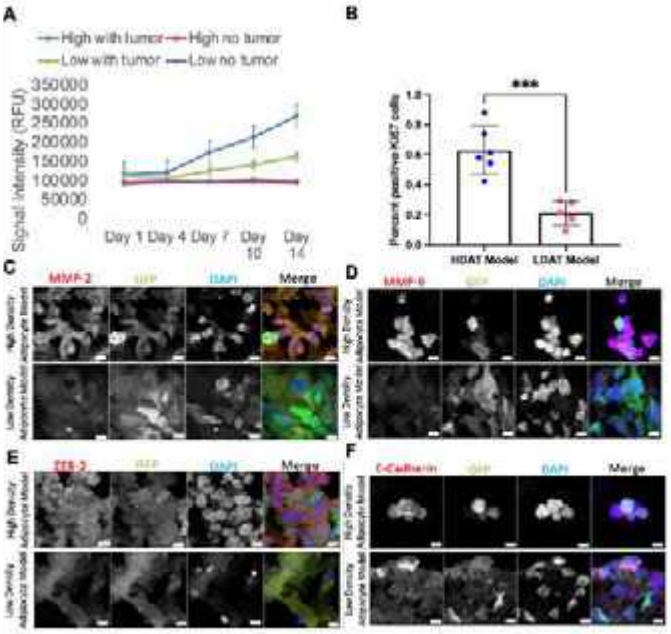

Figure 2: A) Alamar blue assay results over the course of the 14-day culture period (n=3). B) Quantification of the Ki67 stain. n=3, and 5 images were used for each sample to quantify signal intensity. Immunofluorescent images of the tumor spheroid stained for (C) MMP-2, (D) MMP-9, (E) ZEB-2, and (F) E-Cadherin. Scale bars: 10 µm. For statistical significance, Welch's t-test was performed for (B) * denotes statistical significance with P<0.001.**

Finally, we showed that the tumor spheroid (expressing GFP) within the higher density adipocyte model has an increase in tumor progression factors MMP-2 (Fig. 2C), MMP-9 (Fig. 2D), and ZEB2 (Fig. 2E), and a decrease in tumor suppression factor E-Cadherin (Fig. 2F). Through the staining, we showed 86%, 112%, and 171% increase in MMP-2, MMP-9, and ZEB2 expression, respectively, within the tumor spheroid of the HDAT model compared to LDAT model. E-Cadherin, conversely, decreased by 45% in the case of the HDAT model as compared to the LDAT model. Even though the MMP-2 quantification is the only statistically significant difference, we can still see a large change between the two models for E-Cadherin, ZEB2, and MMP-9.

DISCUSSION

Through this investigation, we were able to create a 3D bioprinted obese breast cancer model. This 3D bioprinted obesity model is the first printed fat tissue model related to investigating the progression of breast cancer. This model is also more biomimetic than previous obesity models in that it utilizes hASCs differentiated into adipocytes and human collagen to compose the model. Severe obesity within the breast tissue was modeled using an increase in adipocyte density throughout the collagen gel within the model.

. Over the course of the culture period (14 days), both models containing tumors increased their Alamar blue signal. Our results showed an increase in Alamar blue assay signal over the course of the 14-day culture period and a significant increase in Ki67 positively stained tumor cells within the HDAT model. Previous studies confirm our findings [3, 4]. It has been shown that adipose tissue causes an increase in proliferation for both melanoma cell lines and breast cancer cell lines with adipose tissue grafts even causing an increase in growth of residual cancer cells that remain in the body after treatment.

Next, we wanted to study how the increase in adipocyte density affects the expression of specific tumor progression and tumor suppression factors. After the 14-day culture period, the models were fixed, cryosectioned, then immunostained for common tumor progression factors MMP-2, MMP-9, and ZEB2, as well as tumor suppression factor E-Cadherin. Previous literature [5-7] has consistently shown an increase in expression of MMP-2, MMP-9, and ZEB2, and a decrease in E-Cadherin expression for those cancer cells affected by surrounding adipocytes, which confirm our immunostaining results from our 3D models.

Our study shows that increasing adipocyte density within our obese model causes an increase in proliferation and tumor progression factors and a decrease in a tumor suppression factor. These results suggest that the increased adipocyte density is another contributing factor to how obesity supports breast cancer progression. This work is the first of its kind to utilize 3D bioprinting of fat tissue for breast cancer research. This model will allow for the recapitulation of a more human replicative environment, through utilizing human cells and collagen, and can contribute to the field of breast cancer research through testing novel breast cancer drugs on the model in the future. The 3D bioprinted obese breast cancer model better replicates the severe obese microenvironment and helps to solve issues of previous models.

IN VIVO PULMONARY AND THORACIC WALL INJURY RISK FROM BEHIND ARMOR BLUNT TRAUMA

Justin A. McMahon (1), Parker R. Berthelson (1), Alexander V. Stotka (1), Barney J. McEntire (2), Robert S. Salzar (1)

INTRODUCTION

Body armor is designed to protect military personnel from penetrating injuries and the blunt energy resulting from backface armor intrusions. However, the deformations of some armor designs result in high-rate loading to the wearer's torso. This loading may result in skeletal and physiological damage through an injury modality known as behind armor blunt trauma (BABT) [1-3].

Current body armor design standards are based upon experimental testing from the 1970s in which matched-pair experiments were performed on goats clad with soft body armor and blocks of 20% ballistic gelatin [4]. From these experiments, an armor design criterion of 44 millimeters (mm) of backface deformation (BFD) was developed, and this level of BFD was correlated with a 10% risk of lethality in the goats [5]. However, the elastic nature of the ballistic gelatin caused difficulties in quantifying the BFD following the impact, resulting in the adoption of Roma Plastalina No. 1 (a modeling clay with a similar observed response to the ballistic gelatin) as an armor backing [6]. The 44 mm clay standard has since been adopted by the National Institutes of Justice (NIJ) for use in ballistic body armor performance standards, with its scope being expanded to include both hard and soft body armor evaluations. Although there has been apparent success using the 44 mm standard and clay testing methodology, the standard has limited or no correlation to physiological injury, and the resulting armor designs are heavy, with the potential of being overly conservative in protection [7].

Biological models must be used to assess the underlying injuries associated with BABT to develop body armor based on standards equated to physiological injury. Specifically, live animal models must be used to study the physiological response of the body at BABT levels of impact. Previous biomechanical studies have used the porcine model to represent the human thorax, as it approximates the thoracoabdominal anatomy, physiology, and biomedical responses of a human [8-11]. It is expected that pulmonary injuries due to BABT, such as pulmonary contusion and pneumothorax, will be a focus of study due to the association of these injuries with severe morbidity and mortality [12]. This study aimed to quantify pulmonary and chest wall injury risk from BABT by varying impact energies to produce a range of injury severities.

METHODS

A custom pneumatic impactor was designed to simulate impacts that would cause BABT by accelerating a 0.245 kilogram (kg) indenter into a porcine thorax at velocities ranging from 10 to 50 meters per second (m/s). The indenter was 3D printed using carbon fiber-reinforced nylon (Onyx, Markforged) and its impact surface contour was designed to approximate the BFD profile of rigid body armor protecting against a generic ballistic threat. The indenter was equipped with a single-axis accelerometer (Endevco 7270A) sampled at 500 kilohertz (kHz) with a 100 kHz antialiasing filter. Accelerometer data were further filtered using a four-pole phaseless lowpass Butterworth filter with a cutoff frequency of 2 kHz.

The 27 adult Yorkshire porcine specimens (average mass = 45.0 ± 3.6 kg) tested in this study were selected to approximate the effective mass of the 50th percentile male human torso (approximately 39.6 kg [13]). Before testing, all animal testing and handling protocols were approved by the University of Virginia (UVA) Animal Care and Use Committee (protocol: 4379-12-21) and the U.S. Army Animal Care and Use Review Office (protocol: MT21006.031.e002). Porcine specimens were then procured and allowed to acclimate for a three-day period upon arrival. On the day of the experiment, the specimen was induced using Telazol, and maintenance anesthesia was applied using 2% isoflurane in medical air under positive end expiratory pressure. Specimens were injected with a local analgesic (bupivacaine) subcutaneously at the impact location and were placed on a heating pad during experimentation to maintain thermoregulation. Each specimen was connected to a patient monitor to monitor heart rate, blood oxygen (SpO_2), respiratory rate, and body temperature, with at least 15 minutes of baseline vitals collected prior to the impact event. The specimen was then positioned under the impactor with the impact location flush against the barrel and orthogonal to the indenter. Twelve specimens were impacted over the cranial lobe of the right lung (around ribs 6 through 8), and 15 were impacted over the caudal lobe (around ribs 9 through 11).

Post-impact, the specimens' heart rate and SpO_2 were monitored for at least 15 minutes to ensure vitals returned to a stable condition. Once the specimen was determined to be stable, it was removed from anesthesia and returned to its housing, where continuous monitoring for well-being continued for 6 hours. If the animal was determined to not be recoverable at any time post-impact, the specimen was humanely euthanized with Euthasol via an ear catheter. After approximately 6 hours, the specimen was reinduced for computed tomography (CT) imaging. Specimens were humanely euthanized after CT, and a comprehensive necropsy was performed to determine the extent of the injuries from the impact event. Lung and chest wall injuries were recorded for each specimen and were then assigned a severity score based on the American Association for the Surgery of

Trauma (AAST) Injury Scoring Scale [14-15] with input from the necropsy and radiology.

Preliminary injury risk functions (IRFs) were developed based on the injury data from impact testing. The indenter accelerometer was used to calculate impact energy, which was selected as the most favorable predictive metric for a variety of observed injuries. These values were then used as left and right censored inputs into a survival analysis where IRFs were generated using a Weibull distribution.

RESULTS

Impact energies ranged from 21.9 to 247.5 joules (J), and injury results ranged from no injury up to a grade 4 on the AAST injury scale for both lung and chest wall injuries. The distribution of injury severities can be seen in Table 1, with a grade of 4 being the most severe.

Table 1. AAST Injury Severity Distributions.

	Uninjured	AAST 1	AAST 2	AAST 3	AAST 4
Chest Wall	1	3	10	10	3
Lung	6	10	4	6	1

The most severe injury case seen in the chest wall was a flail chest in which eight rib fractures were observed in total. A large expanding hematoma was seen in the most severe lung injury case. Preliminary IRFs were generated using indenter energy as the predictor metric to assess injury risk for AAST injury severities and are presented in Figures 1 and 2. Impact energy was chosen as an exemplary metric to compare the injury risk across different anatomical structures. The 50% injury risk for Chest Wall 2+, 3+, and 4+ were 40.32 J, 104.29 J, and 228.85 J, respectively. The risk of Lung Injury 2+ and 3+ were 121.64 J and 163.48 J, respectively. A Lung Injury 4+ was not generated due to only having one 4+ injury case.

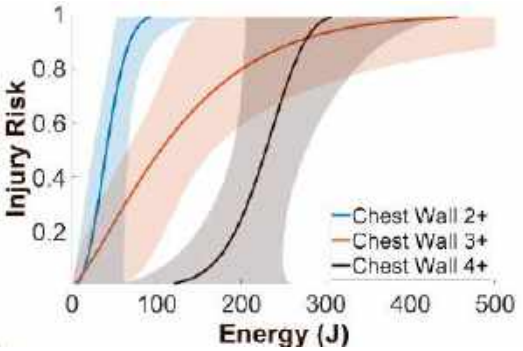

Figure 1: Injury risk across AAST Chest Wall Injuries 2+, 3+, and 4+ with 95% confidence intervals.

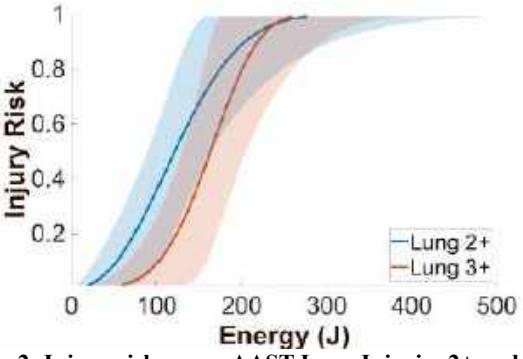

Figure 2: Injury risk across AAST Lung Injuries 2+ and 3+ with 95% confidence intervals.

DISCUSSION

There have been limited studies on the physiological injuries that result from BABT to the thorax. This study adds insight to the existing literature on BABT by conducting live porcine experiments that can be used to quantify the risk of physiological injuries and lead to body armor optimized for weight and performance. Regarding the observed chest wall injuries, only a relatively low amount of energy was required to cause three or more rib fractures graded at AAST level 2+. However, it took much more energy to induce injuries that would be classified at the more severe grades of 3+ and 4+. Looking at the lung injuries, more energy was needed to produce similar severity lung injuries as compared to the chest wall. This is most likely due to the ribcage absorbing much of the energy from impacts at lower severities. As the impact energy increased, flail rib fractures were induced, and more of the impact energy transferred through to the lung, causing more severe pulmonary injuries.

These results are comparable to findings observed by Gryth et al. and Günther et al. [11, 9], whose experiments used body armor and live munitions. In the study by Gryth et al., a large hematoma and contusion were observed on the impacted lung during the post-test necropsy of one of their specimens. Similarly, the highest severity lung injury observed in this study resulted in a hematoma of comparable size to that seen by Gryth et al. Also, multiple specimens in this study had pulmonary contusions similar to the one shown in Günther et al. These results indicate that the generic indenter is capable of reproducing injuries comparable to those found in tests with body armor and live munitions.

Further work is ongoing to understand the injury tolerance of different thoracic regions to BABT. Current body armor designs do not account for regional variations in anatomical stiffness, criticality of underlying organs, and physiological response of the torso. Due to the complex nature of the human thorax, regional variations in anatomy could result in varying injury tolerance during BABT. These local variations in injury tolerance would allow body armor design to be optimized for weight based on the local injury criteria associated with each thoracic region.

INTRODUCTION

The greater thoracic vessels are targeted in multiple cardiovascular surgeries and are central to a well-functioning circulatory system. They undergo remodeling under altered hemodynamic conditions which can either improve outcomes or drive comorbidities and complications. A necessary first step in understanding their remodeling process is quantifying their structure and function in the native circulation. Here we use consistent methods to quantify and compare microstructural features and biaxial biomechanical properties of the following six greater thoracic vessels in a wild-type mice: ascending thoracic aorta (ATA), descending thoracic aorta (DTA), right subclavian artery (RSA), right pulmonary artery (RPA), thoracic inferior vena cava (TIVC), and superior vena cava (SVC). We report similarities and differences in structure and mechanics of these vessels.

METHODS

Mechanical testing: All live animal protocols were approved by the Institutional Animal Care and Use Committee of Yale University. Adult male mice (C57BL/6J from Jackson Labs, ME) between 14 and 20 weeks of age were euthanized with an intraperitoneal injection of Beuthanasia-D (150 mg/kg), with death confirmed upon exsanguination. Vessels were harvested, perivascular tissue and fat gently removed, and small branch vessels were ligated with suture. Each vessel was then cannulated on custom glass micro-pipettes and secured with 6-0 sutures, then mounted in our custom biaxial device [1] and subjected to active and passive testing. For active testing, specimens (n = 5–6 per group) were immersed within a buffered Krebs-Ringer solution that was maintained at 37 °C and bubbled with 95% O_2 and 5% CO_2 to maintain pH 7.4. Active preconditioning consisted of two sets of vasoconstriction with 100 mM KCl (50 mM for SVC) at a fixed pressure and axial stretch below *in vivo* conditions. Following preconditioning, the vessels were contracted with 100 mM KCl at a pressure P_{active} (Table 1) and specimen-specific *in vivo* axial stretch. This protocol consisted of 5 min of equilibration, 15 min of contraction with 100 mM KCl, and 10 min of relaxation following washout of KCl with a fresh Krebs-Ringer solution.

Table 1: Summary of group-specific mechanical testing parameters used in biaxial quantification of active and passive mechanics

Vessel	Pressure active test (mmHg)	P_{min}-P_{max} (mmHg)	~f_{max} (mN)	Pressure force-length tests (mmHg)
ATA	90	10-140	58.8	10,60,100,140
DTA	90	10-140	44.1	10,60,100,140
RSA	90	10-140	19.6	10,60,100,140
RPA	15	5-40	9.8	5,15,25,40
TIVC	3.5	1-30	3.4	3.5,5,10,30
SVC	1	1-30	1.5	1.5,5,10,30

Active tests were followed immediately by passive tests upon replacement of the Krebs-Ringer solution with a Hanks buffered physiologic solution at room temperature. Preconditioning involved six pressure cycles from P_{min} to P_{max} at the specimen-specific value of *in vivo* stretch (Table 1) to elicit a pseudoelastic behavior. Testing consisted of seven protocols: cyclic pressure distension from P_{min} to P_{max} at three different fixed axial stretches (0.95, 1.00 and 1.05 times the *in vivo* axial stretch) and axial force extension from ~ 0 mN to f_{max} at four different fixed pressures (P_{fl}). Region-specific mechanical testing parameters are summarized in Table 1. Passive mechanical data was fit to a pseudo strain energy function which included a neo-Hookean term for elastin-dominated amorphous behaviors and four families of fibers (along axial, circumferential, and two symmetric

diagonal directions) described by a Fung-type exponential relation to model passive smooth muscle and collagen-dominated behaviors. Mechanobiologically relevant quantities such as mean biaxial wall stress and material stiffness were computed from the energy function at pressures and axial stretches of physiological relevance. Details of these calculations can be found in our prior work [2,3,5].

2 Photon Imaging: Following mechanical testing, samples (n = 3–6 per group) were incubated in a fluorescent nucleic acid stain (SYTO™ 61 at 2 μM) for 1 h, then stored overnight at 4 °C in a buffered physiological solution. For imaging, they were mounted on a fixed biaxial loading frame to simulate the *in vivo* condition and placed within the field-of-view of a two-photon microscope (LaVision Biotec TriMScope) operated with a Titanium-Sapphire Laser (Chameleon Vision II, Coherent). The excitation wavelength was tuned to 840 nm, and signal detection was set at 390–425 nm for second harmonic generation (SHG) from collagen structures, 500–550 nm for auto-fluorescent signals of elastin structures, and above 550 nm for fluorescence of cell nuclei. For samples containing cardiomyocytes (namely, the SVC), the signal from these cells were detected between 500 and 550 nm and above 550 nm. All imaging was completed within 48 h following sample harvest. An Olympus 20X water immersion objective lens (NA 0.95) allowed acquisition of 3D image stacks with a x, y-plane (i.e., axial-circumferential plane) field-of-view of 500 μm × 500 μm and a z-step in the radial direction of 2 μm. Samples were imaged under comparable load conditions, which were *ex vivo* equivalent vessel-specific *in vivo* axial stretch and representative pressure. 3D images were post-processed using ImageJ v1.53 and MATLAB R2020a as described in our previous work [4].

Volume fractions (VFs) were defined as the average black and white pixel ratio for all components between boundaries defined by thresholding and segmenting using constant thresholds, defined using the Otsu method on a training set [4].

RESULTS

Note that all results are reported as mean± standard error of mean and in order as ATA, DTA, RSA, RPA, TIVC and SVC. Vasoconstriction in response to 100 mM KCl at *in vivo* conditions was -16.80±1.354,-20.55±2.051,-9.316±0.7258,-31.15±2.547,-9.672±0.4944 and -9.006±0.9139% for the ATA, DTA, RSA, RPA, TIVC and SVC, respectively; computed with respect to basal outer diameter pre-contraction. Vasoconstriction was the highest in RPA, and similar between the ATA and DTA. RSA contractility was low, despite being a systemic artery, and was similar to the thoracic veins. Passive mechanics for all six regions were computed at subject-specific axial *in vivo* stretch and representative group-specific physiologically relevant pressures. Stored energy (92.52±3.88, 63.98±3.61, 46.09±3.28, 10.96±1.01, 9.45±2.35 and 0.59±0.07 kPa) and circumferential stress (257.22±7.22, 210.80±8.14, 147.62±4.42, 27.72±1.67, 19.13±1.88 and 4.27±0.42 kPa) tended to lessen down the vascular tree but reductions in circumferential stiffness (1.24±0.05, 1.03±0.06, 0.87±0.03, 0.09±0.01,0.76 ±2.12 and 0.06±0.01) were non-monotonic. Stored energy and circumferential stress were similar only between the RPA and the veins.

Quantification of the multiphoton images confirmed a decreasing elastin volume fraction (49.95± 3.737, 40.58± 3.810, 31.32± 3.554, 29.14 ±5.509, 9.198± 2.545, 1.243± 1.068) and increasing collagen volume fraction (23.29±1.912, 38.16±2.957,42.71±2.005, 49.41±3.354, 62.71±3.776 and 63.02±6.207) down the vascular tree. The overall fraction of cells was relatively constant across (26.77± 2.871, 21.27±2.251, 23.62 ± 2.967, 21.45± 3.063, 35.74± 7.257 and 28.10 ± 4.121) all six regions. Noticeable differences in orientation of collagen and cells were observed across different regions (data not shown).

DISCUSSION

Similarities and differences across systemic, pulmonary, and venous circulations highlight underlying design principles of the vascular system. We submit that the protocols and results from this study will help pave a way forward for a similar study in human vessels, which will be needed to predict evolving changes during a surgical correction.

INTRODUCTION

While many processes in mammalian physiology may be suitably modeled to take place under isothermal and isobaric conditions, there are important cases where spatiotemporal variations in temperature and pressure must be allowed. Moreover, biological tissues and cells may interact with an environment at a different temperature or pressure, such as ambient air flowing in the lungs, injurious heating (e.g., burning) or cooling (freezing) of skin by external fluids, or potentially detrimental thermal effects of medical procedures, such as laser ablation or cryotherapy. A recent expert review article illustrates how modeling can improve our understanding of soft tissue injuries resulting from pressure and temperature [1]. To better understand how to model such processes, it becomes necessary to expand the open-source finite element software FEBio [2] to include variations in temperature in its fluid mechanics module. By expanding standard thermodynamics methodologies, we propose novel methods for assessing energy exchanges during reactive and thermal processes involving biological fluids.

METHODS

Currently, FEBio models fluid dynamics assuming isothermal conditions (uniform and constant temperature) [3]. In this study we introduce thermal effects in the existing fluid dynamics module to analyze thermofluid processes. In practice, this task involves adding the axiom of energy balance to the governing equations, to incorporate temperature changes and various sources of heat, as outlined below. The detailed theoretical developments underlying the FEBio fluid solver have been reported previously [3], where we adopted a function of state for the fluid pressure, relating it to the fluid dilatation. For isothermal applications it is common to model fluids that are in liquid form, where the function of state for the pressure involves the liquid's bulk modulus. In thermofluid analyses however, it makes sense to also model compressible fluids, such as ideal and real gases, whose pressure depends on dilatation and temperature. In this presentation, we expand this concept by incorporating a dependence of the pressure function of state on temperature. Below, we provide an overview of the governing equations for this thermofluid framework, along with results from a FEBio finite element implementation.

In our fluid dynamics framework [3], the governing equations include the kinematic constraint of eq.(1) between the fluid volume ratio J^f and the fluid velocity $\boldsymbol{v}^f$, which produces an exact solution for the fluid mass density,

$$\dot{J}^f = J^f \operatorname{div} \boldsymbol{v}^f \,,\ \rho^f = \frac{\rho_r^f}{J^f}. \tag{1}$$

Here, ρ^f is the fluid mass density in the current configuration while ρ_r^f is the fluid mass density in the reference configuration, when $J^f = 1$. The fluid volume ratio is related to the fluid dilatation e^f via $e^f = J^f - 1$. The other governing equation is the linear momentum balance,

$$\rho^f \dot{\boldsymbol{v}}^f = \operatorname{div} \boldsymbol{\sigma}^f + \rho^f \boldsymbol{b}^f \tag{2}$$

where $\boldsymbol{\sigma}^f$ is the fluid stress tensor and $\boldsymbol{b}^f$ is a user-specified specific body force acting on the fluid, such as gravity. For thermofluid analyses, these equations are supplemented with the axiom of energy balance,

$$\rho^f \dot{u}^f = \boldsymbol{\sigma}^f : \operatorname{grad} \boldsymbol{v}^f - \operatorname{div} \boldsymbol{q} + \rho^f r \tag{3}$$

where u^f is the fluid's specific internal energy, $\boldsymbol{q}$ is the heat flux, and r is the specific heat supply from user-specified sources (such as microwave heating or Joule heating). The fluid stress $\boldsymbol{\sigma}^f = -p^f \boldsymbol{I} + \boldsymbol{\tau}^f$ can be separated into a gauge pressure term p^f and a viscous shear stress $\boldsymbol{\tau}^f$, where $\boldsymbol{I}$ is the identity tensor. From basic thermodynamics it can be shown that p^f depends on the absolute temperature T and J^f (or e^f), thus $p^f = p^f(T, J^f)$. Note that fluid viscosities, such as the shear viscosity η^f appearing in $\boldsymbol{\tau}^f$, may also vary with temperature and volume. Using the decomposition of the stress into pressure and viscous contributions, we may rewrite the energy balance as

$$\rho^f c_v^f \dot{T} = (\boldsymbol{\tau}^f - T\frac{\partial p^f}{\partial T}\boldsymbol{I}) : \boldsymbol{D}^f - \operatorname{div}\boldsymbol{q} + \rho^f r, \qquad (4)$$

where $c_v^f \equiv \partial u^f/\partial T$ is the specific isochoric heat capacity of the fluid and $\boldsymbol{D}^f$ is the fluid rate of deformation tensor. This form of the energy balance shows how we can solve for the temperature T in a finite element formulation, by adding the energy balance to the virtual work statement used in a standard isothermal formulation.

One of the challenges is to formulate suitable constitutive models for the functions of state $p^f(T,J^f)$ and $c_v^f(T,J^f)$. Here we adopt ideal gas law for illustrations. For the heat flux $\boldsymbol{q}$ we use Fourier's law of heat conduction, $\boldsymbol{q} = -k^f(T,J^f)\operatorname{grad} T$ where $k^f(T,J^f)$ is the thermal conductivity. Since p^f depends on the nodal degrees of freedom T and e^f, the finite element implementation allows users to prescribe a desired pressure on a boundary by modeling it as a constraint between T and e^f.

RESULTS

Numerically, the most challenging aspect of thermofluid analyses is the ability to model convective heat transfer, especially when using high Peclet numbers. Therefore, we illustrated our implementation of the thermofluid framework of FEBio using two representative problems, one for free convection and the other for forced convection.

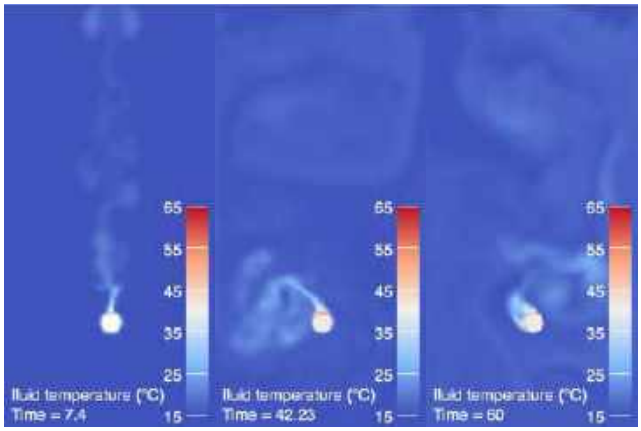

Fig. 1: Thermofluid solver example showing free convection of air modeled as an ideal gas in a 0.7 m × 1.4 m domain, under the action of gravity, around a ∅ 6 cm cylinder heated to 65 °C, in a closed container. Initial air temperature was 15 °C.

For free convection, we modeled a rectangular 2D fluid domain, 0.7 m × 1.4 m × 0.01 m, under the action of gravity g, with zero fluid velocity and normal heat flux along all lateral sides. The initial, uniform, fluid temperature was 15 °C, whereas the initial fluid gauge pressure increased linearly from zero at the top surface, according to $p^f = \rho_r^f gy$, where y was the vertical downward coordinate. A cylindrical surface (∅ 0.06 m) located at the center of the bottom half was assigned zero fluid velocity, and a prescribed temperature of 65 °C at time $t = 0^+$. The analysis was modeled to run for 60 s. The fluid used the properties of air as an ideal gas with constant specific heat capacity. The mesh had 10720 nodes and 5204 hex8 elements, biased near all no-slip boundaries. Temperature variations in this free convection problem are displayed in Fig. 1, at three representative time points.

The second example employed planar Poiseuille flow in a rectangular domain, 0.1 m × 0.06 m × 0.002 m, with a prescribed pressure drop of 1 Pa along the length. No-slip conditions were prescribed on the top and bottom faces. The fluid was modeled as gaseous O_2, using ideal gas law with temperature-dependent specific heat capacity and constant thermal conductivity. The initial uniform fluid temperature was set to 50 °C and the inlet temperature (left face) was set to 60 °C at time $t = 0^+$. The mesh had 16482 nodes and 8000 hex8 elements, with mesh biases near the no-slip boundaries. The analysis was run for a modeled duration of 0.5 s, during which the fluid accelerated from 0 to 1.3 m/s. The flow distribution evolved from plug profile to parabolic profile with increasing time. The peak Peclet number achieved at the highest velocity was $Pe \approx 4500$.

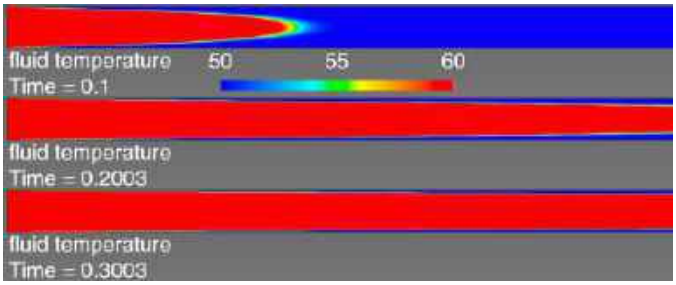

Fig. 2: Forced convection of gaseous oxygen in 10 cm × 0.6 cm rectangular domain, under a prescribed pressure drop of 1 Pa (left to right). Initial gas temperature was 50 °C and the prescribed inlet temperature was 60 °C. At 0.5 s the velocity reached 1.3 m/s, producing a Peclet number of 4500.

Snapshots of the temperature distribution at three representative time points (Fig. 2) demonstrated that there was negligible heat conduction in this problem, which was dominated by heat convection, as could be assessed from the very sharp temperature profile flowing through the domain. Most notably, the solver could handle outward flow of this sharp temperature profile across the downstream face.

DISCUSSION

Results demonstrated that the code could properly combine large variations in temperature with gravitational or convective effects, to model the flow of a heated gas in closed or open domains, optionally in the presence of buoyancy forces leading to unsteady flow and vortex shedding. The ability to model convective heat transfer across open boundaries, at high Peclet numbers, may be particularly helpful for realistic modeling applications. The development and implementation of a novel thermofluid solver in FEBio, as well as its successful application in simulating free and forced convection, highlights its potential for a wide range of biomedical applications.

To complete this framework, we plan to introduce constitutive models for real gases and real liquids, which can reproduce p^f, c_v^f, k^f and η^f reported in standard thermodynamics tables [4].

INTRODUCTION

Atrioventricular valve regurgitation (AVVR) is a leading cause of morbidity and mortality. Transcatheter edge-to-edge repair (TEER) is an effective and minimally invasive intervention for the treatment of AVVR in adults that avoids the increased risks associated with open heart surgery [1,2]. AVVR is also a serious complication in children and young adults with congenital heart disease (CHD). However, to date, application of TEER in CHD has been limited and the effect of TEER on leaflet function and mechanics in CHD is unknown [3].

Successful application of TEER therapy relies on the delivery of a clip to a precise location on the atrioventricular (AV) valve leaflets. In this setting, patient-specific modeling and simulation has facilitated successful TEER interventions in CHD [4]. However, simple image-derived modeling does not allow the clinician to preoperatively evaluate the effect of TEER on valve function or the effect of intervention on leaflet mechanics [5]. Further, the effect of clip size and shape on the resulting valve mechanics is unknown. 3D image-derived finite element (FE) modeling has begun to provide a method for "virtual valve repair", and several studies have simulated TEER intervention in AV valves [6]. This study aims to understand the effect of clip selection on a pediatric mitral valve model exhibiting posterior leaflet prolapse using an open-source pipeline as a foundation for further development of computational pre-intervention planning and assessment in CHD.

METHODS

Model Geometry: An existing image-informed regurgitant mitral valve model exhibiting posterior leaflet prolapse was discretized with 4-node linear quadrilateral shell elements [7]. Models for the base and arms of four MitraClip G4 clips (Abbott Cardiovascular, Plymouth, MN, sizes NT, NTW, XT, XTW) were adapted from the ValveClip Device Simulator module in the SlicerHeart extension for 3D Slicer (www.slicer.org) and meshed with 4-node tetrahedral elements in FEBio Studio. Valve and clip models are shown in **Figure 1**.

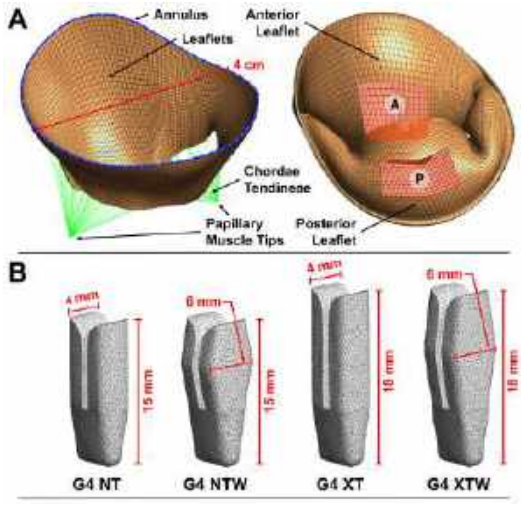

Figure 1: Models of (A) mitral valve and (B) MitraClip G4 clip

Initial Valve Simulation: FE simulation of the prolapsed mitral valve was performed using the FEBio dynamic solver (V2.4.0, University of Utah) as previously described [8]. Briefly, fixed displacement boundary conditions were assigned to the valve anulus and papillary muscle tips. Leaflet tissue was represented with an isotropic Lee-Sacks constitutive model:

$$\psi = \frac{c_0}{2}(I_1 - 3) + \frac{c_1}{2}\left[e^{c_2(I_1-3)^2} - 1\right] + \frac{1}{2}K(\ln J)^2 \qquad (1)$$

where c_0, c_1, and c_2 are material coefficients, I_1 is the first invariant of the right Cauchy-Green deformation tensor, K is the bulk modulus, and J is the Jacobian of the deformation gradient. Chordae tendineae were represented as tension-only 2-node springs with a nonlinear force-

displacement response. A 100 mmHg ventricular pressure was applied to the ventricular surface of the valve until the valve reached steady state, and the closed valve geometry was exported.

Valve Clip Simulation: The base and arms of the clip were represented as separate rigid bodies. The closed valve geometry was used as a reference to position the valve and clip for ideal leaflet capture. FE analysis was performed in steps (**Figure 2**). In analysis step 1, the valve was closed as described in the initial valve simulation, and clip arms were opened via a rigid rotation. In analysis step 2, the ventricular pressure was released to allow the valve leaflets to fall onto the clip arms, and a sticky contact was initiated between the leaflets and clip. In analysis step 3, the clip was closed via a rigid rotation, and the ventricular pressure was re-applied to close the clipped valve until it reached steady state.

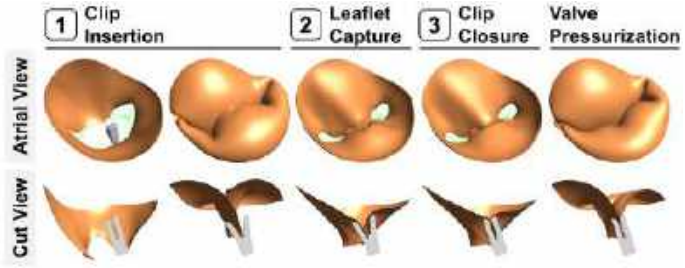

Figure 2: FE pipeline. Boxed numbers indicate analysis steps.

RESULTS

Outcome results of the FE TEER simulations are summarized in **Table 1** and **Figure 3**. Average 1st principal stress over the full valve model was slightly lower for all four clip types compared to the non-clipped valve, and average 1st principal strain remained relatively consistent. When isolating the belly regions of the anterior and posterior leaflets (A and P as defined in **Figure 1**), there was little change in average stress and strain in the A region, but stress and strain were higher in the P region for all clip types versus the non-clipped valve. Valves clipped with the taller XT and XTW clips showed the highest stress and strain in the P region.

Contact area (CA) increased for all clip types compared to the non-clipped valve, with the largest contact area in the wider NTW and XTW clips. The posterior leaflet capture gap (PCG), or the distance of the posterior leaflet free edge from the clip base (used to quantify the quality of leaflet capture), was larger for the taller XT and XTW clip models.

Table 1: Summary of outcome metrics after valve closure.
CA = contact area; PCG = posterior leaflet capture gap.

Clip Type	Avg. 1st Principal Stress (kPa)			Avg. 1st Principal Strain			CA (mm^2)	PCG (mm)
	Full	A	P	Full	A	P		
No Clip	282.2	570.8	330.2	0.231	0.274	0.192	89.2	--
G4 NT	261.5	570.0	346.9	0.234	0.285	0.294	256.3	2.56
G4 NTW	261.9	571.0	348.7	0.234	0.283	0.297	270.9	2.22
G4 XT	251.8	571.9	423.3	0.228	0.285	0.321	257.2	4.00
G4 XTW	252.3	575.4	425.7	0.228	0.286	0.323	267.3	3.67

DISCUSSION

This study provides a foundation for TEER simulation through the comparison of valve mechanics across MitraClip G4 clip types via an open-source FE modeling pipeline. These methods can be extended to further aspects of pre-intervention decision making, such as clip placement and number of clips, offering an approach to TEER planning that is valuable in pediatric populations with heterogeneous anatomy.

The differing trends in average stress and strain across the full valve model and targeted A and P regions highlight the importance of studying regional metrics for a full understanding of post-clip leaflet mechanics. Here, while average strain in the full valve remained relatively constant across clip types, the increased strain in the P region with taller clips suggests that clip selection may impact long-term valve durability. The increased PCG with the taller XT and XTW clips suggests clip selection could also impact the quality of the repair. If modeling indicates a large leaflet capture gap on either leaflet, a "staged leaflet capture" technique could be considered, wherein leaflets are grasped sequentially and the clip is repositioned between the capture of the first and second leaflets [9].

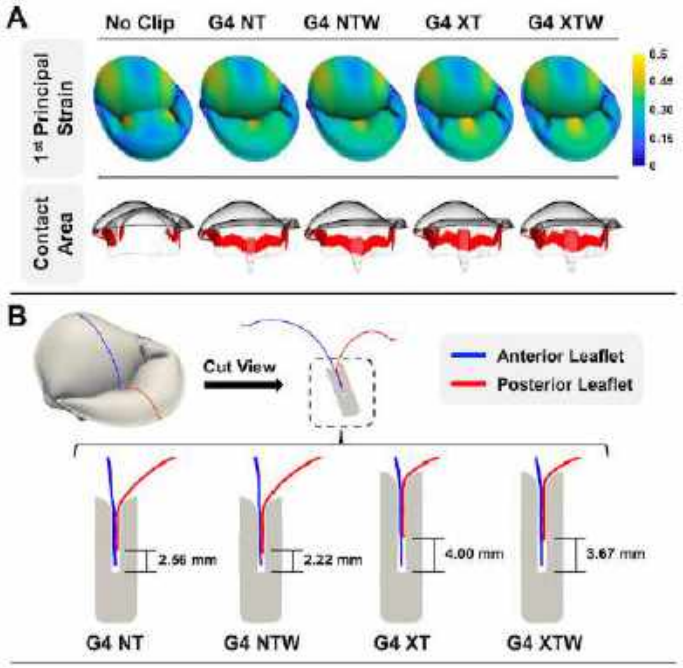

Figure 3: (A) Mechanical and functional outcome metrics, and (B) posterior leaflet capture gap (PCG). Results suggest increased posterior belly region strain and larger PCG with taller clips.

As a foundational study, there are opportunities to improve this simulation pipeline for more accurate image-derived TEER modeling. The existing prolapsed mitral valve model has several limitations, as previously discussed [7], and future models will include dynamic annulus and papillary muscle movement. In addition, the clip was applied to the leaflets in a fixed position, which may have limited the movement of the leaflets during the final valve pressurization. Future work will implement the release of this fixed constraint as well as include clip displacement to achieve sequential, independent leaflet capture for more comprehensive TEER simulation.

INTRODUCTION

Atrioventricular valve regurgitation is the most prevalent form of valve disease in developed countries. The purpose of the mitral valve is to regulate blood flow from the left atrium into the left ventricle. This is achieved by two leaflets supported by chordae tendineae. The chordae tendineae are string-like tissues composed of collagen fiber that anchor the valve leaflets to papillary muscles in the ventricle and support the valve leaflets during ventricular contraction. During mitral valve closure the free edge of the leaflets come together to create a coaptation zone and prevent the regurgitation of blood from the left ventricle into the left atrium. [1,2]

Finite element (FE) models are emerging as a tool to understand valve function, dysfunction, and inform valve repair [3,4]. This abstract explores use of linear trussses, specifically chordae density, in our FE simulations relative to an established open-source workflow using spring elements [3,5].

METHODS

Image-Informed Mitral Valve Creation: To create the FE simulations of mitral heart valves, the open-source platforms 3D Slicer (www.slicer.org) and FEBio (V2.4.0 University of Utah) were used. An existing image-informed mitral valve model was meshed into 4-node linear quadrilateral (Quad4) shell elements [3,5]. The chordae tendineae in this model were assumed to be 2-node springs with a nonlinear force displacement response [6]. Spring models are simple to implement however, truss elements offer the advantage of being able to be assigned material properties and structured into a branching configuration to present a more accurate physiology.

Chord Generation: We implemented custom code in the SlicerHeart Valve FEM Export module to generate chordae insertion points on the leaflets from papillary muscle nodes. The region of chordae generation was defined as 1/3 the leaflet starting from the free edge. Chordae density was varied from 6 chords/cm^2 to 25 chords/cm^2 with branch lengths of 4.5 mm and radials of 4. Valve and chordae are shown in **Fig 1**.

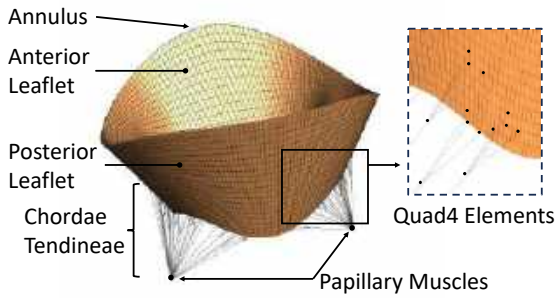

Figure 1. Finite Element Simulation

Finite Element Simulations: FE analysis was completed via dynamic simulation in FEBio. The mitral valve leaflets were modeled with the Lee-Sacks constitutive model [3] and assumed to have a thickness of 0.36 mm. The chordae were considered as linear truss elements with a stiffness of 40,000 Pa, and a cross-sectional area of 0.05 mm^2. The leaflet annulus and papillary muscles were fixed to prevent rigid body motion. A linearly ramped 13.3 kPa (100 mmHg) pressure surface load was applied to the ventricular leaflet surface over 0.0005 s and maintained until 0.01 s to achieve steady state [7]. A Kamensky contact was considered for the valve leaflets to model valve closure [8].

Analysis: Each valve was flattened to 2-dimensions and separated into anterior and posterior leaflets with the chordae insertion points identified (**Figs. 1-5**). Next, the first, second, and third principal strain on the flattened models were extracted from the FEBio simulation. Finally, using our existing spring model as the reference [3,5], the

element centroid error and first principal strain error were computed using an in-house python script.

RESULTS

The surface-to-surface error, strain, and strain error are shown in **Figs. 2-5**. Surface-to-surface error analysis identifies 10 chords/cm^2 as the most accurate, however there is a larger discrepancy in the commissure region (**Fig. 2**) and in the body of the posterior leaflet (**Fig. 3**). Interestingly, the first principal strain is similar for all chordae densities (**Figs. 4,5**).

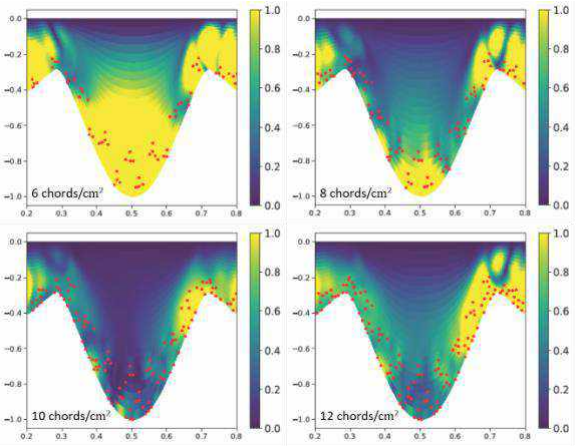

Figure 2. Surface-to-surface error: anterior leaflet

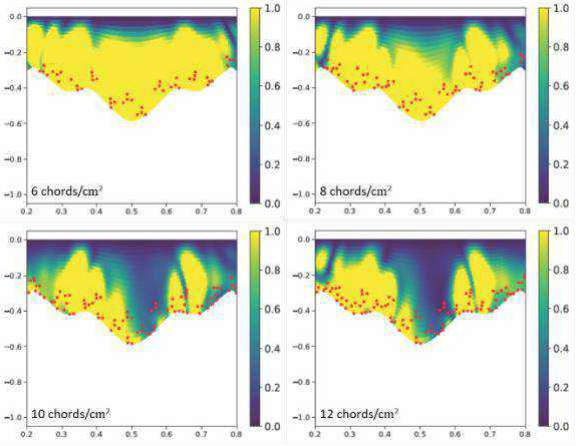

Figure 3. Surface-to-surface error: posterior leaflet

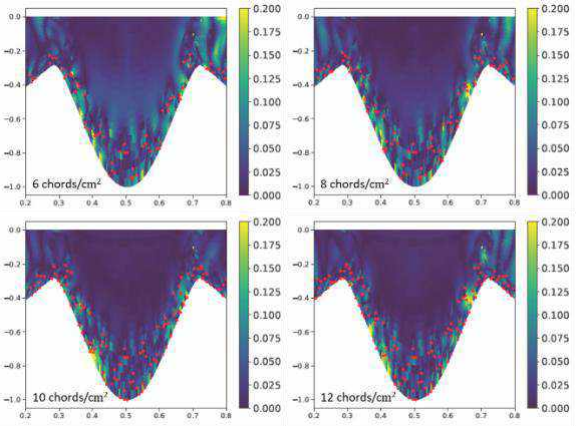

Figure 4. First principal strain error: anterior leaflet

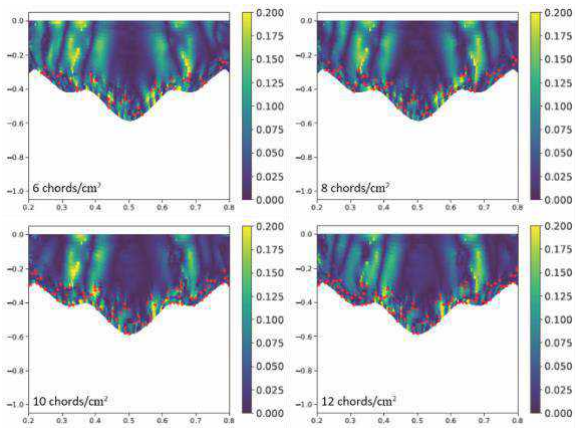

Figure 5. First principal strain error: posterior leaflet

DISCUSSION

We contribute a framework for investigating the effect of chordae model type and density on mitral valve dynamics. We found that the chordae properties primarily influence valve closure with minimal impact on the leaflet strains (**Figs. 4,5**). This suggests that chordae properties may primarily alter the valve function with minimal impact on the leaflet mechanics. The results further demonstrated that the chordae density influences the mitral valve closure with an optimal density of 10 chords/cm^2. Interestingly, we observed non-uniformities in the surface-to-surface error that may suggest the commissures and posterior leaflet require different chordae densities to appropriately capture valve function (**Figs. 2,3**). In our experimental experience, these regions may have larger chordae densities and require further refinement to appropriately capture valve closure.

Several limitations should be acknowledged for this study. This model assumes chordae tendineae as linear truss elements with uniform material properties, cross sectional area, and branching. In reality these chordae exhibit nonlinear behavior with varying geometries. Also, in these simulations the annulus and papillary muscles were fixed rather than dynamic as observed *in vivo*.

We can build upon this study to increase our understanding of mitral valve closure. In the future we can explore additional variables including chordae insertion area, branching length, number of branches, and heterogenous chordae structure. Also, in FE simulations optimizing the linear truss element material properties could provide more accurate valve closure. Additionally, future integration of image-derived models could bridge the gap between computational FE modeling and valve function. In summary, linear truss elements can produce similar valve closure to springs with notable differences in the commissures and posterior leaflet that can be addressed in future exploration.

INTRODUCTION

Induced pluripotent stem cell (iPSC)-derived endothelial cells (dEC) are crucial for developing vascularized tissues and modeling vascular diseases, but the existing differentiation protocols suffer from two major challenges. First, the protocols yield high percentage of undesired cell lines that share the mesodermal lineage such as fibroblasts, reducing the yield of dEC and necessitating removal of these cell lines to prevent fibroblast overgrowth. Second, there is a lack of efficient protocols that target specific subvariants of dECs, namely into lymphatic endothelial cells (LEC), which are useful for developing lymphatic organoids and promoting wound healing. iPSCs undergo changes to membrane potential as they differentiate, suggesting that a potential method to improve the yield of dEC may be to target membrane polarization of iPSC.[1]

Another method to improve the specificity of differentiation protocols into LEC may be to take advantage of its unique metabolic characteristics. LECs rely heavily on fatty acid oxidation for its metabolic needs and for generation of acetyl-CoA used for activation of VEGFR3, an LEC-specific marker with a positive feedback loop to a master lymphatic regulator gene, Prox1.[2] Therefore, in this study, we explore the use of polarizing molecules and acetyl-CoA precursor molecule to improve both the yield of total dECs and specifically the LECs. Additionally, we explore the use of convolutional neural network coupled with machine-learning based segmentation algorithm to identify the desired dECs and LECs from imaging data without relying on immunofluorescence or flow cytometry data.

METHODS

Based on the existing differentiation protocol for dEC published by Harding and colleagues, we developed the following modified protocol (Fig 1A). We induce mesodermal identity through 2 days of treatment with 6μM of CHIR99021, a Wnt-pathway activator. Then we induce endothelial progenitor characteristics through 2 days of treatment with 50ng/mL of VEGF-A, FGF2, and BMP4 along with 10nM of ouabain, a small molecule that causes depolarization. Cells are passaged and replated to density of 50,000 cells/cm^2. Lastly, we treat the cells with 100ng/mL of VEGF-C and up to 50mM of sodium acetate (NaAc) for 4 days to induce LEC markers. To analyze the effects of our treatments, cells were passaged either after the endothelial progenitor induction stage or the LEC maturation stage.

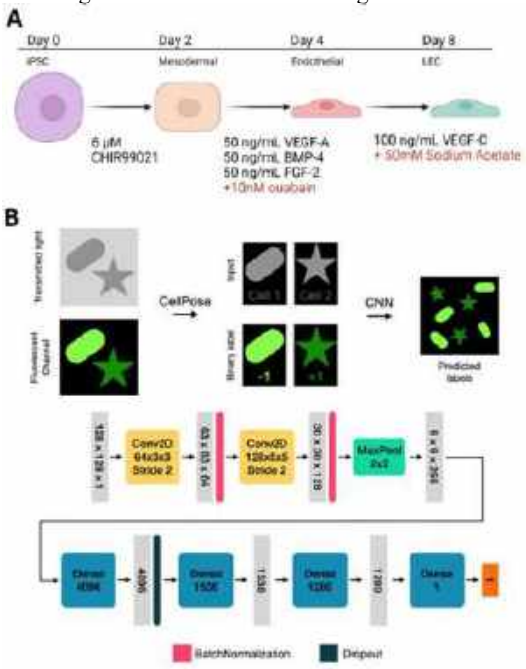

Figure 1. A) Schematic for the proposed differentiation protocol. B) Overview of the machine learning algorithm design.

We also created a deep learning model using Keras library in Python to distinguish between endothelial cells and fibroblasts (Fig 1B). The model first processes the image into smaller segments centered around each cell identified using Cellpose library, which uses backbone U-net based neural network to accurately segment non-circular cells such as ECs. We then use each of the segments to train a network consisting of three convolutional layers and four dense layers, whose depth are optimized using Keras-tuner library. We pre-stained the ECs with fluorescent dye and re-plated stained ECs with unstained fibroblasts in 1:1 mixture at approximately 20,000 cells/cm^2 immediately before imaging. Each segment generated by the algorithm was labeled as either EC or fibroblast based on the presence of fluorescent signals within the cell boundary.

RESULTS

After 4 days, following the endothelial induction and treatment with ouabain, we performed flow cytometry for CD144, an endothelial marker, and Tra-1-60, a pluripotency marker. We observed a significant increase in the yield of CD144+ endothelial cells from approximately 50% to 70% when the iPSCs were treated with 10nM of ouabain during the endothelial progenitor induction stage (Fig 2A). All cells were Tra-1-60 negative and ouabain treatment during the mesodermal stage did not affect CD144+ yield, indicating that ouabain specifically affects cells in the mesodermal-endothelial state rather than drive iPSC in general towards differentiation.

After 8 days, we performed qPCR and flow cytometry for various LEC markers and CD31, a mature endothelial marker and found a significant increase in lymphatic markers PDPN and Prox1 when treated with 50mM NaAc (Fig 2B-C). We replicated the method across three iPSC cell lines and saw an increase in PDPN+/CD31+ LECs from approximately 5-10% to 40-60% with NaAc treatment (Fig 2D). The differentiated cells also produced comparable levels of reelin and retained the ability to form networks on a Matrigel surface (Fig 2E-F).

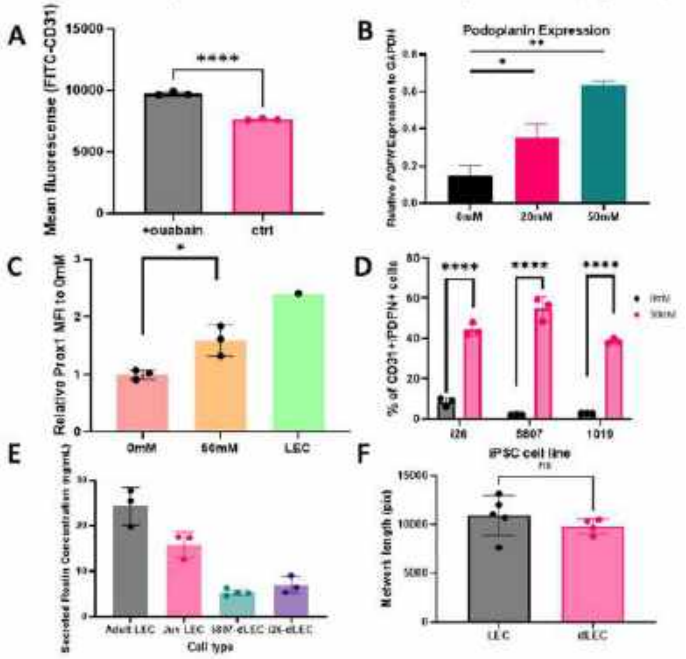

Figure 2. A) Mean expression of CD31 in cells differentiated with and without ouabain. B) qPCR results showing an increase in PDPN expression with higher NaAc treatment. C) Average Prox1 expression increased with treatment with NaAc. D) Percentage of CD31/PDPN+ cells following differentiation. E) ELISA results showing Reelin secretion. F) Network length quantification after network formation assay.

Using the optimal model, we confirmed that the accuracy of the model reaches approximately 80% (Fig 3A). The dataset was approximately 60% fibroblasts and 40% endothelial cells. We observed that the model begins to overfit by 200 epochs, which is when the validation loss reaches similar value to the training loss. We tested the optimized model on a testing image and generated the output image based on the predictions of the model (Fig 3B-C). We observe that the model accurately predicts most cells, but it misclassifies cells that are closely packed due to difficulties in segmenting dense cell clusters.

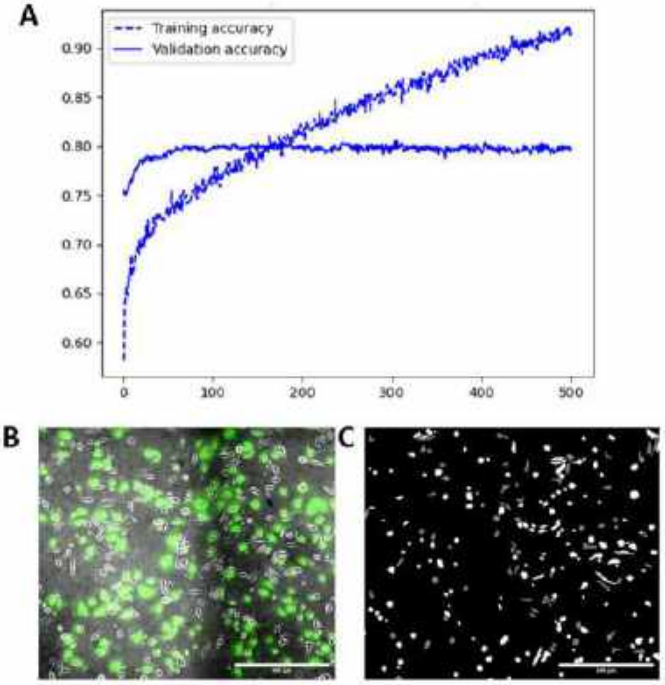

Figure 3. A) Training and validation accuracy curves for model trained on dataset of 10000 cells. B) Input image to the machine learning algorithm. Green fluorescence is overlaid and indicates VEcad+ population. C) Output image from the network indicating VEcad+ cells as white.

DISCUSSION

Our differentiation protocol improves both the yield of CD144+ dECs and PDPN+/CD31+ mature LECs, which will be useful lymphatic and vascular tissue engineering research. We also developed a potential tool that can be used to distinguish dECs from the byproducts such as fibroblasts and fibroblast-like cells, which will help researchers quickly determine the efficacy of their differentiation protocols.

OSTEOTOMY HAS VARIABLE EFFECTS ON CONSTRUCT STIFFNESS OF CADAVERIC TIBIAE: IMPLICATIONS FOR FUNCTIONAL EVALUATIONS

INTRODUCTION

Osteotomies are a surgical technique utilized by orthopaedic surgeons to alter and reshape bony morphology. For example, slope reducing osteotomies cut and remove a wedge of bone on the anterior side of tibia to reduce the posterior tibial slope. Individuals with tibial slopes ≥12.0° are at an increased risk for failure following anterior cruciate ligament reconstruction (i.e., graft failure) [1]. Therefore, surgeons may perform a slope reducing osteotomy in combination with a ligament reconstruction depending on the individual's tibial slope to reduce the risk of rupture [2]. However, the time zero effects of performing osteotomy cuts on the tibial construct's stiffness may be altered which influences the deformation of the complex. Changes in stiffness have implications for osteotomies in patients, material testing protocols, and functional evaluations utilizing the assumption of rigid bodies. Therefore, the objective was to quantify the stiffness of Intact, Osteotomized Native Slope, and Osteotomized Increased Slope states.

METHODS

Seven fresh frozen cadaveric tibiae (61.5 ± 12.6 years, 6 females and 1 male) were dissected and all soft tissue removed. The tibia was potted in an epoxy compound (Bondo; 3M) and secured with a custom aluminum clamp to the base of a uniaxial material testing machine (Figure 1). Three tibial construct states (Intact, Osteotomized Native Slope, and Osteotomized Increased Slope) underwent a non-destructive cyclic compression testing protocol. All surgical procedures including the osteotomy and external fixation were performed by a fellowship trained orthopaedic surgeon with five years of experience. The tibial complex was preloaded to 5.0N and then preconditioned for 30 cycles between 5.0 and 125.0N. Thirty cycles were chosen for preconditioning based on preliminary testing to determine the number of cycles required to minimize hysteresis. Finally, the construct was cyclically loaded between 5.0N and 250.0N. The construct was allowed to rest for thirty minutes in between states and continuously hydrated with saline.

For each construct, the secant stiffness was quantified during the 50th loading cycle. In the Osteotomized Native Slope state, the osteotomy cut was made and the bone removed during the cutting process was replaced with a thin PLA 3D printed wedge to account for the blade thickness of the oscillating saw and maintain the native slope value (Figure 1). The wedge was approximately 1.0mm thick. Similarly, when the slope was increased, a larger wedge printed from PLA was inserted and the construct was fixed with an external fixator (three carbon rods and four Schanz pins). The external fixation configuration was determined based on preliminary testing to maximize rigidity. The slope was increased by approximately 12.0° (the same wedge was inserted to each specimen) to ensure each tibia would hit the slope threshold where osteotomy is indicated [3]. Secant stiffness was chosen due to the complex loading condition (i.e., compression, tension, shear) that occurs when cuts are made to the bone and multiple materials are in the construct. Thus, due to the varying materials in the system, the modified secant stiffness is most appropriate as it provides an average response of the entire complex (calculated as the slope of line connecting first and last point of loading cycle) [4].

Since the data was not normally distributed, the Friedman test was utilized to determine if any differences existed between the secant stiffness of the three states. If the Friedman test was significant, Wilcoxon Sign Ranked tests were used to compare all states. Then, a Bonferroni correction would be utilized to correct for multiple comparisons. Since the current study assessed all pair-wise comparisons, significance was set at $p<0.017$ for post-hoc testing based on the correction for multiple comparisons.

RESULTS

The median and interquartile ranges (25th percentile, 75th percentile) for the Intact, Osteotomized Native Slope, and Osteotomized Increased Slope stiffnesses were 546.5 N/mm (501.5, 602.7), 520.3 N/mm (465.6, 638.0), and 456.1 N/mm (339.8, 490.4), respectively.

Specimen specific data for each construct state are shown in Table 1. Utilizing the quartile-based coefficient of variation (interquartile range/median), the interquartile range was 18.5%, 33.1%, and 33.0% of the median stiffness for the Intact, Osteotomized Native Slope, and Osteotomized Increased Slope. Thus, variability in the data increased following the osteotomy and increased slope.

Overall, the median stiffness for the Osteotomized Native Slope was 4.8% smaller compared to the Intact state. The Osteotomized Increased Slope median stiffness was 12.3% smaller compared to the Osteotomized Native Slope state, and the Osteotomized Increased Slope state median stiffness was 16.5% smaller compared to the Intact state. All specimens experienced decreased secant stiffness following each change in construct state, with the exception of specimen 1 and 4 (essentially no change between Osteotomized Native Slope and Increased Slope states). No statistically significant differences in secant stiffness at the 50th cycle between states were found. Specifically, following post-hoc tests with Bonferroni correction, there was no difference in stiffness between the Intact state and Osteotomized Increased Slope state ($p=0.043$). No difference in stiffness was observed between the Osteotomized Native Slope state compared to the Osteotomized Increased Slope state ($p=0.028$). No difference was found between the Intact and Osteotomized Native Slope states ($p=0.176$).

DISCUSSION

The major findings from the current study were: 1) Performing an osteotomy and increasing the slope did not significantly decrease the tibial construct stiffness, and 2) based on the interquartile ranges for each state, there is large variability in stiffness changes for different tibial construct states. The first finding suggests that performing the osteotomy cut in isolation or in combination with increasing the slope does not significantly affect the tibial constructs' stiffness. However, all specimens experienced decreased or no change in secant stiffness following each change in construct state, with the exception of specimen 1. Furthermore, specimen 3's secant stiffness for the Intact and Osteotomized Native Slope states were much higher and could be due to better bone quality observed while handling the specimen.

Based on the large interquartile ranges, quartile-based coefficient of variation, and limited sample size, assuming the stiffness does not change may be inappropriate on a case-by-case basis. The finding has implications for surgery in older individuals and experimental studies utilizing robotic testing systems to evaluate knee function following osteotomy. Osteotomies in the coronal plane (e.g., medial closing or lateral opening wedge) are often used in older patients to relieve symptoms associated with lateral compartment degeneration [5]. Thus, surgeons should consider the variable time-zero effects of performing osteotomies on the bony construct's stiffness. Furthermore, during experiments utilizing robotic testing systems to evaluate knee function and in-situ forces in ligaments, researchers should establish quantitative checks to ensure the principle of superposition [6] is not violated (i.e., rigid body assumption holds). For example, the magnitude and direction of the in-situ force should be checked to ensure the magnitude and direction (tensile force) are reasonable. Care should be taken when applying external fixation to ensure rigidity of the construct is maximized.

The primary limitation of the current study is that an increased slope was simulated by performing an osteotomy and inserting a plastic wedge to maintain the increased slope. However, this methodology has been utilized in peer-reviewed published literature with cadaveric specimens [7]. Thus, the current work has implications for surgical procedures and future experimental work evaluating the effects of osteotomy on knee function. Future work will quantify the bone quality of cadaveric tibiae and determine the association with secant stiffness.

INTRODUCTION

Tumor microenvironments undergo marked changes in extracellular matrix (ECM) and vascularity that affect cancer cell signaling, drug delivery, and effects of therapy (*1*). Tumors also contain an abundance of leaky blood vessels combined with a compromised drainage system due to poorly functioning lymphatic vessels, resulting in elevated interstitial fluid pressure. These aberrations in ECM composition and vascular function manifest in biophysical changes in tissue stiffness, ECM pore size, and interstitial diffusive and convective transport. Perfusion, interstitial pressure, and altered ECM composition comprise specific cancer phenomena that are difficult to examine *in vivo*. Here, we used several biomimetic 3-D microfluidic systems that couple systematic evaluation of interstitial flow-potentiated angiogenesis and lymphangiogenesis with detailed characterization of ECM physical properties determined by the ECM composition. The focus of these studies are the effects of glycosaminoglycans (GAGs), such as hyaluronic acid (HA), in modulating the bioactivity of the ECM by altering the structural properties of fibrillar collagen, in controlling angiogenesis in the presence of interstitial flow.

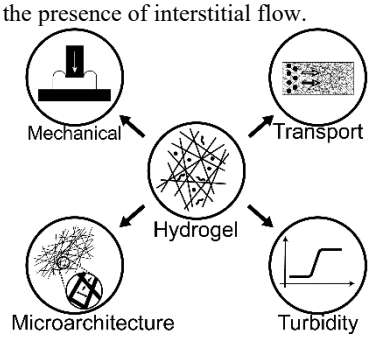

Figure 1. Biophysical characterization scheme for hydrogels. We assay collagen supplemented with GAGs for indentation stiffness (mechanical), hydraulic permeability (transport), confocal reflectance microscopy (microarchitecture), and turbidity (aggregate formation) (*2-4*).

METHODS

We have developed a characterization scheme for fibrillar collagen-based hydrogels (Figure 1) (*2-4*), which measures coupling between ECM mechanics and transport properties mediated by different GAGs (*5*). These methods uniquely position us to define interrelationships among physical properties of the ECM and interstitial flow. We have also developed several microfabricated microvessel models described below.

RESULTS

We recently reported that endothelial cells integrate physical cues derived from matrix HA during angiogenesis induced by interstitial flow (*5*) (Figure 2). A novel finding was that HA enhances interstitial flow-mediated angiogenic sprouting through its alterations to ECM stiffness and pore size. We have also developed a microtissue-engineered model that mimics the microanatomy of initial lymphatic capillaries and enables quantification of lymphangiogenesis and lymphatic vessel permeability (Figure 3). We show that interstitial flow is maximum at the blind-ended region (Fig 3D), thereby mimicking the fluid absorption characteristics of lymphatic capillaries (*6*). We demonstrate that interstitial flow (5 μm/s) alone, and in absence of a pro-lymphangiogenic molecule (e.g., CXCL12 or VEGF), preferentially induces lymphangiogenesis at the blind-ended region of the lymphatic vessel (Fig 3G).

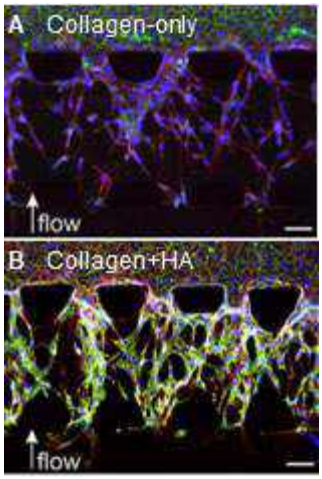

Figure 2. HA enhances interstitial flow-mediated sprouting angiogenesis. Human umbilical vein endothelial cell (HUVEC) sprouting induced by interstitial flow (~10 μm/s) in A) 3 mg/ml collagen-only and B) 3 mg/ml collagen and 1 mg/ml HA matrices(*5*).

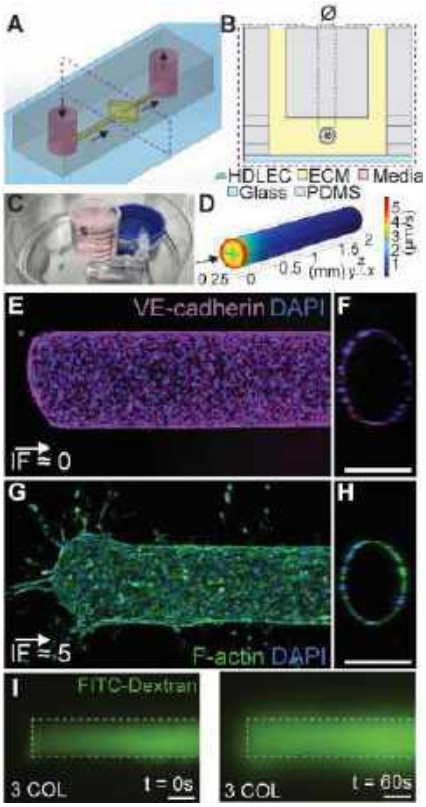

Figure 3. Micro-engineered and perfusable blind-ended lymphatic vessel. A) Schematic of a PDMS-based microfluidic device containing human dermal lymphatic endothelial cells (HDLECs) assembled into a patent lymphatic vessel. **B**) Transverse cross section of vessel surrounded by ECM. The microvessel absorbs fluid into its lumen originating from the upstream media port. ⊗ denotes fluid flow into the vessel. **C**) Photograph of vessel-containing microfluidic device setup. **D**) COMSOL analysis of interstitial flow. **E**) Confocal projection and **F**) cross section of a blind-ended and quiescent HDLEC-lined microvessel stained at day 4 for endothelial junctions (VE-cadherin, magenta) and nuclei (DAPI, blue) in a 3 mg/mL collagen gel under static flow conditions. **G**) Confocal projection and **H**) cross section of a blind-ended microvessel stained at day 4 for F-actin (Phalloidin, green) and nuclei (DAPI, blue) in a 3 mg/mL collagen gel under interstitial flow potentiated by an interstitial fluid pressure gradient. **I**) Measurement of lymphatic microvessel permeability using 20 kDa FITC-Dextran as a fluorescent tracer. Images were recorded at t = 0 and 60 s after loading of the dye. Dashed box outlines engineered lymphatic vessel. Scale bars are 200 μm.

DISCUSSION

Using 3D microfluidic biomimicry with detailed characterization of hydrogel scaffolds, we investigated how ECM physical properties influence interstitial flow-mediated sprouting angiogenesis and lymphangiogenesis. Key observations include the addition of HA to collagen-based hydrogels significantly enhances the initial extension and sustained elongation of endothelial sprouting in response to interstitial flow. Moreover, in a blind-ended lymphatic vessel, sprouting preferentially occurred at the leading edge where interstitial flow was highest or a local maximum. Taken together, these novel findings comprise important advancements toward refining our understanding of angiogenesis and lymphangiogenesis that is mediated by the biophysical microenvironment. Moreover, these results will help inform future developments in pro-angiogenic biomaterials and *in vitro* disease models (e.g., organs-on-a-chip) for interrogating mechanisms of vessel outgrowth and remodeling.

ESTABLISHING A COMPREHENSIVE COLLECTION OF ETHICS RESOURCES FOR BMES AT THE ONLINE ETHICS CENTER: ASSESSING AND STRUCTURING MENTORING RESOURCES

Anjelyka T. Fasci (1), Sanjana Prashanth (2), Andrew O. Brightman, Ph.D. (2), Robert L. Hood, Ph.D. (1)

(1) Department of Biomedical Engineering, University of Texas at San Antonio, San Antonio, TX, USA
(2) Weldon School of Biomedical Engineering, Purdue University, West Lafayette, IN, USA

INTRODUCTION

In the dynamic landscape of Biomedical Engineering, the ethical considerations surrounding research, teaching, and training play a pivotal role in shaping the character and impact of the biomedical engineering community[1], [2]. Ethics, in this context, refers to the principles and standards that guide professionals in making morally sound decisions, ensuring responsible conduct in every aspect of their work. The commitment to ethical practices is fundamental in engineering, fostering trust, accountability, and integrity within the Biomedical Engineering Society (BMES). Recognizing the evolving ethical dimensions, the BMES Ethics Committee undertakes the crucial task of aggregating resources to equip members with the necessary knowledge and insights.

The impetus for this initiative stems from the Ethics Committee's dedication to addressing the multifaceted challenges posed by ethical considerations in all aspects of professional life and practice. This study was focused on the realm of mentoring within Biomedical Engineering. Mentorship, a cornerstone in the development of future engineers, involves a symbiotic relationship that extends beyond technical proficiency. It encompasses the transmission of ethical values, instilling a sense of responsibility and integrity in the mentees[3]. This emphasis on ethical mentorship aligned with the special session at the 2023 Annual BMES Conference, focusing on "Establishing and Sustaining Effective Mentor/Mentee Relationships."

Moreover, drawing inspiration from the 2022 paper on "Ethical Practices and Tips for Improving Engineering Faculty-Student Research Relationships," the committee acknowledges the evolving nature of ethical considerations, particularly in the academic and research spheres, resulting in the 2022 revision of the BMES ethics code of conduct[4]. Mentorship and leadership, integral components of scientific endeavors, take on added significance when viewed through the ethical lens. Mentorship goes beyond the mere transfer of technical knowledge; it becomes a guiding force that shapes the ethical compass of future scientists and engineers[3].

In recognizing the critical role of mentorship, our study aims to evaluate the available resources, identify gaps, and lay the groundwork for enhancing ethical discourse. Through a thorough examination, we seek to contribute valuable insights to the ongoing conversation on mentorship ethics, aligning with our commitment to cultivating responsible and ethical practices within the realm of scientific mentorship.

METHODS

In systematically organizing ethical resources, the student research team collaborated with mentors to formulate a comprehensive plan, aiming not only to accumulate but critically evaluate and categorize existing resources on the Online Ethics Center for Engineering and Science (OEC). Virtual brainstorming sessions facilitated nuanced discussions on potential categories addressing diverse ethical challenges in Biomedical Engineering. Using an organic approach, the team identified foundational terms for mentorship discussions, exploring OEC resources and uncovering new categories.

With a deliberate focus on the "Mentors and Trainees" section, the team centralized addressing the ethical minutiae of mentorship. This was a trial-by-trial process, in which the team read each individual resource and placed them in the appropriate categories, which then lead to the creation of new categories if there was a trend that required such action. This resulted in 14 categories for the resources to be organized.

RESULTS

As shown in Figure 1, the 14 categories have a variety of wealth. Critical gaps in mentorship coverage surfaced, notably in various mentoring types like Community, Team, or Reciprocal mentoring. These omissions highlight an oversight, leaving potential guidance gaps for those engaging in these dynamics.

Additionally, the analysis revealed a lack of discussion on negligence within the mentor-mentee relationship, a crucial aspect needing attention and direction. This gap raises considerations for enhancing ethical discourse, emphasizing the need for comprehensive insights on recognizing and addressing negligence from both mentor and mentee perspectives. Of particular significance is the identified diversity gap, including age, sexual identity, race, and gender.

Figure 1 Mentorship Category Resources

The age distribution, depicted in Figure 2 (1989-2022), reveals a shortage of recent materials, suggesting a potential gap in addressing contemporary ethical challenges. While historical context is rich, the limited representation of recent perspectives underscores the need to incorporate modern viewpoints. This consists of inclusion, diversity, and boundary setting, items which are vital for guiding the next generation of biomedical engineers in navigating the ethical complexities inherent in their roles as mentors and leaders.

On a positive note, abundant resources were available for protocols, training, boundaries, and power dynamics prove invaluable for those entering mentorship. These serve as foundational guidance for navigating mentor-mentee complexities. Despite strengths, identified gaps emphasize the continuous need for refining resources in mentorship ethics within Biomedical Engineering's diverse and evolving challenges[4].

DISCUSSION

This finding underscores the dynamic nature of the ethical landscape in Biomedical Engineering, shaped by evolving societal norms, technological advancements, and interdisciplinary collaborations. While historical perspectives offer valuable insights, relying exclusively on past materials may inadvertently neglect the unique ethical dilemmas emerging in the rapidly changing discipline. The scarcity of materials from the last two decades emphasizes the urgency of infusing the ethical discourse surrounding mentorship and leadership with contemporary perspectives. This infusion is vital for addressing novel challenges presented by advancements in technology, changes in research methodologies, and evolving expectations within academic and professional settings.

In light of these observations, broadening the scope of ethical considerations gains added significance. Actively incorporating modern perspectives ensures alignment with current standards, resonating with challenges in today's rapidly evolving landscape. Recognizing the importance of not only filling resource gaps but also adopting a forward-looking, inclusive approach is essential. As the field advances, an adaptive and contemporary ethical framework becomes indispensable for fostering responsible conduct, integrity, and ethical leadership within the engineering community.

Figure 2 Mentorship Resource Ages

Acknowledging the wealth in the "Mentors and Trainees" resources, the study identifies three critical areas for improvement. Firstly, recognizing the need to address content scarcity, especially in diversity-related categories like age, sexual identity, race, and gender, underscores the imperative of fostering a more inclusive ethical framework in the engineering community. Secondly, a recommendation is made for the reorganization of OEC resources to enhance usability, aiming for a more accessible platform that fosters responsible conduct.

Lastly, the study emphasizes the pressing need for expanding contemporary ethical mentoring resources that engage with the evolving landscape of the scientific and engineering community. Ethical considerations in mentorship and leadership should not be static; they should evolve to address contemporary issues, ensuring that future engineers are equipped to navigate the ethical complexities of their profession. This research serves as a foundational step towards a broader initiative, collecting and organizing pertinent materials for the changing landscape of mentoring ethics in bioengineering and biomedical engineering.

ACKNOWLEDGEMENTS

Dr. Andrew O. Brightman, OEC Fellow for Ethics in Biomedical Engineering, and Dr. R. Lyle Hood, BMES Ethics Committee Chair, led the team using OEC resources. Each professor mentored a student in identifying, evaluating, and organizing materials for the Biomedical Engineering Society. COMPARING REGIONAL VARIATIONS IN RADIODENSITY WITH STIFFNESS IN AN ATHEROSCLEROTIC HUMAN AORTA

Carly L. Donahue (1), Victor H. Barocas (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Atherosclerosis is a vascular disease characterized by the buildup of plaque in the arterial wall and local tissue remodeling in response to both biological and mechanical cues [1]. Atherosclerotic lesions can be visualized *in vivo* by computed tomography (CT)-based technologies, which are often used to calculate local tissue density for the detection and assessment of atherosclerotic plaques in the clinical setting [2].

In the aorta, atherosclerotic lesions are associated with several life-threatening conditions, such as the formation and failure of aneurysms, pseudoaneurysms, and aortic plaque rupture [3]. Notably, each of these complications is largely mechanical in nature. While many studies have sought to characterize the mechanical properties of plaque lesions [4]; few [5] have focused on the mechanical changes to the nearby vessel wall. Understanding these alterations is crucial, as they play an important role in the formation, progression, and failure of the aforementioned complications.

The current work assessed the correlation between local tissue radiodensity from micro-CT analysis and the heterogeneous local stiffness obtained from biaxial testing of human cadaveric aortic tissue samples. We tested the hypothesis that higher tissue radiodensity indicates a larger local stiffness.

METHODS

Sample Preparation: A total of 8 cruciform-shaped samples (example in Fig. 1A) were dissected from a fresh human cadaveric aorta (75M, Anatomy Bequest Program, U of Minnesota), 4 from the ascending thoracic aorta and 4 descending thoracic aorta. The samples had widths of 20-25 mm and an average thickness of 2.0 mm.

Mechanical Testing: The samples were speckled and mounted into the grips of a planar biaxial system (Instron-Sacks, Norwood, MA, Fig. 1B). Samples were submerged in 1XPBS throughout the experiment. A 0.1 N preload was applied to each arm before testing. The Generalized Anisotropic Inverse Mechanics (GAIM) protocol [6] consisting of 15 different deformations was applied. All extensions were to 15% grip strain at a displacement rate of 10 mm/min. All tests were video-recorded for subsequent DIC analysis.

Micro-CT Analysis: Samples were laid flat on a foam stage, sprayed with 1XPBS for hydration, and scanned with an average resolution of 85.1 μm (NSI, Rogers, MN, Fig. 1C). Scan times were ~7 minutes. Regional values for radiodensity were reported in Hounsfield units (HU).

Inverse Mechanical Analysis: Regional differences in CT radiodensity were used to partition the sample into 10 homogeneous sub-regions as described in [7]. Using the surface deformation determined from DIC analysis and the forces on the boundary, the 2-D linear stiffness tensor C was determined for each partition [6]. The largest eigenvalue of C, the Kelvin Modulus, is a measure of the material stiffness of the partition.

Comparisons and Statistical Analysis: The local material stiffness was mapped to the average through-thickness radiodensity for each partition. Linear regression was used to assess their correlation.

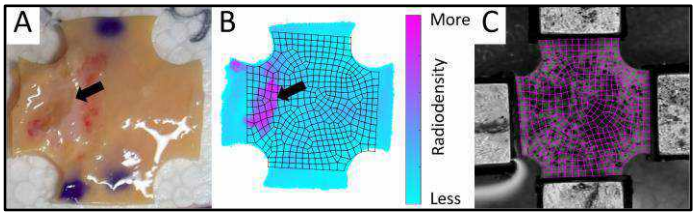

Figure 1: A) Aortic sample with atherosclerotic plaque lesion (arrow). B) Average through-thickness radiodensity measured via micro-CT. The arrow points to the denser plaque region. C) Biaxial tensile test. The overlaid mesh shown in B and C was used to map radiodensity to mechanical results.

RESULTS

Six of the eight samples had at least one calcified plaque lesion (HU >300, Fig. 2A). The other two samples showed early signs of atherosclerosis, but the micro-CT did not show a calcified lesion. The partitioning algorithm segmented the calcified regions from the surrounding aortic media. In most cases, this was determined to be the stiffest part of the sample (e.g., Fig. 2B).

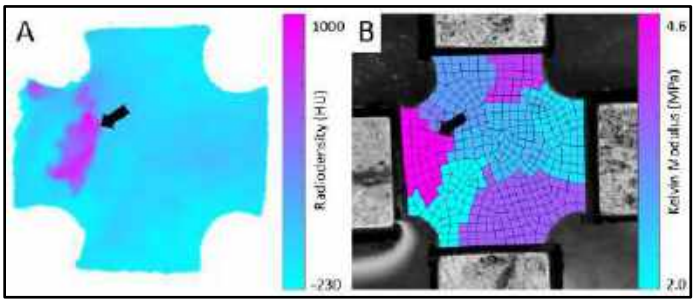

Figure 2: A representative sample. Average through-thickness radiodensity (HU) measured via Micro-CT. The arrow points to the calcification. B) Stiffness of each homogeneous partition (Kelvin Modulus, MPa) measured via inverse mechanical analysis. The stiffest region (arrow) corresponds to the calcification.

Figure 3 shows the correlation between the average partition radiodensity (HU) and the partition stiffness (Kelvin Modulus, MPa) for all partitions of all eight samples. Overall, stiffness is positively correlated with tissue radiodensity, as shown by the positive slope of the linear regression ($p < 0.0001$). The highest densities showed high Kelvin moduli, and there were many low-radiodensity, low-modulus partitions. However, there were also some low-radiodensity, high-modulus partitions, and many partitions fell outside of the confidence bounds demonstrating a rather weak fit of the data ($R^2 = 0.173$).

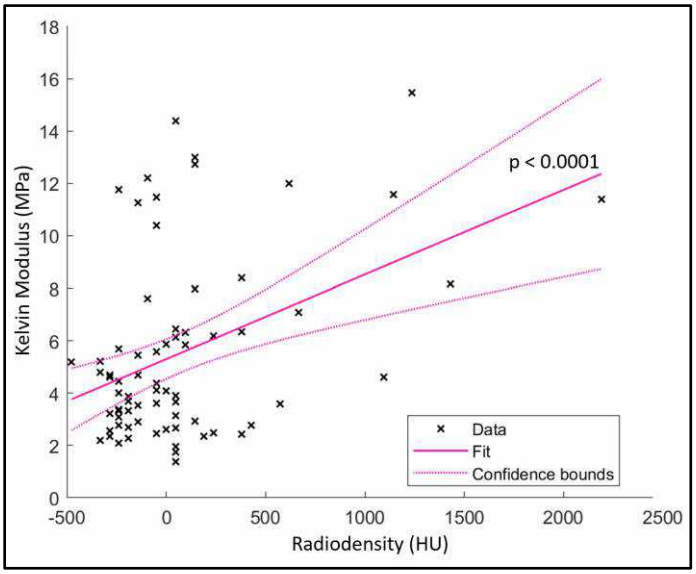

Figure 3: Radiodensity measured via micro-CT (Hounsfield units, HU) vs. Kelvin modulus (MPa) measured via inverse mechanical analysis for each partition. The solid red line shows the linear regression, and the dotted lines show the confidence bounds.

DISCUSSION

The present study investigates the biomechanical interplay between calcified plaque lesions, as identified by increased local tissue radiodensity, and the local stiffness of a human aortic wall measured via biaxial testing. The stiffest regions, identified through inverse mechanical analysis, consistently coincided with calcified areas, emphasizing the impact of advanced atherosclerotic disease on tissue stiffness. Overall, the results reveal a positive correlation between tissue radiodensity, assessed through micro-CT, and local stiffness measured via biaxial testing, corroborating the existing body of literature that associates atherosclerosis with augmented vessel wall stiffness [8,9].

The prominence of partitions with low radiodensity but high stiffness introduces complexity to the relationship between radiodensity and stiffness. As a result, there is a weak fit of the data to the linear model, as indicated by the modest R^2 value, suggesting that factors that go undetected by micro-CT, such as non-calcified components, different stages of plaque development, or tissue crosslinking, may contribute to the stiffness of the tissue [10]. Further investigations into the compositional diversity of atherosclerotic plaques and the adjacent medial tissue as well as their biomechanical implications are warranted to comprehensively understand the observed variations.

This study is one of the few that establish a correlation between micro-CT-derived radiodensity and the mechanical properties of blood vessels [11]. However, it is important to acknowledge the inherent limitations associated with our methodology, particularly in the assumptions made during the Generalized Anisotropic Inverse Mechanics (GAIM) analysis. First, the use of a 2D mesh assumes uniform sample thickness and material properties through the thickness, introducing potential inaccuracies. Second, the material behavior of each partition is assumed to be linear, oversimplifying the complex nature of arterial tissue behavior. While these limitations may introduce quantitative errors, they do not take away from our overall conclusions.

In conclusion, the observed correlation between tissue radiodensity and stiffness, despite its nuances, underscores the potential of utilizing CT imaging to assess the biomechanical implications of plaque lesions. Since CT is non-invasive and is routinely used to monitor many patients with vascular disease, especially many aortopathies, a CT-based mechanical assessment could potentially improve our ability to evaluate clinical risk and manage atherosclerosis-related conditions.

CONCENTRIC CONTRACTION DURING UNLOADING PREVENTS STRAIN SOFTENING IN THE MOUSE URINARY BLADDER

INTRODUCTION

Current methods of *ex vivo* bladder mechanical testing employ techniques used to test passive tissues (*e.g.* skin and tendons), where the tissue is loaded and unloaded passively in tension [1]. During passive-only testing, bladder tissue does not fully return to the original configuration and subsequent loading shows increased tissue compliance, which is called strain-softening. In passive tissues like skin and tendon, strain-softening does not occur either *in vitro* or *in vivo*; in the bladder, strain-softening is prevented via detrusor contraction [2]. It is thought that strain softening in the bladder occurs due to slippage of actomyosin cross-bridges during passive distension and is reversed via cyclical contraction of detrusor smooth muscle cells during emptying [3]. Here we present a novel mechanical testing method that incorporates passive distention and optogenetic contraction to prevent strain-softening and enable us to accurately measure the material properties of bladder tissue.

METHODS

To induce contractility *ex vivo*, we crossed *ChR2(H134R)-EYFP* mice (JAX, #024109), with *SM22-Cre^{tg}* mice (JAX, #017491), in which Cre recombinase is under the control of the mouse smooth muscle protein 22α promoter. SM22-*Cre^{tg};ChR2(H134R)-EYFP* mice express channelrhodopsin-2 and enhanced yellow fluorescent protein (EYFP) in smooth muscle cells (SMCs), enabling contraction of the bladder via blue-light stimulation (450-490 nm) and visualization of SMCs via EYFP. We utilized a floating platform mechanical testing system (Fig 1) that allows for mechanical testing and imaging while submerged in phosphate buffered saline (PBS). Optogenetic contraction was induced via a 500 mW, 455 nm diode laser (Opto Engine) and optical fiber patch cable (RWD Life Science), with a circular spot size of 50 mm^2 to generate an approximate irradiance of 10 mW/mm^2.

Two mechanical testing protocols were used. First, a passive-only protocol was used to demonstrate an example of field-standard mechanical testing. In this protocol, circumferential bladder rings were excised, mounted onto the testing system, and stretched using a force-mediated approach where a 100 µN tare load is added. Then the tissue was cycled between 0-20 mN of tension for 5 cycles. Following this protocol, the load cell was detached from the mechanical testing setup to allow unconstrained sample movement. The bladder was then contracted via the addition of acetylcholine chloride, to a final bath concentration of 0.1 mM, to allow the bladder to freely contract.

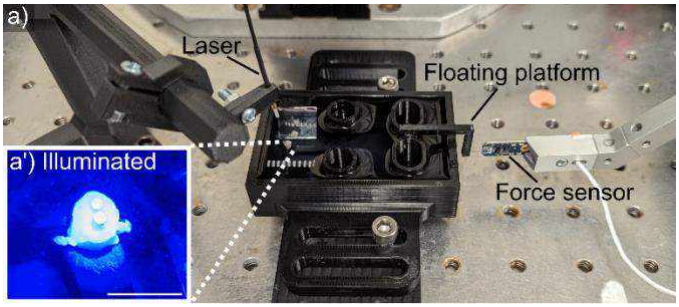

Figure 1: Mechanical testing setup used for both methods of mechanical testing. (a') For optogenetic contraction tests, the bladder was stimulated via the 455 nm laser.

The second protocol utilized optogenetic contraction during the unloading stage to recapitulate the active contraction that occurs during micturition *in vivo*. After a 100 µN tare load was added, the tissue was loaded to 10 mN, unloaded to 0 mN, then contracted via optogenetic stimulation while the tissue was returned to the original unloaded length. This cycle was repeated 5 times.

RESULTS

Passive-only testing (Fig. 1) resulted in substantial strain-softening. This is revealed by the increase in unloaded tissue length at zero force (Fig 1a, the unloading phase stops at displacements greater than 0), and

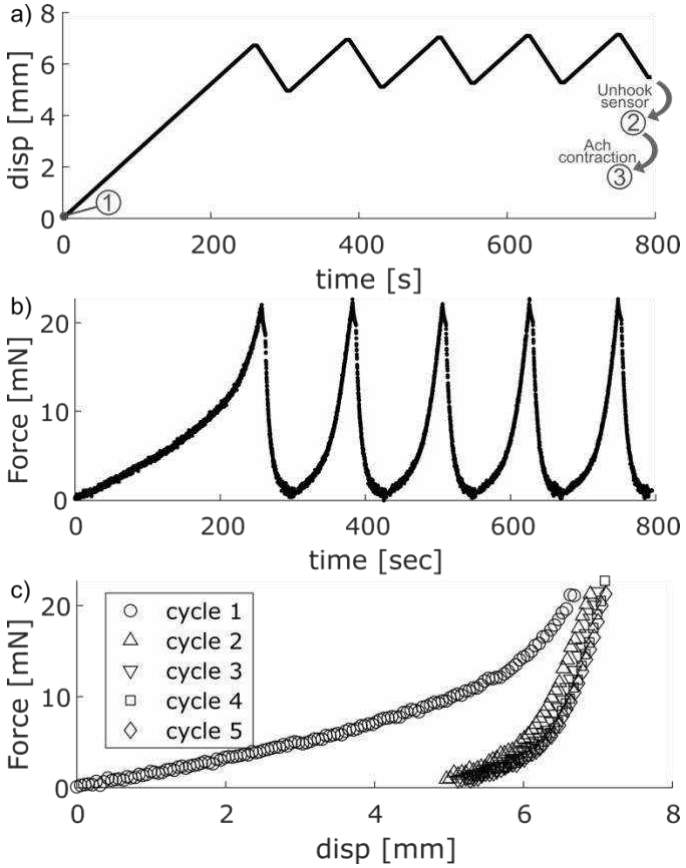

Figure 2: Mouse bladder ring mechanical data collected using the field-standard passive-only deformation method. a) Displacement history, b) force history, and c) force-displacement loading curves.

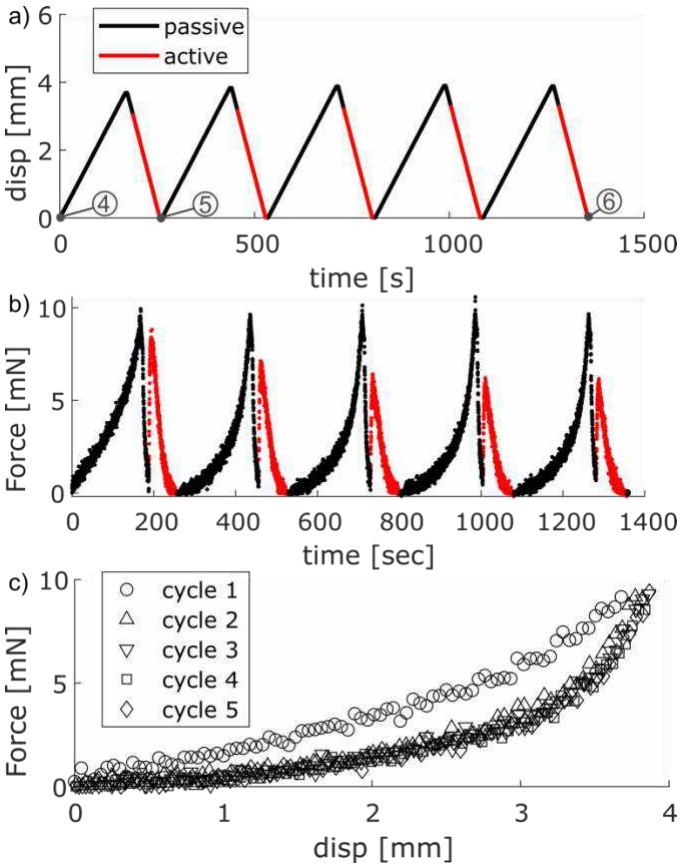

Figure 3: Mouse bladder ring mechanical data collected with an optogenetic concentric contraction protocol. a) Displacement history, b) force history, and c) force-displacement loading curves.

increased tissue compliance (Fig 1c, rightward shifted force-displacement loading curves). When the concentric contraction protocol was used, the tissue was able to return to its original unloaded length (Fig 2a, active contraction during unloading returns displacement to zero). After this contraction, subsequent passive loading curves (Fig 2c) were repeatable and not rightward shifted.

Following mechanical testing with the passive-only protocol, unloaded bladder rings remained in a deformed state (Fig 4, top row). Subsequent contraction of the unloaded bladder via addition of acetylcholine allowed the bladder to return to its original unloaded configuration (Fig 4). Using the optogenetic concentric contraction mechanical testing protocol, the bladder configuration returned to the unloaded configuration after all 5 cycles (Fig 4, bottom row).

DISCUSSION

Current field-standard methods of *ex vivo* bladder mechanical testing lead to strain softening that is not recovered until contraction is applied. This limits the ability to translate *ex vivo* mechanical data to *in vivo* mechanics. Applying contraction during the concentric phase of deformation prevents strain softening. We are working to combine the optogenetic-induced contraction with multiphoton imaging to uncover the effect of detrusor contraction on ECM configuration. Ultimately, we plan on implementing the morphological and mechanical data in an FE model that will be used to evaluate the importance of ECM organization on the mechanical response. The combination of experimental and computational methods will be useful in evaluating bladder dysfunction and improve predictions of pathological changes in bladder function.

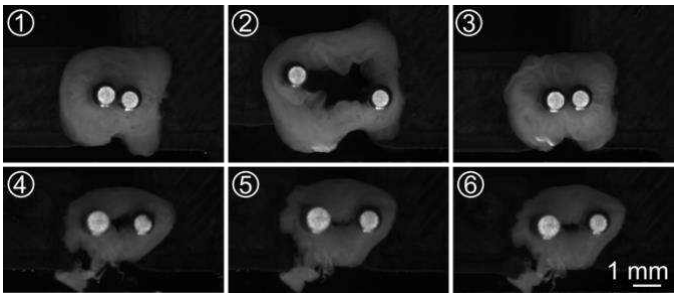

Figure 4: Top row shows ring from control mouse (1) before testing, (2) after testing, and (3) after contracting with acetylcholine. Second row shows ring from SM22-*Cre^{tg};ChR2 mouse* (4) before testing, (5) after cycle 1 + active contraction and (6) after cycle 5 + active contraction. Numbers indicate when brightfield images of rings were acquired at different stages of loading as illustrated in Figs 2 and 3.

INTRODUCTION

While most cerebral aneurysms remain stable over the years, their rupture results in 50% mortality and morbidity, thus necessitating comprehensive methodologies for their risk stratification. Variations of Wall Shear Stress (WSS) have been established to correlate with the growth and rupture of an aneurysm[4]. Subject-specific computational fluid dynamics (CFD) models can provide high-resolution WSS distribution for aneurysmal arteries[1], however numerical results depend on multiple modeling assumptions. Alternatively, 3-directional phase-contrast Magnetic Resonance Imaging (4D flow MRI) can capture velocity fields over the cardiac cycle, enabling non-invasive *in vivo* assessment of cerebral blood flow dynamics[2]. However, the spatiotemporal resolution and image noise can limit the accuracy of 4D flow measurements, affecting in turn the accuracy of MRI-based WSS estimates. These limitations hindered the adaptation of 4D flow MRI in both research and clinical settings. Recent studies demonstrated that 4D flow MRI data can be enhanced by using fluid dynamics principles to estimate and reduce the error of measured velocity fields[3,5]. This study aims to compare WSS distribution based on velocity fields derived from CFD simulations and from 4D Flow MRI in cerebral aneurysms. By evaluating similarities and discrepancies in WSS obtained from these alternative approaches, we provide the groundwork for examining the capabilities of 4D flow MRI in providing hemodynamic factors discriminating between stable and unstable cerebral aneurysms.

METHODS

The aneurysms used for this study were scanned on a 3T Siemens Skyra scanner at Northwestern Memorial Hospital with prospective ECG gating and during free breathing. Cerebral arteries were imaged using dual-*venc* 4D flow MRI using a high *venc* of 100 $^{cm}/_{s}$ and a low *venc* of 50 $^{cm}/_{s}$ (1x1x1 mm, TR/TE/flip-angle = 6.3 ms/3.47 ms/15°).

A two-step process was used for image segmentation. Initially, an automated segmentation approach based on the Standardized Difference of Means of the measured velocities was applied to identify MRI voxels with statistically significant net flow effects. Subsequently, a higher-resolution flow mask was obtained from a Time-of- Flight (TOF) MR angiography, using the open-source tool ITK-SNAP. The resulting flow segmentations were coregistered using the Coherent Point Drift algorithm to apply the TOF-based mask to the 4D Flow data. The Universal Outlier Detection method was then applied to the 4D flow data to eliminate spurious velocity measurements. Additionally, in-house phase unwrapping algorithm was applied, and conservation of mass was enforced through a least squares-based global optimization approach.

Vascular geometries and inflow waveforms obtained from MRI data were also used for numerical simulations of the flow using open-source SimVascular software. Blood flow was assumed laminar, and Newtonian and the vessel walls were assumed rigid. The Womersley profile was prescribed at the inlet and RCR boundary conditions were used for each of the outlets. Iterative adjustments were made to the resistance and capacitance parameters by performing several simulations to obtain physiological range of the pressure waveform. Mesh independence of the numerical solution was achieved by obtaining solution on grids with different resolution.

The resulting velocity fields from CFD and 4D flow MRI were used as the starting point for calculating WSS distribution. The WSS is calculated using the radial basis function-generated finite difference method (RBF-FD) a "mesh-free" method based on the localized RBF-interpolant in a compact finite-difference mode. This method can approximate the differential operator at the center node x_1 with a linear combination of the values of a function of $u(x_i)$ of n surrounding nodes:

$$\mathcal{L}u(x_1) \approx \sum_{k=1}^{n} w_{1,k}\, u(x_i) \qquad (1)$$

In this expression, $\mathcal{L}$ represents the derivative operator and $w_{1,k}$ denotes the RBF-FD weights obtained by solving the system below:

$$\begin{bmatrix} \phi & e \\ e^T & 0 \end{bmatrix} \begin{bmatrix} w \\ \mu \end{bmatrix} = \begin{bmatrix} \mathcal{L}\phi \\ 0 \end{bmatrix} \quad (2)$$

where the $\phi_{k,l} = \phi(\|.\|)$ is the RBF function, e is an identity column vector with n entries, $\mathcal{L}\phi$ is the column vector of derivative values of RBF, and μ is constant that ensures the summation of all RBF-FD is zero. Subsequently, the 4D flow-based velocity field was augmented by applying the pressure-gradient induced velocity gradient correction (PG-VGC) method[3] which corrects the velocity gradient based on the reconstructed pressure field gradient to improve the WSS estimation. The conservation laws of mass and linear momentum are incorporated to formulate a linear system. This linear system is used to estimate the velocity-gradient errors with a least-squares approach. The error is then subtracted from the velocity gradient to improve the assessment of WSS. In order to use consistent methods for WSS calculations from both modalities, the same RBF-FD method was applied to obtain WSS from the velocities computed with SimVascular. The resulting WSS distributions were then compared to assess whether physics-based 4D flow MRI reconstruction improves the agreement between the image-based and CFD-based results[3].

RESULTS

Here we show a representative case of an internal carotid artery (ICA) aneurysm. The time-averaged WSS (TAWSS) was calculated for each method and the results were normalized by the TAWSS spatially averaged over a healthy segment of the vessel. The TAWSS obtained directly from SimVascular and calculated from SimVascular-computed velocities with the RBF-FD method were in close agreement as shown in Figure 1 (a) and (b). However, these distributions were noticeably different from TAWSS computed from 4D flow MRI data processed by both RBF-FD and PG-VGC in Figure 1 (c) and (d). Despite that, there are regions of high TAWSS and low TAWSS just before the flow enters the aneurysm, over its wall, and after the flow exits the aneurysm, that are shared across the distributions, obtained with alternative methods.

Figure 2 shows the violin plots for the TAWSS distribution over the aneurysm wall obtained with each method. Both CFD-based TAWSS distributions are similar, while the RBF-FD applied to 4D flow MRI results are different from those obtained with the PG-VGC method.

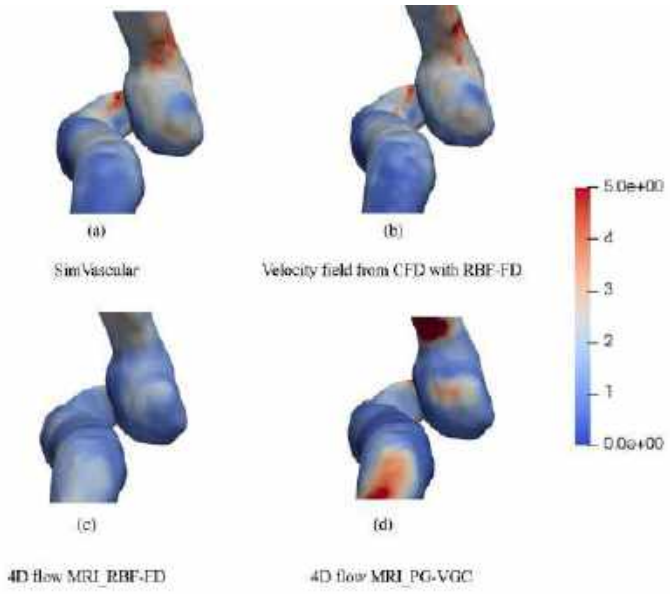

Figure 1: Normalized TAWSS obtained from CFD and 4D flow MRI for an ICA aneurysm.

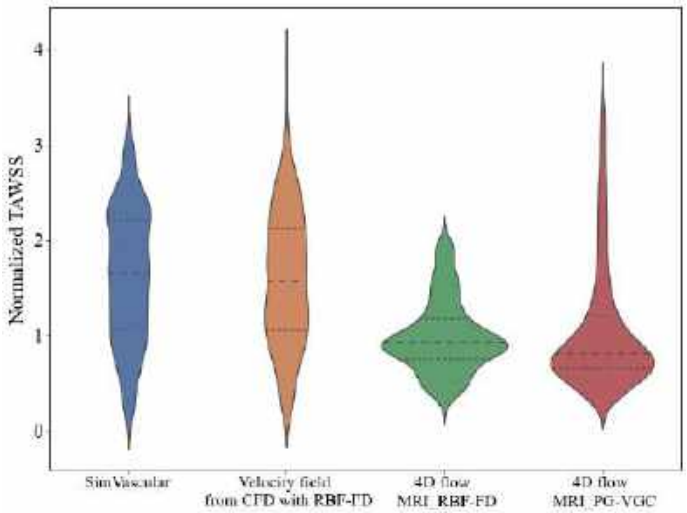

Figure 2: Distribution of normalized TAWSS over the ICA aneurysm obtained from CFD and 4D flow MRI.

DISCUSSION

In this study we compare WSS distributions in an ICA aneurysm computed from CFD and from *in vivo* 4D flow MRI data augmented with PG-VGC method. The WSS was computed from the numerical and MRI-based velocity distributions using the same numerical schemes. This study demonstrates the effect of spatial and temporal resolution on velocity measurements and the resulting discrepancy in the WSS distribution. Additional studies where the same methods are applied to more aneurysmal geometries will allow us to better understand 4D flow limitations in measuring near-wall velocities and improve the accuracy of image-based WSS estimates.

A CASE STUDY: COMPUTATIONAL MODELING OF HEMODYNAMICS IN A PATIENT WITH END STAGE RENAL DISEASE UNDER HEMODIALYSIS VIA ARTERIOVENOUS FISTULA WITH PULMONARY HYPERTENSION

Fatemeh Bahmani (1), Kaitlin Southern (1), Alex Vadati (1), Veeranna Maddipati (2), Stephanie M. George (1)

(1) Department of Engineering, East Carolina University, Greenville, NC, USA

INTRODUCTION

Arteriovenous fistula (AVF) hemodialysis in end stage renal disease (ESRD) patients may lead to pulmonary hypertension (PH), left ventricle dysfunction and heart failure. Cardiovascular problems are the main cause of high mortality rates among ESRD patients who undergo hemodialysis via a surgically created AVF [1]. Understanding the role of arteriovenous fistula creation and characteristics on pulmonary artery (PA) hemodynamics and cardiac output could assist in managing treatment plans and performing kidney transplant before cardiac failure occurs. It is suggested to monitor fistula flow, pulmonary artery pressure and ejection fraction at least six months after the fistula creation to diagnose pulmonary hypertension and intervene to prevent heart failure [1, 2].

Several studies have investigated the increased incidence of pulmonary hypertension in ESRD patients who undergo hemodialysis via arteriovenous fistula and examined the relationship between the fistula blood flow volume, pulmonary artery pressure (PAP) and cardiac output (CO). A fistula with flow rates greater than 1-1.5 L/min is considered a high flow fistula [1]. The prevalence of PH in hemodialysis patients has been reported to be 14% - 43.7% [2-4]. However, these studies defined PH using doppler echocardiography and different diagnostic criteria: sPAP ≥30 mm Hg [2], mPAP≥25 mm Hg [3], sPAP ≥35 mm Hg [4]. No PH was reported in patients who received peritoneal hemodialysis. It is observed that temporary fistula closure or kidney transplant will return the cardiac output and pulmonary pressure to their normal range [4]. The mechanism of PH incidence in ESRD patients who undergo AVF hemodialysis is still ambiguous. Several hypotheses are mentioned in the literature as potential explanations of PH prevalence in ESRD patients. The potential causes might be excessive cardiac output, anemia, and fluid overload. Also, the change in hormones and metabolism may lead to artery constriction and increase the pulmonary artery resistance which may cause pulmonary hypertension. Yilga et al. suggested that increased cardiac output may not be the primary reason for PH incidence in ESRD patients, but increased resistance of vessel wall and decreased response of the pulmonary vasculature could be the main cause. The arteriovenous access for hemodialysis causes an excessive cardiac output and the pulmonary vasculature with increased resistance has lower response to the increased cardiac output to maintain the blood pressure [4].

The goal of our study is to use computational fluid dynamics (CFD) to model the subject-specific blood flow in the pulmonary artery and arteriovenous fistula in a single ESRD patient who was undergoing hemodialysis and developed pulmonary hypertension. This is a unique case study as the imaging data used to create both models were acquired at the same time from the same patient. The results will be compared with findings from the literature.

METHODS

The data acquisition from the patient was approved by East Carolina University Internal Review Board (UMCIRB 19-000708). Here we report the complete results for one subject. This individual was an African American male, 41 years of age at the time of imaging, had been diagnosed with PH via right heart catheterization (RHC) several months before the time of imaging and was undergoing hemodialysis through a mature surgically created arteriovenous fistula. Data measured by RHC of pulmonary artery is listed in table 1.

Table 1. Right heart catheterization data of the patient

mPAP (mm Hg)	PCWP (mm Hg)	PVR (Wood units)	Cardiac Output (L/min)
54	35	2.07	8.2

The MR imaging was performed using a Siemens Aera 1.5 T scanner which uses a gradient echo (GR) imaging sequence. The subject's pulmonary artery geometry was reconstructed using 22 slices with 8 mm thickness from short axis cine scan. The transient velocity waveform of the cardiac cycle just past the leaflets of the pulmonary

artery was obtained using phase-contrast magnetic resonance imaging (PCMRI). For imaging of the fistula, the patient was in the supine position in the MR machine. This allowed for the brachial AVF to be captured in the images. The PCMRI images were processed with an in-house MATLAB code to obtain the PA and AVF data included in table 2.

Table 2. Mean PA and AVF data from PCMRI image processing over one cardiac cycle

	Vessel area (cm^2)	Velocity cm/s	Flow rate (mL/min)	PA diameter (cm)
PA	10.243	6.756	4146.751	3.611
AVF	0.075	17.609	1967.494	0.308

The patient specific pulmonary artery and fistula geometries were reconstructed using the segmentation techniques in Mimics 20.0 (Materialise, Inc., Plymouth, MI). The models were then imported into ANSYS Workbench (ANSYS, Inc., Canonsburg, PA) where the computational mesh was generated, and fluid flow simulations were set up using ANSYS Fluent. Blood was taken to be a non-Newtonian fluid with Carreau viscosity model and a density of 1060 kg/m^3. The transient velocity waveform was implemented at the inlet boundary and the outlets were taken to be zero pressure gradient outlets for pulmonary artery and an 84% proximal vein (PV) and 16% distal artery (DA) split flow outlet for fistula.

RESULTS

Here we report on both pulmonary artery and arteriovenous fistula hemodynamics from the same patient based on data acquired at the same time. The volume rendering of blood velocity and contour of wall shear stress in pulmonary artery at peak systole are shown in figure 1. Volume rendering of blood flow velocity in arteriovenous fistula at peak systole and the velocity waveform implemented at the inlet of proximal artery are shown in figure 2. Pulmonary artery and fistula parameters obtained from CFD simulations are included in table 3.

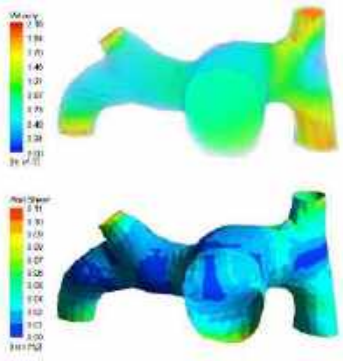

Figure 1. PA volume rendering of velocity (top) and contour of wall shear stress at peak systole (bottom)

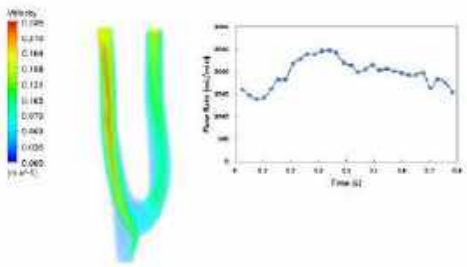

Figure 2. AVF volume rendering of velocity at peak systole (left) and AVF inlet volume flow rate across one cardiac cycle (right)

Table 3. Summary of PA and AVF results from CFD simulation

	Volume Weighted Average Velocity at Peak Systole	Max WSS at Peak Systole (mm Hg)	Max time-Averaged WSS (mm Hg)	Mean of Time Averaged WSS (mm Hg)
PA	0.847 (m/s)	0.114	0.039	0.008
AVF	7.89 (cm/s)	0.131	0.112	0.004

DISCUSSION

Pulmonary hypertension has a prevalence of up to 43% in ESRD patients who receive hemodialysis via AVF [2-4]. The summary of data obtained from echocardiography to study the relationship between AVF flow rate and PA pressure reported in literature is listed in table 4.

Table 4. Literature data of ESRD patients under hemodialysis

Study	No. of patients	PH criteria	% w/ PH	PAP range (mm Hg)	PAP mean±SD (mm Hg)	CO	Fistula flow rate
Beigi 2009	34	sPAP>30 mm Hg	14	11.4-45 (all patients)	19.9±9.17 (all patients)	5500 mL/min before fistula vs 5680 ml/min after fistula	2750 mL/min w/PH 1322 mL wo/PH
Acarturk 2008	32	mPAP≥25 mm Hg	43.7	8-39 all patients 25-39 w/PH patients	32.2±4.7 w/PH va 14.4±4.4 wo/PH	No data	Median 978.0 mL/min (Interquartile range 762.0–1584.5)
Yilga 2003	58	sPAP>35 mm Hg	39.7	37-65 (w/PH patients)	44±7	6.9 L/min w/PH vs 5.5 L/min wo/ PH	No data

As seen in table 6 higher AVF blood flow rates are observed in ESRD patients with PH which is correlated with high cardiac output (p=0.017) [4] and cardiac index (r=0.453, p=0.014) [3]. Our AVF flow rate of 1967.494 mL/min obtained from PCMRI is relatively high compared to normal.

While echocardiography is a useful tool for initial screening of PH, it is reported to be of moderate accuracy. RHC is the gold standard to diagnose pulmonary hypertension and we have used RHC for PH diagnosis. Also other studies have focused on the CFD of PA while we have included CFD of both PA and AVF. Using MRI and CFD provides better insight into the hemodynamics of PA and AVF.

We have obtained an mPAP value of 54 mm Hg from RHC, mean wall shear stress of 0.008 mm Hg for PA and 0.004 mm Hg for AVF from CFD. Our results and data from other studies [5] show lower values of WSS in PH patients compared to normal which could be used as a measure for PH diagnosis.

It is claimed that diminished vasodilatory capacity of pulmonary artery due to calcification and increased resistance may play a role in developing PH in ESRD patients [4]. Endothelin 1 (ET-1) which is a vasoconstrictor is increased in chronic renal patients [6]. Our future goal is to recruit more patients to study the effect of AVF alterations on pulmonary artery hemodynamics.

INTRODUCTION

The anterior cruciate ligament (ACL) connects the femur and tibia, preventing anterior tibial translation and helping to limit rotation of the tibia relative to the femur. It is vital in maintaining proper mechanics of the joint [1]. ACL tears are very common, especially in athletes, with more than 200,000 of these injuries happening annually in the US alone. More than half of these injuries are non-contact, meaning further research into the mechanics of the ligament could help prevent these injuries occurring [2].

Studies have examined the mechanics of isolated ACLs in a variety of ways, including repeated submaximal loading and collecting full field strain data for constitutive modeling using magnetic resonance (MR) imaging [3, 4]. Protocols like these often require testing over a period of time or lag time between tissue extraction and testing. Once the ligament is removed from its natural environment, it begins to dehydrate, which causes the tissue to stiffen, making tissue hydration a primary concern in mechanical testing. Often, tissues are frozen so that they do not have to be used immediately, but this also affects the mechanical properties of the tissue and causes the water in the tissue to leave, causing lower MR visibility [5]. While phosphate buffered saline is often used to combat tissue dehydration, studies have shown that many tissues will become oversaturated with fluid if soaked in PBS and that the best buffer to maintain the physiologic level of hydration is tissue dependent [6, 7].

Therefore, this study aims to determine what storage solution will maintain the physiological hydration level of the ACL; and how this solution affects the mechanical properties and MR imaging capabilities of the ACL.

METHODS

Ovine tibiofemoral joints were purchased from a local abattoir and the anteromedial (AM) bundles of the ACL were extracted. We utilized the following solutions to test the hydration level of the ACL after soaking for either 2 or 12 hours:

- phosphate buffered saline (PBS): PBS is commonly used to maintain the hydration of tissues.
- bovine synovial fluid: The ACL is contained in synovial fluid in its natural environment.
- polyethylene glycol (PEG): PEG 20000 was used so that the molecule was large enough not to absorb into the ACL. A range of concentrations were tested.
- ophthalmic gel: Ophthalmic gel is a non-newtonian fluid commonly used to maintain hydration of canine eyes.
- unsoaked tissue contained in nitrile glove: Nitrile gloves were used to create a climate chamber around the ACL because of their low permeation rate.

For mechanical testing, ACLs were soaked in PBS, synovial fluid, ophthalmic gel, or PEG 8% weight/volume for 0, 2, or 12 hours. Then the ligaments underwent loading in the main fiber direction with a 5% strain at 1 Hz for 60 cycles. The peak force of each loading cycle was then plotted against the natural log of time (or cycle number) to identify a change in material properties by soaking time and solution. Finally, separate ACLs were segmented and soaked in PBS, ophthalmic gel, and PEG 8% to determine the effect of these solutions on MR signal amplitude.

RESULTS

The relationship between swelling ratio, soaking solution, and soaking time is shown in Figure 1.a. PEG 8% w/v had a swelling ratio with no significant difference from zero. This indicates the hydration level did not significantly change after soaking.

The rate of force decay shown in Figure 1.b was compared between samples using Student's T tests. None of the samples in buffers at time 0

differed significantly from the unsoaked samples. All of the buffers led to a significantly larger rate of force decay after 12 hours, though PEG 8% w/v had the smallest change. A linear regression was performed to determine the effect of swelling ratio, soak time, and initial peak force on the rate of force decay. When the rate of force decay was normalized by the initial peak force, both soak time and swelling ratio were significant predictors of the rate of force decay.

Soaking in all of the tested buffers led to an increase in signal amplitude and T_2^* during MR imaging as shown in Figure 2. These changes were not significantly different between solutions, so changing the soaking solution does not affect the capabilities of MR imaging.

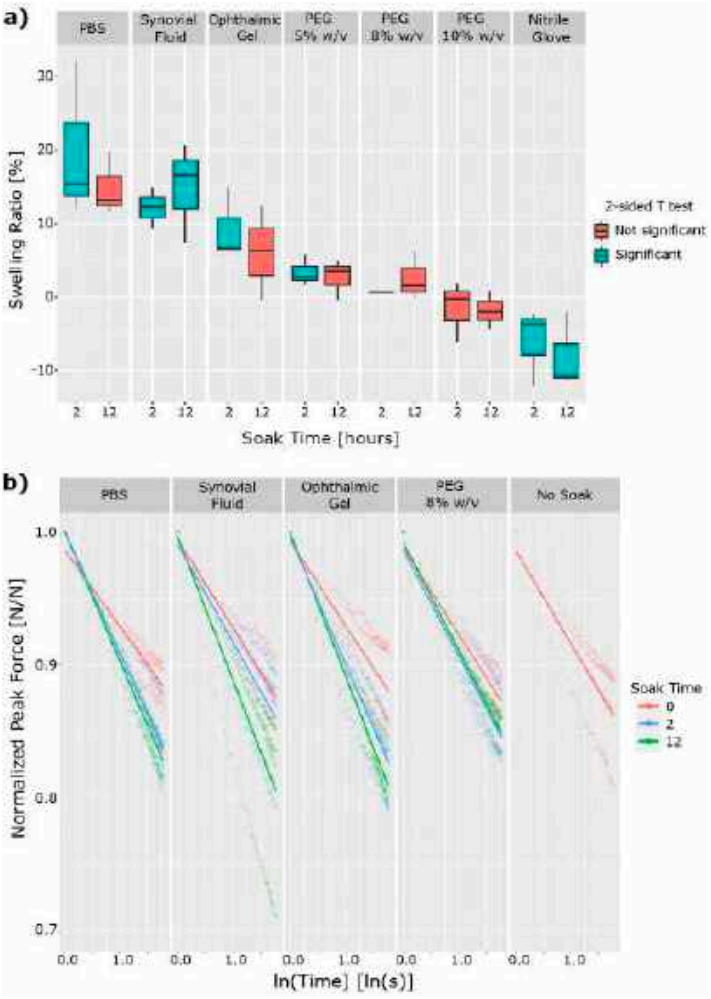

Figure 1: a) The swelling ratios for AM bundles of ovine ACLs, by soaking solution, after 2 or 12 hours of soaking at room temperature. A two-sided T-test determined whether each group was significantly different from a swelling ratio of 0 (i.e. no fluid uptake). b) The peak force from each loading cycle was plotted on a semi-log plot with time and we define the slope of these plots as the rate of force decay.

DISCUSSION

As mechanical testing of ligaments becomes more complex and nuanced, maintaining the physiological conditions of the ligaments becomes more important. These results suggest that there is some level of degradation occurring in the ligaments after 12 hours and that the ingress of water "softens" the materials. Maintaining the physiological hydration level helps to reduce the changes in mechanical behavior over time. Moreover, we see that soaking ACLs in synovial fluid causes an uptake in fluid, which leads us to believe that the boundary conditions and connective tissue in the joint play a more important role in the hydration and mechanics than previously thought. Future work will investigate this.

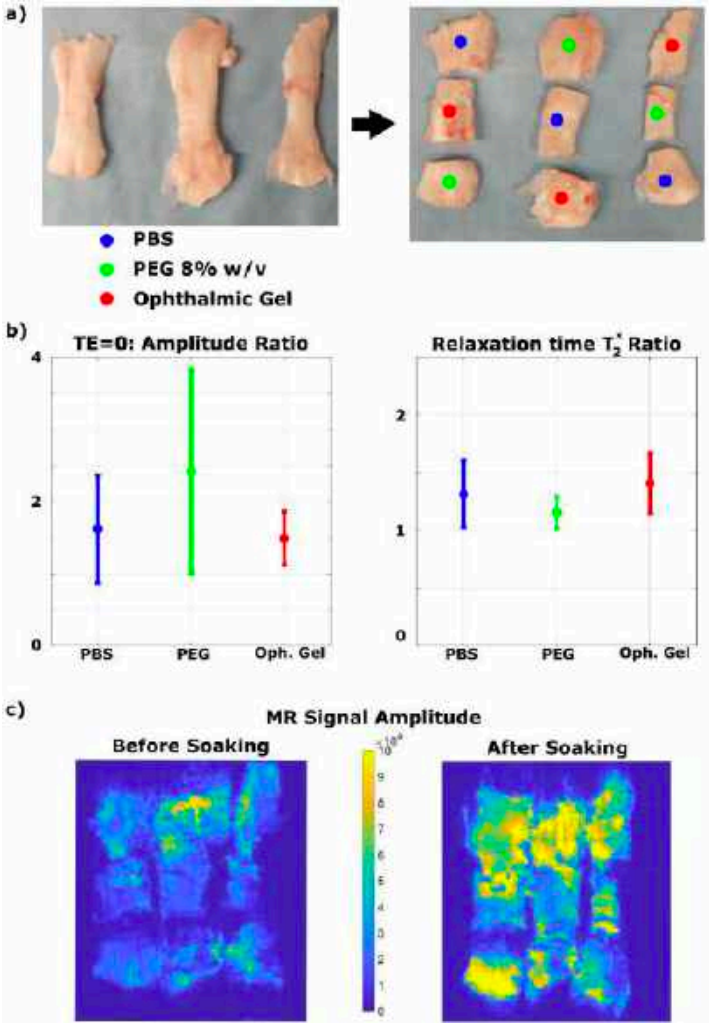

Figure 2: a) Three ovine ACLs were segmented into approximately equal length sections. One section from each was soaked in PBS, PEG 8% w/v and Ophthalmic Gel. b) The per voxel signal amplitude increased by a factor of 1.5-2.5 after soaking overnight and the relaxation time increased by a factor of 1-1.5. c) The scaled signal amplitude shows where fluid was taken up into the tissue.

ON THE MARGINATION OF WHITE BLOOD CELLS

Thien-Tam Nguyen (1), Trung B. Le (1)

(1) Department of Civil, Construction, and Environmental Engineering
North Dakota State University Fargo ND, United States

INTRODUCTION

The margination of white blood cells (WBCs) has been the focus of extensive experimental and numerical studies [1, 2] due to its importance in bio-engineering[3]. Although the exact mechanism of this phenomenon is yet to be fully understood, it has inspired the development of a new generation of micro-carriers for targeted drug delivery. These carriers, mimicking the margination behavior of WBCs, could address the challenges in drug delivery [4]. Therefore, identifying important factors in WBC margination could be valuable in designing and advancing the development of next-generation micro-carriers. A deeper understanding of phenomena such as the margination of WBCs could open up new avenues for targeted drug delivery systems and further advance the field of biomedical engineering.

In this work, a series of numerical experiments using a hybrid dissipative particle dynamics (DPD)-computational fluid dynamics (CFD) solver is used elucidate the role of the WBC membrane stiffness in the deformability and trajectory of WBCs in microchannel flows.

METHODS

The White Blood Cell is modeled in two parts, namely the membrane and the cytoplasm. Our method of choice for the latter component is the Dissipative Particle Dynamics (DPD) method. The cytoplasm is a gel-type fluid that mediates all chemical transportation and signaling processes. While different cytoplasmic organelles exist, the DPD method allows the grouping of atoms and particles that make up these ”little organs” into particle-like entities through a coarse-grained representational process.

The membrane of WBC is also modeled with DPD (Table 1). However, for this particular component, an initial configuration is required to generate the network of DPD particles into the shape of the desired cell. We have used an equation for a sphere to achieve the initial shape of all the WBCs. A standard calibration procedure for the DPD method calls for testing the membrane configurations in the equilibrium and the stretching tests. We have carried out these tests with five configurations of the WBC membrane having from 200 to 4000 particles. The stretch test mimics a pair of microbeads pulling the WBCs in opposite directions with a total force of 15 micro-Newton.

Our study of leukocyte membrane stiffness consists of a series of numerical experiments using the calibrated model of the cell from the above step in a microchannel flow. The interaction between the cell and the fluid is a two-way interaction. To achieve this goal, the DPD method is two-way coupled with a CFD solver with the implementation of the curvilinear immersed boundary (CURVIB) method. The CFD solver utilizes three-dimensional, unsteady incompressible continuity and Navier-Stokes equations in a discrete form [5]. The discrete equations are integrated over time using a fractional step method. For solving the momentum equations, we use a Newton-Krylov solver in the momentum step, and a GMRES solver with a multigrid pre-conditioner is used for the Poisson equation.

We used Pointwise software to generate a rectangular microchannel whose width and height are five times the cell’s diameter, while the length is 20 times. The WBC configuration has the same number of particles for both the cytoplasm and the membrane for all the simulations, which are 65 and 660, respectively. We come to decide on these numbers based on the results of the calibration tests. The location of the cell is at the center of the crosswise plane of the blood plasma grid while being at a distance of 5 times the cell diameter from the left wall to minimize the impact of prescribed conditions at the inlet. The total number of grid points is 3 million. Uniform velocity is prescribed at the inlet while a fully developed profile is prescribed at the outlet. No-slip wall is prescribed for other faces to complete the boundary conditions. We fixed the WBCs in place and disabled two-way coupling (FSI) for the first 1000 time steps. During this time, the CFD solver would reach a steady-state solution, and an equilibrium state should be reached for the cells. Only then, the FSI module was enabled.

Table 1: Cell parameters of the DPD method for modeling the White Blood Cell.

Cell Diameter (μm)	Shear Modulus ($pN/\mu m$)	Persistence Length (μm)	Maximum Extension Length (μm)	Bending Stiffness (Nm^2)	Force Coefficient (J)
7.0	$4.7E+3$	$1.8E-3$	0.59	$1.5E-24$	$2.4E-18$

RESULTS

Figures (1) and (2) show the continuum mesh adaptively changed according to the movement of the cell. As the result of the CURVIB method, the Navier-Stokes solver only solved for flow solutions in the volume without the occupy of the cell's volume. A trace of the WBC (region with zero velocity submerged within the flow field) can be tracked in many cut planes without visualizing the DPD particles. Our method allows the hemodynamics outside the cell to be captured in high fidelity.

By tracking the top and bottom DPD points and plotting them in tandem with the cell's displacement, Figure (2) clearly shows that the WBC was rolling when migrating downstream. The traces of immersed nodes on vertical and horizontal middle-cut planes further tell the direction of the movement, which is upward and toward the right wall.

In DPD formulation, the shear modulus μ_0 characterizes the stiffness of the cell's membrane. Thus, we test the shear modulus from the range of Red Blood Cells (RBCs) ($10^1 pN/\mu m$) to 2 orders of magnitude greater range ($10^3 pN/\mu m$). In a similar implementation of the DPD method for the case of RBCs, it has been reported [6] that the membrane requires at least 500 DPD particles to behave accurately in the numerical experiments. This explains the 660-particle configurations in our setup.

The behavior of circulatory cells to their membrane stiffness has been studied in detail, as evidenced by the results presented in Figure (3). It was found that the spherical cell with the RBC membrane's stiffness behaved similarly to this type of circulatory cell. The cell membrane deformed quickly and attained an equilibrium shape, which propagated along the flow in a straight line, with no visible rolling during the maneuver.

However, when the membrane stiffness doubled within the first order of magnitude, the cell's trajectory became more chaotic and sensitive to instantaneous changes in the flow. Observing the tracers' paths, it was noted that the trajectory had multiple sudden changes, but no visible rolling occurred during the cell's maneuver. This was the case where the cell executed the quickest displacement toward the right wall.

From the latter half of the second order of magnitude to the WBC range, rolling became a stable behavior. As depicted in Figure (3), the cases of $750pN/\mu m$ and $5000pN/\mu m$ had almost identical trajectories despite a significant leap in membrane stiffness value. These findings shed light on the behavior of circulatory cells in different membrane stiffness conditions and can inform future research in the field.

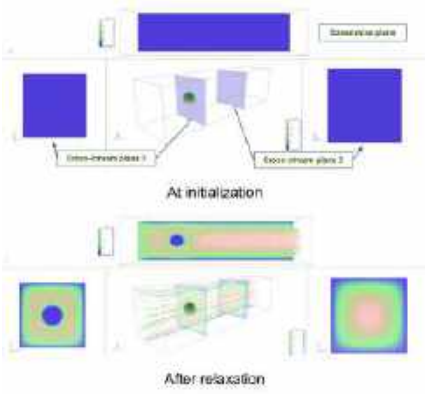

Figure 1: The flow fields at initial condition (up) and fully converged (bottom) are the results of the relaxation step by the 3D incompressible Navier-Stokes solver.

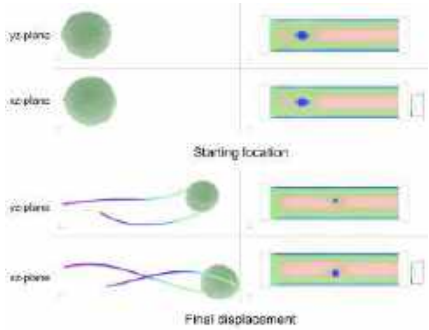

Figure 2: Displacement of the WBC (in green) from the starting location to the last snapshot of the simulation. The rolling behavior is highlighted by tracking two particles in the membrane (left). CFD-DFD coupling allows two-way interaction between the fluid and the cell (right).

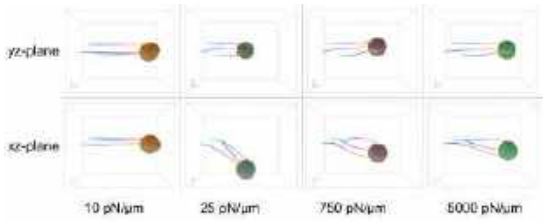

Figure 3: Differences in rolling behavior of circulatory cells where the membrane stiffness differs.

DISCUSSION

Our findings could have significant implications for the development of micro-carriers for targeted drug delivery. By mimicking the stiffness of the WBC membrane, these carriers could potentially navigate through the bloodstream with greater precision and efficiency, ultimately leading to more effective drug delivery. Further research in this area is necessary to fully understand the potential applications of these findings in the field of biomedical engineering.

ACKNOWLEDGEMENTS

We acknowledge the financial support from the ND-EPSCoR via the ND-ACES grant (NSF Grant number 1946202). Our computational simulations in this study were performed using the computational resources of the Center for Computationally Assisted Science and Technology (CCAST) at North Dakota State University. We want to express our deepest gratitude toward Dr. Amit Joshi of the Medical College of Wisconsin for providing us with an excellent experiment movie and professional insights that led us to the subject of this study.

STENT RETRIEVER REMOVAL FORCES IN AN EXPERIMENTAL STROKE MODEL WITH PORCINE CAROTID ARTERIES

INTRODUCTION

In the United States nearly 800,000 strokes occur each year, 87% of which are classified as an acute ischemic stroke (AIS) [1]. AIS, a result of the sudden occlusion of a cerebral artery, is typically treated by a mechanical thrombectomy (MT), either through aspiration or stent retriever (SR) techniques. MT is a transfemoral endovascular approach used to achieve recanalization and can increase the treatment window up to 24 hours [2]. While SR MT is the predominantly used method, a meta-analysis comparing the efficacy outcomes of direct aspiration and SR MT identified no significant difference in good clinical outcomes [3]. Despite its clinical success, adverse outcomes including hemorrhage and thrombus embolization can also still occur [4]. To improve the degree of revascularization and limit the risk of complications, experimental circulatory flow systems are used to assess various parameters of SR MT.

Previous studies conducted in our lab used an experimental flow loop to identify the forces required to achieve thrombus dislodgement by the SR (i.e., removal force) in various cerebral artery models made of PVC tubing [5]. These *in-vitro* models offer a more practical approach for testing devices but, in many cases, do not capture the frictional and adhesive forces that occur between SRs and vessel walls. To more accurately mimic *in-vivo* conditions, and to assess the influence of the vessel wall material on thrombus removal force, experiments were conducted using commercial SRs and porcine carotid arteries (CAs) and compared to data collected previously in PVC models.

METHODS

A circulatory flow system (**Fig. 1**) was developed using a peristaltic pump (VWR 3300), fluid reservoir, and a cerebral artery model. Water was circulated at a flowrate of 300 mL/min within the system to mimic typical cerebral artery conditions. To perform an SR MT procedure, a 6x30 mm Solitaire2 SR (Medtronic) within a Phenom27 microcatheter (Medtronic) was passed through a hemostatic valve into the flow loop (**Fig. 1**). The SR was then deployed within the arterial model and connected to a force gauge (MXmoonfree) attached to a stepper motor (kdScientific) which ensured the SR was pulled at a constant speed for 15 seconds and the maximum removal force was recorded.

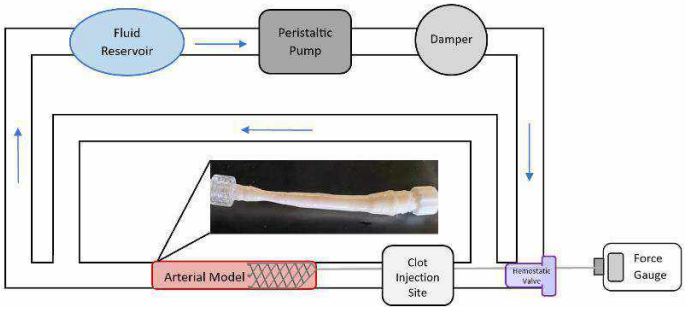

Figure 1: Schematic of experimental circulatory flow loop used to evaluate SR MT removal forces.

For these experiments, two different cerebral artery models were incorporated into the flow loop: porcine CAs and straight PVC tubing that tapered from 5.5 to 3.3 mm in diameter to represent naturally constricting cerebral arteries. Porcine CAs were obtained from Lampire Biologics and were stored in PBS at 4 °C until experimental testing. To ensure the CAs did not dry out between testing, one CA was prepared and tested, while the other CAs were kept stored in PBS. Prior to testing, the tunica

adventitia layer was carefully removed from the CA, and it was cut to be approximately 3 inches in length. The porcine CAs naturally taper, as seen in **Fig.1**, and therefore the inner diameters at each end were measured with digital calipers before proceeding to the next preparation stage. Each CA end was then stretched over a male plug to socket connecter and adhered with Loctite super glue to ensure its attachment to the flow loop without fluid leakage. Care was taken throughout the entire CA preparation process so as to not damage the inner endothelium of the vessel samples. Prior to testing each CA, a marker was made on the SR and catheter devices so that the length of the SR deployed within the system and the distance it is pulled during each MT trial could be controlled across all trials.

RESULTS

The maximum SR removal force for each experimental test parameter is summarized in **Table 1**. For these experiments, 3 different porcine CAs were used to create a sample size of n=20, 8 SR MTs were performed with CAs #1 and #2 and 4 SR MTs were performed with CA #3.

Table 1: SR removal force for each model material

Test Parameter	Sample (n)	Average Removal Force (N)
PVC	20	0.25 ± 0.01
Porcine	20	0.31 ± 0.05

A comparison of the PVC tubing and porcine artery model materials is displayed in **Fig. 2**. From this, a greater SR removal force is observed with the porcine CAs. A one-way ANOVA with significance at $p < 0.05$ was performed on the resultant data and indicated a significant difference in the SR MT removal forces between the two arterial model materials ($p = 5.69E-7$).

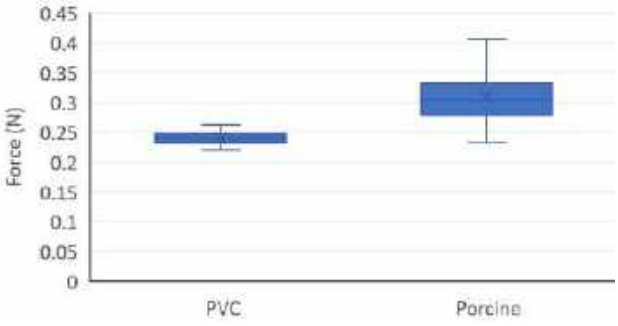

Figure 2: Maximum SR removal forces from PVC and porcine arterial model materials.

DISCUSSION

Experimental circulatory flow loops modeling AIS are typically used to evaluate the performance of SRs, and EA fracture and embolization [6]. These *in vitro* flow loops include either patient specific or simplified cerebral artery geometries, usually composed of silicon, glass, or plastic materials [6]. Many of these models, however, do not take into consideration the interaction between the SR and vessel wall, which can influence the SR performance and overall MT outcome [7]. Pulling the SR during the thrombus retrieval process can also lead to SR elongation or collapse, and the friction between the SR and endothelium can cause the vessel to stretch or tear [7].

Studies have also indicated that the SR to vessel wall interaction is a key component of successful recanalization [8]. These results have led us to the hypothesis that the vessel wall material influences the SR removal force (i.e., pulling of the SR to dislodge the thrombus), and should be a factor considered in the development of any experimental model of AIS.

This study compares the SR removal forces in a benchtop experimental model of MT performed using both porcine CAs and PVC tubing arterial models. The porcine CAs used in these experiments tapered from approximately 4.9 to 3mm in diameter, which was similar to the tapering in the PVC tube models (~5.5 to 3.3mm). A comparison of the average SR removal forces indicates that a higher force was required in the porcine CAs (0.31 ± 0.05 N) than in the PVC tube (0.25 ± 0.01 N). These results indicate that accurately representing the interaction between the vessel endothelium and nitinol SRs in *in-vitro* models can lead to higher removal forces than previously expected.

The coefficients of kinetic friction between SRs and various AIS model materials were previously investigated in our lab [9]. The results, presented in **Table 2**, provide further evidence that the higher removal forces found in this study may be due to the higher friction coefficients between SRs and carotid artery materials compared to PVC and other non-biological materials.

Table 2: Coefficients of kinetic friction between nitinol SRs and common arterial model materials [9]

Test Material	Coefficient of Kinetic Friction
glass	0.18 ± 0.05
PVC	0.61 ± 0.06
silicone	0.78 ± 0.06
bovine CA	0.73 ± 0.17

Future work will focus on incorporating embolus analogs (EAs) into the flow loop to mimic an AIS. EAs will be lodged within the arterial models, both PVC tubing and porcine CAs, and previously stated flow loop protocols will be repeated to measure the SR removal forces. Higher SR removal forces are expected in both the PVC and porcine models with the presence of an EA when compared to the results collected without an EA. Therefore, we hypothesize that greater SR removal forces will be observed with porcine CAs, since we predict that the EAs will also have greater adhesion and friction with vessel walls.

FLEXIBLE ROTOR BLADES IN LVADS: INVESTIGATING IMPLICATIONS FOR HEMOCOMPATIBILITY

Shweta Karnik (1), Shobana Santhanam (1), Charles Federico (1), Huang Chen (1), Lakshmi Prasad Dasi (1)

(1) Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, USA

INTRODUCTION

Heart failure (HF) is one of the leading causes of death, affecting nearly 6.2 million people in the United States (US)[1]. The preferred surgical therapy for end stage HF is heart transplantation; however, this therapeutic option is progressively limited due to the limited availability of donor hearts.

Left Ventricular Assist Devices (LVADs) have emerged as a standard of care for patients suffering from end stage HF as both bridge-to-transplantation and destination therapy[2,3]. After the discontinuation of two prominent LVADs in the last few years, namely Thoratec HeartMate II (now Abbott lab) and HeartWare HVAD (now Medtronic), Abbott's HeartMate III remains as the only implantable LVAD on the market.

Despite its clinical success, LVAD therapy is associated with serious morbidities and mortality[4,5]. Complications such as thrombosis can result in LVAD failure, requiring a potential second open-heart surgery for device replacement in the patient. Hemocompatibility plays a critical role in determining the long-term operation of the device.

Conventionally, LVADs have been designed to operate efficiently at a single operating condition i.e 5 L/min, 90mmHg. However, while implanting an LVAD, the operating speeds are often modified to match the device output with the patient's cardiac output. This would result in device operating at off design points, potentially compromising both hemocompatibility and longevity of the device.

To address this, we have developed a novel LVAD prototype with flexible rotor blades. Our hypothesis is that the mechanoresponsive behavior of flexible blades will enable them to deform as a response to the complex inflow conditions. With an optimized geometry and flexibility, this would not only improve the hemocompatibility of the LVAD but also offer a wider range of operation with optimal efficiencies.

In this study, we investigate the hemocompatibility implications of deploying flexible rotor blades in a centrifugal LVAD under adult physiological conditions (5L/min, 90mmHg). We will also explore the hydrodynamic performance of these LVAD prototypes at adult physiological condition i.e 5L/min,90 mmHg.

METHODS

Design and Manufacturing

Three designs were chosen for producing rigid and flexible rotor blade LVAD prototypes each. The blade thickness and height were fixed at 1.2mm and 7mm respectively. The inlet angle of the blades was set at 20º whereas the outlet angle was varied from 30º to 70º with 20º increments as shown in Figure 1. The rigid rotor blades were 3D printed using a J850 Pro (Stratasys Ltd, MN, USA) whereas the flexible rotor blades were casted using polyurethane resin of shore hardness 60A.

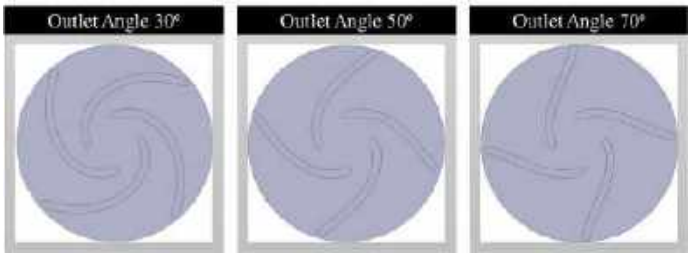

Figure 1: Novel LVAD Prototype Designs.

In vitro Hemocompatibility Assessment

The blood damage caused by both rigid and flexible blade LVAD prototypes was evaluated using porcine blood in a blood circulation loop (Figure 2). It consisted of a motor to drive the rotor, a flow probe, pressure transducers upstream and downstream of the rotor and a pinch valve to vary the downstream resistance.

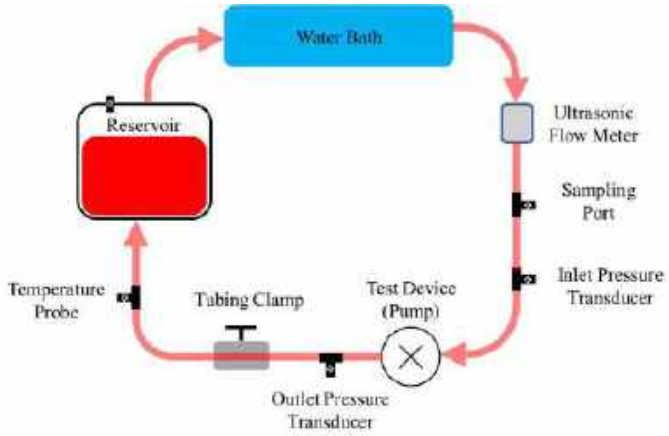

Figure 2: Blood Circulation Loop Schematic.

The blood circulation loop (BCL) was tuned to the adult physiological condition and blood samples were collected every 60 minutes over a period of 6 hours. The blood samples were centrifuged to prepare plasma. Hemolysis and platelet activities were quantified using commercially available enzyme-linked immunoassays (ELISA).

Hydrodynamic Performance Evaluation

The hydrodynamic performance of the LVAD prototypes was evaluated on a benchtop setup like the BCL. A blood mimicking 40% wt glycerin solution was used as the working fluid. The mounted rotor was driven at 3000 RPM, and the flow produced by the rotor was measured as the pinch valve incrementally increases downstream resistance. To characterize hydrodynamic performance, the gradient of the pressure-flow curve and the efficiency were measured.

$$gradient = \frac{P_4 - P_6}{4-6} \frac{mmHg}{L/min} \quad (1)$$

RESULTS

For a rigid rotor blade with an outlet angle of 30º, the gradient at adult operating conditions was – 11.52 mmHg/ (L/min)$^{-1}$ whereas its flexible counterpart had the gradient of – 11.12 mmHg/ (L/min)$^{-1}$. As the outlet angle increased, the pressure/flow gradient decreased for rigid rotor blade prototypes.

Results for the remaining hydrodynamic evaluation and hemocompatibility assessment is currently being generated and will be presented at the conference.

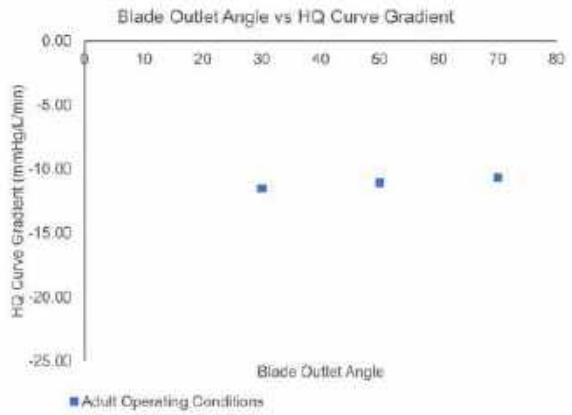

Figure 3: Effect of Outlet Angle of HQ curve gradient for Rigid Rotor Blade LVAD Prototypes.

DISCUSSION

The flexible rotor blade LVAD prototypes proposed in this study will be a positive step towards enhancing hemocompatibility of LVADs and thereby increasing device longevity. Preliminary results show that flexible rotor blades can generate a 'flatter' pressure-flow curve, a characteristic that is desirable. This would not only improve the preload sensitivity of the LVAD but also offer a wider range of operation with optimal efficiencies.

CHARACTERIZATION OF THE BASAL ENDOTHELIAL GLYCOCALYX

Zoe L. Vittum (1), Solomon A. Mensah (1,2)

(1) Biomedical Engineering, Worcester Polytechnic Institute, Worcester, MA, United States
(2) Mechanical Engineering, Worcester Polytechnic Institute, Worcester, MA, United States

INTRODUCTION

The endothelial glycocalyx is a transmembrane grass-like structure that encompasses endothelial cells serving to transduce extracellular signals, regulate vascular permeability, and inhibit the adhesion of leukocytes [1,2,3]. Glycoproteins and proteoglycans are the core proteins of the glycocalyx [1]. Glycoproteins have short carbohydrate chains attached while proteoglycans are glycoproteins that have glycosaminoglycan (GAG) chains attached [1,4]. GAGs are long repeating chains, the main GAG chains are hyaluronan, chondroitin sulfate (CS), various moieties of sialic acids (SA), dermatan sulfate, and heparan sulfate (HS) [1].

The glycocalyx along the lumen of the vessel is referred to as the apical glycocalyx which is directly exposed to shear due to blood flow. The basal glycocalyx is present at the smooth muscle cell interface. Historically, the apical and basal glycocalyx have been independently investigated due to the differences in their local environment and stimuli. The apical glycocalyx has been at the forefront of research efforts due to its direct role in mechanotransduction of shear forces due to flow [5,6]. The basal glycocalyx has also demonstrated sensitivity to shear forces [5,7]. Shear forces due to flow are transmitted from the apical glycocalyx through the cell cytoskeleton to basal glycocalyx components promoting alternate signaling pathways and influencing cell migration and morphology [7,8,9]. For example, Beayens et al. found that the mechanisms that instigate elongation and directional alignment may be independently regulated by apical and basal glycocalyx elements through investigation of core protein knockdown [7]. Their results suggest the apical and basal glycocalyx may play differing roles in sensing the magnitude and direction of shear stress [7].

Syndecan-4 is a predominantly basal proteoglycan that is colocalized with adhesion molecules, integrins, and cytoskeletal elements to form focal adhesions [1,5,7]. Evidence of the basal glycocalyx's shear response has been gathered through investigating syndecan-4 and attached heparan sulfate chains as little to no evidence of other proteoglycans and glycoproteins and their function in the basal cell membrane have been presented in literature [5,7]. Yet, investigation of endothelial cell shear force transmission often ends with probing cytoskeleton and focal adhesion structure for morphological differences leaving the basal glycocalyx's response to shear largely unknown.

Here we begin characterizing the basal glycocalyx through visualization of both the apical and basal glycocalyx encompassing the endothelial cell in static culture. Future experiments will include probing the basal glycocalyx after exposure to physiologically normal shear forces. Positive glycocalyx signal in both experiments indicates the presence of glycocalyx core proteins attaching extracellular glycocalyx components to the cell. Deviations observed in coverage and thickness of the basal glycocalyx signal between the static and flow cell's basal will indicate a remodeling response of the basal glycocalyx in response to shear. The observed response will shed light on how the basal core proteins and attached chains are adapting to shear on the basal surface of endothelial cells. Results of this study will aid in developing a deeper understanding of how the endothelial cell wholistically senses and responds to shear.

METHODS

Human lung microvascular endothelial cells (HUVECs) were maintained in Microvascular Endothelial Cell Growth Medium (Signma Aldrich) at 37 °C and passaged using 0.05% trypsin-EDTA at 70–80% confluence. Passage five HLMVECs were plated at 100,000 cells/mL on 24 mm x 24 mm fibronectin coated glass cover slips (Fisher Scientific) and allowed to adhere and remain in static culture for 18 hours after plating.

Slides were fixed with 0.4% paraformaldehyde and experimental groups were permeabilized with a series of 0.3% Triton X-100 (Thermo Fisher Scientific) treatments. The Triton X-100 treatment included a series of three 5-minutes exposures to 0.3% Triton X-100 and 5-minute PBS washes. Immunostaining using Wheat Germ Agglutinin (WGA)

(Thermo Fisher Scientific) as primary antibody and Alexa-flour 488 conjugated anti biotin (Thermo Fisher Scientific) as secondary antibody was used to label the overall glycocalyx. The slides were mounted with Flouromount DAPI Mounting Media (Thermo Fisher Scientific) for nuclei visualization. Confocal Z-stack images were taken with a 3 µm slice thickness. Image J was used to develop Z-direction orthogonal views of the to visualize the glycocalyx expression encapsulating the cell.

RESULTS

Preliminary results of staining of the apical glycocalyx, and both apical and basal glycocalyx are shown in Figure 1A and Figure 1B respectively. The HLMVECs were stained with WGA which targets all glycocalyx components (Fig. 1A, 1B). The glycocalyx signal is shown as green and the nucleus as blue. Figure 1A shows the nonpermeabilized result where only the apical glycocalyx is exposed to the immunofluorescent antibodies. In Figure 1A cell boundaries can be easily distinguished and the orthogonal view distinctly shows the apical glycocalyx coverage over the nuclei of the HLMVECs. Figure 1B shows the permeabilized result where Triton-X100 treatment was used to expose the basal glycocalyx to immunofluorescent antibodies. In the permeabilized group (Figure 1B) the glycocalyx signal is localized around nuclei structures, cell boundaries are not visualized as in Figure 1A. The orthogonal view of Figure 1B shows glycocalyx signal throughout the area that is expected to be occupied by the cell. This effect can be seen in the overlap of glycocalyx (green) and nuclei (blue) signal in the orthogonal view that is not present in Figure 1A. Finally, nuclei signal was observed at Z planes above and below the expected regions. This can be seen through observation of the orthogonal nuclei signal in Figure 1B and comparison to Figure 1A.

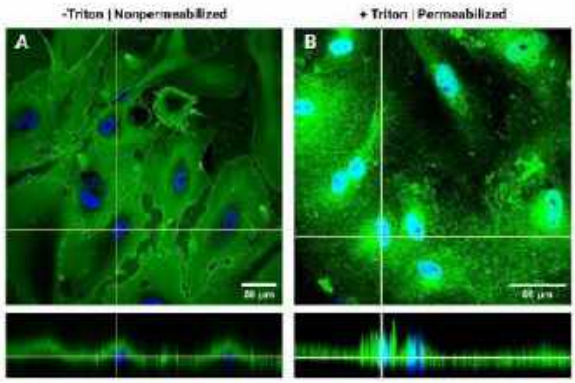

Figure 1: Glycocalyx coverage in static cultured HLMVECs in the apical (A) and apical and basal (B) cell.

DISCUSSION

An extensive literature review was conducted to understand how the basal glycocalyx has been previously investigated and characterized. Unfortunately, limited literature is present describing the basal glycocalyx. Existing literature and knowledge roots from select studies investigating Syndecan-4 signaling mechanism and recent studies of syndecan-4 knockdown and expression levels [7,10]. Therefore, limited data is present to compare the results presented here and future experiments. Visualizing and localizing basal glycocalyx structures, akin to the studies conducted on apical glycocalyx elements such as syndecna-1, would fill this gap in our understanding of the basal glycocalyx [11].

The preliminary results presented display positive staining for the glycocalyx with good visualization of the apical glycocalyx as seen in Figure 1A. The orthogonal view of Figure 1A also clearly depicts the glycocalyx coverage of cell bodies as seen by the coverage undisrupted signal over the nuclei. The preliminary attempt of visualization of the apical and basal glycocalyx, as shown in Figure 1B, was disrupted due to the permeabilization treatment utilized. The glycocalyx signal seen overlapping with the nuclei signal throughout the anticipated cell body area is hypothesized to be due to a collapse of the cell membrane as a result of permeabilization. The permeabilization protocol will be optimized for visualization of both the apical and basal glycocalyx without compromising the structure of the cell. This will be achieved by altering the Triton-X100 concentration and exposure time. Confocal Z-stack images will also be taken with 0.5 µm slice thickness for increased sensitivity in orthogonal visualization.

In future experiments, the presence of specific GAGs including HS, CS, and SA will be probed. Evidence of other GAGs in the basal glycocalyx is limited in literature, findings will not only shed light on the distribution and presence of specific GAGs in the basal glycocalyx but also the presence of core proteins. While WGA signal in the basal cell also implies the presence of core proteins, the roles and binding patterns of the individual GAG chains will provide more insight on the possible core proteins and their function in the basal glycocalyx.

Once static visualization is achieved future experiments will probe the basal glycocalyx signal after 30 minutes and 24 hours of shear exposure. In the basal cell we expect to observe an increase in glycocalyx expression and coverage at 30 minutes with expression decreasing to static levels at 24 hours. This is due to findings presented by Zeng et al. in 2016 where syndecan-4 expression was measured at multiple time points [10]. It was found that at physiologically normal shear rates the expression of syndecan-4 increases rapidly after onset of shear peaking at 30 minutes [10]. This timeline corresponds to the timeline of cytoskeleton and focal adhesion remodeling which syndecan-4 has been shown to regulate [5,6,7,10]. The cumulative knowledge from this study will be used to further complete existing models of endothelial cell force transduction and eventually shed light on how different components of the basal glycocalyx contribute to and modulate crucial endothelial cell signaling pathways.

ACKNOWLEDGEMENTS

INTRODUCTION

Osteochondral allograft (OCA) transplantation has been used with increasing frequency and success to resurface joints and treat defects in articular cartilage. Despite the increased use of OCA transplantation and improvement in live tissue preservation methods, limitations in the application of OCAs persist. When selecting donor tissue, matching the size and curvature of the transplanted allografts to the native joint is crucial, as allografts that are incongruent with the native joint locally increase contact stresses and can instigate a cascade of negative repercussions.[1-3] Bendable osteochondral allografts (BOCAs) were developed to address this need, allowing surgeons to augment the articular curvature of allograft explants by machining grooves in the underlying bone.[4] Live OCAs show superior functional outcomes when compared to nonliving tissues, as attempts to transplant frozen, decellularized, or lyophilized tissues have yielded significantly worse functional outcomes than live OCAs.[5,6] Since clinical standards recommend that only allograft samples with >70% chondrocyte viability should be considered candidates for transplantation as OCAs,[6] it is important to verify that the process of creating bendable osteochondral allografts does not induce chondrocyte apoptosis or increase the risk of surgical complications by introducing pathogens.

In this study, we used an established canine patellofemoral joint model to analyze a method of machining live osteochondral tissue for transplantation in accordance with federal regulations. We hypothesized that this novel method would enable us to ship live (viable) OCAs from the donation site to the machining site, then store, image, machine, and ship again for transplantation, without compromising chondrocyte viability or tissue aseptic status.

METHODS

With IACUC approval (#16680), whole patellae (n=16) were harvested from adult purpose-bred canines at the University of Missouri at Columbia. Samples were procured within 24 hours of euthanasia and preserved in Missouri Osteochondral Preservation System (MOPS) media at room temperature for overnight shipping to Columbia University in the city of New York.[3,8]

Six patellae were used for ex-vivo testing of the impact of machining and reshaping the articular surface on chondrocyte viability. Whole patellae were transferred under aseptic conditions into custom-built polysulfone fixation rigs. Samples were secured into sterile single-use PLA inserts with Adafruit low-temperature fixation thermoplastic (Fig. 1). Patellae were scanned in a VivaCT 80 μCT scanner with an isotropic 78 μm voxel resolution. Resultant DICOM files were processed in 3D Slicer to create models of the patellae within the fixation rigs (www.slicer.org). Sample-specific CNC milling machine cutting paths were generated in the HSMworks application (autodesk.com) incorporated within SOLIDWORKS 2022 (solidworks.com). Machining was performed in a purpose-built laminar airflow machining cabinet with UV sterilization cycles run between samples. All patellae were planed on their anterior surface, creating shell allografts, then 1.6 mm wide grooves were milled through the subchondral bone to the tidemark to enable bending of the articular surface in BOCAs.[9]

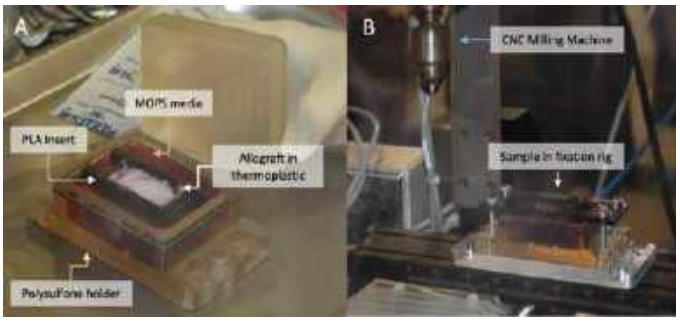

Fig. 1: Aseptic allograft machining process. A: Patella fixed in in removable insert in MOPS bath for scanning and machining. B: Patella cut in sterile enclosure to create bendable allograft.

Following grooving, BOCAs were stored in polystyrene culture dishes with MOPS media at 20 °C. After 14 days, sterilized rubber strips were placed in the machined grooves of three BOCAs (expanded treatment group) to increase the surface radius of curvature along the medio-lateral direction. Expanded samples were maintained thusly for 24H, 48H, and 72H while control samples (remaining three BOCAs) were maintained without expansion for the same period (Fig. 2). The articular cartilage of the BOCA samples was resected and assessed for cell viability using an assay kit (Invitrogen).

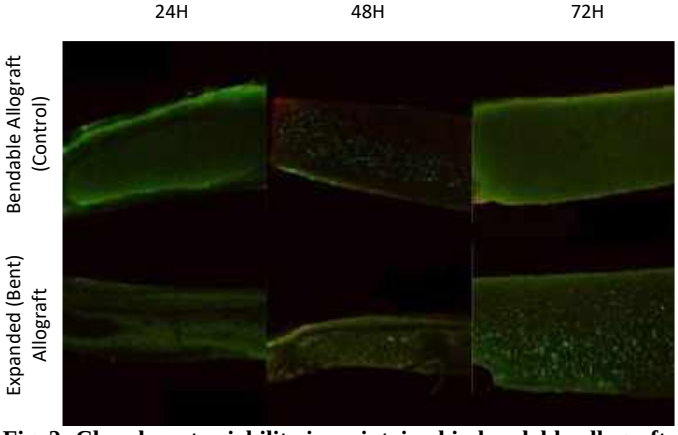

Fig. 2: Chondrocyte viability is maintained in bendable allografts following aseptic machining and sustained alteration of medio-lateral articular surface curvature in BOCAS.

Once the ability to create live machined allografts was established, remaining canine patellae (n=10) were fixed in machining rigs as described above and machined to create a shell allograft group (OCAs, n=5) and a grooved BOCA group (n=5) for shipping and in-vivo surgical transplantation in the canine model. Live OCAs and BOCAs were shipped back to the University of Missouri. Upon reception, media samples and allograft tissue samples were sent for aerobic and anaerobic culture before transplantation, to check for clinically relevant microbial growth. After aseptic conditions were confirmed in all samples, allograft bone was treated with saline pulse lavage and autologous bone marrow concentrate before being fixed in the contralateral stifle joints of five purpose-bred research hounds using bioresorbable pins (Figure 3) with IACUC approval (#16680). The total time between retrieval of patellae from the dogs and transplantation as allografts was 33 days. Donor patellae were not size-matched to the recipients such that BOCAs were expanded or compressed, while OCAs were anatomically positioned for best fit. Dogs were recovered from surgery, provided analgesics and antibiotics, and restricted in activity for 1 month, then provided leash walking, socialization, and enrichment activities.

RESULTS

Cell viability tests on the first batch of machined patellae (n=6, Fig. 2) indicated high levels of chondrocyte viability in the BOCA (88%) and expanded allograft groups (93%) across the measured timepoints.[10]

In the second batch (n=10), clinically relevant microbial growth was absent in the cultures of the patellar allografts and media at the time of transplantation. At three months post transplantation radiographic and gross assessments of canine knees revealed mechanical failure of the BOCAs. The 1.6 mm wide grooves in the BOCA group were too wide for maintaining canine patella structural integrity, resulting in fissuring, fragmentation, and resorption with corresponding trochlear erosions (Fig. 3). The canine study was terminated, and allograft ground tissue and synovial fluid were analyzed using aerobic and anaerobic culture. No microbial growth developed in the retrieved allografts or was measured in the synovial fluid. Viable chondrocytes were present

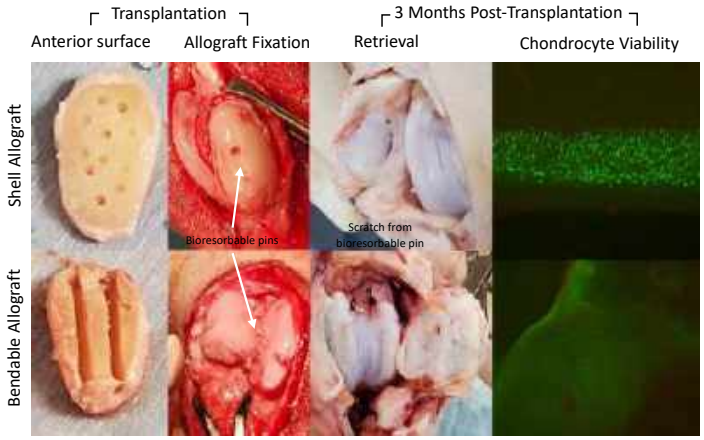

Fig. 3: Canine shell and bendable allograft implanted in canine stifle joint. Allografts were fixed in the patellofemoral joint with a single resorbable pin. Chondrocyte viability was sustained in shell and bendable BOCA allografts, but damage to bendable allografts resulted in changes in hyaline tissue morphology.

in both bendable and shell allografts and shell OCAs maintained hyaline cartilage morphology following 3 months of transplantation (Fig. 3). The BOCAs showed changes in cell phenotype and tissue remodeling in the articular cartilage in response to the tissue fracture.

DISCUSSION

This study establishes the clinical viability of live sterile tissue machining to modify the shape of extant living osteochondral allografts. BOCAs machined from living osteochondral tissue explants demonstrated clinically acceptable levels of cell viability ex vivo (>70%, Fig. 2) following machining, storage in culture media, and sustained bending.[11] This study also demonstrated the successful ability to perform high-precision aseptic machining of live osteochondral tissue, shipping back-and-forth between two states, without inducing apoptosis in the tissue chondrocyte population or introducing foreign pathogens, leading to successful transplantation of allografts in dogs. However, allograft fissuring, fragmentation, and resorption with corresponding trochlear erosions was noted in BOCAs (Fig. 3), attributable to weakening the strength of these allografts by using a groove width better suited for human allografts.

Results confirm that machining of grooves in live osteochondral allografts can be achieved successfully in a practical setting involving shipping of tissue samples between locations and transplantation into animals. However, the specific width of grooves adopted for this canine study, originally intended for human-sized tissue samples, showed that there exists a risk of compromising structural integrity in grooved allografts. A study is currently underway to optimize the width of machined grooves for further preclinical testing in a dog model, so that BOCAs can safely be used without compromising allograft strength.

INTRODUCTION

Pelvic organ prolapse (prolapse) is a common gynecologic condition characterized by the descent of pelvic organs from their normal anatomic position. Women have a 12.6% risk of undergoing prolapse surgery by the age of 80[1]. Prolapse can be treated via a sacrocolpopexy, in which synthetic mesh is attached to the anterior and posterior walls of the vagina. Around 300,000 women undergo prolapse surgery each year, with direct costs exceeding 1 billion dollars annually[2]. The economic burden of prolapse is expected to increase as the population ages[3].

Surgical procedures involving synthetic mesh are limited by significant complication[4-7]. Pain and exposure of the mesh through the vaginal epithelium are the most reported complications[8]. Studies indicate that these complications are a result of two primary factors: 1) a mismatch of the stiffness between the mesh and vaginal tissue resulting in a stress shielding phenomenon, and 2) mesh deformation (pore collapse and mesh wrinkling)[9]. The surgical meshes used in prolapse procedures are manufactured primarily from polypropylene, which is orders of magnitude stiffer than vaginal tissue; therefore, it must be extruded into thin fibers and then knitted. Studies demonstrate that stiffer meshes are associated with a maladaptive remodeling response characterized by degeneration and atrophy[10].

Polycarbonate urethane (PCU) is a promising alternative to polypropylene. It is a biocompatible medical grade polymer that has been used in long-term medical implants[11]. PCU can be tuned to match the stiffness of the vagina and it is tough enough to withstand the physiologic loads involved in sacrocolpopexy procedures. Additionally, instead of being knitted, PCU membranes (devices that are like meshes but have no knots) can be readily 3D printed[12-14].

In this study, we hypothesized that PCU membranes would result in a more favorable host response, characterized by the preservation of vaginal smooth muscle structure and function, as compared to polypropylene mesh. To test this hypothesis, we evaluated the effects of polypropylene meshes and PCU membranes on the smooth muscle layer of the vagina in a rabbit model.

METHODS

Meshes: PCU membranes (PCU EMs) were 3D printed from a lower stiffness grade of PCU (EM low) and a higher stiffness grade of PCU (EM high) that are within the range of the stiffness of the vagina. Commercially available polypropylene meshes, Restorelle (Coloplast, USA) and Gynemesh PS (Ethicon, USA) were chosen for comparison. Prior to implantation, the PCU EMs and polypropylene meshes were cut to a size of 1cm x 2cm.

Animals and Surgical Procedures: New Zealand White Rabbits (n=22) were used in this study according to the University of Pittsburgh Institutional Animal Care and Use Committee (IACUC #22030732). All rabbits were retired breeders and housed in standard cages with access to food and water *ad libitum*. PCU EMs and meshes were implanted in a total of 12 animals, with six constructs (membranes and/or meshes) implanted per rabbit (three on the anterior wall and three on the posterior wall). The membranes and meshes were not placed on tension, so that the effects of the material could be evaluated in the absence of tension. Sham animals in which no construct was implanted served as controls (n=10). Sample size for the constructs were as follows: EM low (n=24), EM high (n=24), Restorelle (n=12), and Gynemesh (n=12). Membrane and mesh-vagina complexes were explanted after 12 weeks.

Smooth Muscle Morphology and Thickness Quantification: Explanted complexes were fresh frozen in optimal cutting temperature compound, cryosectioned at 7um, and stained with Masson's Trichrome. Tissue sections were imaged at 4X with a Nikon Ni-E microscope. The smooth muscle layer of each tissue section was digitally outlined, and a custom Python script was used to calculate the average thickness of the smooth muscle layer.

Vaginal Contractile Function: Membrane and mesh-vagina complexes, 2mm x 7mm, were clamped along the circumferential

direction, attached to a force transducer, and submerged in oxygenated Krebs solution at 37ºC. Complexes were treated with a 120 mM KCl solution to evaluate muscle-mediated contraction (a direct measure of smooth muscle contraction). To account for differences in sample dimensions, the responses were normalized by tissue volume.

Statistical Analysis: ANOVAs, Kruskal-Wallis tests, and post hoc tests were performed as appropriate. Statistical significance was set to $p<0.05$ unless specified otherwise.

RESULTS

Qualitatively, the organization and density of the vaginal smooth muscle bundles in the PCU EM low group most closely resembled Sham (Figure 1). Implantation of PCU EM high and the polypropylene meshes appeared to have reduced the density of the smooth muscle bundles.

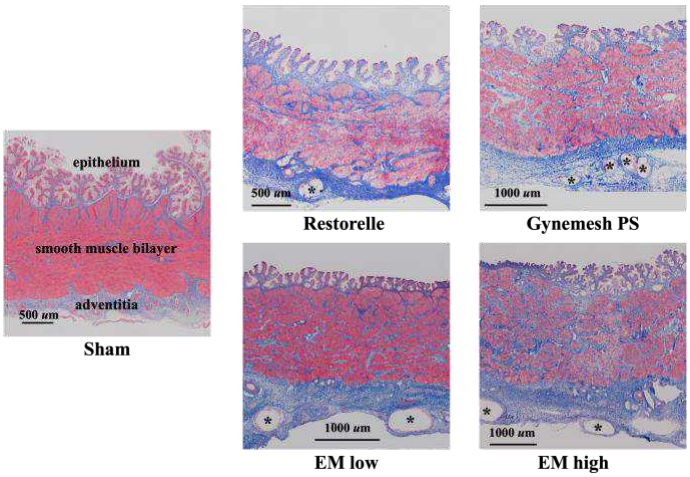

Figure 1: Masson's trichrome stain of membrane and mesh-vagina complex tissue sections. *indicates membrane/mesh fiber.

The thickness of the smooth muscle layer was not significantly impacted by the implantation of the PCU EMs compared to Sham and Restorelle (p-values>0.05, Figure 2). However, relative to Gynemesh PS, the smooth muscle layer was 28% ($p<0.005$) and 34% ($p=0.005$) thicker for EM low and EM high, respectively.

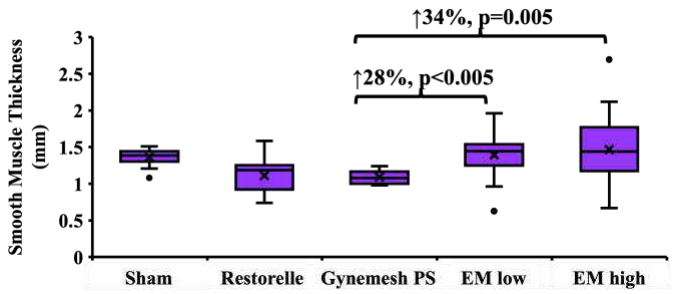

Figure 2: Vaginal smooth muscle layer thickness was not significantly impacted by EM implantation.

The contractile function of the vagina significantly decreased following implantation of the PCU membranes and polypropylene meshes relative to Sham ($p<0.001$, Figure 3). However, vaginal contractile function was not significantly different between the PCU EMs and the polypropylene meshes (all p-values>0.05).

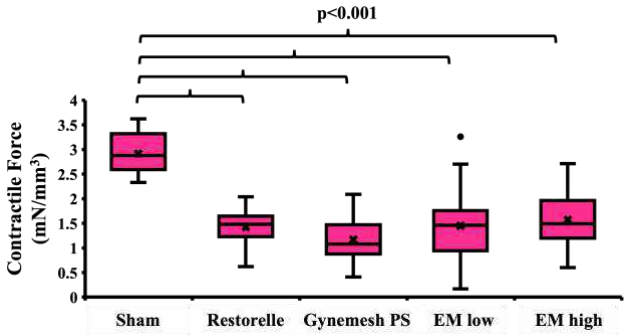

Figure 3: Vaginal contractile function in response to 120 mM KCl.

DISCUSSION

Overall, the structure of the smooth muscle layer was preserved after implantation with PCU EM low. However, the PCU EMs and polypropylene meshes had a similar effect on the function of the vagina. The observed decline in vaginal contractile function for the PCU EMs is likely due to the relative thinness and low stiffness of the rabbit vagina compared to human and non-human primate vaginal tissue. Future studies will use the non-human primate model to overcome the thickness and stiffness limitations of the rabbit vagina. Additionally, the small size of the constructs (1cm x 2cm) and the absence of tension may have minimized differences between the EMs and meshes. Thus, studies using the full-length (3cm x 12cm) membranes and meshes implanted on the rabbit vagina are ongoing.

The low stiffness of the EMs required that they be constructed of more material to meet physiologic loading demands, making them substantially heavier than polypropylene meshes (169 g/m^2 vs 42 g/m^2). The results of this study suggest that heavier devices, if manufactured from a low stiffness polymer, are still associated with a favorable host response. This is contrary to polypropylene meshes in which heavyweight meshes lead to poor outcomes[10]. These findings also suggest that the impact of a lower weight PCU EM should be explored.

Overall, the results of this study support the use of PCU as an alternative to polypropylene for prolapse repair devices, and additional studies are underway to further evaluate the PCU EMs.

INTRODUCTION

The vagina is a fibromuscular organ involved in pelvic organ support. Vaginal structural integrity is dictated by the underlying extracellular matrix (ECM) composition. Changes in the vaginal composition alter the vaginal mechanical properties, such as stiffness and extensibility. The loss of structural integrity of the vaginal fibromuscular layer may contribute to clinical problems such as pelvic organ prolapse (POP). POP develops more frequently in the anterior vaginal wall (34.3%) compared to the posterior (18.6%) [1]. Studies in human tissues suggest that local differences in vaginal wall mechanical properties may contribute, however, local vaginal structure-function relationships are not fully understood, nor are vaginal dynamics with POP risk factors such as age and injury [2,3]. Towards this end, and due to limited access to human vaginal tissue, mouse models are widely used in reproductive and POP studies to elucidate fundamental structure-function relationships and potential evolving structural mechanisms of pelvic floor stability [4-6]. To evaluate regional tissue composition, Raman spectroscopy (RS), a light-based technique that measures the photons scattered by the interaction between laser light and molecular bonds, can measure tissue components at a small scale. RS has previously been employed to quantify cervical composition such as total collagen, elastin, and actin and demonstrated its ability in regional composition assessment [7]. Furthermore, noninvasive measurements of cervical tissue composition based on RS correlate with biomechanical changes [7], yet this approach has not yet been extended to the assessment of the vaginal wall. Herein we proposed to leverage RS and biaxial testing to elucidate local vaginal structure-function relationships in the murine anterior and posterior walls. We hypothesized that posterior murine vaginal wall would be stiffer than the anterior, and that Raman coefficients of total collagen, elastin, and actin would be higher in the posterior wall compared to the anterior. Potential correlations between mechanical properties and ECM components were also evaluated.

METHODS

10 vaginas were collected from wild-type C57BL/6 mice (IACUC UTSW approved, 10-11 months of age) and stored at -20 °C. Before the testing, specimens were thawed at 4°C overnight. The anterior and posterior walls were separated by cutting longitudinally along the midlines of two sides and tested individually (Fig 1A). The unloaded thickness was measured by laser scale. The sample was speckle coated by airbrush with black alcohol ink (Fig 1B). Then the tissue was mounted on BioTester 5000 (CellScale, Waterloo, ON, Canada) and recorded unloaded grip-to-grip length in circumferential and axial direction. The displacement-controlled equibiaxial tensile testing was performed with a preload of 10mN, a stretching rate of 0.25%/s, and a target displacement of 15% of the original length, and test settings were based previous biaxial studies [8,9]. The tissue was preconditioned with 5 rounds of tests of 5 cycles followed by 10-minute equilibration. Then 8 cycles of equibiaxial tests were performed, and the last loading cycle was used for analysis. A MATLAB program adopted AL-DIC algorithm was applied to track the deformation and calculate the Green-Lagaragian strain and first Piola–Kirchhoff stress. A bilinear function fit strain-stress data to determine toe and linear moduli, which were calculated as the slopes of the toe and linear regions and served as metrics of material stiffness at low and high strain (Fig 1C).

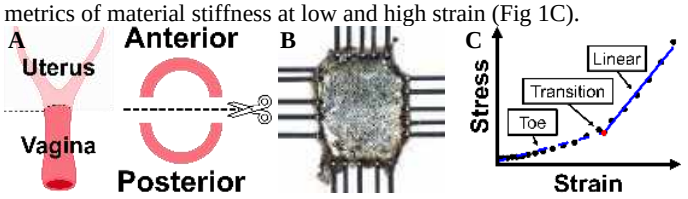

Figure 1. (A) Vaginal wall isolation. (B) Speckle-coated tissue. (C) Bilinear fitting of strain and stress.

After mechanical testing, anterior and posterior samples of 6 mice were subjected to RS to evaluate the Raman coefficients of total collagen, actin, and elastin. A 785nm laser (Innovative Photonic

Solutions, Plainsboro, NJ, USA) and fiber optic probe (EmVision, Loxahatchee FL, USA) in conjunction with an imaging Raman spectrograph (EmVision) equipped with a thermoelectrically cooled back-illuminated CCD (Teledyne PI, Trenton NJ, USA) was utilized to acquire ten spectral repetitions of the sample at 6 regions of interest. Standard protocols and materials were used for system calibration and data preprocessing, including Savitzky-Golay smoothing, and background subtraction as previously outlined (Fig 2) [10]. A non-negative least squares analysis of the data against a database of pure sample spectra was conducted to calculate regional Raman coefficients of total collagen, elastin, and action. The coefficients of 6 regions from the same sample were averaged for each vaginal wall sample. The normality and homogeneity of variance of moduli and regional Raman coefficients were evaluated by Shapiro-Wilk and Levene's tests. Paired sample t-tests or nonparametric alternative, Wilcoxon tests, evaluated potential differences between anterior and posterior walls in biomechanical properties and regional Raman coefficients of each protein. Pearson correlations were calculated between moduli and averaged Ramen coefficients.

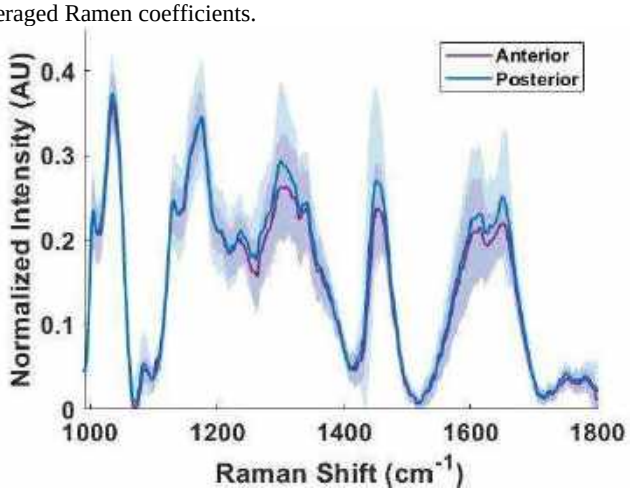

Figure 2. Normalized Raman spectra (mean +/- standard deviation) per group showing the differences in signature between the anterior (purple) and posterior (blue).

RESULTS

The moduli were normally distributed with equal variance. When comparing circumferential linear moduli between anterior and posterior vaginal walls, the linear modulus was significantly lower in the anterior wall compared to the posterior (Fig 3A, p=0.04). No other significant differences were identified in moduli between vaginal walls.

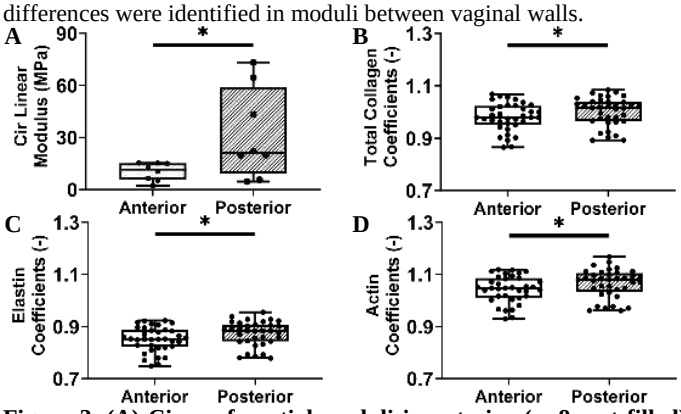

Figure 3. (A) Circumferential moduli in anterior (n=8, not filled) and posterior (n=8, shadow) walls. Comparison of regional Raman coefficients of total collagen (B), elastin (C), and actin (D) between anterior (n=36, not filled) and posterior (n=36, shadow) walls.

For composition, total collagen coefficient was significantly lower in the anterior wall compared to the posterior (Fig 3B, p=0.03). The elastin coefficient (Fig 3C, p=0.01) and the actin coefficient were significantly lower in the anterior wall compared to the posterior (Fig 3D, p=0.01). Circumferential linear modulus of the posterior wall strongly negatively correlated to averaged coefficients of total collagen (R=-0.92, p<0.01), elastin (R=-0.96, p<0.01), and actin (R=-0.98, p<0.01). No other significant correlations were identified.

DISCUSSION

Herein, the circumferential stiffness was significantly higher in the posterior vaginal wall compared to the anterior, which is consistent with observations in the human vagina [2]. The increased stiffness coincided with a higher regional Raman coefficient of total collagen in the posterior wall compared to the anterior. Collagen fibers are largely responsible for providing tensile strength and stiffness in soft tissues. Additionally, high regional Raman coefficients of elastin and actin were identified, suggesting that the posterior wall has higher collagen, elastic fiber, and smooth muscle cell content. The higher stiffness in the posterior wall may potentially contribute to the lower incidence rate of POP involving the posterior compartment compared to the anterior compartment [1]. Additionally, strong negative correlations were identified between posterior circumferential stiffness and regional Raman coefficients of total collagen, elastin, and actin. This may suggest that circumferential stiffness of the posterior vagina decreases when ECM fibers and smooth muscle cells become less dense in the tissue, which may be due to aged mice used in this study. However, further study is needed to address the underlying microstructural mechanisms, as well as the processes of remodeling in each wall with age and other POP risk factors such as vaginal delivery and injury. Interestingly, anterior and posterior vaginal wall stiffness in the axial direction was not statistically significant, which may be due to anisotropic distribution and alignment of elastic and collagen fibers and merits further investigation [5].

One limitation of this study was the lack of quantification of collagen and elastic fiber microstructure, such as orientation and undulation. Additional work employing RS analysis would permit quantification of fiber orientations providing additional information on vaginal structure-function relationships [11]. It is also necessary to quantify other ECM components such as fibulin-5 [4]. This study used only aged mice, and future comparison between age groups is needed to understand vaginal dynamics. Overall, this study observed that murine vaginal walls were significantly stiffer in the circumferential direction in the posterior wall, highlighting the importance of quantifying local vaginal function and composition to develop more therapeutic regimes for POP.

INTRODUCTION

Advanced maternal age is correlated with adverse outcomes in pregnancy and parturition such as spontaneous abortion, prolonged labor, and postpartum hemorrhaging [1]. While the etiology of these risks are not fully understood, changes in the uterine extracellular matrix (ECM) with age may contribute. The uterus is principally composed of collagen fibers, elastic fibers, and smooth muscle cells (SMC). Collagen fibers impart the uterus with native tensile strength while elastic fibers provide the ability to stretch and recover. Collectively, the passive mechanical properties of soft tissues are primarily attributed to fibrous components such as collagen and elastic fibers as well as non-fibrous components such as glycosaminoglycans. For successful pregnancy and parturition, the contractile active behavior of the SMC work in conjunction with the passive components of the matrix. Prior mouse models have been employed to understand the relationship between uterine contractility and age[2], [3], however the changes in passive mechanical properties and underlying composition of the uterus with age remain unknown. Further, the passive material stiffness and amount of elastic fibers increases in the murine vagina with reproductive age[4], [5]. Biaxial extension-inflation protocols are useful methods to quantify multiaxial mechanical properties while maintaining native tissue geometry, while Raman spectroscopy provides a molecular signature of tissue that is sensitive to the types and amounts of multiple ECM proteins and components. Therefore, the objective of this study was to quantify the passive mechanical properties and composition of the nulliparous murine uterus with age using biaxial extension-inflation protocols and Raman spectroscopy. We hypothesize that there will be an increase in stiffness and ECM components with reproductive aging.

METHODS

Animal Care. 9 female nulliparous wildtype C57BL/6 mice were used (UTSW IACUC approved). Mice were divided into three groups: 2-3 months, 4-6 months, and 10-11 months of age (n=3/group). **Specimen Preparation**. Mice were euthanized via cervical dislocation and uterine horns were dissected from the reproductive tract (Fig 1). One uterine horn was randomly allocated to mechanical testing while the other was used for Raman Spectroscopy. The tissue was frozen at -20°C. Prior to testing, the tissue was defrosted for one hour at 4°C. **Biomechanics**. The uterus was cannulated onto a biaxial extension inflation device (Danish MyoTechnologies, Aarhus, Denmark) in calcium free Kreb's Ringer Buffer and equilibrated at 37°C (Fig 1). The physiologic length was restored by extending the tissue to the length where force remained constant over a range of increasing pressure [6]. To achieve consistent and repeatable measurements, five cycles of preconditioning was performed [7], [8]. Following, three cycles of pressure-inflation testing were performed at the physiologic length, -2% and +2% of the physiologic length. Force length testing was performed by cycling between -2% and +2% of the physiologic length at pressures of 10, 67, 133, and 200 mmHg [7], [9]. **Raman Spectroscopy**. Compositional analysis was conducted on the opposite uterine horn in the 2-3 month and 10-11 month uterus (n=3/group). The tissue was opened longitudinally. Ten spectra were acquired at each of six regions of interest (Fig 1) using a 785nm laser (Innovative Photonic Solutions, Plainsboro, NJ, USA) and fiber optic probe (EmVision, Loxahatchee FL, USA) in conjunction with an imaging Raman spectrograph (EmVision) equipped with a thermoelectrically cooled back-illuminated CCD (Teledyne PI, Trenton NJ, USA). Data was preprocessed for analysis through Savitzky-Golay smoothing and background subtracting as previously described[10]. **Data Analysis.** First Piola-Kirchhoff stress-stretch curves were calculated in the circumferential and longitudinal direction. To determine the toe and linear moduli, a bilinear function fitted the stress-stretch curves. Material stiffness at low strain was determined as the slope of the toe region while material stiffness at high strain was determined as the slope of the linear region. A non-negative least squares (NNLS) fitting analysis was performed against a database of pure sample spectra to determine the concentration

of total collagen, elastin, cholesterol, and lipids [11]. **Statistical Analysis.** Lilliefors and Levene's test evaluated if the mechanical data was normally distributed and met the assumption of homogeneity of variance, respectively. To determine if age and direction influenced material stiffness, the Scheirer Ray Hare (SRH) test was performed followed by Dunn's test if appropriate for the toe and linear moduli. The Shapiro-Wilks test evaluated the normal distribution of the NNLS coefficients in each group. To determine if age affected ECM composition, a Kruskal-Wallis test was performed for each component of interest.

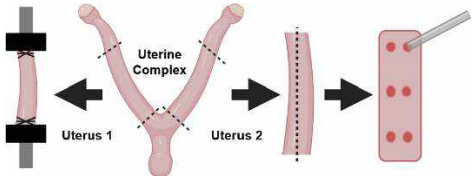

Figure 1. Dissection of the murine uterus. One uterine horn was randomly allocated to mechanical testing and cannulated onto an extension-inflation device. The other uterine horn was randomly allocated for Raman Spectroscopy wherein the tissue was rolled out by a singular longitudinal cut. A fiber optic probe assessed six regions.

RESULTS

Biomechanics. An increase in age increased distensibility demonstrated by the rightward shift in both the circumferential and longitudinal directions. For the toe moduli, significant differences were identified in material stiffness with respect to age ($p=0.003$) while direction ($p=0.15$) and interactions ($p=0.80$) were not significant. When compared to the 2-3 month uterus, material stiffness significantly decreased in the 4-6 month ($p=0.02$) and 10-11 month ($p=0.003$) uterus. A SRH test identified significant differences in the linear moduli with respect to age ($p=0.008$) and direction ($p=0.03$). The interactions were not significant ($p=0.80$). When compared to the 2-3 months, material stiffness significantly decreased in the 4-6 month ($p=0.04$) and 10-11 month ($p=0.009$) uterus (Fig 2A). Within each age group, material stiffness was significantly greater in the circumferential direction than the longitudinal direction ($p<0.05$). **Raman Spectroscopy.** The four NNLS coefficients of interest (total collagen, elastin, lipid, and cholesterol concentrations) saw a significant increase in the 10-11 month uterus ($p < 0.001$) as opposed to the younger group (Fig 2B).

DISCUSSION

This study quantified passive mechanical properties and composition in the uterus with respect to reproductive age. The uterus displayed an increase in distensibility and a decrease in material stiffness with age. While aging is largely associated with an increased in stiffening of soft tissues, the observed trends are in agreement with previous work in the murine cervix [2]. The increase in distensibility in the uterus may be the result of 10-11 months characterizing reproductive aging but not fully aged or menopausal tissue. The 10-14 month old C57 mouse is correlated to 38-47 human years while 18-24 months is correlated to 56-69 human years [12]. In this intermediary aging process, it is possible that immature collagen fibers are being produced without the degradation of elastic fibers, thus resulting in increased distensibility and decreased material stiffening. Additionally, a significant increase in total collagen was found in the older age group. This finding is in agreement with previous studies wherein insoluble collagen deposition increased with age [13]. While an increase in collagen is typically associated with an increase in material stiffness, Raman Spectroscopy can only detect the total collagen signal, which is not able to distinguish mature and immature collagen content or changes in the type I: III collagen ratio.

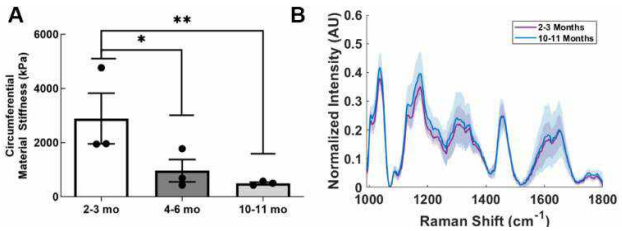

Figure 2. (A) The circumferential material stiffness of the murine uterus aged 2-3 (white), 4-6 (grey), and 10-11 (light grey) months (n=3/group) at high strain. An SRH test showed significant differences between direction ($p=0.03$) and age ($p=0.008$) with no significant interactions. Compared to 2-3 months, material stiffness significantly decreased in the 4-6 month ($p=0.03$) and 10-11 month ($p=0.009$) uterus. (B) The average of the post-processed 2–3-month (purple) and 10–11-month (blue) spectra ± standard deviation plotted against the Raman shift in inverse centimeters.

A significant increase in elastin signal with age was also identified. Prior work in the vagina detected a larger amount of elastic fibers in older age groups but a decrease in fiber length and width [5].This may suggest a decrease in functional elastic fibers resulting in altered mechanics. Finally, cholesterol and lipids increased in the older uterus. Elevated cholesterol levels are detrimental to uterine SMC contractile potential, which may correlate with prolonged labor [14]. Further, lipids associated with decreased tissue distensibility were identified in the cervix of mouse models with delayed parturition [11]. Future studies are needed to investigate how these changes in cholesterol and lipids affect uterine function with age. Taken together, the decrease in material stiffness correlated with an increase in ECM components may suggest fiber-specific remodeling rates of the uterus with age.

This study is not without limitations. The uterus is responsible for exhibiting contractile behavior to facilitate processes such as pregnancy, and parturition. Prior studies demonstrate an important relationship between SMC and ECM properties [5]. While investigating active contractile behavior of the uterus with age and pregnancy is of interest, initial studies in the passive, nulliparous state are critical to establishing a fundamental baseline of uterine mechanical behavior with age. Quantifying the uterine mechanical and compositional properties with age may provide key insights to improve outcomes related to advanced maternal age.

INVESTIGATING THE INFLUENCE OF GAG DIGESTION AND CORNEAL CROSSLINKING ON COLLAGEN FIBRIL ORGANIZATION

INTRODUCTION

The cornea, a transparent tissue at the front of the eye, plays a crucial role in refraction and protection. Its mechanical and optical properties are governed by the extracellular matrix (ECM), specifically the stroma, which comprises 90% of the corneal thickness. Collagen fibrils within the stroma, arranged in pseudo-hexagonal arrays, interact with proteoglycans (PGs), forming a lattice-like structure. Glycosaminoglycan (GAG) side chains of PGs, including chondroitin sulphates (CS), dermatan sulphates (DS), and keratan sulphates (KS), contribute to interfibrillar GAG duplexes, maintaining collagen fibril organization [1]. Studies reveal diverse models for PG-collagen interactions, emphasizing the significance of GAG-GAG interactions. It has been observed that genetic mutations affecting PG lumican lead to disrupted collagenous matrix, impacting corneal transparency [2]. Microstructural changes are expected to influence corneal mechanical properties. For example, in keratoconus, KS GAG chains have been observed to reduce significantly. Thus, in order to clarify the role of GAGs in the structural properties of the cornea, it is important to investigate the relation between KS GAGs and corneal stromal microstructure.

Corneal crosslinking (CXL) treatment enhances corneal mechanical properties, particularly in keratoconus. Previous studies showed conflicting results regarding collagen fibril diameter changes post-CXL [3, 4]. This research employs transmission electron microscopy (TEM) to investigate GAG effects on corneal ECM organization before and after CXL. The hypothesis posits GAGs as being crucial in defining corneal microstructure, prompting the use of keratanase enzyme for GAG depletion and subsequent characterization of CXL-treated samples.

METHODS

Porcine eye globes were collected from a slaughterhouse and brought to the laboratory on ice. Samples were divided into four groups: control, control CXL, enzyme, and enzyme CXL. For GAG depletion, corneal strips were immersed in a keratanase II enzyme solution (0.1 U/ml) with 100 mM sodium acetate buffer for 20 hours at 37°C and pH 6.0. The corneal strips in CXL groups underwent a conventional CXL protocol, involving soaking in a 20% dextran 0.1% riboflavin solution for 30 minutes, followed by irradiation with UVA light (3 mW/cm2, 370 nm) for an additional 30 minutes [5]. For the transmission electron microscopy, corneal tissue blocks (Figure 1) from each group were fixed in 2.5% phosphate-buffered glutaraldehyde, washed, and post-fixed in osmium tetroxide [6]. After staining, dehydration, and resin embedding, semi-thin sections were cut, stained with Toluidine blue, and examined under a light microscope for tissue preservation. Ultra-thin sections were contrasted and examined using a JEOL JEM-1400 Flash transmission electron microscope, and images were captured at various magnifications for detailed analysis of fibril diameter & interfibrillar spacing using Image J software.

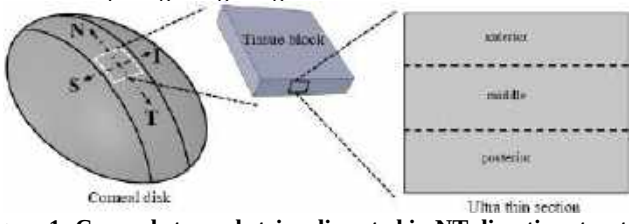

Figure 1: Corneal stromal strips dissected in NT direction, treated, and analyzed with TEM.

RESULTS

Figures 2 and 3 show electron micrographs of the anterior cornea at various magnifications for control, control CXL, enzyme, and enzyme CXL conditions. Keratocytes, collagen lamellae, and individual collagen fibrils are visible. Grey regions between fibrils, seen in control samples, suggest PGs/GAGs, confirmed by their reduction in GAG-

depleted samples. Micrographs for middle and posterior regions were similarly obtained to assess microstructural changes due to enzymatic digestion and CXL treatment (results not shown).

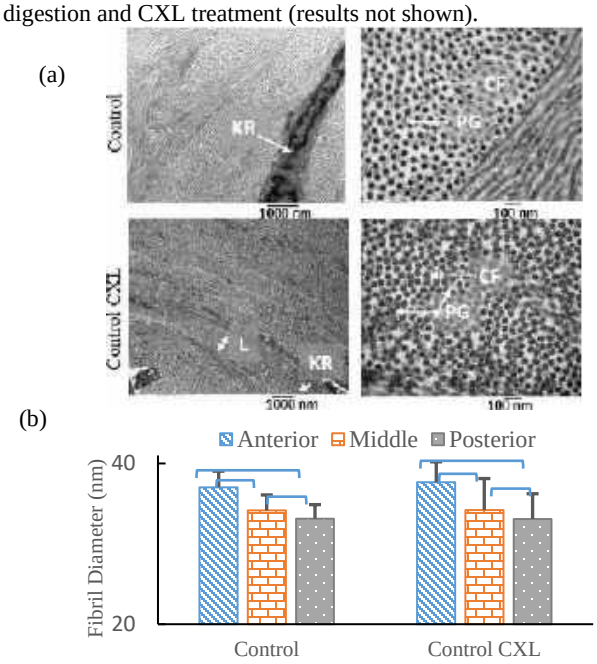

Figure 2: (a) Typical Electron micrographs of anterior corneal stroma for control and control CXL specimens. Marked features include keratocytes (KR), collagen lamellae (L), and collagen fibrils (CF) with white arrows. (b) The effect of CXL treatment on regional variation of collagen fibril diameter. Vertical bars indicate one standard deviation, and horizontal brackets denote significance.

Collagen fibril diameter analyses (Fig. 2-3) revealed no significant changes due to CXL or enzymatic digestion. However, a notable regional difference was observed, with anterior collagen fibrils significantly larger than posterior ones in control samples ($P < 0.05$). Center-to-center distances showed no significant regional differences, except in control CXL samples (data is not shown here). CXL treatment significantly reduced interfibrillar spacing in the anterior and middle parts of the control and GAG-depleted samples ($P < 0.05$). Enzymatic GAG removal increased interfibrillar spacing in anterior and posterior regions ($p < 0.05$), indicating loosely packed collagen fibrils in enzyme-treated specimens.

DISCUSSION

The primary objective of this work was to investigate the impact of GAGs and CXL on the arrangement of corneal collagen fibrils using transmission electron microscopy (TEM). Notably, the anterior porcine corneal stroma displayed larger collagen fibril diameters compared to the posterior region (Fig. 2). Interestingly, the fibril diameter exhibited a reduction through the thickness of control samples, measuring ~37 nm in the anterior, ~34 nm in the middle, and ~33 nm in the posterior regions. Neither CXL nor enzymatic digestion showed a significant impact on collagen fibril diameter. This observation was contrary to previous TEM findings but in agreement with X-ray scattering studies [3, 4]. The consistent results between TEM and X-ray diffraction point towards species-dependent effects of CXL on fibril diameter, as seen in rabbit cornea studies that reported increased fibril diameter post-CXL, highlighting variability across species. Additionally, Keratanase digestion followed by crosslinking demonstrated no significant effect on collagen fibril diameter.

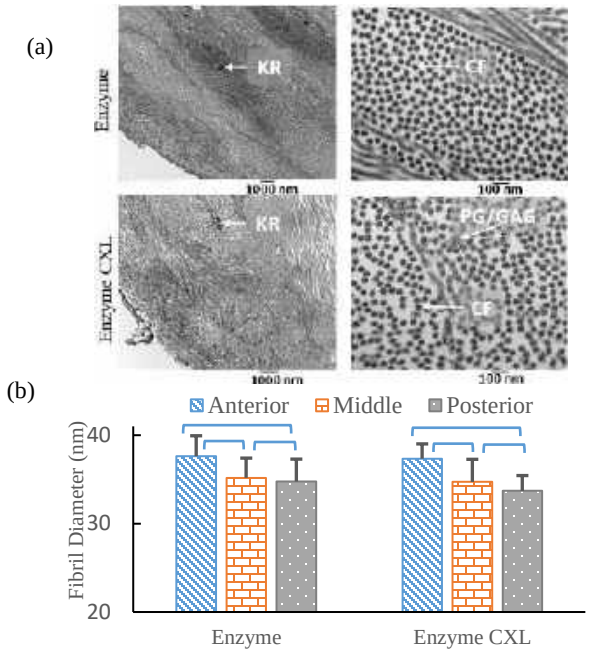

Figure 3: (a) Typical electron micrographs of anterior corneal stroma for enzyme and enzyme CXL specimens. Marked features include keratocytes (KR), collagen lamellae (L), and collagen fibrils (CF) with white arrows. (b) The effect of enzyme and CXL treatment on regional variation of collagen fibril diameter. Vertical bars indicate one standard deviation, and horizontal brackets denote significance.

Center-to-center distances between adjacent collagen fibrils were also calculated. Control samples showed no significant through-the-thickness center-to-center distance variation, averaging about 55 nm. CXL treatment significantly reduced this distance in anterior and middle layers ($P < 0.05$), aligning with previous reports on pig and human corneas. The posterior region remained unaffected. Enzyme-treated samples had significantly larger values than controls ($P < 0.05$), and CXL treatment decreased center-center distances significantly ($P < 0.05$). GAG removal led to loosely packed collagen lamellae, increasing this distance, while CXL treatment added crosslinks, stiffening the interfibrillar domain and compacting collagen lamellae.

The study used porcine corneas because of human donor tissue scarcity; however, it provided valuable insights into microstructural changes in corneal mechanical properties resulting from cross-linking (CXL) and GAG removal. Our ongoing research involves human corneas to identify potential microstructural differences contributing to a deeper understanding of corneal biomechanics.

INTRODUCTION

The stomach is a muscular organ located in the upper abdomen, between the esophagus and the small intesline. Responsible for functions like food storage, mechanical and chemical digestion, and the production of gastric juices, its motility is controlled by electrical signals. Any electrophysiological or mechanical dysfunction in the stomach may contribute to various gastrointestinal conditions, including gastric motility disorders, gastroesophageal reflux disease, functional gastrointestinal disorders, among others. Therefore, both electrophysiology and mechanics are indispensable factors in comprehensively studying the physiology and pathology of the stomach.

The personalized electromechanics modeling for the stomach is crucial, providing a more precise, individualized approach to diagnosing, treating, and understanding gastrointestinal conditions. This advancement holds the promise of improving patient outcomes and driving progress in medical knowledge and technology. Despite being in its early stages, efforts are underway to develop this field [1]. Remarkable improvement in the medical imaging technology now enables high-resolution and real-time imaging of the stomach, enhancing the accuracy of stomach modeling.

In this work, we present a comprehensive workflow tailored to model the electromechanics of patient-specific stomachs. Within this workflow, we study the segmentation methodology, stomach mechanics, fiber generation, and electromechanics coupling. The goal is to extend this workflow to more patients (~15) to get more generalized characteristics of the human stomach. This initiative aims to establish a foundational understanding of the physiology and pathology of the stomach.

METHODS

The entire workflow is shown in **Fig. 1**. We acquire the 3D CT data of the abdomen of a healthy male patient. Using the open-source software – Simvascular (https://simvascular.github.io/), we segment the 3D CT data to construct a finite element analysis (FEA) model of the human stomach. The model spans from the lower esophageal sphincter (LES) to the pyloric sphincter (PS) plane. Considering the small thickness of the stomach wall, we segment the lumen of the stomach and assume the thickness based on literature [2].

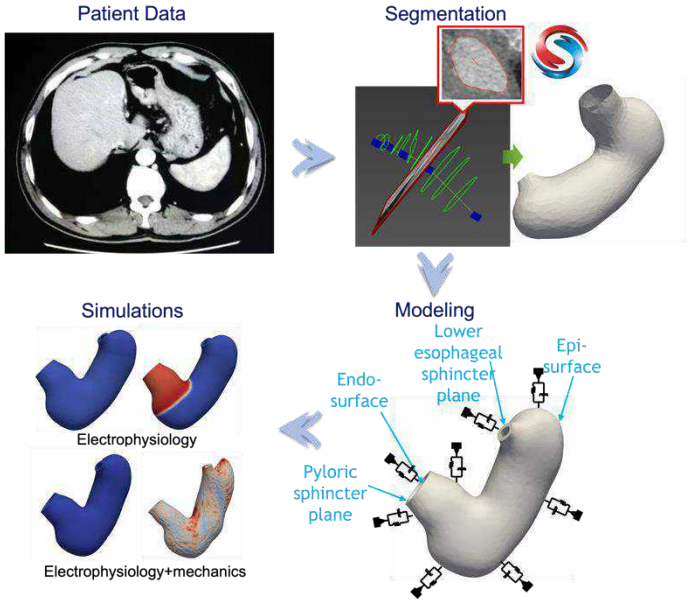

Figure 1: The workflow for stomach electromechanics modeling. FEA model is segmented from the patient CT data. The fiber orientation is generated on the 3D stomach model using a rule-based method, and subsequently, electrophysiology and solid mechanics coupling simulation is conducted and analyzed.

After that, we develop a rule-based fiber assignment algorithm, inspired by myocardium fiber orientation work [3], to assign the muscle fiber orientations to different locations within the stomach model (**Fig. 2**). By solving three Laplace-Dirichlet problems with distinct Dirichlet boundary conditions, we obtain the transmural distance ψ_{EPI}, and two other distances ψ_{LP} (LES-PS) and ψ_{LA} (LES-Apex). Adapting the method from [3], we calculate the local coordinate system and establish the orthotropic fiber orientation. Stomach muscle fibers exhibit distinct orientations in different layers: oblique in the innermost layer, circularly in the mid-layer, and longitudinally in the outermost layer. To determine the orientation angle of the fibers, a series of threshold values are defined and applied across the transmural distance.

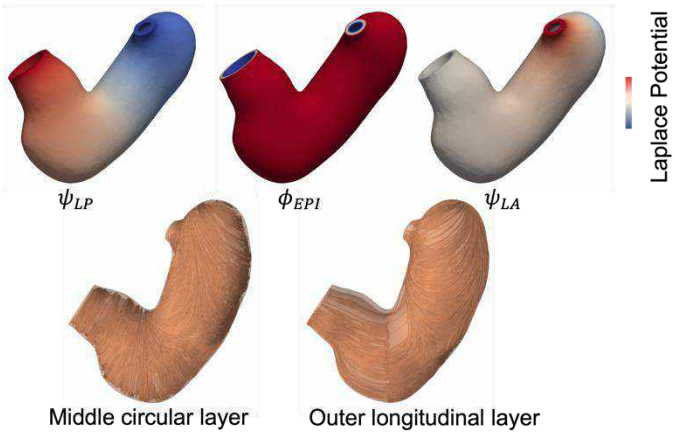

Figure 2: Top: The solutions to 3 Laplace boundary problems. Bottom: Generated fiber orientations for different muscle layers.

To account for tissue support at the lower esophageal sphincter plane, pyloric sphincter plane, and the effects of the epi-surface serosa, Robin boundary conditions are implemented with appropriate stiffness and viscosity. The unified variational multiscale formulation [4] is employed to solve the domain problem. The constitutive model comprises a passive component, described by a Holzapfel-Ogden (HO) model with a viscous part [5], and an active component driven by electromechanics coupling. The electrophysiology model involves simulating the monodomain equation for transmembrane potential and the Sathar ionic model [6]. Pacemaker cells are defined as elements at the pyloric sphincter plane, while non-pacemaker conducting cells extend through the stomach body to the fundus. Elements in the fundus are designated as insulators, as the fundus does not contract.

RESULTS

In **Fig. 3**, the results of electrophysiology simulations are presented. The top panel illustrates stimulus and potential changes over time for pacemaker cells, replicating the typical depolarization-repolarization curve of potential vs. time with the stimulus. The bottom panel displays corresponding potential maps for the 3D stomach model, revealing the clear travel of electrical signals activating the entire stomach body except for the fundus. The signals then gradually repolarize to the resting state.

In **Fig. 4**, the results of the active contraction simulation are illustrated. The dominant factor in active contraction is the active stress induced by electromechanics, as shown. The volume undergoes a significant reduction during contraction and subsequently relaxes to the resting state, accompanied by a decrease in active stress.

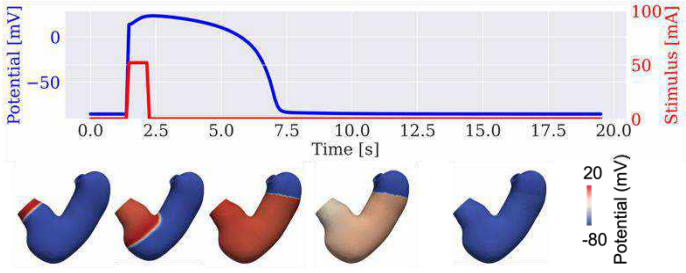

Figure 3: Results of electrophysiology simulations. Top: The stimulus and potential changes with time for pacemaker cells. Bottom: Corresponding potential maps for the 3D stomach model.

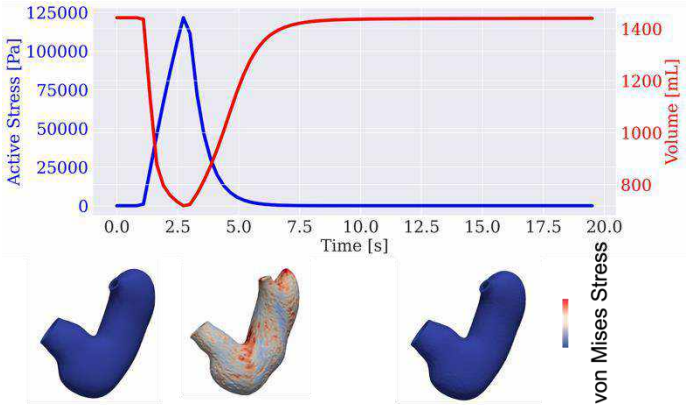

Figure 4: Top: Active stress and volume changes with time during the active contraction simulation. Bottom: Corresponding deformation and stress field for the 3D stomach model.

DISCUSSION

This work demonstrates a proof-of-concept application of a personalized modeling framework to simulate the electrophysiology and solid mechanics coupling for a 3D stomach model derived from the patient CT image. By laying this groundwork, the research paves the way for developing more sophisticated computational models to quantify the electromechanical properties of the digestive track under various conditions, including those with defects or diseases

To move forward, we will study the coupling of the current electromechanics model with fluid to account for the effects of food and water. We will then extend this framework to all of our available patient data, thereby obtaining statistically meaningful electromechanics characteristics of the stomach. The final goal is to establish a mature workflow to predict and design treatments for the stomach-related defects and diseases. This initiative is geared towards enhancing patient outcomes through informed and tailored treatment strategies.

INTRODUCTION

The anterior cruciate ligament (ACL) provides stability to the knee, primarily by limiting anterior tibial translation. ACL injuries are common amongst athletes. The anterolateral ligament (ALL) is also believed to provide rotational stability to the knee. During an ACL reconstruction, the ALL may also be reconstructed if there is concern for residual rotational instability.

A common clinical technique to diagnose ACL injuries is called the pivot shift. During a typical pivot shift, the physician applies a valgus torque to the tibia while flexing the knee from 0° (fully extended) to 90° [1]. However, the pivot shift is a binary diagnostic – a "clunk" indicates injury, while no "clunk" indicates no injury.

During *in vitro* testing, loading profiles are applied to the joint under different surgical conditions and the resulting kinematic responses are used to assess the biomechanical effects and to ultimately make surgical recommendations. To assess surgical conditions relating to the ACL and other ligaments in the knee, quasistatic and dynamic loading profiles that aim to replicate clinical exams like the Lachman and Pivot Shift are often utilized [2,3]. While quasistatic loading profiles have been successful in evaluating anterior stability, rotational stability is not often reported. Dynamic loading profiles have shown to engage the joint rotationally, but they are complex as commanded loads dynamically change in all degrees of freedom (DOF).

The novel *rotary pivot shift* presented in this study aims to reduce the variables that can produce a positive pivot shift and as such, does not involve dynamic flexing of the knee. All commanded loads and flexion angle are constant throughout except for external rotation (ER) torque. Initial loads position the joint in a subluxed state and ER torque is increased until reduction occurs.

The goal of this study was to verify that the *rotary pivot shift* loading profile can produce a positive pivot shift in an ACL deficient knee and that it could be used to assess and quantify rotary stability in the knee joint under varying ligamentous injury and surgical conditions.

METHODS

Rotary Pivot Shift Loading Profile

The rotary pivot shift loading profile consisted of four static loads:

- 50 N Medial Drawer
- 50 N Anterior Drawer
- 150 N Compression Force
- 15 Nm Valgus Torque

ER torque was increased from -0.5 to 11 Nm until reduction occurred.

ACL Deficient Verification

One ACL deficient fresh-frozen cadaver knee specimen was procured and tested using a simVITRO® Universal Musculoskeletal Simulator (Cleveland Clinic, Cleveland, OH) and a 6-axis force/torque (FT) sensor (Omega160, ATI, Apex, NC). During setup, each specimen was rigidly mounted to the robot in full extension. Coordinate systems were established for the tibia and femur and spatial relationships between the knee, robot, and FT sensor were quantified and established. Kinematics and kinetics were calculated based on these spatial relationships and FT sensor measurements.

The rotary shift loading profile was executed on the specimen at four (4) flexion angles (15°, 20°, 25°, and 30°). Anterior tibial translation (ATT) and External tibial rotation (ETR) were evaluated at each flexion angle to determine whether a shift had occurred.

.

ALL Rotary Stability Evaluation

One fresh-frozen cadaver was prepared and tested using the same lab setup as in the ACL deficient validation. This specimen underwent testing at three surgical conditions:

- Intact
- ALL injured
- ALL reconstructed

The ALL injured state was created by transecting the ALL near its tibial insertion with a scalpel. The ALL was reconstructed using a hamstring allograft that was secured using suture anchors at the anatomic origin on the femur and insertion on the tibia. The graft was tensioned with the knee in full extension and neutral rotation In each condition, the ACL was kept intact in order to eliminate variables surrounding surgical effectiveness of an ACL reconstruction.

For each of these conditions, the rotary shift loading profile was executed at 30° flexion.

ETR difference between a common ER torque value that occurred after reduction for all surgical conditions and 0 Nm was calculated. The ETR differences were normalized to intact to easily compare the relative rotational stability of the surgical conditions to intact.

RESULTS

ACL Deficient Evaluation

A positive shift occurred at each of the four flexion angles (15°, 20°, 25°, and 30°). Figures 1 and 2 display the ATT and ETR as a function of ER torque and were shifted to 0 mm and 0° at 0 Nm ER torque, respectively, to better display differences. These results indicate that the rotary pivot shift can be performed at any flexion angle from 15° to 30°. 30° was selected for simplicity, as this flexion angle is the prescribed angle for the Lachman test. A positive shift in an ACL-deficient knee confirmed that the rotary pivot shift loading profile performed as intended.

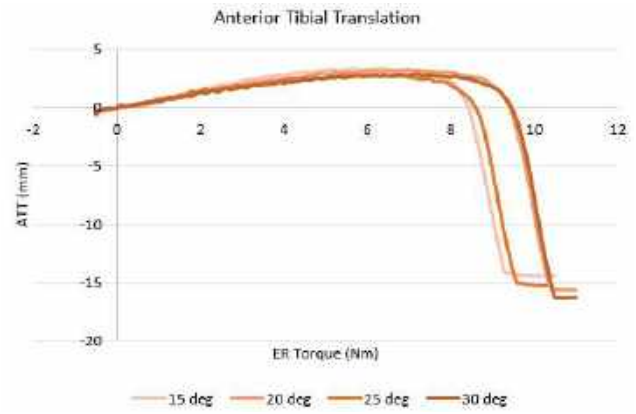

Figure 1: Anterior tibial translation at 15°, 20°, 25°, and 30° of flexion

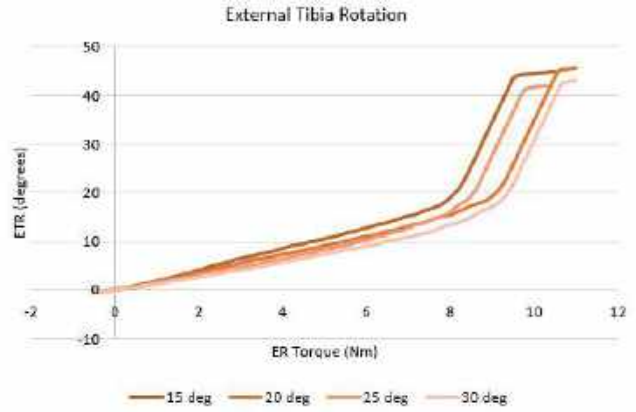

Figure 2: External tibial rotation at 15°, 20°, 25°, and 30° of flexion

ALL Rotary Stability Evaluation

Figure 3 displays ETR for the three surgical conditions. The ETR plots were shifted to 0° at 0 Nm ER torque to better display differences. For all surgical conditions, the knee reduction occurred before 4 Nm ER torque and so the ETR difference between 0 and 4 Nm was calculated for comparison. The intact knee rotated 19.1°, while the ALL injured knee rotated 20.7° (108.4% of intact), and the ALL reconstructed knee rotated 12.1° (63.2% of intact). This data indicates that differences in rotational stability can be detected with the rotary pivot shift.

