WEDNESDAY, JUNE 29	3:45pm - 5:15pm

Nano, Micro, and Multi-Scale Mechanics in Cell and Tissue Engineering — Wilson B

Session Chair: X. Sherry Liu, *University of Pennsylvania, PA, United States*
Session Co-Chair: Nadeen Chahine, *Feinstein Institute, NY, United States*

3:45PM **A Chemo-mechanical Model for Extracellular Matrix and Nuclear Rigidity Regulated Size of Focal Adhesion Plaques** SB³C2016-679
Xuan P. Cao[1], Yuan Lin[2], Tristan Driscoll[3], Janusz Franco-Barraza[4], Edna Cukierman[4], Robert Mauck[3], Vivek Shenoy[5], *[1]Materials Science and Engineering, University of Pennsylvania, Philadelphia, PA, United States, [2]Department of Mechanical Engineering, The University of Hong Kong, Hong Kong, Hong Kong, [3]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [4]Fox Chase Cancer Center, Philadelphia, PA, United States, [5]Department of Materials Science and Engineering, University of Pennsylvania, Philadelphia, PA, United States*

4:00PM **A Predictive Multiscale Model for Simulating Flow-Induced Platelet Activation: Correlating with In-Vitro Results** SB³C2016-690
Peng Zhang[1], Chao Gao[1], Jawaad Sheriff[1], Marvin J. Slepian[1, 2], Yuefan Deng[3], Danny Bluestein[1], *[1]Biomedical Engineering Department, Stony Brook University, Stony Brook, NY, United States, [2]Departments of Medicine and Biomedical Engineering, University of Arizona, Tucson, AZ, United States, [3]Applied Mathematics Department, Stony Brook University, Stony Brook, NY, United States*

4:15PM **Cell Organization Dictates Stress Generation in Tissue Engineered Cell Sheets** SB³C2016-665
Inge A. E. W. van Loosdregt[1], Patrick W. Alford[2], Cees W. J. Oomens[1], Sandra Loerakker[1], Carlijn V. C. Bouten[1], *[1]Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands, [2]Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

4:30PM **Impacts of Maturation on the Nanostructure and Nanomechanics of the Meniscus Extracellular Matrix** SB³C2016-948
Qing Li[1], Feini Qu[2, 3], Biao Han[1], Robert L. Mauck[2, 3], Lin Han[1], *[1]School of Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia, PA, United States, [2]McKay Orthopaedic Research Laboratory, University of Pennsylvania, Philadelphia, PA, United States, [3]Translational Musculoskeletal Research Center, Philadelphia Veterans Administration Medical Center, Philadelphia, PA, United States*

4:45PM **Linking Mitral Valve Interstitial Cell Deformation to Biosynthetic Response: Implications for Mitral Valve Repair** SB³C2016-802
Salma Ayoub[1], Chung-Hao Lee[1], Connor T. Hughes[1], Giovanni Ferrari[2], Michael S. Sacks[1], *[1]The University of Texas at Austin, Austin, TX, United States, [2]University of Pennsylvania, Philadelphia, PA, United States*

5:00PM **Mechanical Effects of Dynamic Binding between Tau Proteins on Microtubules during Axonal Injury** SB³C2016-111
Hossein Ahmadzadeh[1], Douglas Smith[2], Vivek Shenoy[3], *[1]University of Pennsylvania, Philadelphia, PA, United States, [2]Penn Center for Brain Injury and Repair and Department of Neurosurgery, University of Pennsylvania, Philadelphia, PA, United States, [3]Department of Materials Science and Engineering, University of Pennsylvania, Philadelphia, PA, United States*

WEDNESDAY, JUNE 29	3:45pm - 5:15pm

Modeling and Mechanosensitivity — Wilson C

Session Chair: Clark Hung, *Columbia, NY, United States*
Session Co-Chair: Malisa Sarntinoranont, *University of Florida, FL, United States*

3:45PM **Age-Related Differences in Human Dermal Fibroblast Mechanosensitivity to Hyaluronic Acid Dermal Filler** SB³C2016-877
Aribet M. De Jesus[1], Sathivel Chinnathambi[1], Mariam El-Hattab[1], Douglas K. Henstrom[2], Edward A. Sander[1], *[1]Department of Biomedical Engineering, University of Iowa, Iowa City, IA, United States, [2]Department of Otolaryngology - Head and Neck Surgery, University of Iowa, Iowa City, IA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