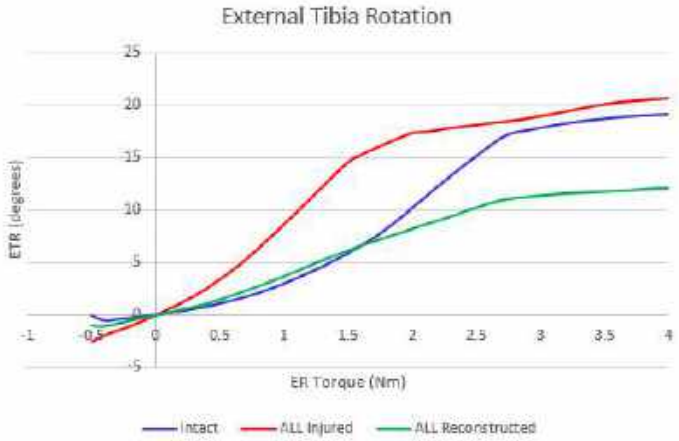

Figure 3: External tibial rotation of the intact, ALL injured, and ALL reconstructed conditions

DISCUSSION

This study evaluated the effectiveness of a new loading profile, called the rotary pivot shift, in measuring rotary stability of the knee joint. The results demonstrate success using the rotary pivot shift for one specimen. Further, the rotary pivot shift was able to demonstrate that minor differences in tibial rotation can be induced under different surgical conditions.

Another advantage of the rotary pivot shift is that it is only dynamic in one DOF, which means it does not require a multi-DOF simulator and can be performed with a single axis machine and deadweights.

Future work will include application of this loading profile to a statistically significant number of specimens to ensure the ramp pivot shift can be validated. Additionally, we want to consider scaled down loads to see if positive shifts can be induced while reducing the stress on the joint to make it more effective when used in a larger testing suite to evaluate time-zero surgical repairs.

REGIONAL CORRELATION OF STIFFNESS AND PERFUSION IN THE HUMAN BRAIN AT 7T MRI THROUGH MR ELASTOGRAPHY AND ARTERIAL SPIN LABELING TECHNIQUES

Caitlin M. Neher[1], Em R. Triolo[1], Mehmet Kurt[1]

[1]Mechanical Engineering Department, University of Washington, Seattle, WA, USA

INTRODUCTION

The mechanical properties of the brain give us insight into disease states and open avenues for new methods of medical diagnosis[1]. It is known that brain tissue gets softer as we age[2], but it is unknown whether and how tissue property changes are related to the branched cerebral vascular system in health and disease. Research suggests that changes in cerebral blood flow may be correlated with cognitive deficits in mild cognitive impairment[3], amyloid-beta deposits in Alzheimer's disease (AD)[4], and even diseased liver tissue[5]. However, there is limited research investigating the relationship between perfusion and tissue stiffness in the healthy human brain. In Alzheimer's disease it is unknown how the cascade of associated events contributes to its pathogenesis, but amyloid-deposits, tau tangles, tissue softening, hypoperfusion, and metabolic changes are disease correlates. It has been shown in one preliminary study that perfusion, stiffness, and flux rate are connected in the brain due to higher intravascular pressure that is present in small vessels, coupled with the constriction of vessels in non-compliant tissue[6]. This suggests that perfusion, an indicator of cell metabolic activity and blood volume, will have an impact on the measurable mechanical properties of brain tissue and can be used as a biomarker of underlying pathology. In this study, we utilized the advanced neuroimaging tools of Magnetic Resonance Elastography (MRE) and Arterial Spin Labeling (ASL) to quantify brain stiffness and perfusion non-invasively by voxel. First, a modular pipeline for the post processing and correlation of stiffness and perfusion was developed and used to analyze the collected data from a young control cohort with no known disease. This preliminary dataset serves as a proof-of-concept investigation into how these two metrics may be related in health and disease states of the human brain. Accordingly, the objective of this study was to collect, process, and compare stiffness and perfusion MRI data in a healthy cohort to determine whether these two factors may be correlated.

METHODS

In this study, we obtained pulsed ASL and MRE data from eight healthy volunteers aged 20-35 on a Siemens Magnetom 7T MRI scanner with a 32-channel head coil. The MRE sequence was an echo-planar spin-echo 2D pulse sequence with 3D motion-encoding gradients (TE=70ms, TR=5600ms, GRAPPA=3, 1.1mm isotropic resolution)[7] and a custom pneumatic actuator applied vibrations at 50Hz[8]. The MRE phase magnitude images were masked using SPM12[9], denoised using a MP-PCA algorithm[10] and unwrapped using Segue Phase Unwrapping[11]. The resulting unwrapped displacement data was used to calculate the magnitude of the complex shear modulus (|G*|) using an iterative nonlinear viscoelastic inversion of the time-harmonic Navier's equation[12]. Also acquired at 7T, a PASL sequence was used with EPI readout (TE=39ms, TR=5000ms, 25 repeats, 3.5mm isotropic resolution). Arterial spins were labeled by a 10cm inversion slab proximal to the image slices, with the labeling method Q2TIPS[13]. Subtraction, Bayesian Inference, inversion of the kinetic model of label inflow, and equilibrium magnetization calculations from a proton density weighted (M0) image were used to acquire quantified cerebral blood flow (CBF) in ml/100g/min in accordance with the recommended ASL whitepaper implementation summarized by equation (1) below[14].

$$CBF = \frac{6000*\lambda*(SI_{control}-SI_{label})*e^{\frac{TI}{T_{1,blood}}}}{2*\alpha*TI_1*SI_{PD}} \quad (1)$$

FreeSurfer[15] segmentation was used with a custom MATLAB script to calculate the correlation coefficient of stiffness and perfusion in gray and white matter regions across subjects. Only whole brain white matter was analyzed based on its low SNR due to high arterial transit time and relatively low perfusion[16]. During analysis, images were visually checked and regionally evaluated based on mean, standard deviation,

and volume to determine inconsistencies; no subjects were removed as outliers.

RESULTS

After all subject data was processed and co-registered to the matrix space of each respective T1 image, 3D perfusion maps and elastograms were obtained for each subject; an example of these can be seen in **Figure 1**. As expected, gray matter regions, when averaged across subjects, had higher perfusion and lower stiffness than white matter regions (44.8 ± 4.86 vs. 34.2 ± 8.73 ml/100g/min and 1.57 ± 0.25 vs. 2.42 ± 0.29 kPa, respectively). These findings are consistent with brain stiffness as measured by the magnitude of the complex shear modulus (|G*|) and perfusion values in existing literature.

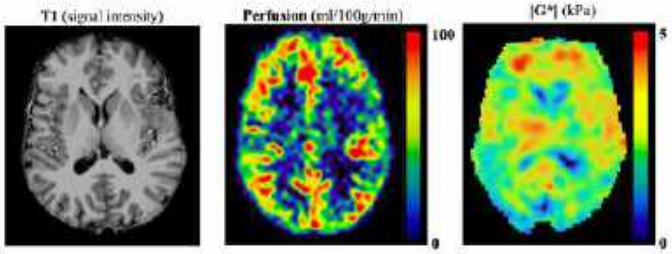

Figure 1: Exemplary axial slice of T1-weighted signal intensity image, perfusion map in ml/100g/min, and elastogram in kPa.

Furthermore, our analysis showed varying strengths of inverse correlation between stiffness and perfusion in some gray matter regions of the brain. Within a cortical gray matter mask, stiffness and perfusion show a strong inverse correlation across subjects (p-value=0.0121, correlation coefficient=-0.823, **Figure 2**). The frontal lobe showed a similar result, with a p-value of 0.0206 and correlation coefficient of -0.787. The white matter across subjects showed a similar, though not statistically significant trend (p-value=0.119, corr. coefficient=-0.596).

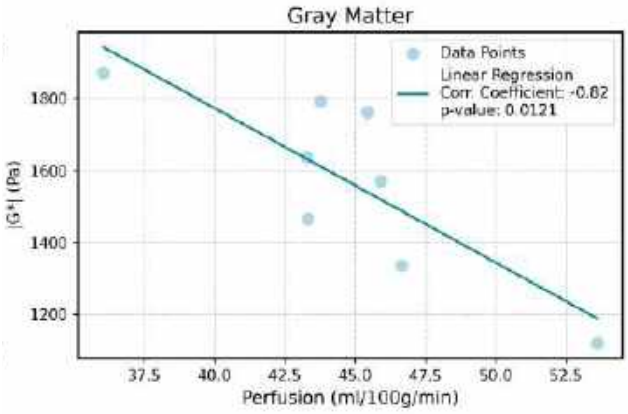

Figure 2: Inverse correlation of stiffness and perfusion in the cortical gray matter, across subjects.

DISCUSSION

Our results showed a strong inverse correlation between stiffness and cerebral blood flow (perfusion) in the healthy human cortex. This result supports our hypothesis that increased blood flow is related to reduced stiffness due to an increase in the relative size of vascular structures[6], a trend that is also consistent with existing research showing reduced whole-brain stiffness following exercise[17], and therefore increased perfusion[18].

These preliminary results, suggesting that there is a measurable correlation between stiffness, a mechanical property of tissue, and perfusion, a measure of blood delivery within tissue, may indicate an underlying biological mechanism that must be investigated further. ASL is unique in the respect that by measuring the delivery of blood to the brain tissue, it is a metric of brain health at the capillary bed level[19]. Unlike other vasculature scans, such as time of flight (TOF) angiography, ASL measures blood delivery rather than blood vessel characteristics. The establishment of correlations between stiffness and perfusion could enhance our understanding of disease pathology in Alzheimer's Disease and other neurodegenerative diseases by highlighting the interplay between tissue mechanics and metabolic and neuroinflammatory changes. To do so, further investigation of this relationship is needed to establish a baseline in the healthy brain. Future work on this study will be accomplished by increasing the pool of healthy controls, acquiring higher resolution and enhanced SNR perfusion data with a pseudo-continuous ASL sequence, and investigating smaller brain regions of interest with different levels of vascularity.

COMPUTATIONAL MODELING OF A HUMAN PLACENTONE

Armita Najmi (1), Noelia Grande Gutiérrez (1)

(1) Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

INTRODUCTION

The placenta is a vital organ facilitating the exchange of oxygen and nutrients between the mother and fetus. During pregnancy, the maternal uterine vasculature undergoes significant changes, including the remodeling of the spiral arteries (SAs) to establish uteroplacental circulation. A better understanding of placenta formation and the factors affecting its function is essential for detecting and predicting pregnancy disorders. While placentation remains understudied due to limitations in imaging modalities and diagnostic tools that can safely be utilized during pregnancy, computational modeling can provide valuable insights. Previous placental blood flow numerical studies have focused on modeling the placentone [1]–[4], which is the basic functional structure of the placenta. These models have typically employed a porous media approach to model the intervillous space (IVS). A common limitation among these studies is their lack of validation against experimental data. Also, there has been insufficient attention to IVS pressure, which is sensitive to the imposed boundary conditions (BCs). Our computational model aims to address these issues. Due to the limited *in vivo* imaging data and the lack of experimental studies, there is still uncertainty regarding the placentone structure. In addition, the effect of modeling assumptions and parameter values in simulation results has yet to be systematically evaluated. In this project, we assessed the sensitivity of uteroplacental hemodynamics to model parameters and examined necessary conditions to ensure physiological simulation results. We used Doppler ultrasound measurements from clinical studies in the literature [5], such as jet length and fluid velocity measured at the SA opening, as targets to tune the model parameters.

METHODS

We constructed a three-dimensional idealized model of a plancentone informed by histology and MRI literature data [6]–[8]. The model consisted of the spiral artery (SA), two veins, and the placentone lobule with a free-of-villi cavity (Figure 1). We simulated variations in the placentone structure including 1) veins location, 2) cavity length, 3) SA remodeling and its remodeling length. We employed a porous medium approach to model the IVS as proposed by prior studies. We assigned two different porosity values to the lobule periphery and its central region (Figure 1) to represent differences in villi density as reported by histology [7] and *in vivo* MRI studies [8].

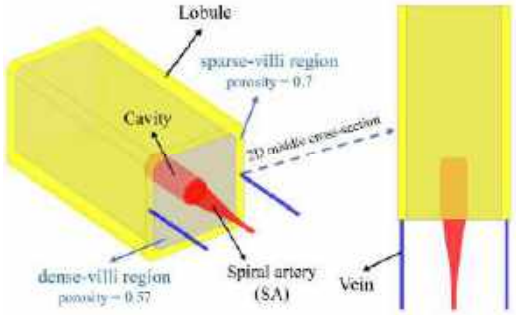

Figure 1: Idealized 3D placentone model including the lobule and the maternal vasculature and its 2D middle cross-section.

We solved the continuity and Navier-Stokes equations that govern blood flow inside the non-porous regions of the placentone (SA, veins, and cavity). The governing equations in the porous region (lobule except cavity), were the Continuity and Darcy-Brinkman equations.

The numerical simulation was performed in SimVascular [9]. We modified SimVascular multiphysics finite element solver, svFSI, to include a porous medium model.

We applied zero pressure BC on the veins outlet surfaces and utilized an at-term inflow BC ($145\ mm^3/s$) on the inlet surface. We set no-slip rigid wall BC on the rest of the surfaces. Most of the previous works in placentone modeling have applied a no-slip wall BC on the lobule side surfaces representing the septa. However, the septa do not extend to the end of the placentone [1]. Therefore, we also simulated the

case of two distinct BCs for the placentone side surfaces: a no-slip rigid wall proximal to the maternal side and a pressure BC on the wall proximal to the fetal side. For the later, a pressure value of 12 mmHg was imposed according to the reported data in the literature [10]–[12].

RESULTS

We validated our implementation of a porous media model in SimVascular against the commercial software COMSOL and obtained good agreement in our simulation results (<4% difference).

Based on measured jet lengths, veins draining the placentone are likely to be in the lobule periphery. Figure 2 shows the velocity contour for the veins located close to the SA and in the lobule periphery.

Fixing the location of the veins to the lobule periphery, we studied the effect of cavity length on the jet length. We observed an increase in jet length with cavity length. However, the rate of increase is reduced for longer cavities. In this case, a cavity length of 7 mm resulted in a jet length of 5.285 mm, comparable to the mean value for a normal, healthy pregnancy as reported via ultrasound (5.3 mm). Figure 3A shows the velocity contour when there is no cavity at the SA opening.

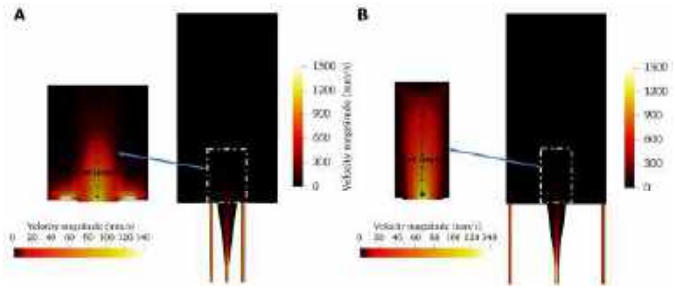

Figure 2: Velocity contour when A) veins are located close to the SA, and B) veins are located in the lobule periphery.

We observed prescribing a rigid wall BC on the entire placentone lateral surface resulted in pressure inside the lobule > 40 mmHg, which is higher than the expected physiological pressure of 12 mmHg [10]–[12]. When we applied a pressure of 12 mmHg on the side surfaces more proximal to the fetus, we obtained physiological pressures inside the IVS. Also, we observed a shorter cavity (6.5 mm) was enough to produce a jet length comparable to the mean jet length for a normal, healthy pregnancy.

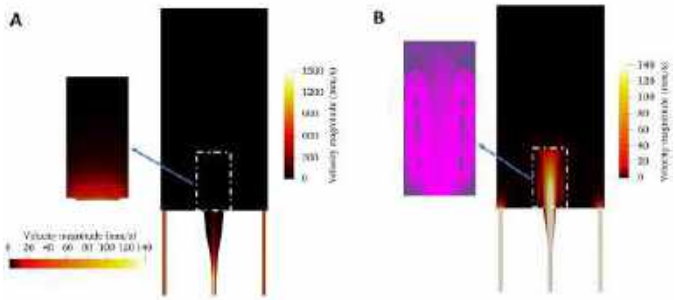

Figure 3: Velocity contour when A) no free-of-villi cavity is considered, and B) remodeling of the SA is incomplete.

Changing the periphery porosity, we observed a slight increase in the jet length (<8%) when the periphery was a sparser villi region.

Computational experiments considering partial remodeling for the SA (60%), representing a diseased case, show higher shear rates (x2.6 healthy case on the cavity side surface), higher velocities (x1.22 healthy case velocity on the upper cavity surface) and strong flow recirculation inside the cavity. Figure 3B shows velocity magnitude and streamlines for the incomplete SA remodeling case.

DISCUSSION

Our simulation results suggest that uteroplacental hemodynamics are sensitive to the structure of the placentone model, and BCs that capture placental physiology are critical to the success of these models.

First, we had to define the SA remodeled part length. We conducted simulations with different remodeling lengths for the SA. We observed that when the remodeled length is too short, there is flow separation inside the SA, which is not expected in a completely remodeled SA. Therefore, we gradually increased the remodeling length to achieve no flow separation and, at the same time, meet the maximum velocities at the SA opening reported from Doppler ultrasound data [5].

Our numerical results show a physiological jet length does not form unless veins are located far enough from the SA opening. Veins must be located in the lobule periphery (Figure 2) to achieve the mean jet length reported for a normal, healthy pregnancy.

We demonstrated the existence of a villi-free cavity at the SA opening is critical to obtaining physiological uteroplacental flow. In the absence of a cavity, no jet at the entry of the IVS is formed (Figure 3A).

The extension length of the septa separating adjacent placentones may significantly affect IVS pressure. When we considered the septa on the entire placentone side surface, we obtained non-physiological IVS pressure values.

Both histology and MRI studies have shown that the lobule peripheral region is a sparser villi region compared to its central part [7], [8]. Increasing the porosity to simulate a less dense peripheral region slightly increased the jet length. This small effect could be biased to selecting a small region as the peripheral region.

Studies suggest incomplete remodeling of the SA is the underlying cause of some pregnancy disorders. For a case of 60% remodeling of the SA, we observe strong flow recirculation inside the cavity and higher shear rates compared to the normal case. These high shear rates can be detrimental to the delicate structure of the villi, and the higher velocities can limit the diffusion of biomolecules between the mother and baby. Moreover, the pressure drop along the SA is three times higher than that of the normal case, suggesting a potential correlation with high blood pressure in preeclampsia.

In conclusion, we have successfully developed a model to simulate uteroplacental hemodynamics, and we have identified optimal model parameters to represent physiological placental blood flow conditions. In our first attempt at modeling uteroplacental hemodynamics, we modeled the SA as a straight conduit along the penetration depth. Our Ongoing work is focused on analyzing the effect of SA tortuosity.

INTRODUCTION

A single traumatic impact to cartilage triggers a chondrocyte injury response that includes mitochondrial dysfunction, cell death, and eventual breakdown of cartilage tissue, resulting in post-traumatic osteoarthritis (PTOA).[1-3] Due to the limited natural repair abilities of cartilage, there is a clinical need for new approaches to treat cartilage injuries and prevent PTOA progression. The objective of this study was to investigate metformin as a potential treatment for impact-induced cartilage injuries. Metformin, a well-established oral antidiabetic medication,[4] also prevents the onset of osteoarthritis (OA) in various animal models.[5-8] However, these models lack a mechanical overload of cartilage that is usually seen in joint trauma. Therefore, this study aimed to assess the effective dose and timing of metformin treatment for impact-induced chondrocyte injury in cartilage explants.

METHODS

Osteochondral cores were harvested from fresh bovine metacarpophalangeal joints and were cultured.[9] Specimens were impacted with a drop tower instrumented with a load cell and accelerometer (**Fig. 1**) and were treated with 0, 10 or 50 mM metformin.[9] Mitochondrial dysfunction (TMRM and MitoTracker Green, both Molecular Probes) and cell viability (LIVE/DEAD viability kit) were determined via confocal microscopy 24 h post-impact.

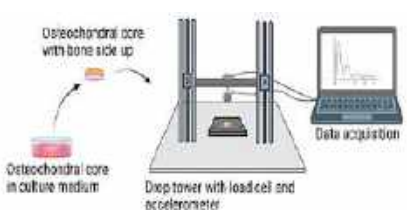

Figure 1: Schematic of drop tower impact model.[9]

Impacted cartilage explants were untreated as controls or were treated with either 1 mM metformin for 28 d or with 50 mM metformin for 24 h post-impact (**Fig. 2**). These treatments were designed to mimic daily oral administration and a single intraarticular injection, respectively. Stress-relaxation indentation was performed before impact and at 1, 7 and 28 d post-impact and was analyzed with a Standard Linear Solid model. Instantaneous (E_0) and equilibrium (E_{eq}) moduli, and time constant (τ) were reported. At 28 d post-impact, GAG content of the tissue was determined with the DMMB assay and in histological sections stained with Safranin-O. Similarly, hydroxyproline (HYP) was quantified with the Chloramine-T assay to determine tissue collagen content. Finally, pyridinoline crosslinks (PYD) were quantified in tissue hydrolysates (Quidel MicroVue PYD ELISA). In addition, medium for each specimen was assayed for GAG and HYP to assess matrix degradation during culture. Significance was set at $p<0.05$ in one-way ANOVAs.

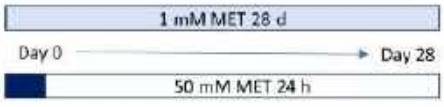

Figure 2: Metformin (MET) treatments representing daily oral administration (1 mM for 28 days) or intraarticular injection (50 mM for the first 24 hours).

RESULTS

Cartilage was impacted with peak stress of 374 ± 33 MPa, impact duration of 0.86 ± 0.08 ms and impact energy density of 22.2 ± 7.9 mJ/mm^3. Mitochondrial polarity was significantly decreased in cartilage explants 24 h post-impact and was rescued with 50 mM metformin but

not the 10 mM dose (**Fig. 3**). Similarly, treatment with 50 mM metformin preserved cell viability at 24 h post-impact significantly better than 10 mM metformin (data not shown).

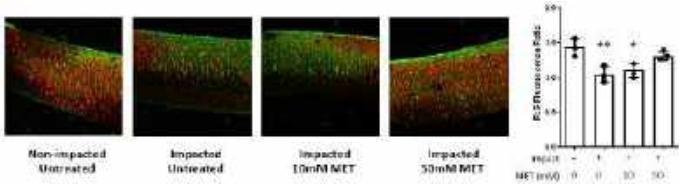

Figure 3: Red:green fluorescent ratio in cartilage treated with metformin (MET) and co-stained with MitoTracker Green (all mitochondria) and TMRM (functional mitochondria stained red) 24 h post-impact. *, ** indicates significant differences from non-impacted control, $p<0.05$.

With the mechanical overload, both E_0 and E_{eq} were maintained at days 1 and 7 (data not shown) but were lower than non-impacted tissue by d 28 (**Fig. 4**). The time constant τ was not altered at any time post-impact (d 28 in **Fig. 4**). Viscoelastic material properties of impacted cartilage did not significantly improve when 1 mM metformin was applied for the entire 28 d culture period but were improved by a single day (24 h) of 50 mM metformin (**Fig. 4**).

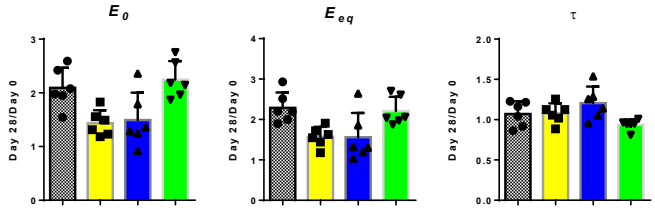

Figure 4: Ratio of material properties of cartilage explants at day 28/day 0. From left to right: instantaneous modulus (E_0), equilibrium modulus (E_{eq}) and time constant (τ). * indicates significant difference from nonimpacted control, $p < 0.05$.

Neither GAG nor HYP content of the tissue were significantly changed by impact or metformin treatments (**Fig 5**), and these results were confirmed with histological sections stained with Safranin-O (**Fig. 6**). Similarly, no differences were detected in the GAG and HYP released to the media (data not shown). However, PYD crosslink density was lower in the impacted tissue, was not significantly changed by exposure to 1 mM metformin for 28 d, and was rescued by 50 mM metformin treatment for 24 h (**Fig 5**).

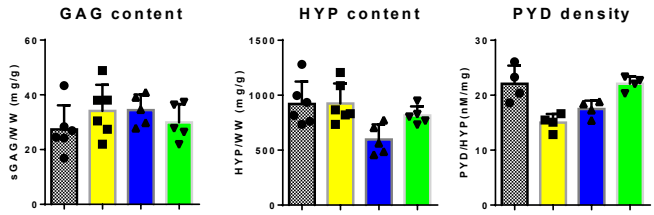

Figure 5: Tissue content of cartilage explants 28 days post-impact. From left to right: glycosaminoglycan (GAG) content per tissue wet weight (WW), hydroxyproline (HYP) content per tissue WW, and pyridinoline (PYD) normalized to HYP. * indicates significant difference from nonimpacted control, $p < 0.05$.

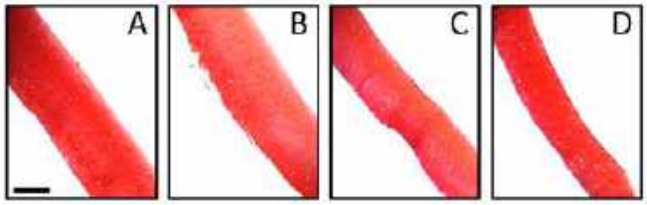

Figure 6: Cartilage sections stained with Safranin-O. A) nonimpacted control, B) impacted control, C) impacted treated with 1mM metformin for 28 d, D) impacted treated with 50 mM metformin for 24 h. Scale bar = 500 µm.

DISCUSSION

This study revealed that a concentration of 50 mM metformin was necessary to rescue mitochondrial dysfunction and cell viability in chondrocytes 24 h post-impact. This concentration is orders of magnitude higher than what is expected in the joint with oral delivery, suggesting that intraarticular injection of metformin may be necessary for effective cartilage injury treatment. To investigate this, we evaluated the viscoelastic properties and biochemical composition of impacted cartilage under two metformin treatment conditions: a lower 1 mM dose of metformin maintained for the entire 28 d culture period, simulating daily oral administration, and a higher 50 mM concentration applied for the first 24 h after impact, representing a single intraarticular injection of metformin. Only the higher concentration maintained viscoelastic material properties of cartilage 28 d post-impact, even though the treatment was limited to the 24 h period following the mechanical overload. These results suggest that rescuing chondrocyte viability and metabolic function during the acute injury phase is required for the long-term preservation of cartilage mechanics.

No significant changes in GAG or collagen content of the tissue were detected with mechanical impact or metformin treatments, nor did biochemical analyses indicate significant tissue degradation during culture. However, impacted tissue exhibited lower PYD density. This decrease in enzymatic collagen crosslinking was rescued with the 50 mM metformin treatment. PYD density was the only biochemical measure that correlated with the changes in material moduli. These findings underscore the sensitivity of cartilage material properties to collagen crosslinking and identify a new mechanism by which a mechanical overload can influence the material behavior of cartilage. Given that increased PYD density is linked to enhanced cartilage wear resistance,[10] these data also indicate that effective metformin treatments may improve functional properties of cartilage following impact injury.

In conclusion, this study demonstrated that 50 mM metformin prevents or delays impact-induced markers of chondrocyte injury and degeneration of cartilage mechanics, suggesting that it may be an effective treatment for cartilage overload injury. Extension of the current findings to an animal model of cartilage trauma may advance intraarticular metformin as a treatment for cartilage injury and the prevention of PTOA.

INTRODUCTION

Spine biomechanics research examines how pathologies, injury, and surgical intervention affects the mechanics of the spine. To examine how different surgical interventions affect spine biomechanics, i*n vitro* testing using a 6 degree of freedom (6-DOF) joint simulator allows for straightforward comparisons. Testing multilevel spines is most often required as interventions commonly bridge multiple functional spinal units (FSU)s and understanding the effects of intervention on adjacent level biomechanics is clinically relevant.

During *in vitro* spine testing, local coordinate systems (CS) must be assigned to individual vertebrae to measure intervertebral motion of individual FSUs. Anatomical CS that only rely on landmarks collected on individual vertebrae are subject to observer variability and are not easily reproduced. Functional CS have been shown to reduce variability in some joints [1]. However, since the spine does not have a unique passive movement path, these methods cannot be used independently to objectively determined vertebral CS.

This study aims to present a Functional-Aggregate method for establishing coordinate systems in the spine using an aggregate of anatomical landmarks from the whole spine to define axis orientations, and kinematics from pure moment motion to optimize origins. We hypothesize that CS variability and resulting kinematic response variation would be reduced with the newly presented Functional-Aggregate CS compared to Anatomical CS.

METHODS

The Functional-Aggregate Method

The Functional-Aggregate method for establishing vertebral CS include the following four steps:

a. Establish Anatomical CS. Anatomical CS are defined from 4 anatomical landmarks (left and right transverse processes, and anterior-rostral and anterior-caudal endplates) displayed in Figure 1.

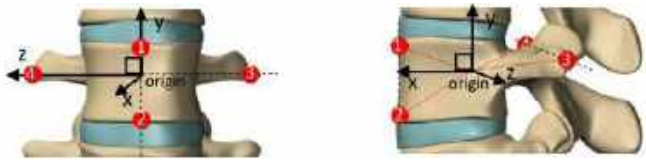

Figure 1: Anatomical Coordinate System

b. Data Collection. Pure-moment testing in the three primary directions must be performed while collecting motion data for each vertebra, and a snapshot of all vertebral kinematics must be collected at the spine's neutral pose.

c. Establish Aggregated Orientations (Figure 2)

Step. 1. At neutral pose, the average z-axis (FE axis) of all included vertebrae is calculated and applied to each vertebra, ensuring a consistent sagittal plane.

Step 2. The anterior-rostral endplate and anterior-caudal endplate points are projected onto the common sagittal plane. A 4th degree polynomial is fit onto the points using the "least absolute residual" method.

Step 3. A vector (pointed rostrally), corresponding to the tangent of the polynomial at the midpoint of the anterior-caudal and anterior-rostral endplate points is the y-axis (AR axis) for each vertebra.

Step 4. The x-axis (LB axis) is the cross-product of the y-axis and z-axis (not pictured).

d. Optimize Functional Origins. Collected kinematic data from pure moment testing is used to redefine origins using the LLS optimization approach for calculating the hip origin [2].

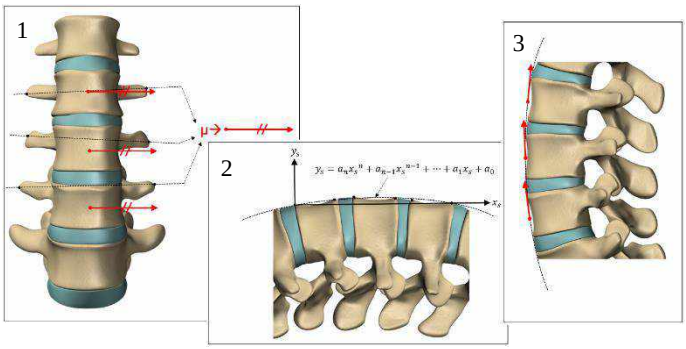

Figure 2: Aggregated Orientation Method

Full Spine Validation

Three observers collected anatomical landmarks from C2-L5 vertebrae on a plastic anatomical spine model. For each observer, Anatomical vertebral CS were established, and Aggregate CS orientation were established across different spinal regions, including Cervical (C2-C7), Thoracic (T1-T12), Lumbar (L1-L5), Cervical + Thoracic, Thoracic + Lumbar, and the Full Spine (C2-L5).

Maximum and average Anatomical and Aggregate CS variation was calculated for each vertebra across the three observers. Paired t-tests compared the variation between Anatomical and Aggregate axis orientations for LB, AR, and FE axes across all vertebrae.

Lumbar Spine Validation

Three human cadaveric spines, T9-Sacrum were secured caudally to a fixed 6-axis force/torque sensor (Delta, ATI, Apex, NC) and rostrally to a 6-DOF robotic manipulator (KR16, Kuka, Augsburg, Germany). Optotrak motion tracking sensors (Northern Digital Inc., Waterloo, ON, Canada) were secured to T12-L5 vertebrae. Three observers collected anatomical landmarks for each instrumented vertebra relative to its respective motion capture sensor. Robotic testing was performed using simVITRO® software (Cleveland Clinic, Cleveland, OH).

To establish Functional-Aggregate CS, motion tracking sensor data was collected during pure moment loading and with the spine in neutral pose. 18 quasistatic pure moment loading conditions (6 uniaxial and 12 combined) were executed to compare kinematic response based on CS definitions.

Anatomical landmarks relative to their respective motion tracking sensor were used to establish Anatomical-CS for each level (Figure 1), and the aggregated landmarks at the spine's neutral pose were used to redefine the CS axes for each level (Fig. 2). Kinematic data from the pure moment testing was used in the optimization for redefining the CS origins, establishing a Functional-Aggregate CS for each level.

Motion capture sensor data from the 18 loading conditions was used to calculate FSU kinematics with Anatomical and Function-Aggregate CS definitions. Average variation of kinematic response across all observers was calculated for each specimen, FSU level, and loading condition combination. Paired t-tests compared the variation between Anatomical and Functional-Aggregate kinematic response for each DOF across all specimens, FSUs, and loading conditions.

RESULTS

Full Spine Validation

Across all levels, average Aggregate CS variation, compared to Anatomical, significantly reduced by 1.35° ± 2.12° (p=0.006), 1.50° ± 2.00° (p=0.002), and 0.87° ± 0.85° (p<0.001), for LB, AR and FE axes, respectively (Figure 3).

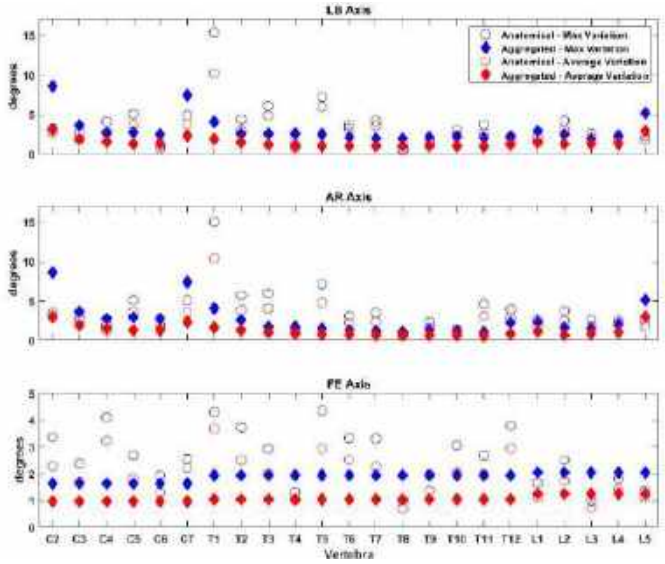

Figure 3: Maximum and average axis orientation variation

Lumbar Spine Validation

Overall, the use of Functional-Aggregate CS significantly reduced FSU kinematic variation compared to Anatomical CS for all DOF (p<0.001) (Figure 4).

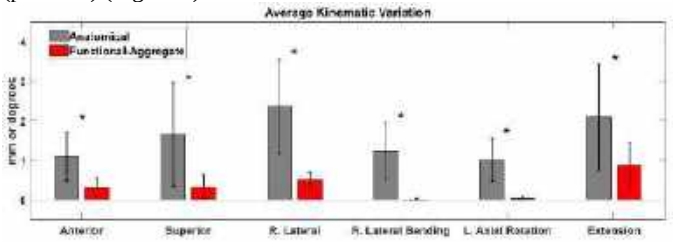

Figure 4: Average FSU kinematic variation and standard deviation. *Significance determined for p-value < 0.05

DISCUSSION

This study examined the variation attributed to CS definition, comparing traditional methods of using anatomical landmarks from a single vertebra to a newly proposed Functional-Aggregate method where aggregation of anatomical landmarks from the entire spine region was used to establish CS orientations and optimization of functional motion was used to establish CS origins.

The method was validated on a full spine model, where average CS axis orientation variation was significantly reduced across all levels compared to Anatomical (Figure 3).

Significant reductions in average kinematic response variation were observed in all DOF during *in vitro* lumbar spine pure moment testing with Functional-Aggregate CS compared to Anatomical. Furthermore, Figure 4 displays *clinically* significant reductions in average kinematic variations for right lateral bending (1.22° ± 0.72°), left axial rotation (0.97° ± 0.53°) and extension (1.20° ± 1.26°), as reported FSU rotations are typically within these orders of magnitude.

We have demonstrated that using Functional-Aggregate CS significantly reduces kinematic response variation. We recommend that Functional-Aggregate CS be used in *in vitro* spine testing.

INTRODUCTION

Tendinopathy is a common and debilitating musculoskeletal condition typically resulting from overuse or accumulation of sub-rupture matrix damage.[1] Although tendon injuries account for over 40% of all musculoskeletal injuries yearly,[2] the limited insight into the pathogenesis of tendinopathy hinders the development of therapeutics aiming to halt or reverse the progression of damage. Sub-rupture tendon injuries are characterized by an increase in apoptosis (programmed cell death),[3] presence of microtears and isolated ruptures in the extracellular matrix (ECM),[4,5] and formation of damage kinks due to plastic deformation of collagen fibers.[6] This pervasive damage to the ECM creates an aberrant loading environment for surviving cells, increasing cell stress and driving them to a catabolic state which promotes degeneration.[3,7] Sub-rupture injuries fail to mount the canonical biological healing response, preventing healing and leaving the tendon subject to further damage accumulation and ultimately rupture.[8]

In contrast, acute tendon ruptures and lacerations induce the canonical biological healing cascade beginning with inflammatory cell infiltration, followed by heightened cell activity and matrix deposition, albeit through scar formation and without reconstitution of the aligned pre-injury tissue structure.[9,10] One likely explanation for the disparate healing responses in acute versus sub-rupture injury types is the presence of cell necrosis, which occurs in laceration and rupture injuries. However, this is notably absent in sub-rupture damaged tendons.[11,12] During necrosis, damage-associated molecular patterns (DAMPs) are released from the injured cell, which activate nearby immune cells and initiate the inflammatory cascade that is critical for tissue repair.[13,14]

To recreate the inflammatory environment that stimulates repair of acute tendon injuries, recent work has examined the use of dry needling in sub-rupture damaged tendon. Dry needling is a clinical intervention wherein the tissue is punctured multiple times with a needle to incite an inflammatory response and disrupt the cycle of chronic degeneration in sub-rupture injuries. However, there is no standard technique for implementing dry needling in tendon. Study designs vary widely and thus so do healing outcomes, with little commentary on what makes this procedure successful in some cases and harmful in others.[15]

As dry needling is an imprecise technique, we expect that the punctures to the tendon cause both cell necrosis and micro-ruptures to the collagen matrix. While ECM micro-ruptures and damage kinks are present in sub-rupture injuries, these types of damage do not trigger inflammation. We believe that this is due to the absence of cell necrosis, which drives inflammation and the subsequent healing cascade in acute injuries. It is possible that sub-rupture injuries do not accumulate enough ECM damage to mount an inflammatory response prior to rupture, however ECM disruption may also be contributing to a catabolic response that prevents effective healing from taking place. The competing effects of cell necrosis and ECM damage could be responsible for the variable healing responses seen in tendon dry needling. This could also explain why both acute and overuse tendon injuries do not heal effectively, whether cell necrosis and inflammation are present or not. Thus, it is critical to develop a precise method for isolating cell necrosis and ECM damage *in vivo* to examine the effects of these two types of damage on inflammation and subsequent healing outcomes in sub-rupture damaged tendons.

To address this, we have developed methods for precise amplified femtosecond laser (AFL) ablation of tenocytes or tendon ECM. This technique uses amplified laser pulses to cause damage to the targeted tissue with sub-micron precision without disrupting the surrounding area. AFL ablation has been used in many biological tissues, such as the cornea and the brain,[16] though this technology has yet to be used in tendon. This study will describe our methodology for *in vivo* imaging of the patellar tendon (PT) in mice and assess the efficacy of AFL ablation at isolating damage to either tenocytes or tendon ECM. Future work will utilize these methods to interrogate mechanisms that drive inflammation and promote effective healing of tendon injuries.

METHODS

Fifteen C57BL/6 mice (16-32wk) were used to optimize *in vivo* cell staining, imaging, and ablation parameters. Cells were labeled by injecting Hoechst 33342 (100µL, 0.1mg/mL), a nuclear-binding dye, into the joint space above the left patellar tendon 2-4 hours prior to imaging. Animals were anesthetized, placed in a stereotax to reduce motion artifacts, and the PT was exposed for imaging. A custom multiphoton imaging setup was used to simultaneously visualize cells labeled with Hoechst and aligned collagen via Second Harmonic Generation (SHG) microscopy. The Ti:Sapphire ablation laser (800-nm, 50-fs, 1-kHz pulses) was then aligned on top of the imaging lasers and the ablation laser energy and number of pulses were gradually increased until successful damage was observed. Laser pulse energies ranged from 200-500nJ with 1-10 pulses. Animals received ablation to cells to induce cell necrosis or ablation to ECM to cause matrix micro-ruptures. Z-stack images (1µm per step for 30µm) were collected immediately before and after ablation, as well as 10 minutes following ablation, and the average intensity of each stack was found using a z-projection in ImageJ. Representative images demonstrate proof of concept for the use of laser ablation to isolate damage to tendon cells and ECM.

RESULTS

Tenocyte nuclei were clearly labeled with Hoechst up to a depth of 40-50µm (Figure 1). Positive Hoechst staining allowed for tenocytes to be precisely ablated without damaging surrounding ECM. Following cell ablation, the damaged region was distinctly contained within the cell nucleus and remained visible 10 minutes post-injury without significant photobleaching (Figure 2B, 2C). Ablation altered the overall shape of the nucleus and decreased nuclear size by over 10%. Similarly, micro-ruptures created in the ECM resulted in an absence of SHG signal which was sustained 10 minutes after ablation (Figure 2E, 2F).

Figure 1: Second Harmonic Generation (gray) and Hoechst-labeled cell nuclei (blue) 0, 20, and 40µm below tendon surface.

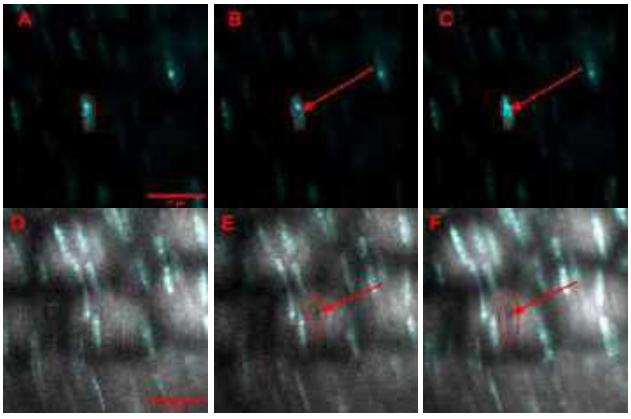

Figure 2: Tenocytes and extracellular matrix immediately before (A,D), after (B,E), and 10 minutes after ablation (C,F). Arrows point to ablated areas showing decreased Hoechst or SHG signal.

DISCUSSION

This study serves as proof of concept for the use of amplified femtosecond laser ablation in tendon. In summary, we have developed a method for marking tenocyte nuclei *in vivo* and precisely targeting cells or extracellular matrix with the ablation laser. Preliminary results provide convincing evidence that this method can isolate damage to cells or matrix.

Interestingly, Hoechst signal of cells was not found to fade 10 minutes following ablation of the nucleus. However, previous work has shown that cells undergoing ablation-induced necrosis do not exhibit an immediate decrease in Hoechst signal, and instead this signal fades gradually over time.[17] To verify that ablation is inducing cell necrosis, we will use propidium iodide in conjunction with Hoechst, allowing us to confirm cell death following ablation. In areas of ECM ablation, the absence of SHG signal represents a disruption to the highly aligned structure of collagen, likely due to unraveling of the triple helix in ablation-damaged fibrils.[18] We suspect that in response to this loss of structure at the injury site, adjacent intact collagen fibers are able to reorganize to bear the load, as has been previously observed in other collagen rich tissues such as the cornea.[19]

One major challenge when using laser ablation *in vivo* is locating and tracking ablated areas across multiple timepoints. Therefore, our next step is to use reporter mice and live cell dyes to examine the effects of ablation on whole tendon cell populations, rather than examining the local response surrounding the ablated region. Specifically, we are using CX3CR1-CCR2 reporter mice to quantify the impact of cell necrosis and ECM micro-rupture on the immune response and subsequent healing outcomes.

Overall, the present study represents an important step towards interrogating the damage component that drives inflammation in tendon. Isolating the effect of cell and matrix damage will allow us to examine their individual and combined impacts on the inflammatory and overall healing response in sub-rupture tendon injuries. We will be able to determine if ECM damage stifles or enhances the healing response and test our hypothesis that cell necrosis drives inflammation in tendon injuries. Our data will inform future work which seeks to modulate inflammation and promote repair in sub-rupture injured tendons to halt or reverse the progression of damage accumulation into ruptures.

INTRODUCTION

Traumatic brain injuries (TBI) remain a serious societal concern, with over 1.7 million injuries occurring yearly in the United States[1]. TBIs typically occur due to sudden head motion resulting from impacts in sports, automotive vehicle crashes, and falls[2]. The mechanical forces transmitted from the head to the brain have been a focus of research that aims to quantify the relationship between input loading and brain tissue mechanics[3,4]. Anatomically-detailed finite element (FE) models or physical surrogates of the brain that predict tissue mechanical response are crucial for understanding brain injury and developing injury mitigation countermeasures. A challenge in brain model development is validation against experimental brain deformation data, especially average response within different demographic groups, such as sex and age stratified cohorts. These average data responses are commonly computed in injury biomechanics to represent a population mean from a set of experimental tests[5]. Recently, we have collected data on the *in vivo* biomechanical response of the brain under harmonic head motion using magnetic resonance elastography (MRE) and impulsive head motion using tagged magnetic resonance imaging (tMRI)[4]. The objective of this study is to compute and compare group average anatomical templates, material properties, and maximum strain templates for the young, mid-age, and older adult brains for male and female populations.

METHODS

Scans from 135 volunteers (68M/67F; 18–73 yrs) were collected using anatomical MRI sequences, and either MRE or tMRI, at three acquisition sites (Table 1). All processed data are publicly available[6]. Structural MRI data was collected at all sites. High-resolution MRE data were acquired at the University of Delaware. tMRI data were collected at the NIH Clinical Center through the Henry M. Jackson Foundation. All subjects provided informed consent under a protocol approved by the Institutional Review Boards of the respective institutions. The structural anatomical images included T1-weighted and T2-weighted MRI scans. MRE data were with a 3D multiband, multishot spiral MRE sequence with OSCILLATE acceleration[7] at 1.5 mm isotropic imaging resolution. Vibration was applied using the Resoundant with pillow actuator at 30, 50, and 70 Hz. The brain tissue material properties from MRE were estimated using the nonlinear inversion algorithm (NLI)[8]. tMRI was acquired using a custom-built MRI-safe device[4,9] that facilitates a repeatable mild axial head rotation of 3-4 rad/s and 200-350 rad/s[2]. Data were acquired using 1:1 SPAMM tagging at a 2 mm spatial resolution with a 20 ms temporal resolution[9]. All tMRI data were processed using HARP-FE to generate strain fields[10]. Details on acquisition and processing have been previously presented[4].

Table 1: Number of subjects within each population.

Age	Sex	MRI	MRE	tMRI
Young (18-21)	Female	9	7	6
	Male	10	6	3
Mid-age (22-49)	Female	38	11	7
	Male	40	9	8
Older (50+)	Female	20	12	1
	Male	18	9	4

Anatomical Template: The ANTs[11] template creation script with multimodal input was used to create average T1w and T2w images. All images were preprocessed by rigidly registering to MNI space, followed by N4 bias correction[12]. The template script calculates an average anatomical template through iterative nonlinear registrations and averaging, followed by a sharpening filter to enhance edges.

MRE Material Property Template: For each population, all subjects were nonlinearly registered using ANTs to the T2w anatomical template using the MRE magnitude images. The spatial transformations were then applied to the shear stiffness and damping ratio maps of each subject at all three MRE frequencies (30, 50, 70 Hz) using linear interpolation. The average response was calculated using an average with a majority vote mask to remove edge voxels.

tMRI Strain Template: tMRI experiments result in 4D data (3D voxels and time) for each of the 6 strain components. To simplify this analysis to a scalar value, the peak maximum principal strain (MPS) across all time for each voxel was chosen. For each population, all subjects were nonlinearly registered using ANTs to the T1w anatomical template using each subject's T1w image. The spatial transformations were then applied to the peak MPS maps of each subject using linear interpolation.

The average response was calculated using an average with a majority mask to remove edge voxels.

RESULTS

The generated anatomical templates are presented in Fig. 1. The templates were qualitatively checked by running the SLANT-CRUISE segmentation algorithm[13] to quantify the brain volumes and ensure consistency with the individual subjects. Features of the aging brain, such as enlarged ventricles, are clearly visible in the older group. Quantitatively, the template brain volumes are larger in males than females and are within 10% of the average brain volumes of individual subject brain volumes within each population.

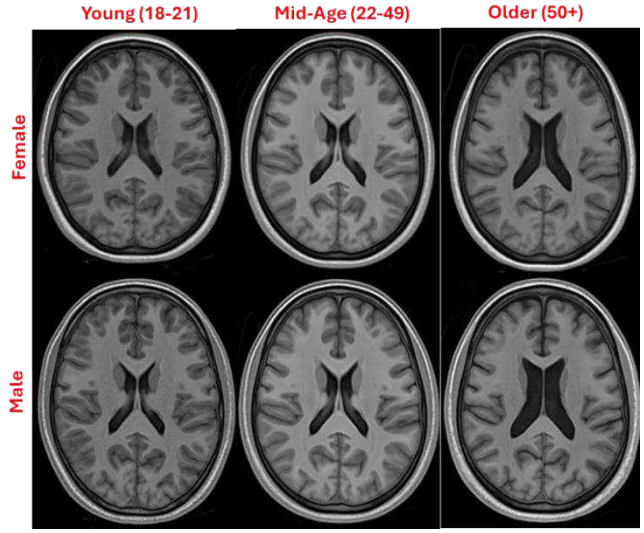

Figure 1: Anatomical T1w templates of all population groups.

The generated MRE material property templates were computed for each population. The templates were similar in the spatial distribution of the stiffness measurements, with the older groups resulting in higher standard deviation and lower magnitudes of stiffness than the younger groups. There were no significant differences in average stiffness magnitude with sex. Cumulative distributions of the 50 Hz stiffness are presented in Fig. 2. The damping ratio averages showed slight differences across population, but no clear trend with sex or age. These observations were similar for templates at 30 and 70 Hz.

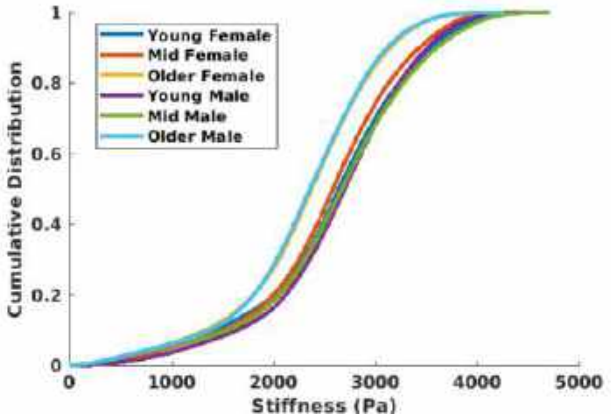

Figure 2: Cumulative distribution of 50 Hz stiffness of the MRE templates for all populations.

The generated tMRI MPS templates are shown in Fig. 3. The older population templates are not shown since the older female group only had 1 subject, and the older male group had two subjects with incomplete field of view during data acquisition, which explains the missing portions of this cross-section. The templates were similar in the distribution and magnitude of MPS, except for the mid-age female group, which had lower magnitudes. There was no significant difference of MPS distributions with sex. There was a slight decrease in peak MPS with age, but the applied head rotational velocities were also smaller in the older groups. More data is needed to draw conclusions for the effect of age on MPS.

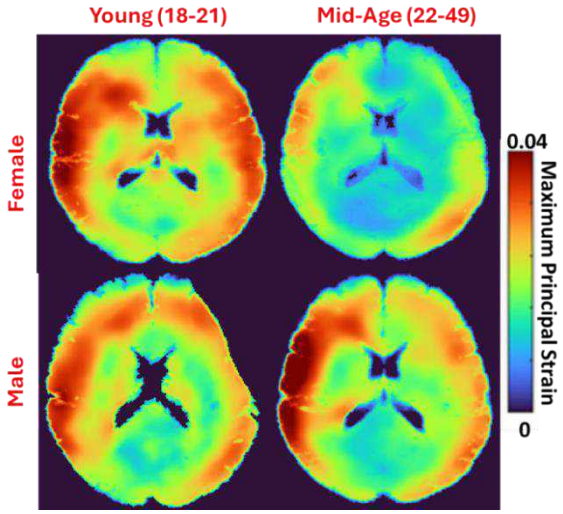

Figure 3: Population-specific peak MPS templates from tMRI.

DISCUSSION

Datasets of brain biomechanics are scarce and usually include a limited number of subjects, hindering group average analysis and FE model validation. Using recent datasets of in vivo biomechanical MRI measurements, this study created population average templates by age and sex for brain anatomy, material properties, and maximum strain. Our results indicate that age is an important consideration in model development. While templates have been created previously for a mix of subjects, this is the first study to generate population-specific templates. The resulting templates, once refined with more subjects, can be used to create population-specific injury prediction tools, such as FE models or physical surrogates.

INTRODUCTION

Millions of people have cobalt-chrome prosthetics with more than a million having metal-on-metal (MoM) hip implants in North America[1]. These types of prosthetics have been shown to release large amounts of metal particles that can oxidize and release toxic heavy metals into the body. As a result, patients can develop cobalturia leading to cardiac and brain disfunction[1]. In addition to the systemic effects of metal release, there is also evidence that the presence of metal implants has led to unintended and sudden hip/femur fracture thus defeating the purpose of the implant. This leaves millions of individuals at risk of complex fractures with few alternatives for treatment due to the unclear cause of these fractures. Increased inflammation leading to bone resorption and cell death due to metal toxicity have both been suggested as possible causes of this increased fracture risk. We hypothesize that metal ion absorption into bone mineral may also play a critical role in controlling bone mechanics and fracture risk.

Bone is primarily composed of biological apatite which has a strong tendency of substituting cations and anions into the lattice. As a result, bone mineral is expected to have a propensity for absorbing heavy metal ions released from the MoM implants. Due to the composite nature of bone, these nanoscale changes can lead to whole tissue mechanical failure. It is therefore essential that we examine that fundamental ways in which metal ions interact with the apatite crystals to unravel the mechanisms associated with the apatite crystal substitutions, change in its mechanical properties and how that leads to fracture initiation under mechanical loading. Here we propose to couple development of an *ab initio*-based model of apatite crystals with Co substitutions, which can capture the interactions at the nanoscale, with x-ray diffraction-based experiments on biomimetic apatites to predict the change in crystallographic properties of apatite crystals exposed to Co. This combined in vitro and in silico approach will allow for a full elucidation of the role that Co substitutions play in modifying apatites and in turn bone health.

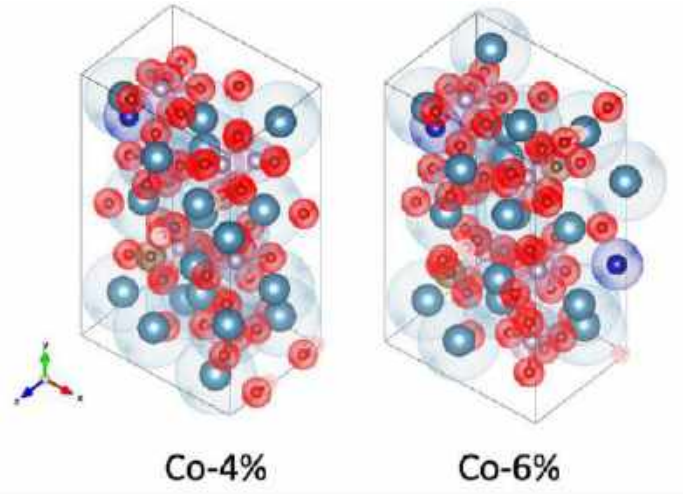

Figure 1: Co apatite samples with 4% and 6% carbonate substitutions, with x-axis corresponds to *a*-axis and z-axis corresponds to *c*-axis.

METHODS

Experimental

Biomimetic apatites with increasing levels of Co were made via one of two aqueous precipitation techniques. First, a solution of calcium nitrate and cobalt nitrate as well as a solution of ammonium phosphate were added to dropwise to sodium bicarbonate in a round bottom flask. The reaction was digested for 2 hours at pH 9 and 65°C. In the second technique, a solution of calcium nitrate and cobalt nitrate was directly mixed with a solution of sodium bicarbonate and ammonium phosphate and allowed to mature for 3 days. Cobalt nitrate levels were varied to the 2nd technique to create apatites with varying levels of Co. In all

cases, the solutions were filtered and rinsed to collect the apatite crystals, which were then dried at 60°C overnight.

Crystals from technique 1 were examined via X-ray Diffraction (XRD) to determine the crystal lattice spacing. Crystals from technique 2 were examined Inductively Couples Plasma-Mass Spectroscopy (ICP-MS) and Carbon-Hydrogen-Nitrogen Analysis to obtain the cobalt and carbonate (CO_3^{2-}) content of the crystals. Raman spectroscopy was used to confirm the apatite phase.

Computational

For studying mechanical properties of apatite crystals, it is more practical to transform it into an orthorhombic cell (*x*, *y* and *z* axes see Fig.1) with the *z*-axis parallel to the *c*-axis. However, it is necessary to double the *b*-axis direction to maintain the periodicity of the lattice in the orthorhombic description. Due to this the unit cell is twice as large as the unit cell and contains 88 atoms for the hydroxyapatite (HAP sample. We use this 88-atom unit cell to substitute Ca atom with Co and add carbonate group to form the 4% and 6% samples.

One of the widely used *ab inito* modeling method is Density Functional Theory (DFT) [2]. There are several previous studies using DFT on biomaterials. The feasibility of using DFT as a tool to predict material property has been widely accepted among the scientific community [3]. The DFT model is used to compute the lattice strains after introducing the Co ion in the HAP crystal.

RESULTS

Apatites containing Co-substitutions were successfully created using both techniques as determined by Raman spectroscopy and XRD. The Co content of the low and high Co apatites made with technique 2 were 0.09 and 0.26 mmol respectively. This increase in Co content was associated with an increase in carbonate content suggesting that there is concomitant substitution of the Co cation with CO_3^{2-}, Fig 2. This is also accompanied by a decrease in mineral calcium (Ca^{2+}) content. Thus, we decided to investigate the combined effect of Co and CO_3^{2-} using DFT.

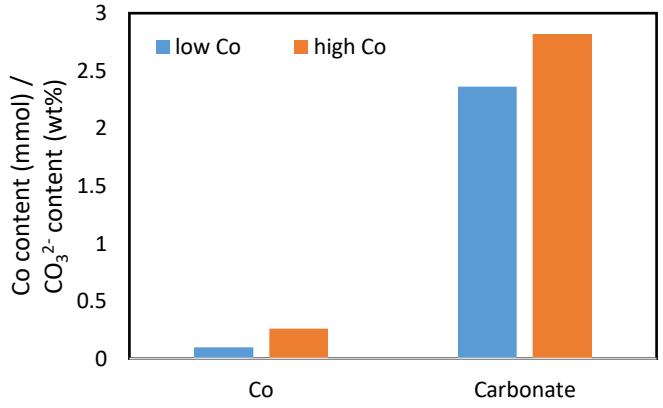

Figure 2: Plot of Co and CO_3^{2-} content showing the concomitant increase in carbonate with increasing Co.

We first calculate the lattice properties of hydroxyapatite crystal using DFT and then use that as a reference point to calculate the difference in the lattice properties when Co substitution occurs. Figure 3 shows the lattice change when Co is substituted along with carbonate ions with concentrations of 4% and 6%. The *a*-axis change of negative value indicates that the Co-4% a-axis is decreasing in length. We observe that as the carbonate concentration changes from 4% and 6%, the decrease in *a*-axis is ~50% smaller. Similarly for c-axis, the trend is same with 4% case having an increase in lattice and 6% case has ~12% lower lattice expansion.

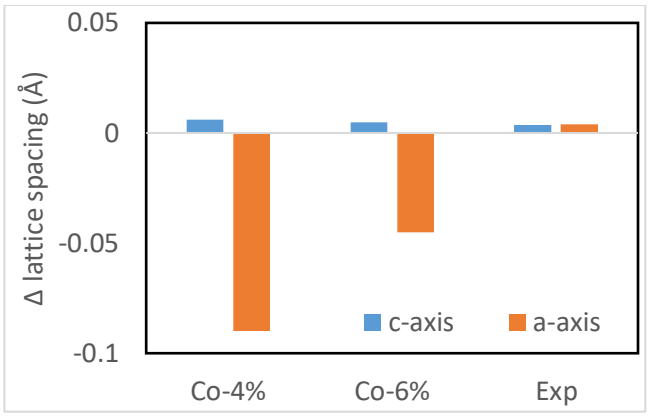

Figure 3: Plot of lattice changes as a function of Co and CO_3^{2-} substitutions. Co-4% and Co-6% represent computational Co apatites with 4 and 6% CO_3 respectively. Exp shows the experimental lattice spacing.

When XRD was performed on the Co-containing apatites made with technique 1, we found that there was a small expansion of the *c*-axis compared to stoichiometric hydroxyapatite in agreement with the DFT models. However, unlike the DFT model, the *a*-axis exhibited expansion of the *a*-axis with Co and CO_3^{2-} substitutions.

DISCUSSION

The addition of Co into solution during apatite precipitation successfully led to the formation of Co-substituted apatites. This suggests that free Co from implant materials could easily substitute into bone mineral during bone deposition. The presence of Co is also associated with increased CO_3^{2-} substitutions. Paired substitutions of anions and cations in apatites is common [4]. This usually occurs to establish charge balance when molecules of differing charge are substituted. Co is expected to exchange with Ca^{2+} in lattice meaning that it could be charge neutral if it carries a valence of +2. However, the apatites exhibit a decrease in Ca^{2+} larger than the uptake of Co pointing to vacancy formation and charge imbalances. DFT was able to successfully model concomitant Co and CO_3^{2-} substitution in apatites. We believe that the difference in the a-axis trend between DFT and experiments could be (a) due to the location of carbonate substitution, as CO_3^{2-} group is planar in nature, (b) the Co substitution location, which is either Ca (1) or Ca (2) sites. Further study is required to determine this.

TOWARDS 3D-3C VELOCITY MAPS FROM SINGLE CAMERA 2D-2C PTV USING PHYSICS INFORMED NEURAL NETWORKS

Amin Pashaei Kalajahi (1), Zayeed Bin Mamun (1), Forouzan Naderi (1), Sangeeta Yadav (1), Roshan M D'Souza (1)

INTRODUCTION

Particle Tracking Velocimetry (PTV) is an experimental method for analyzing complex fluid flows. It involves seeding fluid flows with micron-scale tracer particles, illumination by a pulsed laser sheet, and cameras capturing successive time-resolved snap shots. Fluid velocities are then estimated from displacements of particle images between successive snapshots [1].

PTV relies on low particle density for effective particle correspondence, resulting in sparse spatial velocity data [2]. Recent attempts to improve spatial resolution through physics-constrained machine learning use costly 3D3C PTV data obtained from elaborate PTV hardware configurations [2, 3]. This poses a significant burden on experimental cost and complexity for flow estimations.

We present a novel method utilizing physics-informed neural networks with geometric optics to generate dense 3D3C velocities and relative pressure from sparse 2D2C PTV data. Experiments on synthetic data demonstrate the method's remarkable accuracy in recovering time-resolved 3D velocity fields from sparse 2D inputs.

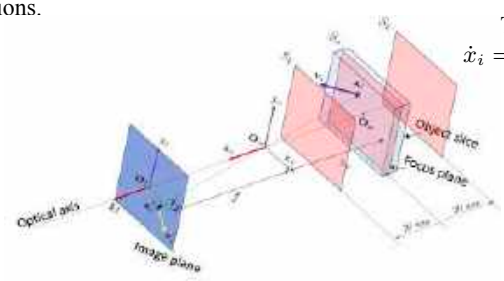

Figure 1: PTV optical setup. S_o is the focus plane in the middle of the object slice. S_1, S_2 are planes where the prediction of the algorithm is tested.

METHODS

Without loss in generality,we model a pinhole camera setup for our image capture process (Fig. 1). A thin sheet (object slice) with thickness Δ of a particle laden flow is illuminated by a laser. The focus plane and image distance from the pinhole are z_o, f, respectively. The location of a particle $\mathbf{x}_i$ at time t is give by Eq. 1.

$$\mathbf{x}_i = \begin{bmatrix} x_i \\ y_i \\ z_i \end{bmatrix} = \begin{bmatrix} x_i \\ y_i \\ z_o \pm \delta_i \end{bmatrix} \approx \begin{bmatrix} x_i \\ y_i \\ z_o \end{bmatrix} \tag{1}$$

Here $\delta_i < \frac{\Delta}{2} << z_o$. This location is mapped to an image location $\bar{\mathbf{x}}_i$ given by

$$\bar{\mathbf{x}}_i = \begin{bmatrix} \bar{x}_i \\ \bar{y}_i \end{bmatrix} = -\frac{f}{z_i}\begin{bmatrix} x_i \\ y_i \end{bmatrix} = -\frac{f}{z_o \pm \delta_i}\begin{bmatrix} x_i \\ y_i \end{bmatrix} \approx -\frac{f}{z_o}\begin{bmatrix} x_i \\ y_i \end{bmatrix} \tag{2}$$

The velocity of the particle in the image is given by Eq. 3 where $\dot{x}_i = u_i, \dot{y}_i = v_i, \dot{z}_i = w_i$.

$$\bar{\mathbf{v}}_i \approx -\frac{f}{z_o^2}\begin{bmatrix} u_i z_o + w_i \dfrac{\bar{x}_i}{f} \\ \\ v_i z_o + w_i \dfrac{\bar{y}_i}{f} \end{bmatrix} \tag{3}$$

We assume that 2D2C velocities and locations with time stamp $(\bar{\mathbf{x}}_i^o, \bar{\mathbf{v}}_i^o, t_i)$ are available through 2D PTV experiments. Given $\bar{\mathbf{x}}_i^o$, we derive the approximate 3D locations $\mathbf{x}_i^o$ using Eq. 1, 2. The locations $\mathbf{x}_i^o$ are the inputs to a multilayer percepteron (MLP) (Fig. 2) which generates as output the predicted 3D velocity $\mathbf{v}_i^{pred}$ and relative pressure p. Using Eq. 3, we then compute the predicted velocity in the image $\bar{\mathbf{v}}_i^{pred}$. The MLP is trained with the loss function given by

$$\mathcal{L} = \alpha \frac{1}{N}\sum_{i=1}^{N} \|\bar{\mathbf{v}}_i^{pred} - \bar{\mathbf{v}}_i^o\|^2 + (1-\alpha)\mathcal{L}_P \tag{4}$$

.

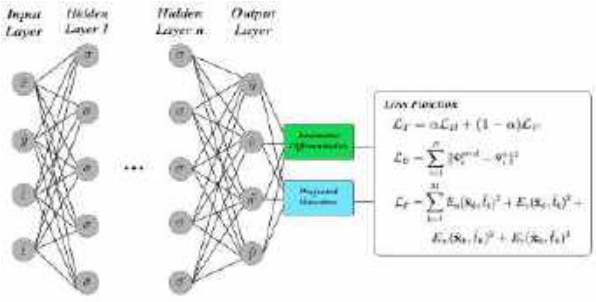

Figure 2: Multilayer perceptron model to represent velocity and relative pressure

Here α is a weighting factor and $\mathcal{L}_P$ is the physics regularizer that penalizes the deviation of the solution from Navier-Stokes and mass conservation equations at a user-defined number of collocation points in object space.

RESULTS

To generate test data, we simulated blood flow with pulsatile boundary conditions in a scaled brain aneurysm geometry using computational fluid dynamics (CFD). We collected velocity snapshots at time intervals of $\Delta t = 15ms$. The unstructured velocity data was interpolated into a regular grid of 2 mm voxels. Within an 107 × 165 × 1 voxels object slice, we picked 800 voxels at random (corresponding to a particle density of 0.05 ppp). 2D projected position and velocity images were constructed based on Eq. 2,3. This approximates the process of generating 2D-2C velocity components from particle image data. Velocity component-wise zero mean Gaussian noise with an SNR of 30 dB was added.

Figures 3 and 4 show the results of our tests. We evaluated the velocity predictions of our algorithm at planes S_1 and S_2 which are 20 mm away from the focus plane S_o, showcasing our algorithm's ability to accurately estimate a dense 3D3C velocity field from the sparse input $\bar{u}$ and $\bar{v}$ shown in the first column of Fig. 3. The following columns of Fig. 3 illustrates a good match between the predictions u^{pred}, v^{pred}, and w^{pred} and the ground truths of u^{gt}, v^{gt}, and w^{gt}.

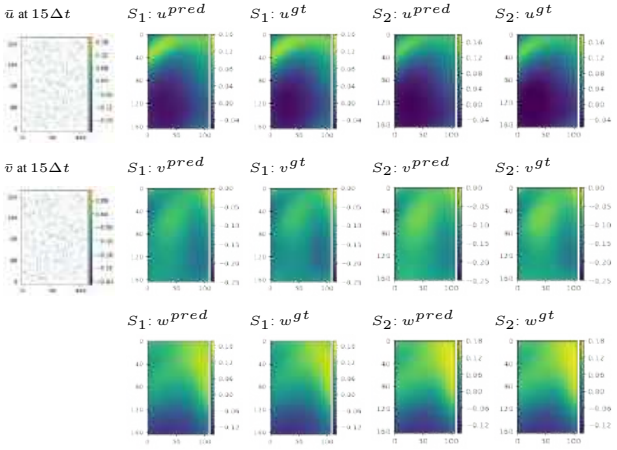

Figure 3: Illustration of predictions $(\cdot)^{pred}$ against ground truth $(\cdot)^{gt}$ for each velocity component and the sparse input data at $15\Delta t$.

Fig. 4 highlights the error metrics for our evaluation. The first column displays strong directional agreement between the predicted and the ground truth vectors through the cosine distance between the vectors at S_1 and S_2. We present minimal absolute error for each velocity component at S_1 and S_2 in the following columns, along with a strong alignment between predictions and ground truth for the entire velocity range in the scatter plots.

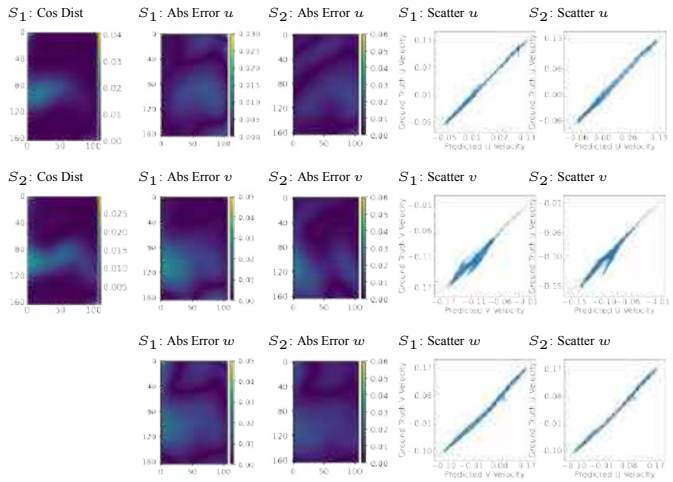

Figure 4: Illustration of error metrics for predictions at S_1 and S_2 at $15\Delta t$.

Table 1 provides a numerical representation of our algorithm's performance at S_1 and S_2. We report the coefficient of determination (R^2) and the root mean squared error (RMSE) for each velocity component. These results prove that our methodology can accurately predict three-dimensional velocity fields with sparse, two-dimensional input.

Table 1: Table of numerical error metrics at $15\Delta t$.

Velocity Component	S_1: R^2	S_2: R^2	S_1: RMSE	S_2: RMSE
u	0.995	0.989	0.00327	0.00587
v	0.889	0.908	0.00803	0.00705
w	0.989	0.991	0.00769	0.00732

DISCUSSION

We have introduced an innovative deep learning approach for estimating 3D3C velocity fields from sparse 2D2C Particle Tracking Velocimetry (PTV) data. In this method, we incorporate the effects of perspective projection using a pinhole camera model into flow physics constrained Multilayer Perceptron (MLP) training to estimate the time resolved 3D velocities. Our approach achieves a highly accurate three-dimensional flow field using only the two-dimensional input from a single camera.

Unlike traditional PTV practices that necessitate a complex experimental arrangement involving three or more cameras for tomographic estimation of three-dimensional velocity maps, our approach is able to accomplish this task with a single camera. This has the potential to reduce experimental costs significantly and enhance accessibility. Currently, our model utilizes a straightforward pinhole camera setup, and future work aims to replace the pinhole with a lens configuration for a more precise representation of modern image acquisition mechanics.

Hydrogel Phantom System as Mechanical Placental Tissue Mimics

Samyuktha Kolluru [1], Adrienne Scott [2], Patrick Yang [2], Michelle Oyen [1,2]

Institute of Material Science and Engineering [1], Biomedical Engineering Department[2], Washington University in St Louis, MO, USA

INTRODUCTION

Pathological complications of the placenta have been linked to alterations in the tissue microscale structure, resulting in changes in mechanical properties. One such complication is fetal growth restriction (FGR), in which an underdeveloped placenta is unable to provide sufficient oxygen and nutrients to the fetus, affects roughly 5-10% of all pregnancies and is a primary cause of stillbirth [1]. From prior literature, it is understood that FGR gives rise to modifications in placental microstructure. However current methods allow detection using clinical US imaging of FGR only later in the gestational period [2]. As FGR affects the transport of nutrients, it is important to study placental properties related to nutrient exchange, including diffusion and porosity. These characteristics are linked to time dependent phenomenon such as viscoelasticity and poroelasticity. Therefore, this project aims to establish a hydrogel system with independently tunable time dependent and independent properties. The variance in mechanical properties is an effect of variable microstructure and the creation of a controllable gel phantom system will allow biomimicking placental tissue microstructure. Further, correlating mechanical properties with raw frequency (RF) data acquired through Quantitative Ultrasound (QUS) lead to the development of a predictive model. This model can be employed to quantify placental microstructure in vivo, enabling earlier detection of deviations from a healthy placenta.

METHODS

Gelatin (300 g bloom) and agar were obtained from Sigma–Aldrich (St. Louis, MO). Gelatin (Gel; 7.5% and 30% w/w) and agar (1% and 3% w/w) gel solutions were prepared by soaking granules in distilled water at room temperature. The stock solutions were stirred in a water bath at 65°C (gelatin) or 90°C (agar) until dissolved. Solutions were left in the warm room without stirring until trapped gas had been released. Composite gelatin- agar gel solutions were mixed by volume fraction of melt solution. Mixtures were moderately stirred at 75°C for 5 min. Single phase solutions and composite gel mixtures were poured into molds to cool for one hour before being placed in a refrigerator to set for 48 hours. Next, the gels were swollen in PBS for 48 hours to achieve gels in equilibrium state prior to mechanical testing. Patients were recruited and a placenta was obtained for indentation testing under an IRB approved protocol. Mechanical testing of all hydrogels and placenta was performed on an Instron with a 5 N load cell. Tests were performed in displacement control using a ramp- hold profile: the displacement (h) is ramped at a constant rate to a fixed level and then held at the peak displacement (h_{max}) for a 300 sec hold time. The load (P) is recorded for the duration of the test. Indentation tests were carried out using a stainless-steel spherical tip with a radius (R) of 12.7 mm. Strain was kept at 5% during indentation, to stay within the linear regime. Thus, peak displacement was set to 1.14 mm according to equation 1. Three indents were performed on each sample, spaced at least 15 mm apart. Data was processed through a poroviscoelastic analysis, and values of stiffness, permeability (κ) and diffusion coefficient (D) were obtained. Pore size (ζ) was calculated as the square root of permeability. Poroelastic response is calculated according to an empirical solution published by [3]. The viscoelastic response is calculated using a generalized Maxwell model, consisting of a linear spring connected in parallel with n number of Maxwell units, containing a linear spring and dashpot connected in series. The poroviscoelastic model involves the coupled effect of poroelastic (PE) and viscoelastic (VE) behaviors as shown in equation 2, where P_∞ is the equilibrium load.

$$\varepsilon = 0.2\ (h_{\max}/\mathrm{R})^{1/2} \quad \text{Eq. 1}$$

$$P_{PVE} = \frac{P_{\mathrm{PE}}(t) \cdot P_{\mathrm{VE}}(t)}{P_\infty} \quad \text{Eq. 2}$$

RESULTS

Pure agar gels did not swell at all, while gelatin gels demonstrated substantial swelling [4]. Therefore, gelatin gels were tested on consecutive days to establish the time required for equilibrium swelling as 48 hours. Stiffness and viscoelastic ratio (measure of the degree of relaxation) were chosen as the metrics for time independent and time dependent properties respectively. The viscoelastic ratio of the material denotes the elastic portion of the material's response. When this ratio equals unity, it indicates time-independent mechanical behavior and a purely elastic material. In contrast, a ratio of zero indicates complete relaxation, signifying a purely viscous material response. Five conditions were targeted, spanning a wide range of low and high stiffness and relaxation levels, with an additional medium variation. Two gelatin-agar systems were defined to create the hydrogel phantom system: 7.5% Gel–3% Agar and 30% Gel–1% Agar system. When agar was the stiff phase (7.5%Gel–3%Agar system), its non- swelling response dominated the single phase and composite gels and gave rise to more relaxation. For gels

based on the stiff gelatin system (30%Gel–1%Agar system), the swelling was directly proportional to gelatin content and thus gave rise to less relaxation. Thus, making single phase and composite hydrogels with varying volume fractions of gelatin and agar created a hydrogel system that successfully encompasses a wide range of stiffness levels and relaxation characteristics (figure 2). The placenta shows substantial relaxation behavior and very small stiffness values.

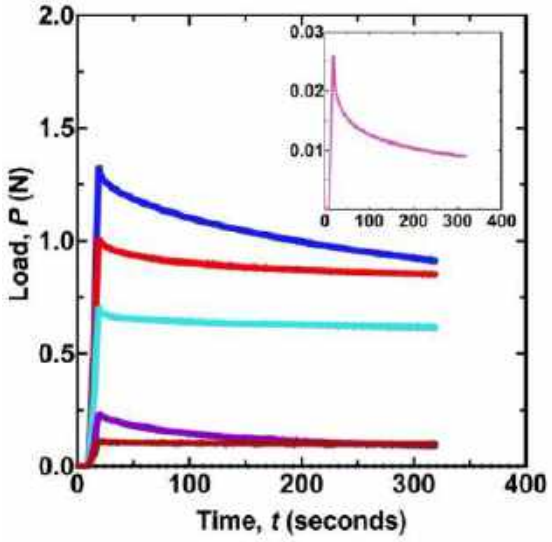

Figure 1: Load (*P*) versus time (*t*) curves of different hydrogel phantoms and placenta (inset) during indentation

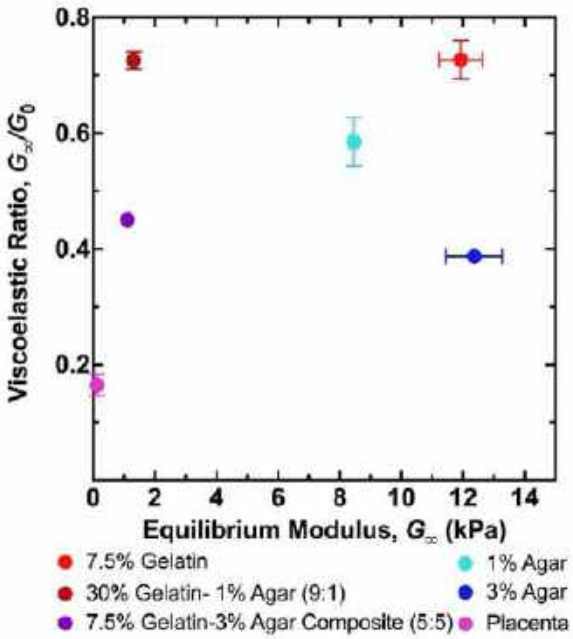

Figure 2: Viscoelastic ratio (G_∞/G_0) versus equilibrium stiffness (G_∞) plot of 5- point system consisting of single phase and composite gels

The diffusion coefficient (*D*) and hydraulic (Darcy) permeability (κ) values showed variation between each gel (table 1) indicating changes in the microstructure.

Table 1- Comparison of diffusion coefficient (*D*), permeability (κ) and pore size (ζ) between gel phantoms

Gel	*D* (mm^2s^{-1})	κ (nm^2)	ζ (nm)
1% Agar	0.0791	5,390	73.4
3%Agar	0.058	418	20.4
7.5%Gelatin	0.0365	1,160	34.1
30%Gelatin- 1% Agar (9:1)	0.119	443	21.0
7.5%Gelatin- 3%Agar (5:5)	0.108	417	20.4
Placenta	0.188	99,720	315

DISCUSSION

Gelatin-agar systems have been used here to demonstrate the wide range of mechanical properties and, more importantly, mechanical property combinations that can be engineered into hydrogels. Change in these mechanical properties results in hydrogels of different microstructures validated by variation in structural properties such as pore size. Indentation testing, with its ease of implementation and established analytical framework, facilitated the identification of individual property transitions in single phase gels and composites, opening a space for design of unique gels ideally suited for mimicking a wide range of microstructure that can be exhibited by placental tissue. Placenta tested in this study shows mechanical properties that fall into this wide range previously reported in literature [5]. Future work involves testing of different placentas acquired from the patients in this study. With more placental tissue data, the gel phantom system can be expanded to fully capture an array of placental properties. Permeability and diffusion data shows variation indicating a change in the microstructure of gels. Through QUS analysis of gels, we can establish a relationship between the gel mechanical properties established here and the effect that they have on RF data, thus enabling a model that can use US for detecting alterations in placental microstructure in vivo. Overall, a predictive model that can identify changes at small length scales using US allows earlier detection of Fetal Growth Restriction (FGR).

INTRODUCTION

As living beings grow older, their cells undergo significant transformations. These cell transformations are a part of the natural aging process and may significantly impact cellular health and functionality. For tissues with high metabolic requirements such as the heart, these alterations may even result in abnormal functionality or complete loss of function, leading to various age-related illnesses or even mortality.

Cardiovascular diseases (CVD) are predominant among the elderly population and are an increasingly frequent global problem that goes beyond national borders. Systematic analyses of worldwide epidemiological data consistently identify CVDs as the primary cause of death worldwide - thus emphasizing its significance to public health agendas by necessitating multifaceted approaches for prevention, management, and treatment [1]. In most cases, CVD research utilizes young animal models despite prevalence of CVDs increases significantly with age. In addition, there are inherent differences in the cardiovascular systems of animals and humans which limits the translatability of findings from these studies into the clinical setting [2].

Effective cardiovascular therapies and interventions depend on having a reliable knowledge of its pathology. An aged human-heart tissue model can provide a means of studying the mechanistic intricacies of cardiac aging as they relate to CVD pathogenesis. This understanding forms a basis for therapeutics that may help decrease negative consequences associated with age on cardiovascular health.

Current studies in cellular aging mechanisms have shown that cells experience increased apoptosis, cellular senescence, and waste accumulation [3,4,5] with age however there is a gap in knowledge regarding the development of aged tissue models in a short period of time that accurately replicate the complexities of age-related cardiovascular diseases. This research seeks to bridge this gap by establishing an induced pluripotent stem-cell (iPSC) derived cardiomyocyte (CM) aged tissue model, induced by oxidative stress to accelerate the aging process. This will provide a way for readily available physiologically relevant tissue models that can be used for enhanced drug discovery and therapeutic interventions in cardiovascular medicine.

METHODS

iPSC Differentiation into Cardiomyocytes: First the iPSCs are differentiated into cardiomyocytes (iCMs) utilizing established protocols [6]. This differentiation process ensures the generation of functional cardiomyocytes that mimic the properties of native heart tissue. Additionally, we implemented an approach that enabled a comprehensive examination of the impact of oxidative stress on cells at varying stages of differentiation, adding a nuanced layer to our understanding of the aging process in iCMs. For each experiment, we evaluated how the cells responded to oxidative stress in two distinct states: immature and mature iCMs. The immature state corresponds to iCMs that started receiving treatment on day 9 of the differentiation process, allowing minimal time for maturation. In contrast, the mature iCMs initiated treatment on day 21, which gave an extended period for maturation and growth.

Inducing Aging Through Oxidative Stress: Following successful differentiation, iCMs were subjected to varying concentrations of hydrogen peroxide (H_2O_2) to induce in vitro aging. Four concentrations—50 μM, 100 μM, 200 μM, 300 μM —were used to represent low, moderate, and high oxidative stress levels. Additionally, short, medium, and long exposure durations, specifically, 7, 15, and 21 days, were implemented to assess the impact of oxidative stress exposure times on the aging process.

Assessment of Aging: The degree of aging induced by oxidative stress was assessed in aged cells where non-aged cells at the same day of differentiation were used as controls. Apoptotic cell percentage was determined using CellEvent™ Caspase-3/7 Green dye

and performing image analysis. Senescent cell percentage was determined using a senescence-associated β-galactosidase (SA-β-gal) staining kit. Sudan Black B (SBB) staining was utilized to assess cellular waste accumulation patterns which increases with aging. Quantification of the results were performed through image analysis using ImageJ and 5-10 images were used for quantification of each sample.

Statistical Analysis: Statistical analysis of the collected data was conducted using student's t-test to compare the effects of different oxidative stress levels and exposure durations on aging markers. The sample number was 3 for each experiment and significance where ** represents $p<0.001$ and *** represents $p<0.0001$.

RESULTS

The study revealed a notable increase in apoptotic cells, waste accumulation, and senescence with increasing H_2O_2 concentrations (Figure 1, 2) and showed differences between the mature and immature cell groups.

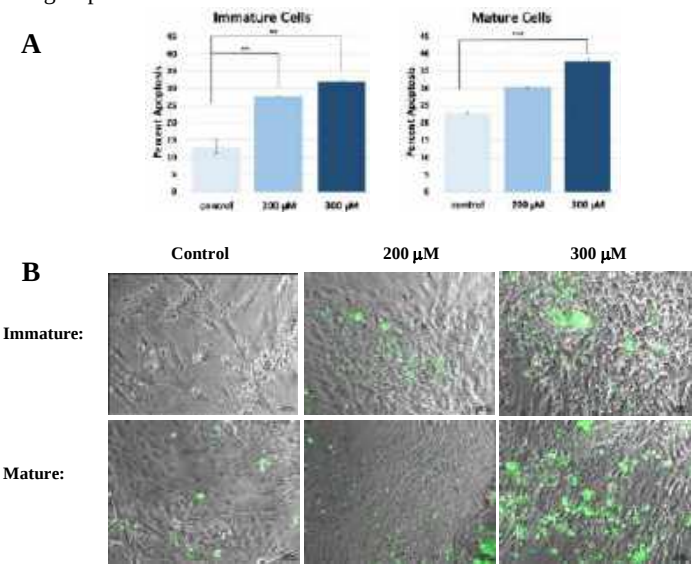

Figure 1. (A) Percentage of apoptotic cells in immature and mature iCMs aged for 7 days exposed to 200 and 300 µM H_2O_2. (B) Bright-field and fluorescence images of iCMs showing apoptotic cells (green) after different aging treatments.

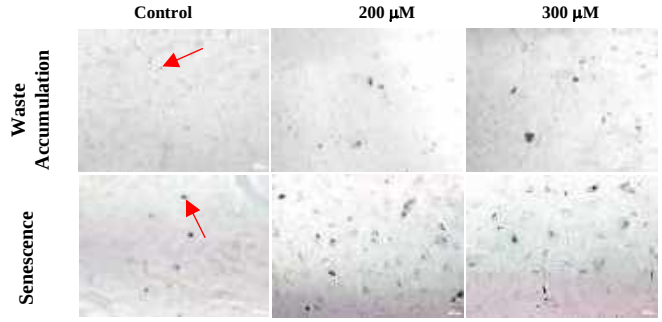

Figure 2. Bright-field images of iCMs show an accumulation of lipofuscin granules (top row) and senescent cells (bottom row) after different aging treatments, examples shown with red arrows.

As can be seen in Figure 1, for immature cells aged for 7 days in control, 200 µM, and 300 µM concentrations, apoptosis rates were 13.1%, 27.7%, and 31.9%, respectively, while mature cells displayed higher rates of apoptosis at 22.9%, 30.3%, and 37.8% for the same conditions, respectively. We also showed when exposed to 50 µM and 100 µM concentrations for 15 days, immature cells exhibited apoptosis rates of 7.4%, 15%, and 18.4%, and mature cells showed rates of 10.3%, 18.8%, and 24%, respectively (data not shown).

In addition to apoptosis levels, we also determined lipofuscin accumulation and senescence in iCMs after in vitro aging. Figure 2 shows qualitatively that with increased H_2O_2 concentration an increase in lipofuscin granules and senescent cells is achieved.

DISCUSSION

Our results align with the current understanding that cellular aging mechanisms in the heart involve increased apoptosis, cellular senescence, and waste accumulation. We observed a trend of increase in these aging markers, notably apoptosis, with added oxidative stress, which concurs with the current understanding that oxidative stress accelerates and greatly contributes to cellular aging mechanisms [7], thus can be used for developing readily available aged cardiac tissue models.

Investigating the rate of apoptosis revealed that the optimal treatment condition for achieving accelerated in vitro aging is exposing immature iCMs to 200 µM or 300 µM H_2O_2. Even though exposing the mature iCMs yielded similar or higher rates of apoptosis, our goal of achieving accelerated aging within the shortest possible duration is satisfied using immature iCMs. The 15-day treatment group exposed to 50 µM and 100 µM H_2O_2 exhibited lower rates of apoptosis for both immature and mature iCMs but additional testing currently being performed will be needed to help comprehensively understand the impact of these concentrations on cellular behavior and response.

This information offers a novel contribution to the field. Our results show that elevated apoptosis levels, along with lipofuscin accumulation and senescence can be induced within a short duration (7 days) and a high concentration of H_2O_2 when compared to the control. This presents a potential way for aging cells in an efficient time frame to create aged tissue models. While our study provides valuable insights into iCMs aging, ongoing analyses focusing on other aging markers such as p21 expression and contractility abnormalities that are more prevalent in the aged population are in progress. Such additional data will further strengthen our conclusions based on the presented findings.

The observed differences in aging markers between immature and mature cells highlight an additional factor in the experiment. Future studies could delve deeper into the molecular mechanisms underlying these observations and test various differentiation timeframes.

In conclusion, this research provides a foundation for advancing our understanding of iCM aging and offers potential implications for pathologically relevant, age-appropriate tissue model development to be used in drug discovery of cardiovascular medicine. By researching the interplay between oxidative stress, cell maturity, and aging markers, this study contributes to the broader topic of CVDs and sets the stage for further exploration into therapeutic paths for cardiovascular health in aging populations in more realistic model platforms. The challenges emphasize the need for ongoing refinement of further tests to enhance result reproducibility and reliability.

INTRODUCTION

Tissue-level growth and remodeling accompany development, wound healing, adaptation, and aging. Growth processes depend on extrinsic (environmental) and intrinsic (genetic, metabolic) stimuli. As such, substantial effort has been directed to mathematically relate tissue growth with various stimuli. Kinematic growth is a popular approach where the local growth is defined exclusively as a change in shape resulting from kinematic assumptions [1-2], rather than via the axiom of balance in the context of constrained mixture theory [3]. This approach has been applied to predict growth in musculoskeletal and cardiovascular applications, cancer, development, and wound healing.

Despite the popularity of kinematic growth theory, accessibility via open-source software and reproducibility are lacking. The simple intuition behind kinematic growth belies its complicated implementation. Prior studies have been implemented in commercial software as user subroutines (that generally are not publicly available). Further, there are several strategies available for implementing coupling kinematic growth with reaction-diffusion equations to provide an explicit, physiological growth signal. Our objective was to implement and cross-validate kinematic growth coupled with chemical kinetics in the open-source software frameworks Finite Elements for Biomechanics (FEBio) and FEniCS [4-5]. FEBio solves biomechanics and biotransport problems and includes a user-friendly GUI (FEBio Studio). FEniCS is an open-source program for solving PDEs from user-defined variational forms in Python or C++. It requires proficiency in numerical methods and software development. We generated test problems that defined growth in response to chemical species (c^α, 1-way coupling), or additionally allowed chemical kinetics to respond to feedback from the growth-driven stress (**σ,** 2-way coupling).

METHODS

Kinematics: The motion of a particle is denoted $\mathbf{x} = \chi(\mathbf{X}, t)$ where $\mathbf{X}$ is position in the reference frame and $\mathbf{x}$ is in the current frame. The deformation gradient is $\mathbf{F} = \partial\mathbf{x}/\partial\mathbf{X}$. Kinematic growth theory postulates an intermediate configuration due to growth that facilitates a multiplicative split of $\mathbf{F}$ [1-2,6]:

$$\mathbf{F} = \mathbf{F}_e\mathbf{F}_g, \qquad \mathbf{F}_g = \mathbf{I} + \sum_{i=1} \vartheta_i \mathbf{n}_{0,\mathrm{i}} \otimes \mathbf{n}_{0,\mathrm{i}}\,. \tag{1}$$

Here, $\mathbf{F}_e$ is the (short-time) elastic contribution and $\mathbf{F}_g$ is the (long-time) growth contribution. During growth, each orthogonal material orientation $\mathbf{n}_{0,i}$ has an associated stretch ϑ_i due to growth. The rate of this stretch is given by $\dot{\vartheta}_i = k(\vartheta_i)\phi$, where $k(\vartheta_i)$ is a bandpass function that prohibits uncontrolled growth/resorption, and ϕ relates hypothesized changes of mass or microstructure to stimuli by kinematic constitutive assumption(s).

Chemical kinetics: Chemical kinetics for each species α were governed by conservation of mass including diffusion and reactions:

$$\frac{dc^\alpha}{dt} = D\nabla^2 c^\alpha + \sum_i \nu_i^\alpha \hat{\zeta}_i\,, \tag{2}$$

where c^α is concentration of species α, D is diffusivity, ν_i^α is the net stoichiometric change of α for a given reaction i (note: $\nu_i^\alpha = 0$ for reactions not involving α) and $\hat{\zeta}_i$ is total molar supply of all species associated with reaction i [7]. For 1st order mass-action reactions with reaction rate k_i, the molar supply was the product $\hat{\zeta}_i = k_i\Pi_\alpha c^\alpha$. For biochemical signaling networks, production rates were formulated as normalized Hill activation/inhibition functions with interactions modeled via Boolean logical operators [8-9].

Hyperelastic Mechanics: The Cauchy stress $\boldsymbol{\sigma_e}$ was evaluated relative to the intermediate configuration. Materials were represented as neo-Hookean solids:

$$W(\mathbf{C}_e) = c_1(I_1 - 3) - 2c_1 \ln J_e + K(\ln J_e)^2, \tag{4}$$

$$\boldsymbol{\sigma_e} = \frac{1}{J}\mathbf{F}_e\mathbf{S}_e\mathbf{F}_e^T = \frac{1}{J}\mathbf{F}_e\left(2\frac{\partial W(\mathbf{C}^e)}{\partial \mathbf{C}^e}\right)\mathbf{F}_e^T, \quad (5)$$

where $J_e = \det(\mathbf{F}_e)$, $\mathbf{C}_e = \mathbf{F}_e^T\mathbf{F}_e$.

Test Case 1: We first introduced a "toy-model" to highlight features of kinematic growth coupled with spatially varying chemical kinetics. The growth of a cubic tissue specimen was simulated along the z-axis ($\vartheta_1 = \vartheta_2 = 0$) for 10 years. The mass-action chemical system studied was $\mathrm{A} + \mathrm{B} \rightarrow \mathrm{C}$. Growth was related to c^{C} via $\phi(c^{\mathrm{C}}) = \mathrm{d}c^{\mathrm{C}}/\mathrm{d}t$. We first investigated 1-way coupling of growth to chemical kinetics. Here, the production of A was given by $\hat{\zeta}_q^{\mathrm{A}}(\mathbf{X})$ (Fig 1). We next investigated 2-way coupling of growth to mechanosensitive chemical kinetics. Here, the production of A ($\hat{\zeta}_q^{\mathrm{A}}(\mathbf{X}, I_1)$) increased w.r.t $I_1 = \mathrm{tr}(\boldsymbol{\sigma})$. The source $\hat{\zeta}_q^{\mathrm{B}}$ and decays $\hat{\zeta}_d^{\mathrm{A}}$, $\hat{\zeta}_d^{\mathrm{B}}$, and $\hat{\zeta}_d^{\mathrm{C}}$ were constant.

Test Case 2: An aneurysm was modeled to grow for 8 years in response to matrix metalloproteinase (MMP) downstream of transforming growth factor-β (TGFβ) and intermediate signaling members MAPK, Smad, and TIMP (Fig 1) [8]. The chemical system was modeled as a network of normalized Hill activation/inhibition functions. Growth was related to c^{MMP} via $\phi(c^{\mathrm{MMP}}) = 2.5\ \mathrm{d}c^{\mathrm{MMP}}/\mathrm{d}t$, $\vartheta_1 = \vartheta_2, \vartheta_3 = 0$. For 1-way and 2-way cases, $c^{\mathrm{TGF\beta}}$ was given as $c^{\mathrm{TGF\beta}}(\mathbf{X})$ or $c^{\mathrm{TGF\beta}}(\mathbf{X}, I_1)$ respectively (Fig 1). The decay for each species $\hat{\zeta}_q^{\alpha \neq TGF\beta}$ was constant. Prescribed $c^{\mathrm{TGF\beta}}$ increased w.r.t I_1.

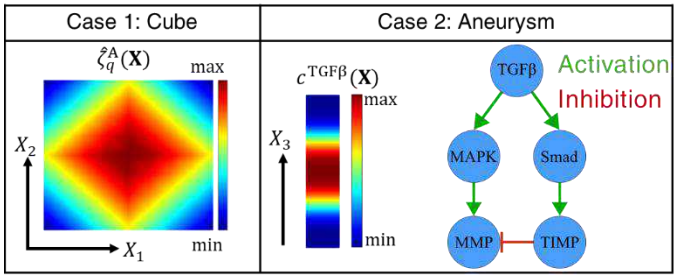

Figure 1: Cube) Spatial variation in $\hat{\zeta}_q^{\mathrm{A}}(\mathbf{X})$. Aneurysm) Left: Spatial variation in $c^{\mathrm{TGF\beta}}(\mathbf{X})$. Right: Signaling networks.

RESULTS

Case 1: Globally 3D growth emerged from locally 1D growth. Qualitative agreement is shown between FEBio and FEniCS (Fig 2). Values of I_1 were greatest along the edges of the specimen and smallest on the interior. Max stresses, deformation, $\hat{\zeta}_q^{\mathrm{A}}$, and c^{C} were reduced by 2-way coupling. Introducing diffusivity to the 1-way case yielded similar trends but with less differential growth and spatial variation.

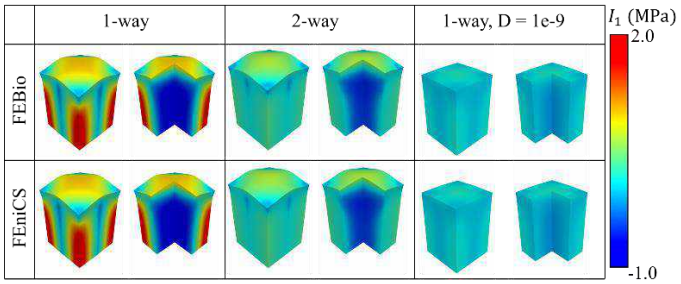

Figure 2: Results for vertical growth after 8 years are displayed for each growth rule alongside a ¾ cut view. Different growth formulations resulted in different solutions of similar problems.

Case 2: Growth occurred primarily in the radial directions (X_1, X_2) with qualitative agreement between FEBio and FEniCS (Fig 3). High stress gradients formed within the lumen near the edges of the aneurysms. Again, stresses decreased for the 2-way and diffusing formulations. Diffusivity delocalized growth, resulting only in vessel dilation. A double-aneurysm was produced by increasing the max value of $c^{\mathrm{TGF\beta}}$.

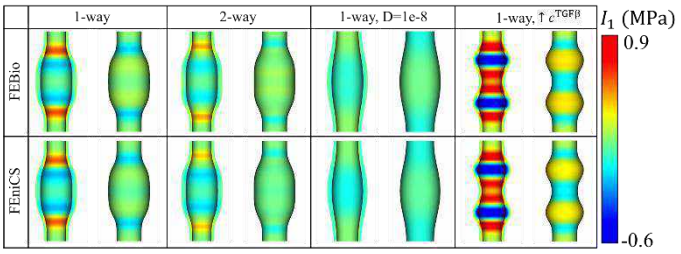

Figure 3: Comparison of aneurysm growth with luminal and abluminal views for each case. 2-way coupling and diffusion facilitated stress dissipation. Increasing $c^{\mathrm{TGF\beta}}$ resulted in a double aneurysm.

DISCUSSION

We implemented and cross-validated kinematic growth coupled to systems biology in FEBio and FEniCS. Our results demonstrate the variability of kinematic growth formulations, reiterating the need for reproducibility and careful selection of constitutive assumptions. Improved accessibility was achieved by implementing these features in FEBio, which allows user-friendly model development in a GUI. Similarly, FEniCS has modern features such as auto-differentiation and just-in-time compilation of C++ code from user-supplied Python scripts. The source code and input files will be available on GitHub and FEBio's online model repository.

FEBio models were limited to formulations of $\mathbf{F}_g$ where ϑ depends directly on chemical concentration (which may evolve via mechanosensitive kinetics). Formulations of $\mathbf{F}_g$ where ϑ depends directly on stress or strain would require modifications to the code and new linearizations. In contrast, the FEniCS implementation could easily be adapted for other stimuli by modifying a few lines in the Python script. Such changes could be linearized via auto-differentiation which would automatically be recompiled at runtime. In the future, we may incorporate similar features in FEBio to support user-defined kinematic growth without requiring code changes or separate software releases.

The test cases we developed are phenomenological examples that may be used to explore growth mechanisms. For instance, double aneurysms emerged in our model since the equilibrium MMP distribution was not monotonic with respect to the TGFβ distribution. This suggests that localized biological processes may produce delocalized downstream effects.

INTRODUCTION

Cervical spondylotic myelopathy (CSM) is a progressive neurological disorder that reduces patient quality-of-life and functional ability. C3 laminectomy, as part of a cervical laminoplasty, may improve decompression and reduce postoperative morbidity, such as pain. Despite the benefit, complete laminectomy may result in instability. We performed an analysis of cadaveric spines to determine the effects of C3 laminectomy on C2-C3 stability and range of motion during C4-C6 laminoplasty.

METHODS

Eight human-cadaveric spines (C1-T2) were mounted to a six degree-of-freedom robotic testing system (simVITRO®) and underwent preconditioning with pure moment loading of ±1.5 Nm in flexion/extension (FE), axial rotation (AR), and lateral bending (LB) to minimize viscoelastic effects. For testing, a 30 N head compressive force was maintained as a head load while ±1.5 Nm moments were applied to the native spine in FE, LB, AR, and in the coupled directions of flexion with axial rotation (FE±AR) and extension with axial rotation (E±AR). Total Spine, C2-C3, and C3-C4 range of motion (ROM) was collected during each applied moment test. After testing, left sided open door laminoplasties were performed at C4, C5, and C6 (Stryker). The specimens were tested again with the above approach. A complete C3 laminectomy was then performed and testing was repeated.

RESULTS

At C2-C3, there were statistically-significant differences in ROM during left-axial rotation ($p = 0.030$) and combined A-flexion and left-axial rotation ($p = 0.009$) between surgical states. At C3-C4, there were statistically-significant differences in ROM during right-axial rotation ($p=0.007$), overall flexion ($p<0.001$), combined A-flexion and right-axial rotation ($p = 0.011$), and combined F-flexion and right-axial rotation ($p=0.042$). On quaternion difference analysis, at C2-C3, there were no statistically-significant differences in ROM between the two surgical states. At C3-C4, ROM during overall flexion ($p<0.001$), combined flexion and left-axial rotation ($p=0.016$), combined flexion and right-axial rotation ($p=0.021$), and right lateral bending ($p=0.011$) were significantly different.

DISCUSSION

Augmenting standard C4-C6 laminoplasty with C3 laminectomy significantly alters the biomechanics at C3-4. Further studies are necessary to determine the clinical correlations of these findings.

PATIENT-SPECIFIC LONG-TERM PREDICTION OF TRANSCATHETER EDGE-TO-EDGE MITRAL VALVE REPAIR

Natalie T. Simonian (1), Sneha Vakamudi (2), Mark J. Pirwitz (2), Michael S. Sacks (1)

INTRODUCTION

Mitral regurgitation (MR) is the most common valvular disease in the United States affecting over 2% of the population and is expected to double by 2030 due to population aging. The etiologies of MR span a wide range including primary degeneration of the mitral valve (MV) leaflet tissue (DMR), or secondary causes, such ischemia or non-ischemic cardiomyopathy (FMR). However, MR of any type is a major prognostic factor of mortality: the risk of mortality with severe MR at five years is 36% and even moderate MR nearly doubles the risk of mortality in patients with multiple cardiac comorbidities [1].

Recently, transcatheter MV repair methods such as the MitraClip have been of great interest as the technique is generally safe and improves patient outcomes. However, its efficacy compared to other treatment options (replacement, undersized ring annuloplasty, and pharmacological management) has been unclear, with the outcomes largely dependent on MR etiology, MR severity, and existing comorbidities. The landmark MITRA-FR and COAPT studies found diametrically opposite outcomes in terms of mortality and unplanned hospitalization when comparing MitraClip to pharmacological management [2,3]. Though the precise cause for this discrepancy remains unclear, generally it can be attributed to differences in left ventricle size relative to MR severity between the two study cohorts [4]. Despite updated guidelines, TEER recurrence rates remain inferior to those for surgical MV repair. Moreover, 49% of patients with severe MR are denied surgical intervention [5], and up to 50% of patients with FMR are excluded from the current AHA/ACC criteria [6]. These critical limitations coupled with contradictory clinical trial findings strongly emphasize the need for a patient-specific approach to MR treatment planning.

Furthermore, the MV has the capability to remodel in response to sustained changes in equilibrium. The long-term consequence of permanently stretching the leaflets together and restricting their motion has also never been studied and is likely a key mechanism that drives MitraClip failure. We have previously demonstrated that the MV *plastically* deforms after myocardial infarction, with permanent distortions in annular dimensions, leaflet size, and leaflet stretch [7]. Moreover, we have also shown that altered mechanical loading stimulates changes in MV biosynthesis on the cellular and molecular levels [8]. Therefore, as the MitraClip constitutes a particularly exaggerated shift in homeostasis, we hypothesize that the MV leaflets will undergo a substantial plastic deformation in response to the device.

Standard-of-care real-time 3D echocardiography has advanced to the point that high-resolution images of the patient's MV can be acquired over multiple cardiac cycles. By integrating our previous work on MV plasticity models with the wealth of patient-specific data contained in these preoperative clinical images, we aim to develop a *long-term predictive MV repair model* to quantitatively optimize treatment strategies and achieve maximum repair durability.

METHODS

First, we developed a finite-element model of the full, patient-specific MV apparatus using our previously published methods [9]. As the MV chordae tendinae (MVCT) are not typically visible on standard-of-care rt-3DE imaging, we quantified the MVCT insertions and origins from 5 CT-imaged excised human hearts. Then, we segmented the MV leaflet geometries and papillary muscle (PM) positions for 5 patients from their *preoperative* rt-3DE images. By mapping the population-averaged MVCT insertion density map onto the patient leaflet geometries, we were able to generate patient-specific full MV apparatus models that incorporated both the leaflets and MVCT network.

For preoperative leaflet closure, we defined the segmented end-diastolic (ED) to end-systolic (ES) annular and PM displacements as Dirichlet boundary conditions and applied a ventricular pressurization. Given that patient-specific material properties are impossible to obtain from rt-3DE imaging, we calibrated the tissue material model by iteratively adjusting MV leaflet and MVCT prestrains such that the

Figure 1: Predictive TEER simulation progression with full patient-specific MV apparatus.

change in l^2-norm between the simulated and segmented preoperative ES geometries was less than 5%. We then utilized this fully calibrated MV model to simulate MV repair scenarios by implementing 3D MitraClip models directly onto the MV leaflets (Fig. 1).

Next, we built on our previous work on MV plasticity in response to myocardial infarction to model the long-term consequences of the MitraClip on the MV leaflets [10]. The MV tissue is modeled as an incompressible composite of collagen fibers and an isotropic matrix, and we assume all time-dependent behaviors are constrained to the matrix phase, where bond scission and healing continually alters the stress-free configuration of the matrix according to first-order kinetics. We also assume that the time-scale required to induce a plastic response in the MV leaflets is sufficiently large that only *sustained* changes in leaflet strain would affect leaflet geometry and function e.g. the permanent approximation of the MV leaflets by a MitraClip device. The matrix component of the second Piola-Kirchoff stress tensor, $\boldsymbol{S}_m$, can be defined as follows:

$$\boldsymbol{S}_m = \mu_m \left[e^{-kt}(\boldsymbol{I} - C_{33}\boldsymbol{C}^{-1}) + \int_0^t k e^{-k(t-\tau)} (\tilde{\boldsymbol{C}}^{-1} - C_{33}\tilde{C}_{33}^{-1}\boldsymbol{C}^{-1} d\tau \right] \quad (1)$$

We fit the plasticity rate constant k using additional rt-3DE imaging taken 3-months post-TEER in a subset of consented patients.

RESULTS

With the fully calibrated preoperative MV apparatus model, we were able to *predict* the post-TEER ES geometry to within a millimeter and closely match the leaflet strain patterns when compared to simulations that directly applied postoperative boundary conditions. We also found notable stress concentrations on the MV leaflets at the locations where the MitraClip devices were placed (Fig. 2A). This stress concentration was accompanied by a local change in MV leaflet strain (Fig. 2B). It is this sustained change in MV leaflet deformation that we hypothesize results in the MV plasticity response.

In the follow-up simulations, we were able to reproduce key effects of TEER repair at the 3-month time point using our plasticity model. We noted substantial changes in the MV functional state over time in the ED configuration, where strains are principally induced by permanent distortions in geometry. Specifically, we observed highly compressive circumferential strain on both leaflets in the region of the clip, and slight radial extension in the same region (Fig. 3).

DISCUSSION

Given the persistent challenges and controversies surrounding optimum MR treatment strategies, there is an urgent need for patient-specific methods for predicting treatment outcomes, specifically with a focus on long-term repair durability. Here, we have presented an approach for *predicting* the postoperative state of the MV apparatus both immediately after TEER repair and at 3 months post-repair using standard-of-care, preoperative clinical imaging alone. This pipeline allows us to quantitatively interrogate the impact of the TEER procedure on MV behavior, such as shifts in deformation and nonphsyiological

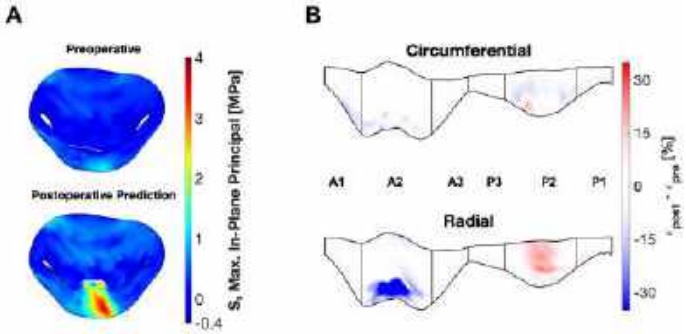

Figure 2: A. Pre- and postoperative maximum in-plane principal Cauchy leaflet stress. The MitraClip induces a notable stress concentration on the posterior leaflet. B. Differences in leaflet strain from pre- to post-TEER, in the circumferential and radial directions. The Carpentier segment where the MitraClip is placed undergoes substantial changes in deformation due to the leaflet approximation.

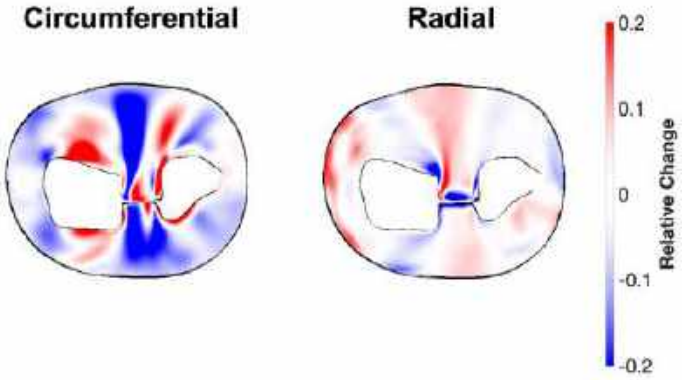

Figure 3: Relative change in leaflet strain from immediately post-repair to 3 months after the procedure. There is notable compression in the circumferential direction, as well as some extension radially locally in the region of the MitraClip.

stress concentrations, as well as the consequences of this permanently altered state on *long-term MV function*. Thus, we can elucidate mechanistic drivers of repair failure, which constitute key targets for optimized treatment durability and efficacy. Our results, which reveal continued MV remodeling in response to the MitraClip, underscore the importance of a long-term view of repair success in the context of MV function, rather than a reductive focus on immediate MR reduction.

INTRODUCTION

Diabetes has an increasing prevalence and currently affects over 400 million people worldwide [1], exerting a massive socioeconomical burden to the healthcare system of most countries. As an important risk factor for a broad range of cardiovascular comorbidities, diabetes plays a multifaceted role in the mechanical functions and pathologies of the aortic wall. Diabetes patients show signs of accelerated age associated aortic stiffening [2]. On the other hand, several nationwide statistical investigations demonstrated a negative association between diabetes and the risk of aortic dissection [3,4]. Correspondingly, studies based on animal [5] and *in vitro* [6,7] models of diabetes have provided biomechanical evidence supporting the clinically observed effects of diabetes on the stiffness and dissection propensity of aorta. However, there lacks a comparison of the mechanical and failure behavior between diabetic and nondiabetic human aortic tissues. Such data will not only shed light on the pathological development of diabetic aorta from a mechanistic perspective, but also may provide a foundation for creating high-fidelity computational models that could ultimately lead to the establishment of novel metrics for aorta health assessment and prediction for diabetic patients. In this study, using biomechanical testing approaches, we aim to demonstrate the effect of type-II diabetes on the mechanical and failure properties of human descending thoracic aorta (DTA).

METHODS

Planar biaxial tensile test

Human proximal DTAs with type-II diabetes ranging from 30 to 81 years of age were collected and divided into three age groups: <40 (n=2), 40-60 (n=8) and >60 (n=5) years. Planar biaxial tensile tests were conducted to characterize the mechanical properties of aorta. Briefly, square samples with a size of approximately 2.5 × 2.5 cm were biaxially preloaded with 5 N/m tension and preconditioned with 40 N/m cyclic tension. Samples were subsequently subjected to 200:200 N/m equibiaxial loading, from which the peak stretches were obtained to evaluate the stiffness of each sample as well as the degree of anisotropy defined as $(\lambda_L - \lambda_C)/[0.5\ (\lambda_L + \lambda_C)]$, where λ_L and λ_C are the peak stretches in the longitudinal and circumferential directions of the sample, respectively. A positive degree of anisotropy corresponds to a higher circumferential stiffness, whereas a negative degree of anisotropy corresponds to a higher longitudinal stiffness. In addition, the areal strain under 200:200 N/m equibiaxial tension, obtained as $\lambda_L\lambda_C$-1, was used to evaluate the overall stiffness of each sample [8]. Two samples were obtained from each aorta for biaxial tensile testing except for two aortas due to limited tissue size.

Peeling test

Peeling tests were conducted to characterize the failure properties of aorta. Briefly, two rectangular samples with a size of approximately 15 × 6 mm were obtained from each aorta. The long edge of one sample was oriented in the circumferential direction of the aorta while that of the other sample was oriented in the longitudinal direction. The adventitial and intimal layers of each sample were removed. The medial layer of each sample with an incision was peeled apart with an extension rate of 0.2 mm/s. The peeling force and displacement was recorded until complete delamination. The interlamellar toughness is calculated as $F_m[1+(l/L)]/w$, where F_m is the mean peeling force, w is width of the sample, and l and L are bonded length of the sample in the deformed and initial states, respectively [9].

Statistical data analysis

Experimental data including the peak stretch, areal strain, degree of anisotropy, mean peeling force/width and interlamellar toughness are summarized using bar graphs for each age group and are presented as mean ± standard error of the mean. Biomechanical testing results from diabetic human DTAs were compared to those from their age group-matched nondiabetic counterparts from our previous study [10].

Unpaired t – tests were performed to compare results between the diabetic and nondiabetic samples. Across different age groups, one-way analysis of variance (ANOVA) was used with Bonferroni correction to evaluate the effect of aging on the mechanical and failure properties of both nondiabetic and diabetic samples. $p<0.05$ was considered statistically significant.

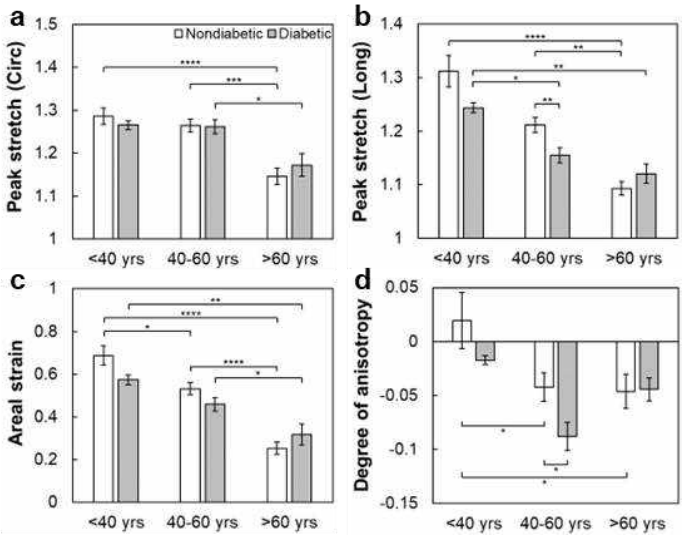

Figure 1: Effect of type-II diabetes on the planar biaxial tensile properties of aging human DTA. Data were obtained under 200:200 N/m equibiaxial tension. Error bars represent standard error of the mean. (*p<0.05, **p<0.01, ***p<0.001, ****p<0.0001).

RESULTS

Results of planar biaxial tensile tests are presented in Fig. 1. A stiffening effect of aging on the biaxial mechanical behavior of the aorta can be observed for both nondiabetic and diabetic samples. No significant difference was observed in the circumferential peak stretch and areal strain between nondiabetic and diabetic aortas of all age groups. However, diabetes was found to accelerate aging-associated aortic stiffening in the longitudinal direction between 40-60 years of age, as revealed by the significantly lower peak stretch as well as degree of anisotropy ($p<0.05$) in the diabetic samples of the 40-60 years group (Figs. 1b and 1d). In addition, for diabetic samples, no significant difference in the degree of anisotropy was found across three age groups, as opposed to the significant decrease in the degree of anisotropy after 40 years of age exhibited in nondiabetic samples ($p<0.05$) (Fig. 1d). Therefore, diabetes expedites the reverse of anisotropy of the aorta with aging. In fact, higher longitudinal stiffness exhibited in all diabetic samples examined regardless of age.

Results of peeling tests are presented in Fig. 2. Diabetes enhances the dissection resistance capability of the aortic wall. Such effect is more prominent after 60 years of age. Compared with nondiabetic samples, in the >60 years group, diabetic samples demonstrated significantly higher longitudinal peeling force/width ($p<0.05$) and circumferential interlamellar toughness ($p<0.05$) (Figs. 2b and 2c). Also, for diabetic aortas, the same level of dissection resistance capability was sustained as the patient passes 60 years of age, as opposed to the significant decrease of longitudinal interlamellar toughness between 40-60 and >60 years groups ($p<0.05$) (Fig. 2d). Furthermore, diabetes has a more prominent effect on the failure behavior of the aorta along the circumferential direction than the longitudinal direction, as circumferentially no significant difference was found in the peeling force/width and interlamellar toughness across three age groups, while longitudinally both the peeling force/width and interlamellar toughness decreases significantly after 40 years of age.

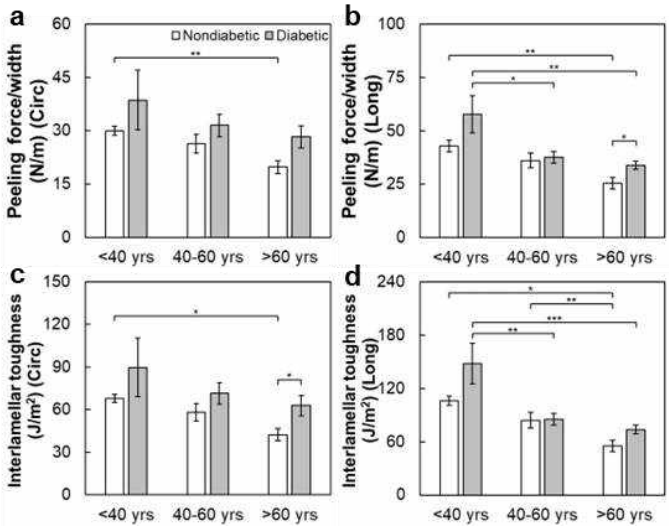

Figure 2: Effect of type-II diabetes on the dissection properties of aging human DTA. Error bars represent standard error of the mean. (*p<0.05, **p<0.01, ***p<0.001).

DISCUSSION

The current study provides, to the best of our knowledge, the first experimental results illustrating changes of human aorta mechanics under the effect of type-II diabetes. Diabetes results in complex multifaceted alterations in the mechanical and failure behavior of the aging aorta (Figs. 1 and 2). The increase of stiffness and interlamellar toughness found in aortas of diabetic patients (Figs. 1 and 2) is consistent with clinical observations [2-4]. Through a combination of chemical and biological pathways, diabetes could have a comprehensive impact on the compositional and structural properties of the aortic wall. In particular, excessive glucose molecules react with amino groups of extracellular matrix proteins to form advanced glycation end-products, which cause nonenzymatic crosslinking of extracellular matrix fibers and could elevate tissue stiffness and toughness [7].

In conclusion, diabetes accelerates aging-associated stiffening in the longitudinal direction of human DTA under 60 years of age and increases the dissection resistance capability of human DTA with a more drastic effect after 60 years of age. Quantitative microscopic imaging and biochemical analysis is needed to resolve the structural mechanisms underlying the altered mechanical and failure properties of the aorta and to gain a better understanding of diabetes-induced aortic remodeling and pathology.

INTRODUCTION

During pregnancy, the vasculature of the placenta and umbilical cord connects the pregnant individual and fetus. The importance of this connection is demonstrated by the increased risk of negative outcomes when the umbilical and placental vasculature are malformed. The risk of developing cardiovascular disease increases for both parent and fetus [1], and the risk of stillbirth is also elevated [2]. Of particular interest in the current study is vascular abnormality associated with gestational diabetes mellitus (GDM) [3]. Gestational diabetes occurs solely during pregnancy and results in increased blood glucose levels due to insulin resistance. Within the United States, GDM is becoming more prevalent, increasing 37% from 2016 to 2021 to impact approximately 8% of pregnancies [4]. Therefore, it is necessary to better understand how GDM influences umbilical and placental vascular development.

In utero ultrasound measurements show GDM causes increased umbilical arterial wall thickness [5]. Additionally, *in utero* shear-wave elastography measurements have shown placental stiffening due to GDM [6]. While these differences have been observed, the mechanisms that underlie anomalous remodeling and possible stiffening of the umbilical vasculature in GDM remain unclear. Here, we used complementary morphological quantification and mechanical testing to investigate how GDM impacts the development and mechanical properties of umbilical arteries.

METHODS

Human umbilical cords from either healthy or GDM full-term pregnancies were collected after delivery. The two umbilical arteries (UAs) were dissected from the cord (Fig. 1A-B). Dissected UA segments (1-3 cm long) were cut transversely into small (~2 mm long) explants to create 2 replicate rings (Fig. 1B). All cords analyzed were from female fetuses and the reported n represents the number of vessels studied.

To quantify changes in morphology, the vessel wall thickness (h) and inner (lumen) diameter (d_o) were measured and the wall-to-lumen ratio (h/d_0) was calculated (Fig. 1C). Values for wall thickness for an individual explant were measured and averaged across 4 locations using ImageJ [FIJI]. The inner diameter was taken as the initial pin distance of mounted explants at its pre-stretched state for circumferential mechanical testing (Fig. 1D). A one-sided, two-sample Students' t-test was used to determine significance for morphological quantification.

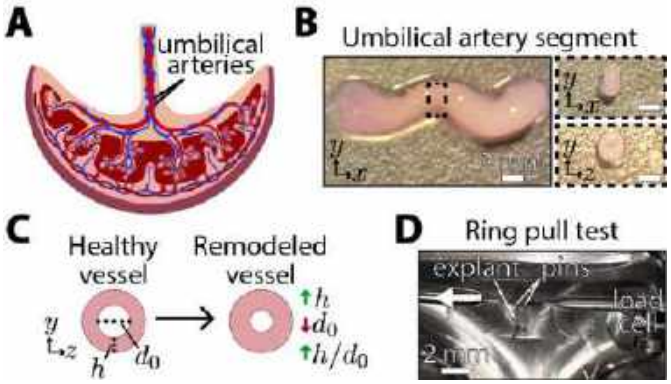

Figure 1: UA Dissection and Quantification Methods. (A) Schematic of umbilical and placental vasculature. Umbilical arteries are noted. (B) Representative dissected umbilical artery segment and explant (inset). Insets show longitudinal (top) and transverse (bottom) view. (C) Schematic of inward remodeling. Wall thickness (h) increases, inner diameter (d_0) decreases, and the wall-to-lumen ratio (h/d_0) increases. (D) Representative UA explant mounted for ring pull testing.

To investigate the mechanics of these same vessels, the explants underwent circumferential testing using a ring pull test [DMT Organ

Bath System 820MO]. Explants were stretched by 10%, 15%, 20%, 30%, and 40% ($\lambda = 1.1, 1.15, 1.2, 1.3, and\ 1.4$) and allowed to equilibrate for 5 minutes following each applied stretch. The resulting force exerted by the tissue was recorded, at a rate of 1000 Hz. The equilibrium force (F_{eq}) at each stretch was calculated for each individual explant. The viscoelastic response was quantified by taking the ratio of the equilibrium force to the peak force (F_{eq}/F_p). Next, the Cauchy stress in the circumferential direction ($\sigma_{\theta\theta}$) for each explant was calculated:

$$\sigma_{\theta\theta} = \frac{F_{eq}}{2A} \quad (1)$$

where A is the deformed cross-sectional area of the explant. Finally, the Young's modulus (E) of each explant was calculated:

$$E = \frac{\sigma_{\theta\theta}}{\epsilon} \quad (2)$$

where ϵ is the strain. A two-way ANOVA with a Tukey post-hoc test or a two-sided, two-sample Students' t-test were used to determine significance for mechanical analysis.

RESULTS

Umbilical arteries from GDM pregnancies had significantly increased vessel wall thickness (h) and decreased lumen diameter (d_0) as compared to healthy pregnancies (Fig. 2A-B). These changes due to GDM were suggestive of inward remodeling (Fig. 1B). Indeed, the morphological changes result in a significant increase in the wall-to-lumen ratio of UAs from GDM pregnancies as compared to healthy pregnancies (Fig. 2C).

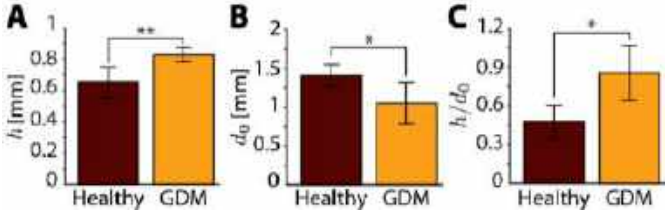

Figure 2: Morphology of Umbilical Arteries. (A-C) Average wall thickness (h) (A), inner diameter (d_0) (B), and wall-to-lumen ratio (h/d_0) (C) for healthy and GDM UAs. Error bars are standard deviation. Healthy: n = 4, GDM: n = 6. *p<0.05, **p<0.01.

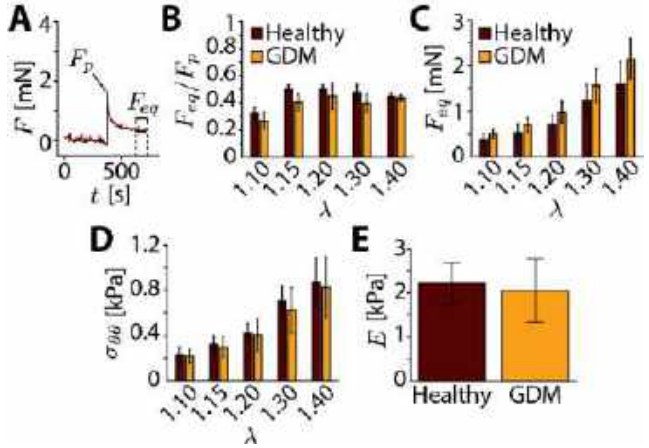

Figure 3: Mechanics of Umbilical Arteries. (A) Representative force (F) vs. time (t) curve shown for 10% stretch ($\lambda = 1.10$). The peak force (F_p) and equilibrium force (F_{eq}) are shown. (B-D) Mean ratio of equilibrium force to peak force (B), equilibrium force (C), and Cauchy stress ($\sigma_{\theta\theta}$) (D) vs. stretch for healthy and GDM UAs. (E) Mean Young's modulus (E) for healthy and GDM UAs. Error bars are standard deviation. Healthy: n = 4, GDM: n = 6.

The viscoelastic response of the vessels was observed when the applied stretch resulted in an initial peak force (F_p) that relaxed to an equilibrium force (F_{eq}, Fig. 3A-B). The relaxation was slightly greater (i.e. F_{eq}/F_p was slightly lower) for the GDM UAs, but the result was not significant. The measured equilibrium forces were slightly higher, although not statistically significant, in GDM UAs as compared to healthy UAs (Fig. 3C). However, there was no difference between GDM and healthy UAs when comparing the Cauchy stress values (Fig. 3D). The Young's modulus for each condition were also similar amongst both groups (Fig. 3E).

DISCUSSION

These data suggest GDM can cause morphological differences in umbilical arteries that do not impact the material behavior of the tissue. Vessel morphology is connected to hemodynamics, which has been shown to be altered in fetuses of GDM pregnancies [7]. Specifically, the resistive index, which is inversely related to lumen diameter, has been shown to increase in GDM pregnancies [7]. The morphological changes quantified here could explain why differences in fetal hemodynamics arise in GDM.

The similar material properties of the UAs from healthy versus GDM pregnancies is counterintuitive to the well-established arterial stiffening observed within adults with diabetes [8,9]. Unlike the adult vasculature, umbilical arteries are undergoing rapid changes as they develop over the course of pregnancy. Despite this growth, UAs from healthy pregnancies maintain constant material properties that do not change with gestational age [10]. Therefore, it is possible the UAs from GDM pregnancies similarly seek to maintain these same material properties but must adapt their vessel morphology and/or structure as they develop to counteract diabetes-related vessel stiffening.

The umbilical cords used for this analysis were obtained from pregnancies of female fetuses to eliminate possible differences due to fetal sex. Future studies to investigate how GDM impacts the morphology and mechanics of the umbilical vasculature within male fetuses as well as any sex-dependent differences are needed.

INTRATUMORAL COMPRESSION PROMOTES PRONEURAL TO MESENCHYMAL TRANSITIONS IN GLIOBLASTOMA

Allison McKenzie Johnson (1), Lylah Cox (2,3), Joseph Chen (1)

INTRODUCTION

Glioblastoma (GBM) is the most prevalent and malignant brain cancer, accounting for over half of all brain cancer diagnoses and carrying an average life expectancy of 14 months after diagnosis [1,2]. The lethal nature of this cancer is due to the rapid invasion and recurrence despite multimodal, aggressive treatment [3]. Reports suggest that a critical driver of this progression is proneural to mesenchymal transition (PMT), a phenotypic switch that cause cells to become increasingly migratory and therapy resistant [4]. Current therapies target this phenomenon through biochemical avenues, which has not been effective [5]. However, emerging studies have suggested that PMT is highly sensitive to biophysical cues, which drugs currently do not target, and thus new investigations into the biophysical axis is warranted [6]. The tumor microenvironment is mechanically complex, with varied ECM stiffness, elevated shear stress from fluid flow, and increased compressive stress all mediating cancer progression and invasion [7]. Although ECM stiffness and shear stress are well studied, Intratumoral compression is much less understood. Intratumoral compressive stress is experienced by the tumor as it rapidly expands against the surrounding tissue, experiencing a normal force back against the tumor [8]. Due to the dense nature of the brain ECM, the normal force pushing back is expected to be high, therefore increasing the compressive stress on the tumor [8]. Compressive stress is shown to increase invasive potential in epithelial cancer, but the mechanism by is still poorly understood [9]. This research aims to elucidate the mechanism by which compression activates PMT to identify novel therapeutic targets for pharmacological intervention.

METHODS

The compression device was designed to allow for varying amounts of compression while maintaining sterility and cells' access to cell culture media (Figure 1). The design utilizes a 24 mm diameter with 0.4 µm pores to allow for nutrient exchange with the media below but inhibit migration through the transwell. Atop the cell monolayer is a 2% agarose gel and a 3D printed cup containing tungsten carbide discs to induce compression.

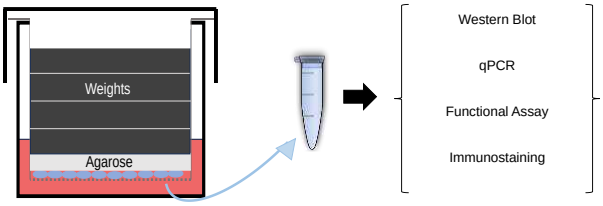

Figure 1. Compression Device design and intended use.

U251s were cultured then seeded for 24 hours before being compressed under 1 kPa pressure. After 72 hours, the cells were lysed, fixed, or replated. Cells were lysed in RIPPA with a Protease inhibitor then a BCA was done. Protein levels were normalized, and a Western Blot was run on a 14% acrylamide gel. The blot was stained for CD44 before being imaged via an Odyssey-XF. Densitometry was done via ImageJ. For Immunostaining, cells were fixed in 10% Formalin with Triton. Cell monolayers were stained for Ki-67, Zeb1, and DAPI. Cells were imaged via an Olympus BX51M. Nuclear localization and fluorescent intensity were quantified via ImageJ. For the functional assay, the cells were lifted with Trypsin EDTA, and replated on tissue culture plastic. After 24 hours, the cells were imaged every 15 minutes for 24 hours at 10x on a Nikon Eclipse TE2000-U. Quantification of cell speed and persistence were done via ImageJ.

RESULTS

To confirm that our system is applying compression to the cells, we assessed nuclear shape and circularity. We found that compressed cells showed appeared flattened and how a significant decrease in

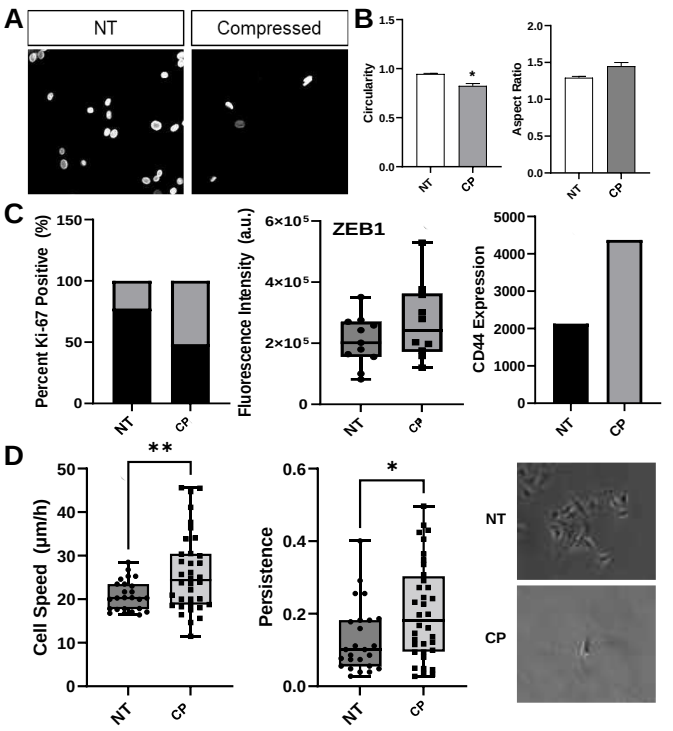

Figure 2. DAPI staining shows significant changes in nuclear size and shape in response to compression (A). Proliferation decreases due to compression but ZEB1 and CD44 both increase (B), indicating a mesenchymal shift. Functional assessment shows significant increase in cell speed and persistence after compression (C).

circularity and an increase in aspect ratio, indicating an elongated morphology (Figure 2 A,B). To determine the effect of compression on cell proliferation, we stained both conditions with Ki-67 and evaluated nuclear localization. We found that the compressed condition showed less Ki-67 nuclear localization than the non-treated cells (Figure 2C). To assess the potential PMT shift, compressed and non-compressed cells were stained for ZEB1, a mesenchymal transcription factor seen in the early stages of PMT, and CD44, a marker of the mesenchymal phenotype. For ZEB1, the fluorescent intensity was higher in the compressed population than the non-compressed, providing evidence of a shift to a mesenchymal phenotype (Figure 2C). CD44 staining revealed higher CD44 levels in the compressed condition, supporting a shift towards a mesenchymal phenotype (Figure 2C).

To test whether there was a functional effect in compressed cells, a 2D motility assay was conducted. The non-treated condition showed proliferative cells that maintained cell-cell contact with little migration. However, the compressed cells exhibited large lamellipodial protrusions and were more migratory and persistent (Figure 2D).

DISCUSSION

In this study, we developed a compression platform to investigate the effect of increased compressive stress on PMT in U251 GBM lines. We confirm that our compression platform is capable of squeezing cells by showing that compressed cultures displayed elongated nuclear shape. Using this platform, we found that compressed cells proliferated less, which may point to a more migratory phenotype. Additionally, we observed an increase in mesenchymal markers ZEB1 and CD44 in the compressed population. The upregulation of these markers is significant because they were activated in the absence of any other stimulus, providing evidence of the pro-malignant effect of elevated compressive stress. Through a 2D motility assay, we show that compressed cells migrated faster and more persistently regardless of any chemotactic cue. This indicates an innate increase in migration potential after compression. Compressed cells also had much larger cell area with extended lamellipodial protrusions, which supports a migratory phenotype.

Collectively, these results show that intratumoral compressive stress alone can promote the shift towards a more mesenchymal and malignant phenotype. In patients, this compressive stress may increase the likelihood of tumor cell invasion into the surrounding tissue, which may help it evade the initial surgical recission and propagate new tumors. Future work will examine the mechanism by which compression promotes a mesenchymal shift in GBM by interrogating the nuclear mechanotransductive axis. The identification of new targets in this axis may lead to the development of novel therapies for this deadly disease.

INTRODUCTION

High Intensity Focused Ultrasound (HIFU) stands out as a non-invasive modality gaining prominence for the localized treatment of deep-seated malignant tumors. To enhance the effectiveness and validate the applicability of HIFU procedures, researchers have devised diverse *in vitro* [1, 2] and *in vivo* models [2, 3]. The literature reveals a spectrum of experiments involving *in vitro* models employing tissue mimicking materials (TMM) and turkey/chicken breasts, progressing to *in vivo* models featuring mice. Currently, the majority of HIFU research revolves around mouse tumor models.

In the area of cancer research, an array of mouse strains is readily available, primarily sourced from Jackson Laboratory in Bar Harbor, ME. The judicious selection of mouse strain is important for seamless experimental flow in tumor studies. Cincinnati Children's Hospital and Medical Center (CCHMC) locally houses three mouse strains, all originating from Jackson Laboratory: NOD/SCID GammaC-/- (NSG), NSG-SGM3 (NSGS), and Homozygote J:NU (Nude). These three types of mice were assessed in this study for developing a mouse tumor model.

The NSG mice, with their severe immunodeficiency due to scid and IL2rgnull mutations, have become pivotal in cancer research. Their compromised immune system allows efficient engraftment of human cells, facilitating studies on tumor biology and the testing of potential cancer therapies. The NSGS mice, an advancement in cancer research models, express human IL3, GM-CSF, and SCF. This modification enhances engraftment of myeloid lineages and regulatory T cells, making them particularly relevant for immuno-oncology studies. These mice provide a superior platform for investigating complex interactions between the immune system and cancer. Nude mice, characterized by athymia and immunodeficiency, have been fundamental in cancer research for decades. Their lack of T cells enables successful transplants of tumor cell xenografts, contributing to studies on tumor growth and drug testing in oncology. While not capturing full immune complexity, Nude mice remain relevant in specific contexts, offering insights into tumor biology and early-stage drug evaluations.

A human PC3 (CRL-1435) prostate cancer cell line used for developing the tumor model in mice is provided by American Type Culture Corporation (ATCC). The PC3 cell line is initiated from a bone metastasis of grade IV prostatic adenocarcinoma from a 62-year-old, White, male.

METHODS

The experimental cohort was comprised of two male mice from each of the three selected strains, totaling six mice. All animal studies were approved by the internal ethics and the local government committees. To establish the cell line-derived xenograft model, 6 to 8 weeks old male mice with a bodyweight around 30 g were engrafted subcutaneously with 1×10^7 PC3 cells into the right flank. Mice were group-housed under pathogen-free and controlled environmental conditions (21 ± 1.5 °C temperature, $55 \pm 10\%$ humidity and a 12 h light–dark cycle).

The PC3 cells were procured from ATCC, and the thawed contents of the vial were transferred to a 75 cm^2 tissue culture flask. A growth medium was formulated using F-12K as the base medium, supplemented with 10% fetal bovine serum (FBS) and 1% Penicillin-Streptomycin (Pen-Strep). Rigorous filtration was employed to eliminate potential contaminants. The cells were cryopreserved using DMT solution.

For cell culture, a mixture of 9 ml of the prepared medium and approximately 1 ml of frozen cells were placed in a 50 ml centrifuge tube and spun at room temperature. Cell counting, facilitated by a cell counter, revealed a visible white cell pellet at the tube's base. The culture was then incubated at 37°C, with a waiting period of 2-3 days for confluence. Subsequently, subculturing ensued to attain the desired cell quantity. Ethanol was used to sterilize all equipment before subculturing, and 0.25% (w/v) Trypsin-0.53 mM EDTA solution aided

in cell detachment. The cells were observed under an inverted microscope until the cell layer dispersed, typically within 5 to 15 minutes. The addition of 6 to 8 ml of complete growth medium facilitated aspiration, and sub cultivation was carried out from 1 culture vessel to 3 culture vessels. Medium renewal occurred 2 to 3 times per week, maintaining consistency across subsequent passages.

For the injection procedure, PBS served as the medium, and a 0.2 ml solution containing the requisite cell count was injected using a 27-gauge needle. Post-injection, all mice underwent observation for abnormal behavior. Tumor monitoring involved regular measurements 2 to 3 times weekly over a 5 to 7 week growth period. The area surrounding the tumor was consistently shaved to facilitate clear observation. The tumor measurement was done using digital calipers.

The tumor was assumed as an ellipsoid and the following formula was used to calculate the surface area of the ellipsoid.

$$SA = \left(\frac{4\pi((ab)^{1.6}+(ac)^{1.6}+(bc)^{1.6})}{3}\right)^{1/1.6} \quad (1)$$

The following formula was used to calculate the volume of ellipsoid.

$$V = \frac{4}{3}\pi abc \quad (2)$$

where a, b and c are the three dimensions of the ellipsoid.

RESULTS

Figure 1 illustrates the temporal progression of *tumor surface area* growth. Data collection commenced on the tenth day post-tumor cell injection, considering the initial small size of the tumors. This figure depicts the mice's tumor surface growth fitted to a parabolic profile. The initial tumor growth is characterized by a slow pace. Notably, NSGS mice exhibit a larger tumor surface area until approximately day 26, after which NSG mice surpass them, and the gap in surface area widens over time. Beyond day 40, NSG mice demonstrate a surface area of approximately 17 cm², NSGS mice exhibit around 13 cm², and Nude mice present approximately 11 cm². This highlights that, by the end of day 40, NSG mice possess a tumor surface area: about 31% larger than NSGS mice and 55% larger than Nude mice.

Figure 2 illustrates the temporal evolution of *tumor volume* growth. Similar to the surface area data, the figure displays the tumor surface area growth of mice fitted to a parabolic profile. Until approximately day 24, NSGS mice exhibit the largest tumors among the three strains; however, from that point onward, NSG mice surpass the others in tumor size. By day 40, a discernible distinction in tumor size emerged, with NSG mice boasting the largest tumor volume, Nude mice presenting the smallest, and NSGS mice fell in between the two. Specifically, the tumor volumes at day 40 are approximately 0.8 cm² for NSG mice, 0.52 cm² for NSGS mice, and 0.4 cm² for Nude mice. This indicates that, by the end of day 40, NSG mice have a tumor volume about 54% larger than NSGS mice and 100% larger than Nude mice.

In summary, both the tumor surface area and volume results consistently indicate that NSG mice exhibit the most robust tumor growth among the three experimental groups. This is evident from their larger tumor volume and surface area.

DISCUSSION

This research establishes that the NSG mice are better suited for tumor research based on tumor growth. NSG mice have the larger tumor surface area and volume compared to the other two over the established growth period. One can select this strain for HIFU research involving mice. One secondary factor that could have been considered is the Nude mice having no fur. They are very easy to handle as one must shave the tumor area of NSG and NSGS mice. As the most important parameter for developing a model is tumor size, the tumor surface area and volume of Nude mice is extremely low compared to the other two strains. Hence, they were not considered suitable for development of mouse tumor model.

Limitations: There are other strains of mice provided by Jackson Laboratory and those could be considered as well. This research only focuses on the three strains that are available at CCHMC. Only two mice of each category were taken for observation. More mice from each category can be observed in the future to strengthen the current results. Digital calipers were used for tumor measurement. While it is relatively easy to measure the two dimensions of the tumors with calipers, it was somewhat complex to accurately measure the depth of the tumor.

EXPERIMENTAL AND COMPUTATIONAL MODELING OF BRAIN SHUNT PERFORMANCE

Bryan C. Good (1), Ashley Handy (1), Alyson Matushek (1), Stephanie C. TerMaath (1)

(1) Mechanical, Aerospace, and Biomedical Engineering
University of Tennessee
Knoxville, TN, USA

INTRODUCTION

Hydrocephalus is a condition in which an excess amount of cerebrospinal fluid (CSF) accumulates within the ventricles of the brain, leading to elevated intracranial pressure. Approximately 1 of every 500 infants is born with hydrocephalus, making it the highest cause of brain surgery in children [1]. The most common treatment for this condition is the surgical placement of a brain shunt to drain CSF from the ventricles to other parts of body. However, brain shunts have extremely high failure rates, with a majority of patients needing a device repair or replacement within 10 years [2]. Therefore, the objective of this research is to develop experimental and computational models of brain shunts (both catheter and valve) that capture *in vivo* conditions and to characterize CSF transport under normal and shunt failure operation.

METHODS

Ventricle Parameter Study on VP Catheter Performance

Computational models of VP catheters inside ventricles of varying size, geometry, and choroid plexus (CP) location were created using SolidWorks. Additional patient-specific ventricle models were reconstructed from CT images using the open-source Slicer. The VP catheter has 4 rows with 4 tapered drainage holes (0.8mm diameter) in each row. The catheter is 200 mm long with 1.2 and 2.5mm inner and outer diameters, respectively.

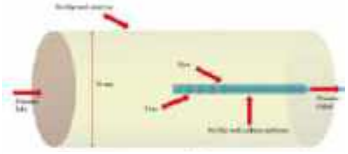

Fig 1: Baseline computational model.

The baseline fluid chamber was modeled as a cylinder (30mm diameter and 60mm length) to represent a simplified ventricle (**Fig. 1**). Additional 'small' and 'larger' cylindrical models were created (**Fig. 2**) to investigate the role of ventricle size on catheter performance.

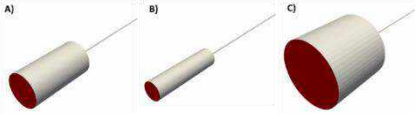

Fig 2: Ventricle size on catheter performance.

Patient-specific ventricle models (**Fig. 3**) were reconstructed from healthy 10-year-old patients (LV1, LV2, and LV3), a hydrocephalus patient (LV4), and a patient with a slit ventricle anatomy (LV5). For each of the five models, three different catheter locations were also considered: Kocher point, and normal and pushed Frazier points.

Fig 3: Patient-specific ventricle geometry on VP catheter performance.

The CP is the main source of CSF production, and its size, shape, and location can be unique for each patient. Therefore, the effect of CP geometry and location on catheter performance was studied (**Fig. 4**).

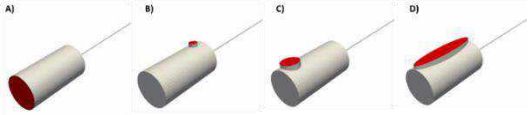

Fig 4: Choroid plexus (red) shape and location on VP catheter performance.

Steady vs. Pulsatile Pressures on VP Catheter Performance

Prior CFD simulations were run with fixed pressure boundary conditions (BCs), with static intracranial pressures (ICP) from 5-20 mmHg. The pulsatile effects of varying ICPs were also investigated using two ICP waveforms (**Fig. 7A**); a simplified periodic waveform adapted from [3] and a hydrocephalus patient pressure waveform. Following each CFD simulation, postprocessing was performed to analyze ventricle flow patterns, CSF flow through the catheter, and wall shear stresses (WSS) as parameters of shunt performance.

Experimental Models of Brain Shunt Valve Performance

Static and dynamic experimental flow models were developed to evaluate the performance of brain shunt valves. Two commercial valves were evaluated statically (**Fig. 6A**) (Medtronic Strata II and Codman Programmable Valve) and one evaluated dynamically (Delta 2.0, Medtronic). For static testing, both explanted failed valves and new

valves of each type were connected to a hydrostatic water column (where "ICP" was controlled by varying the height of water) and an electronic balance used to measure the resultant flow rates over time. For dynamic testing (**Fig. 6B**), the catheters were placed into a water-filled balloon to represent the ventricle's elastic properties. Surrounding the balloon was a 1:1 mixture of ultrasound gel and water that closely mimicked the properties of brain matter. A plastic skull surrogate enclosed the gel and balloon to limit the expansion of the ventricle, as occurs in vivo. CSF production and flow into the model was controlled with an IV infusion pump at a rate of 21 ml/hr. A pressure transducer (Grainger) and flow sensor (Sensirion) were inserted into the model to measure the resultant ICP and shunt drainage, respectively

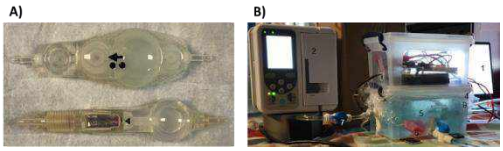

Fig 5: A) Strata II and Codman valves used for static testing. **B)** Delta 2.0 valve used for dynamic testing.

RESULTS

Parameter studies were performed to determine the individual effects of ventricle size and shape, CP size and location, and pressure BCs on CSF flow and WSS distribution (both known to correlate with shunt obstruction).

With regards to CSF flow through the catheter (**Fig. 6A**), no significant differences were observed with changing ventricle size (left), CP shape and location (middle), and in patient-specific ventricles (right). In all cases, approximately 43% of the total CSF flow exited through catheter hole #1, with the % flow splits decreasing exponentially with hole distance. Differences of 1-2% were observed between the small and large cylinder models, <1% between the different CP models, and < 1% between the different patient-specific models.

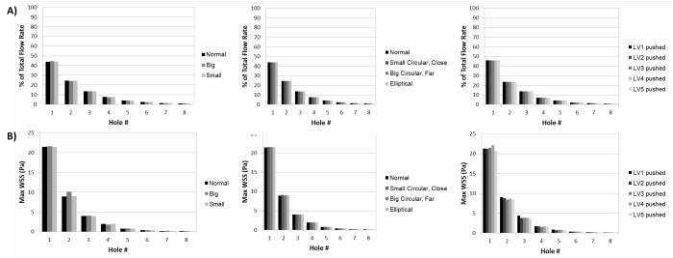

Fig 6: Ventricle size (left), CP (middle), and patient-specific effects on catheter **A)** flow rate and **B)** WSS.

For WSS (**Fig. 6B**), the highest values occurred in drainage hole #1 in all cases (~22 Pa) and decreased with additional hole distance. WSS differences of 1-12% were observed between the medium and large cylinders (right), with the greatest difference at drainage hole #2, 1-2% differences between the different CP models (middle), and <10% differences between the different patient-specific models (right).

Two pulsatile pressure waveforms (simplified periodic and hydrocephalus patient) were also applied as inlet BCs (**Fig. 7A**). The periodic waveform lead to flow rates ranging from 10-30 ml/min, while the hydrocephalus patient waveform generated smaller flow rates variations (13-17 ml/min). Comparing parameters for drainage hole #1, flow rates behaved similarly but with less pulsatility overall (**Fig. 7B**). However, when normalized against total catheter flow (**Fig. 7C**), the % flow split in each hole did not vary with time and was not significantly different from static ICP cases. The same trends were also observed with WSS over time (**Fig. 7D**), with fluctuations between 6-38 Pa with the simplified waveform and 11-16 Pa with the hydrocephalus waveform.

Experimental testing of the Strata II valve (**Fig. 8A**) confirmed the new valve followed pressure-flow curves from Medtronic (black) at a 1.0 performance setting, while the failed valve exhibited significant over drainage (red). The Codman valve (**Fig. 8B**) displayed unique pressure-flow behaviors due to its secondary SiphonGuard valve that maintained a ~20mL flowrate at excess ICPs. The new Codman valve

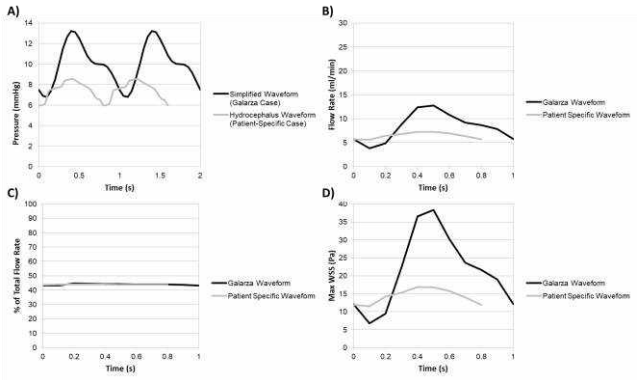

Fig 7: A) Simplified and hydrocephalus pressure waveforms [3]. Comparison of drainage hole #1 **B)** flow, **C)** normalized flow, and **D)** WSS.

displayed a linear pressure-flow relationship up to 100mHg, while the explanted valve had a lower flow rate and stayed open until 150mmHg. For dynamic testing, the Delta valve demonstrated varying drainage behaviors depending on increases in ICP, as CSF filled the ventricle model over time (**Fig. 8C**). ICP built up linearly, causing the valve to open between 8-16mmH,g depending on the valve setting, and quickly returned to a baseline ICP of approximately 5mmHg.

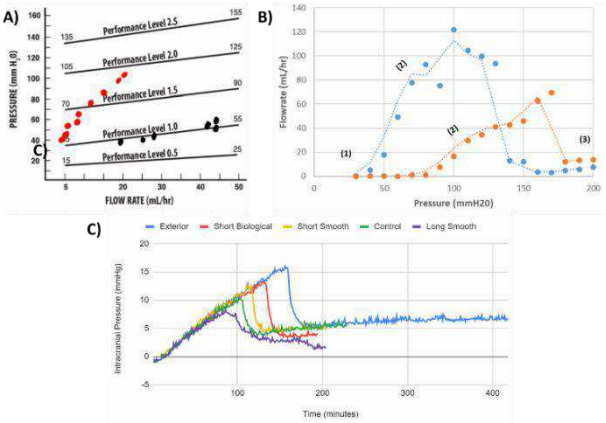

Fig 7: Static testing of new and explanted **A)** Strata II and **B)** Codman shunt valves. **C)** Dynamic testing of a new Delta 2.0 shunt valve.

DISCUSSION

Computational models of brain shunt catheters were developed, and ventricle and CP parameters varied, to determine that they do not play a significant role in catheter performance. Specifically, we determined that a simplified ventricle model will achieve the same catheter outcomes as patient-specific models. It was also determined that catheter flow rates, as well as WSSs, scaled linearly with increasing static ICP but not with pulsatile ICP. Further experimental testing of commercial brain shunt valves displayed significantly different pressure-flow behaviors between new and explanted valves and valves of different types. While the CFD studies did not include valves, future simulations will incorporate their opening and closing behaviors and be validated against the presented experimental data.

EVALUATION OF SPINE BIOMECHANICS USING MICRO-COMPUTED TOMOGRAPHY

Hutomo Tanoto (1), Yuxiao Zhou (1)

(1) Department of Mechanical Engineering, Texas A&M University, College Station, Texas, USA

INTRODUCTION

The overall prevalence of spine fracture is approximately 30.5% [1]. Due to the complicated structure of spine, its intricate biomechanical function remains inadequately understood. This study focuses on studying the biomechanics of healthy and osteoporosis human spines using a combination of micro-computed tomography and image correlation method, to characterize the 3D (three-dimensional) mechanical deformation inside the vertebrae under axial compressive loads. Investigating the biomechanics of the spine is fundamental to understanding its health and function and provides significant implications for the pathological fragility of the spine affected by various diseases such as osteoporosis.

METHODS

Mechanical testing coupled with micro X-ray computed tomography (**micro-CT**) and digital volume correlation (**DVC**) is a non-contact method that can measure both the structures and 3D full-field internal mechanical deformation vector field in bone under external forces at sub-millimeter resolution. It has been used to measure mechanical strain in engineering materials [2], [3], trabecular bone [4]–[7], knee [8], spine, and shoulder bone [9]. In the PI's prior work, this method was used to study the biomechanics of human shoulder bones [10], bones with rheumatoid arthritis [11], human jaws [12], and to numerically optimize oral surgery procedure [13], [14].

In this study, *ex vivo* mechanical tests were performed on healthy and osteoporosis human cadaveric vertebrae. Each spine was placed inside a loading device (CT5000TEC, Deben, Suffolk, UK), and the loading device was placed inside a micro-CT chamber (NSI Micro-CT System, North Star Imaging Inc., Rogers, MN) (**Figure 1**). A multi-step axial mechanical loading procedure was performed multiple CT scans were collected: no-load (Scan#1)---1000 N---hold---(Scan#2)---2000 N (or fracture)---hold---(Scan#3)---Fracture---hold---(Scan#4). Prior to each scan, the sample will be held in position for 50-minutes to relax bone from viscoelastic effect. A 30-minutes scan with 160 kV, 0.175 mA and aluminum filter will give images with isometric resolution of 25.4 µm. Image segmentation was performed on the micro-CT images using the watershed tool in Avizo 3D analysis software (Thermal Fisher Scientific, Burlington, MA) to digitally remove background and extract only the spine volume in the images. The 3D full-field mechanical deformation in spine was calculated by correlating the corresponding loaded images with images at no-load state (Scan#1) in DaVis software (LaVision Inc., Germany). Mechanical strain was calculated by taking partial derivative of the 3D deformation vector field.

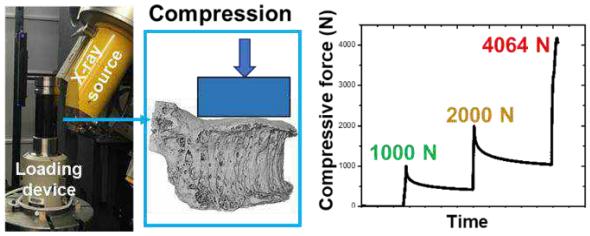

Figure 1: Experiment setup and loading profile.

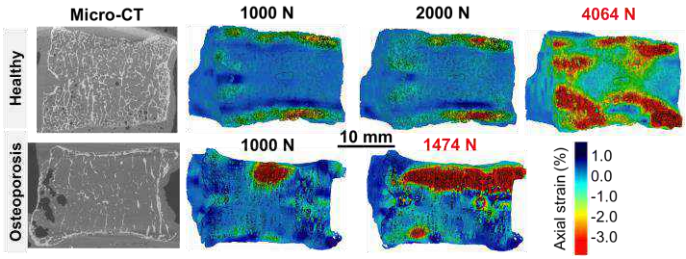

Figure 2: Axial strain distribution in healthy (T9) and osteoporosis (T10) spines.

RESULTS

The axial strain in healthy (T9) and osteoporosis (T10) vertebrae under different mechanical forces were shown in **Figure 2**. Micro-CT image shows reduced thickness and number of trabeculae in osteoporosis bone. The results indicate that under axial compressive loads, strain concentration appeared close to the endplate in both healthy and osteoporosis spine. Both healthy and osteoporosis vertebrae failed in endplate region. In osteoporosis spine, the strain range was much higher than that in healthy spine.

DISCUSSION

The complicated mechanical strain distribution in spine observed in this study is consistent with results in literature [15]–[17]. This is due to the nonhomogeneous distribution of trabeculae structure inside vertebra. This study has some limitations. First, only one vertebra was studied in each group, and a larger number of specimens should be included in future study. Second, we only added compressive mechanical forces to a single vertebra. The physiologically realistic mechanical forces experienced by spine are complicated, and the mechanical reaction in an isolated vertebra is different without the presence of surrounding vertebrae and the intervertebral disc. A more comprehensive study including more vertebrae and multi-axial mechanical loading will help understand the pathological fragility in spine with osteoporosis.

INTRODUCTION

Traumatic brain injury (TBI) is a leading cause of death and disability worldwide, affecting an estimated 10 million people annually, including both civilians and military personnel. TBI results from rapid brain tissue deformation, typically in response to an impact applied to the head. Recent research employing magnetic resonance imaging (MRI) has revealed that damage to the interface between the brain and skull occurs frequently because of TBI [1]. However, the precise transmission of motion from the skull through the interface to the brain during an impact remains unknown. This is primarily due to the challenges in simultaneously quantifying brain and skull motion in vivo [2]. Recent studies have indicated that the bone marrow of the skull provides excellent signal during non-invasive magnetic resonance elastography (MRE), suggesting its potential utility in quantifying skull-brain motion [3]. However, validation and optimization of MRI and MRE methods for skull-brain measurement is difficult since the motion is not known. Physical phantoms offer one approach to validate the methods, but most existing phantom models have been used to simulate only the brain [4]. Because understanding the specific role of boundary conditions between the marrow and brain layers is essential to validate the accuracy in characterizing the biomechanical relationship between the skull and brain, we created two phantom models to assess MRI investigations related to the mechanics of the skull-brain interface.

METHODS

Our biofidelic MRI brain phantom, namely, the skull-brain phantom (SBP), was developed using a cylindrical container, where the inside of the mold represents the brain region and the cavities inside the wall represent marrow within the skull (**Fig. 1a**). Because the amount of marrow is not uniform throughout the medullar cavity region of skull, the cavities representing marrow in the phantom were divided into eight slots. The inner brain region was filled with polyacrylamide (PAA) gel and the skull slots were filled with 100% fat and 50% fat solution at adjacent slots in alternating fashion. Two different boundary conditions were implemented in the brain region: 1) attached boundary condition, where the PAA gel sticks to the container wall ("SBPa") and 2) unattached boundary wall, where the gel had a smaller diameter and the container wall was covered with Teflon tape, preventing the gel from adhering with container wall ("SBPu"). In the mold fabrication process, two identical cylindrical molds (outer diameter: 12.2cm; inner diameter: 10.16cm; length: 20.32cm) were 3D printed using Acrylonitrile butadiene styrene (ABS) plastic for both SBP models. The bottom end caps had protrusions to fix the gel in the mold at that end, while the gel was kept free at the top end. To make it air-tight, the mold end was covered with a silicone gasket followed with an acrylic endcap tightened by nylon screws. A complete fabricated mold is shown in **Fig. 1b**.

The process of gel fabrication for these phantom models was modified from methods previously reported in the literature [4] to prevent swelling. PAA gel was used as a brain tissue simulant due to its easily tunable material properties at room temperature fabrication. PAA was the product of the cross-linking of two monomers, Acrylamide and Methylene-bis-Acrylamide (MBA). Briefly, 150.0 g of acrylamide (purity ≥ 98.0%) was dissolved in 1500 mL deionized water in a vacuum flask at room temperature to generate a 10% (weight/volume) solution. After the acrylamide was fully dissolved, 10 g of *N,N′*-methylene-bis-acrylamide (MBA, purity 99%) was added. Once the solution was homogenized, 1.30 g of ammonium persulfate was added to initiate the crosslinking of the two monomers of acrylamide. At these steps, the air was vacuumed inside the flask before and during stirring the solution. Finally, upon the addition of 2.667 ml of *N,N,N′,N′*-tetramethylethylenediamine (TEMED, purity 99%), the solution was poured immediately into the brain region of the molds following the addition of TEMED.

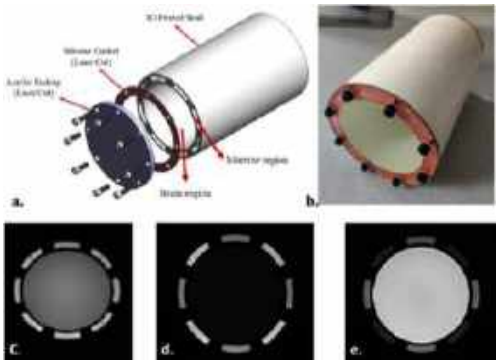

Figure 1: a) Schematic of SBP mold, b) Fabricated mold, c) T1-weighted image, d) and e) Dixon image showing fat and water in the mold correspondingly.

For the marrow, we used 100% fat and a 50% fat-water emulsion in alternating slots for both phantoms. For 100% fat, we used Crisco (Proctor and Gamble, Cincinnati, OH) vegetable shortening. The recipe of 50% fat-water emulsion was modified from previous methods [5]. For the water component, we used 10% (weight/volume) PAA solution with 200 mL deionized water and respective proportion of chemicals, as described above. For the fat component, 2 ml of Span80 (Polyoxyethylene (80) sorbitan monooleate) was added with 200 ml of peanut oil and stirred at 150°C 1100 rpm for 5 minutes. The oil solution was slowly added to the PAA solution (50 – 50 fat water mixture) at room temperature. Finally, 3.6 ml of TEMED was added to the solution while it was stirred at 200rpm. After homogenizing through stirring, the mixture was poured in the marrow slots of the SBPs.

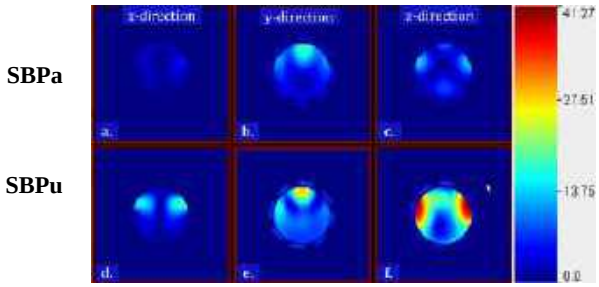

Figure 2: Displacement (μm) in x, y, z direction shown for SBPa phantom l (a-c) and SBPu (d-f) for 50 Hz.

MRE experiments were employed for preliminary testing. The phantoms were placed on a soft "pillow" driver attached to a pneumatic actuator system (Resoundant Inc., Rochester, MN, USA) with the long axis approximately parallel to the bore of the scanner. The pillow applied an excitation in the "anterior-posterior" (AP) direction, which was orthogonal to the long-axis, represented as the y-axis in all images. Using a multi-shot spiral imaging sequence designed for fat-water analysis [6], MRE displacement data were acquired in five slices for three separate scans at 30, 50, and 70 Hz, with 2.5 mm isotropic imaging resolution and the following acquisition parameters: FOV = 120×120 mm, slice thickness = 5mm, phase offset = 4, motion encoding gradient = 21.5mT/m, 2mT/m. All imaging data were acquired on a Siemens 3T Prisma MRI scanner with a 20-channel head/neck coil. MRI data processing was performed in MATLAB R2020a (MathWorks, MA, USA) to compute pixel-wise total displacements from the phase of one period of motion across the phase offsets for the simulated brain and marrow compartments. To investigate the effect of boundary conditions, *motion transmission* was computed as the ratio of average displacement in marrow regions to the average displacement in the brain.

RESULTS

A T1-weighted image for a SBPa is shown in **Fig. 1c**. A Dixon MRI sequence [7], which separates fat and water components, was also applied to visualize the brain and marrow simulants (**Fig. 1d, 1e**). As expected, the marrow slots containing 100% fat exhibited a brighter signal in the fat component images, and the fat-water emulsion slots were visible on both fat and water images. The displacement components at 50Hz (**Fig. 2)** showed a similar pattern in both phantoms with an increase magnitude in SBPu compared to SBPa. **Fig. 3** shows the total displacement in both phantoms at different frequencies for a central slice. Minimal displacement was also observed in regions with fat. The motion transmission was plotted along different frequencies in **Fig. 4**. While there is a reduction in relative displacement with increasing frequencies is shown in SBPa (from 30 Hz to 70 Hz) and SBPu (from 30 Hz to 50 Hz), the relative displacement increased at 70 Hz for SBPu, likely due to the lack of time to transmit motion at higher frequencies.

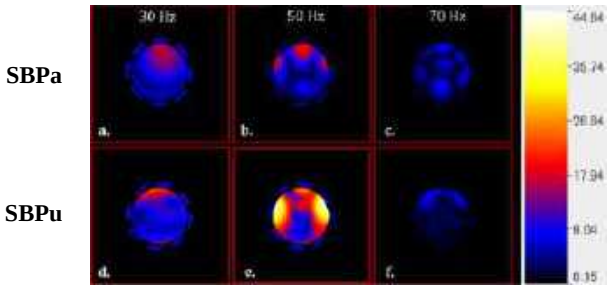

Figure 3: Displacement (μm) shown for SBPa (a-c) and SBPu (d-f) in a central slice for 30, 50 and 70 Hz.

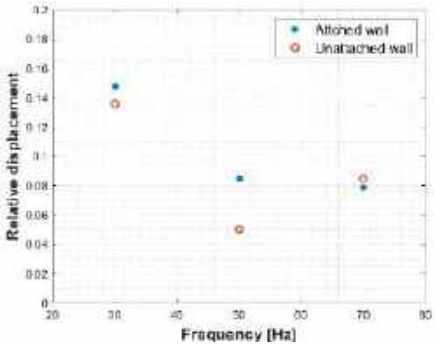

Figure 4: Relative displacement between marrow and brain region showing the effect of boundary conditions at 30, 50 and 70 Hz.

DISCUSSION

The transmission of harmonic motion was studied using two different phantom models for different frequencies, and the results suggest that the relative transmission of motion was higher with an attached wall compared to the unattached wall. Due to the lack of attachment to the container wall, the oscillation imparted more motion in the SBPu model at lower frequencies. In addition, the pattern of displacement was different at different harmonic frequencies, suggesting a frequency dependency in the motion of the PAA gel representing brain. The developed phantoms will allow investigations into alternative metrics and acquisition techniques to maximize sensitivity to changes in skull-brain interface that can subsequently be used for clinical research. In addition, these data could be further used to investigate the change in viscoelastic properties of the material.

METHOD FOR EXTRACTING INTACT SKULL-BRAIN SAMPLES FOR EX-VIVO MECHANICAL TESTING

INTRODUCTION

Traumatic brain injury (TBI) results from trauma to the head causing mechanical damage to the brain tissue. While TBI fatalities have remained constant at 18.5 per 100,000 since 2010, TBI hospitalization rates have tripled from roughly 70,000 in 2006[1] to over 210,000 in 2020[2], disproportionally affecting youth athletes (largely unreported[3]), elderly populations (32% of hospitalizations in 2020[2]), and military personal (40-60% of deployed service members[4]). Therefore, while the efforts to reduce TBI related deaths have been largely successful, further research is required to understand nonfatal injuries. A range of complex physical symptoms including loss of consciousness, headache, nausea, and dizziness[5] require coupling head-level mechanical loading, tissue-level mechanics, and ultimately cellular-level (axonal) strains to understand TBI[6].

A critical tool in this process is finite element (FE) modeling, which predicts cellular-level strains by accurately modeling the organ- and tissue-level response of the brain to load. Boundaries and interfaces, including connections between adjacent tissue types, dramatically affect model prediction accuracy. The complex anatomy of the brain gives rise to multiple interfaces between adjacent types of thin, interfacial tissues, such as the meninges (Fig 1). Previous FE models have focused on the cortex and skull, often neglecting[7,8] or treating the meninges as a simple, uniform tissue[6,9,10] with material behavior based on isolated tissues.

However, obtaining intact samples of the skull-brain interface for *ex-vivo* mechanical testing has proved difficult[11] due to the immense stiffness gradient from the skull (G = 1.38 GPa[12]) to the cortex (G = 1.43 kPa[13]). During dissection, the outer most layer of the meninges (dura mater) tends to separate from the skull due highly organized collagenous sheets[14], while the inner most layer (pia mater) tends to separate from the cortex since it is often only a single cell thick[14] (Fig. 1). The challenge in maintaining intact tissues is exacerbated by an average meningeal thickness of 500 µm in humans (300 µm in pigs) and a significant amount of fluid flow through the arachnoid mater.

Therefore, the objective of this study was to demonstrate a method for obtaining intact samples of the skull-brain interface for *ex-vivo* mechanical testing.

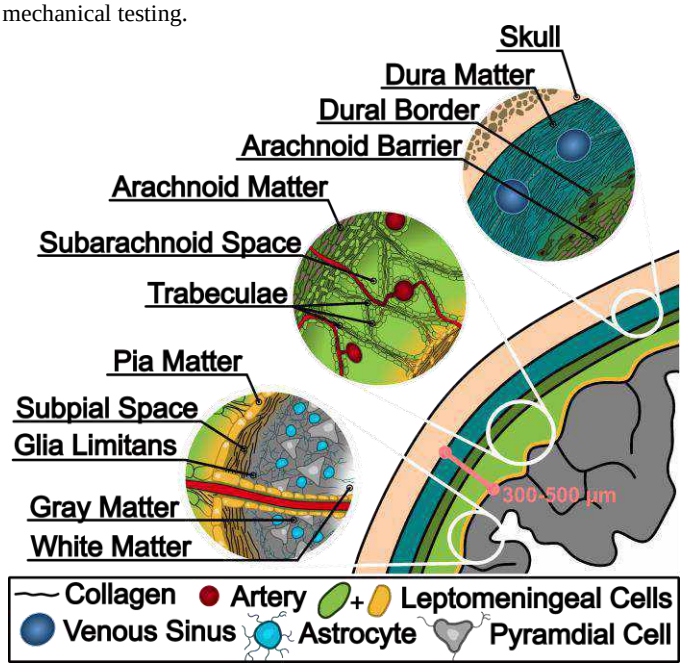

Figure 1: Skull-brain interface anatomy highlighting the dura mater, arachnoid mater, and pia mater that make up the meninges.

METHODS

Porcine heads were collected from the Swine Research and Teaching Center (SRTC), Arlington, WI. Tissue was collected from skeletally mature animals (n = 2, Female, 2.5 and 4 years) from another

study (IACUC #A006267-R01-A01) and were sacrificed via penetrating captive bolt. The most superior portion of the brain was not affected by the bolt. The porcine heads were separated between the occipital bone and first cervical vertebra, creating an access plane at the most caudal part of the mandibles and occipital bone (Fig 2A). Tissue was collected within 1 hr of sacrifice, transported (1 hr) on ice, and stored at -20°C before sample collection. While the effect of post-mortem stiffening[15] and temperature[16] on cortex and meningeal mechanics have been thoroughly investigated, the tissue was used to demonstrate a sample collection procedure, and the freezing step can be eliminated in future testing.

The skull was exposed by cutting through the soft tissue starting lateral to the caudal occipital bone and cutting to the dorsorostral parietal bone (Fig 2B). Using an 18 TPI reciprocating saw, part of the mandible, temporal bone, and zygomatic bone were removed with a horizontal cut parallel with the most ventral point of the eye socket. The outer periosteum of the remaining temporal bone and parietal bone was removed with scalpel and forceps to reduce potential clogging of the bone saw blade. Using a 36 TPI stainless steel bone saw at 100-200 RPM, the temporal and parietal bones were gently ground away until the dura was exposed (Fig 2B).

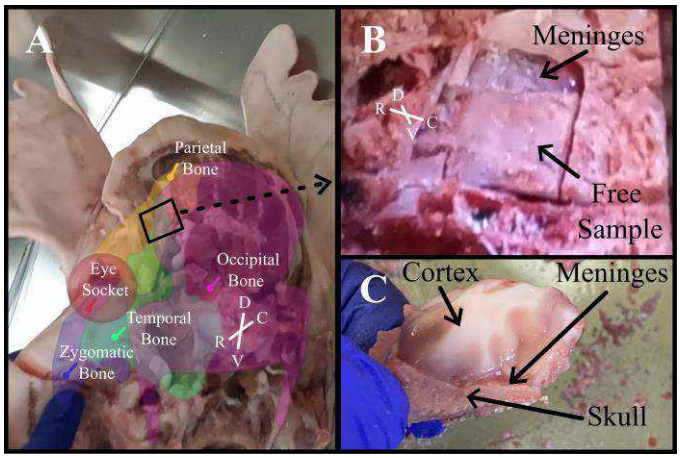

Figure 2: Diagram of (A) cut plane with bones indicated for reference, (B) separated skull, and (C) final removed sample (marked as the box in A). Dorsal (D)-Ventral (V) and Caudal (C)-Rostral (R) axes are shown for reference.

Two sets of orthogonal parallel cuts were made ~30 mm apart next to the exposed dura (Fig 2B), using the thickness of the skull as a reference for cut depth. The dura directly below the cuts often separated from the skull; therefore, the disconnected portions of the freed skull were slowly ground away until only the connected portions remained. The meninges and cortex were cut using a scalpel beginning ~10 mm away from the sample and moving towards the sample area to avoid skull-dura separation. A scalpel was inserted in the occipital bone spinal column entrance to make a horizonal cut ~20 mm inferior to the most dorsal surface of the cortex. To remove the sample from the head, forceps grasped the free skull end to gentle pull upwards while the inserted scalpel gentle pressed upwards on the cortex.

The weight of the cortex was enough to cause separation at the skull-dura and pia-cortex interface (Fig 3C). Therefore, a simple proof-of-concept separation test was captured via highspeed camera (Phantom V211 at 100 FPS). The sample was gripped with the skull superior to the cortex, allowing the weight of the cortex to naturally separate the interface.

RESULTS

After development of the extraction method, 2 of 3 attempts resulted in samples. Throughout the separation test, multiple portions of the skull-dura and pia-cortex interface failed. An isolated portion of the pia-cortex interface is shown in Figure 3 where a clear separation was visible over 600 ms. Separation began at the most superior portion of the interface (Fig. 3B) and continued downwards (Fig. 3C) until a new equilibrium was established (Fig. 3D).

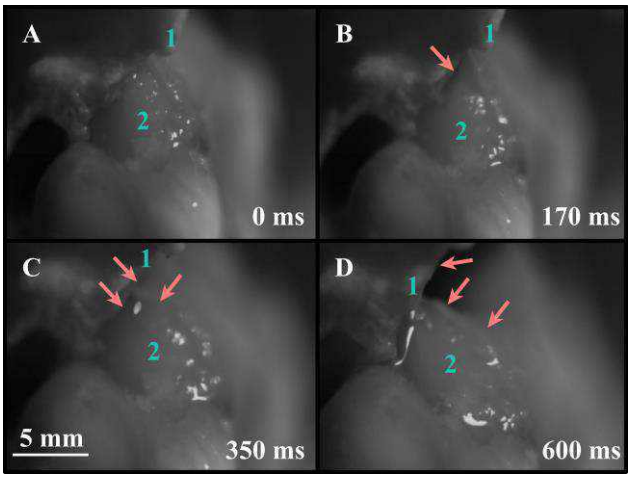

Figure 3: Separation between meninges (1) and cortex (2). (A) Intact boundary, (B) initiation of separation at red arrow, (C) progression of separation at red arrows, and (D) final equilibrium after separation.

DISCUSSION

This study provides a method for extracting intact skull-brain interface samples for *ex-vivo* mechanical testing. Preliminary mechanical tests indicate that adjacent layers were connected upon extraction and separated after an applied load (Fig. 3). The sample tended to separate at the dura-skull interface compared to the pia-cortex interface. Internal separation of the meninges could not be observed.

Future research will develop steps to obtain smaller samples (10 mm x 10 mm) with less cortical tissue (~10 mm) to reduce natural separation due to the weight of the cortex. Once separated, a phosphate-buffered saline (PBS) drip will be used to maintain cortical tissue hydration and minimize adhesion of the cortical tissue and scalpel. Finally, a wider paddle instead of a scalpel will be used to support the bottom of the sample during the final removal step. In conclusion, this study presents a novel method for extracting intact samples of the skull-brain interface that can be used for *ex-vivo* mechanical testing.

INJECTABLE SYNTHETIC PLATELET-BASED THERAPY ENHANCES CLOT FORMATION IN SYNOVIAL FLUID JOINT INJURY MODEL

INTRODUCTION

Anterior cruciate ligament (ACL) injuries can occur due to sports or other activities and constitute a major clinical problem, affecting about 200,000 people annually in the United States.[1] While extra-articular injuries of the joint, such as medial collateral ligament (MCL) injuries, are able to heal, intra-articular injuries, such as ACL injuries, have a limited healing capacity. This is believed to be due, in part, to the proteolytic environment of the synovial fluid (SF) surrounding the ligament and the low presence of necessary clotting factors such as fibrinogen and thrombin hindering the healing process by not allowing fibrin scaffolds to form (Fig. 1A).[2, 3] During early healing, platelets interact with fibrin to form a clot at the injury site and to attract cells (Fig. 1B).[4] Fibrin-based therapies have been investigated to enhance healing in the joint but lack the ability to maintain stable clots for cell infiltration in proteolytic environments like SF.[2] Additionally, SF is known to become less viscous due to overproduction of proteases upon joint injury which may further reduce the ability of clots to form and healing ability to occur.[5] Novel synthetic platelet-like-particles (PLPs), made with fibrin-binding motifs coupled to ultra-low crosslinked (ULC) poly(N-isopropylacrylamide) microgels, are highly deformable and have been shown to induce stable fibrin clotting and fibrin scaffold retraction by mimicking natural activated platelets in plasma.[6] Prior work has indicated that incorporation of PLPs in addition to fibrinogen and thrombin into synovial fluid can induce ideal levels of clotting and can further promote fibrin stability.[7] **The objective of this study is to assess clot-forming ability of PLPs in a low-viscosity SF joint injury model and a high viscosity healthy SF model. We hypothesized that PLPs can improve mature and stable clotting in low viscosity SF.**

METHODS

Pooled porcine synovial fluid collected from 6-9-month old male and female pigs (Innovative Research, Inc) were used to assess clot formation. Clots were formed on glass slides using a solution of 70% (v/v) synovial fluid, 1X HEPES buffer, 2 mg/mL purified fibrinogen, and 0.5 U/ml of thrombin. In PLP treatment groups, 0.5 mg/mL PLPs were added to the clot mixture. As previously described, ULC poly-NIPAM-co-acrylic acid particles were coupled to a fibrin fragment-E-targeting antibody to synthesize PLPs.[6] After 2 and 24 hours of polymerization, z-stack images of clots were taken by confocal microscopy (Zeiss 880). Images were analyzed for fibrin density and fibrin branching using ImageJ by quantifying black to white pixel ratio and maximum number of branches per fiber, respectively, as compared to a SF + fibrinogen-thrombin (FT) clot control. The clot mechanics of each group was assessed under oscillation using an Anton-Paar MCR 92 rheometer (1% shear strain, 1 Hz frequency, 25°C, 15 hours). Low viscosity (LV) SF, representative of an injured joint, and high viscosity (HV) SF, modeling a healthy joint, with clotting factors were compared to those with added PLPs at various concentrations.

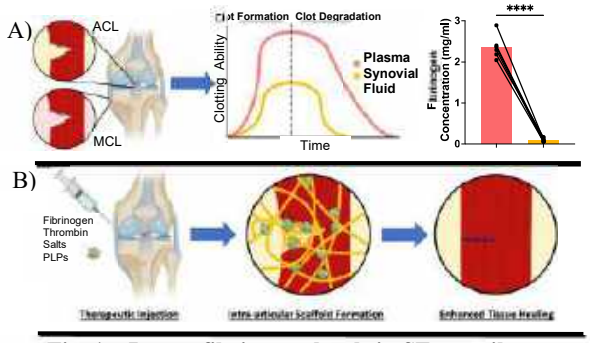

Fig. 1 – Lower fibrinogen levels in SF contribute to improper clotting (A). The therapeutic mechanism of action of PLPs combined with clotting factors are shown for ACL injury healing (B). ****=p<0.0001

To create low viscosity SF (injury model), 10 μg/ml of

hyaluronidase was mixed into high viscosity (healthy) SF and incubated in a water bath (37°C) for 1 hour. Afterwards, the same procedure as non-treated SF was used for inducing clotting and performing analyses comparing naturally low and high viscosity SF to the treated SF with and without PLPs.

To check if the studied FT matrix allows prolonged cell retention and activity, bovine fetal mesenchymal stem cells (MSCs) were seeded onto FT and FT+PLP clots at 0.5 mg/ml PLPs. Confocal z-stack images were taken after day 1 and 6. An alamarBlue metabolic activity assay was performed after 21 days.

A one or two-way ANOVA test (depending on groups), followed by Tukey's multiple comparison's test, was used to determine statistical significance between groups (alpha=0.05).

RESULTS

The addition of clotting factors (fibrinogen and thrombin) induced clotting in synovial fluid within 2 hours as determined by significantly higher scaffold density analysis (Fig. 2A). Notably, the addition of at least 1.0 mg/ml PLPs resulted in significantly higher scaffold density and branching in LV SF compared to SF+FT. However, adding PLPs to high viscosity (HV) SF showed no further significant clotting after the addition of clotting factors. Rheological testing also indicated significantly higher maximum shear storage modulus achieved by adding PLPs to LV SF + FT and lower overall time to reach maximum stiffness and clot degradation in LV SF than HV SF (Fig. 2B).

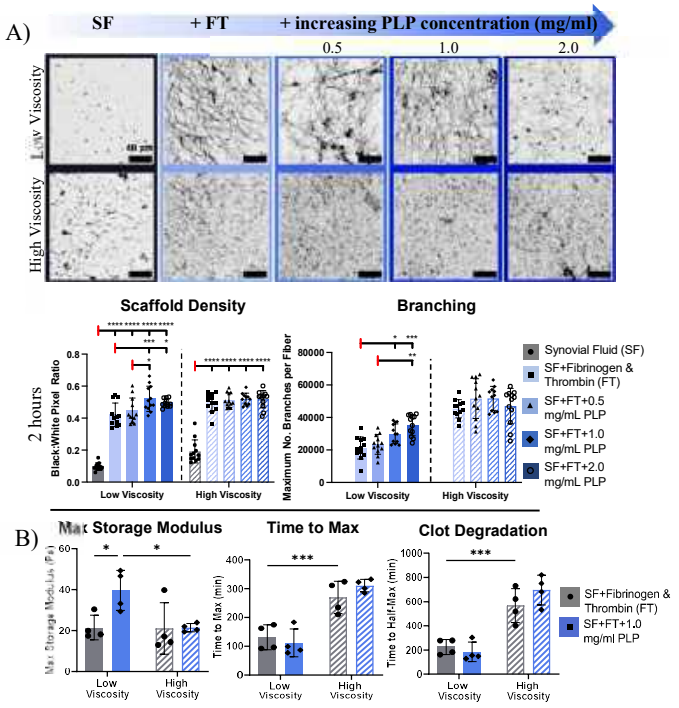

Fig. 2 – Effect of fibrinogen and thrombin (FT) with doses of PLPs on clot formation within low and high viscosity SF. Confocal z-stack images of clots taken 2 after polymerization with scaffold density and fibrin branching analyzed (A). Rheological analysis of clots +/- PLPs over 15 hours (B). *=p<0.05; **=p<0.01, ***=p<0.001; ****=p<0.0001

The addition of hyaluronidase to high viscosity SF achieved similar scaffold density to naturally LV SF and significantly lower maximum storage modulus than before treatment (Fig. 3A). Treated SF with clotting factors FT was visibly less dense than non-treated HV SF, more similar to LV SF (Fig. 3B). Scaffold density and branching analysis showed the significant effect of PLPs in increasing scaffold density and branching in hyaluronidase-treated SF but not in naturally HV SF (Fig. 3C.) Additionally, FT and FT PLP clots were shown to support cell retention and metabolic activity for the length of the cell study (21 days, data not shown).

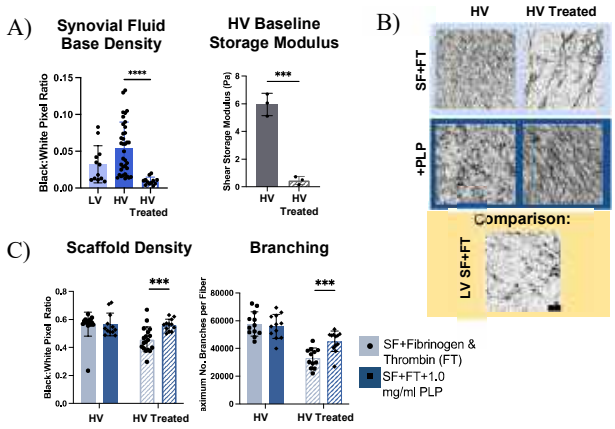

Fig. 3: Hyaluronidase (HAase) treated HV SF acts as a joint injury model comparable to LV SF. Characterization compared treated SF to LV and HV SF by confocal scaffold density analysis and rheology (A). Confocal images (2hrs) of clots within HV and treated HV SF with clotting factors and 1.0 mg/ml PLPs is compared to LV SF +FT (B) and analyzed (C). ***=p<0.001

DISCUSSION

PLPs, along with clotting factors fibrinogen and thrombin, were able to successfully establish stable fibrin clots in LV SF, simulating a joint injury environment. These results support our hypothesis. PLPs allowed stable fibrin network formation, required to withstand the fibrinolytic environment of the surrounding SF, whereas non-PLP groups were less stiff. Specifically, the addition of at least 1 mg/ml of PLPs was shown to promote denser, highly branched, and more stable clotting in both LV SF and HAase treated SF via scaffold density, branching, and rheological analyses, respectively, within 2 hours of polymerization. Consistent with literature on PLPs in dermal applications[6], it allows initial local stiffness and maintained structure of the scaffold, important in the healing process to allow for cell-infiltration and tissue remodeling. A limitation is that the presence of enzymatic activity within the SF was not measured. However, even for the same SF, lowering the viscosity was able to recreate the experimental findings for the naturally LV SF environment, indicating the potential of the model to simulate some aspects of the joint injury environment. Future studies will explore cell viability and migration rates of cells embedded in a PLP-laden FT scaffold and the ability of this injectable therapeutic to enhance ACL healing in-vivo.

EVALUATING THE PERFORMANCE OF EXTENDED KALMAN FILTER VS. UNSCENTED KALMAN FILTER FOR DISPLACEMENT ESTIMATION

INTRODUCTION

Lumbar mobilization is a technique that has been used by physical therapists as a standard intervention for lower back pain [1]. It involves a clinician (such as a physical therapist) applying small oscillatory motion to the lumbar spine. These motions are categorized into four grades [2]. The levels of mobilization are distinguished by both the range of oscillation amplitudes and the maximum displacement [3]. The therapist places the pisiform surface of their hand or both thumbs over the selected spinous process of the patient's lumbar spine. The double-handed grip used for manual manipulation provides better control and precision during mobilization. While spinal mobilization is pivotal in the realm of physical therapy, it relies on subjective assessment of the motion by the clinician. This can result in variability that can impact the effectiveness of the treatment and make it difficult to train students in the techniques.

An inertial measurement unit (IMU) is a small and inexpensive device that can be used to quantify lumbar mobilization [4]. IMUs contain a 3-axis of an accelerometer, a 3-axis of a gyroscope, and a 3-axis of a magnetometer that can capture the small, oscillatory, hand motions. To determine hand orientation and displacement fusion of the data from these sensors is required using different filtering techniques such as a Kalman Filter [5]. In this research, the use of an Extended Kalman Filter and an Unscented Kalman Filter were compared to Bias-corrected Integrated Acceleration for sensor fusion of the IMU data.

METHODS

For this study, an Arduino Nano BLE Sense microcontroller connected to the inertial measurement unit (Adafruit Absolute Orientation Sensor, BNO055). A circuit board is designed to integrate with the hand wrap device shown in Figure 1. The IMU's displacement can be determined by double integrating of the acceleration data over time. However, this integration process is susceptible to signal drift owing to signal noise. To mitigate this issue, filtering techniques such as Kalman Filter are employed on the IMU data. The Kalman Filter leverages a mathematical model and IMU sensor measurements to real-time estimate the system's state. For these calculations, the rotation around three axes of a Cartesian frame $R_x(\varphi), R_y(\theta), R_z(\Psi)$ are defined in the body frame of the hand in local North-East-Down (NED) coordinate system.

Figure 1: Hand wrap prototype

Extended Kalman Filter (EKF)

The Kalman estimator is designed to determine the position vector in a two-dimensional Cartesian coordinate by updating the Kalman state vector recursively. The state vector, denoted as X, is represented as a 6-by-1 column vector, encompassing position components (x and y), velocity components (V_x and V_y), and acceleration components (a_x and a_y).

$$X = \begin{bmatrix} x \\ y \\ V_x \\ V_y \\ a_x \\ a_y \end{bmatrix} \quad (1)$$

The state model is based on the classical laws of motion.

$$x = x_0 + V_x.dt \quad (1)$$
$$y = y_0 + V_y.dt \quad (3)$$
$$V_x = V_{x0} + a_x.dt \quad (4)$$
$$V_y = V_{y0} + a_y.dt \quad (5)$$

The filter algorithm is assumed to be a discrete time linear dynamic system that can be represented by the state space model:

$$x_k = F_k x_{k-1} + B_k u_{k-1} + w_k \quad (6)$$

where F_k is the state matrix, B_k is the input matrix, u_k is the control vector and w_k is a zero-mean, gaussian distributed process noise. Please note that since the system is time variant F, B depend on the time k and for LTI systems, they can be assumed to be a constant matrix. The measurement assumed to be a linear function of the state variable shown as:

$$y_k = H_k x_k + v_k \quad (7)$$

where H_k is the measurement matrix and v_k is a zero-mean, gaussian distributed measurement noise and w_k and v_k are mutually independent. A fundamental constraint of the Kalman filter lies in its dependency on both the dynamic system and measurement functions being linear with respect to the state variables. To address this limitation, the extended Kalman filter (EKF) acts as a modified version of the standard Kalman filter, specifically designed to accommodate nonlinearities in either the system or measurement models. The state variable can be written as:

$$x_{k+1} \approx f(\bar{x}_k, u_k) + \frac{\partial f}{\partial x} . (x - \bar{x}_k) + w_k \quad (8)$$

$$y_k \approx h(\bar{x}_k) + \frac{\partial h}{\partial x} . (x - \bar{x}_k) + v_k \quad (9)$$

where $\frac{\partial f}{\partial x}$ is the Jacobian at the current estimate in real time which defines F_k and $\frac{\partial h}{\partial x}$ is the Jacobian which update the covariance estimate.

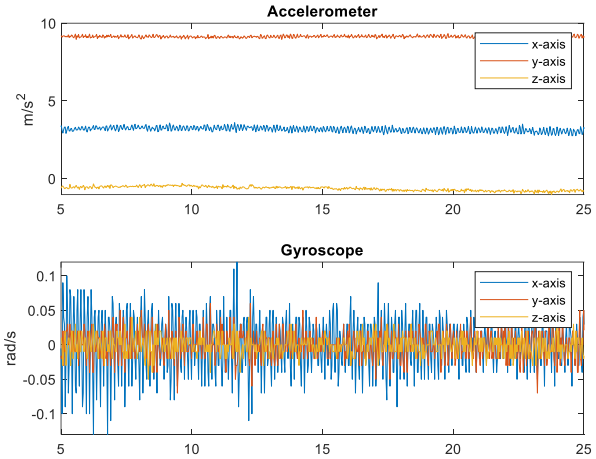

Figure 2 Raw accelerometer and gyroscope data from the IMU during grade III lumbar mobilization. Oscillation is primarily observed in the x axis while some rotation is also observed.

Unscented Kalman Filter (UKF)

An Unscented transform tracks the characteristics of a nonlinear distribution and Unscented Kalman Filter is chosen to find the propagation of the sigma points through the assigned nonlinear functions. The unscented transform is applied at prediction and update steps. The number of sigma points are 2L +1 where L shows the number of the states, and the scaling factors are assumed to be $\lambda = \alpha^2(L + \kappa) - L, \alpha = 10^{-3}, \beta = 2, \kappa = 0.$

The mean and covariance can be computed as

$$\hat{x}_{k|k-1} = \sum_{i=0}^{2n} W_i^{(m)} \hat{x}_{k|k-1}^i \quad (10)$$

$$p_{k|k-1}^x = \sum_{i=0}^{2n} W_i^{(c)} (\hat{x}_{k|k-1}^i - \hat{x}_{k|k-1})(\hat{x}_{k|k-1}^i - \hat{x}_{k|k-1})^T + Q \quad (11)$$

where $W_i^{(m)}, W_i^{(c)}$ are the weights can be found as a function of the scaling factors which contain some prior information about the states. The UKF is derivative-free and gives us second order accuracy.

Integrated Acceleration Data

The two filters were compared to the displacement obtained by the double integration of the raw accelerometer data.

Data Collection and Assessment

Motion data was collected during the grade III lumbar manipulation motions performed by an experienced physical therapist. This data was part of a pilot study on measuring hand movement during lumbar mobilization and was approved by the University of Kansas Medical Center Human Subjects Committee.

RESULTS

The estimation problem was implemented in MATLAB. The sampling frequency of the wearable device was calculated to be 41.25 Hz. Figure 2 shows the raw accelerometer and gyroscope readings from the IMU sensor. Looking at the estimated displacement from these signals, significant drift was observed in the integrated acceleration data after 50 seconds. The UKF filter was found to have some initial large oscillations before obtaining a stable, drift free, assessment of the displacement oscillations. The EKF filter was also found to be largely drift free but appears to have some error in estimating oscillations relative to the integrated accelerometer data over short time windows.

DISCUSSION

While IMUs have the advantage of small size and low cost relative to other motion capture technology, IMUs may not be the first choice for position estimation. Apart from addressing the displacement estimation drift due to integration of acceleration, there are challenges with removing gravitational acceleration readings. These obstacles can be overcome by using high pass filtering and sensor fusion algorithms such as complementary filters, Madgwick filters, or Kalman filters to mitigate the effects of gravitational acceleration and integration drift. This study found that both the Extended Kalman Filter (EKF) and Unscented Kalman Filter (UKF) algorithms can be employed for position estimation. UKF's superior ability to track mean and covariance through a method known as the unscented transform appears to be beneficial in comparison to EKF. Future research will examine the performance of these filters against other of displacement such as motion capture systems.

BUBBLER SYSTEM DESIGN FOR REMOVAL OF OXYGEN FROM MEDIA IN AN OPEN TESTING ENVIRONMENT

Margaret H. Capalbo (1), Spencer E. Szczesny (1,2)

(1) Biomedical Engineering, The Pennsylvania State University, University Park, PA, USA
(2) Orthopaedics and Rehabilitation, The Pennsylvania State University, Hershey, PA, USA

INTRODUCTION

Tendinopathy affects approximately 5% of people at some point during their lifetime, but little is known about what causes the disease [1]. Recent data suggest that hypoxia is associated with early tendon degeneration [2]. Additionally, our own recent data from a tendon explant model show that tendon degeneration is induced with fatigue loading only under hypoxic conditions. However, understanding the mechanism linking hypoxia and tendon degeneration is difficult since adjusting oxygen levels for in vitro experiments is usually limited to closed environments (e.g., incubator, microscope enclosure). Specifically in the case of studying tendon degeneration in an explant model, there is a need for a system that can deoxygenate an open in vitro environment to study the relationship between hypoxia, mechanical loading, calcium signaling, etc. This requires a gas bubbler system that is capable of driving oxygen levels in the media bath down from 21% (typical atmospheric concentration) to 8% or even 3%, which are physiologic and hypoxic oxygen levels, respectively, for rodent Achilles tendons [3]. Therefore, the objective of this study was to build and optimize a bubbler system that will bring oxygen levels of the tendon explant environment to 3%.

METHODS

Bubbler System Design: The bubbler consisted of a 1000 ml glass reservoir, two peristaltic pumps, two potentiometers, tubing, and a basin (Fig. 1). A QWORK 1/4" Flare Inlet and Outlet Connection Nitrogen Flow Indicator was used to control the rate of nitrogen flow from a nitrogen gas tank into an opening in the lid of the reservoir to deoxygenate the bottle. The reservoir's lid had a total of four ports; the two with tubing from the pumps and the free port were sealed, while the port with the nitrogen tube was unsealed to allow extracted oxygen and excess nitrogen out of the reservoir. Each pump had the capability of a flow rate up to 150 ml/min and was connected to a 100 Ω potentiometer to control the flow. Tubing with an inner diameter of 3/16" and a length of 30.5" was attached to the inlet and outlet of each pump. The inlet of one pump and the outlet of the other pump were placed in the reservoir with the opposite configuration placed in the basin to create a closed loop system. The Creality Ender-3 3D printer and PLA filament were used for the printing of the testing basin.

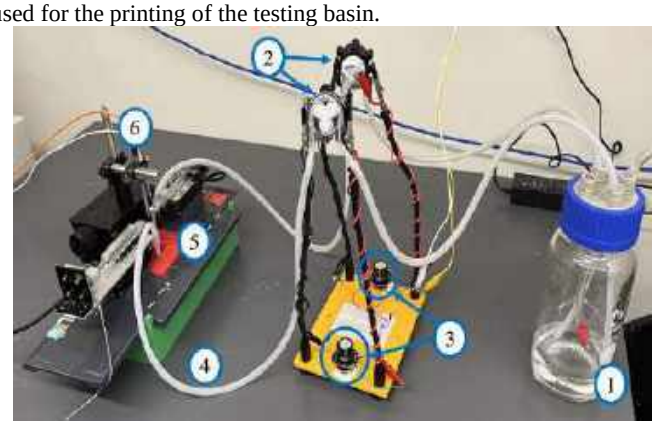

Figure 1: Schematic of the bubbler design: reservoir (1), peristaltic pumps (2), potentiometers (3), tubing (4), basin (5), oxygen and temperature sensors (6). Not pictured: nitrogen tank and flow rate indicator.

Design Optimization: Three flow rates (35, 55, 80 ml/min), three total media volumes (100, 200, 300 ml), and three basin designs were tested to determine the optimal bubbler design. Basin designs were adjusted to provide three different combinations of surface area-to-basin volume ratio and basin-to-total volume ratio (Table 1). A constant flow rate of nitrogen into the reservoir was maintained at 65 cubic feet per hour. Water was added to the reservoir, which was primed for 20 minutes for the water to reach a deoxygenated state at room temperature. A PyroScience OXF1100 oxygen sensor and Pt100 temperature sensor were connected to a FireSting-O2 oxygen meter and placed in the basin to measure the oxygen saturation. The pumps were turned on and

oxygen saturation was collected over 15 min. Between each combination of testing parameters, all water was returned to the reservoir and primed.

Table 1: Properties of experimental basins

	V (ml)	SA (cm^2)	SA:V (cm^2/ml)	V_b:V_t (100 ml)	V_b:V_t (200 ml)	V_b:V_t (300 ml)
1	4.80	6.40	1.33	0.048	0.024	0.016
2	8.80	17.60	2.00	0.088	0.044	0.029
3	6.48	8.10	1.25	0.065	0.032	0.022

Data Analysis and Statistics: Two time points (5 min and 15 min) were chosen to measure the stability of the oxygen concentration in the basin. To account for signal noise, the last 15 sec of data prior to each time point were averaged. Since the measurements received from the oxygen sensor were in terms of oxygen saturation (0 – 100), these values were converted to the percentage partial pressure of oxygen (P) using,

$$P = 21s/100 \quad (1)$$

where s is the oxygen saturation. The effect of the basin volume-to-total system volume (Vb:Vt) on the oxygen levels was tested via a linear regression. All other parameters were tested for significance with a one-way ANOVA followed by Tukey's post-hoc test. Significance was set to $p<0.05$.

RESULTS

Oxygen levels were only significantly affected by the total system media volume (Fig. 2). While oxygen levels were inversely proportional to the basin volume-to-total system media volume ratio (Vb:Vt), the effect was not statistically significant (p=0.12) (Fig. 2A). The oxygen levels with a 200 ml total system volume was significantly lower than 100 ml and 300 ml (Fig. 2C). There was no effect of surface area-to-volume ratio of the basin or pump flow rate on oxygen levels. The lowest oxygen level after 15 min was 2.84%, which was achieved using 200 ml with Basin 1 at a pump flow rate of 80 ml/min (Table 2). In general, the oxygen level increased over time from 5 to 15 min, with a significance difference between the time points.

Table 2: O_2% for Basin 1 in relation to all other parameters

Basin 1	100 (ml)		200 (ml)		300 (ml)	
	5 min	15 min	5 min	15 min	5 min	15 min
35 (ml/min)	7.858	7.273	2.896	4.758	4.281	6.383

DISCUSSION

This study presents a simple bubbler system to deoxygenate media in an open environment. The bubbler can reach a minimum oxygen level of 2.84%, which is a hypoxic state for rodent Achilles tendons [3]. Additionally, many combinations grant 8% oxygen, which will enable comparison to physiologic oxygen responses of rodent Achilles tendons [3]. The only factors significantly impacting the oxygen level were total system media volume and time. The optimal total system media volume is 200 ml likely because it is small enough to be easily deoxygenated but large enough to provide a stable reservoir of deoxygenated water. While not statistically significant, the trend toward lower oxygen levels with lower Vb:Vt makes sense since a small basin volume lowers the amount of media exposed to air and allows for reoxygenation. However, it was surprising that the basin surface area-to-volume ratio was not significant, which suggests that the surface area exposed to the atmosphere did not cause enough of an oxygen exchange to alter the oxygen percentage. Still, the fact that the oxygen level increased over time suggests that oxygen was reentering the media. It is unclear if 15 min is sufficient for the system to reach equilibrium, which is important for long experiments. Still, this system will enable experiments requiring oxygen control in an open environment. Therefore, the role of oxygen in tendinopathy as well as possible oxygen treatments can be further investigated with this system.

A NOVEL METHOD FOR STUDYING MECHANOTRANSDUCTION: COMPLEX FORCE FREQUENCY APPLICATION USING MAGNETIC VORTEX MICRODISCS

Matthew J. Holler (1), Elena A. Rozhkova (2), Valentine Novosad (3), Scott T. Wood (1)

INTRODUCTION

The current understanding of how cells respond to static and dynamic mechanical forces, particularly as it relates to mechanotransduction, is limited by the lack of an accurate and reliable way to precisely apply mechanical forces using complex frequency profiles in a research environment.

The primary challenge for this type of research lies in the empirical approach that is widely adopted for determining discrete frequencies of applied forces in mechanotransduction studies. This fails to accurately determine the optimal frequencies for force application and is made even less reliable due to the complex nature of cellular motions and intracellular responses to mechanical stimulation.

A method to precisely apply mechanical forces using physiological frequency profiles would deeply enhance the study of mechanotransduction. This would not only provide further tools to grow the fundamental understanding of cellular biology, but also lay a framework for innovative new therapeutic strategies, particularly in diseases where mechanotransduction plays a key role in the pathophysiology [1].

To gain a deeper understanding into the mechanotransduction mechanisms of chondrocytes, we have proposed the use of biofunctionalized magnetic vortex microdiscs for the purpose of applying tensile forces to specific cellular integrins. Magnetic vortex microdiscs, when exposed to an alternating magnetic field, can induce measurable and specific mechanical forces at complex frequency profiles to a single cell. They can provide the specificity needed to appropriately observe changes in cellular behavior such as the catabolic force or frequency thresholds for specific integrins. To accomplish this goal, we will employ the use of a very simple electromagnet built and validated in-house. An example of an application of these disks would be to track α5β1 and α1β1 integrins by measuring downstream a myriad of appropriate markers to answer questions such as: How do different levels of static and dynamic tensile forces affect the cellular stress response?

METHODS

It was important to select the optimal design of the magnet system in accordance with the experimental requirements that were posed. The magnet and disk system would be required to apply a controlled force in the range of 5 to 210 pN across the sample. Any magnetic field should be confined to the experimental area and uniform throughout the sample. It was decided that the disks would provide a much higher threshold of control when applying dynamic motion when compared to magnetic beads that have been previously used for similar applications [2].

To properly validate the relationship between the coil voltage (V) and the resulting magnetic field (H), we employed the use of COMSOL for all pre and post construction modeling. This modeling was corroborated using a handheld magnetometer. The force applied to the integrins by the disks will be calculated according to equation 1.

The described process for disk manufacturing involves fabricating magnetic disks (MDs) on a silicon wafer. It begins with the application of photoresist on the wafer, followed by UV exposure through a mask to create a pattern. An organic solvent removes unexposed photoresist. Then, a 5 nm gold underlayer, 60 nm of permalloy, and another 5 nm gold layer are deposited using magnetron sputtering. The MDs are released from the wafer in acetone using a lift-off process. This process enables cost-effective production of uniformly sized MDs with a specific magnetic spin state for use in magnetic storage applications.

The disks are manufactured in conjunction with collaborators from the Center for Nanoscale Materials (CNM) located within Argonne National Laboratory. The final part of disks manufacturing is application of a 5 nm gold coat for the enhancement of biocompatibility and functionalization [3].

Equations

$$(1) \quad F(t) = \frac{2m(t)*H(V,t)}{\pi\beta(t)E}$$

RESULTS

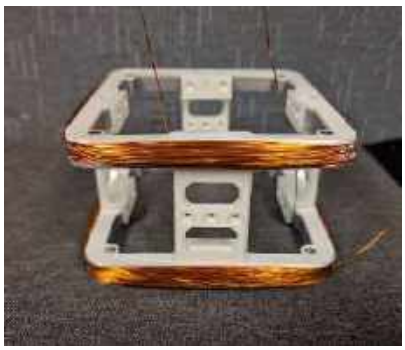

Figure 1: 3D printed Helmholtz Coil

The production and validation of a suitable electromagnet resulted in the development of a small-scale Helmholtz coil that was able to distribute a uniform magnetic field across the sample. The field strength was shown to match the simulation at the lower current that is available without the use of a dedicated benchtop power supply. Upon the arrival of the benchtop power supply, this will be validated again under higher current conditions that still fit the constraints of the wire that is used. Currently, the wire in question is 24 AWG and is rated for use up to 3.5 amps. This amount of current should be suitable to reach past the desired magnetic field strength of 100 Oe.

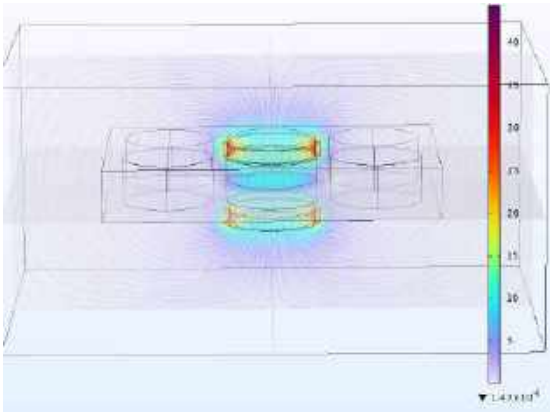

Figure 2: Representative Model of the Electromagnet with a 6-well Plate

The production of wafers during the pre-manufacturing process was completed under direct supervision of experts in the field of nanofabrication at the CNM. Each wafer was observed through optical microscopy to ensure that the shape and size of the disk diameter was ±0.5 µm from the desired size of 3 µm. Through ImageJ analysis, the average disk diameter was found to be 2.903 µm with a standard deviation of 0.048 µm.

DISCUSSION

Mechanotransduction, the process by which cells sense and respond to mechanical forces, is a fundamental aspect of cellular biology with broad implications for health and disease. However, the current understanding of mechanotransduction is hampered by the lack of precise methods to apply mechanical forces at physiological frequencies in research settings. The commonly utilized empirical approach to selecting frequencies for force application that is commonly used has limitations, as it relies on trial-and-error methods to determine force frequencies, that are almost always discrete in nature. However, that approach fails to recapitulate the complex motions of cells that drive many mechanotransduction processes. The research presented here directly addresses this problem and bridges the existing gap by introducing a new method for applying complex frequency profiles to targeted cell surface mechanoreceptors. The significance of this methodology opens doors to a wide range of mechanotransduction studies in different biological contexts and cell types, which will provide valuable insights into how cells respond to mechanical cues in their native environments. These insights could pave the way for a more complete understanding of disease phenotypes and novel therapeutic options.

INTRODUCTION

Coronary artery disease (CAD) is one of the leading causes of mortality, contributing to approximately 360,000 deaths per year [1] . In response, over 400,000 coronary artery bypass grafting procedures are performed every year [2]. Current bypass grafts have up to a 42.8% failure rate at two years after implanting due to blockage by thrombosis or the formation of intimal hyperplasia (IH) [3].

Failure via thrombosis has two major causes. First, interactions between the blood and the graft biomaterial leading to increased platelet deposition and clot formation [4]. Additionally, compliance mismatch between the native artery and the graft has a similar platelet activating effect. Compliance mismatch leads to changes in artery hemodynamics including oscillating sheer stress and sheer stress gradients. Disruption of these stresses facilitates clot formation [5]. Additionally, this disruption causes intimal hyperplasia (IH). IH is characterized by an abnormal migration of smooth muscle cells into the intimal layer of the artery that deposit excess ECM and constrict the inner diameter of the graft [6].

In this study we aim to create a tissue engineered vascular graft (TEVG) that decreases failure via thrombosis by using polyester sulfobetaine urethane urea (PESBUU) - a novel antithrombogenic polyurethane that has been shown to decrease palette aggregation and clot formation *in vitro* [7]. In response to *in vivo* PESBUU TEVG data, this study also looks at using gelatin to create compliance matched PESBUU based TEVGs. Our lab has previously developed CM TEVGs by layering varying computationally optimized ratios of gelatin and polycaprolactone (PCL) [8,9]. During 28 days of remodeling, CM TEVGs showed increased abluminal vascular smooth muscle cell (VSMC) counts and decreased markers of inflammation compared to hypocompliant grafts [10]. Polyester urethane urea (PEUU) was used as a substitute for PESBUU in non-blood contacting surfaces. PEUU is a well-established biomaterial with near identical mechanics to PESBUU and increased cellular infiltration potential.

METHODS

All TEVGs were fabricated via electrospinning. Pure PESBUU grafts were fabricated by spinning 350µL of PESBUU. Compliance matched TEVGs (CM TEVGs) were spun in three layers: a 35 µL inner layer of 100% PESBUU, a 65 µL middle layer of 80:20 PEUU:gelatin layer, and a 125 µL outer layer of 20:80 PEUU:gelatin. All materials were spun out of a 10% (w/v) solution made in HFP onto a 0.1mm mandrel. Gelatin containing grafts were then crosslinked in a genepin solution for 24 hours before being thoroughly rinsed in ethanol. *In vitro* mechanical testing was performed using a custom tubular biaxial mechanical testing device from Cell Scale Inc (Waterloo, Canada). Graft compliance was calculated using outer diameter measurements at the intraluminal pressures seen in *Equation 1*.

$$Compliance = \frac{(OD_{120} - OD_{80}) \,/\, OD_{80}}{120\ mmHg - 70\ mmHg} \quad (1)$$

Grafts were then implanted interpositionally into the abdominal aorta of Sprague Dawley rats for either 28 days (CM TEVGs) or 6 months (PESBUU). During implantation, doppler ultrasound was used to confirm patency and measure inner diameter and hemodynamics. CM TEVGs were scanned weekly and PESBUU grafts were scanned weekly for the first four weeks and then monthly until the end of the study. To calculate *in vivo* compliance a population pulse pressure was used (*Equation 2*).

$$Compliance = \frac{(ID_{systolic} - ID_{diastolic}) \,/\, ID_{diastolic}}{Pulse\ Pressure} \quad (2)$$

After explant, grafts were frozen in OCT, sectioned, and evaluated for cellular makeup via immunofluorescent staining. All results are presented as mean ± standard deviation. Compliance comparisons were performed via one-way ANOVA with a Tukey post-hoc.

RESULTS

The average wall thickness of the PESBUU and CM TEVGs grafts were 95 µm and 165 µm, respectively. To calculate *in vitro* native aortic compliance, 3 male and 2 female rats were used. Compliance of CM TEVGs was not significantly different than that of native rat aorta. PESBUU grafts were hypocompliant when compared to native rat aorta **(Figure 1)**.

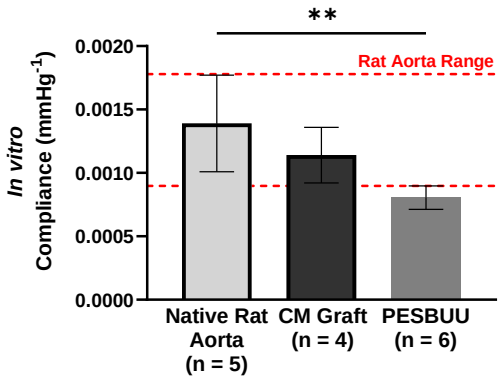

Figure 1: *In vitro* mechanical characterization of electrospun grafts compared to native rat aorta. *, p<0.05

No significant decrease in inner diameters was noted *in vivo* over the 6 month implant period **(Figure 2)**. Ultrasound measurements were taken on 10 rats (6M, 4F) and no differences were noted between sexes. Cells staining positive for α – SMA and CD31 were seen on the inner lumen of the graft. No cell nuclei were present within the graft or abluminally.

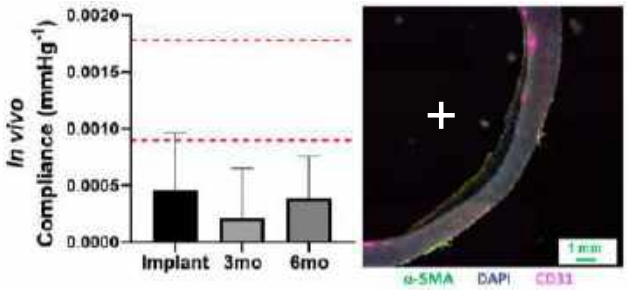

Figure 2: (Left) *In vivo* compliance values of PESBUU grafts over 6 months (n = 11). (Right) Fluorescent image of a representative explanted graft. Plus denotes the inner lumen. Scale bar = 1mm.

Compliance measurements were taken on 6 rats (3M, 3F). Grafts were shown to remain compliance matched post implant but were shown to have a significant decrease in compliance after 28 days of remodeling **(Figure 2).** At 28 days the gelatin dense outermost layer of the CM TEVG appeared to be fully degraded in all samples. Some rats (2/6) degradation of the middle layer was also noted. The presence of VSMCs (α – SMA) and small amounts of endothelial cells (CD31) was noted. There was little to no cellular infiltration into the inner and middle layers **(Figure 2).**

Hemodynamically, the average peak systolic velocity in the CM TEVG after 4 weeks of remodeling was 636.9 ± 288.3 mm/s in females and 1154.1 ± 315.6 mm/s in males. In PESBUU grafts females measured an average 903.9 ± 157.2 mm/s and males measured 891.9 ± 258.8 mm/s.

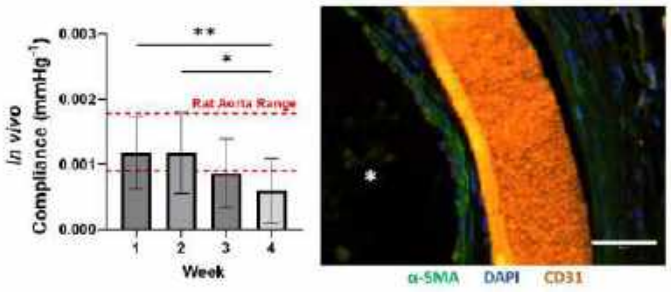

Figure 3: (Left) *In vivo* compliance values of CM TEVGs over 28 days (n = 6). *, p<0.05 **(Right) Fluorescent image of a representative explanted graft.** Asterisk denotes the inner lumen. Scale bar = 50µm.

DISCUSSION

In this study we were able to successfully create CM TEVGs utilizing the antithrombogenic polymer PESBUU by including gelatin into the graft matrix. PESBUU alone was hypocompliant and though we saw no signs of IH in our model (no significant diameter decrease or VSMC buildup) we believe that this is model specific. Additionally, PESBUU showed little to no signs of infiltration nor degradation on its own. There were no shifts in graft compliance, nor material loss.

In response, we successfully modulated the compliance and cellular interaction of PESBUU grafts through gelatin inclusion in out CM TEVGs. These grafts were compliance matched both *in vitro* and *in vivo*, robust enough for implantation, and remained patent over 28 days of remodeling. Unexpectedly, grafts did not remain compliance matched over 28 days of remodeling. We noted an increase in TEVG inner diameter (dilation) in some female rats that likely contributed to decreased compliance numbers. Ultrasound revealed that the hemodynamics within these dilations were abnormal and not fully pulsatile. This may explain why we see sex specific hemodynamic differences in CM TEVGs but not PESBUU grafts. Explant data from these dilated grafts showed advanced graft degradation in PEUU containing layers.

While these initial results are encouraging, there were some limitations within this study. For example, the rat model is not able to capture human hemodynamics and has starkly different clotting dynamics. Additionally, using a population pressure for compliance calculations is less desirable than subject specific pressures. That being said, our initial results are still promising.

As we continue this work we plan to study longer timepoints for CM TEVGs, incorporate growth factors to encourage cellular infiltration, understand sex differences seen in compliance shifts, and move to a larger animal model.

INTRODUCTION

An aortic aneurysm occurs when the aortic wall, either in the thoracic or abdominal segment, weakens and irreversibly dilates. This expansion results from a gradual degradation of the extracellular matrix, especially elastin [1]. Aortic aneurysm ruptures, which happen when the wall stress surpasses the wall strength, resulted in 9,923 deaths in the United States in 2018 [2] and are thus a significant health concern. Understanding and predicting aortic wall tissue strength in aneurysms could have substantial clinical benefits.

To study the effects on mechanical tissue properties, vascular extracellular matrix (ECM) has been modified using protease treatments [4,5]. Correlations have been observed relating the density of concrete and polymers its failure point [6], leading us to hypothesize a parallel behavior in aortic tissue; that is, tissue strength is directly linked to its density. Generally, a diminished extracellular matrix correlates with weaker tissue. We propose that a reduction in wall tissue density may lead to decreased aortic tissue strength.

Diffusion tensor (DT) imaging, a magnetic resonance imaging technique, visualizes the movement of protons across surfaces. Commonly applied in brain imaging to map fibers, it provides measures of anisotropy and diffusivity, which may be indicative of the tissue's local density. This pilot study aims to explore the potential link between proteolytically altered density using diffusion coefficients derived from DT imaging and experimentally measured mechanical properties of porcine thoracic aortic tissue.

METHODS

Porcine Specimen Treatment: Freshly harvested porcine thoracic aortas, sourced from a local abattoir, were prepared into longitudinal rectangular specimens (80mm x 4mm) and immersed in phosphate buffered saline for 12 hours. The initial (untreated) saturated mass and volume were measured for each specimen and initial density calculated as described below. The samples were then submerged in a collagenase (50 mg/mL, n=7) or elastase (0.01 mg/mL, n=7) solution to selectively degrade collagen or elastin, respectively. Sham/control specimens were submerged in pure PBS (n=7). Submerged specimens were then incubated with end-over-end rotation at 37° C for 24 hours. Post-treatment density was calculated (described below) for each specimen following incubation and then uniaxially tensile tested to failure. The stress-stretch curve was used to calculate nominal ultimate tensile strength (UTS) and tangent modulus, and all statistical analysis was performed using an ANOVA with Tukey's post-hoc.

Specimen Density Measurements: Mass (m) of all porcine specimens was measured using a precision balance (PR503, Mettler Toledo, Columbus, OH). The width-length surface area and average thickness were determined from images of the specimens prior to testing. Solid volume (V) was calculated from the measured surface area (SA) and average thickness (t) across the specimen (**Equation 1**).

$$V = SA * t \quad (1)$$

Bulk tissue density (ρ) was determined for each specimen before and after enzymatic degradation (**Equation 2**).

$$\rho = \frac{m}{V} \quad (2)$$

Percent density change (before vs. after treatment) for each specimen was calculated.

Diffusion Tensor Imaging: DT imaging was conducted on a single sample at the University of Pittsburgh Advanced Imaging Center using

an 11.7T/89 Bruker Avance AV3 HD microimaging scanner. The sample was maintained at 37° C inside a 15 mm diameter tube filled with phosphate buffer saline. The scanning process took approximately two hours. Post-scanning, the DT images were processed using DSI Studio (High-Definition Fiber Tractography Lab, University of Pittsburgh, Pittsburgh, PA). We reconstructed the DT images through eigenvector analysis applied to the calculated tensors. For analysis, we focused on the central region of the tissue. The number of voxels analyzed varied by treatment: 56 for the sham tissue, 48 for collagenase-treated samples, and 65 for those treated with elastase. Voxels refer to the three dimensional 'points' and represent the diffusion tensors measured. Voxel count varied by selecting a rectangular region along the center of the tissue and the size of the tissue's central region. Mean and standard deviation of each variable was taken for each voxel in the region of interest and compared between the specimens.

RESULTS

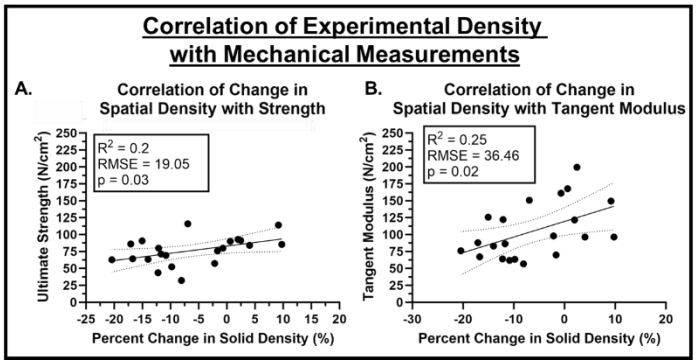

Figure 1: A) Correlation of comparing UTS and experimental density, and B) Correlation of porcine samples comparing UTS and sample density

The results for the porcine aortic tissue show a significant difference in % change in solid density between sham (2.3±5.3%) and both collagenase-treated (-11.8±5.7%, p=0.005) and elastase-treated (-9.2±6.9%, p=0.011) tissue. Parallel differences were also seen for the UTS for the sham (95.70±12.8 N/cm^2) and the collagenase (63.5±16.2 N/cm^2, p=0.024) and the elastase groups (69.9±15.2 N/cm^2, p=0.03). The tangent modulus also showed similar differences between the sham (149.5 ± 30.7 N/cm^2), collagenase (74.8±11.1 N/cm^2, p=0.007) and the elastase groups (90.8±25.0 N/cm^2, p=0.025). Linear regression revealed that density is a significant predictor of UTS for porcine thoracic aorta (R^2=0.2, p=0.03) (Figure 1A). Additionally, density is a significant predictor of tangent modulus (R^2=0.25, p=0.02) (Figure 1B).

Table 1: Diffusion parameters statistically compared from collagenase and elastase groups and compared to the sham group.

	Sham	Collagenase	Elastase
Mean Diffusion	0.073±0.13	0.85±0.08 (p=0.01)	0.77±0.05 (p=0.04)
Axial Diffusion	1.14±0.11	1.23±0.06 (p=0.01)	1.12±0.05 (ns)
Radial Diffusion	0.52±0.16	0.66±0.17 (0.03)	0.60±0.11 (ns)

The DT imaging shows significant differences in calculated parameters from the images. The fractional anisotropy, which is purely isotropic at a value of 0 and more anisotropic as it approaches 1, was significantly different in the collagenase (0.40±0.15, p=0.02) and elastase (0.40±0.04, p=0.01) groups compared to the sham group (0.47±0.08). Additionally for the diffusion parameters, see **Table 1** for statistical comparisons. As diffusion parameters increase, hydrogen ions are more easily able to pass through the tissue. Additionally, **Figure 2** has qualitative images showing each voxel's primary diffusion tensor in color.

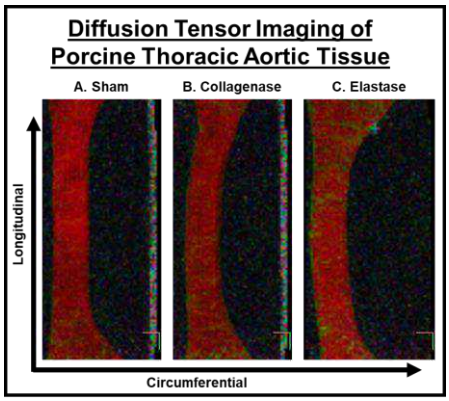

Figure 2: Magnetic resonance Image of diffusion tensors of 3 separately treated specimens (A. Sham, B. Collagenase, and C. Elastase) from the same porcine thoracic aorta. The red color suggests that the primary tensors for tissue microstructure are in the circumferential orientation, blue would be radial, and green longitudinal.

DISCUSSION

Experiments performed in this study revealed that through proteolytic treatments we can manually manipulate (decrease) the bulk tissue density of aortic tissue, which in turn can alter the UTS and tangent modulus (**Figure 1**). The reduction of fractional anisotropy in the elastase and collagenase specimen compared to the sham specimen is consistent with previously presented results that have shown this effect mechanically[8]. Very recently DT imaging has revealed increases in mean diffusivity in proteolytically degraded porcine aorta[9]. To our knowledge, axial diffusivity (circumferential in respect to the porcine anatomy) has not been explored. It is expected that the elastase group would remain unchanged from the sham, as elastase would not remove collagen fibers which are primarily circumferentially oriented. While radial diffusion was significantly different in the collagenase group from the sham treatment, the elastase group was not different than the sham group. The lower density tissues (collagenase and elastase treated) have lower fractional anisotropies (more isotropic), are more diffusive (more porous), and have lower mechanical strength and stiffness than higher density tissue (sham).

This study is limited by assuming that collagenase only reduces the collagen content of the tissue and that elastase only reduces the elastin content. Future work will include histology of the specimens to compare the effect of the degradation on the extracellular matrix. We will also expand our work to relate diffusion values and fractional anisotropy to bulk density values to relative strength determinations in order to explore the potential of DT imaging as a tool to assess bulk tissue density.

INTRODUCTION

Mechanical stimuli and endothelial cell (EC) mechanotransduction are critical for proper vascular morphogenesis.[1,2] We can study this by perturbing the mechanical environment in the endothelium or by manipulating specific mechanosensors and mechanotransducers. However, ECs perceive and transduce mechanical signals through a variety of signaling pathways.[3] Additionally, mechanotransducers may be regulated by multiple upstream inputs and regulate diverse downstream outcomes, not all related to mechanotransduction. It is challenging to dissect which cell behavior and gene expression profiles are regulated by a specific mechanotransducer in response to mechanical cues, especially *in vivo*.

Here we investigate which mechanotransductive pathways are specifically regulated by the transcriptional coactivators Yes-associated protein (YAP) and transcriptional-coactivator with PDZ-binding motif (TAZ) during endothelial mechanosignaling and vascular morphogenesis. We previously identified YAP/TAZ as mechanosensitive mediators of a feedback loop that modulates cytoskeletal tension and focal adhesion (FA) formation to regulate EC motility and vascular morphogenesis.[4,5] These observations position YAP and TAZ as potential key mediators of cytoskeletal-induced transcriptional programs.

METHODS

We performed two types of studies, one in zebrafish larval vessel morphogenesis and one in human EC adhesion adaptation to substrates of different rigidities. In the two experimental models, we perturbed mechanical environment and YAP/TAZ signaling and evaluated transcriptional changes. The parallel structure of this study allowed us to identify mechanotransductive genes and pathways that are specifically regulated by YAP and TAZ *in vitro* and *in vivo*.

We used small molecule inhibitors 2,3-butanedione monoxime (BDM) and Verteporfin (VP) to block heart beat-induced mechanical cues and YAP/TAZ signaling, respectively, during vascular morphogenesis in transgenic zebrafish Tg*(fli:egfp)*^{y1} [6] embryos beginning at 28-29 hours postfertilization (hpf). Fluorescent images were collected using a spinning disk confocal microscope between 28-48 hpf to measure intersegmental vessel (ISV) length.

Sequencing-based gene expression assays were performed in both ECs and zebrafish models. Endothelial colony forming cells (ECFCs) received either YAP/TAZ-silencing siRNA, or scrambled control, and were seeded onto 1kPa or 18kPA methacrylated hyaluronic acid (MeHa) hydrogels at 48 hours post-transfection.[5] Cells were collected for RNA-sequencing at 4 hours after seeding to identify the immediate transcriptional targets of mechanotransduction[5]. In parallel, 'AngioTag' zebrafish embryos[7] were treated with BDM starting at 24 hpf, and collected at 36 hpf for Translating Ribosome Affinity Purification (TRAP). This technique enables collection of actively translating mRNA species via sequencing of mRNAs trapped in ribosomes, pulled down by immunoprecipitation.[7]

Transcriptional changes were analyzed using Gene Set Variation Analysis (GSVA), in R. GSVA is a generalized gene set enrichment method that detects variations of pathway activity over a sample population in an unsupervised manner.[8] We quantitatively compared gene sets expression in the experimental conditions and defined cellular behaviors and signaling pathways regulated by YAP/TAZ mechanotransduction. GSVA was computed using annotations from the Molecular Signatures Database C2 [v7] gene sets (MSigDB). Gene sets with FDR adjusted p-value qFDR < 0.05 were considered significant. Statistically significant differences and fold changes in individual genes were computed via DESEq2 v. 1.36.0.

RESULTS

Pharmacological disruption of heart beat using BDM arrested zebrafish ISV morphogenesis by 35 hpf compared to DMSO controls (Fig. 1A, B). Washing out the inhibitor after 3 hours restored vessel

growth. These data indicate that mechanical cues induced by the heartbeat dynamically regulate ISV morphogenesis. Next, to test for a role of YAP/TAZ signaling in ISV morphogenesis, we repeated this experiment using the YAP/TAZ inhibitor, verteporfin (VP). Like BDM, YAP/TAZ inhibition slowed vessel morphogenesis but could be rescued by inhibitor washout (Fig 1C, D). Together, these data indicate that dynamic mechanical stimulation and YAP/TAZ signaling regulate ISV morphogenesis. However, we need to determine the extent and mechanisms of YAP/TAZ mechanotransduction, per se.

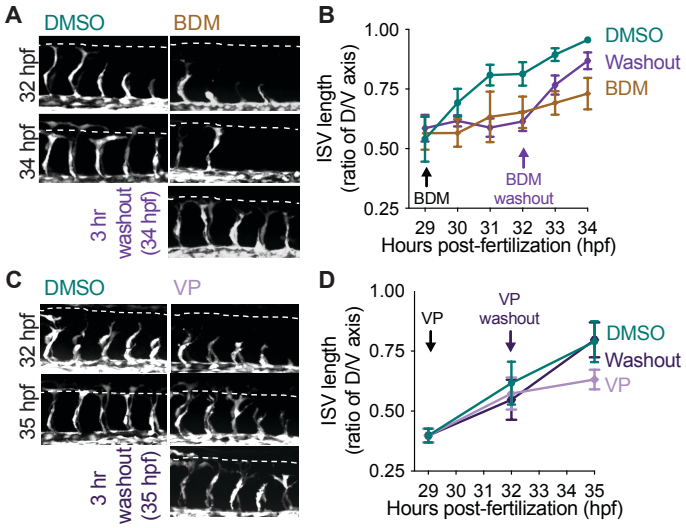

Figure 1. Dynamic mechanical stimulation and YAP/TAZ signaling regulate zebrafish ISV morphogenesis. Representative confocal images of DMSO and BDM (**A**) or VP (**C**) treated zebrafish embryos at 32 hpf (top), 34/35 hpf (middle), or at 34/35 hpf 3 hours of compound washout (bottom). Quantification of ISV length of embryos continuously incubated in BDM (**B**) or VP (**D**) versus the associated washout condition.

To dissect the cellular pathways and genes that are specifically regulated by mechanotransduction through YAP and TAZ, we evaluated changes in gene expression of control and YAP/TAZ depleted ECs cultured on soft (1 kPA) or stiff (18 kPA) matrices (Fig 2A). Because of the duration of YAP/TAZ depletion prior to adhesion and the potential non-mechanotransductive roles of YAP and TAZ, YAP/TAZ knockdown had a greater impact on transcription compared to substrate stiffness adhesion after 4 hrs (Fig 2B). YAP/TAZ depletion of cells cultured on the stiff matrix differentially regulated 989 gene sets (Fig 2B, dark blue panel). From this large list, we extracted 61 gene sets specifically regulated by YAP/TAZ mechanotransduction (Fig 2B, dashed circle, C). Combining gene sets by biological function elucidated several altered pathways, including Wnt/B-catenin signaling (Fig 2D), focal adhesions, mRNA processing, hypoxia response, EGF signaling, and Notch signaling.

To test the extent to which the identified YAP/TAZ-regulated genes and pathways mediate mechanosignaling in vivo, we treated zebrafish with BDM for 3 hours and used TRAP-seq to analyze translating mRNAs in the ECs. Comparing treated versus control conditions, 1194 gene sets were differentially regulated by mechanical cues. We cross-referenced these to the YAP/TAZ-regulated mechanosensitive gene sets identified *in vitro,* and found 39 overlapping. After combining the gene sets by function, we identified 4 pathways of particular interest and regulated specifically by YAP/TAZ mechanotransduction: Wnt/B-catenin signaling, focal adhesions, mRNA processing, and EGF signaling.

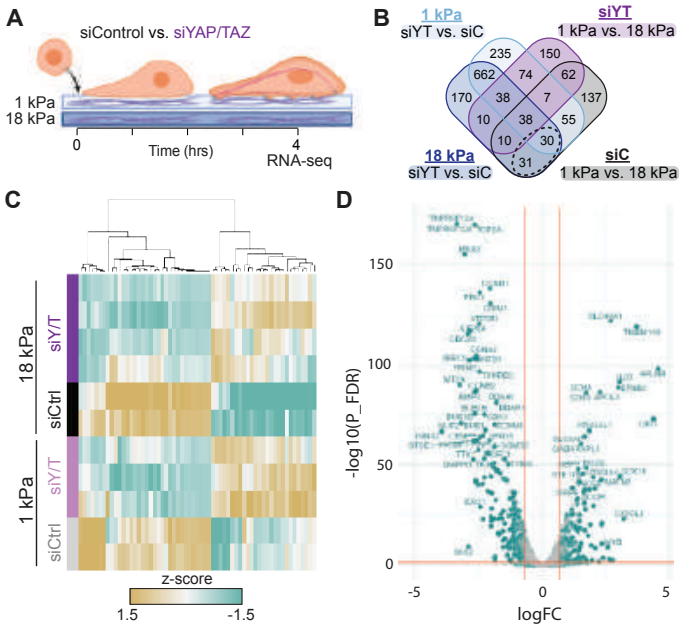

Figure 2. Transcriptional profiling reveals genes and pathways regulated by substrate stiffness through YAP/TAZ signaling. **A.** Experiment schematic: Control or YAP/TAZ depleted ECFCs were cultured on 1 or 18 kPa MeHA matrices. **B.** Differentially expressed gene sets in the four experimental conditions. Those driven by YAP/TAZ mechanotransduction identified in the dashed circle**. C.** Enrichment scores and **D.** example of a pathway (Wnt/B-catenin) of YAP/TAZ regulated mechanosensitive gene sets. Volcano plot shows differentially expressed genes from siControl vs siYAP/TAZ on 18 kPa comparison.

DISCUSSION

Here, we sought to dissect mechanosignaling pathways to identify gene expression profiles that are specifically regulated by YAP/TAZ mechanotransduction in ECs in culture and during vascular morphogenesis. This parallel approach allowed us to identify YAP/TAZ mechanotransductive mechanisms in vascular morphogenesis. Our data suggest that, YAP and TAZ play important roles in endothelial cell motility and mechanosensing through diverse transcriptional programs, including genes and pathways directly controlled by YAP/TAZ mechanotransductive transcription. Future studies will explore how changes in cytoskeletal tension drive the identified pathways, with *in vivo* dissection, using novel optogenetic tools.

INTRODUCTION

Cerebral aneurysms are dilations of the cerebral arteries and, in most cases, patients with cerebral aneurysms do not have any early symptoms. Nevertheless, it is a severe pathology, with a high mortality rate after rupture [1]. Several studies have focused only on the hemodynamics of the flow within the cerebral aneurysm [2]. However, the development and rupture of the cerebral aneurysm are also associated with a combination of other factors such as the geometrical properties of cerebral aneurysm [3].

Computational fluid dynamics (CFD) has been used to assess the development of cerebral aneurysms, with a focus on hemodynamic parameters like wall shear stress to understand rupture status, risk, and growth. While various parameters have been developed, their contributions to cerebral aneurysm dynamics are not fully explored. The association between aneurysm morphology and rupture status is acknowledged, but the specific contribution of each morphologic variable remains unclear [4].

Machine learning (ML) has rapidly advanced and applied in various fields, including clinical medicine. In clinical medicine, the application of ML holds significant potential for enhancing diagnostic capabilities and improving overall medical practices [5].

This research endeavors to predict hemodynamic parameters crucial for assessing the proper treatment for each patient based on hemodynamic parameters. However, recent studies faced challenges due to insufficient data, leading to less reliable results in evaluating these parameters. The ability to determine appropriate patient treatments based on hemodynamic factors has been limited by the inadequacy of data in these studies.

METHODS

In this study, numerical simulations were conducted using Ansys to analyze blood flow and various geometric characteristics of a cerebral artery vessel featuring a saccular aneurysm, as illustrated in Figure 1.

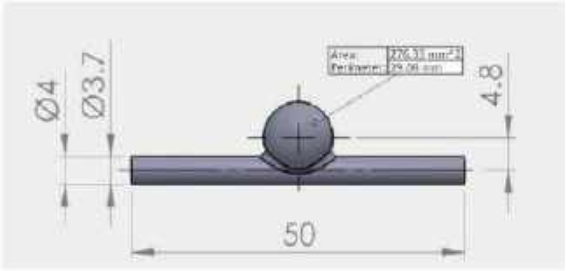

Figure 1 sample cerebral aneurysm

The geometry of the cerebral aneurysm model is based on the work of Souza [1]. Key geometric parameters encompass the vessel length, vessel diameter, distance of the aneurysm center from the vessel axis, distance of the aneurysm center from the origin of the vessel, aneurysm diameter, and vessel curvature, with their respective ranges detailed in Table 1. Also, curvature and radius angle have been considered for some cases.

Table 1 Geometrical parameters ranges

Vessel length	Vessel diameter	Distance from axis	Aneurysm diameter	Distance from origin
5-25 mm	3.4-8.6 mm	3.9-17 mm	5-30 mm	2.5-12.2 mm

The governing equations are the continuity and Navier-Stokes equations solved by utilizing the finite volume commercial software CFX, Ansys 2021 R2. The Newtonian blood flow is considered to be a Steady and incompressible regime, with rigid walls and zero outlet pressure. The investigated blood flow parameters including blood

density, blood viscosity, and blood inlet velocity, each with its specified range are detailed in Table 2.

Table 2 Blood flow parameters range

Blood Velocity	Blood Viscosity	Blood Density
0.14-0.85 $^{m}/_{s}$	0.00345-0.05345 $Pa.s$	1050-1056 $^{kg}/_{m^3}$

For each case, the computational domain includes a mesh with an average of 360,000 control volumes, with a residual error set at 10^{-4}. The convergence rate of 30 seconds per case on average, has been assessed. Output hemodynamic parameters include inlet pressure, maximum wall shear stress (WSS), average wall shear stress, maximum velocity, average velocity, and maximum vorticity inside the aneurysm dome.

Subsequently, machine learning models were employed to predict these output parameters based on input parameters. The predictive models encompassed random forest regressor (RFR), gradient boosting regressor (GBR), support vector regressor (SVR), linear regressor (LR), decision tree regressor (DTR), artificial neural network (ANN), k-nearest neighbors (KNN), and Bayesian Ridge (BR).

RESULTS

A total of 1846 distinct simulations were generated using CFD simulation. Similar to the prior research, the available data proved insufficient for yielding robust results; however, machine learning models require ample data for achieving high accuracy. Subsequently, we normalized all the data and then applied each machine-learning method to predict individual outputs for both normalized and denormalized data and evaluated each model using two metrics: Mean Squared Error (MSE) and R square (R2). The results are presented in Table 3.

Table 3 Results from machine learning models for each output normalized and denormalized

output	Best model	MSE (scaled)	MSE	R2
Inlet pressure	RFR	8.90×10^{-5}	$1.57 \times 10^{+5}$	0.9771
Maximum WSS	RFR	7.01×10^{-5}	$6.23 \times 10^{+1}$	0.9738
Average WSS	GBR	2.44×10^{-4}	1.75	0.9619
Maximum velocity	DTR	3.81×10^{-5}	3.58×10^{-3}	0.9934
Average velocity	DTR	4.37×10^{-5}	3.1×10^{-4}	0.9946
Maximum vorticity	DTR	1.81×10^{-5}	$5.09 \times 10^{+3}$	0.9885

The correlation matrix in Figure 2 illustrates the pairwise correlations among the variables considered in our machine-learning analysis. The values in the matrix range from -1 to 1, where -1 indicates a perfect negative correlation, 1 indicates a perfect positive correlation, and 0 indicates no correlation.

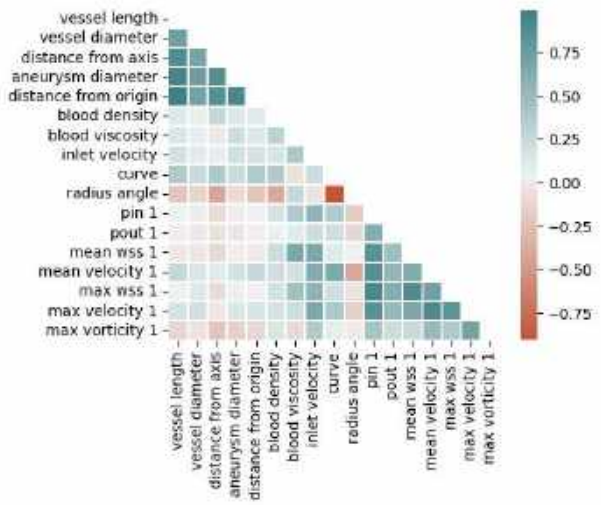

Figure 2 correlation matrix of input and output parameters data

DISCUSSION

Upon applying various machine-learning methods The outcomes, as described in Table 3, provide valuable insights into the efficacy of each machine-learning method in assessing and predicting the intricate hemodynamic parameters under investigation.

As you can see in Figure 2 which shows the correlation between parameters we can conclude that if we consider maximum wall shear stress as one of the critical hemodynamic parameters in cerebral aneurysms it shows that between input parameters blood viscosity and inlet velocity have the most effect on the results that haven't been investigated in previous research. between geometrical input parameters and blood flow input parameters, blood flow parameters show more influence on the output parameters.

These results not only contribute to the understanding of predictive capabilities in hemodynamic modeling but also prompt further considerations for refining methodologies, expanding datasets, and exploring novel approaches to enhance the accuracy of machine-learning predictions in the context of cerebral artery vessel simulations. Future research endeavors may benefit from addressing the challenges posed by limited data availability, thereby advancing the applicability and reliability of machine-learning models in predicting complex hemodynamic phenomena. By calculating hemodynamic parameters you can decide which approach of treatment will be appropriate for each patient.

INTRODUCTION

Cancer is a major cause of mortality and morbidity worldwide, with diagnosis relying heavily on ultrasound (US) imaging [1]. Recent advances in imaging techniques have evidenced the stiffening of tumors as early signs of malignancy. The lateral and axial strains of the tumor microenvironment have been identified as key indicators of malignancy, with mechanical properties such as Young's modulus and Poisson's ratio proposed as potential biomarkers [2]. Regional changes in these markers are mapped using brightness mode (B-mode) in conjunction with elastography. However, B-mode images are often susceptible to motion artifacts, with any subsequent calculations also heavily dependent on the abilities of the operator. Additionally, a majority of current research models the tumor as a linear elastic solid, thus providing a confounded representation of the tumor microenvironment [3]. Most biological tissues are known to behave as incompressible hyperelastic materials, thus necessitating an improvement in the characterization of the mechanical properties of the tumor. We propose an inverse model that uses synthetic images derived from in-silico finite element simulations of a tumor-healthy tissue assembly under compression to estimate a regional map of tumor stiffness.

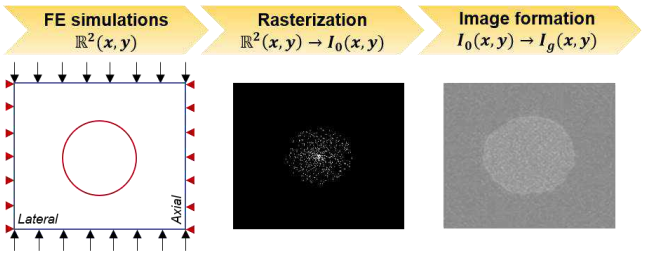

Figure 1: Schematic representation of the in-silico simulations comprising the steps involved in forming the synthetic B-mode images.

METHODS

The proposed methodology comprises the generation of synthetic US images of tumor cells included in healthy tissue (Fig. 1). Images are generated from two-dimensional plane stress finite element simulations of the tumor-tissue geometry under varying degrees of compression. Finally, we use a speckle tracking algorithm to calculate strains and displacements from the deforming geometry to facilitate an inverse model of the same geometry to estimate the mechanical properties of the tumor. *Finite element simulations*: The tumor is modeled as an irregular circle-like structure embedded in the background tissue. Both the tumor and the tissue were modeled as Neo-Hookean Hyperelastic materials of varying properties such that the strain energy function (ψ) was formulated as: $\psi = C(I_1 - 3)$, where C is a material parameter, and I_1 is the first invariant of the right Green deformation tensor. The tissue was axially compressed to 10%, 20%, and 30% of its length, with the lateral boundaries of the tissue assembly fixed in all directions. *Image generation*: The nodal positions of the deforming tissue assembly were estimated through the displacement vectors at each loading step, and were rasterized onto a 2D grid of pre-defined size and spacing. Each node on this grid ($G_0(x,y)$) can be considered as an object in space, and the subsequent US image (I_0) formation can be modeled as a linear system,

$$I_0 = G_0(x,y)H(x,y) + \eta,$$

here I_0 is obtained via the convolution of G_0 with a wave function, H and adding Gaussian noise, η. In this study, H is formulated as a sine kernel of size 5 and frequency of 3 mm to obtain an I_0 of size 256 x 256 with a resolution of 1 mm. *Speckle tracking*: A speckle tracking algorithm implementing normalized cross-correlation between successive image frames was used to calculate cartesian displacements [4]. The displacements between each frame were used to build the deformation gradient, with each tensor projected over all the frames to derive the total deformation gradient. The mean squared errors in

displacements and strains calculated were evaluated between speckle tracking and FE simulations.

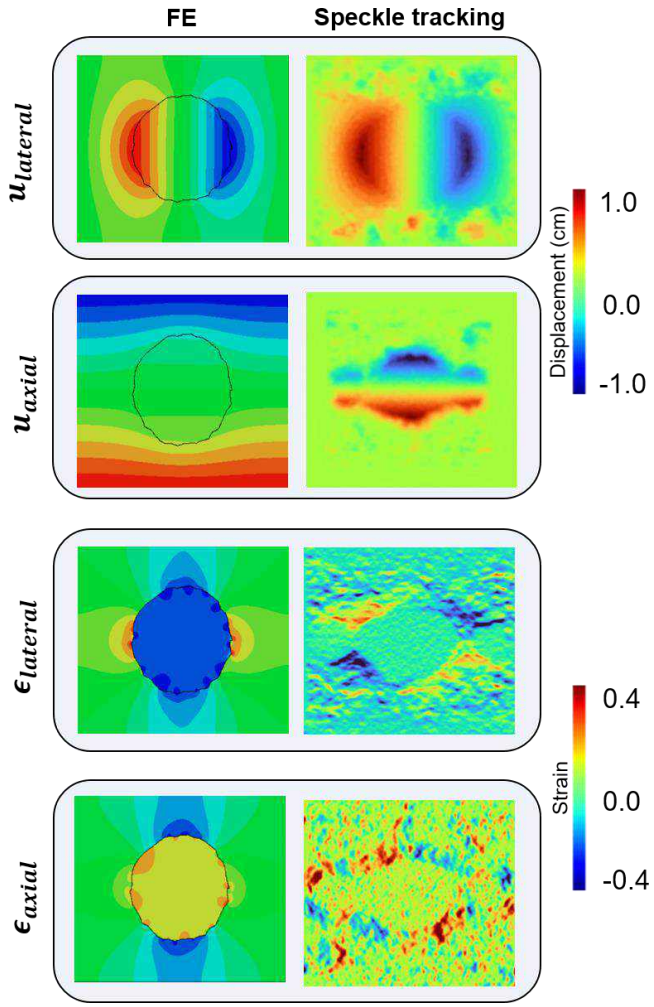

Figure 2: Representative heat maps of the (top) displacement and (bottom) strain calculations at 20% compression through finite element simulations and speckle tracking. ϵ_{axial} and u_{axial} are the axial strain and displacements, respectively. $\epsilon_{lateral}$ and $u_{lateral}$ are the lateral strains and displacements, respectively.

RESULTS

While minimal deformation was observed in both the healthy tissue and tumor at 10% compression, the lateral strains were significantly higher under 20% and 30% compression. Whereas the healthy tissue was observed to expand under compression, the tumor tissue was seen to contract with a mean lateral strain of -0.1245 ± 0.044 at 20% compression (Fig. 2). This transition was especially significant at the boundary between the two tissue classes. Despite the spatial heterogeneity in the deformation patterns under compression, realistic US images were produced through rasterization. As expected, the spatial distinction between the two tissue classes was very minimal. However, the cartesian displacement patterns were qualitatively recapitulated for all loading conditions through speckle tracking. In addition to qualitatively similar displacement patterns, there was good agreement in the mean strain values obtained within the tumor and at the interface at 20% (lateral: -0.1386 ± 0.066, longitudinal: -0.1511 ± 0.056). In contrast, spurious strains were observed at 30% compression, with both lateral and axial strains presenting over 40% error at the interface between the tumor and the healthy tissue. This is indicative of a common limitation in the spatiotemporal description of tissue-tissue interfaces seen in most B-mode US imaging.

DISCUSSION

In this study, we presented a pipeline to facilitate the estimation of the mechanical properties of tumors using standard B-mode US images via inverse modeling. In approaches such as US elastography, the tissue under consideration is compressed prior to the estimation of its mechanical properties. Subsequently, prolonged exposure to such mechanical loading may introduce motion-blur artifacts that may compromise the accuracy of the estimated properties. Indeed, such artifacts are known to compromise image quality and the resulting motion calculations using US imaging. To address such limitations, a well-established material model of tissue biomechanics was incorporated to create a library of varying tumor tissue properties. The ground-truth motion was subsequently estimated to create their corresponding synthetic US images. Realistic images were obtained by using the standard image formation principles of wave-based imaging methods. We presented a series of spatially heterogeneous deformation patterns of tumor inclusion in healthy tissue, with the proposed methodology successfully recapitulating FE simulations at 20% compression. However, at higher levels of compression, spurious strain values were obtained at the interface of the tumor inclusion. We suspect the image quality in capturing the more rapid deformation affects the resulting strain calculations. Sub-pixel motion estimation via speckle tracking is often challenged by rapid deformation, thus necessitating more robust image resolution. We expect these improvements can be facilitated by updating the image formation process through rectification and interpolation to improve the spatiotemporal resolution. However, the aim of this study was to establish the potential inverse relationship between the image-derived strains and stresses to estimate the tumor stiffness effectively. Despite minimal regions of spurious strains, an overall qualitative agreement between the FE- and image-derived strains was obtained. We will conduct a least-squares optimization-based inverse model to estimate tissue stiffness to characterize the mechanical properties of the tumor. We expect our findings to improve the structural characterization of tumors to estimate tumor malignancy effectively through standard B-mode US imaging.

IMPACT OF GAGS REMOVAL AND CXL THERAPY ON CORNEAL STROMAL PROPERTIES

H. Hatami-Marbini (1), M.E. Emu (1)

(1) Department of Mechanical and Industrial Engineering, University of Illinois Chicago, Chicago, IL USA Email. Hatami@uic.edu

INTRODUCTION

The cornea, a transparent tissue at the front of the eye, serves as the protective layer for the internal contents of the eye by resisting external stresses. The mechanical properties of the cornea primarily stem from its extracellular matrix, which is known as the stroma. The stroma is the thickness layer of the cornea and is mainly composed of collagen fibrils and proteoglycans (PGs). PGs are macromolecules that are composed of a core protein to which glycosaminoglycan (GAG) chains are attached. They are important in maintaining the almost uniform collagen diameter in addition to regulating the arrangement of collagen fibrils inside the corneal stroma. The uniform diameter and hexagonal arrangement of collagen fibrils are necessary for corneal transparency. GAGs define the hydration of the stroma because they are negatively charged attract water molecules inside the stroma. They also generate osmotic swelling pressure and contribute to corneal mechanical strength. In addition, they bridge the collagen fibrils and could be important in transferring load among them. The primary GAGs inside the cornea are Keratan Sulfate (KS) and Chondroitin/Dermatan Sulfate (CS/DS). The composition and density of GAGs change due to diseased conditions.

Various eye diseases impact the composition, microstructure, and biomechanics of the corneal stroma. For example, keratoconus is a progressive ectatic disorder in which the cornea loses its mechanical strength and becomes cone-shape. The corneal crosslinking (CXL) treatment has been shown to slow down the progress of keratoconus. The CXL therapy uses UVA light and riboflavin solution to create crosslinks in the corneal stroma [1]. The CXL efficacy is usually assessed by investigating its effects on healthy corneas, i.e. the effects of altered composition and structure of keratoconus cornea are not considered. The purpose of this research was to assess how any reduction of KS GAG content affects the efficacy of CXL treatment. KS GAGs have been shown to decrease in keratoconus; thus, they might explain the significant reduction of tensile strength due to this diseased state [2,3]. For this purpose, we removed enzymatically GAGs from the cornea and used the CXL therapy to strengthen the GAG-depleted samples. We performed uniaxial tensile experiments and pepsin digestion studies to assess the structural integrity and tensile properties of samples before and after the CXL treatment. The findings were compared with the properties of control samples before and after the CXL therapy.

METHODS

Fresh porcine eyeballs were obtained and brought to the laboratory from a local slaughterhouse. The eyeballs were used on the same day by first removing excess tissues and then excising corneal rings with a 2 mm scleral rim. From corneal rims, strips were cut in the nasal-temporal direction. Random assignment was used to place strips into Control, Control CXL, KS II, and KS II CXL groups. Additionally, 8 mm full-thickness corneal discs were prepared for biochemical analysis and pepsin digestion. For GAG depletion (KS II group), corneal strips were immersed in an enzyme solution (0.1 U/ml keratanase II, 100 mM sodium acetate buffer) for 20 h at 37° C and pH 6.0. The thickness of incubated samples was measured and they were washed in PBS before being used in the experiments.

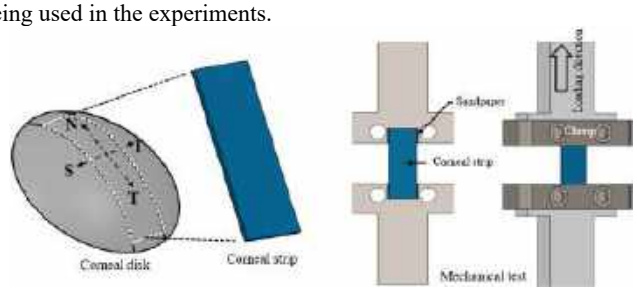

Figure 1: A schematic plot that shows the direction of the corneal strips and the mechanical grip of the uniaxial tensile testing machine.

Corneal strips underwent the conventional CXL protocol, i.e. they were soaked in 20% dextran - 0.1% riboflavin solution for 30 minutes and were then irradiated with UVA light (3 mW/cm^2, 370 nm) for another 30 minutes. Irradiance level was controlled with a UVA meter, and riboflavin solution was replenished at regular intervals during the UV irradiation. Uniaxial tensile tests were performed by an RSA-G2 testing machine (TA Instruments, MD). The samples were mounted into the testing machine using sandpaper to prevent slippage, Figure 1. The mechanical tests began by applying a preload in order to straighten the strips and remove any slack. Then, the initial length of the samples was used to calculate the displacement required to stretch the samples upto 20%. A displacement rate of 3 mm/min was used and the experiments were done without any bathing solution. The duration of the experiments was short and pre- and post-test thickness comparison showed no significant changes in the hydration of samples. The pepsin digestion study used five corneal disks from each group. For this purpose, the corneal samples were placed in 1 g $\geq$ 400 U/mg pepsin in 0.1 M hydrochloric acid (pH 1.2) solution and their diameter was measured. Like previous studies, we did not use any thickness measurement of pepsin digested samples as samples became significantly swollen. Data analysis, performed with the SAS analytic tool, involved Shapiro–Wilk tests for checking normality of the experimental data. ANOVA and t-tests with P value of 0.05 were also done to identify statistically significant differences.

RESULTS

The histological evaluation done by Alcian blue stain (results not shown) confirmed that the keratanase II enzyme treatment significantly reduced staining in GAG-depleted samples, confirming the successful GAG removal in these samples. Figure 2 depicts the tensile response of various groups. Tensile stress and tangent modulus at different strains were calculated from the stress-strain curves. It was found that the CXL procedure increased maximum tensile stress in control samples significantly and GAG depletion reduced the maximum tensile stress significantly ($P < 0.05$). Additionally, the CXL treatment of GAG-depleted samples significantly increased maximum tensile stress ($P < 0.05$). Finally, no significant difference was observed between KS II CXL and Control samples.

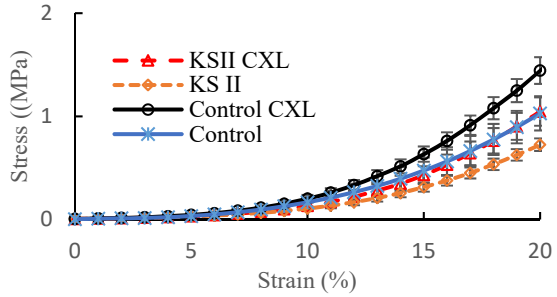

Figure 2: Effect of GAG removal and CXL therapy on tensile stress-strain curves.

Figure 3 shows the variation of the cornea diameter because of the pepsin digestion. Except for CXL-treated Control samples, all other samples were fully digested. GAG-depleted samples were digested significantly faster (average time: 6 days) than Control samples (average time: 9 days, $P < 0.05$). The CXL treatment increased the average digestion time of GAG-depleted disks from 6 to 8 days, which was a significant increase ($P < 0.05$). Figure 3 also shows that the reduction in the average diameter of Control and Enzyme CXL groups did not significantly differ between until day 7.

DISCUSSION

It is known that the CXL treatment is effective in enhancing corneal structural integrity, and thus it could stabilize and halt the keratoconus progression [4]. Extensive research has aimed at improving the original CXL protocol [5]. However, the stiffening effect of this procedure has commonly been assessed in vitro and by using healthy corneal samples. The keratoconus-induced changes in the corneal extracellular matrix were considered in the present work by using KS II GAG-depleted samples. We found that in agreement with previous studies, the CXL therapy significantly increased tensile properties of control samples. Furthermore, we found that removing KS GAGs significantly reduced corneal tensile properties, consistent with a recent finding from our laboratory [2-3]. GAG-depleted samples exhibited marked softening, contrasting with the CXL-induced stiffening in control samples. KS GAGs, forming duplex structures, act as bridges in the corneal stroma, contributing to collagen fibril stability and organization. GAG depletion led to reduced density and softening.

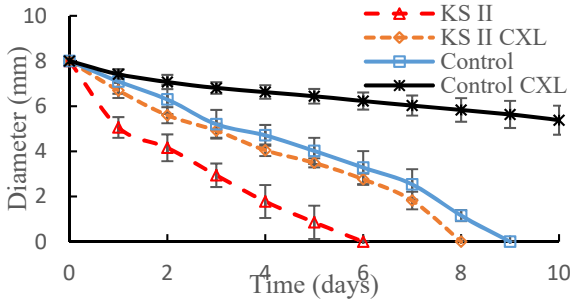

Figure 3: The sample diameter variation over time which was conducted to assess the resistance of samples from various groups to pepsin digestion.

The CXL procedure enhances mechanical properties of keratoconus cornea and halts the disease progression by creating additional crosslinks within PG core proteins and/or between collagen molecules [6]. These additional crosslinks are believed to be responsible for stiffening the tensile response. The present study found that the CXL treatment improved tensile properties of GAG-depleted samples. The CXL treatment also improved corneal resistance to enzymatic degradation, crucial for halting keratoconus progression [7]. We observed decreased enzymatic degradation rates in the CXL-treated Control samples and enhanced resistance in CXL-treated GAG-depleted samples. In conclusion, the present work gave unique insights into the role of KS GAGs in the efficacy of the CXL treatment, highlighting their substantial influence on corneal tensile properties. In continuation of this investigation, we are now comparing the mechanical properties of human and porcine corneas. Expanding upon the foundational knowledge acquired here, our subsequent research delves into the distinctions and similarities between porcine and human cornea, enriching our understanding of corneal biomechanics across species.

USING FIBER MODELING TO UNDERSTAND THE EFFECTS OF MODULATING TISSUE MECHANICAL PROPERTIES AS A PREVENTATIVE TREATMENT FOR GLAUCOMA

INTRODUCTION

Glaucoma is one of the top causes of blindness worldwide. Vision loss in glaucoma is due to damage to the retinal ganglion cell axons that carry visual information from the retina to the brain [1]. The damage initiates in the lamina cribrosa (LC) a region in the posterior pole of the eye. Although the mechanisms lading to neural tissue damage are not yet fully understood, elevated intraocular pressure (IOP) is the main risk factor [2]. Moreover, all current treatments to slow down or stop the progression of glaucoma are based on lowering IOP. However, the treatments to lower IOP have side effects and are not equally effective for every patient [1].

An alternative to lowering IOP has been discussed in the glaucoma community: instead of lowering IOP, perhaps it is possible to reduce the sensitivity of an eye to IOP [3]. Underlying this hypothesis is the idea that some eyes have characteristics that make them more robust, and therefore able to sustain levels of IOP that would hurt other eyes. Thus has surfaced the idea of modulating the mechanical properties of the eye to reduce its sensitivity to IOP [4]. Several approaches have been suggested to achieve this goal, including the use of chemical crosslinkers with or without photoactivation. Proposals of tissue modulation aim at stiffening the sclera with the intent that this translates into lower insult at the LC [3,4].

We propose that it may be possible to modulate the mechanical properties of the LC, with the advantage of acting directly on the region where the effect is desired. Furthermore, we believe that it may be advantageous to modulate LC properties both through stiffening or softening [5].

Our goal in this study was to simulate hypothetical treatments based on local tissue modulation and evaluate their effects on LC mechanics. We hypothesized that the effects of tissue modulation will depend on whether the modulation was done within the LC or in the adjacent sclera, and whether the modulation was done for softening or stiffening the tissues. Finally, we postulate that the effects of the tissue modulation will depend on how the collagen fibers of the LC and sclera bear and transmit the forces over long distances or to other fibers [6].

METHODS

Because of the complexity of the LC it is convenient to use numerical techniques to evaluate and personalize the tissue modulation process to obtain optimal interventions. A section through the LC of a sheep eye was imaged using polarized light microscopy to reveal the collagen density and fiber architecture. Based on this image, two specimen-specific computational models were built representing extremes of the fiber behavior: a highly dissipative conventional continuum model (CC) and a novel direct fiber model (DF). In the CC model, the tissue mechanical properties are simulated according to a constitutive formulation with a functional representation of fiber orientation and anisotropy. In this model, the fibers and forces are "smeared" within the elements and their boundaries. In the DF, the fiber bundles carry forces over long distances (Fig 1). The actual properties of the fibers themselves are modeled in the same way, but the models differ in how they are integrated and how the fibers interact and transfer forces. Both models were used to simulate a canal expansion of 10%. Regions of the LC and sclera were selected for stiffening or softening.

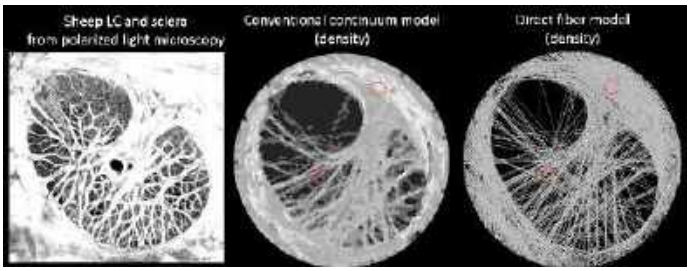

Figure 1: Based on an image of a sheep LC (left) two models were constructed (middle and right). Shown are density maps overlaid with circles indicating the location of tissue modulation, one in the LC and another in the sclera.

RESULTS

Tissue modulation had significant effects on the response of the whole region (Fig 2), with effects that were different for softening and stiffening.

The force dissipation process had large effects on the effects of the modulation. In the CC models, the changes were confined primarily within the area where tissue properties changed, with changes in the LC spreading farther than those in the sclera. In the DF models, the largest effects of the modulation were also localized to the place of change, but some substantial differences extended far from the change.

Figure 2 (below): Contour level plots of displacement, stretch and stress for the models as reconstructed (top row), and of the differences due to stiffening or softening of the LC or sclera. All modulations had clearly discernable effects on all three outcomes, but with different magnitudes and distribution.

DISCUSSION

The collagen fibers of the LC and sclera form complex interweaving bundles spanning mm-scale distances in the optic nerve head. On the one hand interweaving suggests that forces are easily transferred between the fibers and thus dissipated in the close vicinity of a tissue property change. On the other hand, long fibers can carry forces over long distances, suggesting that the effects of changes can spread far. Our modeling results indicate that accurately predicting how LC and sclera respond to tissue modulation requires a more detailed understanding of how fibers transmit the forces in actual tissues. We suspect that none of the two modeling approaches we used is entirely appropriate as both imply assumptions that are known to be violated in actual tissues, and thus cannot be considered fully reliable. However, we posit that by considering both modeling approaches it is possible to gain a more comprehensive understanding of how tissues may respond to modulating their mechanical properties.

Our results suggest that modulating the LC properties, including for softening, has the potential to improve the LC mechanical environment as much as modulating the sclera.

INTRODUCTION

Computational models are pivotal in the progress of cardiovascular applications enabling the creation of patient-specific designs of stents, grafts, and patches [1-5] for virtual surgical planning, the visualization of surgical outcomes, and the prediction of the mechanical behavior of the repaired or reconstructed arteries [5,6]. However, the precision of these models is often challenged by patient-specific factors including variations in arterial wall thickness and the specific parameters that define the material properties of the arteries. Another complex factor is the pre-stretch of arteries, which refers to their natural tension without any external forces. Recognizing and integrating these individual factors is crucial to refine the precision of computational models, which in turn, can significantly improve the effectiveness of surgical planning for cardiovascular conditions.

METHODS

In this research, the deformation response of a porcine pulmonary artery (PA) under a pressure increase of 13 mmHg from diastolic to systolic phase [7], was analyzed using finite element software FeBio [8]. The study conducted a thorough analysis to understand how changes in material properties and arterial wall thickness impact the artery's deformation. The established Holzapfel-Gasser-Ogden (HGO) [9] model provided the framework for characterizing the stress-strain relationship of the arterial wall. Different model complexities were considered as shown in Fig. 1. To investigate the effect of wall thickness, the arterial wall was modeled in two ways: as a single-layer structure (intima-media, IM) and as a dual-layer structure (IM and adventitia, ADV) with constant and varying wall thicknesses (t). To study the influence of the heterogeneity of material properties across the PA, HGO parameters were varied based on ex-vivo data derived from the literature [10] in different regions of the PA, namely main PA (MPA), bifurcation region (B), left PA (LPA), and right PA (RPA), as illustrated in Fig. 1(d). The material constants used in each PA region are listed in Table 1. The circumferential strain as a result of pressure increase on the luminal wall was calculated [11]. To assess the influence of t and HGO parameters on the circumferential strains, a sensitivity analysis was carried out by varying the parameters within their standard variation [10,11]. Adjustments to model parameters and t were made to match the observed circumferential strains in vivo [11]. Furthermore, a pre-stretch state [12] was added to the model at the end-diastolic phase to examine its impact on both stress and circumferential strain outcomes using the prestrain gradient available in FeBio [8].

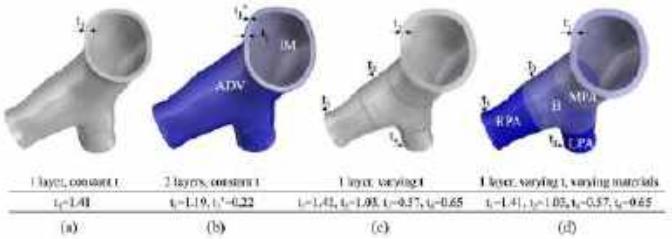

Figure 1: Computational model of PA walls with different wall layers and thicknesses. The unit of thickness is mm [11].

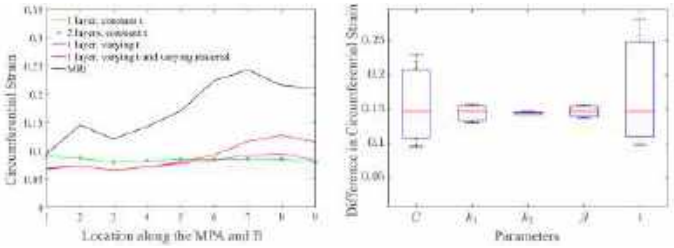
Table 1: HGO model parameters in different regions of PAs [10]

	MPA	B	LPA	RPA
C (kPa)	40	30	43	82
k_1 (kPa)	66	80	247	473
k_2	0.53	0.67	0.61	0.78
β (degrees)	18.9	55.24	39.96	15.14

RESULTS

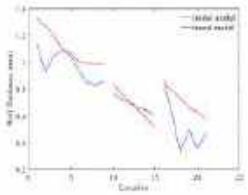
The circumferential strains along the MPA and B regions obtained using different models are shown in Fig.2a. The results revealed that to replicate the strain response measured in-vivo by magnetic resonance imaging (MRI), it is necessary to incorporate a variation in wall thickness across different regions, and a single-layer model sufficed for this purpose. The sensitivity analysis showed that the strain response was most sensitive to variations in thickness, *t*, and isotropic shear modulus, *C*, of the artery wall (Fig. 2b).



(a) (b)

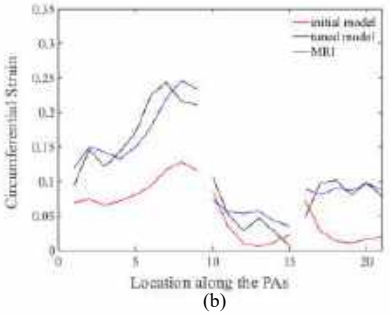
Figure 2: a) Circumferential strain outcomes of various models. The x-axis shows the PA centerline locations where circumferential strains were measured. b) The difference in circumferential strain resulting from varying parameters [11].

Using this knowledge, we tuned the model parameters for the porcine model until the deformation results were within 10% of the MRI-measured deformations. The initial and tuned *t* along the PAs are shown in Fig. 3a. On the x-axis, positions 1 to 9, 10 to 15, and 16 to 21 correspond to MPA, LPA, and RPA, respectively. Below the figure, the table presents both the initial and tuned values of C in each region of the PA, alongside the range of the values specified in the literature [10]. Initial, tuned, and MRI-measured circumferential strains were presented in Fig. 3b.



(a)

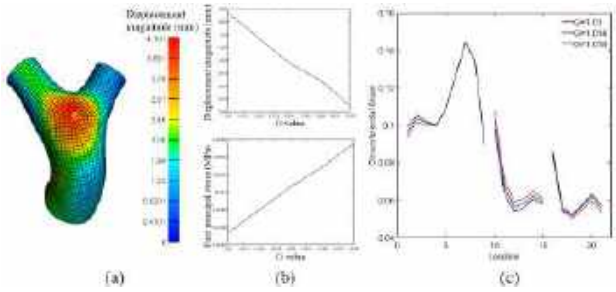
C			
	initial	tuned	range
MPA	40	35	40.77±11.02
B	30	21	30.03±11.52
LPA	45	60	45.24±71.72
RPA	82	80	82.61±90.54



(b)

Figure 3: a) Wall thickness variation of initial and tuned models b) Initial, tuned, and MRI-measured circumferential strains [11].

In the final part of our analysis, as depicted in Fig. 4, we plotted the displacement magnitude (Fig.4a) on the PA walls and examined the impact of varying the pre-stretch value, G. By focusing on a specific node in region B, where the displacements are relatively higher, we noted that an increase in G resulted in a decrease in displacement magnitude (Fig. 4b, top) and an increase in the first principal stress (Fig. 4b, bottom). To further understand the influence of pre-stretch on deformation across the entire PA walls, circumferential strains were plotted for G values of 1.01, 1.014, and 1.018 in Fig.4c. We observed that in the proximal MPA and the distal RPA, deformations increased with an increase in G. In contrast, the LPA exhibited a decrease in circumferential strain. This pattern suggests that pre-stretch may be influenced by geometric factors. Similarities in circumferential strain trends in the LPA and RPA, were observed. It is important to note that the RPA has a larger diameter (approximately 11.66 mm) compared to the LPA (around 10 mm), and a thinner wall (0.57 mm versus 0.65 mm). Additionally, the LPA and RPA do not branch off from the MPA in a perfectly symmetrical manner. Consequently, the large deformation observed in region B, near the LPA and RPA, might contribute to different deformation effects in these areas.



(a) (b) (c)

Figure 4: a) Displacement magnitude on the PA walls at a pre-stretch value of G=1.01. b) Displacement magnitude (top) and first principal stress (bottom) for a selected node in region B with increased G. c) Circumferential strains at different G values.

DISCUSSION

Our modeling framework aims to deepen insights into the influence of arterial wall parameters and to predict the biomechanical response of arteries. For procedures like artery reconstruction, understanding post-surgical shape deformations is crucial, as they can lead to suboptimal outcomes. Our model offers the capability to anticipate these shape changes before surgery. In our upcoming research, we plan to validate this model against the actual post-surgical results of reconstructed arteries. Furthermore, we intend to refine the pre-stretch input of our model by experimentally measuring residual stresses, which will allow us to derive a prestrain gradient using ex vivo porcine PAs. As we acquire more comprehensive data from human arteries, it will become possible to convert these animal models into patient-specific ones.

A NOVEL DIFFUSION TENSOR MYOCARDIAL MATERIAL MODEL USING NEURAL NETWORKS FOR FORM DETERMINATION

Benjamin J. Thomas (1), Christian L. Goodbrake (1), Michael S. Sacks (1)

(1) James T. Willerson Center for Cardiovascular Modeling and Simulation, Oden Institute for Computational Engineering and Sciences and the Department of Biomedical Engineering, University of Texas, Austin, Texas, USA

INTRODUCTION

Cardiac tissue is a very complex structure made up of myocytes, blood vessels, and extracellular matrix. The structure also exhibits changes in orientation that can be seen throughout the heart. Determining the effects of structural changes is critical to improving the treatment of cardiac pathologies. Due to these large variations in structure, the tissue is modeled as a nearly incompressible, anisotropic material, where anisotropy is typically modeled through the use of pseudo-invariants giving a measure of strain in certain directions.

Diffusion Tensor Magnetic Resonance Imaging (DTMRI) is an established non-invasive method to obtain the structural properties of fibrous tissue. The diffusion tensor itself has not been fully incorporated in these models, but rather only used to determine the local material orientation. As the diffusion tensor **D** contains much structural information, it seems logical that **D** should be fully incorporated into the material model. However, one ongoing problem in developing new material models is that of determining its form. This is typically done by trial and error and often results in sub-optimal results. By utilizing a machine learning approach, one can give a generic form of the model, with very little prior knowledge, dependent on the diffusion tensor and see which terms are important through the training process.

Neural networks are universal function approximators, allowing them to achieve a good fit to a broad range of problems. By constraining the architecture in a specific way, one can obtain an architecture of neural network that fits most material models dubbed Constitutive Artificial Neural Networks [1]. Extending this idea, the neural network can be inserted into an inverse modeling framework for anisotropic materials, leveraging automatic differentiation to obtain the gradients required to train the system. The method can then be used to determine how the diffusion tensor plays a role in the material model.

METHODS

Given each force-displacement pair, we want to obtain the material parameters for the strain energy function without knowing the exact form it takes. The neural network will represent the arbitrary forms of strain energy functions possible through compositions of functions. Creating the neural network is straightforward since it is a composition of functions beginning with the deformation gradient **F**.

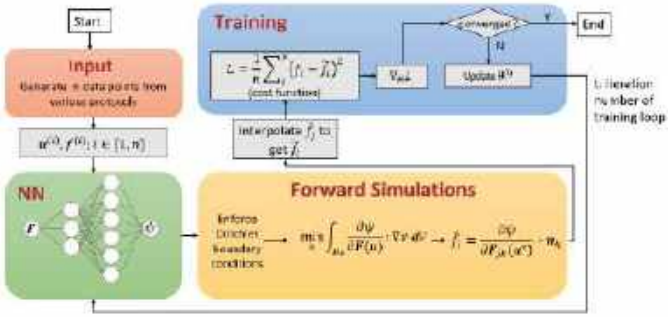

Figure 1: The inverse modeling pipeline from input data until convergence.

Extending the idea to anisotropic materials, the strain energy is no longer a constant scalar field since **F** now has dependence on position, **x**. Thus, a finite element framework is required to solve for the material parameters to capture the variation. The software JAX-FEM was used to incorporate the neural network structure in a finite element package. Now, incompressibility must be enforced weakly through a nearly incompressible formulation depending on det(**F**),

$$\psi_J(\boldsymbol{F}) = \alpha(J(J-1) - \ln(J)) \tag{1}$$

The final strain energy has contributions from the neural network and the incompressible term where α is increased until J ≈ 1 for all elements. The final strain energy is thermodynamically consistent, so the First

Piola-Kirchoff Tensor, **P**, can be found by automatic differentiation with respect to **F** which can give of the force on the respective face.

As seen in Figure 1, an initial model form is chosen, can be with extra terms. The displacements are used as boundary conditions dependent on the protocol. The nodal displacements are solved for, which are then used to calculate the forces from the neural network. The loss, the mean squared error of forces, is now minimized to achieve the desired parameters.

With this method of determining form, one can also add structural information into the form of ψ. For cardiac tissue, the diffusion tensor gives the structural data we desire by distinguishing fiber and sheet directions of the tissue. The diffusion tensor is sampled on a 1 cm^3 grid, so the values used are interpolated onto the mesh are normalized, so integrating ρ in (2) will equal 1. The spatial variation of the diffusion will account for the anisotropy of the material giving us a structural model of the form:

$$\rho(\theta,\phi) = n(\theta,\phi)^T \boldsymbol{D} n(\theta,\phi) \tag{2}$$

$$\psi(\boldsymbol{F}) = \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \int_{0}^{\pi} \rho(\theta,\phi)\hat{\psi}(\boldsymbol{F},\theta,\phi)\sin(\phi)\, d\theta d\phi \tag{3}$$

Where the total strain energy $\psi(\boldsymbol{F})$ is calculated from $n(\theta,\phi)$, the normal vector in spherical coordinates, **D,** the diffusion tensor, and $\hat{\psi}(\boldsymbol{F},\theta,\phi)$, the function made from the network mentioned previously.

RESULTS

Testing our inverse modeling method, we used the model and diffusion tensor data described in [2] by Li. The Li dataset comes from 5 specimens of ovine ventricular myocardium with various degrees of anisotropy. Synthetic data was generated to know the true parameters, where the Li model contains 6 pseudo-invariants to cover the ranges of stress seen in the different specimens. An initial guess was determined by finding parameters under the assumption of a homogeneous material model. These initial estimates were then used to determine the anisotropic parameters to obtain the desired fit seen in Figure 3 with the corresponding loss in Figure 2.

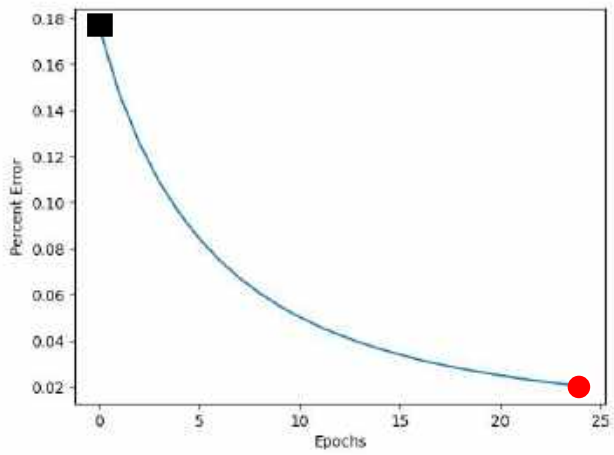

Figure 2: Training curve for learning the Li Model where the black square and red circle corresponds to points in Figure 3 taking roughly 1.5 hours to train.

Using the same data as above along with the force-displacement pairs, the new structural model described in (3) was tested using a strain energy function as follows:

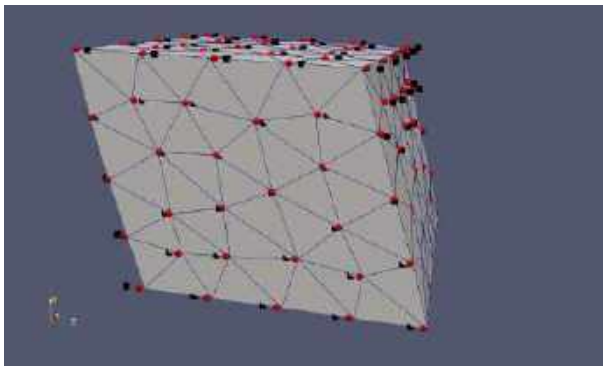

Figure 3: Specimen after pure shear in X1/X2 direction. Black squares represent prediction with initial estimate, red spheres are the prediction after training, and the wireframe is the true solution.

$$\hat{\psi}(\boldsymbol{F},\theta,\phi) = \sum_{i=1}^{5} c_i (I_4 - 1)^{2i} + \sum_{j=1}^{5} d_i (I_5 - 1)^{2i} \tag{4}$$

The specific strain energy was chosen for its ability to capture anisotropy as well as the ease of implementation. The same process of the initial guess was done as before to determine an estimate of the parameters c_i and d_i. Then the inverse method was used to determine the anisotropic parameters for the material where we only needed the first three terms of I_4 with results shown in Figure 4.

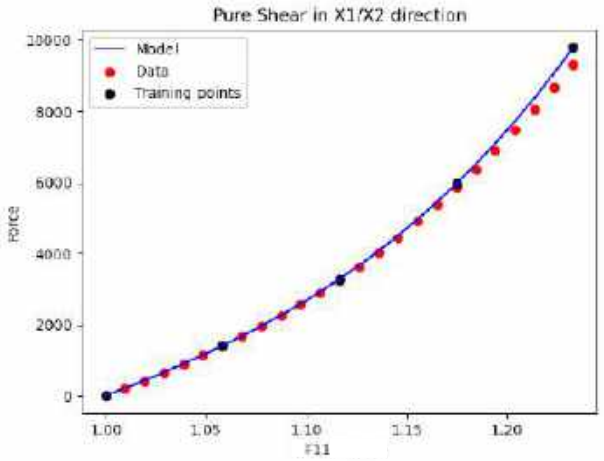

Figure 4: **Force vs. displacement curve for pure shear in the tensile direction.**

DISCUSSION

The framework provided allows us to determine the material model form from the given data, by seeing which parameters go to 0, eliminating guess work in form determination. We can incorporate structural information into the model through diffusion tensor data. Moreover, the models are no longer locally homogeneous because the diffusion tensor varies spatially. This culminates into a simple material model given by (3) and (4) fully describing the anisotropy of the myocardial tissue.

INTRODUCTION

High Intensity Focused Ultrasound (HIFU) is a non-invasive procedure that has gathered clinical interest for tumor ablation. Its effectiveness has been demonstrated through *in vitro* and *in vivo* models. The key to treating tumors lies in applying sufficient acoustic power to induce necrosis. However, the challenge arises as high acoustic power may inadvertently cause collateral damage to neighboring tissues, resulting in issues like skin burns, and damage to blood vessels and nerve cells. To address this, external heat absorbers such as nanoparticles have been employed to reduce power requirements and exposure durations.

Numerous researchers have explored the use of nanoparticles to enhance thermal effects and decrease power requirements. For instance, Dibaji et. al. [1] utilized magnetic nanoparticles (mNPs) in tissue-mimicking materials (TMM), while recent studies have shown the efficacy of gold nanoparticles (gNPs) in achieving enhanced thermal effects, both *in vitro* and *in vivo* [2].

In a study by Devarakonda et al. [3], the impact of gNPs during HIFU procedures was investigated for 0% gNPs concentration and 0.125% gNPs concentration. However, there is a possibility of injected gNPs being washed away by the bloodstream, diminishing their presence around the tumor, and hindering the intended temperature enhancement. Considering this, the current study emphasizes the use of gNPs functionalized with antibody fragments (Fab) to ensure they adhere to the tumor after injection.

Ouyang et al. [4] discovered that over 15% of functionalized nanoparticles reach the tumor when administered via tail vein injection, provided the number of injected nanoparticles exceeds 1 trillion, a condition met in the present study. In a previous study from our lab [3], a 0.125% concentration (maximum) of non-functionalized gNPs was used. The current research, however, utilizes 15% of the 0.125% concentration, resulting in a required tumor domain concentration of 0.01875%, considering the use of functionalized nanoparticles.

METHODS

Each NSG mouse in the experiment was injected with 1×10^7 PC3 tumor cells. Mice were then housed and monitored at Cincinnati Children's Hospital and Medical Center (Cincinnati, Ohio). The tumor growth was monitored for 4 – 6 weeks. The size of the tumor was measured regularly 2-3 days per week. Once the tumor was roughly above 10 cm in both transverse and longitudinal direction, it was deemed suitable for treatment. This was done to ensure that the treatment can be done in at least two zones of a particular tumor.

The functionalized gNPs construct was prepared following several steps reported by Dockery et. al. [5]. A solution of gNP-CO2H/N3 (81 mL, 2.14×10^{13} gNPs/mL) in filtered, pH8 1X PBS was stirred at room temperature in a freshly cleaned 250 mL round bottom flask. 501 mg Fab-DBCO (~10 Fab/gNP from 1 mg/mL stock) was added to this stirring solution. The reactants were stirred for 1 hour at room temperature. After 1 hour the reaction was stopped. The solution was centrifuged (45k x g, 2 hours, 4˚C), and resuspended in 40 mL filtered pH8 1X PBS. This was followed by another centrifugation (45k x g, 2 hours, 4˚C) with resuspension in 6 mL filtered pH8 1X PBS. Subsequently, a final centrifugation step (21 k x g, 1 hour, 4˚C) followed by resuspension in 2 mL (0.62×10^{15} gNP/mL) filtered, pH8 1X PBS was done.

Figure 1: Schematic representation of functionalization of dendronized gNPs with cancer specific targeting antibody fragment, Fab, starting from citrate gNPs.

The resulting concentrated solution was characterized using DLS and UV-Vis spectroscopy. The Z-average of the particle size was 27.49 nm and the maximum absorbance wavelength was 525 nm. The synthesis of intermediate dendrons and materials is described in the literature [6].

Gold nanoparticles (gNPs) were injected 24 h before the treatment. Mice were put in an incubator at 40˚C for 1 h before gNPs injection. The solution containing gNPs had a distinct purple color, such that it can be visible around the tumor after the injection.

A clinical MR-HIFU system (Sonalleve V2, Philips Medical Systems, Vantaa, Finland), integrated into 1.5 T (T) whole body scanner (Philips Ingenia, Healthcare, Best the Netherlands) was used for the scanning of the mouse tumors. The MR-HIFU system contains a 256-element phased array HIFU transducer that can be used to focus energy to small volumes within the tumor. The diameter of the array transducer and the operating frequency are 140 mm and 1.2 MHz. The focal spot of the HIFU bean was ~2 mm in radial direction. Further details about the MR-HIFU system can be found in Devarakonda et. al. [2].

On the treatment day, the mice were prepared by shaving around the tumor, applying Nair, and injecting with anesthesia. A set of two mice were placed under the HIFU transducer for the treatment. They were covered with acoustic gel to avoid the formation of bubbles and cavitation. MR images were taken before and after the treatment. The treatment was done first by locating the tumor with test sonication and then applying the assigned power with therapy sonication. The temperature rise using MR Thermometry was observed and recorded for analysis. The mice were kept for 4 h after the treatment under analgesia and then euthanized.

RESULTS

The reference body temperature was taken as 37 °C to calculate the temperature rise in all cases. Figure 2 shows the temperature rise data fitted to a linear profile for two cases: 0 % gNPs and 0.01875 % gNPs concentration cases. It illustrates the temperature rise (°C) using acoustic powers of 30 W and 40 W for gNPs concentration of 0% (hashed blue line) considered as the baseline case. Notably, the temperature rise was approximately 10°C and 17°C for 30 W and 40 W acoustic powers, respectively. When the acoustic power was elevated from 30 W to 40 W with 0% gNPs concentration, the temperature rise increased by 70%. A discernible linear trend is evident, characterized by a slope of 0.41 with R^2 value of 0.99.

Figure 2 also illustrates the temperature rise (°C) at acoustic powers of 40 W and 50 W for gNPs concentration of 0.01875% indicated by solid red line. The temperature rise was around 21°C and 30°C for 40 W and 50 W acoustic powers, respectively. An increase from 40 W to 50 W with 0.01875% gNPs concentration resulted in an increase in temperature rise of 42.8%. A linear trend is observed, featuring a slope of 0.58 with R^2 value of ~ 1. Therefore, the slope of temperature rise is higher in the 0.01875 % gNPs case than in the 0 % gNPs case (Figure 2).

In Figure 3, the temperature rise (°C) is presented for the same acoustic powers of 40 W, but with two different gNPs concentrations: 0% and 0.01875%. Notably, the temperature rose to approximately 18°C with 0% gNPs concentration and 21°C with 0.01875% gNPs concentration at the same 40 W acoustic power. This indicates that the temperature rise at 0.01875% gNPs concentration was 17.3% higher than the 0% gNPs concentration (or baseline case). Figure 3 also shows the temperature map around the focal pixels at acoustic power 40 W for both 0 % and 0.01875 % gNPs concentration.

DISCUSSION

The findings of this study highlight that the temperature rise increases with or without the use of gNPs as acoustic power increases. Also, most importantly, it shows that the temperature rise is higher for the case with gNPs in comparison to the case without gNPs for the same acoustic power. This underscores the significant impact of using functionalized gNPs in enhancing thermal effects at the same acoustic power.

Limitations: The study currently provides results for the 0% gNPs case at acoustic powers of 30 W and 40 W, and for the 0.01875% gNPs case at acoustic powers of 40 W and 50 W. Notably, data for the 0% gNPs with 50 W acoustic power and 0.01875% gNPs with 30 W acoustic power are not presented as these aspects are part of an ongoing study, and their findings will be shared in future presentations. Additionally, the current results are based on two mice in each category, and a more extensive study involving four mice in each category is part of an ongoing study.

INCREASING STUDENTS' EXPOSURE TO RESEARCH VIA APPLIED HOMEWORK PROBLEMS INTEGRATED IN RESEARCH MANUSCRIPTS

Sean Harrington (1), Turner Jennings (1), Ana I. Vargas (2), Frederick Sebastian (2), Rouzbeh Amini (1,2)

(1) Department of Mechanical and Industrial Engineering, Northeastern University, Boston, MA, USA
(2) Department of Bioengineering, Northeastern University, Boston, MA, USA

INTRODUCTION

Experiential learning, the process of integrating real-world problems and academics to create broadly applicable learning outcomes, is a pillar of the Northeastern University learning model. The experiential learning program provides an opportunity for students to apply the models learned in a classroom setting to real-world examples. While pathways to apply the same techniques to research opportunities exist, fewer students participate in research opportunities.

High school and undergraduate education coursework focuses predominantly on design-focused industry applications for the knowledge developed. As a result, for many undergraduate students, the concepts of academic research remain opaque. Integration of research into coursework mostly begins at a graduate level, artificially limiting the population of students engaged with research to those who are already demonstrating an interest in continued education. While lower undergraduate participation in research compared to industry opportunities is at least partially due to the student's anticipated career trajectory (Fig. 1), it is possible that the lower student participation in research is partially due to fewer opportunities to see how to use classroom knowledge in a research setting.

Existing research has shown that exposure to research through classwork increases undergraduate participation and performance in research [1, 2]. Such experiences have been shown to increase student GPA and reduce time to graduate [3]. While the value of participation is well known to the research community, the added value can be unclear to students who may not be able to relate fundamental STEM concepts to cutting-edge, modern scientific inquiry.

We share a framework herein for increasing undergraduate exposure to research through writing research manuscripts with integrated homework problems [4–8]. Examples of our existing papers published using the framework are included to highlight how undergraduate-level concepts can be extracted from complex papers in a way that encourages students to contextualize the course material in terms of potential applications to recent research. The methods discussed herein encourage researchers to broaden the reach of their manuscripts, with benefits to the research community, teaching community, and to the general efficacy of STEM graduates.

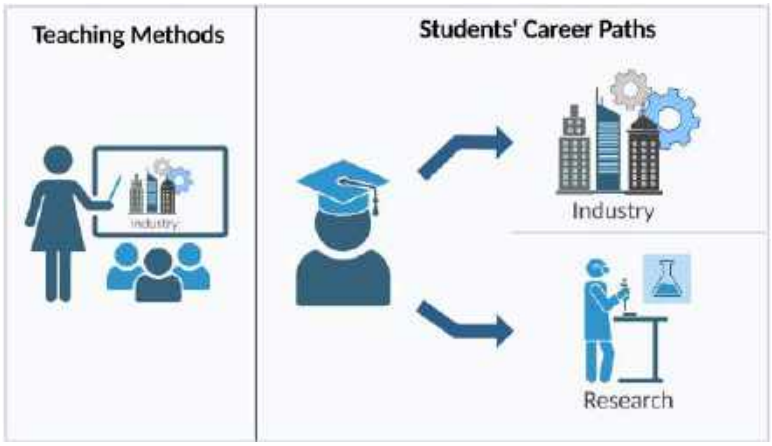

Figure 1: While conventional applications of engineering education often revolve around industry-centric design, research has increasingly emerged as a significant career avenue for numerous biomedical engineering students.

FRAMEWORK

To create a homework problem which encourages students to contextualize their classroom learning in terms of possible research applications, the following criteria have been defined:

1. The problem should be developed with a concept or course in the relevant field in mind.

2. The problem should directly align with the key theoretical concepts or findings presented in the research manuscript. It should serve as a practical application or extension of the research.

3. The problem should require the student to read the manuscript to understand the theoretical framework relevant to the problem.

Existing problems using this framework, examples of which are included hereunder, were developed by adapting existing classroom example problems to describe the core mechanics of the research performed in the related manuscript. Such an approach requires students to read the contents of the manuscript to understand how the simplified problem is foundational to the research performed, while encouraging the student to identify relationships between the simplified models and methods taught in undergraduate coursework and the more complex concepts derived from them used in cutting edge research.

While adhering to the same structural framework, our approach to conceptualizing problems for each paper took diverse paths. On one occasion, the problem originated from discussions among co-authors even before the paper was written. In another instance, a graduate student, serving as the primary author, independently crafted the problem. Additionally, on a separate occasion, the problem arose as a response to a reviewer's inquiry, prompting the authors to delve into and elucidate a fundamental concept.

EXAMPLES

The following "homework problem" examples were included in research manuscripts to bridge theoretical classroom concepts with practical research applications aiming to enhance students' critical thinking skills and comprehension of the research showcased in the specific manuscript.

1. *Undergraduate level biomechanics course—Using kinematics of rigid bodies [7]*: This research manuscript centers around an experimental phantom setup aimed at determining the accuracy of strain measurement in a magnetic resonance imaging (MRI) device. The homework problem posed a straightforward question, intending to establish connections between concepts such as angular velocity and the motion of the phantom. The calculations were mandated to be performed within the imaging plane, in accordance with the specifications of the MRI machine. Within this study, the experimental phantom setup serves as a crucial component, acting as a testing ground to assess the precision of strain measurements within the unique environment of an MRI device. The homework problem, designed to bridge theoretical concepts with practical research applications. The necessity to conduct calculations within the specific imaging plane prescribed by the MRI machine adds an additional layer of complexity and relevance to the research. This careful consideration ensures that the homework problem not only explores the theoretical aspects but also aligns with the practical constraints and requirements imposed by the imaging technology.

2. *Undergraduate level biomechanics course—Using the Law of Laplace to study aortic remodeling during pregnancy [4]*: In the homework problem presented in this manuscript, students are tasked with computing the percentage change in circumferential wall stress within a tubal tissue (specifically, the aorta) between late-gestation and control groups. They should utilize the data provided in the manuscript and apply the Law of Laplace to calculate the stress. Additionally, students are required to investigate the influence of hypertension by incorporating various blood pressures into the analysis of vessel wall stress. This problem provides insights into the biomechanical adaptation of the aorta during pregnancy and how these adaptations are modified in the presence of hypertension.

3. *Undergraduate engineering statistics course—Applying qualitative and quantitative analysis of metadata [5]*: This problem involves data analysis from the most recent SB^3C abstracts or an equivalent conference. A table is provided that outlines abstract counts categorized by the availability of ex-related data, including both sexes, balanced representation, only males, and only females. Students are assigned the responsibility of filling out the table and subsequently comparing their gathered data with the provided information. This exercise offers a practical application of statistical concepts within the realm of metadata analysis.

4. *Higher-level biomechanics or continuum mechanics course—Biaxial data analysis of hyper-elastic materials [6]*: This problem guides students through calculations of stresses and strains in a hyperelastic material using a provided dataset. The first part involves deriving the deformation gradient tensor and subsequently calculating the right Cauchy-Green deformation tensor and Green-Lagrangian strain tensor. In the second part, students have to determine the first Piola-Kirchhoff stress, considering sample thickness and applied loads. The students then have to create stress-strain plots. This problem provides a hands-on, comprehensive analysis of the mechanical responses of planar tissues under biaxial extension.

APPLICATIONS IN TEACHING

In most undergraduate engineering curriculum, homework problems resemble problems that the students would see in industry. Mechanical Engineering students receive countless truss bridge and transverse beam problems in Statics, Mechanics of Materials, and Finite Element Analysis, and while this exposure is great for someone who makes a career in building bridges, it has much less relevance to someone who aims to make a career in academia or research.

For example, a student in Mechanical Engineering will see many examples of pressurized pipes, and learn the Law of Laplace through many variations of the same problem. We propose that instead of assigning the students 3 homework problems with 3 pressurized pipes, the instructor instead assigns one research paper, such as a paper on the structural remodeling of the aorta in pregnancy [4], and assign the problem at the end of the paper for homework. The students would get the same amount of practice with pressurized pipes, but see a real-world application of the topic.

In this example, the students use what they've learned in class to calculate the stress in the walls of the aorta. They would be able to see how the aorta remodels during pregnancy to accommodate the higher volumetric output of the mother's heart during pregnancy. This method of instruction gives the students the same practice as the normal textbook problems, while showing the students a unique application of the topics they are learning in class.

CONCLUSIONS

The proposed framework aims to enhance undergraduate exposure to research by incorporating research manuscripts with integrated homework problems. The criteria for creating these problems involve aligning them with relevant field concepts, directly connecting to key theoretical concepts in the research, and necessitating manuscript reading for understanding. We aimed to illustrate how undergraduate-level concepts could be extracted from complex papers, encouraging students to contextualize course material in terms of potential applications to recent research.

INTRODUCTION

Heart failure with preserved ejection fraction (HFpEF) is a complex clinical syndrome that is characterized by a stiffened myocardium. However, little is known about the local myocardial deformation pattern [1–4]. In HFpEF, global indices of ventricular function, such as ejection fraction (EF), and echocardiographic indices of stiffness fail to capture the local adaptive remodeling that occurs in the myocardium [4]. Local indices, however, such as strain could provide insights into early changes in myocardial deformation. Current imaging-based measures of strain, which rely on the quantification of the circumferential and radial Green strains (E_{CC} and E_{RR}, respectively), do not qualify changes in the myocardial microstructure, and therefore lack clinical intuition and utility. Furthermore, the Green strains are not physically meaningful when the deformation is finite, which may compromise the reproducibility of the computed stiffness in finite element formulations [5, 6]. Due to the variation of the fiber orientation across the myocardial wall, the Green strains also do not capture the known transmural heterogeneity (i.e., subendocardial to subepicardial) of the deformation in relation to the myocardial microstructure [10].

To address the limitations of the Green strain, Criscione et al. developed a set of strain attributes that are optimized for one-fiber family materials, such as the myocardium. These strain attributes relate to the deformation of the myocardial microstructure [1–5]. Additionally, Srinivasa formalized a method, known as QR decomposition, to decompose the deformation into an orthogonal rotation tensor and an upper triangular stretch tensor. The components of the upper triangular stretch tensor are physically meaningful and mathematically tractable and are directly related to Criscione et al's strain attributes and have other major advantages [7]. Hussein et al. then utilized both QR decomposition and the strain attributes proposed by Criscione et al. to develop the Criscione–Hussein model for the myocardium, a constitutive model that was shown to represent the biomechanical behavior of the myocardium better than the Fung and the Holzapfel–Ogden models [6].

Because the strain attributes have yet to be quantified in humans, the goal of this work was to thus quantify the local changes in *fiber shortening and laminar thickening strain attributes* (α_2 and α_3, respectively) in human myocardium, which relate directly to the myocardial microstructure. Laminar thickening is defined as the deformation of the radial–cross-fiber plane along the radial and cross-fiber directions. Strain measurements were based on in-vivo displacement measurements acquired using displacement encoding with stimulated echoes (DENSE) MRI [8]. We hypothesized that fiber shortening and laminar thickening strains will capture greater transmural heterogeneity in myocardial deformation compared to the standard measurements of circumferential and radial Green strains.

METHODS

In 10 healthy humans (6 males ages 25-59 years and 4 females ages 22-31 years), ECG-gated cine DENSE MRI was used to measure pixel displacement in the basal, mid, and apical short axis (SA) orientations of the left ventricular (LV) myocardium [8]. (1) For each SA orientation, the mean and standard deviation of α_2, α_3, E_{CC}, and E_{RR} were calculated globally over the cardiac cycle. (2) Subsequently, to display the transmural variation in strain, the LV myocardium was represented by an AHA 16-segment model, and each segment was divided into 3 layers: subendocardial, midmyocardial, and subepicardial. α_2 and α_3 were calculated by assuming a transmural variation in the fiber orientation from -70° (outer wall) to +80° (inner wall) [9]. Finally, a paired *t*-test was used to assess if the difference between the mean E_{CC} and α_2 as well as the E_{RR} and α_3 per SA region were significant.

RESULTS

In the basal, mid, and apical myocardium, α_2 and α_3 revealed greater insights into the changes in the myocardial microstructure than

E_{CC} and E_{RR}. To illustrate, while the mean E_{CC} and mean E_{RR} were comparable, the mean α_2 was found to be greater than the mean α_3 by two-fold, indicating that *each myocardial region underwent more global fiber shortening than laminar thickening* (**Figure 1**).

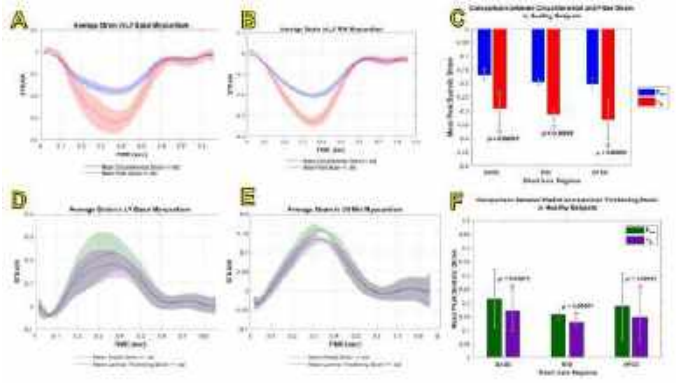

Figure 1: Mean E_{CC} (blue) & α_2 (red) and standard deviation for (A) basal and (B) mid SA view. (C) Mean peak systolic E_{CC} & α_2 for all 3 SA regions. Mean E_{RR} (green) & α_3 (purple) and standard deviation for (D) basal and (E) mid SA view. (F) Mean peak systolic E_{RR} & α_3 for all 3 SA regions.

There were significant differences between both peak systolic α_2 and E_{CC} in the basal ($p = 1.7\times10^{-9}$), mid ($p = 7\times10^{-8}$), and apical regions ($p = 9.9\times10^{-9}$). Likewise, there were significant differences between both peak systolic α_3 and E_{RR} in the basal ($p = 1.1\times10^{-9}$), mid ($p = 1.1\times10^{-9}$), and apical regions ($p = 1.9\times10^{-9}$). See **Table 1**.

Table 1: Measured mean peak systolic E_{CC}, E_{RR}, α_2, and α_3 in the basal, mid, and apical myocardium.

	E_{CC}	α_2	E_{RR}	α_3
Base	– 0.17 ± 0.002	– 0.29 ± 0.002	0.21 ± 0.006	0.17 ± 0.008
Mid	– 0.20 ± 0.002	– 0.31 ± 0.005	0.16 ± 0.007	0.13 ± 0.006
Apex	– 0.20 ± 0.004	– 0.33 ± 0.003	0.19 ± 0.003	0.15 ± 0.001

Figure 2 shows the transmural strain distribution across the myocardium for the mid SA image in peak systole.

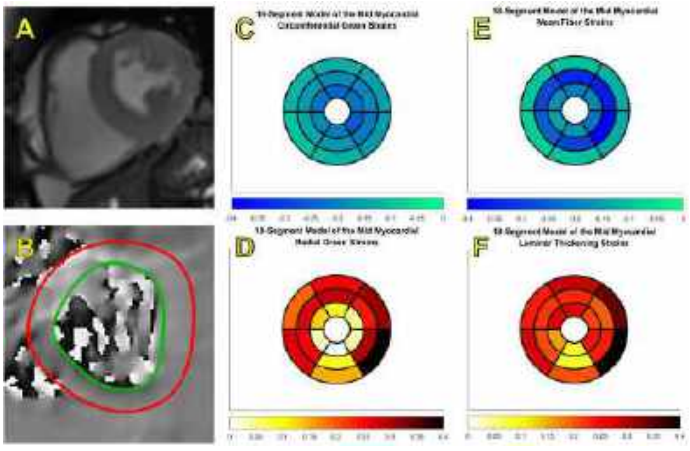

Figure 2: (A) Cine image for orientational reference. (B) Phase SA image of DENSE. Transmural distribution of (C) E_{CC}, (D) E_{RR}, (E) α_2, and (F) α_3 in mid SA region.

DISCUSSION

The goal of this study was to quantify the fiber shortening and laminar thickening strains *in vivo* and compare them to the more commonly used circumferential and radial strains. This study is the first that quantifies Criscione et al.'s strain attributes in the human myocardium. In our data (see **Table 1**), both α_2 and E_{CC} increase from base to apex in peak systole. Likewise, both α_3 and E_{RR} show a reduction in strain from base to mid and an increase from mid to apex in peak systole. Our results show the magnitudes of E_{CC} and E_{RR} were comparable; however, α_2 was double that of α_3 (**Figure 1**). This indicates that the strain attributes show greater transmural heterogeneity compared to the Green strains (**Figure 2**).

One of the seminal studies that sought to quantify the peak systolic Green strains was that of Costa et al., where the transmural variation in the peak systolic myocardial strain was quantified [10]. Our results agree with Costa et al.'s where E_{CC} increased from base to apex, which also agrees with other tagged MRI studies in humans [10–12]. Costa et al. also reported increasing radial thickening from base to apex and uniform fiber shortening (which were both based on Green strains) [10]. However, our work shows that the mean fiber shortening increases from base to apex whereas the laminar thickening decreases from base to mid but increases again from mid to apex. Thus, it appears that the choice of strain (Green vs Criscione et al.) reveals different conclusions about the myocardial microstructure, and thus care should be taken as such conclusions would prove significant for predicting and elucidating patient-specific pathophysiology in disease states such as HFpEF.

Our study is limited in that it needs histological data and/or diffusion tensor MRI data to validate our conclusions about changes in the myocardial microstructure. Additionally, we utilized 2D DENSE data when 3D DENSE would reveal a more complete picture. 3D DENSE would measure all 9 components of the strain tensor as opposed to just 4, producing a more robust means of comparison.

In conclusion, fiber and laminar thickening strain provide deeper insights into the myocardial microstructure compared to the circumferential and radial strains. Furthermore, measurements of such strains could provide clinicians with more mechanistic insights into the LV remodeling process and may serve as predictive markers of adverse remodeling in HFpEF.

INTRODUCTION

The urinary bladder, a structurally intricate organ, is characterized by its remarkable distensibility and capacity for muscular contraction, integral to its primary function of urine storage and expulsion. The bladder's multi-layered architecture, incorporating a transitional epithelium known as urothelium, high compliance lamina propria, contractile detrusor muscle layer and mechanically protective adventitia, enables it to fill under low pressures and generate sufficient intravesical pressure for near complete emptying, as evidenced in studies [1-6]. However, the advent of senescence introduces a spectrum of structural and functional impairments, significantly attenuating bladder function, a phenomenon extensively documented in gerontological literature [7,8].

In the domain of gerontological research, elucidating these age-associated morphological and functional transformations within the bladder is crucial for developing effective treatments for age related changes including incontinence and increased residual urine. Animal models of aging are needed for investigations of the multifaceted aspects of age-related bladder pathophysiology and provide a platform for developing therapeutic modalities [9]. Hypoxanthine, a purine metabolite that can be a source of potent reactive oxygen species (ROS) has shown great promise in addressing this need as it has a demonstrated ability to generate senescence related structural and functional changes in the murine bladder [9].

Here, we use this murine model of aging to explore one aspect of age-related changes– bladder geometry. While changes to the mechanical properties of rat bladder wall during aging have been studied [10], little attention has been given to age related changes in bladder geometry. The shape and wall thickness of the bladder directly impact the ability of the SMC in the wall to generate pressure in the bladder lumen and therefore have a primary impact on voiding effectiveness.

METHODS

Changes to bladder geometry were assessed in intact, unfixed bladders harvested from control and hypoxanthine treated 3-4-month-old female Sprague-Dawley rats. 3D data sets on bladder geometry including wall thickness were obtained at multiple states of inflation using high resolution micro-CT imaging (Skyscan 1272, Bruker) **Figure 1.** Briefly, following extraction and urine evacuation from control (N=5) and from animals treated with hypoxanthine in their drinking water for 10 mg/kg/day for 3 weeks (N=5), the bladders were placed in Hank's buffer solution containing inhibitors of muscle contraction. The bladders were then mounted on a custom inflation

Figure 1: Skyscan 1272 benchtop device (left) Traditional X-ray micro-CT depiction of internal Image Processing(right) [11]

system and preconditioned for 4 cycles of inflation from 5 to 35 mmHg, controlled using a programmable pump (BS-8000, Braintree Scientific). The intact bladders were then scanned under high resolution micro-CT at a fixed pressure of 7 mmHg and 35 mmHg within a 15 mL humidity-controlled chamber. The micro-CT scans were conducted at settings of 50 kV and 200 μA, 20 μm resolution, and 0.25-degree rotations over the complete 180° rotation, generating data that was post-processed to create 3D STL models of each bladder. Bladder volume and wall thickness were quantified using software tools including Simpleware ScanIP and Materialize 3-matic. Additionally, the bladder compliance was calculated as the change in volume divided by change in pressure from 7mmHg to 35mmHg. To assess asymmetry in wall thickness, four lines were drawn across the bladder lumen, orthogonal to the

longitudinal axis, **Figure 2**. Asymmetry was assessed using a wall uniformity index (WUI), defined as the ratio of maximum to minimum wall thickness across each line with WUI = 1 for perfectly uniformity (equal thickness) and tending to zero with increasing nonuniformity. Data were averaged from the mid lumen (WUI from two middle lines). Data are presented as mean ± standard deviation, with statistical validation using an ordinary one-way ANOVA, significance ($P<0.05$).

RESULTS

The asymmetry of the dome walls was significantly greater in the treated animals than controls (WUI $=0.85 \pm 0.11$ for control, WUI $= 0.48 \pm 0.18$ for treated, $P < 0.01$) [9]. This difference in symmetry is visible, for example, in Figure 2, where the bisected cross sections are shown for representative (A) control and (B) treated bladders. It is striking that despite these significant differences, the average wall thickness was maintained (control 0.65 ± 0.28, treated $0.64 \pm 0.20, P < 0.01$) [9]. The asymmetry can be seen in the deviation about this average. For example, in Figure 2(B), the average wall thickness for the treated bladder is 0.47 ± 0.25 mm. In contrast, the control bladder (A), demonstrates a relatively uniform thickness. 0.27 ± 0.03 mm.

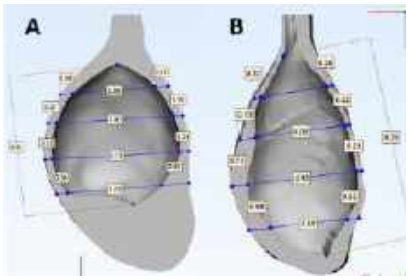

Figure 2: Bisected bladder geometries for control and treated bladders held at 7 mmHg (units in mm)

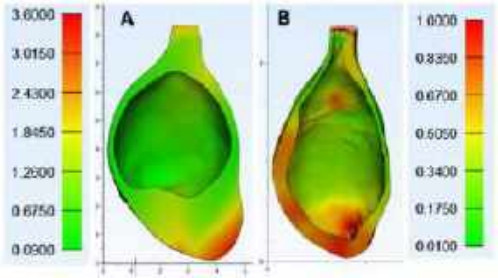

Figure 3: Visualization of Bladder Wall Thickness Variability in Rat Models at 7mmHg.

Figure 3 provides an alternate visualization of the spatially varying wall thickness in these same bladders, where wall thickness is visible as color contours. The control bladder (A) has nearly a uniform wall thickness in the mid lumen region, consistent with a value of WUI close to one. In contrast, the hypoxanthine-treated bladder displays a varied coloration, with red zones signifying areas of greatest thickness.

Moreover, the bladder compliance is decreased in treated versus control animals (4.7 mm^3/mmHg and 5.3 mm^3/mmHg, respectively). Additionally, the average luminal volume at 7mmHg is increased in treated bladders compared with control bladders (42.9 ± 36.5 mm^3 versus 22.4 ± 10.9 mm^3.

DISCUSSION

Several aspects of the geometry of hypoxanthine-treated bladders are substantially different than those of controls. The lumen volume of treated bladders at low pressure is nearly double those of controls. Moreover, the compliance was substantially reduced in the treated bladders. Namely, a larger change in pressure would be required for the same change in volume, suggesting voiding will be impaired. Both trends were also seen in bladders of older rats [10], though different methods were used in this earlier study.

In addition, the current study found the dome walls of treated bladders are less uniform than controls, with a WUI nearly half that of controls. The homogeneity in wall thickness across the control bladder dome would be expected to be associated with a more uniform mechanical stress distribution during micturition cycles, likley important for optimized voiding and filling.

In stark contrast, hypoxanthine-treated bladders exhibited pronounced wall thickness asymmetry, despite having an average wall thickness close to that of controls. This variation would, in turn, lead to a more heterogeneous stress distribution across the bladder dome. Moreover, thickened regions may be susceptible to hypoxia injury unless there is a concomitant increase in feeding vessels.

FUTURE WORK

The current work is an important step toward understanding ROS driven changes to the bladder geometry. Future studies are needed to understand the causes of these changes. It is possible that the urethral resistance increases in treated animals, which would be expected to drive an increase in bladder size, based on prior studies of bladder outlet obstruction [12]. Wall heterogeneity could follow if ROS-damaged bladders had impaired ability to maintain a constant wall thickness during this period of growth. Alternatively, abnormalities in bladder thickness due to heterogeneities in ROS driven changes could result in diminished bladder function, that in turn could drive remodeling changes that increase the bladder size.

An additional key area for future research involves examining the structural alterations linked to variations in bladder wall thickness. It's crucial to ascertain whether thicker areas are caused by fibrosis or smooth muscle cell hypertrophy. In contrast, it remains unclear which components are reduced in thinner sections of the wall. Such knowledge is not only scientifically fundamental but will also contribute to the development of computational models that assess how these structural changes affect bladder functionality and adaptation. Furthermore, upcoming studies will investigate the applicability of this ROS and oxidative stress-based animal model to human conditions and potentially other illnesses. This line of inquiry becomes even more relevant considering findings that show an increase in bladder wall thickness, underscoring the importance of understanding the wider effects of reactive oxygen species on bladder dynamics.

INVESTIGATING NONLINEAR INTRINSIC VISCOELASTICITY OF COLLAGEN TYPE II IN IMMATURE BOVINE ARTICULAR CARTILAGE

Kimberly R. Kroupa (1), Jeffrey A. Weiss (2,3) Gerard A. Ateshian (1,4)

INTRODUCTION

The mechanical behavior of articular cartilage is conferred by its extracellular matrix (ECM) structure. Composed primarily of proteoglycans (PGs), collagen (COL), and interstitial water, each component plays both independent and cooperative roles in sustaining articular contact. The bulk of PGs are aggregates, i.e. chondroitin sulfate and keratin sulfate, which hold a strong negative charge, producing Donnan osmotic pressure and contributing to the compressive stiffness of the tissue [1-3]. The interwoven type II collagen network counteracts this swelling and provides tensile strength. Together, crowding of these constituents creates the permeable ECM.

Under loading, interstitial fluid will pressurize in the ECM [4]. As the fluid flows through the porous matrix, friction between fluid molecules and the solid matrix dissipates energy, producing flow-*dependent* viscoelasticity. Flow-*independent* viscoelasticity, or intrinsic viscoelasticity, arises instead from the friction between molecules of the solid itself. In compressive loading, the creep and stress relaxation responses of cartilage are dominated by the flow-dependent effect. [2,3, 5,6]. In tensile loading, due to the large ratio of tension to compression nonlinearity of collagen, the response is instead dominated by the intrinsic viscoelasticity [7, 8]. Thus, modeling or isolating the contribution of intrinsic viscoelasticity in compressive loading responses of cartilage is difficult to achieve in the native tissue.

In 1990, Schmidt et al. [9] developed a sequential digestion protocol to remove more than 90% of PGs from cartilage, leaving a nearly pure collagen type II matrix. They measured the tensile response of the digested tissue and compared to native tissue. Under tensile creep testing, PGs were found to limit sudden stretching of the tissue, suggesting a protective role over the collagen matrix during sudden load application. However, the presence of PGs did not affect the equilibrium response of cartilage in any significant way. This method of isolating cartilage constituents overcame the limitations of confounding flow-dependent and intrinsic viscoelasticity in tension.

Similarly, we postulate that by removing nearly all PGs from the cartilage tissue, using this same digestion protocol, the flow-dependent response and fluid pressurization of cartilage under confined compression becomes negligible, producing a response dominated by the intrinsic type II collagen properties. As such, we propose to investigate the intrinsic viscoelasticity of immature bovine articular cartilage by 1) measuring the response of near-completely PG-depleted cartilage tissue under compression, and 2) performing parameter optimization to develop a suitable viscoelastic material model.

METHODS

Sample Preparation: Cylindrical cartilage explants were harvested from the condyles of 8 immature bovine knee joints (∅ 5 mm). Middle and deep zones were retained, with a thickness of 2.23 ± 0.3 mm. To date, 150 explants have been digested of proteoglycans (PGs) using the protocol in [9], as verified with a DMMB assay. Mechanical Testing: Samples underwent stress relaxation testing in unconfined compression. A 10 g tare load was applied to mitigate a toe region response. Then, 10% strain was applied at a rate of 1 μm/s and held for 1800s while the sample relaxed. Young's modulus E_Y was estimated from equilibrium load, displacement, and sample geometry [10]. Samples were allowed to relax for several hours, then retested at 40% strain, and held until an equilibrium load was reached, up to 2 hours (n=2).

Modeling: A finite element model was generated in the open-source FE software FEBio (www.febio.org) to replicate the experimental data. A unit cube (one hex8 element) was aligned with the XYZ-coordinate axes (Fig. 1). Fixed displacement boundary conditions were prescribed normal to each of the coordinate planes, resulting in a homogeneous state of strain and stress in the model. On the Z-face, the displacement profile of experimental strain was prescribed using a rigid 'platen'.

Material Model: Collagen was modeled using reactive viscoelasticity [13], with Type I bond kinetics, and elastic neo-Hookean models for strong and weak bonds, with modulus E and Poisson ratio $\nu = 0$.

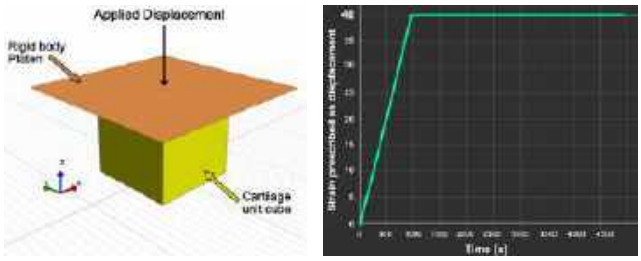

Figure 1: (A) Model geometry showing unit cube of cartilage and rigid body platen in contact with Z+ face. The load response on the platen represents stress (Figure 2, yellow) (B) Displacement profile from experimental data, prescribed on the platen

due to the lack of radial expansion (bulging) noted during experimentation [11]. A reduced relaxation function was selected by trial and error [15], landing on the continuous relaxation spectrum [12]:

$$g(t) = \frac{\tau_2 e^{\frac{-t}{\tau_2}} - \tau_1 e^{\frac{-t}{\tau_1}} + t\left[Ei\left(-\frac{t}{\tau_1}\right) - Ei\left(-\frac{t}{\tau_2}\right)\right]}{\tau_2 - \tau_1} \quad (1)$$

where Ei is the exponential integral function. Here, shortest time constant for relaxation is τ_1 and longest is τ_2. A power-law cumulative distribution function (CDF) was used to account for recruitment of weak bonds with increasing strain [15], with the form:

$$F(\Xi) = \mu_0 + \mu_1 \left(\frac{\Xi}{\Xi_0}\right)^{\alpha} \quad (2)$$

This function starts at μ_0=1, and rises with exponent $\alpha = 2$ and coefficient μ_1, increasing with a measure of strain Ξ, scaled by Ξ_0, where $\Xi = \|\boldsymbol{E}\|$ and $\boldsymbol{E}$ is the Lagrange strain tensor. A parameter optimization was performed to fit for E_e, E_b, τ_1, τ_2, μ_1, Ξ_0 from stress data of 40% strain tests, where e and b refer to strong and weak bonds, respectively.

RESULTS

The fitted values of the six material constants for two representative samples are listed in Table 1. Parameter optimization on the experimental 40% strain transient stress response data (Fig. 2) resulted in the fits shown, with $R^2 = 0.99$ for samples 1 and 2. The model exhibited slight undershoot at the peak stress (~900 s), reaching 90% of the experimental maximum, and slightly faster relaxation than observed.

Table 1: Material parameters fit for samples S1 and S2

Param.	Value	
	S1	S2
E_e (kPa)	18.8	19.8
E_b (kPa)	551	946
τ_1 (s)	10^{-3}	1.2×10^{-3}
τ_2 (s)	65.9	66.4
μ_1	27.8	21.8
Ξ_0	0.854	0.991

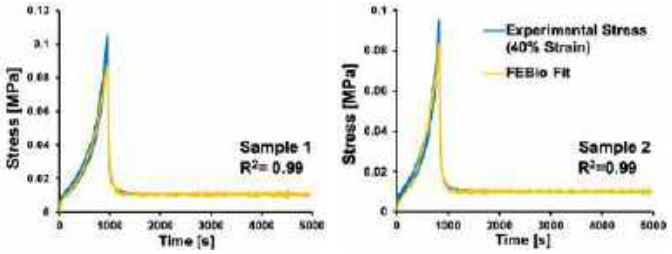

Figure 2: FEBio fit of 40% strain stress response (yellow), compared to experimental data (blue). S1 $R^2 = 0.99$, S2 $R^2 = 0.99$

These fitted values were then used to predict the response to the experimental stress response data at 10% strain (Fig. 3). These predictions consistently undershoot the experimental response over the duration of testing, but they maintain the profile of the experimental data well (R^2 =?). Here also, the model relaxed slightly faster than experimental data. Noise in the experimental data was due to the actuating stepper motor's resolution (~0.5 μm per step).

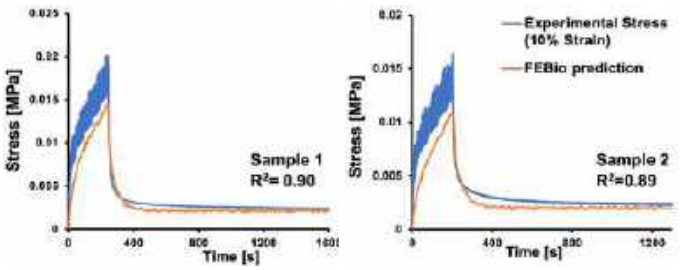

Figure 3: FEBio prediction of 10% strain stress response (orange), compared to experimental data (blue). S1 $R^2 = 0.90$, S2 $R^2 = 0.89$

DISCUSSION

This study demonstrates that near complete digestion of PGs allows us to characterize the intrinsic viscoelasticity of the porous type II collagen matrix of articular cartilage. Two samples were tested preliminarily, producing reasonable fits (Fig. 2) and predictions (Fig. 3). The fact that the prediction at 10% strain underestimates the experimental response suggests that the viscoelastic response is strain-dependent (thus, collagen is nonlinearly viscoelastic). These preliminary findings suggest that we may need to fit data from multiple ramp-and-hold stress relaxation tests (e.g., four times 10% strain, instead of a single 40% strain test). This refinement in the testing protocol will be explored next.

In 2015, we proposed [13] to model nonlinear viscoelasticity using the reactive viscoelasticity framework, where strain energy density in a material depends on the stored energy of strong and weak bonds in the tissue [14]. *Strong bonds,* such as covalent bonds [15], bind collagen together, and make up the elastic part of a load response (Figs. 2&3, see stress plateau >1500 s). *Weak bonds,* such as hydrogen bonds (formed by electrostatic attraction of local electrical charge variations along the length of collagen fibrils), become stressed under loading, then break and reform in a stress-free state. This time-dependent reaction produces the viscous contribution to the tissue load response (Figs. 2&3, see stress peak, which decreases rapidly according to τ_2 as bonds break and reform <1000 s). As the tissue is compressed, it is sensible that more local charges come into proximity to one another, giving rise to the need for weak bond recruitment, represented by the power CDF [14].

As expected, the values fitted for E_e (Table 1, n=2) agree with the average equilibrium modulus of PG-depleted cartilage explants, 18.9 ± 3.7 kPa (n=30). The fitted values for E_b (Table 1) were far greater than E_e, in accordance with observations of a large increase in stress with strain (Fig. 2), implying that intrinsic viscoelasticity is very significant in the type II collagen matrix of immature bovine articular cartilage, potentially playing a major role in the protection of the tissue against damage under loading, as explained in our recent theoretical study [14]. In our ongoing studies we will continue to investigate the best model to fit to experimental unconfined compression stress-relaxation data on PG-depleted cartilage samples, to acquire more insights into cartilage structure-function relations.

DISPLACEMENT PROPAGATION IN PRESTRESSED TWO-DIMENSIONAL FIBROUS NETWORKS

Ashutosh Mishra (1), Hamed Hatami-Marbini (1)

INTRODUCTION

Fibrous networks, serving as fundamental structural components in numerous materials such as paper, fabric, rubber, cytoskeleton, and soft tissues, have captured the interest of researchers for a long time [1]. The intriguing aspect lies in how these network structures not only contribute to the structural integrity of materials they compose but also influence their characteristics and functions. For instance, studies show that non-woven fabric benefits from fiber networks in holding and absorption, while rubber's cross-linking network structure provides its distinctive elasticity. Likewise, fibrous networks play a vital role in biological materials, with one such notable example being the Extracellular Matrix (ECM). Ubiquitous in all tissues, ECM primarily consists of various macromolecules, with collagen as the predominant fibrous protein organizing into networks. The ECM, with its network structure, plays a central role in various physiological processes, including cell growth, homeostasis, cell migration, differentiation, and morphogenesis [2].

A distinct feature of biological materials like the ECM, is nonlinear strain stiffening. This characteristic enables these materials to stiffen as per the applied strain, setting them apart from the non-biological materials [3]. Recent studies have also highlighted another interesting aspect of biological fibrous networks— the presence of residual stresses. These residual stresses play a crucial role in biological materials, such as supporting the mechanics of heart functioning in cardiovascular tissues and alveolar ducts in lung tissues [4][5]. These residual stresses, or prestress emerge from different factors like fluctuations in water concentration within the interstitial fluid, contraction in embedded fibroblast cells, or even from the early stages of development in the ECM [6]. These prestresses are known to induce anisotropy in collagen fibrous networks, even altering stiffness and modifying the onset of strain stiffening in these structures [7][8]. Therefore, it is evident that prestress is a fundamental aspect of fibrous networks and recognizing prestress as a fundamental influence on fibrous networks, its consideration becomes vital in their modeling and analysis.

The ECM also plays a crucial role in cell-cell communication, where cells within the ECM perceive and respond to their environment and neighboring cells. Previous studies have shown that contracting cells within fibrous ECMs can transmit displacement and forces over considerable distances relative to their size. However, previous studies often overlook the presence of residual stresses when analyzing networks subjected to local contraction. As highlighted earlier, prestresses are significant and should be considered when modeling and analyzing ECM network structures. Therefore, the aim of this study is to investigate the propagation of displacement through ECM generated due to cellular contractions in the presence of residual stresses.

METHODS

To simulate a fibrous network, a 2D regular network consisting of triangular unit cells is generated, with dimensions L in both directions. Each fiber, with a length of l_0, crosslinks at nodes with a local connectivity of 6. As known, biological fibrous networks exhibit a random and sub-isostatic nature, where the average connectivity falls between 3 and 4. To achieve this randomness and desired network connectivity, fibers within the network are removed with a probability of 1-q, where q is the probability of retaining fibers, until the desired connectivity is reached. To simulate a contracting cell embedded in the network, fibers inside a circular inclusion at the center of the network are removed. The inclusion's radius, R_c, is carefully chosen to maintain a ratio of $l_0/R_c \geq 0.4$. Network dimensions are selected to be at least 40 times greater than R_c to minimize any boundary effects.

The fibers in the network are modelled as athermal planar beam elements with a circular cross-section having area A, Elastic Modulus E, and Moment of Inertia I. These fibers have an axial modulus $\mu=EA$ and bending modulus $\kappa=EI$. A dimensionless bending rigidity, denoted as $\bar{\kappa} = \kappa/\mu l_0^2$, is set at 10^{-3} for this study unless otherwise specified.

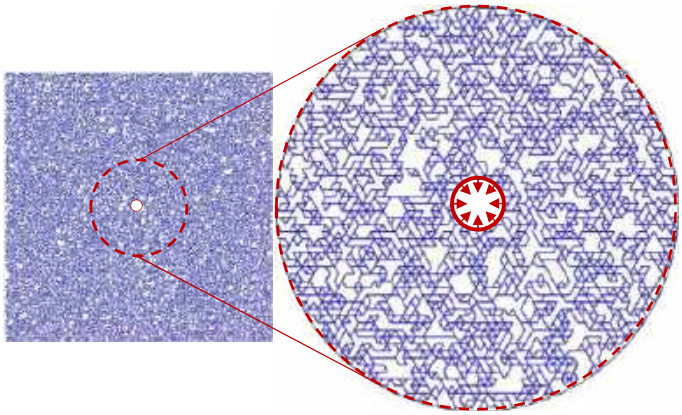

Figure 1: The diluted fibrous network with the center inclusion region where isotropic contraction is applied

Additionally, to accurately capture fiber deformation, the fibers in the network are subdivided into multiple elements. Figure 1 shows the diluted fibrous network with central inclusion where isotropic contraction is applied to mimic the cellular contraction.

To introduce residual stress to the network, nodes along the top boundary are either moved towards or away from the bottom boundary, while the bottom nodes remain fixed. The nodes along the vertical boundaries are subject to periodic boundary conditions. After applying prestress, the center inclusion undergoes isotropic contraction towards the network center, while ensuring the nodes at the network boundary remain fixed in their positions. The contraction is incrementally applied till 30%, resulting in localized contractile deformation.

RESULTS

The random networks were subjected to various levels of prestress in both tensile (away from the bottom or postive) and compressive (towards the bottom or negative) directions. In figure 2(a-c), the displacement propagation within the random network is illustrated under +5%, 0%, and -5% uniaxial prestress, respectively, due to 30% isotropic cell contraction at the center inclusion. The results clearly shows that the magnitude of displacement is most pronounced in the vicinity of the network center, diminishing gradually with increased distanceas observed in previous studies [9]. The propagation of displacement through the network also depends on the direction of prestress applied. When -5% prestress is applied, the displacement spreads further compared to the non-prestressed network. In contrast, +5% prestress results in a quicker reduction in displacement spread, concentrating nearer to the center of the network.

To quantify the observations the normalized radial displacement ($\hat{U}$) and normalized radial distance ($\hat{R}$) were obtained by dividing radial displacement (Ur) and radial distance (R) by the radius of the inclusion center (R_c), respectively. The findigs, shown in figure 2(a-c), were then fitted to the following mathematical expression

$$\hat{U} = A\hat{R}^{-n} + B\hat{R}^{n} \quad (1)$$

where A, B, and n are fitting coefficients. The coefficient n indicates the rate of displacement decay. A lower value n suggesta a more spreadout displacement field. Figure 2d illustrates the average normalized radial displacement with respect to the normalized radial distance of the nodes for different applied uniaxial prestress values.

DISCUSSION

The deviation in displacement propagation behavior in random networks, compared to a linear elastic continuum, can be attributed to compression weakening and fiber reorientation mechanisms. Previous

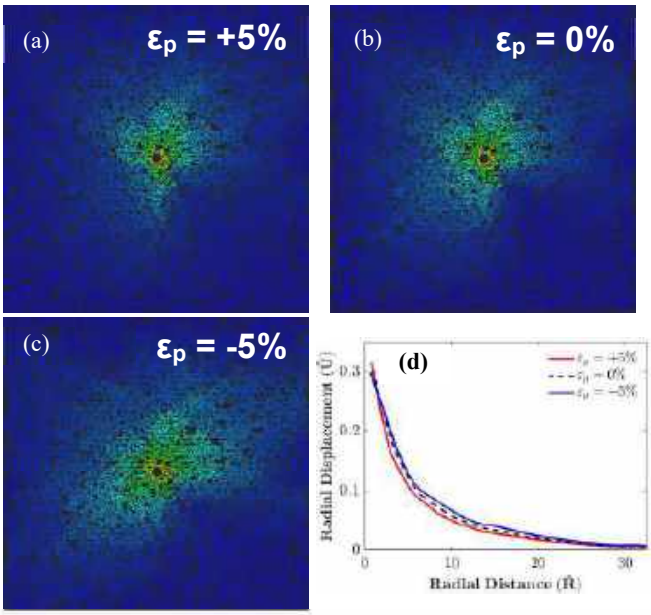

Figure 2: The propagation of displacement within random fibrous networks under (a) +5%, (b) 0% and (c) -5% uniaxial prestress subjected to 30% local contraction; (d) The smoothened average normalized radial displacement with respect to the normalized radial distance of the nodes for multiple values of the applied uniaxial prestress obtained using expression (1)

studies emphasize the crucial role of prestress in altering matrix stiffness. Negative prestress reduces overall network stiffness, allowing lower-energy deformations like bending and buckling when subjected to isotropic contraction, intensifying these mechanisms. Reduced stiffness enhances fiber reorientation, allowing fibers more easily align in response to applied forces, contributing to increased displacement propagation. Conversely, positive prestress increases stiffness, making fibers less prone to bending and favoring stretching, thus restricting displacement spread, and leading to reduced propagation.

In summary, this study highlights the impact of prestress on the extent of the displacement field in fibrous networks. Positive prestress led to a higher n-value compared to the non-prestressed network. Networks with greater stiffness showed decreased transmission of displacement compared to less stiff networks. Future investigations should delve into the influence of fiber bending rigidity and average network connectivity. Additionally, considering the composite nature of ECM, as suggested by recent studies, could be a valuable aspect for exploration in future research.

DIGITAL TWIN DEVELOPMENT AND FATIGUE OPTIMIZATION OF NOVEL POLYMERIC TAVR DEVICES TAILORED FOR PATIENT-SPECIFIC NEEDS

Brandon J. Kovarovic (1), Kyle J. Baylous (1), Ryan T. Helbock (1), Oren M. Rotman (1), Marvin J. Slepian (2), Danny Bluestein (1)

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has emerged as a minimally invasive alternative to high-risk surgical procedures, deploying a stented bioprosthetic valve within the aortic valve. Despite its rapid adoption and surpassing surgical valve procedures in 2019 [1], TAVR is associated with persistent clinical complications, primarily stemming from the limitations of chemically-fixed tissue bioprosthetic valve material.

The unknown *in vivo* durability of the leaflet structures poses a significant challenge, with structural valve degeneration (SVD) and wear leading to valve failure [2]. TAVR, originally intended for high-risk patients, now includes lower-risk and younger patients, further emphasizing the need for durable alternatives. Complications such as leaflet tissue damage during crimping and deployment phases, as well as thrombosis-related issues, remain prevalent. Testing and prediction of device fatigue (both leaflet and stent frame durability) has been limited to complex and costly *in vitro* accelerated wear testing that does not capture psychological motion/interaction of the device.

To overcome these challenges, polymeric valve alternatives are being explored. Polymeric technology offers the flexibility to design optimal valve configurations, considering ease, cost-effectiveness, and control of polymer manufacturing. While attempts at polymeric valve devices date back to the 1950s, limitations in available materials hindered progress. Key requirements for polymeric TAVR devices include hemocompatibility, flexibility, and exceptional durability (25 years in vivo). However, challenges arise in compressibility compared to tissue materials, necessitating design modifications to facilitate crimping into reasonable delivery catheter sizes.

This study presents the development of a polymeric TAVR device, from the concept surgical valve and progressing through material refinement and *in silico* optimization of the device performance and fatigue life prediction. Digital twin modeling utilizing patient models and complex beating heart model (Living Heart Model, Dassault Systemes, Vélizy-Villacoublay, France) allowed the optimization of

Figure 1 - Timeline for PolyV-2, and the PolyV-B device for BAV patients.

both devices for trileaflet and bileaflet patient anatomies. The latest generation, PolyV-2 27 mm (PolyNova Cardiovascular Inc, Stony Brook, NY), showcases advancements in polymeric TAVR technology, addressing key limitations and offering a promising solution to enhance durability and mitigate clinical complications associated with tissue valves (Fig1). The PolyV-B is the latest concept optimized polymer valve specifically designed to address the special needs of bileaflet aortic valve (BAV) patients, who are currently treated with commercial TAVR devices that are intended to restore the typical trileaflet aortic valve circular orifice configuration. When deployed in BAV patients whose valve's orifice is eccentric, such devices may perform poorly.

METHODS

The PolyV-2 device builds upon the advancements and success of the cross-linked styrene-isobutylene-styrene (xSIBS) based thermoset material known as "Flexamer." This material has recently demonstrated anti-thrombotic characteristics [3] and remarkable durability, enduring the equivalent of 25 in vivo years through 1 billion accelerated wear cycles [4]. The development and optimization of PolyV-2 aimed to achieve several key objectives, including the generation of larger valve sizes, establishment of suitable radial anchoring forces, targeting an 18F delivery catheter, enhancing valve performance, and implementing a

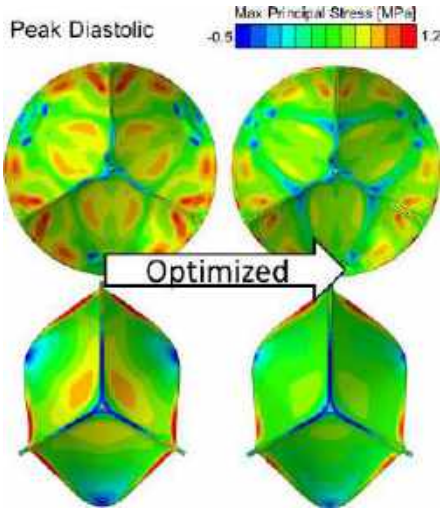

Figure 2 - Max principal stresses during peak diastole of the PolyV-2 (top) and PolyV-B (bottom) and the impact of the variable thickness optimized design.

"sutureless" molding approach. The primary focus was on designing for sutureless molding, allowing for the casting of both the leaflets and sleeve onto the stent frame in a single operation. This innovative approach eliminates a significant source of manufacturing error associated with the multi-day hand suturing of tissue to the stent frame. The design process involved in silico trials, leveraging finite element analysis (FEA) with Abaqus 2022 by Dassault Systemes. The optimization sequence included refining the stent frame design, followed by optimizing the leaflet profile, and finally fine-tuning the leaflet thickness (Fig 2). These steps were crucial in achieving the desired goals of larger sizes, effective anchoring, catheter compatibility, improved performance, and sutureless molding. The PolyV-B was optimized with a similar methodology [5], but with the assumption that the final stent will be eccentrically deployed, and asymmetrical leaflets will be used to achieve the highest device performance in the non-ideal deployment.

The PolyV-2 was compared to commercial tissue valve alternatives in the Living Heart Model v.2019 (The Living Heart Project, Simulia, Dassault Systemes) and simulated using ABAQUS Explicit. The simulation involved crimping the stents to the appropriate diameter and retracting the outer sheath, simulating the deployment procedure within the native aortic valve. Following stabilization, the heart was allowed to beat, and the stent deformation was tracked over three cycles until repeatability was achieved.

FEA was employed to assess the fatigue resistance of the stent models, utilizing the nitinol material properties as defined by Pelton et al [6]. Given the unique hyperelastic characteristics of self-expanding nitinol stents, the analysis tracked both the mean strain (over the loading cycle) and the strain amplitude (change in strain over the cycle) of each element node. Pelton's defined curve (Fig 3) established limits, with mean absolute principal strains over 8% and strain amplitudes over 0.4% indicating a risk of fatigue failure. Conversely, values below the curve were considered indicative of no risk of fatigue failure. This approach provided a comprehensive evaluation of the fatigue resistance of the stent models, contributing valuable insights into their performance under dynamic conditions.

RESULTS

The PolyV-2 design (Fig 3) was iterated to optimize achieving the highest radial force with a lower crimping volume of the stent (total volume must be reduced due to the incompressiblity of the polymer). The PolyV-2 prototypes were evaluated for hydrodynamic performance (ISO 5840 2021) and achieved greater performance (Effective orifice area >2.0 cm^2) compared to commercial tissue valves of similar size. Hydrodynamic testing also confirmed the adequate anchoring force with the larger (>120mmHg) diastolic back pressures, confirming the success of in depth *in silico* testing prior to manufacturing.

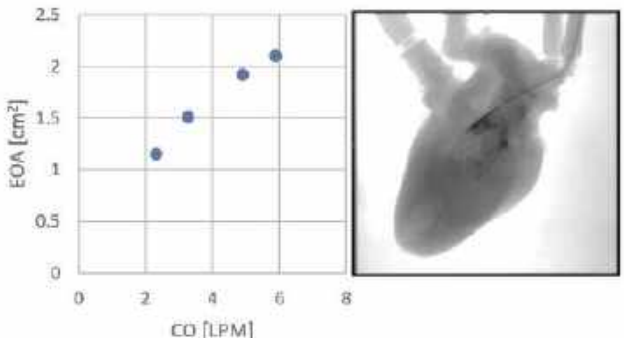

Figure 3 - (Left) Hydrodynamic performance (EOA) vs the cardiac output of the PolyV-2, (Right) Angiogram of the deployed PolyV-2 in an ex vivo ovine heart.

The PolyV-B was evaluated in patient-specific models and compared to commercial tissue valves [5], and with the optimization process achieved *in silico* performance 10-50% larger than the commercial alternative. The beating heart fatigue analysis demonstrated (Fig 3) the PolyV-2 struts were optimized to reduce the strain in stent joints and thus achieving better fatigue resistance in the top and mid element compared to the commercial stent and similar fatigue in the annulus region.

DISCUSSION

This study demonstrates the utility of digital twin modeling for cardiovascular device optimization, design to address specific anatomies and to help predict fatigue life of the device *in vivo*. By placing more effort in the design of the device, the PolyV-2 is able to mitigate the common pitfalls of previous polymeric valves failures [4]. The PolyV-2 is currently ongoing acute and chronic ovine trials. The initial *in silico* evaluation of the PolyV-B demonstrated superior performance and ability to design a device to address a currently neglected patient population with a unique anatomy.

COMPUTATIONAL ANALYSIS OF THE EFFECT OF TYPE B AORTIC DISSECTION ON PULSE WAVE VELOCITY AND PULSE WAVEFORM SHAPE

Marisa S. Bazzi (1), Hadi Wiputra (2), Rumi Faizer (3), Victor H. Barocas (2)

INTRODUCTION

Aortic dissection (AD) is a severe condition associated with high morbidity and mortality [1]. AD is often managed using medical therapy alone when showing no complication and confined to the descending region of the aorta (type B dissection). However, the 3-year survival rate for those cases is only 78%. The prognosis of patients surviving an acute type B dissection is uncertain, and frequent imaging and clinical follow-up are recommended to identify signs of the progression of the disease such as severe aortic dilation (diameter > 60 mm), rapid aortic dilation (> 10 mm/year)[1, 2].

Diagnosis based on geometrical quantities such as diameter and growth rate often fails to provide a comprehensive diagnosis, resulting in inadequate prediction of the actual risk [3]. In order to address this issue, the exploration of alternative diagnostic measures has become popular. One promising avenue involves leveraging pulse wave velocity (PWV) or extracting diagnostic insights from pressure waveforms. Carotid-femoral PWV is a standard technique to measure arterial stiffness [4], and it has numerous advantages over, e.g., MRI or contrast CT, in terms of examination time, cost, and lack of contrast agent. In addition to PWV, pressure tonometry can provide a full waveform, which may be informative regarding the health of the aorta.

Here, we tested the hypothesis that the PWV or pressure waveform is altered by the presence of a type B dissection. To isolate the effect of dissection on the PWV and the pulse waveform, we used a patient-based geometry, and removed the dissection to create a non-dissection case. Both geometries were used as the basis for fluid-solid-interaction simulations with the same boundary conditions, so the effects on the pulse wave, and PWV were only based on presence of the dissections.

METHODS

We used a patient-based geometry with a type B dissection [5] as shown in Fig 1A, and manually removed the dissection using Meshmixer to create a similar model, but without dissection, as shown in Fig. 1B. For both geometries, we solved the unsteady blood flow problem using the svFSI solver [6]. Resistor-capacitor-resistor boundary conditions were used for the outlets, and a flow waveform was imposed in the inlet, with boundary conditions kept the same for both the dissection and no dissection cases. Wall mechanics were described as neo-Hookean, and a Robin type boundary condition was imposed in the outer surface of the wall to account for the viscoelastic support of the outer arterial wall. All simulations were run for ten cardiac cycles. Other computational details followed Baumler [5].

The pulse waveforms were then extracted from the inlet (before the dissection) and outlet. PWV was calculated by the time lag between the wave foot [7]. The waveforms were analyzed by the metrics of [8] (shown in Figure 1C) to obtain a broad measure of change in wave shape. In addition, the waveforms were compared in the frequency domain to identify any finer-scale changes induced by the presence of the dissection.

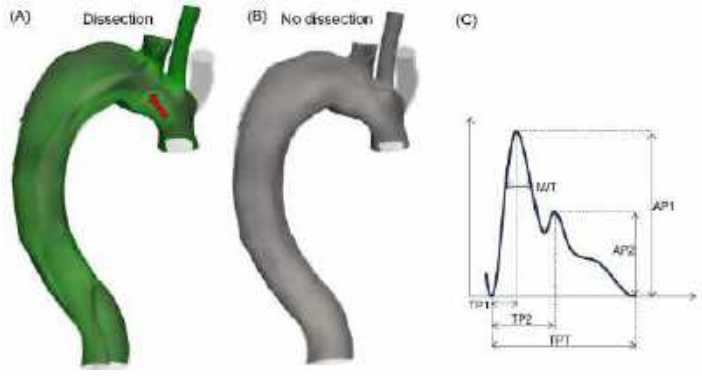

Figure 1: Patient-based geometry with a (A) type B dissection starting in the aortic arch (red arrow), and a (B) no-dissection geometry, by manually removing the dissection in (A). (C) Pulse waveform with shape metrics [8].

We also performed analysis of the pulse wave, treating the aorta as linear time-invariant system [9] using the formula:

$$H = F(h, f) = \frac{F(aa, f)}{F(da, f)}$$

Where F is the Fourier function, H is the Fourier transform of the transfer function h, f is the frequency, aa and da and the ascending and descending aorta pressure waveforms, respectively.

RESULTS

Figure 2 shows the inlet and outlet pressure waveforms for both non-dissection (A) and dissection (B) cases. The most striking effect is that the inlet and outlet waveform shapes were both altered by the dissection. For example, the dicrotic notch (red arrows) was at a higher pressure in both the inlet and outlet waveforms for the dissection case, and it occurred slightly later in the cardiac cycle. Additionally, there was a decrease of about 15% in the PWV for the dissection case relative to the no dissection case. These effects are summarized in Table 1.

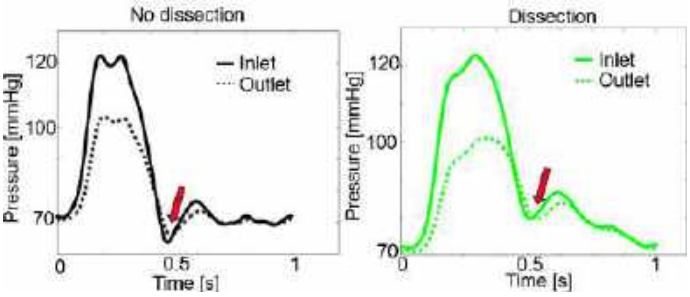

Figure 2: Pulse waveform for (A) no dissection and (B) dissection, solid lines are inlet pressure waveform and dotted lines are outlet waveform. Red arrows point to the dicrotic notch.

When analyzing the shape metrics (Table 1), we observe that the time metrics such as crest time (TP1), dicrotic wave time (TP2) and interwave time (IWT) were slightly larger for the dissection model, although the significance of the small changes, if any, is not clear. In contrast, we observe that measurements associated with pressure difference throughout the cardiac cycle, such as systolic amplitude (AP1) and dicrotic wave amplitude (AP2) had larger vales for the dissection case, with the AP1 difference quite pronounced.

As the pulse pressure travel from the ascending to the descending aorta, there is attenuation in pressure (|H| < 1, Fig. 3) across all frequencies. On average across the frequencies, the attenuation was more severe in models in dissection (mean: 0.54) than in those without dissection (mean: 0.61).

Table 1: Waveform measurements.

	Dissection	No dissection
PWV [m/s]	9.2	10.9
Dicrotic notch inlet [mmHg]	79	64
Dicrotic notch outlet [mmHg]	79	66
TP1 [s]	0.22	0.21
TP2 [s]	0.57	0.55
TPT [s]	0.95	0.96
IWT [s]	0.27	0.24
AP2 [mmHg]	14	3.6
AP1 [mmHg]	50	48

DISCUSSION

The most important result of this study is the observable changes in the pulse characteristics when a dissection is added to an otherwise unchanged aorta. Although this result is not surprising, it suggests the potential for pulse wave measurements to contribute to risk assessment in patients with chronic aortic dissection.

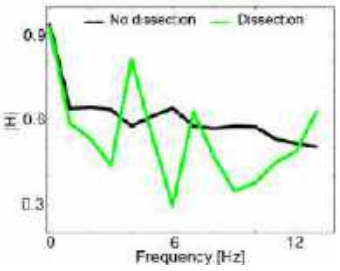

Figure 3: Amplitude of the pulsed pressure transfer function (H) for no dissection and dissection case.

The change in PWV is potentially significant since PWV is often used as an assessment of aortic health [10]. While the aortic stiffness is routinely estimated from PWV, we found in our computational model that the PWV was altered considerably even though the mechanical properties of the aortic wall were not changed, serving as a reminder that both aortic geometry and aortic wall stiffness contribute to PWV.

Similarly, we observed that the shape of the pulse waveform changed between the non-dissection and dissection cases despite the same inlet flow profile and the same outlet boundary conditions. Shape changes were also seen in the frequency domain. Since the difference between the inlet and outlet pressure waveforms would be expected to correlate roughly with clinically measured differences between the carotid and femoral pressure waveforms, these results suggest that PWV, in conjunction with more detailed analysis of waveform features in different locations, may be able to provide insight into the status of a chronic dissection.

It must be emphasized that this study used only one geometry and only imposed one change (+/- dissection), whereas every patient is different in many ways. The results here suggest numerous potential pathways for future study but should be taken as suggestive, not conclusive.

THE IMPACT OF SEX AND HORMONE-DIFFERENCES ON HEART VALVE DISEASE

INTRODUCTION

Tricuspid valve disease is an extremely common disease that can lead to high morbidity and mortality [1]. In fact, in more than 1 million Americans, tricuspid valve disease is severe enough that it requires treatment [2]. In more than 75% of those cases, tricuspid valve disease is considered functional [3]. That is, the valve itself is considered intact, while other causes are to be blamed for the dysfunction of the valve; for example, left-sided heart disease or pulmonary hypertension. We recently discovered that functional tricuspid valve disease may not be so functional after all [4]. In fact, we found that sheep with "functional tricuspid regurgitation" had valves that were maladapted. That is, their valves remodeled by changing their microstructural organization and composition, and showed cellular markers of inflammation. As a consequence, those leaflets also became larger, thicker, and stiffer. We also showed in a computational study that this change in thickness and stiffness contributes to valvular dysfunction, putting into question the concept of "functional tricuspid regurgitation." [5] Thus, tricuspid valve maladaptation may be a novel treatment target. Specifically, pharmacologically suppressing the observed maladaptative changes may relieve millions of patients suffering from tricuspid valve disease.

In the next step toward understanding tricuspid maladaptation as a cause of valvular dysfunction, we are investigating sex-dependent differences in the severity and frequency of maladaptive markers. This is an exciting question, as valvular disease is observed more frequently in women than men [6]. Thus, should we discover that maladaptation is more pronounced in female subjects than male subjects, we may contribute a first explanation for the cause of sex differences in heart valve disease. In addition to investigating the impact of sex on heart valve maladaptation, we are also interested in investigating the impact of hormonal differences within a sex. To this end, we also compare castrated and non-castrated male sheep. Thus, the overall objective of this study is to compare the severity of tricuspid valve maladaptation in female, castrated male, and non-castrated male sheep.

METHODS

We will base this study, as our previous ones, on a large animal model of pulmonary hypertension. To this end, we sedate female and male (both castrated and non-castrated) sheep, perform a mini-sternotomy, and band their pulmonary arteries. We then tighten the snare around the pulmonary artery just short of hemodynamic collapse. Afterward, we recover the animals for approximately 12 weeks, at which point we sacrifice them, excise their valves, and quantify three maladaptive markers. First, we quantify leaflet area based on images taken of the flattened-out valve on a calibrated grid. Next, we quantify thickness. To this end, we image the valve using an optical profilometry technique [7]. Finally, we remove 7x7 mm leaflet samples from each leaflet and test those samples biaxially using standard planar biaxial protocols [8]. We compare those metrics to control animals that did not undergo banding but are matched to the disease subjects in terms of age, weight, and sex.

We compare all data using a linear mixed model as implemented in the R package afex. We consider $p \leq 0.05$ as statistically significant.

RESULTS

We have analyzed the data for 30 animals of the planned total of 100 animals for this study. Thus, the results presented below are preliminary but will be finalized by the time we present this work at SB3C. Moreover, we show data in Figures 1, 2, and 3 representatively for the anterior leaflets only.

Specifically, in **Figure 1**, we representatively show the total anterior leaflet area for castrated male and female sheep for both the control and the disease groups. We found that leaflet area depends on disease ($p<0.01$). That is, in this study, too, tricuspid valve leaflets maladapted due to pulmonary hypertension by increasing the leaflet area. Additionally, we found that the three leaflets differed from each other, i.e., the anterior, posterior, and septal leaflets had differing areas

(p<0.001). Additionally, we found that leaflet size depended on sex (p<0.001). Noteworthily, in our limited preliminary study, we did not find any significant interaction effects.

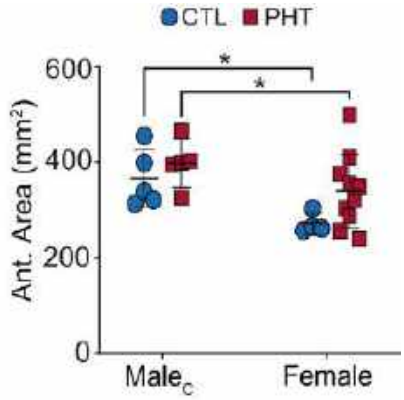

Figure 1: Leaflet area representative of the anterior leaflet of both castrated male and female sheep from the control and disease groups. Each data point represents one subject. CTL = Control, PHT = Pulmonary hypertension (i.e., disease). * p<0.05, **p<0.01

In **Figure 2**, we show both an example thickness map leaflet as well as our preliminary data comparing the mean leaflet thickness between male castrated and female sheep (representatively for the anterior leaflet only). Here, we find that leaflets also maladapted by thickening (p=0.013), as we have found in our previous work. We also found that thickness differed between leaflets (p<0.001) but did not find any differences due to sex or hormones (p=0.69).

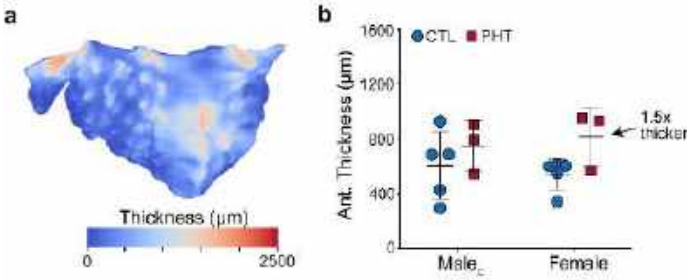

Figure 2: (a) Leaflet thickness map representatively shown for a control, female, anterior leaflet. (b) A comparison between the thickness of the anterior leaflets for castrated male and female sheep of the control and disease group. Note that we reduced the full-thickness maps as shown in (a) to scalar values by averaging the thickness maps across each leaflet center. Each data point represents one leaflet. CTL = Control, PHT = Pulmonary hypertension (i.e., disease).

Finally, in **Figure 3**, we representatively show the biaxial tension-stretch curves for a female anterior leaflet, comparing the disease and the control group. We also show stiffness at large strain (calf stiffness) and stiffness at small strain (toe stiffness) in both radial and circumferential directions. While the mean curves appear different between the control and disease groups, a statistical comparison between the leaflet stiffness at both large strain (p=0.74) and small strain (p=0.22) failed to show differences between them. Similarly, a comparison between castrated males and females also fails to show differences for both metrics (p=0.73 and p=0.77, respectively).

DISCUSSION

Our preliminary data of this very large study supports our prior findings in that we see that sheep with pulmonary hypertension have large leaflets, thicker leaflets, and may (albeit currently unsupported) have stiffer leaflets. Importantly, the objective of this current study was to investigate sex differences. Here, we found the first evidence that tricuspid valve leaflets, in general, may show some sex-dependence. That is, we found that leaflet size depended on sex. A first suspicion may be that animals of different sexes may be of different weight. However, even when corrected for weight, our observed difference persists. At this point, we did not find sex-dependent differences in leaflet thickness or stiffness. Additionally, we did not find any interaction effects between sex and disease. In other words, we have not yet found evidence that maladaptation is more or less prevalent in female sheep. Lack of evidence may be due to underpowering or due to lack of effect. Given the preliminary nature of our data, we are confident that including our additional animals (~70) will further power our study and provide a confident answer to the question as to whether heart valve disease, specifically maladaptation, depends on animal sex and hormones.

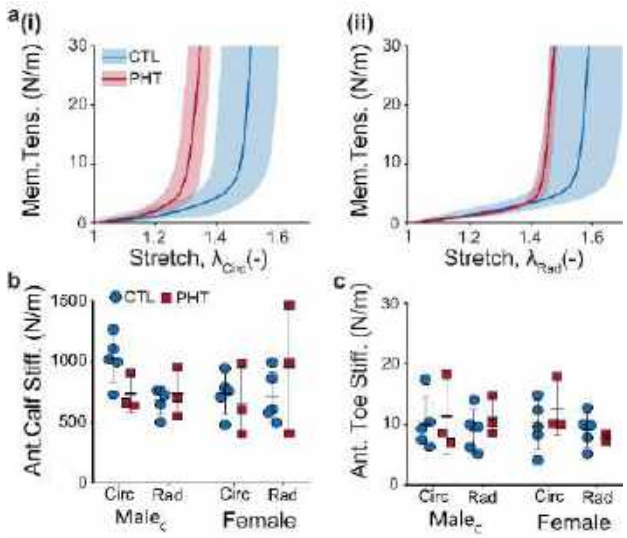

Figure 3: (a) Biaxial tension-stretch curves representatively shown for a female anterior leaflet in circumferential (i) and radial (ii) directions. (b) Calf stiffness (i.e., at high strain) and (c) toe stiffness (i.e., at low strain). Each data point represents one leaflet. CTL = Control, PHT = Pulmonary hypertension (i.e., disease).

INTRODUCTION

Arterial growth and remodeling (G&R) is the process by which living tissues adapt their physical and mechanical properties in response to biomechanical stimuli, aiming to maintain a homeostatic stress level in the vessel walls [1]. This process is generally balanced in healthy arteries but can become disrupted in the presence of diseases such as aneurysm and atherosclerosis. In the case of ascending thoracic aortic aneurysm (ATAA), disrupted homeostasis leads to continuous growth and weakening of the vessel wall, significantly increasing the risk of rupture [2]. A major challenge in managing ATAA involves accurately predicting which patients are at high risk of a ruptured aneurysm, since traditional measurements like aneurysm diameter and growth rate often provide insufficient diagnostic accuracy [3].

Recent research suggests that alternative biomarkers, especially those linked to blood flow dynamics, might offer additional insights into the disease [4]. Yet, these biomarkers, whether they are simple and geometrical or more complex and related to blood flow dynamics, tend to only indicate the likelihood of a rupture, without providing much insight into the disease's progression over time.

In this study, we investigated progressive G&R of aortic tissue using a subject-specific approach based on previous work by our collaborator on the *Fbln^{SMKO}* mouse model [4] . The data set used included longitudinal CT imaging and mechanical testing. The computational model used a simplified G&R model in conjunction with fluid-solid-interaction (FSI) simulations tailored to individual mice.

METHODS

We used a synergistic combination of FSI and G&R models. The model is split into tuning and validation stages. For the tuning stage, information for two-month-old and four-month-old mice was used to fit the growth parameters. For the validation stage, the tunned parameters are used to predict the 6-month growth and compare the resulting geometry to the CT image.

Subject-specific FSI simulation: The unsteady blood flow simulation was solved for a subject-specific geometry using the svFSI solver [10]. RCR boundary conditions were used for the outlets, and a waveform was imposed in the inlet. Wall mechanics were described as neo-Hookean, with the neo-Hookean constant adjusted for each mouse based on postmortem mechanical testing. A Robin-type boundary condition was used to account for the viscoelastic support of the outer arterial wall [14]. The time average wall stresses were extracted for each element and used as input for the growth and remodeling (G&R) model.

G&R model: Aortic wall growth was modeled as kinematic growth in response to chronic changes in the hemodynamics. The growth laws were based on Alford et al. [17]. To account for tissue remodeling, we assume that material property changes follow the total growth.

$$W_{Total} = J_g(t) W_{NH} \quad (1)$$

where $J_g(t)$=det(F_g) is the total growth for each element. To solve for the growth over the full vessel, we used the prestrain framework in FEBio2.9.1 [20].

Fitting growth parameters: During the tuning stage, the time constants associated to circumferential (T_θ) and axial (T_s) growth were used as fitting parameters. The choice was based on our ability to calculate both change in radius, and axial growth from the images. Measurements of circumferential growth and axial lengthening were used for the optimization of the growth parameters. For the circumferential growth, equally spaced rings from the heart to brachycephalic trunk were created as shown on Fig 2A. For the axial lengthening, the distance between two consecutives centroids was calculated. Optimization was conducted by comparing the grown-based geometry to the medical-based geometry at 4 months. A set of parameters was fitted for each of ten mice.

Model performance assessment: To evaluate the radial performance of the growth model for both tuning and validation, we used percentage error given by:

$$\Delta r\% = \frac{r^m - r^p}{r^m} \times 100 \quad (2)$$

where r^m is the image-based measured radius and r^p is the model prediction radius

RESULTS

Detailed analysis of a representative case: To begin, we examine the performance in both the tuning and the validation stage of a specific mouse, mouse 2. This mouse was selected due to its development of severe aneurysm, showcasing significant growth from the 2-month to 6-month mark, with an approximate 90% increase in the maximum diameter. Figure 1 depicts the 2-month geometry (A) and the contrast between the geometry projected from the model (B) and the geometry extracted from CT scans (C). Figure 1D displays the temporal evolution of the average radius of the predicted geometry (green) compared to the in-vivo measurements (blue). The model slightly underestimates the average radius at 4mo and overestimates it at 6mo.

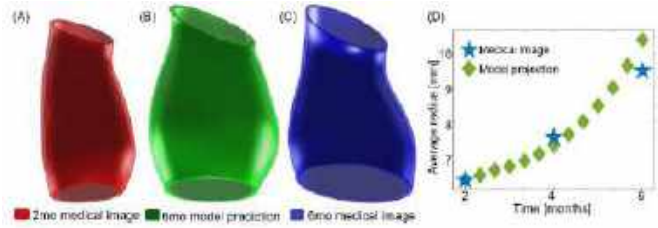

Figure 1: (A) 2mo medical image obtained in vivo and used as the initial geometry for the growth model, (B) 6mo projected geometry from the growth model and (C) 6mo in-vivo geometry obtained from medical images. (D) time evolution of the average radius of the model (green) compared to in vivo measurements (blue).

Model Performancee: Model performance was assessed as described in Eq. 2. The proximity of Δr to 0% indicates the effectiveness of the model fit. The analysis was performed in 4 rings along the geometry, named R2 (blue), R3 (red) R4 (yellow) and R5 (purple), as shown in Figure 2A. Rings R1 and R4 were the rings at inlet and outlet and were excluded from the analysis to avoid bias from the boundary conditions. Figure 2B shows the performance results for the tuning stage. Negative Δr% means the model geometry exceeded the in vivo measurement. Conversely, positive Δr% means the model geometry was narrower than the in vivo measurement. The average results show that the model was effective in capturing the 4-month geometry, with the minimum Δr% being -0.26% for mice 7 and 9 and the maximum Δr% of 9% for mouse 10. Most of the mouse models showed local errors between -8.5% (ring 4, mouse 5) to 11.8% (ring 4, mouse 2).

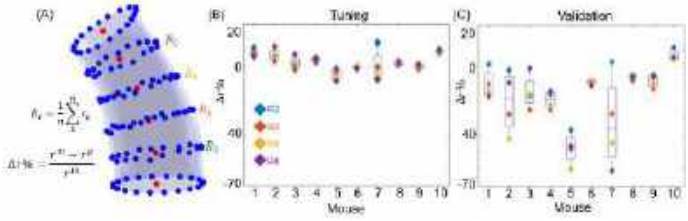

Figure 2:Performance analysis for the tunning data set (B) and validation data set (C). The tuning captures how well the model can tune the projected 4-month to the observed 4-month growth using the G&R time constants. The validation data set used the fitted parameters found in the tuning stage and compared the model-projected growth for 6mo to the observed 6-month geometry.

Figure 2C displays the analysis conducted on the validation dataset, using the parameters derived in the tuning stage to predict the 6-month geometry. Notably, the model's radial performance varied across different mice within this stage. Mouse 8 had the best performance, exhibiting minimal discrepancies across the rings with and a Δr=-5%. Conversely, mice 5 and 7 demonstrate poor performance. Despite these variations, the model's overall performance on the validation dataset showed a positive outcome. Eight out of ten mice showed an |Δr|<=20%,

DISCUSSION

This study applied a combination of (1) subject-specific modeling (2) fluid-solid-interaction FSI simulations, and (3) a simple growth and remodeling law to maladaptive growth and remodeling of the ascending thoracic aorta in the *Fbln*^{SMKO} mouse. All three aspects of the simulations were important. The subject-specific models allowed mouse-specific analysis including comparison to longitudinal data. The FSI simulations provided accurate estimates of pressure-induced wall stress and wall shear stress. The growth and remodeling model predicted the time evolution of aortic growth in response to calculated stresses. The validation step showed highly encouraging results: 80% of the models demonstrated an error less than 20% when compared to in-vivo measurements, with 40% of cases exhibiting errors less than 10%.

The computational model successfully captured the overall growth of the aorta in the *Fbln*^{SMKO} mouse and provided insights into the local growth patterns. However, some limitations need to be addressed for the model to be more widely applicable. Currently, the model primarily considers hemodynamic factors, yet substantial evidence points to the critical role of biochemical factors such as inflammatory markers and matrix metalloproteinases in growth and remodeling [5]. Incorporating these elements into the model framework could significantly heighten its predictive accuracy. This study also focused on a relatively small number of mice. While the results are encouraging, validating the model with a larger dataset is essential to confirm its generalizability. Additionally, investigating the model's performance across different mouse models of ATAA would further strengthen its applicability, and perhaps provide insights into how different genetics challenges drive aneurysm formation and growth.

Despite its limitations, this study has made significant contributions to the understanding of ATAA progression. The development of hemodynamics-driven G&R models offers a promising approach for personalized risk assessment and treatment planning for patients with ATAA.

INTRODUCTION

Abdominal aortic aneurysm (AAA) is a localized dilation of the abdominal aorta that can be devastating when ruptured, with up to a 90% fatality rate reported in the literature[1,2]. Due to this high mortality rate, it is important to determine the likelihood of rupture as accurately as possible. Currently this is guided by the size of the AAA, with the threshold for determining whether to surgically intervene being 5.0 cm for female patients and 5.5 cm for male patients[3]. However, studies have reported that 7 - 23.4% of aneurysms between 4.1 and 5.5 cm rupture[4,5].

Female patients specifically suffer from the unsuitability of the size criterion to guide surgical intervention, with a rupture rate between three and four times higher that of their male counterparts[1,6]. Literature investigating potential causes of this difference in AAA rupture rates between sexes has been conflicting, with factors including intraluminal thrombus (ILT)[7], differences in elastin and collagen concentrations[8], and stiffness of tissue[9] being just a few potential points of interest. Previous attempts to improve on the diameter threshold specifically for female patients, such as aortic size index[10], have not been widely adopted into clinical practice.

Our lab and others have established the importance of biomechanical considerations in predicting AAA rupture risk.[11,12] Historically, however, biomechanical analysis of AAAs has focused largely on male patients, likely due to the higher prevalence of AAAs in males, and have not considered sex differences. Understanding sex-based differences in AAA biomechanics is important for creating models that can accurately assess rupture likelihood in both male and female patients.

In this study we present a sex-based analysis on the abilities of various morphological and biomechanical parameters, both alone and normalized to patient-specific diameter, to predict aneurysm rupture.

METHODS

A multicenter study was conducted between the University of Pittsburgh Medical Center (UPMC) and the Mayo Clinic on AAA patients identified using ICD 9/10 and CPT codes with chart review to confirm diagnosis. Patients were identified from a retrospective database from the Health Record Research Request, a service of the University of Pittsburgh Department of Bioinformatics in partnership with UPMC, for cases between 2004-2019 and all patients within the Mayo Health system between 2021-2023. Medical images from Mayo Clinic were extracted and delivered through a material transfer agreement #DUA00004445 to the University of Pittsburgh team. The images were processed using a well-established computational pipeline to extract the region of interest, perform 3D surface reconstruction, and apply material properties to the AAA wall and ILT[12]. The wall stress analysis was performed by constraining the proximal and distal boundaries of the AAA and pressurizing to an ideal systolic pressure of 120 mmHg. A custom in-house MATLAB (MathWorks Inc., Natick, MA, USA) script was used to extract additional one-, two-, three-, and higher dimensional morphological indices[12].

This study consisted of a total of 381 patients, 108 of which were female. Of the 273 male patients, 12 underwent surgical repair and 10 experienced rupture. Of the female patients, 3 patients underwent surgical repair and 3 experienced a rupture event. Due to a limited sample size, the repair and rupture groups were pooled into one "unstable" group for this study. All AAA not in the unstable group were put into the "stable" group. Statistical comparisons of various clinical variables, biomechanical, and morphological indices were performed using a two-tailed Mann-Whitney non-parametric test. These comparisons were performed between sexes, but also within sexes to investigate differences in parameters between groups with and without ILT as well as above and below the respective threshold for each sex.

Previous literature has investigated using normalization techniques as predictors of aneurysm rupture, specifically for women[10]. To investigate the predictive capabilities of the biomechanical and morphological indices, each patient's maximum diameter was divided by each metric. Cumulative distribution curves representing ruptured

and repaired aneurysms as a function of each metric were created as previously described[10]. Thresholds for each metric were established by determining the inflection point of the cumulative distribution curve for female and males. The known outcome of stable or unstable AAA was then predicted based on this threshold and the predictive capability of that metric was evaluated using a confusion matrix.

RESULTS

Female patients were found to have significantly different morphological and biomechanical metrics than their male counterparts (**Table 1**). Additionally, significant differences were found when comparing patients above and below the diameter threshold as well as when comparing patients with and without ILT. Specifically, female patients in the unstable group had significantly lower lumen surface area values. Stable female patients had significantly lower wall volume, ILT volume, and asymmetry values than male patients in these groups. Comparing female patients above and below the 5 cm threshold, patients above the 5 cm threshold had significantly higher ILT volume and peak wall stress than those under the 5 cm threshold.

Table 1: Comparison of male and female biomechanical and morphological indices for stable and unstable groups

	Stable			Unstable		
	Female (n=102)	Male (n=251)	p-value	Female (n=6)	Male (n=22)	p-value
Maximum Diameter (cm)	3.89 ± 1.6	4.59 ± 1.4	<.001	4.67 ± 0.8	5.42 ± 1.0	0.131
Wall Volume (mL)	59.6 ± 62.3	77.9 ± 66.2	<.001	88.1 ± 47.4	119.4 ± 52.5	0.104
Lumen Volume (mL)	33.7 ± 27.3	47.2 ± 31.6	<.001	45.7 ± 21.9	64.1 ± 33.8	0.198
Mean Wall Asymmetry	30.0 ± 25.9	37.67 ± 25.8	.002	53.1 ± 13.0	60.4 ± 12.3	0.287
Max Wall Asymmetry	57.2 ± 50.4	73.4 ± 51.5	<.001	103.27 ± 24.1	117.09 ± 24.4	0.240
ILT Volume (ml)	25.9 ± 44.0	30.7 ± 42.5	.067	42.4 ± 35.9	55.3 ± 30.0	0.218
Asymmetry Factor cm^2	0.29 ± 0.61	0.51 ± 0.68	<.001	0.98 ± 0.01	0.95 ± 0.03	0.314
Lumen Surface Area cm^2	75.7 ± 33.3	94.6 ± 33.1	<.001	87.2 ± 26.5	126.3 ± 36.0	0.025
Peak Wall Stress N/cm^2	16.1 ± 6.3	19.7 ± 6.6	<.001	19.5 ± 4.8	23.4 ± 6.9	0.287
Mean Wall Stress N/cm^2	8.8 ± 3.0	10.1 ± 2.8	<.001	9.4 ± 3.8	10.4 ± 3.0	0.911

Thirty-two different biomechanical and morphological parameters were evaluated for predictive capability. An example of the cumulative distribution plot and confusion matrices can be seen in **Figure 1**.

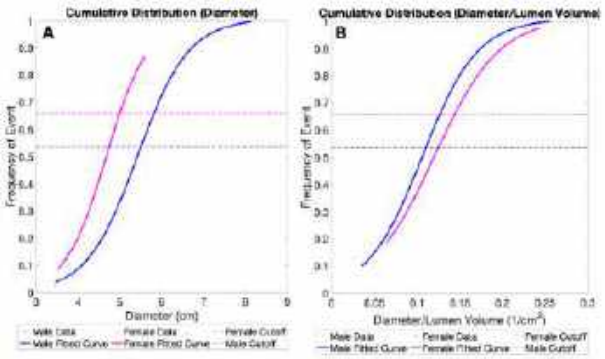

Figure 1: Cumulative distributions for (A) diameter and (B) diameter/lumen volume demonstrating cutoffs at 5 cm and 5.5 cm for female patients and male patients, respectively.

Of the thirty-two different metrics evaluated, there were several parameters that outperformed diameter in predicting unstable aneurysms. For female patients, six parameters (asymmetry[4], lumen volume, diameter/mean wall stress, diameter/peak wall stress, diameter/neck height, and diameter/asymmetry) predicted the same outcomes as maximum diameter. The parameters predicted more stable outcomes for males as compared to females, with 74% of metrics predicting stable outcomes more often for male patients and only 43% of metrics leaning towards stable predictions for female patients. The parameters that best predicted the unstable group, are shown in **Table 2**. For male patients, the maximum diameter criterion ranked among the highest accuracy rate for unstable prediction, while it ranked among the lowest for unstable prediction for female patients.

Table 2: Morphological and biomechanical parameters as ranked by true unstable percent accuracy

	Sex	Diameter Cut Off (cm)	True Stable	False Unstable	False Stable	True Unstable	Percent Accuracy
Maximum Diameter Criterion	M	5.50	67.8%	24.2%	3.3%	4.8%	72.5%
	F	5.00	78.7%	15.7%	3.7%	1.9%	80.6%
Maximum Lumen Asymmetry	M	4.72 ± 0.88	54.2%	37.7%	1.1%	7.0%	61.2%
Maximum Wall Asymmetry	M	4.72 ± 0.88	54.2%	37.7%	1.1%	7.0%	61.2%
Diameter/Lumen Volume	M	4.82 ± 0.50	57.9%	34.1%	1.1%	7.0%	64.8%
Diameter/Wall Volume	M	4.98 ± 1.05	63.0%	28.9%	1.5%	6.6%	69.6%
Diameter/Peak Wall Stress	M	5.11 ± 0.56	66.7%	25.3%	2.6%	5.5%	72.2%
Lumen Surface Area	M	5.17 ± 0.24	67.4%	24.5%	3.3%	4.8%	72.2%
Diameter/Mean Wall Stress	M	5.21 ± 0.21	67.8%	24.2%	3.3%	4.8%	72.5%
Mean Wall Stress	M	5.23 ± 0.19	67.8%	24.2%	4.0%	4.0%	71.8%
Diameter/Lumen Volume	F	4.28 ± 0.49	67.6%	26.9%	1.9%	3.7%	71.3%
Diameter/Maximum Lumen Asymmetry	F	3.93 ± 0.00	59.3%	35.2%	1.9%	3.7%	63.0%
Diameter/Mean Lumen Asymmetry	F	4.32 ± 1.04	70.4%	24.1%	1.9%	3.7%	74.1%
Diameter/Maximum Wall Asymmetry	F	3.93 ± 0.00	59.3%	35.2%	1.9%	3.7%	63.0%
Diameter/Mean Wall Asymmetry	F	4.32 ± 1.04	70.4%	24.1%	1.9%	3.7%	74.1%
Diameter/Wall Surface Area	F	4.51 ± 1.40	73.1%	21.3%	1.9%	3.7%	76.9%

DISCUSSION

Maximum AAA diameter, the current threshold for surgical intervention of AAAs, does not always accurately predict AAA rupture, particularly for female patients. We identified several parameters that were able to predict unstable aneurysms better than maximum aortic diameter for female patients, including diameter/lumen volume, diameter/maximum lumen asymmetry, and diameter/mean lumen asymmetry. For male patients, maximum aortic diameter was among the top predictors of unstable aneurysm.

Previous literature has suggested differences in ILT characteristics between female and male patients[7]. The findings in this abstract support this idea, as female patients in the stable and repair groups both had significantly smaller ILT volume as compared to their male peers. Additionally, female patients with AAAs above the clinical threshold had significantly larger ILT volume as compared to those below the clinical threshold. Asymmetry was also statistically significant between females and males. While asymmetry has been previously investigated as a diagnostic tool[4], sex-based differences have not been previously demonstrated. In the future, ILT and asymmetry could be interesting metrics to further investigate.

Due to the small sample size of female patients, the repair and rupture groups were pooled for this study and not all metrics were able to be evaluated. Female patients have been historically underrepresented in AAA biomechanics studies, likely due to decreased prevalence rate as compared to male patients but despite an increased rate of rupture among female patients[1,6]. The current study provides a biomechanical and morphological sex-based analysis. Widening understanding of the biomechanical differences between female and male patients could better inform both clinical decision making and prediction models, leading to improved outcomes for female patients.

MRC2 IS NECESSARY FOR TYPICAL CERVICAL REMODELING IN RODENT PREGNANCY

INTRODUCTION

In pregnancy, the cervix must undergo dramatic remodeling to allow for a healthy, full-term pregnancy and successful delivery [1]. Defects in cervical remodeling contribute to preterm birth (PTB), defined as birth before 37 weeks. PTB is a serious pregnancy complication leading to detrimental health effects for the mother and offspring [2]. In mice, pregnancy spans a 19-day period in which the cervix softens during the first 17 days and ripens on days 18-19. This process is possible because the complex structure of the cervix is comprised of muti-scale components including collagen [3, 4]. Fibrillar collagen I is the main constituent of the extracellular matrix (ECM), significantly influencing the cervix's tissue mechanical properties [5]. Our prior studies demonstrate continuous collagen turnover suggesting a balance between collagen synthesis and degradation in the cervix of pregnant and non-pregnant mice. However, how collagen degradation is achieved during physiological cervical remodeling is not yet defined. One route for collagen degradation is through intracellular pathways, which involve the uptake of cleaved collagen fragments. The mannose receptor C type 2 (MRC2) expressed in fibroblast cells plays a role in ECM remodeling via receptor-mediated endocytic action [6].

This study uses mice lacking MRC2 expression to determine if loss of the MRC2 intracellular endocytic pathway compromises collagen turnover efficiency to impact the mechanical properties of the cervix. Utilizing the whole cervix of wild-type (MRC2 +/+) and knockout (MRC2 -/-) mice at non-pregnant (NP), mid-pregnancy (d12), and late-pregnancy (d18) time points, this work aims to better understand the mechanical behavior of the cervix in pregnancy.

METHODS

Mouse cervix samples were collected from three time points in pregnancy, NP, d12, and d18. For each time point, 1 MRC2 -/- and 1 genetically matched MRC2 +/+ were collected. Samples were prepared for whole specimen tensile loading using an Instron universal material tester, as previously described [7]. The sample was first allowed to swell for 2 hours in phosphate buffered saline (PBS) with 2 mM ethylenediaminetetraacetic acid. A preload of ~0.001 N was applied to ensure the sample was in contact with threaded sutures. The loading protocol consists of 2 main sections: 1) 3 cyclic load-unloads and 2) stress relaxation ramp- holds followed by a load to break (Fig. 1).

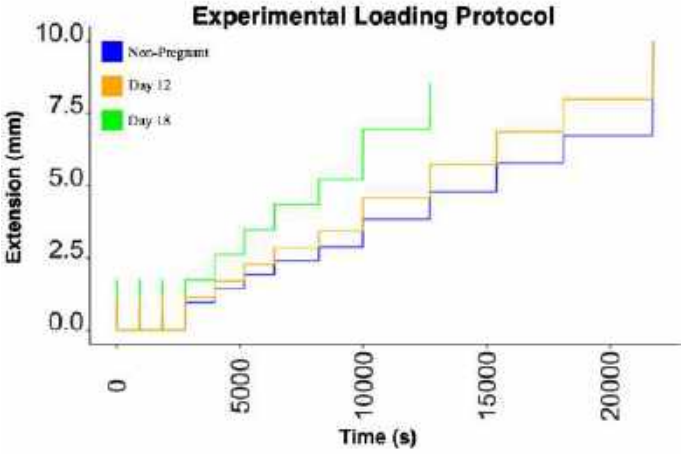

Figure 1: Mechanical testing profiles for Instron tensile testing of non-pregnant, mid-gestation, and late-gestation murine cervix.

Tests were performed at a strain rate of 10% of the cervical opening per second (mm/s) determined for each cervix individually. The sample was held at zero displacement between each cyclic load for 20 minutes to recover and equilibrate. For each ramp-hold, the cervix is stretched vertically via the regimen in Fig. 1. Measurements were taken at 1/s and 1/120s while holding to record deformation of the sample. For this initial mechanical analysis, we compared force-displacement

curves of the cyclic loading section and force-time curves of the stress relaxation section between MRC2+/+ and MRC2-/- samples.

RESULTS

The engineering stress-stretch curves of the 3rd, 4th, and 5th load cycle for MRC2+/+ and MRC2-/- mice at NP, mid, and late-gestation time points are shown in Fig.2. At the NP time point, the MRC2+/+ cervix was stiffer than the MRC2-/- cervix. At the d12 and d18 time points, the MRC2-/- cervix reaches higher stresses and steeper slopes than the d18 MRC2+/+ cervix indicating that the MRC2-/- cervixes are stiffer at these time points (Fig. 2).

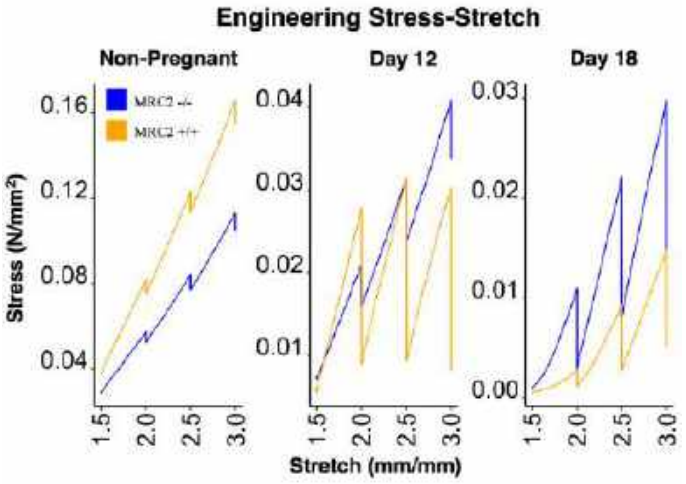

Figure 2: Engineering stress (force divided by initial cervical area) versus engineering stretch (current cervical opening divided by initial cervical opening) of non-pregnant, mid-gestation, and late-gestation cervixes in both MRC2 -/- and MRC2 +/+ mice.

For the NP samples, there is no apparent difference between MRC2 -/- and MRC2 +/+ cervixes in their force-relaxation patterns (Fig. 3). Equilibrium forces are similar for NP samples as well. However, MRC2 -/- tissue displays higher peak and equilibrium forces at d12 and d18 gestation time points (Fig. 3). This indicates a difference in mechanical function at mid and late-stage pregnancy in MRC2 -/- mice versus their MRC2 +/+ counterparts.

DISCUSSION

These preliminary results are a portion of what will be explored in this study, focusing on MRC2-/- murine cervical biomechanics over the course of pregnancy. Overall, the MRC2-/- cervixes do not function differently from their MRC2+/+ counterparts in non-pregnancy. There is a shift, however, in both mid and late-pregnancy, as MRC2-/- and MRC2+/+ samples differ in their equilibrium forces at d12 and d18. Higher forces and steeper slopes as seen in the MRC2-/- mice in Fig. 2, indicate that without the uptake of collagen by MRC2, the murine cervix has a stiffer modulus. The extensibility of MRC2-/- cervixes in NP, d12, and d18 mice is not altered, as these cervixes can still deform to the same level as MRC2+/+ cervixes. This hints at dysfunctional turnover of cervical collagen in MRC2-/- mice during pregnancy. Despite the increase in stiffness, MRC2-/- have normal parturition timing. This is supported by our observation that even though the cervix is stiffer, it can still stretch to levels beyond what would be observed in typical pup delivery. Collectively these studies suggest that the MRC2-mediated intracellular pathway of collagen degradation is necessary for optimal collagen turnover during cervical remodeling.

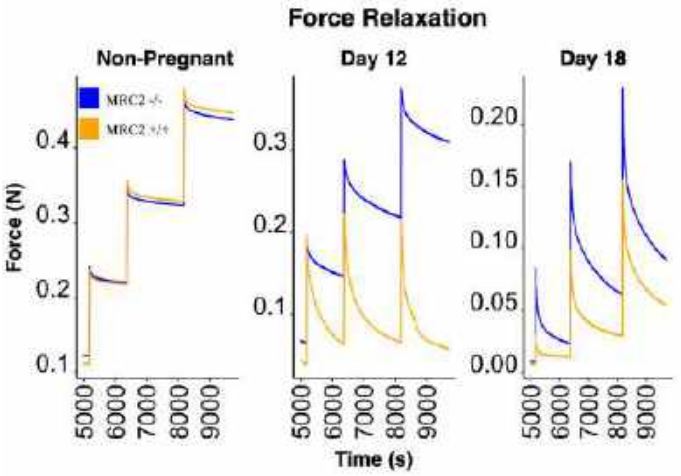

Figure 3: Force on MRC2 -/- and MRC2 +/+ murine cervix at non-pregnant, mid-gestation, and late-gestation time points over the course of three ramp-holds to display tissue relaxation behavior.

The effect of knocking out MRC2 on viscoelasticity and how it manifests structurally needs to be explored further by increasing sample size of this study and performing inverse finite element analysis to determine material properties of MRC2-/- cervical tissue and then comparing to MRC2+/+ tissue. Currently, this study is limited in its sample size and does not capture early pregnancy effects. Additional samples are currently being tested, and further analysis will be conducted on this dataset. Rupture stress, locking stress, initial stiffness, equilibrium stress, and model fit will be calculated using inverse finite element analysis to tease out more nuanced differences between MRC2-/- and MRC2+/+ mice. These initial results provide evidence to support a functional role of intracellular collagen degradation via MRC2 in physiologic cervical remodeling. This framework of understanding is necessary to define pathways of abnormal cervical remodeling associated with preterm birth.

INTRODUCTION

Risk of concussion or mild traumatic brain injury (mTBI) is significantly variable across different individuals. For patient-specific risk assessment using computational models, we need to incorporate the anatomical details that contribute to variabilities in the predicted injury response (such as brain tissue maximum strain and strain rates). Currently, some FE models used to study mTBI incorporate cortical folds [1-4], while some don't [5].

Previous studies have investigated the effects of cortical folds on strain distributions on single subjects [1]. This study aims to investigate the contribution of variations in cortical folds across 20 individuals on the variability in the risk of concussion under a given loading through subject-specific finite element (FE) modeling.

METHODS

We created detailed gyrencephalic (with cortical folds) and smoothed lissencephalic (without cortical folds) models of 20 individuals. The cohort consisted of 11 males and 9 females with ages ranging from 9 to18 years old (head volume 1.09×10^6 mm^3 – 1.31×10^6 mm^3). Comparing the peak strains and strain rates from the models with and without cortical folds provides insight into the role of gyri-sulci on the brain deformation mechanics. The strain and strain rate variability between the two types of models also provides insight into the contribution of cortical folds on the variability of the strain response found between individuals.

The detailed subject-specific gyrencephalic 3D FE models were developed from each individual's MRI scans: T1-weighted (T1w), T2-weighted (T2w), and diffusion tensor imaging (DTI). Models included the brain parenchyma, cerebrospinal fluid (CSF), meninges (dura, falx, and tentorium), and skull. An automated brain segmentation was performed on FreeSurfer to segment different parts of the brain. The skull was segmented using FSL. The meninges and sub-arachnoid CSF were added manually in 3D Slicer after combing the FreeSurfer and FSL segmentations.

The lissencephalic (without cortical folds) models were generated by modifying the detailed gyrencephalic models. The heterogenous subarachnoid CSF was replaced by a uniform 1 mm layer of CSF lining the meninges (dura, falx, and tentorium). The cerebral segments were replaced by one segment 'cerebrum' filling between the subarachnoid CSF and the deep brain structures.

The axonal tract orientations were incorporated from DTI through an anisotropic hyper-viscoelastic material model [6]. The models used a voxel-based mesh of 1 mm size that allowed the capturing of fine anatomical details (gyri and sulci), numerical mesh convergence, and led to faster model generation times.

Simulations were conducted in an explicit time scheme on Abaqus software. A sinusoidal half-wave rotational acceleration 10 krad/sec^2 resulting in angular velocity of 60 rad/sec (10 ms pulse width) was applied to the skull in the three principal anatomical planes (axial, sagittal, and coronal) in separate simulations. The injury metrics, such as 95th percentile maximum principal strain (MPS95) and maximum principal strain rate (MPSR95), were calculated for the entire brain. The 95th percentile strains are generally chosen so that numerical outliers in highly complex FE mesh will be excluded. The results

from the axial rotations are shown in this abstract and discussed to understand the contribution of cortical folds on brain mechanics and on the variability of the injury response across individuals.

RESULTS

We observed peak strains on the outer surface of the brain in both models (with and without cortical folds), as shown for four representative subjects in Figure 1. However, higher strain concentrations are found in the deeper brain regions, specifically between the lateral ventricles and the lateral sulcus, in the model with the cortical folds under axial rotation. This was not pronounced in the lissencephalic models without the cortical folds (Figure 1).

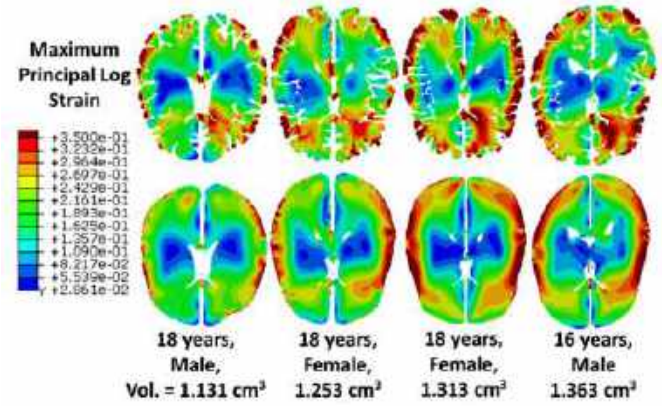

Figure 1 Maximum principal strain distribution in models with (top) and without (bottom) cortical folds for 4 representative subjects

We also calculated the MPS95 and MPSR95 over the duration of the simulation. Figure 2a shows the average (solid line) and minimum-maximum range (shaded region) of the MPS95 for 20 subjects for the models with cortical folds (red) and the models without cortical folds (blue). Figure 2b shows the average and range of the MPSR95 for both types of models.

There was a variability of 35% in MPS95 and as well as in MPSR95 among the gyrencephalic models. For the same subjects, the smooth lissencephalic models had a variability of 33% in MPS as well as MPSR. We found reductions of 18% and 19% in the peak value of the average MPS95 and average MPSR95, respectively after smoothing out the cortical folds.

DISCUSSION

We observe high strains in the outer surface of the brain under rotational boundary conditions typical of head impacts. As the skull starts to rotate, it starts to shear the tissue next to it and sends down a shear wave to the center of the brain. As the wave travels to the deeper brain regions, it quickly gets dissipated due to the viscous nature of the brain tissue and CSF, resulting in larger strains on the outer surface of the brain.

In the models with cortical folds, we also capture strain concentrations, especially between the lateral ventricles and lateral sulcus, which are caused by the sharper geometrical features. Smoothing out the folds and fissures reduces strain localizations and thus reduces the MPS95 and MPSR95. Adding the cortical folds also introduces CSF in between gyri, effectively making the region softer than in the lissencephalic model, also contributing to a higher deformation. This result is in contrast with the previous study that found a 12% increase in the strains by removing cortical folds from the model [1]. Multiple modeling parameters including material properties can result in these differences, and we are currently exploring them in detail.

The variability in the peak MPS95 and MPSR95 results directly from the anatomical differences. The variability in the models with a smooth cortical surface stems from the head shape and size. On the other hand, in the models with cortical folds, differences in the cortical folding pattern and a more heterogeneous skull-brain interface also contribute to the brain injury mechanics.

Our simulations demonstrate the importance of incorporating cortical folds in subject-specific head models for the assessment of brain deformation and mTBI risk under rotational loading.

REVISITING MURRAY'S LAW IN PULMONARY ARTERIES: EXPLORING BRANCHING PATTERNS AND PRINCIPLES

Sofia Altieri Correa (1), Amirreza Kachabi (1) Mitchel J. Colebank (1), Naomi C. Chesler (1)

(1) Edwards Lifesciences Foundation Cardiovascular Innovation and Research Center, and Department of Biomedical Engineering, University of California, Irvine, Irvine, CA, USA

INTRODUCTION

Nearly 100 years ago, Murray [1] formulated the most well-recognized structure-function relation for the optimal branching pattern of vascular networks based on a minimum energy principle. He introduced a cost function that balanced the pressure-flow energy required to pump blood with the metabolic energy required to maintain blood temperature. Assuming steady, fully-developed laminar flow in all vessels, and that metabolic energy is proportional to blood volume, Murray predicted that volumetric blood flow rate in any branching vessel (parent or child) is proportional to the cube of its diameter. A corollary prediction is that the parent diameter cubed is equal to the sum of the daughter branch diameters cubed.

Experimental studies to test the validity of these relationships have predominantly been conducted in systemic blood vessels and different optimization models has been proposed [2][3][4][5]. However, fewer studies have investigated if these principles hold in the pulmonary circulation. The present work experimentally examines the relationships between parent and child diameters in pulmonary arterial networks. Our results show that the cubed relationship does not hold and that blood flow rate proportional to diameter raised to the power ≈1.88 is observed in our data. We consider principles that may govern these branching patterns following Murray's approach.

METHODS

We generated and analyzed arterial networks for five healthy canines from magnetic resonance angiography images that were obtained previously [6], as depicted in Fig. 1. First, we created three-dimensional (3D) segmentations of pulmonary artery (PA) geometries through the application of 3DSlicer [7]. Subsequently, the Vascular Modeling Toolkit was employed to convert these 3D segmentations into centerline networks [8]. Finally, we post-processed the specific networks using custom MATLAB software, extracting length, radius, and connectivity data for each network [9].

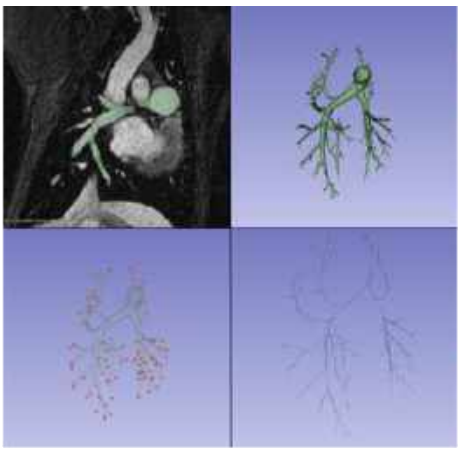

Figure 1: 1D arterial network extraction for one subject from MRI images.

Murray was the first to establish a link between the radius and flow rate of a vessel segment. He introduced an energetic cost function, denoted as E, which sums the energy required to pump blood (flow, Q, multiplied by pressure drop, ΔP) with the metabolic cost to maintain body temperature (assumed to be proportional to blood volume) for a single vessel of radius r and length L (Eq. (1)), where K_1 is an unknown constant. Additionally, he assumed fully developed laminar flow within the vessel and a fluid viscosity μ (Eq. (2)).

$$E = Q\Delta P + K_1\,\pi\,r^2 L \quad (1)$$

$$E = \frac{8\mu L}{\pi r^4} Q^2 + K_1\,\pi\,r^2 L \quad (2)$$

In accordance with Murray's minimum principle, when this relationship is differentiated with respect to radius and minimized (i.e., set to zero), an optimal condition exists (Eq. (3)) and for these assumptions flow rate Q is proportional to the cube of radius (Eq. (4)):

$$r = \left(\frac{16\mu}{k_1\pi^2}\right)^{\frac{1}{6}} Q^{\frac{1}{3}} \quad (3)$$

$$\Rightarrow Q \propto r^3 \quad (4)$$

Because flow is conserved at any branching, $Q_0 = Q_1 + Q_2$, where Q_0 is the flow in the parent vessel and Q_1, Q_2 are the flows in the daughters, hence:

$$r_0^3 = r_1^3 + r_2^3, \quad (5)$$

where r_0 represents the radius of the parent vessel, and r_1 and r_2 denote the radii of the daughter vessels of the bifurcation.

Following the acquisition of radius values for all branches from the healthy canine data, we proceeded to solve the following equation for the exponent (x) in Eq. (6) at each bifurcation for each subject using MATLAB software.

$$r_0^x = r_1^x + r_2^x \quad (6)$$

RESULTS

Figure 2 shows the optimal exponent for each bifurcation across all subjects. Overall, the resulting mean exponent value is 1.88 (±0.62).

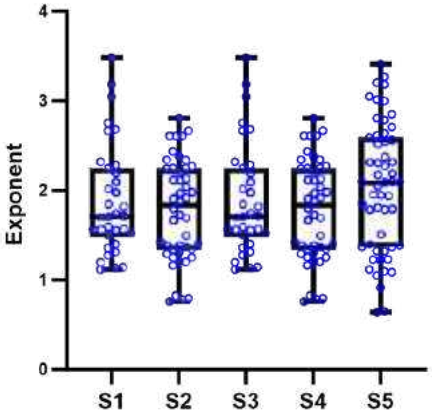

Figure 2: Exponent values for the bifurcations for each subject (S).

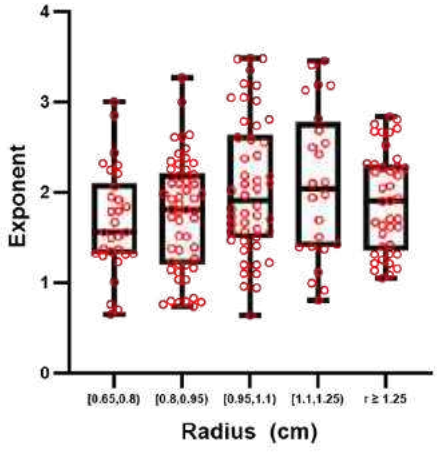

Figure 3: Exponent values grouped in terms of the radius size.

In Fig. (3), the exponent values are presented, organized based on the size of the radius of the smaller daughter in the bifurcation, including all bifurcations and subjects. The values of the exponent are observed to lack a direct dependence on the radius of the bifurcation vessels and, consequently, on the generation within the PA branching tree.

Given that pulmonary arteries are much shorter than systemic arteries, we explored replacing the Poiseuille flow assumption with a Bernoulli (blunt profile) flow assumption as in Eq. (7), where B is an unknown constant.

$$E = B\frac{Q^3}{r^4} + K_1\,\pi\,r^2 L \quad (7)$$

Differentiating this expression with respect to r, we obtain:

$$\frac{dE}{dr} = (-4)B\frac{Q^3}{r^5} + 2K_1\pi r L \quad (8)$$

And, setting this to zero, we obtain:

$$Q \propto r^2 \quad (9)$$

In addition, we explored balancing the energy required to pump blood with the need to have a large surface area to facilitate gas exchange in the lungs. In that case, a new cost function, Eq. (10) can be written where the second term is not proportional to the volume of the vessel but to its surface area:

$$E = B\frac{Q^3}{r^4} + K_2 2\pi r L \quad (10)$$

where K_2 is an unknown constant. By optimizing Eq. (10) with respect to r we obtain

$$\frac{dE}{dr} = (-4)B\frac{Q^3}{r^5} + K_2 2\pi L \quad (12)$$

$$Q \propto r^{5/3} \quad (13)$$

such that the flow rate is proportional to the radius raised to the power of 1.67.

DISCUSSION

The mean exponent value for pulmonary artery branches in this sample of healthy canines was 1.88±0.62, which is much lower than 3.0 expected for Murrays' Law. The assumptions of blunt flow and a principle governing branching based on surface area instead of flow yielded improved predictions of the exponent. In addition, our results show a relatively consistent pattern in exponent values across PA subjects' bifurcations and different generations. The observed variation in results may be attributed to manual MRI image segmentation. Further analysis downstream in the PA branching tree is needed to explore whether the exponent value increases as branching radius decreases. Additionally, studies in other species including humans are necessary to support our measurement of patterns and interpretation of branching principles in pulmonary arteries.

SENSOR FUSION ALGORITHM TO IMPROVE ACCURACY OF ROBOTIC SUPERPOSITION TESTING USING A 6-DOF POSITION SENSOR

To quantify the contribution of specific ligaments to overall biological joint movement, the principle of superposition has been used for nearly 30 years [1]. This principle relies on using a robotic test system to move a human joint to the same position before and after transecting a specific ligament. The difference in force at the same position is assumed to be the transected ligament's contribution to passive joint stability. However, the test system's ability to accurately return the joint to the commanded position is dependent on the compliance of the system's various components, which is often neglected [2]. Errors in position of only 100-200 microns can result in -25% error in computed ligament tension in a relatively compliant artificial knee joint. In stiffer cadaver knees, computed ligament tension at peak load can be underestimated by more than 50% [3].

Optical 6-DOF motion capture sensors can be more accurate than robot encoders to measure joint position because their signal is able to account for system compliance. However, they can have 10-100 times more noise than a robot encoder position signal. By fusing low-noise robot position data with a higher accuracy motion capture system (i.e. an optical 6-DOF position sensor), this combined signal can be placed into the control loop of a cadaveric biomechanical test system to greatly reduce the commonly overlooked historical accuracy challenges of superposition testing [2,4].

This study has two aims. First, to develop a sensor fusion algorithm that safely and effectively fuses robot position with 6-DOF position sensor data so in can be used within a real-time control loop. Second, to demonstrate the accuracy of the sensor fusion technique by validating that superposition computed ligament tension in an artificial knee joint matches directly measured tension and comparing these results to traditional techniques.

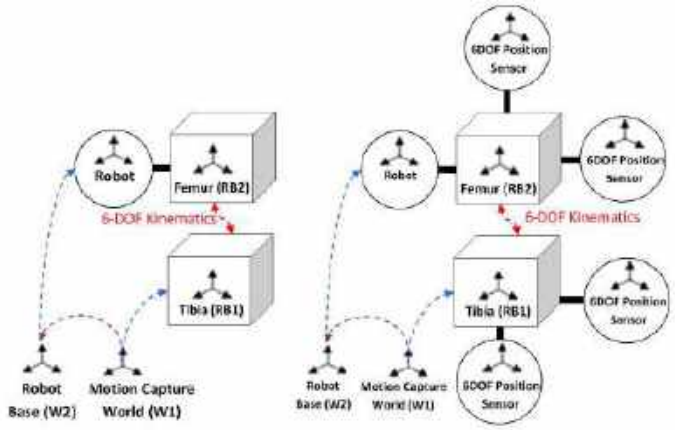
METHODS

The Sensor Fusion Algorithm

In typical testing systems (**Figure 1A**) the relative relationship of Rigid Body 1 secured to the base and Rigid Body 2, secured to the robot end-effector (for example the tibia and femur, respectively) can be described with the following kinematic chain:

$$T_{RB1\_RB2} = T_{RB1\_w1} T_{w1\_w2} T_{w2\_Robot} T_{Robot_0\_RB2} \quad (1)$$

Where the two dynamically changing 4x4 homogenous transformation matrices are the robot position relative to its base (T_{w2_Robot}), and the relative 6-DOF position of rigid body 2 relative to rigid body 1 (T_{RB1_RB}). Robot$_0$ refers to the initial position of the end effector at digitization. Robot refers to the end effector's position throughout time.



A: Traditional **B: Sensor Fusion**

Figure 1: Kinematic Chains with Varying Control Schemes

To minimize inaccuracies due to compliance in the system control loop, 6-DOF position sensors must be added to the kinematic chain (**Figure 1B**). These sensors are represented by $T_{Robot\_Robot_0}$, a dynamically changing matrix that is highlighted in blue below.

$$T_{RB1\_RB2} = T_{RB1\_w1} T_{w1\_w2} T_{w2\_Robot} T_{Robot\_Robot_0} T_{Robot_0\_RB2} \quad (2)$$

$T_{Robot\_Robot_0}$ is the spatial relationship between where the position sensors calculate the robot to be and where the robot was relative to the sensors when first digitized. In eq. (2), the precision and bias are directly dependent on the noise, accuracy, and placement of the motion capture markers. Filtering may be done on the motion capture marker data to decrease noise injected into the control signal.

It should be noted that eq. (2) is simplified for ease of reading, and the algorithm used within the validation software was generalized to also compensate for base compliance. In addition, multiple 6-DOF position sensors could be added to a given rigid body to add measurement redundancy. The algorithm was used to compensate for compliance in biological joint pose, gravity compensation, and load transformations. These abilities differentiate this sensor fusion algorithm from other similar visual servoing algorithms used in robotics literature [5].

Most importantly, safety parameters were also added to the sensor fusion algorithm. Motion capture markers may be occluded, passive markers might be mislabeled by a tracking system, or a marker might suddenly come back into view causing an instantaneous kinematic correction. Therefore, the algorithm also included a sensor integrity handler that performs various safety checks to reduce the risk of dangerous system motion. The sensor fusion algorithm that performs compliance compensation with a sensor integrity handler to make the system safe is collectively called eXactoPOSE®. More details on eq. (2) are included in patent US 11,745,341 B2.

Validation of the Sensor Fusion Algorithm

To validate the algorithm, a ligament phantom spanning an artificial knee joint was used [6]. A single axis load cell (Futek LCM300) was mounted on a spherical rod end pin and directly measured force through the ligament phantom during superposition testing. Similarly, a motion capture system (OptiTrack, Corvalis Oregon) served as the 6-DOF position sensor and the markers were placed close to the artificial knee joint. These measurements were collected at the same time as the 6-DOF kinetics & kinematics measured by a 6 axis force/torque sensor (Omega, ATI, Apex, NC), and a 6-DOF robot (KR 300, KUKA, Augsburg, Germany).

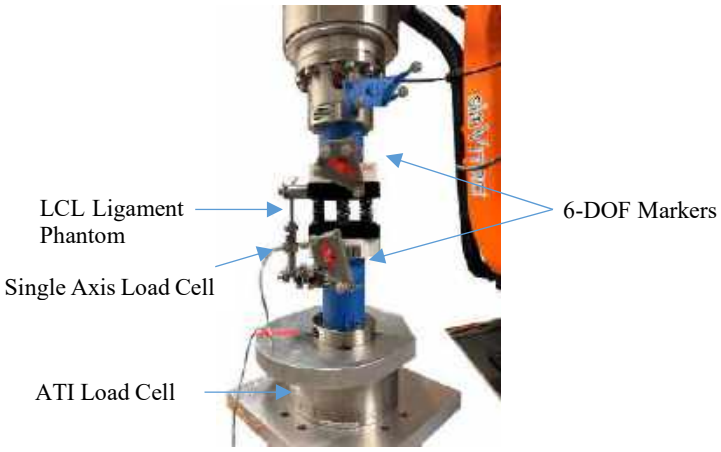


Figure 2: Artificial Knee with LCL Ligament Phantom

A force control test was performed by personnel at the University of Wisconsin-Madison while using a simVITRO® test system (Cleveland Clinic, Cleveland, OH). The test consisted of a ramp to 15 Nm of Varus torque, while maintaining a constant compression force of 50 N. All other DOF were initially in force control and prescribed 0 N or 0 Nm, except flexion angle, which was prescribed a 0° rotation angle. This testing protocol was used to maximize force going through the LCL during testing. After the force control test, the resulting 6-DOF kinematics were played back in position control while changing 2 independent variables: LCL (intact or deficient) and robot control methodology (traditional or sensor fusion). Superposition computed LCL tension was calculated as the vector difference in force measured by the 6 axis force/torque sensor during LCL intact and deficient trajectories. Superposition computed LCL tension was compared to tension directly measured by the load cell for both robot control methodologies.

RESULTS

There was a notable difference between the traditional superposition tests and those fusing an optical 6-DOF position sensor. In particular, the difference in red and blue lines in **Figure 3A** show that the traditional control technique underestimated ligament stiffness by about 25%. In contrast, tension values in **Figure 3B** track similarly, indicating that sensor fusion does not underestimate ligament contribution. The sensor fusion superposition computed force data was filtered to reduce motion capture induced noise in the data.

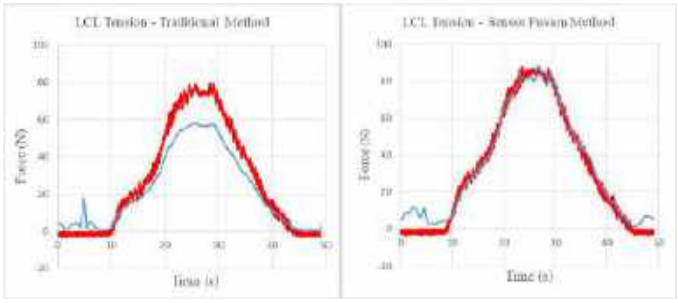

Figure 3: Superposition Computed LCL Tension using Traditional and Sensor Fusion Methods for Kinematic Control.

DISCUSSION

This study demonstrates the effectiveness of using 6-DOF position sensors within a sensor fusion algorithm for mitigate errors in ligament tensions computed using superposition testing. The errors shown in Figure 3 may in fact underestimate the magnitude of commonly overlooked errors in estimating ligament tension when using traditional superposition techniques because the artificial knee is less stiff in compression than a cadaveric knee [3]. In future superposition testing, the compliance of various equipment should be measured and reported or 6-DOF position sensors should be used to improve the accuracy of controlling joint motion. The stiffness of the system components is less important if using position sensors in the control loop. Ultimately, better estimates of ligament contribution to passive joint stability should enable researchers and device manufacturers to better design and refine medical devices and surgical techniques in the future.

EFFECTS OF RESIDUAL STRESS ON THE BUCKLING AND TWISTING BEHAVIOR OF ARTERIES

INTRODUCTION

Residual stress exists in arteries and significantly affects the stress distribution in the arterial wall, thus affecting the growth and remodeling of the arterial wall [1-3].

However, it is unclear how residual stress would affect certain mechanical behaviors of arteries such as pressurized inflation (P-V curve), torsion (axial twisting) and buckling [4-5].

Accordingly, the objective of this study was to evaluate the effects of residual stress (opening angle) on the mechanical behavior of arteries.

METHODS

The arterial wall was assumed to be a homogenous nonlinear elastic material described by the Holzapfel-Gasser-Ogden two-fiber strain energy functions [6]:

$$\psi = \frac{c}{2}(\bar{I}_1 - 3) + \frac{b_1}{b_2}[exp(b_2(\bar{I}_4 - 1)^2) - 1] \quad (1)$$

where b_1, b_2, and c are positive material constants. $I_1 = tr\ (F^T F)$ is the first invariant. $I_4 = \lambda_\theta^2 \sin^2 \alpha + \lambda_0^2 \cos^2 \alpha$ is the invariant that reflects the stretch ratio in the two diagonal fiber directions, with α denoting their alignment angle. The Cauchy stress can be expressed in terms of the strain energy

$$\boldsymbol{\sigma} = \mathrm{p}\mathbf{I} + \mathbf{F} \cdot \frac{\partial \mathrm{W}}{\partial \mathbf{E}} \cdot \mathbf{F}^{\mathrm{T}} \quad (2)$$

The lumen pressure and axial tension in arterial segments under lumen pressure can be expressed as [4,5]:

$$p_i = \int_{r_i}^{r_e} (\sigma_{\theta\theta} - \sigma_{rr}) \frac{dr}{r} \quad (3)$$

$$N = \pi \int_{r_i}^{r_e} (2\sigma_{zz} - \sigma_{rr} - \sigma_{\theta\theta}) r dr + \pi r_i^2 p_i \quad (4)$$

wherein r_i and r_e represent the lumen and outer radius, and subscripts r, θ, z represent the radial, circumferential and axial directions, respectively. The mechanical properties were determined by free-end pressurized inflation testing [4,5]. The experimental data were fitted with these equations to determine the material constants by minimizing the error function using the nonlinear least square function in Matlab. Considering the effect of residual stress (opening angle), the material properties of the arteries were obtained in two approaches – including and ignoring the opening angles.

These material constants were then used in buckling analysis and torsion analysis to determine the effect of residual stress on the bent buckling and twisting behavior of the arteries, respectively. The critical pressure of the arteries buckling at different axial stretch ratios were obtained using the buckling equation previously developed [7]:

$$p_{cr} = \frac{N + (\frac{n\pi}{l})^2 H}{\pi {r_i}^2} \quad (5)$$

The torque-rotation angle relationship of the arteries were determined using the torque equation [5]

$$T = 2\pi \int_{r_i}^{r_e} \sigma_{\theta z} r^2\, dr \quad (6)$$

We simulated the buckling and torsion of porcine carotid arteries using experimental data obtained from our previous studies [4]. Numerical simulations were done using a custom code in Excel.

RESULTS

Our simulations demonstrated that fitting the pressure-diameter-length curves obtained from pressurized inflation experiment data with and without considering the opening angle leads to different set of material constants. For a given set of material parameters, ignoring or including the opening angle leads to different pressure-diameter relationships. The vessel is less stiffer when including the opening angle as compared to the inflation curve ignoring the opening angle (Fig. 1).

The residual stress slightly increases the critical pressure of arteries, mainly in the higher axial stretch ratio range (Fig. 2).

When subject to torsion at given pressure and axial stretch ratio, the arterial wall is stiffer against twisting deformation when opening angle is considered compared to the twisting when the opening angle is ignored (Fig. 3).

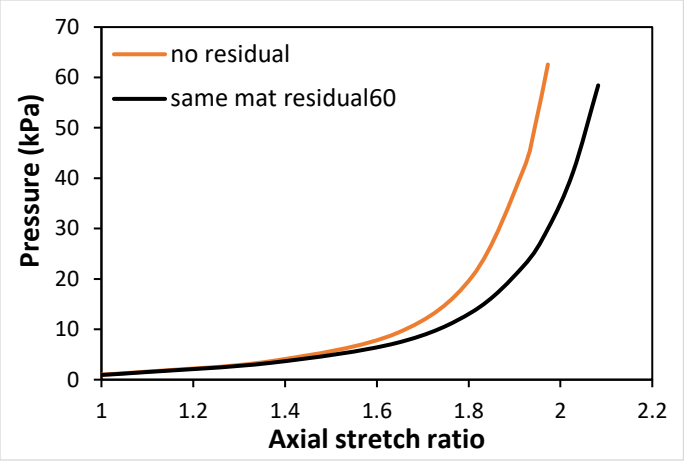

Figure 1: Pressure-diameter relationships of an artery subject to pressurized inflation at a fix axial stretch ratio of 1.3. The black curve, "same mat residual60" refers to the case an opening angle of 60 degrees is considered.

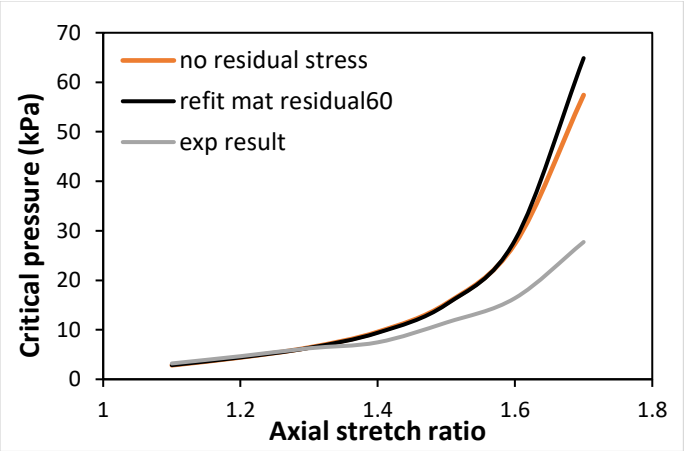

Figure 2. Critical pressure as a function of axial stretch ratio. The black curve, "refit mat residual60" refers to using material constants obtained with an opening angle of 60 degrees.

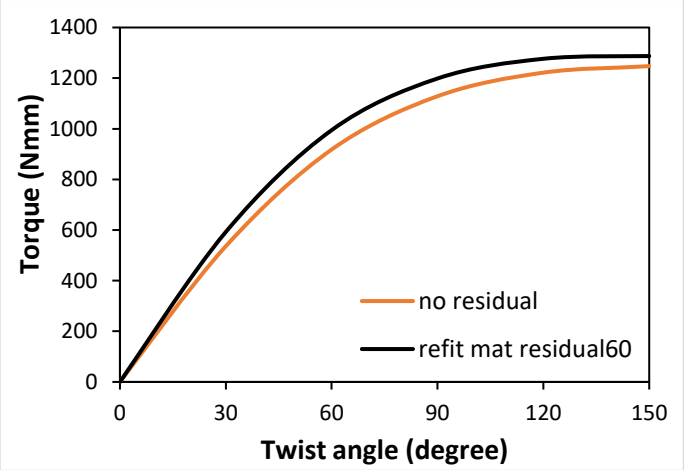

Figure 3. Torque-twisting angle relationship of an artery subjected to torsion at a given lumen pressure (10kPa) and axial stretch ratio (1.3).

DISCUSSION

Our results demonstrated that residual stress affects the pressurized inflation, torsion, and the bent buckling behavior of arteries. In mechanical analysis of arteries, it is necessary to include residual stress as it not only affects the stress distribution in the arterial wall, but also affects deformation behaviors of the artery. It is also necessary to consider the residual stress when determining the material constants.

INTRODUCTION

Approximately 80% of women undergoing vaginal delivery experience some degree of perineal lacerations [1]. To predict the likelihood and severity of such lacerations, prescribe preparatory measures, or recommend an alternative mode of delivery (i.e., cesarean section), computational tools that can simulate vaginal delivery in real-time are needed. While experimental investigations have explored the mechanisms of vaginal lacerations in rats [2, 3], computational methods have yet to be employed for modeling and predicting such lacerations. Regrettably, sophisticated finite element (FE) models of the reproductive system prove to be computationally intensive, rendering them impractical for real-time interventions [4,5].

We have recently applied reduced order modeling techniques, including a feed-forward neural network model, to describe the deformations of a rat vaginal canal with and without a tear [4,5]. In this study, we implement a variety of machine learning (ML) models and compare them to determine which model most effectively captures the deformations of vaginal canals with tears. Our analysis demonstrates the potential of these ML techniques as valuable real-time predictive tools for anticipating maternal birth trauma.

METHODS

We conducted FE simulations reproducing experimentally observed deformations of rat vaginal tissue subjected to inflation testing to generate data for this ML study. The geometry, boundary conditions, and material model parameters for the FE simulations are reported in our recent investigation of projection-based and data-driven reduced order modeling techniques [4]. Specifically, we considered eight unique combinations of mean preferred fiber orientations in three equally sized anatomical regions of the vagina (distal, mid, and proximal region). Each combination was utilized to simulate the response to 30 intraluminal pressures, ranging from 2.5 to 75 kPa, in equal increments. This generated a total of 240(=8x30)

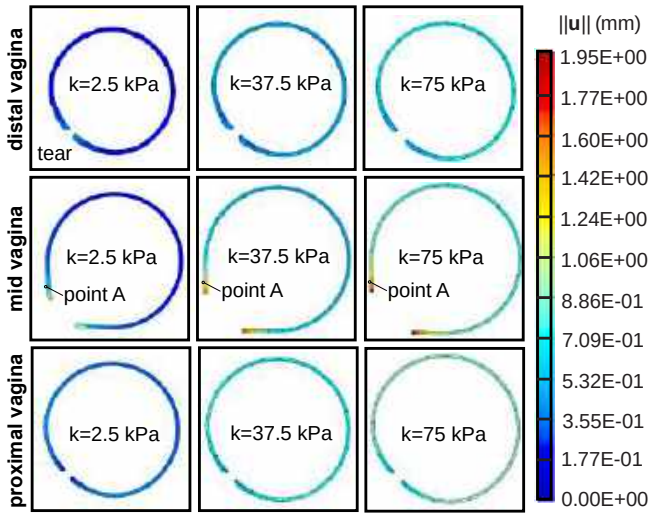

Figure 1: Magnitude of the displacement vector u at different cross-sections of a vaginal canal with a tear at increasing intraluminal pressures. Point A is an arbitrary node at which ML models are compared in Figure 3.

simulations that formed our snapshots, each with 10,257 degrees of freedom. Figure 1 displays the magnitude of the displacement vector in the proximal, mid, and distal vagina (cross-sectional views), under minimum, medium, and maximum pressure values for one combination of mean preferred fiber orientations.

We then compared four distinct ML algorithms: support vector machine (SVM), stochastic gradient descent (SGD), random forest (RF) and extreme gradient boosting (XGBoost). We chose the SVM

technique for its well-known power to capture complex relationships in data, its ability to maximize the margin between data points of different classes, and its superior performance in high-dimensional spaces. The SGD technique was chosen for its versatility as an optimization algorithm for linear regression problems, demonstrating computational efficiency and suitability for large datasets owing to its stochastic nature. We selected the RF ensemble learning method which combines multiple decision trees to enhance accuracy and robustness due to its effectiveness in capturing non-linear relationships between input features and the target variable. Lastly, the XGBoost method, which is an optimized implementation of gradient boosting, was employed for its suitability in handling large datasets and complex regression tasks. It incorporates regularization techniques to prevent overfitting, thereby improving generalization to new data.

We utilized four input parameters, three mean fiber orientation values, one for each anatomical region, and one intraluminal pressure value. The outputs were the components of the displacement vectors at the nodal points. Concerning data splitting, we partitioned our FE snapshots into training and test data with an 80% to 20% ratio, respectively. Prior to the split, random shuffling of the snapshots was applied. Additionally, we employed the grid search method to optimize hyperparameters during the model training process. Then, in order to compare the performance of the different ML models, we computed R^2 scores for each model as follows:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(u_i - \hat{u}_i)^2}{\sum_{i=1}^{n}(u_i - \overline{u}_i)^2} \quad (1)$$

where u_i is the displacement component associated with the i^{th} snapshot, $\overline{u}_i$ is the mean of displacement components for the i^{th} snapshot, $\hat{u}_i$ is the predicted value of displacement component for the i^{th} snapshot for a given ML model, and n is the total number the FE snapshots (n=240). Averages of R^2 scores were computed for all ML models that were trained using each algorithm for all the degrees of freedom.

RESULTS

The R^2 scores for each model are illustrated in Figure 2 for both the training and test datasets. SVM exhibited the highest performance, achieving a score exceeding 0.99. Subsequently, SGD, RF, and XGBoost follow as the next best-performing models.

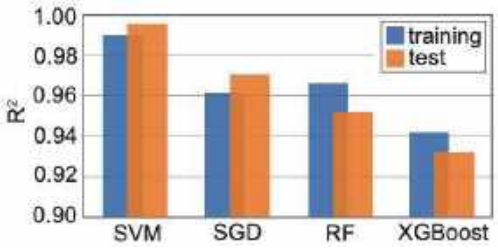

Figure 2: R^2 scores of each ML model for predictions of both training and test data for the entire dataset containing 240 snapshots, each with 10,257 degrees of freedom.

The predicted values generated by each model are compared to the actual values from the FE simulations at an arbitrary point A shown in Figure 1 and are visually presented for the test dataset in Figure 3. Each point on the graph represents a snapshot with a unique set of inputs corresponding to point A. The gray line represents the ideal case scenario, and points aligning with this line indicate superior model performance.

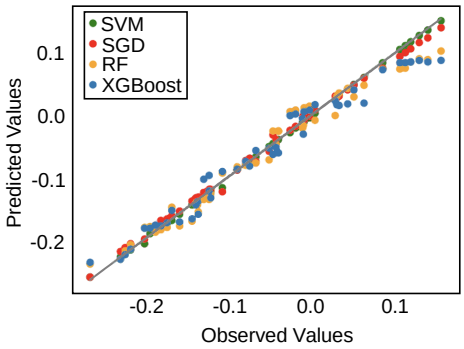

Figure 3: ML model predicted vs. observed values at point A reported in Figure 1.

We utilized *Google Colab's* CPU runtime with 12.7 GB of accessible RAM for training the models. Table 1 displays the necessary time for both the training and prediction phases of each model.

Table 1: Training and prediction time for each model for all snapshots and degrees of freedom

Model	Training Time (s)	Prediction Time (s)
SVM	68.42	2.51
SGD	17.74	2.59
RF	399.97	28.84
XGBoost	1671.99	13.10

DISCUSSION

We successfully employed four ML algorithms to predict the effect of a tear on the mechanical behavior of vaginal tissue by training data obtained from FE simulations. The SVM model demonstrated superior performance, exhibiting the highest R^2 score. Its predictions for various sets of inputs were remarkably accurate, closely aligning with the ideal line (Figure 3). Additionally, it ranks as the second fastest model in terms of training time and the fastest in prediction time with 2.51 seconds. Among the considered models, XGBoost exhibited the lowest performance and longest training time. However, it still achieved an R^2 score exceeding 0.93 for both the training and test datasets. SGD and RF demonstrated intermediate performance, with SGD slightly outperforming RF and being the fastest model with a training time of 17.74 seconds. This study shows that ML techniques can generate rapid and real-time simulations of vaginal deformations, decreasing the computational time required for FE based simulations and expediting their integration into clinical settings.

INTRODUCTION

During pregnancy, maternal anatomic structures undergo vast remodeling to accommodate the load of the growing fetus. Insufficient tissue remodeling can lead to serious pregnancy complications such as preterm birth (PTB, delivery before 37 weeks gestation), which affects 10% of deliveries worldwide and is the leading cause of infant mortality [1]. Due to inherent risks and complexities associated with studying pregnancy *in utero*, computational modeling, coupled with experimental data, has emerged as an invaluable tool for studying the biomechanics of pregnancy and has enabled the quantification of tissue stress and stretch throughout gestation. In previous studies, computational models of human pregnancy have enabled us to better understand loading patterns on the proximal cervix for different patient anatomies [2-3].

To understand the growth and remodeling during pregnancy, the murine model has been widely utilized to characterize the mechanical behavior of the cervix. However, there are distinct differences between human anatomy and mouse models, as mice have a gestational period that is 12 times faster, bicornate uterine horns, large litter size, and placental structural and physiological differences [4]. To evaluate the mouse as a mechanical model for pregnancy, the goal of this research is to compare the pattern and magnitude of mechanical loading of the murine cervix and uterus with human pregnancy. Using finite element analysis (FEA) and histological sections of the whole murine reproductive track, this study quantified the stretch of the mouse uterus from the non-pregnant state until early pregnancy (day 6 of an 18.5-day gestation). Future studies will include quantifying the mechanical environment of the murine uterus and cervix for the full gestation.

METHODS

Uterine and cervical tissue samples were collected from wild-type mice at nonpregnant (NP, n=5), mid-pregnancy (d6, n=3) and late-pregnancy (d18, n=2) timepoints. Samples were acquired from the coronal plane and included entire cervical and uterine geometries. Slices were fixed in 10% formalin for 24 hours, transferred to 70% ethanol, and paraffin embedded. To appreciate the general tissue structure (collagen, mucin, muscle distribution), 5-μm sections were stained with Movat pentachrome. Using stained images, dimensions were measured and recorded in ImageJ for maximum right and left uterine horn diameters, cervical length, cervical diameter, and cervical canal diameter for all samples. Membrane thickness was also measured on d6 samples.

Three-dimensional models of murine reproductive anatomy were generated for each of the five nonpregnant samples. To build these models, the uterus and cervix were identified and traced using a spline in Solidworks (Dassault Systemes, Vélizy-Villacoublay, France). By assuming symmetry about the coronal plane, the cervical and uterine diameters were used to create a lofted circular profile, following the direction of the outer spline and creating an appropriately scaled and anatomically accurate geometry (Fig. 1). The uterine cavity was then traced and generated for each model, and a membrane and cervical canal was added using previously measured thicknesses. Each model was then embedded in an abdomen. The posterior half of each geometry was used for computational efficiency, and models were discretized into elements using Hypermesh (Altair Engineering Inc., Troy, MI). The meshed geometry was imported into FEBio Studio (v1.3.0) where finite element analysis (FEA) was performed.