4:00PM **A Comparison of Phenomenological and Thermodynamically Consistent Approaches to the Modelling of Cells Subjected to Dynamic Loading** SB³C2016-1113
Patrick McGarry[1], Vikram S. Deshpande[2], *[1]National University of Ireland Galway, Galway, Ireland, [2]University of Cambridge, Cambridge, United Kingdom*

4:15PM **Modeling the Gas Foaming Process for Expanding Electrospun Nano iber Membranes in the Third Dimension** SB³C2016-707
Zhuoran Li[1], Jingwei Xie[2], **Linxia Gu**[1], *[1]Dept. of Mechanical & Materials Engineering, University of Nebraska-Lincoln, lincoln, NE, United States, [2]Department of Surgery-Transplant and Holland Regenerative Medicine Program, University of Nebraska Medical Center, Omaha, NE, United States*

4:30PM **A Model for Biological Fibers Derived From Implicit Elasticity** SB³C2016-48
Alan D. Freed, *Mechanical Engineering, Texas A&M University, College Station, TX, United States*

4:45PM **Chemically Conjugated Growth Factors on Electrospun Biomimetic Scaffolds Enhance Cell Adhesion and Proliferation** SB³C2016-31
Hannah M. Pauly[1], Ketul C. Popat[1, 2], Nicholas J. Dunne[3, 4], Daniel J. Kelly[5], Tammy L. Haut Donahue[1, 2], *[1]School of Biomedical Engineering, Colorado State University, Fort Collins, CO, United States, [2]Mechanical Engineering, Colorado State University, Fort Collins, CO, United States, [3]School of Mechanical and Aerospace Engineering, Queens University of Belfast, Belfast, United Kingdom, [4]School of Mechanical and Manufacturing Engineering, Dublin City University, Dublin, Ireland, [5]Trinity Centre for Bioengineering, Trinity College, Dublin, Ireland*

5:00PM **Finite Element Modeling of Cell pH and Ca^{2+} Regulations for Chondrocytes with Mixture Theory** SB³C2016-854
Chieh (Jay) Hou[1], Eben G. Estell[2], Clark T. Hung[2], Gerard A. Ateshian[1], *[1]Mechanical Engineering, Columbia University, New York, NY, United States, [2]Biomedical Engineering, Columbia University, New York, NY, United States*

WEDNESDAY, JUNE 29 | 3:45pm - 5:15pm

Musculo-skeletal Soft Tissue Mechanics — Wilson D

Session Chair: Richard Debski, *University of Pittsburgh, PA, United States*
Session Co-Chair: Suzanne Maher, *Hospital for Special Surgery, NY, United States*

3:45PM **Block Co-Polymer Based Hydrogels for Meniscal Replacement** SB³C2016-36
Kristine M. Fischenich[1], Jackson T. Lewis[1], Travis S. Bailey[1, 2], Tammy L. Haut Donahue[1, 3], *[1]School of Biomedical Engineering, Colorado State University, Fort Collins, CO, United States, [2]Chemical and Biological Engineering, Colorado State University, Fort Collins, CO, United States, [3]Department of Mechanical Engineering, Colorado State University, Fort Collins, CO, United States*

4:00PM **Effects of Mechanical Load on Scaffold-Cartilage Integration: A Computationally Augmented Biological Model** SB³C2016-914
Supansa Yodmuang[1], Hongqiang Guo[1], Tony Chen[1], Caroline Brial[1], Peter A. Torzilli[2], Russell Warren[2], Suzanne Maher[1], *[1]Biomechanics, Hospital for Special Surgery, New York, NY, United States, [2]Tissue Engineering, Regeneration and Repair Program, Hospital for Special Surgery, New York, NY, United States*

4:15PM **Skeletal Muscle Permeability: Direct Experimental Evaluation and Modeling Implications** SB³C2016-103
Benjamin B. Wheatley[1], Gregory M. Odegard[2], Kenton R. Kaufman[3], **Tammy L. Haut Donahue**[1], *[1]Mechanical Engineering, Colorado State University, Fort Collins, CO, United States, [2]Mechanical Engineering-Engineering Mechanics, Michigan Technological University, Fort Collins, CO, United States, [3]Department of Orthopaedic Surgery, Mayo Clinic, Rochester, MN, United States*