Material properties, boundary conditions, and contacts were defined within FEBio Studio. For preliminary model development, material parameters were used based on experimental values obtained in human pregnancy computational model [5-7]. Neo-Hookean material properties were assigned to the uterus, membrane, and abdomen. The cervix was modeled as a passive fiber composite material with a compressible neo-Hookean ground substance and a mid-pregnancy cervical fiber stiffness value [8]. The uterus and cervix were tied together, and both structures were tied

to the abdomen. The membrane was tied to the uterus and cervix, and a uniform pressure was applied to the intrauterine membrane for each non-pregnant anatomy. The x,y, and z planes of the abdomen were fixed.

All models were loaded to 0.6 kPa. The cervix and uterus were then examined to understand how the magnitude and pattern of tissue stretch and stress begin to evolve in a murine pregnancy.

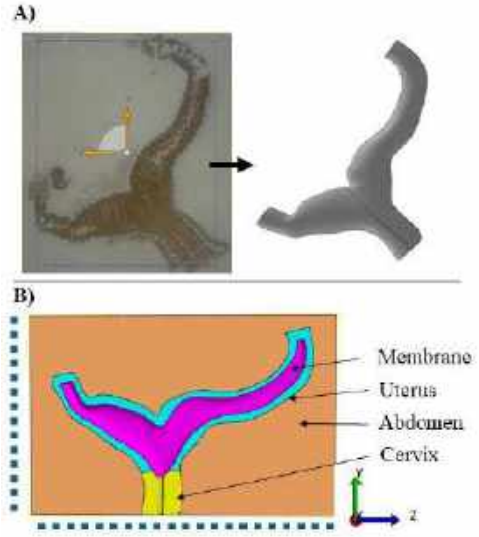

Figure 1: (A) Build process for mouse geometry involves tracing stained images and using a loft to create 3 dimensional CAD model. (B) FEBio geometry generated from CAD model.

RESULTS

Average caliper measurements recorded from tissue samples for each gestational timepoint are shown in Table 1. Left uterine diameter (Left UD) and right uterine diameter (Right UD) were recorded for n=5 NP, n=3 d6, and n=2 d18 samples. For two samples, the cervix boundaries were unclear. Cervical Length (CL), cervical diameter (CD1) and cervical canal diameter (CD2) were recorded for n=5 NP, n=2 d6, and n=1 d18 samples. Table results show increasing uterine diameters for later gestational time points. While uterine diameters show a clear trend, there is no clear trend amongst gestational groups for cervical measurements.

For each mouse anatomy, deformed configurations were examined and compared to the reference configuration (Fig. 2). All samples had increased left and right UD in response to the applied load.

Using the deformed anatomies, the pattern and directionality of the first principal Lagrange strain and Von Mises stress were examined for each model (Fig. 3) by mirroring the proximal cervix about the coronal plane. We notice higher stress and stretch occur around the cervical canal, which is more concentrated on the left and right sides of the canal than the anterior and posterior.

Table 1: Caliper Dimensions from Tissue Samples (mm)

	Left UD	Right UD	CL	CD1	CD2
Nonpregnant	2.25	1.91	1.66	1.63	0.23
D6	3.46	3.74	1.82	1.41	0.15
D18	9.64	12.23	2.52	2.32	0.25

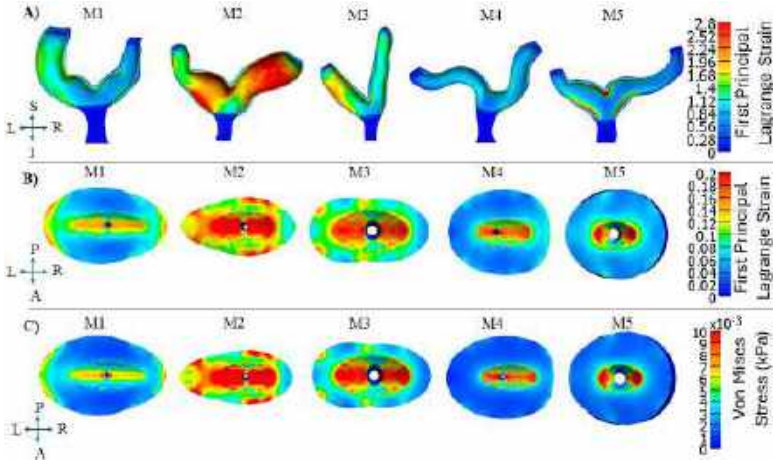

Figure 3: (A) First principal strain. (B) First principal cervical strain (C) Von Mises cervical stress. Anatomical directions are provided.

DISCUSSION

These computational results show the feasibility of modeling the murine reproductive tract during pregnancy. Here, initial proximal cervix loading maps were generated from this study. Moving forward, further work is needed to characterize loading patterns in the mouse model and compare them to other species. For example, in the human model, the fetal membrane is tied to the uterus and allowed to slide on the cervix. To create a direct comparison between mouse and human proximal cervix loading, this contact condition will be replicated in a future version of the mouse FEA model. Additionally, physiologically relevant mouse material properties will be incorporated into the model. Mouse cervical properties have previously been measured and reported from tensile stress-relaxation tests [9]. Uterine properties will be obtained by replicating this testing protocol on recently acquired mouse uterus samples.

The limitations of this study are not trivial. Although tissue samples included samples from different gestational time points, the sample size was small. It did not provide insight into the relative changes each mouse's anatomy undergoes as a longitudinal study would. Additionally, although this model shows promise in replicating the strain experienced during the first trimester of mouse pregnancy, it is not yet able to replicate the large amount of deformation that this anatomy experiences at a late pregnancy timepoint (day 18).

INTRODUCTION

Metastatic breast cancer is one of the leading causes of deaths in women worldwide [1].Therefore, it is crucial to focus on the study of its mechanism and treatment. Imitating the tumor microenvironment, including the extracellular matrix (ECM), in metastatic breast cancer research is of utmost significance. This approach enables to create a more accurate representation of the conditions in which cancer cells grow and spread, shedding light on the intricate process of metastasis. It also plays a pivotal role in drug development, as it allows for testing the efficacy of anticancer drugs under conditions that closely resemble those found in the body. The stiffness and permeability of the ECM can significantly influence the behavior of cancer cells. Increased ECM stiffness is often associated with enhanced cancer cell migration and invasion, contributing to tumor progression. This is because stiffer ECMs can enhance the mechanical signals that are transduced into the cells, promoting more aggressive behaviors in cancer cells [2].On the other hand, ECM permeability affects how nutrients, signaling molecules, and cells themselves move through the tumor environment, impacting tumor growth and metastasis [3].Moreover, understanding how cancer cells interact with the ECM and other microenvironmental factors is crucial in identifying resistance mechanisms and developing novel therapeutic strategies to combat drug resistance. Additionally, the study of interstitial flow within the tumor microenvironment is gaining increasing importance in metastatic cancer research. Interstitial flow influences various aspects of tumor behavior, including cell migration and the transport of nutrients and signaling molecules. Its role in metastatic cancer cannot be understated, as it affects the ability of cancer cells to invade surrounding tissues and disseminate to distant organs [4]. Investigating interstitial flow dynamics provides valuable insights into the mechanics of metastasis and offers potential targets for therapeutic intervention. Therefore, comprehending the interplay between interstitial flow and metastatic breast cancer progression is a critical avenue of research in advancing our understanding and treatment of this disease. Most previous methods of studying migration involve a monolayer cell culture system together with hydrogels, which is unable to either recreate the tumor migration nor to sufficiently mimic tumor microenvironment [5]. Lack of interstitial flow and usage of only single gel-based cell culture limits control of matrix properties therefore impedes structural imitation of the extracellular matrix as well as tumor microenvironment. To overcome this limitation, we have developed a microfluidic dual-gel cell culture model, which can better mimic the heterogeneous nature of the tumor ECM, providing a more accurate model for studying cancer cell migration and behavior. By incorporating varying stiffness and permeability characteristics in different gel regions, we can more effectively study how these ECM properties influence cancer progression and response to therapies, while controlling the interstitial flow. The current results represent an initial phase in developing the final dual-gel system. Currently our focus has been on encapsulation cells within GelMA microbeads. Moving forward, the dual-gel system will be enhanced by incorporating collagen between the microbeads.

METHODS

The dual-gel cell culture model was manufactured through standard soft lithography using a single-layered structure of PDMS (polydimethylsiloxane). Gelatin Methacryloyl (GelMA) was chosen as the primary gel due to its unique properties and characteristics. GelMA is biocompatible and provides a natural microenvironment that closely mimics the extracellular matrix of tissues, making it highly suitable for cell culture. 7 million/mL GFP-tagged MB-MDA 231 were encapsulated in 7.5% GelMA using a PDMS microfluidic droplet device and packed to another PDMS microfluidic device (Figure 1) through inlet, where they were trapped in a chamber by the pillars and

cultured using continuous flow at 0.5ul/min for 7 days via a syringe pump in a 5% CO_2/37°C incubator. Live-dead assay was performed after 7 days using ethidium homodimer staining. Prior to the experiment, all cells were stained with CellTracker Green, a fluorescent dye making living cells appear green under fluorescence microscopy. Additionally, dead cells were identified using ethidium homodimer, a compound that penetrates only dead cells and makes them appear red under fluorescence. Images were captured, showing cells in two colors: green for live cells and red for dead cells. To determine cell viability, the images were analyzed by counting the total number of cells (green-stained) and the number of dead cells (red-stained). Cell viability was calculated by subtracting the number of dead (red) cells from the total number of cells (green) and then multiplied by 100 to obtain the cell viability percentage. Experiments to study metastasis will be performed using the same chip design (Figure 1), but encapsulated in 7.5% GelMA will be cancer Associated Fibroblast (CAFs) and MB-MDA 231 will be seeded around the beads. Second gel will also be introduced.

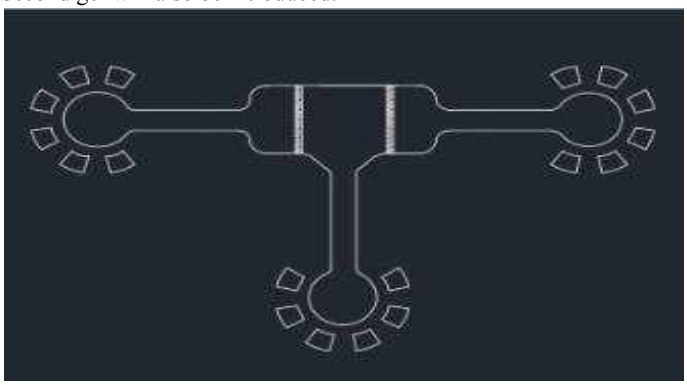

Figure 1: CAD design of microfluidic device used for culturing of GelMA microbeads. The chamber is 1mmx1mmx200um.

RESULTS

Micropillars were able to successfully trap microbeads inside of the chamber during the constant flow creating a two-layer packing as shown in Figure 2.

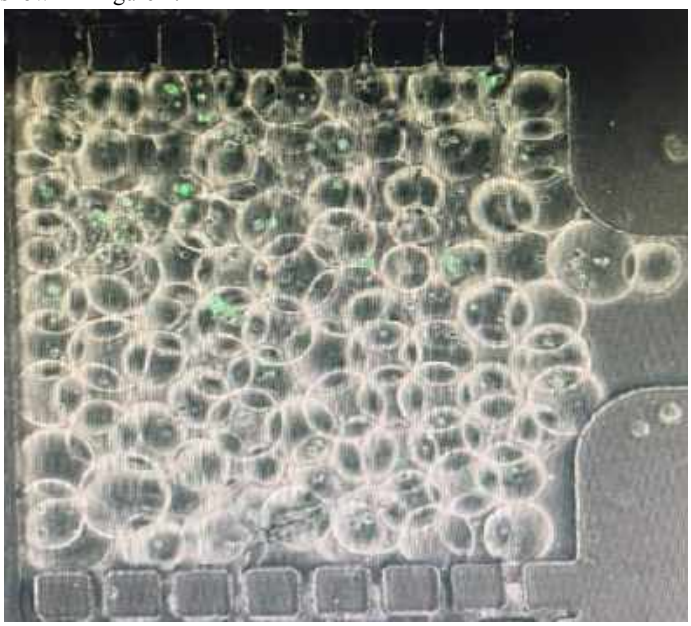

Figure 2: PDMS microfluidic device packed with encapsulated in GelMA GFP MB-MDA 231.

Live-dead assay of encapsulated in GelMA GFP MB-MDA 231 cells after 7 days of continuous flow at 0.5ul/min showed over 95% viability, as shown below on the Figure 3.

B)

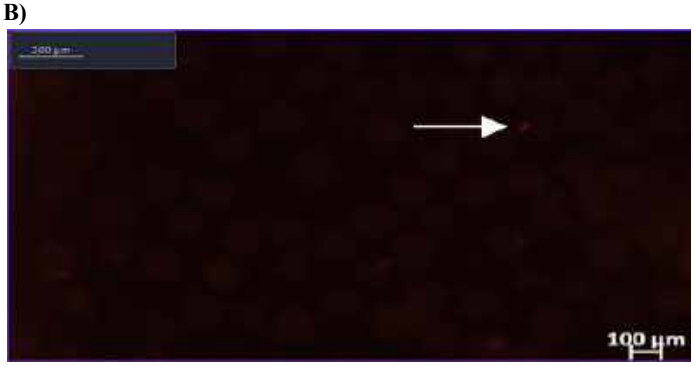

Figure 3: Pictures of live-dead assay made by fluorescent microscope.
A) Image representing live population of MB-MDA 231-green.
B) Image representing dead population of MB-MDA 231- 2 red cells shown with an arrow.

DISCUSSION

The novel dual-gel cell culture model combines the encapsulation of cells within GelMA via a droplet device and their subsequent cultivation in a continuous flow system. This approach has maintained high cell viability, with over 90% viability observed after seven days, which hold big hopes and potential for future research applications. By introducing a secondary gel and incorporating an additional cell line, it will more accurately replicate the complex interactions within the tumor microenvironment,which is crucial for understanding the dynamics of cancer progression and metastasis.The potential of this dual-gel system extends beyond basic research and holds significant promise for informing the development of targeted cancer therapies.

INTRODUCTION

The American College of Obstetrics and Gynecology's diagnostic criteria for chronic pre-existing hypertension is having either a systolic pressure ≥ 140 mmHg or diastolic pressure ≥ 90 mmHg before pregnancy [1]. Chronic hypertension affects approximately 1 in 20 pregnancies and its prevalence in pregnancies continues to increase. Blood pressure typically decreases by 5-10 mmHg near the end of the first trimester and starts to return to pre-pregnancy values around the start of the third trimester [1]. This decrease is seen in normotensive pregnancies and chronic hypertension pregnancies, but not in preeclamptic patients [2].

The maternal cardiovascular system goes through dynamic changes during pregnancy to meet the demands of perfusing the gestation, especially during the exponential growth seen later in pregnancy. Studies on C57BL/6J mice demonstrate comparable cardiovascular changes during pregnancy to those observed in humans [3]. Additional studies utilizing pressure overload models, such as the transverse aortic constriction model, have found that pregnancy had a positive effect on cardiac remodeling compared to non-pregnant controls [4].

In this study, our objective was to non-invasively characterize cardiac remodeling in a small animal model of chronic hypertension with pregnancy. We used a combination of ultrasound imaging and non-invasive blood pressure measurements to longitudinally monitor the physiological adaptations that occur during chronic hypertension in pregnancy.

METHODS

Nine nulliparous female mice (C57BL/6J; 10 weeks old) were used in this study. Cardiovascular health was assessed using a non-invasive blood pressure monitoring system (CODA, Kent Scientific Corporation, Torrington, USA) and high-frequency ultrasound for echocardiography (Vevo3100 Imaging system, FUJIFILM VisualSonics, Inc., Toronto, ON, Canada).

A subset of five mice were randomly assigned to be in the hypertensive cohort (AngII cohort). The remaining four mice were assigned as the normotensive-pregnant cohort (control cohort). After baseline assessment, a mini-osmotic pump (Azlet 2006, Durect) was implanted subcutaneously to dose 1000 ng/kg/min angiotensin II (AngII) for 6 weeks [5]. The mice were re-evaluated via ultrasound to establish a hypertensive baseline (HT baseline). The mice were then paired 2:1 with male mice (C57BL/6J; 2-6 months old) to induce pregnancy. Mice from the control cohort were immediately paired after the initial assessment. After pairing, the mice were assessed every 3-4 days using high-frequency ultrasound to identify gestation [6].

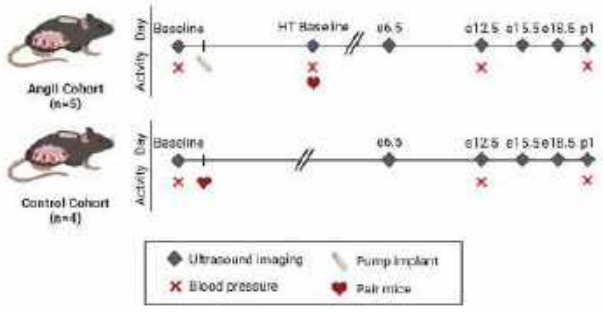

Figure 1: Experimental timeline for AngII and control cohort. Created with BioRender.com.

Mice from both cohorts were imaged at embryonic day 6.5 (e6.5), e15.5, e18.5, and the first day postpartum (p1) using a 40 MHz central frequency transducer. The experimental timeline for both cohorts is outlined in Figure 1. ECG-gated Kilohertz Visualization images of the long axis of the left ventricle were analyzed using Vevo Lab software

(Figure 2). After segmentation of the endocardium of the left ventricle, we can estimate the volume of the ventricle throughout the cardiac cycle, stroke volume (SV), ejection fraction (EF), and cardiac output (CO). Blood pressure was also acquired on e12.5 and p1.

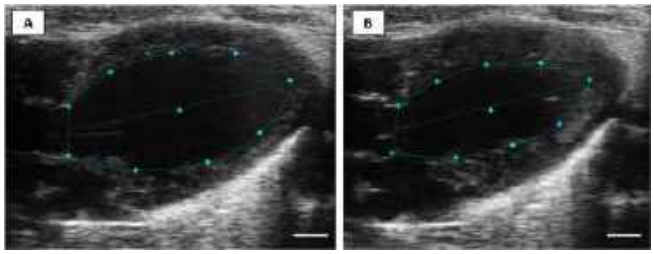

Figure 2: Representative long axis B-mode images of the left ventricle at (A) diastole and (B) systole with segmentation points shown in cyan. Scale bar = 1 mm.

The normality assumption was assessed under a Shapiro-Wilk test and homoscedasticity was assessed under a Levene's test. The parameters were analyzed using a two-way ANOVA with post-hoc Tukey pairwise comparisons. Parameters were considered significant when the p-value(*p) was less than 0.05.

RESULTS

Mice were considered hypertensive if there was at least a 10 mmHg increase from baseline mean arterial pressure (MAP). For the AngII cohort, this occurred approximately two weeks after mini osmotic pump implantation. There was a significant decrease in MAP in the AngII cohort compared to their hypertensive baseline and control group at e12.5 (Figure 3).

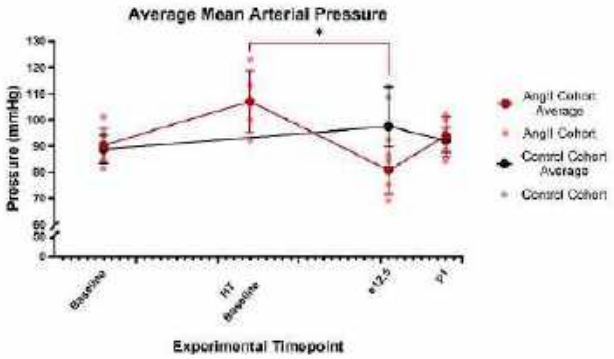

Figure 3: Longitudinal average mean arterial pressure displayed as average ± standard deviation. *p<0.05.

Mice in the AngII cohort had a significant decrease in EF from their baseline to HT baseline (Figure 4A). They also had a significant increase in diastolic volume on days e12.5 and e15.5 compared to their HT baseline (Figure 4B). Similar increases were seen in CO on e15.5 and SV on e15.5 and p1 for the AngII cohort (Figures 4C and 4D).

DISCUSSION

The relationship between systemic hypertension, pregnancy, and acute cardiac remodeling is multi-faceted and complex. Our murine results suggest potential counteracting effects of pregnancy-induced volume overload and hypertension-induced pressure overload. The AngII cohort of mice had blood pressure data that followed similar trends compared to a human study which reported a decrease in blood pressure during the beginning of pregnancy, followed by an increase in the later stages [1]. The SV and CO results of the control cohort were similar to previously reported values at their respective embryonic days for our control mice [3].

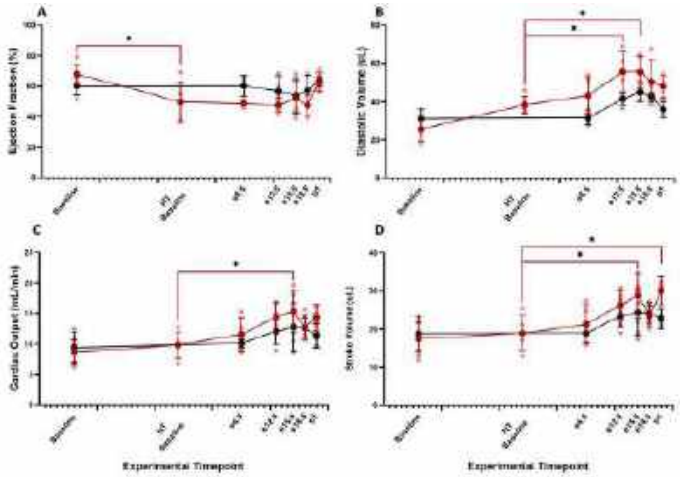

Figure 4: Longitudinal average (A) ejection fraction, (B) diastolic volume, (C) cardiac output, and (D) stroke volume displayed as average ± standard deviation. *p<0.05.

We observed similar trends in diastolic volume throughout pregnancy in both cohorts, as diastolic volume continued to increase from baseline to e15.5, followed by a slight decrease. However, we see on average a higher diastolic volume in the AngII cohort compared to the control cohort on corresponding embryonic days. This suggests that the AngII-induced pressure overload leads to more pronounced eccentric hypertrophy. AngII also significantly decreased the EF after the mice became hypertensive. This was expected as AngII is known to stimulate collagen formation in the extracellular matrix of cardiovascular tissue, which leads to hypertrophy and ventricular stiffening [7]. The similarities that we observed in SV and diastolic volume trends could explain why EF remains relatively similar throughout pregnancy.

Ongoing histological analysis will provide insight into the composition of the extracellular matrix and compositional differences between cohorts. Altogether, this study using mini osmotic pumps to subcutaneously infuse AngII in pregnant mice has provided key insights into how chronic hypertension influences cardiac remodeling during pregnancy. Additional work is needed to translate these findings into therapeutics aimed at helping patients with pre-existing hypertension, pregnancy-induced hypertension, and/or preeclampsia.

INTRODUCTION

Elastography is a medical imaging modality that is used to determine mechanical properties of biological tissues. There exist various elastography techniques that use ultrasound [1] or magnetic resonance imaging. Optical coherence elastography (OCE) is a more recently developed technique that applies optical coherence tomography (OCT) imaging modality. Wave-based OCE is based on excitation of elastic waves in tissues. Wave velocity obtained from the OCT images is related to the shear modulus of the probed material, using elastic wave theory. Wave-based OCE has been used to infer stiffness of various soft biological tissues.

Previous research mainly focused on the application and validation of elastography technique on the phantoms [2]. Recently, OCE has been applied to determine stiffness of biological tissues such as eye cornea [3] and skin [4]. Ultrasound elastography has been used to determine mechanical properties of arteries *in vivo*, such as sheep and human common carotid artery [5]. In this study, OCE was applied to determine local shear modulus of human anterior cerebral arteries (ACAs), which was then compared with tissue properties from mechanical test.

METHODS

OCE measurement

ACA samples, approximately 1.5 cm long and 2 mm in diameter, were mounted on a custom device and placed under the OCE setup (Fig. 1). The ACA samples were then pressurized up to 120 mmHg using 1×phosphate-buffered saline (PBS) solution with OCE measurements made every 20 mmHg. The elastic waves were excited by a piezoelectric actuator with frequencies range from 1 kHz to 100 kHz. The OCE system is operated in a M-B scan mode to acquire traveling waves data along the longitudinal direction of the ACA.

Figure 1: OCE measurement of ACA cannulated on a custom device and pressurized up to 120 mmHg.

The propagation of the guided wave was analyzed from arterial wall displacements using the method previously described [3]. Briefly, to calculate wave speeds, at each frequency, Fourier transformation was performed on the displacements in the wavenumber k domain. An experimental dispersion curve was then plotted.

Shear modulus from OCE measurement

Lamb wave theory was used to describe the wave guided by the arterial wall [6] allowing a dispersion relation to be obtained. Fluid-solid-fluid interface interactions were considered while deriving the dispersion relation as the following [1]:

$$4k_L^2\eta\beta\cosh(\eta h)\sinh(\beta h) - (2k_L^2 - k_s^2)\cosh(\beta h)\sinh(\eta h) = \eta/\eta_f * k_s^4\cosh(\eta h)\cosh(\beta h) \quad (1)$$

where h is the artery thickness. The Lamb wavenumber $k_L = \omega/c$ is calculated from experimental data, where ω is the angular frequency of excited wave, and c is the experimentally obtained wave speed. The

shear wave number $k_s = \omega\sqrt{\rho/\mu}$ that depends on shear modulus μ, and the material density ρ. Other parameters $\eta \approx k_L$ and $\beta = \sqrt{{k_L}^2 - {k_s}^2}$.

To determine shear modulus μ, the dispersion relation in Eqn. 1 was fitted to the dispersion curves obtained from OCE experiments.

Artery stiffness from mechanical testing

Biaxial inflation-extension testing was performed on ACAs using a pressure myograph [7]. Briefly, samples were stretched to their *in vivo* stretch ratio and inflated up to 120 mmHg pressure, while the axial force, transmural pressure and outer diameter were recorded. Circumferential stretch and stresses were calculated. Tangent modulus was then determined as the slope of the circumferential stress-stretch curve for all tested pressure values [7].

Local shear modulus obtained using the OCE method was then compared to the tangent modulus from mechanical testing.

RESULTS

Displacement maps were generated for all samples at every pressure value. For each tested frequency ranging from 1 kHz to 100 kHz, images of arterial wall displacements that caused by traveling waves were generated (Fig. 2). The alternating red and blue pattern represent the positive and negative vertical displacements, respectively. At higher frequencies the distance between the minimum and maximum vertical displacements is smaller due to smaller wavelength.

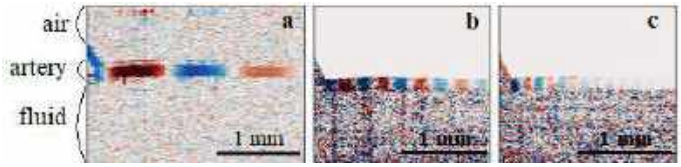

Figure 2: Displacement maps at frequencies of (a) 10 kHz, (b) 30 kHz, (c) 50 kHz in an ACA wall pressurized to 80 mmHg.

We introduced a cutoff frequency that ranges between 15-30 kHz, after which Lamb wave theory is applicable to describe the guided elastic wave in the artery [6]. At frequencies higher than the cutoff frequency, the dispersion relation from Eqn. 1 fits the experimental data well (Fig. 3).

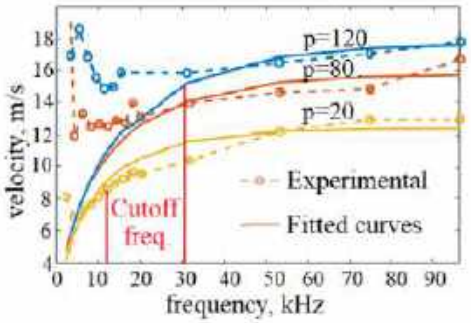

Figure 3: Experimental data (dotted lines) and fitted with Eq. 1 dispersion curves (solid lines) for given sample at 20 mmHg , 80 mmHg and 120 mmHg pressure.

From the fitted curve the local shear modulus of the ACA was obtained at each tested pressure. Figure 4 shows the comparison of shear modulus from OCE and tangent stiffness from mechanical test for an ACA sample. The local shear modulus increases from 0.22 to 0.44 MPa as pressure increases from 20 to 120 mmHg, while the tangent modulus obtained from mechanical test increases from 0.34 MPa to 4.6 MPa.

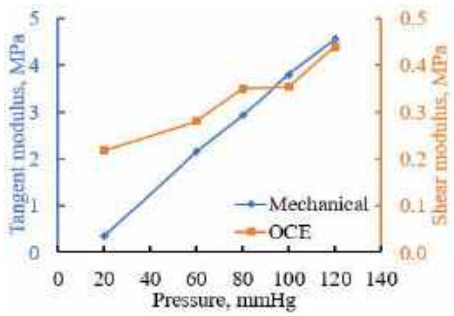

Figure 4: Comparison of shear modulus from OCE to tangent modulus from mechanical testing of an ACA sample at pressures from 20 to 120 mmHg.

DISCUSSION

Both local shear modulus and tangent modulus increase with pressure due to stiffening of the artery. The ratio between local shear modulus and tangent stiffness obtained from biaxial extension-inflation mechanical test decreases from 0.6 to 0.1 as the pressure increases (Fig. 4). While further studies are still needed to understand such discrepancy, it is important to point out the differences in the two testing modalities. Firstly, shear modulus measured with OCE is local, and limited by 5-10 wavelength or scan length (typically < 3 mm), while the mechanical test measures the averaged tissue level properties of the whole artery. Secondly, the mechanical test is a quasi-static experiment, while OCE is a dynamic test, therefore viscoelasticity will play an important role. Finally, shear modulus from OCE experiment is measured in the longitudinal direction, whereas tangent stiffness was obtained in the circumferential direction, which is important to consider for such an anisotropic material as ACA.

A cutoff frequency was specified when interpreting the experimental data using Lamb wave theory (Fig. 3). Our results show that at low frequencies the wavelength is comparable to the arterial radius. In this range Eqn. 1 derived from the Lamb wave theory that assumes wave propagation in a flat plate, will not be applicable to describe guided wave propagation in curved artery.

In this study, Lamb wave model was used under the assumption of fluid-solid-fluid interface interaction. Similar assumption was made in a previous study that applied dynamic wave elastography *in vivo* [5], assuming the connective tissue around the artery is significantly softer than the arterial wall. Study is underway to develop a Lamb model with air-solid-fluid interface interaction, which may describe the experiments more accurately.

In this research OCE was successfully applied to determine local shear modulus of ACA samples. Further studies are underway to understand the comparison of measurements from different modalities, and the mechanical properties of ACAs with the progression of neurodegenerative disease, such as Alzheimer's disease.

INTRODUCTION

The female reproductive tract is unique in its ability to undergo significant remodeling and large deformations during pregnancy. Due to ethical considerations, these remarkable changes have been understudied in human subjects, limiting our understanding of the effects of pregnancy on women's health. For example, there are still many unknowns about the reversible and irreversible alterations in the mechanical properties of reproductive tissues that occur in women with pregnancy. Researchers have relied on animal models such as rodents, ewes, swine, and primates to investigate the mechanical properties of the reproductive organs throughout pregnancy [1]. *Ex vivo* reproductive tissues from mice and rats have been used to quantify the biaxial mechanical properties of the vagina and uterine body using inflation testing [3-7]. In these studies, each reproductive organ was either tested in isolation [3-6] or its deformations were characterized only partially [5-7], providing an incomplete picture of the *in vivo* mechanical behavior of the organ. Rodents can be adopted as a model for pregnancy research as long as differences between mice and humans are well understood. By using advanced magnetic resonance imaging (MRI) technology, we have recently documented pregnancy-induced *in-vivo* remodeling of the reproductive organs in mice, taking advantage of mice's short gestation period, ease of animal husbandry, and low cost [2]. In this study, to better simulate the *in vivo* physiological conditions, we performed *ex vivo* inflation testing of the entire murine reproductive tracts with full-field deformation measurements of the main component of the tracts.

METHODS

The current study was conducted with the approval of the Institutional Animal Care and Use Committee (IACUC) at Virginia Tech. Sexually mature 3-4 months old nulliparous (virgin) CD1 mice (Charles River Laboratories Inc., Wilmington, MA) were sacrificed using CO_2 asphyxiation, followed by cervical dislocation. The reproductive tract (from introitus to ovarian fat pads) were isolated from each mouse. Extraneous connective tissue and fat were removed, without compromising the integrity of the reproductive tract. The intact reproductive tract was connected to a stainless-steel dispensing needle via the introitus. The ovaries, oviducts, and the tips of the uterine horns were occluded in methyl 2-cyanoacrylate before being loosely tied with sutures at the ends of the uterine horn. This allowed the reproductive tract to freely extend and shift during testing while maintaining an upright orientation. Specimens were speckled with an aerosol fast dry gloss black paint for non-contact strain measurement (Figure 1).

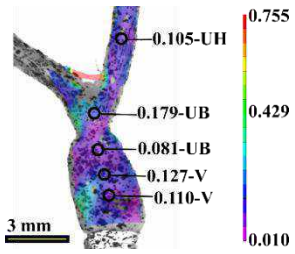

Figure 1: Hoop strain maps of one representative murine reproductive tract at 88 kPa luminal pressure.

Testing was performed on a custom-built inflation set up described elsewhere [3,4]. Briefly, specimens were immersed in a phosphate buffered saline (PBS) filled tank at room temperature, connected to a pressure transducer (Max capacity: 345 kPa, Omega Engineering Inc., Norwalk, CT) and computer-controlled syringe pump (New Era Pump Systems Inc., Farmingdale, NY) via plastic tubing. Each tract was preconditioned by 20 cycles of infusion and withdrawal of PBS to a pressure of 0 to 10 kPa at a flow rate of 2 ml min^{-1} using a closed-loop analog control sensor interface (ANABOX-11, New Era Pump Systems Inc., Farmingdale, NY) [4], followed by 40 cycles of a fixed 0.11 ml volume at a rate of 4.7 ml min^{-1}. It was then unloaded to 0 kPa and infused with PBS (flow rate of 0.47 ml min^{-1}) until rupture. Images were collected at 4 Hz during testing via two CMOS cameras (Basler ace A2440-75 um, Basler Inc., Exton, PA) equipped with c-mount lenses (Xenoplan 2.8/50, Schneider Optics Inc., Hauppauge, NY). Non-contact strain measurements were computed on the dorsal side of the reproductive tract using a calibrated 3D digital image correlation system (Vic-3D 9, Correlated Solutions, Columbia, SC). The average Lagrangian normal strains in the hoop and axial directions were collected over small circular regions at the vagina, uterine body (connection of the uterine horns to the cervix and vaginal fornix), and uterine horns (Figure 1).

RESULTS

The average pressure at rupture and average volume infused in the reproductive tract (n=5) was 73.95 ± 19.67 kPa and 0.673 ± 0.155 ml. Tissue rupture occurred away from the introitus, the clamped end, at seemingly random locations within the uterine horn wall. Deformations in the hoop direction were larger than those in the axial direction in each region of the reproductive tract; at times, almost double (Figures 2 and 3). Both strains were non-linearly correlated with the applied pressure; the uterine horns and uterine body had a more variable pressure-strain relationship across specimens (Figure 3 depicts change in regions for n=1).

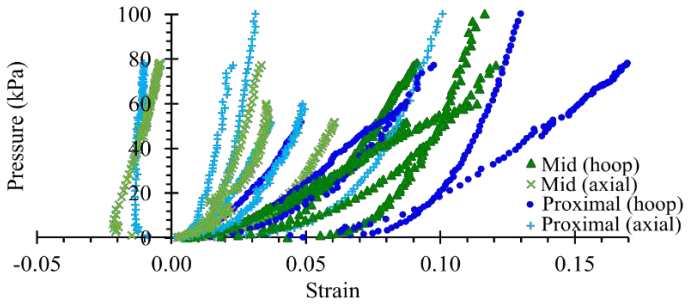

Figure 2: Hoop and axial strain versus pressure for the mid and proximal vagina (n=5 specimens).

For the vagina, the maximum strain in the hoop direction was consistently larger (0.129 ± 0.032, mean ± standard deviation) than the maximum strain in the axial direction (0.060 ± 0.060) (Figure 2). At the uterine body, the maximum hoop strain was 0.284 ± 0.264 with the maximum axial strain equal to 0.123 ± 0.045. Regions of the uterine horns had more variations in strain along both directions, with strains in the hoop and axial yielding a maximum value of 0.200 ± 0.125, and 0.105 ± 0.041, respectively.

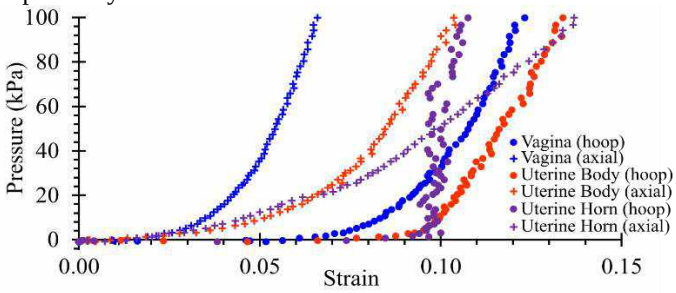

Figure 3: Hoop and axial strain versus pressure for the vagina, uterine body, and uterine horns of one reproductive tract (same as in Figure 1).

DISCUSSION

To our knowledge, this is the first study that reported the full-field deformations of the entire reproductive tract simultaneously without isolating the vagina, uterine body, and uterine horns in response to increasing intraluminal pressure, up to failure. Differences in magnitude of hoop and axial strains in the vagina (Figure 2) align with previous inflation studies of the *ex-vivo* rat [3,4] and mouse vagina [5,6]. Measurements of local strains in multiple anatomical regions suggest mechanical differences between the proximal and the mid vagina (Figure 2). These findings could be also determined by geometric differences of the organs as quantified *in vivo* in our recent MRI study [2]. Direction-dependent differences in strains (e.g., the hoop strain being greater than the axial strain) are not consistent in the uterine body and uterine horns (see, e.g., pressure-strain data for the uterine horn in Figure 3). This may be the result of their overall irregular geometry and variations in wall thickness. Our strain values are higher than those reported in published studies on murine reproductive tissues likely due to differences in testing modality and applied pressures [6,7]. We plan to conduct additional tests on entire murine reproductive tracts, including from mice at different time points during gestation. This research represents an important first step in evaluating mice as an animal model for examining reproductive tissue deformations during pregnancy. In addition to enhancing our understanding of mouse physiology, this work can provide valuable insights into human pregnancy and contribute to the generation of research hypotheses in the field of women's health.

INTRODUCTION

Abdominal Aortic Aneurysm (AAA) is a serious condition where the distal end of the body's main blood vessel, the aorta, dilates abnormally. This dilation can be life threatening if the vessel ruptures. Various factors contribute to its development, including aging, smoking, high blood pressure, plaque buildup in arteries (atherosclerosis), and male gender [1]. At its early stages, an AAA often shows no symptoms, making it challenging to detect without proper screening. However, as the aneurysm grows larger, it can cause severe abdominal or back pain. A ruptured aneurysm is a medical emergency and can be fatal. Doctors typically diagnose AAA using imaging methods such as ultrasound, computed tomography (CT), or magnetic resonance imaging exams.

AAA clinical images can be segmented semi-automatically or automatically to identify specific regions of interest (ROI). Semi-automatic methods often require initial guidance through seed points and commonly use deformable models or active shape models [2]. Our study introduces an innovative automated segmentation technique to identify the AAA lumen and outer wall boundaries. The method does not require specialized AAA knowledge or specific segmentation software. What makes it unique is its high accuracy and reliability due to a carefully crafted diverse training dataset, ensuring precise results. The segmentation methodology not only establishes a robust foundation for comprehensive biomechanical assessment of AAAs, but also exceeds the speed of conventional segmentation methods.

METHODS

We used the patch-based dilated U-Net architecture for segmentation and identification of the AAA lumen and outer wall boundaries, evolving from Ronneberger *et al.'s* U-Net model [3]. In the U-Net architecture, dilation rates play a crucial role in how the network sees the image through its convolutional layers. In addition to its architectural components, our methodology integrates patch-based processing, which is a technique that subdivides large image stacks into smaller, manageable patches. These patches undergo individual processing, enabling efficient analysis and segmentation of extensive datasets. Furthermore, data augmentation strategies are employed to expand the training dataset and enhance model generalization.

Overall, the 2D U-Net's patch-based dilated model efficacy for AAA segmentation lies not only in its architectural intricacies, incorporating dilation rates for enhanced feature extraction, but also in its practical approach leveraging patch-based processing and data augmentation to handle extensive image datasets effectively. These methodological aspects collectively contribute to the model's precision and scalability in medical imaging tasks. Figure 1(a) shows the patch-based dilated U-Net model, 1(b) illustrates the overlaid binary mask, while 1(c) and 1(d) provide a visual representation of the coronal and sagittal planes, respectively.

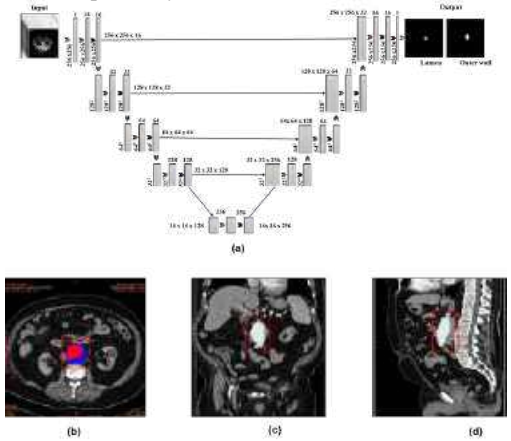

Figure 1. The overall model architecture for AAA segmentation and visualization of the reconstruction.

The dataset utilized in this study is a compilation of 2D high-resolution CT images acquired from screenings conducted at Allegheny General Hospital (Pittsburgh, PA) and Northwestern Memorial Hospital (Chicago, IL). To ensure ethical compliance and data integrity, this study received approval from the Institutional Review Board (IRB) at each medical center. The images in the dataset exhibit variation in slice thickness, ranging from 1 mm to 3 mm, and possess a resolution of 512 x 512 pixels. They were carefully annotated using a specialized script called AAAVASC (v.0168, The University of Texas at San Antonio), enabling a semi-automated approach for vessel wall detection [2].

RESULTS

Utilizing a patch-based dilated U-Net model, trained with 4268 CT contrast-enhanced images, and tested with 1385 images, accurate boundaries for the lumen and outer wall were identified. Figure 2 illustrates the segmentation protocol followed in our approach, outlining the anatomical components, and leading to the 3D reconstruction of the AAA geometry. The results shown in Table 1 indicate a substantial overlap between the predicted result segmented by the model and the ground truth.

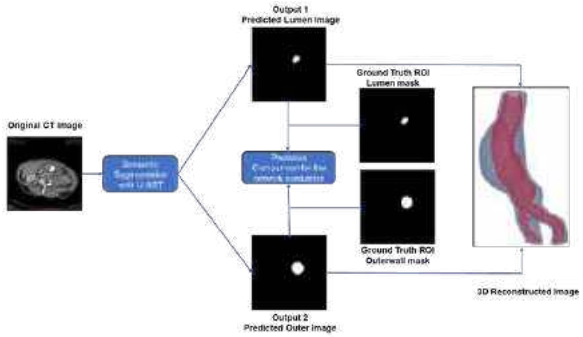

Figure 2. Image segmentation, identification of the lumen and outer wall ROIs, followed by 3D reconstruction.

Table 1. Performance evaluation based on image segmentation of 18 AAAs and 4 complex AAAs with high tortuosity.

Metric	Lumen	Outer wall	Complex AAA 1	Complex AAA 2
Accuracy	0.9995	0.9992	0.9995	0.9994
Sensitivity	0.9482	0.9666	0.9587	0.9695
Precision	0.9667	0.9674	0.9660	0.9785
MCC	0.9566	0.9660	0.9617	0.9736
Dice Coefficient	0.9562	0.9658	0.9616	0.9737
Specificity	0.9998	0.9996	0.9998	0.9997
IOU-Score	**0.9175**	**0.9354**	**0.9269**	**0.9492**

We observed small differences between the original ground truth measurements (L1, O1) and our model's predictions (L2, O2) for the left common iliac artery (Area_1) and right common iliac artery (Area_2) regions. For example, for Area_1, the original lumen area (L1) was 0.7244 mm², while the predicted lumen area (L2) was 0.7265 mm², yielding a difference of 0.0021 mm². Similar subtle variations were noticed in the outer wall area measurements. Despite these differences, the overall discrepancies between the original and predicted ROIs appear to be small. Conversely, the differences between the original measurements (L1, O1) and those obtained by different observers (I1, I2) are more noticeable. This underscores the greater level of variability in the segmentation results amongst human observers than between the original measurements (made by clinical experts) and our model's predictions. In evaluating diameter and normalized diameter of the common iliac arteries, the differences between original and predicted values are acceptable. For Diameter_1, the original and predicted diameters differed by 0.052 cm, while Diameter_2 showed a 0.0624 cm difference. Normalized diameter differences were 0.0032 cm for Diameter_1 (Norm) and 0.0005 cm for Diameter_2 (Norm).

Table 2. Statistical measures of the model.

	L1	L2	O1	O2	I1	I2
Area_1	0.7244	0.7265	1.0834	1.0878	0.7533	1.1217
Area_2	0.7237	0.7272	1.0830	1.0876	0.7514	1.0989
Diameter_1	4.4366	4.4886	6.7379	6.7120	4.4424	6.7693
Diameter_1 (Norm)	1.2447	1.2415	1.4552	1.4587	1.2347	1.4537
Diameter_2	1.2430	1.2425	1.4540	1.4589	1.2357	1.4376

DISCUSSION

In routine clinical practice, determining the size of an AAA often involves manual measurement of the maximum diameter, which is often susceptible to substantial inter-observer variability. Our fully automated model excels in AAA segmentation, outperforming other deep learning methods with exceptional DICE scores of 0.9616 and 0.9737 for the lumen and outer wall ROIs, respectively. The model's accuracy is evident, particularly in cases with complex tortuosity, when compared to other lumen [4–6] and outer wall [7, 8] ROI methods. It also has exceptional speed, measured at 17 ± 0.02 milliseconds per frame to generate the final segmented output.

An inherent limitation of our study lies in the model's dependency on contrast-enhanced CT images. To moderate this constraint, our future roadmap includes integrating unenhanced images into the training dataset once an adequate volume of patient data becomes available. This prospective addition of unenhanced images is pivotal, given that a subset of AAA patients experience delayed adverse reactions to radiographic contrast media, ranging from 1% to 23%, occasionally escalating to moderate or severe levels [9]. Moreover, future enhancements will augment our dataset with diverse CT images. This expansion in training data holds promise for refining the model's performance across varying clinical scenarios and anatomical presentations.

INTRODUCTION

Residual aortic dissections (RAD) commonly occur (43-77% of cases) following the surgical repair of a Stanford Type A aortic dissection.[1] They are characterized by a residual patent false lumen (FL) occurring along the aortic arch and/or descending aorta. RADs increase the risk for aortic growth and rupture and therefore require frequent monitoring including computed tomography angiography (CTA) scans. CTAs can help determine risk of rupture based on diameters and growth rate. CTA scans have high spatial resolution and excellent image quality but cannot reveal hemodynamic changes or assess hemodynamic features in the FL. Establishing a method that incorporates the characterization of the complex blood flow in RADs may improve the identification and treatment of high-risk patients.

Many studies have aimed to identify specific hemodynamic metrics that can predict thrombus or growth rate in aortic dissections, such as pulse wave velocity (PWV), entry tear flow, and wall shear stress (WSS).[2-4] However, due to the geometric and hemodynamic complexity, it can be challenging to consistently detect patterns, particularly in RAD cases. These cases often have entry tears in the arch and have undergone varying degrees of aortic repair, causing unique blood flow patterns in each individual subject.

4D flow magnetic resonance imaging (MRI) combined with CTA analysis enables a regional assessment of both geometric and hemodynamic differences to better understand the effect of Type A aortic repair. Here, we present a preliminary investigation of local, *in vivo* hemodynamic and geometric changes in RAD cases of varying severity.

METHODS

Patient Demographics and Data Collection. RAD patients who were outpatients at Emory University Hospital were enrolled in this study under approval from the Institutional Ethics Committee. Patients signed a written informed consent before undergoing testing. 4D flow MRI was acquired one-month post-Type A repair on three subjects (P1-3; 2 male) with residual Type A aortic dissections and one control (male) using a 3T scanner (Siemens PrismaFit) at Emory University Hospital. We used the following imaging parameters: Retrospective ECG gating, *VENC* = 150 cm/s, *TE* = 2.39 ms, flip angle = 7°, and 25 time frames. Post-processing included eddy current and anti-alias correction and noise masking using previously developed methods (Mathworks, Natick, MA).[5,6]

CTA-derived 3D model. CTAs were clinically acquired pre- and post-Type A repair. We segmented the image volumes using VMTK and Slicer for visualization and characterization of the geometry.

4D Flow MRI data. 3D true (TL) and false lumens (FL) were also segmented from 4D flow MRI magnitude images (Materialise Mimics, Belgium) to guide 4D flow MRI data analysis. The following quantifications were performed.

Streamlines visualization in TL/FL. A main advantage of 4D flow MRI is the quantification and visualization of blood flow velocity. We used the 3D lumen segmentations in Ensight (v.2021 Ansys, PA, USA) to visualize streamlines and observe patterns such as vortical and reverse flow as well as the extent of flow in the FL.

Wall shear stress (WSS). WSS estimates drag caused by blood flow on the aortic wall. WSS has been associated with changes in the FL growth and thrombus formation. Using a previously established method (van Ooji, P., GitHub Repository, 2017), WSS vectors were calculated using Equation 1:

$$\overrightarrow{WSS} = \mu \dot{\varepsilon} \vec{n} \qquad (1)$$

where μ is the blood viscosity ($3.2 \cdot 10^{-3}$ Pa·s) and ε and n are the rate of deformation tensor and normal vector, respectively.

Pulse wave velocity. Used as a proxy for arterial stiffness, PWV measures the velocity at which the blood flow waveform propagates through the arteries. Using the 3D true lumens extracted from the

magnitude image, PWV was estimated by measuring planes placed perpendicular to flow direction throughout the aorta and calculating the time delay between flow waveforms at each point calculated using cross correlation to provide a mean estimate of PWV [2].

RESULTS

CTA models revealed varying size and extent of dissections in RAD cases both before and after surgical repair of the ascending aorta, as shown in Figure 1. We observed that P1 had the smallest false lumen that fully thrombosed before the 4D flow MRI acquisition, while P3 had the largest and exhibited a patent FL along the entire descending aorta.

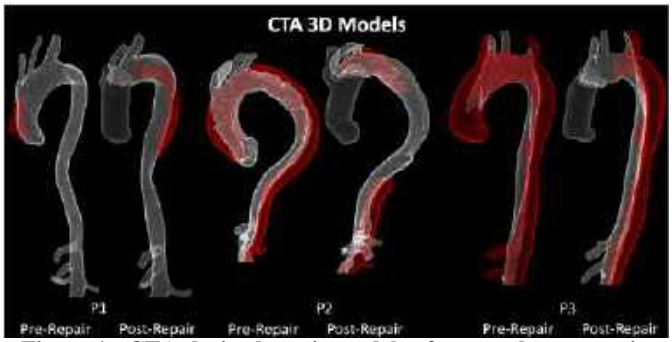

Figure 1: CTA-derived aortic models of pre- and post-repair Type A aortic dissection patients with residual false lumens (red).

Wall shear stress revealed regions of high stress in the RAD cases, particularly on the outer curvature in the ascending aorta, where the graft is located (Figure 2). However, low WSS was found in the false lumens. The estimated WSS in the control case had less heterogeneity and distribution of values compared to the RAD cases. This observation was helpful for confirming the abnormal WSS patterns found in the RAD cases.

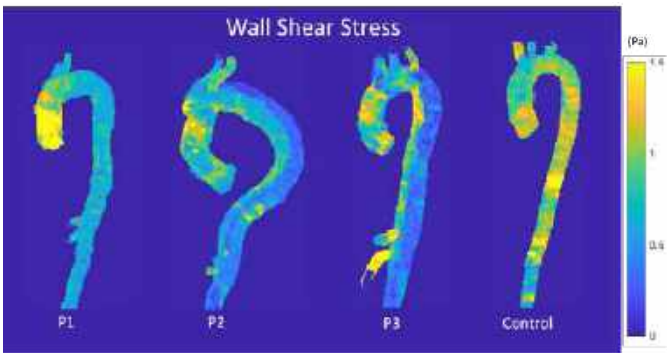

Figure 2: Mean intensity projections of wall shear stress in three RAD cases and one control subject.

Pulse wave velocity was measured in all cases in the true lumen or whole aorta. With the control PWV of 6.1 m/s, we found that P1 with no patent false lumen was higher than the control (13.7 m/s) and P2 and P3 were lower (3.2 and 2.6 m/s). Waveforms at each plane were also plotted in both true and false lumens (Figure 3A). From the velocity streamline estimation, slow and recirculating flow was observed in the false lumens (Figure 3B).

DISCUSSION

While most studies have investigated mean or peak systolic hemodynamic metrics in RAD cases [2-4], this study focused on detecting regional differences within and between cases. In the case of P2, the localized TL region of high velocity and WSS near the brachiocephalic artery (Figure 3B,C). Interestingly at the 3-month follow-up CTA, a leak between the graft and the native tissue was detected at the level of max WSS. PWV varied greatly between cases with P1 (thrombosed false lumen) having a higher than normal PWV and P2 and P3, lower.

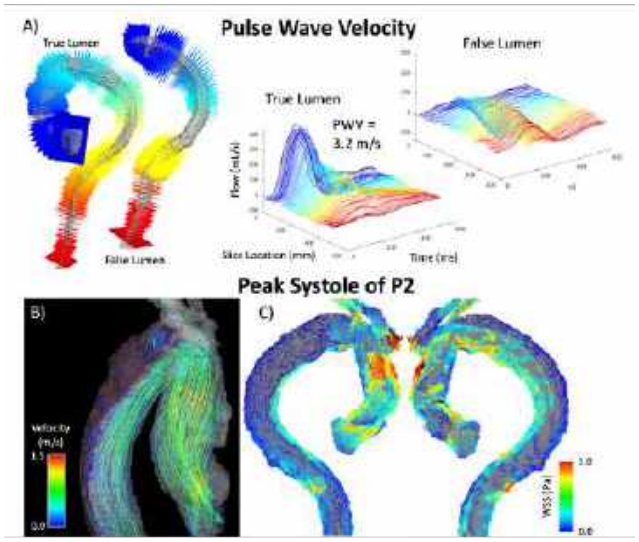

Figure 3: A) peak systolic velocity streamlines in the true and false lumen of P2 and B) WSS vectors; C) planes and flow waveforms used in PWV estimation

There are a few limitations to note within this study. With a limited sample size, this preliminary investigation cannot reveal any significant trends from the properties measured but can highlight the high variability in presentation and results from follow-up of Type A repairs. In addition, WSS values may be unreliable when derived from 4D flow MRI because of partial volume effects and segmentation errors.[7] However, when the analysis is performed in a consistent way, intra- and inter-subject differences can still be appreciated.

This study established the feasibility of measuring hemodynamic metrics using 4D flow MRI and its clinical value in the study of RAD. It also demonstrates the importance of regional analysis, where localized high WSS correlated with the location of a leak found in a follow up CTA. This type of regional analysis may be useful for improving the ability to monitor and treat patients. Future work will include the enrollment of more subjects and investigation of additional hemodynamic metrics.

ACKNOWLEDGEMENTS

We would like to acknowledge the effort of the healthcare team that acquired the images and performed the procedures and the patients willing to participate in this study. We would also like to acknowledge Dr. Michael Markl and his team for sharing their 4D flow post-processing procedure. OSCILLATORY SHEAR STRESS MODULATES LYMPHATIC PROGENITOR CELLS MATURATION INTO LYMPHATIC VESSELS WITH ANTI-CANCER PHENOTYPES

INTRODUCTION

Lymphedema is a chronic condition characterized by the swelling of tissues caused by the failure lymphatic valves which can be congenital or caused by diseases. Lymphatic valves provide a one-way flow of lymph that aids intrinsic pumping in the lymphatic system. Our research group have previously reported that human pluripotent stem cells (hPSCs) can be differentiated into lymphatic endothelial cells (LECs) to form lymphatic capillaries [1]. However, these lymphatic vessels lack lymphatic valve that is required for lymphatic pumping. Since oscillatory shear stress (OSS) has been shown to regulate lymphatic valve morphogenesis in vivo [1-2], we hypothesize that physiological OSS can induce LECs maturation and morphogenesis into lymphatic valves.

METHODS

Juvenile LECs and hiPSC-derived LECs (differentiated using our previously reported step-wise protocols) were cultured onto *ibidi* µ-Slide I 0.6 Luer channel slides. Slides were coated with 40-60 µg/mL fibronectin. OSS (at 0.5 dyne/cm^2 and 10 dyne/cm^2) were applied to all LECs with the *ibidi* Pump System for 48 hours. For oscillatory flow, the pump changed flow directions every 4 seconds. Immunostaining was conducted and imaging was done on revolve fluorescence microscope and confocal microscope. Image analysis was conducted on ImageJ utilizing the directionality and circularity plugins. Real-time PCR was conducted with human angiogenesis array panels. Statistical analyses were unpaired *t*-tests with P = 0.05 conducted on GraphPad Prism V10.

RESULTS

OSS Induces Mature Lymphatic Cell Morphology in hiPSC-Derived LECs In response to the two differing physiological OSS flow rates, both juvenile and dLECs demonstrated a cellular alignment in response to the flow direction (**Figure 1A-B**). Furthermore, the presence of 'zipper-like' junctions between individual cells increased in the high OSS flow rate condition compared to the low OSS flow rate (**Figure 1A**). These cells also demonstrated a transformation to a more cuboidal-shape cell morphology in response to the OSS flow rate, especially at the high OSS flow (**Figure 1C-D**).

The static juvenile and dLECs did not demonstrate similar flow alignment to cells under OSS (**Figure 1A-B**). There was also a lack of 'zipper-like' junctions between the cells and an elliptic-shape cellular morphology which is expected in cells that are not lymphatic-valve forming (**Figure 1C-D**).

OSS-Dependent Expression of Lymphatic-Valve Forming Markers in hiPSC-Derived LECs In response to OSS, dLECs demonstrated previously observed patterns of genetic expressions in genes known to play significant roles in lymphatic valve development *in vivo*. A major finding was the increase in *Prox1* expression under low OSS flow rates and the expected decrease in *Prox1* expression at high OSS flow rates that occurs to maintain the longevity and functionality of lymphatic valves. The dLECs also had an upregulation of *FOXC2,* which is an important upstream transcription factor to *Prox1*, that has been highly associated with lymphatic valve development. *CDH5*, which encodes a required adherens junction protein VE-cadherin for lymphatic valve development and maintenance, was increasingly upregulated as OSS flow rates increased. Confocal images obtained demonstrates these varying trends in lymphatic markers **(Figure 2A-B)**.

An increase in other genes relating to lymphatic maturation as OSS flow rate increases was also observed demonstrating its capability to display favorable lymphatic-valve forming properties (**Figure 2C**).

Cancer-Related Gene Expression Dependence on Varying OSS Flow Rates Real-time PCR results from the array panel demonstrated OSS flow rate dependent expression of multiple genes in the hiPSC-derived LECs, especially at the high OSS flow rate (**Figure 3A**). Three genes (*NRP2, CXCL12,* and *ITGAV*) that were upregulated in response to the high OSS flow rate were identified to be previously associated with tumor growth and anti-tumor immunity within the lymphatic

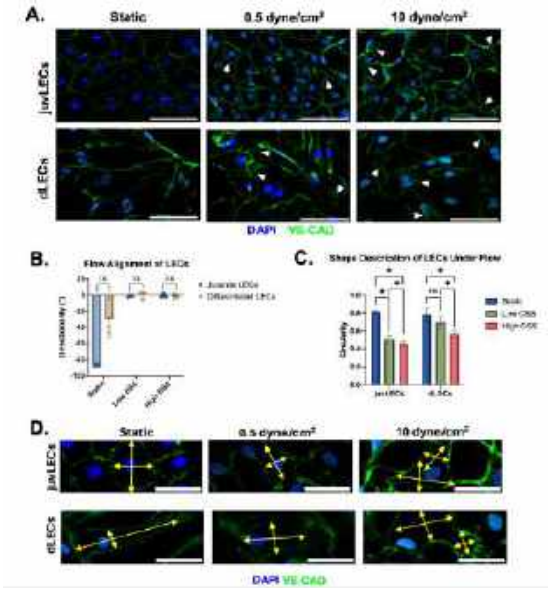

Figure 1: dLECs undergo the same alignment as LECs and transform into a cuboidal shape under OSS. A) VE-CAD (green). DAPI (blue). "Zipper-like" junctions are identified by the white arrowhead. system [3-5]. **Figure 3B** demonstrates the OSS flow rate dependent expression of these genes in dLECs.

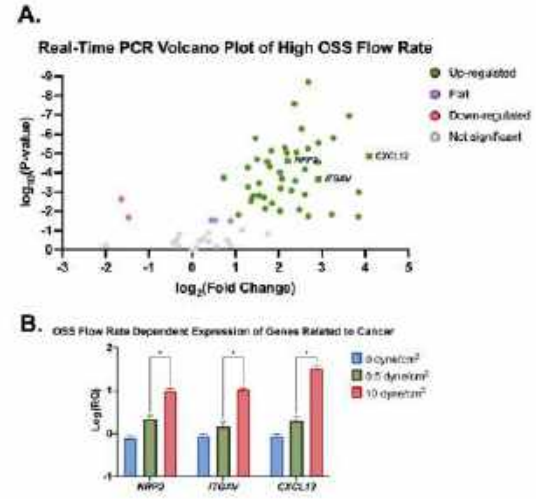

Figure 3: OSS Induces Anti-Tumor Phenotypes in dLECs. A) Each dot represents a gene. Labelled genes of interest. **B)** Relative quantification of cancer-related genes (n=4).

DISCUSSION

The morphological properties and genetic expressions obtained from exposing hiPSC-derived LECs to low and high OSS flow rates demonstrates its efficiency in maturing into lymphatic-valve forming cells. The dLECs were able to respond to OSS and remodel its shape similarly to juvenile LECs as well as demonstrate the unique 'zipper-like' junctions in mature LECs. Moreover, the dLECs demonstrated a favorable change in the expression of genes primarily responsible for lymphatic valve development in response to different physiological OSS flow rates. Overall, it was demonstrated that the hiPSC-derived LECs were able to mimic the mechanotransduction responses that are crucial during lymphatic valve development. Furthermore, it was identified that the OSS flow rate significantly decreased or increased the expression of genes that can promote tumor growth and T-cell decumulation. Other sources of LECs have been extensively studied and was considered when assessing our findings. Nevertheless, these findings support the use of hiPSC-derived LECs in the regeneration of biomimetic lymphatic vessels to provide treatment opportunities for lymphedema as well as provide preliminary understanding of the lymphatic system's role in cancer.

INTRODUCTION

Mechanical testing and characterization of vascular tissues has been a key tool in developing material models and measuring failure properties. Uniaxial extension testing of biological soft tissues has allowed for a basic understanding of the strength of material and mechanical behavior when stretched to failure. For engineering materials such as ductile metals, the concept of a yield point or proportional limit exists when transitioning from elastic to plastic deformation. This is problematic for nonlinear materials such as biological soft tissues, as there is no clear demarcation of where a potential proportional limit may exist.

The current method for engineering materials relies on a 0.2% offset method, in which a parallel line for the linear elastic region is drawn. However, there is no clear method for identifying the proportional limit in biological soft tissues other than to manually choose a point where the stress decreases. Christensen introduced a modified offset method to identify the stress-strain curve for Hookean materials [1]. The modified yield point occurs when a linearly extrapolated stress value exceeded the actual observed stress by 5%.

Acoustic signals have been used in the past to measure various aspects of engineering materials and biological soft tissues. The more pertinent being acoustoelastic behavior using ultrasonic waves to recover nonlinear strains of materials during extension testing or compression testing (where the elastic wave velocities are a function of stress). In this study, we investigate whether an audible acoustic signal can be detected during uniaxial extension testing. To achieve this, an acoustically augmented testing apparatus that records audible noises from XPS silicone (Silicones Inc., High Point, NC, USA) and porcine during uniaxial extension testing was designed and manufactured.

METHODS

Uniaxial Extension Testing Apparatus – The apparatus was designed and manufactured to be modular using a linear rail, stepper motor, and an aluminum double t-slot frame (**Figure 1**). A custom mount was CNC milled out of aluminum to mount a stainless-steel rod that connected to a clamping mechanism. The stepper motor was attached to a 3D printed top mount that could be sealed to an acrylic base.

Electronic Components, microcontrollers, load cell, and stepper motor – Two Arduino Uno (Arduino, Somerville, MA, USA) microcontrollers were used in parallel with a custom printed circuit board (PCB). The PCB allowed for a coupled approach to perform precision microstepping for the stepper motor (at a rate of 3 mm/min) while synchronously recording data from a 3 kg load cell. A HX711 (Sparkfun Electronics, Niwot, CO, USA) load amplifier was used to rescale the analog sensor values. Precision weights were used to calibrate the

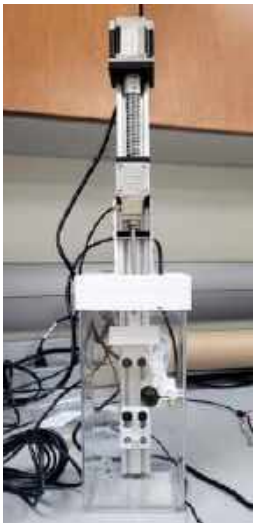

Figure 1: Uniaxial extension testing apparatus with stepper motor and hydrophone.

load cell (1, 10, 50, 100-, 500-, 1000-, and 3000-gram weights).

Python Graphical User Interface and Firmware – A custom C++ script was uploaded to an Arduino board to read the raw load cell sensor values in real time. A separate script was loaded to control a stepper motor that communicates with a custom python graphical user interface (GUI) to control the movements of the stepper motor. The python GUI was built to plot the load/displacement curve in real-time while recording acoustic signals from the hydrophone.

Experimental testing of XPS silicone and porcine aorta – A composite material was created by molding a paper towel in between two layers of XPS silicone. The test specimen was cut into a rectangular strip (30 x 4 mm). The composite material was used for feasibility testing whether the hydrophone could hear audible tearing during experimentation. Additionally, porcine aorta was procured from a local butcher and cut into rectangular strips (30 x 4 mm). The uniaxial extension tests were performed using an extension rate of 3 mm/min. Custom disposable laser-cut clamps were mounted onto the uniaxial extension testing device. Sound deadening foam was placed around the acrylic base to remove ambient noise. Lastly, the acrylic base was filled with water, and the experimental test was performed while 'listening' to the specimen via the hydrophone.

RESULTS

A custom uniaxial extension testing apparatus with hydrophone was successfully designed and manufactured (**Figure 1**). Tearing of the composite silicone and paper towel material was audible during feasibility testing, providing a basis to continue with the porcine aorta. **Figure 2A** is an example of a force-displacement curve of a test with porcine aorta. A small audible tear was detected (green oval) in **Figure 2B** prior to a drop in force (0.2 N). **Figure 2C** shows a center tear of the specimen at failure.

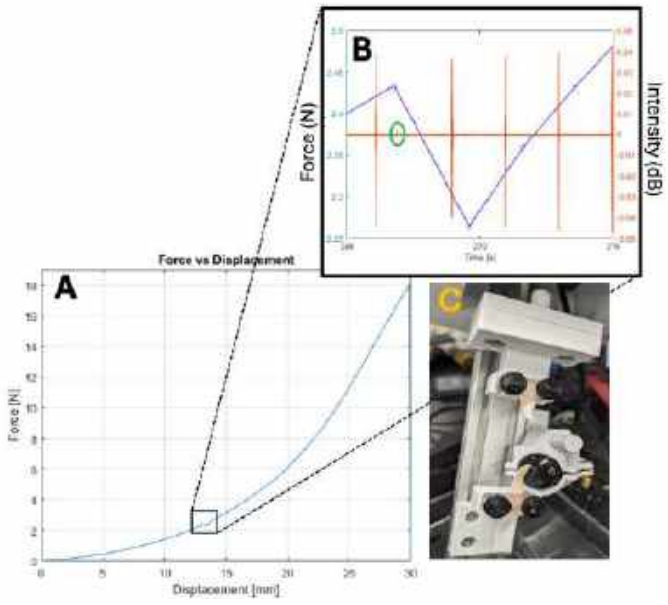

Figure 2: A) Force-displacement curve of a porcine aorta test, B) is a small audible noise (0.1 dB) that precedes a drop of force (0.2 N), C) a center tear of the porcine specimen.

DISCUSSION

In this study we performed a pilot study to determine whether acoustic signals could be detected during uniaxial extension testing. The tearing of the composite material indicated that the audible noise was directly related to a pre-failure force. An audible noise was present in porcine aorta that preceded a drop in force prior to failure. However, it cannot be definitively stated that this reduction in force is indicative of the proportional limit or yield point.

Typically, material models are fit to a theoretical proportional limit that is visually inspected after uniaxial or biaxial extension testing. The point that is chosen is much higher than the range of strain than the initial tear from our apparatus detected. Additional studies have performed uniaxial extension testing with concurrent multiphoton imaging [2] that allows for visualization of collagen and elastin fibers in real time. In addition, the concept of rupture potential index or the ratio of stress to strength has been used to assess risk based on biomechanical factors [3]. The current study may provide a basis for using a theoretical proportional limit rather than strength as it may possibly indicate where vascular dysfunction may occur [4]. Although the preliminary results from the testing apparatus are interesting, there are limitations to the study. There is no visual confirmation of damage to collagen or elastin fibers that were paired with the initial results. Future studies will utilize multiphoton imaging after stopping the test when the first audible tear is detected. The stepper motor provided additional noise within the system, creating periodic noise (**Figure 2**). It is possible that a tear may have been overridden by the noise from the stepper motor. The apparatus could be redesigned by introducing a damper to the stepper motor or decouple the load cell from the aluminum frame to reduce noise.

The overall study provided a method to listen to tissue specimens during mechanical testing. The potential for understanding a potential proportional limit in biological soft tissues could lead to new discoveries regarding fatigue and pre-failure limits of tissues that progress to a diseased state.

ACKNOWLEDGEMENTS

CLINICAL VALIDATION OF THE PSCOPE HYBRID FRAMEWORK FOR CARDIOVASCULAR PREDICTIVE MODELING

INTRODUCTION

Various Cardiovascular predictive modeling (CPM) approaches have been developed to aid clinicians in diagnosing, prognosticating, and treating cardiovascular diseases but there has been a shortage of efforts to clinically validate their accuracy.[1,2,3,4,5,6,7]

The Physiology Simulation Coupled Experiment (PSCOPE) is a hybrid modeling framework that can be implemented as a mechanistic CPM tool. It couples a physical fluid experiment to a lumped parameter network (LPN) simulation to model the closed-loop feedback between simulated cardiovascular physiology and fluid dynamics in a physical experiment. Previous studies verified the modeling capabilities of the PSOCPE framework by demonstrating its correspondence with a multiscale computational standard when both approaches were used to model a Fontan graft obstruction in the cavopulmonary pathway.[8] In this study, we validate the PSCOPE framework by comparing its predictions directly against clinical data. The study is designed to validate the CPM capabilities of PSCOPE in predicting the post-surgical physiology of a patient after implantation of the HeartMate 3 LVAD. We will also offer context on how these predictions can potentially assist clinicians in achieving favorable post-surgical outcomes.

METHODS

We obtained ICU health records for three adult patients implanted with the HeartMate 3; this data includes at least 3 days of continuous (high volume) pre-surgical and post-surgical acquisition of various flow rate and pressure measurements. A dynamic moving variance analysis was applied to the pre-surgical time series data of each flow rate and pressure parameter. The evaluated variance in each window of this analysis quantifies the data precision of the corresponding pre-surgical timeframe. We used the median of each parameter in the most precise timeframe (minimal variance) as the reference value to characterize the pre-surgical physiology of each patient (Table 1). We then tune an LPN model to match the derived median values, thereby constructing a virtual patient replicating the pre-surgical physiology of each patient. The PSCOPE framework models the LVAD implantation by coupling the virtual patient to a physical HeartMate 3 device flow experiment (Fig 1). The resulting hybrid model produces an estimation of flow rate and pressure parameters that characterize the post-surgical physiology of the virtual patient. We characterize the real-world post-surgical physiology of each patient by the median value of ICU measurements acquired in the first 12 hours after implantation. To quantify the CPM performance of the PSCOPE framework, we evaluate the difference between the PSCOPE predictions and the corresponding post-surgical clinical measurements.

RESULTS

The percentage difference (1.3% - 44.9%) between the PSCOPE predictions and the post-surgical clinical data across the three patients reveal variability in the performance of PSCOPE as a CPM tool. PSCOPE accurately predicted an increase in cardiac output for two of the three patients but was unsuccessful in predicting a non-intuitive decrease in cardiac output for one of the patients. Notably, PSCOPE demonstrates significantly better estimations of mean pressure values (4.5% - 25.7%) compared to their systolic and diastolic counterparts (3.5% - 44.9%). (Table 2).

DISCUSSION

This work assesses the accuracy of PSCOPE in modeling the surgical implantation of a HeartMate 3 device via a virtual patient. The PSCOPE estimations correctly predicted the observed clinical trends of increase/decrease in critical parameters—including mean/diastolic aortic pressure and mean pulmonary artery pressure—between pre-surgical and post-surgical physiology for all three patients. Lastly, the results suggest that PSCOPE can more accurately predict mean pressure values and may have limitations in capturing the pulsatility of the patient's hemodynamics after LVAD implantation. Overall, these

findings provide context on how PSCOPE physiology estimates can be interpreted to potentially guide patient-specific decision making in the surgical planning process.

INTRODUCTION

Transcatheter Aortic Valve Replacement (TAVR) has become a popular therapy for aortic stenosis patients over the past twenty years as a minimally invasive alternative to open heart surgery. It has primarily been performed in older, high surgical risk patients, but is now becoming standard of care even for younger patients (life expectancy > 10 years) with low surgical risk. Current research indicates that transcatheter heart valves (THVs) last about ten years and fail even earlier in chronic renal failure patients [1]. Therefore, it is more likely that TAVR candidates may face degradation or failure of their first THV in their lifetime. Consequently, clinicians must consider future interventions, such as redo-TAVR, to adequately provide lifetime management for TAVR patients.

Redo-TAVR poses risks that can lead to further complications if not properly considered at the time of index valve implantation. Namely, coronary obstruction (CO) is a potentially fatal complication that is nearly twice as common in redo-TAVRs than a primary TAVR [2]. A patient's risk for CO may vary based on the type and deployment depth of THVs as they interact with the patient's unique native anatomy. One emerging methodology of pre-procedural planning is the use of computational modeling to digitally reconstruct patient specific anatomy and visualize its interaction with the THV during TAVR, thus aiding the prediction of possible adverse outcomes. In this study, we aimed to assess CO risk for a variety of redo-TAVR combinations using DASI Simulations' *PrecisionTAVI*, a predictive modeling software which implements reduced-order modeling to simulate TAVR. These combinations included balloon-expandable and self-expanding valves as well as variation in deployment depth.

METHODS

Pre-procedure computed tomography (CT) scans were obtained for TAVR patients who fit the following criteria (n=7): 1) low-to-intermediate surgical risk; 2) were less than 80 years old; 3) have a tricuspid native aortic valve. *PrecisionTAVI* predictive modeling software was used to simulate 4 deployment variations of the index TAVR in the 3D reconstructed models from the pre-CTs; the balloon-expandable (BE) and self-expanding (SE) THVs were deployed at annular and sub-annular depths to achieve "high" and "deep" deployments, respectively. A subsequent second TAVR was then simulated at both high and deep deployments for the following combinations: BE-in-BE, SE-in-BE, BE-in-SE (Figure 1).

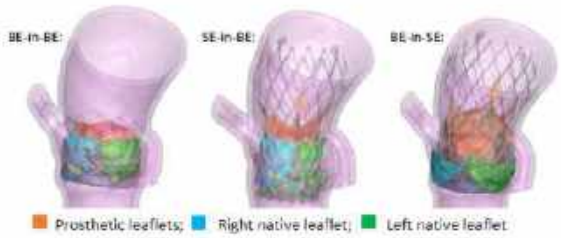

Figure 1: Main treatment pathways investigated.

A total of 112 simulations were executed (Figure 2). CO risk for the left and right coronaries was assessed after both the first and second TAVR using a previously validated biomarker shown in Figure 3 [3].

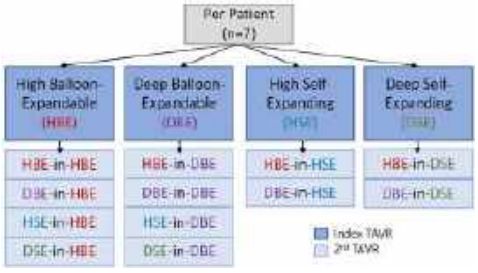

Figure 2: Deployment combinations simulated per case.

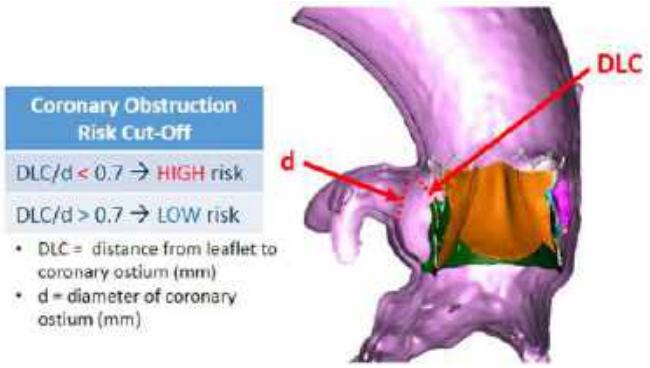

Figure 3: CO risk biomarker from Heitkemper et al.

Then, for both the first and second TAVR simulations, the average DLC/d values for the left and right coronaries were obtained for each THV type and deployment depth as well as their standard deviations. T-tests were performed to determine the statistical significance of CO risk in both coronaries as it changed from first to second implantation for all combinations.

RESULTS

For the first TAVR, deep deployment of the BE THV yielded the highest DLC/d averages of 1.82 and 2.38 for the left and right coronaries, respectively, as shown in the top chart in Figure 4.

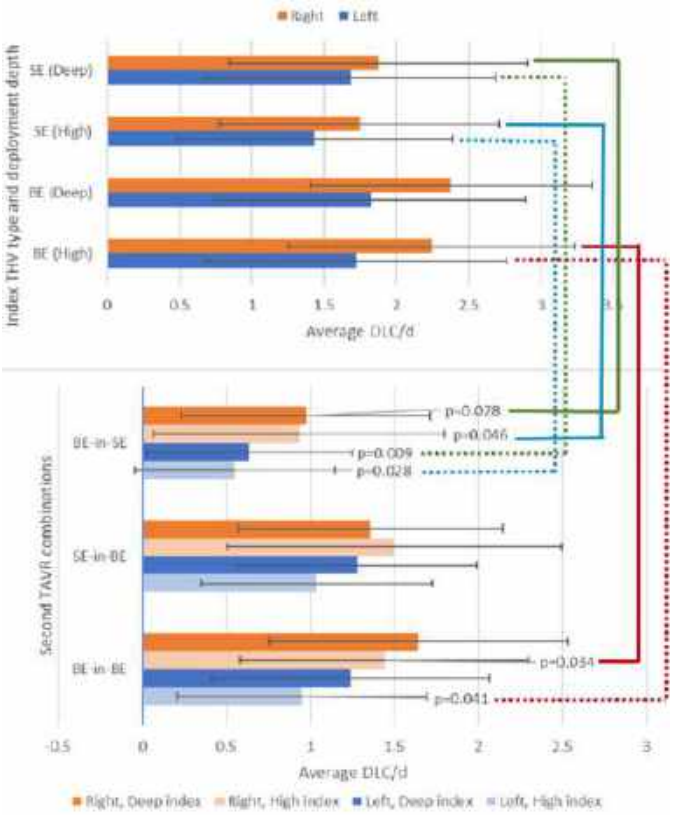

Figure 4: Average DLC/d for first and second TAVR*
***p-values applicable to high second deployments.**

It is important to note that the bottom chart in Figure 4 displays values averaged from both high and deep second THV deployments for visual simplification, though all combinations were statistically analyzed. For the second TAVR, high deployment of a BE THV in an SE index THV, regardless of index valve deployment depth, had the lowest DLC/d averages, ranging from 0.55-0.63 and 0.93-0.97 for the left and right coronaries. This deployment scenario also displayed a significant decrease in DLC/d from first to second THV ($p<0.05$ for left and right coronaries). Additionally, the HBE-in-HBE scenario exhibited a large decrease in DLC/d values from first to second deployment ($p<0.05$ for left and right coronaries).

DISCUSSION

High DLC/d averages in both coronaries for a deep index BE THV indicates that this THV type and deployment depth minimizes CO risk the most for this patient cohort. In contrast, the low DLC/d averages found for a high SE index THV indicates higher risk for CO in both coronaries upon the first TAVR. The statistically significant reduction in DLC/d average from first to second TAVR suggests that a high index THV deployment may not be most optimal from the standpoint of CO during a second TAVR.

Changes in DLC/d averages from first to second TAVR were calculated for each combination, but most were not found to be statistically significant. This can likely be attributed to the large standard deviations that arose from variation in coronary ostia diameters, coronary heights, and varying degrees of calcification in the leaflet and coronary regions.

Although this study included a limited number of cases, the initial findings propose that this novel method of computational modeling can be implemented to analyze trends in larger patient cohorts and enhance patient specific TAVR lifetime management, which is currently non-standardized.

INCUBATION IN PHYSIOLOGICALLY RELEVANT OXYGEN CONDITIONS CHANGES LYMPHATIC ENDOTHELIAL CELL GENE EXPRESSION AND VESSEL MORPHOLOGY

INTRODUCTION

Lymphatic Endothelial Cells (LECs) exist *in situ* in an environment which contains 3-5% oxygen [1]. Their behavior is regulated by Hypoxia Inducible Factors (HIFs), which stabilize at oxygen levels below 6% [2]. HIFs influence LEC proliferation, migration, metabolism, and extracellular matrix remodeling [3]. Hif2α is associated with daily cellular function at physiological oxygen levels [4]. Meanwhile, Hif1α has been linked to hypoxia, inflammation, and fibrosis [5]. While Hif1α is necessary in wound healing and adapting to sudden hypoxia (as in the case of a heart attack or stroke), overexpression of Hif1α and downregulation of Hif2α has been shown to exacerbate lymphatic disorders such as lymphedema [6].

LECs are typically cultured *in vitro* at 21% O_2. By doing so, an inaccurate model of lymphatic behavior is created, which can lead to difficulties when trying to replicate *in vitro* results *in vivo* [7].

Successful tissue engineering relies on an accurate representation of the *in situ* environment of the target tissue. In this study, LECs are cultured at 3-5% to examine changes in gene expression over the course of seven days, as well as changes in vessel formation.

Over the course of incubation at 3-5% oxygen, *Hif2α*, *Lyve1*, *Prox1*, and *VEGFR3* gene expression were increased. Furthermore, vessels grown in 3-5% oxygen appeared thicker and better developed than those grown in 21%. As such, culturing LECs in physiologically relevant oxygen may lead to the more efficient engineering of lymphatic tissues, as well as create *in vitro* models that more accurately reflect native LEC behavior.

METHODS

LECs were seeded and allowed to attach for 24 hours in 21% O_2. After changing their media, the cells were placed in an incubator containing 5% CO_2, 92% N_2, and 3% O_2. O2 concentration in cell media was measured using a 6-well PreSens Optical Oxygen Sensor (PreSens, Regensburg, Germany). Media changes were performed on day 3 and day 6 with media that had been pre-acclimated in the 3% O_2 incubator overnight. Changes in gene expression were evaluated using RT-PCR relative quantification (RQ). For this assay, LECs cultured in 21% O_2 for 24 hours were used as a control. A vessel formation assay compared the tube-forming ability of LECs cultured 3 days in 21% O_2 and kept in 21% to form vessels, LECs cultured for 3 days in 21% O_2 but moved to 3-5% O_2 to form vessels ("no conditioning"), and LECs that had been previously cultured in 3-5% O_2 for 3 days ("pre-conditioned") and left in 3-5% to form vessels. To facilitate vessel formation, LECs were seeded on Matrigel with 50ng/mL VEGF-C. All experiments were completed in triplicate. Statistical analysis of PCR RQ was performed with GraphPad Prism Version 10 (La Jolla, CA). Student's t-tests were performed to analyze differences between timepoints, with significance levels set to $P \leq 0.05$.

RESULTS

An increase in *HIF* transcription as a response to physiological oxygen was confirmed over the course of 7 days (Figure 1).

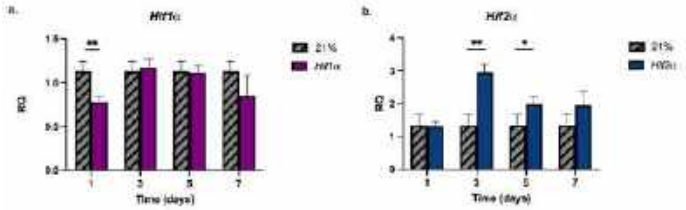

Figure 1. Physiological oxygen increases *Hif2a* expression but not *Hif1α*. * P<0.05, **P<0.01.

While *Hif1α* decreased on day 1 and then recovered to similar levels expressed by LECs in 21% oxygen, *Hif2α* significantly increased by day 3 to 3-fold its initial expression.

To observe the impact of increased *Hif2α* on LECs long-term, the expression levels of *Lyve1*, *Podoplanin*, *Prox1*, and *VEGFR3* were measured. These genes were chosen for their involvement in hyaluronic acid binding and motility, cytoskeleton remodeling, maintenance of LEC identity, and lymphangiogenic growth factor binding, respectively [8–11]. Compared to cells cultured at 21% oxygen, cells cultured in 3-5% oxygen, after an initial decrease, had significant increases in *Lyve1*, *Prox1*, and *VEGFR3* that peaked on day 5 (Figure 2).

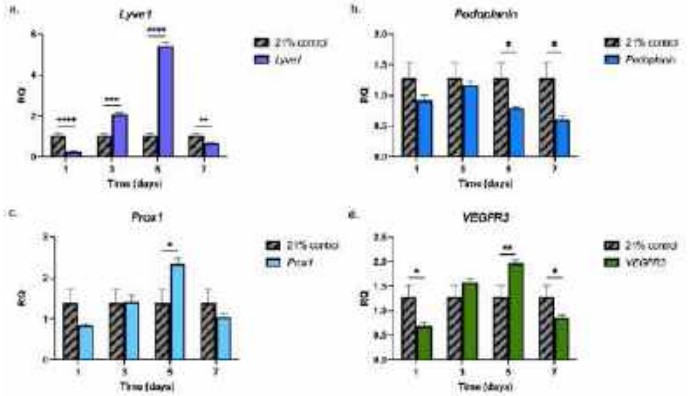

Figure 2. LEC characteristic gene expression. * P<0.05, **P<0.01, ***P<0.001, ****P<0.0001.

By day 5, *Lyve1* expression increased 5.5-fold, while *Prox1* and *VEGFR3* increased 2-fold. *Podoplanin* expression never reached its 21% oxygen expression level and decreased significantly on days 5 and 7.

Changes in LEC gene expression when incubated at physiologically relevant oxygen conditions also influenced LEC vessel formation ability. Qualitatively, LECs cultured in 3-5% oxygen formed thicker vessels than LECs cultured in 21% oxygen (Figure 3).

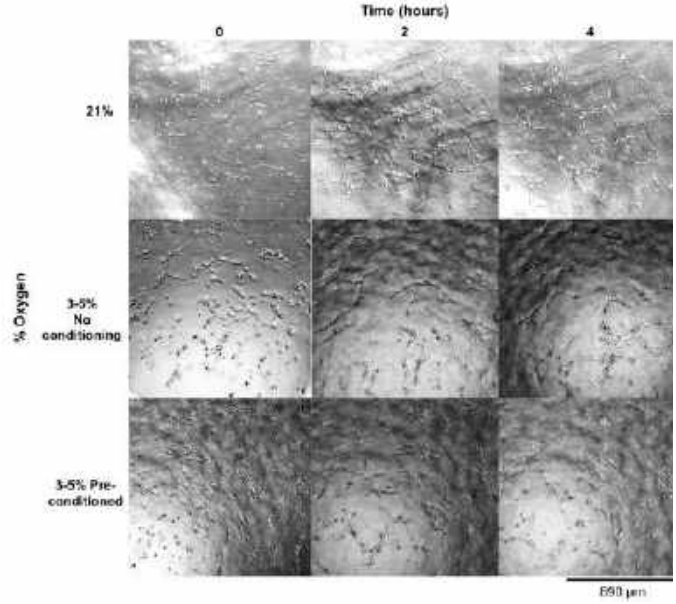

Figure 2. Influence of 3-5% oxygen on LEC vessel formation.

This was true for both LECs that had been previously cultured in 21% oxygen and moved to 3-5% oxygen for vessel formation (no conditioning) as well as LECs that were grown for three days in 3-5% oxygen and then kept in 3-5% oxygen for vessel formation. Although it appears that the pre-conditioned vessels are more numerous than vessels grown with non-conditioned cells, a quantitative analysis needs to be performed to verify this conclusion.

DISCUSSION

This study examined the impact of long-term culture at physiologically relevant conditions on LEC gene expression and vessel formation. In line with previous studies conducted on cells in 3-5% oxygen, *Hif2α* expression was increased (Figure 1) [5]. Increases in LEC markers *Prox1* and *VEGFR3* also matched previous literature, as *Prox1* has a known hypoxia response element which binds HIFs, and low oxygen concentration is known to upregulate general *VEGFR* expression [11], [12] (Figure 2). The decrease in *Podoplanin* was unexpected, as it is typically upregulated under hypoxic conditions [13]. However, these experiments were conducted under 1% oxygen, indicating that *Podoplanin* is not upregulated by *Hif2α*, which is the HIF upregulated at 3-5% oxygen. The gene that showed the largest increase in gene expression, *Lyve1,* has been found to be upregulated in macrophages under hypoxic conditions [14]. However, its role is understudied. Although it has been correlated with wound healing and migration, it is not essential for lymphatic development and therefore has not been focused on in the field [15, 16] . Its large upregulation suggests that it has an additional, unknown role in the body that is missed when cultured *in vitro* at 21% oxygen.

Preliminary results suggest that the changes in gene expression caused by physiological oxygen result in morphological changes in vessels formed *in vitro* (Figure 3). Although a quantitative analysis is still needed, it appears that vessels formed in 3-5% oxygen are not only thicker than those developed in 21%, but appear more organized than vessels grown with cells that overexpress *Hif1α*, which mimics a hypoxic environment [17]. As *Hif2a* contributes to lymphatic vessel stabilization, culturing LECs in physiologically relevant oxygen concentrations may lead to more accurate lymphatic models for research, as well as more robust vessels for applications in tissue engineering.

MAPPING NONLINEAR MECHANICAL PROPERTIES OF EX VIVO BRAIN TISSUE USING MR ELASTOGRAPHY WITH APPLIED PRE-STRAIN

Olivia M. Bailey (1), Alexa M. Diano (1), Ali H. Lateef (1), Elise A. Corbin (1), Curtis L. Johnson (1)

INTRODUCTION

Traumatic brain injury (TBI) is defined as a disruption in typical brain function, or other evidence of brain pathology, caused by an external force such as blast or blunt impact[1]. Computational modeling is a promising method used to investigate TBI because it enables the understanding and analysis of human brain tissue behavior during injury across a continuum of applied impacts[2]. These models require advanced experimental data on mechanical properties of the brain, which can be acquired using magnetic resonance elastography (MRE)[3–5]. However, MRE only returns linear mechanical properties in the small strain regime, and brain tissue has been shown to exhibit nonlinearity, specifically with compressive strain, which is critical for modeling high strain and strain-rate injuries[6,7]. Here, we perform MRE with incremental compressive pre-strain on *ex vivo* bovine brain tissue samples to provide insight into the nonlinear behavior that brain tissue may exhibit during injury. This experimental data was fit using a two-term Mooney-Rivlin model to extract relevant nonlinear parameters that can be incorporated into computational TBI models.

METHODS

Samples: Fresh calf bovine brain samples were purchased from a local butcher, cut into approximately 8 x 8 x 3 cm^3 sections, and encapsulated in a 0.65 wt.% agarose phantom to minimize boundary interference and assist with wave penetration. The phantoms were stored at 4°C to gel and brought to room temperature prior to scanning.

Imaging: Using a Siemens 3T Prisma MRI scanner with a 20-channel head/neck coil, MRE data was collected on the tissue-agar phantoms using a 2.5 mm^3 resolution echo-planar imaging sequence. The Resoundant pneumatic actuation system (Rochester, MN) was used to induce 75 Hz vibrations with four phase offsets.

Pre-Strain: Axial pre-strain was applied using a custom-made MR-compatible incremental compression device (Figure 1) that allowed us to control strain and strain-rate. Turning the top knob lowers the plate onto the sample (0.98mm/360° turn). MRE and T1-weighted magnitude images were collected at baseline and each sequential compression state. A nonlinear inversion algorithm was used to determine the voxel-specific mechanical properties at each compression state[8].

Figure 1. CAD model illustrating the incremental compression device at various levels of applied compression.

Experimental Analysis: To evaluate voxel-specific strain, we used nonlinear registration between the magnitude images at each compression state compared to baseline. The resulting registration warp field was used to calculate deformation gradient tensor, $\boldsymbol{F}$, which in turn was used to define the left Cauchy Green strain tensor, $\boldsymbol{B}$. The component of $\boldsymbol{B}$ corresponding to uniaxial strain equates to $\boldsymbol{a}^2$, where $\boldsymbol{a}$ refers to the applied strain and is used as a model input parameter.

$$\boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T = \begin{bmatrix} 1/\boldsymbol{a} & 0 & 0 \\ 0 & \boldsymbol{a}^2 & 0 \\ 0 & 0 & 1/\boldsymbol{a} \end{bmatrix} \quad (1)$$

Modeling: The voxel-wise experimental data (i.e. stiffness and strain at each compression state) was fit to a two-parameter Mooney-Rivlin hyperelastic model, below, that has been shown to appropriately capture tissue nonlinearity in compression[9]. For this analysis, we modeled the bovine tissue-agar phantom as a homogeneous, isotropic, and incompressible, hyperelastic material.

$$\mu_0 = C_1 + C_2 e^{-b} \quad (2)$$

Here, μ_0 is the voxel stiffness for each compression state (kPa), and the two material coefficients determined from the model are C_1 and C_2. The first coefficient, C_1, corresponds to baseline stiffness (kPa), while C_2 relates to the nonlinear parameter ($kPa * mm/mm$) of the material. The voxel strain, b (mm/mm) is calculated as ln(**a**).

RESULTS

One representative phantom was used for this analysis where nine compression states were achieved, starting at baseline and ending at approximately 6% global strain. Figure 2, below, depicts the relationship between apparent stiffness and applied pre-strain, where we saw a 28% increase in apparent stiffness from 2.6 kPa to 3.4 kPa as pre-strain was applied. The highly spatially varying strain sensitivity of brain tissue, displayed in the strain fields shown in Figure 2, emphasizes the importance of a voxel-specific analysis rather than whole-phantom viscoelastic property and strain estimation.

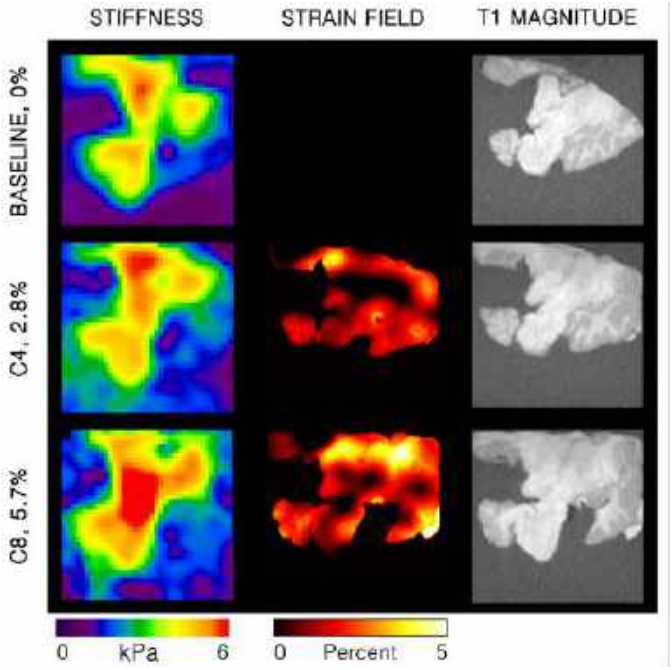

Figure 2: Apparent stiffness (left), strain field (middle), and a T1-weighted magnitude image (right) displayed across three states of compression (baseline, middle, and final compression).

Using the two-term Mooney-Rivlin model, outlined above, material coefficients, C_1 and C_2, were fit at each voxel across all compression states. Figure 3, below, illustrates these masked tissue property maps overlayed on the baseline T1-weighted magnitude image.

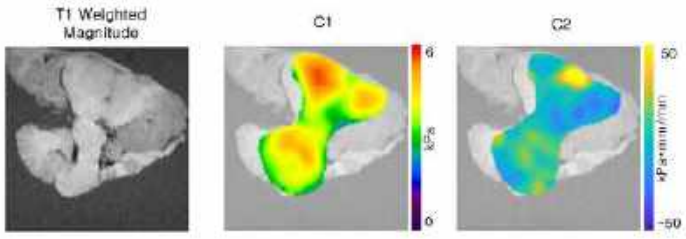

Figure 3: Model coefficients, C1 and C2, calculated at each voxel independently across all compression states.

C_1 is the model coefficient corresponding to baseline tissue stiffness and appears to be an appropriate estimate of the bovine brain stiffness. C_2, which is the material property related to tissue nonlinearity, further highlights the spatial variance within the brain tissue section. Figure 4, below, shows the relationship between applied pre-strain and apparent stiffness fit with the Mooney-Rivlin model for one representative voxel.

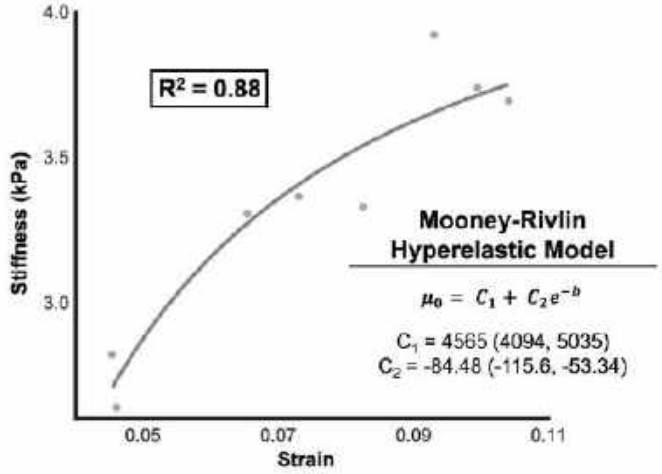

Figure 4: Plot depicting the Mooney-Rivlin model fit at one representative voxel across each compression state.

The model proved to successfully fit the experimental data with an R^2 value of 0.88 for this voxel. Across a randomly selected 200 voxels, the average R^2 value was 0.80, further indicating a satisfactory fit between the model and our collected MRE with pre-strain experimental data.

DISCUSSION

For this analysis, MRE was used to obtain experimental results of the relationship between viscoelastic properties and applied pre-strain through incremental compression. We fit this data to a two-term Mooney-Rivlin hyperelastic model to characterize the material nonlinearity exhibited by the increase in apparent tissue stiffness from applied compression. Our preliminary results show adequate agreement between the model and our experimental results. This experiment serves as proof-of-concept for capturing tissue nonlinearity, and subsequent investigations will ensure that proper mechanical testing guidelines for appropriate sample preparation are followed. Future work seeks to test the fit of multiple models to investigate which best captures the nonlinear viscoelastic properties of bovine and human cadaveric brain tissue measured from pre-strain MRE experiments. Long term applications of this study will use nonlinear property values from MRE to supplement computational TBI models.

INTRODUCTION

Glioblastomas (GBMs) are tumors that originate in astrocytes, a type of glial cell found in the brain. Gliomas are physically and molecularly heterogeneous among the patient population. This leads to the vast differences in patient response to treatment and the poor long-term outcomes observed. The brain is a difficult tissue to study and model due to the complex cell differentiation, the diverse loads it experiences, and its low stiffness [1, 2].

A subset of major mechanical models are biphasic continuum models which treat the brain as a complete solid-fluid mixture. In this framework, the cells, vessels, and extracellular matrix are defined as solid while the fluid medium is composed of interstitial fluid. These models can account for the forces imparted by both states. Tumor interstitial fluid pressure (TIFP) is an important feature of the fluid state which greatly impacts the stresses felt in the peritumoral region [3]. A limitation of many brain tumor models is the lack of clinically relevant tumor data. These models often embed in-silico tumors of a spherical shape [4]. In practice, gliomas are highly variable and do not always take on a spherical shape. In-silico models lack experimental data regarding tumor properties and structure.

The objective of this project is to create patient-specific image-based computational models. Individualized brain models allow for a personalized treatment plan to improve patient response and long-term outcomes. For example, mechanical fields–velocity, stress fields, and pressure maps–within and around tumors can inform injection site selection for drug delivery or paths of tumor invasion.

The present study utilizes experimental data from rats implanted with 9L tumors. Dynamic Contrast-Enhanced Magnetic Resonance Imaging (DCE-MRI) techniques are employed *in vivo* to quantify key features of the tumors. In this study, the methods are applied to radiation-treated 9L rat models and untreated 9L rat models to predict the mechanical fields.

METHODS

Mechanical Model. The present model is an application of previous work by Rey et al., [5, 6]. The model is a biphasic model which accounts for the solid and fluid components of the brain. The continuum-based approach treats the tissue as a continuous medium containing an equal mixture of solid and pore space at every point in the material. In the model, the solid phase is defined as the cells, extracellular matrix, and vessels with non-linear neo-Hookean behavior, as described by equation 1.

$$\boldsymbol{\sigma}_s = \lambda J^{-1} \ln(J)\, \boldsymbol{I} + \mu J^{-1}(\boldsymbol{b} - \boldsymbol{I}) \qquad (1)$$

$\boldsymbol{\sigma}_s$ is the solid Cauchy stress tensor, $\boldsymbol{b}$ is the left Cauchy-Green tensor, and $\boldsymbol{I}$ is the identity tensor. The Jacobian, J, is the determinant of the deformation gradient tensor, $\boldsymbol{F}$. The Lamé parameters, λ and μ, are tissue-specific constants related to Young's Modulus and Poisson's ratio. The fluid phase is the interstitial fluid described by Darcy's law and Starling's equation. The equations account for the fluid production at every source and govern the flow of fluid in the pore space. Isotropic tumor growth was modeled with the FEBio Prestrain plug-in. The implementation of the plug-in and specific material properties is described by previous models [5, 6].

Animal Model. Animal studies were conducted at Henry Ford Hospital according to the Institutional Animal Care and Use Committee standards. The 9L cell line is a Fischer rat-derived gliosarcoma immunogenic line. Tumor cells were embedded in the right hemisphere and allowed to grow (n=8). A subset of the animals (n=3) was radiation treated with 25Gy. TIFP measurements are taken via wick-in-needle (WIN) methods [7].

DCE-MRI. A novel component of this approach comes from the use of DCE-MRI techniques. DCE-MRI along with pharmacokinetic compartmental modeling theories are used to acquire important

information on tumors of interest [8]. These parameters include heterogenous maps of the volume transfer constant (K_{trans}), plasma volume fraction, and extravascular extracellular volume fraction. The extravascular extracellular volume fraction represents the porosity of the tissue and is used in this study to scale the hydraulic conductivity of the tumor. The K_{trans} map represents vascular permeability and is used to scale the vessel wall hydraulic conductivity, a component of Starling's law.

Computation. Each mesh element is considered a source, and each element corresponds to one MR voxel. The resolution of the mesh is 58x68x20 (x, y, z) for a total of 78,880 hexahedral elements corresponding to the MR voxel dimensions. Voxel models have been described by our lab in the past [5, 6]. The model was solved via finite element analysis using FEBio (FEBio.org, version 2.0) and conducted in MATLAB (MathWorks Inc., MATLAB, version R2023a) using the GIBBON add-On (gibboncode.org, version 2018).

RESULTS

Overall, we see similar trends shown by our previous models for the U251 orthotropic cell line [5,6]. For both treated and untreated 9Ls we observe elevated fluid pressure in the tumor center (Figure 1) Currently, the model utilizes an average TIFP value from WIN measurements to scale the vascular pressure when applying Starling's law. With this, the model is generally able to predict trends in TIFP along the centerline of the tumor (Figure 2).

Further, the initial findings of the WIN experiments reveal differences in pressure between the irradiated and unirradiated animals: the irradiated animals have a higher TIFP. The increase in pressure leads to elevated velocities at the tumor rim. Similarly, there is an increase in bulk stress at the tumor center and rim (Figures 3 and 4).

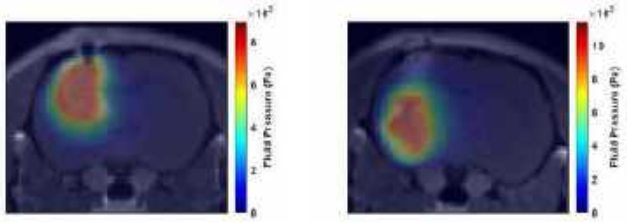

Figure 1: Fluid pressure (Pa). Left: FL221 irradiated animal. Right: FL223 unirradiated animal.

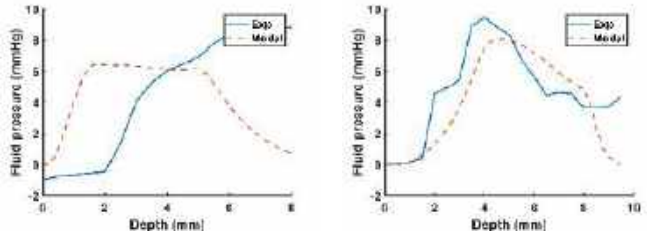

Figure 2: Modeled pressure versus WIN measurements. Left: FL221 irradiated animal. Right: FL223 unirradiated animal.

Further, the initial findings of the WIN experiments reveal differences in pressure between the irradiated and unirradiated animals: the irradiated animals have a higher TIFP. The increase in pressure leads to elevated velocities at the tumor rim. Similarly, there is an increase in bulk stress at the tumor center and rim (Figures 3 and 4). Additionally, there is an impact on the principal solid stresses. In all three principal directions, the model predicts tension (radial stress) within the tumor: with the irradiated animal having higher levels of tension. In contrast to the tumor center, the first principal stress produced hoop stress at the tumor boundary in both treated and untreated animals.

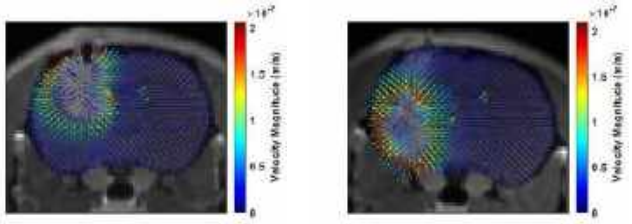

Figure 3: 10% maximum velocity magnitude in (m/s). Left: FL221 irradiated animal. Right: FL223 unirradiated animal.

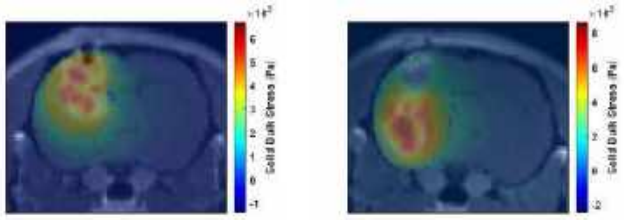

Figure 4: Predicted bulk stress maps. Left: FL221 irradiated animal. Right: FL223 unirradiated animal.

DISCUSSION

The model presented depicts elevated pressure and stress due to tumor growth and vascular leakiness. The elevated pressure leads to higher velocity magnitudes in and around fluid-filled spaces such as the CSF-filled ventricle spaces and at the brain surface. Previous have quantified interstitial fluid flows within regions of interest, such as the white matter tracts [9]. However, further work is required to validate the predicted solid stress fields.

The purpose of our computational model is to contribute to the understanding of the mechanical environment created by gliomas. A future application, the impact on drug distribution and metastasis. In addition, this model can be adapted to model human brains as the input parameters are based on constituent properties scalable to humans. This will allow for the formation of a unique treatment plan.

INTRODUCTION

Lymphatic endothelial cells (LECs) play a critical role in the formation and maintenance of the lymphatic vasculature, which is essential for the immune system, fluid balance, and tissue repair. However, LECs are often difficult to study in vivo and in vitro models that accurately mimic their behaviors and phenotypes are limited. In a variety of diseases, such as cancer and chronic inflammation, the integrity of LECs is disrupted, leading to lymphatic dysfunction and immune suppression[1,2]. To understand many of these mechanisms and pathophysiology, it is imperative to have a reliable in vitro culture system that can preserve the phenotype and characteristics of LECs. Another important aspect of having a robust in vitro culture system for LECs is tissue engineering. Nowadays there have been tremendous efforts to generate lymphatic vessels using functional biomaterials like hydrogels[3,4]. Often it is not realized that just having a more complex and physiologically relevant 3D system will not result in better tissue engineering unless the rudimentary 2D culture is optimized as well. Therefore, it is important to culture LECs on a coating that supports their proliferation, survival, and functional activity over extended periods of time. Currently, LECs are cultured mostly on treated plastics or conventional coatings like fibronectin or collagen. Compared to other ECM proteins, the use of Hyaluronan (HA) has been shown to hold promise in the culture of vascular endothelial cells. Here, we describe the development of a novel synthetic coating based on HA to preserve the phenotypes and characteristics of LECs.

METHODS

Dopamine-modified HA (HA-DP) is generated by causing a reaction between sodium hyaluronate solution and dopamine in presence of DMTMM and MES buffer. Conjugation of dopamine group to HA was confirmed using 1H-NMR. HA-DP was coated on tissue culture plates through polymerization of dopamine under basic conditions. HA-DP was dissolved in deionized water at 5 mg/ml. Prior to adding HA-DP to wells for coating, 20 μL of 10 M NaOH was added per 1 mL of HA-DP. After incubating at 37 °C overnight, the wells were vigorously washed with deionized water before cell culture. HA-DP coating was characterized and quantified using toluidine blue assay, as previously described[5].Briefly, HA-DP coated plate were incubated with 1 ml Toluidine blue O (TBO, Sigma 198161-5G), supernatant was aspirated, and samples were washed properly with 10mM NaOH. At this stage, a picture was taken to show TBO staining of coated wells compared to non-coated ones. Human adult and juvenile lymphatic endothelial cells (PromoCell, Heidelberg, Germany) were expanded and used for experiments between passages 4 and 8, as previously described[6,7]. Briefly, LECs were maintained at 37C with 5 CO2 in Endothelial Cell Growth Medium (EGM-MV2, C-22022, PromoCell). For phenotypic expression, flow cytometry, PCR and immunofluorescence assay were utilized. Prox1, Podoplanin, LYVE-1, VEGFR3 were selected as LEC characteristic markers throughout the experiments. To visualize focal adhesion kinase and F Actin distribution FAK antibody (Abcam, 1:20) and phalloidin (Abcam, 1:50) were used. Conjugated YAP and TAZ antibodies were used to visualize and quantify spatial distribution of YAP/TAZ.

RESULTS

While it is a common practice to culture LEC on tissue culture plastic according to established protocols, we noticed difference in cell morphology and proliferation over different passages. Our FACS data shows that both adult and juvenile LECs lose their characteristic expression and surprisingly fast (Fig.1). This led us to think consider alternatives to traditional coatings.

Though HA is one of the most abundant components of the extracellular matrix (ECM), a naturally occurring HA based matrix is not commercially available, unlike many other constituents like fibronectin and collagen. One top of that as HA itself is negatively charged, just solution of HA is incapable of forming any type of coating on tissue

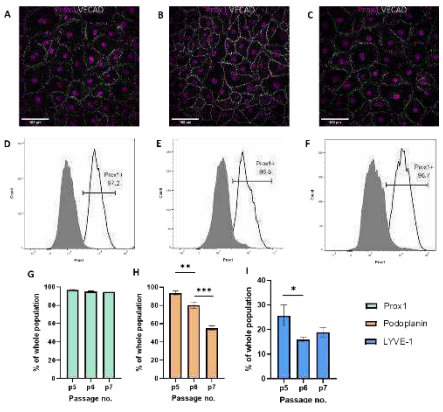

Figure 1. In spite of having similar Prox1 expression LECs exhibit reduced LYVE-1 and podoplanin expression over time.

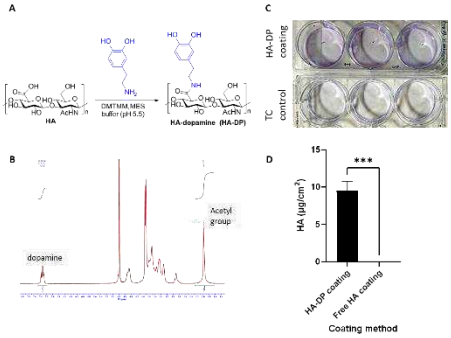

Figure 2. Synthesis and characterization of Ha-Dp polymer

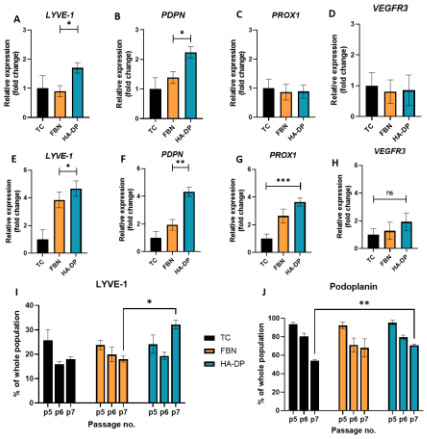

Figure 3. Protein and gene expression of cells over three passages, cultured on different coatings.

culture plastic. To resolve the issue, we synthesized a dopamine conjugated functional HA polymer (HA-DP). After coating the TC plate with the described method, we utilized toluidine blue, a reagent widely used for negative polymer staining, for quantification (Fig.2). Many of the regulatory proteins LYVE-1, podoplanin, VEGFR3 and transcription factor Prox1 collectively control LEC identity, characteristics, proliferation, and migration. Among the known receptors, LYVE-1 interacts with HA and that suggests that we can modulate this aspect and control LEC phenotype. We started culturing LEC on HA coated surface over different passages and found that interaction of LYVE-1- HA not only facilitates better expression of LYVE-1 but other characteristics of LECs like podoplanin and Prox1 as well (Fig.3).

Difference in ECM component often induces different mechanical force on the cells independent of stiffness. Though there is no difference in stiffness between fibronectin and HA-DP coating, we found that late passage LECs showed significantly higher mechanotransduction on fibronectin compared to HA-DP (Fig.4).

It is evident that stress-mediated mechanotransducers YAP/TAZ are critically involved in maintaining lymphatic integrity during adulthood8. Strikingly, lymphatic YAP/TAZ directly but negatively regulates Prox1 transcription and modulates Prox1 activity and lymphatic plasticity[8]. This suggests that comparatively reduced mechanotransduction on HA-DP coating causes suppressed YAP/TAZ activity in LEC (Fig.5) which inversely translates to better Prox1 expression.

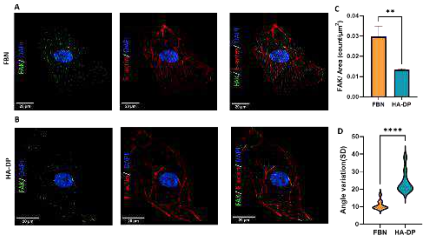

Figure 4. Focal Adhesion Kinase (FAK) Expression of LECs Cultured on Fibronectin and HA-DP Coated Plates.

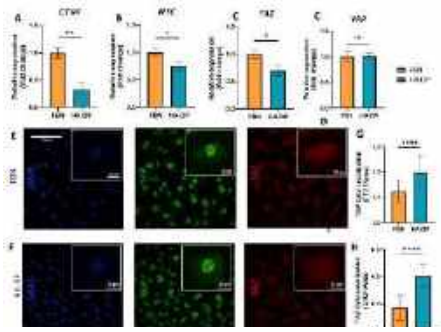

Figure 1. YAP/TAZ Expression for LECs Cultured on HA-DP and Fibronectin Coated Plates.

Collectively, HA-DP is a promising biomaterial to culture LECs in vitro toward their applications in basic lymphatic biology and lymphatic regeneration.

DISCUSSION

While there is no agreement on the best culture condition to culture LECs in vitro, it has been recognized that LECs may start to lose their lymphatic expression overtime during culture. We demonstrated that a simple coating with HA-DP can effectively preserve key lymphatic markers over several passages in vitro. In fact, key lymphatic makers were maintained on high passage (P.7) of LECs cultured on HA-DP, compared to LECs cultured on fibronectin coated plates. Mechanistically, HA-DP caused downregulation of YAP/TAZ, which upregulate Prox1 and therefore maintain lymphatic phenotypes, consistent with previous findings.

INTRODUCTION

Glomeruli, highly organized segments of the kidney that control full circulatory hemodynamics and respond to fluctuations in blood pressure, are one of the most biophysically complex organs in the body [1]. The glomerulus and its unique cytoarchitecture respond to the properties of an altered biomechanical environment that are governed by, among other factors, cyclic fluid flow. A prime example of a stressful condition the glomeruli face is glomerular hypertension. Due to high capillary tensile stress caused by high pressures, the glomerular basement membrane (GBM) increases in thickness and surface area[2]. Podocytes, visceral epithelial cells, are one of the main regulators that maintain glomerular cytoarchitecture[3]. In response to the expansion of the GBM, podocytes try to adapt and remodel to maintain coverage of the GBM[2]. The podocyte cytoskeleton is mechanosensitive, and its filaments remodel as a result of the feedback from biomechanical changes in the glomerular microenvironment[4]. Our understanding of the mechanosensitive characteristics of the actin cytoskeleton is therefore integral to our ability to counter the pathophysiology of foot process effacement and overall podocyte loss. LIM-nebulette, which is specific to podocytes within the glomerulus, is an actin-associated protein that has been shown to localize to actin stress fibers and focal adhesions in other cell types. Among other cell biological roles that have been previously explored, it has been shown to be a key actin binding partner in podocytes, particularly under Adriamycin induced stress[5]. We have previously shown that LIM-nebulette controls cytoskeletal resilience and impacts calcium dynamics.[5]. Here we investigate LIM-nebulette's mechanosensitive role in glomerular podocytes under biomechanical stress.

METHODS

We have developed a large-scale automated biaxial cyclic stretcher (Figure 1) equipped for six 10 cm stretchable dishes and can fit in a standard incubator. The dishes consist of a silicone membrane between two stainless steel rings. When loaded on the stretcher, the stage moves the dishes down a set displacement, corresponding to calibrated strain over a Teflon cup indenter. The device was calibrated by tracking dots drawn onto a membrane undergoing indentation. The stretcher is programmable via a graphical user interface (GUI) to adjust strain, frequency of motion, and duration of experiment. Differentiated mClover-LIM-nebulette and mScarlet-LifeAct expressing immortalized podocytes were seeded onto stretcher dishes and stretched at 10% Eulerian strain for 30 minutes. Three conditions were tested on these dishes: unstretched (control), stretched, and unstretched 10 μM blebbistatin, a myosin IIA inhibitor, treatment. After 30 minutes, 12 mm cut outs were taken from the dishes for confocal microscopy. Separately, the cells were seeded and differentiated on glass coverslips. Live cell total internal reflection fluorescence (TIRF) imaging was performed on cells with and without 1 μM cytochalasin D, an actin repolymerization inhibitor, and 200 μM blebbistatin.

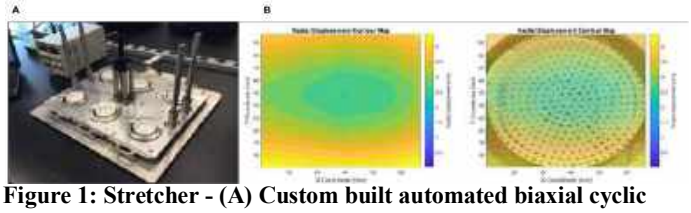

Figure 1: Stretcher - (A) Custom built automated biaxial cyclic stretcher. (B) Strain field of calibrated deformable silicone surface that cells are seeded onto for stretching.

RESULTS

Differentiated immortalized human podocytes that stably express mClover-LIM-nebulette and mScarlet-LifeAct cyclically stretched at 10% strain and a frequency of 1 Hz for 30 minutes were observed to have a change in the spatial expression of LIM-nebulette. At 30 minutes of stretch nebulette localizes to the periphery of the cell when

compared to control as measured via LIM-nebulette intensity distribution across 4 radial bins extending from the center of the cells. Bin 1 was established as closest to the nuclear region and bin 4 closest to the cell periphery (Figure 2). In control and blebbistatin conditions nebulette localizes more at the nucleus and perinuclear regions of the cells; however, the blebbistatin treated podocytes have higher perinuclear LIM-nebulette distribution.

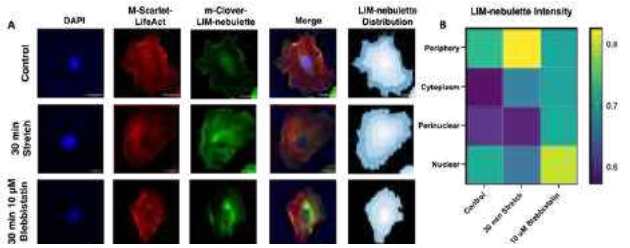

Figure 2: Stretched Podocytes - (A) 20x magnification 3x zoom confocal images of m-Clover-LIM-nebulette and m-Scarlet-LifeAct differentiated human podocytes seeded on silicone membranes and cyclically stretched at 10% strain, 1Hz for 30 min (n=1012) or treated with 10 µM Blebbistatin for 30 min (n=687) or control (n=896). (B) Heat map of LIM-nebulette intensity distribution in subcellular regions for each condition. Scale bar = 50 µm.

LIM-nebulette mediates stress fiber repair after acute injury in cytochalasin D model. At T = 0 minutes of TIRF microscopy on the cells, nebulette appears to localize to the focal adhesions (FA) and stress fibers (SF). After 10 minutes of 1μM Cytochalasin D treatment, disruption of SF and nebulette was observed. The cells were then washed, and at T = 30-60 minutes, post wash, nebulette returns in a wave like pattern (Figure 3) to the vicinity it was before, and SF start reforming.

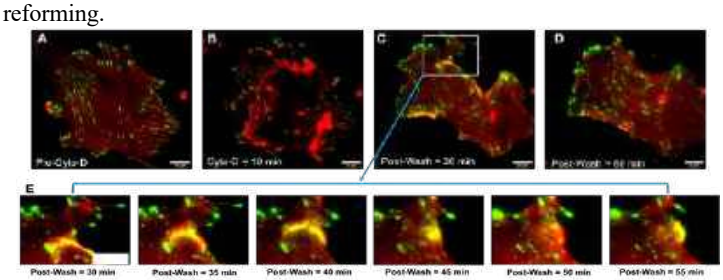

Figure 3: Actin injury model. Nebulette (green) LifeAct (red). (A) Before treatment with 1μM cytochalasin D. (E) Inset of 30-60 min sequence between C and D in 5 min intervals. Scale bar = 25 µm.

Recruitment of LIM-nebulette into focal adhesions (FA) depends on intracellular tension. Contraction was inhibited using 200 μM blebbistatin (Figure 4). 10 minutes after blebbistatin addition, contraction was fully inhibited and nebulette expression decreased at the FA, while the actin SF remained intact. After washing, contraction resumed and nebulette returned to the FA upon recovery **(**Figure 4).

DISCUSSION

Differentiated mClover-nebulette and mScarlet-LifeAct expressing immortalized podocytes were seeded onto dishes. After a 24-hours, the dishes were placed onto the stretcher overnight at 1% pre-strain to allow the cells time to adapt. Next, the stretcher was programed to run for 30 minutes at 10% biaxial Eulerian strain, which was determined prior to seeding cells (Figure 1). When compared to the control cells, the stretched podocytes displayed increased intensity at the cell periphery, which suggest increased expression of nebulette at the edges of the cell. This localization to the periphery could suggest that nebulette goes to the leading and lagging edges of the cells to stabilize attachment to the underlying extracellular matrix during mechanical stretch. In the control, nebulette intensity at the periphery is lower and appears to localize near the nucleus, most likely in the endoplasmic reticulum near the nuclei, where it is being translated. In the contraction inhibited condition, there was increased intensity of nebulette in the nuclear and perinuclear regions when compared to the other conditions. This suggests that nebulette localization throughout the cell has a dependence on myosin IIA contractility. Contraction provides less tension than our external stretch model. We have previously shown that LIM-nebulette crosslinks vimentin filaments with the actin cytoskeleton[5]. It is noteworthy that under reduced cytoskeletal tension conditions with blebbistatin, the distribution of nebulette is more perinuclear and filamentous suggesting increased affinity with intermediate filaments. We hypothesize that inhibited contractility, will leave cryptic binding sites in a closed or inactive conformation and therefore, not exposed. This in turn would leave nebulette with less binding sites at the FA.

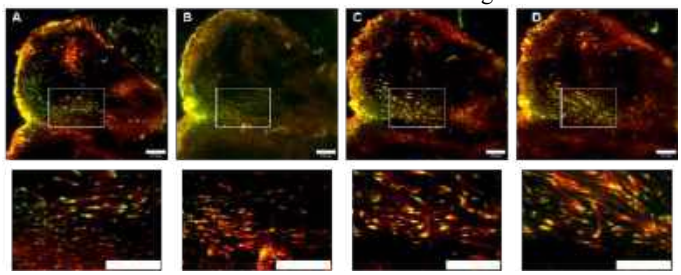

Figure 4: Myosin IIA inhibition (A) Control, nebulette is expressed at focal adhesions. (B) Blebbistatin induced contraction inhibition, nebulette expression at the FA is reduced. Upon washing, contraction is no longer inhibited and nebulette expression increases at (C) 30 and (D) 60 min. Scale bar = 25 µm.

To assess nebulette's role in a cytochalasin D induced acute injury model and recovery, the cells were observed using a TIRF microscope under incubated conditions to see real time dynamics of nebulette. After about 5 – 10 minutes of imaging the control state, 1 μM cytochalasin D doped media was added for 10 minutes. During treatment actin dysregulation and aberrant cell morphology occurred. Nebulette remains at focal adhesions. Following the 10 minutes treatment, cells were washed and imaged for recovery for an hour. Nebulette returned to anchor actin fibers in a wave like pattern and fibers and cell shape returned to resemble that of the control. For the blebbistatin treated cells, after 10 minutes of blebbistatin exposure, present actin fibers remained intact, but nebulette expression decreased (Figure 10B). The blebbistatin treatment was washed and replaced with fresh media and after 30 minutes (Figure 10C) and 60 minutes (Figure 10D) of recovery, nebulette expression increased as it returned to the focal adhesions. These observations suggest that nebulette plays a mechanistic role in podocytes' response to biomechanical stress.

INTRODUCTION

Shoulder pain accounts for millions of physician visits annually and is associated with enormous healthcare costs [1,2]. Rotator cuff (RC) tears are found in more than 20% of the population, increase with age, and contribute to shoulder pain [3,4] with the supraspinatus tendon (SST) the most involved component [5]. Treatment for RC tears typically involves conservative care (i.e. rehabilitation) and/or surgical repair with a shared goal to decrease pain and improve function.

Rehabilitation aims to guide progressive mechanical loading via exercise to drive tissue adaptation [6] while surgery repairs torn tissue to restore anatomy and replicate biomechanical properties. Thus, both pathways are informed by underlying mechanical function. However, pain recurrence is common and RC repair failure rates remain high [7,8]. Taken together, this suggests a lack of understanding of the complex loading of the RC within the glenohumeral joint (GHJ).

Our current understanding of RC mechanics is based on *ex vivo*, uniaxial tensile tests despite evidence suggesting regional-dependent, inhomogeneous material properties of the SST [9,10]. These studies are limited in that they rely on static imaging to assess strain or have not explored clinically relevant end ranges of motion. End ranges of elevation and rotation place the GHJ, and SST, into vulnerable positions and are of high clinical interest. However, dynamic, *in vivo* study of RC strain would be highly invasive and is currently infeasible.

A better understanding of the mechanical behavior could lead to improved management of RC tears while also contributing valuable tissue properties/boundary conditions for future modeling studies. Thus, the purpose of this work was to determine the influence of GHJ position and SST load on sub-failure strain behavior of the SST *in situ*.

METHODS

A single fresh-frozen osteoligamentous cadaveric right shoulder specimen (Age: 71, Male) with no history of GHJ pathology was used. Soft tissue was removed to expose the RC tendons without violating the capsule. The lateral acromion was removed to visualize the intact SST. The medial aspect of the RC muscles was removed leaving 1-2 cm proximal to the muscle-tendon junction where Krackow stitches were placed in the (1) supraspinatus, (2) subscapularis, and (3) infraspinatus/teres minor for the application of load.

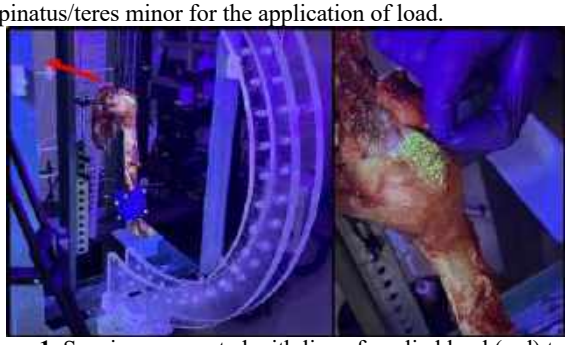

Figure 1. Specimen mounted with line of applied load (red) to SST (A). Speckled SST with identification of footprint (B).

The scapula was mounted to a custom jig (**Fig.1**) and the RC tendons loaded along their line of action [11] to seat the humeral head within the glenoid: subscapularis = 41 N, infraspinatus/teres minor = 40 N, and supraspinatus = 21 N. The SST was speckled using dried UV-reactive paint in conjunction with UV light emitters. Two Nikon D7500 cameras were used for surface strain tracking (F-stop: 5.6, ISO- 1250, 4k resolution, 30 FPS). Five infra-red motion capture cameras were used to quantify glenohumeral kinematics using retroreflective markers and provide real-time feedback of GH position (**Fig. 1**). The initial position was recorded, and the system was bore-sighted with the humeral epicondyles perpendicular to the plane of the scapula.

Preconditioning was performed via cyclic passive motion and tensile SST loading prior to each trial. Sevel trials were performed: 1) neutral position (neutralGH); 2) constrained elevation preventing axial rotation (constrainedElev); 3) elevation with natural axial rotation

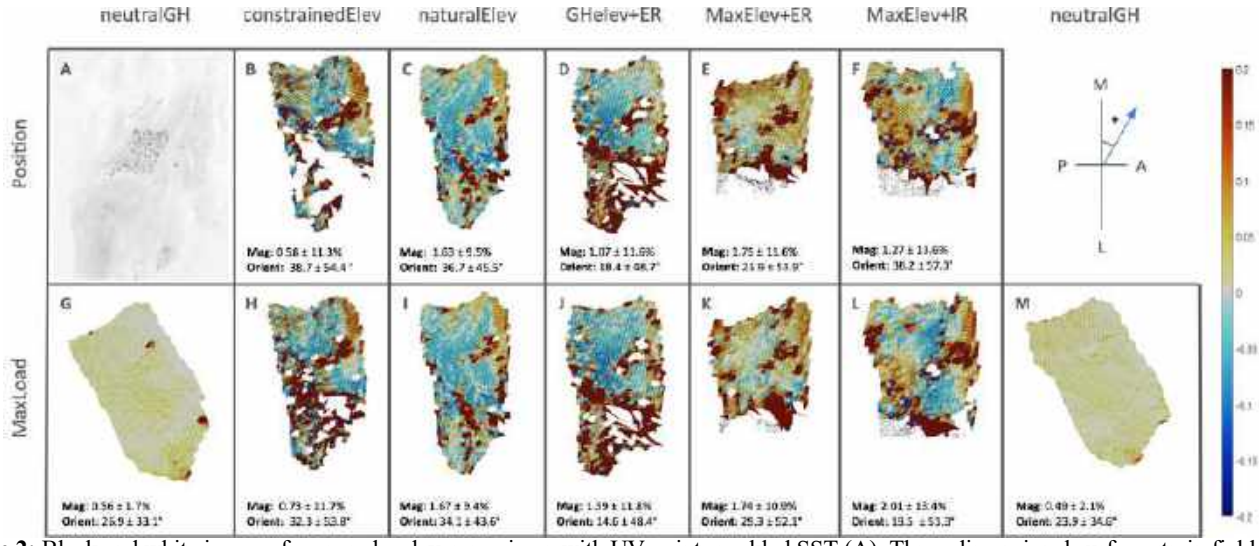

Figure 2: Black and white image of prepared cadaver specimen with UV-paint speckled SST (A). Three-dimensional surface strain fields of SST at GHJ 'Position' [top row] and 'MaxLoad' [bottom row] for trials 1 through 6 with additional neutral GH trial (B-M). Mean strain magnitude and orientation shown for each trial. Anatomical directions (M: medial, L: lateral, A: anterior, P: posterior) and sample orientation direction shown.

(naturalElev); 4) elevation with max external rotation (GHelev+ER); 5) maximum GH elevation with max external rotation (MaxElev+ER); 6) max elevation with max internal rotation (MaxElev+IR); and 7) retest neural position (staticGH). All trials began in the neutral position. The humerus was manually moved into the test position and SST was loaded to 100N (Tindeq, Norway), ~15% of ultimate tensile strength [12].

Strain was calculated during arm positioning and application of SST load, with the neutral position as reference for all trials. Mean 1st principal Lagrangian strain magnitude (% strain) and orientation (°) relative to the long axis of the SST, along with their respective standard deviations. Two discrete instances were investigated: 1) test position ('Position') and 2) test position with additional SST load ('MaxLoad').

RESULTS

No structural damage was observed throughout testing (**Fig. 2 G&M)**. Qualitatively, SST faces were most visible in neutral position and natural GH elevation (**Fig. 2G, 2C, 2I**). The tissue demonstrated buckling on itself near the tendon footprint when approaching 90° of GH elevation as evidenced by holes in the strain maps, this improved following the application of load (**Fig. 2B vs 2H**). Buckling was also observed during max elevation trials with the addition of internal and external rotation that did not resolve with the application of additional load resulting in no data for that area of the tendon (**Fig. 2E-F, 2K-L**).

Mean strain magnitude increased from the neutral position to each of the test positions and further after the application of additional load. Approximately 68% of the surface strain vector orientation was distributed between 6° posteromedial and 60° anteromedial with a mean orientation of 27° anteromedial in the staticGH position (where 0° is perfectly medial approximating the tendon's long axis). Mean strain orientation became more off-axis moving from the neutral position to each test position with exception of trials 4 and 5 where the application of ER resulted in a more medial mean vector orientation (**Fig. 2D-E**). The application of additional load to the SST resulted in mean vector orientation more in line with the tendon's long axis (**Fig. 2 Bottom)**.

DISCUSSION

These results suggest that GHJ position has a greater influence on mean SST strain than uniaxial loads, up to 100 N. This finding is consistent with previous work demonstrating the influence of testing angle on surface and intra-tendinous SST strain behavior of excised tissue [9,10]. Inhomogeneous strain was observed across the tendon surface with strain near the tendon footprint (i.e. more lateral) appearing higher than the mid-tendon in all elevated GH angles where the footprint was visible which has been reported previously [9]. Thus, the mean magnitude % strain may be a poor representation of the environment.

The orientation of mean strain across the tendinous surface becomes more aligned with the long axis of the tendon between 'Position' and 'MaxLoad' time points in all but 1 dynamic trial, evidence that GHJ position impacts SST line of action.

Reproducing clinically relevant joint orientations revealed challenges when collecting surface strain of the SST. There were several instances of observed 'buckling' at ≥ 90° GH elevation angles, where the border between tendon insertion and midsubstance appeared to collapse on itself. Interestingly, the application of additional load seemed to reduce the buckling in the pureElev trial as exhibited by an increase in the number of faces represented in the MaxLoad panel. The complex nature of tendon behavior from neutral to each trial's 'Position' also resulted in holes across the face of the tendon with exception of naturalElev where non-tensile strain appeared in greater proportion hinting at a protective role of typical GH elevation kinematics. Large rigid body translations of the tendon made it difficult to track each point through the duration of the motion. However, it was critical that the strain measurements for each trial were based upon the same neutral (i.e. bore-sighted) position. These challenges are most starkly reflected in the trials with drastic GH elevation and axial rotation in which the insertion site of the tendon did not produce any data.

INTRODUCTION

Increased posterior-distal directed slope of the tibial plateau (i.e., tibial slope) is associated with increased risk of first-time, noncontact anterior cruciate ligament (ACL) injury [1] and ACL graft failure after surgical reconstruction of this ligament [2]. While tibial slope is often thought of as a non-modifiable risk factor for ACL injury, performing a slope-correcting, sagittal-plane, high tibial osteotomy (HTO) is thought to reduce the risk of ACL and ACL graft failure by reducing force on the ACL [3].

The biomechanical effects of tibial slope on both ACL force and knee kinematics remain poorly understood. Previous in vitro biomechanical models have several limitations. One study assessed two extreme increments of tibial slope, which does not quantify the biomechanical effect of tibial slope increments that are common in the natural knee [4]. Another cadaveric model included more refined increments of tibial slope; however, they utilized a loading system with limited degrees of freedom that did not allow coupled rotations, an important determinant of ACL force [2]. Finally, another cadaveric model correlated tibial slope measured in healthy knees to ACL strain under loads simulating a drop jump [5]. This study did not isolate tibial slope as a controlled, independent variable. Therefore, the observed relationship may have been influenced by other anatomical factors that impact knee mechanics including laxity, volume of the tibial spine, and femoral notch width.

To overcome these limitations, we developed a computational model to allow controlled changes of tibial slope in well-defined increments and motion of the tibiofemoral joint in all anatomical planes. We addressed the following research question: What is the effect of simulated slope changing HTO on ACL force, anterior tibial translation (ATT) and coupled internal tibial rotation (ITR) under serially applied compressive and valgus loads?

METHODS

Computational models of the tibiofemoral joint were developed from ten cadaveric, right knees (five male, five female; age: 33.0±6.9 years) in four major steps [6]. In the first step, each knee underwent MRI and CT scanning; then, 3D geometries of the bones, cartilage, and menisci were reconstructed using image processing software (Mimics Materialise, Inc., Leuven, Belgium). Then, using the 3D rendering of the tibia, the native tibial slope was measured using a previously published method [7]. Second, each of the ten tibial bony geometries were imported into reverse engineering software (Geomagic Wrap, Morrisville, NC) to conduct a virtual anterior closing wedge HTO (Fig 1a). To simulate the HTO procedure a medial-lateral axis was first identified. This axis was parallel to the line connecting the center of the medial and lateral tibial plateau passing through the tibial insertion of the posterior cruciate ligament. The proximal tibia was then rotated about this axis from +15° (posterior tibial slope) to -3° (anterior tibial slope) in increments of 3° (Fig. 1b). In the third step, bony geometries of all seven increments of tibial slope and the associated meniscal, and cartilage geometries for each of the ten knees were integrated with the insertions of the cruciates, collaterals, capsule, and peripheral and root attachments of the menisci and imported into a multi-body dynamics (MBD) software package (MSC software; ADAMS, 2021-4, Newport Beach, CA) (Fig. 1c) [8]. In the MBD software, tissue stiffnesses were standardized via population mean values from the literature, and ligament slack lengths were standardized using a previously published optimization algorithm [8]. Fourth, loads were applied to the computational models simulating a clinical pivot shift maneuver, which consisted of serially applied compression (100 N) and valgus (4 Nm) at 15° of flexion (Fig. 1d). Outcome measures were force carried by the ACL at the peak applied loads, and ATT and coupled ITR. Outcome measures were not normally distributed; therefore, medians and quartiles were reported. Outcome measures were compared among all seven levels of tibial slope (15° to -3° in 3° increment) using a

nonparametric Kruskal-Wallis test with Least Significant Difference (LSD) post-hoc correction for multiple comparisons (α=0.05).

RESULTS

Decreasing lateral tibial slope from +15° to -3° reduced ACL force by a median of 82.5 [60.6 107.7] N ($p<0.01$) and reduced coupled ITR by 16.5° [15.0° 21.0°] ($p<0.01$) (Fig.2). The effect of each 3° increment of slope on coupled ITR was not the same. Specifically, the decrease in coupled ITR from +15° to +6° of tibial slope was not statistically significant, while this decrease from +6° to -3° of lateral tibial slope was a median of 10.2° [8.1° 12.0°] ($p<0.01$). Finally, the effect of the tibial slope on ATT was not statistically significant.

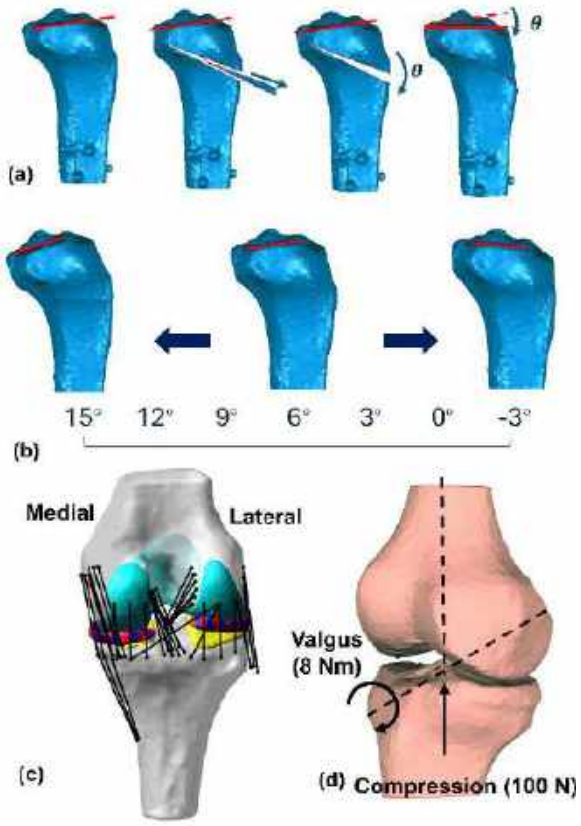

Figure 1: Computational modeling workflow consisted of performing simulated anterior closing wedge HTO (a); in increments of 3° from +15° to -3° (b); assembling the multibody computational model (c); and applying loads at 15° of flexion (d).

DISCUSSION

Our most important finding was that changing tibial slope via HTO influences both coupled ITR and ACL force under combined compression and valgus loads. Our findings suggest that reducing tibial slope via HTO decreases ACL force by decreasing coupled ITR.

Model predictions of decreased ACL force and coupled ITR with reduced tibial slope corroborates previous cadaveric studies [2, 3]. For example, Yamaguchi et al. [4] found that under applied compression and valgus loads, decreasing the tibial slope from +8° to -3° reduced both ACL force and ITR by 30 N and 9°, respectively. This previous work assessed a 10° change in tibial slope.

By also assessing tibial slope at intermediate increments of 3°, we found that the ability of HTO to reduce coupled ITR and ACL force varied among knees, especially, with tibial slopes between 0° and 9° (Fig. 2). For example, ACL force in knees with 6° of tibial slope ranged from 12.3 to 119 N. This finding suggests that additional geometric features like notch width and tibial spine height and offset may act in combination with tibial slope to either magnify or counteract the biomechanical impact of this surgery. Therefore, our modeling approach may be used to help identify those patients who may benefit most from HTO. This speculation requires further investigation.

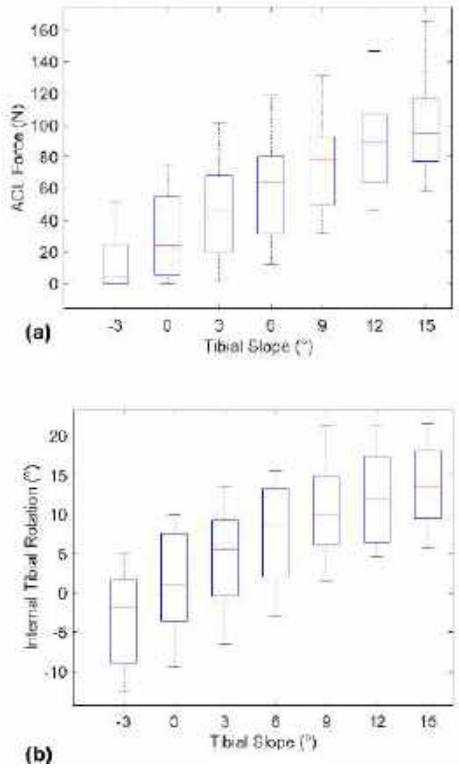

Figure 2: Boxplots of (a) resultant ACL force and (b) coupled ITR vs. tibial slope. Red lines are medians. The whiskers extend to the most extreme data points not considered outliers.

In conclusion, we developed an efficient workflow for studying the biomechanical impact of HTO via computational modeling. Our study confirmed that tibial slope modulates coupled ITR to reduce ACL force. This computational workflow may ultimately be used to identify those individuals who may most benefit from this surgical treatment.

INTRODUCTION

In patients with some forms of congenital heart disease, such as Tetralogy of Fallot (TOF), surgical relief of right ventricular outflow tract (RVOT) obstruction and RVOT reconstruction often result in severe pulmonary insufficiency and the need for pulmonary valve replacement [1-5]. Transcatheter pulmonary valve replacement (TPVR) has evolved over two decades and is increasingly utilized in patients with deteriorating right ventricle to pulmonary artery conduits and surgically implanted bioprosthetic valves, in addition to use in native or surgically repaired RVOT [3,4,6]. Designed as a less invasive alternative to surgery, TPVR is the preferred intervention today, overtaking conventional surgical methods [2,4,6].

Unfortunately, over 70% of patients with native (non-conduit) RVOT are not candidates for traditional balloon-expandable transcatheter pulmonary valves (TPV) [1,3,6]. As such, self-expanding TPV which conform to the heterogenous RVOT are increasingly applied to this complex population but require precise matching of the optimal TPV to an individual patient [3,4,6]. While finite element (FE) simulations to inform TPV placement are emerging, these simulations are not yet routinely applied to determine patient candidacy or inform device selection in TPVR.

In order to meet this need, we developed a workflow for the image-derived FE simulation of TPV deployment into simplified and image-derived models of the RVOT.

METHODS

This workflow utilizes four open-source programs: 3D Slicer (www.slicer.org), SlicerHeart [7], Tetwild [8], and FEBio [9]. The Institutional Review Board at the Children's Hospital of Philadelphia approved this study.

TPV Models: We focused on three widely available TPV device options for TPVR in pediatric patients: the Alterra (Edwards Lifesciences, Irvine, CA), and two Harmony TPV devices, the TPV-22 and TPV-25 (Medtronic, Minneapolis, MN). All three are made of self-expanding nitinol wire. TPV dimensions were obtained from micro-CT of the devices in their expanded state. The TPVs were fabricated Fusion 360 (Autodesk, San Francisco, CA) and re-meshed as tetrahedral elements with TetWild.

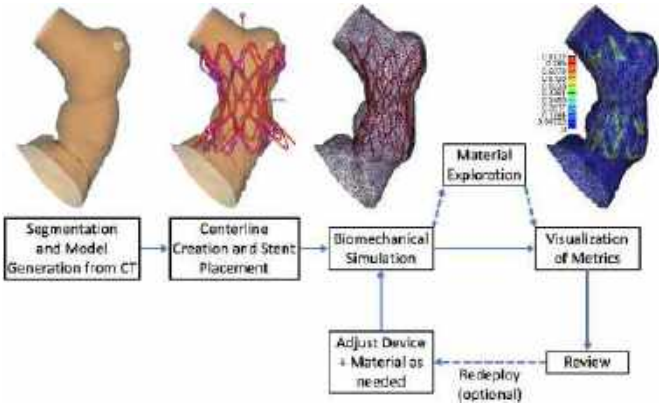

Figure 1: Modeling workflow.

TPV Placement: We created the TPVR Simulation module in SlicerHeart. The module allows the TPV device to be placed along a defined centerline and adjusting its location based on imaging or user preferences.

Vessel Geometry: The three idealized vessel models of varying complexities were constructed using the tube creation part of the TPVR Simulation module. The patient-specific RVOT model was segmented in 3D Slicer from previously acquired CT images.

FE Simulation: Our dynamic FE simulations are carried out in FEBio. The TPV must be constrained within a ~8 mm (25 Fr) catheter system. We apply a normal displacement to the tube that surrounds the

device to compress it uniformly from 28mm to 8 mm and push the TPV into the vessel, simulating release from the delivery catheter system.

A Neo-Hookean model is introduced for the TPV and the tube. We use an uncoupled Mooney Rivlin constitutive model for the vessel. A single node in the TPV is given a zero-displacement condition along the Z axis to prevent the TPV from sliding during compression. Potential-based contacts are instituted between the geometries. In the second analysis step, the tube is expanded at the same rate at which it was compressed, allowing the TPV to self-expand. Contact area between the vessel and the TPV was visualized and exported from FEBio at the last time step.

RESULTS

First, we virtually implanted three TPV into a simple, cylindrical vessel. Our simulations showed device-specific contact with the vessel, with the TPV-22 having the least amount of contact. The TPV-25 and Alterra demonstrated similar contact in the most proximal and distal rows of cells. The TPV-22 would not be ideal in a vessel of this size because its radius is too small relative to the vessel, evidenced by the limited amount of contact between the vessel and the TPV (**Fig. 2**).

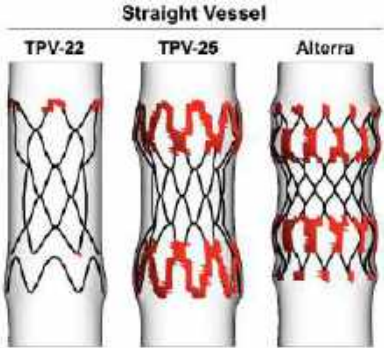

Figure 2: Contact area for the TPV-22, TPV-25, and Alterra, respectively, in the idealized 30 mm tube-like vessel.

Next, we deployed the TPV-25 in four different vessel geometries of increasing curvature and complexity. All simulations successfully converged. All four experienced similar contact at the end of the TPV devices, around the farthest rows of cells. No contact was made near the central part of the TPV for our straight, idealized vessel (**Fig. 3**). The vessel with minor curvature (Vessel A) exhibited some contact along the inside of the curve, while the more curved vessel (Vessel B) saw higher contact in this area. The patient-specific vessel has mild curvature on either side of the TPV with respect to the centerline; consequently, small areas of contact coexist with these features. Contact in Vessel A appeared most similar to the patient-specific model. Higher contact was found in areas of higher curvature.

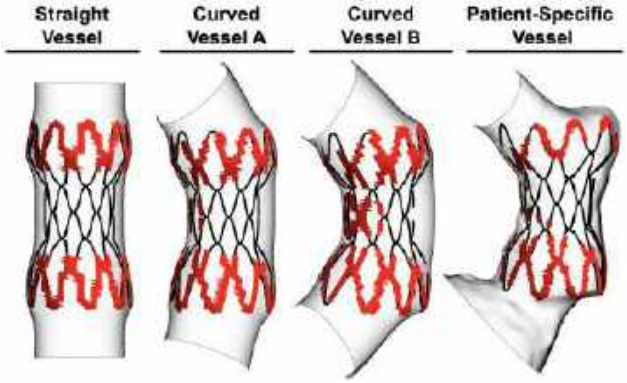

Figure 3: Contact area for the TPV-25 in the curved vessels and patient-specific vessel.

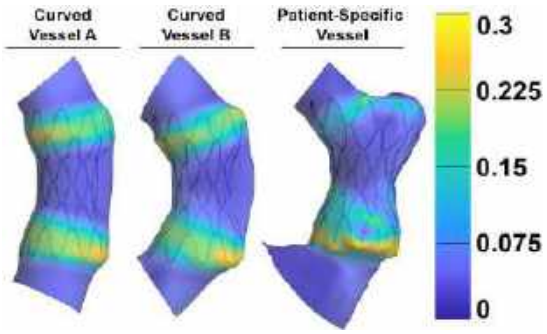

Figure 4: First Principal Strain for the TPV-25

DISCUSSION

We demonstrate initial application of an integrated open-source workflow for simulation of self-expanding TPV deployment in both simplified and image-derived, patient-specific RVOT geometry. We show realistic behavior for the three existing commercially available devices, as well as early visualizations of vessel and device contact. While our initial driving application is TPVR, this open-source framework is fundamentally applicable to any self-expanding device across a range of cardiovascular applications.

Current limitations include modeling of complex TPV structure in a simplified form and capturing contacts in our simulations with many degrees of freedom. Specifically, the TPV-22 and TPV-25 consist of individual nitinol wire rings sutured together rather than a solid metal structure. This may influence our computational results and is difficult to capture mechanically. In addition, our current TPV model utilizes volumetric tet elements, which are computationally expensive relative to beam elements. We will incorporate beam elements in the future. Finally, patient-specific RVOT material properties will be challenging to obtain, and further parameter estimation and sensitivity analysis are needed before reliable clinical application can be considered.

In the future we will continue to explore the range of material properties seen in the RVOT using parameter estimation and sensitivity analysis. We will utilize a new material model for the TPV to better reproduce the known superelasticity and shape-memory capabilities of the nitinol wire [10]. In addition, we will build from these initial results to create an integrated image to simulation workflow. This will consist of machine learning based-segmentation of the RVOT from CT and MRI images, and easy selection and placement of the desired TPV in the RVOT within SlicerHeart with export for simulation in FEBio. Results of simulation will then be displayed in an intuitive form within SlicerHeart to inform patient candidacy and optimal device selection.

INTRODUCTION

Blast-induced traumatic brain injury (bTBI) is the most common and concerning injury for warfighters during the ongoing era of asymmetric warfare. Traumatic brain injury (TBI) involves diffused microscopic injuries at the cellular level which are invisible to non-invasive standard imaging methods like computer tomography (CT) and magnetic resonance imaging (MRI). A recent post-mortem study [1] indicates the occurrence of chronic traumatic encephalopathy (CTE) is low for bTBI compared to impact TBI. CTE may not result from bTBI because brain tissue strains tend to be low (1% to 1.5%) even for relatively high blast exposures of 30 psi [2]. The primary cause of neuronal injury in the brain tissue due to blast wave interaction is still not completely understood.

Both numerical and experimental studies [3], observe high intracranial pressure due to blast wave interaction with the brain tissue. This study hypothesizes that the occurrence of high negative intracranial pressure leads to cavitation-induced primary neuronal injury in the brain tissue for overpressure magnitudes of blast waves ranging from 15 kPa (2 psi) to 105 kPa (15 psi). The warfighters are repetitively exposed to low-level blasts during handheld weapon system training [4]. The key objectives of the study are,

1. To develop a high fidelity framework to numerically predict high-resolution intracranial pressure field maps in the human brain tissue due to low-level blast waves
2. To understand the relationship between incident low-level blast wave parameters, cavitation bubble size, and risk of bTBI

METHODS

The high-fidelity cavitation-induced neuronal injury framework is performed in three steps as follows,

1. Predict intracranial pressure (ICP) field map of the brain by numerically modeling the blast wave interaction with a high-fidelity human body model (GHBMC-M50-Pv5.3.4)
2. Calculate maximum bubble size at the element level using ICP history data as input to a cavitation bubble growth model
3. Quantify primary neuronal injury based on estimates from cavitation growth model and in-vitro micro-cavitation experiments on neuronal tissue cultures

Modelling of Blast Wave Interaction

Blast wave interaction experiments on human surrogates or animals are challenging and limited to low spatial-temporal resolution. Various computational techniques and high-fidelity human brain models were developed in the past decade to understand the biomechanics of bTBI. The majority of the computational techniques consist of blast wave generation and Fluid-Structure interaction (FSI) capabilities. In this study, we implemented the Prescribed Inflow-Arbitrary Eulerian-Lagrangian (PIF-ALE) approach [5] using LS-Dyna to model ideal Friedlander blast wave interaction with the high-fidelity GHBMC (Global Human Body Models Consortium) model as shown in Figure1. The PIF-ALE approach models the ideal Friedlander blast pressure wave ($P(t)$) in Eq.(1) more accurately compared to the ConWep (Conventional Weapon System)-ALE approach.

$$P(t) = P_a + P_i = P_a + P_o(1 - \frac{t}{t_o})e^{-\frac{t}{t_o}} \tag{1}$$

where P_a(101.3 kPa) is the atmospheric pressure. P_o and t_o is the positive blast wave overpressure magnitude and duration, respectively.
The frontal blast wave was generated by defining temporal curves of volume change ($V(t)$), temperature change ($T(t)$), and particle velocity ($V_r(t)$) at the front surface (as shown in blue in Figure1) of the cuboid domain using the expression below [5],

$$V(t) = \left(\frac{P_a}{P(t)}\right)^{1/\gamma} \tag{2}$$

$$T(t) = T_0 V(t)^{1-\gamma} \tag{3}$$

$$V_r(t) = \frac{5P_i}{7P_a} \times \frac{a}{\sqrt{1 + 6P_i/7P_a}} \tag{4}$$

where a is the ambient speed of sound (340 m/s), T_0 (293 K) is the initial temperature, and γ is the ratio of specific heat (for air, $\gamma = 1.4$). The rear surface (as shown in black in Figure1) of the cuboid ALE domain was assigned as a non-reflecting boundary condition. All the remaining surfaces (as shown in red in Figure1) were assigned as slip boundary conditions.

Cavitation Bubble Growth Model

Inertial cavitation is characterized by explosive bubble growth and collapse due to negative pressure, which is known to cause neuronal tissue injury. Past research has related the extent of neuronal injury to the maximum bubble size. We implement a cavitation model based on the Keller-Miksis equation [6] for spherical bubble dynamics assuming isothermal conditions, incorporating the neuronal tissue properties (shear modulus, density, viscosity, and sound speed) and incorporating the effect of the local intracranial pressure-time profile. The neuronal tissue is modeled using a non-linear Kelvin-Voigt material model with Neo-Hookean elasticity. Our model is solved numerically using an explicit multi-stage time marching technique. The model predicts the maximum bubble radius due to the elemental intracranial pressure history of the brain tissue. A reduced model is being developed, which we plan to incorporate into the FE model.

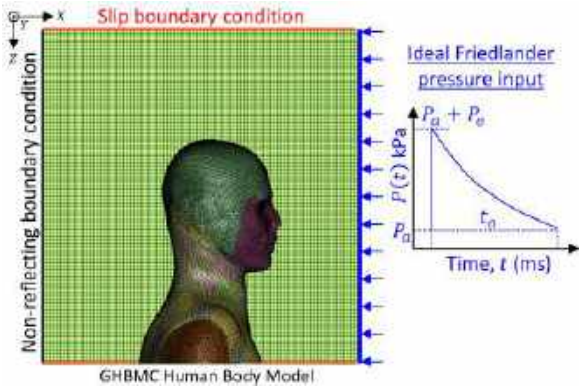

Figure 1: Boundary conditions applied over 3D cuboid ALE domain (in green). a) Non-reflecting boundary condition (in black) on the rear surface, b) slip boundary on all side surfaces (in red), and c) temporal input curve (volume, temperature, and particle velocity) on the front surface (in blue) to model an ideal Friedlander blast pressure wave. No constraint is applied to the Lagrangian elements of the GHBMC-M50-P v5.3.4 model. Dimension of the cuboid Eulerian domain is 570 mm (in X-axis) $\times$ 600 mm (in Y-axis) $\times$ 600 mm (in Z-axis). Eulerian domain is modeled with a total of 950,000 elements (each hexahedral element with an edge length of 6 mm). GHBMC-M50-P v5.3.4 consists of a total of 2.2 million elements.

Cavitation-Induced Neuronal Injury Estimate

We estimate neuronal injury based on our recently established injury thresholds for primary injury under high strain-rate loading as occurs during cavitation. Here, critical injury thresholds are detailed for several structural neuronal biomarkers as well as complete cell loss derived from an established 3D in-vitro neuronal tissue TBI model [7]. The experimental study establishes a non-linear relationship between the cumulative probability of neuronal injury and the threshold value of critical hoop stretch experienced by neuronal cells during a cavitation loading event. As an example, at hoop stretch values equal to 1.2 and 2, the cumulative probability of neuronal tissue injury is 10% and 100%, respectively. The hoop stretch, which can also be expressed in terms of tissue strain, depends upon the ratio of the equilibrium and the maximum radius of the cavitation bubble estimated using the bubble growth model.

RESULTS

We have demonstrated our proposed framework by performing a preliminary study for three cases based on measured blast over-pressures from heavy weapon training [4]. The details of the frontal blast characteristics i.e. overpressure magnitude and duration for each case are tabulated in Table 1. The percentage volume of cavitation-induced neuronal injury in grey and white matter are tabulated in Table1. The percentage neuronal injury volume for a particular tissue (white or grey matter) is the ratio of the sum of elemental volume with the likelihood of injury and the total volume of the tissue. It is observed from blast wave interaction simulation that the effect of overpressure duration is insignificant because the blast wave reflected from the human body attenuates the temporal effect of the on-coming blast wave. For the blast exposures of 2 psi and 4 psi, the volumetric estimates for neuronal injury are negligible compared to blast exposure of 15 psi.

DISCUSSION

We developed a high-fidelity numerical framework with the capability to model low-level blast wave interaction with the human brain tissue for quantifying cavitation-induced neuronal injury. Using this framework we can better understand the biomechanics of TBI and the risk of injury in warfighters exposed to low-level blasts during the handheld weapon system training. The analysis shows that the blast overpressure magnitude has a significant effect on the risk of cavitation-induced neuronal injury compared to overpressure duration. One of the main limitations of the current study is that cavitation injury likelihood results are highly sensitive to the choice of initial cavitation bubble size. We plan to explore the experimental evidence of initial cavitation bubble size for brain tissue in our future work.

Table 1: Percentage of white and grey matter volume with 50% likelihood of cavitation-induced neuronal injury for three different low-level blast exposures.

Case number	Blast wave characteristics	Percentage volume with 50% likelihood of neuronal injury	
		White matter	Grey matter
1	104 kPa (15 psi) & 6 ms	3.2%	2.8%
2	13.8 kPa (2 psi) & 1 ms	0.02%	0.33%
3	27.5 kPa (4 psi) & 1 ms	0.03%	0.36%

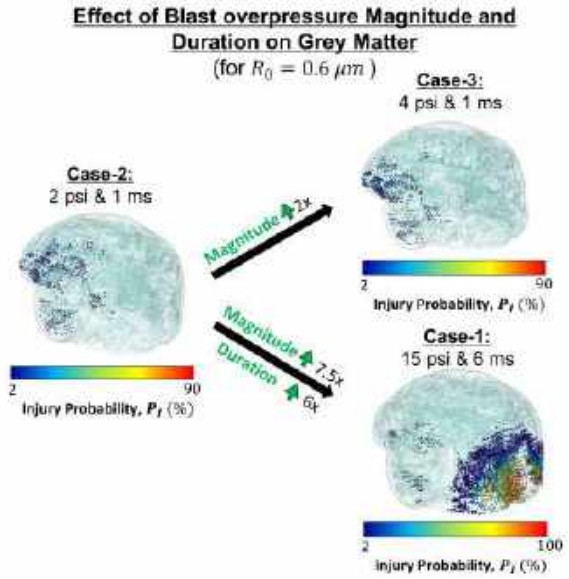

Figure 2: Discrete contour plots for three different frontal blast exposures illustrating the effect of a blast overpressure magnitude and duration on the likelihood of cavitation injury in grey matter region of the brain tissue. Each spatial point illustrates the centroid of the element colored (rainbow spectrum from blue to red) based on the value of the neuronal injury probability ranging from 2% to 100 %. R_0 is the initial cavitation bubble size with a value equal to 0.6 μm.

INTRODUCTION

Obstructive sleep apnea syndrome (OSAS) is a prevalent condition characterized by repeated episodes of airway collapse during sleep, with negative long-term health effects. A better understanding of OSAS may improve diagnosis and treatment [1], [2], [3]. E*ffective compliance* (EC) is a potential biomarker that includes tissue compliance and airway muscle activity in the pharyngeal airway, and has been shown to correlate with OSAS severity [4], [5]. Calculating EC requires dynamic airway geometry and pressures. Previous papers calculated EC over brief moments in time by simulating airway pressures with computational fluid dynamics (CFD). However, it would be infeasible to use the same methods to calculate EC over longer periods of time due to long simulation run times [4], [5]. This is not ideal because OSAS patients exhibit different breathing behavior over the course of sleep, all of which may reveal a fuller picture of OSAS. As an alternative to CFD, we explored using a neural network (NN) to estimate airway pressures.

METHODS

Image-based CFD: Dynamic volume MR imaging and physiologic data from 5 OSAS subjects was used to train and evaluate the performance of a NN. Data from each subject included airway geometry and synchronized flow for 960 frames in time over ~8 minutes. A semi-automated machine learning algorithm [6] segmented the airway volume for each fame. The airway pressure field was calculated with a custom semiautomated CFD system (Altair HyperMesh, ANSYS Fluent, Python), with a low-resolution mesh. The simulation method was verified using high-resolution CFD of sample frames, and had run times much shorter than the ones in [4], [5]. Following CFD, airway centerlines were found using the *Vascular Modeling Toolkit* [7]. Area and average pressure distributions vs. the airway centerline position (Fig. 1) were extracted for each frame.

The goal was for the NN to predict airway pressures, given information on airway geometry and flow rate. Inputs to the NN were 32-point arrays for centerline section areas, change in centerline coordinates, and flow rate (ex. [a1, a2, a3, ...]). The output (dp) was an array for the change in centerline section pressures. Elements in arrays corresponded to locations along centerlines, and were ordered from inlet to outlet (Fig. 1). The "change" description for arrays refers to a change of quantity between adjacent centerline locations. Pressures relative to the inlet (p) were calculated from a cumulative sum of dp.

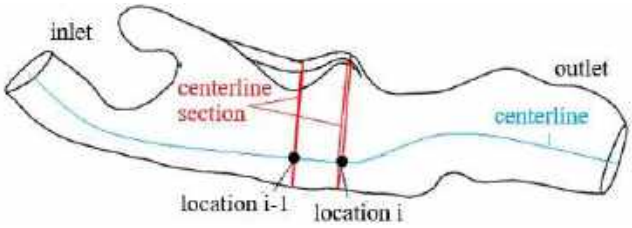

Figure 1: Airway geometry, centerline, and sections, for a single inhalation frame. (Centerline direction reversed for exhalation.)

Several considerations based on fluid mechanics were made when designing the NN. The architecture was inspired by *WaveNet*, a NN for generating audio waveforms [8]. dp was calculated from 1D causal convolutions that prevented elements of dp from being affected by input elements corresponding to downstream centerline location. Dilated convolutions ensured that the receptive field for calculating elements of dp was large enough to include all upstream inputs, so that flow details can be implicitly accounted for in the hidden layers.

Mean squared error loss was used for training. Models were trained with data from 4 of the 5 subjects, and tested on data from the remaining subject. A model was trained to test on each of the 5 subjects. Training was done on a commercially available 32-processor, *AMD Ryzen Threadripper PRO 5975WX @ 3.59 GHz* (Lenovo).

RESULTS

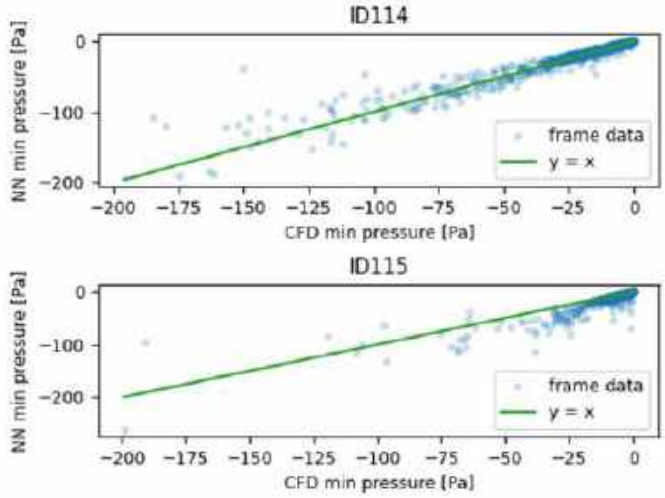

Figure 2: NN Predicted vs. CFD minimum p (symbol) across all test frames, compared to identity line, for two sample subjects.

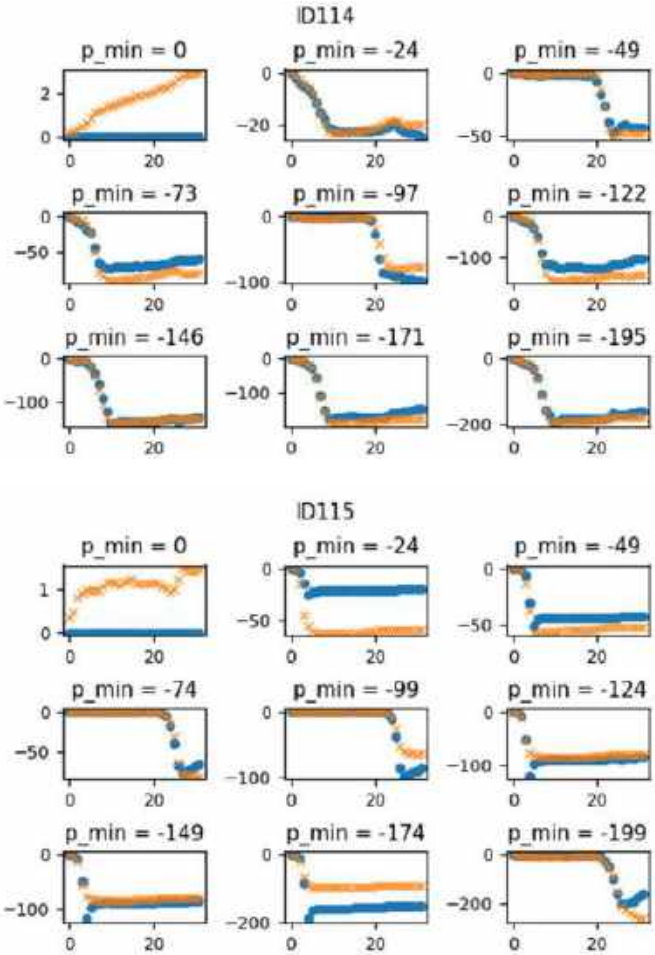

Figure 3: Samples of frame $p(x)$ (x = distance from inlet, y: p [Pa]) by CFD (●) and NN (×); CFD minimum p also shown.

Low resolution CFD run times were ~5 minutes per frame. The training time for each NN model was < 1 hour. Once trained, the NN models predicted dp for their respective test data in < 1 minute.

Results are shown for two sample subjects. In some subjects, e.g. ID114, CFD minimum p was predicted well by the NN, while predictions for subject ID115 strayed from the identity line, with the NN often predicting more extreme pressure drop (Fig. 2).

Figure 3 shows p distribution along the airway centerline for samples of both inspiratory and expiratory frames. Except for when p is negligible (order 1 Pa), NN and CFD resolved the same p trends along airway. Relatively high percent errors resulted from a small number of bad dp predictions near the velopharynx, indicated by narrowest region of the airway in Figure 1, and the highest slopes in Figure 3.

DISCUSSION

Extrapolation of low-resolution CFD run times gives ~3 days to process 960 frames, a significant improvement in through-put compared to the estimated years it would take high-resolution CFD to do the same. The NN is faster still, being able to model airway pressures almost instantly once trained.

Based on [9], [10], and our own comparisons of low to high-resolution CFD, we estimate that the NN has potential to predict p with errors as low as 10-20%, compared to the 15-37% from a simple Bernoulli's estimate. The main advantage of the NN model over other 1D or lumped parameter models is its robustness to the complexity and variety in airway shapes. In addition to instant predictions, another advantage of the NN over CFD is the simplicity with which it represents the relationship between airway geometry and pressures. Whereas 3D airway geometries are required for CFD, the NN works only with simple arrays. These arrays are easier to manipulate, making them more suitable for developing Fluid-Structure Interaction or other dynamic simulations.

Subjects where the NN model performed poorly seem related to problems with the training dataset. For example, the training set used to predict on ID115 had cross-section areas consistently larger than in the test set. Plots for ID114 and 2 other subjects (not shown) suggest that this NN can model pharyngeal airway pressures from airway geometry as well as low-resolution CFD can, when the airway size is represented in the training data.

Future work will include adding subjects to the training and testing datasets, revisiting high-through-put CFD model postprocessing methods to improve training data quality, and exploring the use of scaling to create synthetic data with a wider range of cross-section area. Ultimately the models will be used to dynamically visualize the distribution of effective compliance in patients with OSAS.

INTRODUCTION

Traumatic brain injuries (TBI) are caused by impacts to the head resulting in brain dysfunction and lifelong complications. According to the defense health agency, the department of defense has reported 485,000 TBIs for military service members worldwide [1]. To study which impact parameters cause damage, it becomes necessary to develop a surrogate model for human tissue due to the limitations in observing *in vivo* impact. Polyacrylamide (PAA) hydrogel is used to emulate the material properties of human brain tissue [2,3]. To measure shear properties in a living human volunteer, shear waves are propagated from a passive driver into a volunteer's head while being scanned with magnetic resonance imaging (MRI) [2]. The data collected is reconstructed through the use magnetic resonance elastography (MRE) to display shear properties. **Figure 1** shows agreement with healthy human volunteer data in terms of shear stiffness (μ) but is inadequate in terms of the damping ratio (ξ).

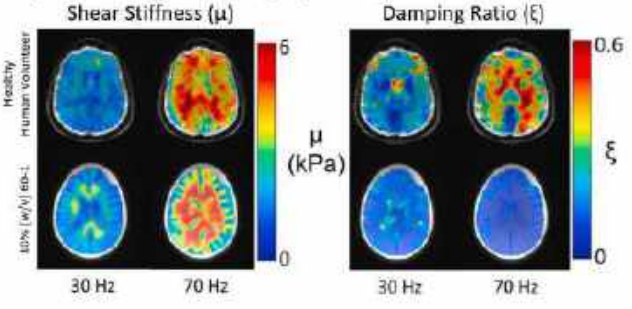

Figure 1: Measurements of shear stiffness and damping ratio of human tissue and 10% (w/v) 60-1 obtained from MRE. Adapted from [2]

The 10% (w/v) 60-1 formulation demonstrates an elastic component or storage modulus (G') of 1-3 kPa which is comparable to brain tissue; however, the viscous component or loss modulus (G") is deficient as seen in **Table 1**. The tangent of the phase angle (tan(δ)) is used to compare the value of G" to G', a ratio of the viscous and elastic contributions, as seen in **Eq. 1**. The complex modulus is a Pythagorean relationship that combines G' and G" into a singular value as seen in **Eq. 2**. The rheological properties of the PAA hydrogel can be converted to MRE material properties as shown in **Eq. 3** and **4** allowing comparison to in-vivo human tissue. According to **Figure 1**, since the shear stiffness is on par with brain tissue, the damping ratio needs to be increased.

$$\tan(\delta) = \frac{G''}{G'} \quad (1)$$

$$G^* = \sqrt{G'^2 + G''^2} \quad (2)$$

$$\mu = \frac{2|G''|^2}{G' + |G^*|} \quad (3)$$

$$\xi = \frac{G''}{2G'} \quad (4)$$

The objective of this research is to increase the viscous component of the PAA hydrogel while maintaining its stiffness, to accurately replicate human brain tissue. Previous findings suggest that increasing crosslinker present in the PAA hydrogel increases the G" value [3]. Additionally, two other methods were attempted: the addition of linear acrylamide chains (LAC) to produce a semi-interpenetrating polymer network and the addition of dextran to increase the amount of free water [4,5]. LACs are shown to help increase the viscous component of a hydrogel by acting as damping pockets; the LACs are not crosslinked with the overall gel network. Dextran is a polysaccharide that can interact with the water present in a material to limit the amount of water bound to the acrylamide backbone chain. Water affected by dextran effectively becomes free water and able to flow about the gel matrix freely due to the non-interaction between dextran and the acrylamide backbone.

Table 1: Material properties of human brain tissue vs 10% (w/v) 60-1 PAA formulation [2]

	Rheological Properties			MRE	
Material	G' (kPa)	G" (kPa)	Tan(δ)	μ (kPa)	ξ
Human Brain Tissue	1 - 2	0.2 - 0.4	0.3	1 - 3	0.1
10% (w/v) 60-1 PAA	1 - 2	0.05 - 0.1	0.05	1 - 3	0.025

METHODS

Acrylamide (purity 98%), Methylenebisacrylamide (MBA, purity 99%), Ammonium persulfate (APS, ACS, purity 98%), N,N,N',N'-Tetramethylethylenediamine (TEMED, ReagentPlus, purity 99%), and Molecular Weight 450,000 – 600,000 (450k MW) and Molecular Weight 40,000 (40k MW) Dextran from Leuconostoc mesenteroides was purchased from Sigma-Aldrich USA.

To synthesize a PAA hydrogel with the formulation of 10% (w/v) 30-1 is as follows: 10.0 g of acrylamide and 0.333 g of MBA are mixed into 100 mL of degassed DI water. 0.086 g APS and 0.177 mL of TEMED mixed in to initiate and catalyze the reaction. The solution is transferred to a 25 mm disc mold and allowed to polymerize for 24 hours and is then placed in an isotonic solution to swell for 24 hours.

LACs length can affect material properties, two lengths of LACs were produced, the formulations outlined in **Table 2**. The length of the LACs is directly affected by the amount of APS present in the solution, and APS signifies the quantity of chains. Synthesis of LAC stock solution uses the chemical amounts outlined in **Table 2** mixed into DI water. The solution is heated to 37°C for 2 hours to allow for polymerization of the acrylamide monomers. Once polymerized, the LAC stock solution is stored at 4°C until needed.

Table 2: Long and short LAC formulation

Material	Long	Short
DI Water (mL)	200	200
Acrylamide (g)	14	14
APS (g)	0.1	1
TEMED (mL)	0.01	0.01

To modify the PAA hydrogel to incorporate LACs: 20 g of LAC of desired length is added to a graduated cylinder. Water is added and gradually stirred until 100 mL is reached and the mixture is homogeneous. The diluted LACs are degassed for 10 minutes and the acrylamide, MBA, APS and TEMED are added. Modifying the PAA hydrogel to incorporate dextran is as follows, 1.4 grams of dextran mixed into 100 mL of DI water. The dextran water mixture is then degassed, and components are added as stated previously. The same molecular weight of dextran is added to DI water to swell the dextran PAA gels. To test the effects of dextran and LACs and any combinational effects of the two on PAA hydrogels, an experimental matrix was developed outlined in **Table 3**.

Table 3: Experimental matrix, 10% (w/v) 30-1 PAA hydrogel base for each formulation with LAC and/or dextran.

10% (w/v) 30-1 PAA (Control)	Short LAC	Long LAC
40k MW	40k MW Short LAC	40k MW Long LAC
450k MW	450k MW Short LAC	450k MW Long LAC

Each PAA hydrogel was tested on a strain-controlled rheometer, ARES, with 25 mm parallel plate geometry. A frequency sweep was performed at 1% strain from 1 to 81 Hz. The G', G" and tan(δ) values were collected for each formulation and averaged together (n=9) to analyze the trend.

RESULTS

As seen in **Figure 2** the G' tends to be roughly 1 kPa for each formulation, LAC containing formulations being slightly lower. LACs work counterproductively and undermines the goal of increasing the loss modulus. Notably, at frequencies lower than 10 Hz the 450k MW shows an increase in G" compared to the control, but at the higher frequencies this trend begins to diminish. High frequency damping is desired as seen in **Figure 1** when comparing PAA to the human brain tissue. Though there is a slight increase in the viscous nature of the PAA using dextran, the change did not result in the desired 0.2 tan(δ).

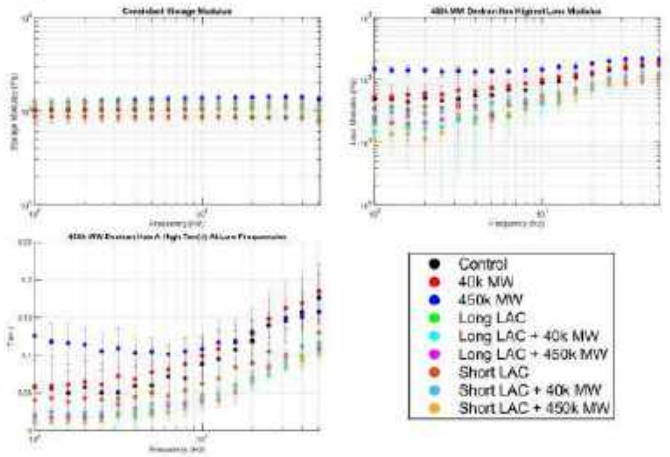

Figure 2: The storage modulus, loss modulus, and tan(δ) of various formulations outlined in Table 3.

DISCUSSION

LACs are undesirable for the project's objectives and there are no advantageous combinational effects of combining LACs and dextran. Though the dextran does appear to increase the G", at higher frequencies the prevalence of free water diminishes compared to the properties of the hydrogel matrix itself. Next steps would be to experiment with larger quantities of dextran. An issue with dextran is the scale up cost, synthesizing small batches using dextran is reasonable, but should a full-sized brain phantom gel be synthesized, dextran would quickly become the costliest reagent. Though the experiments did not yield the desired results, it has demonstrated that increasing the loss modulus is possible.

INTRODUCTION

The endothelial glycocalyx (GCX) plays a crucial role in determining vascular permeability and maintaining endothelial integrity [1]. Despite being studied for over four decades, its functions have only recently become the subject of in-depth research. The GCX is a layer of proteins that coats the luminal surface of endothelial cells (ECs), comprising various transmembrane proteins serving as mechanotransducers for cellular responses [1,3]. One of its primary functions is to regulate the contraction or dilation of blood vessels in response to changes in blood flow [4]. Studies indicate that the proteins constituting the GCX, connected to the cytoskeleton, can influence the reorganization of cytoskeletal proteins and other biochemical activities [5]. Diseases like atherosclerosis or invasive procedures such as pneumonectomies can lead to damage to the GCX, adversely affecting vasculature [2].

A pneumonectomy involves the removal of either the right or left lung, typically due to conditions like cancer or traumatic injury. This highly invasive and high-risk procedure is associated with elevated morbidity and mortality rates. The redirection of blood to one lung and its associated vasculature during a pneumonectomy increases pressures, velocity, and shear stress throughout, with shear stress post-pneumonectomy being double the magnitude observed in arteries under normal conditions [6,7,8].

While the direct relationship between pneumonectomy and GCX is not well understood, there is a potential link between the redirection of blood flow and GCX health. It is hypothesized that the changes in blood flow and the increase in shear stress detrimentally affect GCX and, consequently, endothelial cell health [9].

To better comprehend the relationship between GCX and endothelial cell health, an in vitro pneumonectomy model was developed. Although literature on actual in vivo shear stress changes is limited, precise values were calculated using computer simulations in SolidWorks and COMSOL based on a pneumonectomy scenario.

METHODS

Using SolidWorks, a model of a vascular system was developed as a control no-pneumonectomy (NP) model and a left pneumonectomy (LP) model. Average right and left pulmonary artery (PA) diameter for this model was determined by available literature to be 19.8mm and 22.1mm, respectively [10]. This value was used to set the scale and measure CT scans of pulmonary vasculature in ImageJ Fiji to obtain diameters for selected segments, and branches in the system. These values were used to create a 3D model that represents the PA and its branches in SolidWorks, as shown in Figure 1.

Figure 1: CT Scan of right pulmonary artery, measured and used to develop complete NP (right) SolidWorks model

Both models underwent fluid simulation in COMSOL to analyze and observe areas of high shear stress and to calculate require flow rates during testing (Figure 3). Several sections of interest in the model were selected by notable differences in shear stress between NP and LP models. Average shear stress was calculated for each of these areas of interest using MATLAB and was used to show the fold change of the shear stress between the NP and LP models (Figure 4).

Once vessels of interest were chosen, they were individually replicated in SolidWorks to create a positive mold for PDMS casting

(Figure 2). A plexiglass enclosure (Figure 2) was machined to secure the mold and to attach tubing for media flow through the model.

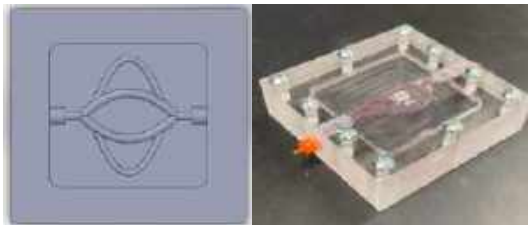

Figure 2: 3D model (left) of PDMS mold that can be modified to simulate a pneumonectomy. The mold is inserted into the flow case and secured (right)

Once cast, each half of the PDMS mold was coated with fibronectin to promote cell adhesion and seeded with $1x10^6$ human lung microvascular endothelial cells (HLMVECs), in endothelial growth medium (Sigma Aldrich) at 37°C and allowed to attach and proliferate for 24 hours. The molds were then placed in the plexiglass enclosure and clamped together (Figure 2) and connected to the flow system. Media was pumped through the system to expose the cells to 10-12 dyn/cm^2 of shear stress due to fluid flow for 24 hours. and connected to the flow system.

Immunostaining was used to quantify differences in expression of GCX. Following exposure to flow, cells were fixed in 4% PFA and stained using Wheat Germ Agglutinin (Thermo Fisher Scientific) primary antibody and AF-488 conjugated anti-biotin (Thermo Fisher Scientific) as secondary antibody (Figure 5). DAPI was used to display cell nuclei.

RESULTS

COMSOL simulation showed shear stress due to fluid flow to be significantly increased in certain areas in the LP model, as shown in Figure 3 by the color map. These areas of greater shear stress were selected as areas of interest.

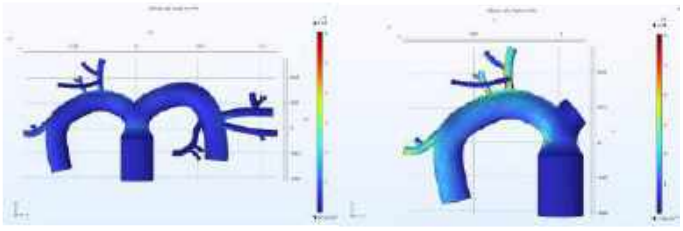

Figure 3: COMSOL shear stress simulation results for NP (left) and LP (right) models. Red areas show high shear stress

The change in shear stress in the selected areas was calculated to be more than 6 fold as shown in Figure 4.

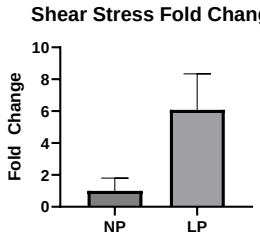

Figure 4: Fold change in shear stress calculated from COMSOL simulations

Preliminary testing of the seeded molds in the flow system for 24 hours revealed successful adherence and confluence of human lung microvascular endothelial cells on coated PDMS surface, forming a lumen. This was visualized via brightfield imaging as well as immunocytochemistry (ICC) with WGA and DAPI (Figure 4). In Figure 4, the green represents the WGA staining for GCX components, and the blue represents cell nuclei.

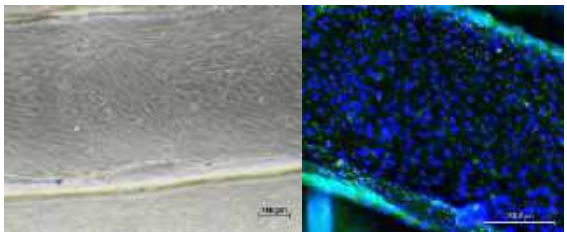

Figure 5: Brightfield image of cell coverage and alignment after exposure to flow (left). ICC results in NP model (right) stained for WGA (green) and DAPI (blue)

DISCUSSION

While our current knowledge of shear stress changes following pneumonectomy is limited, initial tests using this model suggest its capability to simulate post-pneumonectomy conditions. The digital simulation effectively highlighted significant variations in shear stress after the invasive procedure, pinpointing bifurcations as potential sites for increased damage to the glycocalyx.

Despite limitations in the molding process, including low surface resolution and frequent irregularities, preliminary immunofluorescence results indicated a healthy glycocalyx and a complete lumen after 24 hours of flow exposure. Future experiments will involve analyzing COMSOL results in MATLAB to quantify shear stress, closely examining and quantifying glycocalyx staining. Mold refinement and immunostaining will be conducted to confirm the formation of physiologically accurate lumens. Additionally, diverse pneumonectomy and bifurcation models will be developed and validated.

This study demonstrates the potential accuracy of our model as a vascular representation, with ongoing refinement and validation efforts. Future research will explore various vascular shapes, bifurcation types, use a more physiologically relevant matrix like collagen, and conduct quantitative analysis of glycocalyx health. Understanding the glycocalyx's role in vascular health post-pneumonectomy may provide insights into reducing morbidity and mortality rates after surgery.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Solomon Mensah for valuable direction, support and discussions, and WPI for providing laboratory space and funding for the project through the startup package provided to Dr. Solomon Mensah.

The Impact of Natural Estrogen and Progesterone Cycling on Cardiac Function in Mice

Thaotho H. Nguyen (1), Cassandra K. Conway-O'Donnell (1), Naomi C. Chesler (1)

(1) Edwards Lifesciences Foundation Cardiovascular Innovation and Research Center, and Department of Biomedical Engineering, University of California, Irvine, Irvine, CA, USA

INTRODUCTION

Heart disease is the leading cause of death for all sexes and most racial and ethnic groups in the United States [1]. Prior to menopause females are less likely to develop overt cardiovascular disease (CVD) compared to age matched males [2]. However, post-menopause CVD onset increases substantially until the incidence of CVD in females surpasses that in males [3]. This disparity in heart disease is attributed to decreasing levels of estrogen and progesterone after menopause, however, the roles of female sex hormones in heart function are not well understood. Estrogen and progesterone cyclically rise and fall during the menstrual cycle with the highest amount of estrogen occurring immediately prior to ovulation and rising levels of progesterone occurring in the luteal phase [4]. In women just prior to ovulation, systolic blood pressure and soft tissue compliance increases [5][6]. In contrast, in women during the luteal phase, in which progesterone is rising and estrogen levels are falling, heart rate increases, and systolic blood pressure decreases [5].

The 28-day (on average) human menstrual cycle and the 4-day (on average) mouse estrous cycle share some similarities. In both cases, the cycles consist of distinct phases. The mouse estrous cycle includes four phases: proestrus, estrus, metestrus, and diestrus. Proestrus is characterized by the preparation of the reproductive system for mating, similar to the human follicular phase. The estrus phase, often referred to as the "heat" period in animals, aligns with human ovulation when the egg is released. Metestrus and diestrus in mice correspond to the luteal phase in humans, involving changes in the uterus and hormonal fluctuations [7]. Despite species differences, understanding the impact of these cycles in mice is crucial for reproductive research and can provide valuable insights into the effects of the menstrual cycle in women.

The goal of this study was to quantify the impact of the estrus cycle on cardiac function in mice to better understand the heart function of women in the premenopausal state. Knowledge of natural fluctuations in heart function that occur due to natural variations in sex hormones in females could help inform cardiovascular research and limit variability in data that results from those natural variations.

METHODS

All animal procedures were approved by the University of California, Irvine Institutional Animal Care and Use Committee (IACUC).

Transthoracic Echocardiography: Daily transthoracic echocardiography using a Vevo 3100 ultrasound system was conducted for five days to assess the morphology and function of the left ventricle, aorta, and pulmonary artery in a group of five (5) C57BL/6 female mice at 6-weeks-old using a 40Mhz probe. The mice were initially anesthetized with 5% isoflurane and maintained at 2% isoflurane during the entire procedure. A heated platform was used to maintain the body temperature at 37°C. Imaging was conducted daily at the same time and for 5 consecutive days. B-mode and M-mode images were taken of the left ventricle. B-mode and pulse wave doppler were used to measure geometry and blood flow velocity in the aorta and pulmonary artery.

Visual Assessment of Estrous Cycle: After performing echocardiography, a visual examination of the vaginal cavity was performed to ascertain the phase of the estrous cycle. Estrous cycle phase was assessed visually by observing the color, moistness, and aperture of the vaginal opening [7]. Whereas proestrus is characterized by swollen, pink, and moist tissue, the vagina in estrus loses some pinkness and moistness but remains open. Metestrus can be identified by the slight closure of the vaginal canal, pale color, and presence of white cellular debris; in diestrus the vaginal canal is closed, has a pale color, no swelling, and no debris [7].

Data Analysis: Vevolab 5.8.0 software was used to analyze the echocardiogram images. Echocardiographic parameters including left ventricle anterior wall (LVAW) and posterior wall (LVPW) thickness in systole and diastole, left ventricle internal dimensions

(LVID) at diastole and systole (LVIDd and LVIDs respectively) were evaluated in M-mode by averaging measurements obtained over a minimum of three consecutive cardiac cycles. LV ejection fraction (EF), LV fractional shortening (FS), and LV posterior wall thickness (PW) were calculated in Vevolab software by using the following formulas:

$$EF\ (\%) = 100 \times [(LVEDV - LVESV)/LVEDV] \quad (1)$$
$$FS(\%) = 100 \times [(LVID_d - LVID_s)/LVID_d] \quad (2)$$
$$LVPW = 100 \times [(LVPW_s - LVPW_d)/LVPW_d] \quad (3)$$

EKG was also measured using surface electrodes and heart rate was determined with Vevolab software.

After analysis, parameters were categorized into one of the four stages of the estrous cycle as determined by the visual assessment. In total, 23 echocardiograms were analyzed. Subsequently, a normality and logistic regression were conducted on all parameters. If all tests yielded normal results, ANOVA was performed to compare serial measurements within the groups with P values < 0.05 were considered statistically significant. All statistics were performed using GraphPad Prism. Repeated measured statistics were not performed since not all animals cycled through all four phases. Diestrus was observed and reported but omitted from the statistical analysis, as the diestrus phase was only observed twice in the 5 mice during the 5-day testing period. One mouse was excluded from the data starting on day 3 due to an adverse reaction to anesthesia.

RESULTS

As shown in **Table 1**, heart rate (HR) did not vary over the course of the estrus cycle. Stroke volume (SV) tended to be higher in metestrus and diestrus than proestrus or estrus, but the differences were not significant. Cardiac output (CO), calculated as the product of HR and SV, also was not significantly different between cycle phases. Both fractional shortening (FS) and ejection fractioning (EF) showed a significant change with natural fluctuations in estrogen and progesterone in the female mice in this sample. As shown in **Figure 1**, FS and EF were significantly lower in mice in metestrus compared to mice in proestrus.

Table 1: Heat rate (HR), stroke volume (SV), ejection fraction (EF), fractioning shortening (FS), and cardiac output (CO) expressed as mean ± standard error.

Parameters	Proestrus N=7	Estrus N=5	Metestrus N=8	Diestrus N=2
HR (BPM)	532.0 ± 36.0	506.9 ± 48.0	480.4 ± 36.2	506.3 ± 4.6
SV (µL)	26.8 ± 5.0	26.3 ± 8.1	30.4 ± 4.7	36.8 ± 8.6
CO (mL/min)	14.2 ± 3.0	13.2 ± 4.0	14.7 ± 3.1	18.6 ± 4.5

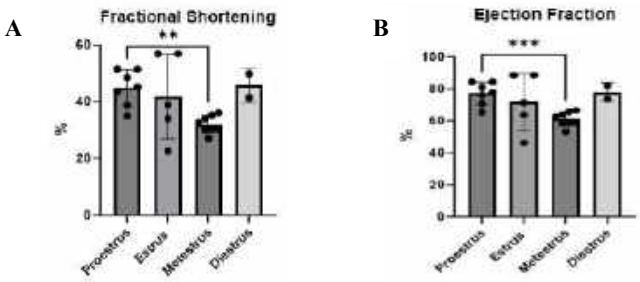

Figure 1. Mice in metestrus exhibited a significant decrease in fractional shortening (FS) and ejection fraction (EF) in compared to mice in proestrus (**P < 0.001 and ***P < 0.0001).

DISCUSSION

Female sex hormones, specifically estrogen, have been considered cardioprotective [8]. However, research on the role of female sex hormones on cardiac function in premenopausal women is lacking. Historically, female sex was excluded from clinical studies and animal research prompting the NIH Policy on Sex as a Biological Variable in 2015. This study sought to better understand the impact of hormonal fluctuations in the mouse estrous cycle on cardiac function using echocardiograms. Our investigation found increased fractional shortening and ejection fraction during proestrus compared to metestrus. Overall, we found that increasing estrogen levels in the estrous cycle can influence cardiac contractility.

Kwissa et al. found a significantly shorter left ventricle ejection times in the mid-luteal phase compared to the late follicular phase of the menstrual cycle in human women [9]. Similarly, our findings show that cardiac contractility (fractional shortening) increased at proestrus, a phase characterized by high estrogen levels. These findings underscore the necessity of not only including females in cardiovascular research but also accounting for the specific phase of the estrous cycle.

One limitation of our study was that the mice did not reliably cycle through all phases of the estrous cycle during a five-day data collection window. The limited data points for the diestrus phase prohibited quantifying cardiac function for all estrous phases. Also, the visual assessment method of determining estrus cycle phase can be complemented by employing vaginal cytology [7].

In conclusion, our investigation sheds light on the intricate relationship between the estrous cycle and cardiac dynamics. By connecting our major findings to existing literature and emphasizing the role of estrogen, we advocate for a refined approach to cardiovascular research that considers both sex and estrous cycle phases which may help improve timing for medical interventions in premenopausal women and prompt animal researchers to report estrous phase as a variable within the study. Future work to expand the findings of this study could include taking serial blood pressure measurements and including mitral and tricuspid valve jet velocities in the analysis.

INTRODUCTION

Wound healing is a critical biological process essential for the restoration of skin integrity following injury. Understanding the mechanisms underlying the healing process in chronic wounds has an immense clinical significance, as it enables us to predict the efficiency of clinical interventions and improve both current healing time and patient outcomes. Having the capability to quantify wound tissue's characteristics and identify its chemical structure will advance our understanding on mechanisms involved in the healing process. Clinical studies have reported that the structure of tissue surrounding a healing wound changes significantly during the healing process. Based on these findings, the tissue surrounding a chronic wound and the peri wound area have gained significant clinical attention where application of particular treatments is expected to promote the healing by stimulating the tissue [1-6]. In contrast, the role of chemical modification and its interplay with structural changes during the healing process, which can greatly improve the design of intervention strategies and patient outcome, have been elusive. This study introduces innovative methods for observing and quantifying wound healing in mammalian models, specifically through detailed microscopic examination of mice skin.

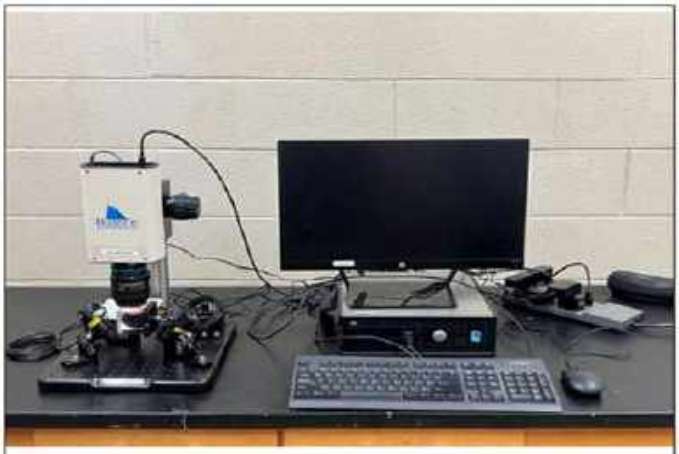

Fig1. Our in-house developed microscope.

METHODS

We use near-infrared (NIR) spectroscopy imaging to acquire the structural and chemical characteristics of wound tissues. We have already developed a microscope using NIR to explore how the measured tissue characteristics corelate with the healing trajectory of old and young mice (Figure 1). We focused on the absorption and reduced scattering coefficients of the skin surface as key parameters indicative of structural and biochemical changes during tissue repair.

RESULTS

Present results chronologically or in order of importance. Describe the major results in the text, referencing the figures and tables parenthetically as appropriate. Our data revealed notable differences in skin surface characteristics. The examined areas showed variation in the absorption coefficient, correlating with increased vascular activity and cellular proliferation. Additionally, the reduced scattering coefficient demonstrated variations, suggesting alterations in the skin's collagen structure.

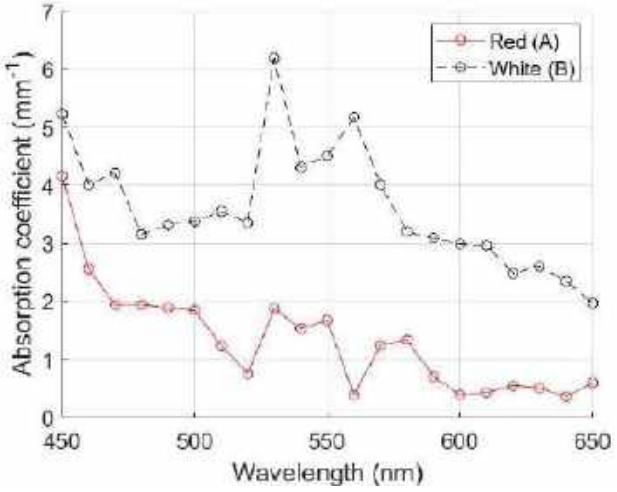

Figure 2: Absorption Coefficients Variability within same Mice Tissue Samples at Various Wavelengths. This graph displays the absorption coefficient (mm^-1) across wavelengths ranging from 450 nm to 650 nm for two distinct areas of the same tissue sample. Area Red (a) and White (B) demonstrate significant variability in absorption, indicating heterogeneity in biological processes such as vascularization. This intra-sample variation underlines the complexity of the wound healing process and may inform the development of localized treatment strategies.

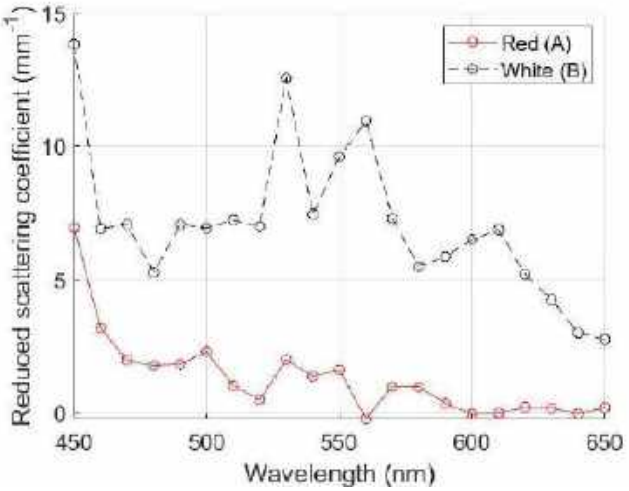

Figure 3: Intra-sample Variance in Reduced Scattering Coefficients of Healing Tissue. The graph depicts the reduced scattering coefficient (mm^-1) across wavelengths from 450 nm to 650 nm for two different areas within the same tissue sample undergoing wound healing. The Red (A) area shows a markedly lower scattering coefficient compared to the White (B) area, suggesting a denser and possibly more organized tissue structure in Red (A). The disparity between the two areas underscores the non-uniform nature of tissue regeneration and could be indicative of different stages or qualities of healing within the tissue sample.

DISCUSSION

The observed variability in the absorption and reduced scattering coefficients within distinct areas of the same tissue sample elucidates the heterogeneous nature of wound healing. The Red (A) area's lower scattering coefficient suggests a more orderly tissue matrix, likely indicative of advanced healing stages characterized by organized collagen deposition. Conversely, the White (B) area exhibits higher scattering, potentially reflecting an earlier healing phase with less organized tissue structure.

The absorption coefficient differences signal varying degrees of chromophore presence, such as hemoglobin, within the tissue, hinting at differential vascularization levels. The Red (A) area's increased absorption could correlate with heightened vascular activity, a vital component of the proliferative phase of healing, supplying the wound with necessary nutrients and oxygen. These distinctions emphasize the complexity of the wound healing continuum, where multiple phases co-exist within a single wound milieu.

These findings underscore the need for a nuanced understanding of wound healing, advocating for a tailored approach to treatment. Current therapeutic strategies may benefit from being adapted to the localized conditions of wound sites, aligning interventions with the specific healing stage evident in each area.

Future investigations should focus on a longitudinal analysis to track these biophysical parameters over time, providing insight into the temporal dynamics of wound healing. Correlating these optical characteristics with histological and molecular markers will also be paramount to confirm the physiological processes driving the observed data. Such multidimensional analysis might reveal critical insights, potentially translating into more effective, personalized wound management strategies.

LOW BACK PAIN TREATMENT OPTIONS BASED ON STATISTICAL SHAPE MODELS: SPINAL DECOMPRESSION SURGERY VERSUS NON-OPERATIVE

Mary Foltz (1), Alexandra Seidenstein (2), Amit Jain (2), Jill Middendorf (1)

INTRODUCTION

Low back pain is a pervasive issue affecting approximately 28.9% of the US adult population [1]. A significant portion of these individuals have compression of the neural structures. The precise compression of these neural structures is not well understood. Treatment options to decrease pain include spinal decompression surgery and non-operative options, with subjective clinical guidelines. Patient-specific indicators may help to inform on optimal treatment. Current evidence points to patient-specific factors such as smaller spinal cord cross-sectional areas and facet joint angles that may occur in patients with spinal stenosis [2,3]. However, these factors as well as other standard clinical measures do not fully explain the differences.

Previously, statistical shape models (SSMs) have been used to identify patient-specific variations within the lumbar spine [4]. These models have identified and shown variations in curvature and vertebral body sizes that are difficult to identify. To our knowledge, the SSMs have not been used to distinguish between patients indicated for spinal decompression surgery and non-operative treatment options.

Additionally, the shape variations identified from SSMs can be incorporated into finite element models of spinal decompression surgeries. Finite element analysis can assess how patient-specific geometries affect the biomechanical factors contributing to adverse post-surgical outcomes. Targeting the patient-specific geometries could help to determine the best treatment option based on key patient-specific variations.

Therefore, this study aims to determine differences between patient-specific geometries associated with individuals recommended for spinal decompression surgery compared to non-operative treatment.

METHODS

In this study, we used a sample of an open-access Lumbar Spine MRI dataset collected from 515 patients with symptomatic back pain [5]. We analyzed two MRI slices (mid-axial and mid-sagittal planes), from 21 randomly selected vertebral regions. Each axial MRI slice was chosen such that the slice passed through the center of the facet joint and the intervertebral disc. Then, an orthopaedic spine surgeon (AJ) used axial and sagittal MRIs to classify a patient as recommended for a spinal decompression surgery or a non-operative approach.

We used a previously published customized SegNet algorithm for lumbar spinal anatomy to automatically segment out the 21 images [5]. Specifically, we extracted the disc and posterior elements in the axial images and used a custom code to extract mathematical (automatically) and anatomical (manually) landmarks (Figure 1). Mathematical and anatomical landmark points were then used to compare the regions.

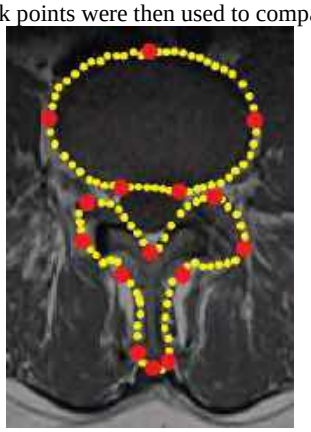

Figure 1: Sample axial MRI with anatomical (red, large circles) and mathematical (yellow, small circles) landmark points.

Two anatomical landmark points (posterior left disc and spinous process tip) were used to align regions. We calculated the average shape and covariance matrix. From the covariance matrix, we calculated the eigenvectors, eigenvalues (λ), and weighted matrix. The principal components (PCs), variance (λ), and weights were extracted and

evaluated for the 95% explained variance to ensure a comprehensive representation. Square-root of the variance represented the standard deviation for each PC. The percent of total image explained by a given principal component was determined by dividing a PC's standard deviation by the sum of all standard deviations. The number of standard deviations away from the average was then calculated by normalizing an image's weight by the standard deviation of the PC. Differences between these normalized weights were separated into surgically indicated and non-operative groups for comparison.

RESULTS

The statistical shape model can be used to understand variations in the shapes. This model discovered a total of 20 PCs shapes. The first 13 PCs represented over 95% of the shape variance, therefore consistent with other SSM approaches only the first 13 PCs were considered in this analysis. Of these 13 PCs, the first 4 PCs account for 55% of the total standard deviation (Figure 2). PCs with lower numbers always account for a higher percentage of the total shape variation.

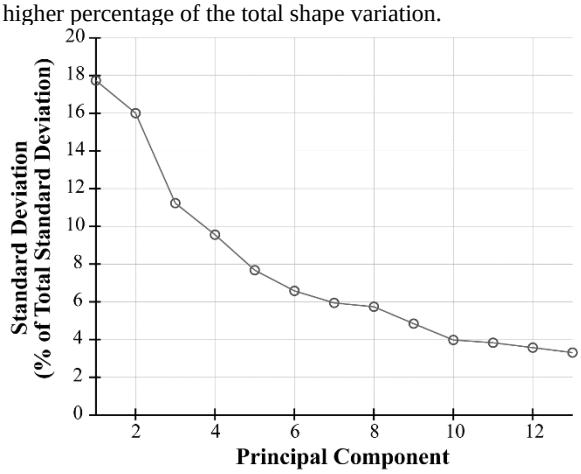

Figure 2: Percent of Total Shape Standard Deviation accounted for by a given Principal Component.

When the weights of each PC are split between surgically indicated and non-operative groups, there was no difference observed for most PCs (Figure 3). However, PC4 shows a trend toward a difference between surgically indicated and non-operative groups. PC5 through PC13 were analyzed but the data was not shown for clarity.

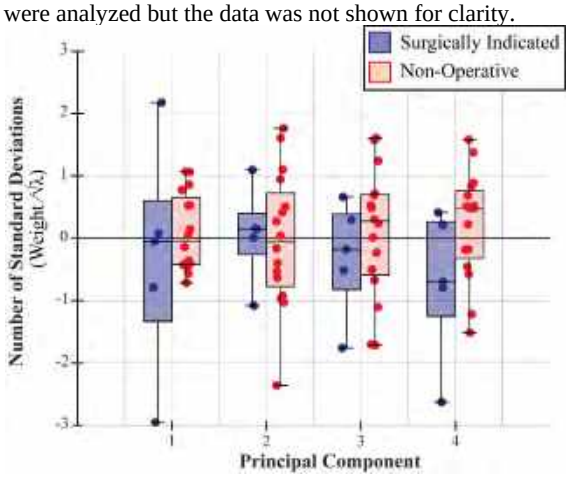

Figure 3: Principal Components for those surgically indicated (blue) and non-operative (red) treatment options.

A visual representation of the standard deviation of a PC can help indicate how the spinal shape varies (Figure 4). An increase in PC1 appears to increase the size of the intervertebral disc region and narrow the posterior elements. PC4 has a subtle change that appears in the gap between the facet joint and the intervertebral disc. This gap decreases slightly in the surgically indicated group.

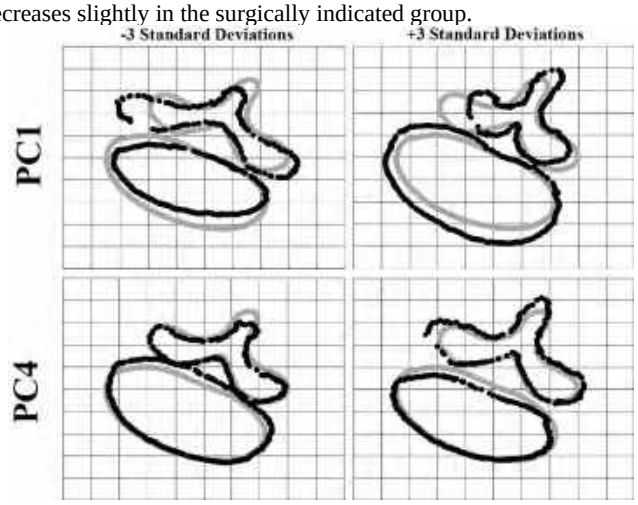

Figure 4: Average Statistical Shape (in gray) with -3 and +3 standard deviations on the left and right, respectively: PC1 (top row, black), PC4 (bottom row, black).

DISCUSSION

In our current analysis, a comprehensive examination of spinal element shapes revealed no discernible differences between those surgically indicated and non-operative groups. This lack of differences most likely means that all spinal variations in patients with low back pain must be considered for biomechanics analysis of spinal decompression surgeries. However, there did appear to be a trend with PC4, which visually indicated a decrease in the gap between the intervertebral discs and facet joint regions. This decrease in gap space is to be expected since foraminal space decreases during stenosis [2].

This study provides an initial dive into studying these axial images, and there are some limitations. First, we took an overarching look at the images, and we need to reveal additional patterns (i.e., spinal level, region specifics, anatomical structures). Second, only 5 surgically indicated cases were included. This underscores the need for continued research and refinement of our analytical approaches to capture the intricacies of patient-specific geometry that may relate to biomechanics and patient-specific treatment options.

Nevertheless, the results shown here provide evidence to support the use of SSM in identifying differences between spinal shapes associated with lumbar spinal decompression surgeries and non-operative treatments. Applying this approach could prove useful for developing a more comprehensive understanding of spinal element shapes and their potential impact on biomechanics.

INTRODUCTION

Preeclampsia (PE), a hypertensive disorder of pregnancy, is one of the leading causes of infant and maternal death worldwide [1]. Currently, most treatments focus on mitigating maternal symptoms, including increased blood pressure and seizures [1]. However, the only definitive treatment is delivery, but even that is not perfect. PE causes increased long term risk of hypertension, stroke, and heart disease for both the mother and the child [2]. Preterm delivery causes increased likelihood of other complications for the infant, including diabetes and neurodevelopmental impairments [3]. Despite the dangers of this disorder, the root cause is not fully understood due to it being a complex multi-system pathology.

One of the hallmarks of PE is angiogenic dysfunction. One cell line affected by PE that may play a role in this dysfunction is Endothelial Colony Forming Cells (ECFCs), a type of endothelial progenitor cell that supports new vessel development and homeostasis. ECFCs have been seen to be influenced by *in utero* diseases and have therapeutic potential with vascular disorders [4, 5]. In this study, ECFCs isolated from umbilical cord blood were used to understand the phenotypic and genetic differences between healthy and preeclamptic ECFCs (PRECs).

METHODS

Human ECFCs and PRECs were isolated from cord blood samples with a variety of gestational ages. These cells were provided through clinical trials by members of the Indiana University School of Medicine, Dr. Laura Haneline and Dr. David Haas. ECFCs and PRECs were stained for endothelial markers including CD31, CD144, and Von Willebrand factor (vWF).

Angiogenic potential was assessed using a Matrigel tube formation assay and quantified using the plugin Kinetic Analysis Vasculogenesis (KAV) [6]. Flow cytometry and FlowJo were used to quantify EdU and DNA content stains for cell cycle analysis. To assess migration, a wound healing assay was imaged every hour for 24 hours with changes in area calculated using a protocol by BioTek Instruments. For senescence, passage 12 cells were fixed and stained based on Abcam's protocol for the Senescence Detection Kit. Cytokine secretion was assessed using R&D Systems Proteome Profiler Human Angiogenesis Array Kit and Proteome Profiler Human Cytokine Array Kit. The samples were quantified using ImageJ.

Four biological replicates selected for preeclamptic and healthy ECFCs (n=3) Real-time qPCR was performed for *LYVE-1, Prox-1,* and *GAPDH* in addition to the TaqMan Array Human Angiogenesis Panel. Statistical analysis was done with GraphPad Prism. Student's t-test or ANOVA was used to compare ECFCs and PRECs.

RESULTS

To better understand how PE affects tube formation, cells were seeded onto Matrigel and allowed to grow for 9 hours. The ECFCs formed clear, organized networks **(Fig. 1A)**, while the PRECs tended to have more cells clumping together and incomplete loops **(Fig 1B)**. When quantified using KAV, network area, an indicator of morphological shifts, was decreased in PRECs compared to their healthy counterparts **(Fig. 1C)**. Together, this indicates that the PRECs exhibit lower angiogenic potential than ECFCs.

Proliferation was assessed through cell cycle analysis. Cells were stained with EdU to identify cells in the S-phase and PI/RNAse for DNA content. The PRECs have less cells in the G0/G1 phase and more cells in the S-phase, indicating that they are more proliferative **(Fig 2A)**. Other *in utero* diseases affect migration indicating PE may also have an effect [4]. Therefore, migration was assessed using a wound healing

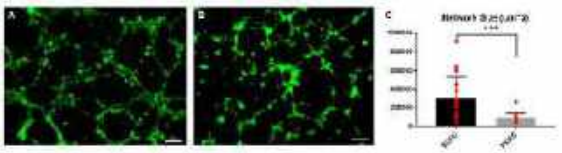

Figure 1: Angiogenic potential of (A) ECFCs and (B) PRECs. KAV was used to quantify the (C) network size ***p < 0.001. Scale bar = 250 µm.

assay. ECFCs closed the wound sooner than the PRECs **(Fig. 2B)**. Finally, passage 12 cells were stained for senescence. While passage 12 is higher than was used for other experiments, it is a lower passage than when a more senescent population is expected. PRECs had a higher percentage of senescent cells compared to the ECFCs **(Fig. 2C)**.

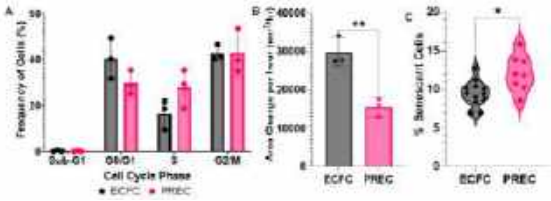

Figure 2: (A) Proliferation was examined using cell cycle analysis. (B) A wound healing assay was used to quantify migration. (C) Senescence was investigated using a β-gal assay. *p<0.05, **p<0.01. Scale bar = 1000 µm

Since PE is a hypoxic disorder, inflammatory cytokines were evaluated. A proteomics assay showed that PRECs see an increase in CXCL1/GROa, IL-8, and MIF and a decrease in Serpin E1 **(Fig. 3A)**. These were not significant due to high variability between biological replicates. PRECs cause a noticeable dysregulation of angiogenesis associated proteins **(Fig. 3B)**. Serpin E1 and IL-8 followed the same pattern as previously seen. Urokinase plasminogen activator (uPA) was downregulated as expected as it is inhibited by Serpin E1. FGF basic and MCP-1 were noticeably upregulated and Pentraxin 3 was downregulated, but there was no statistical significance due to high variability between biological replicates.