4:30PM **Investigating Deep Pressure Induced Deep Tissue Injury Using MRI and 3D Finite Element Analaysis** SB³C2016-122
Willeke A. Traa[1], Mark C. van Turnhout[1], Jules L. Nelissen[1], Gustav J. Strijkers[2], Klaas Nicolay[1], Dan L. Bader[3], Cees W. J. Oomens[1], *[1]Department of Biomedical Engineering, University of Technology Eindhoven, Eindhoven, Netherlands, [2]Department of Biomedical Engineering and Physics, Amsterdam Medical Centre, Amsterdam, Netherlands, [3]Department of Health Sciences, University of Southampton, Southampton, United Kingdom*

4:45PM **Effects of Meniscal Transplantation on Knee Joint Contact Mechanics and PostOperative Articular Cartilage Imaging** SB³C2016-815
Hongsheng Wang, Matthew Koff, Hollis Potter, Scott Rodeo, **Suzanne A. Maher**, *Hospital for Special Surgery, New York City, NY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

5:00PM **Site- and Force-dependent Strain Behavior in the Porcine Anterior Cruciate Ligament** SB³C2016-1040
Satoshi Yamakawa[1], Richard E. Debski[2], Hiromichi Fujie[1], *[1]Tokyo Metropolitan University, Hino, Japan, [2]University of Pittsburgh, Pittsburgh, PA, United States*

WEDNESDAY, JUNE 29 | 3:45pm - 5:15pm

Extracelluar Matrix Mechanics in Aneurysms — Annapolis 1

Session Chair: Ken Monson, *University of Utah, UT, United States*
Session Co-Chair: Shamik Bhattacharya, *St.Mary's University, TX, United States*

3:45PM **A Comparative Study of the Mechanical Response and Fiber Structure in an Elastase Induced Aneurysm Model in Rabbits and Human Cerebral Aneurysms** SB³C2016-1112
Chao Sang[1], Xinjie Duan[1], David F. Kallmes[2], Ram Kadirvel[2], Yonghong Ding[2], Daying Dai[2], Khaled M. Aziz[3], Juan R. Cebral[4], Anne M. Robertson[1], *[1]Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA, United States, [2]Department of Radiology, Mayo Clinic, Rochester, MN, United States, [3]Department of Neurosurgery, Allegheny General Hospital, Pittsburgh, PA, United States, [4]Department of Bioengineering, George Mason University, Fairfax, VA, United States*

4:00PM **A Structural Finite Element Model for Lamellar Unit of Aortic Media Indicates Heterogeneous Stress Field After Collagen Recruitment** SB³C2016-676
James R. Thunes, Joseph Pichamuthu, Julie A. Phillippi, Thomas G. Gleason, David A. Vorp, Spandan Maiti, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

4:15PM **Development and Evaluation of an Image Analysis Approach for the Study of Recurrence in Coil Embolized Cerebral Aneurysms** SB³C2016-166
Anna Schumacher[1], Luca Antiga[2], Tatiana Correa[1], David Hasan[3], Madhavan Raghavan[1], *[1]Biomedical Engineering, University of Iowa, Iowa City, IA, United States, [2]Orobix Srl, Bergamo, Italy, [3]Neurosurgery, University of Iowa, Iowa City, IA, United States*

4:30PM **Effect of Penta-galloyl Glucose on Murine AAA: Material Parameter Optimization and Finite Element Implementation** SB³C2016-791
Mirunalini Thirugnanasambandam[1], Dan Simionescu[2], Eugene Sprague[3], Beth Goins[4], Geoffrey D. Clarke[4], Hai-Chao Han[5], Krysta Amezcua[1], Oluwaseun R. Adeyinka[1], Ender Finol[1], *[1]Department of Biomedical Engineering, University of Texas at San Antonio, San Antonio, TX, United States, [2]Department of Bioengineering, Clemson University, Clemson, SC, United States, [3]Department of Medicine, University of Texas Health Science Center at San Antonio, San Antonio, TX, United States, [4]Department of Radiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, United States, [5]Department of Mechanical Engineering, University of Texas at San Antonio, San Antonio, TX, United States*