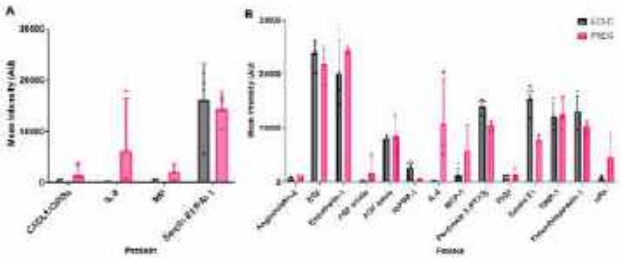

Figure 3: Proteomic analysis of ECFCs and PRECs for (A) inflammatory and (B) angiogenesis associated proteins.

To better understand this functional shift, a 94 gene angiogenesis PCR panel was run with four ECFC and PREC cell lines. Fibulin 5 (*FBLN5*) and proto-oncogene, receptor tyrosine kinase (*KIT*) were significantly upregulated with fold change greater than 2 **(Fig. 4A)**. These genes influence vessel sprouting, proliferation, and migration. In addition, some lymphatic associated genes were upregulated in PRECs compared to ECFCs. Lymphatic vessel endothelial hyaluronan receptor 1 (*LYVE-1*) was increased in PRECs compared to ECFCs and lymphatic endothelial cells (LECs). However, it was not statistically significant due to high variability between biological samples. Prospero homeobox protein 1 (*Prox-1*), the "master regulator" for lymphatic markers, was seen to be significantly upregulated as well **(Fig. 4D)**.

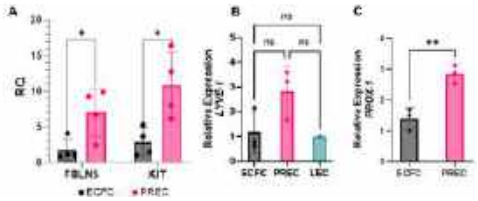

Figure 4: (A) Fold change for *FBLN5* and *KIT*. Four biological replicates were used for ECFCs and PRECs (n=3). PCR was for (C) *LYVE-1* and (D) *Prox-1*. GAPDH was used as an endogenous control. Three biological replicates were used for PRECs, ECFCs, and LECs (n=3). **p<0.01, and *p<0.05

DISCUSSION

As a result of PE, PRECs exhibit increased proliferation and senescence while tube forming ability and migration are decreased. The increased proliferation may be compensatory for the premature senescence. While functional changes are to be expected, ours do not align exactly with other studies as no additional growth factors were added during our experiments. These functional changes indicate what genetic pathways should be explored.

Therefore, angiogenesis associated genes and proteins were investigated. Serpin E1 was decreased and IL-8 and uPA were increased in PRECs compared to ECFCs. Serpin E1 and uPA play a role in extracellular matrix degradation, which could cause changes in soluble factors. *FBLN5* and *KIT* were also found to be upregulated in PE. These genes play a role in proliferation, angiogenic sprouting, and migration [7,8]. Together these findings support the functional changes previously seen. In addition, inflammatory proteins production was primarily increased in PRECs. Higher inflammatory response could lead to excessive activation of the immune system. Lymphatic associated genes *LYVE-1* and *Prox-1* were also increased in PRECs. This may mean that the PRECs are experiencing lymphatic mimicry.

Overall, these experiments indicate specific genes and pathways to explore further. One limitation of this study is that PRECs were from more mild PE cases based on gestational age. More severe cases may see other genes or proteins dysregulated.

Collectively, these results provide insight into PE at the cellular level and provide potential biomarkers. In addition, these genes and proteins could be targeted to restore angiogenic potential in PE and improve the health of infants born from preeclamptic pregnancies.

LOW STRAIN RATE CYCLIC LOADING AND RECOVERY EFFECT ON THE FATIGUE PROPERTIES OF THE ANTERIOR CRUCIATE LIGAMENT

Peter M. Kuetzing (1), Ulrich M. Scheven (1), Ellen M. Arruda (1,2,3)

(1) Mechanical Engineering, University of Michigan, Ann Arbor, MI, USA

INTRODUCTION

Anterior Cruciate Ligament (ACL) injury affects a wide demographic of athletes, spanning from professional to youth sports, plaguing an estimated 34 per 100,000 residents in the United States alone each year and disproportionately affecting females aged 12 to 17 [1]. Progress in understanding ACL failure mechanics is slowed by the hierarchical structure of collagen, complex ligament-bone insertion site, and non-uniform cross-section. Recent advancements in full-field methods and constitutive modeling have provided insight into static loading conditions [2]. However, the mechanism of fatigue and its role in ACL failure has remained illusive.

During gait, the ACL is loaded in tension when counteracting anterior tibial translation (ATT) and internal rotation brought on by contact between the femoral condyles and tibial slope. The estimated physiological strain that resembles walking is approximately 5% at 1 Hz [3]. The ACL may see considerably higher strain rates through actions like jumping. Repeated heal striking on cadaveric knees at forces 4 times body weight have been shown to cause ACL failure in under 70 cycles [4]. However, ACL failure often occurs from a single high strain event. This may be attributed to a reduction in the ACL failure criterion threshold caused by the culmination of many smaller fatigue cycles. Our goal was to probe the effects of low strain rate fatigue, akin to walking, the effect of recovery times between sets of loading cycles, and the loading history on ACL mechanics.

METHODS

Ovine knee morphology is anatomically comparable to that of a human knee and has widely been used to study ACL mechanics [5]. We procured ovine legs (n=24) which encompassed the intact knee joint, tibia, and femur from 12 separate animals. The left and right legs of each animal were purchased from a local butcher at the same time. Dissection of a randomly selected knee, left or right, was completed the same day the animal was slaughtered. During dissection, the ACL was split into the anteromedial (AM) and posterolateral (PL) bundles. The bone beyond the entheses were cut to a create an AM bundle and bone complex. The isolated AM complex was soaked in 7 mL of either Polyethylene Glycol (PEG) 8% w/v (n=8), Ophthalmic Gel (OG) (n=8), or Bovine Synovial Fluid (SF) (n=8) for 12 hours and stored at 4°C during that time. The following morning, the complementary leg was dissected, its AM complex extracted and soaked in the same solution type in an identical manner.

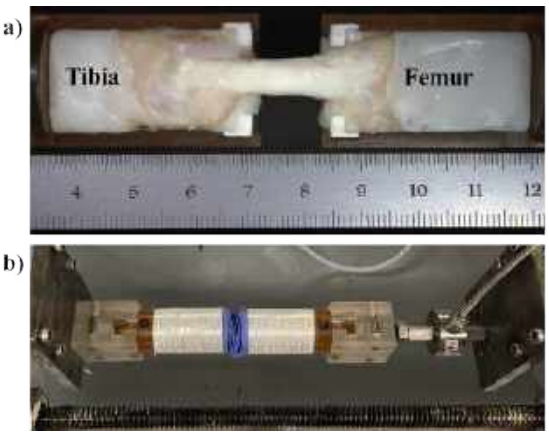

Figure 1: Experimental Setup: a) AM bundle and bone complex in the bottom half of the custom clam shell pots, b) Enclosed sample, hermetically sealed with nitrile sleeve and fiber reinforced tape.

The AM bundle and bone complex was affixed in custom clam shell pots which held the bone fixed and allowed the ligament to expand freely (Figure 1a). The gauge length, defined as the central region of straight fibers before splay into the enthesis occurs, was determined using ImageJ which became the basis for calculating 5% strain. The AM bundle was then covered with a nitrile sleeve and the edges sealed with fiber reinforced tape to create a hermetically sealed environment to reduce drying out (Figure

1b). The nitrile sleeve was left empty (n=12) or filled with 5 mL of the same soak solution type (n=12) for the duration of mechanical testing.

Each AM bundle was fatigued by displacement controlled uniaxial tension for 8 sets of 60 cycles, each at 5% strain and 1 Hz, for a total of 480 cycles in an ADMET Micro Tester. Breaks, referred to as recovery times, of varying duration were taken between fatigue sets while the AM complex remained unloaded. After an initial baseline experiment of 60 cycles, the duration of recovery times of the first of the animal's AM bundles increased from 1, 2, 4, 8, 15, 30, to 60 minutes between sets. Conversely, the duration of recovery times of the second of the animal's AM bundles decreased from 60, 30, 15, 8, 4, 2 to 1 minute between sets. Ultimately, a total of 192 sets of 60 cycles were measured. At the onset of each set, the ligament was loaded to 0.5 N to ensure fiber engagement prior to loading. Load and displacement data was analyzed in MATLAB.

RESULTS

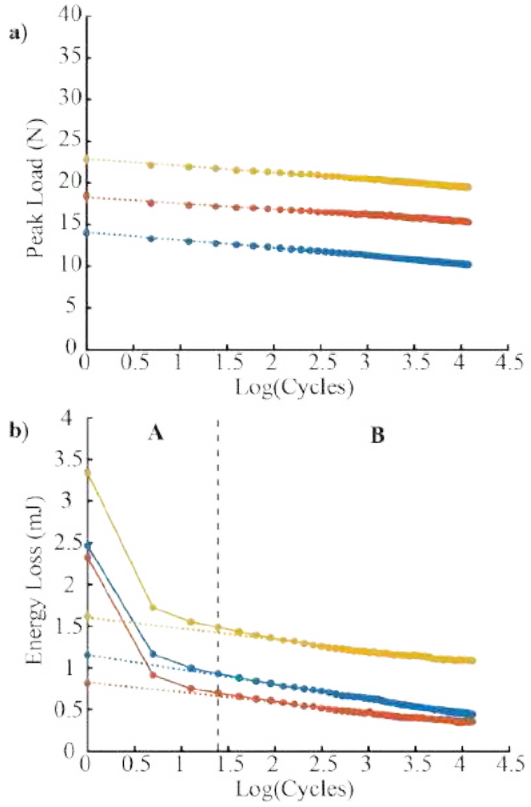

Figure 2: Data from three representative samples. a) Peak Load versus Log(Cycles) with linear fit of cycles 1 through 60, b) Energy Loss versus Log(Cycles) with linear fit of cycles 4 through 60 and two regions, labeled A and B.

The peak loads of each cycle per 60-cycle set were linear when visualized on a semi-log plot (Figure 2a). This was further confirmed by a chi-squared statistic close to one. The energy loss of each cycle per 60-cycle set fell into two distinct linear regions, A and B (Figure 2b). The first region was marked by a significant energy loss drop over the first three cycles. The second region began by the fourth cycle and continued to the end of the test. Moreover, this dual region phenomenon was present in each 60-cycle set irrespective of recovery time duration. As expected, the greatest energy loss occurred in the first cycle and decreased due to the viscoelastic nature of collagen [6]. This energy loss was often two and half times greater than the energy loss of the fourth cycle while the difference between the fourth and 60th cycle's energy loss is considerably less. The energy loss increased as the AM complex was subjected to more cycles, although the difference between the energy loss from the 1st and 4th remained roughly the same. These results were consistent and observed for all samples (n=192).

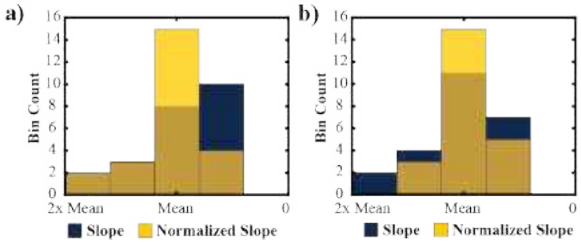

Figure 3: Histograms from baseline fatigue sets (n=24) of the linear fit slopes and normalized slopes for a) Peak Load vs. Log(Cycles), cycles 1 through 60, and b) Energy Loss vs. Log(Cycles), cycles 4 through 60.

The distributions of measured slopes (n=24) for peak force and energy loss are plotted (Figure 3a, 3b). The width of these distributions is affected by intrinsic materials properties and by the geometric variability of our samples. In order to separate the two, the values of the slopes were divided by the back extrapolated y-intercept (symbol ⧫ in figure 2). Figure 3 shows the distribution of slopes before division and after. The distributions of slopes normalized by the intercepts ⧫ are observed to be narrower and more uniformly distributed than those found in the raw data.

DISCUSSION

There are two distinct linear regions of energy loss, A and B (Figure 2b), which persist with all independent variables. The large energy dissipation seen in Region A may indicate the presence of a macroscale injury prevention mechanism through collagen fibril uncrimping during tensile deformation [6].

The ACL has a highly irregular geometry, is anisotropic, and may have nonuniform fiber engagement during loading. Furthermore there is considerable variability in the overall geometry of samples used in this study. Therefore, a dimensionless fatigue parameter was calculated by dividing the slopes of linear fits in figure 2 by the y-intercept of those fits. This enabled a quantitative comparison of fatigue parameters of samples having variable geometries. Previous data published from this lab indicated that the MCL, whose splay is less severe than the ACL, has greater energy loss in the entheses as opposed to the mid-section [7]. Future work will leverage the optical images of each specimen (n=24) to further explore the effects of geometrical factors on normalization.

INTRODUCTION

Atrial fibrillation (AFib) is an irregular rhythm disorder in the upper chambers of the heart, affecting millions of people worldwide, and has a high risk of stroke [1]. While personalized modeling of the electrical activity in the left atrium (LA) has been instrumental in targeted ablation [1], a personalized electromechanical model of LA plays a vital role in understanding the mechanisms for clot development, assessing the risk of stroke, and planning treatment. However, unlike the left ventricular myocardium, the LA myocardial electromechanics remains relatively less studied. This is partly attributed to the scarcity of data on atrial thickness, myofiber orientation, and robust cellular activation models. Here, we introduce a workflow to model the electromechanical interactions in an LA model derived from time-dependent image data. Our robust workflow incorporates machine learning-based segmentation and model creation, an efficient optimization framework to extract passive mechanical parameters, and a recently developed implicit modular approach to couple the 3D LA myocardium model with a zero-dimensional (0D) lumped parameter network (LPN) model of the circulatory system. This workflow will be a stepping stone toward developing a multiphysics model of LA, coupling electromechanics and blood flow, to study AFib and stroke.

METHODS

Our workflow begins with constructing an LA myocardium from a patient's time-resolved 3D CT data (**Fig. 1**). Clinical data acquired include cuff blood pressures and electrocardiogram (ECG) waveforms (**Table 1**). Subsequently, we employ a deep neural network-based whole-heart mesh reconstruction framework [2] to segment the LA blood pool, and extract lumen volumes and nodal displacements at select landmarks during the cardiac cycle. We then choose the segmented LA during its relaxed state (early systole, ~20%R-R) and prescribe a uniform thickness (~2mm) to construct the LA myocardium [3]. Further, we follow a Laplace-Dirichlet rule-based approach to prescribe myocardial fiber directions [4].

Table 1: Clinical characteristics of a healthy subject

Item	Blood pressure	Heart rate	PR interval	QRS duration	QT (ms)
Value	98/53 mmHg	87 BPM	182 ms	88 ms	384 ms

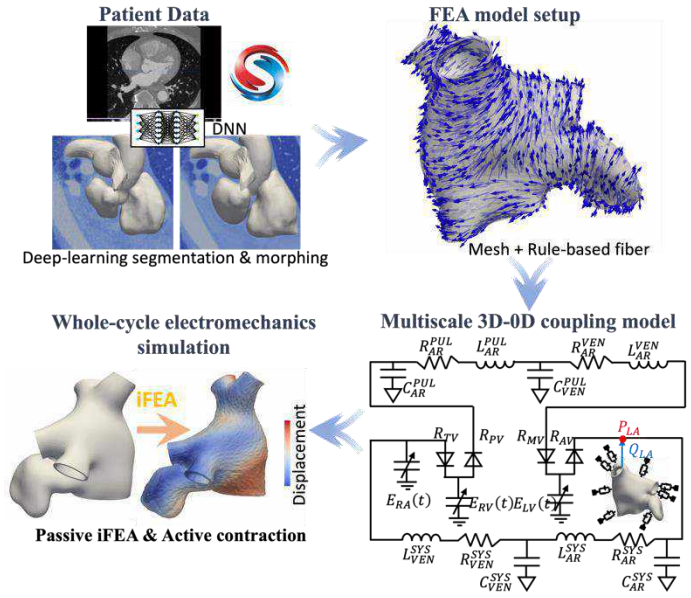

Figure 1: Workflow for LA electromechanics modeling. FEA model is segmented from the patient CT data using neural newtorks. A multiscale coupled 0D/3D model is personalized to simulate LA electromechanics.

Subsequently, we employ a differential evolution algorithm to estimate the parameters of the closed-loop LPN model [5] to match the clinical targets, including the min/max aortic pressures and the four-chamber volumes. The LPN incorporates a surrogate model of the LA with time-varying elastances to model the pressure-volume (PV) relations of all the four chambers (left/right ventricle/atrium), assemblies of capacitor-resistor-inductor to model the circulatory system, and diodes to model the cardiac valves.

We conduct inverse finite element analysis (iFEA) with a novel multilevel optimization scheme to extract passive material properties of the LA myocardium. Our iFEA scheme [6] includes an outer loop iterating on constitutive model parameters to match image-based LA volumes and local nodal displacements during passive expansion. The inner loop estimates a reference stress-free configuration using Sellier's algorithm, considering a set of material parameters and pressure load set by the outer loop. The pressure profile during LA passive expansion is obtained from the tuned LPN model. This process enables extraction of patient-specific LA material properties fitting time-dependent, image-based LA topology under personalized pressure loads.

In each forward FEA simulation during iFEA iterations, we apply physiologically relevant boundary conditions, including Robin boundary conditions, to model tissue support on pulmonary veins, the mitral valve plane, and the epicardial surface, and LPN-based hemodynamic pressures. We employ the Holzapfel-Ogden (HO) material model with a viscous component as the constitutive model for the passive myocardium, and a stabilized FEA solver to simulate the passive nonlinear elastodynamics equations [7].

We now focus on tuning the active component of the myocardium. We replace the tuned surrogate model of the LA with the 3D model, coupled to the rest of the 0D LPN model. The coupling between the 3D and 0D models is achieved using our recently developed, modular, implicit method [8]. Briefly, at each time step, the pressure and flow rates are iteratively exchanged between the 3D and 0D solvers until convergence, taking into account the resistance induced by the 0D fluid on the 3D solid model. This additional resistance is critical to ensure smooth convergence and resolve isovolumic phases (for ventricles). We assume an active stress model to couple the atrial myocyte excitation with the tissue deformation. We then adjust the active stress parameter to fit the volume change during atrial contraction. We employ the Nygren model [9] to simulate the local myocyte dynamics, coupled to an anisotropic diffusion-based monodomain model to simulate the propagation of the transmembrane potential across the myocardium. An efficiently implemented implicit-explicit (imex) scheme with operator-splitting is employed for time integration, while FEA is used to resolve spatial diffusion. Numerics for mechanics and electrophysiology are implemented in our multi-physics FEA solver, svFSI [10].

RESULTS

Table 2 shows the best-fit passive material parameters of the LA myocardium.

Table 2: Best-fit passive material parameters of the LA.

Parameter	a **(Pa)**	b	a_f **(Pa)**	b_f
Value	25.3	8.24	41400	17.9
Parameter	a_s **(Pa)**	b_s	a_{fs} **(Pa)**	b_{fs}
Value	287	15.9	216	11.4

Fig. 2 shows the results of iFEA (**Fig. 2A**) and the simulated 3D-0D coupled LA model across six cardiac cycles (**Fig. 2B-C**). Notably, both the LA and LA appendage (LAA) experience substantial contraction and expansion during the heart cycle (**Fig. 2B**), along with physiological pressure-volume (PV) loops and the activation map (**Fig. 2C**). Our model captures the classic "8"-shaped atrial PV loop, comprising the active "booster" pump, reservoir, and conduit functions.

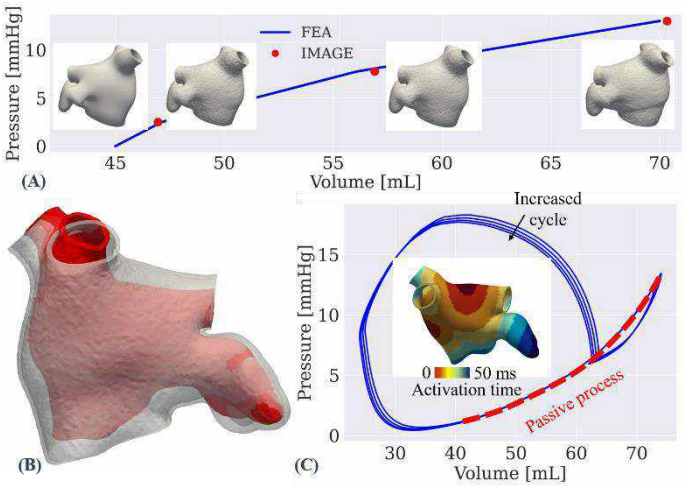

Figure 2: Results of (A) iFEA optimized PV-relation during passive atrial filling and comparison against image-based measurements and (B-C) the 3D-0D coupled simulation for six cardiac cycles. (B) LA model at the most contracted (red) and fully expanded (gray and transparent) states. (C) PV loops for the LA.

DISCUSSION

This work demonstrates a proof-of-concept development of a personalized modeling framework that tightly integrates phase-resolved image data and other clinical measurements with a comprehensive electromechanical model of LA , coupled to a closed-loop LPN model of the cardiovascular system. Our robust framework employs machine learning to automate segmentation, versatile optimization methods for characterizing passive mechanical properties, and efficient and modular coupling between the 3D and 0D models. The method was demonstrated to resolve the physiological mechanical response of the left atrium.

To assess the senstitivity of certain assumptions in our model, we will compare the effects of different fiber generation methods, the assumption of uniform thickness, and extend the analysis to multiple patients. We will explore using machine learning methods such as the graph neural network to design emulators that can substantially accelerate iFEA for characterizing LA passive mechanics.

By laying this groundwork, the research paves the way for developing comprehensive multiphysics computational models integrating myocyte dynamics with tissue deformation, blood flow, and potentially, the blood coagulation cascade. This enables us to quantify the role of electromechanical disruptions during AFib on the changes in blood flow, leading to clot development. Ultimately, this may lead to better assessment of the risk of stroke in AFib patients, and develop individual treatment strategies.

INTRODUCTION

Intracranial aneurysms (IAs) are known to have a strong correlation with hemodynamic stress[1, 2]. Previous studies have considered the associations between fluid dynamic parameters and rupture status. However, failure is a local phenomenon and it is known that even ruptured aneurysms can have regions of "healthy wall"[3, **?**]. There is a need for studies that consider local flow and local wall conditions. In this regard, local collagen architecture and local flow have been previously co-mapped [4, 5]. Recently, we have introduced a new imaging pipeline that makes it possible to compare local wall pathology and hemodynamics of IA[6]. The current study utilizes this platform to compare SMC actin and hemodynamics, providing novel insights into the relationship between local IA pathology and blood flow.

METHODS

Two IA dome specimens (one unruptured and one ruptured) were harvested during surgery at Allegheny General Hospital (Pittsburgh, PA) and fixed in 4% paraformaldehyde. The patients were a 61-year-old female and a 60-year-old male with IAs of 7 mm and 8.9 mm, respectively. The specimens were stained with monoclonal mouse anti-human smooth muscle actin clone 1A4 IgG2a antibody (Dako, Denmark) and Alexa Fluor 488 goat anti-mouse IgG2a (Invitrogen, USA), both diluted to a 1:100 ratio with 1% normal goat serum. The stained samples were scanned with a multiphoton microscope (Nikon A1R MP HD, Tokyo, Japan) and reconstructed with IMARIS 10.1.0 (BitPlane AG Zurich, Switzerland). The scanned SMA images were analyzed and categorized into three types: high density (Type 1), low density (Type 2), and no signal (Type 3) using cluster analysis presented previously [6]. Hemodynamic analysis was performed using the techniques described in [7]. The simulation was performed for 2 cardiac cycles with a timestep of 0.01 seconds. The volumetric meshes were composed of tetrahedral elements with a minimum resolution of 200 um. Critical points within the wall shear stress (WSS) vector field were detected, counted, and averaged over the cardiac cycle. The vortex core line was derived using the previously described technique [8].

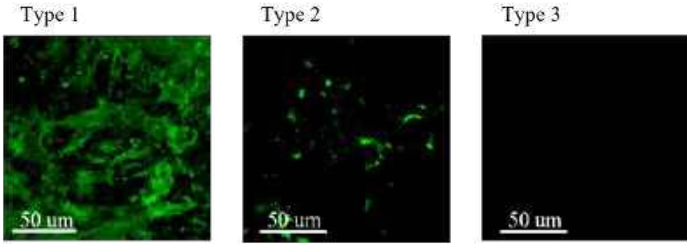

Figure 1: Categories of wall region based on smooth muscle cell actin density

RESULTS

Figure 2 presents the results of the SMA signals from MPM, cluster analysis, and hemodynamic analysis for Case 1 and Case 2. The MPM results reveal that the αSMA signals appear as two large islands in Case 1 and as small scattered islands in Case 2. The distribution of SMA Types 1, 2, and 3 are 59%, 15%, and 26% in Case 1, and 17%, 53%, and 30% in Case 2, respectively. In Case 1, the sample is segmented into four regions: Region A, the top left quadrant with Type 1 SMC; Region B, the right half of the sample with Type 1 SMC; Region C, the left bottom quadrant with Type 3 SMC; and Region D, the area between Regions A and B with Type 3 SMC (as shown in Fig.1(b-i)). In Case 2, the sample is divided into three regions: Region A, the left bottom area with Type 2 SMC; Region B, the top right area with Type 2 SMC; and Region C, the middle strip with Type 3 SMC (as shown in Fig. 1(b-ii)). In terms of hemodynamics in Case 1, region A was exposed to very high WSS (>100 dynes/cm^2) with zero OSI. Region B experienced high WSS (>35 dynes/cm^2) with high OSI.

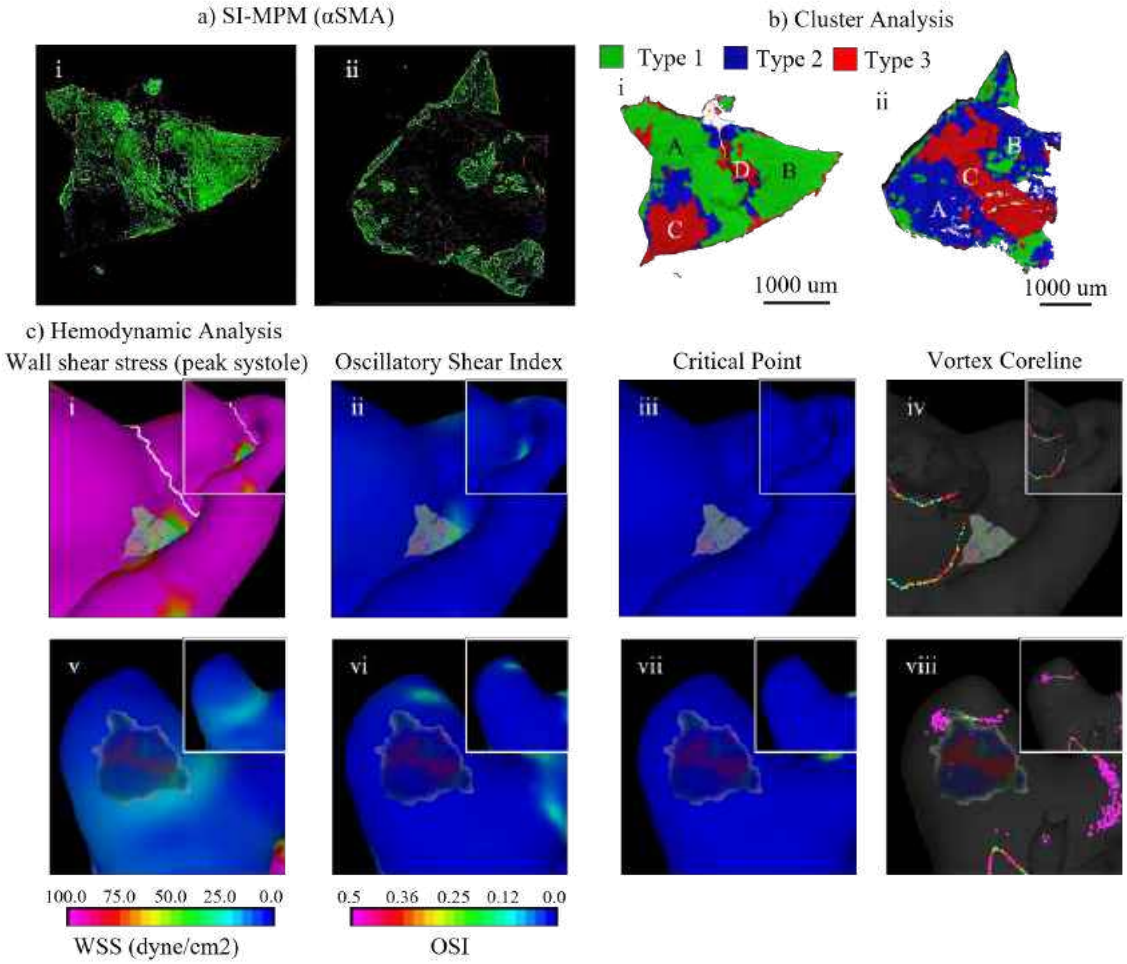

Figure 2: Comparison of smooth muscle cell actin types and hemodynamic parameters

Region C was exposed to very high WSS with zero OSI, similar to Region A. Region D was exposed to a high spatial WSS gradient. In Case 2, region A experienced normal WSS (15-20 dynes/cm^2). Region B was exposed to low WSS (<15 dynes/cm^2), and region C had normal WSS (around 15 dynes/cm^2). All three regions had zero OSI. No critical point or vortex core line was present in either Case 1 or Case 2.

DISCUSSION

Previous hemodynamic studies have proposed that both high and low WSS, along with OSI can instigate maladaptive remodeling of IA wall [9, 1]. Here we explore one crucial feature needed for remodeling, namely, viable SMCs. In Case 1, despite regions A and C having similar hemodynamic characteristics, we observed SMC of two extreme types: high density and no signal. Interestingly, region B, which was exposed to high WSS and OSI, only displayed high-density SMC. These observations imply that the majority of the IA wall in Case 1 was robust to extreme flow conditions, aligning with the fact that this case remains unruptured. In Case 2, despite flow conditions being close to those observed in non-pathological cerebral arteries, the SMC types were relatively sparse across the sample. Collectively, these two cases demonstrate some IA walls can have dense SMCs despite flow conditions that have been associated with increased rupture risk (high WSS and high OSI). A possible explanation for increased risk is that other components of the wall, such as collagen fibers, are degraded. We also demonstrated SMCs can be greatly diminished even under flow conditions that are considered "healthy". This suggests other flow parameters or mechanical factors, such as intramural stress, may be important. To draw definitive conclusions about the relationship between flow and SMCs, further studies with larger sample sizes are necessary. It is also important to consider other cell types, such as endothelial and inflammatory cells, to fully understand wall remodeling.

INTRODUCTION

Accurate anisotropic material properties of the brain are needed to improve computational models of traumatic brain injury [1]. Brain tissue is difficult to mechanically characterize, however, because it is encased within the skull and stiffens after death [2]. Magnetic resonance elastography (MRE) can noninvasively map brain material properties in humans. Furthermore, anisotropic properties can be extracted from MRE data through a new inverse-finite element (FE) method called transversely isotropic nonlinear inversion (TI-NLI) [3]. Anisotropic properties characterized by TI-NLI include shear and elastic moduli in the fiber direction (μ_1, E_1, respectively), shear and elastic moduli transverse to the fiber direction (μ_2, E_2, respectively), and degrees of shear and tensile anisotropy ($\phi = \mu_1/\mu_2 - 1$ and $\zeta = E_1/E_2 - 1$, respectively). TI-NLI has accurately mapped simulated MRE data while demonstrating reproducibility on human data [3]. However, further evaluation of the accuracy of TI-NLI is needed using phantoms with known anisotropic mechanical properties.

The purpose of this study was to design a phantom with known anisotropic properties and then test if TI-NLI can detect these properties. We designed scaled 3D printed lattices (Fig. 1a) such that, when embedded in a soft gel (Fig. 1c), the resulting composite mimics anisotropy in brain white matter ($\phi \cong$ 0–0.6, $\zeta \cong$ 0.1–1.6) [3,4]. We mechanically tested lattices and modeled composite behavior to predict phantom mechanical properties, and finally performed MRE on a phantom (Fig. 1c) and mapped anisotropic properties with TI-NLI.

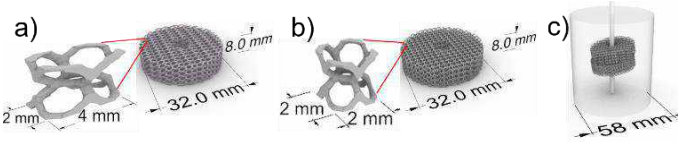

Fig. 1 a) Scaled unit cell and macrostructure; b) unscaled unit cell and macrostructure; c) illustration of phantom with actuator rod in middle.

METHODS

Design and fabrication of lattices and phantom: Previous work demonstrated that vintile unit-cell based structures with directional scaling achieve anisotropy [4]. Both scaled (anisotropic) and unscaled (isotropic) designs were tested and included in the MRE phantom. Macrostructures with 300μm strut diameters were generated in Rhino3D (TLM, Inc.) and printed with a LumenX+ DLP printer (CELLINK) using PEGDA Start PhotoInk™. Macrostructure discs of 15mm diameter × 4mm height and 10×10×10mm cubes were tested in shear and compression, respectively. The MRE phantom contained two 32mm diameter discs: one with a scaled lattice (Fig 1.a) and one with an unscaled lattice (Fig 1.b). To make the phantom, a plastic container was filled with 11 wt% gelatin (Knox) at 30°C, into which two lattices were submerged at a slight angle with a 3.2mm diameter Delrin actuator rod positioned in the middle (Fig 1.c).

Mechanical testing: Shear moduli of 3D printed lattices were determined in directions parallel (μ_1) and transverse (μ_2) to scaling direction through shear testing on a custom apparatus [4]. Elastic moduli in the principal directions E_1 and E_2 were determined from unconfined compression at 10% strain (HR 20, TA Instruments). *FE modeling:* FE models (Abaqus) simulated shear and unconfined compression in 14 separate cases to predict shear and elastic moduli for lattices and lattice-gel composites, using experimentally determined linear elastic E = 3 MPa for the 3D printed material, a range of stiffnesses for the gelatin matrix (E_{gel} = 11–24 kPa) and assuming ν = 0.499 for all materials. Prescribed displacement boundary condition (BC) of 1% compressive or shear strain was performed in a single linear step, assuming infinitesimal strain. Meshes used hybrid quadratic tetrahedral (C3D10H) elements; mesh refinements determined an appropriate mesh density. One symmetry BC was used in shear models while three symmetry BCs were used in compression models.

MRE experiments: MRE was performed at 400 Hz and 600 Hz on a 9.4T Bruker MRI scanner using a modified EPI sequence [5] with the

following parameters: 60x60x36 mm field-of-view; 1mm^3 isotropic voxels; motion-encoding gradients (MEG) 5 cycles at 66 mT/m for 400 Hz and 8 cycles at 132 mT/m for 600 Hz; 8 time points/period; TE/TR = 40/3600ms. Harmonic waves were induced by a central rod driven by piezo actuator (APA150NM, Cedrat) with sinusoidal voltage (LA75C amplifier, Cedrat; 40V amplitude). T1 and T2 images were collected. Sample temperatures ranged from 20–24°C before and after testing.

MRE analysis: Masks were applied to isolate the phantom volume. Phase wrapping was removed from displacement data (FSL PRELUDE, FMRIB). T1 images visualized lattices and ITK-SNAP software was used to identify the principal fiber direction of the scaled lattice for input to TI-NLI. TI-NLI mapped anisotropic properties μ_2, ϕ, and ζ on the 600 Hz dataset (μ_1, E_1, and E_2 are computed from these). Distributions of properties were taken from a circular region of interest (ROI) containing lattice (or pure gelatin) within 2D slices.

RESULTS

Mechanical testing and FE modeling found that $\mu_1 > \mu_2$ and $E_1 > E_2$ for scaled lattices (Fig. 2). Simulation of composite behavior of scaled lattices predicted that as gelatin matrix stiffness increases, ϕ and ζ decreases (Fig. 3).

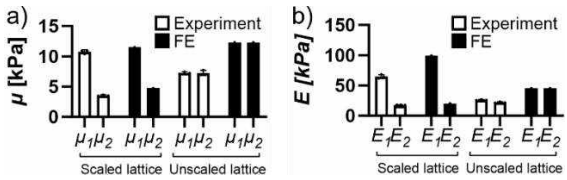

Fig. 2 Experimental results and FE predictions for a) shear modulus μ and b) compressive elastic modulus E in directions 1 (axial) and 2 (transverse) for scaled and unscaled lattices.

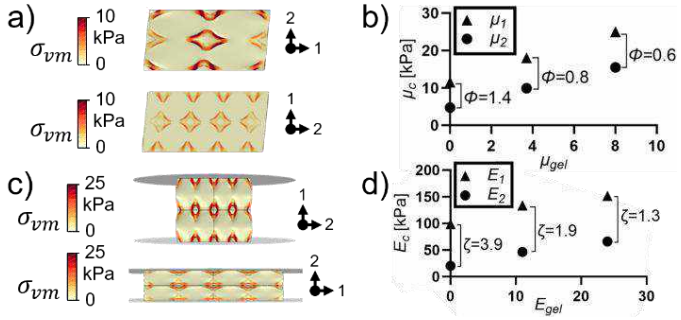

Fig. 3 FE predictions of composite behavior; a) von Mises stress (σ_{vm}) fields during shear in 1-direction (top) and 2-direction (bottom). b) Composite shear moduli μ_c for 1- and 2-directions, and resultant ϕ, for a range of gelatin stiffness μ_{gel}. c) σ_{vm} fields during compression in 1-direction (top) and 2-direction (bottom). d) Composite elastic moduli E_c for 1- and 2-directions, and resultant ζ, for a range of gelatin stiffness E_{gel}. 10× deformation scale factor shown in models.

In the MRE phantom, lattice geometries were visible in T1 images (Fig. 4.a). MRE images of displacement fields visualized elliptical waves in the scaled lattice region (Fig. 4.b). TI-NLI mapped properties in both lattice regions, which were 60–80% stiffer than the gelatin region (Fig. 4.c,f), and both lattice regions exhibited positive ϕ and ζ values, with the scaled region having the highest median ϕ and ζ of 0.7 and 0.6, respectively. Between FE composite predictions (Fig. 3) and TI-NLI results (Fig. 4) for the scaled lattice region, when assuming μ_{gel} = 8 kPa, the median properties fitted by TI-NLI had 3% difference for μ_2 (15.5 kPa (FE) vs. 16 kPa (TI-NLI)), 14% difference for ϕ (0.7 (FE) vs 0.6 (TI-NLI)), and ζ had 50% difference (1.3 (FE) vs 0.6 (TI-NLI)).

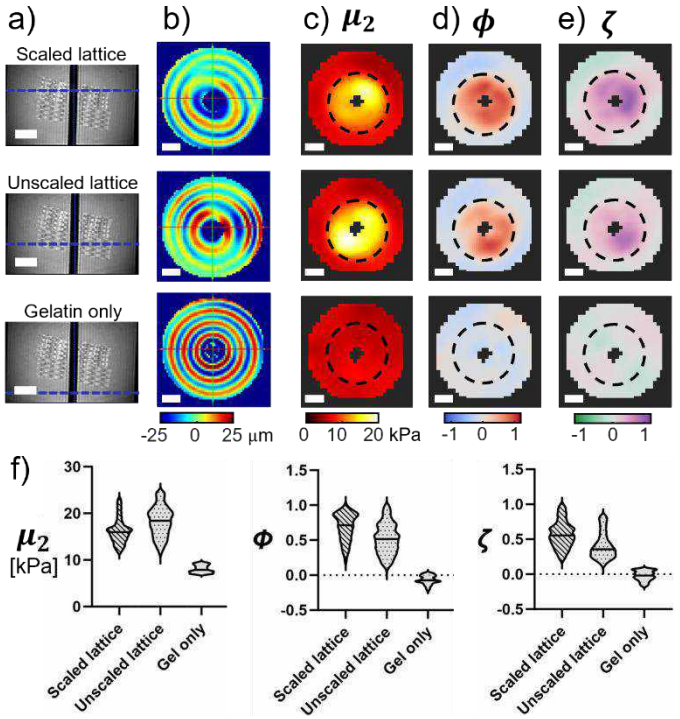

Fig 4 (a-e) MRE imaging results for scaled lattice region (top row), unscaled lattice region (middle row), and gelatin only (bottom row). a) T1 side view images; blue line indicates slice for corresponding row of images. b) Displacement field at one time point; c) transverse shear modulus μ_2; d) shear anisotropy, ϕ; e) tensile anisotropy, ζ. Scale bars = 1 cm. f) distribution of anisotropic properties within each ROI.

DISCUSSION

Our transversely anisotropic lattices demonstrated anisotropy through mechanical testing, while the TI-NLI algorithm successfully detected anisotropic material properties from MRE data. To evaluate TI-NLI, we sought to understand the behavior of our lattice composites through testing and FE modeling. Agreement between scaled lattice mechanical test data and FE models provided a foundation from which FE models could then predict composite behavior. Composite FE model predictions were useful for evaluating TI-NLI and suggested that TI-NLI was accurate for μ_2 and ϕ estimates but less sensitive to ζ. The unscaled lattice region was determined by TI-NLI to have non-zero ϕ and ζ; this may be the blurring of results from the adjacent scaled region, as the effective resolution of TI-NLI is limited by wavelength (~7 mm).

Successful detection of anisotropic properties improves our confidence in TI-NLI, which may enable more accurate models of traumatic brain injury. Controlling anisotropic properties in gel composites may also be useful to evaluate new anisotropic ultrasound elastography techniques [6] and in tissue engineering applications like spinal cord regeneration where anisotropic scaffolds are desired [7].

CONNEXIN-43 POSITIVE CELL RATIO IS NOT MODULATED BY SEVERITY OF DAMAGE OR CHANGE IN CYCLE NUMBER IN TENDON FATIGUE INJURY MODEL

Benjamin B. Johnston (1), Nelly Andarawis-Puri (2,3)

INTRODUCTION

Tendinopathy is a common chronic musculoskeletal disorder, frequently resulting from accumulation of sub-rupture fatigue damage. These injuries disrupt the structure of the tendon, and do not innately repair, worsening mechanical properties and ultimately increasing risk of rupture. Development of therapeutics to halt or reverse the progression of sub-rupture induced tendinopathy is hindered by the paucity of data regarding onset and progression of the disease. To fill this gap in knowledge, our lab has developed a tunable fatigue loading injury model in the rat patellar tendon (PT) to examine changes in cellular and biological markers that are associated with onset and pathogenesis of tendinopathy.[1] In this injury model, diagnostic non-damaging mechanical tests are performed immediately before and after a cyclical fatigue loading protocol to allow calculation of four parameters that are established as effective metrics of the damage induced by the fatigue loading cycles.[2] Accordingly, our model allows us to evaluate biological outcomes in the context of this induced damage, in addition to the applied number of damaging cycles.

We have previously shown that apoptosis and expression of matrix remodeling genes are directly regulated by the severity of induced damage, but not cycle number, and were ultimately associated with a lack of repair.[3,4] Accordingly, we evaluated the effect of blocking apoptosis via pan-caspase inhibition to determine whether an effective repair response could be induced by increasing the number of healthy cells available to repair the damage. Surprisingly, this intervention further worsened mechanical properties and increased cellular markers of stress.[5] The removal of damaged cells via apoptosis is a necessary part of the response to any injury, but the lack of repair following fatigue loading leads us to suspect that the intense apoptotic response is not limited to catabolic cells. The heterogeneous nature of matrix damage induced by fatigue loading suggests there may be a population of otherwise healthy cells residing in less damaged regions in which apoptosis is induced by the unchecked spread of apoptotic signals from catabolic cells in more highly damaged regions. Broad inhibition of apoptosis does not differentiate between these cell populations, and forces survival of catabolic cells, furthering tendon degeneration. We therefore seek to identify how apoptotic signals may be spread from damaged to otherwise healthy cells to identify potential targets by which apoptosis could be more specifically limited.

Connexin-43 (Cx43) gap junctions (GJ) are a mechanosensitive communication mechanism present between tendon cells which play an important role in coordinating the tissue level response to loading during homeostasis via transmission of secondary messengers.[6] Cx43 gene expression and GJ communication transiently increase following application of physiological levels of strain to tenocytes in vitro.[7] Importantly, Cx43 has been implicated in the spread of apoptotic signals in other cell types, including osteoarthritic chondrocytes.[8] Given the knowledge from these in vitro studies that Cx43 is mechanosensitive and can spread apoptotic signals, we suspect that fatigue loading facilitates changes in Cx43 presence and function which contribute to increased apoptosis and further disease progression.

The objective of this study is to quantify changes in Cx43 positive (Cx43+) cell ratio following fatigue loading and correlate these changes with mechanical damage parameters and cycle number to investigate how the presence and role of Cx43 may impact tendinopathic disease progression. We hypothesize that time, damage, and cycle number are modulators of Cx43+ cell ratio following fatigue injury.

METHODS

Twenty-four 9-month-old female Sprague Dawley rats underwent cyclic fatigue loading of the PT to either 100- or 7200-cycles at 1-40N, 1 Hz per our established protocol.[1] Pre- and post-load diagnostic data were collected as previously described and four damage parameters (elongation, change in hysteresis, change in loading stiffness, and change in unloading stiffness) were calculated using custom MATLAB code.[2] Animals were cage active until sacrifice 3- or 7-days post injury, when injured and contralateral hindlimbs were processed for histology.

Samples were sectioned at 6µm thickness and stained for Cx43 (1:500; abcam11370) with a NucRed counterstain. Fluorescent images were collected and Cx43+ cell ratio was quantified using ImageJ FIJI.

Following data collection, Cx43+ cell ratios were normalized against the mean of naïve samples collected during the same week to account for seasonal effects that commonly impact rodents.[9] 3-day 100-cycle, 7-day 100-cycle, 3-day 7200-cycle, and 7-day 7200-cycle groups were then compared to naïve using a Wilcoxon rank sum test. Subsequently, damage parameter data for both days were categorically split into "high" and "low" damage groups via sum of squares minimization. Mann-Whitney tests and Kruskal-Wallis tests with Dunn's posthoc were used to compare data with two groups or three or more groups, respectively. Data analysis and statistics were performed using R and GraphPad Prism; * $p<0.05$, # $p<0.1$.

RESULTS

Cx43+ cell ratio significantly increased for all loaded samples vs. naïve (Fig. 1A). Comparing the effect of cycle number across time showed that Cx43+ cell ratio significantly increased for 3-day 100-cycle and 7-day 100-cycle groups compared to naïve and trended similarly for 3-day 7200-cycle and 7-day 7200-cycle groups (Fig. 1B).

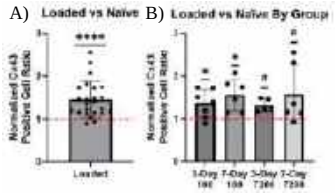

Figure 1: (A) Normalized Cx43+ cell ratio increased in loaded tendons vs. naïve. (B) Normalized Cx43+ cell ratio increased vs. naïve for 100-cycles of loading at 3- and 7-days and trended the same for 7200-cycles of loading at both days. Red dashed lines indicate naïve levels. **** $p<0.0001$

We next divided the data into "high" and "low" damage groups for a given day, independent of the number of loading cycles. Comparison of induced damage confirmed that change in hysteresis, elongation, and change in unloading stiffness are significantly greater for high than low damage groups at both days (Fig 2A-C). Change in loading stiffness increased for high compared to low damage at 3-days and trended towards the same at 7-days (Fig. 2D). Change in Cx43+ cell ratio was not different between high and low damage groups for any of the four parameters at either day (not shown).

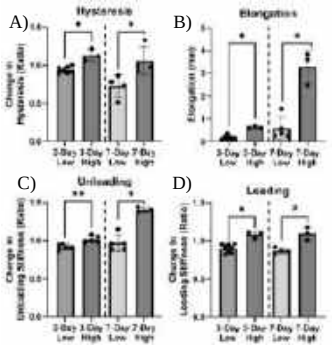

Figure 2: (A) Change in hysteresis, (B) elongation, and (C) change in unloading stiffness were significantly greater in high than low damage groups at both 3- and 7-days. (D) Change in loading stiffness was significantly greater in the high than low damage group at 3-days with a trend towards the same at 7-days. ** $p<0.01$

We then assessed the data for differences between the 3- and 7-days groups of each parameter in a given damage tier. Induced damage did not differ between 3- and 7-day groups with high change in hysteresis, low change in unloading stiffness, and low and high change in loading stiffness; subsequently, change in Cx43+ cell ratio did not differ between 3- and 7-day groups in any of these cases (Fig. 3A, C, D). If the amount of induced damage was different for 3- and 7-day groups in the same damage tier of the parameter in question, we did not compare change in Cx43+ cell as we would be unable to determine if any difference was correlated with time or the difference in damage.

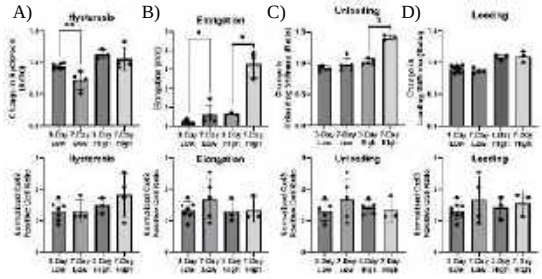

Figure 3: The high damage groups at 3- vs. 7-days were not different for change in (A) hysteresis and (D) loading stiffness, and the low damage groups at 3- vs. 7-days were not different for change in (C) unloading stiffness and (D) loading stiffness. Change in Cx43+ cell ratio was not different between 3- and 7-day groups at either damage severity for any parameter. ** $p<0.01$

DISCUSSION

Contrary to our hypothesis, we did not observe a correlation between changes in Cx43 and changes in induced damage. This suggests that the damage parameters evaluated here do not regulate changes in Cx43+ cell ratio in tendon following fatigue loading. This finding also highlights some potential limitations of this study. First, Cx43 can localize to the cytoplasm, cell membrane, or cellular protrusions, with location dictating function. While not quantified in this study, Cx43 localization has been observed to change in a load dependent manner in vitro, and more work is necessary to determine if Cx43 localization, and thus function, vary following loading in our model.[7] Second, this study does not evaluate Cx43+ cell ratio on a regional basis. The different loading environments of the insertion, midsubstance, and origin regions of the PT affect the molecular response to loading, and future work will include additional analysis to determine if changes in Cx43+ cell ratio are also region dependent.[3,4]

While the increase in Cx43+ cell ratio was surprisingly not cycle dependent, these findings are consistent with our previous data showing that the increase in apoptosis post loading is also independent of cycle number.[3] We have observed ECM disruptions, including damage kinks and widening of interfibrillar spaces, sustained for 7 or more days following any number of fatigue loading cycles.[1] Additionally, Cx43 expression is increased by underloading of tendon cells.[10] It is plausible that these ECM disruptions could lead to underloading of individual cells despite macroscale physiological loading, increasing Cx43+ cell ratio regardless of the number of loading cycles. The sustained ECM disruptions could also explain the surprising lack of time dependency of change in Cx43+ cell ratio seen here, as the effects of stress deprivation on tenocyte Cx43 expression were similarly observed out to 7- days.[10]

This work demonstrates that Cx43+ cell ratio is not correlated with induced mechanical damage parameters following fatigue loading, but it remains to be evaluated whether the role of Cx43 changes independent of positive cell ratio to contribute to disease progression.

INTRODUCTION

Biphasic lubrication theory [1] is one of the major joint lubrication theories in which the interstitial fluid supports the majority of loads applied to joint surfaces. Proteoglycans (PGs) are thought to be important constituent material that improves the lubrication property of ground substances by attracting water molecules. However, it is impossible to quantitatively determine the effect of PG on the lubrication properties using articular cartilage specimens. Our previous study revealed that the addition of PG powder to polyvinyl alcohol (PVA) hydrogels improves lubrication properties, but that an excessive addition of PG powder conversely increases friction [2]. The reason for this was considered to be ploughing friction occurred due to the softening of PVA hydrogel. In the present study, PG/COL hydrogels were developed by adding PG with either type I collagen (COL1) or type II collagen (COL2) to PVA hydrogels, and their frictional properties were investigated.

METHODS

PVA powder of 6.0 g (P0469, Tokyo Kasei Kogyo Co., Ltd., degree of polymerization: about 1700, degree of saponification: 97.0-100.0 mol%) was dissolved in ultrapure water (approximately 19.93-23.60 g depending on the amount added and the type of COL) to prepare a PVA solution of 40.0 g (Fig. 1). PG powder including dextrin (DEX) (Proteoglycan F, ICHIMARU PHARCOS Co., Ltd.) was dissolved in either 10.86 g of COL1 solution or 9.00 g of COL2 solution with 10 x phosphate buffered saline, to prepare PG/COL solution. The mixture of these solutions was poured into Petri dishes (10 g each) and preserved at 8°C, 50%RH until the weight change of the solution settled down, and cast dry films were produced. The films were then immersed in 333 mL of ultrapure water for more than 72 hours to produce PG/COL hydrogels. Percentage of PG of the solid elements in the hydrogels was 1.2 wt% (PG/COL (I)), 3.3 wt% (PG/COL (II)) and 5.0 wt% (PG/COL (III)). For comparison, hydrogels consisting of only COL1 (COL1) or COL2 (COL2), and PG hydrogels without collagen (PG(I), PG(II), PG(III)) were prepared. The composition of the solid elements in each gel is shown in Fig. 2.

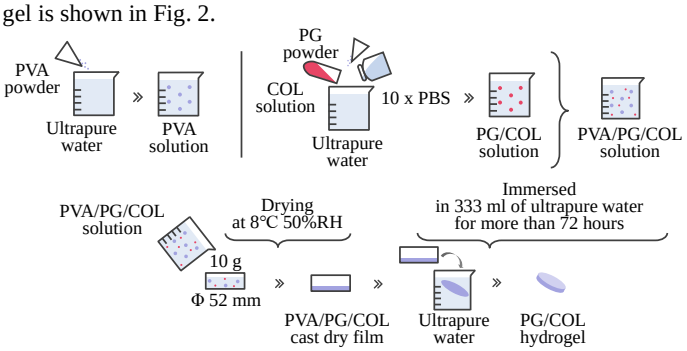

Fig.1 Preparation of PG/COL hydrogels, and COL and PG hydrogels

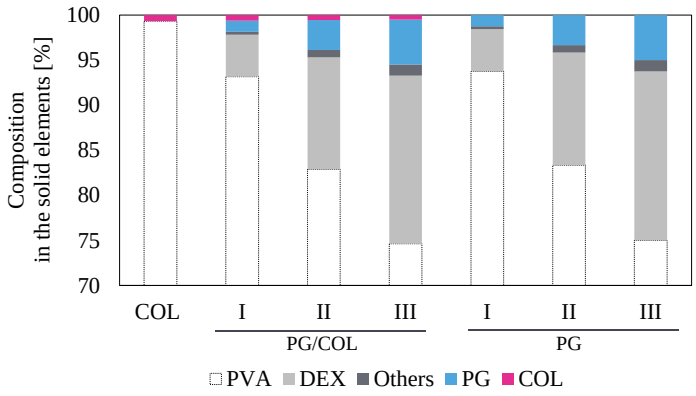

Fig. 2 Composition of the solid elements in hydrogels

Scanning electron microscopic (SEM) observation was performed for the cross section of the hydrogels using a SEM (VE-8800, KEYENCE Co.). The hydrogels were punched to 18 mm long × 10 mm wide specimens and fixed in a fluid bath filled with 37°C saline solution. A dynamic mechanical analysis was first performed for the hydrogels using a dynamic viscoelasticity tester (Electro Force 5500, TA Instrument) to determine the storage and loss moduli of the hydrogels. A reciprocating friction test was then performed for the hydrogels against an alumina ceramic sphere of 6.00 mm in diameter at the condition of a vertical load of 0.9 N (maximum surface pressure 1.51 MPa), preload time of 5 s, friction velocity of 10.0 mm/s, and friction stroke of 10 mm for 50 cycles trips (total friction distance 1,000 mm).

RESULTS

SEM images of the hydrogels are shown in Fig. 3. Laterally aligned many pores of approximately 200 μm in lateral length are included in PG/COL1 and PG/COL2 hydrogels, with the largest member observed in PG/COL2 hydrogels.

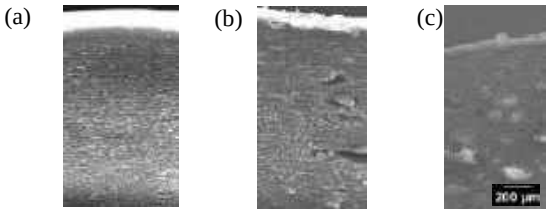

Fig.3 Cross-sectional SEM images of
(a) PG, (b) PG/COL1 and (c) PG/COL2 hydrogels

The storage moduli of COL hydrogels were approximately 0.4 MPa (Fig.4). The addition of PG increased the moduli with the significant increases observed in PG/COL1 (I) and PG/COL2 (I) hydrogels, although the moduli decreased with the increase of PG. Note that the modulus was significantly lower in PG (III) hydrogels than in PG/COL (III) hydrogels.

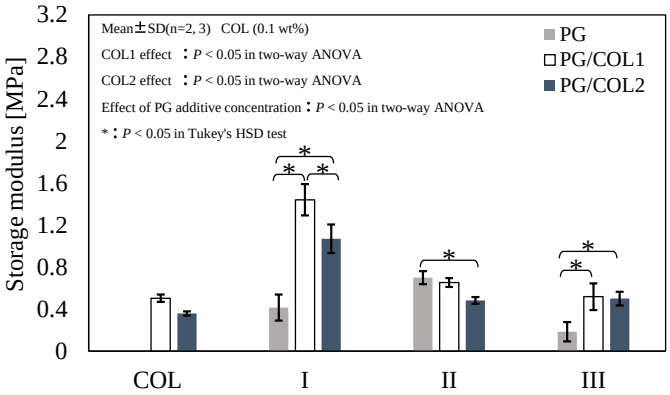

Fig.4 Storage modulus of COL,
PG/COL1 and PG/COL2, and PG hydrogels

The coefficients of dynamic friction at the beginning (distances 0-200 mm) and the end (distances 800-1000 mm) of friction were indicated in Fig. 5. In COL hydrogels, the coefficient of dynamic friction was the highest (0.035-0.050) among all the specimens at the beginning of friction, and significantly decreased during friction. In PG hydrogels, the coefficient of dynamic friction remained lower level (0.016) when the percentage of PG in the solid elements was 1.2 wt% and 3.3 wt%, but significantly increased (0.035) when the percentage was 5.0 wt%, with a significant increase observed during friction. In contrast to these comparison groups, the coefficient of dynamic friction in PG/COL groups remained lower level (0.015-0.023) during entire friction, with the lowest observed in PG/COL1 group.

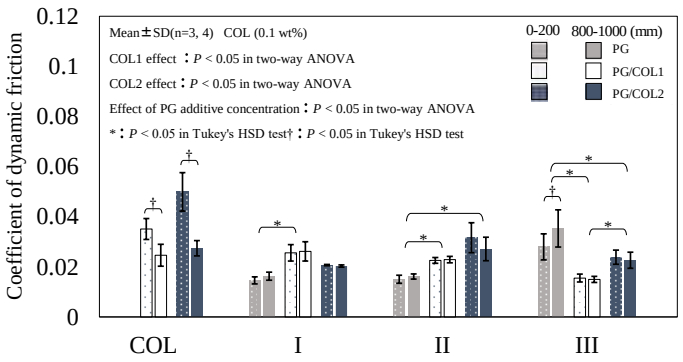

Fig. 5 Coefficient of dynamic friction of COL,
PG/COL1 and PG/COL2, and PG hydrogels

DISCUSSION

The coefficient of dynamic friction was higher in COL hydrogels than in other hydrogel, in particular, at the beginning of friction. It is suggested that friction increased due to the lack of water retention ability in the hydrogels. The coefficient of dynamic friction increased with the increase of PG in PG hydrogels. Based on the biphasic lubrication theory, gels retaining much water exhibit excellent lubrication properties when fluid load support ratio of water increases. However, it is thought that the high-water retention of PG caused the PG hydrogels to soften as indicated in the dynamic mechanical analysis test, and resulted in friction increases due to ploughing.

The coefficient of dynamic friction was significantly higher in PG/COL hydrogels than in PG hydrogels when the percentage of PG in the solid elements was 1.2 wt% and 3.3 wt%. However, the trend became opposite when the percentage of PG was 5.0 wt% in those hydrogels. Note that the storage modulus was significantly higher in the PG/COL hydrogels than in PG hydrogels at the condition. It is suggested that better lubrication properties and adequate moduli can be achieved with the increase of PG in collagen-included PVA hydrogels.

BUILDING HOME-MADE OPTICAL TWEEZERS TO STUDY THE MECHANICAL FORCES OF THE CHONDROCYTE CYTOSKELETON IN THE CONTEXT OF OSTEOARTHRITIS

Samantha L. Smith (1) and Scott T. Wood (1)

(1) Department of Nanoscience and Biomedical Engineering, South Dakota School of Mines, Rapid City, South Dakota, United States

INTRODUCTION

One way to measure forces in cells is by using optical tweezers. Commercially available optical tweezers are very expensive, costing around $200,000, which makes utilizing this technique inaccessible for many laboratories. Luckily, a low-cost version can be made using parts from a DVD burner. Using the optical pickups of a DVD burner, we can build an optical tweezer assembly that is capable of single cell isolation [1]. In this study, home-made optical tweezers will be built for future use in characterizing integrin motion in chondrocytes for research on osteoarthritis (OA).

OA is a debilitating disease of the cartilage that results in pain, deformity, and loss of function for those who suffer from the disease. OA is the most common form of arthritis and is a major cause of disability in older adults. It is typically referred to as degenerative joint disease, which can be misleading because it is not simply a process of wear and tear, but an abnormal remodeling of joint tissues driven by inflammation. Pathologic changes seen in OA include degradation of cartilage, growth of painful bone spurs, inflammation, and degeneration of ligaments, all leading to joint failure [2]. Surprisingly little is known about the mechanisms that result in the degeneration of the joint that occurs in osteoarthritis.

Chondrocytes are highly specialized, metabolically active cells in articular cartilage that play a major role in the development of OA. These cells work constantly to regulate the surrounding extracellular matrix (ECM) but have a limited potential for replication which contributes to their poor intrinsic healing capacity. Chondrocyte survival depends on an optimal chemical and mechanical environment. Their homeostasis is regulated by mechanotransducers called integrins that respond to mechanical stimulation from the surrounding ECM [3]. In previous experiments integrin motion of chondrocytes was characterized using Atomic Force Microscopy (AFM) force measurement [4]. The AFM experiments on chondrocytes produced exciting results, but there were difficulties differentiating the signal from thermal noise. Because of this we decided to use optical tweezers for validation and to provide more information on chondrocyte integrin motion.

Optical tweezers can be used to directly measure forces that are applied to optically trapped objects. The basic principle behind optical tweezers is the momentum transfer associated with bending light. Light carries momentum that is proportional to its energy in the direction of propagation. Because of this, any change in the direction of light, by either reflection or refraction, will result in a change of the momentum of the light. If an object bends the light, changing its momentum, conservation of momentum requires that the object must undergo an equal and opposite momentum change. This change in momentum is what creates the force that traps the object [5]. By attaching specific molecules to polystyrene microspheres, we can study the forces acting on the molecules under various conditions and use these results to model their physical behavior.

In this study, a home made optical tweezer assembly is built for the future investigation of the movement of the actin cytoskeleton of chondrocytes in the context of OA. The proposed optical tweezer assembly is made from the optical pickups of a DVD-RW drive that is integrated into an inverted microscope with the help of a 3D printed stand and light filters to protect the microscope's camera. The total cost of this assembly is estimated to be about $700. Utilizing this optical pickup build increases the accessibility of this technique by providing a method for optical tweezer experiments at a significantly lower cost.

METHODS

Optical traps behave like linear springs because the trap exerts a linear restoring force on the object. The force of the optical trap can be described as shown in Equation 1, where k is the trap stiffness and Δx is the radial displacement of the bead in the trap. The trap stiffness can be determined experimentally by the application of viscous drag.

$$F = -k\Delta x \quad (1)$$

At low Reynold's number, Stoke's law gives the force on a sphere in a uniform velocity flow field in Equation 2, where η is the viscosity of the fluid, d is the diameter of the microsphere, c is the correction factor for proximity to the glass surface, and V is the velocity of fluid flow [5].

$$F = 3\pi\eta dcV \quad (2)$$

In order to define the trap stiffness, a controlled viscous drag force must be applied to a trapped microsphere. Stoke's law, which describes the motion of spheres through a viscous medium, can be used to determine the applied force. This applied force, along with the experimentally measured displacement of the sphere within the trap, can then be used to determine the trap stiffness.

Using the optical tweezer setup shown in Figure 1, we can measure the basal integrin forces that are present in the chondrocyte cytoskeleton. By functionalizing the beads with fibronectin, we can form a bond between the bead and a chondrocyte that is adhered to a glass surface. By optically trapping the bead and tracking the movement of the bead within the trap we can record the basal forces that are being exerted by the cell on the bead. This information can then be used to validate the results of the AFM experiments and provide more information on the dynamic movement of the chondrocyte cytoskeleton.

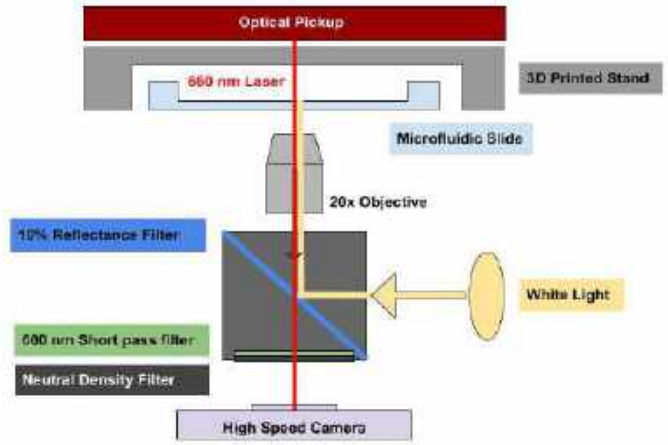

Figure 1: DVD optical tweezer assembly.

RESULTS

To build the optical trap, the optical pickup assembly of a DVD RW drive is integrated into an upright microscope without compromising its imaging modalities. As typically employed, the optical pickup is an electronically steered and stabilized microscope that extracts information from DVD discs. The DVD burner's laser diode is capable of providing the necessary power and focusing optics needed for optically trapping micron-sized particles and cells [1]. The mechanical components from the DVD burner can be used to control the focus of the laser and steer the optical trap to target and capture cells.

The optical pickup assembly used in this project is pictured in Figure 2. Using these optical tweezers, we were able to successfully trap and move a 4 μm glass bead. Unfortunately, soon after trapping the bead the laser diode unexpectedly burned out. Although the laser diode still produced the expected spectrum, the laser power was measured to be less than 10 μW rather than the expected 60 mW, and the laser was no longer capable of forming an optical trap. We initially suspected that the damage was due to electrostatic discharge, as no procedures to prevent this were in place. After sourcing a new optical pickup, we used an antistatic wrist strap when handling the optical pickups to prevent this type of damage, but the measured power of the new laser was still less than 10 μW. Because of this, we plan to investigate the wiring and operating specifications of the pickups as well as exploring other optical pickup sources. Once operational, we plan to measure the optical tweezer's trap strength, as well as the trap strength as a function of voltage. Then, we can begin working on extending its use to cells and developing a protocol for measuring the dynamic motion of the actin cytoskeleton in chondrocytes.

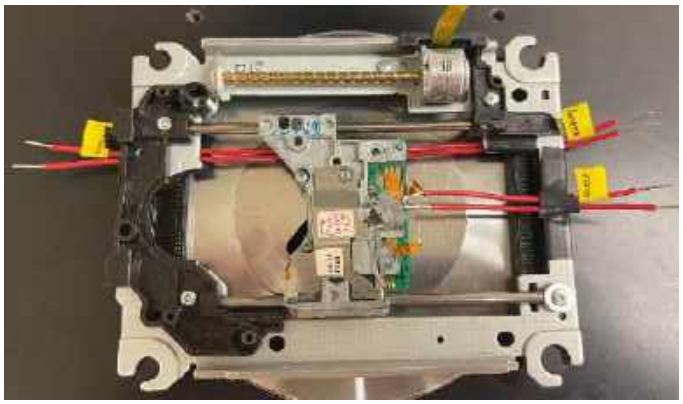

Figure 2: DVD optical pickups.

DISCUSSION

Surprisingly little is known regarding the cellular forces that are present in chondrocytes This project aims to provide a method to unveil the mechanical forces that are necessary for regulating chondrocyte homeostasis. The hypothesis driving this experiment is that the dynamic motion of the actin cytoskeleton, which influences homeostasis in chondrocytes, can be measured using a low-cost optical pickup setup. The project's outcomes will supplement the current understanding of why chondrocytes respond differently to static and dynamic forces. The success of this project will not only provide a path to advance the understanding of OA pathogenesis but also provide a foundation for developing strategies to combat the disease.

OA stands as a leading cause of disability in the developed world, affecting over 32.5 million US adults [6]. Clinical treatments for OA are often limited to pain management and joint replacement due to an incomplete understanding of how this highly complex disease develops. This research will help reveal the intracellular mechanisms for regulation of chondrocyte homeostasis, providing much needed background for advancements in tissue engineering and OA-related healthcare. Additionally, the use of the optical pickup setup for measuring cellular forces in chondrocytes enhances the accessibility of this technique, making optical tweezer experiments more feasible at a significantly lower cost. The affordability of this setup makes it an optimal tool for teaching applications across diverse communities, including those with limited resources.

TACKLING HETEROGENEITY IN CANINE OSTEOSARCOMA- A BIOMECHANICAL ANALYSIS OF HISTOTRIPSY-TREATED AND UNTREATED BONE

INTRODUCTION

Osteosarcoma (OS) is a rare, aggressive bone cancer and one of the most common malignancies in children and adolescents.[1] The survival rate for OS has not improved in decades due to the refractoriness of metastatic disease to therapy.[1] The combination of chemotherapy, surgical resection, and radiotherapy has improved patient outcomes; however, some patients may not qualify for surgical resection due to tumor characteristics or disease progression.[2] Many patients who do continue with treatment suffer from metastasis, infection and reduced limb mobility and function post-treatment.[2] Non-surgical options for primary tumor treatment remain extremely limited.

Recently, canines are being explored as a comparative oncology model for the development of effective clinical OS treatments. Canine OS shares several biological characteristics with human OS (e.g. disease presentation, genetic complexity, and histological characteristics) rendering it an ideal model to explore comparative and translational OS research.[3,4] OS accounts for over 85% of bone tumors in canines, with 95% of patients presenting with spontaneous micrometastases and high levels of pain at time of diagnosis. Current treatment options for canine OS are limited, the most common involving tumor resection via limb-salvage or limb-amputation surgery and adjuvant chemotherapy. Some dogs may not qualify for limb amputation, and serious complications after limb-salvage surgery such as implant failure and infection occur.[3,5]

Histotripsy is a noninvasive, non-thermal ablation technique that uses ultrasound to mechanically destroy tissue. Previous histological *ex vivo* studies on canine bone have demonstrated that histotripsy effectively ablates primary OS tumor tissue without causing cell death or damage to normal surrounding bone.[6,7] Although the effects of histotripsy on OS bone have been explored histologically, its biomechanical effects on the structural integrity of bone and tumor tissue have yet to be determined. The objective of the current study is to determine the biomechanical effects of histotripsy on OS tumor and adjacent grossly normal bone tissue as a crucial next step in developing a non-invasive limb-salvage treatment option for canine osteosarcoma. We hypothesize that histotripsy does not significantly alter the biomechanical properties of treated bone and can safely be used without altering the biomechanics of surrounding, normal bone.

METHODS

Ten amputated limbs from canine patients with primary OS tumors undergoing standard-of-care limb amputation were acquired under an approved institutional IACUC protocol (22-091). *Ex vivo* histotripsy ablation with a dosage of 1000 pulses/point was applied to the OS tumor and a matching volume of grossly normal bone with a custom setup utilizing 1-2 cycle histotripsy pulses at a pulse repetition frequency of 500 Hz. Bone tissue from a treated tumor (AT), treated grossly normal bone (AN), an untreated tumor (UT), and untreated grossly normal bone (UN) were extracted for biomechanical testing (**Figure 1**).

Figure 1: Canine forelimb with an OS tumor in the distal ulna. Representative locations from which specimens were extracted are highlighted.

Cubic specimens (7.5mm x 7.5mm x 7.5mm) were cut from the trabecular bone sections and subjected to repeat (n=3) compressive loading with a 20N preload in three anatomical directions (medial-lateral, anterior-posterior, and superior-inferior) until just below the yield point to assess potential differences in anisotropy and to determine the elastic modulus of each sample. A final compression test to failure along the primary axis of loading (superior-inferior axis), was performed to determine the yield and ultimate compressive stresses of each tissue. UT specimens (n=7) were microCT scanned prior to testing at a 17.5x17.5x17.5 μm voxel resolution for qualitative assessment.

Rectangular beam specimens (15mm x 2mm x 1mm) of cortical bone were cut from each specimen along the longitudinal bone axis and subjected to 3-point bending until failure.

Compressive and bending moduli, calculated from the slope of the linear region of the stress-strain curves, and maximum stresses were determined to assess the impact of histotripsy on tissue stiffness and strength, respectively.

A linear mixed effects model was used to assess the impact of loading direction and tissue on the compressive moduli of the trabecular bone specimens. A Kruskal-Wallis test was used to assess elastic and post-yield behavior of the cortical bone specimens and post-yield behavior of the trabecular bone specimens. Where necessary, Dunn's test was performed as a post-hoc measure to compare data between groups. The alpha value was set 0.05 and p-values were adjusted for multiple comparisons.

RESULTS

The material properties of a total of 67 cortical beams and 36 trabecular cubes were analyzed. For the cortical bone specimens, elastic modulus was significantly higher in grossly normal bone (UN and AN) groups than in tumor tissue (UT and AT) groups (**Figure 2, Table 1**). No significant differences were found between untreated and treated grossly normal bone or between untreated and treated tumor tissue groups. Maximum stress followed a similar trend; normal bone specimens were significantly stiffer than tumor tissue specimens, and no differences were found between treated and untreated specimens in either the normal bone or tumor tissue groups (**Table 1**). No significant differences were found in the mechanical properties for the trabecular bone specimens; however, UT specimens exhibited both a higher value and range regarding elastic modulus, maximum stress, and yield stress/strain than the other groups (**Figure 2,3**).

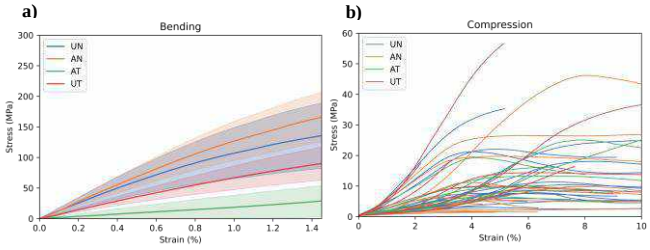

Figure 2: Failure mechanics for (a) cortical bone under 3-pt bending (b) trabecular bone under compression

Table 1: Mechanical properties of UN, AN, UT, and AT cortical bone specimens for 3-pt bending tests. Data reported as median (IQR).

		Condition				
Compression	Property	UN	AN	UT	AT	(p)
	Maximum stress (MPa)	14.7 (12.8)	8.42 (12.8)	17.4 (12.0)	13.3 (9.65)	0.262
	Elastic modulus (MPa)	363 (328)	224 (255)	631 (451)	185 (186)	0.312
	Yield strength (MPa)	8.80 (10.8)	3.13 (12.03)	11.8 (9.46)	9.58 (9.24)	0.162
	Yield strain (%)	2.12 (1.45)	1.94 (1.26)	2.18 (1.28)	2.88 (0.485)	0.104
Bending	Property	UN	AN	UT	AT	(p)
	Maximum stress (MPa)	189 (99.1)	214 (63.6)	116 (109)	115 (114)	<**0.001***
	Elastic modulus (GPa)	12.2 (6.85)	12.9 (4.91)	6.57 (6.47)	4.95 (7.07)	<**0.001***
	Elastic work (J)	1.05 (0.401)	1.11 (0.341)	1.05 (0.766)	0.902 (1.07)	0.956
	Toughness (MJ/m³)	3.93 (1.97)	8.35 (5.79)	2.80 (2.27)	2.23 (3.22)	<**0.001***

Differences in UT composition were qualitatively analyzed via micro-CT, showing a wide range in densities (**Figure 3**). Regarding anisotropy, stiffness was often higher in the primary loading direction, but no significant differences were found within the three loading directions between groups. As such, data was grouped by tissue type for the remainder of the statistical analyses.

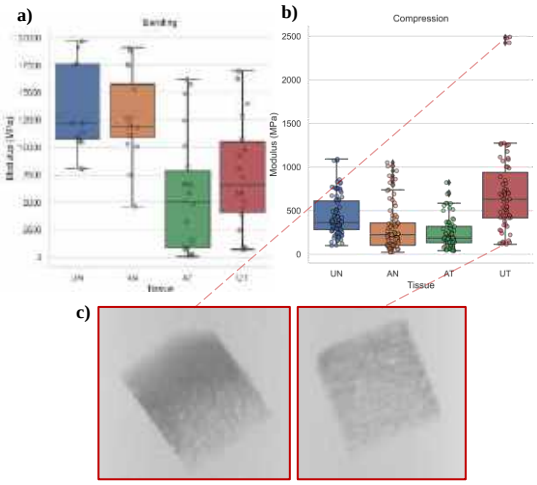

Figure 3: Elastic modulus distribution for a) cortical bone b) trabecular bone specimens. MicroCT projections of Selected UT specimens, demonstrating the range in density of the trabecular network.

DISCUSSION

The similarities between the biomechanical properties of untreated and treated normal bone specimens support our hypothesis that histotripsy tumor ablation does not detrimentally affect the biomechanical properties of grossly normal bone. Similarities between untreated and treated tumor tissue specimens carry the same implication. However, the clinical nature of this pilot study prevented complete control over key variables such as tissue donor characteristics (age, weight, breed, etc.), the anatomical location from which sample tissue was extracted (i.e., radius, ulna, tibia, femur), and sample size. As such, the detected differences between groups may have been influenced by the anatomical location of each of the samples as well as donor demographics. Furthermore, significant differences may be masked by the high variation shown in the calculated properties. To address these limitations, future controlled studies on the biomechanical effects of histotripsy dose on healthy and OS tumor tissue should be performed to establish treatment guidelines. Further exploration into the properties and composition of untreated OS tumor tissue, which shows a high degree of heterogeneity, using density calibrated imaging will also be imperative in understanding and refining the relationship between histotripsy dose and tumor tissue mechanics. Ultimately, the results of the current work will aid in the development and advancement of effective, non-invasive, patient-specific treatments for clinical OS.

INTRODUCTION

Intracardiac hemodynamics plays a crucial role in cardiac efficiency, yet the intricate patterns of atrioventricular blood flow are not fully understood. While deviations in wall motion serve as direct evidence of an apparent clinical ailment, exploring intracardiac hemodynamics shifts the emphasis from diagnosing diseases to predicting their onset and progression [1]. The estimation of vortical flow structures in the left ventricle (LV) has recently emerged as a potential hemodynamic marker for various pathologies. Specifically, aberrant vortices and vortex rings are found to be associated with an increase in viscous energy loss during LV filling (diastole) which then necessitates an increase in mechanical energy to preserve the cardiac output during LV contraction (systole) [2]. Hemodynamic analysis of atrioventricular flow is necessary for valvular diseases such as mitral valve prolapse (MVP). MVP is characterized by the incursion of one or both mitral valve leaflets into the left atrium by more than 2 mm. Affecting approximately 2-3% of the adult population in the United States, the only definitive treatment for MVP is surgical intervention, which may involve repair or replacement with mechanical or biological prosthetic valves [3]. Therefore, understanding the hemodynamic factors influencing cardiac remodeling before and after mitral valve surgery is essential.

In this work, using magnetic resonance imaging (MRI), we introduce a novel patient-specific fluid-structure-interaction (FSI) modeling to characterize the LV hemodynamics in a patient with MVP. Our method extends upon previous MRI-based methods, with our approach leveraging non-rigid estimation of myocardial deformation and phase contrast (PC-)MRI images to create a four-dimensional (4D) map of intraventricular flow in the LV. We analyze traditional hemodynamic markers, such as kinetic energy and flow velocities, in addition to vortex analysis.

METHODS

An in-house non-rigid image registration framework was implemented over the short-axis (SA) MR image stack of a post-surgery MVP patient (n=1) to evaluate deformation. The framework extends upon the optimization-based registration problem introduced by [4] to find the best transformation in aligning a reference frame.

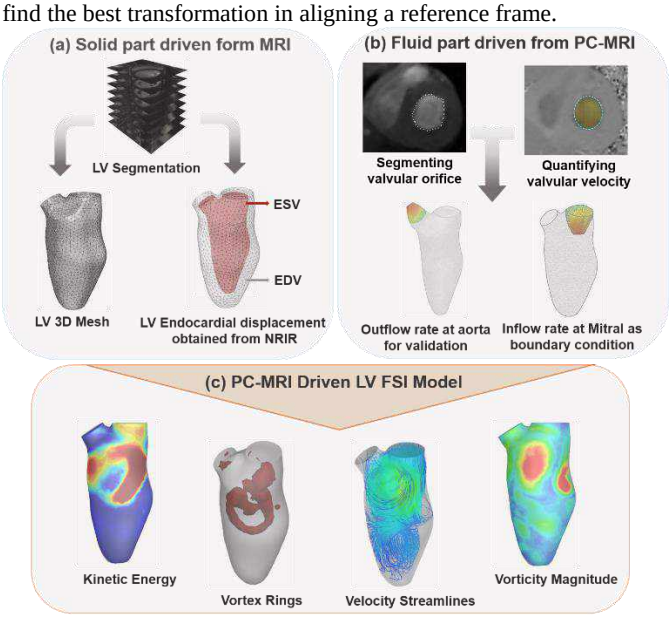

Figure 1: (a) Reconstruction of LV geometry using short-axis MR images and implementation of the NRIR method to obtain the endocardial wall displacement from end-diastolic and end-systolic volumes. (b) The flow rate using PC-MRI velocity measurements over the mitral and aortic orifices. (c) The LV hemodynamic characterizations, derived from the FSI modeling.

In this study, the LV endocardium in SA MRI images was segmented over all slices. This process involved creating endocardial contours at each time point, followed by resampling and smoothing through Delaunay triangulation and radial basis functions to enhance 3D segmentation quality. The LV wall for analysis was reconstructed at end-diastole (ED), mapping displacements from subsequent time points onto it with a least-squares method(Figure 2a).

Using PC-MRI, a non-invasive imaging method capable of assessing the velocity of blood flow in all three directions, the blood flow velocity field was calculated at the deforming mitral and aortic orifices. The integrated mitral flow rate was implemented in the model and the aortic flow rate was used for further validation (Figure 3b). For the governing equation, the incompressible Navier–Stokes equations with the arbitrary Lagrangian-Eulerian (ALE) formulation were used, and the continuity and the momentum equations were solved to assess the LV hemodynamics (Figure 4c).

RESULTS

Following the FSI modeling, the LV vorticity magnitude was calculated in a cardiac cycle(Figure 2). At early diastole, the inflow jet of the E-wave enters the LV and creates two counter-rotating vortex formations, while the dominant vortex forms close to the aortic outflow tract and extends through the intraventricular septal wall. The two vortices reach their maximum size in the diastasis phase. With the onset of systole, the two remaining vortices shrink and get ejected out of the LV as the contraction proceeds to the peak systole.

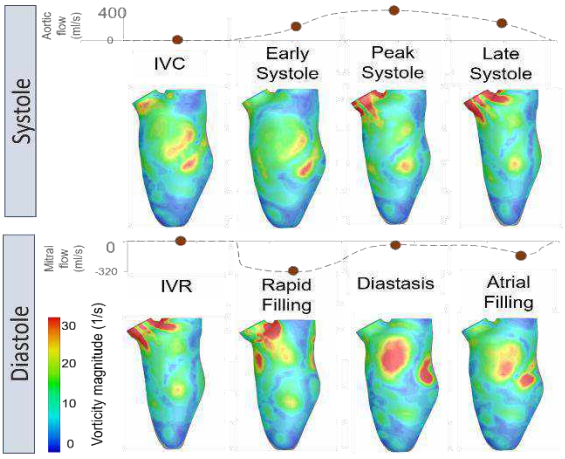

Figure 2: Vorticity magnitude in the transversal plane, crossing the mitral and aortic orifices. The top row illustrates the vorticity magnitude in the systole while the bottom row depicts the vortices in the diastole.

Furhermore, the iso-surface vortex rings in a cardiac cycle were acquired (Figure 3). As depicted, there are three main vortex rings formed in a cardiac cycle. One surrounding aortic outflow track in early systole, and two main vortex rings formed with E-wave and A-wave inflow jets at the mitral valve.

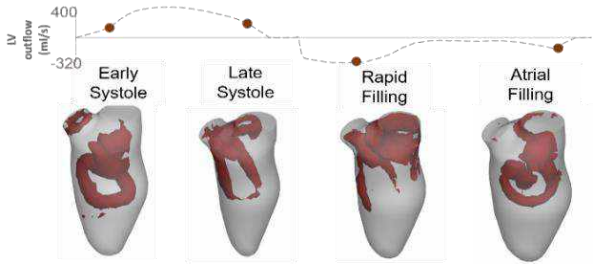

Figure 3: Iso-surface vortex rings illustrated in a cardiac cycle. Three main vortex rings were detected corresponding to the early systolic outflow jet, E-wave, and A-wave of diastolic inflow jets.

For validation, the flow velocity at the aortic orifice was measured from PC-MRI (Figure 4a), and the integrated volumetric flow rate was compared with the FSI model(Figure 4b). As no boundary conditions were imposed to model at the aortic orifice, the ejection curve of the flow at the aortic orifice is mainly implied by the moving wall, reinforcing the accuracy and robustness of the method.

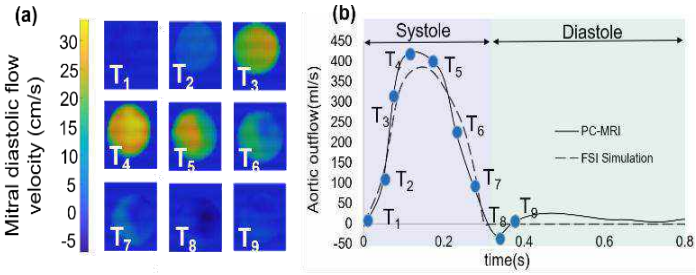

Figure 5: (a) 2D-PC-MRI-derived flow velocity at the short axis view of the aorta during the systole. (b) The aortic volumetric outflow rate captured from PC-MRI compared to the aortic flow assessed by the FSI modeling in a cardiac cycle.

DISCUSSION

In this study, we introduced an innovative patient-specific modeling approach to characterize LV hemodynamics. Our approach focused on integrating standard MRI and phase contrast images with moving boundary modeling obviating the need for complex electromechanical models of the myocardium to mimic LV hemodynamics. Hence, using MRI scans, a patient-specific LV model was introduced with a dynamic endocardium wall motion with a patient-specific flow boundary condition at the mitral valves to improve the fidelity of the model.

Per literature, under normal conditions, one vortex fills the entire LV chamber during diastole to minimize the kinetic energy loss and maximize the LV function[5]. In contrast, in cases of impaired flow due to MVP, two main vortices are typically reported in the LV; which is consistent with our results [6]. Although our model did not include a valve construct, all vortical properties, such as the position and circulation of the vortex rings, agreed with previous studies [7]. This highlights the utility of our approach in describing the impact of potential LV pathologies and, consequently, characterizing the association between LV wall motion and intracardiac hemodynamics. This study was carried out on a patient with MVP prior to mitral valve surgery. We are currently extending our research to include post-surgery data from the same patient, aiming to explore the changes in the formation of vortices within the LV post-surgery.

INTRODUCTION

Gliomas, which include glioblastomas and a subtype known as diffuse astrocytic glioma that shares molecular characteristics with glioblastoma (categorized as WHO Grade 4 astrocytoma), are the most frequently occurring and most severe type of malignant primary brain tumors found in adults [1]. Unfortunately, glioblastoma patients have a poor prognosis, with survival times typically being short despite aggressive treatment. The standard approach to treating glioblastoma involves surgical removal followed by radiotherapy and chemotherapy. Moreover, the likelihood of long-term survival with glioblastoma is increased by precise identification of pathological features through brain MRI, with subsequent confirmation by histopathology.

Glioblastomas present a challenge for diagnosis and treatment as they are highly variable in appearance, shape, and histology. Given the crucial nature of the pathological feature segmentation, the task is typically performed manually by experienced neuroradiologists. However, the segmentation process is time-consuming, tedious, and error prone as evidenced by variations in assessments among different radiologists (inter-rater variability) and the same radiologist over time (intra-rate variability) [2]. To address these challenges, computational segmentation algorithms have been developed that streamline the labeling process and minimize variability. Deep learning algorithms have recently become the primary choice in this context, largely due to advances in the computational power of modern graphic processing units (GPU), and algorithms. However, effectively training these models requires large amounts of data.

The Brain Tumor Segmentation Challenge (BraTS) is an annual international competition that aims to evaluate the state-of-the-art models by providing an ample dataset of fully labeled, multi-institutional images of patients with varying degrees of gliomas. The BraTS Challenge is divided into tasks; in this work, we use the datasets from Task 1 and Task 2. Task 1 data includes images of gliomas and labels of their sub-regions, namely: the enhancing tumor, the peritumoral edema, and the necrotic and non-enhancing tumor core. The annotations are combined into 3 nested subregions: whole tumor (WT), tumor core (TC) and enhancing tumor (ET). Task 2 provides similar images taken from patients in Sub-Saharan Africa (SSA).

What distinguishes the Task 1 (US) and Task 2 (SSA) datasets? In the US, 3T MRI machines are widespread in clinics and are commonly used to image brain tumors, while in SSA, 1.5T MRI is most used due to financial constraints. The lower MRI magnetization results in a significant drop in imaging contrast and resolution, which reduces the accuracy of segmentations and consequently the quality of medical care for patients in SSA. Additionally, there is limited internet connectivity throughout clinics in SSA, so acquiring and uploading imaging data to a cloud for dissemination to research institutions is very difficult. Clinic availability, transportation costs, among other systemic issues limit the accessibility to tumor treatment in SSA, and this manifests as patients typically being imaged at more severe tumor stages. As a result of these disparities, the available BraTS SSA Glioblastoma dataset is significantly smaller and of lower resolution than the USA dataset (60 subjects vs. 1126 subjects, respectively).

Machine learning methods in the field of transfer learning provide a way to bridge the gap in segmentation quality between models trained on US and SSA datasets by "transferring" insights gained from a larger domain (or dataset in this instance) to a smaller one. In this work, we experiment with two distinct transfer learning approaches. Our first approach consists of fine-tuning a well-performing model trained on Task 1 data by "freezing" components of the model and training the unfrozen components of the model on Task 2. Our second approach is directly inspired by the theory of domain adaptation, which suggests that for effective domain transfer, predictions should be based solely on features

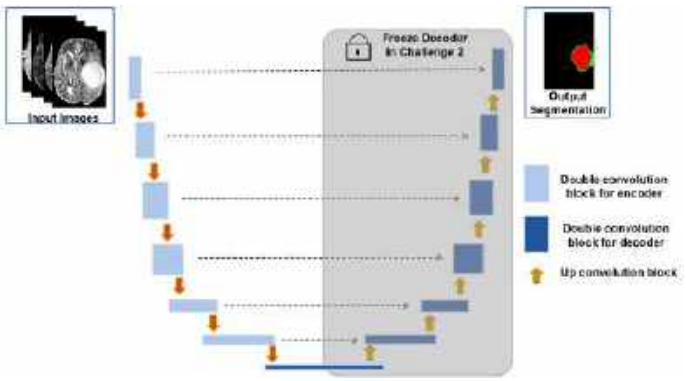
that are domain-invariant. To this end, we adapt the concept of Domain Adversarial Neural Networks (DANN) [3], which explicitly removes domain dependent features during parameter optimization. We compare the results of the two approaches to baseline neural networks trained on the independent domains and demonstrate improvement in transfer learning.

METHODS

Data: The BraTS 2023 Task 1 Glioma training dataset includes 1126 samples of multiparametric MRI (mpMRI) scans for each patient comprising a native T1, post-contrast T1-weighted, T2-weighted, and T2 Fluid Attenuated Inversion Recovery (T2-FLAIR) volumes. The dataset was preprocessed by applying DICOM to NIfTI file conversions, and coregistration to the same SRI24 anatomical template. Additionally, the images were resampled to a uniform isotropic resolution (1mm3) and skull-stripped to maintain anonymity.

Approach 1—Fine-tuning by freezing layers: For this approach, we begin with the Optimized U-Net [4] neural network architecture proposed by NVIDIA, which took first place at the BraTS 2021 challenge in the validation phase. The Optimized U-Net was found by extensively searching for the optimal depth of the U-Net encoder, the number of convolutional channels and post-processing strategy. The model was then trained on the Task 1 Glioma dataset using the Adam optimizer with no weight decay and am exponentially decaying learning rate with initial value of $6e\text{-}5$. The official training dataset was divided into a 90:10 training-validation split. After each epoch, the model was evaluated on the validation hold by calculating the Dice and HD95 score between the model prediction and the ground truth for regions of ET, TC, and WT, and then averaging these scores for each subject. The validation scores are then collectively averaged after each epoch, and the model with the highest score was used.

Upon training the original model, we then experimented by freezing various combinations of model components, including the encoder, decoder, and bottleneck layers. Freezing in this context of transfer learning refers to the designated layer's weights and biases being prevented from updating during training. After freezing, the models were fine-tuned by training on the Task 2 dataset. The models were compared using the average Dice and HD95 scores for the three regions (ET, TC, WT).



Example Figure 1: Figure caption centered below the graphic.

Approach 2—Deep Adversarial Neural Network (DANN): DANN [3] aims to learn features that are both discriminative and domain-invariant by optimizing a neural network comprising two classifiers: a label predictor, which provides segmentations and is used both during training and testing, and a domain classifier that discriminates between domains during training. The optimization process minimizes the label classifier loss while maximizing the domain classifier loss, promoting the emergence of domain-invariant features through an adversarial optimization.

Our implementation of the DANN approach consists of a backbone convolutional encoder-bottleneck-decoder architecture (such as U-Net [5] in this case) for segmentation, with an additional domain classifier the bottleneck layer. By embedding domain adaptation into the process of representation learning, the final classifications are made based on features that are both discriminative and invariant to domain changes. In the context of transfer learning between Task 1 and Task 2, we expect the model to leverage domain-invariant features common across domains for segmentation.

RESULTS

The results presented in Table 1 indicate that the freezing decoder approach resulted in the most improvement in Dice Score over the baseline Challenge 2 model which was trained only on the Task 2 dataset. Additionally, the results indicate that the model trained only on the Task 1 dataset (under "Challenge 1 model" in Table 1) produced the largest improvements in HD95 score.

Example Table 1: Lesion-wise scores for the Freezing Layers Experiment.

Experiments	Dice				HD95			
	ET	TC	WT	mean	ET	TC	WT	mean
Challenge 2 model	0.6524	0.6925	0.5972	0.6474	81.96	70.49	120.81	91.09
Challenge 1 model	0.7188	0.7424	0.6433	0.7015	**52.35**	**48.16**	101.58	**67.36**
Freeze encoder layers	0.6745	0.7143	0.5810	0.6566	80.40	69.80	142.55	97.58
Freeze middle layers	**0.7392**	**0.7533**	0.6484	0.7136	57.27	55.10	114.41	75.59
Freeze decoder layers	0.7200	0.7358	**0.7039**	**0.7199**	59.21	60.21	**86.48**	68.63
Freeze nothing	0.7159	0.7214	0.6764	0.7046	68.72	67.43	103.55	79.90

DISCUSSION

The presented approach provides a systematic procedure to improve fairness in segmentation in the low-resolution Task 2 domain by training a model with data from another domain. The results of the freezing layers approach indicate that freezing the network's decoder improves segmentation fairness. This result is different from what is expected, since typical transfer learning approaches involve freezing the encoder. This discrepancy between the theory and results is potentially a byproduct of the small Task 2 dataset being nonrepresentative of the distribution of images in its domain. The DANN approach is presently being explored for transfer learning and the preliminary results are encouraging.

GROWTH PLATE AND ITS ROLE IN PEDIATRIC ACL INJURIES

Isaac. Woodward (1), Antonis. Stylianou (1)

(1) Department of Mechanical Engineering, University of Missouri – Kansas City, Kansas City, MO, USA

INTRODUCTION

Over the last few decades, as competitive youth athletic activity has become more common, anterior cruciate ligament (ACL) injuries have become more common in the pediatric and adolescent populations [1,2]. ACL injuries are much more likely to occur in adolescent females than males [3,4] with injury incidence rate reaching its peak in males between 19-25 years old whereas in females the incidence rate is highest at 14-18 years old [5]. Understanding the reasons behind the incidence rate discrepancy between males and females can help us in treatment and prevention of the injury. Anatomical, muscular and hormonal differences have been correlated to ACL injury risk but no studies have looked into the role of the growth plate (physis) in ACL injury mechanics.

Novaretti et al (2018) speculated that the presence of an open physis may play a role in bone bruising patterns after an acute ACL injury as the energy dissipates across the physis. Data from this study demonstrated that patients with an open physis at the occurrence of an ACL rupture have unique bruise patterns compared to those with a closed physis. In skeletally immature patients the bone bruise pattern is less frequently observed in the tibial and femoral metaphysis [6]. Since closure of the physis occurs in females much earlier than males, it is possible that the physis plays a protective role in relation to the ACL and may explain part of the discrepancy in ACL injuries between the sexes in the adolescent population.

The purpose of this pilot study was to investigate the effect of the open physis in ACL strains under different loading scenarios using a finite element model of the knee joint.

METHODS

The finite element models were created from a de-identified MRI dataset of a pediatric knee joint with an open physis. Geometries for the femur, tibia, fibula, anterior and posterior cruciate ligaments and medial and lateral collateral ligaments, tibial and femoral cartilages, and the tibial and femoral growth plates were segmented using 3d Slicer (www.slicer.org). Two models were created: model 1 included the growth plates and model 2, where the growth plates were fused by removing the growth plates and then filling the resulting space thus fusing the proximal and distal parts of the tibia and the femur (Figure 1).

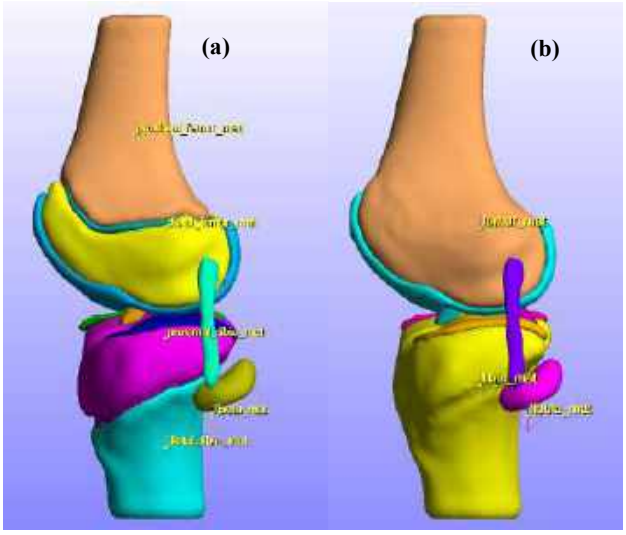

Figure 1: Model 1 with open growth plates (a), Model 2 with fused growth plates (b).

Finite element models were built in FEBio [7]. All bones were modeled as rigid bodies and cartilages, growth plates and ligaments

were meshed with linear tetrahedral elements. Cartilage and growth plates were modeled as nearly incompressible Neo-Hookean materials and all ligaments were modeled as nearly incompressible, transversely isotropic hyperelastic Neo-Hookean materials [8]. Rigid contacts were used for connecting ligaments, cartilage and growth plates to bones and frictionless sliding elastic contacts were created between femoral and tibial cartilages.

Four simulations were run on each of the two models. An unloaded 7mm anterior tibial translation, an unloaded 5-degree internal tibial rotation, a 250 N axial compression with a 7mm anterior tibial translation, and a 250 N axial compression with a 5-degree internal tibial rotation.

RESULTS

Average Lagrange strain and effective stress in the same central region of the ACL ligament (Figure 2) were computed and the results are tabulated in Table 1.

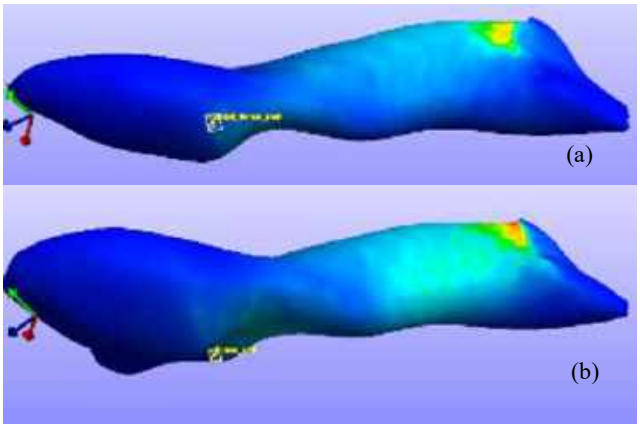

Figure 2: Effective stress maps for the case of loaded internal tibial rotation, model 1 (a), model 2 (b).

	Unloaded Translation		Unloaded Rotation	
	Model 1	**Model 2**	**Model 1**	**Model 2**
Stress(MPa)	15.635	16.575	0.128	0.243
Strain	0.471	0.470	0.016	0.031
	Loaded Translation		**Loaded Rotation**	
Stress(MPa)	20.320	20.980	0.088	0.136
Strain	0.539	0.545	0.011	0.015

Table 1: Stress and strain calculated in the central region of the ACL.

During anterior tibial translation, effective stress is 5.67% and 3.15% lower in model 1 (model that has the open growth plate) for the unloaded and loaded cases, respectively. For internal tibial rotation, effective stress is 47.23% and 35.47% lower in model 1 for the unloaded and loaded cases, respectively.

DISCUSSION

The main finding of this preliminary study is that the open physis can have a protective role on the ACL during loading. Both stress and strain are significantly lower in the model with the open physis especially in the case of internal tibial rotation. The reduction is more moderate in the case of anterior tibial translation however there is still a decrease in stress and strain when the physis is present.

Since closure of the physis happens at different ages between males and females, this result may explain part of the differences seen in ACL injury incidence rates between the sexes during adolescence.

This study has several limitations. Both models were created by a single knee MRI and only two simple loading conditions were investigated. The study needs to be conducted on a much larger sample of knee geometries to establish the validity of the results. In addition, the loading conditions investigated are fairly simple and done in isolation. Simulations should be conducted in cases where anterior tibial translation happens simultaneously with internal tibial rotation and in cases where knee adduction is present.

A NEURAL-NETWORK FINITE-ELEMENT APPROACH TO MODELING OF MULTIBODY CONTACT OF TRILEAFLET HEART VALVES

Kenneth L. Meyer (1), Christian Goodbrake (1), Shruti Motiwale (1), Michael S. Sacks (1)

(1) Oden Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, Texas, USA

INTRODUCTION

Computational modeling in directing patient-specific therapies has great potential to provide accurate predictions and determine optimal treatments. This is especially true for the treatment of heart valve disease due to the complexity of heart valve function, geometry, and highly nonlinear leaflet tissue behaviors. Solving the partial differential equations governing heart valve closure using the Finite Element Method (FEM) has been achieved on a patient-specific level but remains too slow to implement in clinically relevant timeframes. To simulate heart valve closure in clinically relevant timeframes, we have begun development of a Neural-Network Finite Element (NNFE) approach [1]. The NNFE approach has been shown to simulate the deformation of a single leaflet with no constraints subjected to a pressure load with error of 0.1% when compared to traditional FEM simulations [1]. The advantage of this method is its speed and scalability; for fine meshes, speedups of 100x are observed for forward simulations [1]. The functionality required to simulate contact between a deformable and rigid body has been recently implemented in the NNFE framework [2]. In this work, our goal is to extend this to implement full multi-body contact in the NNFE approach for a full tri-leaflet heart valve. We achieve this by first implementing contact with a single leaflet against frictionless symmetry planes, followed by implementing full multi-body contact simulations of the closure of a tri-leaflet heart valve.

METHODS

First, we select a material model to predict heart valve leaflet deformation. Heart valve leaflets undergo relatively large deformations and exhibit highly non-linear behavior. Thus, a hyper-elastic material model is used to accurately capture this behavior. Our choice of strain energy density function Ψ is:

$$\Psi = \Psi_{int} + \Psi_{vol} \tag{1}$$

where

$$\Psi_{int} = C_{10}(\bar{I}_1 - 3) + \frac{c_0}{2}\{\exp[c_1(\bar{I}_1 - 3)^2] - 1\} \tag{2}$$

$$\Psi_{vol} = \kappa J_{ref}(J(J - 2 + D_1) - D_1\, log(J) - D_1 + 1). \tag{3}$$

Ψ_{int} describes the internal hyperelastic strain energy of the system, and Ψ_{vol} describes the volumetric energy that is zero when $\mathrm{J} = 1$, i.e. when there is no change in volume. $C_{10}, c_0,$ and c_1 are constants determined in [3] and κ and D_1 are parameters tuned to determine the strength of the volumetric energy term; they determine the compressibility of the material. Additionally, $I_1 = \mathrm{tr}(C)$ and $\bar{I}_1 = J^{-2/3} I_1$ where C is the right Cauchy-Green deformation tensor. $\bar{I}_1$ is used in place of I_1 because we discretize the leaflets with solid finite elements. Scaling I_1 by a factor of $\mathrm{J} = \det \mathrm{F}$ accounts for distortion during deformation, as we are using solid elements.

The leaflets used during NNFE training in this work had a fixed basal attachment and commissure attachments and deviatoric constants of $\kappa = 1\mathrm{E}4$ kPa and $\mathrm{D} = 1\mathrm{E}9$ were used. In the NNFE framework, *our objective function is the gradient of potential energy* Π:

$$\mathcal{L}(\theta, p) = \nabla\Pi(u, p) \tag{6}$$

During NN training within the NNFE framework we train over all admissible ranges of boundary conditions. Once the network is trained, it can be used to compute the displacement field of a body subjected to a specific boundary condition within this admissible range. In this work, we use the NNFE approach to train a NN that learns the displacement field of tri-leaflet heart valve for the range of pressures they experience during closure. During training, we minimize our objective function for a range of pressures $\mathrm{p} = \{\mathrm{p_i} \in [0.0, \mathrm{p_{max}}]\}_{\mathrm{i=1}}^{\mathrm{n}}$, where the sample $\mathrm{p_i}$ are generated using a Halton Sequence. These pressures are inputs to the NN, as shown in the flow chart below.

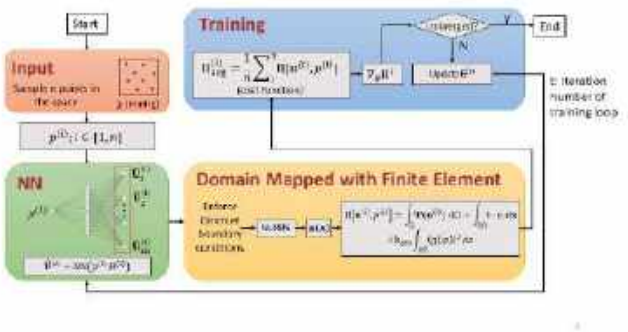

Figure 1: NNFE Training Pipeline (with Contact)

The NNFE approach uses Finite Elements to discretize our domain, so during each epoch, we use this discretization to enforce boundary conditions and compute the gradient of the total potential energy of the system. This process is shown below, note that it does *not* involve training on data.

This work adds contact to a structural model of heart valve leaflets within the NNFE framework. An energy penalty term is used to discourage penetration between a leaflet and a plane, and later a leaflet with another leaflet to simulate contact [2]:

$$\Pi = \int_\Omega \Psi \, d\Omega + \int_{\partial\Omega} t \cdot n \, ds + k_{pen} \int_{\partial\Omega} \langle -g(\varphi) \rangle^2 \, ds \qquad (7)$$

This term computes the signed distance from a body to another body using a gap function g to check for penetration, where $\langle x \rangle = min(x, 0)$. In the multi-body setting, we can integrate multiple gap functions g^{ij}, the signed distance from the i^{th} to the j^{th} leaflet. The distance from a point on one leaflet to another leaflet is defined as $min\, d\left(x_i, x_j\right)$, where x_i and x_j are nodes on the meshes for the i^{th} and j^{th} leaflets. A contact penalty $k_{pen} = 20.0$ was used to penalize penetration in this study.

RESULTS

Contact between a single leaflet of a tri-leaflet heart valve and a frictionless symmetry plane was simulated first. Below, the FEM simulation of this leaflet under a 30mmHg pressure load in FEniCS is shown, where the frictionless symmetry plane is shown in the background in grey, where u is the displacement field:

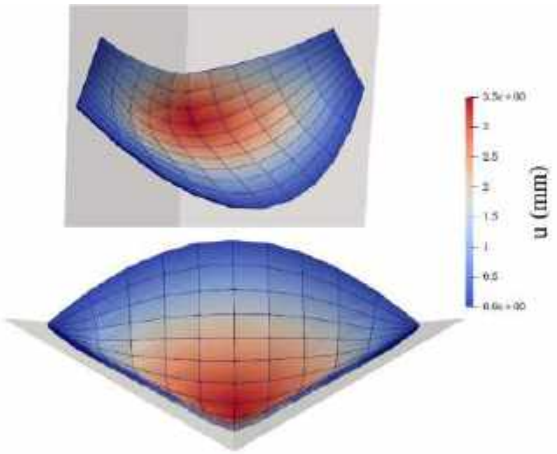

Figure 2: A Single-leaflet Contact Result Using FEM (Side/Top)

This shows that the contact energy penalty term succeeds in capturing the deformation of a heart valve leaflet with solid elements. The L_∞ error of the NNFE solution and a FEniCS is 0.9mm, which will be improved upon with further NN training and debugging. The speedup of the NNFE method remains with the implementation of contact, which is advantageous as it allows high-fidelity simulations to be run cheaply, which is a requirement to use this method in a clinical setting:

	Runtimes	
# control points	**NNFE**	**FEniCS (FEM)**
147	5.34s	89.36s
720	5.75s	788.53s

Table 1: NNFE Runtimes Scale Better than FEM

A result using the NNFE approach was obtained for multi-body contact for a tri-leaflet heart valve. A NN was trained to predict the closure of a tri-leaflet heart valve, and below is the displacement produced by the network for a tri-leaflet valve under a pressure load of 30mmHg:

Figure 3: Multi-body Contact, Open and Closed States

This demonstrates that full multi-body contact in the NNFE framework is achievable as a physiologically accurate deformation of a tri-leaflet heart valve with contact between each leaflet pair is observed. This is the first successful multi-body contact simulation achieved in the NNFE framework.

DISCUSSION

Our findings are consistent with results seen while studying the deformation of a flat plate with the NNFE approach – the NNFE simulations are significantly faster without a large loss in accuracy [1]. The convergence of the solution with mesh refinement has not yet been rigorously studied. Additionally, the scalability of the NNFE approach needs to be verified in the multi-body contact setting. Lastly, there is a small orifice in the center of the valve; this can likely be eliminated by improvements to the NN training process. Once these are improved upon, different types of boundary conditions can be trained over. This includes geometry; we hope to use the NNFE approach to train a NN over ranges of admissible geometric parameters - including leaflet height and tilt angle – to predict displacement fields under a given load.

INTRODUCTION

Local disruptions in collagen quality can result in aberrant tissue properties leading to bulk scale failure [1]. It is unclear if disruptions to tissue structure and composition manifest similarly in all tissues. Moreover, the early detection of collagen dysfunction is complicated by the inherent variability within tissues that is challenging to account for with standard statistical methods. Finally, a non-invasive method to detect tissue dysfunction continues to be an urgent need. Therefore, the objectives of this study were to (1) assess the effect of systemic collagen dysfunction on tissue microstructure and composition, (2) develop a machine learning model for predicting collagen dysfunction based on microstructure, and (3) evaluate the capacity for diffusion tensor magnetic resonance imaging to quantify tissue dysfunction.

METHODS

Animal model: A transgenic missense mutation Col3a1^{G938D} [2] that mimics the collagen dysfunction of vascular Ehlers-Danlos Syndrome was used. Pairs of Achilles tendon and cervix from a 61 day-old Col3a1$^{G938D/+}$ female and a littermate control (WT) were harvested.

Diffusion tensor MRI: DT-MRI was used to providing non-invasive inferred measures of microstructure [3]. DT-MRI data of the cervices were obtained using a 9.4T MRI scanner (Bruker). Following calibration procedures and structural imaging, DTI data were acquired using a spin-echo sequence (repetition time, 2000 ms; echo time, 20 ms; b-value, 500 s/mm^2; 12 diffusion-encoding directions; slice thickness, 1 mm; in-plane resolution, 0.1x0.1 mm^2). The diffusion tensor was estimated by regressing the signals on the b-value and diffusion-encoding matrix using a weighted least squares method. The eigenvalues and eigenvectors were estimated using singular value decomposition. The longitudinal and perpendicular diffusivities and fractional anisotropy were calculated.

Tissue sectioning: Tissues were embedded in optimal cutting temperature media for cryosectioning (sagittal, tendon; transverse, cervix) at -20ºC. Adjacent sets of 50 and 5 μm thick sections were used for microstructural and compositional measurements, respectively.

Microstructural measurements: Second harmonic generation (SHG) imaging was used to quantify collagen microstructure. A femtosecond laser (MaiTai DeepSee, Spectraphysics) producing 70-fs centered at 780 nm was used to illuminate the sample while a confocal microscope (Zeiss LSM 710, Oberkochen) imaged the tissue sections using a 40 × 1.2 NA water-immersion objective lens. Backward SHG signals were collected from each image volume (80x80x50 μm). The out-of-plane collagen fiber orientation (ϕ) and the three-dimensional dispersion of the collagen fibers (SV: spherical variance) according to previous work [4]. Analyses were performed in Matlab (Mathworks).

Compositional measurements: High-definition Fourier transform infrared (HD-FTIR) spectroscopic imaging [5] was used to quantify changes in protein secondary structure. HD-FTIR images were obtained on a Cary 670 spectrometer (Agilent) coupled to a Cary 620 microscope (Agilent) using a 15x reflective objective in high-magnification mode with a 128x128 element focal plane array (FPA) Mercury-Cadmium-Telluride liquid nitrogen cooled detector providing 1.1 μm square pixels. Background spectrum was acquired at 128 coadditions per pixel on a clean area of the slide. Each spectrum was baseline corrected to account for scattering and truncated to the lower noise spectral range of 900 to 3800 cm^{-1}. Initial data was processed in Python with further data processing and analysis occurring in either ENVI (L3Harris Geospatial) or Matlab.

Specifically, we spectroscopically quantified the components of the Amide I band (sensitive to protein secondary structure [6]), glycosaminoglycans and two of the major collagen cross-links (pyr and deH-DHLN) and mapped their spatial distribution as a function of anatomical location.

Predictions of tissue origin and dysfunction using microstructure: We evaluated two prediction tasks using machine learning: (1) WT tissue origin (inner cervix, outer cervix, or tendon) and (2) detection of

missense mutation using SHG images. For classification settings, we used stratified cross-validation, i.e., where each split of train and test is proportional to the distribution of class labels of the whole dataset. Results were evaluated using 5-fold cross-validation and compared against a random performance baseline of 25% accuracy.

RESULTS

The morphological effect of a collagen III missense mutation was more clearly seen in the cervix than tendon. The cervix in TM mice was smaller in diameter and had a smaller cervical canal than WT (Fig 1E).

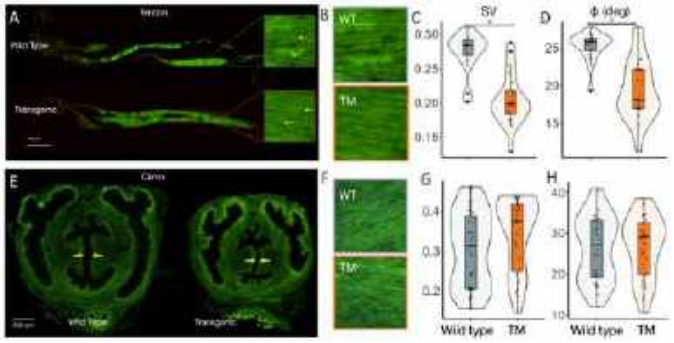

Figure 1: Tissue specific changes from Col3a1 mutation (TM)

Collagen III missense mutation disrupted tendon, but not cervix, collagen microstructure. There were distinct and measurable microstructural differences in tendon with the Col3a1 mutation. Fibers were more heterogeneous in the WT group (Fig 1B) and measured as a decrease in SV (Fig 1C) in contrast to the trend of the cervix. The Col3a1 mutation markedly decreased the degree of alignment (ϕ, Fig 1D) in tendon but had no effect in the cervix.

Collagen missense mutation affects more than collagen content. On average there were significant spectral differences between the WT and TM samples including absorbance at 1336 cm^{-1}, 1392 cm^{-1}, 1452 cm^{-1}, and line shape differences in the Amide I (1640 cm^{-1}) and Amide II (1536 cm^{-1}) bands and are indicative of differences in protein composition and secondary structure. The spatial variation in Amide III (collagen) normalized intensity at 1240 cm^{-1} (Fig 2A) highlights collagen content across the tendon with increased heterogeneity in WT. Spectral differences in tendon were also found at 1080 cm^{-1} (phosphate stretch), Amide I and II, and 1744 cm^{-1} (C=O stretch). Similar variations were found in the cervix but at different spectral values. The spatial distribution of the Amide I normalized intensity (1516 cm^{-1}) was increased between the IZ and OZ of the cervix and the vaginal wall (Fig 2C,E) and decreased intensity in WT (Fig 2D).

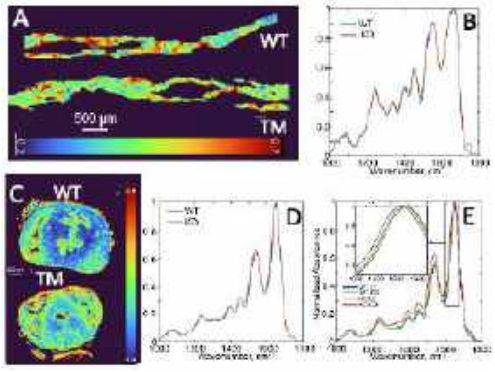

Figure 2: Missense mutation changed Coll III distribution in tendon (A,B) and cervix (C-E).

Predicting tissue origin and missense mutation: The machine learning model accuracy for predicting WT tissue origin (tendon, inner cervix, or outer cervix) was 96.4 (± 0.03)% (Fig 3A). This model was also able to differentiate TM from WT tendon with 94.4 (± 0.06) % accuracy (Fig 3B).

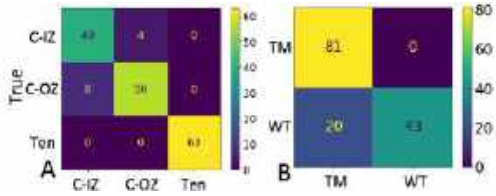

Figure 3: Accuracy of prediction of WT tissue origin (A); between WT and TM (B).

DT-MRI measurements were sensitive to the effects of collagen III mutation. Longitudinal diffusivities and fractional anisotropy decreased in cervix with missense mutations (Fig 4). There was no effect on diffusion in the perpendicular direction. FA maps reveal spatial heterogeneity.

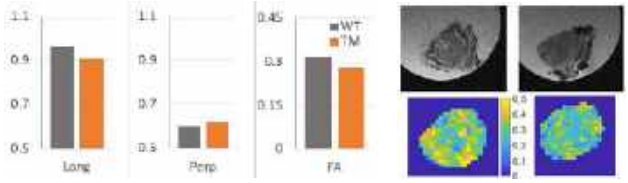

Figure 4: Diffusion tensor metrics of inner zone in cervix indicative of tissue microstructure. Spatial map of FA (bottom

DISCUSSION

The effects of collagen III on structural determinants of tissue quality were tissue specific. The overall size of the cervix was affected by the missense mutation but only subtle changes in fiber dispersion. In contrast there were clear differences in tendon fiber dispersion and orientation between the WT and TM; however there was overlap in SV values. Some of the WT mice had portions of tendon with similar structural phenotypes as those with the collagen mutation indicating that genetic mutations in collagen manifest heterogeneously.

Accordingly, the missense mutation altered the spatial distribution of the Amide bands in both tendon and cervix. The missense mutation decreased collagen III heterogeneity along the tendon length. Similar radial changes were found in the cervix: the outer zone became enriched in type III collagen whereas the inner zone in type I. Changes in Amide I may be due to increased triple helix (1637 cm^{-1}) and α-helix vibrations (1658 cm^{-1}) [6]. The variation in C=O stretch in tendon between WT and missense mutations may indicate differences in glycosaminoglycan (GAG) content and composition [7].

DT-MRI diffusion metrics complemented the microscopy results providing additional evidence of subtle changes in cervix microstructure wherein the longitudinal diffusion was most sensitive. Importantly, these data indicate the potential of DT-MRI as a non-invasive imaging modality to detect the effect of collagen dysfunction.

We were successful in using machine learning to develop a predictive model of tissue origin and dysfunction with high accuracy. The capacity to distinguish tissues using a single model suggests that a single principle of structure-function may be possible - even for tissues with clearly distinct biological functions such as tendon, cervix. Future work by our group aims to confirm and expand upon these results to provide novel, clinically viable metrics of tissue function.

ACKNOWLEDGEMENTS

We are grateful to the lab of H Dietz for donating the tissues.

PROFIBROTIC AND MYOFIBROBLAST ACTIVATION GENE EXPRESSION IN RIGHT VENTRICULAR CARDIAC FIBROBLASTS IN PULMONARY ARTERIAL HYPERTENSION

Giuditta Monti (1), Yufan Li (1), Daniela Valdez-Jasso (1)

Department of Bioengineering, University of California, San Diego

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a vascular disease characterized by a sustained rise in mean pulmonary arterial pressure exceeding 20 mmHg [1]. Despite being 4 times more predominant in women, men have worse outcomes and lower survival rates [2]. In PAH the right ventricle (RV) can adapt to the pressure overload. However, if left untreated, this often results in right heart failure. Thus, RV function is an important predictor of morbidity and mortality in PAH patients [3].

Clinical data have shown RV diastolic stiffening in PAH patients [4]. Our group and others have used the well-established rat model of PAH (sugen-hypoxia) and found RV myocardium diastolic stiffening to be a mechanism to compensate for the sustained pressure [4]. When examining the passive tissue properties of the intact and decellularized myocardium via planar biaxial mechanical testing, our group found significant remodeling of the collagen extracellular matrix (ECM) [5]. However, in this same study, the collagen concentration did not appear to be significantly different [5]. When we measured profibrotic and myofibroblast gene expression in RV tissues, we found them to be upregulated. Thus, we inferred that RV cardio fibroblasts (CFs) have a role in RV remodeling and investigated their response to mechanical stimuli (i.e. substrate stiffness and stretching). We thus hypothesize that in PAH these RVCFs get activated, leading to an increase in myofibroblast population, collagen production, and ECM remodeling, which leads to progressive RV diastolic stiffening.

METHODS

Adult cardiac fibroblasts were isolated from right ventricular (RV) free wall harvested from normotensive male Sprague–Dawley rats (Charles River Laboratories, Wilmington, MA, USA) and cultured in two T75 flasks per animal. After reaching confluency, cells were detached and platted onto collagen-coated circular hydrogels (12 mm diameter) on a PDMS membrane (200,000 to 300,000 cells were plated on each hydrogel). The remaining cells were platted back in a T75 flask and used in following experiments, up to 3 passages. Thus, up to six experiments can be completed with the cells isolated from one RV. The hydrogels were designed and produced to be at 7 kPa or 40 kPa, the approximate stiffness experienced by cells in healthy or pathological conditions, as reported by Jang et al [6]. To account for the strain experienced by the fibroblasts in pathological conditions due to the changes in pressure, and thus vessel diameter, the PDMS membranes were biaxially stretched by 10% in a custom-made 3D-printed polycarbonate circular stretcher. The control group was plated on 7kPa hydrogels on unstretched membranes [7]. To exclude the role of animal serum from our data, the cells were fed serum-free DMEM media at the time of stretch, 24 hours before being harvested and lysed. The isolated RNA was then used to synthetize cDNA and run qPCR to determine the changes in gene expression due to both changes in stiffness and stretching. The cells cultured on each gel constitute one analyzed sample. The mRNA of Collagen 1a1 (*Col1a1*), Collagen 3a1 (*Col3a1*), Elastin (*Eln*), lysyl oxidase-like 1 (*Loxl1*), α-smooth muscle actin (Acta), fibronectin 1 (Fib1), and muscleblind-like protein 1 (*MBNL1*) were measured and normalized to the housekeeping gene 18S ribosomal (Figure 1). The data was analyzed using two-way ANOVA, with stiffness and stretch being the fixed factors.

RESULTS

Profibrotic and Myofibroblast Activation Gene Results:

QPCR analysis of RVCFs harvested from male rats and cultured on hydrogels of different stiffnesses (7 kPa and 40 kPa) and with different stretch (none or 10%) showed that all the analyzed genes changed under these conditions. More specifically, the profibrotic genes *Col1a1*, *Col3a1*, and *Fn1* genes were upregulated on a stiffer substrate in cells derived from male rats. The myofibroblast activation genes *Loxl1* and *Acta* were also upregulated when the samples were stretched (**Figure 1)**. Each dot in Figure 1 represents one sample (cells cultured on one single hydrogel).

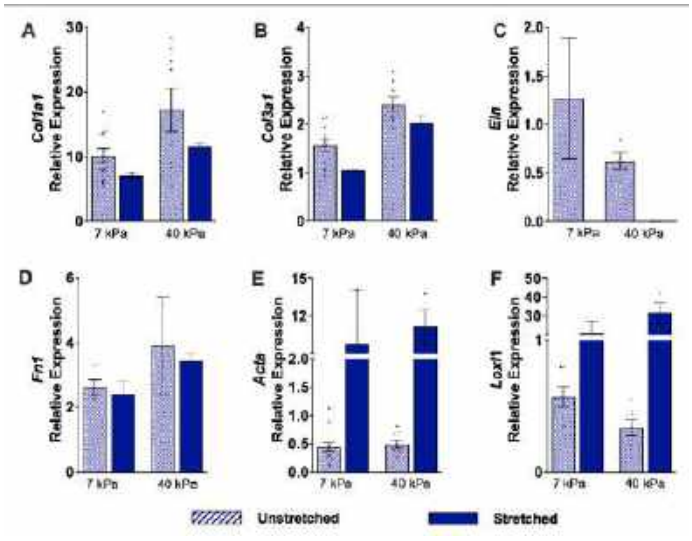

Figure 1: Relative expression of profibrotic genes (A) *Col1a1* (B) *Col3a1,* (C) *Eln,* (D) *Acta,* (E) *Fn1,* (F) *Loxl*1 in RV cardiac

fibroblasts isolated from male rats and cultured on different substrate stiffness (7 kPa and 40 kPa representing normotensive and PAH conditions) and stretch (10% or none). The expression is relative to the housekeeping gene 18S and plotted as mean ± standard errors of the mean of mRNA levels. *p<0.05 stiffness and # p<0.05 stretch.

DISCUSSION

Our studies on male derived RV fibroblasts show a significant upregulation of profibrotic genes due to increased substrate stiffness (*Col1a1, Col3a1, Fn1*) (**Figure 1**). The myofibroblast activation genes *Acta* and *Loxl1* were significantly upregulated by stretch, but not by stiffness (**Figure 1**). Thus RV male-derived cardiac fibroblasts respond more to changes in substrate stiffness and myofibroblast activation genes to stretch. While our preliminary data are limited to male rats, we are expanding our study to include fibroblasts collected from female rats. Based on our mechanobiology studies on PAAFs, we have observed significant differences in profibrotic gene expression between male and female derived cells [7].

Based on the findings from a detailed literature review, we found that MBNL1 is crucial to myofibroblast activation in myocardial hypertrophy [8]. Since myofibroblast activation also occurs in PAH, we hypothesized that the RNA-binding protein *MBNL1* plays a role in myofibroblast activation in PAH [9]. Preliminary qPCR results on a control sample (male RVCFs on a 7 kPa gel, with no stretch) showed that the *MBNL1* primers we designed can detect the gene with high specificity, and that this gene is expressed in rat RVCFs (**Figure 2A**). In addition, *MBNL1* expression increased when samples were stretched (10%) and on a stiffer substrate (40 kPa) (**Figure 2B**).

A study by Elhasnaoui et al. on primary tumor cells showed that estrogen is a key modulator of *MBNL1* concentration [10]. Thus, we hypothesize that *MBNL1* relative expression is upregulated in the RV and modulated by estrogen, making *MBNL1* one of the intermediaries in the pathways that make PAH sex dependent. As a further step in understanding the role of sex hormones in PAH, we will incorporate estrogen studies to study its potential role in upregulating or downregulating the analyzed genes.

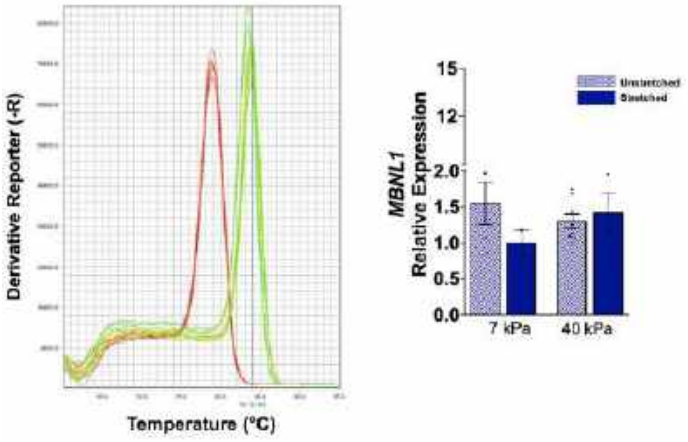

Figure 2: (A) The red peak in the melt curve represents the housekeeping gene 18s as control. The green peak represents *MBNL1*. This plot shows that the primers were designed correctly and *MBNL1* is in fact expressed in RV cardiac fibroblasts. (B): *MBNL1* relative expression in male rats changes as fibroblasts are stretched and on a stiffer substrate.

Finally, our experimental data will be employed to expand the biochemical model developed by Saucerman et al. [11] This model maps the cellular pathways of cardiac fibroblasts to provide quantitative predictions of the biomechanical outputs using normalized Hill-type ordinary differential equations [11].

HEMODYNAMIC ANALYSIS OF SINOTUBULAR JUNCTION PLICATION TECHNIQUES DURING ASCENDING AORTIC REPLACEMENT

Hannah Zhai (1), Yurui Chen (1), Yu Hohri (2), Hiroo Takayama (2), Vijay Vedula (1)

(1) Department of Mechanical Engineering, Columbia University, New York, NY, USA
(2) Department of Surgery, Columbia University Medical Center, New York, NY, USA

INTRODUCTION

The sinotubular junction (STJ) plays an important role in the function and motion of the aortic valve. [1] In some cases of STJ dilation, it is coupled with an aortic root aneurysm, for which current guidelines recommend aortic root surgery if the root diameter is >4.5cm. [2] However, root surgery is not recommended if the STJ dilation occurs without a root aneurysm, as the longer operative time introduces unnecessary risks. [3] These patients with STJ dilation, but without root aneurysms (see Fig 1a), are treated by ascending aortic replacement surgery.

The typical replacement surgical procedure is a secure proximal anastomosis technique, in which a prosthetic graft is secured to the native aorta using a simple suture technique to shrink the STJ diameter, shown in Fig. 1(b). In this work, we aim to evaluate the hemodynamic performance of a new technique, which utilizes a Hegar dilator to tighten the graft in the STJ region to a specific optimal size based on preoperative computerized tomography (CT) imaging. After tightening, the graft is anastomosed with the primary prosthetic graft.

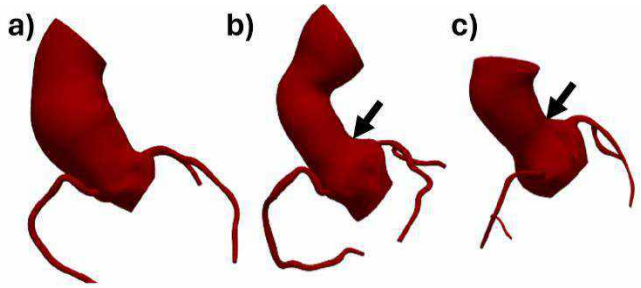

Figure 1: Patient-specific models of ascending aorta. a) before surgery; b) Patient A: after surgery, old surgical method; c) Patient B: after surgery, new method.

In this preliminary analysis, we evaluate the hemodynamic patterns in the ascending aorta for two patients, one from each surgical method. We aim to visualize the blood flow in the STJ region after both surgeries using personalized multiscale computational hemodynamics modeling, and examine if the new technique restores 'normal' flow patterns.

METHODS

We use SimVascular's workflow to perform multiscale patient-specific blood flow modeling in ascending aorta with coronary circulation (Fig. 2).[4,5]

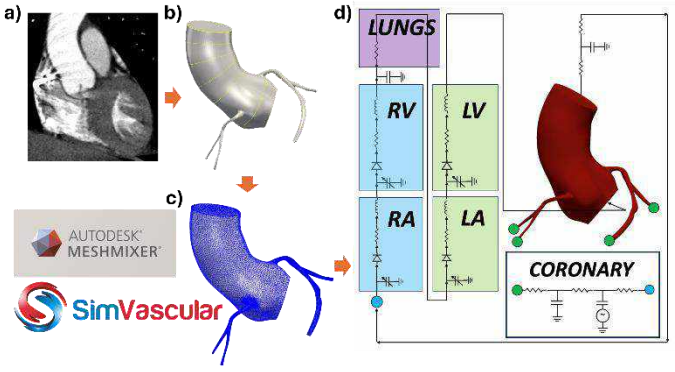

Figure 2: Workflow for multiscale patient-specific blood flow modeling. a) CT images of the ascending aorta. b) Segmentation and model creation pipeline. c) Mesh using boundary layers and local refinement. d) Schematic of the closed loop 0D/3D model used for multiscale blood flow simulation.

The image-to-flow pipeline (Fig. 2) to evaluate the hemodynamic patterns for each case begins with the CT images, where segmentation was performed using SimVascular to extract the aorta, starting from the aortic root through a short portion of the ascending aorta, with major

coronaries (Figs 2a,b). [4] The surface was then exported as a triangulated surface and was smoothed at the vessel bifurcations and refined in Meshmixer (Autodesk Inc.). The refined model was then reimported back into SimVascular, where the surface and volumetric meshes were generated, employing regional refinement for the coronaries, with a boundary layer mesh in the ascending aorta (Fig. 2c). The total number of tetrahedral elements for each model was ~1M. The 3D model was coupled to a 0D lumped parameter network (LPN) model of the circulatory system to apply physiologically relevant boundary conditions (Fig. 2d). The parameters of the LPN model were tuned manually to fit clinical data (Table 1).

Table 1: Patient Clinical Data

	Patient A (old method)		Patient B (new method)	
	Pre	Post	Pre	Post
BP (mmHg)	120/70	129/79	146/96	130/88
HR (bpm)	59	74	70	85
Height (in)	65		67	
Weight (lb)	175		179	

We modeled blood as an incompressible Newtonian fluid and assumed the walls to be rigid. We employed stabilized finite element methods to simulate blood flow with the implicit, second-order accurate, generalized-α time integration method, implemented in a validated open-source solver, *svFSI*.[6] The coupling between the 0D and 3D flow solvers is achieved using a modular, implicit coupling approach to resolve the multiscale interactions between the 3D and 0D flow solvers. [7] The resulting nonlinear equations are solved using the bi-partitioned method for incompressible flows with backflow stabilization. [8] Blood flow simulations were performed for pre- and post-operative models for each patient, from each surgical method, and the resulting hemodynamics were compared.

RESULTS

The resulting velocity and pressure fields, flow rates, and wall shear stresses were simulated for each case, for six cardiac cycles until the LPN flow rates and pressures were equilibrated. A representative flow field and flow rate waveforms at the inlet and various outlets are shown in Fig. 3 for the preop model (Patient B).

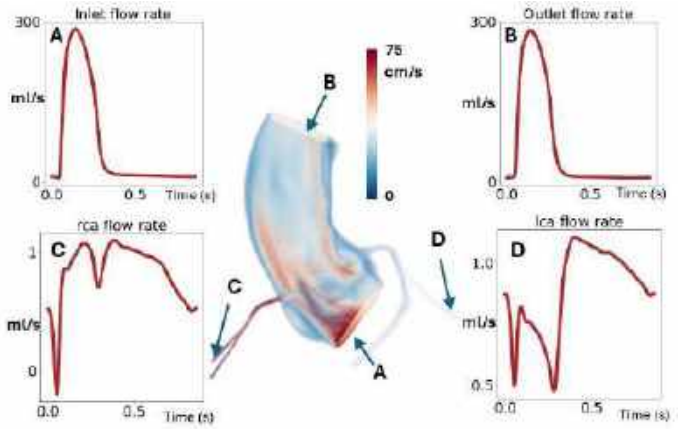

Figure 3: Flow field during peak systole and time-varying flow rates at various boundary faces (A-D) for Patient B, pre-surgery.

Additionally, the time-averaged wall shear stress (TAWSS) was computed for each of the four models and is shown in Fig. 4. We note that the TAWSS appears to be generally elevated in the STJ region in the postoperative models, with the newer method (Patient B) demonstrating a higher degree of elevation.

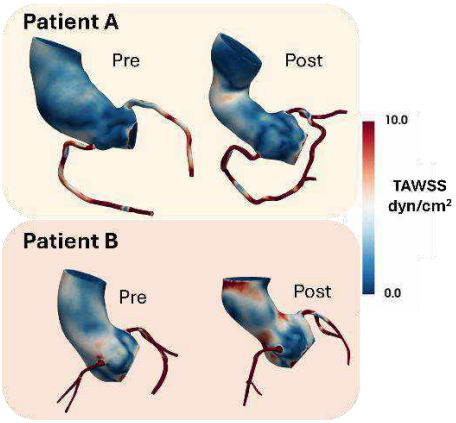

Figure 4: Comparison of TAWSS between the two surgical methods, pre- and post-surgery. (top, Patient A) old; (bottom, Patient B) new method.

DISCUSSION

Here, we performed patient-specific blood flow modeling for two patients with STJ dilation and compared two surgical techniques to address it. Our preliminary analysis found that the TAWSS increased in postoperative models, with a marked increase in the newer method, where the dimensions of the aorta are closer to a normal value, compared to the older method. However, further analysis is required against healthy subjects to understand the hemodynamic implications of the newer surgical reconstruction technique.

One of the limitations of the current model is that the boundary conditions for the pre/postop simulations for both patients were different, tuned to match the patient's blood pressure at the time of CT imaging. This resulted in changes in the LPN parameters, including cardiac output. To perform a fair comparison between the two methods, we plan to virtually apply the new surgical technique to patients who underwent the old surgical method, by morphing the STJ diameter to the size of the Hegar dilator that the new technique would have used. Additionally, we plan on simulating both surgical methods with the same boundary conditions tuned to the preoperative model, to determine the differences between the two procedures independent of variations such as the patient's blood pressure at the time of measurement.

Further, to address the current limitations of the preliminary analysis, we additionally plan to include fluid-structure interaction (FSI) with the aortic valve to measure aortic insufficiency, a major health concern in these patients, and perform blood flow modeling without a rigid wall assumption. We will employ the material properties of the prosthetic graft while performing FSI simulations to capture realistic deformations and hemodynamic stresses. We will perform this analysis on multiple patients to demonstrate statistical significance.

INTRODUCTION

Breast cancer is the most common cancer type among women in the United States [1]. The American Cancer Society estimates that the number of new cases will reach 310,720 and the number of deaths will reach 42,250 in 2024 [2]. These prognostics highlight a need for the early detection and treatment of breast cancer. Furthermore, breast cancer development can lead to metastasis. Metastasis causes high mortality in most cancers because cells migrate from the primary site and spread to lymph nodes or distant organs [3]. During the initial stages of metastasis, cancer cells migrate by degrading and moving through the ECM (extracellular matrix) of the surrounding tissue. Studies postulate that metastasis is driven by cell invasion and migration through the ECM during those initial stages. Therefore, a deeper understanding of the cell-matrix dynamics is necessary to identify the necessary steps towards metastasis prevention.

Cell migration is affected by interstitial flow through individual and collective contributions of various biological phenomena. The connection between interstitial flow and cell migration is of key interest because interstitial flow is linked to extracellular matrix permeability and provides direct mechanical cues via shear and normal stress. To identify the mechanisms that regulate cell migration, it is necessary to manipulate interstitial flow velocity and extracellular matrix permeability independent of parameters such as stiffness and cell-binding site density. Previous studies have used single gel-based cell culture models to study cell migration, but these models are limited by the interconnection between various properties of a hydrogel. To improve traditional single gel-based cell culture models used to observe cell migration, we propose a dual-gel dual-porosity 3D cell culture matrix that enables independent control of key matrix properties that retains and mimics the structural heterogeneity of the extracellular matrix. We study the morphology and migration of GFP MDA-MB 231 breast cancer cells under controlled interstitial flow in a dual-gel matrix consisting of stiffer primary GelMA-PEGDA (gelatin methacryloyl-polyethylene glycol diacrylate) microgels, acting as the main cell adhesive, and a secondary softer alginate hydrogel in the interstitial spacing of the primary matrix, acting as a control mechanism for permeability and directly compare with our previous study that used collagen as a secondary gel. Our results confirm that the microfluidic dual-gel cell culture model improves the single gel-based cell culture model and allows quantitative studies on interstitial flow effects on cell behaviors.

METHODS

The microfluidic dual-gel dual-porosity cell culture model is manufactured through standard soft lithography using a layer of PDMS (polydimethylsiloxane). The cell culture model shown in Figure 1 consists of: (1) four culture chambers measuring 1000 μm × 1000 μm × 200 μm that are surrounded by 30 μm square filters, (2) two microgel injection inlets labeled A1 and A2, (3) four outlets labeled C1, C2, C3, and C4, (4) two cell injection inlets labeled B1 and B2, and (5) a central inlet used for medium injection labeled D. The PDMS layer is bonded to a coverslip via oxygen plasma treatment.

The 100 μm diameter GelMA-PEGDA microgels are made by crosslinking monodisperse droplets generated by a PDMS droplet generating device. The microgels consist of an aqueous solution of: *20 wt.%* PEGDA, *8 wt%* GelMA, and *0.5 wt.%* Irgacure 2959 as the dispersed phase, and HFE oil with *2 wt%* Fluorosurfactant as the continuous phase. The sodium alginate solution consists of an aqueous solution of *1.5 wt%* sodium alginate, 15 mM $CaCl_2$, and 7.5 mM DM-Nitrophen.

Following the microfluidic model fabrication is degassing and microgel injection. The densely packed microfluidic devices, shown in Figure 2, are placed under the biological hood for UV sterilization. After sterilization, cells are seeded at a 8×10^6 *cells/mL* cell density. We allow 24 hours for the cells to adhere to the microgels before we fill the interstitial space between the microgels by the softer secondary alginate

gel. The migration behavior of the cancer cells can be compared to the dual gel system we previously studied using collagen as the secondary gel. In both studies, the cells are cultured under interstitial flow of 5 μm/s. After 24 hours of live cell imaging, we assess cell viability using ethidium homodimer staining.

The study using collagen as the secondary gel uses Collagen Type I 1.5 *mg/mL* collagen concentration and 5×10^6 *cells/mL* cell density. The collagen solution is kept below 4°C to avoid gelation. After cell seeding the microfluidic device is placed in an incubator at 37°C and 5% CO_2 for two hours for gelation. The collagen study uses RFP MDA-MB 231 cells and as a result cell viability tests use Calcein AM. The collagen iteration of the study computed 4D tomographs using Imaris software. Using Imaris allows spot tracking to automatically capture and track cell migration over the length of the 24-hour imaging with the appropriate modifications. Live cell imaging is captured using confocal microscopy (Zeiss LSM 800).

RESULTS

First, the microfluidic dual-gel cell culture model is characterized using: (1) volume fraction of the primary gel matrix, (2) confining pore size, (3) interstitial fluid velocity, (4) stiffness, and (5) permeability. Interstitial flow promotes amoeboid mobility. The collagen study showed a 90% viability over three days, shown in Figure 3, verifying the feasibility of our 3D invitro cell culture model. Experiments were conducted multiple times to confirm reproducibility. Cell migration behavior is quantified by analyzing: (1) motility, (2) migration speed, (3) persistence, and (4) cells aspect ratio. The primary gel matrix promotes cancer cell motility with mesenchymal-like morphology. The presence of the GelMA-PEGDA microgels caused a high percentage of mesenchymal-like cells due to the microgels' strong cell binding surface. At a 8 *wt%* concentration, GelMA offers more cell binding sites than collagen at 1.5 *mg/mL* concentration.

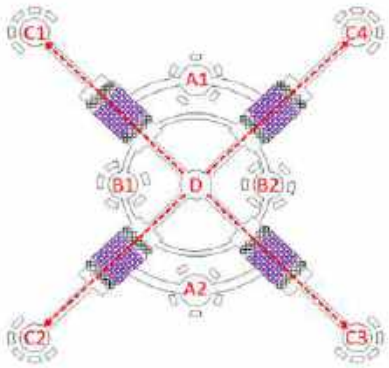

Figure 1: Schematic of the microfluidic cell culture chip. The red dashed arrow shows the direction of the fluid flow.

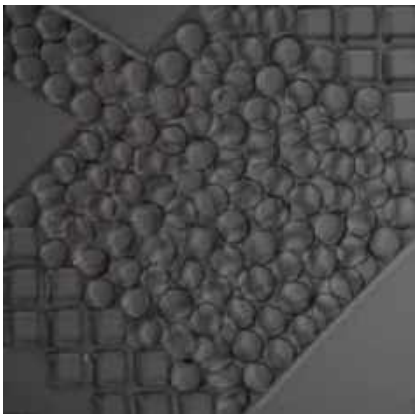

Figure 2: Confocal image of densely packed GelMA-PEGDA microgels in microfluidic device.

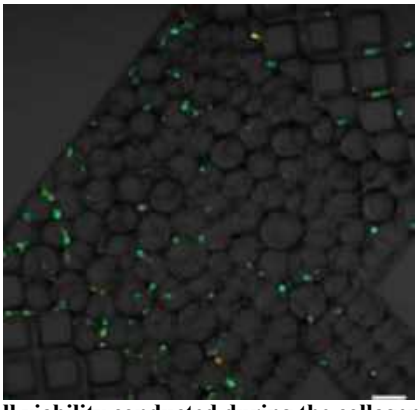

Figure 3: Cell viability conducted during the collagen study using 2 μM Calcein.

DISCUSSION

Our results and observations are consistent with previous studies that state interstitial flow promotes MDA-MB 231 cells in 3D cell culture towards the amoeboid cell morphology and motility. This is explained by low adhesion molecules present such as fibronectin during flow, as flow takes away the cell-secreted adhesion molecules. This phenomenon prevents fibril assembling which further prevents durable adhesion formation with ECM fibers. Our proposal to replace collagen with alginate will corroborate our findings because alginate has no cell-binding sites. Our dual-gel dual-porosity cell culture chamber effectively demonstrates that the stiffness of the primary gel is the dominant local mechanical property that regulates cell migration behaviors. With the substitution of collagen with alginate, we will eliminate all the cell-binding sites of the secondary gel and open the platform to a range of other studies.

A THERMODYNAMICS-BASED APPROACH FOR ESTIMATING VENTRICULAR EFFICIENCY: APPLICATION IN PATIENTS WITH SINGLE VENTRICLE PHYSIOLOGY

INTRODUCTION

Patients with congenital heart disease (CHD) have complex cardiovascular malformations and compromised blood circulation. One method for assessing energetics in complex CHD is through the estimation of ventricular mechanical efficiency (VE). Current approaches for VE estimation require invasive cardiac catheterization-based pressure-volume loops and inferior vena cava (IVC) occlusion, which makes it unsuitable for routine clinical exams. A new model for VE estimation is developed based on thermodynamic principles that eliminates the need for IVC occlusion and could be estimated using radiographic and hemodynamic metrics obtained during routine clinical exams. The developed model aims to provide additional information about ventricular performance, which may aid in clinical diagnosis and surgical treatment planning.

METHODS

The ventricular efficiency model VE_{Thermo} was developed based on the thermodynamic analysis of energy exchange occurring during each cardiac phase W_{1-2}, W_{2-3}, W_{3-4} and W_{4-1} (Figure 1). VE_{Thermo} is defined as the ratio of energy in blood flowing out of the ventricle to the total energy expected to be consumed by the ventricle during a complete cardiac cycle (Eq. 1). VE_{Thermo} is then compared with ventricular efficiency approximated from the pressure-volume area (PVA), VE_{PVA} (Eq. 2) [1]. In this work, VE_{Thermo} and VE_{PVA} are used to assess the ventricular performance of patients with single ventricle physiology (SVP) at different stages of single ventricular palliation.

This study was approved by the UCLA Institutional Review Board and utilized retrospective clinical data from 17 SVP patients who had undergone clinical cardiovascular magnetic resonance imaging (MRI) exams at 1.5T or 3.0T. The data included in the simulations consisted of 4D MUSIC and cine MRI, 2D and 4D flow MRI, cardiac catheterization-based aortic (P_{aortic}) and ventricular pressures ($P1$, $P2$, $P3$, and $P4$), and vital signs (heart rate, blood pressure, pulse oximetry). MRI DICOMs were analyzed in Circle cvi42 and 3D Slicer to obtain ventricular end-systolic volume (ESV), end-diastolic volume (EDV), and aortic flow rate (Q_{aortic}). Baseline data for 19 healthy female volunteers aged 20 to 50 years, denoted by 'Left Ventricle (LV) in 4-chamber heart' were used for comparison. Student's t-test was used to compare the difference between the mean VE of each SV palliation stage and healthy LV. Next, errors for estimation of VE_{Thermo} based on non-invasive blood pressure (NIBP) versus cardiac catheterization-based pressure in SVP patients were analyzed.

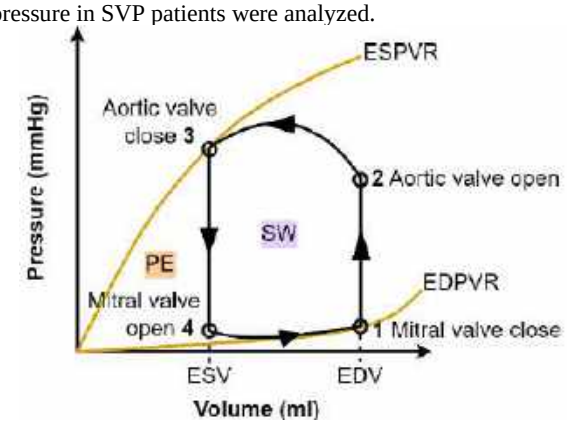

Figure 1: Pressure-Volume loop for left ventricle. EDV, end-diastolic volume; ESV, end-systolic volume; EDPVR, end-diastolic pressure-volume relationship; ESPVR, end-systolic pressure-volume relationship; PE, potential energy; SW, stroke work

$$VE_{Thermo} = \frac{P_{aortic} * Q_{aortic}}{HR * (W_{1-2} + W_{2-3} + W_{3-4} + W_{4-1})} \quad (1)$$

$$VE_{PVA} = \frac{P_{aortic} * Stroke\ volume}{Stroke\ work + \frac{1}{2} * ESV * P_3} \quad (2)$$

RESULTS

Ventricular energy expended in each cardiac phase as a percent of total energy consumed by the ventricle per cardiac cycle (E_{in}) for SVP patients is shown in Table 1. Figure 2 shows the variation of stroke work (SW) and VE_{Thermo} for SVP patients and healthy volunteers across a spectrum of age range. SVP patients had a SW range of 0.05 J to 0.86J, an ejection fraction (EF) range of 46 % to 77 %, and VE_{Thermo} range of 11.8 % to 35.3%. For healthy volunteers, the SW range was 0.47 J to 1.33 J, the EF range was 51.62 % to 78.15 %, and the VE_{Thermo} range was 25.97 % to 40.47 %.

Table 1: Ventricular energy expended during each cardiac phase

Process	Cardiac phase	(% of E_{in}) Mean	(% of E_{in}) Std. dev	Sample size
1 - 2	Isovolumic contraction	31%	4%	17
2 - 3	Systolic ejection	41%	6%	17
3 - 4	Isovolumic relaxation	24%	5%	17
4 - 1	Diastolic filling	4%	1%	14

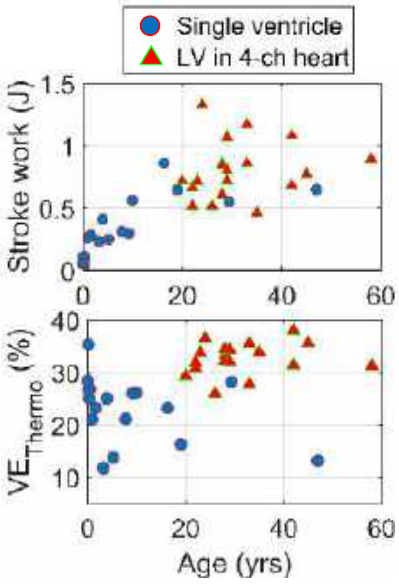

Figure 2: Stroke work and VE_{Thermo} vs age.

Figure 3 shows the variation of VE_{PVA} and VE_{Thermo} in healthy volunteers (LV in 4-ch heart) and in patients with SVP palliation. VE_{PVA} and VE_{Thermo} models in patients with SVP palliation showed a decreasing trend in mean ventricular efficiency (denoted as ×). A significant difference was found between the mean VE_{PVA} of pre-SVP and post-Fontan stages and also between healthy LV and post-Fontan (marked by * in Figure 3). A moderate correlation ($r = 0.57$, $p < 0.5$) was found between VE_{Thermo} and VE_{PVA}. NIBP for SVP patients differed from cath aortic pressure by up to 24 mmHg, but VE_{Thermo} based on NIBP differed by only 1.4 % to -3.2 % compared to VE_{Thermo} based on cardiac catheterization pressure.

DISCUSSION

First, this study demonstrates the potential of VE_{Thermo} for assessing ventricular performance in complex CHD based on themodynamic principles. Next, VE_{Thermo} and VE_{PVA} show that the ventricle's pressure-volume cycle may be less efficient as SV palliation progresses (Figure 3). Reduced ventricular efficiency observed in this study may explain the reduced performance of Fontan patients in exercise tests compared to healthy subjects [2][3]. While previous literature reports reduced cardiac function in SVP patients due to abnormal circulatory physiology, this study facilitates quantification of the change in ventricular efficiency. Reduced ventricular function in SVP patients is also evident by the lower SW for SVP patients relative to the SW of healthy volunteers, who have a typical 4-chamber heart circulatory system (Figure 2).

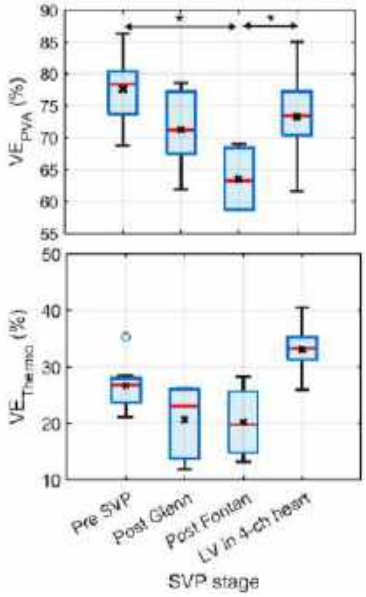

Figure 3: VE_{PVA} and VE_{Thermo} vs SVP stage.

In addition, VE_{Thermo} is expected to be sensitive to losses in the setting of ventricular systolic failure and valve regurgitation but less sensitive to diastolic failure. Using hemodynamic data from published articles, VE_{Thermo} was lower for heart failure with reduced ejection fraction patients than the normal values (~30 %). In contrast, VE_{Thermo} was near to normal or greater than normal for heart failure with preserved ejection fraction and hypertensive patients. Similar observations of near-normal or even increased ventricular efficiency in pressure overloading conditions have also been noted[4].

Strengths of this model include the simplicity and omission of the requirement for invasive IVC occlusion. VE_{Thermo} could also be estimated using NIBP (with limited accuracy) as an approximation to aortic pressure and ventricular diastolic pressures (P_1 and P_4), which were estimated analytically using the energy distribution in Table 1. Such approximations can facilitate computation of VE_{Thermo} non-invasively using routine cardiac MRI or echocardiograms in combination with data from routine vital signs. Limitations from the current work include accuracy with which the input parameters were estimated, and the small sample size used in deriving model parameters.

In conclusion, VE_{Thermo} serves as a direct metric for cardiac performance and may provide additional diagnostic information but is less invasive for patients with CHD.

INVESTIGATING THE RANGE OF CELL CLUSTER BIOMECHANICAL BEHAVIOR WITH CLUSTER SIZE

INTRODUCTION

Successful tissue engineering requires that biomaterials survive implantation and mechanically mimic the native tissue. Better predictive modeling and rationale design of engineered biomaterials would help advance the field. An important step for understanding the complex biomechanics of natural and engineered tissues is understanding the mechanical behavior of simpler multicellular systems. 3D cell clusters up to ~1 mm diameter (e.g., spheroids) are model systems in between single cells and tissues that are useful for understanding tissue mechanics [1]. These multicellular aggregates contain cell-cell junctions with paracrine signaling and partially recapitulate the adherent state that most human cells experience.

Cell cluster biomechanics has been studied using many of the same techniques used for single cell biomechanics. This includes bulk techniques that deform the whole cell cluster (e.g., parallel-plat compression), localized techniques that contact a small area (e.g., AFM), and interior perturbations (e.g., cavitation) [2]. From these studies, we know that the mechanical behavior of cell clusters is determined by the interaction of intercellular junctions, cell contractility, and the ECM, with some mechanical models proposed [1].

Other aspects of cell cluster biomechanics remain underexplored. All measurements have been performed on cell clusters from a narrow size range. At most, cluster size differs by a factor of 2 in a single study. *How does cell cluster biomechanics change across a wide range of sizes?* As a viscoelastic biomaterial, how fast a cell cluster is deformed and where the force is applied will affect its biomechanical response. The timescales of most spheroid mechanics measurements are on the order of seconds to several minutes to days [1, 2]. *How do cell clusters behave at millisecond timescales?* We are aware of only one study using microfluidics that probed clusters on a millisecond scale [3], compared to tens of studies with timescales on the order of seconds and longer. This timescale is important for clinical applications. For cancer metastasis, there is increasing recognition that invasive progression of cancer is not only driven by single invading cells but also by collective invasion of multicellular clusters [4]. It follows that the biomechanics of these clusters—including in circulation as they flow through vessels and capillaries—will be important factors for understanding metastasis and treating cancer.

In this work, we begin to address the questions of cluster biomechanics variation with size and millisecond timescales. Here we measure and compare the deformations of single cells and cell clusters of 2 sizes in non-contact flow conditions using microfluidics.

METHODS

PANC1 pancreatic cells (ATCC) were used. Suspensions of 3 million cells/mL containing mostly clusters with some single cells were created by gently and non-vigorously resuspending trypsinized cells. The cell clusters were suspended in aqueous 0.8% w/v methyl cellulose in phosphate buffered saline (viscosity $\mu = 110$ m·Pa).

Cell clusters were stretched in a microfluidic extensional flow device (300 µm wide, 200 µm deep), commonly called a cross-slot, consisting of two channels that intersect at 90 degrees and generate a linear extensional flow field (**Figure 1**). The cell cluster suspension and buffer solution were infused at flow rate of 4 mL/hr from two opposite inlets (extensional strain rate $\Omega = 123\ s^{-1}$). Flow focusing with a buffer sheathing flow is used to center clusters on the central streamline. Videos were captured of single cells and clusters entering the straight inlet channel (Poiseuille flow) and stretching in the central extensional flow region using brightfield microscopy at 10x (Zeiss Axiovert 200M) and a high-speed camera (KAYA Instruments JetCam, 1,300 fps). Image processing was done in MATLAB (MathWorks). Contours of the deformed cells and clusters in each movie frame were detected using the level set method [5]. From each contour, the shape metrics used to quantify deformation were the contour bounding box (width, height) and strain $\varepsilon = (a–b)/(a+b)$ where the a and b are the major and minor axes of the best-fit ellipse, respectively (**Figure 1**). The equivalent

diameter is calculated from the contour's 2D projected area: d = sqrt($4A/\pi$). For single cells that achieved quasi-static strain near the stagnation point, the cell shear elastic modulus G was calculated using the mechanical model $\varepsilon = (5/2)\mu\Omega/G$ from our previous work [6]. For this study, the deformations of single cells (average d ~ 20 µm, N = 3), smaller clusters (7 – 10 cells, d ~ 50 um, N = 3), and larger clusters (> 30 cells, d ~ 70 um, N = 3) were analyzed and compared.

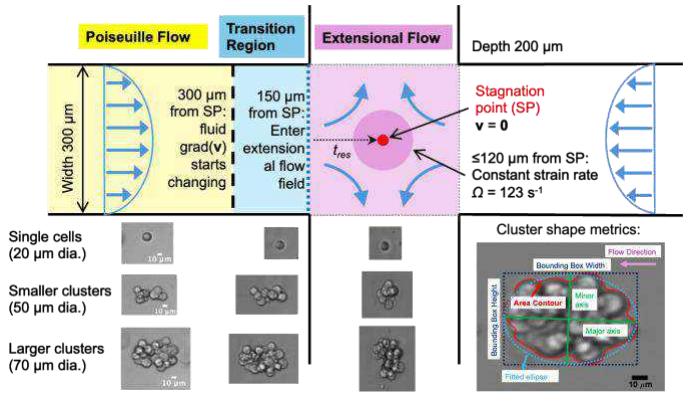

Figure 1: Schematic of the experimental set up, cluster shape metrics, and representative single cell and cluster images from the three major fluid flow regions.

RESULTS

Similar deformation trends arose for all sizes as the objects passed through the different flow zones, though the amount and rate of change of deformation varied with cluster size. In the Poiseuille flow region, objects were elongated in the flow direction. The clusters were more deformed away from a sphere shape than single cells, as seen in images (**Figure 1**) and with bounding box Δ(width) (**Figure 2A**, **Table 1**). In the transition region where the velocity gradient as measured by PIV (data not shown) began to change, objects started to compress to a spherical shape followed by elongation in the perpendicular outlet flow direction within the extensional flow region. The clusters stretched more than the single cells, as seen in bounding box Δ(height) and strain magnitudes (**Figure 2**, **Table 1**). Taken together, this indicates that single cells were stiffer than multicellular cluster sizes even for the smaller 7-10 cell clusters.

The softer clusters more rapidly deformed in response to changing hydrodynamic forces (t_{AR}, **Table 1**) and did not reach a quasi-static deformation like the single cells (**Figure 2B**). The larger clusters changed shape more than twice as fast as the smaller clusters in the extensional flow region (slope in **Table 1**, **Figure 2B**). The larger the cell or cluster, the less time it dwelled in the extensional flow region due to the lack of active trapping at the stagnation point (t_{res}, **Table 1**).

Table 1: Average shape metrics ± standard deviation for single cells and two cluster sizes (N =3 for all). Figures 1 & 2 explain table quantities.

	d [µm]	BB Δ(W) [px]	BB Δ(H) [px]	t_{AR} [ms]	t_{res} [ms]	Slope Δ strain/ ms
Single Cells	21±4	3.3±1.5	3.7±1.5	31±6	30±11	---
Smaller Clusters	48±6	21±12	16±13	17±3	20±10	0.0064± 0.0009
Larger Clusters	71±5	21±6	25±11	14±1	16±8	0.017± 0.008

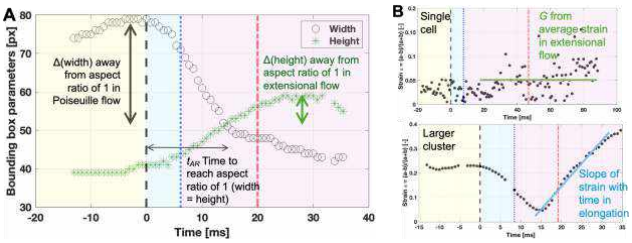

Figure 2: A) Representative bounding box width and height history for a cell cluster. B) Representative strain histories of a single cell (top) and larger cell cluster (bottom). Larger clusters deform more than single cells even though they dwell for a shorter time in extensional flow. Axes shading reflects flow region.

DISCUSSION

Cluster mechanical behavior in our experiments is reminiscent of droplet deformation behavior in linear flow fields [7]. In future work, we will use inverse finite element methods applied to our cell cluster stretching data to test which proposed spheroid mechanical model– an elastic or viscoelastic solids or a liquid with an apparent surface tension [1] – is more valid in different size ranges. Application of a model would also disentangle cluster size from amount of deformation, a limitation of the current study, by providing intrinsic mechanical properties.

Our finding that single cells are stiffer than clusters made of the same cell is consistent with a previous study that found 130-µm-diameter spheroids to be 10 times softer than single cells [3]. The single cell shear elastic modulus G = 630 ± 120 (average ± std. dev.) is similar to previous measurements of suspended cells in microfluidic devices (~ 1 kPa [8]. The large variation in G can be attributed to the small magnitude of the single cell strains that resulted in noise and scatter. Higher flow rates and stronger hydrodynamic forces would improve the signal-to-noise ratio for the single cells. Though more study is needed, we observed individual cells within clusters visibly stretching, sometimes more than the single cells studied here. Further study into the deformation of individual cells within clusters could provide helpful insights that link single cell to cluster mechanical behaviors.

Our future work includes greatly expanding the size range of spheroids from single cells up to about 1 mm diameters using agarose micro-molds (Microtissues). Based on the study presented here that explores a narrow range of cluster sizes yet seems to indicate deformation differences between 10-cell clusters and >30- cell clusters, we anticipate changes to both the elastic and viscous parts of cluster viscoelastic behavior with size.

INTRODUCTION

The Gliomas are the most common primary malignancies in the central nervous system (CNS). This heterogeneous group of tumors is characterized by their resemblance to glia that perform a variety of important functions including support to neurons.[1] The treatment for gliomas patient generally consists of surgery, radiotherapy, and chemotherapy and the outcomes of patients with gliomas vary widely according to the glioma type and prognostic factors. Due to the superior soft tissue contrast, multimodal MRI images, which allow the complexity and the heterogeneity of the tumor lesion to be better visualized than a CT scan, have become the golden standard for surgical decision-making for glioma patients. However, visual identification of tumor margins in CT or MRI remains a challenge for neurosurgeons and researchers. Clinically, brain tumor masks are often obtained through Magnetic Resonance Imaging (MRI) scans, which require experienced radiologists to manually segment tumor sub-regions. This is a long process that is unscalable to the needs of all patients. Thus, the recent growth of machine learning technologies holds promise to provide a reliable and automated solution to segmentation to save time and help medical professionals with this process.

Deep learning techniques have been widely used in brain tumor segmentation. UNet model is the state of art for tumor segmentation.[2] UNet architecture confirm the shortcomings of traditional training frameworks, as the predicted segmented masks do not capture the high spatial variation or physically realistic structures of the diffused tumor structure, making them unreliable for clinical use. A novel architecture is needed to tackle this challenge. Generative modeling techniques have seen great improvements in recent times.[3] Specifically, Generative Adversarial Networks and Denoising-Diffusion based models have been used to generate desired images of greater quality and with greater control over the specifics of images. Also, the Diffusion model has been applied to medical image segmentation successfully. However, the model performance still has room for improvement when compared to previous UNet models.[4][5]

In this work, we introduce a framework called Re-Diffinet, for modeling discrepancy between the outputs of a segmentation model like UNet and the ground truth, using the advantages from Denoising Diffusion Probabilistic Models and UNet model. By explicitly modeling the discrepancy, we intend to improve over the previous segmentation model, and exploit diffusion models' ability to generate finer details.

METHODS

Dataset: The training dataset provided for the BraTS23 challenge [4] consists of 1,251 brain MRI scans along with segmentation annotations of tumorous regions. The 3D volumes were skull-stripped and resampled to 1 mm^3 isotropic resolution, with dimensions of (240, 240, 155) voxels. For each example, four modalities were given: native (T1), post-contrast T1-weighted (T1Gd), T2-weighted (T2), and T2 Fluid Attenuated Inversion Recovery (T2-FLAIR). Example images of each modality are presented in Figure 1. Segmentation labels were annotated manually by one to four experts. Annotations consist of four classes: enhancing tumor (ET), peritumoral edematous tissue (ED), necrotic tumor core (NCR), and background (voxels that are not part of the tumor).[6]

Training details: Our network is implemented in Pytorch and MONAI on 4 NVIDIA A40 GPUs. The baseline UNet model was trained using an optimized UNet model.[7] The diffusion model architecture is shown in **Figure 1a**. The model was trained using a compound loss function includes DICE loss, BCE loss, and MSE loss for diffusion model. The model was trained for 200 epochs using the Adam optimizer with a learning rate of 0.0001 and a weight decay equal to 0.0001. To generalize the network's performance and evaluate its reliability, a 5-

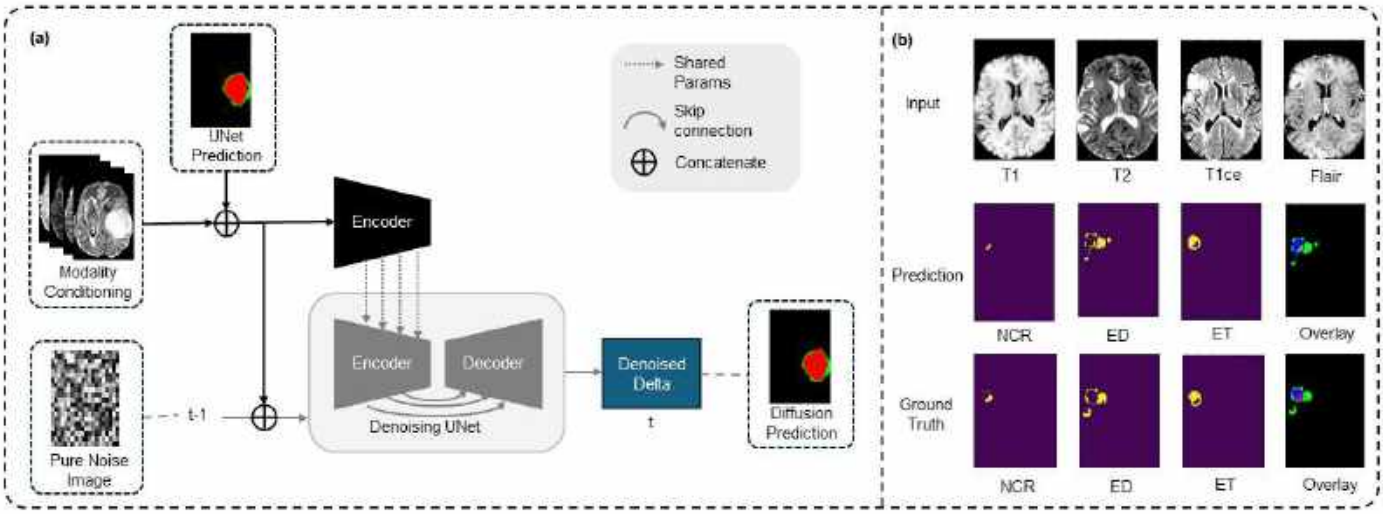

Figure 1: (a) Model architecture of Re-DiffiNet which aims to model the discrepancy using Diffusion. (b) Model predictions of segmentation results of three segmented labels produced by our network and on BraTS2020 dataset. First row shows the four input contrasts, second row shows our model predictions, and the third row shows the ground truth labels.

fold cross validation was performed. The data were randomly shuffled and equally split into 5 groups as training validation.

RESULTS

The results of 5-fold cross validation are shown in **Table 1**, which reports the Dice Score (DICE) and 95 percentile Hausdorff distance (HD95) and the average scores of all methods on the three overlapping regions whole tumor (WT), tumor core (TC) and Enhancing tumor (ET) for the BraTS2023 dataset (**Figure 1b**). We found that while using the diffusion model to directly output the tumor segmentation mask does lead to improvements over the UNet model, the improvements are modest: 0.12% improvement in Dice, and 5.61% improvement in HD95 score.

On the other hand, with Re-DiffiNet we found a 16.28% improvement in HD95 score, indicating the benefits of modeling discrepancy using diffusion models. The improvement in Dice score was again marginal: 0.55%.

DISCUSSION

In this research, we proposed a 3D medical image segmentation framework, named Re-DiffiNet, based on the diffusion model, which models medical image segmentation as a discrete data generation task. The proposed algorithm could predict the difference between the UNet prediction and ground truth labels, leveraging the advantages of the diffusion model to improve segmentation robustness.

The results also show that the diffusion probabilities model has the potential to refine the medical image segmentation model by appropriately conditioning the MRI contrast. Future research could investigate the behavior of the diffusion model to better quantify the uncertainty introduced in the segmentation label inference stage of the model.

Overall, our work presents an important contribution to the field of medical image segmentation, demonstrating the effectiveness of the Diffusion model in the 3D medical image segmentation task. The proposed method has the potential to facilitate more precise and accurate diagnosis and treatment of medical conditions, ultimately leading to improved patient outcomes.

INTRODUCTION

Vascular models are a valuable tool for understanding fluid flow through the vasculature in organs. Vascular models have been used to inform surgical procedures such as coronary artery bypass graft surgery [1] in the heart, partial liver resection surgery [2], and superior cavopulmonary connection surgery in the lungs [3]. In each of these cases it is important for clinicians to understand the effects that surgical intervention has on the behavior of flow, including wall shear stresses, pressure drops, and distribution of flow throughout the organ.

Patient specific models can be obtained through medical imaging techniques like computed tomography (CT) scans and magnetic resonance imaging (MRI), however the level of detail and depth of the images is often limited, and does not capture the small scale vessels. Researchers have developed algorithms capable of generating vessels to greater levels of detail [4, 5]. Some algorithms are initialized with patient specific geometries containing the higher level vessels [6, 7], while others generate completely synthetic models [5]. For medical applications requiring large amounts of data such as training machine learning models it can be difficult to obtain a sufficient amount of patient specific models. Therefore, algorithms capable of generating high quality synthetic data with high degrees of variability similar to that of the patient population are highly desirable [8].

The most common algorithm for generating vascular models is constrained constructive optimization (CCO) [4]. The CCO algorithm iteratively generates new vessels within a specified domain, optimizing the local structure at each bifurcation with each added vessel. The primary limitation of the CCO algorithm is that it does not allow for explicit control of the trajectory or terminal location of vessels. This is a desirable property when modeling organs such that arteries and veins connect at a common location and flow can be simulated through the entire vasculature.

In pursuit of this objective, we implement the space colonization algorithm which was initially developed to model botanical trees [9]. With the addition of target attractor concept from [10] we are able to explicitly control the location of terminal vessels to create fully connected models of vasculature in organs. Our algorithm simply requires a mesh of the organ, and allows for a high degree of customization through algorithmic parameters to generate vascular models which closely match anatomical data, or to generate models of varying levels of depth and topological variability.

METHODS

Point Sampling: Starting with a triangle mesh of the organ, we utilize the Möller-Trumbore ray-triangle intersection algorithm to efficiently sample random points inside the mesh. These points are used as the attractors for the space colonization algorithm. The number of points sampled can affect the topology of the generated model and is detailed in the discussion section. We also perform k-means clustering with on this point cloud to obtain k target attractors that are spaced evenly throughout the domain. The number of target attractors, k, directly corresponds to the level of detail in the generated model.

Space Colonization Algorithm: The space colonization algorithm is an attractor based growth method, meaning that the vasculature is generated by adding new vessels (growth) towards points (attractors) in the domain. There are three parameters which must be defined in the algorithm: step distance (D), kill distance (d_k), and sphere of influence (d_i). These parameters have a strong influence on the topology of the generated model as detailed in the discussion. We represent the generated vasculature with "nodes" and "vessel". A vessel connects any two nodes, and a node can have any number of vessels entering and exiting it. At each iteration of the algorithm we look for attractors within d_i of the existing nodes, referred to as "active attractors". A new node is added at a distance D in the average normal direction of the active attractors from their respective node. Once all new nodes have been added for a given iteration, we look for attractors within d_k of existing nodes, and eliminate those attractors from the point set. In this way, the model is incentivized to grow towards regions of the domain which have no existing nodes.

Target Attractors: The addition of the target attractor concept stipulates that a target attractor cannot be removed from the point set until it is explicitly reached by a node. When the only active attractor for a node is a target attractor and is within a distance D, the target attractor is grown directly to and subsequently removed from the point set. The algorithm terminates once all target attractors are reached.

Pruning: Since we aim to create a fully connected model, we want our model to only terminate at the location of target attractors. Thus, it is necessary to prune our model, or trim off the unnecessary vessels. We start at the terminal vessels and traverse the model in reverse to the root vessel. All vessels which are not traversed are pruned from the model.

Radius Assignment: At this point, we have generated all the vessels in our model, but we have not assigned radii to any vessels. We simply need to specify the radius of the root vessel, and then all subsequent radii are assigned according to Murray's law. Murray's law has been shown to closely model the relationship of radii at junctions in biological vascular networks as detailed in [11].

RESULTS

Morphological Validation: We demonstrate the ability of our algorithm to generate models which agree well with morphological data from real human livers as detailed in Fig. 1 and Tab. 1. We determine the generation a vessel belongs to using the Strahler ordering method which considers the topological connectivity of the vessels in the model.

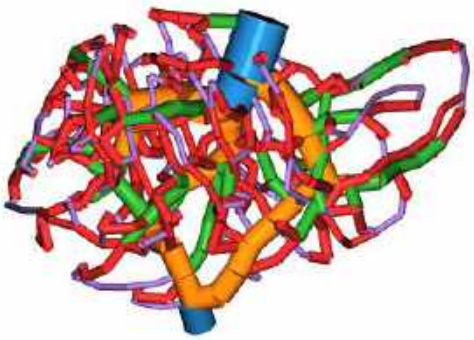

Figure 1: Lung vasculature model of portal and hepatic veins with vessels colored according to Strahler generation.

For organs with well known primary vessels like the liver, we can perform a staged approach to the space colonization algorithm where we run the algorithm twice. First, to initialize the primary vessels, namely the left and right portal veins, and the left, middle and right hepatic veins. These initialized vessels can be seen in orange in Fig. 1. Then, the full space colonization algorithm can be run from this initialized model to obtain better agreement to real human models.

Table 1: Morphological statistics by Strahler generation for portal vein (PV) and hepatic vein (HV) from space colonization model depicted in Fig. 1, as well as from anatomical corrosion cast of real human liver from [12]. Lengths and radii in mm.

	Space Colonization			Anatomical		
Generation	Count	Length	Radius	Count	Length	Radius
PV1	1	34.38	6.71	1	35	7.3
PV2	2	35.00	4.82	2	35	6.3
PV3	5	30.95	3.35	7	33	4.0
PV4	25	36.80	2.28	27	32	2.1
PV5	80	28.08	1.67	80	27	1.5
HV5	80	27.29	2.72	76	19	1.1
HV4	22	27.99	3.68	33	28	1.7
HV3	5	23.18	5.06	18	33	2.4
HV2	3	40.00	6.99	3	74	5.0
HV1	1	91.37	11.54	1	68	13

Topological Variability: We also highlight the ability to vary the topology of generated models by changing various parameters within the space colonization algorithm. Smaller values of D, d_k, and d_i lead to vessels that have more tortuosity, while larger values lead to more direct vessels as illustrated in Fig. 2. The density of the attractor point cloud can also have an effect on the topology of the generated model. For the same set of space colonization parameters, sparse point clouds will result in more tortuous models, while dense point clouds result in smoother, more direct models at increased computational cost.

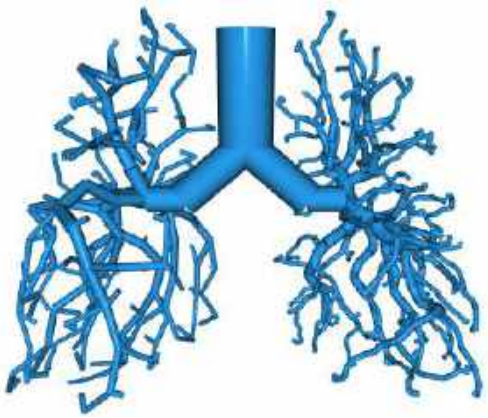

Figure 2: Pulmonary artery model where each lung is generated with unique space colonization parameters. The left lung (reader's view) is generated with $D = 20$, $d_k = 22.5$, $d_i = 25$, while the right lung is generated with $D = 5$, $d_k = 10$, $d_i = 15$. Units in mm.

These results illustrate the ability of the space colonization algorithm to generate models which agree with known morphological data, as well as the ability to generate highly customizable models with large degrees of variability. Currently we do not generate models to the full level of depth seen in biological organs [12] or some published algorithms [5]. The space colonization algorithm is uniquely able to create fully connected models that allow for flow throughout the entire organ by controlling the trajectory of terminal points with the target attractor concept. This target attractor concept also lends itself well to a staged approach where primary vessels can be accurately initialized as discussed in the morphological validation section, and could be extended to create even more complex models as mentioned in the discussion.

DISCUSSION

This work illustrates a novel approach to algorithmically generate vascular models in a variety of organs. We demonstrate the capability of the approach to generate realistic models that agree well with morphological data, in the case of the liver. We also demonstrate how models with varying topologies can be generated by varying parameters of the algorithm, in the case of the lung. Future works can further develop on the space colonization algorithm by implementing a staged approach which varies space colonization parameters as the vasculature is grown, such that primary vessels appear more direct, and later vessels are more tortuous as is the case in the pulmonary vasculature. The fully connected models can be used to simulate flow throughout whole organs to investigate the global distribution of flow, as well as local flow effects caused by morphological and topological variations. Overall, we see this algorithm as an enabling technology for researchers and clinicians to rapidly develop models of vasculature that can be used for a multitude of applications.

CHARACTERIZING THE INFLUENCE OF PROTEOGLYCANS ON PASSIVE AND VISCOELASTIC MATERIAL PROPERTIES OF FEMALE PELVIC FLOOR SKELETAL MUSCLES

Megan R. Routzong (1), Francesca B. Sesillo (1), John B. Rudell (1), Marianna Alperin (1,2)

INTRODUCTION

The skeletal muscles of the pelvic floor are critical to the mechanical support of pelvic organs and tissues and maintenance of their continence and sexual function. In females, the pelvic floor muscles (PFMs) are impacted by pregnancy and vaginal childbirth. Pregnancy-induced remodeling of the PFMs must take place in response to the loads imposed by the growing fetus and uterus. Then, during vaginal delivery, they must stretch considerably, often to the point of mechanical failure, to allow passage of the fetus through the birth canal. Such injuries predispose women to the development of pelvic floor disorders later in life, with vaginal parity (the number of times one has given birth vaginally) being their greatest epidemiologic risk factor.

Studies have shown that pregnancy significantly impacts the mechanical behavior and structure of the pelvic floor muscles.[1,2] However, the mechanisms underlying these changes are poorly understood. It has been shown that the extracellular matrix (ECM) contributes significantly to passive tensile stiffness and load-bearing capacity of skeletal muscle.[3] The structure of skeletal muscle ECM is primarily established by collagen fibrils. Proteoglycans (proteins linked to glycosaminoglycans (GAGs)) also make up a large component of the ECM and are known to regulate multiple cellular processes.

We aimed to characterize the contributions of PFM ECM and GAGs (specifically chondroitin sulfate (CS)) to passive mechanics and viscoelastic properties via multi-step stress-relaxation tests of PFMs with and without decellularization and enzymatic degradation of CS. We hypothesized that decellularization would impact elastic moduli, particularly at peak stresses, while CS degradation would impact relaxation time constants.

METHODS

PFMs (specifically the pubocaudalis (PCa) portion) were harvested from three-month-old, nulligravid, female Sprague-Dawley rats (Envigo, Indianapolis, IN) immediately after sacrifice. All procedures were carried out with the approval of and in compliance with the University of California San Diego IACUC.

Samples were dissected under a dissecting microscope to form muscle bundles approximately one third the width of the entire muscle and then divided into three experimental groups: non-perturbed (control muscle group), decellularized (decell group), and Chondroitinase ABC treated after decellularization (decell+ABC group). Muscles were decellularized by incubation in Latrunculin B to disrupt actin filaments followed by alternating osmotic stress via potassium iodide, potassium chloride, and water. Samples underwent a final incubation in DNAse I, were washed in water for two days and stored at 4°C. Samples undergoing CS degradation via Chondroitinase ABC were then incubated at 37°C for 1 hour prior to mechanical testing.

Mechanical testing consisted of multi-step stress-relaxation tests using a microscope mountable isolated muscle system with a 50mN load cell (1530A and 400C, Aurora Scientific, ON, Canada). One end of each sample was sutured to the lever arm of the load cell while the other was a fixed post via small magnets. Initial lengths, widths, and thicknesses were measured and the displacements required to created 9 steps in 11% strain increments were determined. Nine steps at 11% strain were chosen instead of 10 steps at 10% strain due to a limit in the software's maximum number of step inputs. Displacements were controlled and resulting forces measured via LabChart (ADInstruments, Dunedin, NZ). Each step consisted of a 0.05s ramp up to the desired strain followed by 120s of relaxation at constant strain. Samples were tested to 99% strain or failure in a bath of relaxing solution.

To characterize the mechanical behavior across the entire strain range tested, a straight line was fit to the peak (obtained at end of the 0.5s ramp up) and equilibrium (obtained 1s before the next ramp up) stress-strain curves (**Figure 1**). A straight line was chosen after initial observations of the first few datasets. The coefficient of the linear equations served as the peak and equilibrium elastic moduli (E). All calculations were done in Matlab (MathWorks, Natick, MA).

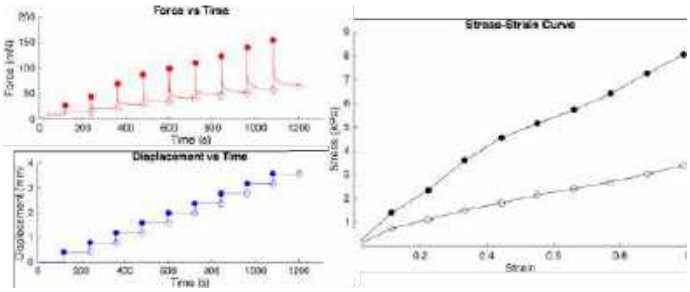

Figure 1: An illustrative example of the multi-step stress-relaxation protocol and generation of peak (filled circles) and equilibrium (empty circles) stress-strain curves.

A viscoelastic analysis was carried out using only the first stress-relaxation step. A 3 Maxwell unit generalized Maxwell Model (3mGMM) was used. This spring-dashpot model equation, simplified based on assumptions specific to stress-relaxation testing, was fit to our data using a linear algebra approach. The stress relaxation curves were smoothed with a second order Savitzky-Golay finite impulse response smoothing filter to reduce noise and then numerical integrations were performed using the trapezoidal rule over 1s intervals. First, second, and third order integrations were performed. By expressing stress in terms of its integrals (or derivatives), the problem is reduced to solving a system of linear equations, allowing the parameters of the 3mGMM equation to be solved for. The negative reciprocal of the determined exponential values was computed to determine the relaxation time constants ($\tau_{1\text{-}3}$). The coefficients were converted to elastic moduli ($E_{0\text{-}3}$) by dividing by the constant strain value. In this format, the subscripts of τ and E denote which Maxwell unit they belong to while E_0 is the lone spring. Mechanical parameters were compared between control, decellularized, and decellularized+ABC groups.

RESULTS

The decellularized muscle group exhibited the largest average peak and equilibrium elastic moduli, while the decell+ABC group exhibited values smaller than the decell group (**Figure 2**).

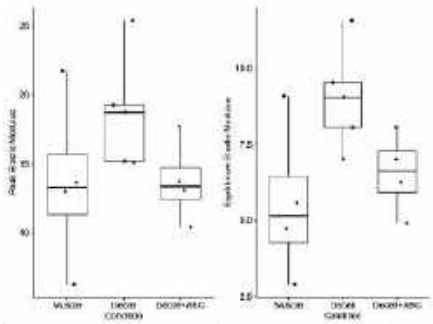

Figure 2: Peak and Equilibrium Elastic Moduli for Each Group

The control muscle group exhibited the smallest $E_{1\text{-}4}$ values, on average (**Figure 3**). The decell group exhibited the largest E_2 values. Considering the fastest time constants (τ_1), the decell group's was faster than the other two. For slower time constants ($\tau_{1\text{-}2}$), the decell+ABC group exhibited the fastest values on average.

Decellularization generally increased elastic moduli, both those fit linearly and using the 3mGMM, compared to control muscle samples. Meanwhile, CS degradation increased τ_1 but decreased τ_3 on average compared to the decell group. The decell and decell+ABC groups only demonstrated meaningful differences in elastic moduli within the linear analysis, not those fit by the 3mGMM.

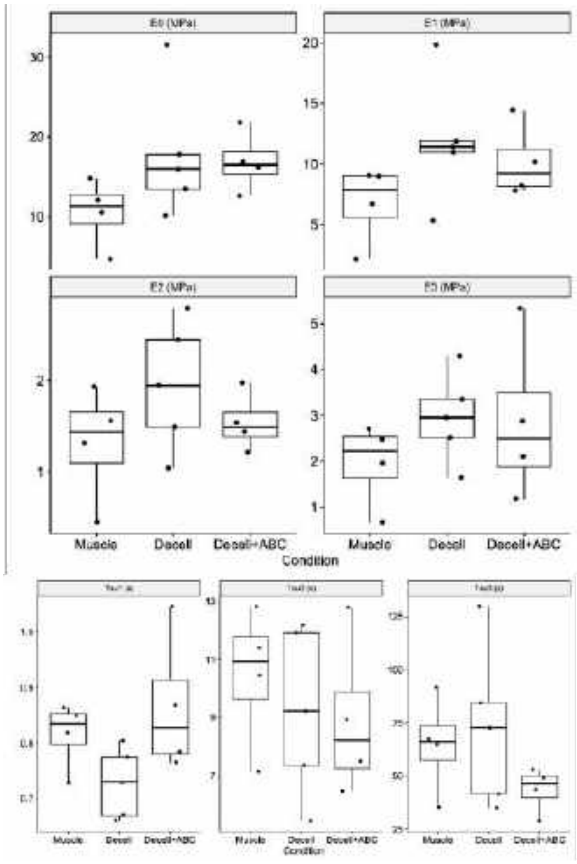

Figure 3: 3mGMM Parameter Values for Each Group

DISCUSSION

Corresponding with our original hypothesis, our findings show that decellularization increases the elastic moduli (though both peak and equilibrium values comparably) compared to control muscle while CS degradation impacts the relaxation time constants; increasing τ_1 and decreasing τ_2 compared to the decell group. This supports that CS (and GAGs in general) significantly contribute to the passive mechanics and viscoelastic properties of PFMs and the ECM specifically, by increasing relaxation times at short scales and decreasing them at longer scales. Future directions will involve evaluating mid- and late-pregnant PFMs to quantify these relationships in pregnancy and hind limb muscles to serve as non-pelvic controls.

SIMULATION OF THE VISCOELASTICITY OF CLOTS CONSIDERING RED BLOOD CELLS AND FIBRIN NETWORK

Ryan C. Mueller (1), Jifu Tan (1)

(1) Mechanical Engineering, Northern Illinois University, Dekalb, IL, USA

INTRODUCTION

About 30 people die every minute because of heart attack or stroke in the world[1], which is about 30% of the total mortality. Clots play a major role in these cardiovascular diseases. Decades of research have made great advances in biochemistry and cell biology of clot formation, however, how does clot respond to applied force, i.e., the constitutive law, remained largely unknown. As a heterogeneous material, clot is mainly made of red blood cells (RBCs), platelets, fibrin network, plasma and other components such as leukocytes, neutrophil extracellular traps, von Willebrand factor (vWF), etc[2]. The interplay between those components determines the mechanical response of clots. RBCs were assumed to play a passive and minor role in clot mechanics previously, however, they started to gain attention recently[3]. As an important component of clots, RBCs' volume fraction can be as high as 63%[4]. In this paper, we will develop a computational model considering the venous clot with trapped red blood cells and fibrin network to investigate the viscoelastic properties of clots.

METHODS

Venous blood clots are modeled as a mixture of red blood cells and fibrin. Red blood cells are modeled as coarse-grained cell membranes[5–9], The potential energy for an RBC is given by, $U(\boldsymbol{X}_i) = U_{stretch} + U_{bending} + U_{area} + U_{volume}$ where $U_{stretch}, U_{bending}$ are the stretching and bending potentials, respectively. They are given by

$$U_{stretch} = \sum_{j\in 1\ldots N_s} \left[\frac{k_B T l_m}{4 l_p}\frac{3x_j^2 - 2x_j^3}{1-x_j} + \frac{k_p}{l_j}\right], \quad (1)$$

$$U_{bending} = \sum_{j=1\ldots N_s} k_b(1 - cos(\theta_j - \theta_0)) \quad (2)$$

where $U_{stretch}$ is based on the worm-like chain (WLC) model[10]. Other parameters can be found in Ref.[11]. Individual fibrin fiber is modeled as worm-like chains using the same potential format as $U_{stretch}$ but with different parameters that are taken from Ref.[12]. Both the cell and fibrin models are implemented in LAMMPS (Large-scale Atomic/Molecular Massively Parallel Simulator) [13], with further simulations extending to Palabos (Parallel Lattice Boltzmann Solver)[14] to handle the simulations relevant to shear flow. The cells and fibrin are coupled with fluid flow through the Immersed Boundary Method (IBM)[11, 15].

RESULTS

Separate simulations were carried out to calculate the mechanical and dynamic properties of blood clots. To find the equivalent Young's Modulus for the clot, a random clot structure was generated in a 20 μm^3 box. The clot is composed of 6 red blood cells and 151 fibrin fibers. Each red blood cells and fibrin structure are made up of 2562 and 15 particles, respectively. The interaction between particles are modeled as Morse potential. The clot is then compressed by a plate (Fig. 1a) with a velocity of 4.8 mm/s. The forces acting on the plate were measured, then the stress was computed and compared against linear strain to calculate the modulus of elasticity. Shear modulus and viscosity was calculated through a shear flow experiment. The blood clot structure was immersed in a fluid under Couette flow conditions (Fig. 1b) with a shear rate of 600 s^{-1}. The shear stress on the clot was compared against the shear rate or shear strain to compute the viscosity and shear modulus, respectively.

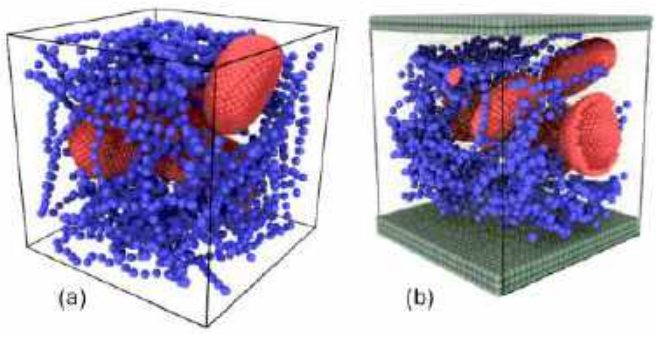

Figure 1: Simulation snapshots of clots under (a) vertical compression and (b) pure shearing flow.

Storage and loss modulus, the two main properties defining a rheological material, were found through a shear flow simulation with oscillating wall velocities. In the simulation, the shear strain oscillated between positive and negative values, resembling a torsional viscometer. The results were then verified in an equilibrium stress autocorrelation simulation.

Property	Value	Experimental	Ref
Elastic modulus	157 mPa	0.1-1500 Pa	[16]
Shear modulus	600 Pa	150-700 Pa	[17]
Storage modulus	100-1000 Pa	800-1200 Pa	[18]
Loss modulus	100-1000 Pa	200-500 Pa	[18]

Table 1: Simulation results for clot mechanical properties

Through the clot compression simulation, an elastic modulus of 157 mPa was calculated. A shear modulus of 600 Pa was found from the shear flow simulations, as shown in Table 1. The rheological properties, storage and loss modulus, were found through the stress autocorrelation simulation with the help of Green-Kubo formulations. The storage and loss moduli were both in the range of $10^2 - 10^3$ Pa. Most of the simulation results are within the range of experimental measurement, as shown in Table 1. Further detailed analysis will be reported in the full paper.

DISCUSSION

Clot mechanical properties such as Young's modulus and shear modulus strongly depend on clot composition, the structure of fibrin (e.g., branching or cross-linking), and the adhesion between fibrin and cells. The complete understanding of the mechanical and dynamic properties of blood clots remains elusive. This paper presents some preliminary studies for the viscoelasticity of clots, demonstrating the feasibility of numerical models to characterize clot mechanics based on the composition of clots. Such a model potentially has the ability to predict the mechanical strength, toughness, and viscoelasticity of the clot with given composition.

EXPLORING THE POTENTIAL ROLE OF SEX-BASED BRAIN STRUCTURAL VARIATIONS IN SUSCEPTIBILITY TO TRAUMATIC BRAIN INJURY FROM A BIOMECHANICS PERSPECTIVE

B. Jafari (1), M. Memar (1)

(1) Department of Biomedical Engineering and Chemical Engineering, University of Texas at San Antonio, San Antonio, TX, USA

INTRODUCTION

Sex differences in the human brain neuro-structure are increasingly recognized as one of the underlying factors contributing to the sex variations in the prevalent incidence, onset, and development of neurological disorders and brain injuries [1]. In particular, when it comes to traumatic brain injury (TBI), studies using finite element models (FEM) of brain have shown that the overall and regional differences in brain structure can directly or indirectly affect how the brain deforms under head biomechanical loadings during traumatic events [3, 4]. Furthermore, the brain deformation is proven to be correlated with the occurrence and pathology of TBI [2]. For instance, a brain FEM study showed that applying the same impact kinematics to head models with different sizes, or the same size but a different shape, resulted in different peaks and distributions of strain especially in the corpus callosum (CC), a critical location for traumatic axonal injury [3]. Another FEM study investigated the mitigating role of cerebrospinal fluid (CSF) under head injuries and showed that CSF reduces maximum brain strains and provides a protective buffer against impacts [4].

Although there are evident sex-related differences in various brain regions, research exploring these differences at both the macro- and meso-scale levels remains limited and all the previously developed FEMs of brain have been biased toward males. Moreover, we have previously shown that these sex-based structural differences cannot be addressed by global and uniform scaling [1]. Therefore, in this study, we aim to investigate the anatomical features and volumetric measurements of brain (macroscale), along with diffusion tensor imaging (DTI) metrics and the connections between brain regions (mesoscale), to explore sex-specific variations in the brain structure from biomechanics perspective. Such information is crucial for future studies involving FEMs in the field of brain biomechanics particularly when examining the impact of sex-specific differences on the onset and outcomes of TBI.

METHODS

In this study, subcortical brain segmentation was performed on magnetic resonance images (MRI) from 500 females and 500 males using the FreeSurfer software. The details about dataset used herein can be found in [1]. The final brain masks had the size of 256×256×256 with a voxel size of 1.0 mm×1.0 mm×1.0 mm. The total brain volume (TBV) along with the volume of several regions including CC and CSF were calculated for all subjects. The absolute volumes of the segmented regions were normalized by the TBV of each subject to obtain the fractional volumes and investigate whether the sex variations are proportional to the TBV. The sex-based structural differences were evaluated by the Mann-Whitney test with a significance level of $p=0.05$.

The diffusion-weighted MRIs of the same dataset underwent DTI analysis and fiber tractography using DSI-Studio software. The orientation distribution functions for images were aligned using subject-specific frameworks, employing Q-space diffeomorphic reconstruction technique. These frameworks were generated by a nonlinear registration of widely-used ICBM-152 T1-common space to T1-MRI head from each subject image. “FreeSurferSeg” atlas in DSI-Studio was adapted to optimize the best selection of regions in brain tractography resulting in the 23 regions of interest (ROIs). These regions include Corpus callosum (CC), Left Cortex (L-Co), Left Cerebral white matter (L-Cr-WM), Left Cerebellum white matter (L-Cb-WM), Left Cerebellum grey matter (L-Cb-GM), Left Thalamus (L-Th), Left Putamen (L-Pu), Left Pallidum (L-P), Left Hippocampus (L-Hi), Left Amygdala (L-Amg), Left Accumbens (L-Ac), Brainstem (BS), Optic chiasm (OX), Right Cortex (R-Co), Right Cerebral white matter (R-Cr-WM), Right Cerebellum white matter (R-Cb-WM), Right Cerebellum grey matter (R-Cb-GM), Right Thalamus (R-Th), Right Putamen (R-Pu), Right Pallidum (R-P), Right Hippocampus (R-Hi), Right Amygdala (R-Amg), Right Accumbens (R-Ac), Cerebrospinal fluid (CSF). We also mapped the refined atlas to the common space of each individual subject. Fiber tracking was then conducted on each subject in DSI-Studio, employing

Euler tracking algorithm [5]. For each subject, scaler metrics including fiber anisotropy (FA) and mean diffusivity (MD) were derived and the brain connectivity matrix was calculated using 1000000 fiber tracts. The matrix cells (count*FA) were calculated using the count of connecting tracts passing through pairs of regions multiplied by the mean FA values measured on those tracts as a quantification of connection strength between the two ROIs. Independent-samples Mann-Whitney U tests were performed on DTI metrics and the pair-wise connections to examine the distribution of these metrics for all 23 brain regions across the two categories of sex.

RESULTS

Significant difference was observed in the distribution of TBV between male and females with males having larger values and wider distribution compared to females (Figure 1). In addition, the distribution of both the absolute and the fractional volume of CC was significantly different across sexes, and female population was observed to have a larger CC, proportional to their brain. Regarding CSF, while the fractional volume distributions were mostly similar across sexes, the absolute values were noticeably higher in males.

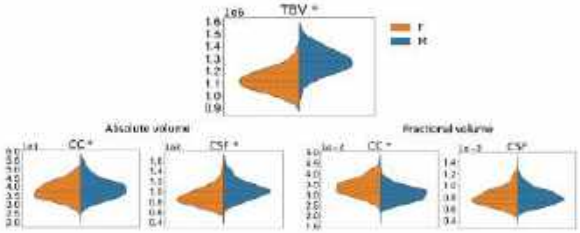

Figure 1: Sex-based comparison of the distribution of volumes for TBV, CC, and CSF. The asterisk * symbol shows a statistically significant difference

The difference values between mean regional FA and MD in females and males (Figure 2) shows that FA values are significantly larger in majority of regions with highest difference in CC which is known as the largest white matter structure. This trend was the opposite for MD values. These significant differences were observed in 70% and 91% of the regions for the FA and MD values, respectively.

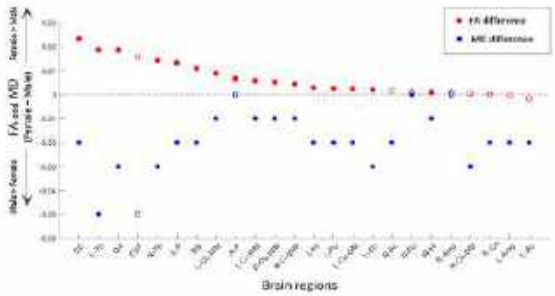

Figure 2: Sex differences in the FA and MD values (median of population) across brain regions. Filled markers denote regions with statistically significant differences ($p < 0.05$)

The heatmap shown in Figure3-a indicates that in 70% of the region pairs, there is a significant sex difference in the brain connectivity (count*FA). The strength connectivity difference matrix between female and male populations (Figure3-b), obtained by subtracting their respective median connectivity matrices (count* FA), shows stronger connections, including interhemispheric white matter and those from left and right cortical regions, passing through CC, in females compared to males.

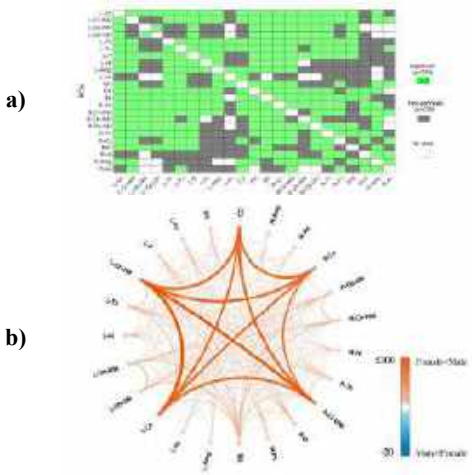

Figure 3: a) Statistical comparison of the component of brain connectivity matrix between female and male subjects (green shows significant difference), and b) the median female-male connectivity difference matrix (count* FA)

DISCUSSION

The distribution of volumetric parameters as well as the DTI metrics and the strength of connections were significantly different for most of the brain regions across males and females. Due to such intricate sex-based structural variations at macro- and meso-scales, and the inaccuracy of global linear scaling [1], developing separate brain templates and FEMs for males and females are highly encouraged to investigate sex-specific TBI mechanisms and protection interventions.

Exploring sex-specific brain vulnerability to TBI reveals different patterns at both macroscale and mesoscale levels. From the macroscale perspective, males have a larger brain volume potentially leading to greater deformations during impacts, making them more susceptible to TBI. This is further supported by the smaller fractional volume of CC, indicating higher vulnerability in males. However, the larger absolute volume of CSF in males may provide better cushioning, mitigating the risk of TBI in males. On the mesoscale, females exhibited higher FA values for most ROIs and stronger inter-hemispheric connections which could influence their TBI exposure differently. Furthermore, larger volume and higher FA for CC as well as its stronger connections in females may suggest a lower susceptibility to TBI in CC in females.

All in all, our findings may suggest a possible higher TBI vulnerability in males compared to females undergoing same head kinematic accelerations from brain structure perspective. However, this possibility may be counterbalanced by the sex-based variations in head kinematic severity and hormonal dynamics. The interaction of sex-specific brain FEMs with further biological research is promising to unravel such complex interplay of factors influencing TBI vulnerability in males and females.

INTRODUCTION

Breast cancer invasion is driven by both cell autonomous and micro-environmental factors. Among the intracellular programs that sustain malignancy, the transcriptional coactivators yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ) regulate gene expression as part of the Hippo pathway [1]. In terms of micro-environmental effects, the role played by a collagen-rich extracellular matrix (ECM) is particularly acute in breast cancer, where collagen densification and alignment impact tumor progression [2]. YAP and TAZ are known to respond to biomechanical cues, through the process of mechanotransduction [3], and to metabolic pathways [4]. As oncoproteins, YAP/TAZ are localized in the nucleus of cancerous epithelial cells with elevated rates of malignancy. Therefore, YAP/TAZ activity is expected to enhance cancer cell invasion, cell-ECM interactions, and metabolic plasticity. However, it is yet unknown how YAP/TAZ activity impacts ECM mechanics and metabolism during breast cancer invasion. Hence, in this study we used tumor spheroids to investigate how nuclear activation of YAP/TAZ regulate a mechano-metabolic crosstalk between ECM mechanics and cell metabolism, thereby influencing invasion in complex 3D micro-environments.

METHODS

Control MCF-10A cells and the doxycycline-inducible nuclear mutants TAZ(4SA) and YAP(5SA) [5] were used to form multicellular spheroids (~10^3 cells/spheroid). Such spheroids were embedded into a 3D network of rat-tail collagen I via established methods [6]. Control, TAZ(4SA), and YAP(5SA) spheroids were cultured for 4 days in graded collagen concentrations (1, 2, 3, and 4 mg/mL), supplemented with MCF-10A growth media [7] with (+Doxy) or without (-Doxy) doxycycline. Each spheroid was imaged immediately after embedding (day 0) and at days 2 and 4 to characterize the dynamics of invasion. For each day, time-lapse imaging (every 10 minutes for 8 hours) was conducted using a Nikon AX confocal microscope equipped with an environmental chamber (37°C, 5% CO2) and a 10× objective. Bright field (DIC) images were acquired to quantify the dynamics of invasion, while confocal reflection images were collected using an excitation wavelength of 488nm to capture the structural effects of collagen remodeling. Matrix displacements due to spheroid-generated traction forces were measured from time-lapse movies [8] as a measure of collective contractility. Micro-mechanical changes due to permanent remodeling of the collagenous ECM by invading cancer cells were measured using 3D Magnetic Twisting Rheometry (3D-MTR), a novel method developed in our laboratory. Briefly, iron oxide beads were embedded in the collagen matrix surrounding each tumor spheroid. At days 0, 2, and 4, a homogenous torque was applied to all beads through the application of coordinated magnetic fields (via two orthogonal sets of coils mounted on a custom microscope insert). Confocal image stacks were acquired both before and after magnetic stimulation and compared using digital image correlation algorithm. The magnitude of the 3D displacement field around each bead was compared with that produced by a finite element model and the difference was minimized to estimate the unknown material properties of the local collagen network. For the sake of simplicity, collagen was modeled as a neo-Hookean material $W = c/2\,(I_c - 3)$ and the associated Young's modulus $E = 2c(1 + \nu)$ was used to report local material properties, where the Poisson's ratio ν was determined in preliminary experiments by means of uniaxial unconfined compression.

In terms of metabolic activity, we cultured each cell type as a 2D monolayer and used a Seahorse Assay followed by a Click-iT EdU cell proliferation assay to measure differences in cell metabolism and proliferation. Spatio-temporal heterogenities in cell metabolism associated with 3D invasion were mapped out using Fluorescence Lifetime Imaging (FLIM) of the metabolic cofactor NAD(P)H. FLIM image stacks were acquired at days 0, 2, and 4 using a multiphoton microscope (Olympus FVMPE-RS) and analyzed using published methods [9]

RESULTS

The mutant cell lines TAZ(4SA) and YAP(5SA) formed larger spheroids and displayed increased EdU nuclear incorporation, thus indicating an increased rate of proliferation. After embedding, Control MCF-10A spheroids invaded collectively in low and intermediate density collagen, with modest remodeling of the collagen network. Conversely, MCF-10A TAZ(4SA) and YAP(5SA) spheroids cultured in low density collagen generated higher displacements in the ECM, aligned collagen fibers radially and invaded more aggressively, both as continuous multicellular protrusions and as single cells (Figure 1). A Seahorse Assay performed on 2D monolayers shows that activation of TAZ leads to an increased respiratory capacity and a higher glycolytic activity while activation of YAP leads primarily to a higher glycolytic activity. FLIM on 3D TAZ(4SA) spheroids shows a consistent reduction in the ratio of free (α1) to bound (α2) NAD(P)H. With invasion, metabolic heterogeneities arise within the spheroid core, which shows an optical signature consistent with glycolysis while the spheroid periphery displays a shift towards oxidative phosphorylation (Figure 2a). Quantification of spheroid-generated contractile forces (Figure 2b) shows that matrix displacements at the end of day 4 are modest in control MCF-10A spheroids while the TAZ(4SA) mutants display the largest extent of matrix remodeling and invasion. Such differences in contractile forces translate into a heterogeneous material stiffening of the collagen matrix, as measured by 3D-MTR (Figure 2c).

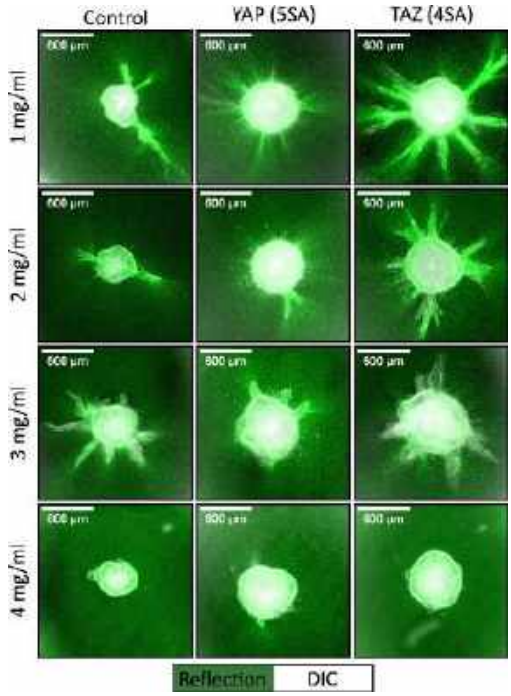

Figure 1: YAP/TAZ activation results in increased proliferation, as indicated by larger spheroid size. Control MCF-10A spheroids invade collectively, with modest remodeling of the collagen network. In comparison, YAP(5SA) and TAZ(4SA) spheroids in low collagen densities align radially the surrounding matrix and invade more as individualized cells.

DISCUSSION

Tumor invasion is known to depend on the physical properties of both cells and the ECM and is fueled by metabolism. Here, we show that activation of nuclear YAP/TAZ impacts breast cancer spheroid proliferation regardless of the extracellular micro-environment, while migration, generation of contractile forces, and collagen remodeling are favored especially in low collagen density. We also show that activation of YAP/TAZ alters the metabolic profile of tumor spheroids in a spatially and temporally heterogeneous manner, with a metabolic shift towards glycolysis in the spheroid core while the invasive edge shifts towards oxidative phosphorylation. Future work will investigate the mechanistic links between YAP/TAZ, ECM mechanics, and cell metabolism and explore how they impact breast cancer invasion.

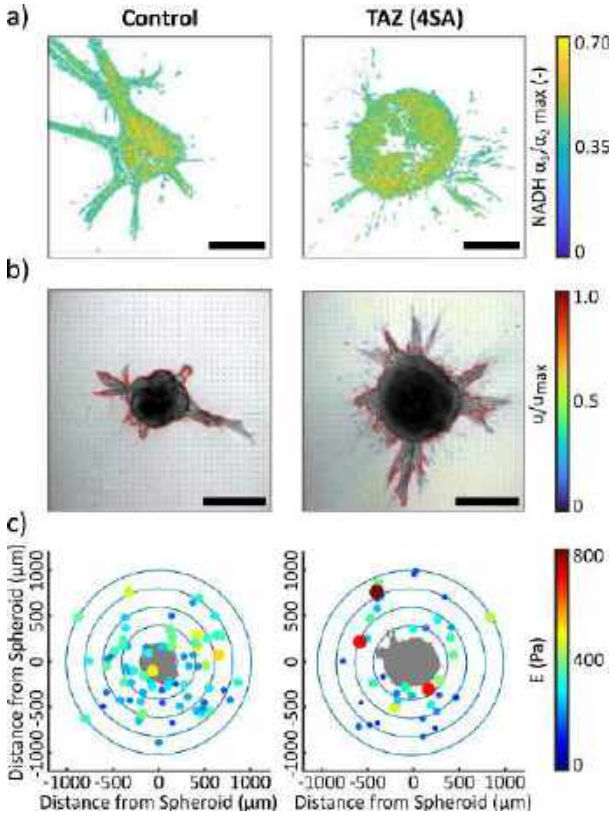

Figure 2: Comparison of the (a) glycolytic activity, as measured by Fluorescence Lifetime Imaging (FLIM), (b) 3D matrix displacements, as measured from timelapse images of invading spheroids, and (c) mechanical remodeling of the ECM, as measured by 3D-magnetic twisting rheometry, between MCF-10A control (left) and TAZ-activated (right) spheroids. TAZ activation results in altered metabolism and in increased structural remodeling and mechanical stiffening of the surrounding ECM. Scale bar: (a) 250μm, (b) 500μm.

ACKNOWLEDGEMENTS

We acknowledge Professor Xaralabos Varelas (Boston University) for providing the cell lines MCF-10A TAZ(4SA) and YAP(5SA). This project was funded in part by The University of Texas at Dallas Office of Research and Innovation through the SPIRe program.

INTRODUCTION

Colorectal cancer (CRC) remains one of the most common causes of cancer-related deaths in the United States [1]. Over the past decades, public awareness has led to increased rates of routine colonoscopy screening, thereby causing a decline in the incidence of average onset colorectal cancer (AO CRC), which affects patients above 65 years of age. Meanwhile, early onset colorectal cancer (EO CRC), which affects patients under 50 years of age, has been rising at an alarming 2% per year and is expected to increase by 124% by the year 2030 [2]. The precise etiology of EO CRC remains unknown, with no unique mutational drivers. Epidemiological studies have indicated that chronic, low-grade inflammation could represent a pathogenic mechanism in the EO CRC patient cohort [3]. It is well established that collagen remodeling and overall tissue stiffening are hallmarks of fibrosis and inflammation. However, there is a lack of biomechanical data on EO CRC. Therefore, we hypothesized that fibrotic stiffening could represent a quantifiable hallmark of EO CRC. To test this hypothesis, we investigated the structural and biomechanical properties of colonic tissue specimens harvested from patients undergoing surgical resection. The objectives of this work are threefold: 1) to compare, for the very first time, the biomechanics of tissues from AO and EO CRC; 2) to quantify properties from matched cancerous and normal tissues; 3) to investigate both local (mesoscale) and global (macroscale) mechanical properties of the human colon.

METHODS

We investigated both cancerous and matched normal samples harvested from patients undergoing surgical resection. For each sample we punched two cylindrical specimens (4 mm in diameter) and subjected them to four local indentation tests and to one global unconfined compression test to determine its material properties. Indentation was performed in 5 incremental steps, each with a magnitude equal to 1% of the original height of the sample and interspersed with 1-minute hold phases. Steady state force values from the hold phases (F) were graphed versus displacement (δ) and fitted using a solution from linear elasticity [4],

$$F = E\left(\frac{2R}{1-\nu^2}\right)\delta, \tag{1}$$

where E represents the unknown Young's modulus, R = 35 μm is the radius of the cylindrical indenter and ν = 0.5 is the Poisson's ratio for an incompressible linear material. Instead, unconfined compression was performed in 8 incremental steps, each with a magnitude equal to 2.5% of the original height interspersed with 2-minute hold phases. The Poisson's ratio ν was calculated by finding the best fit line between the axial and radial strain. Steady state values of the equilibrium Cauchy stress were fitted using a neo-Hookean strain energy density function,

$$W = \frac{c}{2}\left(I_C - 3\right), \tag{2}$$

where c represents an unknown material parameter and I_C represents the first invariant of the Cauchy-Green tensor. To allow for comparisons, the global Young's modulus was determined as $E=2c(1+\nu)$. Histological examination was conducted using Hematoxylin and Eosin (H&E) and Picrosirius Red (PSR) staining from formalin fixed and paraffin embedded (FFPE) blocks. To determine the underlying content and organization of fibrillar collagen, H&E stained slides were imaged using second harmonic generation (SHG) imaging, while PSR stained slides were imaged under polarized light (PSR) microscopy. Collagen fiber length, width, and orientation from SHG images were analyzed using the ImageJ plugin Ridge Detection [5], while the percentage of the tissue area occupied by thick (red–orange) and thin (yellow–green) birefringent collagen fibers from PSR images was determined using an established Matlab code for quantitative histology [6]. Statistical comparisons were conducted using a two-way ANOVA to assess

differences between normal and cancerous samples and between AO and EO tissues. Post-hoc pairwise comparisons were performed using the Bonferroni correction, and $p < 0.05$ was considered significant.

RESULTS

We collected biomechanical data from 21 AO CRC patients and 15 EO CRC patients. Local indentation data (Figure 1a-b) indicates that cancerous tissues from EO are materially stiffer than their AO counterparts. Intriguingly, we observed the same trend in matched normal tissues, with EO tissues revealing a stiffer behavior than AO tissues. Global compression data (Figure 1c-d) confirm our findings from indentation and reveal that, under 20% compression, these tissues display a mild but noticeable nonlinearity, which becomes more pronounced when looking at individual stress-strain curves. Interestingly, under the assumption of linear elastic behavior and using a Poisson's ratios measured from each specimen, we calculate Young's moduli that are comparable to those obtained using local indentation. These results are limited to the analysis of steady-state equilibrium data and do not incorporate time-dependent behaviors. Ongoing efforts are aimed towards the analysis of stress-relaxation data from global compression using a Maxwell-Wiechert model [7]. Regardless, the observed mechanical trends are corroborated by trends in the collagenous microstructure. Analysis of PSR stained slides (Figure 2a) reveal that EO normal tissues display an increased fraction of thick (red) collagen fibers with respect to AO normal tissues (Figure 2b). Instead, both AO and EO cancers reveal an increase in thin (yellow-green) collagen fibers with respect to normal. Analysis of H&E slides imaged via SHG (Figure 2c) confirms these trends by showing that collagen fibers in cancer samples are thinner than collagen fibers in normal samples. In addition, collagen fibers from EO cancers are thicker (Figure 2d) and more aligned (not shown) than collagen fibers from AO cancers. This finding correlates with the fact that EO cancers display a highly invasive and metastatic behavior [2].

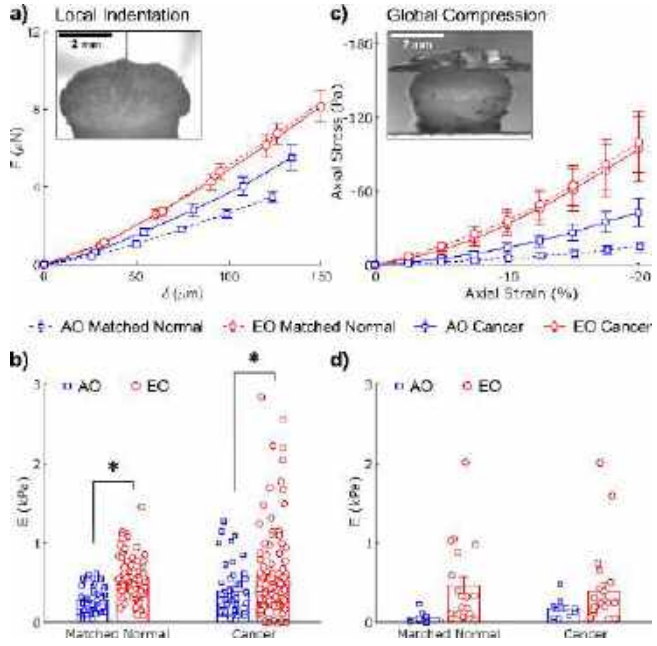

Figure 1: (a) Average force-indentation (*F-δ*) data from local indentation tests. (b) Young's modulus *E* quantified from indentation data. (c) Average axial stress-axial strain data from global compression. (d) Young's modulus quantified from compression data. Insets in both (a) and (c) show representative tissue specimens undergoing mechanical testing.

DISCUSSION

Fibrotic stiffening of tumors is known to impact cancer progression and metastasis. In this work we combined local and global mechanical testing to investigate the biomechanical hallmarks of human EO CRC. Using these methods, we found that differences between normal and cancer tissues are not as pronounced as previously reported [8]. Instead, we find that not only cancerous but also normal tissues from EO patients are stiffer than those from AO patients, thereby suggesting that mechanical stiffening may play a role in the development of colorectal cancer early in life. Future work will be aimed at quantifying the presence of markers associated with chronic inflammation in the stroma, and with increased mechanosensing in the colonic epithelium.

PHYSICS BASED MACHINE LEARNED CONSTITUTIVE MODELS FOR FIBROUS MATERIALS

Jacob S. Merson (1), Nishan Parvez (1)

(1) Department of Mechanical, Aerospace, and Nuclear Engineering, Rensselaer Polytechnic Institute, Troy, NY, USA

INTRODUCTION

Fibrous biological materials are exceedingly difficult to model with relevant length and timescale spanning more than nine orders of magnitude. Accurate modeling of fibrous structures continues to be a key issue driving the emergence of new analytical material models that can account for more detailed micro-structural information and non-locality [1, 2]. Another area of growing interest is to use multiscale methods to capture the material behavior across three orders of magnitude [3]. Although these methods provide a substantial increase accuracy, they are astoundingly expensive when using RVEs that are large enough to eliminate size effects requiring use of supercomputers and specialized numerical methods [4, 5].

Another recent trend in biomechanical modeling is to use machine learning methods to predict the solution of boundary value problems or material properties. Amazing progress has been made in predicting solution fields, however these methods are typically sensitive to boundary conditions and require re-training for applications to novel geometries as one might see in patient specific geometry. Here, we consider developing surrogate models for the constitutive response of fibrous materials. Previous works have shown the importance of incorporating constitutive constraints such as frame indifference, and polyconvexity into the machine learned models which aids in the training performance and ensures that the model will be usable for a finite element analysis [6–8].

Here, we investigate the use of a novel neural network architecture and a large library of constitutive data that has been generated by the MuMFiM, a multiscale finite analysis code for fiberous materials [5]. For hyperelastic materials, much of the literature focuses on training the energy response with a high degree of accuracy, however we have found that due to the high problem dimensionality, the derivatives (i.e., stress and stiffness) are not capture well if they are not included in the training process. To that end, we use H2 Sobolev minimization.

METHODS

Fiber Networks. Random fiber network structures are created by seeding a box with points sampled from a uniform random distribution. A Delaunay triangulation is constructed based on the seed points and fibers are placed along the edges of the triangulation. The fiber generation box is then trimmed by placing new nodes fiber nodes along the trimming surfaces and removing the outer portions of any fibers. The edge length of the generation box is three times the trimmed edge length of the Representative Volume Element (RVE) which minimized any impact in boundary effects which are present in the triangulation procedures.

Training Data Generation. Homogeneous displacement boundary conditions are applied to the RVE through a prescribed deformation gradient F_appp. And, the RVEs are solved to static equilibrium using the dynamic relaxation methods described in [5]. The material stiffness are constructed using a finite difference method described in [5]. The use of dynamic relaxation and finite difference allows the method to solve for a static equilibrium state even when the system may have a non-invertable Jacobian at some points in the load path due to sub-isostaticity, or non linearity such as snap-through and buckling.

When constructing the range of deformation gradients to sample, we are interested in controlling the minimum and maximum stretches so that when using the constitutive models in a real analysis we can detect if they are outside of the applicable training ranges. Since we measure the second Piola-Kirchoff stress, we use the Green Lagrange strain as a work conjugate measure. Thus, we can construct our prescribed deformations from the positive definite set of stretch tensors. To this end, our routines start with the principle stretches as this allows control over the fitting range.

We construct the principle stretches using latin hypercube sampling and sample a rotation matrix R from a uniform distribution. To construct the right stretch tensor U we perform a change of basis by finding $U^* = RUR^T$

Neural Network Structure. The network architecture is based on the Input Convex Neural Network [9]. This architecture requires that all activation functions are convex and that only positive weights are used. This ensures that the network outputs will be convex with respect to the inputs. In this work, the inputs are the scaled invariants of the deformation gradient and the output is the energy. The architecture has two hidden layers each with four nodes. We found that layer pass-through improve the training performance. A mean squared error loss function was used. We used an 80/20 test/train protocol. The network architechture is shown in figure 1.

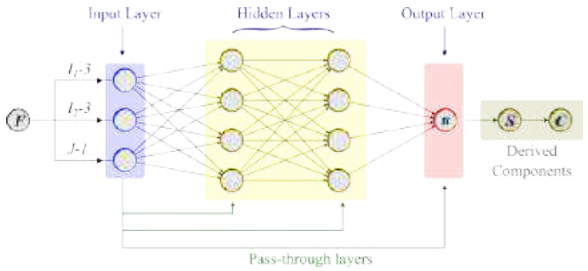

Figure 1: Neural network architecture.

The loss functions included the energy only ($H0$), energy and stress ($H1$, first derivatives), and energy, stress, and stiffness ($H2$, first and second derivatives). The derivatives were computed using autodifferentiation in PyTorch.

RESULTS

Figure 2 shows the loss function for the energy, stress and stiffness over 50 epochs for the $H0$, $H1$, and $H2$ training protocols. Here we see that the stress and stiffness loss are significantly reduced by including the derivatives in the loss function during training.

Figure 3 shows the truth plots for the six independent components of the stress tensor. Here we see exceptional agreement between the true and predicted values of the stress.

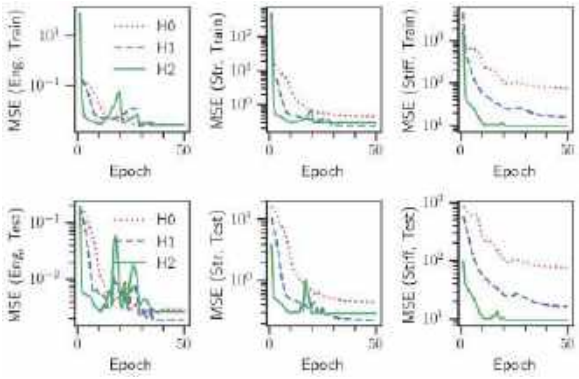

Figure 2: Mean squared error loss function for energy, stress, and stiffness for $H0$, $H1$, and $H2$ training protocols.

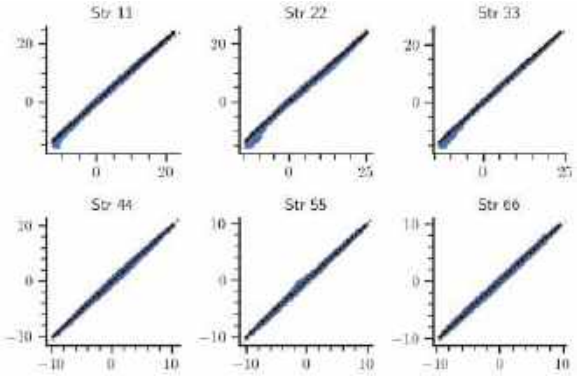

Figure 3: Truth plots for the stress.

DISCUSSION

We developed a novel neural network architecture and used Sobolev training to obtain excellent material predictions for biological materials. Our methods use the network architecture to enforce both polyconvexity through the use of the Input Convex Neural Network, and frame-indifference through the use of the invariants as network inputs.

The resulting material models have been deployed into a multiscale finite element code (results not shown here) and the overall results closely matched those of the full multiscale analysis. And reduced the solution time such that problems of interest could be solved on a laptop rather than a supercomputer. Further work is needed to include fiber anisotropy and damage.

A COMPUTATIONAL MODEL TO SIMULATE THE ROUGHNESS OF NARROWED CORONARY AND CEREBRAL ARTERIES IN DIABETES MELLITUS PATIENTS AND TO DESIGN EFFECTIVE TREATMENT STRATEGIES

S. Piskin (1)

(1) Department of Mechanical Engineering,

INTRODUCTION

Cardiovascular diseases (CVD) pose a significant threat to human health, ranking as the leading cause of death in many Western countries. Atherosclerosis, a prevalent type of CVD, primarily affects the carotid and coronary arteries and is associated with various risk factors, including hypertension, diabetes, high cholesterol levels, smoking, oxidative stress, and age [1]. Treatment options for atherosclerosis in coronary artery disease (CAD) or carotid artery disease include stent implantation through interventional cardiology or open-heart surgery with bypass grafting. Diabetes mellitus (DM) is a common comorbidity in CAD patients, significantly influencing disease severity, treatment strategy, and patient prognosis [2].

Computational hemodynamics (CH) is an innovative in-vitro method to design coronary artery bypass grafting (CABG) procedures or anticipate the short-term and long-term impacts of treatment. Wall shear stress (WSS), a critical biomarker that CH can predict, is linked to the patency of the graft or the narrowed artery following revascularization surgery. However, whether high, low, oscillating or any other WSS derivative causes artery restenosis or CABG closure remains a topic of debate. Numerous clinical and computational studies are ongoing to identify potential correlations. Despite the vast number of patient populations, the computational hemodynamics of CABG for DM patients is not a well-established field. Another crucial aspect of hemodynamics is the roughness of the artery surface [9] or the graft. Recent research has characterized surface roughness in the healthy left anterior descending (LAD) coronary artery [3-4]. However, the effect of roughness on hemodynamics is not fully understood. It can significantly alter the WSS distribution. In this study, we employ a computational model to analyze and compare the flow dynamics of DM patients with healthy controls. We also investigate the effects of wall roughness on WSS in the DM patient model.

METHODS

Two computer-aided models were constructed and simulated using computational fluid dynamics (CFD) techniques. To isolate the geometric influence on hemodynamics, simplified models of coronary arteries were developed. Figure 1 depicts the geometry of a coronary artery with mild stenosis. The wall roughness is set to zero (0) for the smooth artery surface and 0.001 meters (height) for the rough wall.

The three-dimensional (3D) continuity and steady-state Navier-Stokes (NS) equations (Equations 1 and 2) were solved using ANSYS Fluent (ANSYS Inc, PA, USA), a commercially available computational fluid flow solver. The inlet boundary was assigned a velocity profile, and the outlet boundary was assigned a pressure outlet. The artery geometry was based on the typical size of a coronary artery [5], with a length of 30 millimeters and a diameter of 5 millimeters. The wall roughness height was set to 0.5 micrometers, and the roughness coefficient was set to 0.5, assuming uniform roughness.

$$\boldsymbol{\nabla} \cdot \boldsymbol{u} = 0 \tag{1}$$

$$\rho \boldsymbol{u} \cdot \boldsymbol{\nabla} \boldsymbol{u} = -\boldsymbol{\nabla} p + \boldsymbol{\nabla} \cdot [\mu(\boldsymbol{\nabla} \boldsymbol{u} + (\boldsymbol{\nabla} \boldsymbol{u})^T)] \tag{2}$$

where $\boldsymbol{u}$ is the velocity vector, p the pressure, t the time, ρ and μ the density and the dynamic viscosity of the blood, respectively. In addition to the Navier-Stokes equations, the standard k-ε turbulence model was incorporated to account for turbulent flow conditions. The transport equations for the k-ε model are presented in Equations 3 and 4.

$$\frac{\partial}{\partial t}(\rho k) + \frac{\partial}{\partial x_i}(\rho k u_i) = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + G_k - \rho\epsilon \tag{3}$$

$$\frac{\partial}{\partial t}(\rho \epsilon) + \frac{\partial}{\partial x_i}(\rho \epsilon u_i) = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\epsilon}\right)\frac{\partial \epsilon}{\partial x_j}\right] + C_{1\epsilon}\frac{\epsilon}{k}G_k - C_{2\epsilon}\rho\frac{\epsilon^2}{k} \tag{4}$$

where x_i and are the spatial coordinates, k the turbulence kinetic energy, ϵ the rate of dissipation of turbulence kinetic energy, μ_t the turbulence viscosity, σ_k (=1.0) and σ_ϵ (=1.3) the turbulent Prandtl numbers for k and ϵ, respectively, G_k the generation of turbulence kinetic energy due to the mean velocity gradients, and $C_{1\epsilon}$ (=1.44) and $C_{2\epsilon}$ (=1.92) are constants. μ_t and G_k are computed by Equations 5 and 6, respectively.

$$\mu_t = \rho C_\mu \frac{k^2}{\epsilon} \tag{5}$$

where C_μ (=0.09) is a constant, and

$$G_k = \mu_t S^2 \tag{6}$$

where S is the modulus of the mean rate-of-strain tensor, defined as $S = \sqrt{2S_{ij}S_{ij}}$. Viscosities are taken $3.5{\cdot}10^{-3}$ Pa·s and $6.8{\cdot}10^{-3}$ Pa·s [6-7] for healthy subject and diabetes mellitus patient, respectively. Densities are assigned 1060 kg/m^3 for both groups.

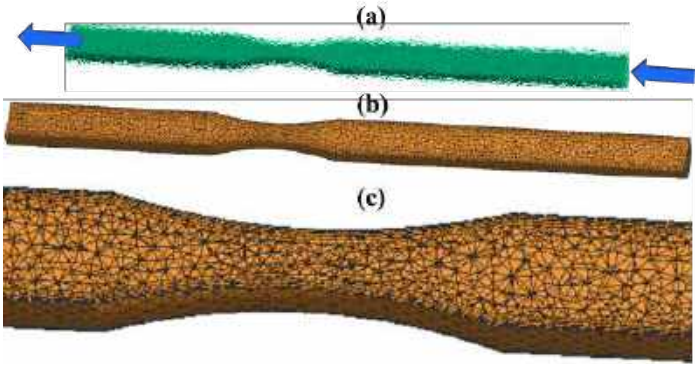

Figure 1: (a) Coronary artery model geometry with representative wall roughness and inlet and outlet boundary conditions, (b) Three-dimensional mesh with boundary layer at the proximity of the wall (c) Zoomed-in view of the mesh around the stenosis zone.

CFD simulations were conducted until the variables u_x, u_y, u_z, p, k, and ϵ reached a convergence criterion of an iteration difference of 10^{-5}.

RESULTS

The WSS distribution across the artery for all three cases was generated: healthy control, DM patient, and rough and smooth wall. Wall shear stress is consistently higher near the artery wall compared to the center of the lumen. This trend is consistent across all conditions, regardless of the presence of diabetes or the roughness of the vessel wall (not shown in the figure). Figure 2 illustrates the pressure distribution pattern which aligns with the expected physiological behavior of a linear pressure drop along the length of the artery except the stenosis region.

Table 1 summarizes the spatially averaged WSS (SAWSS) for all cases: healthy control, DM patient under rough and smooth wall conditions. The wall roughness (height) has been varied to assess its impact on SAWSS. The nominal roughness value is based on literature data, while the other two heights represent hypothetical scenarios of diseased arteries or medical device surfaces. These simulations provide insights into the design of potential treatments or medical devices.

Figure 2: Pressure distribution for the healthy case

Table 1: Spatially averaged wall shear stress (SAWSS) values

SAWSS	Healthy (Pa)	Diabetes Mellitus (Pa)
Smooth wall	107	175
Rough wall (=$3{\cdot}10^{-6}$ m) [3]	107	175
Rough wall (=$3{\cdot}10^{-5}$ m)	108	176
Rough wall (=$3{\cdot}10^{-4}$ m)	92	157

DISCUSSION

Individuals with diabetes mellitus often present with blood viscosity levels that differ significantly from healthy individuals. If they also have coronary artery or carotid artery stenosis, additional caution is necessary when selecting cardiovascular disease treatment options. To address this issue, we have developed an in-silico model to analyze the hemodynamic effects of lumen or medical device roughness in patients with diabetes mellitus. Our preliminary study found that natural wall roughness does not significantly alter spatially averaged wall shear stress (SAWSS) in either healthy individuals or patients with diabetes mellitus (DM). However, when wall roughness increased to approximately 3 × 10^-4 meters, SAWSS decreased moderately, by approximately 15% for healthy subjects and 10% for DM patients. This reduction in SAWSS is consistent with the observed roughness of deployed stents [8].

The study's preliminary results suggest that engineered roughness in novel stents or bypass grafts could be used to modulate wall shear stress (WSS) in patients with diabetes mellitus (DM). This could potentially improve the outcomes of interventional or surgical procedures. However, further research is needed to validate these findings and refine the simulations using real coronary or carotid artery geometries and real-world surgical scenarios.

INTRODUCTION

Tissue engineering as a field holds great promise for both repairing damaged or diseased tissues as well as correcting congenital defects. While use in clinical applications is of critical importance to improve human health, engineered tissues also hold great value in other important areas, such as drug discovery and study of disease mechanisms. The ability to create tissues with controllable mechanical properties is of the utmost importance in reliably creating tissues with known properties, and often is an elusive goal for many tissue engineering systems.

We have been using Gelatin Methacrylate (GelMA) in our lab to investigate the role of the mechanical environment on cellular behaviors in many systems, such as cancer cell transformation and migration as well as stem cell differentiation[1,2]. GelMA is easily remodeled by a variety of cell types having abundant binding and degradable domains, and the mechanical properties are easily tunable within soft (100-1000 Pa) to moderate stiffness (1000 – 5000 Pa) ranges, however reliably achieving stiffer properties (10 – 15 kPa) has been difficult for us to achieve using GelMA alone. We have previously demonstrated the ability to increase the stiffness of GelMA hydrogels by creating a co-polymer with PEGDA (up to 100 kPa), however the handling and encapsulation techniques are more complicated, and less tolerated by cells [3].

In this study we will investigate which system, cells encapsulated in pure GelMA or PEG-GelMA, is a better hydrogel platform for creating model cardiac tissues using C2C12 myoblast cells. The goals will be to achieve a physiological stiffness range of 5 – 15 kPa, while not sacrificing cell health, morphology or remodeling capacity. Results of these studies will be used in parallel studies of creating engineered cardiac tissues using a contractile bioreactor system with electrical stimulus using both C2C12 and human mesenchymal stem cells.

METHODS

Gelatin methacrylate was created as previously described, by reacting aqueous gelatin (300 bloom from porcine skin) in PBS (10% w/vol) with varying amounts of methacrylic anhydride (0.25 ml, 1.25 ml, 5 ml, 10 ml) to create a group of GelMA precursors with varying degree of methacrylation (low, medium, medium-high, high). The resultant mixture was reacted at 50°C for 2-3 hours under agitation, then quenched with 2-3x volume of PBS and then dialyzed for roughly 1 week to remove the excess methacrylic acid from the reactant. The resultant mixture was then lyophilized until dried and stored at -20°C until further use.

Hydrogels were created by mixing GelMA precursor at concentrations of 7.5-15% w/vol with 0.1% w/vol Irgacure 2959 in PBS and irradiating 2 ml of the mixture for 1-3 minutes with 365nm UV light. Cell laden gels were made similarly by adding the above mixture to a cell pellet, mixing, then polymerizing as described and immediately being placed in a well plate with 1-2 ml growth media. Cells were cultured using standard techniques and flasks using standard DMEM with 10% fetal bovine serum (FBS), 1% penicillin-streptomycin-neomycin and 2% L-Glutamine.

For mechanical tests, polymerized GelMA from all 4 groups will be created at 5%, 7.5%, 10%, 12.5% and 15% concentrations, then incubated for 24-48 hours at 4°C in PBS to achieve maximal swelling. Roughly 4-6 samples from each gel will be created with a 5mm biopsy punch and compressed at a fixed strain rate to determine the stress-strain properties. Elastic modulus will be determined using a Matlab script which finds the slope of the 0-5% strain range from the stress-strain curve. Similar studies will be attempted with pure PEGDA (1000 Da) in similar concentrations, as well as GelMA-PEGDA copolymers of various combination keeping the overall gel concentration at 15%.

Candidates with stiffnesses in the ranges of 5 – 15 kPa will then be evaluated with C2C12 cells in static 7 day cultures to determine cellular phenotype. Cell proliferation, alignment and cell-cell interconnectivity

will be evaluated using microscopy at 2-3 points in the 7 day culture period to evaluated cell behavior in response to stiffness. Live/Dead stain will also be performed according to manufacturer directions to assess cell viability at similar time points.

RESULTS & DISCUSSION

In general, the stiffness increases both with gel concentration as well as the degree of methacrylation. However handling GelMA of concentrations 7.5% and above becomes more complicated as it reversibly gels at room temperature and must be kept at 37°C to prevent this. Similar concerns for co-polymers are ensuring complete mixing and miscibility, while also maintaining cell viability. We expect that several combinations of co-polymers will yield appropriate stiffness ranges, but that cell viability & migratory properties will be inversely proportional to the PEGDA concentration.

PITCH COMPETITION: A RAPID NOVEL ASSAY FOR MEASURING HEMOGLOBIN-OXYGEN AFFINITY

Rucha Natu[1], Zoe Sekyonda[2], Yuxuan Du[1],John Hinshaw[3], Peter Galen[3], Umut Gurkan[1,2,3]

(3) Hemex Health Inc, Portland, Oregon, USA

PROBLEM STATEMENT

Hemoglobin (Hb) delivers Oxygen (O_2) to the tissues through binding, transport and dissociation. Modifying the Hb-O_2 affinity is a promising approach for treatments developed for hemoglobinopathies like sickle cell disease (SCD), hypoxemia related to pulmonary diseases, wound healing and ischemia among others [1] [2] [3]. After US FDA's approval for Voxelotor in 2019 [4] which improves Hb-O_2 affinity for treatment of SCD, new interest has spawned in modification of Hb-O_2 affinity for SCD treatment [5] [6]. In this context, measuring Hb-O_2 affinity quantitatively reported as p50 (the partial pressure of oxygen at which Hb is half-saturated with oxygen) has gained importance.

Currently p50 is determined using complex instruments like tonometers, Hem-O-Scans, and TCS Hemox Analyzers. However, these are not ideal for point of care (POC) screening due to high cost, complex operation, bulky equipment (including nitrogen cylinders), long testing time and limited throughput [7]. Globally, an estimated 400,000 babies are annually born with hemoglobinopathies. In the USA, SCD affects more than 100,000 individuals and reduces life expectancy by approximately 30 years [8]. Most of the affected population resides in underserved areas with limited access to high rescource facilities. p50 measurement is important for treatment monitoring but is underutilized due to technical and operational limitations. Our technology-Rapid Hemoglobin Oxygen Dissociation Assay (RHODA) provides a rapid measurement of Hb-O_2 affinity, to screen for Hb-O_2 affinity disorders, determine cellular oxygen availability, and monitor the effectiveness of O_2-modifying therapies for SCD patients. Translation of this laboratory-based technology to a commercial device by integration with a platform for HB variant screening will enable rapid screening and therapy monitoring in one place.

TECHNOLOGY/SOLUTION DESCRIPTION

Hb-O_2 affinity is determined via measuring Hb-O_2 saturation level (SO_2, %) and oxygen partial pressure (pO_2, mmHg) [9]. RHODA uses the principle that when hemoglobin binds with oxygen, it changes its conformation and this affects the pattern of light absorption in the specific range of wavelengths. In the RHODA test, a small sample of blood (few µl) is mixed with a buffer to adjust the pH for rapid deoxygenation of blood. A fluorescent dye is used as the marker to indicate dissolved oxygen. Assay is run in two steps: 1) it uses chemically induced deoxygenation and measures the absorption and amount of spectral shift. Using the spectral shift, we determine the rate of oxygen dissociation as an oxygen affinity index. Then 2) we measure the emission intensity of fluorescent dye to determine pO_2 and SO_2 which are used to calculate p50.

We plan to integrate the laboratory-based RHODA technology with an existing commercial platform- Gazelle developed by Hemex Health Inc. The Gazelle reader includes a cuvette based optical system designed for malaria diagnosis. The two-part cuvette used for malaria testing will be modified to be used as a one-step cartridge for RHODA. The bottom part of the cartridge will be used to perform fingerstick and absorb blood using capillary interface. Absorbed blood will be collected in the bottom part. The bottom part will also incorporate fluorescent markers for oxygen sensing. The top part of the cuvette will be modified to contain the buffer and chemical components for inducing deoxygenation. On locking the two parts, the contents from the top will mix with the blood and will deoxygenate the blood. The cartridge will be inserted into the Gazelle platform. Gazelle optical system will be modified to use two light sources 1) Broad-spectrum light and 2) Fluorescent excitation light. A compact spectrometer will collect transmitted light from the cuvette to determine the absorption spectrum of the blood sample over time as it is deoxygenated. The fluorescent emission will be measured with the same spectrometer. The Gazelle software will be programmed to calculate the pO2 and SO2 and display the values on the Gazelle screen. The Gazelle platform is already equipped for POC Hb variant testing. RHODA will complement the

application of the platform. Figure 1 details the proposed setup for RHODA and the modified cuvette to act as a one-step cartridge.

BUSINESS CASE

More than 7% of the world's population carry hemoglobin gene mutations resulting in Hb variants resulting in sickle cell disease among other blood disorders [10]. Most of this population lives in the underserved areas around the world. HPLC is the gold standard in Hb Variant testing, however, is suited for high resource laboratories. POC diagnostic testing provided by the Gazelle Hb Variant test invented at CWRU and commercialized by Hemex Health Inc has been distributed in over 27 countries with more than 400,000 tests conducted on Gazelle. The Gazelle Hb variant test has proven to be game-changing in POC settings for Hb variant diagnosis, but Gazelle currently doesn't support therapy monitoring that improves Hb-O_2 affinity. A diagnostic system that can be used for screening and Hb-O_2 affinity treatment monitoring is urgently needed. Addition of RHODA will complement the Gazelle Hb Variant test. Optimal management of SCD requires early diagnosis and treatment monitoring. Treatment monitoring and management will benefit from rapid and affordable POC testing, which RHODA will enable.

On incorporating the RHODA technology, the upgraded Gazelle RHODA will be marketed as a device. RHODA test kits containing single use two-piece cartridges will be sold to use with the platform. With a few simple steps, the platform will display results for oxygen affinity measurement from a few µl of blood within minutes. Based on the prior progress and preliminary results, we do not anticipate major challenges in technology. The approach of determining oxygen affinity by measuring spectral shifts during desaturation has been clearly demonstrated in preliminary work. We anticipate some challenges in adapting the laboratory sample preparation technique-including the fingerstick, blood collection and mixing with buffer to one step cartridge for users with minimal laboratory skills. Making this process reproducible and consistent among different users provides an engineering challenge. To solve this challenge, we are experimenting with different cartridge designs and attachments. In case of failure to addressing these challenges, the cuvette design will be modified.

Analytical and clinical validation for the device will be conducted according to FDA "Bioanalytical method validation guidelines" [11]. Following FDA guidelines and consultations from regulatory experts will enable us to engage with FDA in the early stage of device development. Unlike the current analyzers, Gazelle based RHODA is advantageous as it is compact, portable, easy to use, does not require additional training and allows rapid analysis of oxygen affinity in POC settings using few µl of blood. Due to these advantages, RHODA will target low to moderate resource clinical labs and hematology clinics in, and outside USA. The existing market base for Gazelle will prove advantageous for marketing the upgraded platform.

FROM LIGHT TO RELIEF: REVOLUTIONIZING PAIN MANAGEMENT WITH OPTICAL BLOOD-SPINAL CORD BARRIER MODULATION

H. Dave(1), T. Leong(1), E. David(4), T. Price(4,5), Z. Qin(1,2,3,5)

(4) Department of Neuroscience, The University of Texas at Dallas, Richardson, Texas, USA
(5) Center for Advanced Pain Studies, The University of Texas at Dallas, Richardson, Texas, USA

PROBLEM STATEMENT

Spinal cord diseases encompass a range of conditions, such as multiple sclerosis, spinal stenosis, spinal tumors, and chronic pain. High-impact chronic pain is a concept that incorporates the pain burden and disability in the chronic pain population, can be inflammatory or neuropathic, and impacts about 5-8% of the United States population. Individuals suffering from high-impact chronic pain frequently find minimal relief from oral medications and may undergo invasive procedures and rely on spinal drug pumps or stimulators for pain relief, all of which contribute to higher health expenditures. The development of effective therapies is notably hindered by the blood-spinal cord barrier (BSCB), which poses a significant challenge in delivering treatments directly to the affected areas. [1-5]

Conventional treatment options, including surgical interventions and systemic drug administrations, face limitations due to the presence of the BSCB. Innovations such as focused ultrasound with gas-filled microbubbles aim to open the blood-brain barrier to transiently improve therapeutic delivery. However, this method faces challenges, including the potential for acoustic-thermal deposition in surrounding bones and the complexity of spinal geometry, which have impeded its application to the spinal cord.[6] Consequently, there is an urgent need for a robust, reliable, and minimally invasive technique to breach the BSCB and increase the availability of therapeutics via systemic administration with minimal side effects.

TECHNOLOGY/SOLUTION DESCRIPTION

Leveraging the pioneering OptoBBB technology developed in our lab, [7,8] this current technology (Opto-BSCB) focuses on using short-pulsed laser light to stimulate vascular-targeted gold nanoparticles (AuNPs) in the spinal cord as an efficient mechanism for enhancing the permeability of the BSCB. **(Fig. 1A&B)**. This cutting-edge method facilitates the direct delivery of pain-relief medications to the spinal cord, representing a significant advancement from the current invasive surgical procedures.

As a proof of concept, our Opto-BSCB technology works efficiently in modulating the permeability of the BSCB in the spinal cord. The innovative optical approach facilitated the delivery of a peptide, inducing itch behavior, within a specific 24-hour window. **(Figure 1C & Figure 2)** This successful proof-of-concept validates the technology's ability to modulate neural responses and showcases its potential for targeted drug delivery in the spinal cord.

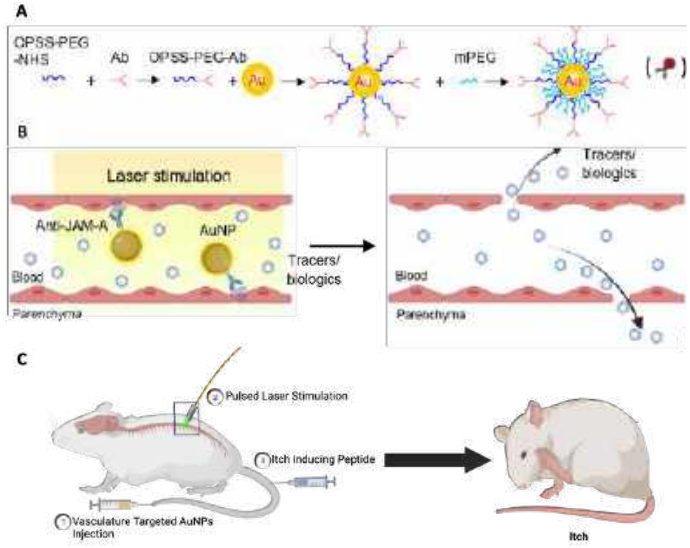

Figure 1. Schematic of (A) Synthesis method for brain vasculature targeting nanoparticles. (B) Mechanism of enhanced BSCB permeability. (C) Method of BSCB modulation and peptide/therapeutic delivery.[9]

Crucial technical steps to bring current Opto-BSCB to market include optimizing delivery parameters, conducting comprehensive safety and efficacy studies, and scaling up manufacturing processes for AuNPs. Preclinical trials with larger animal models like porcine and non-human primates are vital for validation. Navigating regulatory pathways and cost optimization are essential for market entry. We are currently validating our Opto-BSCB technology in porcine models. **(Figure 3A)**

(B) Fluorescent intensity difference between the two regions. (C) Elevated itching activity was observed in mice with an open BSCB compared to control mice with an intact BSCB. (C and D) Effects of BSCB modulation on motor skills and temperature in the hind paws.

BUSINESS CASE

1. **Identification of Patients, End Users, and Payers:**
   - **a.** Patients: The primary focus of this technology is on individuals experiencing high-impact chronic pain. It aims to significantly alleviate the discomfort and improve the quality of life for patients.
   - **b.** End Users: Clinicians specializing in neurology, neurosurgery, and pain management will be crucial in facilitating the adoption of OptoBSCB. Their acceptance would be essential for adopting and administering this innovative treatment.
   - **c.** Payers: Entities in the healthcare system responsible for financing medical treatments, such as insurance companies, healthcare institutions, and government health agencies, would eventually be responsible for funding the expenses related to OptoBSCB treatment.

2. **Potential Hurdles to Market:**
   - **a.** Manufacturing Challenge: This involves setting up a dependable manufacturing process for the components of OptoBSCB, including the AuNPs and vascular targeting protein. Ensuring consistent product quality is critical, and scalability may pose a challenge. Also, precisely controlling the laser parameters would be crucial.
   - **b.** Regulatory Strategy: In the United States, the FDA, specifically its Center for Devices and Radiological Health (CDRH), would oversee the approval and regulation of medical devices and technologies like OptoBSCB. This would involve comprehensively evaluating safety, efficacy, and quality before approving medical use.
   - **c.** Marketing Strategy: Our marketing strategy for OptoBSCB revolves around understanding patient and doctor needs, educating healthcare professionals, and building credibility. We'll engage with experts, conduct clinical trials, and work on reimbursement agreements. Online presence and patient advocacy will play a significant role in increasing awareness and adoption.

3. **Anticipated Risks:** As we plan to commercialize OptoBSCB technology to improve spinal cord disease treatment, we acknowledge potential challenges. These include regulatory hurdles, competition, proving OptoBSCB's effectiveness, gaining healthcare professional support, scaling up production, and addressing legal matters. Successful risk management is crucial for our research to benefit spinal cord disease patients through OptoBSCB. (Detailed Strategy - **Figure 3B**)

PROBLEM STATEMENT

Deep vein thrombosis (DVT) occurs when a blood clot forms in the deep veins, typically in the legs (**Figure 1**). The clot reduces return blood flow to the heart, resulting in pain and swelling. Each year, as many as 900,000 people are affected by DVT and associated pulmonary embolisms [1]. Post-thrombotic syndrome (PTS) is a condition that can occur after DVT. It involves long-term symptoms of pain, swelling, and skin discoloration. This chronic condition occurs because the blood clot damages the vein and valves permanently, diminishing the vein's normal function. PTS affects up to 50% of patients who have experienced acute DVT [2]. PTS is not fatal to the patient, but it results in a significant decrease in quality of life and bears significant healthcare costs of up to $22,445 per patient per year in addition to DVT costs [3].

There is a significant challenge in the medical community when it comes to understanding the progression from acute DVT to PTS. It is understood that the damage to the vein walls and valves causes regurgitation of blood past the valve, leading to pooling and ultimately resulting in chronic symptoms. The clinical problem is that a patient's diagnosis is delayed up to six months from the onset of the blood clot. This delay exists because there is no method to detect PTS until after the treatment of DVT. Clinical evaluation is the primary method of diagnosing PTS. A separate clinical survey and ultrasound imaging offer supplemental confirmation. None of these methods provide a risk assessment for preventing the disease or offer discernability between an acute blood clot and PTS. This problem is exacerbated further in Black individuals, where the prevalence of thrombosis and blood clot-related diseases is higher [4, 5].

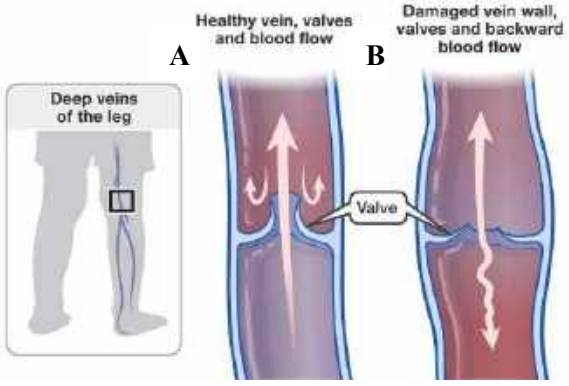

Figure 1: A) Shows a healthy vein with normal blood flow through the deep vein. **B)** Depicts a deep vein that has been afflicted by a blood clot and the valve has been damaged, resulting in backward blood flow.

Providing a method to predict the risk of a patient developing PTS could help clinicians pre-emptively treat high-risk patients to halt or eliminate the progression to PTS using more extensive compression therapy, aggressive anticoagulation therapy, or surgical intervention. This change in the clinical timeline would result in improved quality of life, reduced healthcare costs, and improved long-term patient outcomes.

TECHNOLOGY/SOLUTION DESCRIPTION

Our team has invented the Delta Cuff to address the problem of predicting the transition of acute DVT to PTS. The Delta Cuff combines hardware innovation with machine learning (ML) to

help clinicians create a care plan tailored to the patient. The first part of our strategy is a non-invasive compression cuff embedded with arrays of specially chosen sensors that will be placed on patients' thighs or calves to measure the bruit-like acoustics of venous flow as an indicator of vein flexibility or compliance. The cuff temporarily occludes venous flow with pressurization and then releases the pressure to observe the waveforms gathered from the sensors (**Figure 2**). This device complements the current standard of care for treating DVT, which is compression therapy.

The second portion of our approach includes creating an ML model that will utilize various data inputs, such as the compliance measured via vibration/audio waveform metrics and patient-specific survey and clinical data. This model will identify patients at risk of transitioning to PTS, enabling clinicians to design a care plan to potentially prevent chronic complications. The Delta Cuff, therefore, addresses the problem through early identification and medical prevention. By combining a pneumatically driven cuff with an intelligent ML model, the system can pre-emptively identify DVT patients at elevated risk of developing PTS. Patients deemed high-risk can be offered more intense surveillance, an extended regimen of anticoagulation therapy, optimized compression therapy, and surgical intervention. All of which can hopefully prevent chronic conditions from forming.

Our team has developed an initial bench-level prototype of the Delta Cuff. A pressure cuff was designed with three separate three (3x3) sensor arrays to record flexibility at different locations around a patient's leg (**Figure 2A)**. A separate box was intended to house all the related electronic and power components (**Figure 2B**). An initial test was conducted to determine whether our bench-level prototype could identify a human subject sitting or standing. The cuff was wrapped around the person's leg, and data collection was performed while they were standing and then while they were seated using the nine sensors, as shown in **Figure 2A**. A pooled average and polynomial fitting of the nine signals were performed. The signal for the person standing was noticeably greater than while seated, indicating our device can discern between different hemodynamic situations or potentially different patient groups.

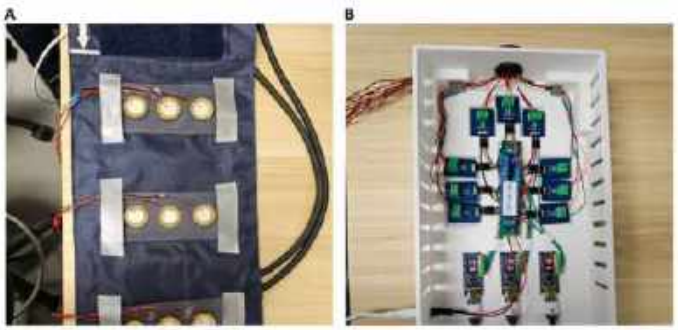

Figure 2: Hardware prototype of Delta Cuff. **A)** PDMS-embedded pressure sensor arrays attached to the pressure cuff. **B)** 3-D printed housing unit for the electronic components of Delta Cuff including Arduino Nano boards, amplifiers, and power distribution block. Not shown in the image are the constant 5V power brick and USB hub.

Moving our technology closer to commercialization will require further prototype development, testing, and validation. We will perform rigorous validation of the Delta Cuff signals and how they relate to disease prediction. This validation will require obtaining IRB approval, gathering data from healthy, DVT, and PTS patients, and determining any distinguishing waveforms in the signal. We will also have to validate our ML model using a training data set and testing data set. The training data set will be used to create the model. Some of the data, the testing data set, will be intentionally held out of the training to validate how well the model performs.

BUSINESS CASE

There is a significant market opportunity for a device that can identify patients at high risk of PTS. With roughly 900,000 cases of DVT each year, each patient would be required to have further testing to see whether they will develop PTS (as it is unknown whether the disease will progress in an individual). To estimate the market size, we researched the compression therapy market, which is closely related to our device. The total global market of compression therapy for vascular diseases such as DVT, leg ulcers, and varicose vein treatment is $3.7 billion and is projected to reach $4.9 billion by 2027. The U.S. has the highest market share, about 50%. We intend to enter this market by partnering with an existing compression therapy vendor. This strategy would allow us to use already established distribution channels to the hospitals, who will be our primary customers. Operating with an established company provides clinical familiarity, making adopting our technology easier.

The primary stakeholder is the physician providing care. After conducting customer discovery interviews with vascular surgeons, we determined that the most effective time to implement the Delta Cuff is in the acute stage of the DVT, immediately at the time of diagnosis. We plan on selling the device directly to doctors' offices and hospitals, with the end-user primarily being primary care physicians, who typically see the patient immediately at the onset of DVT. There would be certain situations where a vascular surgeon may use the Delta Cuff.

The Delta Cuff will follow the 510k pathway with a predicate device, such as doppler ultrasound, which evaluates changes in blood flow through compression. In future design iterations, we will ensure that our sensors do not cause discomfort or pain for the patient. We hope to create various sizes and spacings to accommodate different anatomies. Our long-term development plan includes bolstering our bench-level prototype, conducting testing, determining a potential partner, pre-clinical validation, FDA approval and clinical studies, and reference studies with end users.

PITCH COMPETITION: YOUNGHEARTVALVE – NEXT GENERATION HEART VALVE TECHNOLOGY

Lakshmi Prasad Dasi (1), Srujana J. Joshi (1), Justin Gangwish (2), Nipa Khair (2), Susan P. James (2)

(1) The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA
(2) Department of Mechanical Engineering, Colorado State University, Fort Collins, CO, USA

PROBLEM STATEMENT

In the United States alone, heart disease remains a leading cause of death for both men and women. Aortic stenosis, characterized by the narrowing of the aortic valve opening, is one of the most common heart valve diseases, impacting over 800,000 Americans over the age of 75 in 2019 [1]. While the standard treatment for severe aortic stenosis is surgical aortic valve replacement (SAVR), transcatheter aortic valve replacement (TAVR) has become the preferred approach for the oldest and most frail patients at high risk for open heart surgery. TAVR is a minimally less invasive procedure wherein the replacement valve is delivered to the site of the diseased valve through a catheter. However, not all individuals with severe aortic stenosis are at high risk for surgery. Globally, many patients present with an intermediate or low risk, and would therefore tolerate a SAVR approach. Despite this, many, including a growing number of trained interventional cardiologists, prefer TAVR due to its less invasive nature, lack of need for in-procedure full sedation, shorter hospital stay, faster recovery time, and potential avoidance of long-term anticoagulation therapy. Following the Food and Drug Administration (FDA) approval for the use of TAVR in patients with intermediate risk, the landscape of TAVR in the United States has evolved. Initially approved only for patients aged 80 and above, TAVR is now used to treat patients with aortic stenosis with an average age of 73. However, the current technology limitations continue to preclude younger, more active patients from receiving this option – thereby limiting the full potential and benefits offered by the TAVR method.

Current commercial TAVRs predominantly utilize animal-derived tissue, such as bovine or porcine pericardium, for their leaflets. However, these tissue-based valves face durability challenges, marked by calcification and structural valve degeneration (SVD)[2]. Hypoattenuated leaflet thickening (HALT), resulting from thrombosis, is linked to valve dysfunction and mortality in 10% of commercial TAVRs [3]. Paravalvular leakage (PVL), affecting 8-18% of TAVR patients despite newer designs, can lead to stroke and silent death post-treatment [4]. These concerns not only limit device longevity but also necessitate reinterventions. Beyond performance issues, the manufacturing process for these valves is intricate, involving manual leaflet sewing with thousands of sutures, relying on an animal tissue-dependent supply chain. This complexity increases production costs and restricts global device availability. Thus, there is a pressing need for a synthetic TAVR with superior biocompatibility, hemodynamics, and durability, suitable for patients of all ages and varying aortic stenosis severities.

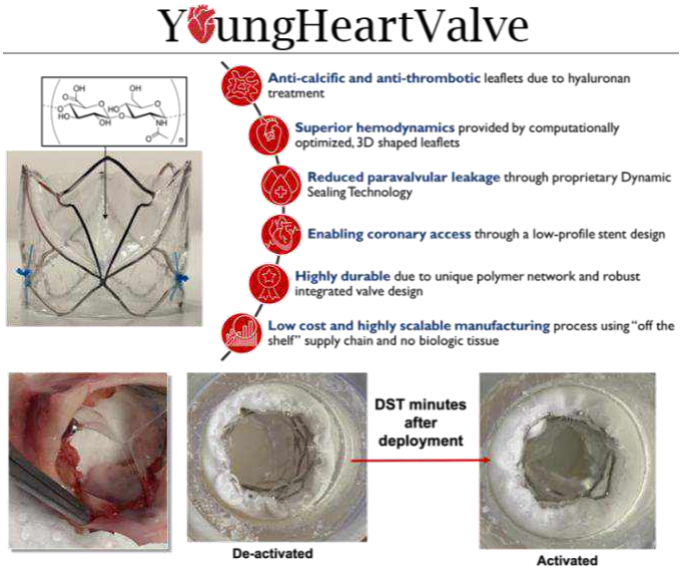

Figure 1: YoungHeartValve's Rejuvenate™ Valve preclinical testing

TECHNOLOGY/SOLUTION DESCRIPTION

YoungHeartValve, Inc. (YHV) distinguishes itself in the competitive landscape of TAVR development by offering a polymeric device that not only overcomes the biocompatibility challenges associated with bioprosthetic tissue but also provides a more cost-effective solution. While several organizations in the market are working on polymeric heart valves, our technological solution stands out by addressing a comprehensive set of market needs, including the prevention of the need for anti-coagulation therapy.

Our commitment at YHV is to commercialize the next generation of heart valves, introducing novelty in polymer material, valve design and manufacturing. The proprietary polymer used is an interpenetrating network of hyaluronan (HA) and linear-low density polyethylene (LLDPE), creating hydrophilic leaflets that are thrombosis and calcification resistant, durable, and precisely 3D-shaped for superior hemodynamic performance [5, 6]. Our first product, the Rejuvenate™ Valve, is a 26 mm balloon-expandable TAVR that incorporates dynamic sealing technology for a reliable annular seal to prevent PVL, which is yet another feature that sets us apart from any competitor. In addition to the material benefits, our "no tissue/no farm" manufacturing automation and supply chain significantly reduce the cost and complexity associated with pericardial-based TAVR systems. This approach opens possibilities for the widespread adoption of this life-saving technology globally. YHV aims to define the next "technology curve" in the evolution of prosthetic aortic heart valves, with the potential paradigm shift for all other heart valve positions treating a multitude of valvular diseases across patient age groups.

The Rejuvenate™ Valve is currently in the pre-clinical developmental stage (Figure 1). The material has successfully undergone in vitro biocompatibility and hemocompatibility tests, meeting ISO 5840 durability requirements. Prototype valves, subjected to acute and chronic animal studies, have shown promising results, especially in a 6-month juvenile sheep model where HA-LLDPE leaflets remained pristine without thrombosis or calcification. The valve design, optimized through computational modeling, ensures excellent hemodynamic performance (pressure gradient of 4.77 mmHg and effective orifice area of 2.33 cm^2) and increased durability by minimizing stresses on the stent and leaflets. Our current focus is on completing detailed ISO 5840 hemodynamic and durability studies on the current valve design with dynamic sealing technology to achieve design freeze. Subsequently, we plan to conduct longer chronic and acute animal studies, with the collected data forming the basis for our FDA presubmission. Furthermore, the 3D shaping, and HA treatment processes are established but not yet automated. Our next objective is to automate these steps for manufacturing reproducibility, collaborating with Contract Manufacturing Organizations (CMOs) to streamline the process. Upon reaching manufacturing freeze, our goal is to initiate first-in-man clinical trials, a crucial step towards obtaining FDA approval.

BUSINESS CASE

Despite the impressive global adoption of TAVR in recent years, with a CAGR of 16-20% and a projected $5 billion for 2023, the forecast indicates a continued growth at a 14% CAGR through 2030. Our strategic timeline involves achieving design and manufacturing freeze, as well as FDA pre-submission by 2026, with enrollment in first-in-human clinical trials in subsequent years. We aim to launch our Rejuvenate™ Valve by 2032-33 (Figure 2).

Regulatory oversight falls under the purview of the US FDA and Center for Devices and Radiological Health (CDRH) for the Rejuvenate™ Valve. It will classify as a Class III device and will require Premarket Approval (PMA), contingent on the FDA's determination of sufficient valid scientific evidence affirming the device's safety and efficacy. We will leverage our manufacturing partner's Quality System, adhering to Design Control practices, and conducting testing in compliance with ISO 5840-3:2021 and ISO 10993:2009 standards at GLP facilities. Additionally, we will also engage with an experience Regulatory Consultant.

Globally, TAVR adoption is supported by reimbursement mechanisms. Hospitals, facilitated by Current Procedural Terminology (CPT) codes, can attain reimbursement from insurance companies for TAVR procedures. Our business model includes estimating annual TAVR procedures in partnering hospitals and supplying TAVRs in bulk. Key stakeholders for Rejuvenate™ valve include interventional cardiologists, cardiothoracic surgeons, and approved patients. Our marketing strategy involves showcasing technological developments at targeted conferences, digital marketing on professional platforms, and an aggressive approach post-preclinical testing, expanding presence at clinical conferences and leveraging connections of advisory board members.

The main challenge for YHV in commercializing the Rejuvenate™ Valve is securing funding and recruiting skilled engineers and project managers for expediting the FDA pre-submission process. Strategic partnerships or collaborations for developing the valve's delivery system, a critical aspect of the device ecosystem, will also be explored. Further steps involve leveraging the platform for diverse devices targeting various valvular heart diseases across patient groups, including pediatrics. Establishments of necessary expertise and clinical connections is imperative for these endeavors.

PITCH COMPETITION: PULSE ELECTRIC FIELD TREATMENT INDUCED ANGIOGENESIS AS A PROMISING THERAPY FOR DIABETIC FOOT ULCERS.

Neeraj Raghuraman Rajagopalan (1), Govindarajan Srimathveeravalli (1,2)

(1) Department of Mechanical and Industrial Engineering, University of Massachusetts, Amherst, MA, USA.
(2) Institute of Applied Life Sciences, University of Massachusetts Amherst, MA, USA.

PROBLEM STATEMENT

Non-healing diabetic foot ulcer (**DFU**) is a severe consequence of uncontrolled and prolonged diabetes mellitus (*DM*, 422 million cases worldwide) manifesting as chronic ulceration at the bottom of the foot in 15% of cases affected with DM. Currently, 15-25% of DFU patients undergo amputation of the foot due to severity of the infection and more than 50% of patients who recovered have had recurrence within 1-3 years, resulting in diminished quality of life (**QoL**) and increased morbidity rate. DFU occurs as a sequelae to insufficient angiogenesis where inadequate blood supply to the affected area results in severe infection coupled with neuropathy and neuronal dysfunction. Current treatment modalities for DFU are either non-invasive (wound dressing, antibiotics & cell therapy) or invasive (skin grafting, debridement or revascularization) focusing primarily on controlling the infection and topical wound care. Despite such clinical significance, *there are no effective treatment methods in the market that can vascularize the wound area to reverse and prevent the recurrence of these ulcerations.* Our proposed treatment modality is designed to address the important problem in the disease model using an existing device with an entirely different set of inputs.

TECHNOLOGY/SOLUTION DESCRIPTION

Our technology uses an existing clinical technique - pulsed electric fields (**PEF**) that is used for solid tumor ablation where microsecond long pulses are delivered at very high electric field strength (**EFS**). Treatment with PEF induces actin cytoskeletal remodeling, loss of tight junction proteins and transient blood-brain barrier (BBB) disruption resulting in increased blood vessel permeability (**Fig. 1A & 1B**), recapitulating the important mechanical cues that play a pivotal role in angiogenesis where endothelial cells (**EC**) and mural cells collectively remodel the matrix. This remodeling facilitates cell migration and proliferation, onsetting of a series of canonical biochemical signaling cascades that are central to induce angiogenesis.

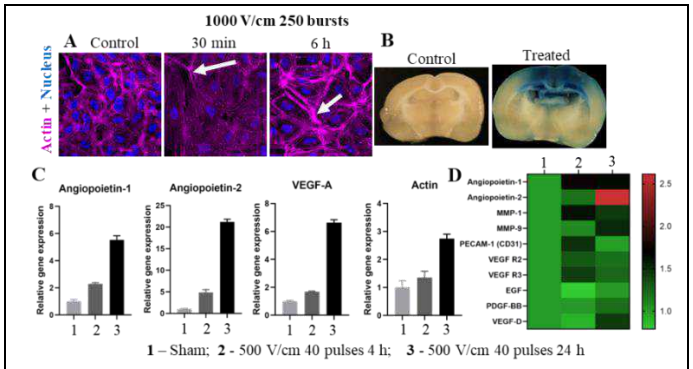

Fig. 1A. PEF applied on a confluent monolayer of HUVECs showed drastic changes in actin cytoskeleton as early as 30 min post treatment and peaks at 6 h where stress fibers are highly concentrated at the junctions between cells. **B.** PEF treated rat brains showed uptake of Evans blue dye injected intravenously at 4 h post treatment. PEF treated cells showed significant upregulation of genes (**C**) and proteins (**D**) attributed to having pro-angiogenic effects at 4 h and 24 h post treatment.

Innovation: Firstly, the application of PEF for reproducing an effect similar to mechanical stimulus opens up a new treatment

modality for therapeutic angiogenesis (**TA**) that is previously unexplored. While it is established that mechanical cues are essential for the initiation of the biomechanical pathways for angiogenesis, currently there is no product or treatment modality in clinics that can be used for such in vivo applications. *Due to the lack of an in vivo mechanical stimulation device for angiogenesis, careful optimization of PEF parameters will present us with a new paradigm for therapeutic angiogenesis in vivo while recapitulating effects similar to mechanical stimulation.* Secondly, PEF is an existing treatment option for tumor ablation therapy and drug delivery and we will be identifying a new set of parameters and waveform for an entirely new set of application.

Our treatment strategy involves the use of a conductive patch that will be placed on the site of the wound (**Fig. 2B**). High frequency low voltage electric pulses will be used with a biphasic waveform that will deliver energy to stimulate the region but not kill the cells. This will avoid muscle and neuronal excitation while stimulating the ECs alone. The region of stimulation can be predicted using established computational models which will help clinicians optimize the treatment strategy specific to individual patients.

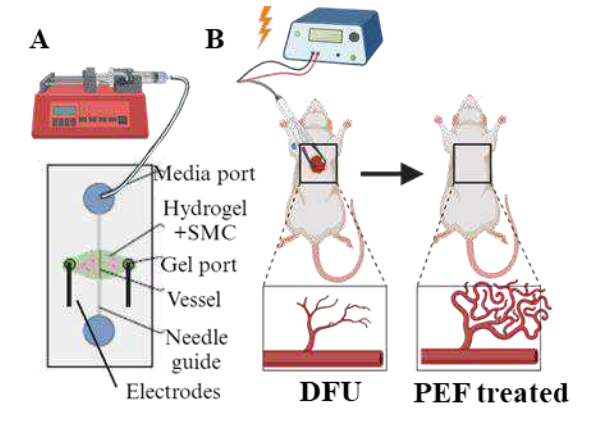

Fig. 2A. Microfluidic model of a blood vessel on a chip. **B.** Rat model of DFU showing PEF induced angiogenesis in wound healing.

The safety of this technology has been validated using in vitro 2-D and 3-D microfluidic models (**Fig. 2A**) and preclinical models across multiple treatment parameter domains used for drug delivery. PEF treated cells have been analyzed for expression of pro-angiogenic factors at different time points at protein and gene levels. Data from PCR and Elispot assays showed increased expression of angiogenic factors like VEGF-A, Angiopoietin 1 & 2 at 4 and 24 h post treatment (**Fig. 2C & 2D**).

The next steps would involve the testing of high frequency biphasic parameters on DFU induced rat models to assess the efficacy of the treatment before it can be translated to clinical trials. We are currently working on optimizing the PEF parameters that can be used on animal models which would give us the desired pro-angiogenic effect on wounds.

BUSINESS CASE

Our promising PEF based technology will impact the therapeutic angiogenesis domain which is currently in the process of finding a simple and reliable solution for diseases pertaining to lack of angiogenesis like DFU, coronary artery disease, Ischemic stroke and retinopathy. Our first clinical target will be towards patients with DFU and this benefit podiatrists who would otherwise treat it with conventional topical wound treatment methods or perform surgery to amputate the leg depending on the severity. This treatment modality may require multiple doses at regular intervals but offers a non-invasive solution.

Patients with DM are prone to DFU and have a poor QoL leading to social, psychological and financial stress. DFU related limb amputation affects African American people who are in a rural setting the most compared to others. Existing treatment methods offer relief to some extent where in most cases, it can only be managed but not completely cured. *PEF treatment offers a simple, inexpensive, highly localized, non-pharmaceutical, non-surgical alternative that can be easily translated to clinic.* This technology will tremendously benefit people in rural areas where an initial training to use the commercially available FDA approved pulse generator will suffice. At present, there is no product in the market that offers a non-invasive treatment method which addresses the core of the problem – angiogenesis and has the potential to treat without involving the need for a surgery. Our product is based on FDA approved predicates that are already in clinical use for over a decade, providing a clear pathway to regulatory approval and this technology is positioned as a non-invasive topical treatment method, thereby qualifying as a Class II device eligible for 510k approval with limited clinical trials documenting safety.

PITCH COMPETITION: TAPPING INTO LIGAMENT TENSION WITH OUR LIGAMENT TENSIOMETER TO ENHANCE OUTCOMES FOLLOWING TOTAL KNEE ARTHROPLASTY

Lesley R. Arant (1), Kai M. Heineman (1), Josh D. Roth (2, 3)

(1) Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, WI, USA
(2) Department of Orthopedics and Rehabilitation, University of Wisconsin-Madison, Madison, WI, USA
(3) Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

PROBLEM STATEMENT

Complications associated with either over- or under-tensioned ligaments following total knee arthroplasty (TKA) have a large public health burden. Under-tensioned ligaments can lead to instability and pain, and over-tensioned ligaments can lead to stiffness and pain[1]. Symptoms associated with over-/under-tensioned ligaments are commonly self-reported as reasons that up to 20% of patients are not satisfied following TKA[2]. With up to 3.8 million patients projected to receive TKA annually by 2033[3], this equates to up to 760,000 patients per year who are not satisfied. Improving rates of patient satisfaction is becoming an important consideration for healthcare systems to maximize their reimbursements in a value-based payment model[4]. Additionally, post-operative complications associated with over-/under-tensioned ligaments are responsible for up to 64% of revision procedures[5]. Assuming a conservative revision rate of 2% and a cost per revision procedure of $37,000[5,6], the economic burden is around $1.8 billion per year, which does not account for other economic burdens (e.g., lost wages).

Despite the well-documented importance of proper ligament tensioning, existing solutions to gauge ligament tension intraoperatively are either subjective or fail to assess tension in an individual ligament. One common technique is a laxity assessment, in which ligament tension is indirectly inferred from joint motion and stiffness[7]. Since this assessment is commonly subjective, its outcomes vary according to a particular surgeon's training and experience[8]. Although distraction devices[9] and contact force sensors[10] provide quantitative measurements, they are unable to assess tension in an individual ligament. Thus, given the lack of adequate devices available, there is no consensus on the proper target or method of assessing ligament tension.

Accordingly, a sensor that provides direct and objective measurements of ligament tension would give orthopedic surgeons the information needed to (1) improve patient function and satisfaction after TKA, and (2) alleviate the economic burden of revision TKAs.

TECHNOLOGY/SOLUTION DESCRIPTION

Our technology, termed a ligament tensiometer, shows promise for filling this gap in a surgeon's toolbox because it provides direct and quantitative measurements of ligament tension. The ligament tensiometer is a handheld device placed in contact with the ligament of interest. It consists of two main components (***Figure 1***): (1) a voice coil actuator that excites low amplitude shear waves in the ligament, and (2) a piezoelectric load cell that tracks the shear wave propagation along the ligament's length. The tensiometer software computes the shear wave speed in the ligament using the time delay between the voice coil actuator and load cell signal (***Figure 1***). The tensiometer software then calibrates measured shear wave speeds to ligament tension using the linear relationship between shear wave speed squared and tension[11,12]. Thus, the tensiometer has the competitive advantage of direct and objective measurements of tension in a specific ligament.

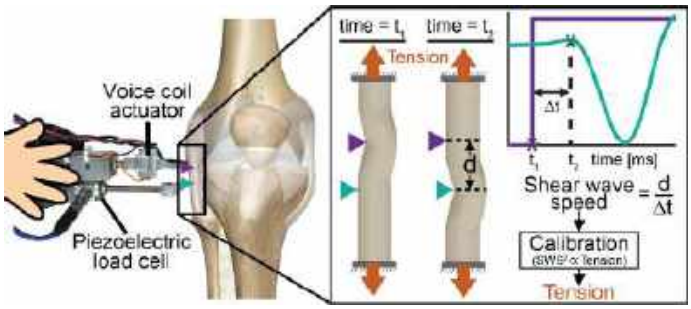

Figure 1: Our ligament tensiometer is a handheld device that uses shear wave speed to measure tension in a particular ligament.

We performed a preliminary error analysis of our tensiometer prototype to assess its accuracy of measuring collateral ligament tension (***Figure 2***). We chose these ligaments to study because their tension is routinely manipulated by surgeons during TKA[13]. We used our ligament tensiometer to measure shear wave speeds in the medial and lateral

collateral ligaments of human cadaveric knees (n = 3) under manually applied loads (***Figure 2a***). We used a calibration algorithm to compute the tensiometer-measured tensions from measured shear wave speeds. We computed the errors between the tensiometer-measured tensions and the gold standard tensions measured using a six degree-of-freedom robot and the principle of superposition[14]. We found that the tensiometer can directly measure ligament tension with low bias errors (***Figure 2b***). Additionally, when we coupled the tensiometer with optical motion capture to track ligament length, the tensiometer could accurately measure ligament engagement length (i.e., length at transition from toe to linear region) (***Figure 2c***). Thus, the tensiometer could be used with existing surgical navigation tools to measure other key metrics of ligament mechanics.

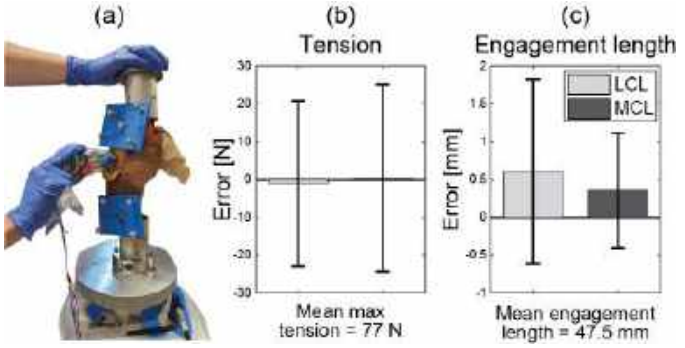

Figure 2: (a) We used the tensiometer to measure lateral and medial collateral ligament (LCL and MCL, respectively) tension during laxity assessments in three cadaveric knees. (b) The tensiometer measured ligament tension with low bias errors. (c) When coupled with optical motion capture, the tensiometer accurately measured ligament engagement length.

The key technical advancement required to take our tensiometer to market is to increase its precision through design optimization. Preliminary data suggests that tensiometer-measured tension is sensitive to tensiometer design factors (e.g., tip spacing, excitation frequency[15]) and use factors (e.g., application force[16], positioning of the tensiometer on the ligament[17]). Thus, our current work is focused on identifying the optimal combinations of these design and use factors that yield repeatable and precise measures of ligament tension, while maintaining the tensiometer's ease-of-use and low bias errors. With this key technical advancement, the ligament tensiometer will be a strong candidate for a marketable product to meet a critical unmet need in orthopedics.

BUSINESS CASE

We validated our initial product-market fit in TKA by completing over 150 discovery interviews through regional and national NSF I-Corps programs (NSF Award #: 2323033). Our total available market will reach 3.8 million TKAs annually by 2033[3]. Even if we conservatively limit this to technology-enhanced TKAs (currently 14.7% of TKAs), the serviceable obtainable market remains 559,000 TKAs annually. In the TKA market, the end users are orthopedic surgeons and their operating room staff who treat TKA patients. The payers are the hospitals, insurance agencies, and the patients who receive the surgery.

Once marketed, we envision the cost structure of the tensiometer to be a one-time payment for the device, followed by the purchasing of disposables and software licenses as needed. At our validated effective cost of $500 per case, a conservative projection of our serviceable obtainable market for TKA applications is $280 million per year. Considering that the tensiometer has potential use in many other procedures, joints, and ligaments (e.g., unicompartmental arthroplasty, ligament reconstruction, and tendon repair), this should be considered a conservative estimate of the patient market size.

Our marketing strategy involves three stages (***Figure 3***). In stage 1, our collaborating "champion" surgeon will test the tensiometer on a small subset of patients at the UW-Madison Hospital. This stage requires IRB approval before the tensiometer can be used in live patients. To fund stage 1, we plan on seeking Small Business Technology Transfer (STTR) phase I and II funds totaling $2.3 million. In stage 2, we will continue to use STTR funding streams to complete a randomized control trial in which we fabricate at least ten tensiometers and send each to a different institution for use by surgeons. This stage will require FDA Investigational Device Exemption. In stage 3, we plan to acquire FDA Premarket Notification 510(k) clearance to enable widespread tensiometer use as a Class II device.

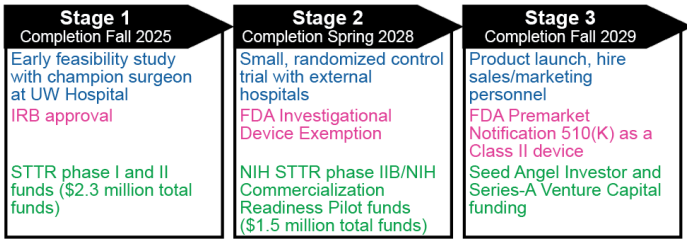

Figure 3: Pathway to market for the ligament tensiometer.

The main hurdle to market is translating our tensiometer from a prototype to a clinically usable device. In particular, the tensiometer components must be either sterilizable or disposable so that the tensiometer can be reused in different patients. Additionally, to decrease manufacturing cost and time and to increase product robustness, the tensiometer housing must not be made of 3D-printed polymers.

The main risk to the developmental pathway of the tensiometer is the reluctance of surgeons to incorporate a new technology into their surgical procedure. If this challenge presents, then we will lean on the support of the existing early adopters to generate more data that supports the benefit of tensiometer measurements to improving patient outcomes. This may lengthen the time to commercialization, but we do not believe this will be a permanent roadblock to translation of our device.

In summary, our three-stage marketing plan aims to recruit surgeons who will fuel the generation of supporting data, which in turn will fuel market expansion. Once commercialized, the ligament tensiometer has great potential to enhance the process of ligament tensioning during orthopedic procedures, leading to more consistent, predictable, and positive surgical outcomes for patients suffering from debilitating orthopedic injuries and diseases like osteoarthritis.

BIOMEDICAL APPLICATIONS OF NOVEL MAGNETOSTRICTIVE COMPOSITE

INTRODUCTION

There is an increasing demand for biomaterials with characteristics that can be altered *in vivo* to enhance tissue properties. One such branch of materials is smart biomaterials that can respond to cues *in vivo* and alter their properties. It is estimated that by 2030 the market size for these kinds of smart polymers will be 8.15 billion US dollars [1]. The primary aim for smart biomaterials is to provide mechanical support, mimic, guide, or induce a tissue or natural process, and/or act as a vehicle for drug delivery [2], [3].

Magnetostrictive materials are a group of smart materials that respond to a magnetic field by altering their domain [2], [4], [5]. The human body is constantly encountering external forces and internal chemical reactions. Some dynamic tissues and processes such as bone, muscle, neurons, and cardiomyocytes may benefit from magnetostrictive materials that produce a strain response. An example of a magnetostrictive material is Terfenol-D, an iron alloy containing terbium and dysprosium [2],[6]. This alloy has a high saturation strain compared to other magnetoactive materials. A magnetic field will induce the Terfenol-D to change orientation, causing strains to be generated [3], [4], [5], [7].

In this context, a novel composite was developed combining Polymethyl methacrylate (PMMA) commonly known as Bone Cement and a particulate form of Terfenol-D (TD). This study delves into the micro-morphology, mechanical properties, and biocompatibility characteristics of this composite material. The combination of PMMA and Terfenol-D opens avenues for innovative materials that could play a significant role in advancing technology and addressing the evolving needs of the health industry.

METHODS

1. Preparation of PMMA and TD Magnetostrictive Composite

1.1 Material Processing To prepare the TD (Nalgene) and PMMA composite, 75mg of Terfenol-D particles (maximum particle size ~300μm) 7.5%w/v was combined with 1g of PMMA and 5mL of Monomer liquid. To effectively mix into a homogenous solution, a Sonicator (QSonica Q55) was used. Control samples were prepared with only PMMA and no terfenol-D. The liquified mixtures were aspirated and dispensed on a glass slide and left under a fume hood until the polymers had completely polymerized and dried.

2. Cell Viability Assays.

1.2.1 MTT Assay. Composites were placed in 96 well plates. 5,000 murine fibroblasts (NIH 3T3, ATCC) were cultured on each sample including a positive and negative control and left in the incubator at 37^0C for 3 days. Then a stock solution was prepared by combining Thiazolyl Blue Tetrazolium Bromide 98% (Acros Organics) (0.5%w/v) to corning phosphate buffer saline (PBS). The media from the wells were aspirated. 10 microliters of stock solution were added to each sample along with 100 microliters of PBS keeping the volume across all wells equal. It was incubated again for 4 hours at 37^oC. Next, all but 25 microliters were removed from the wells and 50 microliters of dimethyl sulfoxide (DMSO, Sigma Aldrich) was added and left to incubate for 10 minutes at 37^oC and measured at a wavelength of 540nm on a spectrophotometer. MTT assay was conducted in triplicates. Kruskal-Wallis is one way analysis of variance was used to determine significance between PMMA/PMMA+TD and positive control (no material).

3. Mechanical Testing

3.1 Dynamic Mechanical Analysis (DMA). Both the PMMA and the PMMA with Terfenol-D composite were cut into rectangles and their dimensions were measured. PMMA was cut to dimensions of 10.15mm x 9.2mm x 0.48mm and the PMMA-TD composite was cut to 16.29mm x 8.82mm x 0.74mm. They were then fastened to the DMA Q800

machine (TA Instruments). The test was conducted at a frequency of 1 Hz, under a tension of 1 newton, and temperature ramp rate of 10^0C per minute with a max temperature of 200^0C. Data was analyzed using TA Instruments software.

RESULTS

During polymerization PMMA gained magnetostrictive properties owing to the addition of TD particles. SEM imaging revealed that this material is relatively nonporous and is embedded with TD particles.

DMA testing was conducted to determine mechanical properties of the samples. TA analysis of the PMMA polymer provided a glass transition temperature of 115^0C and that the PMMA+TD composite was 97^0C, based on Tan Delta. This shows that the composite has a lowered glass transition temperature than that of the PMMA, yet since the glass temperature is still within range, the composite material can be used for in vivo applications.

The biocompatibility of this novel composite was evaluated by MTT assay to measure the materials' cytotoxicity for biomedical applications. After seeding the cells onto the composite for both tests, the samples were incubated for 3 days till cells adhered to the sample. The results from the MTT assay demonstrated high biocompatibility of the composite and polymer compared to the culture-plate only control. Significantly higher live cells were observed in the polymer and composite samples. Overall, the composites' structure and chemical composition provided a basis for rapid cell adhesion and proliferation.

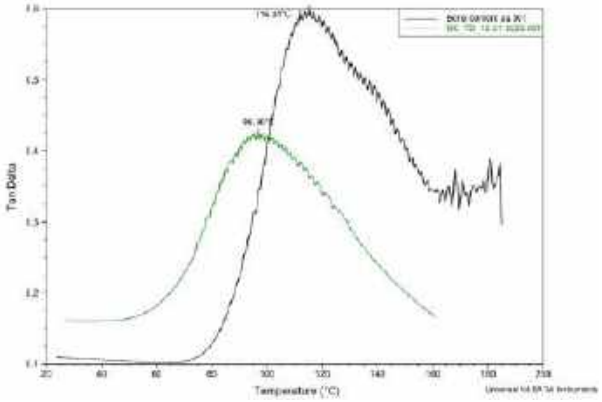

Figure 1. Mechanical Characterization. DMA analysis of composite material

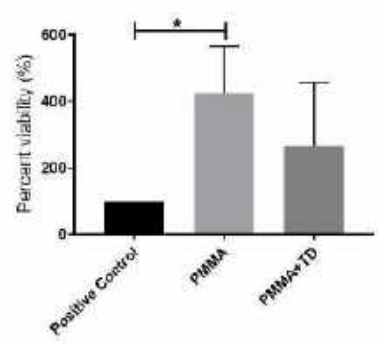

Figure 2. Viability of fibroblasts. Fibroblasts were cultured on PMMA and PMMA+TD samples and cell viability was assessed via MTT assay. N=3

DISCUSSION

These findings demonstrate the potential for this material to be used as a smart biomaterial for humans and animals. The composite's biocompatibility, along with its high melting temperature, and durability shows promise. PMMA is an FDA approved polymer that is already in use clinically. The addition of TD can significantly enhance PMMA's properties. It can be employed in a wide variety of applications such as neural, cardiovascular, and musculoskeletal regeneration. In addition, the materials ability to change shape allows it to be used for diagnostics, drug delivery, and influence tissue and cellular functions. Overall, its behavior makes it an ideal smart material for biomedical applications.

INTRODUCTION

According to the United Nations approximately 65 million people worldwide require a wheelchair for their daily mobility [1]. Wheelchair use can negatively impact community mobility (the ability to move independently) and participation (interaction with peers outside the home) [2]. An individual's community mobility and participation has demonstrated a direct relationship to well-being, overall health, and quality of life [3], making it critical for rehabilitation specialists to monitor patients' mobility to better assign treatments and therapies for recovery. Monitoring these parameters is increasingly important for manual wheelchair users (MWUs) as they present a higher risk of injury [4]. Traditionally, a patient's community mobility and participation is monitored during in-clinic testing [4]. Even though in clinic testing is accurate, it does not completely represent the user's daily mobility.

Alternatively, a user's community mobility and participation can be observed remotely through self-surveys, activity journals and questionnaires. Evaluations like the Life Space Assessment [5] and Wheelchair Use Confidence Scale [6] are commonly used. Information such as the participant's activity level and distance traveled from home is captured in the Life Space Assessment, and confidence utilizing their wheelchair in various situations along with personal assurance is reflected in the Wheelchair Use Confidence Scale. Still, such evaluations are seen as unreliable because of subjective observation.

Similarly, GPS devices have been used as a mode of remote assessment, with increasing promise for delivering explicit results tracking human activity. However, limitations of standalone GPS connectivity result in inaccurate activity detection and insufficient information for community participation [7].

This study illustrates an innovative technique of remote community mobility and participation measurement employing activity journals, GPS, and questionnaires. The technique accounts for weaknesses of established methods, providing comprehensive measurements of the participant's mobility and necessary context regarding their community participation. Data of a wheelchair user over a course of a week is presented in this feasibility study.

METHODS

This study was approved by the University of Wisconsin – Milwaukee International Review Board (protocol #24.059). The participant, a 39-year-old male with a T-8 complete spinal cord injury met with the research team in the University of Wisconsin – Milwaukee Advanced Mobility Biomechanics Lab in August. The participant signed a written consent form and was provided with a paper-based activity journal, commercially available Garmin Forerunner 753XT GPS wristwatch, and instructions of use.

The participant was instructed to wear the Garmin watch and utilize its recording function for the entire duration he was out of home. Upon arrival home, the participant was advised to fill out the day's journal entry entirely. After a week, the participant filled out the Life Space Assessment [5] and Wheelchair Use Confidence Scale (short form) [6]. The Garmin watch recorded the participant's position and heart rate daily. Once returned, the watch data was saved to the Garmin Connect app and the activity journal was transcribed into an Excel File.

The participants' activity journal was organized using a Microsoft Excel spreadsheet to classify the interactions, locations, and barriers. The recorded interactions were categorized based on varying interpersonal relationship types and social group size.

The GPS data was processed using MATLAB R2022b software, where the participants geographical points were mapped out. The locations visited each day were quantified based on the participants journal entries and compared with GPS locational points for further clarification. For example, the journal entry on the third day listed the locations visited as "everywhere" but the GPS data showed that the participant visited 8 locations. Additionally, the watch recorded the participants heart rate and speed that was used for further analysis of their physical activity.

RESULTS

The participant recorded six daily entries in his provided activity journal, while the Garmin watch collected GPS data for five days due to an uncharged battery on the sixth day.

Figure 1 shows the overall route of one trip made by the participant on day three. Table 1 shows the information entered by the participant in the activity journal. Notably, the number of locations visited, barriers encountered, and types of interactions he had each day.

Figure 2 shows the speed and heart rate of the participant for the entire trip presented in Figure 1. At the top, the type of location and wheeling vs driving is displayed, determined based on the participants heart rate, speed, and activity journal.

The participant scored 202 out of 210 possible points on the Wheelchair Use Confidence Scale indicating a lack of comfortability maneuvering imperfect conditions and self-confidence socially. The Life Space Assessment indicated that he has been active around his and surrounding cities but has not recently traveled out of the state.

DISCUSSION

The results from the participant's activity journal (Table 1) and corresponding GPS data (Figure 1) validate that the participant maintained frequent community engagement throughout the week. The participant visited several locations, maintained a higher heart rate when wheeling themselves (Figure 2) and had interactions of varying interpersonal relationships daily. Moreover, the participant faced barriers during the week (Table 1) that could have impacted their community mobility and participation and should be taken into consideration [3].

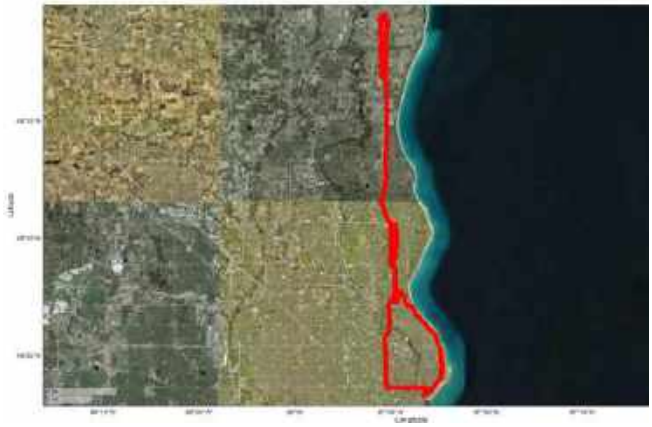

Figure 1: GPS data for one trip on day 3.

Table 1: Activity Journal Data of a Wheelchair User for a Week. Pro: Professional, Rom: Romantic, Fam: Familial (including pets), Plat: Platonic, Txn: Transactional, G: Group (3 or more), P: Personal (1-2 People), E: Exchange.

	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6
# of Location	4	2	8	5	3	3
Barriers	None	Stairs	Big Hill	Tight Space	None	None
Interactions	Pro, Fam	Pro	Rom, Fam, Txn	Plat, Txn	Pro, Plat	Plat, Rom, Fam
Interaction Types	G, P	P	P, E	P, G, E	G	P, G

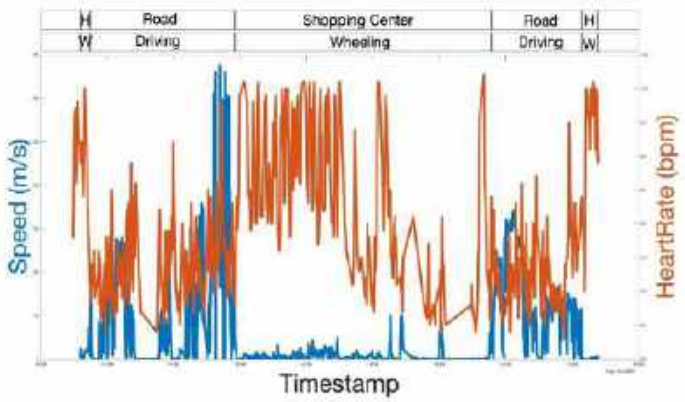

Figure 2: Participant speed, heart rate and activities. W: wheeling, H: home.

Additionally, the results of both the Life Space Assessment and Wheelchair Use Confidence Scale scores reinforce the results from the activity journal and GPS data. Attributing to the participants confidence outside of their home and in different social situations, which is indicative of their community mobility and participation [3].

Furthermore, the methods limitations should be addressed in future studies. This includes the loss of GPS data which is a common occurrence in similar studies [7] and ambiguity of an activity journal, which shows the importance of clear instruction with the participant.

Our combined technique results in more comprehensive information for rehabilitation specialists than activity journals, GPS data, or questionnaires alone. This approach provides both qualitative and quantitative data about the participants' activities and confidence within their community. Overall, the combination of these three methods provides rehabilitation specialists with a comprehensive understanding of their patients' community mobility and participation, allowing for greater patient specific care. Future work will expand this technique to larger populations to better understand optimal rehabilitation and activity promotion strategies for manual wheelchair users.

DEVELOPMENT OF AN AUTOMATED BONE TRANSPORT DEVICE FOR USE IN DISTRACTION OSTEOGENESIS

Chloe R. Brekhus (1)

(1) Department of Mechanical Engineering, Colorado State University, Fort Collins, CO, USA

INTRODUCTION

Distraction osteogenesis is a procedure used to heal severe bone defects, commonly in the long bones of the leg and arm. Large segmental bone defects can result from high energy trauma injuries (like combat-related blast injuries) or surgical bone tumor excision in cancer patients [1], and occur in about 150,000 patients in the US annually [2]. These defects are considered "critical-sized" if nonunion is imminent (i.e., the bone cannot heal on its own), which happens in up to 17% of open tibial fractures [3]. In these cases, distraction osteogenesis is often necessary to regenerate bone.

This procedure involves placing an external fixator around the limb and moving a segment of healthy bone across the defect (Figure 1). The external fixator frame is attached to the limb via pins drilled into the bone, and the middle ring (connected to the transport bone segment) is moved (i.e., distracted) across the gap by manual hardware manipulation. This bone transport process creates tension in the defect, providing mechanical signals to induce bone growth via osteoblast activity and other ossification pathways.

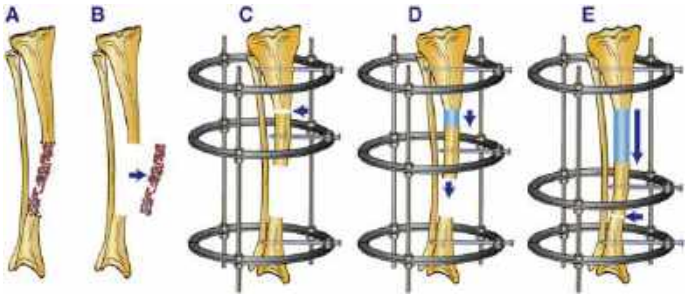

Figure 1: Distraction osteogenesis process [2]: defect removal (A and B), external fixator placement (C), distraction of transport segment (D), and bone regeneration (E).

It has been shown that distracting the bone in smaller increments more frequently optimizes bone regeneration [4], which is difficult to achieve with the current method of manual distraction. Furthermore, manual distraction requires a high-level of patient compliance, as the patient has to manually turn nuts on the external fixator at a specific time each day. The proposed solution is to develop a device that can automatically distract the bone in a nearly continuous fashion to improve bone growth and minimize patient input to the external fixator.

PRODUCT DESIGN

The proposed "auto-distractor" is based on a circular ring external fixation system (Figure 2). Bone transport will be driven by two stepper motors fixed to the middle ring, which is in turn attached to the transport bone segment. This ring slides along the connecting rods via linear ball bearings so that the distraction increment is limited only by the step size of the motor lead screws. Bone transport has been found to be optimized using a rate of 1 mm/day, with at least 60 increments per mm being considered continuous [5]. The selected motors are specified to have a linear travel of 0.0015875 mm/step, allowing for continuous distraction.

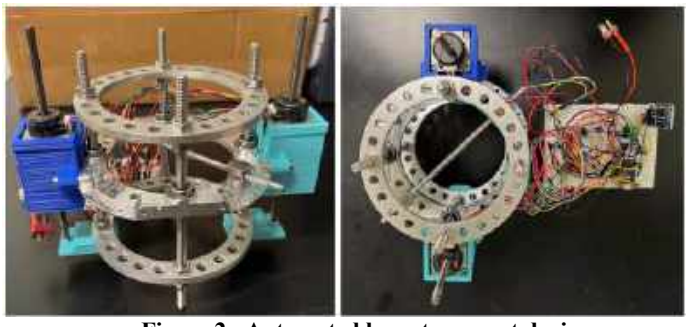

Figure 2: Automated bone transport device.

The motors will be controlled by a circuit (Figure 3) and Arduino code that specifies the time and distance of distraction. The circuit is powered by a 14.8V lithium-ion battery, which directly supplies voltage to the Arduino and motors, and a voltage regulator is used to drop this to 5V going into the stepper motors and encoders. The stepper motor drivers limit the motor current and receive signals from the Arduino to control motor movement. Each motor has an encoder that can sense the position of the motors; when the motors move the expected distance, the Arduino connects to Wi-Fi and emails the user to confirm that distraction has occurred. The motors are coded to automatically move at specific times so distraction happens at regular intervals. Time is kept by the real time clock (RTC) component, which runs on a separate 3V lithium cell battery and continuously sends the updated time to the Arduino.

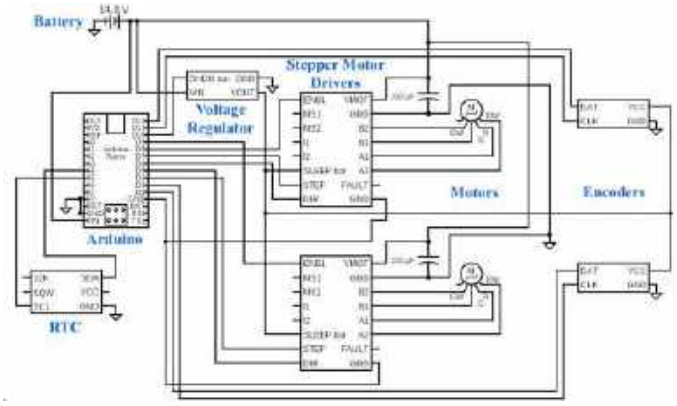

Figure 3: Circuit diagram for the auto-distractor.

This device will be used on patients with large segmental bone defects to improve healing. The surgical process will be essentially the same as current external fixator placement surgeries, with the motors and electronics being placed on the device one week after surgery when the distraction process begins. The novel aspects of the device are the sliding middle ring and motor construct, as well as the use of motor encoders to provide email feedback when distraction occurs. This device should be technically feasible, as the initial prototype was able to complete a successful bone transport in an ovine cadaver metatarsal.

BUDGET & MARKET ANALYSIS

The design budget for this project was $3,000 to cover the cost of components. The prototype shown in Figure 1 cost approximately $2,400, with the largest costs being the custom-machined transport ring ($700) and the customized motors with encoders ($786 for both). This is in comparison to the approximate cost of a manually driven device ("Ilizarov frame") of $730. A study in 2023 found the average total cost of an Ilizarov distraction osteogenesis procedure to be £26,126 (about $33,015) including surgery and hospital stay [6]. Using the auto-distractor would add $1,670 based on the prototype cost, which is only a 5% increase in price. The benefits of this device, including a potentially lower rate of nonunion, fewer overall revision surgeries, and decreased healing time, will likely offset this slightly higher cost. Furthermore, implementing the auto-distractor will not increase surgery time, as the electronic components of the device can be added later when the distraction period starts (usually 1-week post-op).

About 150,000 large segmental bone defects are reported each year in the US [2], and about 37% of critical-sized defects are treated using bone transport [7]. Based on these statistics, it is estimated that 55,500 bone transport procedures are done in the US each year. With only one other automated long bone distractor on the market (the Maxframe Autostrut™) [8], we estimate that 20,000-30,000 devices could be sold each year. At this volume, the expected cost per device is approximately $2,000 due to decreases in the manufacturing cost of the customized parts (motors and transport ring). The projected sales price will then be $3,000, resulting in a profit margin of 50%.

Investment costs in tooling are expected to be minimal for this device. Almost all components of the device are either 3D printed or available off-the-shelf; the only exceptions are the motors and transport ring, for which the manufacture will continue to be outsourced to reduce unnecessary tooling costs. The only machines needed for in-house manufacturing would be a 3D printer and basic soldering equipment, adding up to approximately $1,400. Assuming 25,000 units can be sold, this results in a return on investment of 49.9%.

INVESTIGATING THE EFFECTS OF SURFACE STIFFNESS AND VISCOELASTICITY ON HUMAN MESENCHYMAL STEM CELL IMMUNOMODULATION

Sara J. Olsen (1), Rose E. Leader, (2), Bethany M. Almeida (1)

(1) Department of Chemical and Biomolecular Engineering, Clarkson University, Potsdam, NY, USA
(2) Department of Mechanical and Aerospace Engineering, Clarkson University, Potsdam, NY, USA

INTRODUCTION

Chronic, non-healing wounds are a growing financial and medical burden, with the global wound care market valued at approximately $20B in 2022.[1] Human mesenchymal stem cells (hMSCs) implanted at the wound site are an attractive therapy for chronic, non-healing wounds due to their immunomodulatory behavior.[2] However, hMSCs have low viability, poor engraftment, and a risk of eliciting an immune response, thereby reducing therapeutic potential.[3] Additionally, variability in donor, age, and tissue source results in hMSC heterogeneity.[4] Prior studies have demonstrated that substrate stiffness and viscoelasticity have been shown to modulate hMSC differentiation.[5,6] For example, Engler et al demonstrated that hMSCs commit to different lineages as a function of the elasticity of their culture substrate.[7] They demonstrated that soft matrices mimicking the elasticity of brain tissue yielded neurogenic differentiation, stiffer matrices mimicking muscle induced myogenesis, and rigid matrices that mimic bone resulted in osteogenesis.[7] In addition to substrate elasticity, researchers have looked at the effect of viscoelasticity on hMSC fate, as human tissues are naturally viscoelastic. Chaudhuri et al found that cell spreading, proliferation, and osteogenic differentiation were all enhanced on hydrogels with faster matrix stress relaxation.[8] However, the effects of stiffness and viscoelasticity on hMSC immunomodulation remain largely unknown. Few studies in the literature have examined this; the literature thus far suggests that a soft,[9] more viscous (ie, higher stress relaxation)[10] extracellular matrix maximizes the production of paracrine factors by hMSCs that are indicative of immunomodulation, however other studies suggest that 3D culture of hMSCs is more important than matrix stiffness and viscoelasticity in expressing key immunomodulatory genes.[11] These studies clearly demonstrate the impact that biophysical properties have on the immunomodulatory potential of hMSCs. However, the mechanisms by which these biophysical cues affect immunomodulation have yet to be elucidated. In addition, there is missing from the literature a comprehensive study that seeks to demonstrate the synergistic relationship between matrix stiffness and viscoelasticity on hMSC immunomodulatory for a range of elastic, storage, and loss moduli. Thus, we seek to elucidate the synergistic effects of substrate stiffness and viscoelasticity on hMSC immunomodulatory behavior using highly tunable polyacrylamide (PAAm) gels for a range of biophysical properties towards elucidating the mechanisms by which immunomodulation is affected.

METHODS

PAAm gels were fabricated as described in the literature.[12] Briefly, three gels were fabricated, a low-stiffness gel, a medium-stiffness gel, and a high-stiffness gel. To impart viscoelastic properties to the gels, linear acrylamide was fabricated and mixed with the acrylamide and bis-acrylamide monomer mixture prior to gelation.[6,13] Young's (elastic) modulus (E) was characterized using dynamic mechanical analysis at 37 °C (DMA; DMA850, TA Instruments, New Castle, DE). Viscoelasticity, defined as shear stress-mediated storage and loss moduli, G' and G'', was characterized using a rheometer (AR2000, TA Instruments, New Castle, DE) using a frequency sweep from 0.05 to 50 Hz at 37 °C, a controlled 2% strain rate, and 0.1 N normal force. Values at 0.16 Hz were reported; these values were selected due to their biological relevance.[14] The PAAm gels were coated in fibronectin (Sigma, Billerica, MA) via sulfo-SANPAH to aid cell attachment and bone marrow-derived hMSCs (Lonza, Hopkinton, MA) were seeded at 5,000 cells/cm^2 on the fibronectin-coated PAAm gels. Viability was assessed using a live/dead assay (Fisher Scientific, Hampton, NH), and cellular morphology was characterized by fluorescently staining F-actin using Alexa Fluor 488 Phalloidin (Fisher Scientific, Hampton, NH) and nuclei using DAPI (Sigma, Billerica, MA) and imaging on a Nikon Ti2E inverted epifluorescence microscope (Nikon, Tokyo, Japan).

RESULTS

Table 1 shows the fabrication parameters of each gel formulation, including the expected Young's modulus (E), as well as the measured E, storage modulus (G'), loss modulus (G"), and tanδ.

Table 1. Mechanical characterization of the PAAm gels

	Low (-)	Low (+)	Med (-)	Med (+)	High (-)	High (+)
Expected Values						
% Acryl.	4	4	5	5	5	5
% Bis-Acryl.	0.06	0.06	0.15	0.15	0.30	0.30
% Linear Acryl.	0	4	0	4	0	4
E (kPa)	1.16 ± 0.54	1.16 ± 0.54	4.47 ± 1.19	4.47 ± 1.19	8.73 ± 0.79	8.73 ± 0.79
Measured Values						
E (kPa)	1.44 ± 0.11	1.15 ± 0.08	4.13 ± 0.51	4.99 ± 0.34	8.54 ± 0.55	8.82 ± 0.22
G' (Pa)	164	175	347	329	599	600
G" (Pa)	40.1	110	109	190	237	217
Tanδ	0.25	0.63	0.31	0.58	0.396	0.361

Abbreviations: Acryl, acrylamide; Bis-acryl., N-N' methylene bisacrylamide; high, high stiffness; low, low stiffness; med, medium stiffness; -, without linear acrylamide; +, with linear acrylamide.
Note: n=3 for E, n=1 for G', G", Tanδ

Live/Dead assay confirmed the viability of the hMSCs on these gels (Figure 1A). It is notable that there are fewer cells overall, as well as more dead cells, on the low- and high-stiffness gels in comparison with the medium gels. In addition, morphological analysis demonstrated that cells on low-stiffness gels were rounder and smaller, cells on medium-stiffness gels were larger and more 'spindle-like', and cells on high-stiffness gels were larger and more spread out (Figure 1B).

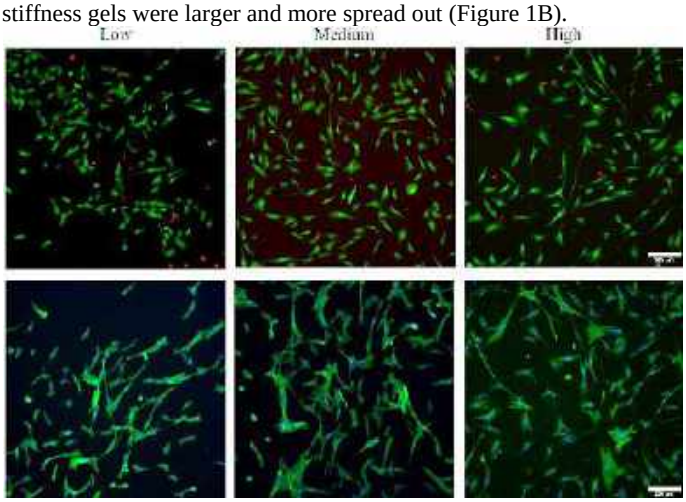

Figure 1: Viability (top) and morphology (bottom) of hMSCs cultured on non-viscoelastic low (left), medium (middle), and high (right) stiffness PAAm gels. Top: Live cells = green, dead cells = red, scale bar = 200 µm; Bottom: F-actin = green, nuclei = blue, scale bar = 200 µm.

DISCUSSION

Mechanical characterization of the gels (Table 1) shows that for low-, medium-, and high-stiffness non-viscoelastic and viscoelastic gels, the measured Young's modulus matched the expected values. Additionally, the storage modulus, which relates to the elastic behavior of materials, increases proportionally with Young's modulus. The loss modulus, related to the viscous behavior of materials, and Tanδ, a ratio measurement indicative of elastic:viscous components with larger Tanδ suggesting increased viscous components, increases as expected from the non-viscoelastic to viscoelastic low- and medium-stiffness PAAm gels. However, the high stiffness gels demonstrate no change in G" or Tanδ. This may be related to the increased concentration of bis-acrylamide yielding a higher chance of the linear acrylamide crosslinking to the acrylamide matrix at its terminal ends. However, these results are from an n=1, and more investigation is required. To investigate differences in crosslinking due to the presence of acrylamide and bis-acrylamide concentrations, a very high-stiffness non-viscoelastic and viscoelastic PAAm gel were also made, with an expected Young's modulus of ~19.66 kPa (8% acrylamide, 0.26% bis-acrylamide, data not shown in Table 1). The measured Young's modulus of these gels was found to be 9.50 ± 0.99, and 20.1 ± 0.94 kPa for the very high-stiffness non-viscoelastic and viscoelastic PAAm gel, respectively. Interestingly, the very high-stiffness gel did show an increase in Young's modulus when linear acrylamide was added. As suggested before, this may be a result of the increase in acrylamide and bis-acrylamide monomer concentration resulting in a greater chance for the linear acrylamide to crosslink at its terminal ends, decreasing the dissipative effects and increasing stiffness.

The viability assay showed a greater number of cells on the medium-stiffness gel compared to low- and high-stiffness gels. The decreased number of cells is likely due to a decrease in focal adhesion formation on these gels. Despite this, all stiffness gels were found to be cytocompatible, with few dead cells present. F-actin and nuclei staining also demonstrated noticeable differences in cell shape between the hMSCs cultured on different stiffness PAAm gels. As differences in hMSC morphology are known to affect hMSC behavior, this demonstrates the potential for variations in immunomodulatory potential as a result of differences in hMSC interactions with the different PAAm gels. Current work is focused on quantifying viscoelastic properties, viability, focal adhesion formation, morphology changes over time, and immunomodulatory potential changes over time by investigating the production of immunomodulatory cytokines by hMSCs cultured on these gels.

MECHANICAL RESPONSE TO COMPRESSION OF THE PIG OPTIC NERVE

K. Metrey (1), A. Korneva (1)

(1) Biomedical Engineering, Virginia Tech, Blacksburg, VA, USA

INTRODUCTION

The optic nerve is a crucial component of the visual system that transmits signals from the eye to the brain. A damaged nerve results in a partial or a complete loss of vision and leads to a significant decrease in the quality of life. Nearly 900,000 individuals are hospitalized after experiencing head trauma, and 50-65% of patients at rehabilitation facilities reported traumatic brain injury impacting their vision.[1] By studying the mechanical behavior of the optic nerve, we can better understand how mechanical trauma affects vision and eventually improve the quality of life of injured individuals. The optic nerve is small, ranging from 2.46 to 5.19 mm in diameter [2] and a soft tissue. This presents a challenge when designing a mechanical testing system to measure the material properties of optic nerves. The compressive properties of the optic nerve have been investigated in just two studies, reporting the elastic moduli, 1.895 and 3.05 kPa.[3, 4] The aim of this study was to measure the mechanical response of pig optic nerves to uniaxial compression. The pig optic nerves showed creep behavior, which can be described by a viscoelastic model.

METHODS

Healthy pig eyes were obtained from the Virginia Tech Meat Center (Blacksburg, VA). The eyes were dissected leaving only the optic nerve and optic nerve head. The outer layer of the optic nerve sheath, the dura mater, was removed leaving intact the inner layer of the sheath surrounding the optic nerve. The specimen was stored in phosphate buffered saline solution at 4°C until testing. The optic nerve was cut to an axial length of 3-4mm using two razor blades separated by a spacer.

Unconfined compression tests and creep tests were performed. Optic nerve samples were weighed before and after testing. Compression was applied to the top of the specimen using cellophane, with weights ranging between 30 to 50 mg. Top-view images were taken using a camera and side-view images using a second camera mounted on an Olympus MVX10 microscope. Photographs were taken by both cameras every 30 seconds for 10 minutes. The images were traced using FIJI (U.S. National Institutes of Health, Bethesda, MD, USA) to measure the height and the diameter of the specimen. An average of the major and minor axes was used for each diameter.

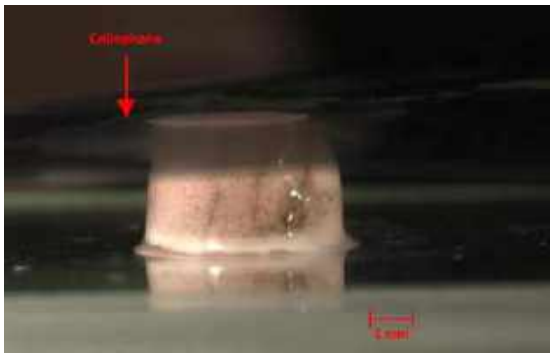

Figure 1: A pig optic nerve sample under compression. Applied load was the weight of a cellophane square. Scalebar 1mm.

Axial strain was calculated as the change in the height of the specimen divided by the initial height. The stress was calculated as the applied force divided by the initial cross-sectional area. The axial strain over time of the creep experiment was fit to the Kelvin-Voigt model for a spring and a dashpot,

$$\varepsilon(t) = \frac{\sigma_o}{E}\left(1 - e^{-\frac{Et}{\mu}}\right) \quad (1)$$

where σ_o was initial stress, E/μ was the time constant, E was the Young's modulus, and μ was the shear modulus. The axial strain over time data was fit to the model with two constants, σ_o/E and E/μ, using the nonlinear least-squares solver (*lsqcurvefit*) in MATLAB

(MathWorks, Natick, MA, USA) and the squared norm of the residuals reported. The initial stress, σ_o, was equal to the force of the applied weight divided by the initial cross-sectional area. The Young's modulus, E, and the shear modulus, μ, were found from the initial stress and the fitted constants.

RESULTS

Pig optic nerves were subjected to unconfined uniaxial compression and found to exhibit creep behavior. The behavior was fit to a simple viscoelastic model, the Kelvin-Voigt model of a spring and a dashpot. Norm of the residuals of the fit to Eq. 1 were 0.0016, 0.00055, and 0.00051, indicating a good fit. The volume of the specimen was measured from images acquired during the creep test. Volume was conserved over time, as seen by the average slope of 0.068 mm^3/min in Figure 2. As the height of the specimen decreased, the diameter increa-
\

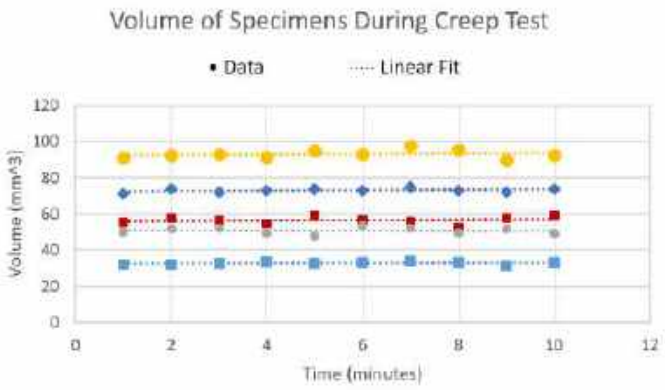

Figure 2: Volume of the pig optic nerve specimens during the creep experiment. Data for 5 specimens and their linear fits.

sed. There was a decrease in the weight of the specimen during the experiment. This was due to an observed loss of fluid from the open ends of the optic nerve.

The compressive creep behavior was similar between the three specimens (Figure 3). The estimated time constants, E/μ, were 0.57, 1.14, and 0.22 minutes. From the time constants of the specimens, the

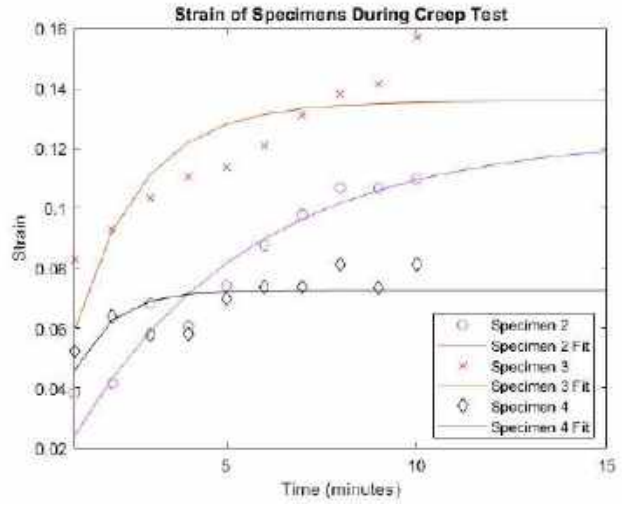

Figure 3: Axial compressive strain of pig optic nerves during the creep experiment. The data for three specimens were fitted to the Kelvin-Voigt viscoelastic model.

steady state equal to 99% of the asymptotic value would be reached in 11 ± 3.51 minutes. Young's Moduli, E, were of the same order of magnitude, with values 144, 321, and 154 Pascals (Pa). The shear moduli, μ, were also of the same order of magnitude, 252, 282, and 718 Pa.

DISCUSSION

Pig optic nerves exhibited creep behavior when subjected to uniaxial compression. This was likely due to fluid loss from the open ends of the nerves. However, fluid loss did not significantly affect the volume of the specimen, which was conserved over time. Fluid did not escape through the layer of the optic nerve sheath, but only through the open top and bottom ends.

The Kelvin-Voigt model for a viscoelastic material was used to fit the preliminary data. The pig optic nerves had an average Young's modulus of 206.3 ± 99 Pa. The steady-state strain was estimated to be reached in 11 ± 3.51 minutes in the creep experiment. Safa et al. performed a similar experiment on pig optic nerve heads, except between two stiff plates with four increasing loads for creep periods of five minutes.[3] The group also found the specimens behaved as viscoelastic materials, like the results of this study. They found that the volume was compressible, in contrast to the results of this study (Fig. 2). Safa et al. also reported that fluid may have escaped during the experiment. Studies by Safa et al. and Boazak et al. reported values for the elastic modulus, 1.895 and 3.05 kPa.[3, 4] These numbers are an order of magnitude higher than the mean elastic modulus of 206.3 Pa found herein.

Limitations during testing included the leaning of specimen when under compression and bending of cellophane due to its dimensions. Both limitations can impact the measurement of the specimen height, affecting the calculated strain and stress values. The material parameters, E and μ, may therefore be affected in those specimens. Hence only data collected on specimens where these limitations were not observed is presented. Future testing will address these challenges.

Additional experiments will be conducted to increase the sample size of the work. To determine if the creep behavior is due to fluid loss, future compression tests will be conducted with specimens where the open ends are sealed. In conclusion, the material properties reported in this study can be used to advance knowledge of the mechanics of the optic nerve and to determine how the tissue responds to impact during traumatic brain injury.

ACKNOWLEDGEMENTS

Funding for this project was from the Virginia Tech Department of Biomedical Engineering and Mechanics.

ADAPTIVE SPORT SOLUTIONS: ASSISTIVE KAYAK MOUNT DEVICE FOR MOBILITY IMPAIRED USERS

Alexander B. Britton (1), Megan P. Parker (1), Douglas T. Wingert (1)

Faculty Advisor
Christine Walck Ph.D. (1)

(1) Mechanical Engineering, Embry-Riddle Aeronautical University, Daytona Beach, FL, USA

INTRODUCTION

In the United States, 12.1% of individuals live with a serious mobility disability impacting their day-to-day lives [1]. In addition, 71% of surveyed people with a mobility impairment reported feelings of emotional stress and isolation. Today, participating in adaptive sports is said to enhance physical well-being and enrich life by fostering meaningful social connections [2]. Recreational kayaking, a versatile adaptive activity, caters to diverse users like stroke victims, paraplegics, and those with mobility impairments. Tailored to individual needs, it fosters inclusivity, promotes equality, and builds community.

Adaptive kayaking products assist the user by securing the paddle in a self-stabilizing mounting device like the one seen in Fig. 1 featuring the most common assistive device used in para-kayaking, the Gamut Paddle Holder by Angle Oar Inc. [7]

Fig. 1: The Gamut Paddle Holder by Angle Oar Inc.

The Gamut Paddle Holder incorporates a ball-in-socket mechanism that, while intended for versatility, unfortunately, restricts its functionality, leading to a more limited rotational range than is ideally desired. This restriction negatively impacts the user's movement patterns, steering them away from optimal performance and efficiency. More specifically steering them toward a teeter-tooter movement pattern versus a forward stroke pattern. Moreover, instances of the design coming apart during use have been reported, further highlighting the need for improvements. Such constraints not only limit the effectiveness of movements but also hinder the development of strength in users. In addition, this device ranges from $315 to $500 per unit [7]. Such a cost can be a hardship for this community. On average, accommodating a disability requires an extra 28% of one's annual income to maintain the same standard of living which leaves little left for extracurricular activities or rehabilitation not covered by insurance.

Therefore, our goal is to develop an assistive device that accurately mimics the natural forward stroke movement in kayaking and securely attaches to the kayak to prevent detachment. Additionally, we aim to make this device affordable, ensuring it is accessible to a wider range of users.

PRODUCT DESIGN

This project aims to improve the common Gamut Paddle Holder by introducing an assistive device featuring a four-bar linkage mechanism. Drawing on motion capture technology, this device is designed to closely replicate the natural path of a forward kayak stroke. The design's motion profile is informed by an analysis of 15 total strokes, indicating dimensions of 768 mm across the mediolateral axis (y), 473 mm in the superior-inferior axis (z), and 502 mm in the anterior-posterior axis (x), as depicted in Fig. 2. This analysis reveals a semi-ellipsoidal motion pattern that emphasizes efficient water slicing during the paddle's down strokes, aiming for a more effective and natural paddling experience.

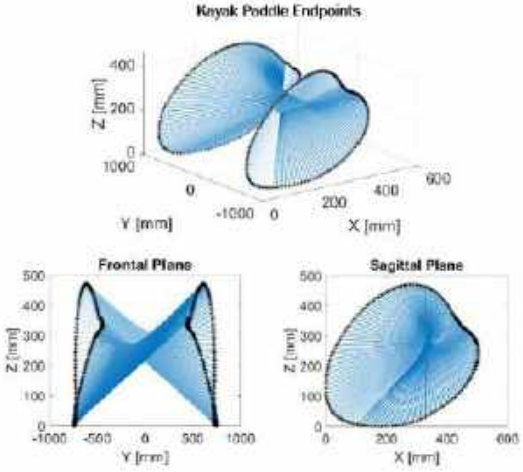

Fig. 2: Full Motion Capture Kayak Stroke Paddle Profile

Central to our redesign was the extrapolation of the kayak's theoretical center point from motion capture data, serving as a foundation for a 3D motion profile in space (Fig. 3a). This critical step accurately accommodates the kayaking stroke's required degrees of freedom, supporting complex, multi-directional movements.

To replicate the 3D motion profile, a crank-rocker mechanism was incorporated, which includes a rotating crank, an oscillating rocker, two stationary ground points, and a connecting coupler. The critical point of the coupler, labeled as "C" in Fig. 3b, aligns with the sagittal plane On-Stroke Position (OSP), where the paddle's center point is attached. To enhance adaptability, boots are fitted on the lower pin joints, offering flexibility in the frontal plane. This allows the device to accommodate

different kayak widths and individual stroke variations. The dimensions of the linkage were finalized after optimizing the stroke profile based on motion capture data in MATLAB. The optimization process ensured that the coupler point "C"'s output profile closely matches the OSP, with a maximum relative error of 3.7%.

Our device focuses on accurately replicating a kayak's forward stroke, targeting the limitations of existing mounts. It goes beyond enhancing the paddling experience, offering a design that supports correct paddling techniques, promotes rehabilitation for joint and muscle strength, and provides a sense of normalcy. Our solution avoids the inefficiency and fragility of "teeter-totter" movements found in traditional mounts. This helps mitigate issues related to mobility impairments, such as mental anxiety and stress, enhancing participation and well-being.[7].

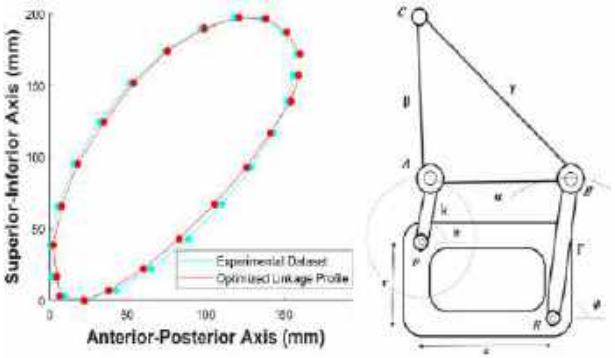

Fig. 3a: Optimized Profiles (left) and 3b) Model Side View (right)

BUDGET & MARKET ANALYSIS

The development of a functional device and the creation of an initial inventory of 90 units are projected to cost approximately $22,000, as shown in Fig. 4. This estimate encompasses the overhead expenses related to the operation of 3D printers, electricity consumption, and the procurement of initial stock materials. Figure 4 breaks down the costs into Year 1 Overhead Costs (left) and Material Costs (right). The expense for producing a single device is estimated at around $105, factoring in the costs for the 3D printing filament necessary for the linkage and the materials required for the base's fabrication.

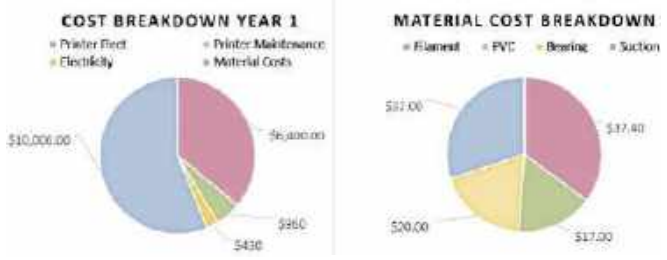

Fig. 4a: Overhead Year 1 Costs (left) and 4b) Material Costs (right)

By setting the retail price at $259.99, we aim to achieve a profitable margin that will allow us to recoup the initial outlay from our starting inventory while offering a price advantage over our competitors, whose products range from $315 to $375. This pricing strategy is particularly relevant considering our survey findings, which indicate that nearly half (44%) of Americans with serious illnesses and long-term disabilities have exhausted their savings, compared to about a quarter (24%) of individuals without disabilities. This stark contrast highlights the critical importance of maintaining a competitive retail price to make our device accessible to those in need.

Our project has entered a partnership with the Oceans of Hope Foundation (OOHF), to sell an initial 40 units at a 10% discount, aiding our financial targets. We are also negotiating with other organizations, including Team River Runner in Orlando and Selkie Ability Inc. in Boca Grande, FL, which both have high annual participation rates, boosting future sustainability and market demand. According to our break-even analysis, shown in Fig. 5, we need to sell 73 devices from our initial inventory of 90 units to start generating a profit. The agreement with OOHF, along with the prospective deals with other organizations, positions us well to achieve and surpass this break-even point. By securing this initial bulk order, we are significantly closer to reaching our sales target, ensuring that every additional unit sold beyond this point contributes to the profitability of our project. This strategic approach highlights the project's financial viability.

Fig. 5: Break-Even Cost Analysis of Overhead and Inventory

The kayaking and canoeing equipment market valuation is currently at $1.3 billion and is projected to grow to around $1.4 billion by 2029 [8]. Adaptive kayaking is a niche market in comparison to the broader paddle sports equipment market, with a smaller total addressable target market of 3.6 million individuals. In addition, the field of adaptive sports is growing as access to technological innovation benefiting those with mobility impairments is increasing. Research shows that the percentage of individuals using adaptive kayaking devices increased from 36% to 68% from 2020 to 2021 [10]. As adaptive kayaking's popularity grows, it is reasonable to expect growth in the addressable market.

In the competitive landscape of adaptive kayaking devices, two standout features distinguish this product: Optimal Stroke Profile Path and Detachability. Unlike competitors such as the Gamut Paddle, which primarily offers stability, our device enhances the kayaking experience by enabling the ideal stroke. Additionally, its detachable design avoids permanent modifications to the kayak, distinguishing it as a significant innovation in the market.

EXOSKELETON FOR SURGERY TRAINING

Jeremy K. Varughese, Andres J. Miramontes (1), Jesse A. Gomez, Andrew K. Gonzales Alayo, Anissa D. Cantu, Luis A. Morales (2)

Faculty Advisors
Dr. Todd Polk (1), Dr. Robert Hart (2)

(1) Biomedical Engineering, University of Texas at Dallas, Richardson, TX, United States
(2) Mechanical Engineering, University of Texas at Dallas, Richardson, TX, United States

INTRODUCTION.

The current method of surgical training relies heavily on in-person instruction and physical guidance by experienced surgeons to convey proper technique to surgeons in training. However, this approach is resource-intensive, time-consuming, and limited in scalability, as it requires a surgeon to dedicate significant time to each individual student. To modernize and enhance the efficiency of surgical education, there is a critical need for the development of an innovative exoskeleton system. This system should provide a streamlined and effective means of training residents in surgical techniques, reducing the dependency on in-person instruction and physical guidance while maintaining the quality of training. Our challenge is to design and implement an exoskeleton solution that can accurately mimic the guidance and feedback provided remotely by experienced surgeons, ultimately improving the proficiency of surgical trainees.

PRODUCT DESIGN

To simplify the project, two subgroups were identified: the *Exoskeleton Glove* and the *Trainer Glove*. Both subgroups utilized an Arduino Nano 33 BLE to communicate with each other, with the Trainer Glove sending data to the Exoskeleton Glove exclusively. Additionally, both gloves are powered by a 9V battery. Further details in the design will be specified in their respective sections under *RESULTS*. The designs settled upon lend themselves from many inspirations in the rehabilitation field, along with novel ideas from the team.

The finger portion of the Exoskeleton Glove was inspired by work done by B. Kang et al. [1] By using fishing line, we can articulate the fingers, and utilizing silicone allows the device to be flexible and lightweight in the portion of the hand that articulates the most, as seen in **Figure 1A**. A passive thumb body, showcased in **Figure 1B**, will provide extra support on the trainee's palm. Our design diverges from the original in that the portions surrounding the fingertips are left open as seen in **Figure 1C.** This is to accommodate a more tactile feel for users, ensuring a more accurate representation of how tools will feel without the Exoskeleton Glove.

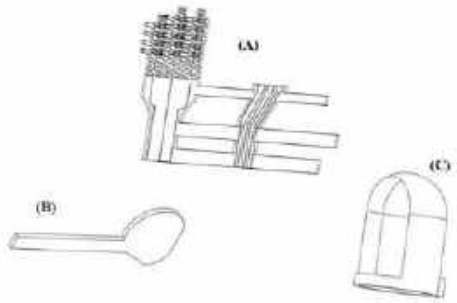

Figure 1: Exoskeleton Glove finger portion components. (A) Main Body (B) Thumb Body (C) Open Fingertip Thimble.

The wrist portion of the Exoskeleton Glove possesses an original design from our team. The wrist assembly, as seen in **Figure 2**, is structured with two stationary red bracelet plates holding a beige slider in between. The blue blocks represent the placements of the motors for the hand actuation. The silver plate is the hand attachment to place on top of the trainee's hand and kept strapped along the palm. Two rods that extrude outside of the red bracelet plates are utilized for mechanical stops to keep from overexerting the trainee wrist. These rods are placed precisely at the 135° angle mark, as surgeons typically do not exceed a wrist rotation of 135° in suturing tasks. The beige slider piece allows the device to move and guide the direction of the wrist, while the two red bracelet plates contain extruding spring clamps in the interior ring for wrist size adjustments. Assessing the necessary spring constant, and relation to the wrist force, we considered **Equation 1** below.

$$F = kx \qquad (1)$$

The *F* denotes the applied force, *x* denotes the distance that the spring is compressed or stretched away from its equilibrium state, and the *k* variable denotes the spring constant.

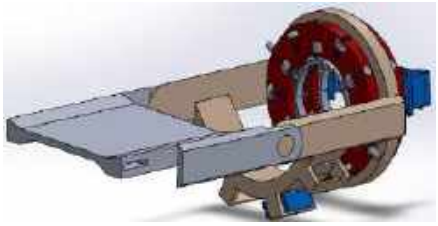

Figure 2: Exoskeleton Glove Wrist Assembly.

Lastly the Trainer Glove, which draws inspiration from Gordon Ng, alumni to UBC [2]. The initial design featured a more open structure, prompting our team to take liberty in designing a case to house the components. A power switch was added along with a toggle switch to allow the user to control the Exoskeleton Glove remotely.

The team selected continuous rotation micro servo motors to facilitate movement with the wrist and fingers on the Exoskeleton Glove. Two of the servo motors will be simultaneously operating to move the wrist portion of the device, while four others will be operating for each the thumb, index, middle, and ring fingers. Assessing the necessary peak stall torque and motor output force, we considered **Equation 2** below.

$$\tau = rF \sin \Theta \qquad (2)$$

The peak stall torque is denoted by τ, radius from axis of rotation to the point of application force is denoted by r, and Θ denotes the control angle from the axis of rotation. The control angle in the wrist portion is 135° as the mechanical stopping rod in our wrist device is set at a 135° point, and the fingers contain a control angle of 90°.

As mentioned before, two Arduino Nano 33 BLE devices are utilized to facilitate Bluetooth communication between the Exoskeleton Glove and the Trainer Glove. The Trainer Glove, specifically, utilizes flex sensors and the MPU-6050 accelerometer to track finger actuation and wrist orientation. These devices are placed in a case that sits behind the gloves respectively. A model of the Trainer Glove is shown in **Figure 3**.

Figure 3: Trainer Glove with devices case and case interior.

To begin remote controlling, the Exoskeleton Glove must be in a predetermined neutral position before allowing the Trainer Glove to toggle on "Trainer Mode". When Trainer Mode is active, the Arduino sends the mapped datapoints from the Trainer Glove to the Exoskeleton Glove via BLE (Bluetooth Low Energy), which is then translated to servo actuation accordingly.

A finite element analysis test was conducted with the theoretical results expressed in **Figure 4**. The top portion represents the wrist slider, and the bottom portion represents the mechanical stop rod. The purple arrows indicate how force is applied onto the device and the green arrows indicate stationary components. The tests indicated how little-to-some deformation would be experienced due to the stress experienced, especially on the body of the rod, though our experimental results have shown no deformation to any component of our device.

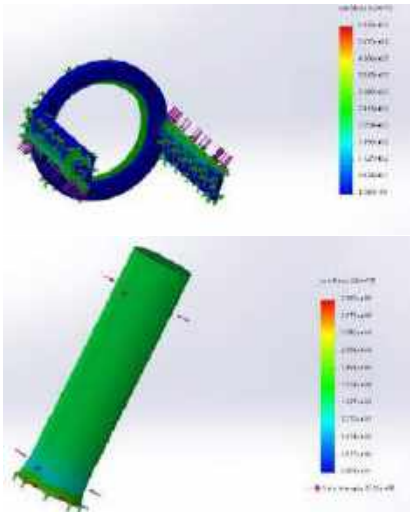

Figure 4: Finite Element Analysis for wrist slider and rods.

Limitations of this study include how we focused our scope on just the dominant arm as the other is used for pressing and holding down, though we understand there could still be learning opportunities there. Another is how Bluetooth communication is somewhat susceptible to external signal noise based on our testing. Bluetooth was still the best choice compared to a Wi-Fi device, as there is far less reliability in that area. Overall, we found that creating two light wearable gloves that communicate via Bluetooth are effective in surgical training remotely.

BUDGET & MARKET ANALYSIS

We were able to build a prototype for $381.36, excluding the price of 3D printed materials and molds as they were provided by the university. Accounting for this and labor costs, the estimated total for a single unit is $391.44.

As the device is targeted towards surgical residents, we can expect a reasonable market size of over 7,650 units per year by the end of the third year with the total resident number totaled over 150,000 as of 2023 [3]. This rate would assume that a 5% market share is captured after three years. The expected manufacturing cost for this volume per unit would be $150 and adding 25% for General and Administrative costs would bring the total manufacturing cost per unit to $187.50. The projected sales price, at a 50% margin level, would be about $375. Assuming investment costs of around $2,000,000, leaving a return of 112.5%. This return would indicate a promising potential for a profitable venture in the medical training device market.

ACKNOWLEDGEMENTS

We express our sincere gratitude to our directors Dr. Robert Hart and Dr. Todd Polk, for their invaluable guidance and support throughout this endeavor. Additionally, we extend our appreciation to Dr. Caroline Park of UT Southwestern Medical Center, and Gene Woten and the UTDesign staff for their insightful collaboration, resources, and funding. Furthermore, our sincere thanks to Senior Robotics Engineer Husam Wadi of Daifuku Intralogistics America, whose expertise contributed greatly to the success of this project.

EPILOG: RAPID EEG DETECTION OF STATUS EPILEPTICUS

R. Chhaya (1), C. Flynn (1), E. Grajales (1), P. Shah (1), D. Xu (1)

Faculty Advisor(s)

D. Adewole (1), E. Berlew (1), D. Dlugos (2), D. Meaney (1)

(2) Pediatric Neurology, Childrens Hospital of Pennsylvania, Philadelphia, Pennsylvania, USA

INTRODUCTION

Status epilepticus (SE) is a medical emergency defined as an enduring seizure or a series of rapidly recurring seizures without a return to baseline neurological activity and stands as the most prevalent neurological emergency during childhood [1]. In some children, the transition into this state, characterized by a decrease in outward movement, can be easily confused with the tiredness and unresponsiveness associated with the comedown from a convulsive seizure. These similarities often cause a delayed response, or no response at all, in the event of SE, leading to a mortality rate of up to 30% [2]. Current seizure detection devices on the market are largely designed to detect the onset of seizures, with little to no emphasis dedicated to seizure termination. Motion-based devices, such as accelerometer-based bracelets and wristwatches, provide no insight into seizure activity once outward movements have ceased, rendering them useless during cases of SE. Current EEG-based devices, such as helmets and caps, either require trained hospital technicians for placement or involve a full-head system that are uncomfortable and inconvenient for rapid application during the seizure comedown period. These shortcomings inhibit the rapid recognition of SE, which is critical for successful treatment. The Epilog EEG headband represents a significant advancement in assistive technology for epilepsy management. Designed for rapid, at-home detection of status epilepticus in children, it provides a vital tool for caregivers, facilitating early intervention and potentially mitigating long-term neurological damage. This innovation enhances the quality of life for individuals with epilepsy by enabling more immediate and effective responses to seizures, thus embodying the essence of rehabilitation science and assistive technologies in supporting individuals with challenging medical conditions.

PRODUCT DESIGN

Our proposed device, Epilog, is an EEG headband designed to be rapidly secured around a child's head during the seizure comedown period after outward movements have ended (Fig. 1). This device will provide a convenient, comfortable, at-home solution for parents to check for SE in their children, leading to greater peace of mind and providing necessary urgency in emergencies. After the visual signs of a seizure have stopped, the caregiver secures Epilog to the child's head (Fig. 2). Epilog immediately begins recording EEG data and feeds it into a machine learning model via Bluetooth for extraction of relevant features for SE diagnosis. Based on the diagnosis, Epilog will alert the caregiver if the child remains in a state of seizure for further medical intervention.

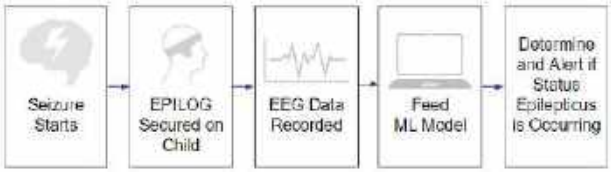

Figure 1. Epilog Use Flow Diagram

Our need specifications for this device include a specificity and sensitivity of at least 85% and 90%, respectively. The false negative rate must be extremely low: the device reporting a seizure is over when it is still occurring may be fatal to the user. For peace of mind and reliable use of the product, the false alarm rate must also be minimized. Furthermore, Epilog offers clinical-level seizure monitoring with the use of eight hospital-grade silver chloride electrodes, ensuring quality signal collection and providing enough channels for accurate seizure detection while maximizing patient comfort and ease of application. Our headband has been designed for at-home use and can be easily applied by a caregiver with minimal training. The addition of attached combs encircling each electrode on the headband allows for EEG collection through diverse hair types.

To achieve the signal resolution necessary for seizure detection, we have built a data acquisition system to collect EEG data that amplifies the signal with a gain of 2,500 and filters it using a bandpass filter selecting from 1.5 - 30 Hz. These frequencies capture the most relevant frequencies for seizure detection while discarding 60 Hz electronic noise from the surroundings. Features are selected by converting data to

the wavelet domain one second at a time and calculating the mean, standard deviation, and power of each relevant EEG frequency band. These features were fed into a machine learning classifier (balanced random forest) to detect the presence of a seizure at each second. We trained, cross-validated and tuned hyperparameters, and tested the model using the CHB-MIT Scalp EEG Database [3], which consists of 22 subjects of various ages and medical backgrounds. The final model is hosted on the cloud and can be accessed using an API and via the Epilog app, which provides an easy-to-use user interface that connects to the headband via Bluetooth and the machine learning model via network requests.

Our proof of concept consisted of three components: the physical headband with the electrodes, the electrical data acquisition and transmission system, and the seizure detection algorithm. We constructed a prototype of the fabric headband to confirm rapid application, with rendering shown in Fig 2. To allow for rapid application of Epilog, we developed a method for simultaneously applying gel to all of the electrodes on the headband, which reduces application time. When not in use, the headband is stored in a dual compartment case wherein the headband lays flat in the upper compartment (Fig. 2). The lower compartment contains tubing that connects the upper and lower compartments through holes that align with the EEG electrodes on the headband. When EEG gel is applied through the tubing, the electrodes are concurrently gelled, and Epilog is ready for use. To test our design's functionality, we inserted the EEG electrodes and wiring into the fabric of the headband and confirmed clear EEG readings.

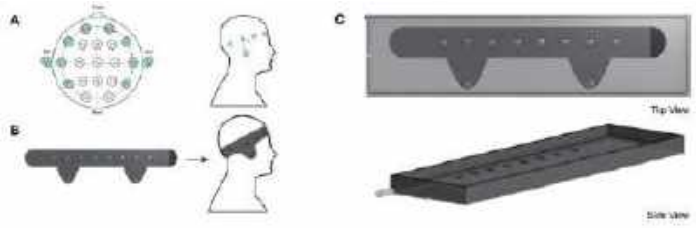

Figure 2. Epilog physical design. **A.** Standard EEG electrode placements and selection. **B.** Epilog headband. **C.** Epilog gel case for rapid application.

For our data acquisition system, we demonstrated that we could read blink artifacts from four electrodes and wirelessly transmit data from eight channels. To test the recording of blink artifacts, we placed four electrodes on the forehead of one subject, who blinked once per 5 seconds for 30 seconds, and repeated this process 5 times. Each blink was successfully captured. To test the transmission of 8 channels of data, which is the final amount for seizure detection, we input eight different sinusoids. Our system was successfully able to record and transmit each of the sinusoids without signal distortion. The technical feasibility of Epilog is firmly established through rigorous engineering and validation processes, highlighted by the development of a machine learning classifier with remarkable performance metrics. In testing with the CHB-MIT Scalp EEG Database, our device achieved a specificity of 0.883 and sensitivity of 0.946, with a ROC value of 0.95, demonstrating its capability for real-time, accurate seizure detection. Despite potential delays from Bluetooth transmission and network requests, Epilog's prediction time remains under 1 second, ensuring continuous, real-time detection. This comprehensive validation process confirms Epilog as a practical, reliable solution, with great potential for real-world deployment in the management of SE.

BUDGET AND MARKET ANALYSIS

We have secured a $600 design budget from the Bioengineering Department at Penn to design, build, and test our EEG headband prototype. This funding, along with access to the department's facilities and materials, will cover many of our initial expenses, enabling us to develop a full prototype within this budget.

For the intellectual property strategy, we would plan to apply for a utility (non-provisional) patent to secure the technology. Currently, related existing patents include US 2021/0267539 A1 for Systems and Methods for Processing Sonified Brain Signals, US 11,471,088 B1 for a Handheld or Wearable Device for Recording or Sonifying Brain Signals, and US 2023/0000416 A1 for Adjustable Geometry Wearable Electrodes.

In analyzing the potential market and financial viability for the EEG headband designed to detect Status Epilepticus, the market size within the United States, focusing on children with epilepsy, is estimated at 470,000 as reported by the CDC [4]. Assuming a conservative market penetration of 10% in the first year, we would expect to sell around 47,000 units. With a projected sales price of $500 per unit, the revenue would be $23.5 million. The strategy to capitalize on this market includes a recommendation from a clinical mentor at the Hospital of the University of Pennsylvania to all applicable patients, and the establishment of partnerships with medical research centers, with initial efforts focused on Penn Medicine.

The estimated manufacturing cost per unit is $150, leading to a total manufacturing cost of $7.05 million for the projected sales volume. Additional investments, including engineering, tooling, and intellectual property costs, are estimated at $2.5 million. Marketing and distribution costs, estimated at 15% of total revenue, would amount to $3.525 million. Therefore, the total costs would sum to $13.075 million. Subtracting the total costs from the projected revenue, we anticipate a profit before taxes and other expenses of $10.425 million. Given the total initial investment of $2.5 million, the return on investment (ROI) is calculated at an impressive 417%. This positive ROI demonstrates the significant profit potential for the EEG headband in the market, even with conservative estimates of market penetration and initial costs.

We also consider several potential risks that could impact our project's success. Regulatory approval presents a significant hurdle, as medical devices must undergo rigorous FDA scrutiny to ensure safety and efficacy. We plan to engage with regulatory consultants early to navigate the approval process efficiently. Our market entry strategy includes highlighting Epilog's unique value proposition of rapid, at-home detection and the potential to reduce long-term healthcare costs, making a compelling case for insurance coverage. Technological adoption by our target demographic is another risk. We plan to address this through comprehensive user education and support, ensuring that the benefits of Epilog are communicated clearly and effectively. By preemptively identifying and strategizing around these risks, we aim to position Epilog for a successful market introduction and sustained impact in epilepsy management.

ACKNOWLEDGEMENTS

We extend our gratitude to the Bioengineering Department at Penn for their financial support and to our faculty advisors for their invaluable guidance and expertise, which was instrumental in the development of Epilog. We also thank collaborators from Penn Bioengineering and Penn Neurology. Their perspectives have significantly enriched our project, highlighting the value of collaboration across fields in creating innovative healthcare solutions.

INTRODUCTION

Glaucoma is characterized as a group of diseases that cause damage to the optic nerve. Such damage is usually —not always—associated with an increase in the intra-ocular pressure (IOP). The profile of the iris and its interaction with the flow of the aqueous humor (AH) in the anterior eye could affect IOP. The AH flows from the posterior chamber of the eye, around the iris into the anterior chamber, and then out through a drainage pathway between the iris and the cornea (Fig. 1). Primary angle-closure glaucoma (PACG), affecting over 17 million people worldwide [1] and a leading cause of blindness [2, 3], is generally caused by pupillary block. During pupillary block, the iris bows toward the anterior, reducing the anterior chamber angle (ACA), the angle between the iris and the cornea (Fig. 1), and subsequently obstructing AH outflow, and increasing IOP [4].

Early diagnosis of PACG improves outcomes, but current diagnostic methods are susceptible to misdiagnosis [5]. In recent years, researchers have studied iris biomechanics and found evidence that higher iris stiffness contributes to the narrowing of the ACA [4, 6–8]. In this study, we aimed to identify the relationship between iris biomechanics and biological sex, a known PACG risk factor [9]. Since PACG is more prevalent among women, we hypothesized that the iris would be stiffer in women, both in a control group and a in group with a history of PACG.

METHODS

This study had 27 total subjects of an Indian population at the LV Prasad Eye Institute in Hyderabad: 14 female (7 healthy; 7 PACG) and 13 male (7 healthy; 6 PACG). Males and females each had healthy group and a group who had undergone laser peripheral iridotomy (LPI) as treatment for the pupillary block associated with PACG. All patients included in this study continued to suffer from occludable ACAs following LPI procedure. The tenets of the Declaration of Helsinki were followed for this study.

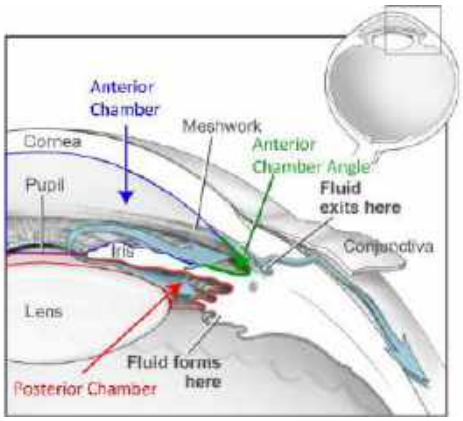

Figure 1: Anterior segment anatomy and aqueous humor flow (image modified from National Eye institute, NIH, Bethesda, MD)

Iris Imaging and Meshing-Our methods have been described in detail previously [4]. Briefly, two anterior segment optical coherence tomography (AS-OCT) cross-sectional images (Fig. 2) were associated with each subject, one in dark conditions (dilated) and one in light conditions (contracted). The image from the light conditions was measured between the iris root and tip to obtain a target distance to be used for the inverse modeling. One side of the dilated iris was traced and meshed, using SOLIDWORKS (Dassault Systèmes, Vélizy-Villacoublay, France) and Abaqus (Dassault Systèmes, Vélizy-Villacoublay, France). Within the pupillary portion of the iris, a region on the mesh of an estimated 7% volume was chosen as the sphincter region. All S8R elements from Abaqus were then converted to 9-node biquadratic quadrilateral elements, using Python.

Numerical Model-The iris was modeled as a two-dimensional (axisym-

metric), isotropic, nearly incompressible (Poisson's ratio $\nu = 0.49$) neo-Hookean solid [4], governed by a stress balance equation:

$$\nabla \cdot \boldsymbol{\sigma} = \mathbf{0} \tag{1}$$

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}_{\text{NH}} + \boldsymbol{\sigma}_{\text{Sph}} \tag{2}$$

where $\boldsymbol{\sigma}$ is the Cauchy stress tensor, defined as the sum of the neo-Hookean stress $\boldsymbol{\sigma}_{\text{NH}}$ and the active sphincter stress $\boldsymbol{\sigma}_{\text{Sph}}$, applied only in the sphincter region of the domain. The magnitude of the sphincter stress was unknown for each subject, so it was fixed to 40 kPa for all subjects, and the resulting elastic modulus E from computations (see the next section) was divided by 40 kPa to obtain E', the so-called normalized elastic modulus [4].

Inverse Finite Element Model-The inverse model in this project was developed by combining the Galerkin finite element method for discretization over a mesh and differential evolution [10] for efficient solution convergence. All programs were developed internally using C and used MUMPS [11, 12] as a sparse solver. All simulations were run using 11 processes on Intel CPUs from Northeastern University's Discovery Cluster in the Massachusetts Green High Performance Computing Center. The shear modulus G was the target of computation, and each trial value for G resulted in a different iris model which deformed uniquely with the same sphincter contraction. We defined a cost function as the absolute difference between the measured distance in the AS-OCT light condition image d_{exp} and that same distance in the simulated deformation d_{sim}.

$$Error = |d_{\text{sim}} - d_{\text{exp}}| \tag{3}$$

Differential evolution minimized the cost function over multiple generations of a population of shear modulus values. When the population converged to a narrow distribution, the shear modulus associated with the lowest error was taken as the computed shear modulus for a particular subject. From there, the elastic modulus was computed as:

$$E = 2G(1 + \nu) \tag{4}$$

and then normalized by division over 40 kPa.

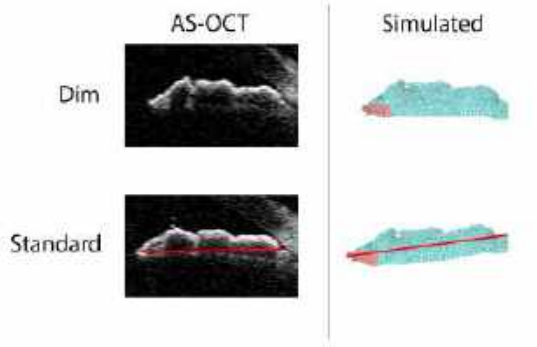

Figure 2: Relationship between AS-OCT images and in-silico model. Red lines indicate measurements of d_{exp} and d_{sim}

Statistical Analysis-A one-tailed Student's t-test was used for comparisons of the normalized elastic moduli between groups, where $p < 0.05$ is considered significant.

RESULTS

Simulations for each subject typically completed between 10 and 20 minutes. In the group of subjects with a history of angle-closure glaucoma, female subjects exhibited a significantly higher normalized elastic modulus E', as compared to males ($p < 0.05$, Fig. 3). In contrast, in the healthy cohorts, no significant difference existed between female and male individuals.

When comparing E' between healthy and post-LPI groups for males and females separately, the female post-LPI group has a significantly higher E' than the female healthy group ($p < 0.05$), though E' is not significantly higher for the same comparison between healthy and post-LPI male groups.

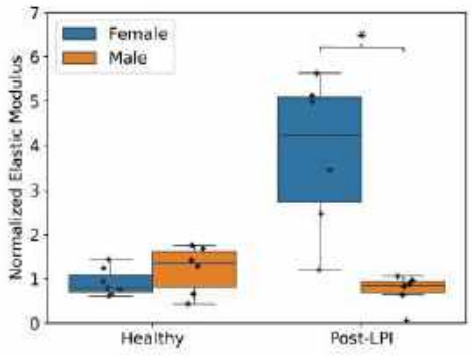

Figure 3: Comparison of normalized elastic modulus sexes in healthy and post-LPI groups

DISCUSSION

Consistent with our proposed hypothesis, we found out that in the cohort with a history of angle-closure glaucoma, the iris was stiffer in female subjects as compared to their male counterpart. Our results, however, were inconsistent with our hypothesis in the healthy group, where female and male iris stiffness were not significantly different. Past research using similar methods has shown a significant increase in iris stiffness among post-LPI subjects, compared to healthy subjects, without distinguishing among sexes [4]. In-vivo image-based modeling in mice has shown a significant difference between iris stiffness in healthy male versus female mice [13]. Since the human tissue has larger variation as compared to animal tissues, we suspect that by increasing our sample size we may be able to identify sex-based differences in healthy human iris, as well. Perhaps since the magnitude of stiffness was much larger in post-LPI female group detection of differences was easier in that cohort with our current small sample size. Conversely, one could also argue that either the biomechanical factors behind PACG are uniquely different between female and male, or females have a higher prevalence of an increased iris stiffness leading to development of PACG.

Quantifying iris stiffness in-vivo comes with difficulties and limitations. The iris model used in this study was isotropic and homogeneous, significantly decreasing the actual complexity of the iris, which consists of multiple layered materials with varying mechanical properties, such as the stroma and the dilator muscle. Additionally, iris contraction was simplified from a combined contraction and relaxation of the dilator and sphincter muscles to just a contraction of the sphincter muscle, which was assumed to have a similar magnitude in all subjects. Despite the limitations of our study, we have, to our knowledge, demonstrated for the first time that in-vivo iris stiffness is significantly greater in female subjects with a history of angle-closure glaucoma. Further research is essential to identify the underlying mechanism of the increased iris stiffness and its correlation with the sex of the individual.

SISTANCE: A TWO-WAY BASE COMMUNICATION SYSTEM FOR DEAF-BLIND STUDENTS

Mackenzie L. Hunt (1), K. Maxim Hansen (1,2), Souleymane Cissokho (1), Timothy G. Johnson (1, 2)

Faculty Advisor(s)

J. Miles Canino (1)

INTRODUCTION

Children with vocal, visual, and/or auditory deficits are constantly faced with communication barriers. They often show signs of frustration because of their limited capacity to interact with the world and meaningfully engage with their surroundings. Because of these restrictions, fundamental learning concepts can take a longer time to develop. A concept that is crucial to the development of basic communication is the ability to simply convey "yes" or "no." Unfortunately, assistive technology for this stage of development is commercially lacking for this target audience.

The most common form of communication education for these students is through a process called associative learning. Associative learning starts with giving a child an object and taking a corresponding action. For example, giving the child a basketball and associating that object with going to the gym. The next step would be introducing the ability to physically communicate preference. This communication process demonstrates a distinction between the desire to take the action or not take the action. To teach a child this process, the object is presented to the child and a decision is conveyed via some physical indication - regardless of what the child actually wants. This physical indication will then produce a corresponding action. After an understanding of the choice communication system is demonstrated, more complex topics can be introduced.

Our team identified features missing from current market products to develop a solution focused on incorporating communication in both the classroom and home environments. Incorporating multisensory learning in a portable device enhances the learning process and establishes independence faster. Once a child is able to communicate if they are sick, hurt, or hungry via a yes/no base communication, the whole world opens up to them. They are newly able to connect to others in a way never experienced before.

Product design

Run by a standard 9V battery, the device's two buttons work to express the two base concepts, "yes" and "no." The blue button, when pressed, plays a low tone, vibrates in quick pulses, and lights shine blue. The red button, when pressed, plays a high tone, vibrates continuously, and lights shine red. If both buttons are pressed, no outputs are triggered. The size of the device allows students of various ages to interact with the system while held in the hand or while resting on a flat surface. In this way, the association of object, choice, and action can be learned in an intuitive way, aided by the tactile features of the system.

A physically distinguishable orientation, proficient dexterity support, size/portability, and two consistent visual, auditory, and tactile stimulations are all required for a successful product. The choice indicators are colored red and blue which are correlated to the color lights that display when the choice is selected. Different sound pitches and vibration patterns also play depending on the button pressed.

It is very rare that a child is both completely deaf and blind and the quality of these senses can vary by day. This means that our device's attempt to stimulate three senses can prove valuable in system and concept discrimination. Similarly, the decision to utilize red and blue are based on the research that red and yellow are most documented to stimulate those that are cortically visually impaired [1]. Having one color more likely to elicit a response, while the other color is less likely, is another important factor when creating two clearly discernible choices. Similarly, few auditory deficiencies cater to higher frequencies while most favor low frequency sound [2], thus the two inputs trigger opposing tones for enhanced distinguishability. The differing vibration patterns also assist in the tactile differentiation of the two choices in cases where there are no other meaningful stimuli for the user. The device in one of the active states is shown in Figure 1.

Figure 1: The Sistance device with the red input button activated - the red LEDs, buzzer and vibrational motor running.

The overall physical design of the device was made to enforce distinguishability. The hemispherical indent on the bottom of the device indicates the directionality of the system while it is in use. The device also utilizes a tactile band that encompasses the outside shell.

Tactile bumps have been added to half of this band to further differentiate one side from the other. Rubber feet are included to increase viability of table play - these rubber feet are also designed with different shapes, indicating device orientation. The overall design allows the child to associate physical features of the product with the button inputs regardless of how the child chooses to hold and interact with the system. As shown in Figure 1, there is ample space between the buttons so children can interact with the device in any way that is comfortable to them, such as using their whole hand or a single finger. Overall, the device is intended for children with no visual or auditory ability, however, the inclusion of light and sound stimulation increases accessibility for those children with basic lingual challenges or nonverbal tendencies..

Budget & Market Analysis

For this project, our team had a budget of $240. Table 1 shows a cost breakdown of each item used to create our prototype, as well as a production cost estimation.

Table 1: Items used to create the prototype with production costs

Item Name	Quantity	Prototype USD/Unit	Production USD/Unit
TPU Filament	1	$29.99	$2.28
Micrcontroller	1	$14.95	$0.45
Button	2	$5.95	$0.38
Vibration Motor	1	$1.95	$1.56
Resistors	4	$0.00	$0.02
RGB LED	4	$0.00	$0.04
Glue	1	$0.00	$0.59
Active Buzzer	1	$0.00	$0.23
Screws	4	$0.00	$0.01
Wires	~	$0.00	$0.02
PLA Filament	1	$0.00	$0.97
Total	-	$58.79	$7.19

This low cost is extremely advantageous in the current market. Table 2 provides details on the costs of possible solutions. Many of these products have extremely high prices due to low competition in the market. This clearly demonstrates how our more reasonably priced product has a competitive advantage in the market. Our device poses as a viable, affordable and portable solution to fill a significant gap in the market for students with deaf blindness.

Table 2: The Cost of other multisensory stimulation devices designed to aid the learning of students with deaf blindness

Assistive Device	Description	Cost
All That Glitters [3]	A multi-dome device that utilizes light, sound and vibration	$299.95
4 Plate Communicator [4]	Switch device with 4 recorded messages and light	$209.95
Tactile Communicator[5]	Tactile switch device with 4 recorded messages	$189.95
Sistance	Out portable tactile device with light sound and vibration	$~30

Our device provides portable multisensory stimulation solutions at a comparatively low price point. We expect to invest around $150,000 in tooling, material and labor. $~60,000 for a plastic injection molding machine[6] as well as $~10,000 for a PCB printer and materials[7]. The remaining will be used to purchase materials at scale and pay for labor. In 2021-2022 over 7.3 million students received special education with ~.5% of these being students with deaf-blindness.[8] This works out to ~35,000 students from this we assume yearly sales of 5,000 to 10,000 units per year. The simple payback of our initial investment would be 1 year or less assuming we sell at least 5,000 units. Ultimately we believe our device is a feasible and valuable portable tool for multisensory associative learning to accelerate the learning process for students living with deaf-blindness.

ACKNOWLEDGEMENTS

We thank Jennie Lee, an educator having extensive experience in this specific form of deaf-blind education for over 20 years, for her insights into the user experience within associative learning. We also thank Karry Hunt, a Physical Therapist with over 20 years of experience working with visually and auditorily impaired persons, for her commentary and consultation on the mobility and dexterity accessably of the interface. Lastly, Carrie Owens, the administrative assistant and SW lending library manager in Warrick County for over 10 years, who helped inform the group of current market products.

ERIAS: A Bluetooth Cardiac Monitoring System for Pediatric Inpatient Use

Angela Song, Daphne Nie, Samir A. Maarouf, Georgia Georgostathi and Alexandra A Dumas

(1) School of Engineering and Applied Sciences, University of Pennsylvania, Philadelphia, PA, USA
(2) Cardiology, Children's Hospital of Philadelphia, Philadelphia, PA, USA

Dr. Tania Khanna (1) and Dr. Maully Shah (2)

INTRODUCTION

Electrocardiogram (ECG) systems are commonly used to measure the electrical activity of the heart in inpatient clinical settings[1]. Despite their prevalence, the numerous wires on standard ECG systems pose challenges to pediatricians and children. Wires are easily disconnected or removed, limiting the usefulness of wired ECG systems for continuous cardiac monitoring[2]. Additionally, wired cardiac monitoring systems limit patient mobility and often become entangled causing frustration to healthcare providers.

While portable ECG telemetry boxes exist, they must be carried around by the patient. To address these challenges, Erias aims to create a wireless ECG monitor that interfaces with a physician computer app for extended trouble-free inpatient heart activity monitoring and detection of cardiac irregularities[3].

To date, our team has developed a core hardware system that uses five leads and a Bluetooth low energy (BLE) chip to seamlessly record and transmit electrophysiological data to our physician interface. Once the data is recorded and transmitted, this information can be visualized on our desktop interface (GUI). Our software system allows a user to access and input patient observations and personal information, visualize live cardiac signals from five leads, and observe live calculations of heart rate as well as ventricular and atrial contraction rate.

Moving forward, we plan to scale down the size of our device using a printed circuit board (PCB), integrate lithium-ion batteries, and work towards additional cardiac parameters for arrhythmia detection on our physician interface. Together, these improvements will help us improve patient mobility and the current standards for cardiac data analysis to redefine the standard of care for inpatient pediatric cardiac monitoring.

Product design

Erias aims to fulfill three main needs: reduce the wires present on pediatric patients for enhanced patient comfort, implement Bluetooth data transmission for improved patient mobility, and integrate arrhythmia detection for streamlined real-time, continuous monitoring of patient conditions. Moreover, to adhere to the current gold standards utilized in pediatric cardiac intensive care units (CICU), we designed our device to derive 5 leads simultaneously from 5 electrodes. Based on these needs, we aimed to fulfill the corresponding design specifications. For the device bulk reduction and mobility, the device was designed to be small and portable, with dimensions of at most 6 cm (diameter) x 2 cm (height) as presented in Figure 1.A Bluetooth low energy (BLE) chip was incorporated into our compact chest pod to fulfill the need for continuous, real-time wireless data transmission, and the data was displayed in our graphical user interface for seamless end-user (clinician) access. Here, physicians can observe five cardiac signals and cardiac metrics (heart rate, atrial rate, ventricular rate, QT interval, and QRS interval) to visualize potential arrhythmias in pediatric patients. The proposed device is designed to not only improve patient experience but also to provide physicians with the required reliable data monitoring and parameters. This approach ensures that the device meets the ethical and quality standards required in engineering medical devices. Our system aims to revolutionize cardiac monitoring by improving patient mobility and comfort and by furthering techniques for accurate cardiac data analysis.

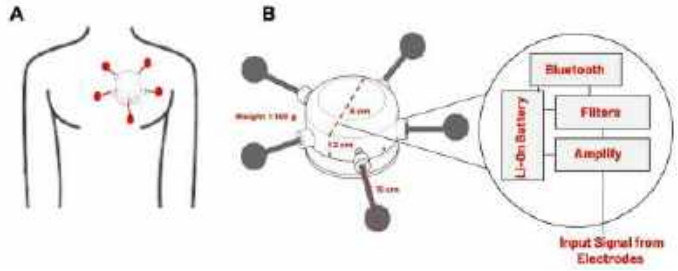

Figure 1. A. Diagram of Erias on chest with extending lead B. Final device schematic with major hardware components.

For the proof of concept, we successfully built a Bluetooth-enabled electrocardiogram device that displays a single lead on an interactive GUI. Next, for the minimum viable product (MVP), we achieved the collection and transmission of five leads from a compact, mobile device for display in an integrated GUI. Upon testing the device on ourselves as users, we saw continuous ECG data streaming on our Bluetooth device, therefore validating our hardware and software design. However, we were unable to fulfill our goal of device compactness as the device itself was measured to be 30 x 30 x 5 cm. For our next prototype (Fig. 2A-E), we continued working on improving the device and adding additional leads. To realize our goals of device compactness and a five-lead ECG system and add to our proof of concept design, we realized that signal filtration needed to be accomplished by software filtering to reduce the number of hardware components. For this prototype, the hardware component aimed to accomplish three main tasks: amplification, derivation of the differential signal, and transmission by an embedded system. The heart, atrial, and ventricular rates were calculated by performing peak

detection for the R peaks and P waves of the ECG signal. The peak detection threshold is defined relative to the patient's baseline to ensure generalizability. The effectiveness and accuracy of the calculations were performed by comparing with the published parameters associated with an online database (Chapman University & Shaoxing People's Hospital) on patients with normal and abnormal ECG signals. From these leads we were able to successfully measure non-sinus rhythms to a 95% accuracy and we are currently working towards detecting non-sinus cardiac parameters to an accuracy of 55%.

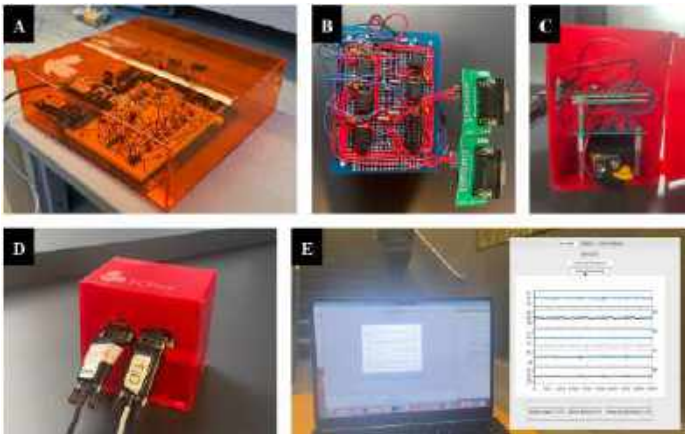

Figure 2. Erias Minimum Viable Product. A. First Iteration of breadboarded 5 lead ECG hardware. B. Protoboarded 5 lead ECG hardware components. C. Image of hardware inside final encasing. D. Image of final MVP device with outer casing containing protoboarded hardware and Bluetooth transmission chip. E. Device being used by an Erias team member to demonstrate patient mobility during live transmission of 5 lead ECG data to a desktop interface.

As we move toward our final product, we still have several specifications to address on both the hardware and software sides of our device. We hope to shrink the scale of our device so it rests on the chest more easily, explore recharging and backup data storage, expand our backend algorithm to include additional cardiac metrics, and explore software compatibility with Epic. Together these improvements will enable us to create a device that is compact and simple to use for clinicians and nursing staff.

Budget & Market Analysis

At present our team has been supplied with $1200 through the Penn Bioengineering (BE) Department's allotment for senior design. In addition to this funding the Stephenson Biomarker Space and Detkin Electrical Engineering Lab has supplied us with free basic circuit components and 3D printing materials for our product development. Our current spending plan has been outlined below in Table 1. As we move forward and begin implementing our PCB we anticipate exploring professional manufacturing costs for our device's circuitry, main body casing and electrodes. However, whilst optimizing our system we have focused upon minimizing costs by collaborating with maker spaces and instructional labs within the Penn Engineering ecosystem.

ECG systems are essential devices across all spheres of medicine, especially inpatient clinics and emergency medicine. Expanding the purview of this technology to a wireless cardiac monitoring allows for improved continuous monitoring for pediatric patients whilst simultaneously transforming the standard of care for all clinical settings. The cardiac electrophysiology market was evaluated at 5.6 billion USD in 2022 and is expected to grow an additional 12% CAGR by 2032. Additionally, it is believed that the rising prevalence of cardiac arrhythmias will only further increase demand for cardiac monitoring technologies. This coupled with the knowledge gained from 20 clinician interviews through Penn iCORPs demonstrated the niche our device would be filling in this enormous market.

Table 1: Budget Breakdown for Erias Development

Item	Price ($)	Quantity	Total ($)
XIAO NRF 52840 Bluetooth Chip	16	1	16
Adafruit Feather	33	1	33
5 Electrode leads and circuit connector	150	2	300
3D Printed CAD design	0 (provided by Penn BE)	N/A	0
Passive filters, Op-amps and other circuit components	0 (Provided by Penn BE or ESE)	N/A	0
5 Electrode single leads	10	5	50
Kardia Mobile ECG system (for studying data collection and processing)	150	1	150
Permanent Circuit Board	50	2	100
Kendall 530 Monitoring Foam Electrodes for Skin Connection	32	4 packs	128
Conductive Gel	10	5	50
Lithium-Ion batteries	6	8 packs	48
Lithium-Ion battery holder (Coin cell)	7	1 pack	7
Pediatric / Neonatal Electrodes	118	1 pack	118
TOTAL			$1000

ACKNOWLEDGEMENTS

We would like to acknowledge Penn's Stephenson Bioengineering Maker Space and the Senior Design teaching staff for their technical support of our project.

A MACHINE LEARNING APPROACH TO MINING HEMODYNAMIC DATA FROM PULMONARY ARTERIAL HYPERTENSION RATS

Jingwen Hui (1), Ethan D. Kwan (1), Daniela Valdez-Jasso (1)

(1) Shu Chien – Gene Lay Department of Bioengineering, University of California San Diego, La Jolla, California, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is characterized by sustained elevated blood pressure in the pulmonary arteries, causing a pressure overload on the right ventricle (RV). The classification and management of PAH is challenging because highly invasive procedures such as cardiac catheterization are required to confirm and track disease progression. Recent studies have described distinct patient remodeling phenotypes and therapy responses, revealing important differences in cardiac structure and function despite hemodynamic similarities [1],[2]. However, patient studies often face limitations in feasibility, invasiveness, and experimental design resulting in insufficient data relative to animal studies.

Our research team has previously obtained invasive measurements of cardiac structure and function involving large cohorts of PAH-induced male, female, and ovariectomized rats. Employing machine learning (ML), we leverage its predictive features and capabilities to explore underlying patterns challenging to discern through traditional methods. To that end, we 1) develop a predictive model using a support vector machine (SVM) with principal component analysis (PCA) for dimensionality reduction, 2) apply SVM and permutation importance analysis to understand quantitative differences across categories, and 3) investigate unexplored parameter relationships relevant to PAH through bivariate data visualization.

METHODS

Data acquisition. Hemodynamic and morphological data were collected from sugen-hypoxia (SuHx) treated rats as previously described [3]. Right-ventricular (RV) and left-ventricular (LV) blood pressure and volume were collected during an open chest procedure using a 1.9F admittance catheter (Transonic, Ithaca, NY) during steady state and vena cava occlusion. All additional hemodynamics metrics (stroke volume, end-diastolic volume, end-systolic volume, ejection fraction, cardiac output, dp/dt max, dp/dt min, pulmonary vascular resistance, end-diastolic elastance, end-systolic elastance, arterial elastance, ventricular vascular coupling) were derived from these timeseries. Morphological measurements (RV thickness, RV mass, Fulton index, animal mass, right/left atrial mass, septal hypertrophy index, liver mass) were collected immediately post hemodynamic studies. Septal Hypertrophy Index is calculated as LV mass divided by the sum of LV mass and septum mass, expressing the relative proportions of the LV chamber wall that make up the septum.

Numerical methods. SuHx animals were categorized as hypertensive if the mean pulmonary arterial pressure (mPAP) exceeds 20mmHg. If mPAP is unavailable, we defined hypertensive subjects as those that exceed 30mmHg for RV end-systolic pressure. Supervised ML, unsupervised ML, permutation importance analysis, and exploratory data visualizations were performed on the dataset comprising nearly equal proportions of male, female, and ovariectomized rats after 4, 8, 12, and 15 weeks of SuHx. Control group is referred to as week 0.

Weeks of SuHx/PAH Predictor

To investigate defining variables from this dataset, we performed PCA and fitted our dataset with a SVM model of Radial Basis Function (RBF) kernel. This model was chosen due to its effectiveness for handling high dimensional data with non-linear boundaries. Data was split into training and testing datasets (80%, 20%). Due to data imputation challenges, we only include RV hemodynamics and morphology data for this task.

Quantitative Categorical Analyzer

Of the rats treated with SuHx, some did not develop PAH. We define this group as non-hypertensive SuHx rats. First, we compared non-hypertensive SuHx *vs.* control rats using SVM and permutation importance analysis. Then we compared non-hypertensive SuHx to

hypertensive SuHx rats (i.e., treated *vs.* untreated SuHx). Through permutation importance analysis, we identify quantitative distinctions among these groups. Permutation importance coefficients quantify the change in our model's performance when the value of a variable is randomly shuffled, indicating the variable's contribution to the model's predictive power.

PAH Parameter Exploration

Leveraging pair plots, we explore correlations between morphological and hemodynamics parameters.

RESULTS

Weeks of SuHx/PAH Predictor

The model predicted PAH stage with 70% accuracy based on the weeks of SuHx. PC1, the most significant component, explains ~30% of the variance, which is more than double to that of PC2. The three variables with the greatest positive loadings of PC1 are RV mass, pulmonary vascular resistance (PVR), and end-systolic pressure (ESP). Conversely, the variables with the highest negative loadings are dp/dt min, ejection fraction, and cardiac output.

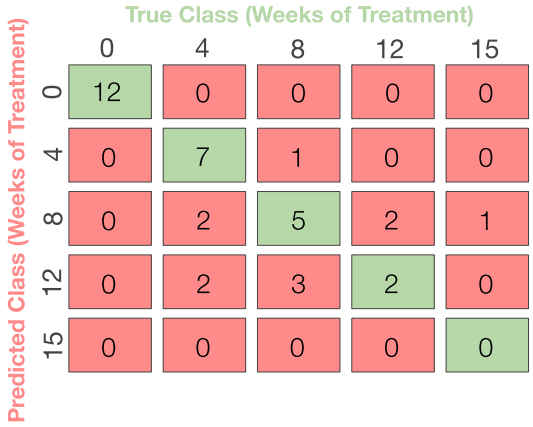

Figure 1: Confusion matrix of SVM shows significant accuracy in early-stage rats (week 4).

Quantitative Categorical Analyzer

The SVM model identifies control rats from non-hypertensive SuHx rats with a 92% accuracy level. The feature permutation analysis shows that the right atrial mass, left atrial mass, and ESP are the most significant indicators with permutation importance of 0.133, 0.075, and 0.036, respectively. On the other hand, SVM distinguishes hypertensive SuHx rats from the non-hypertensive SuHx ones with 100% accuracy. Feature permutation importance identified Fulton index, RV thickness, and RV mass as the key variables with permutation importance of 0.066, 0.039, 0.027, respectively.

$$\text{Permutation Importance} = \text{Original Accuracy} - \text{Permutated Accuracy} \quad (1)$$

$$\text{Accuracy} = \#\text{ of Correct Predictions} / \text{Total } \#\text{ of Predictions} \quad (2)$$

PAH Parameter Exploration

Pair plot visualizations showed previously unidentified relationships between Fulton index and three hemodynamics variables (dp/dt max, PVR, and end-systolic elastance (Ees)). When the Fulton index is low, these metrics tend to remain low. However, when the Fulton index is high, these parameters can vary across a range from low to high. The Pearson coefficients for the Fulton Index with dp/dt max, PVR, and Ees are 0.5878, 0.6033, and 0.4321, respectively.

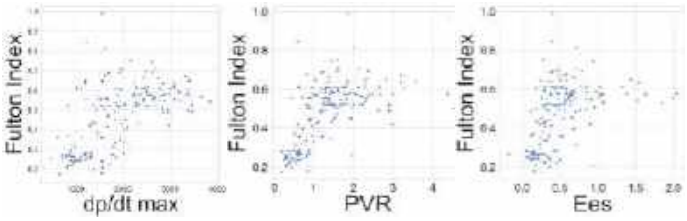

Figure 2: Strong linear correlations between hemodynamics parameters dp/dt max (left), PVR (middle), and Ees (right) and Fulton Index.

DISCUSSION

This study employed ML and data visualization tools to identify defining variables specific to different groups and uncover inter-categorical correlations. The SVM demonstrated exceptional accuracy in the early weeks, needing further fine-tuning to enhance prediction at the later weeks (weeks 8 and 12). Despite the limitations of a dataset with diverse y variables (weeks of treatment), the 70% accuracy achieved is noteworthy, particularly given previous SVM work mainly addressed binary y variables (hypertensive *vs.* normotensive).

The model also revealed distinctive characteristics of non-hypertensive SuHx rats. The right and left atrial masses were lower in non-hypertensive SuHx rats relative to hypertensive SuHx rats. Also, hypertensive SuHx animals displayed elevated values for the Fulton index and RV thickness compared to non-hypertensive SuHx rats, confirming increased right ventricular remodeling as hypothesized.

Also, the metric exploration study revealed correlations between non-invasive measurement of the Fulton Index with key hemodynamics metrics such as dp/dt max, PVR, and Ees. These three parameters are clinically collected invasively through cardiac catheterization. PVR is used as a PAH disease indicator while dp/dt max and Ees are informative variables that help physicians understand chamber stiffness. This finding holds significance by potentially mitigating the invasiveness associated with clinical PAH diagnosis. However, further research is required to unravel the underlying mechanisms and explain the medical relevance of these relationships.

Recent studies of PAH have found success leveraging SVM to perform gene expression categorization and screening for early-stage PAH diagnosis [4]. While this ML-oriented study highlights key correlations and defining parameters within our animal dataset, future improvements are required. These include acquiring and expanding our dataset to eliminate imputations and allowing the implementation of multilayer perceptron (MLP) neural networks that provide flexibility of capturing complex relationships through advanced feature learning and nonlinear transformations.

INTRODUCTION

Lower-limb loss, whether resulting from trauma, disease, or conditions like diabetes, poses significant challenges for individuals. A key determinant of post-amputation quality of life and independence is the acceptance or rejection of the prosthesis. A primary factor influencing rejection rates is the promptness of prosthetic fitting, notwithstanding immediate concerns such as surgical risks and wound healing. In addition to typical surgical risks like infection and anesthesia complications, amputation technique lacks standardization. Surgeons not specialized in limb preservation and prosthetic optimization may differ in their choices for factors like nerve reinnervation, tendon balancing, or residual limb length. A poorly executed amputation can lead to pain, discomfort, and impeded healing, which delays rehabilitation.

The critical recovery period spans the initial six weeks post-surgery, where recovery emphasizes infection prevention, pain management, and early rehabilitation. Fitting a prosthetic limb during this phase is pivotal and correlates with a higher acceptance rate of the device [1]. The use of a shrinker, which reduces swelling and assists in shaping the limb, is standard during this phase. While 17-35% muscle volume will decrease in the initial six months, amputees will face daily and lifelong limb volume fluctuations, impacting prosthetic fit and comfort [2].

Prosthetic fit is further complicated by rigid, static sockets conflicting with dynamic body properties. Developing an interface that supports the rigid socket while allowing dynamic volume and pressure variations in the residual limb would enhance prosthetic comfort and has long been an objective of respective development efforts [3]. However, current adjustable sockets hold inherent problems such as unequal pressure distribution, increased discomfort, improper fit, and mechanical malfunctions persist and are pervasive across all current available sockets on the market. Creating an adjustable socket that allows the user to adjust the device based on current discomfort and fit could reduce rejection rates, necessitating fewer adjustments and increasing prosthetic longevity.

PRODUCT DESIGN

Our innovative socket design is characterized by two distinct sub-systems (Figure 1). The first is a rigid outer shell made in the conventional lamination technique, providing enhanced support and stability. Second, the inner liner consisting of four air cells made of double walled vinyl plastic, encased by a nylon sheath, lining the inside of the shell, each individualized for independent control of air inflow/outflow.

Figure 1: Prosthetic Socket with Inner Liner

To create the air flow, an air valve was placed to the exterior of each airbag, establishing a closed system for air inflow/outflow. For best user interaction, holes were created in the outer shell such that the valve protrudes through the thickness of the socket. Each valve can be individually affixed to a miniature electric air pump, which is light enough for the user to easily attach/deattach to each valve.

We evaluated the capacity of three customizable designs to distribute air most effectively towards the bottom of separate airbags. This was imperative due to our observation of a higher concentration of soft tissue towards the proximal end of the residual limb as opposed to the distal

end. Following informal tests, a zig-zag design presented itself as the optimal choice, with triangular shaped slits along each side of the cell, demonstrating superior air redistribution capabilities (Figure 2).

Figure 2: Zig-Zag Air Bag Pattern

Following the selection of an effective air redistribution method, we transitioned from positioning the air tubing at the top of the bag to a configuration where valves are placed at the bottom of the bag (Figures 3,4). This allows for a better user interaction with the adjustability features.

To minimize direct contact between airbags and human skin, we introduced a nylon sheath casing around the airbags, enhancing durability. Differing from figure 3, in our updated design, the air cells are no longer attached to each other, instead, the nylon casing lines the socket. The casing includes four pockets, that can be opened and closed, designed for individual insertion and extraction of an air bag in each pocket, designed in the event of an airbag malfunction.

Figures 3 (left) and 4 (right): Air Bags Within Nylon Casing

Current adjustable sockets hold inherent problems such as unequal pressure distribution, increased discomfort, improper fit, and mechanical malfunctions persist and are pervasive across all current available sockets on the market. Our socket poses to avoid these issues by completing mechanical testing on the air bags for design strength and ensuring that there is ideal quality control on the seals of the air bags

Technical feasibility of our devices includes qualification testing to account for all of our design specifications to meet the pre-determined acceptance criteria that has been established by the design team. Examples of verification tests include testing the pressure strength of the air bags, testing the mobility, usability, and cleanability of the socket system.

BUDGET & MARKET ANALYSIS

Our allocated budget for this project, spanning across our two-semester Senior Design course, amounted to $1500. As we near the completion of our design, our expenditure stands at a modest $600, covering all design ideations and prototypes thus far.

In terms of market potential, our target audience comprises individuals who are current trans-femoral amputees. Within the United States, this demographic represents approximately 18.5% of the 1.9 million individuals with limb loss, totaling around 350,000 people [4]. From a market perspective, the cost per unit in small-scale production ranges between $8 and $12, contingent upon the precise fitting for the individual's residual limb size. However, in larger-scale production, the cost per unit decreases significantly to between $4 and $8 due to economies of scale. The production process necessitates heat sealing and sewing, with an estimated investment of approximately $100 for efficient equipment on a smaller scale.

Each unit has the potential to add a value of $75, exclusive of the molded hard socket and liner. Estimating our return on investment, with an initial investment of $300 and a projected return of $500 over the course of a year, yields a potential return of approximately 67%.

ACKNOWLEDGEMENTS

We would like to thank Dr. Fielder (Dept. Rehabilitation Science and Technology) for providing valuable support and advice, Dr. Mark Gartner (Dept. Bioengineering), Sarah Frazier-Kim, The Pittsburgh Amputee Support group, University of Pittsburgh's SHRS Orthotics & Prosthetics School, and the Swanson Center for Product Innovation for their gracious contributions and support throughout our design.

LAPPI: THE LIP AND PALATE PROSTHETIC INTERFACE

Serena Carson, Ryan Lim, Ravikiran Ramjee, Andrea Urdaneta, Camilla Whitesel

INTRODUCTION

Cleft lip and/or palate (CLP) is an orofacial birth defect that occurs when a baby's lip and hard palate tissue do not fuse. The manifestation of a cleft lip is an opening in the upper lip, characterized by either one gap in the tissue (unilateral) or two gaps in the tissue (bilateral). The manifestation of a cleft palate is an opening in the roof of the mouth from gaps in the tissue of the hard palate.[1] An immediate concern of CLP in infants is feeding, with CLP infants often unable to breastfeed or traditionally bottle feed.[2] Specifically, CLP infants are unable to create the pressure necessary for breastfeeding (4 psi) and cannot create a true seal around the tip of a baby bottle. CLP causes nasal regurgitation and swallowing of air during feeding.

To treat CLP, reconstructive surgeries can be performed once infants meet certain biomarker thresholds, including age and weight. However, CLP infants are consistently below the 50th percentile for weight up to 5 months of age from inadequate nutrition uptake, which can delay surgery.[3] Current feeding solutions seek to improve feeding efficacy for CLP infants. These include specialized bottles, notably Dr. Brown's 'Specialty Feeding System' and the 'Pigeon Feeder Bottle'. These bottles feature a one-way valve to prevent milk from flowing back into the bottle and allow infants to bite the bottle nipple to receive milk. However, Dr. Brown's bottles are not made specifically for CLP and babies still experience significant regurgitation.[4] With the 'Pigeon Feeder Bottle,' infants experience regurgitation and caretakers must often squeeze the bottle to feed with force. Caretakers are thus forced to resort to feeding techniques to hold the cleft closed while feeding, an inconsistent and ineffective solution. While there are products marketed to allow for bottle feeding, there is no solution that allows CLP infants to breastfeed, preventing them from capitalizing on benefits of immunity, self-regulation, and bonding.[5]

PRODUCT DESIGN

LAPPI, the Lip and Palate Prosthetic Interface, aims to enable a variety of feeding options for infants with CLP, allowing for proper suction and minimal fluid loss to regurgitation. LAPPI is a set of two products to allow infants with CLP to feed with regular bottles and to breastfeed. LAPPI's design consists of a lip cover that occludes the cleft lip and a palate cover that occludes the hard palate (Figure 1). The design of the palate cover intentionally covers a large portion of the roof of the mouth to account for most palate defects. This design choice reflects LAPPI's goal of accessibility, with a generic shape that caregivers can use for most infants within a certain size range. The lip and palate covers are not designed for specific cleft openings or manifestations but will be adjusted in size to fit most presentations of CLP in infants. LAPPI for bottle-feeding (Figure 1A) includes a one-way valve to reduce backflow whereas LAPPI for breastfeeding (Figure 1B) has an open bottom to allow for movement of the mandible. During feeding, caregivers will place LAPPI into the infant's mouth and can use any standard bottle or breast shield product to feed. LAPPI will be made of BPA-Free and FDA-approved food-grade silicone, allowing for s sterilization.

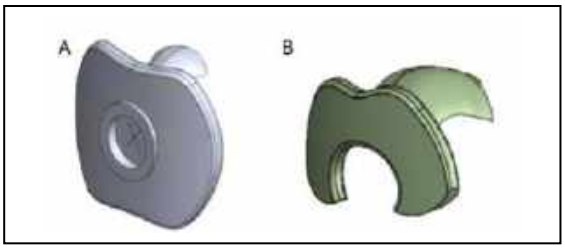

Figure 1: (A) LAPPI for bottle-feeding (B) LAPPI for breastfeeding

LAPPI's Minimum Viable Product (MVP) included a lip and palate cover that was printed in elastic resin. Elastic resin mimicked food grade silicone's flexibility and heat resistance. A 1:1 scale bilateral CLP infant head model was 3D printed in elastic resin and used to create a pressurized bottle-feeding model (Figure 2).

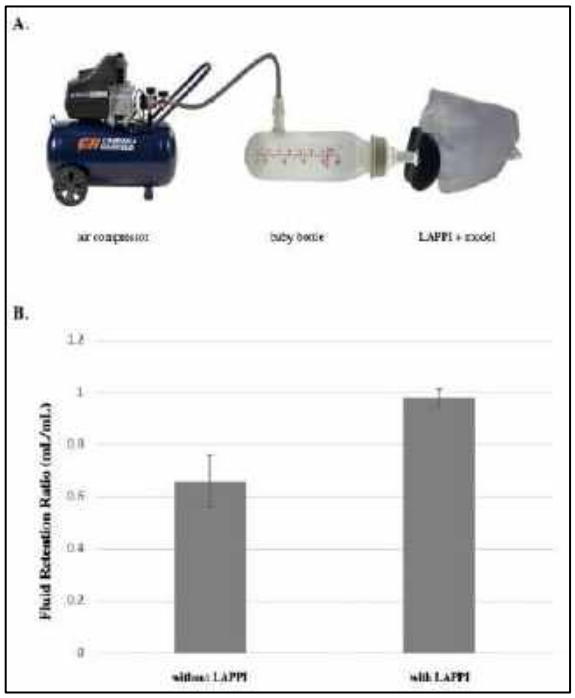

Figure 2: (A) LAPPI for bottle-feeding MVP testing setup (B) LAPPI fluid retention data (n=5, error bars represent standard deviation.

An air compressor was used to create pressure in a standard baby bottle to indirectly create the pressure difference in the oral phase of feeding. The CLP model had two pathways for fluid travel: one representing retained liquid through the esophagus and another representing fluid lost to regurgitation/leakage. The MVP performance was evaluated by analyzing the fluid retention ratio, or the amount of fluid down the esophageal pathway compared to the total amount of fluid through the model. The ratio with LAPPI was significantly higher than without LAPPI, demonstrating its efficacy in occluding the CLP. To preliminarily test LAPPI's efficacy with breastfeeding, a testing setup with a breast model and a syringe pump was made to replicate the pulsatile movement of milk through the breast duct (Figure 3). The fluid retention ratio was calculated with and without LAPPI. Again, LAPPI significantly increased fluid retention.

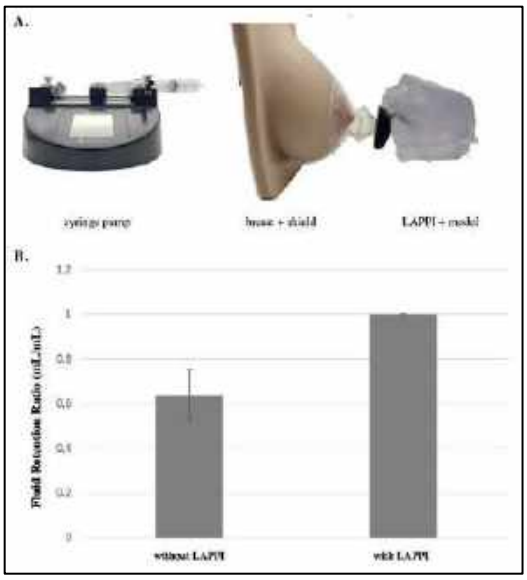

Figure 3: (A) LAPPI for breastfeeding MVP testing setup (B) LAPPI fluid retention data (n=5, error bars represent standard deviation.)

BUDGET & MARKET ANALYSIS

Through the bioengineering department at the University of Pennsylvania, LAPPI has been given a flexible budget of a minimum of $600. To date, LAPPI has spent $210 on equipment used to validate the solution. Current versions of LAPPI have been 3D printed in polylactic acid (PLA) and elastic resin which have been provided by the University of Pennsylvania.

Given the monetary and logistical burden of caring for a CLP infant before and during reconstructive surgery, a solution to occlude CLP defects and allow for stable breast and bottle feeding at a minimal resource burden is paramount. There is a clear place for such a solution in the market, as the current global CLP surgery market is valued at around $408.4 million USD and is expected to grow at a compound annual growth rate of 5% by 2030.[6] To facilitate the feeding of CLP infants, the solution must be compatible with both breast and bottle feeding and be an inexpensive device. The devices must be sterilizable and able to withstand temperatures above 235 ℃. To implement this device, it must be biocompatible and made with FDA approved materials.

Production costs rely on the current price of food-grade silicone that can be used in the molds to create LAPPI. Currently, we aim to have 10 bottle-feeding and 10 breastfeeding-compatible LAPPI devices by mid-March with an initial expense of $200 (estimated from the cost to rent the space and tools required). Once the first several casts and molds are completed, LAPPI production can be scaled up with additional varying costs being food-grade silicone. This limited overhead allows LAPPI to sell for less than $20.

The LAPPI solution will relieve caregivers of the burden of implementing specific CLP feeding techniques as well as increasing feeding efficiency and allowing for more fluid retention. This will enable reconstructive surgery with minimal delay, alleviating CLP for infants without complication and achieving less frequent medical and lactation consultant visits and expenses.

ACKNOWLEDGEMENTS

We thank the Stephenson Foundation BioMaker Space and the University of Pennsylvania Rapid Prototyping Laboratory for allowing us to use their space and resources. We thank Jacqueline Baselier for sharing their CLP infant head model and the University of Pennsylvania Education Commons for 3D printing for us in elastic resin. We thank the Children's Hospital of Philadelphia (CHOP) for providing pacifiers and as a source for CLP clinicians and caregivers.

INTRODUCTION

In sub-Saharan Africa's low-resource healthcare centers, intermittent electricity supply restricts medical interventions, particularly oxygen therapy for patients, during crucial evening hours. The generator only operates during surgeries, leaving hospitals without power most nights. After 13 hours, the generator cannot be restarted, endangering patients experiencing respiratory distress [1]. The prohibitive costs of battery-powered oxygenators exacerbate the issue. These challenges underscore the urgent need for affordable and sustainable solutions to ensure consistent access to crucial medical treatments in areas with unreliable power sources.

Oxygen concentrators draw room air through filters to produce oxygen-rich air, which is then delivered to patients. These units cost approximately USD 2,000, and require constant electrical connection, as well as frequent filter replacements and regular servicing [2]. In low-resource settings, maintenance may be unavailable or improper. A study in southwest Nigeria found that out of 57 concentrators within a facility, only 2 were fit for use, with many blowing room air rather than medical oxygen [3]. Compressed gas cylinders are also used for oxygen therapy; these systems can function without an electrical connection. Compressed gas cylinders also offer the benefit of minimal maintenance being required [2]. This method of oxygen therapy administers a single flow rate of oxygen which must be manually set.

The creation of an oxygen therapy unit that implements the most advantageous features of oxygen concentrators and compressed gas cylinders would benefit low-resource healthcare centers worldwide. The focus of this design is to ensure that it is low-cost, compact, and user-friendly. These criteria aim the project toward low-resource healthcare centers, specifically those with unreliable power sources.

PRODUCT DESIGN

The proposed solution aims to address the needs of stakeholders through the development of a low-cost, battery-operated oxygenator capable of operating for 14 hours without requiring an electrical connection. This is greater than the maximum continuous operating time of oxygen concentrators, which is 12 hours [2]. Healthcare workers can interact with the oxygenator via an app presented on a digital display mounted onto the unit. The app, running on a Raspberry Pi, offers two modes: manual, allowing healthcare workers to set the desired oxygen flow rate, and automatic, utilizing PID control. Real-time patient data, including oxygen saturation [%] as a plot, pulse [bpm], and oxygen flow rate [L/min], are displayed on the interface. A pulse oximeter gathers oxygen saturation data from the patient and sends the raw data to an Arduino, which then communicates it to the Raspberry Pi.

Oxygen is delivered from a pressurized tank through medical-grade tubing to a Venturi mask or nasal cannula for patient administration. The flow regulator being used to control the oxygen stream allows for flow rates between 4 and 15 L/min, as required for in-hospital use. A solenoid valve then regulates oxygen delivery for PID control and is monitored by an in-line gas flow sensor. A humidifier will be implemented to reduce the risk of respiratory mucosa lesions, caused by the dry properties of oxygen gas [4]. The system is battery-powered, using switching voltage regulators for different component voltages. Components are housed in a Meijia case using 3D printed mounts, designed to ensure airflow and prevent overheating, aided by a two-fan system. This compact design facilitates easy transportation within the healthcare center.

The mounts for all components have been modeled utilizing Fusion360 software and a full model of the oxygenator layout is being assembled. The waterproof Meijia case can be seen in Figure 1.

Figure 1: Meijia case with dimensions of 25 x 19.41 x 8.61 inches.

The app's skeleton code, created using CustomTkinter in Python, can update values live via a PySerial connection with the Arduino and can run on the Raspberry Pi. The electrical system design and schematic have also been created. The graphical user interface (GUI) can be seen in Figure 2.

Figure 2: GUI displaying the layout of all live data and limiting values, manual mode is not displayed.

The pulse oximeter module circuit is fully implemented, with other modules and code development ongoing. Key verification metrics for oxygen delivery have also been identified to check key performance indicators such as humidity levels and verification of flow rates. A schematic of the oxygenator system can be seen in Figure 3.

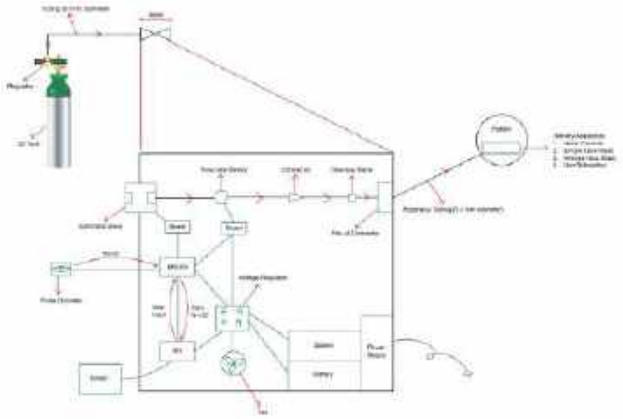

Figure 3: Schematic of the oxygenator system, indicating the flow of oxygen and interactions between all components.

BUDGET & MARKET ANALYSIS

The total design budget for the oxygen therapy unit is CAD 1,000. The cost of materials for the prototype is CAD 800, which accounts for all parts needed for assembly. CAD 100 has been allocated to the assembly of the prototype, and an additional CAD 100 accounts for any costs associated with testing. To remain accessible to low-resource healthcare centers, a markup of 15% will be implemented, or a total of CAD 1,150.

The COVID-19 pandemic highlighted the continual inequity in access to medical oxygen therapy, especially in resource-limited settings, and the need for improvements to prevent unnecessary deaths [3]. The World Health Organization reported that only 28% of health facilities and 34% of hospitals in sub-Saharan Africa have access to reliable electricity [3]. Oxygen-requiring diseases and conditions also account for 1.75 million annual deaths in these locations [3]. There is a major need for accessible oxygen therapy within the target market of low-resource healthcare centers in sub-Saharan Africa. There is also a worldwide need for the product, emphasized by the global market for medical oxygen concentrators being valued at USD 1.75 billion in 2018 [2]. This value was projected to expand at an annual growth rate of 7.4% from 2019 to 2025 [2].

NEXT STEPS

The pathway forward for this project includes a multi-faceted approach aimed at creating an impactful solution for providing consistent access to medical oxygen therapy in resource-constrained settings. First and foremost, we will continue to refine and test the prototype, focusing on optimizing individual components and integrating them into a functional unit. A component of interest is the pulse oximeter, and the accuracy of the oxygen saturation readings depending on a patient's ethnicity and existing health conditions. The oxygen saturation of patients with dark skin tones can be overestimated by up to 2%, increasing the risk of unrecognized hypoxemia [5]. Falsely elevated readings can also occur in cases involving conditions such as anemia [6]. Throughout rigorous testing, we aim to ensure the reliability and efficiency of the system under various conditions.

By exploring innovative design strategies and sourcing cost-effective materials, we aim to make a solution that is affordable for healthcare facilities in low-resource settings, without compromising performance standards. The goal of this project is to have it brought to market and implemented in low-resource healthcare centers throughout sub-Saharan Africa.

ACKNOWLEDGEMENTS

We thank the members of the QBiT for their work on this project and review of this abstract. We are grateful for funding from Dean Kevin Deluzio, and the Sci'73 Foundation.

INTRODUCTION

In the United States, falls are the leading cause of injury-related death among adults ages 65 and older [1]. Despite their goal of assisting with senior mobility, walkers have been implicated with the vast majority (87%) of the nearly 50,000 mobility-aid related falls treated in US emergency departments annually [2]. Of the various forms of walkers available, 2-wheeled (2W) walkers (aka 'front wheeled walkers') are some of the most commonly prescribed mobility aids for users who lack upper body strength but still require adequate stability and support [3]. Despite their prevalence in hospitals and residences across the country, these 2W walkers have proven to be highly susceptible to misuse, consequently increasing the risk of falls and injury for a population that is already vulnerable [4], [5].

Confirmed by previous studies and dozens of interviews with physical therapists (PTs), nurses, walker users, and caretakers, it was found that there are three primary cases in which these 2W walkers are misused: 1. Lifting the walker (instead of gliding at all times) [4], 2. Standing too far back from the walker [6], and 3. Turning the walker too rapidly. See Figure 1 for a diagram of these failure modes. While this misuse can easily be observed and corrected in an in-patient setting, the issue arises when considering that the majority (60.9%) of these walker-related falls occur at home [2].

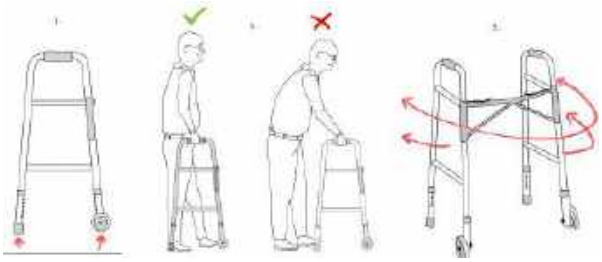

Figure 1. Common Cases of Improper 2W Walker Use

When examining the potential causes of this misuse, a gap in user training and follow-up regarding proper 2W walker use becomes apparent. One study indicated that out of 158 rolling walker users surveyed at a senior living community, only 20% of them were provided with instructions on how to use their devices. Moreover, only 1% of these users were provided with walker reassessment following initial prescription/use [7]. This lack of sufficient training becomes particularly relevant in the context of our conversations with community stakeholders. Multiple PTs and walker-users noted that the prevalence of lifting 2W walkers may be due to confusion between standard 4-legged walker guidance (to lift between every step) and 2W walker guidance (to maintain contact with the floor at all times). The general lack of training and feedback coupled with user confusion between walker-types has likely resulted in the widespread misuse in 2W walkers that is observed today.

In the past decade, a range of advanced walker sensing systems have been developed [8]. Despite their immense potential, these devices either target to replace rollators (4-wheels) as opposed to 2W walkers, attempt to reinvent the walker through expensive, bulky, over-engineered 'smart-walker systems' (that may require entirely new training protocols to use), and/or regularly fail to make it out of research phases due to their inability to integrate with current products. This lack of integration creates an immediate barrier to commercialization. Hospitals and users are less likely to purchase entirely new sets of expensive 'smart walkers' as compared to a mere attachment to existing 2W walkers. More importantly, there are no existing devices that monitor 2W walker lifts, user positioning, and rapid turns.

The prevalence of hospitalizations, misuse, and lack of training related to 2W walker use, particularly in home environments, warrants an immediate solution. With this, there is a strong need for a universally mounting device to continuously monitor and provide feedback for improper 2W walker use to facilitate tailored training interventions and ultimately reduce the risk of falls for patients.

PRODUCT DESIGN

We propose a novel monitoring device that incorporates sensing, feedback, and evaluation of improper 2W walker use. The device utilizes a combination of sensors that can be readily added to the walker to detect lifts, improper positioning, and rapid turns. The mechanical design of the device allows for secure, snap-on mounting to any existing 2W walker design (see Figure 2.) Finally, all monitoring data can be wirelessly transmitted to a secure database for easy mobile phone visualization (for users, caretakers, or healthcare workers).

Figure 2: 2W Walker Monitoring Device Design

To detect lifting of the 2W walker, an ultrasonic (US) sensor is positioned to monitor the height of the walker from the ground and sense when there is an acute increase in distance from the calibrated baseline height. For positioning, an infrared (IR) proximity sensor is placed along the back leg of the walker to face the user at mid-thigh level. Here, it can detect when users are within an appropriate range to quickly diagnose and inform users of unsafe postures. Lastly, an inertial motion unit is used to identify rapid walker turns.

The device also incorporates auditory, visual, and haptic feedback. Auditory feedback is provided with a speaker within the center module. Visual feedback is in the form of an OLED display and LED lights. Finally, haptic cells are mounted onto the aluminum framing of the walker to allow for subtle, yet noticeable vibrations when incorrect use is detected. In addition to the immediate feedback provided to users, historical usage data can be paired with a mobile app for easy visualization by healthcare personnel or users.

This design includes two primary modules that house and securely tether all the electronic components to a user's previously purchased or prescribed 2W walker. The center module (module 1 as annotated in Figures 2 and 3) contains a microcontroller, two US sensors, a centrally mounted gyroscope/accelerometer, and all the feedback methods described previously. Module 2 houses the IR proximity sensor to monitor proper user positioning. These two casings are tethered with a single cable that can be tied to the aluminum framing of the 2W walker.

Figure 3: Isolated Views of Design Modules

BUDGET & MARKET ANALYSIS

Table 1 below summarizes the anticipated budget required to complete the design, manufacturing, and testing of our device to prepare for commercialization. These numbers are calculated based on individual component prices and estimations provided by our faculty advisors.

Table 1: Anticipated Design Budget

DESIGN PHASES	*ESTIMATED COST*
Total Material Cost	$4,000
Contract Manufacturing	$5,000
Testing & Regulatory Approval	$5,000
	$14,000

The market for 2W walkers accounts for 20-30% of the total assistive walking device market, with a valuation of roughly $380M and servicing 320M people [9]. The rising geriatric population indicates this market is expected to grow at a compounded annual growth rate (CAGR) of 7.1% [10]. Since this is a reusable device, annual sales will be limited by a lack of repeat customers. As such, annual sales can be estimated at 500,000 units sold per year.

In bulk, the expected fabrication costs will be approximately $60 per unit. The medical device business model includes high margins of around 60-80%, so the device could reasonably be priced at $200, which is similar to other "smart" walkers. Medicare Part B covers walkers and other assistive devices under its durable medical equipment (DME) policy. Elderly patients will pay 20% of the Medicare-approved amount [11].

The expected return on investment for each unit is $100-$140, which could be reinvested into manufacturing, engineering, or market expansion.

ACKNOWLEDGEMENTS

We would like to thank our senior design teaching assistants Paris Brown, and Lokesh Kumar Manivannan for their guidance. Prototyping funding and resources were graciously provided by the Duke Pratt School of Engineering Biomedical Engineering Department

KINEMATIC SENSITIVITY STUDY OF TOTAL KNEE REPLACEMENT FEA MODEL TO LIGAMENT ATTACHMENT SITE

Elizabeth A. Wynn (1,2), Takayuki Koya (1,3), Markus A. Wimmer (1), Hannah J. Lundberg (1), Steven P. Mell (1)

INTRODUCTION

The demand for total knee replacements (TKRs) has increased significantly in the past decade as the number of TKR procedures has grown from 402,100 to 1.38 million [1]. As the number of TKRs performed each year increases, long-term failure due to mechanical failure, polyethylene wear, and instability remains a prominent concern [2]. In addition, the influence of ligament properties on knee kinematics is not well understood. Computational modeling and finite element analysis (FEA) can be used to better understand TKR failure and instability. To design such a model, a previously published and validated model of TKR contact was modified to include the LCL, MCL, and PCL ligaments [1]. However, it is important to characterize computational models by performing sensitivity studies to reduce the number of parameters required to be varied in future studies. Therefore, the goal of this study was to determine how changing the ligament attachment sites of the LCL, MCL, and PCL impacts knee translation and rotation during flexion, in a computational model of a TKR with realistic ligament properties. To accomplish this goal, a sensitivity study was performed by varying ligament attachment sites using Latin Hypercube Sampling Design of Experiments (LHS DOE), and multiple linear regression analysis was done to understand the sensitivity of attachment site on the maximum anterior-posterior (AP) translation and minimum internal-external (IE) rotation during flexion.

METHODS

FEA Model. A previously published and validated FEA cruciate retaining TKR model was modified to include three ligaments that are kept intact after TKR surgery: the LCL, MCL, and PCL (Figure 1). The tibial component was modeled using 78,108 linear hexahedral elements (C3D8R). The femoral component was modeled using a combination of 4080 quadratic quadrilateral elements (SFM3D8) and 547 quadratic triangular elements (SFM3D6). Contact between these components was modeled using surface-to-surface contact with a 0.04 coefficient of friction. The ISO 14243-1 force control standard was applied as boundary conditions to the FEA model. Flexion was applied to the femur which was otherwise fixed. AP force, axial force, and IE moment was applied to the tibial component. Abduction-adduction and medial-lateral translation of the tibial component were left free.

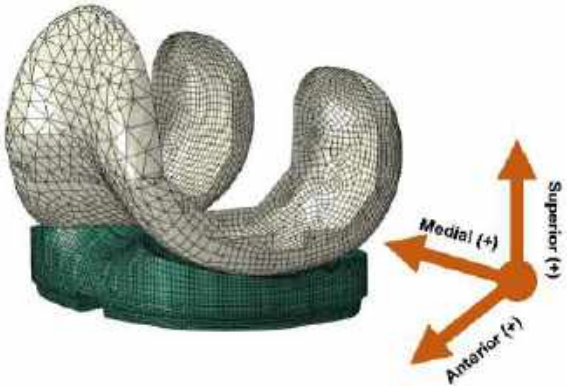

Figure 1: Finite element model. Left-side NexGen CR TKR (Zimmer Biomet).

Parametric Study. To determine the sensitivity of the model kinematics to ligament attachment site, a parametric study was performed. First, the approximate radius of each ligament attachment site was calculated from the average attachment site area and was used as the parameter bounds for a LHS DOE approach [5,8,9,11]. The starting location for each ligament was determined from previous literature [5-11] and confirmed by a trained orthopaedic surgeon. Attachment site locations were then varied parametrically within the determined attachment stie area. Parameters included the superior and inferior attachment points of each of the 3 ligaments, along 3 translational directions, for a total of 18 parameters. The outputs of the

study included the maximum AP translation and maximum IE rotation of the tibial component. A total of 274 simulations were performed.

Ligament Properties. Ligaments were modeled as linear connector elements with a stiffness defined according to previous literature: LCL 59 N/mm, MCL 63 N/mm, and PCL 198.9 N/mm [3-4]. The average length and attachment site areas for each ligament were also obtained from previous literature [5-11]. The LCL had an average length of 69.6 mm, an average femoral attachment site area of 48 mm^2, and an average fibular attachment site area of 43 mm^2 [5]. The PCL had an average length of 37.1 mm, which was calculated by taking the average length between the anterolateral and posteromedial bundles of the PCL, 35.5 and 38.7 mm, respectively [6]. The PCL had an average femoral attachment site area of 209 mm^2 and an average tibial attachment site area of 243.9 mm^2 [8,9]. The MCL had an average length of 94.8 mm, an average femoral attachment site area of 79.7 mm^2, and an average tibial attachment site of 348.6 mm^2 [10,11].

Statistical Analysis. Multiple linear regression analysis was performed using MATLAB v2022b on the total AP translation and total IE rotation throughout the gait cycle. Sensitivity of ligament attachment site on the resulting kinematic parameter was defined as the maximum change in the resulting kinematic parameter due to the change in attachment site parameter.

RESULTS

226 out of 274 FEA simulations successfully converged. Failed jobs had the femoral component fall off the edge of the tibial insert. AP translation was sensitive to six ligament attachment site parameters, five of which were related to the PCL attachment points (R^2 = 0.794, p<<0.001, Figure 2). IE rotation was sensitive to thirteen attachment site parameters across all ligaments (R^2 = 0.842, p<<0.001, Figure 3).

DISCUSSION

The purpose of this study was to modify an existing FEA TKR model to incorporate the LCL, MCL, and PCL ligaments with realistic ligament properties, with the long-term goal of understanding the influence of ligament attachment sites, and properties on knee kinematics. It is important to understand the influence of ligament properties on knee kinematics in order to address TKR failure and instability. In this study, LHS DOE techniques followed by multiple linear regression analysis was performed to determine model sensitivity to ligament attachment site parameters. Our results indicate that TKR predicted AP translation is highly sensitive to the location of the PCL ligament. TKR predicted IE rotation was highly sensitive to the location of the attachment points of several ligaments, with the highest effect due to the location of the PCL. A total of 14 out of 18 parameters achieved statistical significance for at least one of the outputs investigated, indicating that not all ligament attachment site degrees of freedom need to be accounted for in future studies. Depending on the needs of future studies, the effect sizes determined here (some of which are small) could be used to reduce this number further. Limitations of this work include the use of tension-only linear connector elements, that do not account for wrapping, and standardized loading. For future work, we will perform additional statistical analysis on the significance of our results using more jobs and with larger parameter bounds. In addition, we will also investigate sensitivity to additional ligament properties (slack length, material properties), and modeling approach (non-linear material definition, inclusion of wrapping, and area of influence). Future studies will also implement population-specific loading and kinematics to increase clinical relevance. The results of this study demonstrate the impact of ligament attachment on predicted knee kinematics in a finite element model of a TKR, which is important for TKR alignment and ultimately understanding TKR surgery outcomes.

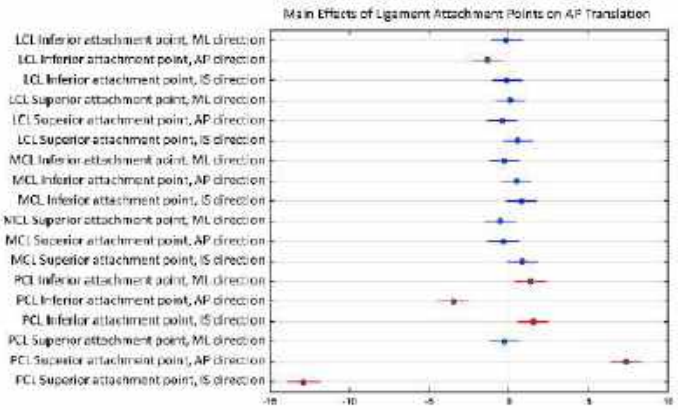

Figure 2: Predicted maximum effect (black circles) on motion due to a change in the corresponding parameter (ligament, location, direction of change). Lines represent 95% confidence intervals for regression models. AP translation was sensitive to six ligament attachment site parameters (shown in red) (R^2 = 0.794, p<<0.001).

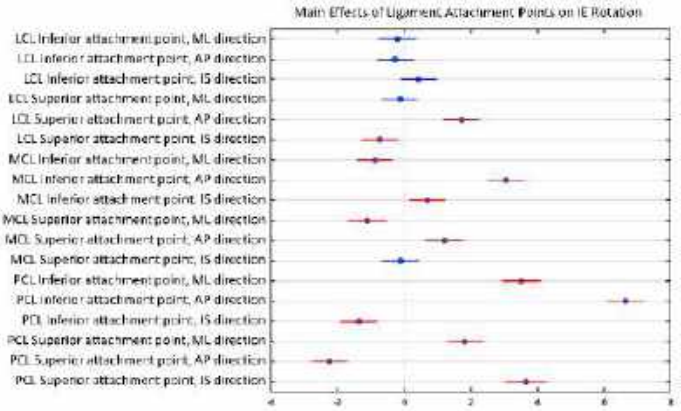

Figure 3: Predicted maximum effect (black circles) on motion due to a change in the corresponding parameter (ligament, location, direction of change). Lines represent 95% confidence intervals for regression models. IE rotation was sensitive to thirteen ligament attachment site parameters (shown in red) (R^2 = 0.842, p<<0.001).

ACKNOWLEDGEMENTS

Philanthropic funding (to SPM) is acknowledged. Thanks to Zimmer for providing CAD models of the NexGen CR TKR.

SEE-RYNGE: A VISUALLY ACCESSIBLE LIQUID MEASUREMENT DEVICE

Chiadika N. Eleh (1), Isaac Kim (1), Liam Y. Pharr (1), Venkatesh S. Shenoy (1), Joey Wei (1)

Faculty Advisors
David F. Meaney, PhD (1), Erin Berlew, PhD (1, 2), Oledayo O. Adewole, PhD (1, 2)

(2) Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A.

INTRODUCTION

Liquid measurement, a daily task for many, is effortlessly carried out by a significant portion of the American population in activities like medication administration and meal preparation. However, for the majority of visually impaired individuals globally, this common practice is challenging due to the strong emphasis on visual ability. This challenge is further exacerbated by the absence of visually accessible liquid measuring devices, forcing visually impaired individuals to estimate measurements themselves or seek daily assistance, undermining their autonomy. In our user research, one poignant instance that deeply resonated with our group involves a blind mother whose child had contracted retinoblastoma. This mother faced the serious risk of having her child taken away because several professionals believed she wouldn't be able to accurately measure her child's necessary medication. This heartbreaking narrative not only underscores the severity of this issue but also serves as the driving force propelling our project forward.

Presently, the market lacks a comprehensive solution that fully tackles the challenge of precise liquid measurement for the visually impaired. The existing options either fall short in providing genuine independence, lack versatility for general-purpose use, or fail to meet the required accuracy standards. Among these alternatives is a makeshift DIY tactile syringe, consisting of makeshift bump dots or knife markings.[1] However, a DIY syringe is a crude, often imprecise alternative and its creation often requires aid from a sighted individual. Another alternative is a syringe specifically designed for diabetes applications (i.e., Count-A-Dose).[2] Although this is a more tactile and refined alternative, it only supports insulin dosage in very small volume ranges. In addition, measuring cups with large text can be helpful for moderately visually impaired individuals who retain some vision. However, such cups lack tactility and precision, and are not a viable option for completely blind users. The final options available are talking measuring cups or kitchen scales that audibly announce the weight or volume being measured. Although the audio feedback is helpful, these devices lack the critical tactility and precision required for precise measurements, particularly in applications such as medical dosage.

After examining these solutions, it was clear to us that the current options available to the visually impaired do not sufficiently nor completely solve the problem of liquid medication measurement for the visually impaired population. Thus, there is a substantial need for a solution that not only addresses the existing accessibility concerns regarding liquid measurement tasks but also empowers the visually impaired population with the tools required to perform activities confidently and autonomously.

PRODUCT DESIGN

See-Rynge is a handheld liquid measurement device for the visually impaired. Our device uses a lightweight stepper motor to draw precise volumes of liquid into a disposable syringe, which can then be easily detached from the device for flexible and immediate use. To accommodate visually impaired users, See-Rynge features tactile buttons for its user inputs, each of which is also associated with a distinct sound cue to provide audio feedback (shown in Fig. 1). These buttons are an On/Off switch, volume increase and decrease buttons, a volume gauge button, and a "Go" button. The user may adjust their desired volume via these buttons or an accessible Bluetooth-enabled phone application. This streamlined workflow ensures that our device empowers users to measure volumes with precision, completely eliminating the reliance on visual feedback. See-Rynge is currently powered by a 9-volt battery, uses a small limit switch as a positional sensor, and is encased within a custom 3D printed housing to ensure that it is lightweight, portable, and comfortable to use.

When compared to current accessible liquid measurement alternatives, See-Rynge offers significant advantages in accuracy and precision while ensuring user independence. See-Rynge is mechanically precise, demonstrating an average volumetric error of only 1.05% in quantitative trials (see Fig. 2). This more than meets ISO standards for syringe accuracy, which range from 3% to 5% error depending on nominal and expelled syringe volumes.[3] Additionally, See-Rynge has been observed to work with no noticeable differences in performance along a wide range of viscosities–testing liquids with poise values of 1E-2 to 1E5–ensuring reliable and versatile use for users. Finally and most importantly, See-Rynge promotes the user's autonomy by allowing them to independently measure liquids.

The minimum viable product version of See-Rynge consists of a functional iteration of our device enclosed within a 3D printed housing with its companion app in a functional, early development phase. At the culmination of the undergraduate senior design curriculum, See-Rynge will utilize injection-molded housing, allowing easier

scaling to mass production–which is accounted for in the following budget and market analysis.

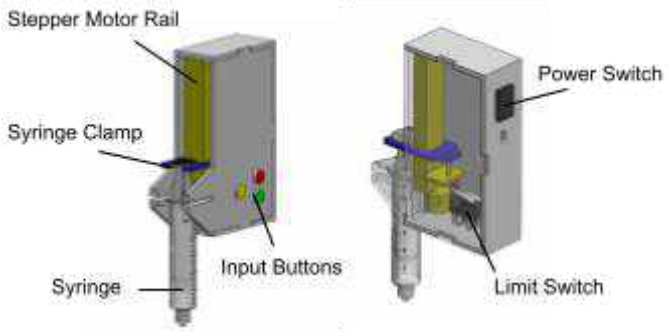

Figure 1: CAD Render of device prototype, with functional components labeled. Microprocessor, battery, and speaker not shown. Housing is composed of 3D printed PLA.

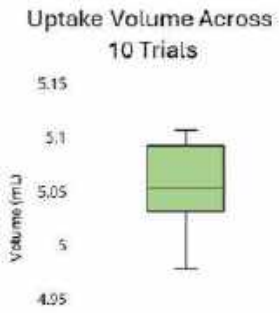

Figure 2. Average volume intaken for a 5 mL test volume. Over 10 trials See-Rynge demonstrated an average volumetric error of 1.05% ± 0.81%.

BUDGET & MARKET ANALYSIS

One million Americans are blind and six million Americans have vision loss.[4] At a National Federation of the Blind Keystone Chapter meeting in December following a hands-on demonstration, blind users were polled on their need for our device. 8 of 12 members responded "Very High Need," while the remaining four members raised concerns about our prototype's design–which has since been modified according to their feedback–whilst acknowledging potential usefulness of an assistive liquid measuring device. At a conservative 60% of the total one million blind individuals, we are able to address a significant need for ~600,000 people immediately. In discussion with primary care providers at Bucks County Blind, they estimated that ~25% of non-blind individuals with vision loss would significantly benefit from an assistive liquid measurement device. These estimates result in a total serviceable available market of ~1.1 million Americans.

As seen in the accompanying budget pro forma (Table 1), we are targeting an initial 1,000 sales for 2025 and 5,000 sales in 2026 at a retail price of $50. Electronics components, including an Arduino Nano microchip, Piezo Speaker, and Lithium-Ion battery are expected to cost approximately $15 per device based on bulk order retail prices. Injection-molded plastic housing is expected to cost an additional $5 per device while product assembly is expected to cost an initial $20 per device in 2025 which will decrease to $15 per device as volume increases in 2026. This provides a total margin of $10 per device in 2025 and $15 per device in 2026. We are anticipating needing $15,000 to complete device development, including the production of 10 working devices for use in demonstrations at trade shows and expos. Our marketing and sales budget will allow our team to visit conferences and trade shows over the next three years, while our general and administrative will cover any additional expenses. Finally, we are forecasting requiring approximately $35,000 for legal fees as we file for a patent and go through FDA trials. We are forecasting a net income of $47,200 by 2026, nearly covering all costs, at only 1% market penetration.

	2024	2025	2026
# of Sales	0	3,000	8,000
Sales	**$0**	**$150,000**	**$400,000**
COGS	$0	$135,000	$320,000
Electronic Components	$0	$60,000	$160,000
Non-Electronic Components	$0	$15,000	$40,000
Labor/Assembly/Packaging	$0	$60,000	$120,000
Gross Margin	$0	$15,000	$80,000
Opex			
Research and Development	$10,000	$5,000	$0
Marketing and Sales	$1,000	$5,000	$15,000
General and Administrative	$1,000	$1,000	$1,000
Legal	$30,000	$10,000	$5,000
Total Opex	$42,000	$21,000	$21,000
EBITDA	-$42,000	-$6,000	$59,000
Depreciation & Amortization	$0	$0	$0
Interest Expense	$0	$0	$0
Pre-Tax Income	-$42,000	-$6,000	$59,000
Taxes	$0	$0	$11,800
Net Income	-$42,000	-$6,000	$47,200

Table 1: See-Rynge budget pro forma projecting 2024-2026.

ACKNOWLEDGEMENTS

We would like to thank the University of Pennsylvania School of Engineering and Applied Science Bioengineering Senior Design Program for their funding and guidance. Additionally, we would like to thank the National Federation of the Blind Pennsylvania (NFB PA), as well as the NFB PA Keystone Chapter in specific, for their constant support and feedback throughout the development of See-Rynge.

INTRODUCTION

Intravenous (IV) insertion is vital for up to 80% of hospital inpatients worldwide [1]. Despite its ubiquity, the procedure is plagued by a substantial failure rate ranging from 30% to 50% [2]. Insertion failure can lead to complications, including arterial or nerve damage, hematoma, and bleeding at the insertion site. Of the successfully placed IV lines, up to 50% may eventually fail before reaching clinical obsolescence [1]. The pervasive failure not only impacts patients and caregivers but also imposes substantial economic burdens on the healthcare systems, necessitating urgent strategies for improvement.

Current techniques for IV insertion training are insufficient in bridging the gap between theory and practice. Online training modules for IV insertion exist but lack the physical aspect, like skin texture and resistance felt during needle insertion. On the other hand, physical models designed to mimic human arms offer a more hands-on experience but come with significant drawbacks. These models can cost up to $3,000, making them less accessible to many healthcare institutions, especially in resource-limited settings [3].

Our solution addresses these shortcomings by providing a training method that is both realistic and cost-effective. By closely simulating the tactile experience of IV insertion at a low cost, we aim to enhance skill acquisition, reduce the rate of insertion failures, and alleviate the associated economic and health burdens.

PRODUCT DESIGN

IV Tutor combines a physical 3D-printed arm model with a virtual guidance system to help the user improve their IV insertion techniques. IV Tutor uses the webcam and ArUco markers for precise 3D tracking to display the needle movement in real-time in 3D Slicer, a user-friendly, free medical software [4]. This software is linked with the webcam through PLUS software to accurately capture the needle's position, offering immediate visual feedback and instructional guidance. The model arm is designed with a neoprene fabric to imitate skin at the insertion site and incorporates anatomically correct vein simulation. This is achieved through a conductive mechanism inside the arm, which mimics a vein's response by altering electrical potential upon needle contact, signaling successful insertion via a microcontroller. The system is enhanced with accelerometers and force-sensitive resistors that deliver precise feedback on needle trajectory and technique. This improves learning outcomes by allowing students to see and adjust their methods in real-time.

The IV Tutor project comprises four sub-teams: Phantom, electrical, software, and research. The phantom team has designed a lifelike arm model using SOLIDWORKS, as seen in Figure 1. The model includes a removable forearm to allow easy access for installing electrical components. The arm is ready for 3D printing, with efforts underway to refine the adhesion of the neoprene fabric to the model for realistic IV insertion simulations[5].

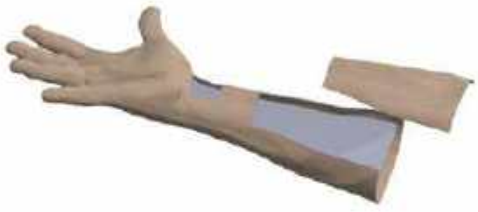

Figure 1: A CAD model of the phantom arm with a removable forearm.

The electrical team has developed a prototype of the vein simulator, which will be integrated into the arm phantom. The simulator utilizes a

Monel wire mesh for the vein due to its puncture-friendly characteristics that maintain electrical conductivity. A 3V3 direct current is sent through the mesh to simulate blood flow. The complete prototype is shown in Figure 2 (a). This configuration incorporates a visual feedback system featuring an LED that illuminates upon needle contact with the vein, as seen in Figure 2 (b).

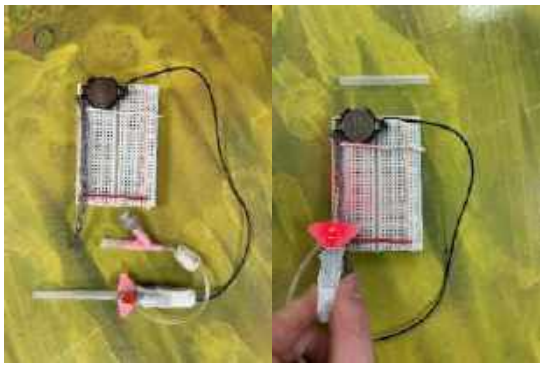

Figure 2: (a) illustrates the entire electrical system of the simulated vein, and IV needle (b) illustrates when the needle touches the simulated vein, an LED flashback is triggered.

The software team has connected the webcam to 3D Slicer, initiating the calibration process for the needle tracking. A GUI is being developed for 3D Slicer to provide information on object tracking and offer instructional notes on system usage and IV insertion methods. In parallel, the size limitations of ArUco Markers are being tested to achieve precise needle calibration.

BUDGET & MARKET ANALYSIS

The IV Tutor project, set at a $760 budget, develops a cost-efficient IV insertion training tool. It allocates $650 towards 3D printing the arm phantom and assembling the vein simulation system. The Software team was budgeted $80 to purchase a webcam, tripod, print AruCo markers, and additional camera setup equipment. 3D Slicer is free and open source, so software costs only come from the setup. The Research team does not require a budget; however, a $30 contingency was added. A 10% markup was added for a sale value of $836.

The nursing education market, which stood at USD 7.85 billion in 2021, is projected to ascend to USD 11.5 billion by 2029, growing at a 4.88% compound annual growth rate (CAGR) [6]. This trajectory underscores an excellent demand for training solutions such as the IV Tutor. With its substantial investment in nursing education, the North American market stands out as a primary market with new technology adoption capacity. Amidst an increasing emphasis on practical skills and the escalating complexity of healthcare challenges, the IV Tutor is positioned to address the dynamic requirements of nursing programs and healthcare institutions.

With over 2,600 colleges or universities in the United States offering nursing degree programs, the opportunities for the IV Tutor in this educational landscape are substantial [7]. This provides a broad avenue for annual sales, highlighting the potential for a favourable return on investment. The IV Tutor is well-positioned to impact the market significantly, enhancing healthcare training standards and contributing to improved clinical outcomes.

NEXT STEPS

The immediate next steps for the IV Tutor project focus on integrating the vein simulator into the 3D-printed arm and refining the navigation system. Enhancements to the arm include improving visibility under the neoprene fabric through structural modifications or LED backlighting. The project also plans to simulate vein movement by employing actuators or nitinol alloys and incorporating a microcontroller for electronics management and PC connectivity. The next steps for the navigation system include attaching AruCo markers to the needle and arm for tracking and investigating various object calibration methods for accurate 3D position display.

IMPLEMENTATION

The IV Tutor project implementation is guided by accessibility, effectiveness, and continuous improvement. With a focus on low-cost considerations, we aim to make the IV Tutor accessible to healthcare institutions worldwide, including those in resource-constrained settings. We plan to collaborate with hospitals, and schools to integrate our training tool into existing educational programs, providing hands-on learning opportunities for nurses and physicians. The research team will gather quantitative and qualitative data involving key metrics such as insertion time and an error rate that can be tracked by the device, allowing for identifying trends that indicate effectiveness. Current plans are to collaborate with Queen's University School of Medicine to integrate the prototype into a cohort of medical students and extend collaborations with local hospitals, enabling comprehensive testing and feedback to improve our solution further.

ACKNOWLEDGEMENTS

We thank the Queen's University class of Applied Science '73 for their financial support towards the Queen's Biomedical Innovation Team. We thank Rebecca Hisey for her support with surgical navigation technology and 3D Slicer. We thank Taylor Sweet from YGK3D for printing our arm phantom.

NON-INVASIVE, QUANTITATIVE ANTERIOR CRUCIATE LIGAMENT INTEGRITY MEASUREMENT SYSTEM

L. Phillips (1), D. Lounsbery (2), J. Ritchie (3), A. Ropars (4) (1,2,3,4)

G. German (1), T. Hookway (2), Q. Wang (3) (1,2,3)

INTRODUCTION

Anterior cruciate ligament (ACL) rupture is a devastating injury that often takes up to a year of rehabilitation before a return to activity. This recovery process suffers from a reliance on indirect milestones such as hamstring:quadriceps strength ratio, patient reported outcome measures, and range of motion. Quantitative assessment of ACL integrity is a promising supplement to current rehabilitation protocols to monitor improvements in ACL function and enable physical therapists to make informed adjustments to treatment plans to reduce reoperation rates. The ACL serves primarily as a stabilizer against anterior movement of the lower leg past the knee; therefore, its integrity can be quantified by measuring linear tibial displacement caused by a force imparted upon the lower leg anteriorly. This is the principle underlying the Lachman test, a physical assessment of ACL integrity performed by orthopedic specialists in diagnosis of ACL rupture.

The main goal of the device is to record anterior tibial displacement while the Lachman test is conducted. The reconstructed ACL's data can then be directly compared to a patient's healthy leg. Cost, safety, performance, and integrability were highly prioritized to select a user-friendly solution for physical therapists and orthopedic surgeons. A device that can assign numerical values to rehabilitation monitoring is relevant in professional sports as well as in research settings to better understand ACL mechanics. Finite element analysis, weight calculations, and conversations with various experts in the field were conducted to verify the design's safety and feasibility. Continuing work during the Spring 2024 semester will involve iterative prototyping and testing prior to presenting the device at a competition in May.

PRODUCT DESIGN

There exists an unmet niche in the rehabilitation of ACL tears for a measuring device to track rehabilitation progress quantifiably. A device for measuring the anterior displacement of the tibia during a Lachman test has the potential to overcome the shortcomings of the current approaches used in the evaluation of ACL integrity. The linear motion of the Lachman test and the isolation of the ACL in resisting this motion both lend themselves well to quantification and consistency in results. The device follows a similar principle to arthrometers, but it has a more simple, affordable design for measuring anterior tibial displacement under 10 lbf at 30° of knee flexion. Displacement measurements are recorded using a gear rack fastened to a sensor tip in contact with the proximal tibia. As the tibia is displaced anteriorly, the gear rack translates along with it, turning a gear fastened to a potentiometer. This potentiometer is part of a Wheatstone bridge circuit, so the changing resistance of the potentiometer changes the voltage output. Voltage readings are collected via DAQ systems such as Arduino. The data collected by this device is plotted in the time domain using MATLAB and stored between measuring sessions periodically throughout the rehabilitation process to evaluate improvements in knee integrity. This plot could be compared against the healthy leg of the patient as well as thresholds formed from a database of measuring sessions to determine the integrity of the ACL in question. The apparatus attaches around the lower leg inferior to the proximal tibia via a neoprene strap passed through 3D-printed PLA clamps situated medially and laterally. Brackets secured to these clamps with screws hold the displacement sensor in place with its point of contact at the proximal tibia. At the start of each data collection session, the sensor tip is calibrated in contact with the proximal tibia without any force being imparted by the orthopedic specialist performing the Lachman test. Future iterations of this device may include robust force measurement to plot force-displacement curves during the Lachman test. Additionally, alterations to the displacement measurement system based on precision, comfort, and cost may be in order using such alternative methods as an inductive transducer or a laser sensor.

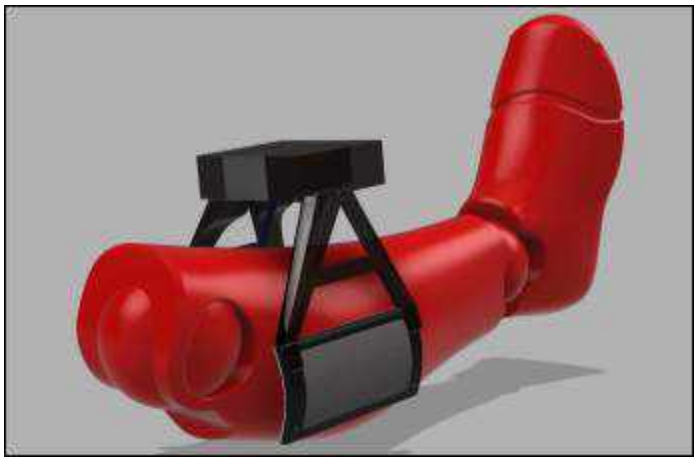

Figure 1: Render of device from Fusion360 displaying lateral clamp placement and displacement probe tip placement on model right leg.

Budget & Market Analysis

The total budget for design and building of the prototype is $2200; the majority of the budget will be used to purchase components. This will include parts such as the iGaging digital indicator to act as a baseline comparison, Arduino Uno Rev3, neoprene velcro straps, etc. This budget will also account for multiple iterations of 3D printed parts through the Watson Fabrication Laboratory.

Interviews for the potential customers of a conceptual prototype of this project were conducted from September 2023 through December 2023, revealing an initial market potential on a small scale. Interviewees included physical therapists, orthopedic surgeons, and athletic trainers, and they stated that a device capable of noninvasively assessing ACL integrity could be incredibly valuable. Individuals in the field of physical therapy and athlete management can work with patients who are largely sedentary, or they can be in charge of ensuring a professional athlete's longevity and health throughout a season.

As a result, there is a vast potential market for this form of device. However, as this device is in early development, a realistic financial manufacturing analysis cannot be performed at this time. Additionally, a return on investment is unable to be determined as this project will be advanced through several more iterations before being finalized and marketed.

While final production costs are not known at this time, one of the most important considerations for this design is to minimize cost while maintaining a high degree of precision and accuracy. ACL injuries are devastating to individuals at all levels of athletic performance, not exclusively professionals. As such, it is imperative that the price of the device is not a limiting factor for anyone to be able to purchase it, regardless of their level within their respective sport.

INTRODUCTION

Open fractures are serious injuries that occur when a high-energy trauma causes a bone to break and puncture the skin.[1,2] The immediate exposure of the wound area along with the soft tissue and vascular damage that occurs fosters an environment for bacterial growth and infection.[3] The risk of infection is due to a range of factors, the principal cause being severity of the wound. Following an open fracture, patients will be taken to the emergency room where their bone is set, however, it is in this hospital setting where the majority of infections are acquired.[5]

There is a clear clinical need for a simple and effective solution to monitor a patient's wound area post-operation as infections significantly impact the prognosis of an open fracture due to complications such as non-union or lack of healing overall.[1] This contributes to patients having increased length of stay in the hospital and may even lead to amputation of the limb.[3,6] Additionally, fracture related infections (FRIs) are shown to significantly deteriorate a patient's quality of life as they report decreased physical function, increased bodily pain, and worse mental health.[6] The economic impact of these complications is also a significant burden for both hospitals and patients. Patients with an FRI directly increase hospital-related costs by eight times and FRI patients are out of work longer which has been shown to significantly decrease their annual income up to 6 years post-discharge.[6]

PRODUCT DESIGN

In order for our device to achieve its maximum potential there are a few key factors that must be taken into consideration: accessibility, portability, and form factor. Our product needs to be light, flexible, and thin enough to fit under a standard cas while being relatively low cost. To achieve this, a comprehensive leg model has been developed to fully test and integrate each separate component of our device. By using different solutions of various pH and temperature, we are able to simulate an infected environment and achieve an accuracy rate of over 90%. Furthermore, to increase the portability we will be moving to RFID technology powered by lithium ion batteries to make our device as energy efficient as possible. The other aspect of our device is centered around the end-user, through the use of an app. This app will be available for both Android and iOS and will display current sensor readings in real time and send messages to patient providers. To ensure patient safety and address circuit shorting concerns, a moisture wicking barrier in contact with the skin will be added. Ultimately we will be testing various 3D printed housing for our Raspberry Pi for efficient form factor and function.

Category	Specification	Target	Justification
Cast Compatibility	Size	< 2cm	Space under fiberglass layer of a cast
	Biocompatible	No interference with wound healing, use non toxic materials	Should not affect the wound healing
	Moisture Wicking	Use Moisture Wicking fabric	Moisture should not add to the infection, or interfere with electronics
Data Collection	pH Sensing	Sense range between 4.0 - 9.0 pH, and incremental changes of 0.5	Range for healthy/infection and incremental change that may occur
	Temperature Sensing	Detect 0.1°C - 2.5°C difference between baseline and wound sensors	Range for healthy/infection and incremental change that may occur
	Impedance Sensing	Sense range between 0-200 mΩ, and incremental changes of 5 mΩ	Range for healthy/infection and incremental change that may occur
	Cast functionality	Sensors stay consistent accurately under cast	Must function under cast or product is useless
Data Transmission	Real Time Tracking	Continuous tracking of data	Need to alert to the onset of infection rapidly
	Algorithm	95% Accuracy 95% Specificity 85% Sensitivity	Matches existing disease detection devices on market
	GUI	Provide real time readings on smartphone	Patient and doctor needs to get alerted of infection

Table 1: Need Specifications for the SmartSleeve+ Device

Studies have demonstrated that growth of bacteria is more optimal in alkaline environments with pH of up to 10. Thus, monitoring the pH of the wound can be a good option to determine the

presence of bacterial colonization within the injury site.[7] Additionally, there has been a strong positive correlation observed between the wound site temperature and the presence of infection, with infected wounds often displaying around a 1.5-2.2$^{\circ}C$ increase[8] compared to stable body temperature. Finally, skin impedance has also been proven to be an effective tool for wound monitoring, as resistance of the skin has been shown to decrease in an infected wound as opposed to a healthy wound.[8]

For ease-of-access for the patient being treated for an open-fracture, sensor data will be wirelessly transmitted to the patients' smartphone via WiFi and warning notices will appear alongside the sensor reading when the readings reach concerning levels so that the patient can easily understand when to consult a doctor.

Our device would fit in seamlessly with current casting procedure workflow, as the device is designed to be compact, so that it can easily fit within the layers of the cast. The physician would just need to replace the stockinette base that is currently used with the modified stockinette base that we fabricated, and then attach the padded layer that contains our temperature sensor to the outside of the stockinette base.

Initially, the product would be targeted towards patients being treated for open fractures, post-operation. With the initial release and integration of our product into the hospital workflow, we hope to decrease the rate of undiagnosed and untreated infections in the United States, and to subsequently reduce the rate of catastrophic outcomes such as limb amputation due to infection.

Long term, we hope to launch our product globally, so as to reduce the impact of open fractures and related traumas on a larger scale. SmartSleeve+ can have a positive economic impact on patients, as our product is fabricated using relatively low-cost materials, and can prevent further complications from the injury that may lead to increased medical treatment down the road. SmartSleeve+ also hopes to bridge socioeconomic gaps and be accessible to impoverished and resource-limited populations as it is reproducible and can very easily be integrated into the existing casting methods and workflow of any hospital quickly.

Figure 1: Prototype of the product (shown left) and smartphone application (shown right).

Budget & Market Analysis

The approximate design budget for this project was around $1,000. However, the cost of materials totalled approximately $400. Money was spent primarily on the temperature sensors, materials to fabricate the pH sensor, and the environment and housing for the device.

As mentioned above, the breadth of this issue is quite large, with around 101,000 people suffering from this trauma annually. The potential market size would include this entire population. At this volume, the manufacturing cost per unit would approximately be $10, and the product would approximately be sold for $12 per unit. The return on the investment using these numbers would be approximately $2 per unit.

ACKNOWLEDGEMENTS

We acknowledge the Penn Bioengineering department for all financial support in procuring the parts for this product. We also would like to acknowledge the Orthopedic Department of Penn Medicine for supplying the casting materials to help us design and model the product.

INTRODUCTION

An estimated 29.2% of Americans over the age of 65 have diabetes [1]. An additional 97.6 million adults were estimated to have prediabetes in the same year, with a significant increase seen over the last two decades [1]. The economic cost of diabetes was found to be about $327 billion in 2017 through reduced productivity and medical costs [2]. Along with diabetes comes the risk of Diabetic Foot Ulcers (DFUs). Diabetic polyneuropathy, one of the main causes of neuropathy in this population, has a prevalence rate of 50% for diabetic patients across their lifetimes [3]. Those with diabetic foot neuropathy have altered gaits that can result in the formation of ulcerations on the feet [4]. Additionally, diabetic individuals with neuropathy are only one-third as active as diabetic individuals that have not lost sensation in their feet [5]. Frequent exercise has been shown to decrease mortality rates by 39% for diabetic individuals [6]. Furthermore, exercise is especially important for those with DFUs as exercise dramatically improves wound healing times [7]. Improving healing for DFUs is of clinical importance. As many as 24% of ulcers lead to amputation, and 85% of amputations in diabetic patients are preceded by ulcers [8]. The 5-year survival rate for patients post-amputation is only 50% [9].

The most effective treatment method of DFUs is off-loading of the affected area. The gold-standard for this is the Total Contact Cast, and there are also Removable Cast Walkers that are removable off-loading boots [8]. While these treatment options are effective at removing pressure from the ulcerated area, they restrict movement, further alter their gaits, and make exercise even more of a difficulty. Therefore, a device that allows individuals to safely offload a portion of their weight so they can safely exercise in their own homes is needed to improve healing times and allow for better outcomes for individuals with DFUs.

PRODUCT DESIGN

This product is intended to safely offload weight from patients with DFUs so that they can exercise within their homes. The device itself is mainly comprised of an aluminum frame that supports an unweighting system. A CAD rendering of the completed device can be seen in **Figure 1**. In this depiction, the box at the center represents the harness that is meant to support the user's weight.

The frame is made from two sizes of aluminum tubing, 1.5-inch square tubing and 1.25-inch square tubing. The 1.5-inch square acts as the base portion of the device, and the 1.25-inch square tubing makes up the upper portion of the device and telescopes into the larger tubing to allow the device to accommodate a range of user heights. Aligned holes in the tubing are used to select the correct height with clevis pins.

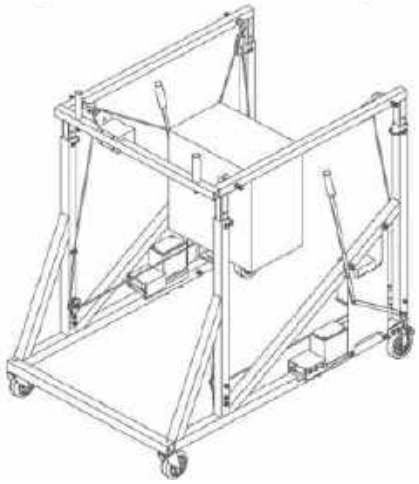

Figure 1: CAD overview of device

The aluminum frame supports the unweighting system of this device. Two electric winches, with a 2000-lb rated load, are used to lift the user and offload a portion of their weight. These winches are each powered by a 12V battery, and three relays are used to control the polarity and power supply to each winch. Each winch operates two separate cables, one that runs to the front of the device, and another that goes towards the back. The winches sit on the bottom of the frame on either side of the device. These cables are then run through a series of pulleys and rope guides around the device. At the center of the device is the harness which the patient dons while using the device. This harness has three aluminum rings that can support a lifting force, one in the front and one on each side. The cables each end in a loop, and carabiners are used to attach the cables to the rings on the harness. The front ring of the harness is connected to the two front cables, and each side ring is connected to the associated cable coming from the rear of the device.

This lifting system is operated by a control panel situated at the

front of this device. A spring-loaded rocker switch with a default off position is used to control the winches' movement. In its default position, the winches are stationary. When pressed upwards, the winches will begin winding the cables in and lifting the harness to offload the user's weight. When pressed down, the winches will unwind and lower the harness.

To first begin using the device, the height must be adjusted using the telescoping portion of the frame so that the top of the frame stands about 4 inches above the hips of the user. This is the ideal positioning of the frame according to analysis performed on the tension in the cables as seen in **Figure 2**. To enter the device, the user may put on the harness first in a seating position or stand in the center of the device where the harness is. The rocker switch is used to control the movement of the harness. Once in the device, the user can begin walking as the device will move on its wheels. As they walk, they can rest their arms on the frame, holding the handlebars shown on the front crossbar of the device. The brakes are easily accessible from extended handles, as seen on either side of the device in **Figure 1**, should the user feel the need to control the device's movement at any time. Once finished, the rocker switch is used to lower the harness so that the user can doff the harness and exit the device.

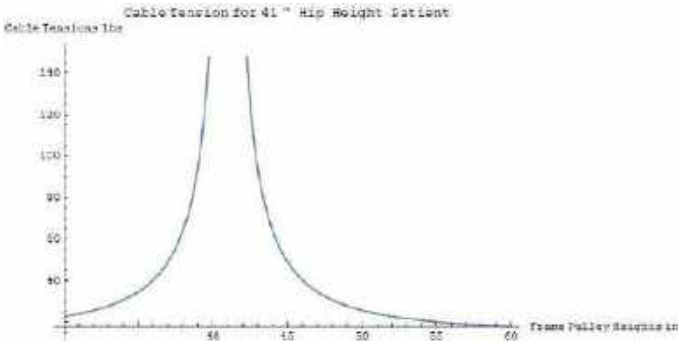

Figure 2: Cable tension as a function of frame height. A hip height of 41 inches requires a frame height of 45 inches to reduce tension.

A beam stress analysis was performed assuming a case of extreme loading, and all calculated stresses were within acceptable ranges for the tubing. Deflection analysis was also performed with an increased loading of 50lb of tension of each of the 4 cables, as seen in **Figure 3**. Even with these high tensions, the beam stresses are not catastrophic and the resulting deflection is minimal. The maximum deflection shown is 0.1 inches and is exaggerated in the rendering.

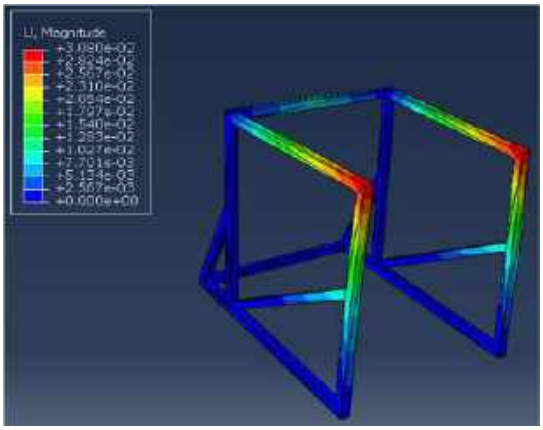

Figure 3: Color-coded results of deflection analysis performed on the frame of the device assuming 50lb of tension on all cables

BUDGET & MARKET ANALYSIS

The expected cost to build this prototype is $3,437.54, which represents $2593.54 in materials cost and an additional $844 in manufacturing costs. The current design budget is $4500, which covers the cost of creating the prototype as well as contingency funds.

The potential market for this device includes all individuals experiencing DFUs. In 2021, 38.4 million Americans had diabetes, and the annual incidence rate of DFUs for those with diabetes can be up to 4% [1] [10]. Assuming this product will reach 5% of this market over the course of a year, approximately 76,800 units may be purchased or rented annually. Each unit will have an estimated price of $2500 to match the current market for relevant products.

To manufacture this product at this scale, materials costs are expected to decrease as items will be purchased in bulk. These costs could reasonably drop to $1500 per product. Labor would be approximated at $200 per assembly, and overhead costs would follow at about $500. This means that each product would have an estimated manufacturing cost of $2200, allowing for a $300 profit margin.

However, there will be investment costs for welding the frame. To employ the use of a robotic welding systems for this product, costs start at $90,000 per system. To create two welding systems, one for each portion of the welded frame, it would cost $180,000. Again, assuming that 76,800 units are sold per year, with a profit of $300 per unit, there stands to be a great return on investment for this product.

ACKNOWLEDGEMENTS

INTRODUCTION

Over 32.5 million people in the United States suffer from osteoarthritis [2]. This disease is characterized by the deterioration of the protective cartilage surrounding the affected joint, causing pain and decreased mobility [1]. The joints most commonly affected include the fingers, the hips, the neck, the lower back, and the knee [2]. Rehabilitation treatments for osteoarthritis consist mainly of regular exercise, maintaining a healthy weight, stretching, and physical therapy [3]. A recent study has shown that applying vertical traction on the patient's knee joint daily for ten minutes over a period of six months reduces pain and discomfort from 7.979±0.3503 out of 10 to 3.189±1.468 out of 10, whereas using traditional techniques, the patients' pain went from a 7.979±0.3503 to a 5.253±0.0751 [4]. Since traction mimics the slight separation of the knee joint, this treatment increases blood flow and promotes hyaline cartilage growth [4, 5].

Traditional knee traction therapy is performed by physical therapists in clinical settings. However, traction therapy currently consists of a cumbersome pulley system which both takes up a lot of space and makes the therapy inaccessible to patients outside of a clinical setting. Currently, there are no medical devices that can perform knee traction therapy and are accessible to home-bound patients. These patients, recovering from knee replacement surgery, have limited mobility and may be unable to complete daily tasks. Thus, seeing a physical therapist multiple times a week may cause unnecessary stress. Our team designed an osteoarthritis symptom mitigation device that makes osteoarthritis therapy accessible from the patient's home. A typical course of physical therapy costs anywhere from $557 to $919, where our at-home therapy would have a cost of $130 and would be cheaper than glucocorticoid injections, where a single injection can cost anywhere from $99 to $172 [6].

Figure 1: Side view of the device attached to a patient's leg

PRODUCT DESIGN

The boot serves as the anchor, keeping the foot planted to the ground with the knee at a 90-degree angle (See Figure 1). The boot also contains inflatable airbags for a more snug fit and anchoring the foot within the boot. Mounted to the boot is a linear actuator that can bear a load of up to 330 lbs. The linear actuator applies an upward force on the underside of the thigh, at the distal end near the knee. This pressure is applied through a 3D-printed leg cradle attached to the linear actuator. Velcro straps secure the thigh to the leg cradle.

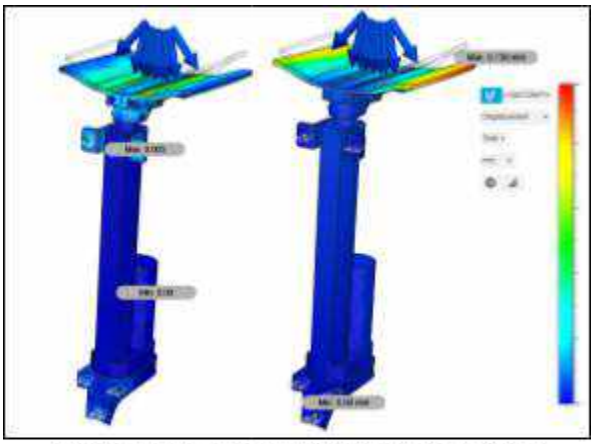

Figure 2: FEA Analysis of force placed on device

Our thigh plate has been engineered to provide structural stability to deliver the force at a 90 degree angle in the y direction while also providing comfort based elasticity for the patient's convenience. After doing an FEA analysis of force loaded on our device, we can verify that there is no deformation in the motion system. However, there is deformation in the socket where we expect it to be present.

The electrical components of the device are wired through an Arduino UNO. A set of relays allows us to change the direction of the linear actuator, which is powered by a 12-volt DC motor. We can measure the pressure applied to the leg with a 50kg load cell force sensor. Our user interface consists of a potentiometer and OLED I2C display. This system allows users to select their weight and then determine how much pressure to apply.

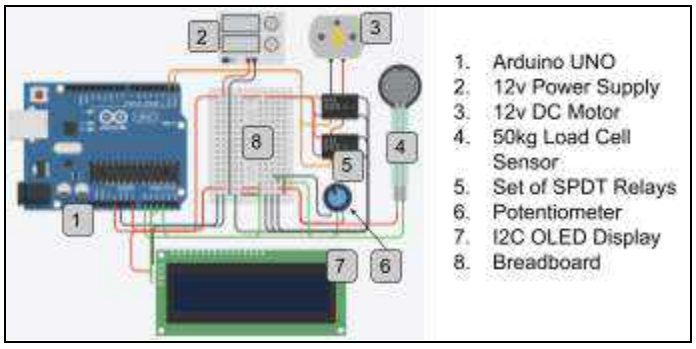

Figure 3: Electrical schematic of the device.

The device includes a failsafe system that utilizes the force sensors. The maximum applied force allowed on the user is 6% of their body weight. When the force sensors detect a force induced on the user that exceeds this maximum force, the linear actuator will retract and the device will turn off. Additionally, the current from the power source will be monitored, and the device will be shut off if the current exceeds 2 amps.

BUDGET & MARKET ANALYSIS

The global market for general osteoarthritis products is expected to grow with a Compound Annual Growth Rate of 8.5% from 2022-2030, forecasting $15 billion in revenue. [8] Our team spent $152.90 on developing the prototype. If brought to market, economics of scale would reduce the cost of production to $83. This is due to theoretical discounts from the individual manufacturers to order 1 million units of all components. After applying a 50% profit margin on the manufacturing cost, the proposed MSRP is $170. This price can be further discounted to patients as the device falls under general traction devices covered by US medical insurance companies. In the long-term, the cost of the electronic components would be significantly reduced due to the capacity of internal production.

Table 1: KneeVive's market price compared to competitors

Traction Device	Description	Cost
Knee Works 300	Wooden static stretcher	$379
KneeVive	Personalized traction therapy	$170
KneeSled PLUS	Locks knee within range of motion	$150
IdealKnee One Pad	Metal bar brace for knee extension	$105

As depicted in Table 1, our device fills a significant gap in the market as it provides an automated traction-based brace therapy at a reasonable price. Unlike other products that rely on a less user-friendly pulley system or stiff brace, our product is easy to use and individualized to fit every knee osteoarthritis patient's needs.

ACKNOWLEDGEMENTS

Funding was provided by the University of Massachusetts Amherst Biomedical Engineering Department and through an award from the Berthiaume Center for Entrepreneurship Tech Challenge. We thank our faculty advisors S. Wojda and G. Srimathveeravalli, as well as staff members of the University of Massachusetts Amherst Maker Space for their guidance and support of this project.

ENHANCING LABOR COMFORT: DEVELOPMENT OF AN ADAPTIVE PRESSURE CLAMP FOR DOUBLE HIP SQUEEZE

C. Beck[1], N. Kibler[2], S. Korah[1]

Faculty Advisor

O. Sayginer[1]

(1) Department of Mechanical Engineering, Temple University, Philadelphia, PA, USA
(2) Department of Electrical and Computer Engineering, Drexel University, Philadelphia, PA, USA

Labor is a challenging and painful process that impacts pregnant individuals both physically and emotionally. The counter pressure double hip squeeze technique is commonly employed by support individuals during labor to alleviate back pain and enhance overall comfort. We introduce an innovative device designed to perform the counter pressure double hip squeeze and tailor its functionality to meet the individual needs of birthing individuals.

INTRODUCTION

Labor is an exhaustive and painful process that affects pregnant people physically and emotionally. Counter pressure double hip squeeze (CPDHS) is an exercise performed during the labor process, aiming to alleviate lower-back pain [2]. This technique applies pressure to the hips to provide pain relief during labor [1]. To achieve this technique, both sides of the hips need pressure that pushes vertically towards the torso [2].

Figure 1: Illustration of CPDHS technique
Illustration by Shanna Dela Cruz. © 1994, 1999, 2005 Ruth S. Ancheta. Reproduced with permission from The Labor Progress Handbook: Early Interventions to Prevent and Treat Dystocia, 1st and 2nd Editions, by Penny Simkin and Ruth Ancheta (Ox- ford: Blackwell Publishing, 1999, 2005)

CPDHS is typically performed by a support person including patient's partner, midwife, or the attending doula [3]. However, manual fatigue can diminish the effectiveness of this technique over time, even with alternating support [3]. Some studies suggest that synchronizing the hip squeeze with the birthing person's breathing can enhance pain relief [4]. Nonetheless, maintaining periodic pressure for extended periods poses a significant challenge.

In this study, we introduce an innovative and low-cost device known as the Adaptive Pressure Clamp (ADAC), designed specifically for performing the double hip squeeze technique during labor. The ADAC offers versatility, as it can be effortlessly attached to the lower back of any pregnant person, regardless of body size. One of the devices' key features is its ability to mimic and replicate the motions applied initially by a support person. Moreover, the ADAC can adjust its motion in synchronization with the respiratory activity of the pregnant person in labor, providing tailored support throughout the birthing process.

PRODUCT DESIGN

ADAC is an electromechanical device comprising of mechanical and electronic components. Some of its key components and their functions are as follows:
Contact Pads: Constructed from medical-grade silicone materials, these pads are suitable for both direct skin contact and cloth/textile contact. They provide excellent grip in both scenarios and feature touch sensors on both sides. These sensors detect the support person, initiate the learning mode, and automatically record motions.
Control Unit: This unit controls all functions of the ADAC. Includes a gearbox, microcontroller, power supply unit, DC motor, encoder, digital display, and an emergency button.

ADAC offers simple installation and removal, requiring no fasteners or straps for secure attachment. Installation involves placing the handles on the patient's hips, ensuring straightforward and hassle-free use. Additionally, in emergency situations, the device is equipped with an emergency button (a physical kill switch) located on the control unit. This switch can be pressed to immediately shut off the device, ensuring rapid response and safety. Preliminary design of the ADAC is shown in Fig. 2.

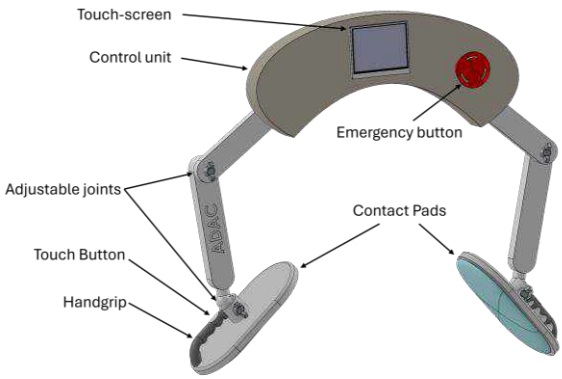

Figure 2: 3D Model of Preliminary Design

ADAC offers three modes to accommodate varying needs and preferences:

Learning Mode: In this mode, the device learns from a support person's application, capturing and storing the applied pattern. Subsequently, it accurately repeats the learned pattern, ensuring consistent and effective performance. To use this mode, the support person must apply pressure to the devices handles in the pattern that is desired. Once finished, the user can simply let go and the device will begin repeating the pattern.

Adaptive Mode: This mode is specifically designed to recognize and synchronize with the patient's breathing patterns, allowing the device to dynamically adjust its operation accordingly. Initially, the user will manually enter the breathing frequency. However, in subsequent stages of device development, a respiratory sensor will automatically gather respiratory information. To activate this mode, simply select the "Adaptive" button."

Manual Mode: For users seeking greater control over the device's operation, the manual mode allows for the manual selection of both the frequency and power of the pressure. This flexibility enables customization to suit individual patient requirements and preferences. To use this mode, the desired motion profile must first be uploaded to the device. The support person can then select the “Manual” menu which will allow them to select their desired profile.

BUDGET & MARKET ANALYSIS

We propose a device that prioritizes affordability, recognizing the significant financial burdens associated with expecting a child. By ensuring affordability, our device can be accessible to expecting families worldwide, particularly in regions with limited access to medical care. Our goal is to achieve a unit cost of $ 50 at large manufacturing scale.

ADAC could be purchased by expecting families or doulas looking to enhance their support services for birthing individuals. According to a price analysis conducted using [5], ADAC offers a relatively affordable option compared to its price and performance with commonly used birthing products such as birthing balls and Doppler fetal monitors.

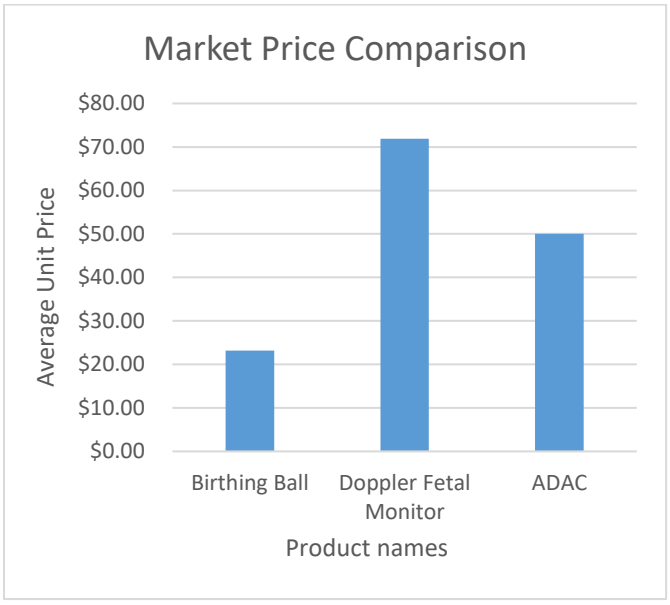

Figure 3: Market price analysis of ADAC vs Similar Products

INTRODUCTION

Cardiovascular disease, particularly myocardial infarction (commonly known as heart attack), remains a leading cause of mortality worldwide, claiming millions of lives annually [1]. Early identification of myocardial infarction remains a challenge due to limited resources. This project proposes an innovative approach, aiming to develop an AI-driven platform for forecasting cardiovascular disease. The system leverages two key components: a trained AI algorithm and a deformable 3D simulation of the human heart and cardiovascular system. The AI algorithm is trained on pre-processed, segmented, and sliced CT scans of de-identified myocardial infarction patients obtained from the SegMed medical image database. During training, the algorithm focuses on identifying blockages in the Left Anterior Descending (LAD) artery, which is the most commonly affected site in heart attacks [2]. Python is utilized for image processing and segmentation, preparing the data for optimal AI training. Following training, the algorithm undergoes validation, troubleshooting, and testing to ensure accuracy and reliability.

Phase two of the project revolves around constructing a simulation platform of blood flow within a detailed 3D model of the heart and cardiovascular system, with specific emphasis on LAD artery blockages using platforms such as Autodesk Inventor, 3D MAX, and ANSYS Fluent software. Blood is modeled as a non-Newtonian fluid, reflecting its complex properties to enable analysis of blood flow dynamics to analyze the consequences of arterial blockages on heart function on each specific patient. The platform allows for replicating specific blockages observed in patient CT scans to provide a tool for validating the accuracy of the AI-based diagnostic algorithm.

PRODUCT DESIGN

The CardioForecaster system is an AI-driven cardiovascular disease forecasting platform designed to predict the risk of heart attacks in patients using cardiac CT scans and 3D heart models.

CardioForecaster is classified as an FDA class 1 medical device and is aligned with regulatory standards for medical devices impacting cardiac disease diagnosis and treatment. As Software as a Medical Device (SaMD), it operates independently of physical medical devices. The platform utilizes open-sourced, de-identified CT scans to justify exemption from Institutional Review Board (IRB) approval.

The design process involved careful consideration of alternative methods and technologies, including imaging types, modeling software, and coding languages. The selection of cardiac CT scans as the primary imaging modality was based on its prevalence in heart attack diagnosis, cost-effectiveness, and ability to visualize the coronary arteries and any plaque buildup present.

Initially, the utilized methodology in this project involves an image segmentation step, where image processing techniques are applied to delineate the areas of interest within the CT scans. This step is essential for isolating the heart muscle and associated arterial structures. Then, each DICOM image undergoes a slicing procedure, being divided into 256 distinct slices with a resolution of 786×786 pixels. The slices are then fed into a combined Convolutional Neural Network (CNN) and Recurrent Neural Network (RNN) model. The CNN component is adept at extracting and learning spatial hierarchies of features from the sliced images, capturing the nuanced patterns and textures indicative of potential arterial blockages. The RNN layer, on the other hand, processes these features over sequential slices, allowing the model to understand the temporal and spatial progression of arterial conditions.

In the second part of the project, CardioForecaster employs a multi-software approach to investigate the hemodynamics within a simulated heart and cardiovascular system, focusing on the effects of Left Anterior Descending (LAD) artery blockages. Initially, a detailed 3D representation of the heart and cardiovascular system is crafted using Autodesk Inventor. Subsequently, these designed models are seamlessly integrated using 3D MAX software, a process that involves the fusion of the heart and cardiovascular system into a singular model.

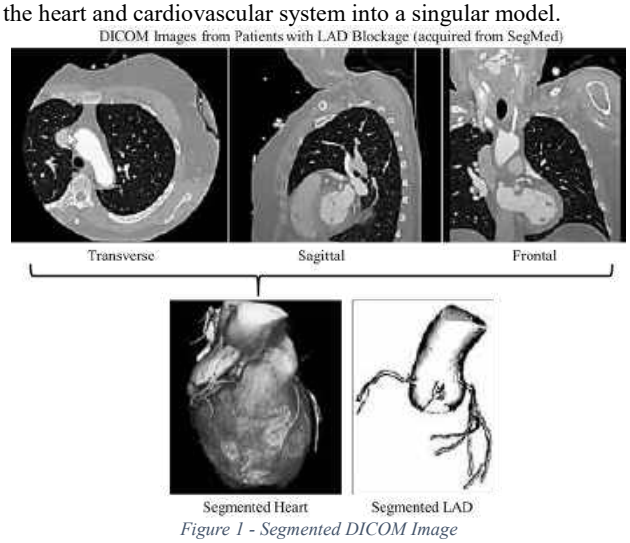

Figure 1 - Segmented DICOM Image

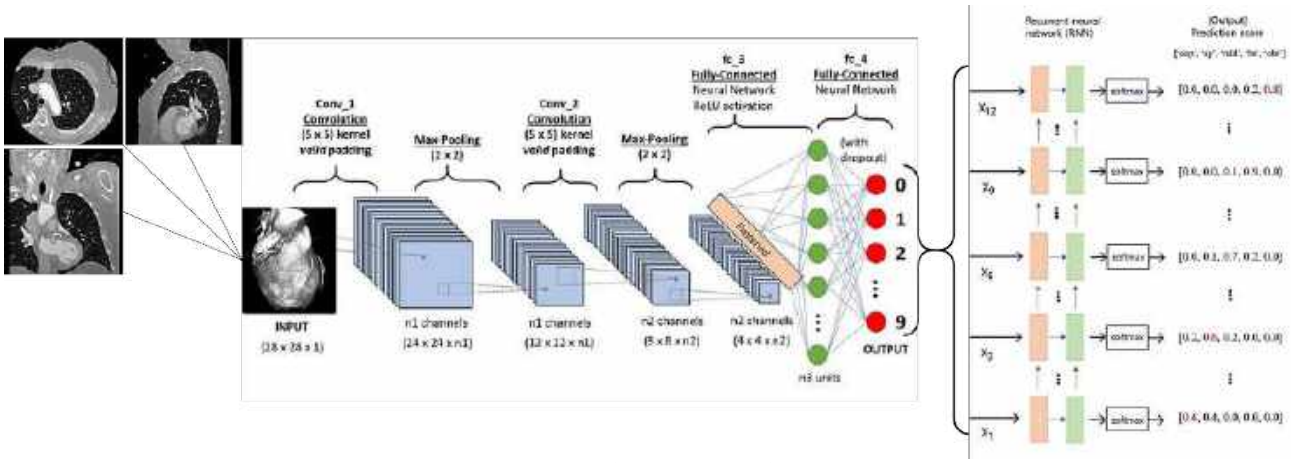

Figure 2 - The employed CNN + RNN algorithm

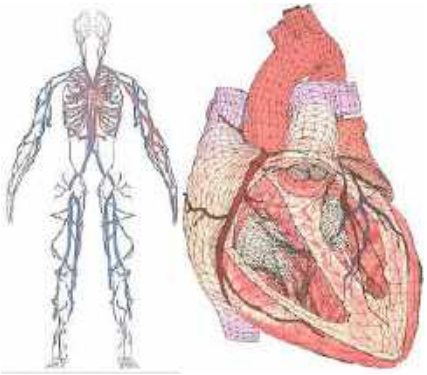

Figure 3 - The Under Study Cardiovascular System in 3DMax

This integration is crucial for maintaining the continuity of the cardiovascular structure and closed-circuit blood flow, which is essential for accurate simulation of simulation of the blood flow dynamics. Following the integration, a mesh of the entire system is generated and imported into ANSYS Fluent, a Computational Fluid Dynamics (CFD) software. ANSYS Fluent is utilized to simulate the blood flow within this system, using fluid dynamics algorithms to model the blood as a non-Newtonian fluid, mirroring its real-life rheological properties. This step enables the detailed analysis of blood flow patterns, velocity fields, and pressure distributions throughout the cardiovascular system under normal and pathological conditions. The simulation further uses the specific blockages identified in the LAD artery, mirroring the obstructions observed in CT scans used in the project's first phase. These blockages are modeled to replicate the exact conditions leading to myocardial infarction, thereby allowing for an in-depth exploration of the resultant hemodynamic alterations. This congruence between the simulated blockages and those identified in CT scans ensures that the model serves as both a predictive tool and a verifiable method to assess the AI algorithm's diagnostic accuracy developed in the project's initial phase.

BUDGET & MARKET ANALYSIS

This project has been completed with approximately $2300 in funding, alongside hardware donations, valued at approximately $300. All software used in this project are open-source or free for educational usage.

The CardioForecaster platform has the potential for broad implementation across 6,120 U.S. hospitals, private clinics, research facilities, and international markets [4]. The project entails an initial investment, notably a $100 million data center and $100,000 for further development. Financial projections, assuming full U.S. hospital adoption, suggest a one-year break-even with $125 million in revenue and a $20,000 license fee, yielding a $100 million annual ROI. Over five years, achieving break-even requires $225 million in revenue with a $7,000 license fee and anticipates a $20 million annual ROI. For a ten-year plan, the revenue need is $350 million with a $5,000 license fee, aiming for a $10 million annual ROI. This simplified financial outlook underscores the platform's market opportunity and economic potential.

CONCLUSION

In summary, the CardioForecaster project marks an advancement in the field of cardiovascular health, using the synergy between artificial intelligence, 3D modeling, and fluid simulation technologies to offer an approach to heart attack risk assessment. By analyzing the dynamics of blood flow and arterial blockages, particularly in the Left Anterior Descending (LAD) artery, this platform sets a new standard in predictive healthcare. The integration of AI with detailed heart models and simulations not only enhances the accuracy of heart attack predictions but also provides insights into the physiological impacts of arterial obstructions, thereby improving patient care and preventive measures.

INTRODUCTION

Vibration analysis is a critical tool for evaluating potential harmful effects on the body from our daily environment. However, experimental testing methods impose a risk on human subjects. As a result, computational modeling is used to evaluate how vibrations impact the human brain without risking subject health. Though the use of finite element head models (FEHMs) has been employed previously [1,2], limitations arise from the geometric bio-fidelity of the meshes used. We hypothesize that the adoption of anatomically accurate meshes that encompass several layers of the human head (skin, skull, cerebrospinal fluid (CSF), grey matter, and white matter) will yield a novel calculation of the free vibration behavior of the brain. Additionally, previous researchers have described the vibration behavior of the head from a single subject-specific or population-averaged model [1,3,4]. We hypothesize that incorporating a range of ages and head geometries will result in varying resonance responses of the brain meshes not currently predicted by existing single models.

To address the need for more population-representative models of brain vibration behavior, we have developed a library of subject-specific FEHMs. Within a MATLAB script, the original meshes were optimized for vibration analysis within LS-DYNA by eliminating elements with poor aspect ratios. With the meshes loaded into the Finite element Analysis (FEA) software, material properties adapted from Iwamoto et al. [5] for the different tissues were applied. Lastly, modal analysis of the skull and brain for the first 50 modes were compared to current literature [1,3, 4, 6-8] for validation.

METHODS

Twenty subject-specific meshes originally derived from MRI images were used [9]. The meshes provided a highly detailed representation of the human head, and all its modeled layers (scalp, skull, CSF, grey matter, and white matter). Development of the tetrahedral element meshes used can be found in the literature [9]. For the scope of our study, a new method of translating the subject-specific meshes into a format for mechanical vibration simulation was developed. Conversion of the meshes to a compatible format was achieved through an internally developed MATLAB script in which the brain mashes were converted from the original file format into keyword input files for the LS-DYNA commercial FEA software. In addition to format conversion, volumetric checks and optimizations were implemented to correct elements with zero or near zero volume. By employing this conversion approach, the meshes became compatible with FEA software, enabling comprehensive modal analysis and determination of the natural frequencies of the human brain, along with the resulting resonant deformations. Once the original files were loaded in, both element and nodal data were extracted and organized within the MATLAB script. Two methodologies for volumetric calculations were employed. Element volume was calculated using Gaussian integration, to align with the volume calculation in LS-DYNA and also using geometric vector operations shown in Eq. 1.

$$V_{exact} = \frac{|(P_1) \cdot (P_2 \times P_3)|}{6} \tag{1}$$

Where $P_{1,2,\&3}$ represent three nodes from a reference node P_4. Calculating each element volume through numerical integration, began by defining Gaussian points and weights for a unit element in isoperimetric space. The shape functions, partial derivatives, and Jacobian matrix were computed. The sum of the Jacobian determinant evaluated at the Gauss points was used to calculate the volume, according to Eq. 2:

$$V_{gauss} = \sum_{i,j,k=1}^{n} w_i w_j w_k \, |J_{jkl}(x, y, z, \xi, \eta, \zeta)| \tag{2}$$

where w_i, w_j, w_k are the weights associated with the Gauss points in the parameter space ξ, η, ζ, and x, y, z are the coordinates of the corresponding points in the physical space.

Both methods of volume calculation were checked for zero-volume elements. To correct zero-volume elements, one node was displaced normal to the plane formed by the other 3 to recover a sufficient aspect ratio. The overall workflow of the described MATLAB script is illustrated in Figure 1.

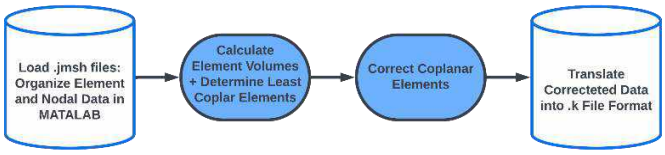

Figure 1. General Workflow of Developed MATLAB Script

Within LS-DYNA, material properties were assigned to the five layers of the model as linear elastic for the scalp and skull (MAT-001), and viscoelastic for the brain and CSF (MAT-061 and MAT-006, respectively). The material properties used were adapted from an existing FEHM [5].

With the 20 subject-specific models fully defined within LS-DYNA, modal analysis of the first 50 eigenvalues of subjections of the model (skull and brain) was conducted. The resulting natural frequencies were compared with the results from existing literature [1,3,4,6-8] for validation.

RESULTS

The natural frequencies associated with modes 1, 5, and 10 of the 20 skull and brain models are shown in Figure 3A and 3B, respectively. The data generated by the newly developed brain meshes are compared to three other studies that used different skull and brain models.

Figure 4 shows similar vibration modes in three typical subject-specific models. While the vibration modes are the same for all three, the natural frequencies are unique in each subject, explaining the variance seen in Figure 3.

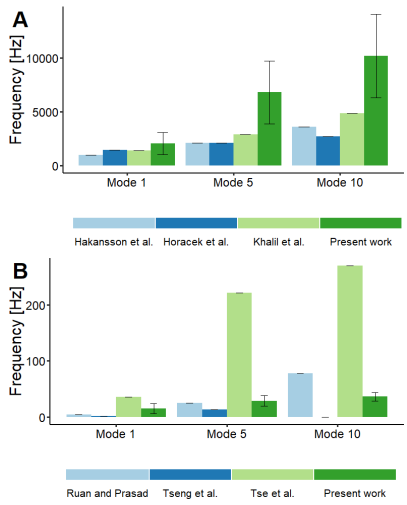

Figure 3. Comparison of (A) calculated natural frequencies of the 20 skull models with validation cases [6-8], (B) calculated natural frequencies of the 20 brain models with validation cases [1,3,4]

DISCUSSION

The original hypothesis was that the introduction of subject-specific head models of diverse geometries would result in varying natural frequencies that are not currently predicted by existing single-averaged models. The results from our initial work support this claim given the evident spread of natural frequencies presented in Figure 3.

As shown in Figure 3A, we observed significant variation in skull frequencies across the different meshes especially in modes 5 and 10. Figure 3B displays the resulting natural frequencies of the 20 brain models. When comparing the results of Figure 3, we observed that the use of the 20 subject-specific models produced a range of natural frequencies both in the skull and brain models. The range of natural frequencies captures the variability in biological geometry. Demonstrating how using subject-specific models as opposed to a single averaged model can provide a more comprehensive characterization of natural frequencies of the human skull and brain.

Figure 3 also shows that calculated natural frequencies can vary with head geometry. However, such disparities could also arise from the distinct methodologies employed in each study. More importantly, our research aligns closely with most of the studies presented in Figure 3, indicating that the newly formulated models maintain consistency with prior calculations.

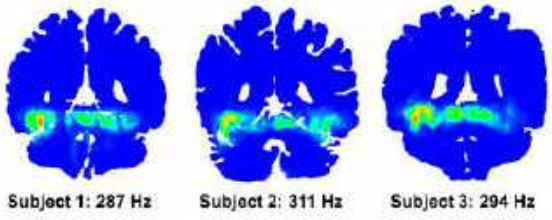

Figure 4. Coronal sections of similar vibration modes across three subject-specific brain models.

With further investigation of the modal analysis of the newly developed meshes, variation between the natural frequency and resulting excitement at the same mode of subject-specific models are shown in Figure 4. Such differences reiterate the contribution of individualized anatomical nuances in the brain, which the subject-specific models feature. The observed variation demonstrates the necessity of using subject-specific models in vibrational biomechanical analysis, as averaged models may not adequately represent unique characteristics that influence the natural frequencies of the human brain.

The tool developed herein has provided a comprehensive subject-specific model of the human head and demonstrated the impact of considering subject-specific models when conducting modal analysis. While this study focused on the natural frequencies of the first 50 modes of subject-specific models, the next steps include the calculation of higher modes and analysis of age-specific models to draw a correlation to variation in skull and brain size and natural frequency. Our framework lays the foundation for impact simulations and the study of general human system interactions.

ACKNOWLEDGEMENTS

TrueDose, AN ADOLESCENT MEDICATION COMPLIANCE IOS APPLICATIONS

N. Cilenti (1), E. Ferguson (1), S. Ford (1), M. Jester (1)
Faculty Advisor(s)
E. Berlew (1)
1. Department of Bioengineering, University of Pennsylvania, Philadelphia, PA

INTRODUCTION

1.a) Use Case

Medication non-adherence is a pervasive and multifaceted problem in adolescents. Core drivers for non-adherence include a desire for autonomy, a lack of parental support, and a sense of invincibility (S. Foster, personal communication, October 3, 2023). TrueDose aims to increase adherence by connecting patients, parents, and physicians; incorporating positive reinforcement; and promoting patient autonomy. TrueDose is designed for all adolescents, with a focus on adolescents required to take complex medication regimens.

1.b) Problem Impact

70% of adolescents are non-adherent to their medications, contributing to 50% of treatment failures, 25% of hospitalizations, and 125,000 patient deaths annually in the US.[1,2] Existing solutions, including pill boxes and reminder apps, target forgetfulness, but are limited as they neglect the complex nature of adolescent non-adherence. Current solutions fail to address the desire for independence, the impacts of incentivization, and the customizable nature of an app that can adapt to adolescents changing medication regimes.

1.c) Scope (Objective)

TrueDose aims to increase medication adherence by targeting the core drivers of non-adherence. TrueDose integrates reminder capabilities, a pill identifier, data analytics, and patient incentives to improve adherence by balancing external support with patient autonomy. TrueDose is designed with patients in mind, but functions with three interfaces to serve as a support network for patients, their parents, and physicians alike, bringing all medication questions to one singular application.

Product design

TrueDose consists of 3 unique interfaces, one for the patient, one for the physician, and one for the parents or guardians. Physicians may create an account as a physician and once logged in are able to register their patients by email. They can then input the medication type, quantity, timing and any other pertinent information for the patient to have.

From the patient perspective, once registered they will be able to view a calendar dashboard of all of their required medications and other general information. At the time they are required to take their medications they will receive a push notification, and if they click on it it will bring them to their camera. They will then take a photograph of their medication on a plain background and the pill algorithm will detect if it is the correct medication. If it is correct the app will instruct the patient to take X number of the medication. If the app detects the wrong medication, it will instruct the patient to try again.

The third interface, the parents interface, allows guardians to monitor their child's medication compliance from afar. They will have the option to enable a two-factor authentication feature or remain in view-only mode. In two-factor authentication mode the parents have the option to approve the medication that was taken. They will get a push notification when their child takes a photo of the medication and then can confirm or deny if this is true. Further they can input incentives based on what makes sense for their family. The goal of the parents interface is to provide a sense of supervision while still giving as much autonomy as possible.

Figure 1: A sample interface for each of the three interfaces of the application.

Budget & Market Analysis

The design budget allotted to TrueDose was $600 per semester of the academic year, resulting in $1200 through the course of the entire design project. The budget has supported design and development of the software and launch onto the apple store.

On its largest scale the market size for our product is adolescents in America. Currently there are approximately 21 million Americans aged 15-19.[3] Within the population of American adolescents, our product is more suitable for adolescents with chronic diseases or complex medication regimes. According to the CDC, nearly 40% of children and teenagers have chronic illness, making the target population closer to 9M adolescents[4]. The population is large and sadly ever growing as more adolescents continue to develop chronic diseases annually.

Within this target population we estimate that we can penetrate 0.01% of this population in the first year, leading to approximately 90,000 adolescents, however when multiplied by 3 as a physician, and guardian is needed for each patient the total number of users is around 270,000 users.

Once launched on the app store, the application is easily accessible to anyone with a smartphone, which is assumed to be the majority of the adolescent population. We aim to charge $5 for the application, keeping the cost low and accessible to all populations. The development costs are very low as the product is fully software. The development costs however fall on the data scientist and software engineers holding the back end of the application together. The cost per unit can be expected to be very low, and the majority of expenses will relate to updating and keeping the software running.

We plan to include advertising and other potential revenue streams later on, but initially are looking to make the app accessible for all and want to keep the cost low. Often people have an aversion to paying for apps, especially when they are more expensive.

Ultimately, TrueDose aims to increase medication adherence in adolescents with the hopes of improving health outcomes in this population.

ACKNOWLEDGEMENTS

We gratefully acknowledge the support provided by the University of Pennsylvania throughout the completion of this project. Additionally, we extend our sincere appreciation to the Bioengineering Senior Design faculty for the mentorship and assistance.

THE SMALLER, THE BETTER?: STUDYING THE IMPACT OF MINIATURIZING LVADS ON HYDRODYNAMICS AND HEMOCOMPATIBILITY

Shobana Santhanam (1), Shweta Karnik (1), Charles Federico (1), Lakshmi P. Dasi (1)

(1) Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, USA

INTRODUCTION

There are approximately 960,000 new cases of heart failure (HF) in the United States every year[1]. While many of these cases are addressed with non-invasive treatment such as medication, severe cases of heart failure require either a heart transplant or a left ventricular assist device (LVAD). While heart transplantation is the gold standard of treatment for extreme HF, the longer waiting periods for donor hearts make it unfeasible for the patients to receive timely and appropriate care. Thus, LVADs have become the new standard of care for HF patients.

An LVAD is a mechanical pump that assists in pumping blood from the heart to the body. It can restore heart function, and prolong and improve patients' lives; however, it is associated with significant complications that can affect its long-term operation [2,3].

Currently, Heartmate 3 LVAD (Abbott Lab, Illinois) is the only FDA-approved implantable device on the market. Approved for long-term usage in adults in 2018, this device aims to minimize blood trauma and eliminate the wear and tear caused by contact bearings using magnetic levitation technology. However, issues such as inlet flow disruptions, material deformations, and halted pumps have been reported by users worldwide[4].

Studies have found that women are at a higher risk of post-LVAD mortality and right-ventricular failure. In a 2-year outcome study of the MOMENTUM 3 (Multicenter Study of MagLev Technology in Patients Undergoing Mechanical Circulatory Support Therapy With HeartMate 3) trial, it was found that women had an increased rate of stroke (adjusted incidence rate ratio [aIRR]: 1.52), major bleeding (aIRR: 1.28) and infection (aIRR 1.14)[5]. One measurable factor that has been connected to these morbidities is the patient's preoperative left-ventricular end-diastolic diameter (LVEDD). Smaller LVEDD, usually defined as less than 60 mm, is independently predictive of worse outcomes after LVAD implantation[6].

Currently, there is only one size of the Heartmate 3 available on the market. A possible solution to higher mortality among smaller patients is to reduce LVAD size based on the LVEDD. This study aims to determine the potential of miniaturizing LVADs and explore its effect on the pump performance and the hemocompatibility.

METHODS

Design and Manufacturing

Three LVAD sizes with rotor outer diameter (OD) of 15 mm, 30 mm, and 45 mm were created. The blade inlet and outlet angles were set at 20º and 30º respectively. Each blade had a set thickness of 1.2 mm and a height of 7 mm. The volute sizes were adjusted to the rotor ODs to ensure design consistency. These prototypes were then 3D printed using a J850 Pro (Stratasys Ltd, MN, USA).

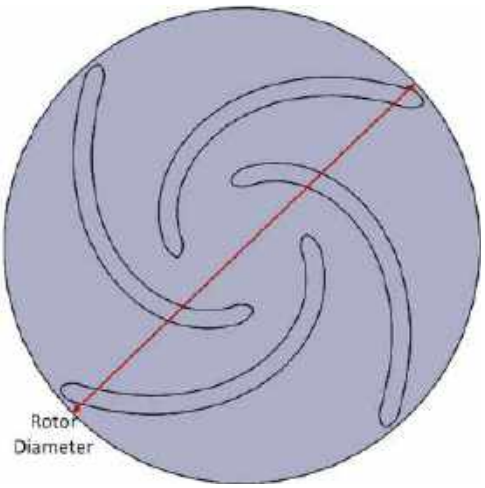

Figure 1: LVAD Prototype with 30 mm Rotor Diameter.

Hydrodynamic Performance Analysis

A bench top loop was set up with a 40% wt glycerin solution that imitates the viscosity of blood. The bench top loop consisted of a reservoir, a motor to drive the rotor, an ultrasonic flow probe to measure the volumetric flow rate, a resistance clamp on the outlet of the device to vary the resistance to flow and produce required pressure and two pressure transducers to measure the inlet and outlet device pressures.

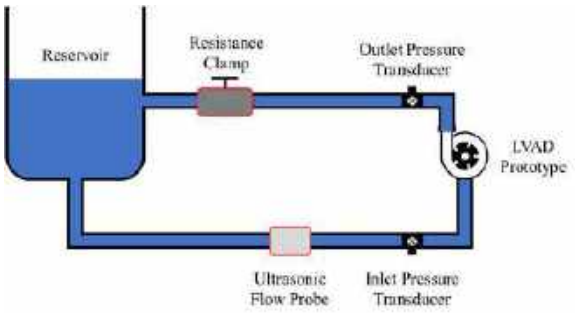

Figure 2: Hydrodynamic Performance Testing Bench-Top Loop Schematic.

The pump was driven at 3000 RPM, the downstream resistance was increased incrementally, and the pressures and flowrates were measured. To analyze the hydrodynamic performance, the hydrodynamic efficiency (η_h) and the gradient of the pressure-flow curve were calculated.

$$\eta_h = \frac{Hydraulic\ Power}{Mechanica\ \ Power} \times 100 \quad (1)$$

$$Gradient_{4-6} = \frac{P_4 - P_6}{4-6} \quad (2)$$

Hemocompatibility Testing

A similar testing setup was used to measure the hemocompatibility of each of the three LVAD prototypes. The experimental procedure included collecting data over a six-hour period and performing each test five times. The loop is adjusted to simulate the pressure and flow conditions of an average adult heart (5 L/min, 90 mmHg). The loop temperature, the operating speed and power consumption of the LVAD prototypes were measured and maintained for each experiment.

The blood samples were collected every 30 to 60 minutes for six hours, following the standard practice recommended by ASTM F1841-19. The collected samples were then centrifuged to obtain plasma for further analysis. Platelet activation and hemolysis were measured using enzyme-linked immunoassays (ELISA) kits.

RESULTS

For the LVAD prototype with a rotor diameter of 30mm, the gradient at adult operating conditions was – 11.52 mmHg/ $(L/min)^{-1}$. The pressure-flow curve is as shown in Figure 3.

Results for the remaining hydrodynamic performance analysis and hemocompatibility testing is currently being generated and will be presented at the conference.

DISCUSSION

The miniaturization of LVAD prototypes proposed in this study will lay a solid foundation to understand its effect on the hydrodynamic performance and the hemocompatibility of LVADs. This knowledge, in turn, will aid in designing the next generation of size appropriate LVADs based on LVEDD.

THERMAL CONTROL OF CIRCADIAN FUNCTION FOR ENHANCED SLEEP ONSET AND BLOOD PRESSURE MODULATION

Kenneth R. Diller, Laura H. Namisnak, Sepideh Khoshnevis (1)

(1) Biomedical Engineering Department, University of Texas at Austin, Austin, TX, USA

INTRODUCTION

Thermoregulatory function is governed very strongly by blood flow between the body core tissues and organs and glabrous skin, particularly in the hands and feet. This vascular network constitutes the heat transfer component of the circulatory system, having its own dedicated control function. The terminal vessels of this flow network are arteriovenous anastomoses (AVAs) which have the capability of vasodilating to a diameter more than an order of magnitude larger than the capillaries that terminate the parallel nutritional network. The heat exchange and nutritional networks have independent control functions, but operate under a single pumping source, the heart. Distribution of blood flow throughout the complete vascular system is regulated primarily by the local flow resistance which, according to Poiseuille's law, is proportional the inverse of the vessel diameter to the fourth power.

Given its key function in thermoregulation, the ability to upregulate AVA blood flow on demand has numerous important clinical and life advantages. Increasing nutritional blood flow is as easy as applying a capsaicin cream that is ubiquitously available over the counter to treat muscle pain. However, AVA blood perfusion is stubbornly resistant to flow enhancement by capsaicin or any other commonly known means to cause an increase in local blood flow in nonglabrous skin.

Several years ago our lab discovered a technique that we have termed Selective Thermal Stimulation (STS) to intervene in the control of blood flow to AVAs on demand [1]. STS may be practiced by simple and safe surface heating along the cervical spine to warm receptors that have key inputs into thermoregulatory control, and specifically to cause parasympathetic relaxation of vasoconstriction of AVAs. The objective is to increase glabrous skin blood flow (GSBF) on demand to access physiological and medical benefits.

METHODS

Since discovering STS the Diller lab has conducted hundreds of exploratory experiments to characterize this phenomenon. Healthy human subjects are placed in a supine position on a comfortable surface in a thermoneutral environment. The clothing ensemble such as shorts and a tee shirt minimize thermal insulation to heat transfer convection with quiescent room air. These experiments are approved by the university of Texas IRB. Instrumentation consists of laser Doppler flow sensors placed on the pad of a middle finger and on the volar forearm. Beat-by-beat blood pressure is monitored via pulse transit time technology. STS is practiced by applying mild warming along the cervical spine either by surface heating or by using a penetrating heat source. In all cases the STS protocol design must adhere to a strict balance between achieving efficacy for increasing GSBF, which in general is proportion to the stimulation temperature [1], and safety, which requires that the temperature within deep tissues not exceed the threshold for thermal injury. This threshold is generally held to be 43°C [2] so that our protocols limit the applied temperature to no higher than 43°C and as the technology has evolved to no more than 41°C. This practice has been worked well since heat applied at the surface would need to diffuse to deeper neurological structures before damage could occur where the temperature would be less than at the surface.

During testing regimens subjects are initially exposed to a thermal accommodation period of about 20 minutes to adjust to the room environment. Next, STS warming is initiated on the skin overlying the cervical spine and maintained for a minimum of 10 to 15 minutes and sometimes as long as one hour. This procedure is practiced by either a flexible polymeric bladder through which warm water is circulated or by direct application of an electrical resistance heater. Sometimes the electric heater is cycled on and off to provide a dynamic stimulus although this method provided no measurable benefit.

Primary instrumentation applied to subjects consists of thermocouples on the skin at the site of STS and at representative glabrous and nonglabrous skin locations and laser Doppler blood flow probes also at glabrous and nonglabrous locations.

RESULTS

Data from an exemplar STS trial is shown in Fig. 1. Following an initial benchmark period of 10 min, an electric heating pad was placed over the cervical spine for 25 min and then physically removed.

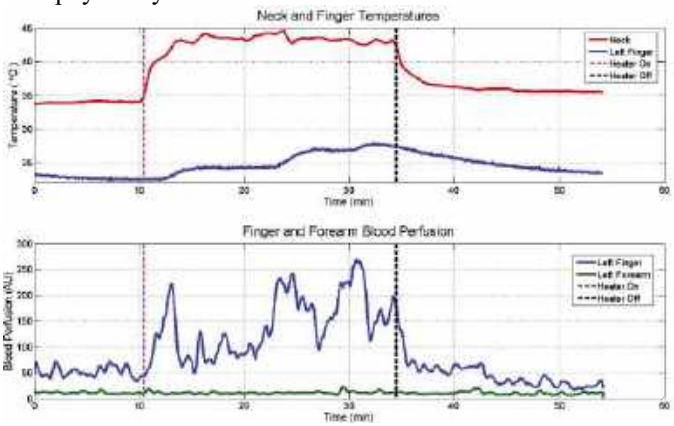

Figure 1. Temperature and blood flow data for an exemplar STS trial. The top panel shows skin temperatures on the cervical spine (red) and a middle finger pad (blue). The bottom panel shows laser Doppler blood flow at a finger pad (blue) and corresponding forearm (green).

The data demonstrate that the subject was vasoconstricted at the start of the trial. There is a strong correlation between the upregulation and downregulation of GSBF in conjunction with the application and removal of STS. The alteration of GSBF begins approximately when the cervical skin temperature rises to the range of 39-40°C. The surface temperature on the finger pad follows the level of blood perfusion measured in the adjacent finger with an approximate 2 min delay as heat diffuses outward from the warm perfused blood to the skin surface. STS has no effect whatsoever on blood flow in the volar forearm.

DISCUSSION

Although STS has important clinical implications for manipulating core temperature to induce or remove a hyper- or hypo-thermic state, the focus of the present study is to enhance the role of glabrous skin blood flow in achieving effective sleep. Opportunities having the greatest potential impact are to enable more rapid sleep onset, to adjust the sleep onset time, and to lower the blood pressure during sleep. Subjects are instrumented with skin thermal sensors on the calf and sole to measure the distal – proximal gradient (DPG) as an indication of GSBF. Trials consist of spending a night in our sleep lab using our prototype bed equipped with STS plus differential mattress temperature zones between the body core and peripheral areas. Fig. 2 presents data for DPG difference of 9 subjects sleeping on the bed on nights for control and for the thermal system activated. The horizontal line indicates the lights out period. [3]

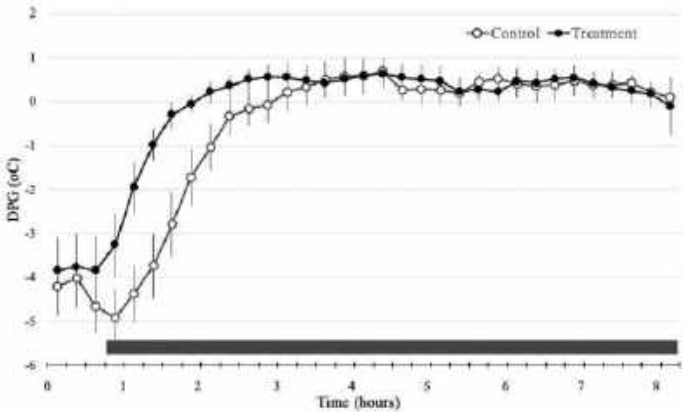

Figure 2. DPG temperature between treatment and control nights for nine subjects. Enhanced GSBF prevails through the first 3+ hours of sleep following initial STS period. Sleep onset latency decreased from 83 to 35 min with the thermal system activated causing greater GSBF ($p = 0.012$).

Data has been gathered from some 90 STS trials in which blood pressure was measured on a beat-by-beat basis to assess whether STS induces a dip in blood pressure in conjunction with AVA vasodilation. A large longitudinal trial by Hermida, et al has documented that sleep time dipping of blood pressure leads to a 43% reduction in the five-year probability of experiencing major cardiovascular events such as an arrest or stroke [4]. Thus, we are engaged in a large-scale statistical analysis of our STS data so identify the efficacy for inducing BP dipping. Initial data indicates a promising outcome.

ACKNOWLEDGEMENTS

COLLABORATIVE PATHWAYS: EMPOWERING PREGNANT AND PARENTING TEENS THROUGH STEM ENGAGEMENT

Oluwatomisin O. Ajayi (1), Emily A. Hoffmann (1), Paige R. Nielsen (1), Lauren E. Tolbert (2), Kyoko Yoshida (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA
(2) Longfellow Alternative High School, Minneapolis, MN, USA

INTRODUCTION

The Pregnancy Research Engineering Group (PREG) at the University of Minnesota (UMN) seeks to understand the mechanics of maternal soft tissue growth and remodeling during pregnancy and discover how and why complications occur [1]. Since research alone cannot help pregnant patients, PREG strongly seeks to not only fill scientific knowledge gaps in pregnancy and women's health, but also uplift and support women through other venues, including by sharing our research with populations affected by pregnancy. Here, we address the need for educational support and resources for the underserved population of pregnant and parenting (P&P) teen girls, who face many obstacles and are at high risk for preterm birth [2]. With only 50% high school and 2% college completion rates, it is evident that P&P girls do not get all the support they need. Among existing college pathway programs available to P&P teens, less than 50% provide opportunities to visit universities, and only 12% pair them with college mentors. These statistics culminate with the reality that although 59% of pregnant and parenting teens aspire to careers that require college education, only 20% enroll, and even fewer finish [3].

To address this issue in our community, we created an outreach program to introduce high school P&P girls to STEM careers, provide them with resources, and encourage them to follow their aspirations. We partnered with Longfellow Alternative High School for pregnant and parenting teens in Minneapolis, Minnesota that provides an Early Learning Center for the students' children and a clinic to support P&P girls (ages 13-21) in finishing high school. In addition to visiting and inviting the students to the research lab on campus during the 2022-2023 school year, we had the opportunity to visit the students this past October and are planning for future visits and campus tours at UMN. Here, we present an outreach activity we developed, which introduced P&P girls to pregnancy biomechanics and research at PREG, an interactive problem-solving activity demonstrating uterine contractions during labor, and post-secondary education opportunities and resources. As a lab that specializes in pregnancy biomechanics, we strive to use our research as a tool to ignite a passion for STEM in P&P students through their personal pregnancy experience with the ultimate goal to provide them with the confidence to pursue STEM education and careers.

PROGRAM DESCRIPTION

We began the outreach activity with an introduction to engineering and PREG. To encourage participation from the P&P girls, we asked them to share their impressions of engineering and STEM. We introduced the concept of engineers as creative problem-solvers and followed with a brief overview of the research goals of PREG to demonstrate how STEM careers contribute to increasing knowledge about their shared experience of pregnancy. Our introduction also included an icebreaker, during which we asked the P&P girls and teachers to share weird or interesting things that happened during their pregnancies. It was a valuable opportunity for the students to connect with each other.

We then introduced the students to the anatomy and physiology of pregnancy and the uterus, which we further contextualized with a realistic, three-dimensional anatomical model (Fig. 1). The crux of our activity was a hands-on learning and problem-solving activity to demonstrate labor contractions (Fig. 2). The students were asked to inflate balloons containing a ping-pong ball which sealed the air. Here, the balloon and ball represented the uterus and fetus, respectively. Working in pairs, we tasked the P&P girls with figuring out the best way to get the ping-pong ball out of the balloon. They were given time to experiment and problem solve, reflecting what engineers would do to overcome a challenge. Finally, we came together as a group to demonstrate that squeezing at the top of the balloon was the best way to extract the ping-pong ball, mimicking how the uterus contracts for labor. The balloon activity concluded with an explanation of the science behind uterine contractions during pregnancy. We demonstrated a finite

element model simulation of the activity, developed in our lab (using FEBio v2.4, Fig. 3), and a video of the first birth captured in an MRI to further contextualize the connection between pregnancy and technology [4].

Our visit to Longfellow concluded with a Q&A session for the P&P girls to ask about the activity and careers in STEM. We had a range of backgrounds and experiences on the panel, including our research advisor, 2 graduate researchers, and 2 undergraduates to provide input from women in different career and life stages. The P&P girls asked questions including, 'Is engineering hard?', 'Are any of you mothers or plan to have children?', 'What is college like?', 'How did you create the FEA model?', and 'Have you found the best ways to recover from pregnancy through your research?' Overall, this provided an intimate opportunity to share personal experiences and challenges in STEM.

Figure 3. Contextualizing the connection between pregnancy and technology.

STUDENT FEEDBACK AND FUTURE DIRECTIONS

The students were incredibly receptive towards the balloon activity, demonstrating curiosity and engagement throughout the session. We followed up with an interview with Longfellow's science teacher, Ms. Lauren Tolbert, to evaluate the presentation and receive feedback. The teachers felt that the concepts covered were fully explained without making the experience too passive and lecture-heavy. The students' enthusiasm reinforced the importance of providing accessible STEM education opportunities to P&P girls. In addition to asking questions, the P&P girls shared their career interests and we found that many are now more interested in pursuing STEM careers. Here are some direct comments from the students and teachers at Longfellow:

> *"I appreciated how friendly and outgoing all the presenters were, and how flexible the lesson was. You all made time for the students to play and explore."*
>
> *"I never saw a visual of how the muscles in our uterus make contractions happen until that presentation."*
>
> *"The lesson was lively and engaging, students enjoyed it and continued talking about it for quite a while afterwards."*
>
> *"I never thought I wanted to be an engineer. If I can study pregnancy and birth, I'm more interested in it!"*
>
> *"It was inspiring for them to see successful students excited about their education, and to hear about the various paths that brought them to PREG."*
>
> *"It was cool to see how the way we pushed on the balloon is the same way our baby is pushed out!"*

Moving forward, we plan to include more visuals, small group work, focusing on think-pair-share and other active learning strategies, and introduce other technical skills, such as programming and engineering design. We also plan to improve on our demonstrations of the FE model and give the P&P girls a behind-the-scenes look at what goes into building a simulation. We will complement our activity with an on-campus tour at UMN for the Longfellow students in the Spring. Overall, we succeeded in sparking curiosity for STEM and engineering in P&P girls, highlighting the transformative impact of targeted outreach initiatives. We will continue to improve and expand this outreach activity to increase access to resources and support for pregnant and parenting students with the long-term goal of diversifying the future generation of engineers and STEM professionals.

ACKNOWLEDGEMENTS

This work was supported by the NSF CAREER Award. We also acknowledge and thank the University of Minnesota's Student Parent HELP center for gifts for the students, Emi Gaçaj for her help with the activity, and the Longfellow High school students and teachers.

CONTROLLING NEURAL CULTURE DENSITY AND ORIENTATION FOR ENHANCED ANALYSIS OF TRAUMATIC BRAIN INJURY ELECTROPHYSIOLOGY

G. Radtke (1), J. Sergay (2), J. Park (1), J. Zhang (1), C. Franck (1)

(1) Department of Mechanical Engineering, University of Wisconsin - Madison, Madison, WI, USA
(2) Department of Biomedical Engineering, University of Wisconsin - Madison, Madison, WI, USA

INTRODUCTION

Approximately sixty-nine million people worldwide suffer a traumatic brain injury (TBI) each year, leading to potentially permanent neural damage and a severe decline in quality of life [1]. For mild TBIs, there is evidence that significant, irregular signal activation and propagation among neural networks within the brain tissue occurs after impact [2]. Nonetheless, quantitative descriptions of the relationship between neural network activity and specific injury mechanics, such as the strain and strain rate of brain tissue deformation, are still largely lacking at the cellular level. A current noninvasive technique to characterize the mechanical threshold for significant electrophysiological disruption utilizes large-scale imaging of fluorescent calcium probes in 2D in vitro neural cell cultures in conjunction with applying strain to the cells. Current computational tools to differentiate calcium signals in individual neurons can only deconvolve fluorescent signals retrieved from the cell somas due to the challenge of soma-neurite overlap within dense 2D cultures. However, signal propagation through neurites and synapses also provides vital network information relevant to altered electrophysiology post-TBI uncaptured by current methods.

To address this gap in knowledge, this study spatially controls the 2D geometric arrangement of in vitro neural networks to better trace intracellular calcium dynamics throughout all neural cell structures. This is achieved via the development of a protocol to micro-contact print (μCP) a cell-adherent protein layer capable of confining single cells directly on stretchable polydimethylsiloxane (PDMS) substrates [3]. Alongside protocol refinement, this study investigates the influence of varying spatial distributions, cell densities, and network branching on functional neural networks and their response to TBI-like loading. Ultimately, the various μCP networks will be subjected to uniaxial tensile stresses to simulate mild TBIs while collecting fast-rate calcium images pre- and post- stretch. This enables comparison between μCP and unpatterned culture electrophysiology and offers insight into potential dysregulation in calcium dynamics [4]. Here, we outline this methodology enabling enhanced spatial and temporal resolution to analyze the effect of physical network parameters on the altered network activity propagation following TBI.

METHODS

Stamp master-molds were fabricated through traditional UV lithography techniques via a PRIMO system (Alvéole), with pattern designs within the master-molds iteratively optimized to confine a single cell to a single unit space (12.5 μm central nodes connected to 7.5 μm wide and 50 μm long extensions) (**Fig. 1a**). To produce stamps, master-molds were coated with 10:1 PDMS (Sylgard 184), cured overnight at 60°C, and cut into stamps (**Fig. 1b**). As partially described in previous work and illustrated in **Fig. 1d**, stamps were then treated with oxygen plasma, coated with a 1 μg/mL laminin/Poly-D-Lysine (PDL) solution, cleaned of excess solution via nitrogen gas, and pressed into contact with an 80 μm thick polyvinyl alcohol (PVA) film [5].

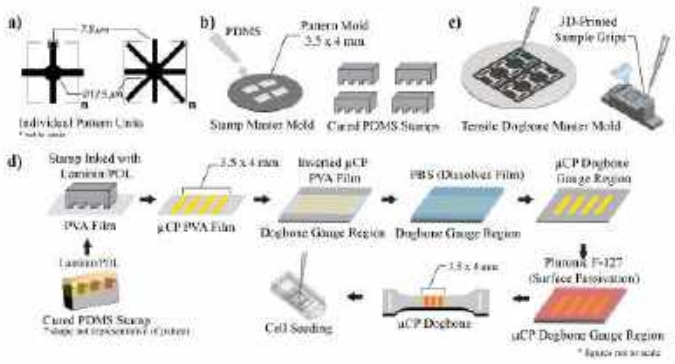

Figure 1: Preparation of μCP neural co-culture. a) Depiction of grid and hexagonal pattern geometry, respectively. Preparation via soft lithography of b) stamps for extracellular matrix patterning and c) tensile dogbone samples within biocompatible grips. d) Overview of sample substrate patterning.

The sacrificial PVA film, as shown in **Figure 1d**, was trans-printed and placed into contact with a prepared PDMS tensile sample (10:1; Syl-

gard 184) within 3D-printed, biocompatible constructs (**Figure 1c**). Subsequent phosphate-buffered saline (PBS) washes dissolved away the sacrificial film. The substrate was, lastly, passivated with 1% Pluronic F-127 to minimize off-pattern adherence and migration and further washed with PBS. Cortical cells from postnatal day P0-P1 Sprague-Dawley rat pups were then dissected and seeded onto the substrate (at a density of 575 $\frac{cells}{mm^2}$) and maintained until maturation at 10 days in vitro (DIV) via media exchange every two days.

Following culture maturation, network activity was captured via optical measurement of fluorescence using the calcium indicator Fluo-4 AM, wherein fluorescence indicates relative intracellular Ca^{2+} concentration. μCP and unpatterned (i.e., wherein the laminin/PDL is applied non-specifically to the sample substrate) culture activity is compared. Timelapse images of network activity within both culture types were acquired at 25 frames per second via epifluorescence microscopy (Nikon Ti2E; 20x objective) at 37°C. Image sequences were binarized within ImageJ, and fluorescent traces were extracted and processed within the NeuroCA application, outputting raster plots of network activity as previously described [6].

RESULTS

Preliminary data are promising, with μCP samples maintaining pattern fidelity and exhibiting electrophysiological activity at 10 DIV. Moreover, μCP cultures exhibit, albeit on a less drastic scale, relatively equivalent global activity to unpatterned cultures. **Figure 2a,c** juxtapose unpatterned and patterned density, orientation, and resolution. That is, the unpatterned culture (**Figure 2a**), while allowing for deconvolution of activity within the cell body, lacks visualization of individual neurites; the patterned culture (**Figure 2c**), however, consistently enables deconvolution of fluorescent signals throughout all intracellular structures. **Figure 2b,d** demonstrates the mentioned coordination in global activity, an indication of network maturity, with coordinated firing observed past 60 second time-mark in the unpatterned sample (**Figure 2b**). In the patterned sample (**Figure 2d**), the network bursts are seen within the first quintile of the timelapse. Thus, we developed and validated a consistent method for control and confinement of neural co-culture growth on a stretchable PDMS substrate.

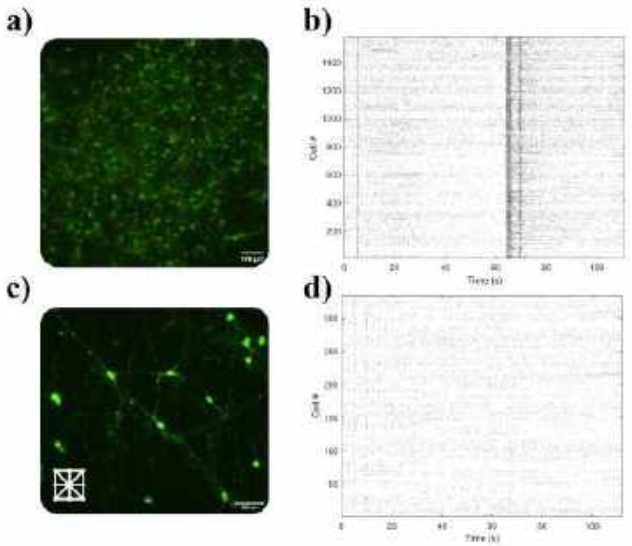

Figure 2: Sample baseline comparison at 10 DIV of electrophysiological activity. a) Unpatterned neural co-culture, seeded at a density of 1,750 $\frac{cells}{mm^2}$ and imaged at 20x magnification (green: Fluo-4 AM). b) Raster plot of unpatterned culture activity. c) Patterned neural co-culture, seeded at a density of 575 $\frac{cells}{mm^2}$ and imaged at 20x magnification, enlarged (green: Fluo-4 AM). d) Raster plot of patterned culture activity.

DISCUSSION

These results are exciting, particularly given their novelty. Numerous examples of μCP single-cell resolution cultures on both rigid and flexible substrates exist within the literature; however, full (2D) control of cell density and neurite orientation – consistently resolving the electrophysiological dynamics of a single cell and its respective protrusions – atop a stretch-ready substrate has yet to be reported. The significance of both variables (i.e., density and orientation) should be noted, as neural culture density is known to influence both culture maturity and global electrophysiological activity, while neurite orientation is heavily implicated in injury susceptibility during mechanical deformation [7, 8].

Braun et al., for instance, report confinement of neurite orientation along one axis atop a PDMS substrate; however, this study lacks control of both density and full neurite confinement. Further, the electrophysiological data extraction from single cells instead relies upon patch clamp methods – lacking global activity resolution [8]. Likewise, the methods outlined by Nagamine et al., while enabling full control of cell density and orientation, lack particular application to the TBI-relevant stretch injury that the methods described in this abstract aim to ultimately model [9].

With method refinement complete, we proceed to the next aim of subjecting μCP cultures to controlled mechanical loading, with the goal of extracting electrophysiological dysregulation within all intracellular structures following loading.

INTRODUCTION

Heart disease remains the leading cause of mortality in the United States, with coronary artery disease (CAD) resulting in 928,741 deaths in 2020 [1]. One treatment option for CAD is a coronary artery bypass graft (CABG). Approximately 400,000 patients undergo CABG each year [2], though these have a high failure rate, of 42.8% [3]. It is hypothesized that this is due to a biomechanical compliance mismatch between the native blood vessel and the CABG, resulting in intimal hyperplasia and thrombosis [4]. To improve patient outcomes, it is crucial to develop a small diameter tissue engineered vascular graft (TEVG) that matches the compliance of the native blood vessel. This study aimed to develop small diameter compliance matched TEVGs and vary their compliances. Two TEVG designs were developed: a poly(ester urethane)urea (PEUU) based graft containing PEUU and gelatin, and a poly(Lactide-co-caprolactone) (PLCL) based graft containing PLCL and gelatin. The inner layer of the PEUU graft utilized a modified PEUU with sulfobetaine groups (PESBUU-50) known for its anti-thrombogenic properties [5]. PLCL was selected as the primary material for the second graft due to its high elasticity and lack of toxic byproducts. Both grafts incorporated a significant amount of gelatin in the outer layer to promote cellular infiltration and remodeling. The production of the grafts involved a trial-and-error approach to ensure they fell within the compliance range. Once compliance matched grafts were achieved the wall thickness was adjusted to create hypocompliant or hypercompliant grafts. Four TEVG designs were developed: thin and thick PEUU-based TEVGs and thin and thick PLCL-based TEVGs.

METHODS

The TEVG polymer mixtures consisted of gelatin isolated from porcine skin (MilliporeSigma), PEUU, PESBUU-50, PLCL (MilliporeSigma). Trilayered PEUU grafts were created by electrospinning solutions of 8% PESBUU-50, 10% 80:20 PEUU:Gelatin, then 10% 20:80 PEUU:Gelatin. All solutions were dissolved in 1,1,1,3,3,3-Hexafluoro-2-propanol (HFP). The solutions were electrospun at a voltage difference of +20 kV, and -4 kV, at a working distance of 10 cm. Trilayered PLCL grafts were fabricated by electrospinning solutions of 10% PLCL, 10% 80:20 PLCL:Gelatin, then 10% 20:80 PLCL:Gelatin. The solutions were electrospun at a voltage difference of +15 kV and -0.5 kV, at a working distance of 10 cm. Both grafts solutions were dispensed onto a rotating target mandrel of 1.1 mm diameter at 1000 rpm at a rate of 10 µl/min. Both trilayered grafts were crosslinked for 24 hours in 0.5% genipin in 200 proof ethanol at 37°C. After crosslinking, the grafts were washed 3 times using 200 proof ethanol.

Four TEVG design groups were tested: thin and thick PEUU based TEVGs, and thin and thick PLCL based TEVGs. The grafts were mechanically tested using a custom microbiaxial mechanical device (CellScale, Waterloo, Canada) (**Figure 1**) that pressurized the samples from 5 mmHg to 120 mmHg in a 37°C heated water bath across 10 cycles, imaging the TEVG outer diameters at a frequency of 5 Hz.

Figure 1: Microbiaxial mechanical device.

Throughout the mechanical tests the captured images were utilized to monitor the outer diameter of the TEVG. The first 9 cycles of the testing were used to pre-condition the graft, and the 10th cycle was the

testing phase. Compliance was calculated using the outer diameters at 70 mmHg and 120 mmHg [4] (**1**). To assess compliance the obtained values were compared to the range of compliance values observed in native rat aortas. Compliance matched values were those that fell within the range of native aortas. Values that fell within this range were considered compliance matched. Grafts with values exceeding this range were classified as hypercompliant indicating excessive elasticity while grafts with values below this range were categorized as hypocompliant indicating excessive stiffness. Compliance values were evaluated in relation to native rat aorta explants. Graft diameters and thicknesses were measured by cutting a cross section and measuring using an Olympus Surgical Microscope. Statistical significances were assessed using ordinary one-way ANOVA with a post-hoc Tukey test for multiple comparisons.

$$\text{Compliance} = \frac{(OD_{120} - OD_{70})/OD_{70}}{50\ \text{mmHg}} \quad (1)$$

RESULTS

The average compliance values of both thick and thin PLCL trilayers were lower than native rat aortas and PEUU trilayers. The average compliance value of thin PEUU trilayers was higher than native rat aortas (**Table 1**). There was a statistical difference ($p<0.05$) in the compliance of the thin PEUU trilayer compared to the thick PEUU trilayer, thin PLCL trilayer, and thick PLCL trilayer. (**Figure 2**). All TEVG designs had a higher average wall thickness than native rat aortas. There was a statistical difference ($p<0.05$) between the native rat aorta wall thickness and the wall thickness of all other designs (**Figure 3**).

Table 1: Average TEVG compliance and wall thickness measurements

Graft Design	Average Compliance ($mmHg^{-1}$)	Average Wall Thickness (μm)
Native Rat Aorta	0.00139	89
PEUU Thin	0.00196	126**
PEUU Thick	0.00114	167***
PLCL Thin	0.00136	159***
PLCL Thick	0.000741*	175***

*/**/*** indicate statistical significance at the 5%/1%/<0.01% in comparison to native rat aortas

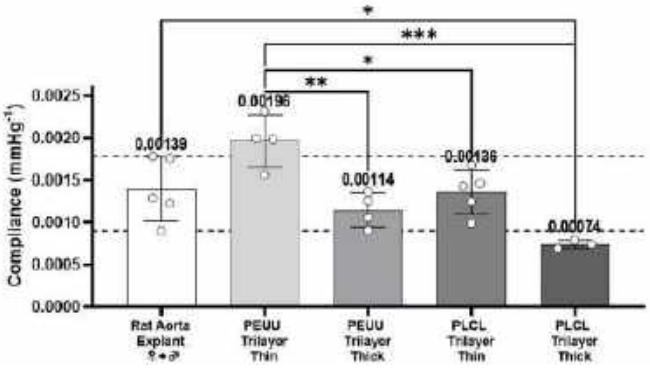

Figure 2: Compliance values of native rat aorta explants in comparison to trilayered TEVG designs, n = 3-5.

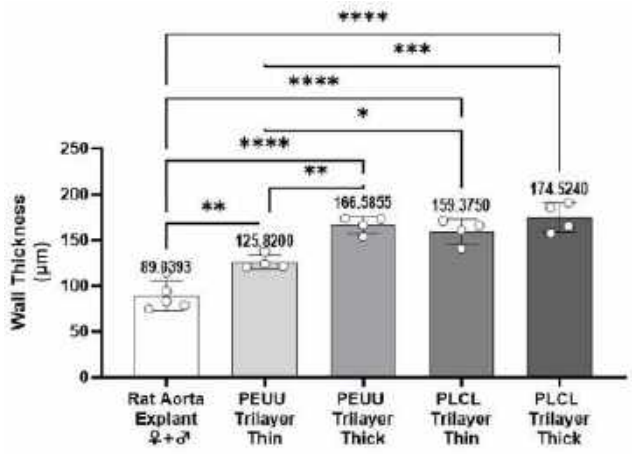

Figure 3: Wall thickness values of native rat aorta explants in comparison to trilayered TEVG designs, n = 4-5.

DISCUSSION

The objective of the study was to develop two compliance matched TEVG designs with tunable compliance. Both the thick PEUU trilayers and thin PLCL trilayers have average values that fall within the compliance range of native rat aortas indicating they are compliance matched. The average compliance value of the thin walled PEUU based trilayers falls above the range of compliance values of native rat aortas, making it hypercompliant, while the average compliance value of the thick walled PLCL based trilayer falls below the range of native rat aorta compliance, making it hypocompliant. The same applies to PLCL trilayers where the average compliance value of thin trilayers matches compliance compared to the average compliance of thick trilayers which are hypocompliant. The difference in average compliance values between thick and thin graft designs of both PEUU and PLCL trilayers suggests that compliance can be modulated by varying the wall thicknesses. All trilayered wall designs were thicker than the native rat aorta wall thickness. The thick PEUU, thin PLCL, and thick PLCL grafts all have relatively similar wall thickness but different compliance values. Compliance is not only impacted by the wall thickness of the grafts but the materials used in the grafts as well. In the future, computational analysis can be utilized to quantify the relationship between wall thickness, biomaterial mixture ratios, and compliance. Future work will also include both *in vitro* and *in vivo* studies to verify the anti-thrombogenicity of PESBUU-50 in TEVGs, as well as the extent of cellular infiltration and remodeling when utilized as an interpositional vascular graft. Trilayered TEVGs can be compliance matched to native rat aortas, and compliance can be modified by changing the graft thickness or materials in the grafts.

INTRODUCTION

Every day, more than 2,100 people in the United States suffer from stroke.[1] 70% of stroke survivors are left with upper extremity impairments leaving them unable to carry out everyday tasks.[2] Physical rehab within the first 3 months post-stroke is critical for maximizing recovery for these patients, but unfortunately 35% of stroke survivors do not receive any physical therapy.[3,4]

Given over 70% of stroke patients are discharged to their homes, the lack of rehabilitative care can be attributed to low participation in outpatient care programs.[5] Reasons for this include transportation issues and limited insurance coverage resulting in high out-of-pocket costs.[6] Without any other option, family members are forced to become the primary source of care for stroke survivors without any training or support system.[7] This responsibility creates enormous physical, psychological, and economic strain for families.

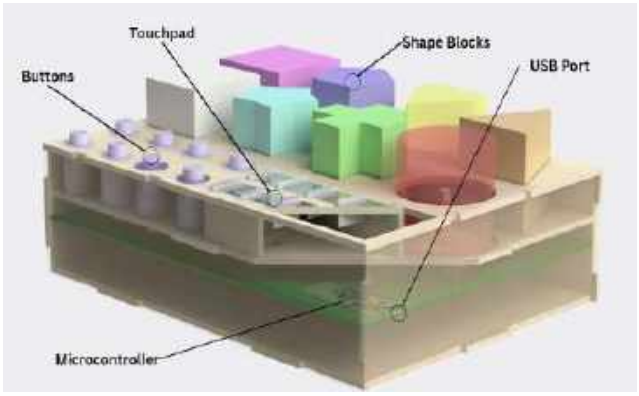
In response to this challenge, mobile health apps utilize widespread smartphone ownership to establish an at-home therapy environment. However, research indicates optimal recovery of hand functionality in stroke patients requires a combination of physical and app-based therapy.[8] Existing app-based therapies lack integrated physical components to simulate conventional physical therapy methods. On the other hand, home rehabilitation tools simulating physical therapy can cost thousands of dollars, more than most patients can afford.

Given these shortcomings in current outpatient and at-home rehabilitation care, there exists a pressing need for a smart device integrating mobile health and physical therapy for at-home use. The most important stakeholder requirements for such a device come from the patients and caregivers themselves. Any product must minimize cost given the already high financial burden placed on families from stroke-related expenses. The smart device must also be user-friendly, require minimal training, and be usable without help from medical professionals given how transportation is a critical barrier to rehab access. Additionally, the device should provide a user experience that is engaging and serves as a source of motivation for patients throughout their rehabilitation process.

PRODUCT DESIGN

Neuragame is an affordable smart home rehabilitation aid integrating physical and app-based components to facilitate recovery from the physical and neurological effects of stroke. Designed for recovering individuals with limited upper limb dexterity, Neuragame allows patients to improve motor skills, memory, and reaction time through gamified exercises. No professional help is required to use the device. All a caregiver has to do is log into the app, connect the device via USB, and simply help the patient navigate the app. Caregivers no longer have to worry about providing rehabilitative care for their dependents.

Figure 1: Neuragame Physical Interface



Caregivers/patients interact with the app to start activities and track progress. Exercises fitting the needs of the patient can be selected with personalized recommendations also being generated based on patient progress. A tutorial video is included in the app to show users how to complete each activity. A patient's progress is recorded offline in an authenticated database with infrastructure available to upload it for a medical professional to view, as requested.

The physical interface is composed of a plastic casing that houses the main printed circuit board (PCB). The encasing is a box-like structure incorporating shape blocks, buttons, and a touchpad (embedded as a separate, smaller PCB in the encasing) for use in the games. The main PCB connects sensors that can detect shape rotations, button presses, and touchpad selections to the microcontroller, which is responsible for communication with the app via USB.

Each part of the board is used in multiple games emulating clinically proven rehab exercises to target distinct aspects of stroke recovery. Modeled after the clinically-validated Nine Hole Peg Test, the blocks can be removed and rotated in games such as "Shape Rotation" for patients to practice hand-eye coordination and improve grip strength. The touchpad promotes stimulus-response, memory, and finger dexterity by simulating piano keys and teaching users to repeat simple patterns through a clinically-proven exercise called finger-tapping. The buttons can be used in a variety of games such as Whack-A-Mole to improve stimulus-response and reaction time by having users press specified buttons in an allotted amount of time. These are just a few examples of games inspired by exercises used in conventional therapy that are integrated in Neuragame. Performance on these clinically-proven exercises are used as recovery markers in providing tailored recommendations.

The technical design takes into account several challenges. One key issue was the app-device communication method. Although wireless communication has become more prevalent, compatibility issues across different smartphone hardware can arise. Instead, USB communication was chosen because of its reliability independent of smartphone hardware and its convenience as a power source for the physical interface. Additionally, connecting the touchpad PCB to the main PCB posed a challenge. Since manually adding wires does not create a reliable connection, a ribbon cable is used instead, similar to the internal connections of a smartphone.

All parts have been designed with manufacturing feasibility in mind. The plastic housing, buttons, and shape blocks of the physical interface can all be produced at high volumes through plastic injection molding, a commonly employed method in commercial manufacturing. For the touchpad and main PCB, the PCB production can be outsourced with a manufacturing facility completing the final assembly of the PCBs and the housing.

BUDGET AND MARKET ANALYSIS

Considering the initial target market of stroke survivors with upper extremity impairments unable to afford traditional physical rehabilitation, the potential US market size is approximately 155,000 individuals annually.[1,2,4] The product, estimated to cost $30 for mass manufacturing, incurs an initial expense of $170,000 for injection molding (for initial production capacity of 100,000 units annually) with no other major investment costs required. Accounting for Neuragame's projected sales price of $70 and $60 expenses per unit (including manufacturing costs & related expenses), there is a 14% net profit margin. Assuming a 20% adoption rate within the US market, Neuragame could generate approximately $2.17 million in revenue annually. With a net profit of about $310,000 annually and the mentioned expenses, the ROI is estimated to be 17%. These projections are specific to the mentioned US market and do not take into account opportunities in other countries. Thus, they should be viewed as highly conservative. The below design budget would allow for complete preliminary engineering testing prior to clinical trials and patent filings.

Table 1: Estimated Design Budget Calculation

Item	Cost
Raspberry Pi Pico H	$30.00
Capacitive Touch 12-Key Sensor	$40.00
Hall Effect Sensors	$10.00
I2C Multiplexer	$17.00
Logic Analyzer	$26.00
Magnets	$20.00
PCB	$200.00
Buttons	$20.00
Wood	$50.00
Assorted Resistors	$30.00
Assorted Capacitors	$30.00
iPhone X (Used)	$200.00
Tecno Smartphone (Used)	$175.00
Vivo Smartphone (Used)	$150.00
Total	$998.00

INTRODUCTION

The development of atherosclerosis tends to occur at branches within the arterial tree, such as the carotid artery bifurcation. The geometric features of the carotid artery bifurcation have been linked to an increased risk factor for atherosclerosis disease, due to the impact of particular geometries on hemodynamic disturbances[1]. These hemodynamic factors include increased complex flow, reduced time-average wall shear stress (TAWSS), and increased oscillatory wall shear index (OSI)- leading to local vasculature endothelial cell dysfunction.[2] Due to the potential relationship between atherosclerotic plaque development and variations in carotid geometries, previous studies have investigated how carotid bifurcation geometry may serve as a predictor of complex flow and vessel wall thickening.[3,4] *This study aimed to analyze the influence of geometric features of the carotid bifurcation on the development of atherosclerosis by comparing 4D Flow MRI analysis in healthy carotid bifurcations and carotid bifurcations in patients with atherosclerosis.*

METHODS

Patient Population and Image Acquisition: All subjects were imaged on a 3T system (MAGNETOM Prismafit, Siemens Medical Solutions). The study population includes subjects with mild atherosclerosis disease (ICA n=10 from 8 patients, 4F, age 72±10, mean stenosis of 40±10%), and healthy volunteers (ICA n=12 from 8 patients, 7F, age 42±13). 4D flow MRI images were acquired for each carotid (FOV=162*200mm^2, resolution=1mm^3; flip-angle=7°; TR=45ms; TE=5ms). Additionally, Multi-slab, transverse, 3D time of flight (TOF) images were acquired to cover the bifurcation (0.5mm, TR=23ms, TE=3.1ms). The carotid artery was segmented from the TOF images using the open-source 3D Slicer Software.

Geometric Analysis: Geometric analysis of the segmented vessels was accomplished using the Vascular Modeling Toolkit (VMTK), an open-source software that has previously been used in the literature for the geometric analysis of 3D vascular segments.[4] The VMTK extension within the 3D Slicer application was utilized to calculate and provide further geometric analysis of the vessels when the centerline is generated within the 3D Slicer (Figure 1). Using the geometric data acquired from VMTK, the bifurcation angle and the internal carotid artery (ICA) angles were determined by using methods described by Thomas et al.[4] The carotid bifurcation angle was determined by taking the difference between the in-plane angles of the ICA and the external carotid artery (ECA). The ICA angle was determined by taking the supplementary angle of the difference between in-plane angles of the common carotid artery (CCA) and ICA.

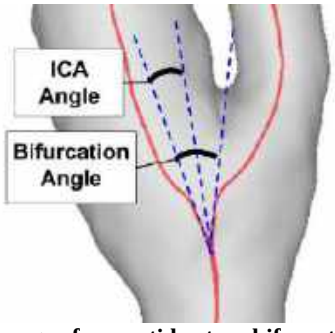

Figure 1. An image of a carotid artery bifurcation centerline visualization from 3D Slicer with the measured bifurcation angle and ICA angle labeled.

4D Flow Analysis: Processing was performed using a custom-written MATLAB code to correct for eddy currents and aliasing, perform noise filtering, and create a 3D magnetic resonance angiogram (MRA)[5]. MRA images were segmented using Mimics and

imported into EnSight (ANSYS Inc, 2019) for streamline visualization and extracting 2D planes. Four planes were placed perpendicular to the centerline: the CCA plane at one CCA diameter (D) below the carotid bifurcation, and the ICA planes at 0.5D, 1D, and 1.5D (ICA 1, 2, and 3 respectively) downstream from the maximum stenosis in subjects with atherosclerosis or from the bifurcation in healthy subjects. TAWSS and OSI have been linked to vascular dysfunction. Therefore, TAWSS and OSI were quantified using MATLAB allowing manual lumen contours as vessel walls for all time frames[6].

Statistical Analysis: The geometric factors were plotted versus TAWSS and OSI data from each vessel, and then a line of best fit was computed and an R^2 value was acquired. The geometric factors and flow data were then divided into healthy and atherosclerotic subjects and t-tests were performed to determine significant differences. The significant factors were then analyzed through 2x2 contingency tables. These factors were given cut offs that gave a minimum sensitivity of 0.7 and then maximized both specificity and sensitivity, giving the bifurcation angle a cutoff of 50°, ICA angle a cutoff of 30°, TAWSS at ICA 1 and ICA 2 a cutoff of 0.3 Pa, and OSI a cutoff of 3%.

RESULTS

Geometric Factors and 4D Flow MRI: TAWSS showed a positive correlation to bifurcation angle (R^2 = 0.39) at ICA 1 (Figure 2). This relationship was not significant between TAWSS and bifurcation angle at CCA (R^2 = 0.1932), ICA 2 (R^2 = 0.1179), and ICA 3 (R^2 = 0.06). No significant correlation was found between any OSI data points and geometric factors.

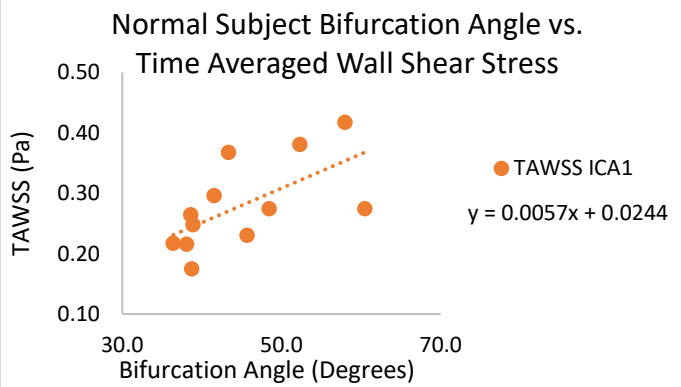

Figure 2. TAWSS ICA 1 plotted against bifurcation angle.

Geometric Risk Factors in Healthy Subjects versus Atherosclerosis Subjects: Several factors were found to be significantly different between the healthy and atherosclerotic subjects including: the bifurcation angle, ICA angle, TAWSS ICA 1, TAWSS ICA 2, and OSI ICA 1. The contingency tables were analyzed for sensitivity, specificity, positive predictive value, and negative predictive value (Table 1).

Table 1. Predictive analysis of geometric and hemodynamic factors on atherosclerosis diagnosis. Equality symbols are used to indicate criteria for higher atherosclerosis risk.

Factor (Cutoff)	Sensitivity	Specificity	Positive Predictive Value	Negative Predictive Value
Bifurcation Angle (>=50°)	0.700	0.750	0.700	0.750
ICA Angle (>=30°)	0.800	0.833	0.800	0.833
TAWSS ICA 1 (>=0.3 Pa)	0.900	0.750	0.750	0.900
TAWSS ICA 2 (>=0.3 Pa)	0.900	0.583	0.643	0.875
OSI ICA 1 (<3%)	0.700	0.833	0.778	0.769

DISCUSSION

The major findings of this study were that 4D Flow MRI showed a significant correlation between the bifurcation angle and TAWSS in ICA 1. It also showed bifurcation angle, ICA Angle, TAWSS at ICA 1 & 2, and OSI at ICA 1 were significantly different between healthy subjects and subjects with atherosclerosis.

Geometric Factor Influence on Wall Shear Stress and Atherosclerosis Risk: Higher bifurcation angles corresponded to higher wall shear stress values in the ICA 1. Furthermore, the bifurcation angle provided a 0.700 sensitivity and 0.750 specificity in separating atherosclerosis subjects from healthy subjects. Larger bifurcation angles were found in atherosclerosis patients, and large bifurcation angles were also associated with higher TAWSS in the healthy subjects. Low WSS is associated with the development of plaque that leads to atherosclerosis, and high WSS develops after the disease has progressed.[7] Higher bifurcation and ICA angles also appear to be good predictors of flow patterns associated with atherosclerosis. Finally, key hemodynamic markers of atherosclerosis such as high TAWSS at ICA 1 and ICA 2 and low OSI at ICA.

In conclusion, geometric factors could be used as one factor in the prediction of atherosclerosis, and the hemodynamics of atherosclerosis seen in this 4D flow MRI study was consistent with previous literature.[7]

Advancing cardiac metrics: computational CMR methods for ejection fraction evaluation

E. Lyon (1); I. Essafri (1); M. Zhang (1); M. Lucero (1); K, Ichimura (2); KR, Stenmark (1); E, Spiekerkoetter (2); VO, Kheyfets (1)

(1) Cardiovascular Pulmonary Research Laboratories, Division of Pediatrics-Critical Care, Department of Medicine and Pediatrics, University of Colorado Anschutz Medical Campus, Aurora, CO, USA.

(2) Department of Medicine, Division of Pulmonary, Allergy and Critical Care Medicine, Stanford University, Stanford, CA, USA.

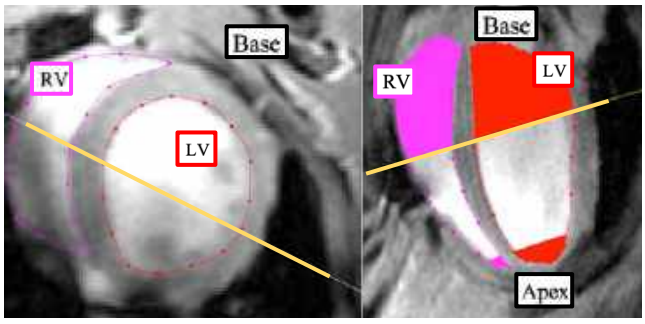
I. Introduction

The ejection fraction (EF, see Eq. 1) is a measure of systolic function that is commonly used in the clinic [1]. Precise EF calculations require accurate right ventricle (RV) and left ventricle (LV) volume measurements. Segmenting the heart cavities from cardiac magnetic resonance (CMR) images is considered the widely accepted, non-invasive, method to acquire LV and RV volumes [2].

$$EF = \frac{End\ Diastolic\ Volume - End\ Systolic\ Volume}{End\ Diastolic\ Volume} \quad (1)$$

For research application, EF is also a commonly used metric to evaluate systolic function in rodent models. A typical CMR image includes multiple short-axis slices (see Fig. 1a), which are acquired along the length of the heart ("transverse plane"), and a single long-axis slice where both ventricles can be seen (see Fig. 1b). Because traditional volume segmentation techniques only rely on the short-axis slices, the accuracy of a volume calculation is limited by the number of short-axis (SA) slices that can be acquired along the transverse plane and the total coverage of those slices.When the 5 short-axis slices fail to cover the entire base-to-apex span (as can be seen in the example Fig. 1b), we suspect it results in omitted volume and an erroneous EF calculation.

The objective of this study was to develop and evaluate different post-processing algorithms that find volume by either only utilizing short-axis slices or combing short-and-long axis slices.



1a. 1b.

Fig. 1. (a) Manually delineated CMR SA slice of the RV and LV (b) LA Slice intersecting the SA slice, showing omitted volume due to SA slice limitations.

II. Methods

Balanced steady state free precession (bSSFP) cine CMR was gathered on nine mice, five Sham (control) and four Pulmonary-Artery-Banded (PAB). Four imaging scans (3 RV, 1 LV) were excluded from the α-shape estimation due to subject movement disrupting acquisition.

A. Segmentation Methods:

CMR segmentation involved the manual endocardium delineation of all required SA slices and one LA slice [3]. The software's intersection of LA and SA slices provided context for segmentation of area with unclear endocardial boundaries.

B. Three Methods for Reconstructing Ventricular Cavity:

We evaluated 3 methods for finding RV and LV cavity volume in rodent CMR images:

1) **Simpson's Disk Summation [4]:** Multiplies the area within the delineated contour by the slice thickness (see Fig. 2a).
2) **SA α-shape estimation:** Estimates cavity volume using short-axis (SA) slices. First, the geometry was aligned so that each short axis slice is parallel to the x-y plane and is stacked from the apex to the base along the z-axis (see Fig. 2a). The most apical point from the long axis view is positioned at the (0,0,0) origin. To create 3D model of the ventricular cavity, an α-shape was created from the short axis slices where each SA slice has 80 known coordinates along the circumference of the cavity (see Fig. 2b).
3) **LA + SA α-shape estimation:** Combines one long-axis (LA) and all available SA slices for volume estimation. After applying model realignment (described in SA α-shape estimation), shape-preserving piecewise cubic interpolation is used to create a 3-dimensional point cloud (See Fig. 2c). An α-shape is then created from the resulting point cloud, which can be used to compute the shape volume.

Standard rodent CMR is acquired with 5 SA slices and assumes the slices will cover most of the volume. This assumption may not be true. We aimed to evaluate how these 3 methods withstand the limitations of data acquisition. Therefore, we segmented each CMR image under two conditions: (1) Using all available short-axis slices (*Non-Truncated*) and (2) removing the most apical and basal slice (*Truncated*). Non-Truncated segmentations incorporate data from more slices to provide a more precise volume estimate. The agreement between Non-Truncated and Truncated was evaluated with linear regression and Bland-Altman analysis. Greater agreement across truncation status indicates higher accuracy in volume measurement.

Fig. 2 compared methods for volume calculation: (a) Simpson's Disc Summation; (b) SA α-shape estimation; (c) LA + SA α-shape estimation

C. Numerical Volume Calculation of an α-shape:

The CMR segmentation for the SA α-shape estimation and LA + SA α-shape estimation were post-processed using our in-house software (MATLAB, MathWorks, MA). There are multiple methods for computing an α-shape volume, but many can result in error when there are holes on the surface. To avoid this issue, we utilized a Monte Carlo technique that randomly assigns the domain 1e6 points while keeping track of the number of points that landed within the α-shape. The ratio of points that landed within the α-shape versus the total number of points assigned to the domain is directly proportional to the cavity volume.

III. Results

Stronger agreement between Non-Truncated and Truncated segmentations is observed with α-shape estimations (SA and SA+LA) compared to Simpson Disc Summation.

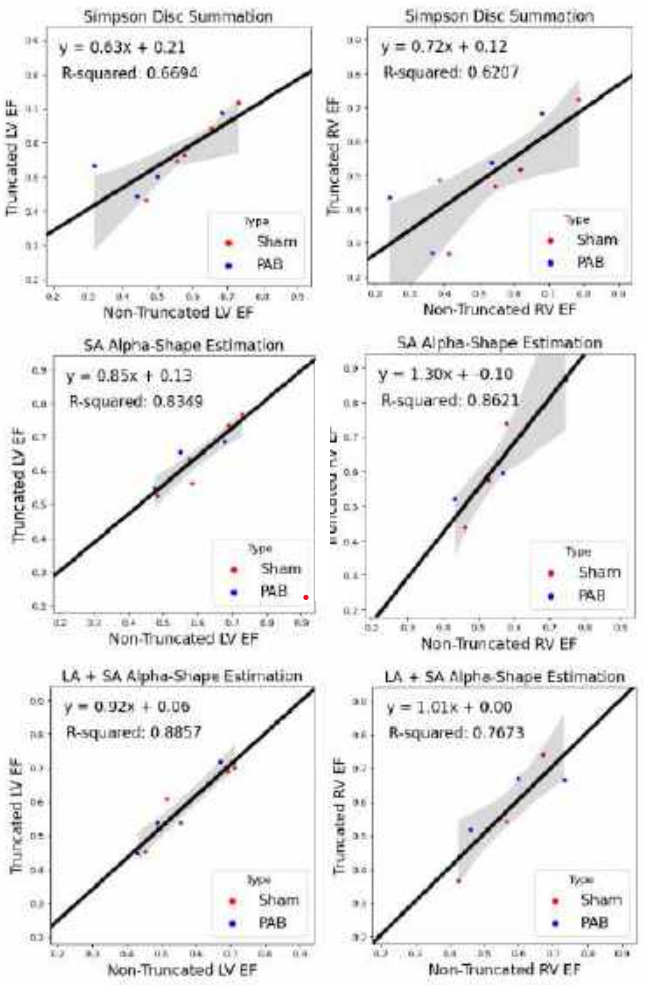


Fig. 3: Linear regression of Non-Truncated vs. Truncated EF estiamtes for LV and RV using three methods.

While correlation analysis offers the degree of covariance, Bland-Altman (BA) analysis measures the agreement between the Non-Truncated and Truncated segmentations. Our findings revealed the LA + SA α-shape method to be the most accurate method of volume acquisition considering BA analysis (see Table 1) and correlation (see Fig. 3).

TABLE I. Bland Altman Analysis

Volume Assessment Method	LV		RV	
	Mean Difference	*±1.96 SD (mL)*	*Mean Difference*	*±1.96 SD (mL)*
Simpson Disc Summation Non-Truncated vs. Truncated	-0.01	± 0.14	0.02	± 0.20
SA α-shape estimation Non-Truncated vs. Truncated	-0.04	± 0.07	-0.07	± 0.12
LA + SA α-shape estimation Non-Truncated vs. Truncated	-0.02	± 0.07	-0.01	± 0.11

IV. Discussion

Given the technical limitations of acquiring CMR images in rodents, our study compared 3 methods for computing ventricular cavity volume in healthy and PAB mice. The Simpson method uses Euler's method for volume integration along the transverse plane with global truncation error on the order of the slice thickness (h). This reveals drastically different EF calculations based on the number of short-axis slices acquired. Discrepancies were more pronounced in the RV due to its unique shape and CMR imaging alignment favoring the LV, resulting in a substantial amount of RV volume being omitted during acquisition. When we improved longitudinal integration along the SA slices using α-shape SA boundary reconstruction of the cavity volume (with global truncation error on the order of h^2), this improved the accuracy of the integration but does not account for omitted RV volume at the base and apex. Finally, when we combined the SA and LA segmentation with α-shape integration, this resulted in the most consistent estimate of RV EF.

Our study's limitations stem from the constraints of rodent CMR images that lack the clear pixel contrast seen in human cardiac imaging so automatic segmentation was not possible. Incorporating additional LA views could further enhance accuracy but is not a routine practice in CMR. Ongoing studies in our lab are cross-referencing CMR with CT-derived cardiac volumes. We are also performing an inter/intra-observer variability study, alongside exploring machine learning techniques for automated segmentation to account for the complexities of rodent imaging.

FULL-FIELD COMPARISON OF PORCINE PULMONARY AND AORTIC VALVE LEAFLET COLLAGENOUS ARCHITECTURE USING QUANTITATIVE POLARIZED LIGHT IMAGING

Shreya Sreedhar (1), Daniel P. Pearce (1), Connor Link (1), Colleen M. Witzenburg (1)

(1) Department of Biomedical Engineering
University of Wisconsin-Madison
Madison, Wisconsin, USA

INTRODUCTION

Aortic and pulmonary valve leaflets play a crucial role in regulating blood flow from the heart to the body and lungs, respectively. Although similar in shape and physiological function, aortic and pulmonary valve leaflets are subject to vastly different loading conditions [1]. The normal transvalvular pressure at rest for the pulmonary valve is 10 mmHg, and 80 mmHg for the aortic valve. Although aortic valves experience pressures 5-8 fold higher than pulmonary valves, they are only about 2 times thicker than the pulmonary valves [2].

Mechanical testing indicates material properties also differ between leaflets from the semi-lunar valves. Uniaxial mechanical testing indicated that pulmonary valve leaflets exhibited a greater degree of mechanical anisotropy than aortic valve leaflets [3]. Similarly, a biaxial comparison of semi-lunar valves revealed greater anisotropy and lower stiffnesses in pulmonary valve leaflets [4]. Although efforts have been made to characterize the full-field structure of aortic and pulmonary valve leaflets individually, there are few studies comparing their full-field collagenous architectures.

Quantitative polarized light imaging (QPLI) is a technique that capitalizes on the birefringent properties of collagen fibers to quantify full-field anisotropy of thin connective tissues. It provides overall incident light intensity (S0), the angle of linear polarization (AoP), and the degree of linear polarization (DoLP) [5]. Our objective was to apply QPLI to porcine pulmonary and aortic valve leaflets to evaluate and compare their heterogeneous structures. We hypothesized that pulmonary valve leaflets would exhibit similar spatial patterns in AoP and DoLP to aortic valve leaflets but would exhibit higher levels of collagen organization.

METHODS

Sample preparation. Aortic and pulmonary heart valves were excised from the hearts of 5–6-month-old pigs obtained from a local butcher (Hoesly's Meats, New Glarus, WI). Leaflets were stored in phosphate-buffered saline (PBS) and frozen at -80 degrees C. Following thawing, leaflets were carefully placed on a black platform and scanned by the LJ-V7080 laser micrometer (Keyence) at 200 Hz to obtain a 3D thickness profile. A sample aortic leaflet is shown in Fig. 1.

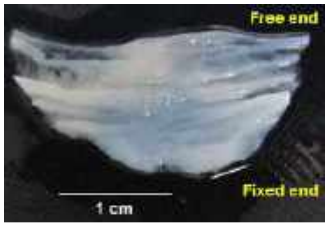

Fig. 1: Sample aortic leaflet

Imaging. Each sample was transferred to a glass platform for QPLI such that its orientation remained the same. The sample was lit by an LED light with a circularly polarized filter and imaged using the Polarization GUI (SpinView) at 20 Hz and the "Polarized8" pixel format.

Data Analysis. For all leaflets imaged S0, DoLP, and AoP were computed from the raw data as done previously [3,5]. Briefly, S0 indicates the overall intensity of incident light. AoP indicates the angle of linear polarization and is a measure of the preferred collagen fiber angle. DoLP indicates the degree of linear polarization and is a measure of fiber angle preference, with a value of 0 indicating no alignment and 1 indicating total alignment. Spatial values of thickness, S0, and DoLP were plotted against one another for each leaflet. A Pearson's correlation coefficient (r) was calculated to quantify the correlation and an α-value of less than 0.05 was considered significant. A Welch's t-test was then applied to determine if there was a significant difference

between the correlation coefficients for the aortic and pulmonary samples.

RESULTS

Fig. 2 includes the raw thickness and S0 values from laser micrometry and QPLI, respectively, for a representative pulmonary leaflet. A visual comparison suggests an inverse relationship between thickness and intensity: in regions of high thickness, S0 was low, and in regions of low thickness, S0 was high. To quantitatively compare the spatial distributions of each metric, a rotational matrix was used to warp the values of thickness to fit the shape of the S0 plot for each leaflet. Aortic valve leaflets had a significantly larger mean spatial thickness (0.80 ± 0.10 mm) than pulmonary valve leaflets (0.67 ± 0.08 mm) (Fig. 4A).

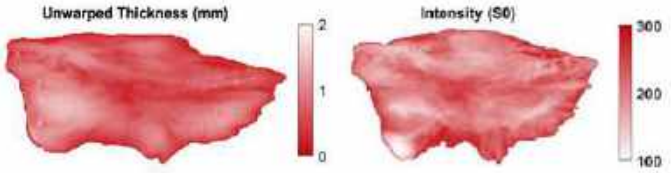

Fig. 2: Unwarped Thickness (left) and S0 (right) for a representative pulmonary valve leaflet.

Fig. 3 includes the S0, warped thickness in mm, DoLP, and AoP in degrees for representative aortic and pulmonary leaflets. In both the representative aortic and pulmonary valve leaflets, S0 and warped thickness follow correlated spatial patterns – in regions of high thickness, there was lower S0. There is also a larger region of low DoLP in the aortic leaflet in comparison to the pulmonary leaflet. AoP is a useful metric when DoLP is high since it provides directionality to the collagen fibers. In the representative leaflets below, the pulmonary leaflet displays more variation in fiber angle than the aortic leaflet.

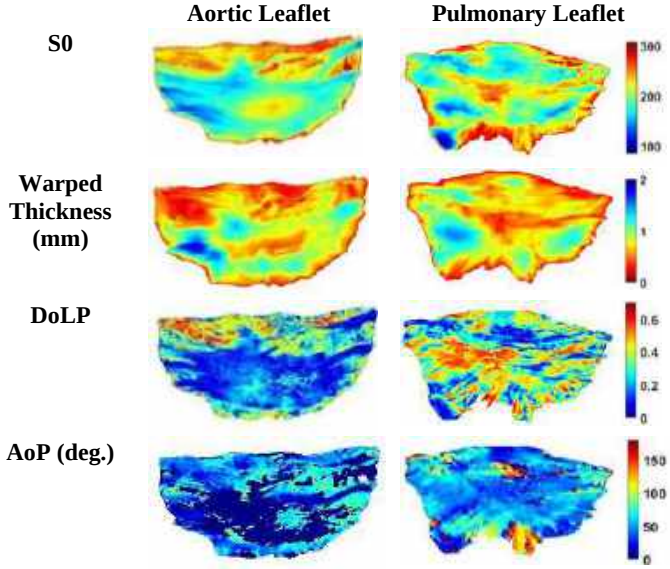

Fig. 3: S0, Warped Thickness (mm), DoLP, and AoP (deg.) for representative aortic and pulmonary valve leaflets.

Fig. 4B-C displays a DoLP comparison, and the correlation coefficient (r) values for DoLP and warped thickness, for aortic and pulmonary valve leaflets. Each metric was computed using a pixel-to-pixel correlation and *p*-values for every sample were below 1e-10. The mean DoLP values were 0.24 ± 0.04 and 0.31 ± 0.04 for aortic and pulmonary leaflets respectively, indicating that DoLP was significantly lower in the aortic leaflets than the pulmonary leaflets. Correlations between DoLP and warped thickness, and S0 and DoLP were more pronounced in aortic valve leaflets. A t-test for S0 and warped thickness was also performed. They were negatively correlated for both aortic and pulmonary leaflets, but there was no difference in correlation between the two groups.

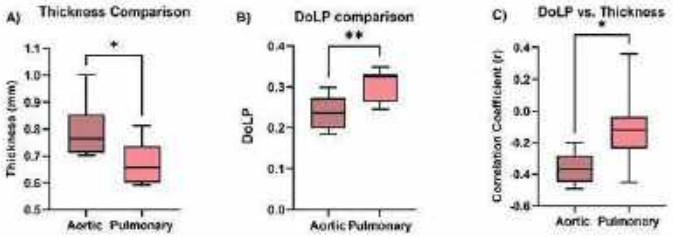

Fig. 4: Box and whisker plot of the A) Thickness comparison, B) DoLP comparison, and correlation coefficient (r) for C) DoLP vs. Thickness. **Indicates statistical significance (α < 0.01). * Indicates statistical significance (α < 0.05).

DISCUSSION

We obtained spatial distributions of S0, AoP, and DoLP for both aortic and pulmonary porcine valve leaflets. All samples showed patterns of low alignment in the belly region, similar to previous studies [6], however, there was a more distinct belly region of disorganized collagen in aortic leaflets. The mean DoLP values were significantly higher for the pulmonary leaflets, indicating a higher level of organization in the pulmonary leaflets. Clinically, heart valve failure is more likely to occur on the left side of the heart, so comparing the ECM organization between valve types can further our understanding of their reason for failure [7]. Furthermore, the aortic valve leaflets exhibited a significantly higher mean thickness than the pulmonary leaflets. However, the observed 15% difference between means is considerably lower than the 5-8 times greater pressure gradient experienced by the aortic valve compared to the pulmonary valve [2]. This disproportionality in thickness and *in vivo* pressure warrants further exploration of the ECM structure in both leaflet types. In addition, both the aortic and pulmonary leaflets exhibited a strong negative correlation between light intensity and thickness, while thickness and DoLP exhibited a much weaker negative correlation, indicating that DoLP provides separate information from S0. Additionally, amongst the various valve leaflets, there appeared to be disparate relationships linking ECM organization and thickness (Fig. 4C); the reason for this remains a mystery and warrants further exploration.

Future work will include a quantitative regional analysis between aortic and pulmonary leaflets to determine differences in spatial trends between the two tissues, as well as dynamic imaging of leaflets during biaxial loading. Dynamic imaging will provide more information on collagen fiber alignment and rotation during alternative loading conditions, which can reveal more about the function of the tissue's ECM. We will also conduct further investigation into the effects of warping and reducing the error involved in warping the thickness scan. Ultimately, studying the full-field organization of each valve leaflet's heterogenous ECM can give insight into how their *in vivo* function relates to their structure and inform therapies and prosthetics seeking to mimic this relationship.

INTRODUCTION

Complications due to preterm birth (PTB, delivery <37 weeks) were the most common cause of death for children under 5 in 2019 [1]. Globally, PTB occurs in about 10% of live births [1]. Despite its clinical importance, PTB is difficult to predict. Current prediction methods are based upon measurements of cervical length (CL) using transvaginal ultrasound, with a shorter cervix associated with increased risk. However, the positive predictive value of a short cervix for predicting preterm birth is only 15-33% for singleton pregnancies [2]. It is known that cervical mechanical integrity is important for term delivery, thus mechanical assessment methods may improve PTB prediction [3].

A novel device for PTB prediction is the Pregnolia system, which tests the stiffness of the cervix via aspiration [4]. The device consists of a vacuum pump connected to a probe placed on the anterior cervical face. Once the probe makes full tissue contact, a negative pressure is applied, pulling the cervical tissue 4 mm into the probe. After this deformation, the vacuum stops, and the final pressure is recorded. Three measurements are taken, and the average is reported as aspirated cervical stiffness (aCS, [mbar]). Recent work has shown that patients with a short cervix and no PTB history who delivered <30 weeks have a significantly lower aCS value than patients with a short cervix who delivered >30 weeks [5]. We believe PTB prediction could be further improved with *in-silico* simulation of this *in-vivo* mechanical test.

The goal of this study is to determine patient-specific cervical material properties using numerical simulation of cervical aspiration efficiently and accurately, which could be used to enhance PTB prediction. Using transvaginal ultrasound images of patient cervices and their corresponding aCS values, inverse finite element analysis (IFEA) was performed on models of patients at low- and high-risk for PTB to find computed cervical stiffness values (cCS). Each patient was modeled with three different levels of cervical geometry fidelity. The resulting material properties were compared to determine the necessary level of geometric detail for application to PTB prediction.

METHODS

To create three-dimensional patient specific cervix models, transvaginal ultrasound images of three low risk for PTB (screened against known PTB risk factors) and three high risk for PTB (CL < 20 mm, no PTB history) pregnant patients were examined and measured. Patients were selected to cover a range of cervical sizes and aCS values. For each patient, three different cervix models were created in SolidWorks: a high-fidelity (HF, ~60 measurements), a medium-fidelity (MF, ~20 measurements), and a low-fidelity (LF, 3 measurements) model. The LF model parameters were identical to those used to model the cervix in previous patient-specific parametric cervical models [6]. MF and HF models were developed for this study.

The boundary of the cervix was labelled in transvaginal ultrasound images by a clinician as previously described (Fig. 1a) [7]. Images were then imported to ImageJ software for measurement. An approximate boundary separating the uterus and cervix was drawn by extending the outer edge of the uterus across the cervix. The cervical canal was used to find the cervical length. The outside lengths of the anterior and posterior regions of the cervix were measured and split into ten percent intervals. At each interval, the cervical diameter (CD) was recorded. Lines collinear with the CD were drawn between the anterior cervical boundary and the cervical canal, as well as between the posterior cervical boundary and the cervical canal to measure the anterior and posterior cervical radii, respectively. Cervical canal measurements were calculated by taking the difference between each CD measurement and its corresponding cervical radii measurements. For HF models, CD angle was recorded as the angle between each CD and the cervical base.

After measurements were recorded, a baseline sketch was made in SolidWorks. In the HF and MF models, CD measurements were incorporated as circles and connected with a spline. Sketched circles were lofted to create the outer boundary of cervical tissue, with the HF incorporating angles between CD measurements. To create the cervical canal, canal diameters were drawn in SolidWorks and connected with a

spline, and a lofted cut was used. To improve computational efficiency, only the left half of the cervix was used (Fig. 1b,c). The LF was modeled as a quarter cylinder, with a radius of half the CD and length of CL (Fig. 1d). To model the aspiration probe, a 4 mm long cylindrical tube was added to the top anterior edge of the cervix. The placement of the probe was based on the clinical instructions for device placement [8].

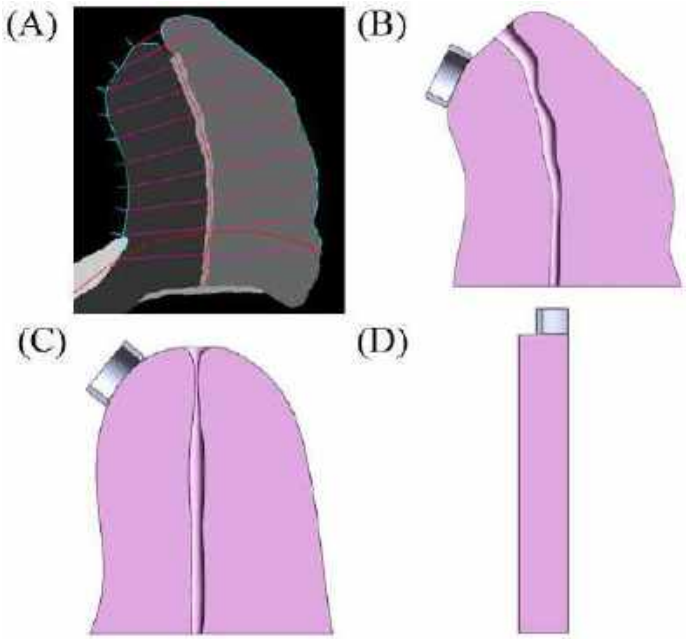

Figure 1: (A) Masked ultrasound image of low risk for PTB patient with parametric measurements. Corresponding (B) HF, (C) MF and (D) LF parametric solid cervical models.

All models were imported to Hypermesh (Altair Engineering Inc., Troy, MI) and meshed with quadratic tetrahedral elements. Models were then imported to FEBio Studio (v1.3.0) for finite element analysis (FEA). Material properties, boundary conditions, and contacts were defined within FEBio Studio. The cervix was modeled as a passive fiber composite material with a compressible neo-Hookean ground substance fit to existing mechanical tissue tests [9]. To simulate the placement of the aspirator in the HF and MF models, the probe was translated in the xy-plane until it made full contact with the cervix while minimizing tissue strain. Once full contact was reached, negative pressure was applied to the section of tissue directly beneath the aspirator to simulate the suction of cervical tissue into the aspirator. Inverse finite element analysis was then performed to find the exact fiber stiffness (cCS) value necessary for the tissue to be deformed by 4 mm (within 1%). cCS values for HF, MF, and LF models were compared to understand how geometric fidelity affected the numerical outcomes of the simulations. Simulation run time was also considered in the analysis.

RESULTS

The LF, MF, and HF models varied in simulation run time and cCS values across all patients. On average, simulation run time was 0.7 hours for LF, 6 hours for MF, and 7 hours for HF models. No clear trend in cCS values were found, with some high cCS values correlating with lower aCS values, etc. (Tab. 1). Additionally, there was no direct correlation between CL, aCS, and cCS values. In future work, birthing outcomes (pre- vs. at-term) will be incorporated into these analyses to understand whether any of the parameters alone or combined accurately predict PTB.

Table 1: CL, aCS, and LF, MF, and HF cCS values for patients at low and high risk for PTB.

Patient #	CL (mm)	aCS (mbar)	cCS (kPa)		
			LF	MF	HF
Low Risk					
P7	48	113	42	33	18
P16	42	89	32	36	20
P32	40	59	14.1	8.3	9
High Risk					
P1	18	81	6	9	7
P2	7	129	9	0.2	0.3
P6	8	23	0.2	1.47	2.6

DISCUSSION

This study analyzed three parametric methods of patient-specific cervical modeling in aspiration simulations. No clear trends between models were found, with differences between fidelities ranging from 0.1-24 kPa. However, it was clear that the LF model had the fastest simulation time, being 4-24 times faster than the MF and HF models. Ideally, the modeling approach for widespread implementation would maintain the trends of the highest-fidelity model but also take the least amount of time to measure and simulate. Ultimately, the HF and MF models presumably display more accurate cCS values (because their geometries bear more resemblance to ultrasound images), but their slow run times make them impractical candidates for population-level analyses. Therefore, in the future, we plan to implement the LF approach in large cohorts of patients at low and high risk for PTB to determine if it alone can improve PTB prediction.

There are several limitations to this study. First, the small sample size limits the conclusions that can be drawn about the best modeling approach, and delivery outcome analysis is necessary. The strain-minimizing approach for probe placement was also a source of inter-model error, as it was geometry-dependent, so different strains were applied to MF and HF models of the same patient. Thus, the difference in cCS values may be partially attributed to discrepancies in tissue strain prior to pressure application. This is one reason that LF models are preferred for future iterations; they do not require any applied strain. It must also be noted that the cervix position during a speculum exam may not be an exact match to the ultrasonic image, potentially making the HF model inconsistent with *in-vivo* conditions. Lastly, a mesh-size convergence study was not performed, though a conservatively fine mesh was used for all models. A coarser meshing scheme may yield faster simulation runtimes with the same resulting cCS value.

3D GEOMETRIC RECONSTRUCTION OF ELECTROSPUN FIBERS

INTRODUCTION

Electrospun fibrous meshes serve as excellent biomaterial scaffolds owing to their structural similarities to extracellular matrices and their tunable material properties due to the electrospinning process. In a previous study modeling the complex biaxial and shear mechanical behavior of these meshes, presence of novel fiber-fiber interactions was observed [1]. Present understanding of electrospun meshes is limited to 2D statistical fibrous network models using a theoretical fiber density, fiber intersection density, and orientation distribution function [2]. This study presents the first accurate 3D reconstruction and structural analysis of electrospun fiber geometry with the goal of understanding how fiber-fiber interactions at the microscale level may impact the bulk mechanical properties of electrospun fibrous meshes.

METHODS

A randomly oriented electrospun polycarbonate urethane fiber mesh was imaged into 3D nanoCT images with a cubic voxel resolution of $(180\ nm)^3$ (Figure 1). Parameters, such as fiber diameter and fiber volume fraction, were collected in ImageJ. Fiber diameter was averaged across 10 randomly chosen fibers within a resliced image. Total fiber volume fraction was calculated by binarizing the nanoCT images and computing the fraction of voxels corresponding to a fiber to the total number of voxels. A grayscale binarization value of 170 minimized image noise. A representative volume element (RVE) size was determined using a convergence analysis for fiber volume fractions; incrementally larger children cubic volume subsets originating from the vertices of the largest possible cubic parent volume $(200\ \mu m)^3$ were created from the nanoCT images. Convergence is reached when the fiber volume fractions for all children subsets converge to a single value.

Custom Python scripts were also written to analyze and model fiber segment lengths and fiber intersection points within the electrospun fiber mesh. First, resliced nanoCT images were imported and cropped to provide smaller cubic subsets of data to analyze. Next, the images were binarized, denoised, and 3D skeletonized to demarcate all fiber centerlines. Using the fiber centerline data, a connectivity plot was created to identify fiber intersections (nodes) and individual fiber segments between fiber intersections (vertices) in a 3D graph structure. Finally, residual image artifacts were removed, fiber segment lengths and the number of fibers per fiber intersection point from the 3D connectivity graphs were extracted, and 3D fiber connectivity was visualized (Figure 2).

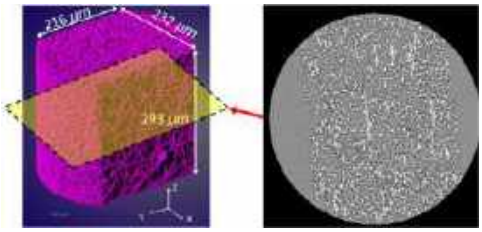

Figure 1: 3D rendering of full electrospun fiber mesh. A cut section depicts one of 1628 original image slices stacked across Z. Image resolution: 345 µm x 361 µm. Voxel resolution: $(180\ nm)^3$.

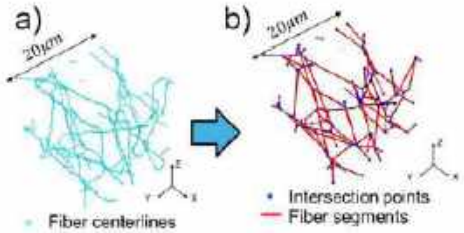

Figure 2: (a) Fiber centerlines and (b) fiber connectivity for a $(20\ \mu m)^3$ cubic volume.

Convergence of fiber segment lengths and convergence of the number of fibers per fiber intersection point were also considered for determining the RVE size. The largest possible cubic parent volume from the 3D connectivity graph (150 μm)^3 was used to create incrementally larger children cubic volume subsets from each of the vertices of this parent volume. Convergence is reached when the fiber segment lengths and number of fibers per fiber intersection point for all children subsets each converge to a single value.

In the next phase of analysis, the established RVE size was used to create a volume mesh for the finite element simulation. The nanoCT images were imported into ORS Dragonfly to generate a surface mesh with triangle elements using the marching cubes algorithm. The surface mesh was then imported into GMSH to create a volume mesh with linear tetrahedral elements using the Delaunay algorithm (Figure 3). The resulting volume mesh for the RVE contained 1,113,547 nodes and 3,465,484 elements. As a preliminary test, a linear ramping uniaxial planar displacement test was simulated using an implicit finite element analysis with Abaqus/Standard for a 20% displacement. The mechanical properties of the RVE mesh were approximated using an isotropic Neo-Hookean material model (C1 = 2.5 Pa, D1 = 0.005 Pa^{-1}).

$$\Psi^{sf} = \begin{cases} c_1(I_1 - 3) + D_1(J-1)^2, & \lambda_f \geq 1 \\ 0, & \lambda_f < 1 \end{cases} \quad (1)$$

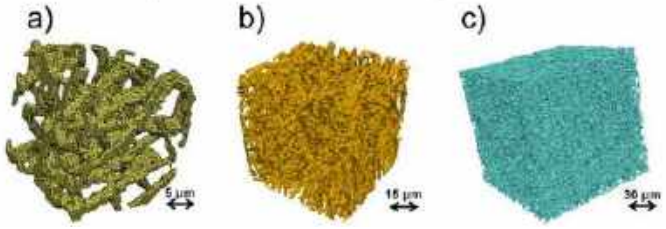

Figure 3: Cubic volume meshes for sizes (a) (25 μm)^3, (b) (90 μm)^3, and (c) (180 μm)^3.

RESULTS

The total fiber volume fraction of the electrospun polycarbonate urethane mesh was 22.14%. The convergence analyses found the RVE size to be a (100 μm)^3 cubic volume because fiber volume fractions from children volume subsets across all parent vertices consolidated at 21.34%; and fiber segment lengths and the number of fibers per fiber intersection point converged to 4.710 ± 2.411 μm and 3.811 ± 1.609, respectively (Figures 4 and 5). Preliminary results for a 20% uniaxial finite element displacement simulation of the RVE demonstrated thinning at the center of the mesh (Figure 6). A nearly linear relationship is found when plotting the sum of forces experienced by the displacement plane with the prescribed displacement (Figure 7).

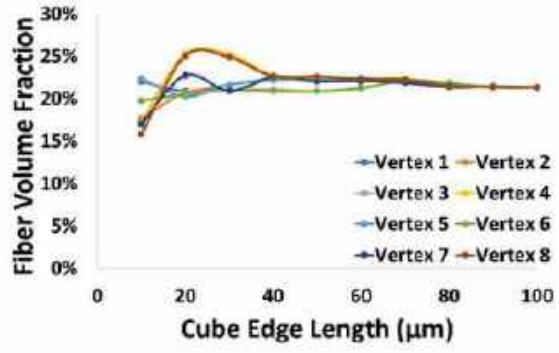

Figure 4: Fiber volume fractions for children volumes converge at 21.34%.

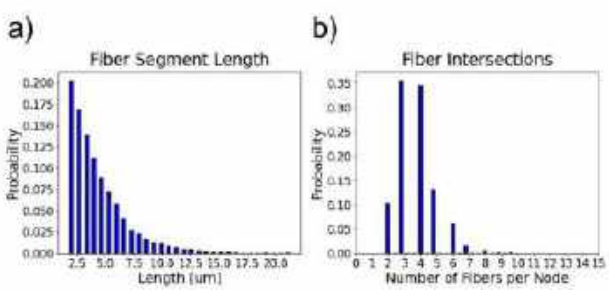

Figure 5: (a) Fiber segment length and (b) fiber intersection distributions for a (100 μm)^3 volume.

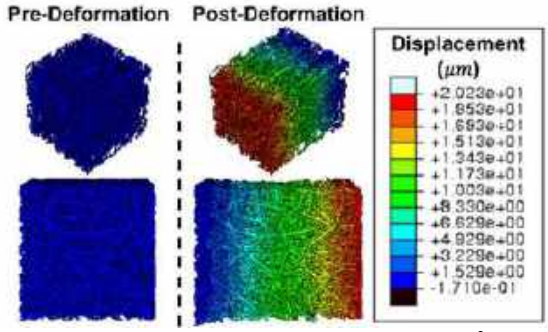

Figure 6: Uniaxial displacement test for (100 μm)^3 fiber mesh. Linear displacement ranges between 0 μm (blue) and 20 μm (red).

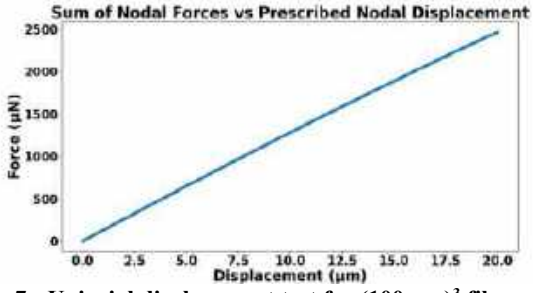

Figure 7: Uniaxial displacement test for (100 μm)^3 fiber mesh. Net force on displaced mesh plane is plot against its linear displacement.

DISCUSSION

This study presents a computational pipeline to develop an accurate and detailed 3D computational model of an electrospun fibrous mesh. Parameters like fiber volume fraction, fiber segment length and number of fibers per fiber intersection point can be extracted to characterize the geometric properties of an electrospun mesh. The linear relationship found from the uniaxial displacement simulation matches the stress-strain trends found in our previous study [2]. Consequent simulations will be performed on the RVE according to the planar biaxial test setup found in [2] and results will be presented at the meeting. Although this study is still in progress, it can grant valuable insight into the bulk mechanics of electrospun fiber meshes based on microscale geometric interactions.

PERSONALIZED FINITE ELEMENT MODELS OF TISSUE EXPANSION FOR BREAST RECONSTRUCTION AFTER MASTECTOMY

INTRODUCTION

Tissue Expansion is a common medical procedure that induces new skin growth to repair large skin defects. It is especially useful in the early stages of breast reconstruction because it can create new skin *in situ* to make space for a permanent breast implant. This method is used in 65% of all breast reconstructions in the United States [1]. However, the current inability to predict the precise amount and location of new skin growth can lead to undesirable cosmetic results and complications, including skin tearing and necrosis, at a frequency of 16% or higher [1]. Our past work has developed and calibrated a mechanical model that predicts local skin growth based on stretch [2]. In this work, we build finite element models of a patient undergoing bilateral breast reconstruction and predict total skin growth in each breast using our computational skin growth model.

METHODS

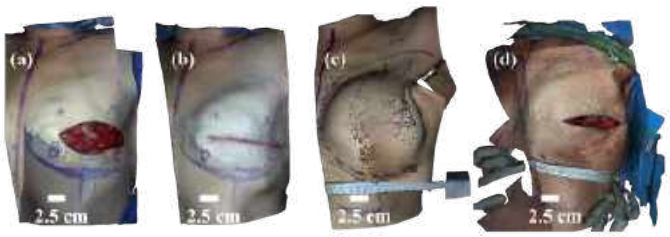

Figure 1: Patient breast scans taken (a) before expander insertion, (b) after expander insertion, (c) after completing the inflation protocol, and (d) immediately after expander removal.

Finite Element Model

Data was collected from a patient undergoing bilateral breast reconstruction (Figure 1 shows the cancerous left breast). To build the finite element models in the software package Abaqus, the surface scans of each breast taken immediately after expander insertion were discretized with 58,260 C3D8 elements for the cancerous breast, and 31,254 elements for the contra-lateral breast. A 14 cm diameter circular expander geometry was created using S4R shell and F3D4 fluid cavity elements. The patient inflation volume protocol (Table 1) was simulated in both breasts.

Table 1: Bilateral Inflation Protocol of Patient

Date [MM/DD]	Volume [ml]	Time [Days]
11/23/21	60	0
11/30/21	180	7
12/16/21	300	23
03/22/22	360	120
09/13/22	450	296

The finite element skin growth model is based on our previous work [2]. Briefly, skin is modeled as a neo-Hookean solid with shear modulus μ. Skin local area deformation is split into growth and elastic parts,

$$\boldsymbol{\theta} = \boldsymbol{\theta}^g \boldsymbol{\theta}^e \quad , \tag{1}$$

with the local area growth rate proportional to the elastic deformation

$$\dot{\theta^g} = k(\theta^e - \theta^{\text{crit}}) \quad , \tag{2}$$

with growth rate parameter k, and critical area stretch θ^{crit}.

Uncertainty Analysis

To account for uncertainty between simulation conditions and the patient treatment, influential simulation design parameters were varied in a design of experiments (Figure 2a). Due to the long time between inflations, we confirmed that the growth parameter had no effect on the final

skin growth and held it constant at $k = 0.48day^{-1}$ based on prior work [2]. The skin shear modulus was also held constant to a realistic value of $\mu = 900kPa$ [3] [4]. θ^{crit} was unknown so a value of $\theta^{\text{crit}} = 1.1567$ from previous work [2] was used initially. Four geometric parameters of interest were sampled, the region of loose skin around the expander tol, the expander offset h, the subcutaneous expander rotation φ, and the expander profile S_x. Their sampling ranges are shown in Table 2. A total of 296 simulations were run between both breasts by sampling the parameters in Table 2 using Latin hypercube sampling.

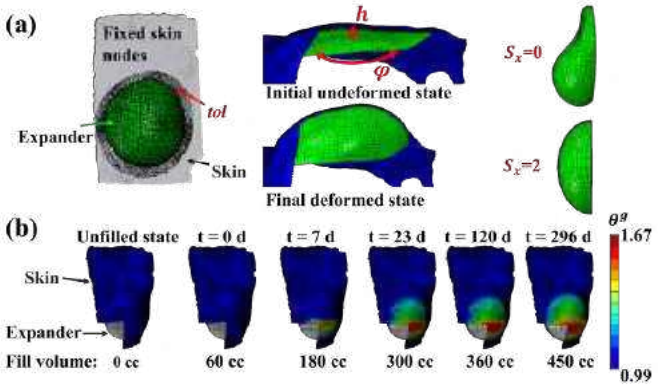

Figure 2: (a) Geometric design parameters varied using LHS and (b) growth θ^g field over time for a single simulation.

Table 2: Ranges for Boundary Conditions

Parameter	Range
tol [mm]	[15, 25]
h [mm]	[2, 10]
φ [deg]	[-15, 15]
S_x	[0, 2]

RESULTS

A representative simulation is illustrated in Figure 2b. As the expander inflates, the skin stretches, deforming more at the apex. Eventually, the stretch surpasses θ^{crit} and skin growth accumulates. The growth field θ^g measures the relative area gain. Contours in Figure 2b show greater growth at the apex. A more useful metric of growth is the integration of the area gain over the entire expanded skin surface, $A^g = \sum A_i^0 \cdot \theta_i^g$ where A_i^0 is the initial element area and θ_i^g is the final growth for each element i on the skin surface.

Simulation nodal coordinates at the final time point were compared against the observed geometry (e.g. Figure 1c for the cancerous breast). The mean distance errors were computed (Figure 3a), resulting in error distributions due to design parameter sampling (Figure 3b, gray). Minimum error thresholds (maximum likelihood) were selected to filter out the simulations that best match the data (Figure 3b, red). By filtering out these best fitting simulations from the overall distribution, the uncertainty in the growth distribution is reduced. The uncalibrated growth prediction distribution $p(A^g)$ is shown in Figure 3c, in gray. After considering only simulations that best match the observed geometry just prior to expander removal, the growth prediction distribution is narrowed (Figure 3c, in red). Since we had access to the relaxed skin geometry after expander removal but before implant placement and the initial geometry before expander insertion (see Figure 1d, Figure 1a), we were able to obtain the experimental values for A^g (Figure 3c, in green). It can be seen that the calibrated area growth predictions based on only *in vivo* data match well the underlying growth value, which can only be measured by removing the expander and measuring the relaxed skin area.

The assumption of the critical stretch $\theta^{\text{crit}} = 1.15$ from previous work is strong, based on porcine experiments [2]. From the results in Figure 3c it appears that this critical stretch is also applicable to human breast skin. However, considering uncertainty in θ^{crit}, greater uncertainty in A^g is shown in Figure 3d.

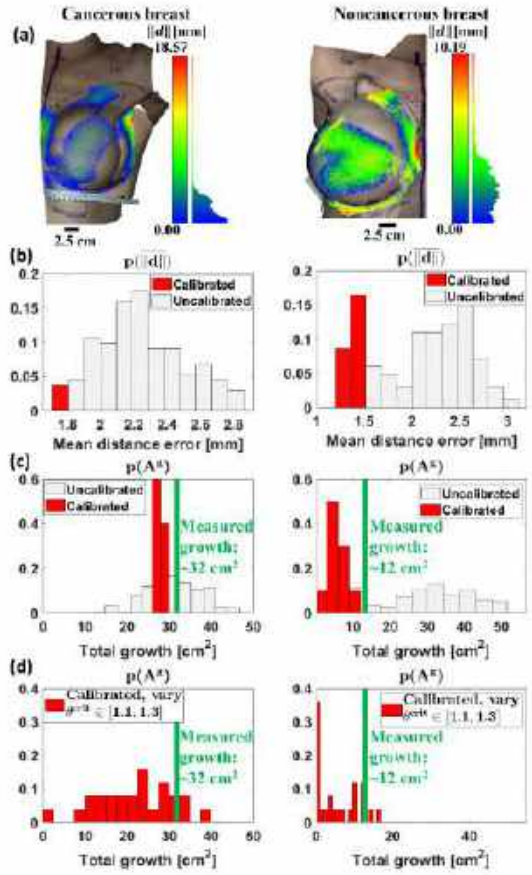

Figure 3: (a) Simulation results aligned with the final surface scan. Mean distance error (b) and total growth (c) distributions for all simulations (grey) and high likelihood results (red) assuming $\theta^{\text{crit}} = 1.15$ align with experimental measurement (green). (d) Growth distribution with additional uncertainty by removing the assumption $\theta^{\text{crit}} = 1.15$ and instead sampling $\theta^{crit} \sim U([1.1, 1.3])$.

DISCUSSION

Our results demonstrate for the first time how tissue expansion can be simulated to make patient-specific predictions in the setting of breast reconstruction. The current simulations are based on extensive prior work validating the model with tissue expansion data in a porcine model [2]. Leveraging that prior knowledge and minimizing the uncertainty with respect to the final deformation observed in-patient, we were able to accurately predict the true skin growth (Figure 3d). More data must be collected to fully characterize the distribution of the growth model parameters in the context of human patients. We anticipate that our model can eventually be used by physicians to inform patient-specific protocols to reduce complication risks, increase the precision of results, and standardize the procedure.

BUILDING ASGR1-OVEREXPRESSED FLUORESCENT REPORTER CELL MODEL FOR OPTIMIZATION OF CRISPR DELIVERY

Yun-I Sang, Morgan Clay, Chun-Wei Chi, Yeh-Hsing Lao

Department of Pharmaceutical Science, University at Buffalo, The State University of New York, Buffalo, New York, USA 14214

INTRODUCTION

CRISPR/Cas9 technology enables precise manipulation at a specific locus of target cell genome through the guidance of its corresponding RNA guide (gRNA). Since the first Cas9 system was reported in 2015, advances in CRISPR/Cas9-mediated genome editing have revolutionized the gene therapy field and led to recent approvals of somatic gene editing therapies with more than 90 ongoing clinical trials and a significant number of different applications in preclinical pipelines,[1] indicating the massive race in the translation of gene editing technologies is currently underway.

Effective delivery is the key to realizing the full potential of this emerging technology. As an exogenous component, CRISPR machinery needs a delivery carrier to reach the target tissue and then enter the target cell. Seeing the recent approval of small interference RNA product applying Asialoglycoprotein Receptor 1 (ASGR1)/N-acetylgalactosamine (GalNac) interaction for in vivo hepatocyte targeting,[2] we are developing new CRISPR delivery approaches adopting this delivery mechanism. As part of this effort, we built an in vitro reporter model to characterize the effectiveness of our designed CRISPR delivery systems, thereby facilitating our screening and optimization processes. Here we present our HEK293T/Ai9-ASGR1 reporter cell model. Integrating both Ai9 (CAG-LoxP-STOP-LoxP-TdTomato) and ASGR1 expression cassettes to the HEK293T cell line, we demonstrate that this reporter cell can be used to screen CRISPR delivery systems and overexpress the ASGR1 receptor on the cell membrane. This in vitro toolkit allows us to screen different GalNac-conjugated CRISPR delivery systems in the downstream pipeline.

METHODS

The Ai9 (CAG-LoxP-STOP-LoxP-TdTomato) expression cassette was first retrieved from the parental plasmid from Addgene (#22799) and cloned to a transposon system then transfected to HEK293T cells. HEK293T/Ai9 stable line was then selected through selection, and TdTomato signal was confirmed by CRE- and Cas9-activation.

The cDNA encoding ASGR1 variant 1 or 2 was then cloned to the lentiviral backbone with a puromycin resistant gene expression cassette. ASGR1-carrying lentiviruses were then generated through co-transfection of ASGR1-trasfer plasmid and packaging plasmids (psPAX2 and pMD2.G) using Calfectin. Media containing lenviruses were collected at 48h and 72h post-transfection and purified using a column method. Viral titer was determined by RT-qPCR using the quantification kit from Abm.

HEK293T/Ai9 cell line was then transduced with ASGR1-lentiviruses (MOI=10). Afterwards, three rounds of puromycin selection were carried out to obtain the final HEK293T/Ai9-ASGR1 reporter line. The level ASGR1 expression for both variants was confirmed by qPCR, while location of ASGR1 confirmed by confocal microscopy.

RESULTS

We first confirmed whether the Ai9 expression cassette was integrated to HEK293T genome. We transfected our generated

HEK293T/Ai9 line with a CRE-encoding plasmid using Lipofectamine 3000. At 48h post-transfection, we were able to detect CRE-activated TdTomato signals and could use this to quantify the efficiency of delivery carrier (Lipofectamine 3000, 35.6 ± 3.5%, **Figure 1A**). To test whether it could be also activated by Cas9, we used our published *Staphylococcus aureus* Cas9 plasmid (Addgene# 207878)[3] encoding Ai9-targeting gRNA to transfect the cell line. Similarly, at 48h post-transfection, we detected Cas9-induced TdTomato signals (**Figure 1B**). These confirm the success of Ai9 cassette integration in the HEK293T cell.

After the second step in generating HEK293T/Ai9-ASGR1 line, we quantified the ASGR1 expression by RT-qPCR. As shown in **Figure 2**, The ASGR1 expression level in the both HEK293T/Ai9-ASGR1 variant 1 and 2 lines was >1,000 times higher than that in the parental HEK293T/Ai9 (ASGR1 variant 1: 1409±119.4 folds; ASGR1 variant 2: 1131±514.5 folds). This confirms the overexpression at the mRNA level in our generated HEK293T/Ai9-ASGR1.

To confirm the location of our overexpressed ASGR1 variant 1 and 2, we carried out immunostaining with ASGR1-specific antibody. The confocal microscope results confirmed that ASGR1 variant 1 is expressed on the cellular membrane, while the parental HEK293T/Ai9 expressed very minimal ASGR1 on membrane as expected (**Figure 3A**). As ASGR1 variant 2 is secreted protein, our immunostaining was therefore not able to visualize it. We also quantified the level using ImageJ. As shown in **Figure 3B**, ASGR1 variant 1-expressing line showed higher intensity than its counterparts (parental HEK293T/Ai9 and HEK293T/Ai9-ASGR1 variant 2), consistent with the results shown in **Figure 3A**. Both qPCR and confocal microscopy results confirm the overexpression of ASGR1 protein in our established cell line model at both mRNA and protein level, and the location of the protein is expected.

DISCUSSION

ASGR1/GalNac interaction has been widely used for small RNA delivery to hepatocyte. Two recent works have also shown the feasibility of using this interaction for CRISPR delivery.[4,5] Our goal here is to establish a cell line model to help our downstream design and optimization of our GalNac-conjugated CRISPR delivery systems for liver targeting. Through two steps of the reporter (Ai9) and ASGR1 expression cassettes, we have successfully established the HEK293T/Ai9-ASGR1 cell model for this purpose. This in vitro reporter model can be used for quantification of gene editing performance (**Figure 1**). The overexpression of ASGR1 variant 1 protein can be used to screen the GalNac-conjugated nanocarriers (**Figure 2**), while two counterparts (HEK293T/Ai9 and HEK293T/Ai9-ASGR1 variant 2) can serve as controls for specificity optimization of the CRISPR delivery carriers (**Figure 3**). Our work here demonstrates a new in vitro model that allows to benchmark the performance of CRISPR delivery systems.

INTRODUCTION

Tendon injuries are one of the most common musculoskeletal injuries in humans[1]. Such injuries can also occur in animals. For example, the superficial digital flexor tendon (SDFT) of the horse is prone to tendonitis[2]. Thus, the SDFT can also serve as a model to study human tendon injuries[3]. SDFT injuries commonly occur in the midsubstance of the tendon, in part due to its smaller cross-sectional area[4]. However, variations in the intrinsic mechanical properties of the tendon could also play a role. Mechanical properties can be studied macroscopically and microscopically, to probe different levels of the hierarchical collagenous extracellular matrix[5]. This can allow mechanics at different scales to be studied independently and determine if a relationship exists between them. The objective of this study was to look at the regional mechanical differences of equine SDFT on the macroscale and microscale and determine if a relationship exists across the length scales.

METHODS

Equine SDFTs were obtained from 3 horses. Subject 1 was a 12-year-old warmblood (WB) mare, Subject 2 was a 4-year-old American quarter horse (QH) and WB filly, and Subject 3 was a 3-year-old QH stallion. The sheath was removed from the outside of the tendon. The tendon was divided into three sections: proximal, middle, and distal. The sections were embedded in Celluclay and sliced into 1 mm thick slices (5-7 slices per section)[6]. From each slice, longitudinal and transverse dog bone punches were taken relative to the long-axis of the tendon using a 10 mm Print-A-Punch[7] and a 1 cm x 1 cm square was taken from the center of the slice for atomic force microscopy (AFM, Asylum Research). Macroscale samples were tested using an Instron (model 5944) with pneumatic clamps to record the elongation and force. The longitudinal and transverse macroscopic samples were pulled to failure at a rate of 1 mm/s. ImageJ was used to measure the gauge length, width, and thickness of the dog bone sample from images taken prior to testing. Stress was calculated by dividing the force by the cross-sectional area, while strain was calculated by dividing the displacement by the length of each sample. The elastic modulus was found by calculating the slope of the linear section of the stress-strain curve using MATLAB. Microscale sections (AFM) were cryosectioned into 10 µm slices. The modulus was found at four points on each sample using a colloidal tip on contact force mode masked and converted to stiffness values using the Hertz model. A one-way ANOVA with Tukey's test (α=0.05) was used for statistical comparisons between subjects and regions separately. Linear regression analysis was done between data for the AFM and longitudinal and transverse testing. Data is presented graphically as mean ± standard deviation.

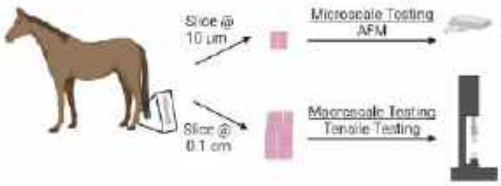

Figure 1: Methodology for testing of equine superficial digital flexor tendon (n=3, age 3-12 yrs. old) at multiple scales

RESULTS

Between subjects, for the macroscale longitudinal modulus, mean values were roughly similar (Fig. 2A). For the macroscale transverse modulus, the mean value for Subject 3 was found to be 2 times larger than Subject 1 and 4 times larger than Subject 2 (Fig. 2B). For the microscale modulus, mean values for Subjects 1 and 2 were 2 times larger than Subject 3. However, no significant differences were found between any subjects for macroscale or microscale testing ($p>0.05$).

Between regions, for macroscale longitudinal samples, the mean values for the proximal and middle sections were about 1.6 times larger than the distal section. For microscale samples, the mean modulus values of the proximal section were about 1.4 times larger than the middle and distal regions. However, for both longitudinal and AFM samples, the differences between regions were not statistically different

(Fig. 3A-B).

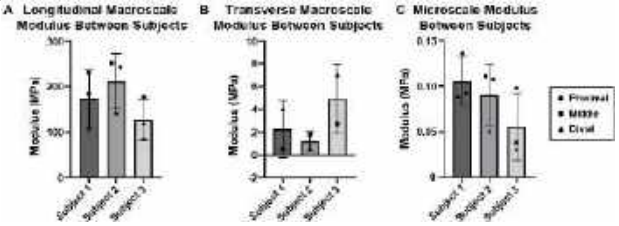

Figure 2: A. Longitudinal macroscale (tensile) modulus for each subject B. Transverse macroscale modulus for each subject C. Microscale (AFM) modulus for each subject

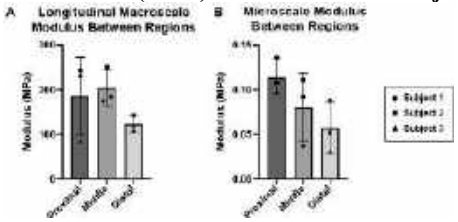

Figure 3: A. Longitudinal macroscale testing data for each region B. Microscale data for each region

Across scales, longitudinal modulus values (170.9 ± 42.6 MPa) were found to be 3 orders of magnitude larger than AFM (0.083 ± 0.025 MPa, $p<0.05$), while transverse macroscale modulus values (2.8 ± 1.9 MPa) were approximately 1 order of magnitude larger than microscale values (Fig. 4A, $p<0.05$). No associations were found between the moduli obtained from microscale and macroscale longitudinal samples ($R^2 = 0.07$, $p = 0.06$), microscale and macroscale transverse samples ($R^2 = 0.02$, $p = 0.50$) and macroscale longitudinal and transverse samples ($R^2 = 0.01$, $p = 0.69$) (Fig. 4B-D).

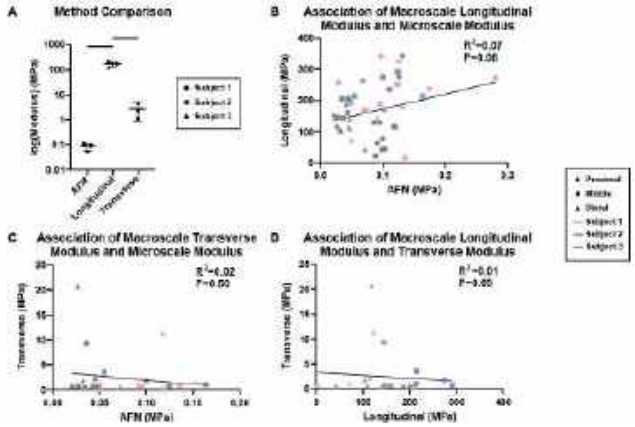

Figure 4: A. Macroscale and microscale method comparison (bar represents $p<0.05$) B. Associations between macroscale longitudinal tensile testing and microscale C. Associations between macroscale transverse tensile testing and microscale D. Associations between macroscale longitudinal and transverse tensile testing

DISCUSSION

This study showed that mechanical properties for the equine SDFT obtained from the microscale are not strongly associated with properties obtained from macroscale testing. Between subjects, there was no consistent rank-order in terms of modulus values.

When looking at the different regions, values were again not consistent in terms of rank-order across the different testing methods. wed by the proximal and distal region. Subject 3 did have an unusually low moduli for the proximal region for the longitudinal testing which may partially explain the difference between the longitudinal macroscale and microscale testing methods. These differences were not studied for transverse samples as the proximal region was too narrow to obtain samples.

Across scales, longitudinal macroscale testing was found to be 3 orders of magnitude larger than microscale testing. Meanwhile, the transverse macroscale testing was only 1 order of magnitude larger than microscale testing. No significant associations were found between either longitudinal or transverse macroscale testing and microscale testing. When looking at the macroscale directionality, no significant association was found between the longitudinal and transverse direction. The lack of association between the longitudinal and transverse directions highlights the anisotropic properties of tendon, in which collagen fibers align along the longitudinal direction. Testing in the longitudinal and transverse directions gives information about the macroscale mechanical properties due to the collagen fibers and the non-collagenous matrix, respectively. The lack of association between macroscale and microscale length-scales highlights the difference in mechanical properties obtained when using different methods to test matrix at different scales.

Previous studies found the longitudinal moduli of equine SDFT to be approximately 1000 MPa; however, those studies looked at the whole tendon rather than thin samples, which may disrupt some of the collagen fibers or introduce clamping effects[8-9]. A similar study for sheep flexor tendon and human MCL found the transverse moduli to be 2 orders of magnitudes smaller than the longitudinal moduli, which was consistent with the results of this study[10-11]. When comparing this to previous data, it can be seen that the AFM modulus found for equine tendon (0.083 ± 0.025 MPa) had similar values to the mean modulus found for wild-type mice tendon of 0.053 MPa[12].

One limitation of this study was a lack of samples, as well as a lack of knowledge on the subject's injury history. It was unknown if any of the subjects used had previous tendon injuries that may have impacted the results of this study. In addition, the loading conditions varied across the scales with macroscale testing being conducted in tension and microscale testing being conducted in compression through indentation.

Overall, this study found that regional differences of the SDFT tendon are not replicated between different length-scales, this may be due to the lack of association found between both longitudinal and transverse macroscale testing and microscale moduli values. This implies that macroscale and microscale mechanical properties of the tendon may differ with respect to age and region of the tendon. Future work will be done to increase the number of samples to help combat the differences caused by subject variability. We also plan to study the multiscale mechanical differences between healthy versus diseased samples.

PREVENTING AND DETECTING NASOGASTRIC TUBE DISLODGEMENT IN INFANT PATIENTS

Jeffrey J. Huang (1), Katherine H. Han (2), Dahin I. Song (1), Suh Kyung Yoon (1)

INTRODUCTION

Nasogastric (NG) tubes are vital for delivering sustenance and medications to patients unable to swallow normally. Annually utilized by over 1.2 million patients in the United States, NG tubes are prone to dislodgement, which occurs when the tip of the tube becomes significantly displaced from its intended position within the stomach[1]. Tube dislodgement is particularly dangerous if pulled into the esophagus, leading to severe or fatal pneumonia[2]. Dislodgement impacts up to 50% of patients, incurring replacement costs of up to $500 and frequently necessitating additional support from interventional radiology[3]. Notably, infant patients face a disproportionate risk, with over 60% experiencing tube dislodgement. This vulnerability is accentuated by their smaller fingers, increasing the likelihood of unintentional tugging[4]. Even a slight displacement of a few centimeters can pose life-threatening risks, due to their shorter stomach. There is no continuous monitoring system for NG tubes, necessitating caregivers – parents, physicians, and bedside nurses – to manually inspect for dislodgement every four hours.

Tools designed to address NG tube dislodgement must fulfill crucial criteria, including effective detection, prevention, and a straightforward, non-invasive setup approach. Unfortunately, current solutions are inadequate, especially when it comes to addressing this issue in infant patients Internal bridles (AMT bridle and CORGRIP retention system) offer partial prevention of dislodgement by looping a rigid tube through the nasal cavity and around the nasal septum[6]. However, this invasive approach is unsuitable for administering to infant patients due to the delicate nature of their nasal epithelia. In fact, the AMT bridle was initially recalled during clinical trials due to an incident where the bridle tore through a patient's nasal septum and became wedged between the torn septum[5]. None of the current standards of practice are capable of both detecting dislodgement and preventing resulting complications.

PRODUCT DESIGN

NG-LOOP, designed for both hospital and home use, addresses the critical need for increased safety and quick detection of NG tube dislodgement events in infants. The core mechanism includes an external bridle for secure tube attachment and an integrated alert system with a magnetic sensor setup, allowing real-time response to dislodgement (Figure 1). The system automatically halts the feeding pump through a Wi-Fi-connected smart plug, preventing aspiration pneumonia. At the same time, caregivers also receive instant notifications via email-to-SMS for prompt intervention. NG-LOOP distinguishes itself in NG tube management, showcasing a unique combination of dislodgement prevention, detection, and complication management with a noninvasive setup.

This system's innovation lies in its ability to promptly alert caregivers and automatically stop the feeding pump upon dislodgement detection. This not only mitigates the potential for harm but also alleviates the burden on healthcare staff, allowing for immediate intervention. The ease of NG-LOOP's application and its non-invasive nature further distinguish it from current practices, offering a proactive solution that prioritizes patient safety and caregiver efficiency.

The retention and alarm system seamlessly integrates into current workflows in hospital and home care settings. The attachment process of the external bridle is designed to be easily incorporated into routine procedures, ensuring a smooth and efficient user experience for healthcare professionals and caregivers. The system modifies existing workflows by automating the detection of dislodgement events, reducing the need for constant visual monitoring. Overall, the device improves the feeding experience for infant patients undergoing NG tube feeding, minimizing disruptions, and promoting stability and comfort, potentially enhancing patient compliance with feeding regimens.

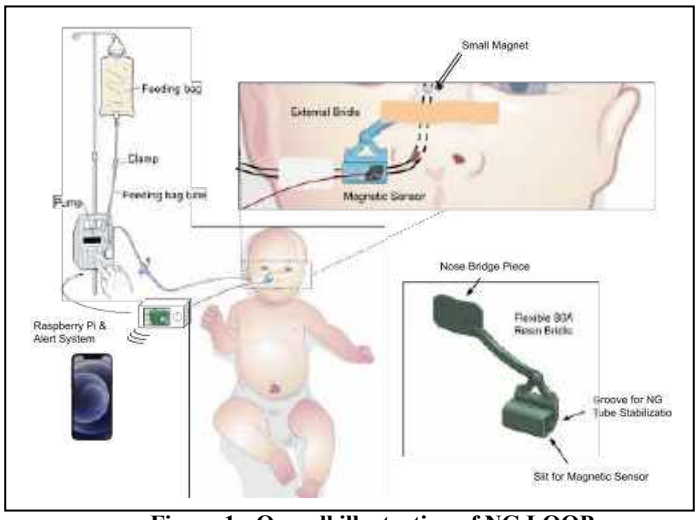

Figure 1: Overall illustration of NG LOOP

The effectiveness of the bridle was assessed using various hanging weights to simulate tube dislodgement, both with and without the bridle. This approach was selected to closely mimic the pull force experienced by infant patients. Tube dislodgement was defined as the displacement of the tube by more than 5cm from its original position within the nostril; this threshold was determined upon discussion with various NICU clinicians at the Children's Hospital of Philadelphia. It was observed that the bridle successfully prevented tube dislodgement 100% of the time, and the average displacement length of the tube with the bridle was significantly lower ($p = 0.00004$) than without the bridle. To ensure magnet security on the NG tube inside the nostril, we simulated an intranasal mucous environment with intense mechanical stimulation for over 2 weeks. For all 5 trials, the magnet stayed completely dry and was not displaced. The performance of the magnetic sensor was assessed by measuring the absolute voltage change at different lengths of magnet/tube displacement. This simulation aimed to replicate the conditions of an actual event where a tube gets dislodged and pulled to the exterior of the nostril. A true positive was defined as when the displacement of the tube by 5cm (as defined above) led to a *change* in sensor voltage reading above the predetermined threshold. The system demonstrated an 85% true positive accuracy rate in detecting tube dislodgement, with both (SMS alert and feeding pump termination) feedback mechanisms being activated in 100% of trials where the difference threshold was met.

BUDGET & MARKET ANALYSIS

While accurate metrics are scarce, one firm, Grand View Research estimates that the global nasogastric tube market was valued at USD 505.1 million in 2022 and is anticipated to grow at a CAGR of 5.3% from 2023 to 2030[6]. This growth is driven by the essential role of nasogastric tubes in medical care, including enteral feeding, medication administration, and diagnostic purposes, particularly for preterm infants. With preterm birth rates ranging from 5% to 18% across 184 countries, the demand for nasogastric tubes is expected to surge, given their critical application in providing necessary nutrition to premature babies. This increasing demand, coupled with the market's expected growth, presents a significant opportunity for investment in engineering and tooling to support the manufacturing of nasogastric tubes.

The development and testing phase of the NG-LOOP prototype incurred a total cost of $3,992.37, encompassing electronic components, development tools, 3D printing materials, and testing equipment. This initial investment provides invaluable insights into the potential manufacturing costs at scale. We estimate further physical device development costs to be $20k and software development costs to be $10K. Assuming economies of scale, which will reduce costs with increased production volume, we can project a more cost-effective manufacturing process for NG-LOOP. If the per-unit production cost could be reduced to around $40-$80 through mass production, it suggests a feasible path to affordability and profitability.

Table 1: Design budget for building prototype

Item	Cost Per Unit ($)	Number of Units	Total Cost ($)
3D printing material and services	68	1	68
Raspberry Pi 4	75	1	75
Smart plug	13	1	13
USB dongle	35	1	35
Pi prototyping HAT	13	1	13
Waterproof wire connectors	1	1	1
Laser cut enclosure	20	1	20
DRV5055 sensor	10	1	10
Medical wrapping	2	1	2
Magnet	5	3	15
		Total Cost =	**$252**

Considering the market's potential size, if we conservatively estimate that a fraction of the global nasogastric tube demand could shift towards the NG-LOOP system for its added safety and efficiency benefits, the unit sales could be significant. Assuming the global market requires millions of nasogastric tubes annually, capturing even a small percentage of this market with NG-LOOP could translate into hundreds of thousands of units sold per year.

Given the manufacturing cost and the added value NG-LOOP provides—including enhanced safety features, automatic feeding pump shutdown, and real-time caregiver alerts—a sales price ranging between $150-$200 per unit could be justifiable. This pricing strategy not only ensures a healthy margin to cover operational costs and reinvestment into further product development but also aligns with the device's innovative benefits and the critical healthcare need it addresses.

NG LOOP revolutionizes NG tube care for infants, delivering safety and peace of mind. This product is essential for any facility or home using NG tubes, offering a new standard in safety and caregiver reassurance.

MRI-BASED MEASUREMENTS OF STRAIN IN THE AORTA: DOES CARDIAC DISEASE IMPACT AORTIC DEFORMATION?

Petra Alsahwi (1), Alice Guest (1), Rylan Marianchuk (2), Dina Labib (2), James A. White (2,3)

INTRODUCTION

Heart disease referral populations have been shown to have a high prevalence of abnormal aortic distensibility [1]. Altered aortic function may serve as a systemic indicator of global cardiovascular health in these populations. However, many factors – such as age and sex and vascular disease – contribute to changes in aortic diameter and strain across each patient's lifespan. Despite a significant amount of research and studies focusing on aortic deformation and strain [2,3], there exists a gap in understanding how these changes manifest in healthy and diseased patients. Knowledge of normal ranges and regional variability in aortic strain from cardiac MRI-based techniques are lacking. Another limitation of current studies on aortic strain is the use of indirect measurement techniques [2]. While indirect measurements can provide a global measure of stiffness, direct measurements of strain can be far more precise allowing for better tracking of strain changes over time. Moreover, a direct measurement technique enables a more localized and complete understanding of aortic deformation [3]. The main objectives of this study were to use direct measurement techniques from cine MRI to determine strain in the descending aorta: both to establish health reference values and evaluate regional differences observed in cardiovascular disease.

METHODS

Two cohorts of patients were studied. The cohort of healthy subjects had 64 studies and the cohort of cardiovascular patients had 84 studies. This cohort consisted of 58% healed myocardial infarction (MI), 20% hypertrophic cardiomyopathy (HCM), 8% non-ischemic cardiomyopathy (NICM), 5% left ventricular non compaction (LVNC), 4% cardiac amyloid, 4% acute myocardial infarction (MI acute), and 1% hypertensive cardiomyopathy (HTNcm). A Cine-MRI sequence was used to capture motion of the aorta over the cardiac cycle. All images were obtained from 4-chambers cardiac MRI studies that capture the descending aorta. Each patient had 30 DICOM images representing time steps in the cardiac cycle. Semi-automated Python code was used to isolate and track the aorta for each patient. The three main techniques used are region growing, convex hull, and optical flow. First, the code focuses on the isolation of the descending aorta from its surroundings by converting the image to grey scale and applying automatic thresholding. If the automatic threshold does not isolate the aorta well enough, the user can enter a threshold repeatedly until the aorta is isolated. The convex hull section then places a contour around the aorta which allows for the tracking of the aortic wall. The tracking is achieved for all time steps by an optical flow function.

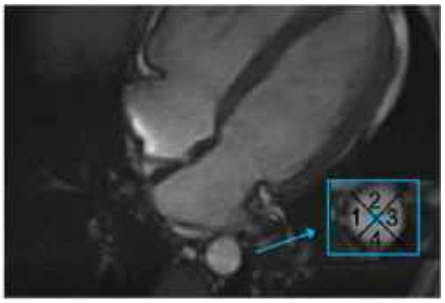

Figure 1: Position of the aorta relative to the heart on MRI image, strain quadrants magnified in the blue inset.

For all 30 phases of the cardiac cycle, the contour coordinates of the aorta were saved and used to determine strain. Equation (1) was used to express changes of the aortic area as strain percentage. Furthermore, the changes along the contour are related to the original contour and quantified as an average for each of the four quadrants as shown in Figure 1.

$$Aortic\ Strain\ Percentage = \frac{(Maximum\ aortic\ area - minimum\ aortic\ area)}{minimum\ aortic\ area} \times 100\% \quad (1)$$

The same code and methodology were utilized for both cohorts.

RESULTS

The healthy cohort comprised subjects of age 46±14. The cardiovascular cohort comprised patients age 60±13. Figure 2 shows aortic area increased with age for both cohorts of patients. The patients with cardiovascular disease showed higher variability in the aortic area while healthy patients followed a tight linear trend.

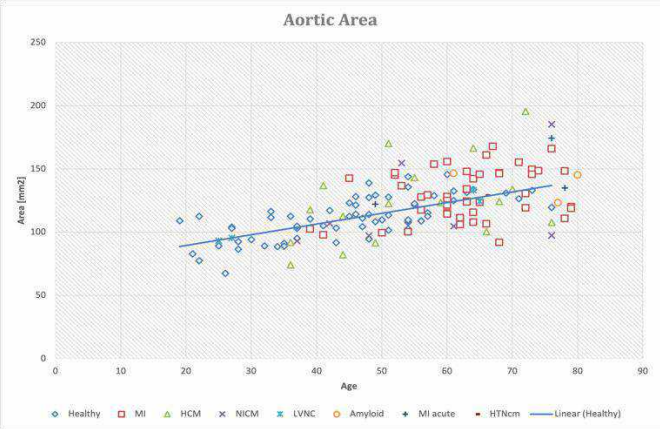

Figure 2: Aortic Area versus Age for two cohorts of patients. Patient cohorts and their cardiovascular diseases are distinguished by color and symbol. The blue line shows a trend for healthy patients.

Figure 3 shows the distribution of circumferential strain in the four quadrants Q1-Q4 for healthy subjects (upper graphs) and cardiovascular patients (lower graphs). The quadrants position is shown in Figure 1. As evident from the box plots and the pie plots, the deformations present in aortas of patients with cardiovascular disease differed from those in healthy aortas, which reached higher strains in all quadrants but Q3 (circumf_strain healthy median 11% IQR7.7%, circumf_strain cardiovascular patients median 9% IQR7.2%). Healthy aortas showed the maximum strain distribution mainly in quadrants one and two; aortas of diseased patients showed maximum strain in quadrants one, two, and three.

Statistical t-tests between the strain in the quadrants for healthy and non-healthy patients showed significant differences between quadrants Q1 ($p=0.003$), Q2 ($p=0.001$), and Q4 ($p=0.0008$). Anova test restricting age to >40 showed that in both cohorts the quadrants had different strain ($p=1.e\text{-}7$).

DISCUSSION

Overall, deformation markers of the aorta were heterogeneously distributed with respect to quadrant location in both healthy volunteers and patients with cardiovascular disease. Quadrants one and two are adjacent to the heart while the other two quadrants are posterior and adjacent to the spine. Considering the effect of the surrounding structures, it would make sense that the healthy aorta deforms more in the direction towards the heart as heart tissues are softer than the spine. Our results showed that for cohorts with cardiovascular diseases, the aorta becomes progressively stiffer limiting its maximum deformation. Moreover, the deformation is more evenly spread across quadrants. This conclusion was also valid when the young patients (< 40 years old) were removed from the cohort of healthy patients to correct for possible age effects. The lower strain in cardiac patients may also indicate a lower stroke volume than in healthy patients. In order to better differentiate the effects of disease versus aging, future analysis will include multivariate statistics to assess whether older healthy aortas deviate from the trend. The differences in distribution of strain across quadrants, however, could not be justified simply by lower overall strain in the diseased aortas. In conclusion, our study showed a unique trend for healthy subjects versus cardiovascular patients with respect to strain distribution in the descending aorta assessed via cardiac MRI. These differences point to altered deformations beyond those explained by aging alone.

OPTIMIZATION OF OBJECTIVE MEASUREMENTS FOR EVALUATING SAGITTAL SYNOSTOSIS DETECTION AND TREATMENT EFFICACY

INTRODUCTION

Sagittal synostosis, the premature fusion of the sagittal suture, occurs in 2-3 per 10,000 live births, and results in cranial malformations that can have severe consequences on brain growth and development.[1] Successful outcomes can be achieved through early diagnosis, surgical treatment, and post-operative cranial orthotics.[2]

Cephalic index (CI), the percent ratio of cranial width to length, is a common metric used to monitor post-operative correction but can be subjective because measurements are made using handheld calipers at the estimated largest equator of the skull (**Fig. 1**). Optical surface scanning, now common at orthotics facilities, provides an opportunity to develop metrics that are more sensitive to cranial correction [3] and that can be automated to remove subjectivity.

The objective of this study was to automate calculation of additional craniometrics and optimize the definitions of those metrics to improve sensitivity.

METHODS

Optical surface scans were performed as a point of standard care in 2-4 months old (n=25, 2.5±0.7 months) infants treated for sagittal synostosis.

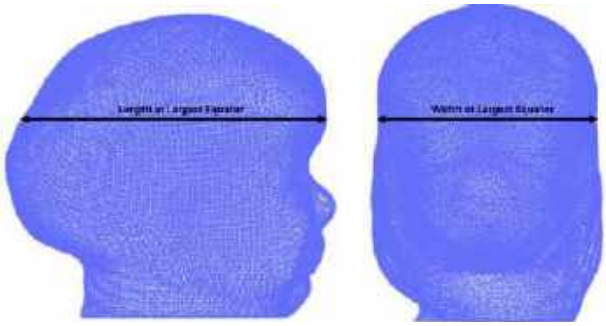

Figure 1. Length and width of a 2-month-old female with sagittal synostosis. Cephalic index is the ratio of width to length multiplied by 100 at the largest cranial equator.

Follow-up scans were obtained 3-13 months later (6.5±2.3 months). Scans from infants without cranial abnormalities were obtained from ages 4-13 months of age (n=33, 6.7±2.6 months).

A custom python script was created to evaluate 3 metrics from the three-dimensional normal and abnormal point cloud data (**Fig. 2**): (1) *Occipital Contour Angle* (OCA): angle created by mirrored lines drawn from the center point of the skull at the sellion level to the occipital bone at an angle, θ. (2) *Vertex Proportionality Index* (VPI): percent ratio of posterior radius r_P to anterior radius r_A, which are drawn from the center point at the sellion level to the

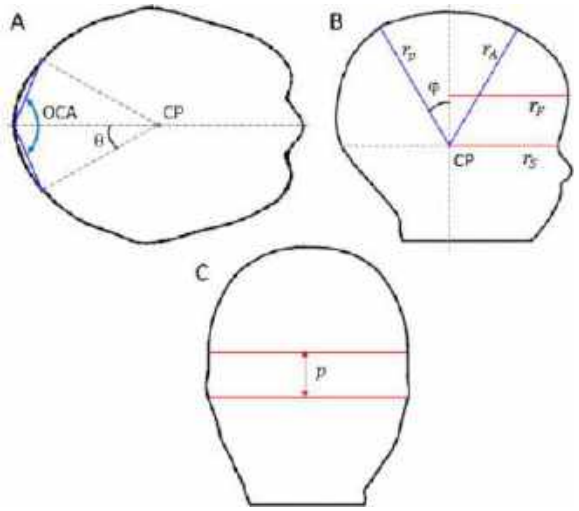

Figure 2. Craniometrics included (A) OCA, (B) VPI and (C) PTI. Optimized values were θ, φ, and *p*.

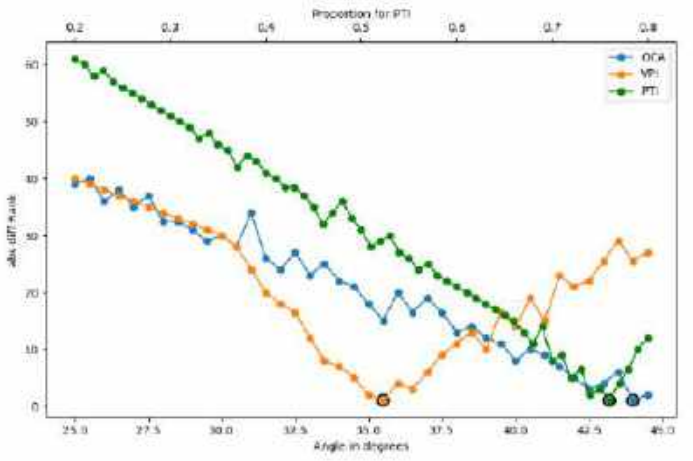

Figure 3. Optimal parameters for each metric were identified with a cumulative ranking of largest differences across all pathological cases. A rank of 1 was the most ideal parameter.

surface of the skull at an angle, φ. (3) *Parietal-Temporal Index* (PTI): percent ratio of the coronal width at the sellion level to the coronal width at a proportion, *p* between the sellion level and the top of the head.

An optimization script was created to identify the most sensitive angle/proportion values for each metric. Angles were varied from 25° to 45° in 0.5° increments for OCA and VPI, and proportions were varied from 20% to 80% in 1% increments for PTI measurements. FSI had no parameters to optimize but was still calculated for each infant. Sensitivity of the metric was evaluated using a cumulative rank-sum on the difference of each metric between initial and final scans within pathological subjects. Measurements with a z-score greater than 1.96 (a 95% confidence interval) relative to the mean of the control group, were marked as pathological, while measurements falling inside the range were marked as normative.

RESULTS

Optimization identified θ=35.5°, φ=44°, and *p*=76% as the most sensitive angle/proportion for quantifying differences between initial and final scans (**Fig. 3**). Use of these optimal metrics identified 6 infants in the control group that may have minor abnormalities not identified by CI, but were determined not to require orthotics. In the confirmed pathological group OCA, VPI, and PTI accurately identified cranial abnormalities in 80%, 88%, and 64%. If all 3 optimized metrics (OCA, VPI, and PTI) were considered, 96% (24/25) of confirmed pathological cases were identified compared to only 80% (20/25) identified by CI. There were no cases identified by CI that were not identified by either OCA, VPI, or PTI.

DISCUSSION

This study automated and optimized 3 cranial metrics as a tool to help identify cranial abnormalities as well as to monitor progress during treatment of sagittal synostosis. The inability of any single metric to identify cranial abnormalities with high accuracy highlights the variability of the infant skull response to sagittal synostosis, and strongly suggests a multi-metric approach is needed, as presented in this study.

The confirmed pathological group consisted of 20 males and 5 females, most of whom were diagnosed around 2 months of age. In other ongoing work in our lab, we find the 0-2 month female infant skull is significantly thicker than the male skull, and may be less immediately responsive to sagittal fusion. Evaluation of sex- and age-specific thresholds for identifying abnormalities may be warranted.

INTRODUCTION

Agent-based modeling (ABM) combined with coarse-grained modeling offers a powerful approach to simulate complex systems like cancerous tissue [1]. ABM focuses on individual agents, such as cells or drug particles, each following predefined rules and interacting with neighboring agents. Coarse-grained modeling, on the other hand, simplifies the system by grouping multiple agents into coarse-grained entities, reducing computational complexity while retaining essential features.

In this study, the ABM component represents individual fibroblasts, collagen fibers, and drug particles, each with specific behaviors and interactions. These agents collectively form the extracellular matrix (ECM) of the tissue. By simulating the behavior of these agents, researchers can analyze properties such as ECM stiffness and the effects of drugs on it.

Combining ABM with coarse-grained modeling allows for a multiscale approach, capturing both microscopic details and mesoscopic behaviors. While ABM provides insights into the dynamics of individual agents, coarse-grained modeling enables the study of emergent phenomena at a higher level of abstraction. This synergy facilitates the analysis of complex interactions within the tissue microenvironment and the effects of interventions such as drug treatments.

Among the various software platforms available for such modeling, LAMMPS MD software stands out for its versatility and usability across scales [2]. Its ability to handle both mesoscopic and microscopic simulations make it well-suited for this project, enabling researchers to explore the mechanical properties of cancerous tissues and evaluate the efficacy of drug therapies in silico. By leveraging the capabilities of LAMMPS MD software, this study aims to advance our understanding of cancer progression and treatment response, ultimately guiding the development of more effective therapeutic strategies.

METHODS

A combination of agent based modeling and coarse grain modeling are being used to drive the project. In order to build the model from ground up, the properties of each component must be validated independently testing the parameters of each component.

In the simulation setup, cells and collagen fibers were coarse-grained to accurately represent their mechanical properties within the range accepted in literature. Coarse-graining involves simplifying complex structures by grouping multiple atoms or particles into larger entities while preserving essential characteristics. For cells, this coarse-graining approach ensures that their mechanical behavior, particularly their Young's modulus, falls within the expected range observed in experimental studies. By coarse-graining cells in this manner, the model strikes a balance between computational efficiency and fidelity to biological reality, enabling simulations that capture relevant biomechanical phenomena.

Similarly, collagen fibers were coarse-grained to ensure that their mechanical properties align with experimental observations. Collagen, as a major component of the extracellular matrix, plays a crucial role in determining tissue stiffness and mechanical integrity. Coarse-graining collagen fibers allows the model to represent their structural and mechanical characteristics while minimizing computational complexity. By incorporating collagen with appropriate mechanical properties, the simulation can accurately capture the interactions between cells and their microenvironment, providing insights into tissue-level behaviors such as deformation and remodeling.

The internal energy of the system was primarily governed by harmonic bonds, reflecting the interactions between coarse-grained

entities such as cells and collagen fibers. Harmonic bonds represent a simplified yet effective model for describing the elastic properties of materials, where the energy of deformation is proportional to the displacement from equilibrium. By employing harmonic bonds as the basis of internal energy, the simulation captures the mechanical responses of cells and collagen to external forces and interactions within the tissue microenvironment. This approach facilitates the exploration of various mechanical phenomena, including tissue deformation, stress distribution, and response to mechanical stimuli, contributing to a deeper understanding of cancer biomechanics and the effects of therapeutic interventions. The energy contained between one harmonic bond is shown in equation (1).

$$E = k(x - x_o) \qquad (1)$$

The young's modulus was calculated by performing a tensile test of a subject and computing the stress tensor corresponding to the axis of deformation. Strain is easily calculated by taking the deformation.

RESULTS

The main results of the project are that tensile tests for fibroblasts and for collagen show promising fidelity to results reported in literature [3], [4].

Figure 2: Visualization of the fibroblast under uniaxial tension.

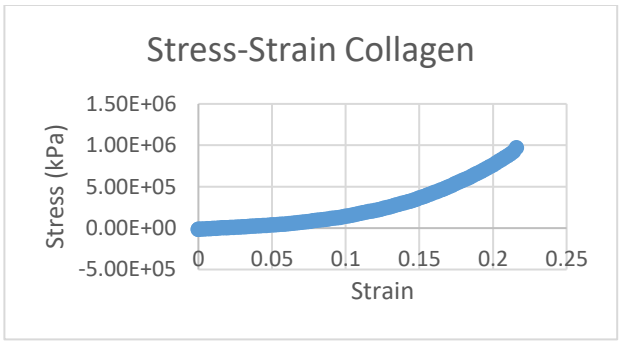

Figure 3: Stress-Strain Curve in (kPa) representing the collagen layer.

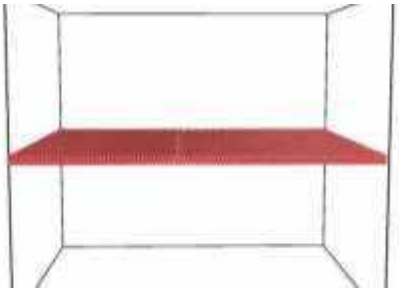

Figure 4: Layer of collagen undergoing uniaxial tension.

DISCUSSION

This research project is under development with progress being made in accurately modelling individual objects, such as cells or drug particles. Future plans are to run simulations with layers of cells and extracellular matrix. representing tissue layers of a tumor microenvironment, while simulating diffusion of drug particles, using random placement of drug particles to study the penetration depth and adherence of the drugs, given their mechanical properties. Extensions for this project are to adapt this model to the patient specific imaging data to tie the model to real-life patient data. The key to the project is its flexibility in defining parameters, since material properties can be adjusted by changing the value of the

ENDOTHELIAL CELL RESPONSE TO HYPERTENSIVE PRESSURE CHANGES

Ashlyn N. Terasaki (1), Mahsa Dabagh (2), Woo-Jin Chang (3)

INTRODUCTION

Hypertension is impacting endothelial cells (ECs) and their health. Our objective is to monitor how ECs response to hypertension and change their shape and interactions with neighboring ECs. For this purpose, we are designing in-house microfluidic devices that will allow the application of fluids with different pressures on ECs. Microfluidic devices are widely used to study various applications. In biomedical engineering research fields, these devices allow for integration of cells, particles, and other substances to observe their behavior under various conditions over time [1]. Polydimethylsiloxane (PDMS) is often used for the fabrication of microfluidic devices, and this is due to the material being inexpensive, transparent, bio-compatible, deformable, and permeable to gas [2].

Although there are many advantages to using PDMS, a drawback for this material when being used with biological samples is its inherent hydrophobicity. This poses a problem when working with cell culture because hydrophobicity impedes the adherence of cells to surfaces. Many methods have been used to make the PDMS more hydrophilic, including the use of extracellular matrix (ECM) proteins as a coating material [3]. By doing this, the PDMS channels of microfluidic devices are made hydrophilic and supports cell culture. Fibronectin has been commonly used as a coating for microchannels in experiments with endothelial cells and it has been shown to encourage cell adhesion to the PDMS surface. A layer of fibronectin or other ECM proteins provides a substrate for cells to adhere and proliferate on if the device is being used for cell culture studies.

In this study, the effects of hypertensive conditions on the vascular integrity will be evaluated using pressurized microfluidic ECs culture device. For experiments that use perfusion culture under pressurized conditions, a pressure pump will be used with microfluidic devices, which allows for control over the flow and pressure that are being introduced into the microchannels [4].

METHODS

1. Microfluidic Device: A three-channel microfluidic device made of PDMS will be fabricated with varying diameters for each channel. There will be an inlet and an outlet for each separate channel to allow for controlled pressure. The pressure will be determined based on physiological hypertension and normal blood pressure, which is relevant to the vessel size. A pressure pump will be used to create the pressure through the microchannels.

2. Fibronectin Coating and Endothelialization of Microfluidic Channels: To create a hydrophilic layer on the PDMS, fibronectin solution will be perfused through the three separate channels and left to incubate to adsorb on the PDMS. PBS will be used to wash away excess fibronectin solution. ECs (HUVECs) will be perfused through the channels at varying pressures for each channel. The cell solution will be incubated to form a monolayer of ECs around the microchannels.

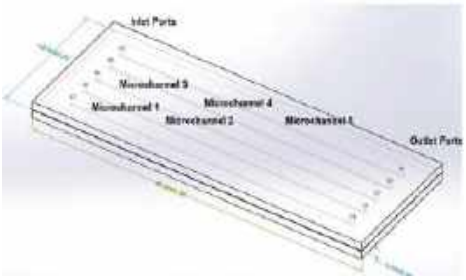
3. Immunofluorescence Detection of the Fibronectin Coating, EC adhesion, and EC Nuclei: To confirm coating efficiency of the Fibronectin layer, fluorescent microscopy will be used. An Alexa Fluor dye that is conjugated with an anti-FN antibody will be introduced into the channels and incubated. The excess dye will be rinsed with PBS. A nuclear stain will be used with the ECs and to visualize the adherence of the cells to the fibronectin coated surface, an anti-human VE-Cadherin antibody (primary antibody) will be added to the channels and incubated. Excess will be washed with PBS. An anti-mouse secondary antibody with Alexa fluor dye will then be added in the channels and incubated. Cells will then be washed with PBS. Images of the channels will then be taken and analyzed.

RESULTS

The effect that hypertensive conditions have on the vascular integrity will be evaluated based on the amount of VE-cadherin that is

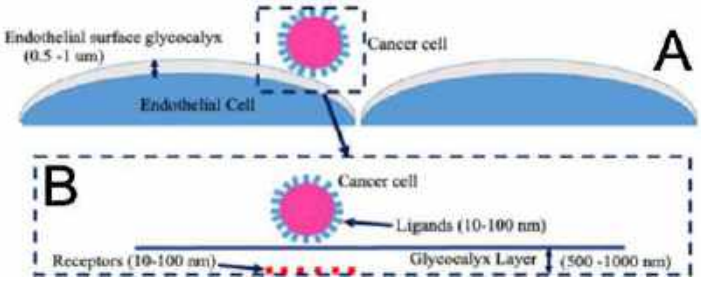
stained ECs. A fluorescent microscope will be used to view the proteins and cells that are stained with the dyes and pictures will be obtained and analyzed for each sample. The results of the normal pressure conditions will then be compared to the hypertensive conditions to see how much of an impact hypertension has on the endothelium wall leakage.

Figure 1:



This schematic represents the microfluidic design that will be used in the experiment. The various sized channels will be aligned parallel to each other.

Figure 2:



This schematic demonstrates how cancer cells adhere to the endothelial cells through their ligands and the receptors on the cell surface. The deformation of ECs exposed to hypertensive condition will impact ECs interactions with cancer cells.

DISCUSSION

By conducting this experiment, the role that hypertension plays in the integrity of the endothelium can be better understood. In cancer metastasis studies, the state of the endothelium affects the behavior of the cancer cell by either promoting or impeding its extravasation out of the vessel [5],[6]. Alterations and compromised integrity of the endothelium can promote the transmigration of cancer cells by providing them with a way in and out of the vessel [7]. Assessing the role that hypertension plays in creating these dysfunctions in the microvasculature is a first step into understanding the effect it has on cancer metastasis, specifically extravasation. Using microfluidics, this scenario can be modeled with endothelial cells, tumor cells, and controlled pressure through the microchannels. Other structures or different types of cells can also be combined with the microfluidic device to further replicate the *in vivo* conditions for metastasis studies [8]. Data obtained from these experiments can contribute to other areas of cancer research such as drug development or diagnostics.

ENGINEERING MESENCHYMAL STROMAL CELLS TO FACILITATE MUSCLE REGENERATION BY CORRECTING OXIDATIVE STRESS

Ali A. Eldeiry (1), Sing-Wan Wong (1,2)

(1) Department of Mechanical Engineering, Colorado State University, Fort Collins, CO, USA
(2) School of Biomedical Engineering, Colorado State University, Fort Collins, CO, USA

INTRODUCTION

Muscle injuries frequently occur as a result of daily activities. The human body is capable of regenerating injured muscle to an extent. However, regeneration often can be compromised when the injury is too severe or underlying complications such as muscular dystrophy exist[1]. While the pathological mechanism is unique between muscle injury cases, there is one main factor commonly contributes to the inhibition of muscle regeneration, the oxidative stress. Oxidative stress is a result from accumulation of reactive oxygen species (ROS), which are mostly generated during post-injury inflammation[2]. These highly reactive molecules are naturalized by anti-oxidative enzymes under normal conditions. Unfortunately, the production of anti-oxidative enzymes often becomes insufficient depending on one's body health or underlying conditions. This imposes the need of providing additional anti-oxidative support to correct the oxidative stress, hence, facilitating muscle regeneration. One way to fulfill the extra antioxidative demand is to intake antioxidative supplements. However, multiple antioxidants are necessary to provide a full spectrum antioxidation as oxidative stress is a result of a collection of varied ROS and different antioxidants are required to neutralize specific ROS. With this consideration, mesenchymal stromal/stem cells (MSCs) can serve as a suitable therapeutic candidate for the purpose because of their multiaxial regulatory role[3]. In this study, we aim to harness the therapeutic potential of MSCs and engineer them through a mechanobiology approach, as it has been shown that the secretome profile of MSCs is sensitive to the mechanical properties of the microenvironment they reside in [4]. We hypothesize that an optimum biomaterials system can be made to enhance the production of antioxidative enzymes from MSCs, then we will apply this novel technology to promote muscle regeneration by correcting the post-injury oxidative environment.

METHODS

One possible approach to engineer the phenotype of the MSCs is by regulating the stiffness of the surrounding microenvironment. For this purpose, we employed alginate hydrogels with Ca^{2+} ionic crosslinking. By altering the concentration of Ca^{2+}, we can consequently adjust the mechanical properties of the hydrogel. The complex modulus, a measurement that can represent both elastic and viscous behaviors of the hydrogels, was then analyzed by an amplitude frequency sweep from 0.1% to 100% strain. To perform this, an HR20 rheometer (TA instruments) was used with an 8mm geometry at 37°C. Hydrogels crosslinked with 15mM-40mM [Ca^{2+}] in 5mM increments were tested.

Once the mechanical properties of the hydrogel were characterized, Murine bone marrow derived MSCs, D1 cells, were encapsulated within the hydrogels and subjected to 1nM, 10nM, and 1μM of hydrogen peroxide (H_2O_2) treatment to mimic the post-injury oxidative environment. Three days after the treatment, RNA from the MSCs was extracted, purified and underwent reverse transcription, then was followed by a quantitative PCR (qPCR) analysis on the expression of three antioxidative enzymes: catalase (CAT), Glutathione Peroxidase (GPX1), and Superoxide Dismutase (SOD1).

RESULTS

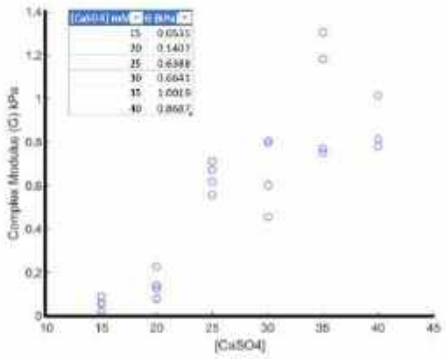

Figure 1: Complex modulus of alginate hydrogels crosslinked with varied [Ca^{2+}]

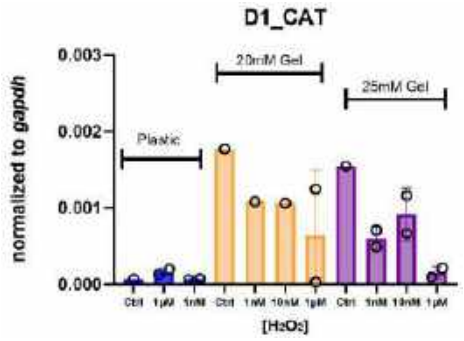
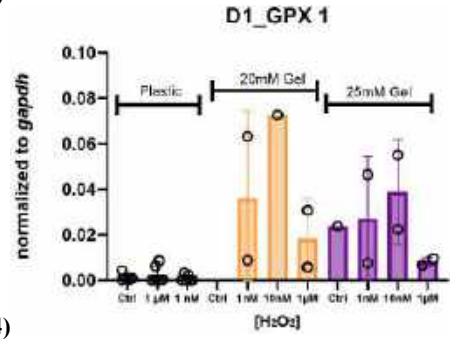
2)



3)



4)

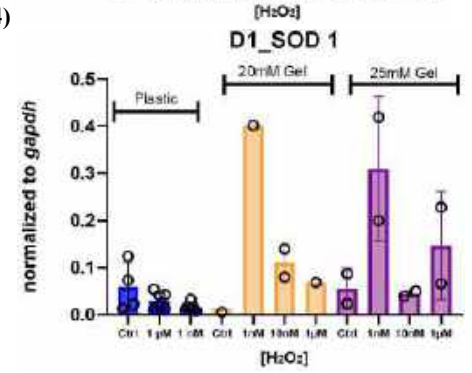


Figure 2-4: Antioxidative enzyme expression of D1 cells encapsulated in hydrogels with H_2O_2 treatments

DISCUSSION

As expected, the complex modulus of the hydrogel is proportionally correlated with the Ca^{2+} concentration. The key observation is that between 20mM and 25mM Ca^{2+} crosslinking, the complex modulus shows a shape jump from 0.1407 to 0.6388 kPa. Due to this large difference, these hydrogel formulations were chosen for the gel encapsulations experiments.

The expression of antioxidative enzymes CAT, GPX1 and SOD1 were reported in figures 2-4. Each enzyme behaves and reacts uniquely to the treatments and conditions. In regard to the H_2O_2 influence on the CAT gene, the control group appeared to have the highest expression and was at its lowest at 1µM. For the GPX1 gene, expression was greatest at the 10nM followed by 1nM, then 1µM, and finally lowest at the control. The trend remains similar between 20 and 25mM gel, but GPX1 expression is not detectable in 20mM gel without H_2O_2 stimulation. Interestingly, the SOD1 featured a separate behavior between the 20mM and 25mM. For the 20mM gel, 1nM H_2O_2 treatment leads to the highest expression of SOD1, followed by the 10nM, 1µM, and lowest in the control group. For the 25mM, the 1nM treatment results in the highest expression, followed by the 1µM, the 10nM, and finally the control. Overall, SOD1 expression is the highest among all three enzymes.

Universally, it is evident that culturing MSCs in gels increases the expression of the antioxidative enzymes. This is related back to the soft nature of the gels compared to the stiff environment a plastic well plate provides. This supports our claim that softer environments will emulate physiological conditions thus facilitating improved enzyme production. Although the findings differ between each enzyme, one conclusion can be made which suggests manufacturing of the enzymes is highest when under conditions closest to H_2O_2 physiological conditions which is 0 to 10nM [5]. Once the ROS content rises too high at 1µM, the enzyme production, on the other hand, is inhibited.

The next phrase of this study is to test our hydrogel-stem cell approach on promoting skeletal muscle regeneration. A C2C12 cell line, mouse satellite muscle cells, will be subjected to a physical scratch injury. Then we will co-culture the engineered D1 cells with the highest antioxidative expression with the injured muscle cell, followed by quantification of muscle regeneration through the expression of biomarkers including MyoD, myogenin, and pac7, which signifying successful muscle regeneration. We will also analyze muscle regeneration through image analysis by measuring the size of the induced scratch over time. Our goal is to demonstrate that engineered MSCs can be an effective method for muscle regeneration.

INTRODUCTION

Mike Nelson is a United States Army veteran who sustained life-changing injuries during his service that caused him to lose his vision. With the loss of his vision, Mr. Nelson experiences many daily challenges that individuals of standard eyesight do not encounter. One of these issues includes transporting his five children in their strollers. Mr. Nelson expressed challenges in navigating strollers and his cane simultaneously and thus has difficulty navigating both. Together with Quality of Life Plus (QL+), a non-profit that pairs wounded veterans with engineering capstone teams, he has tasked Rowan engineers to design a stroller attachment that allows him to pull his children behind him without burdening the use of his cane in front of him, or his ability to navigate outside. The engineering team must ensure that any modifications to the stroller won't impact criteria established in ASTM F833-21, which outlines safety standards for strollers, including their weight-bearing capacity and braking ability.

PRODUCT DESIGN

The veteran requested specific user criteria for a design, including that it must be lightweight, compactable for storage purposes, be comfortable for his children and not interfere with their use of the stroller, and compatible with many varying stroller and cart models while still being able to attach/detach independently. In addition, safety standards established by ASTM F833-21, which all strollers must adhere to, give guidance on certain safety specifications that our design may impact: Strollers and their modifications must accommodate 40kg in loaded weight, and brakes must be able to prevent unwanted rolling of the stroller. To accommodate for this, twist lock wheels were added to the mechanism to give Mr. Nelson a way to lock the wheels in place if needed. For example, if taking a stroller with the hitch on public transportation, Mr. Nelson will have a way to lock the brakes in place.

The final design integrates criteria outlined by Mr. Nelson, QL+, and additional parameters identified by seasoned advisors across physical therapy, occupational therapy, and mechanical design domains. Occupational therapist Darick Wright, mobility specialist Allie Futty of UMass Boston and Mike Mulligan of Blind on the Move were three mobility specialists who provided insight into the daily challenges experienced by someone with a visual impairment. They discussed the importance of maintaining alignment of the body and the white cane when designing the mechanism, which would be a major design criterion to make the design usable, would be to have Mr. Nelson push the hitch instead of pull. Melanie Amadoro of Rowan University, Dr. Smitesh Bakrania of Rowan University, and Barry Hulce of the University of Vermont were both mechanical engineers who provided insight into the mechanical design of the mechanism. Dr. Bakrania initiated the idea of manipulating the stroller wheels with our design rather than implementing a simple clamp onto a bar on the stroller to avoid interference from the children in the stroller. Amadoro expressed the importance of suspension in the tires and choosing a material that is lightweight, inexpensive, and strong. Hulce urged us to seek out the minimum viable product to satisfy the design criteria. The attachment was designed to extend up to 28.5" to accommodate most strollers with varying widths while also being able to contract to fit through any door. Positioned ahead of the mechanism is a pivotal main wheel, synchronized with a user-initiated pulling action by Mr. Nelson. This way he's able to have complete control over the mechanism while also providing safety aspects to prevent possible injuries to the children inside the stroller. The extending platform functions akin to drawer movement facilitated by sliding tracks affixed to the platforms.

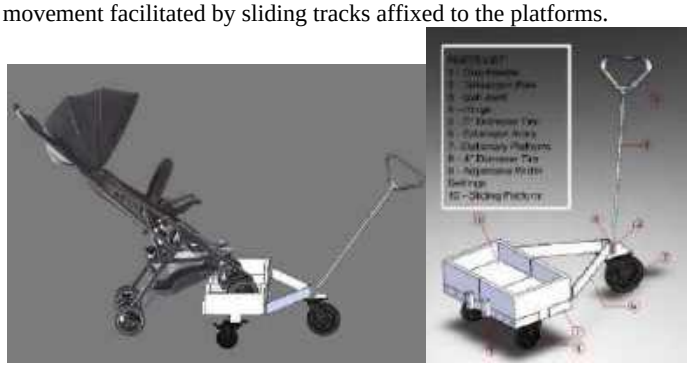

Figure 1. SOLIDWORKS Prototype with Stroller Attached.

The following engineering standards were referenced from ASTM F833-21 [2] to facilitate design and conduct testing for this device:

- 6.1.1 - A parking brake shall be provided on the unit. Each parking brake shall remain engaged during the test as specified in 7.6. Each parking brake shall prevent the braked wheel(s) from rotating more than 90° during the 5th test cycle specified in 7.6.
- 6.2.2 - A stroller shall support a static load of 100 lb (45.4 kg) or 2.5 times the manufacturer's recommended maximum weight, whichever is greater, per individual seating area, when placed in the approximate center of the area intended to support the child occupant.

Since the design utilizes wheels intended to replace the stroller wheels, ASTM standard 6.1.1 was followed to test the parking brakes on the design's wheels. To ensure that the design will not break in compliance with the safety constraints, ASTM standard 6.2.2 was followed when designing for a maximum weight load of the stroller weight plus the weight inside of the stroller.

The prototype that was developed was optimized for testing purposes; however, we look to simplify the design after basic functionality is achieved. We would like to eliminate the boxiness of the platform and condense the overall length of the device so that it is not so difficult to make turns with. We would also like to ensure that the device is as low to the ground as possible to avoid the stroller sitting on a large degree of incline when strapped on top of the platform and putting the child at risk.

BUDGET & MARKET ANALYSIS

The mission statement for Quality of Life+, is to provide custom engineered solutions to veterans whose unique disabilities are not met with commercially available or viable products. Therefore, the initial scope of this project is to design unique accommodation for Mr. Nelson. The sponsor of this project, Quality of Life + provided a budget of $1,500 for the entirety of the project. This sum of money was used to purchase materials to create a physical rendition and prototype of our design as seen in ***Figure 1***. The hope is to spend about $150 on our first prototype, budgeting ourselves to be able to spend the money on the best quality material for the final design. We hope to need no more than two prototypes before being able to send the final design to Mr. Nelson. The local community was generous and donated strollers for us to test our design to make sure it functions correctly and safely for the children and Mr. Nelson.

Despite the narrow scope of the project, we believe this design would be beneficial to all people who utilize a white cane: about 8% of people with vision loss, or roughly 480,000 people in the U.S. utilize a white cane. If we were to attain 10% of our serviceable obtainable market, which would be parents that utilize white canes (~192,000 people), we would be able to satisfy a market size of 19,200 users. Since people with limited vision use a white cane, they cannot use both the stroller and cane at the same time. This design allows both to be comfortably used at once. The costs of our materials for our final prototype total are approximately $80. To stay profitable and to accommodate for the labor needed to complete each attachment, we estimate this universal hitch attachment to cost $124.99.

ACKNOWLEDGMENTS

We would like to acknowledge Quality of Life + who sponsored this project, along with Rowan University and Dr. Erik Brewer for providing us with the necessary resources to succeed. Additionally, the team would like to extend our gratitude to Mike Mulligan of Blind on the Move, Ally Futty, Jen Kaldenberg, and Derrick Wright from the University of Massachusetts – Boston, Barry Hulce from the University of Vermont, Dr. Smitesh Bakrania of Rowan University, and Melanie Amadoro of Rowan University. These individuals allowed us access not only to their time but also to their vast skills and knowledge, allowing this project to move forward at a successful rate.

INTRODUCTION: The collagen molecule is the main building block of connective tissues. Molecules are connected laterally by intermolecular crosslinks [1]. When collagenous tissues are overloaded in tension, collagen molecules can unravel, resulting in molecular denaturation. However, the role of crosslinks in resisting tissue damage is unclear [2]. Molecular dynamics simulations have shown that crosslinks can transfer load between adjacent collagen molecules during axial extension [3]. However, this load transfer mechanism and its role in the damage of collagen molecule assemblies has not been experimentally demonstrated. Hierarchical levels of organization between the collagen molecule and whole tissue further complicate the cascade of load transfer, so multiple organizational levels need to be tested. The objective of this study was to discover the mechanical effect of increased crosslinking during tensile overload of both tendon fascicles and fibrils to explore the role of crosslinks in tendon mechanics. We hypothesized that increased crosslinking would increase the strength and stiffness at both the fibril and fascicle level of tendons thus altering the damage and yield behavior.

METHODS:

Crosslinking: To increase crosslinking in tendon, the low-toxicity chemical genipin was used to form covalent intermolecular crosslinks with amine groups in collagen residues [4]. Rat tail tendon fascicles (RTTFs) were isolated from 12-16 week old male Sprague-Dawley rats. Fascicles were divided into two groups. The Control group was soaked in 1X PBS, while the Genipin group was soaked in 0.25% w/v genipin solution in 1X PBS. Both groups were soaked for 1 hour at room temperature.

Fascicle Differential Scanning Calorimetry: Differential scanning calorimetry (DSC) was performed to confirm increased thermal stability (n=3 in both groups). Hermetically sealed pans with dry-blotted RTTFs were heated from 20-90°C and cooled back to 20°C at 10°C/min. Temperature at onset of denaturation and peak temperature were quantified, along with curve width and curve area.

Fascicle Tensile Testing: Uniaxial tensile testing was performed on RTTFs using a TA Electroforce 3300 (n=8 control, n=6 treated). Cross-sectional area (CSA) was measured using a laser micrometer. Three measurements were taken and averaged. A 0.03 N tare load was applied to each RTTF. The sample was stretched at 0.5 %/s to 20% strain.

Fibril Tensile Testing: Fascicles were soaked for an additional hour and then mechanically agitated to isolate individual collagen fibrils (n=6 control, n=7 treated) [5]. Custom MEMS devices were used to stretch individual fibrils to failure (**Fig. 1**). Each MEMS device was attached

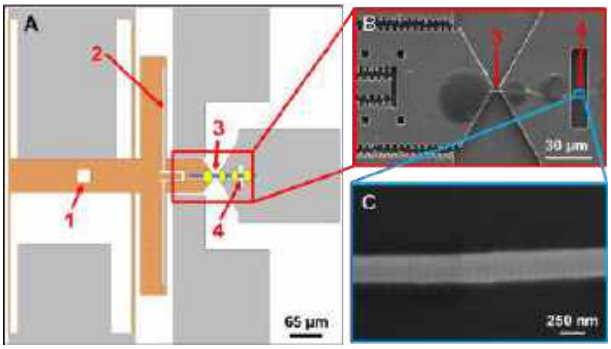

Figure 1: A: The MEMS device. Orange: moveable pad. Gray: anchored pads. Blue line: collagen fibril. Yellow ovals: epoxy droplets. (1) Pinhole. (2) Force gauge beam. (3) Test region. (4) Control region. B: SEM image of the (3) test and (4) control regions. C: SEM image of a collagen fibril.

to a piezoelectric actuator and immersed in PBS. Fibrils were mounted on custom MEMS devices and adhered using UV-curing epoxy drops. A tungsten probe was placed in a pinhole to hold the moveable pad.

Elongation was applied at a constant strain rate of 0.5-1%/s until failure and images of the MEMS device and fibril were acquired at 1 Hz. Images were processed to obtain the displacement of a force-gauge beam integrated with the MEMS device. Beam displacement was converted to applied force using the results of a finite element model of the MEMS device. To calculate fibril CSA, scanning electron microscopy was used to measure diameter of the unstretched region of each fibril. Line tracking was used to measure fibril elongation in the test region and deflection of the force gauge beam. A finite element model of the MEMS device was analyzed to calculate the force applied to the fibril based on the force gauge beam displacement.

Data Analysis: For both fascicle and fibril tensile testing, CSA and gauge length were used to obtain stress-strain curves from force-elongation curves. The yield point was identified as the strain where modulus was reduced by 50%. Data were analyzed using independent t-tests (α=0.05). Green asterisks (*) indicate significant differences.

RESULTS: For DSC, onset temperature (p=0.003), area (p=0.002), and width (p<0.001) were significantly higher for treated samples. Peak temperature trended higher for treated samples but was not significantly different (**Fig. 2**).

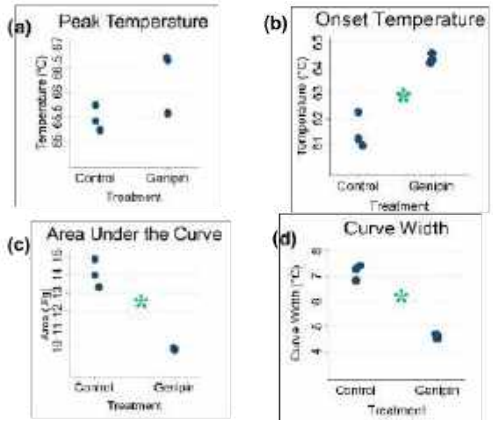

Figure 2: Results of DSC analysis. Peak and onset temperatures (a,b) are measures of thermal stability, while AUC and curve width (c,d) are measures of tissue homogeneity [6].

Genipin treatment produced qualitatively similar changes in the stress-strain curves at both the fascicle and fibril levels, but the changes were much more pronounced at the fibril level (**Fig. 3**).

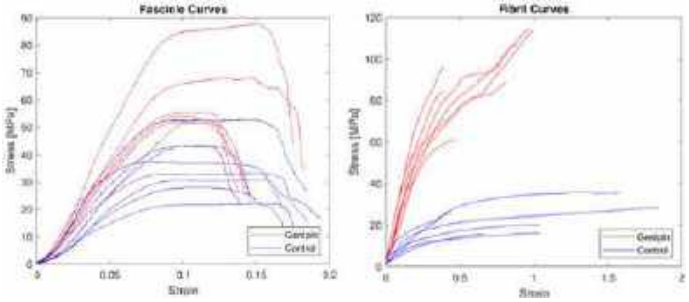

Figure 3: Stress-strain curves for fascicle (left) and fibril (right) tensile tests.

Fascicles treated with genipin sustained significantly higher yield stress (p<0.001), yield strain (p=0.006) and peak stress (p=0.002) (**Fig. 4**). At the fibril level, genipin treatment resulted in higher yield stress and peak stress than control fascicles (p<0.001), but there was no effect of treatment on yield strain. Unlike fascicle level tests, treated fibrils

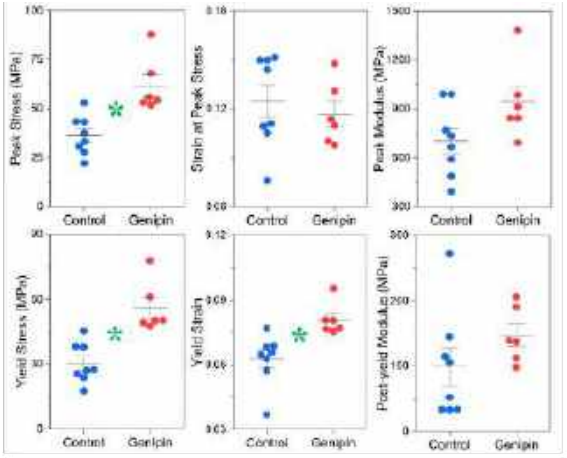

Figure 4: Results for fascicle tensile testing. Peak stress, yield stress, and yield strain were significantly higher for genipin group.

sustained higher peak modulus (p<0.001) but did not differ in peak strain or yield strain (**Fig. 5**).

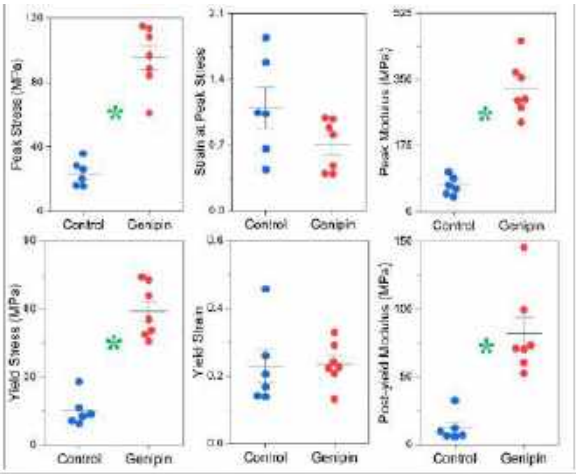

Figure 5: Results for fibril tensile testing. Peak stress, peak modulus, yield stress, and post-yield modulus were significantly higher for genipin group.

DISCUSSION: Increased onset temperature, area, and width confirmed that genipin crosslinking produced a more thermally stable, structurally uniform tissue. At the fascicle level, increased yield stress and yield strain due to genipin treatment resulted in an increase in toughness, but the treatment did not affect peak modulus. This is likely due to sliding between fibers and fibrils. The lateral distance between these structures is too large to be affected by chemical crosslinking. At the fibril level, genipin treatment produced a dramatic increase in yield stress, pre-yield modulus, and post-yield modulus, while the yield strain was unaffected. These results indicate that genipin intermolecular crosslinking increases lateral load transfer between collagen molecules in the fibril.

INTRODUCTION

In 2020, 13.4 million infants were born premature, accounting for over 10% of all births that year [1]. A full-term, human pregnancy is 40 weeks. If an infant is born at less than 28 (70% gestation), between 28 to 32 (70 to 80%), or between 32 to 37 weeks (80% to 92.5%), it is classified as extremely preterm, very preterm, or moderately preterm, respectively [1]. Of the infants that are born before 32 weeks (80% gestation) and weigh less than 1.5 kg, 32% will experience intraventricular hemorrhage (IVH); 75% of these cases will experience long-term neurodevelopmental impairments [2].

Structural deficiencies in the developing cerebral vasculature may play a significant role in the occurrence of IVH [2]. The structural integrity of blood vessels is largely defined by the extracellular matrix proteins elastin and collagen. Elastin is relatively mature by late gestational periods, although collagen components are developing significantly up until the juvenile period [3]. Computational models predict that failure strain and strength of collagen fibrils increase as the collagen triple-helix develops enzymatic cross-links as part of development [4]. Consistent with this, experiments show dramatic increases in sheep cerebral artery mechanical and failure properties with age, although lamb vessels from the earlier preterm ranges have not yet been studied [5]. Recent work from our laboratory further shows that cerebral vessels are damaged with overstretch [6]. Deformations associated with even mild brain motion in premature neonates may therefore disrupt cerebral vessels and lead to IVH. The objective of this preliminary study was to characterize the mechanical properties and damage characteristics of preterm lamb cerebral arteries in comparison to those from adults.

METHODS

Tissue Collection and Preparation: Dissections used procedures previously reported by the Monson group [5]. In short, lamb middle cerebral arteries (MCAs) were received from the Lamb Intensive Care Unit at the University of Utah. Adult sheep MCAs were collected from a local slaughterhouse. For both cases, the head and the top of the skull were removed following euthanasia. The brain was freed from internal attachments, separated from the dura, and placed in a petri dish. The MCAs were removed, starting at the Circle of Willis, using micro scissors and then placed into cold, calcium-free, phosphate-buffered saline (PBS; KH_2PO_4 1.54, $NaCl$ 155.2, $Na_2HPO_4 - 7H_2O$ 2.7 concentration in mM). Using a dissection microscope, surrounding pia-arachnoid tissue was carefully removed with forceps, and branches were ligated using unwound 6-0 silk sutures. Finally, cross sections of proximal and distal ends of the vessel were imaged.

Mechanical Testing: Mechanical tests used procedures previously reported by the Monson group [5]. In short, MCAs were mounted to cannulas using 6-0 suture and a small amount of cyanoacrylate. Using a custom testing system, MCAs were subjected to preconditioning by cycling the pressure from 6.7 to 20 kPa, during which in vivo length (L_{iv}) was determined. MCAs were characterized by a baseline response test by axially stretching MCAs to $1.1 * L_{iv}$ at a quasi-static rate. The MCAs were then axially overstretched to $1.3 * L_{iv}$. The same quasi-static baseline test was subsequentially repeated to evaluate the changes in the baseline stress response as a result of being overstretched. The MCAs were then carefully removed from the cannulas.

Data Processing and Analysis: Consistent with our previous work, MCAs were assumed to be incompressible, homogeneous, circular cylinders with uniform wall thickness [5]. Using cross-sectional images obtained prior to mechanical testing, cross-sectional area and unloaded diameter were determined for each MCA. Data were filtered with a 4th-order, Butterworth, low-pass filter. First Piola-Kirchhoff stress was calculated, and stretch was normalized by the in vivo length (L_{iv}) of each specimen. In vivo stiffness was found by fitting an exponential function to the in vivo portion of the stress-stretch curve and by calculating the value of its derivative at L_{iv}. Softening values (i.e., reduction in stiffness) were calculated by comparing the stiffness values

pre- and post-overstretch. A t-test was used to determine if there was a statistical difference ($p < 0.05$) between the softening values of the adult and preterm samples.

RESULTS

Eight preterm MCAs were tested, with seven within the moderately preterm (80 to 92.5% gestation) range, and one within the very preterm (70 to 80%) range. In a sheep model, a full-term pregnancy is 148 days. Three preterm lambs were born at 128 days (86.5% gestation), two at 120 days (81.1%), two at 119 days (80.4%), and one at 118 days (79.7%). Eight adult MCAs were tested for comparison, all over the age of 12 months.

The stretch-stress curves, pre- and post-overstretch, demonstrated a nonlinear response, typical of soft, biological tissues (Figure 1). The toe regions of the adult and preterm stretch-stress curves were relatively similar, suggesting that there is little difference between the tissues at physiological loads. However, higher stress values were found in adult samples compared to preterm samples at similar stretch values during large deformations. Interestingly, the difference in pre- and post-overstretch values appeared to result in a higher mean softening value in preterm compared to adult samples although this difference was not statistically significant (Figure 2).

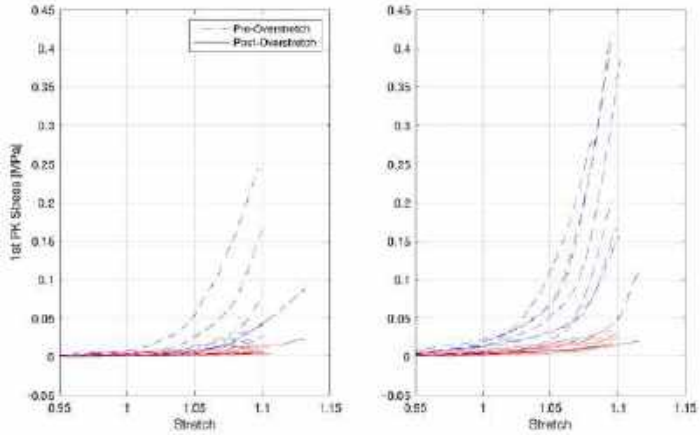

Figure 1: Baseline axial stretch-stress responses pre- and post-overstretch (blue and red, respectively) for preterm sheep born from 118 to 128 days gestation (left) and for adult sheep of at least 12 months (right).

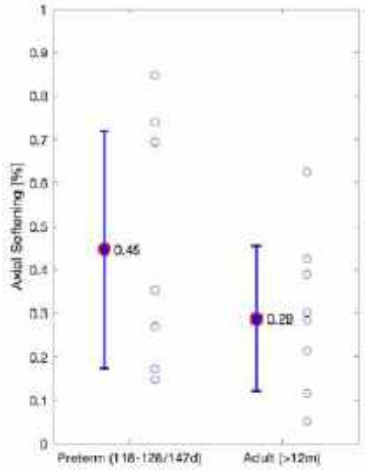

Figure 2: Individual softening values for both preterm and adult samples (blue circles), accompanied with mean (red) and standard deviations (blue lines) for each group.

DISCUSSION

The objective of this preliminary study was to investigate cerebral blood vessel mechanical properties and damage characteristics of preterm lamb cerebral arteries in comparison to those from adults. While samples from the moderately preterm lambs were qualitatively different from adult samples, results unexpectedly show no statistical differences in the reduction of stiffness between the two groups following mechanical deformation.

Consistent with previous results, at low deformations, no significant difference was detected between age groups. This is likely because elastin is the dominant mechanical fiber during low-stretch deformation. Previous work shows that elastin is finished maturing by late gestational periods [3]. All but one of the samples tested were classified as moderately preterm, meaning they correspond with the oldest gestational ages that are considered to be premature. For larger deformations, collagen is the main load carrying mechanical element. Therefore. the difference in stiffness and softening values, although not statistically significant, could be an indication of the underdeveloped enzymatic collagen cross-linking.

The primary motivations of this preliminary work were to better understand the mechanical changes in the cerebrovasculature at different developmental ages following large deformations and to predict how this may contribute to IVH. However, this study mainly included a range of samples from moderately preterm cases; therefore, further mechanical testing will need to be done to include more samples from other preterm classifications, including extremely preterm (less than 70% gestation) and very preterm (70 to 80% gestation). Further research is also needed to link mechanical damage to IVH, specifically how microstructural damage impacts the permeability of the vessel wall.

VITAFLOW - Future of Heart Preservation

J. Jung, N. Newby, S. Tuohy, T. McGoldrick

User Need

Historically, the limited availability of hearts for donation has created a large supply-demand disparity. Recently, advances enabling the usage of "donation after circulatory determination of death" (DCD) hearts, rather than just "donation after brain death" (DBD), show promise in significantly increasing the supply of available organs. Ischemia, or heart damage, limits the distance across which donor hearts can be transported. Ischemia reduces the total available donor hearts, as such engineering a preventative measure to address ischemia is a clear need. To reduce ex vivo heart damage, perfusion is necessary to provide nutrients to the heart during transport and reduce ischemia. With only two platforms achieving clinical success in ex-vivo heart preservation, and high price points of $20,000 - $80,000 per use, there is a clear need for a disruptive, effective, and affordable technology within this field to address the persisting supply-demand gap. Our proposed solution, VITAFLOW, seeks to integrate successful techniques and technologies from ex-vivo preservation and perfusion theory, maintaining efficacy, monitoring, and patient outcomes while drastically reducing costs using sub-normothermic temperature.

Design Inputs

Some of Vitaflow's strictest constraints and requirements are cost of design, temperature regulation, sterility, supply chain issues, and portability. We designed our own parts instead of buying existing solutions and the outcome of our own design efforts allowed us to attain greater user affordability. To address sterility, we plan to incorporate UV light and design our organ transport device for one time use to reduce contamination. For portability, we plan to make a compact carrying structure with wheels and handles to facilitate easy transportation of the donor heart.

Solution

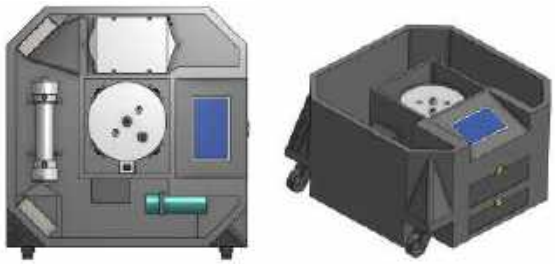

Figure 1. *3D rendering of VITAFLOW*

Our solution contains an oxygenator, , a central heart chamber which will house the donor organ, a temperature regulator module, a pump, sensors, a touch screen, and an Arduino. Our engineered solution addresses our problem. We have developed a system that continuously perfuses and oxygenates normothermic blood through a donor heart. The system is intended to provide an optimal environment for heart preservation. We have real-time sensor data of Sp02, Pressure, pH, and temperature which feed information back into an Arduino microcontroller to regulate the system's environment based on set parameters of the user on the touchscreen.

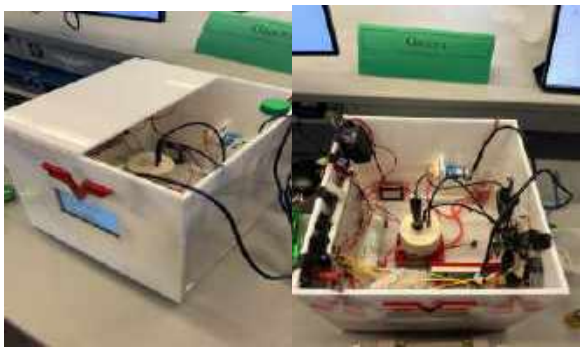

Figure 2. *Minimal Viable Product of VITAFLOW*

The minimum viable product contained a pump, pH sensor and temperature sensors, an oxygenator, a central chamber, a heating and cooling module, and an Arduino with a touchscreen.

Verification of Results

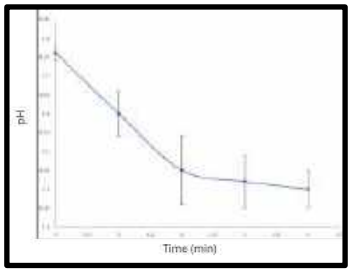

Figure 3. *Time and pH graph for CO2 gas exchange*

Measuring pH showed an initial reading that CO2 could be effectively perfused into our system which indicates effective gas exchange. We used bicarbonate to show that if there was gas exchange pH would be lowered (Figure 3).

Budget & Market Analysis

We have allocated a budget of $600 for the development of a functional prototype. Additionally, we have secured access to a makerspace, which is well-equipped with the necessary tools for the fabrication and testing of components.

We estimate that the manufacturing cost at scale will approximate our initial budget of $600. This is achievable through our decision to fabricate cost-effective parts, thereby ensuring overall affordability. Our pricing strategy positions the product in the retail market at a competitive range of $1000 to $2000, significantly undercutting current market rates.

The annual rate of transplants currently stands at nearly 4,000, a figure we anticipate will rise markedly with the advent of medical device innovations that prolong organ viability. Our product is expected to contribute to and benefit from this upward trend in transplant numbers.

Conclusion

We have been able to meet our requirements without violating our constraints. By fabricating most of our own parts and creating a functioning system that successfully changes the perfusing fluid, we are optimistic about our product design. Potential revisions include automatic injections potential nutrients into the perfusing blood to further decrease ischemic damage and prolong viability. Prolonged viability of donor hearts would contribute to closing the supply demand disparity. Furthermore, our low-cost transport device could potentially expand supply to lower-income parts of the world.

SENSITIVITY OF CONTACT MECHANICS TO FE MODEL GENERATION DECISIONS COMPARED TO VARIATIONS BETWEEN KNEES AND DUE TO PARTIAL MENISCECTOMY

INTRODUCTION

Finite Element (FE) Analysis is useful for understanding the complex contact mechanics of the tibial plateau. FE Models have been used to quantify the difference in joint mechanics between knees with different geometries, as well as between knees with different conditions, such as meniscectomy[1]. Typically, these models are developed from medical imaging of either cadaver knees or patients[2]. For use in clinical applications, it is important to verify that the model is not overly sensitive to uncertainties in modeling inputs. The ASME V&V 40 standard emphasizes this need and presents a framework for completed verification and validation in credible computational models[3]. Many steps in the model generation procedure are automated, however segmentations and model refinement may involve subjective inter-operator decisions related to tissue identification in images. Therefore, the goal of this study was to test the sensitivity of the model to variations in 1.) cartilage thickness, 2.) meniscal attachments and 3.) boundary conditions related to load application location. The effects of these variations were then compared to differences in contact patterns between knees, due to variations in material properties, and resulting from 2 sizes of partial meniscectomy. Based on the incidence of injury, our study focuses on the contact mechanics in the medial compartment.

METHODS

Finite Element models were created from MR Images of four cadaveric knees, potted in a loading fixture designed to apply axial loading during imaging. SPGR (Spoiled-gradient echo) and CUBE image sets were obtained in the non-weight-bearing position, and then again in a loaded configuration, equivalent to 50% body weight. The unloaded images were used for segmentation of soft tissue, and bones were segmented in both positions to determine the movement due to loading. This protocol is based on similar *in vivo* studies[4]. A variety of programs were used in segmentation such as MeVisLab, Amira, and ITK Snap. FE models were created from the segmentations with meshes of hexahedral elements generated using TrueGrid, and simulations were run in Abaqus. Loading conditions for this simulation were based on a transformation matrix from unloaded to loaded position and fixing all degrees of freedom of the knee other than varus-valgus rotation. A load was applied in the axial direction at a femoral reference point to reflect loading during the scan (Fig. 1)[5]. The direction and location of the load was applied to a femoral reference point determined from an automated MATLAB code that established the coordinate systems of the femur and tibia[6]. The cartilage was assigned isotropic properties, and the menisci were transversely isotropic, with stiffer modulus in the circumferential direction. Meniscal attachments were assigned spring stiffnesses to a shared reference point. To evaluate possible variations in material properties, each model was run with 70 different combinations of Young's moduli and Poisson's ratio for the cartilage and menisci. In addition to these baseline conditions, we explored variations in three categories as defined below for the boundary conditions, meniscal boundaries, and cartilage thickness, with each case run through a range of material properties.

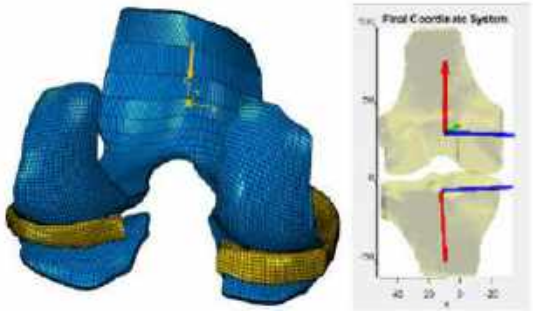

Figure 1: FE Model of the knee represented by tissues, with displayed femur reference point and axial load (left) from tibiofemoral coordinate system (right)

Boundary Condition Modification:

Because the coordinate system is sensitive to changes in bone geometry, segmentation and smoothing can impact the location and orientation of the load. To determine the effect of this variation, the femoral reference point was moved +/-1.3mm in the ML and AP directions, a magnitude equivalent to 1 slice thickness in the MR image sets used for segmentation. Next, the same cadaver images were segmented using two different software tools, Amira and MeVisLab. To account for the difference between resulting segmentations, the rotations of the model were modified by 1 degree in I/E and F/E directions.

Meniscus Modification:

Identifying boundaries between the meniscus and its attachments is challenging during segmentation and sharp edges in the model may impact successful convergence in FE simulations. Therefore, to determine the effect of the length of the anterior horn, the medial meniscus was modified by deleting a region of elements and shortening the meniscus by approximately 7.5mm, effectively lengthening the spring attachments. To study the effect of the geometry of the meniscus, each of the meniscal edges were tapered to reduce high concentrations of contact pressure with the tibial cartilage. For comparison, two sizes of partial meniscectomies were modeled in the posterior medial compartment (Fig. 2).

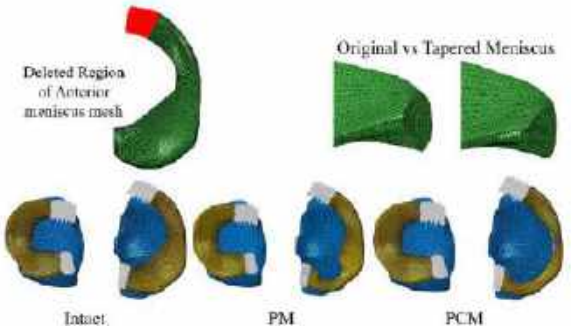

Figure 2: Medial Meniscus Shortening, Tapering, Intact and Meniscectomy Conditions

Tibial Cartilage Modification:

Uncertainty in segmentation may lead to variations in cartilage thickness of approximately one image voxel. Therefore, we modified each model to investigate increases in cartilage thickness of 0.3 mm (Fig. 3). Additionally, the cartilage at the periphery of the knee gradually tapers down, but this could result in distorted hexahedral elements. Therefore, the mesh is often shortened to allow a vertical edge. A different way to model this geometry with hexahedral elements could include a "staircase effect," where rows of elements are removed along the edge of the tibial cartilage. These conditions were run for a representative sample of 25 material property combinations.

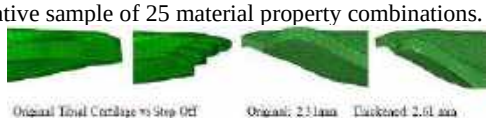

Figure 3: Tibial Cartilage Step Off and Thickening

To evaluate the variations described above, 1355 FE models were run. Our primary interest relates to the role of the meniscus in contact mechanics; thus, we calculated the total contact area on the medial plateau and the fraction of force supported by the meniscus.

RESULTS

The role of the meniscus in carrying contact forces varied greatly between knees, due to partial meniscectomy and due to uncertainty in material properties, with the ~25% of the force through the meniscus in one knee and nearly 100% of the load in two other knees. In contrast, thickening the cartilage resulted in minimal difference in the mean or distribution of the fraction of force through the meniscus for any of the four knee models tested (Fig. 4). Focusing on one knee, creation of the partial meniscectomies greatly reduced the role of the meniscus, with modeling variations related to the boundary conditions or meniscal ends having minimal effect.

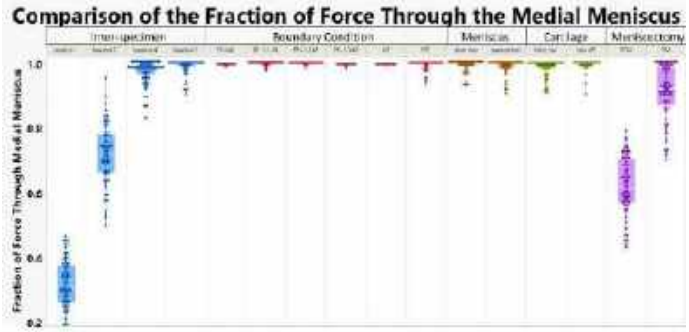

Figure 4: Fraction of Force Through Medial Meniscus between different knees and in one knee

The effects of our modeling variations on contact areas were similar, with differences between knees and differences due to modeling modifications much smaller than differences due to material property variations.

DISCUSSION

Model-generation variations in the FE models did not result in large effect on the outputs of interest. The small variability in outputs relative to variability between knees and meniscectomy conditions demonstrates that the FE model is robust enough to handle small, expected variability in the model making process. There is a larger effect on contact area from the range in material properties than from modification to the models. Our study contributes to further understanding the sensitivity of contact mechanics to model inputs[7,8,9] by focusing on variations resulting from uncertainties in segmentations. This preliminary work focused on variations made on only one cadaveric model, which had a very large fraction of force through the medial meniscus. Future studies will confirm this finding for multiple knee geometries and other model outputs such as locations and magnitudes of peak pressure. Four cadaver models make up a small sample size, and verification analysis should continue with more knees with varying geometries and outputs. Despite these limitations, our sensitivity study showed that the modification of models had a small influence on the primary outcomes of interest relative to the difference between knees and due to meniscectomy.

INTRODUCTION

The Achilles tendon is an integral biomechanical structure that connects the gastrocnemius and soleus muscles of the calf to the calcaneal insertion, facilitating planar flexion of the foot, shock absorption, and storage and release of energy. It is composed of a complex, largely collagenous, matrix that can be analyzed using mechanical properties such as nonlinearity, modulus of elasticity, stress, strain, and viscoelasticity. These mechanical properties allow the tendon to efficiently transmit force which is fundamental to locomotion and injury prevention.[1] Optimal levels of mechanical loading facilitates the growth of a healthy tendon, yet excessive or insufficient loading can lead to damage and give rise to injury.[2] While mechanical load is critically important to maintaining tendon mechanical properties, how this process is coordinated at a cellular level is currently unknown. The overarching goal of this project is to establish voluntary wheel running (VWR) as a model for studying the cellular and molecular regulators of physiological tendon adaptation. We hypothesized that physiological loading through VWR would result in altered tendon material properties that will allow tendons to transfer energy more efficiently (e.g. increased peak stress, elastic modulus, and stress relaxation). In order to assess changes in tendon mechanical properties due to VWR, we developed a customizable 3D printed testing platform and robust protocol.

METHODS

The University Committee on Animal Resources approved all animal studies. 10-week-old male C57BL/6J mice (n=40) engaged in VWR using a slanted saucer shaped wheel, with all run activity being recorded continuously electronically. Control mice were provided with a locked wheel. Mice were sacrificed after 8 or 12 weeks of running, and the right hind limbs were harvested at the knee for testing.

Samples were kept hydrated in phosphate buffered saline (PBS). The plantaris tendon was removed, and the Achilles tendon was isolated while keeping intact the calcaneal insertion. Preserving the insertion point and bone ensured that the distal end of the tendon could be effectively gripped without compromising the tendon mid-substance. The proximal end of the tendon was dissected from the gastrocnemius muscle to maximize gripping surface and increase gauge length.

Custom 3D printed grips were developed through multiple iterations using CAD software (SOLIDWORKS® 3D CAD) and printed using an Original Prusa i3 MK3 3D Printer with 1.75mm polylactic acid (HATCHBOX 3D). To reinforce grip stability and tendon clamping, thread holes for steel screws were created using a T-handle tap wrench. 3M coarse 60-grit sandpaper was affixed to the grips using cyanoacrylate glue to enhance traction and prevent slippage.

Dissected tendons were placed on the prepared grips using a 3D designed alignment tool (Fig. 1A) ensuring a consistent gauge length of 4.35 mm. Tendons were bonded with the grips using cyanoacrylate glue then fastened with steel screws and allowed to cure overnight at 4°C in PBS to ensure polymerization of the cyanoacrylate glue. A 3D-printed PBS bath was designed to fit within the tensile tester (Fig. 1B) ensuring tendon hydration during mechanical testing.

Mechanical testing was conducted using a semi-customized uniaxial microtester (eXpert 4000 MicroTester, ADMET, Inc.). Data was collected using MTESTQuattro®. The cross-sectional area (CSA) of the Achilles tendon was measured using ImageJ from images acquired prior to testing.

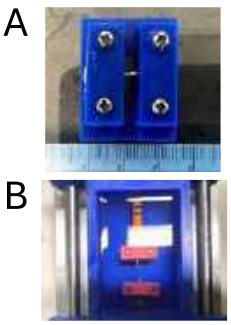

Figure 1: (A) Prepared grip in alignment tool. (B) PBS bath in tensile tester.

The test procedure included an initial preload to a load of 0.1N followed by 10 cycles of loading at 6% strain. Displacement required to reach defined strain percentages was calculated from the gauge length under a preload of 0.1N for each tendon. Tendons underwent stress relaxation phases at both 8% and 16% strain, allowing for a 500-second recovery period at each stage. Finally, a ramp-to-failure test at a rate of 1mm/s was conducted to determine the ultimate tensile strength, stiffness, and elastic modulus of each tendon. Change in stress was calculated by subtracting the equilibrium stress from the peak stress for each phase of stress relaxation. Differences in biomechanical outcomes were assessed by Two-way ANOVA with Tukey's multiple comparisons test (GraphPad Prism 10.1.1).

RESULTS

Following a 4-week acclimatization period, running behavior stabilized at 5 weeks, with an average weekly distance of 123.8 ± 13.5 km (Fig. 2). The average weekly distance from weeks 8 to 12 was 91.59 ± 5.1 km. Throughout the experiment, the 8-week VWR cohort recorded a total run distance of 783.09 ± 49.0 km, while the 12-week VWR cohort averaged 1111.0 ± 131.1 km.

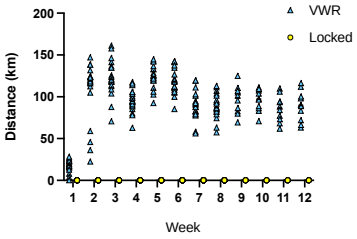

Figure 2: Running distance of mice for 12 weeks of VWR (blue) compared to control (yellow).

There was a significant increase in stress relaxation of VWR tendons compared to locked controls during the 8% stress relaxation phase at 8 weeks, which returned to baseline by 12 weeks (Fig. 3A). We observed no differences in stress relaxation between VWR and control tendons at either timepoint during the 16% phase (Fig. 3B); however, there was a significant decrease in stress from 8 to 12 weeks in the VWR group. At 8 weeks, both peak stress (Fig. 3C) and elastic modulus (Fig. 3D) were significantly increased in VWR tendons compared to controls (~55% and ~44% increased, respectively). Neither difference persisted to 12 weeks. No significant changes were found in peak load or stiffness between VWR and control tendons at either time point (Figs. 3E-F); however, we observed a significant decrease in the stiffness of control tendons from 8 to 12 weeks (Fig. 3F). No significant differences were observed in the CSA of VWR tendons compared to control at either timepoint (Fig. 4).

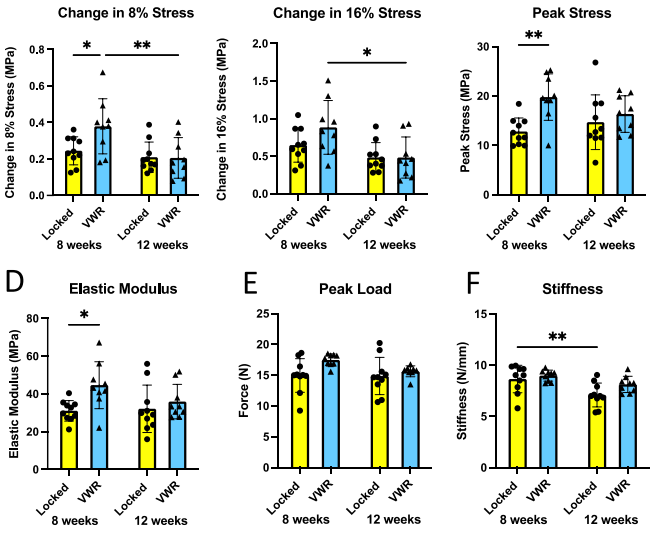

Figure 3: Biomechanical properties of Achilles tendons after 8 and 12 weeks of VWR (blue) compared to locked controls (yellow). Graphs depict (A) Change in 8% Stress, (B) Change in 16% Stress, (C) Peak Stress, (D) Elastic Modulus, (E) Peak Load (F) Stiffness. n=9-10 per group. *p≤ 0.05, **p ≤0.01.

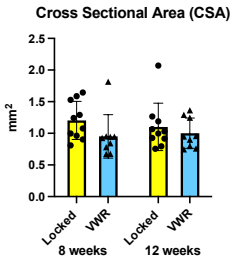

Figure 4: CSA of tendons

DISCUSSION

The strengths of this study lie in the reproducibility of the testing procedure and the physiological relevance of VWR as a model. Results demonstrate that mice have a natural inclination to run without additional stress, and that, in line with our hypothesis, VWR resulted in significant changes in the mechanical properties of Achilles tendons after 8 weeks. Furthermore, a notable achievement of this study was the 100% success rate in the mechanical testing of the tendons by effectively eliminating tendon slippage. Adjusting the tendon dissection method and gripping techniques also ensured that all tendons broke at the mid-substance, facilitating reproducible examination of the major region exposed to physiological loads during locomotion, thus demonstrating that our customized platform provides an accurate analysis of in vivo mechanical properties and adaptation.

In this study, VWR did not induce significant changes in the CSA of tendons. This outcome suggests that 8 to 12 weeks of VWR may not significantly influence tendon morphometry. It is possible that tendon hypertrophy may necessitate a longer duration or a different intensity of mechanical loading. The change in stress relaxation at 8% stress, peak stress, and elastic modulus of tendons were significantly increased after 8 weeks of VWR. These results demonstrate an increase of tendon strength and resilience against applied forces, suggestive of an adaptive response to mechanical load. The lack of significant changes in tendon stiffness at 8 weeks combined with the change in modulus suggests that while no large structural changes occurred, VWR induces changes in tendon material quality. These findings have important implications for understanding the biomechanics of tendons and how exercise may affect tendon mechanics. Interestingly, these differences in 8% stress, peak stress, and elastic modulus did not persist at the 12-week mark, with no notable changes between the locked and VWR groups. This plateau may point to a time-dependent response in tendon adaptation, suggesting that there might be a limit to the extent of change achievable within this timeframe. Future work will examine time-dependent nature of tendon response to mechanical loading and the potential for adaptation over longer periods.

In the future, we aim to tailor the grip design to accommodate anatomically different tendons. This will increase the platform's versatility and broader application in tendon research, potentially being applied across different animal models and tendon structures. This testing platform will also be used to evaluate how genetically altering important mechanosensitive pathways affects the biomechanical properties of tendons, with the ultimate goal of determining how tendons adapt to mechanical load.

INTRODUCTION

The complexity of tumor microenvironments remains a significant challenge in cancer research. Specifically, the differences and interactions between cancerous and noncancerous tissues present numerous obstacles, varying case by case and dependent on the location (e.g., breast, pancreas, etc.). This demonstrates the importance of *in-silico* experimentation built based on patient-specific images to enable more accurate modeling of tissue environments, including the tumor microenvironment. The current study aimed to develop an *in-silico* model of a patient-specific breast tumor tissue which will then be applied to assess the tumor's malignancy through quantifying the forces within the breast tumor tissues.

METHODS

We used the standard and high-definition Fourier Transform Infrared (FTIR) imaging to image and classify to forty tissues to four distinct breast tissue pathology types: "Normal Breast Tissue," "Hyperplasia," "Invasive Carcinoma of No Special Type (NST)," and "Invasive Lobular Carcinoma." Using an FTIR imaging microscope, we will first record high-definition data and apply numerical noise reduction methods to provide high spectral signal-to-noise ratio (SNR). Standard definition data then will be recorded on the same breast tissue samples (tissue arrays from US Biomax) [1-4]. Each image contained six tissue components, including noncancerous epithelial tissue, cancerous epithelial tissue, dense stroma, loose stroma, reactive stroma, and other (e.g., blood vessels).

Image Processing: The FTIR images were received in MATLAB file format and were subsequently processed to extract individual tissue components. For instance, in the case of the malignant tissue images, a separate image was extracted specifically for each noncancerous epithelial tissue, cancerous epithelial tissue, dense stroma, loose stroma, reactive stroma, and other. In total, 31 FTIR files were processed.

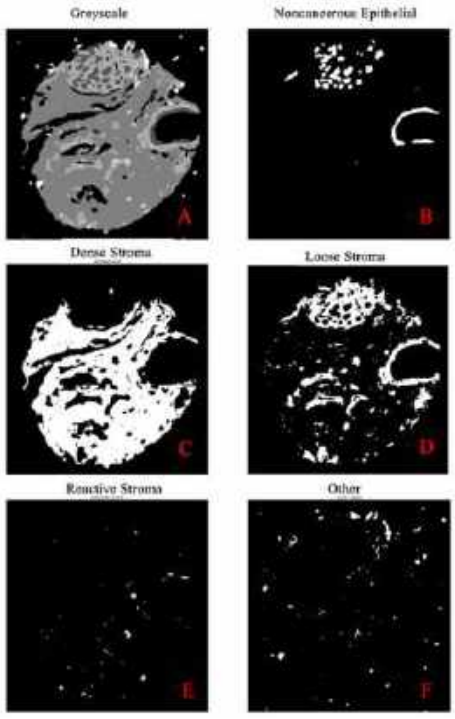

Figure 1. Hyperplasia sample processed in MATLAB. Figure 1A depicts a complete hyperplasia sample in grayscale, with all tissue types of present. Figures 1B-1G depict the individual tissue types extracted from the FTIR images as B) Noncancerous Epithelium C) Dense Stroma; D) Loose Stroma; E) Reactive Stroma; F) Other Tissue. In this sample, no malignant tissue was present.

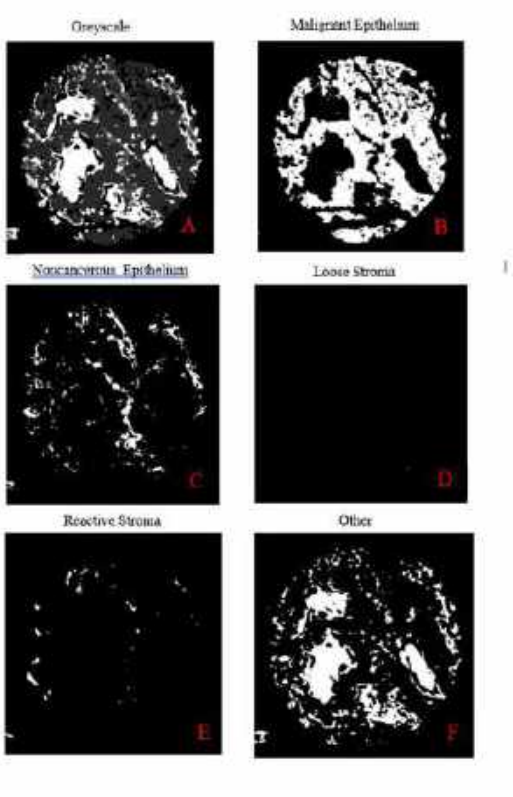

Figure 2. Invasive carcinoma sample processed in MATLAB.
Figure 2A depicts sample in grayscale, with all tissue types present , Figures 2B_G depict the individual tissue types extracted from the FTIR images as B) Malignant tissue; C) Noncancerous Epithelium; D) Dense Stroma; E) Loose Stroma; F) Reactive Stroma; G) Other Tissue.

Image Segmentation: The extracted tissue types were then imported into Mimics, a software application for medical image processing. Segmentation was performed within Mimics to generate three-dimensional representations of each tissue type. These segmented images were then exported in STL format for further analysis.

Discussion:
Our ongoing study focuses on developing in-silico models of breast tumor tissues, leveraging patient-specific data acquired through FTIR imaging. We are planning to the segmented image files exported from Mimics into LAMMPS (Large-scale Molecular Dynamics Massively Parallel Simulator) to build three-dimensional *in-silico* model of breast tumor tissue. Figure 4 depicts our *in-silico* models of four breast tumor tissues as A) Hyperplasia; B) Invasive Carcinoma NST; C) Invasive Lobular Carcinoma; D) Normal Breast. It is clear that the different pathology types display different variations of the tissue, for example, dense stroma tissue (depicted in orange) varies patient to patient [5-6]. These models aim to quantify the von Mises stress magnitude and distribution within breast tumor tissues, considering diverse pathology types. Understanding the mechanical properties is paramount for accurate *in silico* modeling, as these properties are recognized hallmarks in cancer initiation and progression. This study plays a critical role in developing targeted interventions and advancing our understanding of the biomechanical factors influencing cancer progression.

INTRODUCTION

Blood flow in the brain occurs through a highly complex vessel network originating from the ring-like network of supplying arteries named the Circle of Willis (CoW). During arterial insufficiency due to occlusive events such as ischemic stroke, a subsidiary vessel network complements and stabilizes the flow, thereby enabling redundancy [1]. This is referred to as collateral circulation. While the CoW itself enables proximal collateral flow routes, additional smaller distal (leptomeningeal) vessels play a significant role in supporting collateral flow [2]. Collateral flow is recognized to be a key determinant of cerebral tissue damage during stroke, and strongly influences stroke therapy outcome and recanalization success [3]. Despite their importance, collateral circulation remains poorly understood, due to several factors. Distal collateral pathways are small and difficult to image or experimentally study in vivo. Furthermore, the hemodynamic interplay between proximal and distal collateral pathways is poorly understood. Current efforts in collateral assessment are based on imaging, such as the ASPECTS score based on CT imaging [4], and the Perfusion Collateral Index. These metrics are derived solely based on image pixel intensities, and often the underlying hemodynamic patterns remain unclear. Thus, there is a need to develop techniques to characterize cerebral collateral flow. Here, we outline an in vitro benchtop model for a comprehensive understanding of cerebral hemodynamics with collateral flow, that can: (a) incorporate patient anatomy features; (b) identify simple flow descriptors; (c) illustrate proximal-distal collateral pathway interaction.

METHODS

Image-based 3D printing of Circle of Willis: We devised a custom in house workflow to create a 3D printed phantom of the arterial network at the level of the CoW, as illustrated in Figure 1. Specifically, we segment the arterial network upto the cerebral arteries in the CoW to generate a 3D model of the vascular network (SimVascular). Thereafter, we extract centerlines and obtain morphometric features of the CoW network (3DSlicer); which is used to generate a planar projected model of the CoW network (Solidworks). The network is then printed into a physical model using SLA 3D printing with a rigid clear resin.

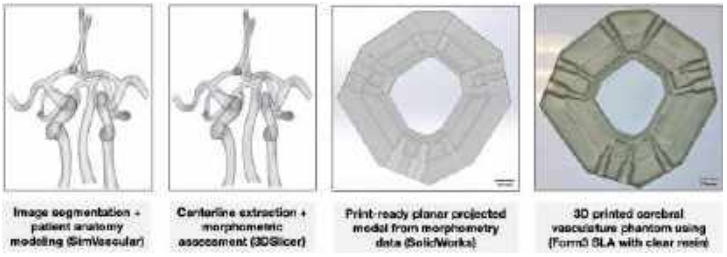

Figure 1: Illustration of the steps in the workflow for obtaining the 3D printed arterial network model for the Circle of Willis (CoW).

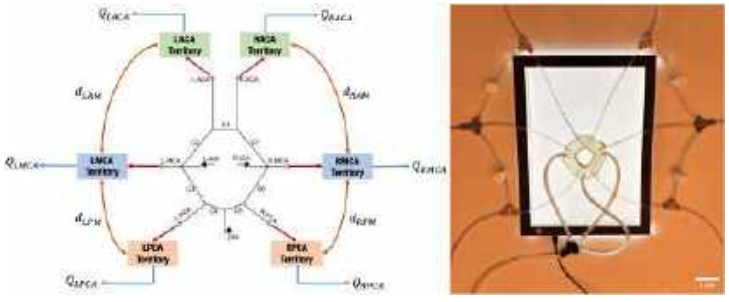

Figure 2: Network model demonstrating the flow pathways (left) and the benchtop implementation of the flow network connections (right).

Flow-loop design: The 3D printed CoW model was incorporated into an in vitro flow loop with distilled water as working fluid. A peristaltic pump was set to deliver total inflow of 650 ml/min, split into the 3 inlets into the model - L+R internal carotid (ICA) and basilar arteries (BA). A custom 3D printed trifurcating flow splitter was designed to map 230.57 ml/min to LICA; 277.95 ml/min to RICA; and 140.16 ml/min to BA. This mimics cervical vessel flow distributions reported in prior works [5]. Hydraulic pathways representing distal collateral circulation were incorpo-

rated via silicone tubing of 3/16 in. inner diameter connected to the outflows between the 6 cerebral arteries as shown in Figure 2, leading to 4 labelled distal collateral routes. Non-contact precision flow control valves were used to control patency/flow for each distal tubing. Finally, a stroke was simulated in the flow-loop by identifying the vessel to be occluded (right or left M1, A1, P1 segment), and 3D printing a solid cylindrical pellet fitted to the inner diameter of that vessel in the model.

Design of experiments: We conducted a set of experiments with a CoW model that had a complete ring anastomosis of the CoW connecting vessels. 6 stroke events were modeled at each of left and right M1, A1, and P1 vessels. Each of the four distal routes were either kept fully open or fully closed. This led to a sum-total of 96 different experiments, and one additional control case with no stroke. For all experiments, the peristaltic pump flow-rate was kept fixed; and volumetric outflow at each of the 6 CoW outlets were measured. Mass balance relation was used to identify measurement errors. Finally, a simplified hemodynamic descriptor was developed by quantifying the proportion of flow into the occluded vessel that was recovered by activating a collateral pathway combination. This is referred to as a collateral recovery ratio in this study.

RESULTS

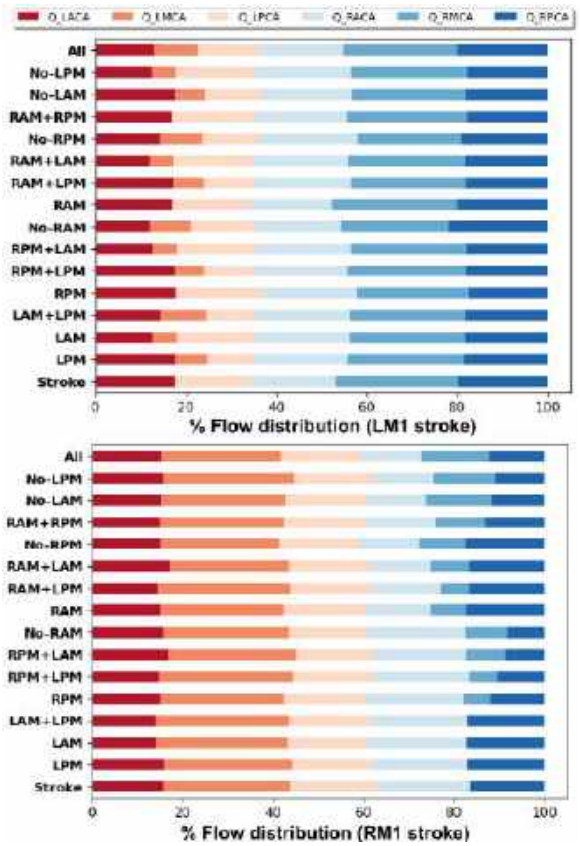

Figure 3: Flow distribution in terms of percentage of cerebral blood flow input for LM1 stroke (top) and RM1 stroke (bottom) as a function of varying distal pathways.

For each stroke location, we computed and compared the volumetric flow distribution across all 6 cerebral artery outlets as function of varying distal collateral pathways. For brevity, here we illustrate these results for the two MCA stroke scenarios (occluded left and right M1 respectively). The distribution patterns, represented in percentage of total cerebral blood flow input, across the 6 cerebral arteries for these two cases are presented in Figure 3. The cases labelled *Stroke* are the scenarios with no distal collateral - hence zero flow recovery onto the occluded vessel outlet. Likewise, cases labelled *All* denote the scenario where all 4 distal pathways were fully open. The measurement error for each of these experiments was less than 3%. The recovery ratio for these left and right M1 stroke scenarios are subsequently computed, and illustrated as a function of distal collateral pathways in Figure 4. The results clearly indicate a fractional or partial flow recovery distal to the occlusion site for both stroke scenarios. We also observe that, for the two MCA stroke scenarios shown here, if neither of the ipsilateral distal pathways are active, no recovery will occur - which is expected from vascular anatomy considerations. However, the findings indicate that the presence of collateral activity in the contralateral hemisphere may influence the amount of recovery; while maximum recovery for the RM1 stroke is noted when all distal routes are active, for the LM1 stroke it is instead observed when only ipsilateral distal routes are open. Additionally, we note that owing to inherent asymmetries in real vascular anastomoses, the flow distributions and recovery ratios are not symmetric between left and right.

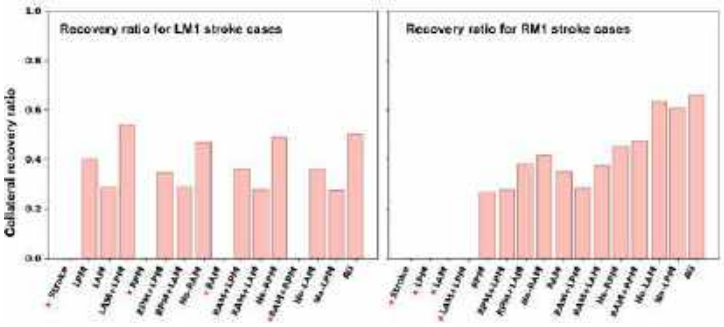

Figure 4: Illustration of computed collateral recovery ratio for LM1 (left) and RM1 (right) stroke cases as a function of distal collateral pathways. zero recovery cases are indicated with a red asterisk.

DISCUSSION

Here we have demonstrated a novel in vitro benchtop model for studying cerebral collateral circulation. To the best of our knowledge this is amongst the first attempts to create an in vitro model of cerebral collateral circulation. The model enables key insights into the collateral circulatory pathways, the hydraulic network type effects, and the extent of flow recovery in an occluded vessel region; as demonstrated in this contribution. The design is flexible to support further advancements. For instance, CoW anatomical variations, as studied extensively in our prior works, can be integrated to study how flow recovery patterns vary with CoW network topology. While the present study only considered distal vessels to be open or closed off, the use of flow control valves enables us to further regulate and vary the extent of distal flow route patency, allowing the recreation of several scenarios for collateral activity. These will inform continuing investigations using our proposed model. Additionally, this contribution presents a framework for quantifying collateral circulation using a fluid dynamics basis; indicating an extent of flow recovery in an occluded vessel as function of distal collateral routes. This has significant clinical implications in enabling better understanding of current metrics for collaterals that are based on imaging alone; and also complement existing image-based methodologies towards advancements in collateral flow characterization techniques in standard-of-care for stroke and ischemic disorders.

INTRODUCTION

Cerebral blood vessels have stiffness values orders of magnitude larger than brain tissue [1] yet when studying the dynamic response of the brain in traumatic brain injury (TBI), the cerebrovasculature is often not accounted for. Additionally, recent studies have suggested that even mild deformations can damage, and soften, cerebral arteries [2]. Significant in vitro testing has been done to characterize isolated vessel softening [2,3], but to meaningfully utilize this information in clinical and research settings, it is necessary to contextualize it and understand the interactions between the vascular structure and other brain tissue. Recent computational studies have found significant differences in brain mechanics with and without major cerebral vessels [4], so it is important to study these discrepancies to ensure dynamic models of the brain are accurate.

A promising method for this characterization is magnetic resonance elastography (MRE). Through the use of specialized phase-contrast MRI sequences and the propagation of mechanical shear waves through tissue, MRE generates stiffness maps based on measured displacements in a material. However, resolutions, which are dependent on the frequency of mechanical vibrations applied to a tissue, are only reliable down to approximately 2 mm^3, with some experimental techniques reaching accurate resolutions of approximately 1-mm^3 voxels in cortical brain tissue (although not vessel structures) with ultra-high field scanners [5]. To begin using MRE to characterize cerebral vessel softening, we aimed to investigate resolution thresholds as a function of the size and stiffness of inclusions, as well as the frequencies used in the imaging.

METHODS

Two MRE phantoms were fabricated to study MRE resolution thresholds: one gel-only phantom acted as a control for comparison to the second phantom. The second inclusion phantom contained three evenly spaced layers of silicone and plastic tubing, ranging from 4 to 10 mm in diameter, to gauge the resolution thresholds of MRE with high-stiffness elements and their effect on the surrounding tissue. Phantoms were made with 50% diluted 125-bloom gelatin, which is typical in brain MRE studies. Stiffness data was acquired using an MRE research pulse sequence on a 3T scanner (MAGNETOM PrismaFit, Siemens Healthineers, Erlangen, DE). Phantoms were strapped to a pneumatic drum actuator and placed in the head coil. MRE data were acquired at mechanical frequencies of 60, 80, 100, and 120 Hz. More precise geometry of the phantoms was obtained from a high-resolution T1-weighted MRI acquisition, for comparison with the MRE data. A tensile test to 1.2 times the original length of the tube was performed on the smallest (4 mm diameter) inclusion to determine its shear modulus for comparison to MRE elastogram data.

A finite element (FE) model corresponding to the gel-only phantom was constructed in FEBio, and MRE was simulated at the same scan frequencies used in the experimental MRE. The FE model used a 1-term Ogden model with a 2-term Prony series to model the gel, and model parameters were extracted from previously reported mechanical tests on minipig brain [6]. The model was constructed as a cylindrical mesh matching the phantom geometry, with rigid boundary conditions on the outer layer of the cylinder (Figure 1). Mesh convergence tests were run on phantom simulations to ensure accuracy. Typically, displacement and point stress values are used to test convergence, but the oscillating nature of the model prevented this. Instead, maximum stress values and distance between shear wave fronts were used as convergence criteria.

RESULTS

In the inclusion phantom, even the smallest inclusion (4 mm diameter) was visible in the elastograms of all four frequencies at an approximate resolution of 1.64x1.64x3 mm. This tubing had an experimentally determined elastic modulus of 3713.2 kPa, and Poisson's ratio of nearly 0.5, giving a shear modulus of 1237.7 kPa for

an isotropic material. While the elastograms provided drastically smaller values of shear modulus in the region of the smallest inclusion, the moduli were notably higher than those associated with the control phantom across all four frequencies (Figure 2). For example, in the 80-Hz scans a maximum stiffness of 4.04 kPa was observed around the 4-mm inclusion compared with the median gelatin stiffness of 3.08 kPa observed in the gelatin-only control phantom. This difference only increased around the regions of larger inclusions. Vessel detection was also observed to be frequency-dependent (Table 1).

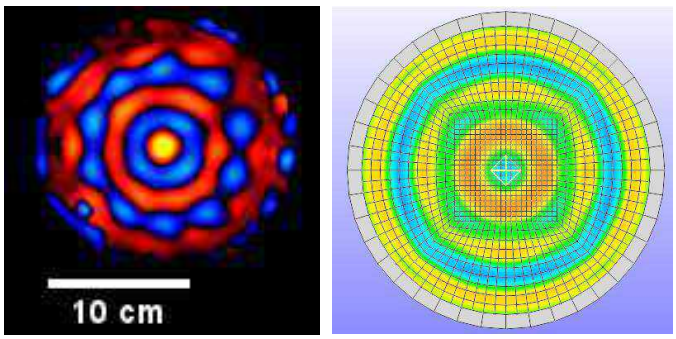

Figure 1: Example of wave similarities in control phantom MRE wave data (left) and FEBio simulation shear waves represented by stress magnitude (right).

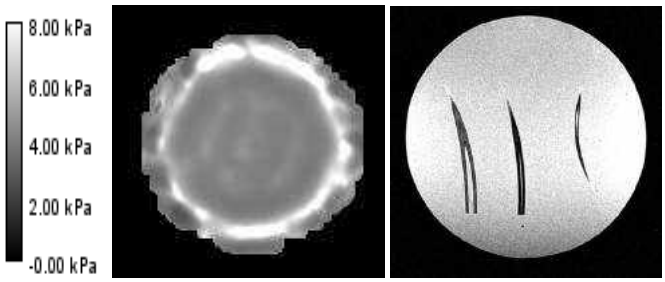

Figure 2: MRE elastogram at 80 Hz (left) and T1-weighted MRI (right) acquisitions of the inclusion phantom at approximately the same slice depth containing the smallest (4 mm) inclusion (rightmost of the three seen in both MRI image and areas of slightly elevated stiffness in elastogram). The color bar on the left corresponds only to the elastogram.

Scan frequency	4-mm Inclusion Stiffness % Difference
60 Hz	6.72%
80 Hz	26.97%
100 Hz	13.70%
120Hz	14.98%

Table 1: Percent difference between measured MRE stiffness values surrounding the 4 mm inclusion and control phantom median stiffness values at same frequencies.

DISCUSSION

The purpose of this study was to explore the use of MRE as a method to potentially measure cerebral vessel stiffness and softening given the affect TBI has been shown to have on the mechanics of the cerebral vasculature. Considering that the tubing used in the test phantoms does not give off any MR signal yet had an impact on the stiffness readings of the surrounding gelatin, the results demonstrate that MRE can detect stiffness inclusions near or below its intrinsic resolution. The notion that vessel stiffness can be detected from their influence on surrounding tissue, despite not generating any signal, is especially promising given that real vessels will contribute MR-detectable signal. Although the inclusions used in this study lack the viscoelasticity of cerebral vessels, the low strains produced in MRE would negate differences between real vessels and the materials used here. With the observed dependence of the surrounding tissue signal on frequency, further work should be done to correlate inclusion shear modulus readings to optimal scan frequency.

Additionally, the FE model predicted the same number of wavefronts and similar wave spacing once steady state had been reached for all four frequencies. Based on similarities between the control scan and FE model predictions, the accuracy of MRE for detecting below-resolution shear modulus changes could be further improved and applied to even smaller vessels. As a continuation of this investigation, an FE model is currently being created with a single tubing element for comparison with single-inclusion MRE phantoms. Ultimately, findings indicate that MRE is certainly a suitable candidate for detecting softening of larger vessels such as the middle cerebral artery, and possibly for smaller vessels as well. This information could be key to establishing more quantitative criteria of vessel softening for further study of TBI.

ACKNOWLEDGEMENTS

Financial support was provided by an award from the Department of Radiology and Imaging Sciences and by the Office of Undergraduate Research, both at the University of Utah. We would also like to acknowledge Brad Bolster, PhD, of Siemens Healthineers for access to the prototype MRE sequence and assistance acquiring data.

INTRODUCTION

Tracheostomy is a surgical procedure that involves the opening of the trachea from the outside of the neck of patients dealing with severe respiratory conditions to maintain a durable airway. [1] Tracheostomy tubes permit air to enter directly into the trachea. The entering air bypasses the upper respiratory airway, causing cold and dry air to enter the lungs, which causes irritation of the lining of the trachea. This leads to complications that can be life threatening.
Current humidification devices used in hospitals have tethering and wasteful setups, usually requiring the use of oxygen tanks.

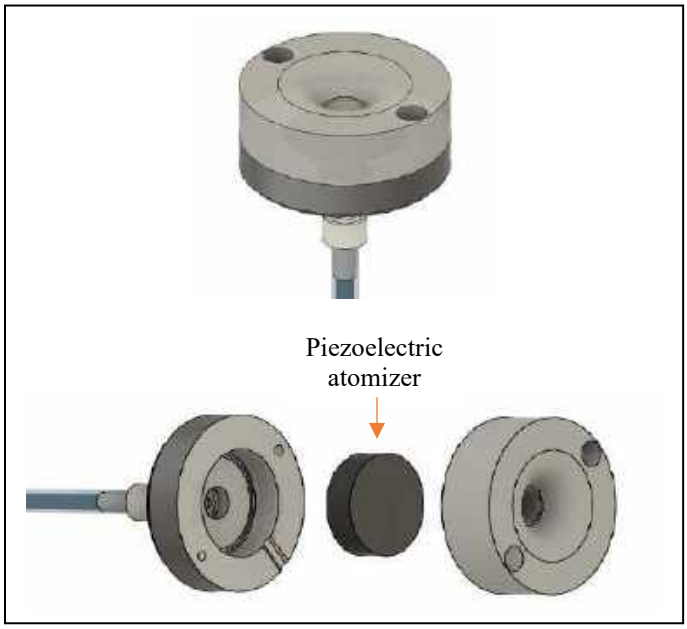

Figure 1: Piezoelectric atomizer holder with attached water tube with luer lock connector. Front view (top) and exploded view (bottom).

Our goal is to reduce the scale of the setup with a portable and efficient humidification device that will untether these patients as to increase their comfort levels and reduce energy and water consumption. Moreover, a device like this one is crucial during natural disasters when patients need to be transported out of the hospital and/or when there is a shortage of resources like oxygen tanks.

The market potential of this product is promising since more than 100,00 patients receive tracheostomies each year, which results in hospital costs of almost 11 billion dollars in the United States alone. [2]

PRODUCT DESIGN

Our proposed design solution is to place a piezoelectric atomizer in an encased holder (Figure 1) near the opening of the trachea. One side of the holder feeds water to the piezo through a tube. On the other side there is an opening through where the atomized water exits. The water tube is connected to a water reservoir encased in a fanny pack that the patient will be wearing (Figure 2). The water reservoir bag uses a step motor that compresses the bag as needed to maintain constant contact between the water in the tube and the piezoelectric atomizer.

BUDGET & MARKET ANALYSIS

The budget allotted for our project was 1000 dollars. We have spent a total of 156 dollars to build and test the prototype. The budget does not include the 3D printed resin components that our project mentor provided us with.

The potential market size of our tracheostomy humidification device is approximately 5,000 units if 3% of tracheostomy patients buy the device, and hospitals acquire 2,000 units every year.

The expected manufacturing cost per unit is approximately 45 dollars. The projected sales price is 120 dollars. The investment cost would be approximately 2500 dollars for a Formlabs 3D resin printer package. The return of investment for the first year could be up to 35,000 dollars if at least 500 units are sold.

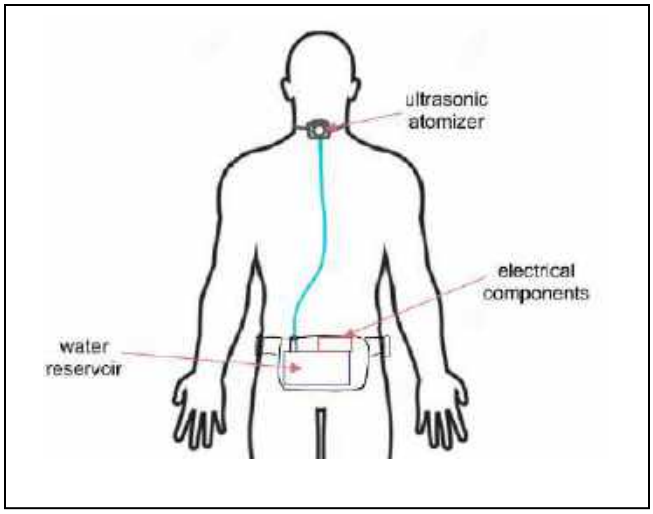

Figure 2: Diagram of the tracheostomy humidification device design solution.

INTRODUCTION

When dealing with fires, firefighters put their bodies through extreme heat stress which can lead to serious issues that have an impact on their health and their ability to react efficiently. Our group is designing and developing a cooling system that can be worn with the current firefighter's gear without impacting the wearer's motion while maintaining a cooler environment inside the suit to tackle this issue. Wearable cooling systems already exist with many of them centered around helping first responders. These systems utilize cooling methods including fans, desiccants, and phase change materials. From reviewing the current market and the literature about these cooling systems our team decided to design a cooling system that utilizes drone motors and propellors to cool air across an array of ice packs that would potentially be cooled by dry ice. The device our group is designing is required to have a total weight below 10 pounds, operate up to 50°C for up to 4 hours, and maintain an internal temperature of 37°C inside the suit.

In today's market, common cooling methods for devices include phase change materials, liquid cooling, evaporation, and fan-based ventilation. Researching cooling vest designs revealed: **Compressed air cooling:** average power 41 W/m2, max power 44 W/m2, unlimited cooling time, capacity 331 W*hr/m2. **Liquid cooling vests:** average power 17 W/m2, max power 60 W/m2, cooling time 151 minutes, capacity 118 W*hr/m2. **Evaporative cooling vests**: average power 4-22 W/m2, max power 6-43 W/m2, cooling time 0-210 minutes, capacity 0-113 W*hr/m2. **PCM cooling vests:** average power 5-23 W/m2, max power 16-92 W/m2, cooling time 0-210 minutes, capacity 0-164 W*hr/m2**. Evaporative and PCM hybrid:** average power 20-22 W/m2, max power 57-88 W/m2, cooling time 194-224 minutes, capacity 127-146 W*hr/m2**. Dry ice at 45°C:** average power 36.6-168.4 W/m2. [1][2]. While dry ice was determined to be the best method in terms of cooling capacity, the difficulty in handling and the hazard from the CO_2 in a confined space make it problematic for the current application. A system based on commercial ice packs and a drone motor was chosen instead.

PRODUCT DESIGN

The inner housing for the cool gel packs, made of ABS filament, has slots that fit 2 to 3 cooling packs (each at 10.8 cm x 2 cm x 13.3 cm) as shown in Fig. 1b. The front of the housing unit has a nozzle-shaped outlet for the flow of air cooled by the cooling packs. Two Arduino Uno R3 boards control the drone motor operated (capable of 5,000 rpm) for a 3-blade 3-in diameter propeller. Two DHT11 temperature and humidity sensors monitor the changes in air temperature and humidity of the system from inlet to exit. A cage attached to the housing holds the drone motor, propeller that protects the firefighters when wearing it as shown in Fig. 1d.

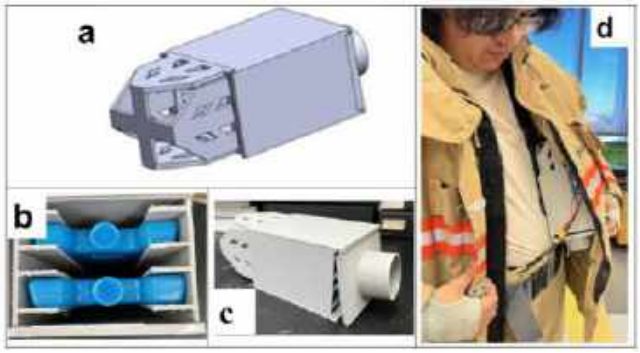

Figure 1: a). SolidWorks assembly of the cooling system, b). Bird's eye view of the inside of the cooling system with cool gel packs, c). Fully assembled model of the cooling system, & d). Cooling device inside of firefighter jacket.

The device is designed to help cool firefighters while wearing bunker suits executing firefighting missions. The device will be attached to the firefighter's overalls with the nozzle end pointing downward. The fan will blow the cool air from the cooled gel packs out through the nozzle end to inside the bunker suit. The attributes making this device unique include: 1) using a combination of ventilation and gel packs to cool the users, 2) as an independent lightweight, low-cost device (not a jacket), 3) providing the users with the option to cool the ice packs to dry ice or liquid nitrogen temperatures, increasing the cooling power, if these materials are accessible.

When planning on what type of pathways for our design, we looked at different variations of on-the-market products, which are shown below in Table 1.

Table 1: Possible Pathways for Project Design

	Design 1	Design 2	Design 3	**Design 4 (chosen)**

Description	Liquid Cooling + Ventilation	Evaporative cooling + Desiccant + Ventilation	Ventilation + Desiccant	Ventilation + Ice pack cooled with Dry ice
Pros	Remove moisture and heat simultaneously. Large coverage of body area.	Desiccant aids sweat evaporation. More effective cooling power.	Great for moisture absorption.	Easy to deploy. Uses readily available parts.
Cons	Bulkiness Low cooling time.	Higher cost Adds moisture into the system.	No direct cooling method. Less cooling power.	Requires freezer or cooler with dry ice.

The pathway that our team agreed on for our project design was ventilation with ice packs or dry ice, which was design pathway four.

When coming up with a design for our device the team bought two on-the-market cooling vests the "Venture Heat Wearable Cooling Fan Vest" and the "NJDGF Unisex-Adult Work Cooling Vest". Tests were run with the vests and how they functioned inside a firefighter bunker suit. The test was conducted by a member going up two floors in a building and testing what area of the body is affected by the cooled air. The team then decided to move away from vests and agreed to build a singular device that could be lightweight and easily removable. The team tested the device in an external and internal environment to assess its affect on the cooling rate of gel packs. The Elegoo Uno R3 boards were programmed using Arduino IDE.

RESULTS

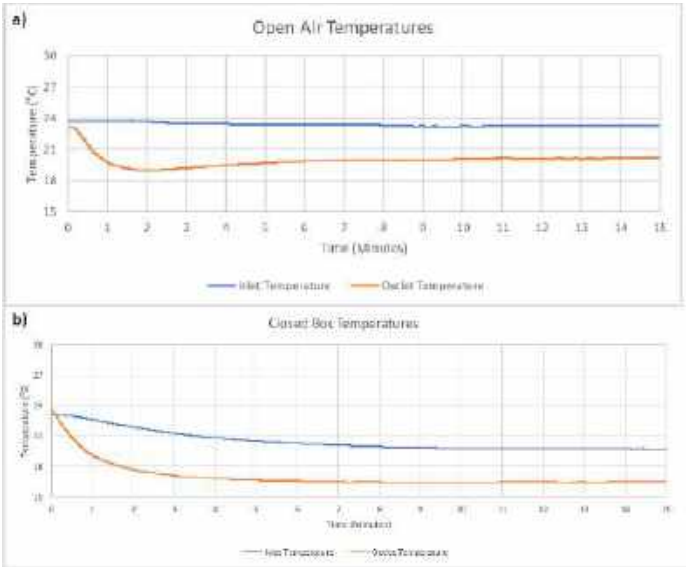

Figure 2: Recorded temperature data at inlet and outlet in an open-air environment (a) and a closed box environment (b).

For testing of our device we performed 2 tests: one with the device in an open-air environment and one with the device in a closed box environment. For each test, the temperature at the inlet and outlet of the device were monitored. The maximum temperature drop was calculated as the difference between the average inlet temperature and the minimum outlet temperature. The ice packs used in each test were frozen to a temperature of -18°C.

The first test (open air, Fig. 2a) resulted in a maximum temperature drop of 4.4°C and a final temperature difference of 3.1°C. The second test (closed air, Fig. 2b) resulted in a maximum temperature drop of 4.1°C and a final temperature difference of 3.2°C.

DISCUSSION & FUTURE WORK

The data from these tests show that our device does create a measurable drop in temperature as air is pushed across the ice packs. Even in a closed box, the device was able to provide a similar drop in temperature as compared to the open-air test and the temperature difference was sustained for the 15-minute duration of each test. In addition to this, the inlet temperature of the closed box test steadily decreased over the duration of the test showing that the device is capable of cooling the entire environment in which it is contained not just cooling intake air.

In the future we would like to implement data collection on humidity to assess its effect on the system as the ice packs melt inside the device. We would also like to test the effect of motor speed on the cooling rate of the device to understand the effect of heat coming off the motor into the system. We will also perform a longevity test to assess for what duration our device can sustain its temperature difference.

BUDGET & MARKET ANALYSIS

The budget for the cooling device was calculated to be $133.68. A breakdown of this budget was $44.60 for the two (2) Arduino boards, $2.62 for the two (2) DHT11 temperature and humidity sensors, $11 for a packet of drone propellors, $22 for the drone motor, $8.46 for eight (8) packs of cool gel packs, $36 for the 5200 mAh battery, and $9 for the ABS printed housing unit. The breakdown of the budget is shown below in Table 2.

Table 2: Breakdown of Budget & Weight of Components

Materials	Weight (g)	Price ($)
Arduino Uno R3 (2)	50	44.60
DHT11 Sensors (2)	44	2.62
Drone Fan (1)	2.56	11
Drone Motor (1)	198	22
Cool Gel Packs (2)	454	8.46
5200 mAh Batter (1)	380	36
Cooling Pack Housing	225.94	9
Total	1354.5 ≈ 3 lbs	133.68

When observing the cost of cooling devices that are on the market shows that the average for the least expensive cooling device was $53.40 and the average for the most expensive cooling device was $556.40. Our device costs $133.68 to manufacture and produce. The number of units that could be sold in a year would be approximately 50,000 to 75,000 units a year. The expected manufacturing cost would be approximately $135. The projected sales price of the device would be $235. The investment costs in engineering this device would be approximately $ 337,500 or a 2% annual fee. The return on the investment would be an annual rate of return of approximately 10 %.

ACKNOWLEDGEMENTS.

We would like to thank Dr. Oguz Yetkin for his guidance and for allowing our team to use some of his materials and Dr. Cheng-Jen Chuong for his guidance and for allowing the team to have access to his lab room.

GONIOTAPE: CREATING A WEARABLE ALERT SYSTEM FOR POST OPERATIVE PATIENTS AND COMMUNICATION TO HEALTHCARE PROFESSIONALS

V. Addanki, C. Shorr, M. Plone

Faculty Advisor(s)

E. Brewer

(1) Biomedical Engineering, Rowan University, Glassboro, NJ, USA

INTRODUCTION

In 2022, there were 2.8 million hip and knee arthroplasties in the United States alone[1]. It can also be noted that around 30% of knee and hip arthroplasty patients from ages 65-74 required total revision[2]. These numbers show that joint arthroplasties can affect much of the population. Not only this, but these procedures also require an extensive recovery, with some patients even requiring follow-up procedures.

Revision surgery involves correcting complications that arise after total joint arthroplasty, such as implant loosening, infection, or component failure. Lack of patient compliance with post-operative care, including activity restrictions and follow-up appointments, can exacerbate these issues and increase the likelihood of requiring revision surgery. Non-compliance may lead to delayed detection of complications and more severe problems necessitating surgical intervention. Studies show that up to 65% of patients can be non-compliant with post-surgical precautions[3]. Therefore, patient education and clear communication from healthcare providers are crucial to ensure adherence to post-operative care guidelines and minimize the risk of complications.

Occupational therapists will provide guidelines to their patients that pertain to range of motion. In a clinical setting, they will practice moving within these guidelines, or precautions, that are provided to them. However, there is no way for the patient or healthcare provider to monitor their compliance outside of this setting. Therefore, there is a need to improve patient compliance to post-operative precautions in order to improve patient outcomes.

Goniotape, a company started by occupational therapists, has teamed up with Rowan University engineering students to develop a solution to this problem. Our solution is a wearable device that aims to improve compliance by monitoring patient movement and providing alerts when a patient is non-compliant. By providing these alerts and allowing the patient to self-correct, we predict a lower rate of revision surgeries in those wearing the device compared to control patients.

In order to success, our device must be able to track the movement of the post-operative patient, including the angle at which the surgical joint is bent for several different planes of motion. Based on this data, the patient will be alerted if they are breaking their precautions. It must be able to detect any shoulder flexion beyond 90°, shoulder abduction beyond °90 hip flexion beyond 90°, hip extension beyond 0°, or hip adduction beyond 0°. These measurements must have an error of <5°, to maintain accurate patient feedback. The targeted prototype will have a localized, wireless communication ability, and in initial stages, intended for a clinical site for preliminary clinical trials that demonstrate the ability the correct failures to patient precaution compliance. Once initial efficacy is determined, the goal will be to develop at-home wearable sensors that communicate to the patients via a mobile phone app.

Creating a device that can closely monitor post-surgical precautions would be largely beneficial to help patients lower their risk of surgical revisions. This would allow patients to recover faster and with better peace of mind that they are not hurting themselves. Furthermore, we believe that there are multiple stakeholders in lower risk of re-surgery – such as benefits for healthcare providers and insurance providers.

PRODUCT DESIGN

In order to achieve this goal, we needed to create a system that could be worn by a patient, can calculate joint movements in real-time, and notify them of potential deviations for post-surgical precaution limitations. The prototype must be able to accurately measure the range of motion of a given joint, initially targeted to be within ±5° of the actual rotational movement. Furthermore, it must be designed in a way that it can be easily worn by a patient, meaning it must be somewhat compact. Our design uses Inertial Measurement Units (IMUs) to track and store patients' movements. The inertial measurement units used for this product are MPU6050s, as shown in Figure 1A, which can track a variety of movements and data using 6-axis degrees of freedoms. This module contains an accelerometer, gyroscope, and magnetometer. Using a microcontroller and the Arduino IDE (Figure 1D), our team has worked to develop a proof-of-concept interface that outputs the angle between the IMUs by monitoring the acceleration of the sensors in the X, Y, and Z axes. The sensors, labeled "A" are connected to printed control boards (C), which allow them to be connected to a multiplexer (Figure 1B), the Arduino board (Figure 1D), and to each other via the connective wires (Figure 1D). There are a total of four sensors, with two on each end of the system. Adjacent sensors will have their data averaged together to mitigate any error caused by sensor drift and ensure

that the data is as accurate as possible.

As the patient moves with the device, multiple accelerometers measure the level of acceleration relative to earth's gravimetric pull in multiple coordinates. By comparing the pull of gravity with respect to each sensor in different coordinate and finding the dot product between them, the relative angle between the sensors can be found. Based on the specific precautions for each individual, this angle output will be accompanied by an alert to the patient with their compliance status. This device will help the patient to adhere to their precautions without the presence of their occupational therapist.

We are currently working with a proof of concept on a printed control board to use in testing. This printed control board plugs into our microcontroller and sensors and is connected to additional modules which can be placed along a patients' body at key joints to better understand their movements. As shown in the figure below, this design will take the form of a medical tape that can be directly adhered to the patient in the future.

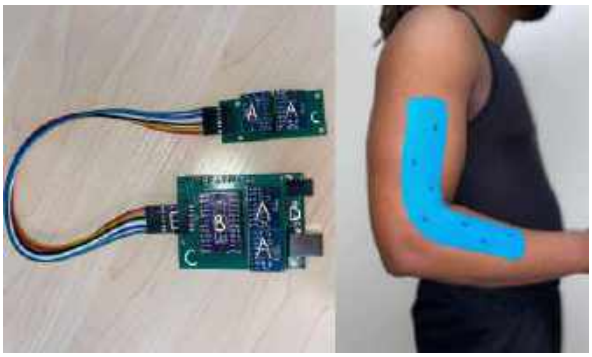

Figure 1: Left side shows current prototype design and right side shows final "tape" design to be implemented in the future. A: IMU Sensors, B: Multiplexer, C: Printed Control Board, D: Arduino Board, E: Connecting wires

BUDGET & MARKET ANALYSIS

There were 50,220 total hip arthroplasty revisions performed in 2014, and incidence rates are expected to increase between 78% and 182% through 2030[2]. The current US market for total hip revisions is $2.7B annually[4], and Medicare estimates that revisions account for 20% of direct costs associated with hip revisions[5]. Our device aims to reduce the incidence rates of revisions for wearers by at least 20%, reducing total health care costs by approximately $110M, which represents our potential market.

Our design budget includes hardware components to create our device. We need sensors, microcontrollers, and other materials (wires, headers, etc) to create more versions of our devices. Additionally, we are looking to upgrade our model to a fully wireless device using Bluetooth modules and a microcontroller with WiFi and Bluetooth capability. Our initial prototype built for clinical testing costs approximately $100. Scaled for manufacturing, and accommodating anticipated changes, we estimate that our final prototype will cost $70 per unit, with bulk ordering and production.

Studies have shown that over a third of users from sixteen different countries use wearables or health apps to record fitness and health, proving that this business model will not only work domestically, but also overseas[6]. Insurance companies are already taking note of tracking in wearable devices. For example, UnitedHealthcare will reimburse Fitbit users as much as $1,500 depending on how much they walk, and users can use this credit towards out-of-pocket medical expenses, such as copays and deductibles[7]. This creates mutual value for the insurance companies, and the patient. This market is relatively untapped, as only 1% of users have worn wearables sponsored by health insurance providers[8]. A key disadvantage of this market is the lack of understanding and cost of these devices. Our device uses inexpensive, very accessible, materials that can easily manufacture devices. With proper documentation, we believe that we can penetrate the market for wearables and create value for multiple parties.

ACKNOWLEDGEMENTS

We would like to thank Sarah Rothenberger, Antonia Trupio, and Cecilia Roling of Goniotape, LLC for assistance in providing market research, design input, information about surgical precautions, funding, and other feedback for the development of this product.

IN VITRO STRETCH INJURY AFFECTS MITOCHONDRIAL MEMBRANE POTENTIAL, CALCIUM CONCENTRATION, AND NUCLEAR MORPHOLOGY IN RAT ASTROCYTES

C. Santacruz (1), A. Yufa (2), S. Shiravi (1), J. Finan (1)

(2) Department of Biomedical Engineering, University of Illinois Chicago, Chicago, IL, USA

INTRODUCTION

Traumatic brain injury (TBI) arises from external forces acting on the head in a range of scenarios, including falls, assault, sports-related accidents, and high-risk occupations. Globally, an estimated 69 million individuals suffer from TBI annually [1]. TBI is not a static condition but rather a progressive process. TBI increases the risk of neurodegenerative disorders such as Alzheimer's disease [2]. However, the pathological processes influencing TBI outcomes are still not fully understood and there are no proven treatments for TBI patients. *In vitro* modeling of neurotrauma provides a valuable opportunity to investigate cellular responses, offering insights into pathophysiological mechanisms and possible therapeutic targets. *In vitro* stretch injury reproduces important pathologies of clinical neurotrauma. Ellis et al. developed a stretched-induced injury model using air pressure to deform flexible substrates with rat cortical astrocytes cultured on them [3]. Our objective is to establish an *in vitro* model of stretch-injury in astrocytes by deforming flexible cell culture substrates using rigid, indenting posts. This approach stretches the cell culture substrate more rapidly and with a more uniform spatial distribution than air pressure. We have already demonstrated this approach in a 96 well format. The goal of this work was to implement it in a 6 well format that would provide more cells per well for assays that require large cell numbers and more readily accommodate indentation experiments to measure cell stiffness.

METHODS

We adapted our custom-built device previously used for a 96-well stretch-injury model [4] to create this 6-well stretch injury model. We designed and built a new 6-well array of indenting posts to stretch flexible bottom 6-well plates. Briefly, we laser cut and stacked layers of acrylic to create a block with an array of holes on the top surface, aligning with the hole positions of the 6-well plate. We turned 1.2" diameter indenting posts from Delrin on a lathe and attached them to the block using screws. We fitted food-safe, dry-running thrust bearings around a boss at the top of the Delrin posts to minimize friction and eliminate the need for lubrication. To quantify the membrane stretch caused by a 4 mm deep indentation, we spray painted cell-free dry plates and indented them while imaging the well bottoms with a high-speed camera. We quantified the resulting strains using the digital image correlation software GOM.

We used an E18 Rat Astrocyte Cortex Culturing kit (BrainBits) to isolate astrocytes according to manufacturer's instructions. We attached sheets of polydimethylsiloxane (PDMS) to 6 well plate bodies using biocompatible double-sided tape and sterilized the resulting plates by immersing them in ethanol for 15 minutes. Then, we coated the cell culture surfaces with poly-D-lysine. We plated the astrocytes onto the PDMS 6-well plates and maintained them for 17 days. On day 17, we traumatized only 2 wells with a 4 mm deep indentation with a duration of 60 ms, leaving 2 wells untraumatized on the same plate. We incubated the astrocytes for 24 hours post-injury at 37°C. We stained our cell cultures with TMRM, Calbryte 520 AM, and Hoechst to assess mitochondrial membrane potential, intracellular calcium concentration, and nuclear morphology respectively. We imaged the cultures with a FV3000 Olympus confocal microscope. We quantified nuclear morphology using area, form factor ($4*\pi*Area/Perimeter^2$) and eccentricity (the ratio of the distance between foci and the major axis

length for an ellipse with the same second moments of area as the region).

RESULTS

The strain was uniformly distributed across most of the well bottom (see Fig. 1A). The average strain trace in a single well during an indentation event peaked near 7% and returned to 0% with a duration of approximately 55 ms, indicating a transient mechanical deformation (see Fig. 1B).

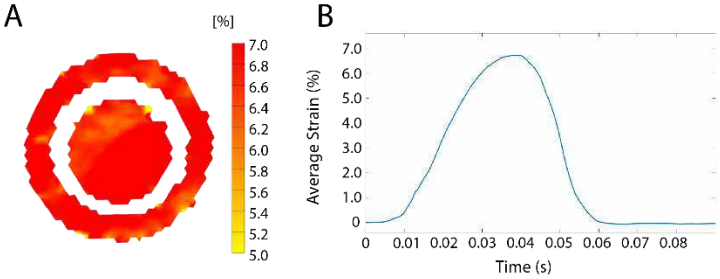

Figure 1: A) Spatial distribution of strain across cell culture membrane at peak indentation depth. The white ring in the distribution occurs because the edge of the washer disrupts the background during digital image correlation. B) Average strain over time during an indentation in a single well.

Injury reduced the intensity of TMRM and Calbryte fluorescence. Additionally, injury reduced the number of visible nuclei, suggesting that some cells detached (see Fig. 2).

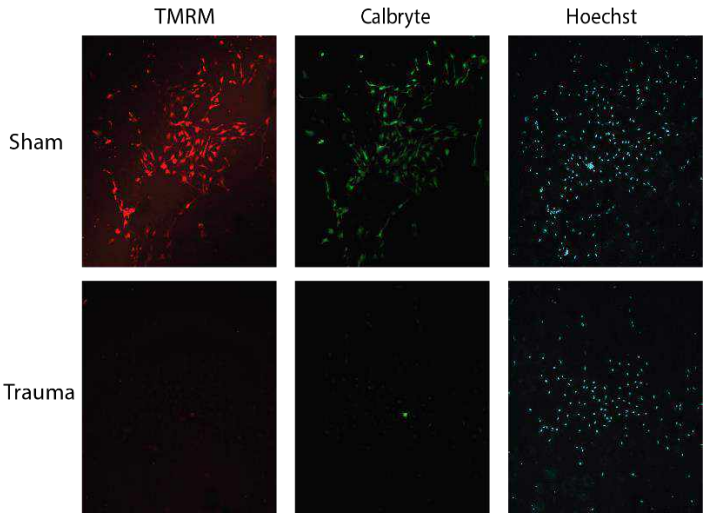

Figure 2: Fluorescent images of sham-treated and trauma cultures.

Trauma created a downward trend in nuclear area (see Fig. 3A). It also created trends in form factor and eccentricity, suggesting that it changed nuclear shape as well as nuclear size. However, the trend in form factor suggests nuclei became less round while the trend in eccentricity suggests nuclei became more round.

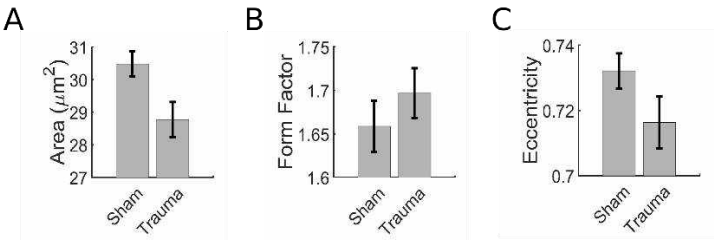

Figure 3: Quantification of nuclear morphology with and with out trauma (error bars = 1 standard error, n=1428 for sham, n = 689 trauma).

DISCUSSION

Our 6-well plate adaptation of our 96 well model achieved a uniform strain distribution with 60 ms pulse duration that is on the same time scale as brain deformations during clinical head impact events [5]. Trauma impairs mitochondrial membrane potential, crucial for cellular energetics, indicating mitochondrial dysfunction (see Fig. 2). These changes are consistent with previously published results from *in vitro* stretch injury models [6]. Reduced Calbryte 520 AM intensity post-trauma indicates a decline in intracellular calcium concentration. Current literature implicates dysregulated calcium signaling in TBI-induced neuronal damage, with excessive calcium influx intensifying cellular injury [7]. Surprisingly, our results point to a post-trauma calcium efflux. Further investigations are necessary to understand the precise mechanisms underlying calcium homeostasis disruption following TBI. Nuclear area trended downwards and nuclear shape parameters changed after trauma. These findings are consistent with a model in which actin stress fibers pull the nucleus into a flattened shape under normal conditions and trauma disrupts these fibers, allowing the nucleus to rebound into a taller shape with a smaller horizontal cross-sectional area. However, the nuclear shape results are contradictory, possibly because our pixel size was too large to allow precise shape quantification. Our *in vitro* model of stretch injury provides valuable information about the cellular responses to traumatic brain injury. In particular, it creates an opportunity to investigate the biomechanical origins of changes in nuclear morphology after trauma.

INTRODUCTION

Every year, there are over 10 million new stroke survivors around the world. Over 7 million will experience upper limb dysfunction while 5 million will go on to develop a permanent disability. One of the main upper limb functions lost is the ability to contract and extend the fingers in a grasping motion. Stroke survivors often experience spasticity of the hand muscles that develop into contractures - a permanent shortening and hardening of the muscle fibers (1). The loss of the gross hand function prevents the patient from performing everyday tasks and living independently which leads to high rates of job loss and depression (2). An effective post stroke rehabilitation plan - characterized by controlled repetitive movements and a personalized, accessible routine - is crucial in regaining as much function as possible and preventing permanent muscle damage (3). Exoskeletons are proven to be significantly beneficial in improving limb function post stroke since they allow for both mechanical support and high control over functionality (4). However, current exoskeleton gloves for gross hand function rehabilitation such as SaeboGlove, Emovo Grasp, IpsiHand, and SYREBO do not meet patient needs in affordability, usability, or functional integration. Our team has therefore developed ExoFlex, an effective and accessible exoskeleton glove for gross hand function rehabilitation.

PRODUCT DESIGN

ExoFlex is an adjustable exoskeleton glove that assists in gross hand function recovery. ExoFlex has a passive extension and active contraction mechanisms to assist with different levels of hand spasticity as well as open fingertips and a portable design to ensure usability. An adjustable 3D printed wrist guard functions to support the wrist to prevent its over-contraction (Figure 1). Additionally, the grasping motion is actuated by EMG signals taken from the flexor digitorum profundus muscle in the forearm which allows for direct motor cognitive control over the glove's functionality (Figure 2).

The passive extension mechanism consists of rubber bands on the dorsal side of the hand (Figure 1D) that extend the fingers away from the palm. The contraction mechanism is actuated by a series of fishing wires anchored by rings around each phalange. When the muscle of the forearm is contracted, the EMG signal triggers the motor to reel in the fishing wires which mimic the function of finger tendons by pulling the fingers into a grasping motion (Figure 1C). When the muscle is not activated, the motor unwinds the fishing wires, allowing for the passive extension mechanism to pull the fingers into a relaxed position. The EMG signal analysis is completed through hardware and software processing. The hardware processing amplifies, rectifies, and filters the EMG signal between 50 Hz and 160 Hz and sends the signal to an Arduino Uno that calibrates, thresholds, and processes the signal. Five seconds of calibration data is taken on startup to adjust to the specific signal strength of the user and encoders are implemented to track and limit the number of motor rotations to prevent over contraction of the fingers.

ExoFlex was evaluated on four fronts: motor response accuracy, contraction aid, and extension aid. The motor response was characterized by the response accuracy to the flexing of the muscles at the EMG placement where 100% accuracy would be the correct motor response in the clockwise or counterclockwise direction in response to each contraction and relaxation respectively 100% of the time. Over 100 trials, final accuracy was determined to be 95%. Another testing factor was the delay time between the muscle contraction to the motor response where the average response time was 1.3 seconds with a range of .4 - 3.5 seconds. The longer delay times were due to the subject flexing the forearm by mistake while the hand had been relaxed.

The contraction aid was analyzed by measuring the phalange angles of the fingers during full motor contraction (Figure 3). This was compared to the angles of the phalanges in fist formation. Overall, ExoFlex was able to perform a rounded grasping motion sufficient in retraining the contraction of the hand. It was found that the contraction of the hand was partially limited by the overall design including the thickness of the rings and the shape of the wrist guard, causing the phalange angles to be smaller than the unhindered hand (Figure 3).

To assess the efficacy of the extension aid, a spring scale was used to quantify the force exerted by the elastic bands on each phalange of the hand. The measurements were conducted under different levels of tightness, achieved by wrapping the bands multiple times around each anchoring peg ranging from 0 loops to 6 loops around each peg. The force exerted by the rubber bands was measured to be 1.5N-6N from the lowest to highest tightness levels.

ExoFlex was designed with the patient's needs at the forefront. Our team spoke to occupational therapists, patients, and doctors in the rehabilitation field to receive insight on design and usability. ExoFlex is therefore more effective and accessible to those who would benefit from the product compared to other exoskeleton gloves (Table 1). First, ExoFlex has significantly cheaper price point, making it more accessible to lower income patients. Additionally, ExoFlex aids in both contraction and extension to account for patients that are hindered in both motions vs. devices that only provide a passive extension mechanism. ExoFlex integrates an EMG control system that allows the user to cognitively activate the grasping function which is crucial in rebuilding the motor cognitive link. The integration of EMG develops the neuroplasticity crucial to successful rehabilitation compared to other gloves on the market that often use a push button to trigger a contraction. ExoFlex is also designed for long-term use with open fingertips that also allow for stroke patients to recover their sense of touch. ExoFlex is lightweight, washable, and portable with a rechargeable battery pack and minimal wires for increased comfort. The overall accessibility and the unique inclusion of both rehabilitation and functionality design features make ExoFlex the preferred choice for stroke survivors going through gross hand function rehabilitation.

Table 1: Product Comparison: *N/A is not available for sale.

	SYREBO	Saebo Glove	Emovo Grasp	Ipsi-Hand	ExoFlex
Cost	$550	$399	N/A*	N/A*	< $150
Open Fingertips	No	No	Yes	Yes	Yes
Integrative Control	No	N/A	No	Yes (EEG)	Yes (EMG)
Portable	No	Yes	No	Yes	Yes

Figure 1: Images of ExoFlex Prototype. Palmar View (A), Dorsal View (B), Grasping Proximal View (C), Grasping Dorsal View (D)

Figure 2: Summary Diagram. The EMG signal is taken from the forearm, processed by an Arduino Uno and sent to the motor which then activates a contraction or releases to allow extension.

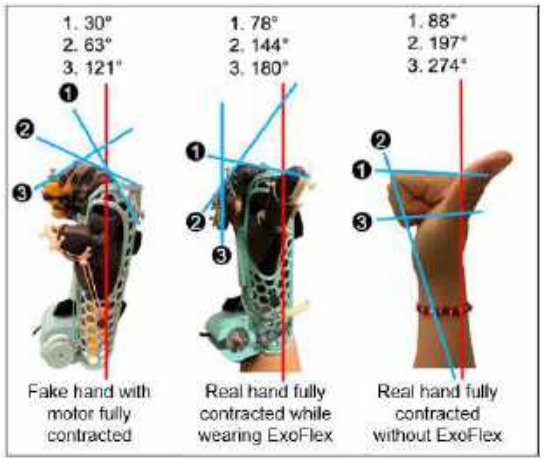

Figure 3: Contraction Analysis. Contraction angle is compared between motor contracted fake hand in ExoFlex, fully contracted real hand in ExoFlex, and the standard - fully contracted hand.

BUDGET & MARKET ANALYSIS

Every year, there are around 600,000 new stroke survivors in the US. With one out of three stroke survivors losing gross hand functionality, there would be a market of around 200,000 new users annually [5]. Additionally, many rehabilitation centers look to purchase assistive devices for both inpatient and outpatient purposes. There are around 2400 stroke rehabilitation centers across the US, further expanding the market for ExoFlex [6]. Current clinically approved exoskeleton gloves on the market such as the Saebo Glove cost $399 with other brands ranging over $500. The cost of ExoFlex at $250 is therefore well below the standard price of similar products on the market. ExoFlex is predicted to have an ROI of approximately 16.7% at the predicted sales price and manufacturing costs. With a net return of $100 per unit and a total available market of 200,000 annually, it is estimated to have a net annual return of $20,000,000 (Table 2).

Table 2: Market Analysis

	Cost per unit ($)	Cost per year ($)
Manufacturing Cost	$150	30,000,000
Projected Sales Price	$250	50,000,000
Value of Investment	$60	20,000,000

A BENCHTOP STUDY OF PHYSIOLOGICAL RESPONSE FOR THE NOVEL SELF-POWERED FONTAN CIRCULATION

Purdy Clayton[1*], Anthony Damon[2], Levi Blumer[1], Keyu Vadaliya[2], Martin Cinelli[2], Megan Parker[1], Ray Prather[1,3], Arka Das[1], Eduardo Divo[1], Alain Kassab[3], and William DeCampli[4]

ABSTRACT

Around 8% of all newborns with a congenital heart defect have only a single functioning ventricle (SV). The Fontan circulation is a result of the third stage surgical procedure to correct the SV anatomy in these patients. Despite successful implementation over the years, this altered circulation is prone to failure, with survival rates of only 50-80% to adulthood. Increased inferior vena caval (IVC) pressure plays a significant role in "Fontan failure." We propose to augment energy in the Fontan circulation with an injection jet shunt (IJS) drawing flow directly from the aortic arch, balanced by a conduit-to-atrial fenestration to approximately preserve the ratio of pulmonary flow (Qp) to systemic flow (Qs). The basic concept involves the injection of a high-velocity jet in the direction of flow, causing flow entrainment, leading to a significant reduction of upstream (i.e., IVC) pressure and enhancement of downstream flow. The "Hardware-in-the-Loop" (HIL) technique has been utilized to embed the supervisory controller into the mock flow loop (MFL) setup on a real-time basis. This automated controller has been developed to maintain the Qs constant by modulating the ventricular preload and the systemic vascular resistance to mimic circulatory response in the presence of shunting IJS flow.

A supervisory control algorithm (SCA) is developed based on the results of system identification and the "Software-in-the-Loop" (SIL) approach, in which the behavior of the Harvard Apparatus Pulsatile pump was characterized. Dynamic real-time adjustments are calculated based on error calculation methods derived from the SIL technique. An error is calculated by comparing the 0D Lump Parameter Model (LPM) of the Fontan circulation in which the ideal biological conditions were generated and measured against experimental output. Error estimations are converted into input signals and sent to a central control module utilizing conversions found during system identification. HIL techniques incorporate the SCA and SIL findings to interface directly with hardware components to manipulate systemic flow in real time. The SCA received corrections to controller input parameters through the usage of the SCA to determine precise corrections to both the Harvard Apparatus and resistance valves located within the testing loop, providing appropriate correction to variations in systemic flow caused by the introduction of the IJS. Supervisory control within the HIL receives input from computational fluid dynamics (CFD) calculations compared with measured Qs output from the Harvard Apparatus to determine correction amounts corresponding to biological conditions.

The MFL replicates a reduced four-compartmental LPM of the Fontan circulation, and it is integrated with a patient generic 3D phantom of the IJS-assisted Fontan with average dimensions matching those of a 2–4-year-old patient. Experimental results are presented and compared to the computational findings on the hemodynamic results and oxygen saturations for various total cavopulmonary configurations.

TITLE – FUNCTIONAL CHANGES IN HYPOXIC NEONATAL BRACHIAL PLEXUS AFTER STRETCH

Dario Duran (1), Meredith Dunbar (1), Anita Singh (1)

(1) Bioengineering Department, Temple University, Philadelphia, PA, USA

INTRODUCTION

Neonatal Brachial Plexus Palsy (NBPP) is a serious condition affecting infants during their delivery and often accompanied by hypoxia. It is characterized by either a stretch or rupture of the brachial plexus [1-7]. Brachial Plexus comprises of C5-T1 spinal roots and depending on the root injured is classified into different types of palsy; Erb's Palsy being the most common one affecting C5 and C6 roots. *In vivo* electrophysiology data of hypoxic neonatal brachial plexus and its association to the stretch response does not exist. This study focuses on reporting the normal, post-stretch and one-hour post stretch latency in the compound action potentials of hypoxic brachial plexus nerves (ulnar and median) in a neonatal piglet.

METHODS

Four neonatal brachial plexus nerves were put through mechanical stretching by clamping the nerve and pulling it to a fixed strain as shown in Fig.1. All procedures were according to the approved IACUC protocol, Drexel University.

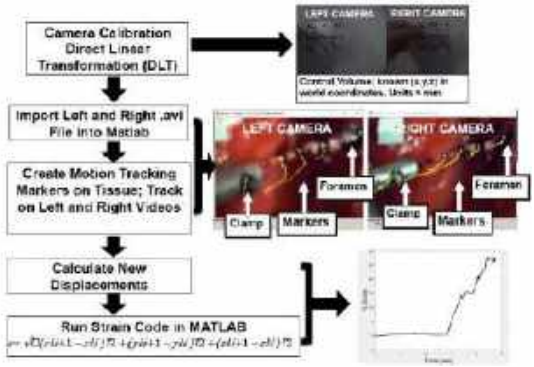

Figure 1: Biomechanical Data Analysis

The electrophysiology and data acquisition set up consisted of an amplifier, stimulator, DAQ system, bipolar stimulating and recording cuff electrodes, ground electrode and a laptop with LabView software as shown in Fig.2.

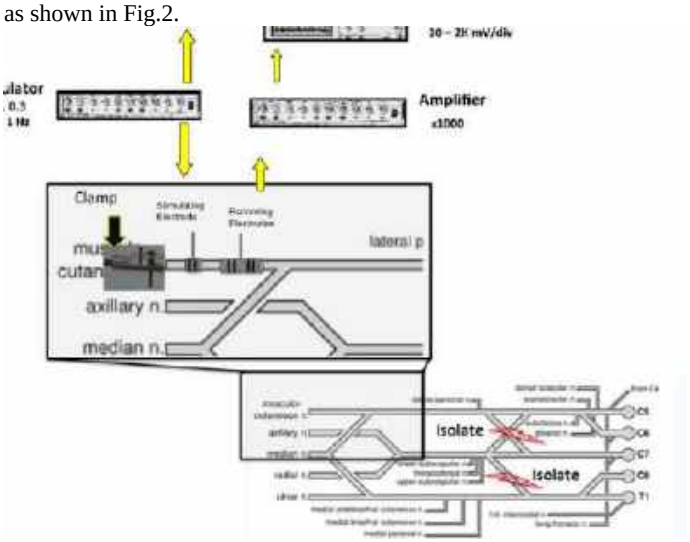

Figure 2: Details of Electrophysiology Recordings

The brachial plexus segment was stretched at known strains and compound action potential was acquired at sampling rate of 20,000 Hz, acquisition time of 1 sec, gain of 10K and duration of 0.1 msec before, after and one-hour post stretch. The stimulus applied was 0-2V with increments of 0.5V. A ZED camera was placed over the nerve being tested to capture the distance between the stimulating and recording electrodes to determine the conduction velocity (CV) and amplitude of

the compound action potentials. Eq. 1 show how to calculate percentage change in latency post-stretch.

% change in latency post-stretch = [latency before stretch – latency after stretch] / [latency before stretch] Eq(1)

A customized MATLAB code was used to determine the latency of compound action potentials recorded for before stretch, post-stretch and one-hour post stretch conditions to check for recovery or conduction block.

RESULTS

Electrophysiological recordings reported immediate conduction block when subjected to a 20% strain (Fig.3). No spontaneous recovery was observed at 1 Hr or 3 Hr. At a 15% strain, the nerve continued to conduct however, a 100% increase in latency immediately post stretch, which did not recover.

Nerves	Before	After	1-hr	3-hr
Median (Strain: 20±10% Load:14.7N)				
Ulnar Secondary Nerve				Median (Strain: 15±8% Load:11.0N)				

Figure 3: Nerve Conduction Data obtained from Stretched Nerve

DISCUSSION

No data is available on the mechanical, and related functional changes in the hypoxic neonatal BP subjected to stretch. This study is the first to a direct correlation between subjected strain and observed functional changes. Data from the study confirms that the extent of stretch directly affects the injury outcomes and spontaneous recovery responses. Strains of 20% or more leads to significant conduction block in hypoxic tissues. Obtained data helps better understand the mechanism of NBPP and can help with prognosis and identification of optimal treatment options., especially in complicated cases including hypoxia.

INTRODUCTION

Falls are the leading cause of fatalities and nonfatal injuries among older adults, impacting over fourteen million older adults annually [1]. The impact of falls can extend beyond physical harm, threatening a person's independence and overall quality of life. Situations involving the simultaneous execution of a motor and cognitive task may lead to falls. These dual task scenarios arise in everyday life (e.g., walking while talking) and pose a significant threat to older adults due to aging-related physical and cognitive changes. Studies have shown that dual task gait is a valuable marker of cognitive impairment and fall risk [2] that replicates the daily-living gait of older adults more closely than single task gait in a lab setting [3].

The current body of literature regarding dual tasks primarily focuses on straight-line gait [2]; however, motor tasks involving postural control and transfers, such as turns, are also common movements. The Timed Up and Go (TUG) test is a validated mobility assessment that combines multiple everyday movements, including straight-line gait, turns, and sit-to-stand tasks. A significant decrease in gait speed or cognitive performance when a dual task (DT) is introduced has been associated with higher fall risk [2].

In a traditional TUG DT assessment, a physical therapist records completion time and cognitive task performance. Wearable sensors, like inertial measurement units and accelerometers, and optical motion capture technology allow for the extraction of more specific gait features beyond the completion time and cognitive task performance. The addition of a DT typically increases number of steps, decreases step length, and decrease step duration among older adults during straight-line gait [2]. The analysis of gait parameters during TUG DT has been minimal, but one study utilized optical motion capture to focus on turn-specific parameters, including time to turn, number of steps taken to turn, and axial segment reorientation [4]. There is little existing information about the impact of a DT on the median step duration of the full TUG motion. We will investigate the effects of a DT on TUG motor performance and kinematic gait parameters with the goal of better understanding realistic fall risk scenarios and informing future DT interventions for the older adult population.

We hypothesized that the TUG performed with a DT would be associated with decreased motor performance (e.g., increased completion time) and altered movement strategies (e.g., more, shorter steps) vs. the TUG without the DT.

METHODS

Healthy older adults (n=8, mean age 70.9 ± 6.0 years) volunteered to participate in this research, in accordance with the IRB. The TUG consists of standing up from a chair, walking three meters forward, making a 180° turn, walking three meters back, and returning to a seated position in the chair (**Figure 1**). Each older adult performed the TUG twice: once without any additional cognitive load, followed by once with a dual task (TUG DT). The cognitive dual task was serial-3 subtraction, where older adults were instructed to count backward aloud starting from a specified number. A physical therapist administered the test.

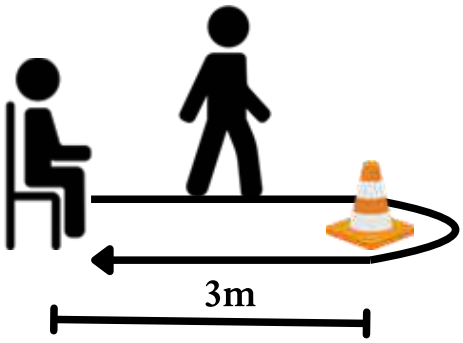

Figure 1: Illustration of the Timed Up and Go (TUG) Assessment.

Optical motion capture (Optitrack, 250 fps) was used to measure movement and a data processing program (MATLAB) was used to compute measures of interest. Measures of interest included: (1) the completion time of the test, measured by the Physical Therapist, (2) the number of steps used, (3) the step length, and (4) the step duration. Measures 2-4 required heel strike events, which were determined using motion capture software to observe the beginning of the foot's rotation in the sagittal plane after the heel contacted the ground. Heel strike times were confirmed with a video review.

Heel strike events were recorded during the straight-line gait and turning motions and did not include sit-to-stand tasks. The end of sit-to-stand and initiation of stand-to-sit movements were observationally identified by continuous increases or decreases in height of any point on the pelvis. This approach accommodated various sit-to-stand task techniques, including tilting the pelvis to initiate the motion and keeping the pelvis relatively flat. By removing sit-to-stand and stand-to-sit subphases from the analysis of walking measures of interest, there were more consistent computations of the measures of interest across participants.

A two-tailed paired sign test was used to evaluate the direction of possible differences between TUG and TUG DT for each measure of interest (α=0.05).

RESULTS

Between the TUG and TUG DT trials, there were increases in completion time (p=0.0078) and total steps (p=0.0156) (**Figure 2**). Median step length (p=0.0703) and median step duration (p=0.2891) were not significantly different across TUG and TUG DT trials (**Figure 2**).

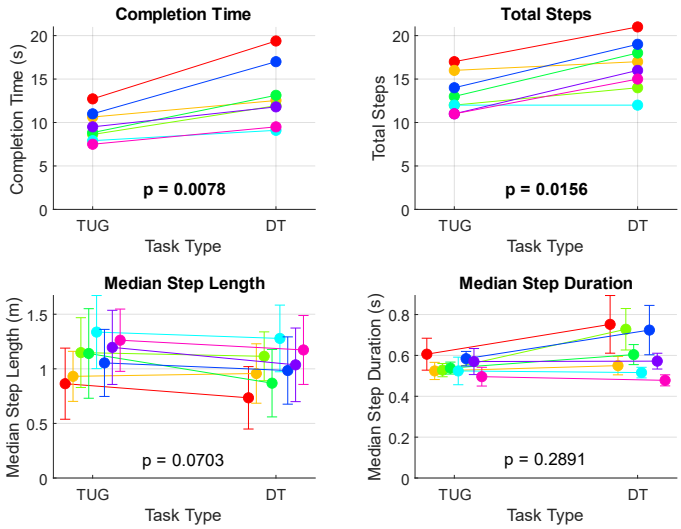

Figure 2: Comparison of Timed Up and Go (TUG) and Dual Task TUG (DT) across outcome measures. Each participant's data are distinct colors; group p-values are included.

DISCUSSION

Our finding that total steps and completion time of the TUG increased with the addition of the DT is consistent with our hypothesis and with the results of previous studies [2]. Though not significant in this small cohort, **Figure 2** shows that median step length during the TUG decreased with the addition of a DT for most older adults. This trend may be significant with a greater sample size.

There was not a clear trend in median step duration during the TUG with the addition of a DT. Most current literature that suggests a DT increases step duration is based on straight-line gait. By using optical motion capture or other biomechanical sensors during the TUG, future work could evaluate the impact of the DT on median step duration during the straight-line gait and turn TUG sub-phases separately.

The findings of this study are limited by the small sample size, which may introduce variability in the results. These results are also limited by the lack of data on the cognitive task performance during DT. The prioritization of either the cognitive or motor task could impact performance. These limitations suggest the need for further research with larger cohorts of older adults to validate and expand these preliminary findings.

The use of optical motion capture to evaluate specific kinematic measures of interest has exciting potential for future research. Future research could build on these results by focusing on the turn phase of TUG or investigating measures like gait variability and path length.

The TUG test with a DT replicates complex daily scenarios that may pose additional fall risk for older adults. Future research that focuses on how the addition of a DT impacts other kinematic parameters and specific phases of the TUG test could expand our understanding of how DT impacts a variety of motions, leading to the development of more specific and effective DT training interventions.

ACKNOWLEDGEMENTS

This study uses existing data from a larger ongoing study (NSF Award#1944207). We thank the volunteer participants.

COMPARATIVE STUDY OF IMAGE-BASED MODELING USING A NOVEL MEDICAL-IMAGE-TO-REDUCED-ORDER-SIMULATION FRAMEWORK

Boyang Gan (1), Numi Sveinsson Cepero (1), Shawn C. Shadden (1)

(1) Department of Mechanical Engineering, University of California, Berkeley, Berkeley, California, USA

INTRODUCTION

Cardiovascular disease (CVD) remains the global leading cause of death. Recent developments in image-based modeling and patient-specific hemodynamic simulation have proven effective in enabling virtual personalized diagnosis, preventive care, and treatment planning without the risks of invasive measures. Despite the growth of such technologies, creating an image-based simulation from medical image (CT or MRI) scans is labor-intensive [1], and performing accurate computational fluid dynamics (CFD) simulations generally requires extensive technical knowledge of numerical methods and supercomputing resources [2].

Developing automated and efficient capabilities to go directly from medical images to simulation results, even if those results are approximate, can be highly informative in several scenarios including timely decision support, screening, boundary condition tuning, uncertainty quantification, treatment design, etc. With this in mind, we have been developing a streamlined process to produce reduced-order model (ROM) simulations of patient-specific hemodynamics from volumetric angiography. This framework leverages lumped-parameter and 1D Navier-Stokes solvers built into our SimVascular software [3, 4] coupled with recent machine learning (ML) model construction we have developed to automate the segmentation of vascular models from medical images. Work towards a medical-image-to-reduced-order-simulation (MIROS) framework we are developing is presented here and used to conduct a comparative study that examines the impact of machine learning models versus traditionally constructed models on ROM simulation results.

METHODS

The MIROS framework relies on automation of the vascular model construction and setting up and running a ROM flow solver to compute flow rate and pressure through each vessel. To verify our implementation, we compared the output of MIROS (i.e. flow and pressure calculations) to ROM flow and pressure calculations using traditional model construction for a series of cases in the Vascular Model Repository (VMR) (http://vascularmodel.org) – herein referred to as the VMR model/results. The main difference between MIROS and VMR is that we employ ML automated vascular segmentation, whereas the VMR models were manually constructed. We also automate the simulation process, but the flow solvers are the same. Also, to ensure consistent comparison of flow and pressure results, we use the same boundary conditions and solver parameters in MIROS as was used to generate the VMR results.

Segmentation. MIROS relies on a novel method called Sequential Segmentation (SegSeg) for automated segmentation of the vasculature. SeqSeg requires a seed point for initialization (chosen at the inlet) and automatically traces the vasculature based on local vessel segments. The method captures bifurcations automatically and traces down branches as long as image resolution and segmentation quality allow. The local vessel segments are averaged together into a global segmentation that is returned as a binary segmentation map, where pixels labeled 1 represent blood vessel and 0 represent background. These segmentation maps are converted to surface meshes using marching cubes and smoothed using Laplacian smoothing to remove pixel artifacts.

Outlet Definition. SeqSeg can capture more vasculature than contained in the manually segmented VMR models. To apply boundary conditions consistently, we generally needed to truncate the MIROS models to terminate at the same approximate location as in the VMR models. We automatically compute the coordinates, radius, and unit tangent vector of each endpoint in each VMR model and then orient and scale clipping boxes to trim the corresponding MIROS model. We also keep the largest contiguous volume, which is then remeshed to produce our desired surface. This workflow is shown in Figure 1 for two representative models (an aortic arch model and an abdominal aorta model).

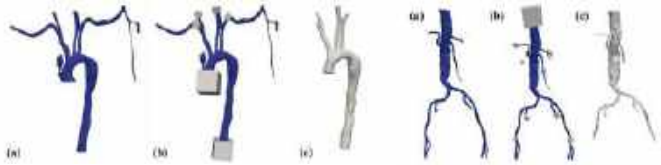

Figure 1: Creating consistent boundaries. (a) ML generated discrete surface (b) clipping boxes on ML surface (c) trimmed and filtered surface

Branch-matching. Because the ML method might capture a different number of branches than existing manually segmented surfaces in the VMR, we must match the branches and apply consistent boundary conditions to only outlets that are in common. Thus, the number of matching branches was determined, and any additional branches were merged into the vessel wall, which then become ignored during centerline extraction.

Centerline extraction. The MIROS and VMR 3D image-based models were used to generate a discrete centerline representation. The centerline extraction was performed using Vascular Modelling Toolkit (VMTK) functions that generated centerlines paths as well as vessel radius information along each vessel path. Both the discrete centerlines paths and associated areas along the paths were required for the ROM flow solver.

Boundary condition file preparation. We applied RCR boundary conditions at all outlets with RCR values tuned to clinical measurements and provided in the VMR [4]. In cases where the VMR contained a branch not included in the MIROS model, we ignore that boundary. Although this does not preserve the global consistency of the boundary conditions, we do this to keep the simulation consistent between MIROS and VMR models.

Solver. ROM simulation of flow and pressure was performed by solving the 1D Navier-Stokes equations using the SimVascular's 1D solver. Blood flow is assumed to be a Newtonian, incompressible fluid in a deforming and elastic domain. The governing equations consist of the continuity equation, a single axial momentum balance equation, a constitutive equation, and suitable initial and boundary conditions [5]. The overall workflow that MIROS models undergo is shown in Figure 2 for a representative model.

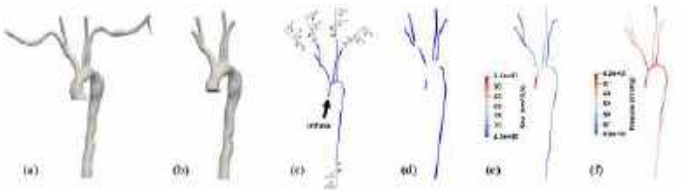

Figure 2: Pipeline workflow. (a) ML based surface (b) trimmed surface (c) centerline extraction (d) 1D model generation with boundary conditions (e)&(f) simulated flow and pressure mapped to centerline

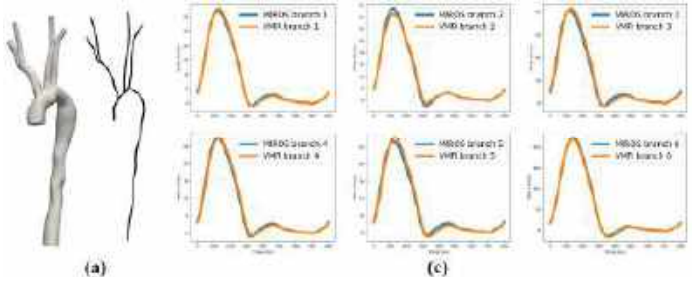
RESULTS

Averaged relative error over time. Each simulation was run for more than 7 cardiac cycles to reach a periodic solution. We compared relative error in mean flow and pressure of the last simulated cardiac cycle. We took the average of relative errors of each branch to get the relative error of the entire model. The results are shown in Table 1.

Table 1: Relative error averaged over the last cardiac cycle.

Surface Name	Relative Error: mean flow	Relative Error: mean pressure
0063_1001	3.575%	7.658%
0090_0001	0.6245%	0.2769%
0131_0000	0.2834%	0.2820%
0146_1001	1.002%	0.7106%
0174_0000	0.3172%	0.1566%
0176_0000	0.3306%	0.1925%
Average	1.022%	1.850%

Qualitative plots of flow and pressure over time. For qualitative comparison, we plotted the average flow and pressure of the same branches between the MIROS and VMR simulations over time to visualize the differences in simulation outcomes between the two modeling methods. As an example, Figure 3 below shows the plots of 0176_0000, whose overall mean relative error in flow was 0.3306% and overall mean relative error in pressure was 0.1925%.



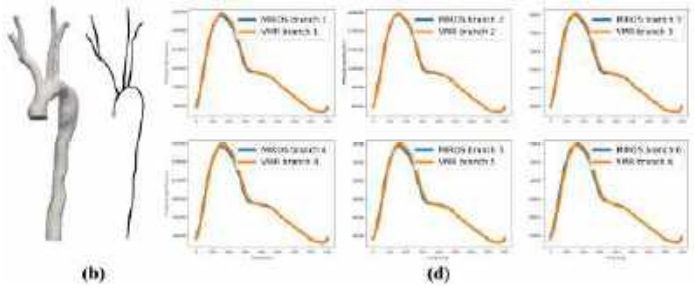


Figure 3. Qualitative comparison of flow and pressure result for each branch. (a) VMR model and its centerline (b) MIROS model and its centerline (c) flow comparison of each branch (d) pressure comparison of each branch.

DISCUSSION

We developed and automated a process for generating patient-specific, reduced-order model simulations of hemodynamics from volumetric angiography, culminating in a Medical-Image-to-Reduced-Order-Simulation (MIROS) framework. This framework significantly accelerates the traditionally hours-long tasks of vascular segmentation and the subsequent setup and execution of flow solvers, reducing overall time to a matter of minutes. Utilizing MIROS, we conducted a comparative analysis to evaluate the impact of different modeling approaches—manual segmentation versus machine learning segmentation—on simulation outcomes. Results indicate relatively modest errors of 1.022% for mean flow and 1.850% for mean pressure when averaged across all models and vessels. Given that consistent boundary conditions were used, these differences reflect errors in geometric reconstruction and are expected to be far less than errors typically associated with uncertainty of boundary conditions. This study demonstrates the efficiency and advantages of employing ML for automated vascular segmentation and highlights MIROS's capability to facilitate rapid hemodynamic simulations.

Limitations and Future Work. There are two noteworthy limitations that arise largely based on the nature of performing a comparative study. First, for some images, there were vessels captured by MIROS not captured by the VMR and vice-a-versa. Our analysis here focused only on models that contained vessels both methods captured. We plan to study this trade-off in future studies. Second, the boundary conditions for the MIROS model were the same as used for the VMR model. While this was necessary for consistent comparison, typical applications of modeling would require generation of de novo boundary conditions. We plan to study the application of MIROS to de novo analysis requiring generation of boundary conditions. Lastly, SimVascular has the ability to perform so-called 0D (also known as lumped-parameter) simulation based on a 3D model. We plan to connect such 0D ROM with MIROS, and to potentially consider more complex boundary conditions, such as used for coronary flow.

EFFECTS OF DETRUSOR CONTRACTION ON URINARY BLADDER EXTRACELLULAR MATRIX ORGANIZATION

INTRODUCTION

The urinary bladder is a hollow organ that stores urine through passive filling and voids urine through active concentric contraction. The bladder undergoes strain softening, a phenomenon where the compliance of a material increases after repeated stretching. This occurs following passive emptying where the bladder is voided without proper detrusor contraction [1]. *In vivo*, strain softening is mitigated by contraction of the detrusor during voiding [2], which we have replicated *ex vivo* using optogenetic stimulation. Current *ex vivo* bladder passive mechanical testing methods are based on protocols for tissues that do not require contraction as part of their normal use (*e.g.* tendon, ligament, skin) and fail to prevent strain softening [3]. Although research has gone into understanding possible causes of this mechanical change, like slippage of actin-myosin cross-bridges [4], the organizational response of the extracellular matrix (ECM) to this change has not been studied. This is important to investigate because the smooth muscle cells of the detrusor are intertwined with the ECM, and the composition and organization of the ECM governs bladder passive mechanical properties. Here we describe a method of quantifying changes in the organization of fibrillar collagen in the bladder using multiphoton microscopy. We will use this method to quantify strain softening during passive mechanical testing, and prevention of strain softening via active concentric contraction using optogenetic stimulation.

METHODS

Loading cycles were carried out using a floating platform mechanical testing system (Fig, 1). The mechanical testing system was comprised of a bath containing a floating platform which was attached to a bladder and a micromechanical testing system (FemtoTools, Furtbachstrasse CH) [5]. Above the bladder, a movable pulsed blue light laser was mounted, allowing imaging and optogenetic stimulation to be quickly swapped between. *Ex vivo* mouse urinary bladders were tested with two mechanical testing protocols, one which utilized passive loading and unloading and one which utilized passive loading and active unloading via optogenetic contraction. After the samples were attached to the floating platform and pulled to a 0.5 mN preload, they were imaged, stretched to a stress of 5 kPa, imaged again, and unloaded. This was repeated five times per sample.

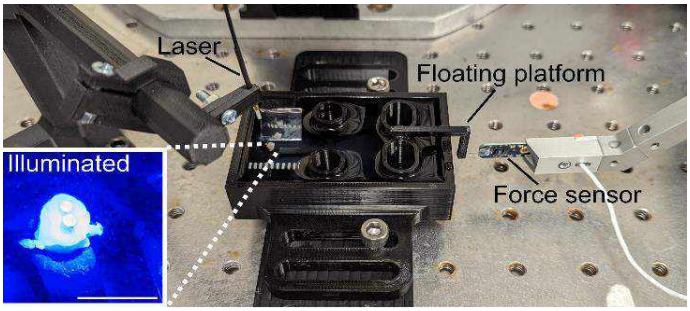

Figure 1: Mechanical testing setup. Stimulation of bladder with blue light laser shown in zoomed in square.

For the active unloading group**,** on demand contraction of the bladder was achieved using a cross of *ChR2(H134R)-EYFP* mice (JAX, #024109), with *SM22-Cre^{tg}* mice (JAX, #017491). These mice express the light sensitive ion channel channelrhodopsin-2 and Enhanced Yellow Fluorescent Protein (EYFP) in smooth muscle cells. This method allowed for the stimulation of detrusor contraction using a 500 mW, 450 nm blue light laser (Opto Engine), pulsed at 100 Hz with 10% duty cycle [6].

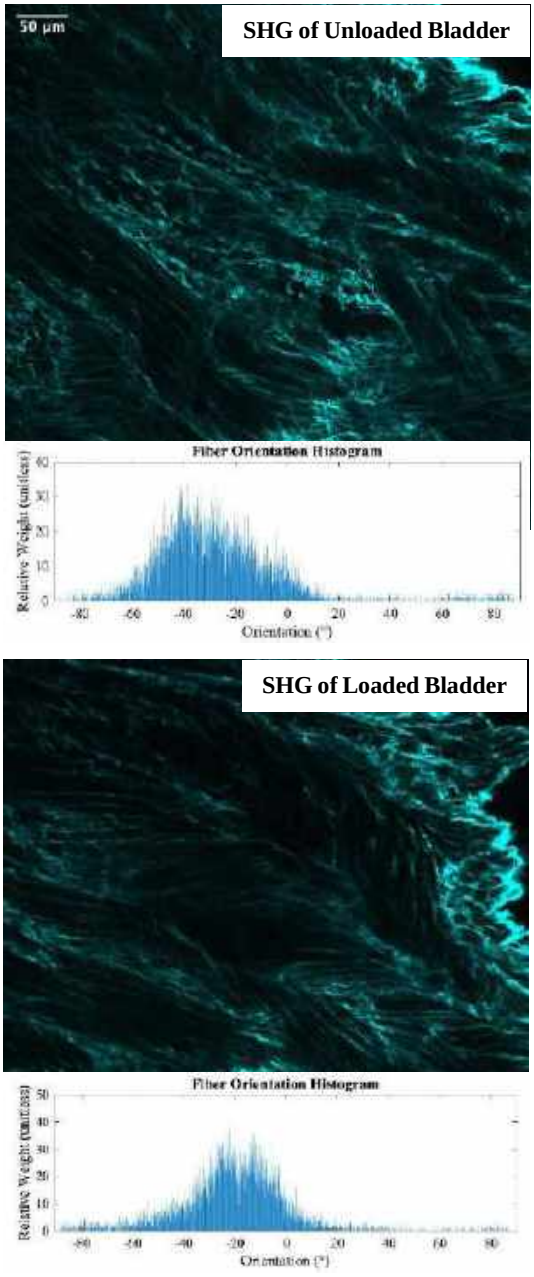

Figure 2: Comparison of loaded vs unloaded orientation distributions.

Imaging of the bladders was conducted from the adventitia to the lamina propria using a 25x objective on an Olympus FVMPE-RS Twin Laser Multiphoton microscope. Second harmonic generation (SHG) of fibrillar collagen and EYFP were exited simultaneously using a wavelength of 920 nm.

The organization of fibrillar collagen was quantified using orientation, coherency, and energy data from the ImageJ plugin OrientationJ [7]. This allowed for the calculation of weighted orientation distributions to represent organization. Furthermore, this data was used in the creation of streamlines that trace groups of fibers to approximate fiber waviness [8].

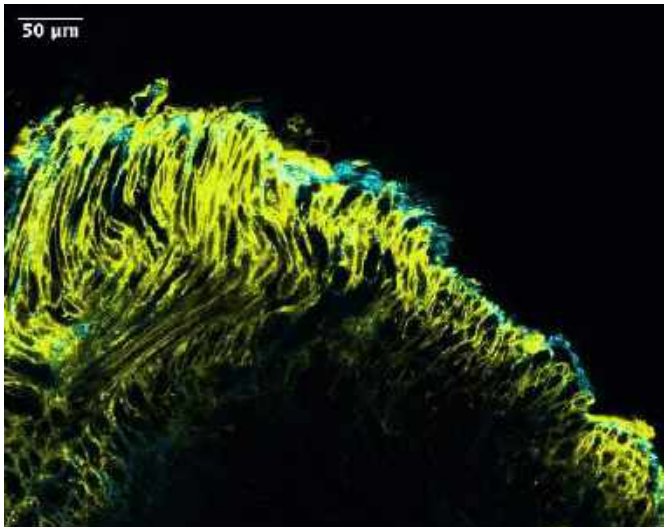

Figure 3: Colocalization of smooth muscle cells (EYFP, yellow) and fibrillar collagen (SHG, cyan)

RESULTS

Qualitatively, fibrillar collagen was wavier in unloaded vs loaded bladders, which was seen quantitatively in the fiber orientation distributions (Fig, 2) where the unloaded bladder had an orientation standard deviation of 24.47° while the loaded bladder had an orientation standard deviation of 21.71°. Furthermore, fibers became more aligned in the direction of applied stretch. Lastly, EYFP and SHG imaging displays the interconnectedness of smooth muscle cells and fibular collagen in the detrusor.

DISCUSSION

Narrowing of the fiber orientation distributions coinciding with a qualitative straightening of fibers indicates that our methods can capture changes in the organization of the ECM. Additional data collection will elucidate differences in the fibrillar collagen organization between the passive and active unloading groups. Additionally, future work will more clearly visualize the structure of the lamina propria and urothelium as the current method of imaging starting at the adventitia leads to minimal to zero signal in these layers. How the aspect ratio of smooth muscle cells responds to loading and unloading will also be investigated to further understand the interplay between mechanical loading, the ECM, and smooth muscle cells. Our long-term goal is to use orientation distributions and fiber waviness from this imaging to inform computational modeling of strain softening and prevention of strain softening via contraction in the bladder.

INTRODUCTION

Neonatal brachial plexus palsy (NBPP) is defined as an injury to brachial plexus (BP) nerves due to over-stretching during complex birthing scenarios. Despite advancements in obstetric care, NBPP has an incidence of 1-4 cases per 1000 live births [1, 2]. Neonatal hypoxia can also occur as a result of obstetric complications, such as disrupted blood supply to the fetus due to umbilical cord compression and can significantly impact the tissues and other organ functions [3]. Characterizing the extent of vascular damage of hypoxic neonatal BP at varying degrees of stretch can further the understanding of the injury thresholds of NBPP.

METHODS

All procedures were approved by the Institutional Animal Care and Use Committee. 15 neonatal piglets (3-5 days old) were anesthetized and exposed to FiO2 of 7% for 1 hour to induce hypoxia and re-perfused to FiO2 of 21%. Using an axillary approach, the BP was exposed, and BP nerves were stretched at a rate of 500 mm/min to predetermined low- (<15%) and high- (>15%) strains. Post-stretch, BP nerves were harvested and OCT-embedded. Ten-µm-thick serial longitudinal sections were stained with Hematoxylin-Eosin (H&E). Using the Olympus BX53 motorized microscope, stained slides were imaged at 10x magnification along the nerve length. Each stitched image was split along its nerve length into regions of interest (ROIs) using a custom MATLAB script [4-5]. An independent-blinded observer scored each ROI for vascular damage on a scale of 0-2 (0-no damage, 1-torn vessel, 2-scattered blood cells, **Fig. 1**).

RESULTS

Based on our modified scoring system, preliminary results show that vascular damage increased with increasing stretch injury **(Fig. 2)**, and similar degrees of damage were observed in the central and peripheral regions of the nerve **(Fig. 3)**.

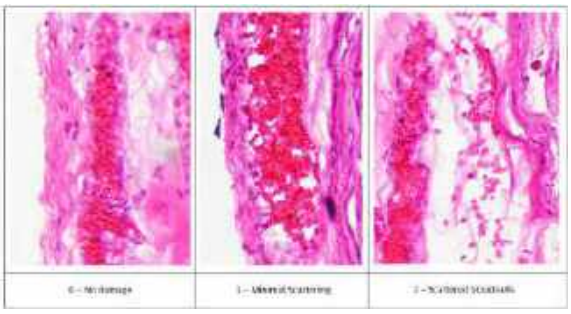

Figure 1: Vascular damage scoring system.

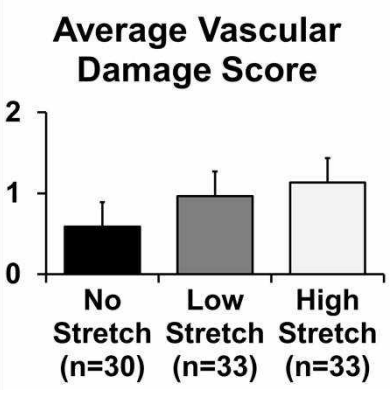

Figure 2: Bar graph of increasing vascular damage with increasing stretch

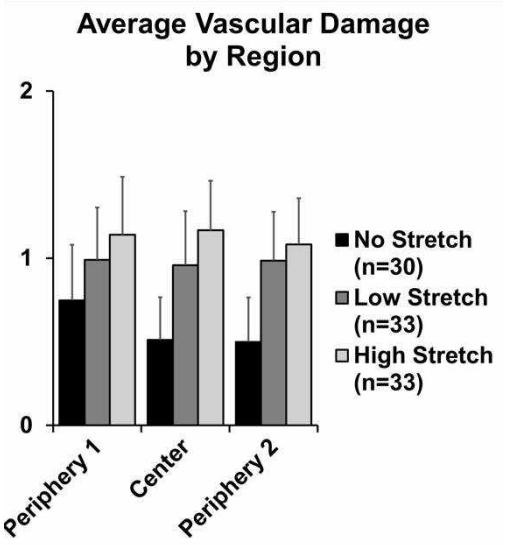

Figure 3: Bar graph of vascular damage by nerve region.

Control	<15 %	>15%
0	8.9 ± 4.0	21.2 ± 6.8

Table 1: Average strain reported for each group.

DISCUSSION

This ongoing study is the first to characterize vascular damage of hypoxic neonatal BP nerves with respect to varying degrees of stretch. Determining the depth of vascular damage of the BP by analyzing the three regions presented in conjunction with the overall vascular damage will provide a more detailed characterization of the injury [7-9]. Due to the anatomical similarities between neonatal piglets and neonatal human BP, this study will help further the understanding of injury thresholds of NBPP.

INTRODUCTION

Hand paralysis is a life changing disability, leading to loss of functionality to grasp objects. This disability typically stems from medical conditions such as stroke, cerebral palsy, or spinal cord injuries (SCI), the last of which can cause incomplete tetraplegia, partial functionality loss in the extremities [1]. According to the National Spinal Cord Injury Statistical Center as of 2023, approximately 302,000 people in the US alone suffer from traumatic SCI, where 47.1%, 142,242 people, have incomplete tetraplegia [2].

Patients living with this disability lose their independence and often require assistance with daily tasks. They must develop new ways to manipulate the objects around them; however, patients experience hand weakness and are forced to use unnatural wrist positions, known as tenodesis grip. Restoring hand functionality would improve their independence and quality of life. Many therapeutic procedures and a few robotic orthotics have been studied but they are high in cost, fail to produce enough hand functionality, or are unintuitive to use, resulting in continued research in advanced orthotics [3]. An EMG-controlled robotic gripper mounted to a wrist brace would allow patients to manipulate everyday objects, leading to an increased quality of life and reduce harmful grips like tenodesis.

PRODUCT DESIGN

Traditional manipulator devices can be expensive, cumbersome to use, and/or large and bulky. To combat these shortcomings, this proposed design is lightweight and inexpensive (< $5,000.00) due to the 3D printed components, and easy to operate by flexing a bicep via electromyography (EMG). Additionally, this device aims to solve a common issue in manipulator devices, range of usage, by making use of flexible, compliant grippers to conform to complex shapes and sizes with improved grip. Furthermore, it can be attached to wrist braces with a dovetail fitting, allowing the device to work alongside assistive devices already in use by patients (Figure 1).

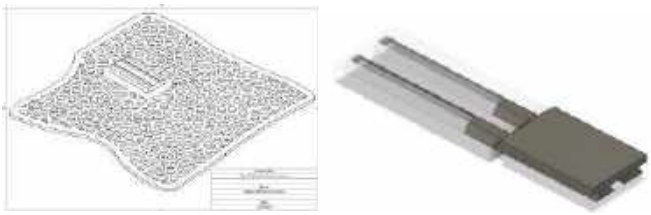

Figure 1: Mount on flexible, 3D printed wrist brace (left) and proposed dovetail attachment mechanism (right).

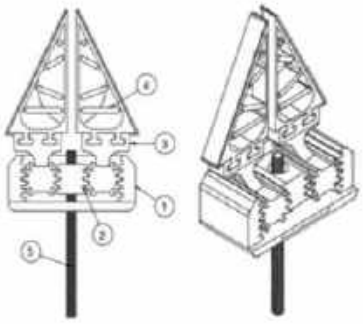
The gripper drive system is composed of a motor, lead screw, rack and pinion gears with claws (Figure 2). If the gripper was driven directly by the motor, the motor would need to maintain torque to grip an object, wearing down the motor and consuming battery power. The single-start trapezoidal lead screw is self-locking, meaning that the slide friction and flank angle maintains the grip without motor torque. The rack translates the linear motion produced by the screw to rotational by rotating the gears attached to grippers, allowing them to open and close.



Parts List		
Part Number	Description	Material
1	Drive System Base	PLA
2	Gear Rack	PLA
3	Gripper Support System	PLA
4	Compliant Gripper Body	TPU
5	Lead Screw	Steel

Figure 2: Gripper Drive System CAD Assembly with Parts List

The triangular grippers consist of two main parts: the compliant gripper body and the support system (Figure 2). The body is flexible, allowing for improved grip and range of applications by conforming to the shape of different objects. Various infill designs and densities for NinjaFlex Thermoplastic Polyurethane (TPU) were tested to determine the most optimal geometry, measured by its overall ability to deform while providing adequate torque. The support system provides backbone along the length and base of the triangle, allowing for maximum torque and maintaining grip alignment.

The EMG circuit is comprised of an instrumentation amplifier (INA), notch filter, and bandpass filter (Figure 3). The INA amplifies low-level EMG signals from around 1 mV to roughly 1 V, while maintaining a large common-mode rejection ratio (CMRR) to reject common mode noise, and high input impedance, ensuring accurate measurement of the low-voltage EMG signal. Two inputs measure the voltage difference across the bicep via skin electrodes. The notch filter removes 60 Hz noise introduced from the transmission line. The active bandpass filter captures signals from 20 Hz to 450 Hz and further amplifies the signal to about 4.3 V. This signal is input to the analog pin of an Arduino, which can only measure up to 5V. When the bicep is flexed, the EMG signal is spiked triggering a Parallax continuous servo motor from the Arduino. With a torque output of 2736 oz-in, the servo motor allows the gripper mechanism to grasp a variety of objects.

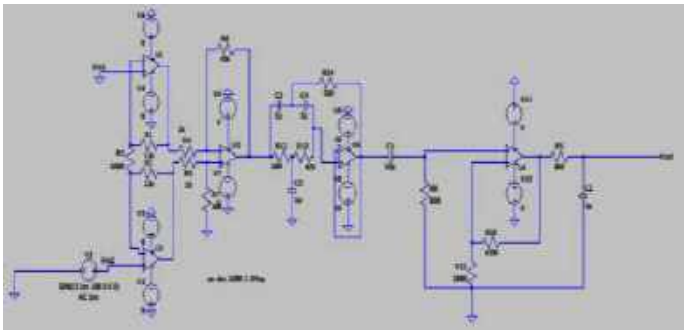


Figure 3: LTSpice schematic diagram for EMG circuit.

BUDGET & MARKET ANALYSIS

About 142,242 people in the US suffer from SCI-induced incomplete tetraplegia with an increase of about 8,478 people each year [2]. Therefore, the first year has a potential market of about 142,242 product sales domestically, with an additional 8,478 sales annually.

The total design cost is $771.80, and the single unit material cost is $114.90 as determined in Table 1.

Table 1: Design Budget

Component	Need	Cost per unit ($)	Quantity used	Total cost ($)
Arduino Teensy	Microcontroller	9.60	1	9.60
Parallax Continuous Servo Motor	Motor	19.95	1	19.95
Lead screw	Gripper drive system	1.05	1	1.05
Threaded fitting	Fits lead screw into Drive system	0.22	1	0.22
Shaft collar	Attached screw to motor	0.49	1	0.49
PLA material	Hard 3D print material	24.99 per kg	11.47 grams	0.29
TPU material	Soft 3D print material & testing	64.00 per kg	290 grams	18.56
Operational amplifier (LM741)	EMG circuit	0.48	5	2.40
Capacitor Set	EMG circuit	9.99	1	9.99
Resistor Set	EMG circuit	9.99	1	9.99
Wire Set	EMG circuit	13.99	1	13.99
Breadboard	EMG circuit	2.95	1	2.95
Electrode Wires	Measure bicep EMG	10.81	1	10.81
EMG pad pack	Electrode-bicep connection	19.99	1	19.99
Unit Material Sub-Cost				114.90
3D printer - Prusa MK3S+	Manufacturing	649.00	1	649.00
Force Sensors	Force testing	3.95	2	7.90
Total Cost				771.80

An additional engineering cost of about $1000.00 is required to improve the design by making it smaller and expanding its performance. Based on materials, development, and labor costs, an approximate sales cost is $500.00 with a manufacturing cost of $250.00 per unit. The developers' return on investment (ROI) is $250.00 for the first unit, $35,560,500.00 for the first year, and $2,119,500.00 each following year. Also, the product could be beneficial for all hand paralysis patients, in addition to those with incomplete tetraplegia, and the product availability can be expanded globally, both increasing the potential for profit. In turn, the profits would fund more printers, materials, and labor for larger production. For the users, the sales price is much lower than the cost of current products on the market, such as robotic hand orthotics which can be priced at $5,000.00. Their ROI relative to similar products is high, as the gripper device provides a light, convenient solution to everyday problems patients may face, while being low in cost.

A FRAMEWORK FOR SLICE-WISE MOTION CORRECTION IN MAGNETIC RESONANCE ELASTOGRAPHY OF THE HUMAN BRAIN

Tyson Lam[1], Emily R. Triolo[1], Mehmet Kurt[1]

[1]Mechanical Engineering, University of Washington, Seattle, WA, USA

INTRODUCTION

Magnetic Resonance Elastography (MRE) is an advanced MR imaging technique that enables the non-invasive measurement of tissue stiffness[1], with emerging applications in the evaluation of brain disorders[2]. Despite its significant potential, MRE is challenged by motion-related artifacts such as non-uniform "Z-striping" (Fig. 1), which can obscure the accurate representation of tissue properties and compromise diagnostic efficacy. These artifacts are often exacerbated by involuntary subject movement during scanning, introducing errors in MRE phase images that can compromise the solution to the inverse problem of viscoelastic inversion and mislead clinical interpretations. Because MRE is a motion-sensitive phase-contrast sequence, any involuntary subject motion will slightly alter the reference phase in the volume during which the subject motion occurred. In MRE sequences with interleaved slice acquisition (often used in EPI-based sequences to reduce volume distortion[3]), these errors therefore affect alternating slices in the volume, and even minute motions can propagate through multiple slice acquisitions.

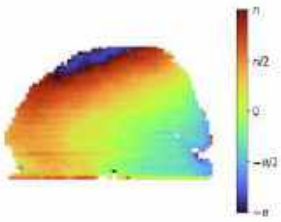

Figure 1: Sagittal view of the brain with "Z-striping" in the lower half of the image (Axial slice acquisition direction).

The current landscape of MRE technology lacks robust solutions for correcting these artifacts, particularly in the context of brain imaging where precision is paramount. Outside of alternative readout gradient structures (e.g. spiral acquisitions[4]), existing methodologies predominantly rely on low-pass filtering (for small motions that propagate through an entire volume) or manual intervention, wherein researchers are tasked with meticulously identifying and rectifying outlier slices on a slide-by-slice and volume-by-volume basis through adjustments in the phase angle. However, considering larger, expansive datasets, enhanced resolution imaging, and the potential for researcher-induced bias, this approach may be deemed highly suboptimal and inefficient.

As such, there is a current need for advanced and automated processing methods capable of mitigating the impact of motion-induced errors and improving the robustness and reliability of MRE scans. This abstract introduces a novel approach using inspired by techniques used in correcting artifacts in standard MRI sequences, specifically repurposing the principles of FSL's Eddy current correction[5]. The proposed method adapts these principles to the unique context of MRE, aiming to effectively identify and compensate for the motion-induced inconsistencies across the Z-axis of the brain scans. By integrating this approach with advanced image processing algorithms, we anticipate a substantial reduction in the presence of Z-striping artifacts during the MRE inversion process.

This work serves as a potential method for enhancing MRE image processing, tackling a widespread and complex challenge in brain imaging. The ambition of this research is to improve the diagnostic accuracy of MRE, potentially impacting the study and treatment of neurological disorders significantly.

METHODS

Ultra-high field MRE data was obtained from healthy volunteers aged 20-35 on a 7T MRI whole body scanner (Magnetom 7T, Siemens Healthineers, Germany) with a 32-channel head coil (Nova Medical, Wakefield, MA). The MRE sequence used was an echo-planar spin-echo 2D multi-slice pulse sequence with 3D motion-encoding gradients (TE=65 ms, TR=4800 ms, GRAPPA = 2, 2.5 mm isotropic resolution)[6]

and a custom pneumatic actuator by *Triolo et al* described applied vibrations at 50 Hz[7].

After each MRE scan, we collected raw data and DICOM images. We used the Gadgetron framework[8] for post-hoc reconstruction to remove artifacts caused by scanner reconstruction error, such as inaccurate value assignment in pixels along phase wrapping lines, by employing advanced coil combination based on a non-linear optimization scheme[9].

Utilizing custom Python scripts, the magnitude images were derived from the complex images reconstructed by Gadgetron and subsequently processed through FSL's Eddy tool[5]. In addition to performing automated motion correction on magnitude images, Eddy also generates a subject motion report map that outlines the standard deviation displacement from the mean for every slice in each volume in an acquisition. It's important to note that while Eddy is not explicitly designed for motion correction in MRE datasets and cannot directly correct phase data, the motion reports it produces were useful in identifying significant phase shifts attributable to extensive subject movement.

Further refinement was achieved through additional custom Python scripts, leveraging Eddy's motion report standard deviation outputs to pinpoint slices of compromised quality (mean slice deviation threshold above 0.5). These identified slices were then subjected to a phase adjustment process, utilizing their adjacent 'good' slices to estimate the approximate phase in these slices as if the subject had not moved.

After Eddy correction, we applied Marchenko-Pasteur Principal Component Analysis (MP-PCA)[10] denoising in a 5×5×5 sliding window for noise reduction without losing anatomical detail or resolution, leveraging MRE acquisition redundancies (48 volumes acquired per slice) to remove noise-only principal components. The difference was then taken between the two sets of phase images acquired with reversed MEGs to acquire wrapped displacement (in radians), and the displacement was then unwrapped using 3D SEGUE unwrapping[11]. We also employed a simple low-pass Butterworth filter to remove the high-frequency striping effect that occurs due to small, irregular subject motions.

The derived unwrapped displacement data was then used to calculate the storage modulus (G'), loss modulus (G"), and therefore the complex shear modulus (G' + iG" = G*) through an iterative, nonlinear viscoelastic inversion of the time-harmonic Navier-Stokes equation[12]. The nonlinear inversion algorithm additionally output reports of G' and G" in the volume as a function of iteration number to assess how the simulation converged.

RESULTS

After processing the subjects, it was observed that, absent any of any corrections beyond the standard pre-unwrapping procedures (Gadgetron, MP-PCA and Butterworth lowpass filtering), our example subject demonstrated difficulty in convergence during nonlinear inversion (Fig. 2), favoring stiffer and unrealistic parameters.

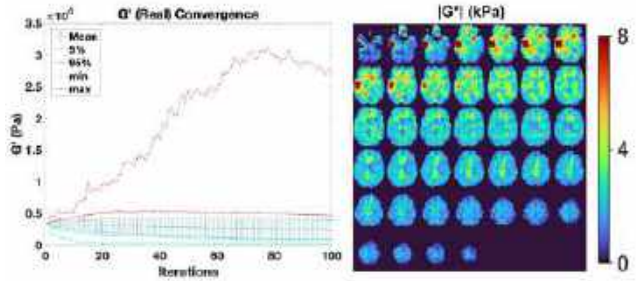

Figure 2. Poor convergence of example subject.

The real component of the complex shear modulus is considered here as it diverges more significantly when there are phase errors from subject motion. In contrast, when Eddy motion correction was performed, by adjusting slices, convergence was achieved with greater consistency with each iteration during the nonlinear inversion process (Fig. 3).

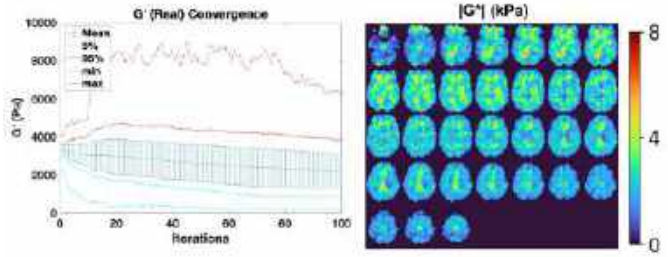

Figure 3. Good convergence of the same example subject when correction is applied.

DISCUSSION

The findings demonstrate the potential of streamlining the QC process, by identifying outliers from phase distortion using FSL's Eddy toolkit and applying correction to outlier slices. While a prior investigation proposed using FSL's Eddy toolkit for motion correction of MRE data, correction was only applied to the magnitude images for segmentation purposes and therefore had no effect on the viscoelastic inversion result[13]. Applying this post-hoc motion correction in phase as well as magnitude is imperative for generating accurate elastograms of subject populations that are more likely to shift during scans (e.g., pediatric population, patients with neurodegenerative disorders).

The subject population described in this study additionally underwent MRE scans at higher resolutions, so future work will involve application of motion correction on, and comparisons to, these higher resolution scans. Further parameter optimization to better suit FSL's Eddy for each of these resolutions will also be investigated.

ACKNOWLEDGEMENTS

This work was supported by NSF CMMI 1953323. The authors would like to thank Ms. Aislinn Diaz for assistance in volunteer recruitment and coordination, Dr. Alex Khegai for his work on the 7T MRE sequence and Gadgetron reconstruction, and Dr. Matt McGarry for providing the nonlinear inversion algorithm and technical support.

INTRODUCTION

Approximately 5% of the world's population suffers from disabling hearing loss.[1] One category in this statistic is conductive hearing loss, which is characterized by damage to the middle ear structures. Although several methods exist to diagnose conductive hearing loss, each has its limitations. Audiometer tests are readily available but only provide a subjective account of the severity of hearing loss with no insight into what structures of the hearing pathway are compromised.[2] On the other hand, CT imaging can indicate what structures are compromised but cannot measure the extent to which sound conduction in the middle ear is affected and exposes the patient to high levels of ionizing radiation.

Beyond diagnostics, a few methods exist to treat conductive hearing loss. The current standard of treatment is exploratory surgery of the middle ear, a procedure with a risk of damage to the ossicle bones and facial nerves.[3] Even with successful surgery, no standard diagnostic test quantifies treatment efficacy.

Optical Coherence Tomography (OCT) is a known diagnostic imaging technology capable of addressing the limitations of current diagnostic tools in a single device, potentially positioning this device as the gold standard for conductive hearing loss diagnosis. OCT imaging data is acquired using broadband near-infrared (NIR) laser light, which enables the system to capture images with a resolution between 10-15 microns. This means the system can resolve the tiny structures of the ear and is sensitive enough to measure the frequency and amplitude of vibrations in those structures in response to a sound of known frequency and sound pressure. An additional use case, enabled by the live imaging data and high resolution, is guidance of surgical instruments during a procedure on the middle ear, which could reduce the risk of permanent anatomical damage from accidental misplacement of surgical tools. The use of infrared light also means patients are not exposed to ionizing radiation during an imaging study.

Our device is an OCT imaging probe that can be inserted into the ear to facilitate imaging and vibrometry of middle ear structures in the sound conduction pathway on *ex vivo* human ear samples. These structures include the Tympanic Membrane, Umbo, Manubrium, and Incus in order of sound propagation.[3] When developed, the proposed device can be used by otolaryngologists, family doctors, and educational hospitals that require gold standard diagnostic technology. Additional users would include researchers studying the middle ear or hearing loss. Ultimately, we seek to create an OCT device that is not only suitable for clinical medical practice but also one that will be an improvement upon current hearing loss diagnostics and treatments.

PRODUCT DESIGN

The challenges with utilizing OCT for endoscopy of the ear are positioning the system near a patient's head, introducing the laser through the ear canal unobstructed, and focusing on the structures of interest. This device addresses these challenges by utilizing a gradient index of refraction (GRIN) lens that is long and narrow enough to pass through the ear canal and focus the NIR laser at the right depth. The GRIN lens will be protected using an otoscope speculum. The lens will be advanced with the assistance of a fiber optic endoscope with a live video of the area surrounding the lens. Our design also utilizes lightweight materials that a single person can easily utilize.

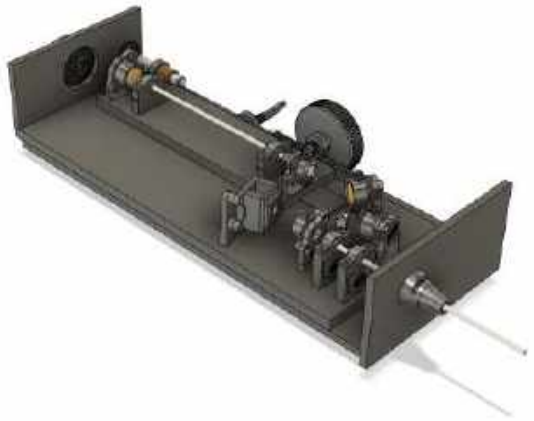

Figure 1. The CAD assembly of the device design was generated in Solidworks. The assembly contains all components of the device design without the case walls to enable easy visibility of internal mechanisms within the device.

Front Assembly

The front assembly of our design serves as the main interface between the internal optics, notably the GRIN lens being inserted into the ear and the patient. The following components all form part of the front assembly: case front panel, otoscope speculum, disposable speculum tip, GRIN lens, GRIN lens sleeve, microphone, speaker, and fiberoptic endoscope. The speculum protects the GRIN lens as it protrudes from the case. The fiberoptic endoscope is attached to the GRIN lens via an elastic resin sleeve, allowing both components to move in unison so that the user can see where the GRIN lens is positioned in relation to the ear canal. The microphone and speaker is designed to sit inside the case near the opening of the speculum to enable vibrometry.

Case

The casing we have designed for our device is fabricated of acrylic panels and includes the stage base, side walls, and front panel. Each panel is designed to interlock with its neighboring panel via teeth-like cutouts. This case serves as a protective barrier between the user and the delicate optical components.

Two-tier Linear Stage

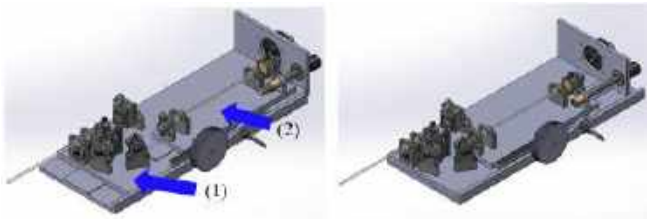

Figure 2: The stage is constructed from acrylic and consists of two portions: the main stage (1) and the reference arm stage (2).

These stages serve three purposes: Provide a stable platform for the optical assembly, allow for calibration of the system, and enable the GRIN lens to be advanced into the ear canal without misaligning the optics. Both stages utilize a dovetail mechanism that allows the user to carefully slide the main stage inside the case, moving the Gradient Index (GRIN) lens into the ear canal. Each acrylic stage is laser cut with post holes to place the optic holders in their ideal positions calculated in the CAD model.

Optomechanics

We designed custom optic holders with the minimum necessary range of adjustability and fabricated them with resin. This allows us to significantly reduce the size and weight of the overall system while maintaining enough rigidity to withstand external disruptions like sudden impacts to the case that would otherwise disrupt the optical alignment. Our optic holder designs are limited to 3 degrees of freedom adjusted via the compression of elastomer bushings. They have a thick base with two prongs to fit perpendicular to and tightly with the stage mechanism.

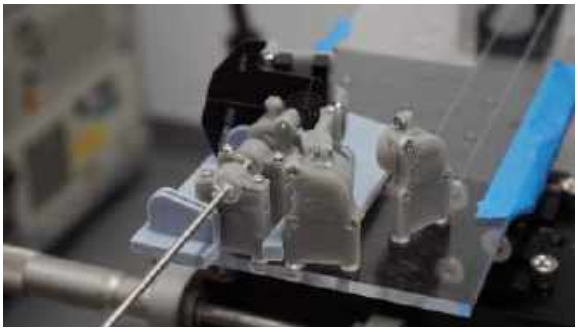

Figure 3. This photo contains the main stage resin optomechanics slotted into our acrylic laser cut panel/stage for a preliminary prototype. In this photo, we have placed the device's true lenses and mirrors into the optic holders and began alignment with a collimated beam.

BUDGET & MARKET ANALYSIS

If OCT becomes the gold standard for diagnosing and testing conductive hearing loss, the total addressable market of our device includes all hospitals that provide inpatient otolaryngology services, any outpatient clinics specializing in otolaryngology, primary care clinics in populations where conductive hearing loss is prevalent, and researchers studying the middle ear. There are 6,120 total hospitals in the United States and about 1,483 practicing otolaryngologists, 97% of whom work in some form of private practice as of 2022.[4] Therefore, we estimate about 7000 total sales of the initial device.

Long-term service of the device, such as replacement of cracked GRIN lenses, sale of proprietary speculum tips, and other accessories and consumables relating to the use of the device will provide additional revenue after the initial sale of the probe.

The material cost to produce one probe is approximately $1,400. Fabrication of the final device from scratch is expected to take about 40 man-hours of labor by a trained professional, so labor costs are estimated to be $1,600 per device. Running costs such as electricity, servicing of tooling machines, and accidental damaging of components during manufacturing is estimated to be $500 per device at a maximum. The total cost estimate is $3,500 per device.

OCT probes in the current market sell for about $9,000. However, our device would be one of the only on the market to be inserted into an ear. Considering the novelty of our probe and current probe pricing, we determined a sale price of $12,500.

Yearly sales will be limited by production time. With a small production team of about 20 employees, we estimate a production of 700 to 1000 units annually. This would equate to an approximate yearly revenue of 8,750,000 to 10,000,000 over the course of 7 to 9 years. A yearly profit estimate would be $6,300,000 to $9,000,000 per year from device sales alone.

Our device is only a probe and cannot capture data unless it is connected to an OCT base unit. A base unit supplying broadband light with a center frequency of 1310 nm would cost about $80,000. Additional components, such as the microphone and data acquisition card, will cost an additional $50,000. This upfront cost would negatively impact the initial adoption of our device but will likely improve over time.

ACKNOWLEDGMENTS

We would like to acknowledge our faculty advisors, Dr. H. Park and Dr. W. Dong, for sponsoring this project and guiding us throughout the design process.

THE FUTURE OF INTRAVENOUS THERAPY INSERTIONS BY USING VEIN FINDER TECHNOLOGY IN EMERGENCY SCENARIOS TO IMPROVE PATIENT SAFETY

U. Akpati, R. Flores, T. Pham

Faculty Advisor(s)

B. Yuan

Biomedical Engineering, University of Texas at Arlington, Arlington, Texas, USA

INTRODUCTION

•First time IV success rates in medical & trauma patients are 80-95%
•IV access is needed in emergency scenarios such as heart attacks to administer medications such as epinephrine or nitroglycerin
•Products such as the Accuvein av500 exist in a hospital setting but there are no options available for use by first responders.
•The av500 uses near-infrared light to penetrate the skin for providing contrast by absorption from de-oxygenated blood in veins.
•The remaining near-infrared is captured by a photodiode then processed to display a negative space in a projection onto the skin.
•A limitation of this product for first responder is that it needs one hand to operate, is dependent on the stability of the operator, and is bulky at 5 x 6 x 20 cm.
•The prototype being developed would allow for a handsfree vein finder that would be affixed to the first responders head to provide a hands-free and reliable way to detect and project vein locations.
•This advancement would incorporate existing technology in a unique design to help in emergency scenarios to provide a stable image on the patient's skin to improve care to those with hypotension or high BMI.
•Utilizing this new scheme, we aim to increase the accuracy for IV placement as well as decrease the time needed to place an IV.

PRODUCT DESIGN

•The enclosure of our portable version of the vein finder was designed in discussion with first responders and has undergone multiple iterations in terms of button placement, charging ports, and sensor positioning.
•Surveys were conducted for 10 individuals on the comfort of the head mounted device.
•For the working principle, a photodetector (FDS1010 - Si Photodiode with 65ns rise time) receives the reflected near-IR signal from the targeted skin region after passing through a 760nm bandpass filter and amplitudes greater than a threshold level will be distinguish as surrounding tissue versus veins.
•A laser that projects at 760nm is ideal as it has high absorbance by deoxygenated blood in veins.
•The laser that will be used to project the mapping onto the skin will have a wavelength of 520nm for maximum visibility in all environments and will be a class 1 laser to ensure patient safety.
•The device will be tested for water resistivity through exposure to moisture and water droplets by spraying water onto the surface to simulate sterilization and it will also be tested for durability by undergoing simulated drop tests.

Figure 2: SolidWorks Model of Wearable Vein Finder Design

BUDGET & MARKET ANALYSIS

The design budget for this product is $1000, which has been provided by the University.

The market analysis has been produced based on a $500,000 budget.

Table 1: Market Analysis of Proposed Vein Finder Product

Requested Budget	$500,000
Engineering/Marketing	$100,000
Manufacturing Cost/Unit	$800
Projected Sales Price/Unit	$1,200

With this model, about 500 units would be produced within a year with a $600,000 revenue and a $100,000 profit.
and any investments costs in engineering or tooling.

INTRODUCTION

The spine stands as the central support for the human body, essential for our everyday movement and stability. However, the spine's pivotal role in our daily lives underscores its susceptibility to injury and degeneration, accelerated by factors such as poor posture, sedentary lifestyles, repetitive movements (such as those in occupations requiring frequent physical exertion), and aging.

Epidemiological trends reveal a significant increase in both acute and chronic lower back pain (LBP), as well as more severe spinal conditions, on a global scale in recent decades. LBP not only stands as a leading cause of disability in the United States but also imposes a substantial economic burden, with the annual cost of treatment reaching $50 billion in the US alone [1, 2]. Globally, back pain has taken the world by storm, growing from 377.5 million confirmed cases to over 577 million in the span of just 3 decades (1990-2017) [3]. Moreover, projections indicate a substantial rise in spinal procedures like lumbar spinal fusions, particularly in larger, industrialized European populations with aging demographics [4].

Despite the concerning rate of growth in global LBP, contemporary industry has been inadequate in fully satisfying the demands of an ever-growing total addressable market (TAM). For example, NeuroMD Medical Technologies - an incumbent in the field - offers a corrective therapy device for back pain that utilizes electrical stimulation to pinpoint and correct the source of LBP. While impressive, they fall short for customers with preexisting medical conditions who are in need of a more traditional solution since previous treatments may respond unfavorably to external electrical signals - i.e. pacemakers. Additionally, traditional lumbar orthosis has also been scrutinized for potentially weakening lower back muscles due to "oversupport," further exacerbating LBP issues in the future [5].

In this paper, the design and development of Vertiflex, a soft robotic based orthosis (Fig. 1) targeting the thoracic and lumbar spinal regions in prevention of lower back pain, capable of tracking and correcting patient posture and movement, is presented. VertiFlex provides just the right amount of somatosensory feedback to the wearer, promoting a conscious awareness of good posture without doing the "heavy-lifting" that a traditional lumbar orthosis would do. With comfort in mind, VertiFlex digs deep into the contemporary criticisms of current, state-of-the-art LBP devices, searching to provide a much-needed service that has the potential to revolutionize the space of lumbar-focused orthotic devices.

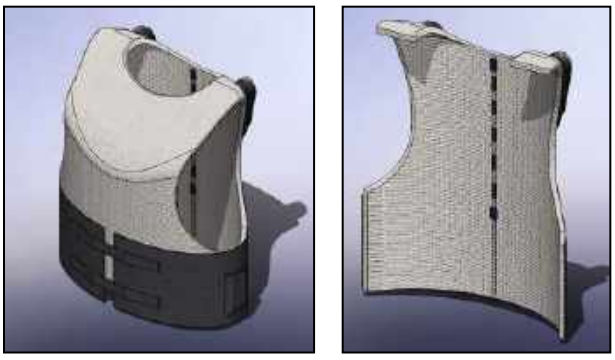

Figure 1. VertiFlex vest exterior with dual-layered canvas and semi-rigid lumbar support

PRODUCT DESIGN

VertiFlex is engineered to address the shortcomings of traditional back braces and at-home posture rehabilitation methods. Its design focuses on providing real-time feedback for spinal strain through an intuitive interface, empowering users with personalized rehabilitation and efficient recovery trajectories. With an emphasis on the thoracic and lumbar spinal regions, VertiFlex combines advanced hardware components with innovative software integration to offer unparalleled

support and correction for spinal health.

VertiFlex's hardware components form the foundation of its functionality, ensuring precise monitoring and effective posture correction. The device incorporates a dual-layered canvas vest designed to house essential hardware, including circuitry, a rechargeable battery pack, and specialized components such as inertial measurement units (IMUs), flex sensors, and pressure sensors, all of which are controlled by a Raspberry Pi. The canvas vest offers durability and flexibility, providing a comfortable fit for users while seamlessly integrating all components for optimal functionality. Positioned strategically at the cervical and thoracic spine regions, IMUs and flex sensors work in tandem to monitor user posture and back movement. IMUs leverage accelerometer and gyroscope data to assess head and neck alignment relative to the thoracic spine, while a band of six flex sensors spanning 30cm along the spine delivers accurate measurements of back flexion and bending. Calibration of IMUs for each user ensures accurate posture positioning, serving as a reference point for evaluating posture alignment.

VertiFlex employs soft robotics technology to actively correct posture deviations detected by the IMUs and flex sensors. The soft robotic component, crafted from silicone (Ecoflex A and Ecoflex B), inflates upon detection of poor posture, exerting gentle pressure to realign the user's spine. Control of air pumped into the soft robotic pouches is managed by PCB circuits based on data obtained from flex sensors. While inflated, pressure sensors are used to offer insight into the internal dynamics of the soft robotics, revealing precise pressure gradients from the air inflation. A dual-pump setup is implemented for each portion of the soft robotic system. With this, each silicone pouch has 2 inputs for tubing connected to the motors and a single output to a solenoid valve. This valve opens as needed to alleviate air pressure during inflation as well as at the conclusion of patient use. To further stabilize the lumbar spine, VertiFlex incorporates a semi-rigid lumbar back brace composed of neoprene for flexibility and high-density polyethylene for enhanced stability. The brace offers support during extension, flexion, and rotation while incorporating velcro fasteners for secure placement. This component ensures optimal spinal alignment and support, further enhancing the device's effectiveness.

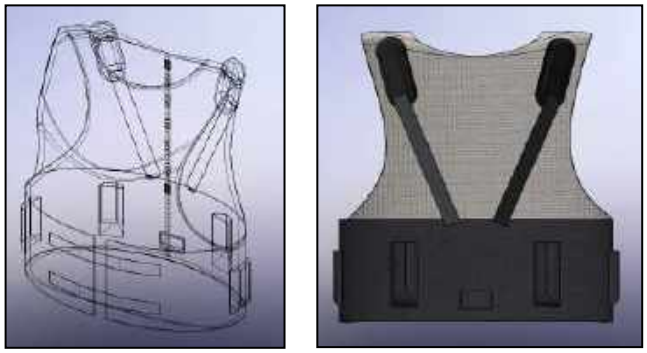

Figure 2. VertiFlex vest outline showcasing incorporated soft robotic silicone pouches, pneumatic air pumps, and semi-rigid lumbar support

VertiFlex seamlessly integrates hardware functionality with a user-friendly software interface, providing users and healthcare providers with valuable insights and tools for effective rehabilitation. The web app interface offers calibration, charts, statistics, and an avatar model for visualizing posture corrections. Real-time data collection and analysis enable the device to track user progress and offer personalized recommendations for posture improvement and pain relief. Machine learning algorithms then utilize this data to offer predictive solutions for strain relief and posture correction. Users can view calibration results, posture charts, and statistics, as well as receive personalized recommendations for posture improvement and pain relief in a user-friendly web app. Seamless communication between users and healthcare providers enables proactive monitoring of progress and adjustment of treatment plans as needed.

BUDGET & MARKET ANALYSIS

Substantial resources will be allocated towards establishing a streamlined production process, targeting an approximate unit cost of $750. These investments encompass materials procurement, initial manufacturing process design, and labor costs. With an estimated 10% of the global population (approximately 770 million) experiencing chronic back pain or conditions necessitating vertebrae rehabilitation, along with moderate market competition and anticipated consumer adoption, the potential market size is projected to range from tens of millions to potentially over a hundred million units annually. The product is meticulously tailored to address this demand, positioning it within a distinct niche market segment.

The company will adopt a business-to-business (B2B) approach, forging direct collaborations with healthcare clinics and physicians to provide the product for prescription to patients. The pricing strategy has been carefully crafted to ensure competitiveness while maintaining sustainable profit margins. With a profit margin of 20% to 30% per unit, the pricing model is set between $999 to $1299 per unit. This pricing structure not only reflects the value proposition of the solution but also offers flexibility to cater to various market segments.

The return on investment (ROI) strategy revolves around enhancing patient communication and engagement, leveraging the product's effectiveness in preventive back pain management. Through targeted marketing initiatives and strategic partnerships, the aim is to capitalize on this ROI while upholding regulatory compliance and industry standards. By adeptly navigating the interplay of budgetary considerations and market dynamics, the product is poised to secure a robust foothold in the market, presenting a compelling solution to individuals grappling with the debilitating effects of back pain.

RAPID THERMAL CONTROL OF LIQUIDS (REALCOOL): DEVELOPMENT OF A FOUR-COMPARTMENT TRANSIENT HEAT TRANSFER MODEL

N.M. Hannon, M.N. Rylander, C.G. Rylander

Walker Department of Mechanical Engineering, The University of Texas, Austin, TX, USA

INTRODUCTION

Existing methods for heating or cooling liquids often rely on conduction of heat through a vessel wall which is time consuming, especially when the vessel is constructed of thermally insulating materials like thermoplastic or glass. Additionally, these methods often do not monitor or control liquid temperature, resulting in final temperature above or below what is desired. For example, most commercially available human milk warmers used to prepare milk for babies consist of a simple water bath and immersion heater. They require the user to wait over 5 minutes to heat a plastic bottle containing 240 mL of pumped and refrigerated milk from ~4-10°C to a serving temperature of ~37°C, and they do not notify the user when the milk has reached the desired temperature.

RealCooL (Rapid Thermal Control of Liquids) is a novel technology and device that can rapidly heat or cool many liquids to a desired user-input temperature. The liquid temperature can be quickly and accurately controlled through a closed loop system which monitors temperature at multiple sites and actuates fluid pumps, valves, and a high-powered heater. The current RealCooL prototype utilizes a 10-plate heat exchanger (HX), two diaphragm pumps, two solenoid valves (to switch between heating and cooling mode), a cartridge heater, and food safe silicone tubing as shown in Figure 1. While this prototype has shown feasibility of rapid and accurate heating and cooling of several liquids, further refinement is necessary to optimize the design for specific applications.

Through extensive interviews conducted during the National Science Foundation National I-Corps™ program, we found a need for a device such as RealCooL to warm human milk for babies, which is the primary use case in this study. In particular, the design should accommodate volumes of milk up to the size of a full bottle (typically 240 mL), and accommodate the unique material properties of milk (*i.e.*; density, thermal conductivity, and specific heat). The system components should be sized appropriately to warm milk from refrigerator to serving temperature in under 2 minutes.

In order to refine the design of RealCooL for the milk warming use case, including optimal selection of components such as heater, HX, and fluid pumps, we needed to better understand the heat transfer processes involved in this system. To do so, we developed a four-compartment transient heat transfer model and compared model results with experimental results generated from our current RealCooL prototype.

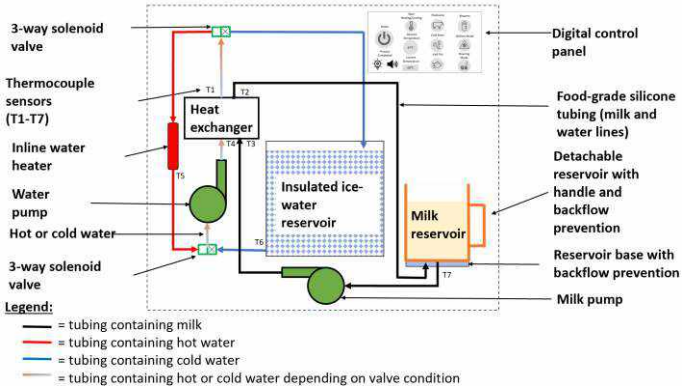

Figure 1: Schematic of RealCooL Prototype

METHODS

We developed a four-compartment transient heat transfer model to represent the RealCooL system and serve as a future tool for design optimization for specific use cases including human milk warming. The system was simplified into four linearly-adjacent compartments: 1) heater, 2) water, 3) HX, and 4) milk. Each compartment was assumed to have spatially uniform temperature throughout, as verified by a low Biot number for the solids and a well-mixed condition for the liquids.

The overall system was insulated from the surrounding environment. An energy balance on each of the compartments was used to determine the governing equation relating the change of temperature with respect to time of the compartment with respect to heat storage (capacitance) of the compartment and heat transfer (resistance) between adjacent compartments. The additional constitutive equations related the convective heat fluxes between adjacent compartments to the temperatures of each compartment [1]. Uniform volumetric heat generation was assumed within the heater. The initial temperature of the heater, water, and HX was 20℃, and the initial temperature of the milk was 10℃. A numerical method (ode45, MATLAB™, USA) was used to solve the system of four coupled ordinary differential equations, resulting in the transient temperature of each compartment.

The model required geometric and material properties for each of the four compartments in order to calculate their respective thermal capacitance as well as resistance to heat flow between them. Values used in the model correspond as closely as possible to the actual manufacturer-specified or measured components in the current RealCooL prototype. The heater is a 304 stainless steel 1500 W cartridge heater (DERNORD, China). The HX is a 10-plate 304 stainless steel HX (B3-5A-10, Duda Diesel, USA). Water and human milk volumes and material properties were obtained from published sources [2]. The heat transfer convection coefficients on interfaces between compartments were calculated based on diaphragm pump (SFDP1-012-035-21, SEAFLO, China) measured flow rates and geometry of contact surfaces via intermediate calculations of dimensionless parameters including Reynolds and Nusselt numbers.

Results of the mathematical model were compared with experimental data collected from RealCooL. 240 mL of fresh dairy milk was warmed from 10℃ to 37℃, and 6 T-type thermocouples were placed throughout the system to gather transient temperature data using a data logger (S220-T8, HUATO, China). The first thermocouple was placed in the milk reservoir. The second thermocouple was placed directly downstream of the cartridge heater, measuring the maximum temperature of the water. Four more thermocouples were placed on each of the four ports of the heat exchanger: milk inlet, milk exit, water inlet, and water exit. The water and milk pumps and heater were all energized at t=0.

RESULTS

The model predicted that RealCooL should take about 52 s to heat 240 mL of milk from 10℃ to 37℃ (Figure 2). All four compartments show a nonlinear temperature dependence on time, with more nonlinearity at earlier times. A small dip in HX and water temperature is observed at the beginning of the simulation, which is caused by the transfer of heat from these components to the cold milk. At later times, as the heater temperature is much greater, the transient temperature of each compartment appears more linearly related to time.

Experimental data gathered with the RealCooL prototype showed it took 72 s to warm 240 mL of dairy milk from 10℃ to 37℃ (Figure 3). Results demonstrated a linear temperature vs. time dependence for all thermocouples. Temperature variation was observed across the four HX ports, with a 5℃ difference in temperature between the water inlet and outlet ports on the HX, and about 3℃ difference in temperature between the milk inlet and outlet ports. The milk outlet temperature is about 3℃ less than the water outlet temperature at all times.

DISCUSSION

The transient heat transfer model demonstrates some of the characteristics experimentally observed with the RealCooL prototype. In particular, at later times, all transient temperatures have a linear time dependence. Additionally, at around 1 minute into both the simulation and experiment, the difference in temperature between water and milk was about 15℃. These similarities provide a level confidence that the assumptions built into the simulation are appropriate.

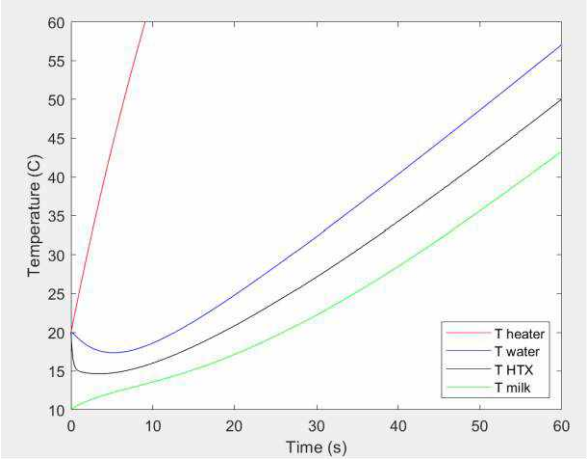

Figure 2: Mathematical Model Data

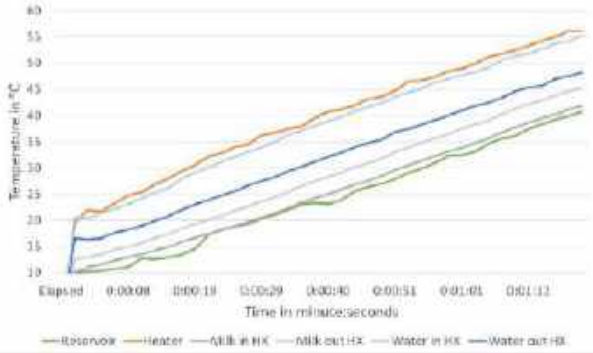

Figure 3: Experimental Data

Unfortunately, there are some discrepancies in the time for the milk to reach the desired final temperature (52 s in the model vs. 72 s in the experiment). The model accuracy may benefit in the future by including a fouling factor on one or both sides of the HX which is an additional realistic resistance to heat transfer and will more closely align the model with experimental results. Additionally, we assumed that there was no spatial variation of temperatures within the HX compartment, which is not accurate based on the four different temperatures experimentally recorded on each port of the HX. However, it may still be acceptable to model the HX as a single compartment with a temperature equivalent to the average of the temperatures at the four ports for purpose of predicting transient milk temperature.

ACKNOWLEDGEMENTS

We would like to acknowledge the National Science Foundation I-Corps™ program for partially funding this project under NSF award #2228384. Additionally, authors MNR and CGR are co-inventors on PCT application WO/2023/240034 related to RealCooL technology.

EFFECTS OF SEMI-OCCLUDED VOCAL TRACT EXERCISE ON VOCAL FOLD BIOMECHANICS AS OBSERVED DURING HIGH-SPEED VIDEOENDOSCOPY

David S. Ford (1), Dimitar D. Deliyski (2)

(1) Department of Speech-Language Pathology, John G. Rangos Sr. School of Health Sciences, Duquesne University, Pittsburgh, PA, USA

(2) Department of Communicative Sciences & Disorders, Michigan State University, East Lansing, MI, USA

INTRODUCTION

Semi-occluded vocal tract exercise (SOVT) is a common technique/posture used in both habilitation and rehabilitation of the voice. By narrowing, but not completely occluding, the vocal tract at one end (e.g. the lips), a backpressure is created, which assists in coupling the source (vocal fold vibration) and the filter (vocal tract) of voicing. This coupling results in various physiologic changes which collectively have a profound impact on voice production. Physiologic changes include: maximized impedance matching by increasing vocal tract inertance [1], better distribution of acoustic energy [2], decreased phonation threshold pressure [3], increased maximum flow declination rate and increased strength of high harmonics [4], a "squaring up" shape of the vocal folds [5], reduced collision pressure during vocal fold adduction [6], increased thyroarytenoid muscle to cricothyroid muscle ratio resulting in thicker vocal folds with a more pliable cover, decreased vertical position of the larynx [7], and relaxation of intrinsic and extrinsic laryngeal musculature during phonation [8].

While the effects of SOVTs are well represented throughout the literature with regard to acoustic and aerodynamic effects, vocal economy and efficiency, and laryngeal biomechanics, most findings were the result of modeling and theoretical constructs. Few studies have investigated SOVTs experimentally and even fewer have explored the effects of the technique *during* SOVT production. This study aims to elucidate these gaps in knowledge by exploring the effect of SOVT exercise on vibratory characteristics of the vocal folds, using objective measures derived from high-speed videoendoscopy.

METHODS

Given the pioneering nature of this study and the timing of data collection occurring at the height of the COVID-19 pandemic, results were treated more as a qualitative proof-of-concept, than a study of statistical significance. There were only two participants (one male and one female) in this study, but the robustness of the collected measures was generated by the large number of "frames" of video data. Neither participant reported current voice, speech, medical, or behavioral impairments that may impact phonatory function, nor a history of voice rehabilitation or habilitation.

A custom-designed high-speed videoendoscopy (HSV) system was used, consisting of a FASTCAM Mini AX200, M4 32GB high-speed camera (Photron USA, Inc., San Diego, CA), controlled by MSI GL63 8SE laptop camera control system, coupled with a 45-mm endoscope lens adapter Model 9117 (Pentax Medical, Montvale, NJ), a 3.5-mm flexible fiberoptic endoscope FNL-10RP3 (Pentax Medical), an audio recording interface (Focusrite Scarlett 2i2 2nd Gen), and an AKG C420 headset condenser microphone for simultaneous capturing of the acoustic signals. The HSV system was used to record sustained /i/ vowel phonation productions from the two vocally healthy adults before, during, and immediately after SOVT exercises at the speed of 4,000 frames per second (fps). The image analysis and measurements were performed using a video viewing software (PFV4 Photron FASTCAM Viewer, Photron USA, Inc., San Diego, CA), which allowed for variable playback speed. The SOVT exercises were phonation into a 19.7 cm plastic straw with a 5.59 mm diameter and submerging the straw into an 8 oz cup filled with 4 oz of water. The protocol amounted to 20 seconds of total recording time, which allowed for partitioning of the camera's memory into two, 10-second partitions as seen in **Figure 1**.

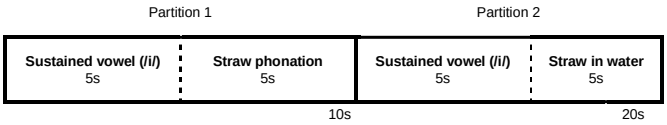

Figure 1: Schematic of memory partitioning of the HSV examination protocol

The specific variables of vocal fold vibratory behavior analyzed were glottal attack time (GAT), which is defined as the time between

the first vocal fold oscillation modulating the airflow and the first vocal fold contact [9], glottal offset time (GOT), which is the time between the final vocal fold contact and the final vocal fold oscillation, and glottal contact closed quotient (GCCQ), which is referring to the intra-cycle ratio (%) the vocal folds spend in the closed phase, relative to the period.

RESULTS

The values for GAT, GOT, and GCCQ are presented in **Table 1**. While complete normative values are not readily available for all measures, reference values for GAT have been reported as follows [9]: in "comfortable" glottal onsets, attack times ranged from -1.4 to 9.6 ms, in breathy glottal onsets, they ranged from 7.6 to 38.0 ms, and in hard glottal onsets, they ranged from -9.5 to -1.7 ms. Perhaps more important than the actual values is the concept that comfortable onsets are generally short and positive, breathy onsets are long and positive, and hard onsets are negative. The two unreported GOT values are because of offsets which were not captured due to anatomical structures obscuring the view of the glottis.

Table 1: Objective vocal fold vibratory measures collected using HSV for each participant

Variable	Participant 1 (M)			Participant 2 (F)		
	GAT	GOT	GCCQ	GAT	GOT	GCCQ
Straw phonation into water	8.8	8.8	.205	35.0	64.0	.023
Straw phonation	8.0	15.0	.019	12.0	26.0	.008
Pre-SOVT /i/	-13.0	7.7	.014	-12.0	-	.014
Post-SOVT /i/	14.0	15.5	.022	24.0	-	.011

*All values in milliseconds

In general, both participants' GAT values trended toward longer, positive values during SOVT exercises, compared to sustained phonation pre-SOVT. This trend was more pronounced for straw phonation into a cup of water than for straw phonation alone. Both participants demonstrated negative GAT values consistent with hard glottal onsets, prior to SOVT production, and with breathy glottal onsets following SOVT production. GOT values cannot be interpreted due to missing data, but it appears the trend would be similar to GAT. The results for GCCQ were more variable with a sizable increase in time spent in the closed phase for participant 1 during straw phonation into a cup of water and a modest increase for straw phonation alone. A similar increase in GCCQ was noted for participant 2, but a decrease in GCCQ was noted for straw phonation alone. **Figure 2** illustrates participant 2's increase in GCCQ from sustained phonation to straw phonation into a cup. It also demonstrates additional descriptive information that was consistent across both participants, the existence of supraglottic activity.

Although not objectively measured, visual inspection of the HSV data revealed anterior-posterior squeezing of the supraglottic structures during participant 2's sustained vowel phonation. This squeeze behavior was not present during either SOVT exercise. There was also lateral squeezing of the false vocal folds during participant 1's sustained vowel phonation, which was not present during the SOVT trials. The extent of the supraglottic activity was much less significant for participant 1 compared to participant 2.

DISCUSSION

The trend of increased GAT across both participants, during SOVT, was expected and supports the notion that that there is a "cushioning" effect on vocal fold contact pressure during SOVT postures. It was somewhat surprising that GAT was longer during straw phonation into water than during straw phonation alone, but this can be explained by the density of the water providing more resistance than the air, therefore requiring more vocal fold collision pressure to overcome the resistance.

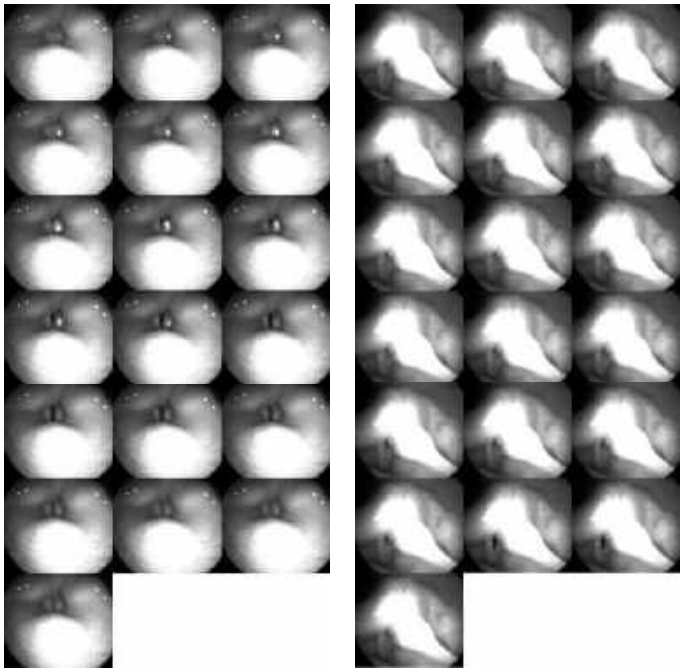

Figure 2: HSV images depicting GCCQ over 19 frames (one glottal cycle in this case) for sustained /i/ (left) and straw phonation into a cup of water (right)

The variability of the GCCQ measure across the participants was somehow both expected and surprising. While it was hypothesized that GCCQ would decrease, due to less "pressing" of the vocal folds during SOVT exercise, paradoxical results were found. GCCQ increased during straw phonation into a cup of water for both participants and during straw phonation for participant 1. The only decrease in GCCQ was observed during straw phonation for participant 2. Perhaps the reason for the increased GCCQ is similar to the previously referenced assumption that the increased resistance provided by the SOVT required additional muscle recruitment to overcome, contributing to a more "pressed" vocal fold posture. This explanation makes more sense for GAT and other measures of glottal onset, since any additional effort required to overcome the SOVT resistance is unlikely to have an impact on vocal fold vibration that persists cycle-after-cycle.

ACKNOWLEDGEMENTS

Data collection for this project was completed entirely at Mayo Clinic Arizona with the assistance of Dr. Stephanie Zacharias and Dr. David Lott.

IN VITRO PLATFORMS TO ASSESS THE SPATIAL RESPONSE TO BURN INJURY AND THERMOEMBOLIZATION

S. Brocklehurst (1), A. Sabaghan (1), M. N. Rylander (1)

(1) Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, USA

INTRODUCTION

The capability to characterize the spatial and temporal thermal and mass transport and biological response to a diverse range of stimuli within physiologically representative experimental systems is of profound importance. Applications for which this would be meaningful include prediction of burn injury response, assessment of treatment efficacy of thermal and chemical based treatments, and measurement of transport of diagnostic and therapeutic agents.

Experimental systems for measuring biological response include *in vitro* and *in vivo* models and *ex vivo* tissue. Existing *in vitro* models fail to capture sufficient physiological complexity while *in vivo* models lack spatial and temporal precision in a cost-effective manner. Computational models exist, but are frequently based on limited experimental data necessary for validation. *In vitro* microfluidic platforms have emerged as an attractive option for mimicking appropriate physiological complexity while enabling the spatial and temporal response to be measured in a high throughput manner.

Our team has been developing advanced, biologically representative *in vitro* tissue platforms for the past 15 years [1-3]. Our platforms model the cellular complexity of the system of interest, mimic the extracellular matrix (ECM) of the respective tissue, and incorporate fully functional blood vessels and lymphatics with physiological flow. This abstract will focus on the development and utilization of these platforms for modeling contact burn injury and thermoembolization.

METHODS

In vitro platforms were created as we have previously published to predict the spatial and temporal response to burn injury [1]. For this application, human dermal keratinocytes and fibroblasts were embedded in collagen type 1 hydrogels in a multilayer structure recreating the epidermis and dermis. Buffer solutions for creating the collagen ECM were prepared by mixing 1X DMEM, 10X DMEM, and 1 M NaOH. The buffer was combined with 6 mg/mL collagen containing fibroblasts at 100,000 cells/mL stock solution in a 1:1 ratio. Two parallel vascular channels were embedded within the dermis and enabled perfusion of physiological flow. To create the vascular channels two shortened 22-gauge blunt tip needles were inserted into the platform and polymerized within the collagen ECM as previously published [2,3]. Keratinocytes were mixed into collagen gels in the same fashion as above, then 120 µL of the keratinocyte-bearing mixture was pipetted onto the top of the platform. Both layers were polymerized together to create a multi-layer structure. After the lower layers were created and placed in an incubator, fibroblast media was added to the platform for culture in the incubator for 24 hours before burn exposure. Platforms were exposed to contact burns for 3 seconds using a 3 mm diameter cylindrical copper tip heated to 50, 65, 75, 85, or 100 °C. Different platforms were exposed to varied vascular flow regimes: no flow, parallel, and opposing endothelial media flow of 520.5 µL/minute in each channel to induce a wall shear stress of 2 dyn/cm^2 for at least 3 seconds before applying the contact burn, and at least 5 seconds afterwards during the cooling phase. The spatial cell viability was measured 24 hours following contact burns for varied flow regimes by means of staining with calcein (stains live cells green) and propidium iodide (stains dead cells red) and imaged with confocal microscopy. Horizontal cross-sections of the platforms were analyzed in 90 µm thick sections and the area of the ablated region was measured for each section using ImageJ. COMSOL Multiphysics (6.1) was used to determine the spatial and temporal distributions of temperature within skin platforms during and immediately after exposure to contact burns similar to our published work [1]. Experimentally measured contact burn ablated volumes were analyzed with computationally predicted spatial and temporal temperature distributions to determine the process coefficients A and E_a for burn injury that best describe the results.

We also used our *in vitro* platforms to characterize the response to thermoembolization treatments that foster changes in ph, temperature, and oxygen concentration and for which the spatial and temporal

distribution can be characterized. For these experiments, *in vitro* platforms consisted of a similar type 1 collagen hydrogel of identical concentration with a single embedded vascular channel. To simulate thermoembolization, 150 µl of 3M and 1M dichloroacetyl chloride (DCACl) solutions dissolved in poppy seed oil were loaded into syringes. These solutions were then injected into the microchannel using a 24-gauge needle and perfused at 10 µL/minute with a syringe pump. A high-resolution infrared thermal camera (model: FLIR T62101) was utilized to monitor temperature distribution in the gel over time, offering a top-view perspective. A K-type thermocouple and ph probe were also used to measure temperature and ph respectively.

RESULTS

Contact Burns: Figure 1 shows the spatial cell viability a function of contact burn tip temperature and model predicted temperature based on the Penne's equation for countercurrent vascular flow in the skin platforms. It is evident that for increasing tip temperatures, the ablated tissue volume increase (Figs. 1A and 2) and temperature elevations are more significant (Fig 1B).

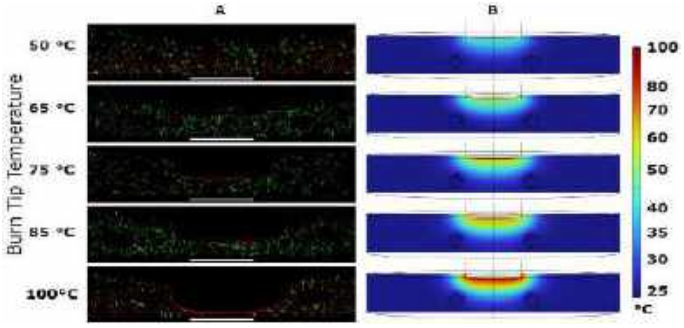

Figure 1- Experimentally measured cell viability distribution and model predicted temperature with varied tip temperatures - A: Cell viability determined with calcein/propidium iodide staining with live cells in green and dead cells in red showing cross sections of skin platforms 24 hours after contact burns. Scale bar = 3 mm. B: Computational model predicted temperature distributions of skin platforms after 3 seconds of contact burn exposure.

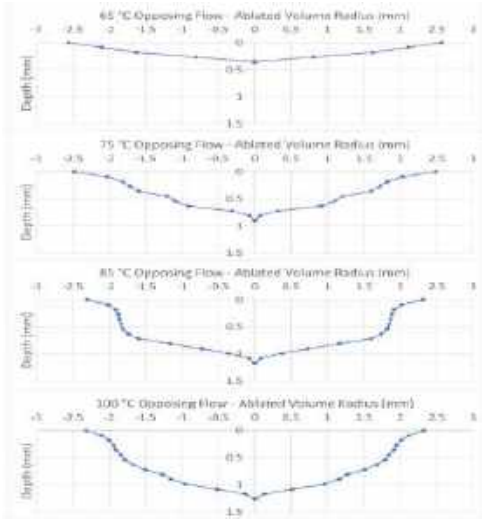

Figure 2- Average cross-sectional profiles of ablated regions of contact burns from contact tips of varied temperature for opposing flow, mm units.

Thermoembolization Results: Figure 3 illustrates the temperature distribution immediately after and 60 seconds following the injection of DCACl solutions (3M and 1M) into the platform vessel microchannel. The interaction of the DCACl solution with the collagen surrounding the microchannel resulted in an exothermic reaction, causing a temperature increase in the injection vicinity. Moreover, the data demonstrates that the higher concentration of DCACl (3M) induces a more pronounced temperature elevation in the platform compared to the lower concentration (1M). This effect extends over a larger spatial area and persists for a longer duration. Additionally, regarding the images taken with the visible light camera, given the use of phenol red in the gel (as a component of DMEM) and knowing the fact that its color shifts to yellow in acidic pH conditions, a notable pH decrease around the injection area is observed over time following the administration of DCACl (3M) which is greater than DCACl (1M). Figure 4 (A) depicts the maximum temperature increase, while Figure 4 (B) displays the pH following the addition of 150 µl of DCACl at concentrations of 1, 3, and 10.4 M to the collagen platform within a 24-well plate, encompassing gel concentrations of 4 and 7 mg/ml. Notably, while the variations in gel concentration does not show a meaningful impact on both temperature and pH, elevating the DCACl concentration from 1 to 10.4 M reduces the pH level. In addition, a slight increase in temperature rise is observed when raising the DCACl concentration from 1 to 3 M. However, temperature rise substantially escalates upon further increase in the DCACl concentration from 3 to 10.4 M.

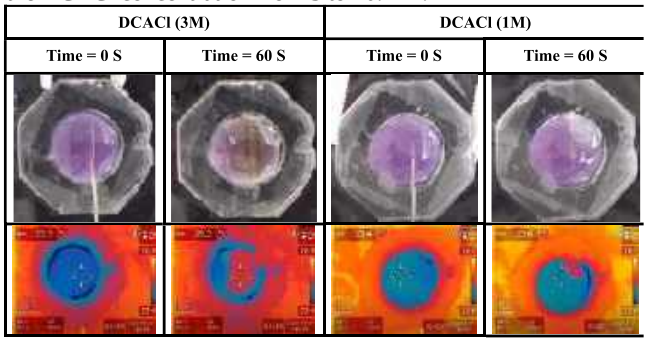

Figure 3- Images of the microfluidic platform taken by visible light camera (1st row) and infrared thermal camera (2nd row) 0 and 60 seconds after injection of DCACl with concentrations of 1 and 3M.

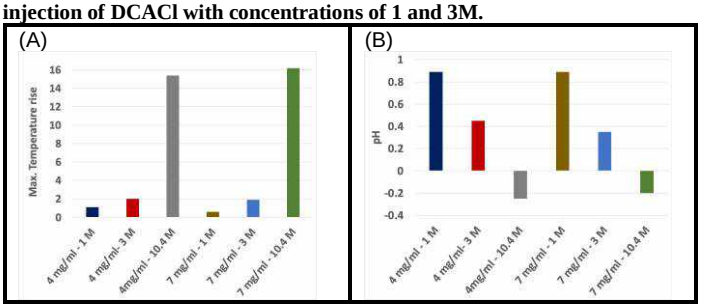

Figure 4- Maximum temperature rise (A) and pH (B) after adding 150 µl of DCACl solutions (1, 3, 10.4 M) to 1.5 ml of collagen gel (4 and 7 mg/ml).

DISCUSSION

The *in vitro* platforms used in this study enabled measurement of pH and spatial temperature and cell viability for varying treatments. This type of quantitative information was not previously possible with animal models or existing *in vitro* systems and will permit prediction of the tissue response critical for treatment planning.

SYNERGETIC EFFECTS OF PERIODICALLY MILD HYPERTHERMIA AND ULTRASOUND TREATMENT ON OSTEOGENESIS IN AGED HUMAN MESENCHYMAL STEM CELLS

D. Dawkins and S. Wang

Biomedical Engineering Department, City University of New York/City College, New York, NY, USA

INTRODUCTION

With a growing, longer lived elderly population, osteoarthritis (OA) is the most common form of chronic arthritis and affects millions of people annually with an inevitable joint degeneration including joint cartilage and subchondral bone [1]. The almost ubiquitous presence of OA amongst this population limits their mobility and increases demand for specialized health care workers, leading to a heavy burden on the financial portion of the healthcare system as a whole [2,3]. During 2019 to 2021, 21.2% of U.S. adults (53.2 million) reported diagnosed arthritis [2], wherein 32.5 million adults are OA patients [3]. Furthermore, OA was the second most costly health condition treated at US hospitals in 2013 [4]. In that year, it accounted for $16.5 billion, or 4.3%, of the combined costs for all hospitalizations [4]. OA has long been viewed and labeled as an inevitable disease due to wear and tear of the joint (articular) cartilage and is seen as synonymous with aging. Cells that compose articular cartilage, chondrocytes, are mostly tasked to maintenance of the cartilage structure and cartilage is not vascularized or innervated, and does not have the capacity to regenerate or repair itself [1]. Articular cartilage is nourished via the surrounding synovial fluid, whose nutrition/biological activities is supported and regulated by subchondral bone. Inflammation is not obviously detectable in the early stage of OA, but become evidential in synovial membrane/joint capsule, leading to thick and cloudy synovial fluid, swelling joint, degeneration of cartilage and subchondral bone, and then subchondral bone spur and pain along the timeline of worsening of the OA development [5, 6, 7]. There is no effective cure for OA currently except whole joint replacement for patients with the late stage of OA and usually over 60 years-old. Pain and inflammation mitigation methods, such as NSAIDs (nonsteroidal anti-inflammation drugs), hyaluronic acid injection, braces/orthotics, and minor invasive arthroscopic surgery to trim off teared cartilage debris [8], are not effective to prevent the progress of OA or tissue repair, especially in mid-aged and old adults [9].

Prevention and tissue regeneration approaches were chosen in our study of this challenge. Targeted therapeutic ultrasound has been proven to heal non-union fractures bone in rat models [10], and has been utilized in physical therapy of muscular skeletal injury due to its portability and non-invasive properties [11]. On the other hand, the previous study from our lab shows that periodically mild hyperthermia (i.e., 1 hour at 39°C for every other day over a couple of weeks) facilitates osteo- and chondrogenic differentiation of human mesenchymal stem cells by ~30% via the regulation of heat shock protein 70 [12-15]. A study into the regenerative and anti-inflammation properties of human mesenchymal stem cells (hMSCs) combined with therapeutic ultrasound to perform thermal and mechanical loading stimulations simultaneously may deliver a different OA mitigation and treatment strategy.

METHODS

In order to investigate the synergetic effects of mild hyperthermia and ultrasound treatment on osteogenesis in old human mesenchymal stem cells, two types of ultrasound (US) transducers were used, plane-wave one to provide ultrasound (US) wave for mechanical loading while focused US transducer to provide heating at 39±0.5°C and mechanical loading. As shown in Figure 1, hMSCs were seeded in 12-well plates at 5,000 cells/cm^2 and US transducers were located under the plate with US coupling get in-between. To produce the waveform required for LIPUS, a single channel function generator (Tektronix, Inc., AFG3251) set to pulse burst mode was used to generate the pulses. LIPUS dictates that the signal must have a 20% duty cycle, with a 1 kHz repetition rate. The focused transducer is a 1 MHz custom cubic immersion transducer constructed specifically for this purpose by NDT Systems Inc. (IEMF0.18) that features a 2-inch focal length with a spherical focus, with an 1-inch diameter element. The 1 MHz cubic plane wave transducer also constructed by NDT Systems Inc., (IEMF0.13) is also

custom made, cubic and features a 0.375-inch diameter element. The pulsing voltage profile was based primarily around the focused transducer: 90 mVrms out to the amplifier for 6 minutes, followed by a drop in voltage to 45 mVrms for 42 minutes, accompanied by one more drop to 40 mVrms for 18 minutes for a total of 1 hour and 6 minutes of exposure to ultrasound pulses. Plates were pulsed every other day for an hour each. To emulate indirect heating conditions as used in the prior experiment, an incubator at 39°C was utilized, and cells were placed into the incubator for 1 hour plus the time taken to maintain a 39°C temperature for at least one hour, once every other day.

To mimic the MSCs coming from mid-to-old people, hMSCs of passage 5 (P5) and 6 (P6) were used in the experiments instead of passage 3 or 4. The standard hMSC growth medium, Dulbecco's modified Eagle's medium, low glucose with 10% fetal bovine serum and 1% penicillin-streptomycin were used. For osteogenic medium, hMSC growth medium was supplemented with 50 µM L-ascorbic acid phosphate magnesium salt n-hydrate, 0.1 µM dexamethasone, and 10 µM β-glycerophosphate disodium salt hydrate. Assays of ALP activity and calcium deposition were performed to evaluate hMSC osteogenesis. Total DNA content of samples was used to normalize the data. ANOVA was used for statistical analysis.

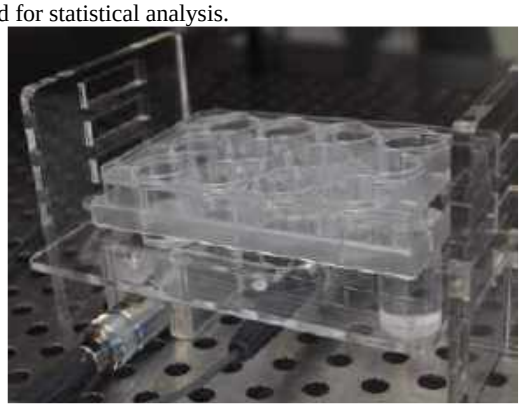

Figure 1: Device set-up to host ultrasound transducers below the 12-well culture plate.

RESULTS

As shown in Figure 2, P5 MSCs undergoing osteogenesis show significantly higher values of ALP activity at both time points (Day 6 and 12) for the US pulsed conditions than that of the incubator 37°C control ($p < 0.01$) condition. Interestingly, for P5 MSCs, there is no significant difference between the incubator 39°C condition and the incubator 37°C control.

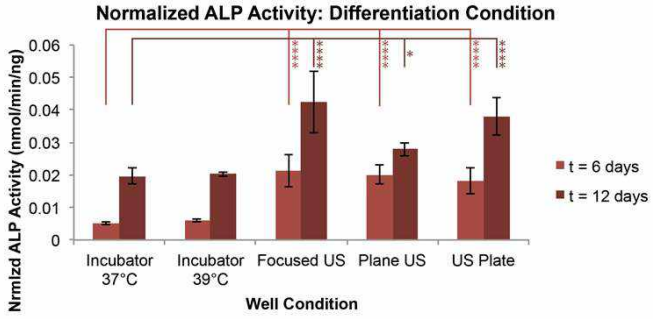

Figure 2: ALP activity normalized with DNA content at 6 days and 12 days for the differentiated P5 MSCs. Error bars denote standard deviation. Lines indicate a comparison to the incubator 37°C control. Statistical significance denoted by ** is equivalent to $p \leq 0.0001$, * is equivalent to $p \leq 0.05$.**

Osteogenic P6 hMSCs on Day 19 of differentiation were used in the calcium deposition assays. Calcium deposition is significantly higher in both US stimulated conditions than that of the incubator 37°C control or incubator 39°C condition (Data not shown here). However, there is no significant difference between the samples of two types of US conditions.

DISCUSSION

The results demonstrate that the synergetic stimulation of thermal and mechanical loading using focused ultrasound can rescue the function of heat-enhanced osteogenesis in older hMSCs. If this synergetic effect exists for chondrogenic differentiation in old hMSCs needs to be further investigated. In addition, separation of the focused transducer and the plane wave transducer in different culture plates should be paramount. In this study, we kind of artificially generated aged hMSCs by passage cells for more than 4 generations using in vitro subculture methods. The same experiments should be repeated using hMSCS isolated directly from aged mammals (e.g. mice) since obtaining hMSCs from aged human being is probably not possible. In terms of mechanism studies of the synergetic effects, mechano-sensing signaling pathways (e.g. TRPV receptors) will be investigated.

ACKNOWLEDGEMENTS

The study was supported by NIH/NIA grant to S.W. and Louis Stokes Alliances for Minority Participation (LSAMP) scholarship to D.D.

KEN DILLER AND BIOHEAT TRANSFER

J. Bischof

Mechanical Engineering Department, University of Minnesota Twin Cities, Minneapolis, MN, USA

ABSTRACT

This talk will celebrate Dr. Ken Diller's retirement by highlighting some of his lasting impact on the field of bioheat transfer. Ken is known not only as an excellent engineering scientist, but also a caring and thoughtful educator, mentor and historian of the field. His contributions range from the first micro-processor controlled cryomicroscope (the prototype of which is shown in Figure 1 (1), to some of the first biophysical studies of islets, blood cells and others during freezing (2-5). As a result of these efforts he also traced the history of the field, especially early cryobiologists which can be seen on his library shelves and led to separate review monographs on Maximov and Sachs (6, 7). He is also a world expert in burn injury having studied and carefully documented and consulted on both cellular and vascular effects of elevated temperature over time effects on tissues (8, 9).

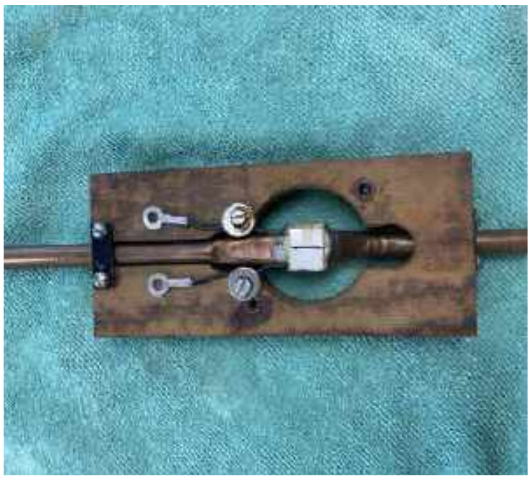

Figure 1: The original Diller cryomicroscope. This device was engineered to observe live cells during freezing processes under the microscope. Note the copper tube to deliver cryogen and electrical leads to provide differential heating to the optical stage in the middle.

During the course of these studies he trained many excellent students in bioheat transfer who are now leaders in both academia and biomedical industry and has been selfless in making time for others not specifically trained in his lab. He also published many chapters including his most comprehensive entitled "Bioheat transfer" in the CRC Thermal Engineering Handbook that I continually return to (10). He also was one of the inaugural editors of the Annual Review of Biomedical Engineering which is one of the top cited journals in the field of biomedical engineering. One impactful outgrowth of his training and mentorship is his leadership in the NSF ERC VaNTH (Vanderbilt-Northwestern-Texas-Harvard/MIT) which revolutionized biomedical educational technologies and led to a biotransport textbook, and dramatic changes in how he and others teach the field biomedical engineering (11). Indeed, his mentorship and support also helped propel my team towards our own National Science Foundation Engineering Research Center (ERC) for Advanced Technologies for the Preservation of Biological Systems (ATP-Bio). In summary, this talk demonstrates the many ways that Ken Diller has substantively contributed to the field of bioheat transfer.

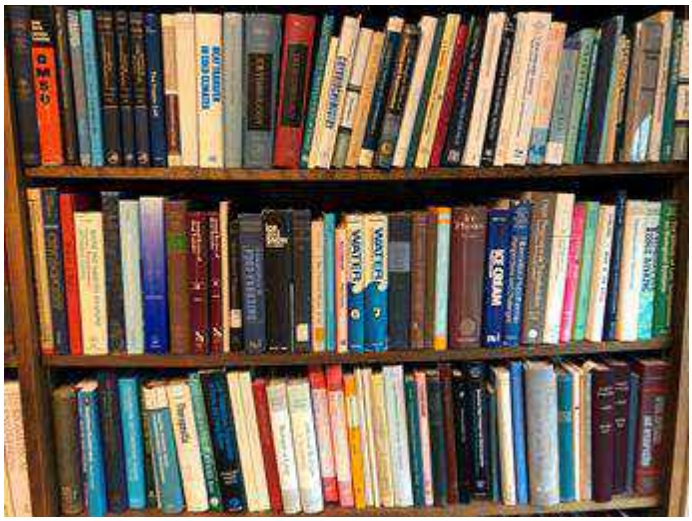

Figure 2: The Diller bioheat library includes many cryobiology classics including a full set of Biodynamica, many bound volumes of Cryo-Letters and Cryobiology. Many of the early works in cryobiology are also present including some of the early German writings from the 19th century. Many of these are still available thanks to Ken Diller's generous gift of this library to the NSF ERC ATP-Bio at the University of Minnesota (ATP-bio.org).

PROFESSOR KEN DILLER'S IMPACT IN CRYOBIOLOGY AND BIOMEDICAL ENGINEERING

M. Toner

Massachusetts General Hospital & Harvard Medical School
Harvard-MIT Health Sciences & Technology
Boston, MA, USA

ABSTRACT

The field of biomedical engineering has been at the forefront of applying quantitative approaches to biology and medicine to advance healthcare. Professor Kenneth Diller's early contributions in low-temperature biology stand out as prime examples of integrating quantitative sciences into biology, significantly shaping the entire field of biomedical engineering. In 1970, he pioneered the development of the modern cryomicroscope (1, 2), a pivotal tool for monitoring thermodynamics, heat, and mass transport phenomena. This innovation provided critical insights into the complex physicochemical processes governing water's fate within biological cells during freezing (3-5). Today, the cryomicroscope is indispensable in every cryobiologist's laboratory. Diller's seminal work also encompasses the development of mathematical models to predict cellular responses to cryopreservation protocols. These models not only enhanced our understanding of the biophysics of cryopreservation but also facilitated the optimization of protocols. The impact of Diller's work extends broadly, from the storage of red blood cells and other blood components for transfusion medicine to the establishment of biobanks for cells and tissues in regenerative medicine. His pioneering efforts have inspired multiple generations of scientists, laying the foundation for advancements in cryobiology and biomedical engineering. This presentation will delve into the profound influence of Diller's early work, particularly in cryobiology, and its broader implications for biomedical engineering.