4:45PM **Mechanical Behavior and Genetic Signaling in Aortic Aneurysms in Newborn Lysyl Oxidase Knockout Mice** SB³C2016-728
Marius C. Staiculescu[1], Robert Mecham[2], Jessica Wagenseil[1], *[1]Mechanical Engineering and Materials Science, Washington University, St. Louis, MO, United States, [2]Cell Biology, Washington University, St. Louis, MO, United States*

5:00PM **In Vitro Rupture Patterns of Ascending Thoracic Aortic Aneurysms** SB³C2016-607
Jia Lu[1], Yuanming Lu[1], Ambroise Duprey[2], Stéphane Avril[2], *[1]Mechanical and Industrial Engineering, The University of Iowa, Iowa City, IA, United States, [2]Ecole Nationale Suprieure des Mines, St. Étienne, France*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

WEDNESDAY, JUNE 29	3:45pm - 5:15pm

Atherosclerosis — Annapolis 2

Session Chair: Frank Gijsen, *Erasmus University Rotterdam, Netherlands*
Session Co-Chair: David Vorp, *University of Pittsburgh, PA, United States*

3:45PM **Assessment of Analysis Methods to Evaluate the Association Between Wall Shear Stress and Coronary Artery Disease in the Clinical Setting** SB³C2016-1036
Lucas H. Timmins[1,2], David S. Molony[1,3], Parham Eshtehardi[3], Michael C. McDaniel[3], John N. Oshinski[1,2], Habib Samady[3], Don P. Giddens[1], *[1]Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Radiology and Imaging Sciences, Emory University School of Medicine, Atlanta, GA, United States, [3]Medicine (Cardiology), Emory University School of Medicine, Atlanta, GA, United States*

4:00PM **Impact of Bi-Axial Shear on Atherogenic Gene Expression by Endothelial Cells** SB³C2016-87
Amlan Chakraborty[1], Sutirtha Chakraborty[2], Venkatakrishna R. Jala[2], Jonathan Thomas[2], **M. Keith Sharp**[2], R Eric Berson[2], Haribabu Bodduluri[2], *[1]Entegris, Inc, Franklin, MA, United States, [2]University of Louisville, Louisville, KY, United States*

4:15PM **Cap Inflammation Leads to Large Plaque Cap Stress Decrease and Strain Increase: MRI-PET/CT-Based FSI Modeling** SB³C2016-28
Dalin Tang[1,2], Chun Yang[1,3], Sarayu Huang[4], Venkatesh Mani[4], Zahi A. Fayad[4], *[1]WPI, Worcester, MA, United States, [2]Southeast University, Nanjing, China, [3]China Information Tech. Designing & Consulting Institute Co., Ltd., Beijing, China, [4]Translational and molecular imaging institute, New York, NY, United States*

4:30PM **MRI based Cap Thickness and Peak Cap Stress Prediction: Man Versus Machine** SB³C2016-782
Annette M. Kok[1], Aad van der Lugt[2], Antonius F. W. van der Steen[1], Jolanda J. Wentzel[1], Frank J. H. Gijsen[1], *[1]Biomedical Engineering, Erasmus MC, Rotterdam, Netherlands, [2]Radiology, Erasmus MC, Rotterdam, Netherlands*

4:45PM **The Relation Between Shear Stress Metrics and Atherosclerosis: a Follow-up Study in the Carotid Arteries of Atherosclerotic Mice** SB³C2016-39
David De Wilde[1], Bram Trachet[1,2], Guido R. Y. De Meyer[3], **Patrick Segers**[1], *[1]Ghent University, Ghent, Belgium, [2]Institute for Bioengineering, EPFL, Lausanne, Switzerland, [3]Division of Physiopharmacology, University of Antwerp, Antwerp, Belgium*

5:00PM **Effect of Stent Oversizing on In-stent Restenosis in the Second Part of the Popliteal Artery** SB³C2016-1132
Azadeh Lotfi[1], Tracie Barber[1], Anne Simmons[1], Ramon Varcoe[2], *[1]Mechanical and manufacturing Engineering, University of new South Wales, Sydney, Australia, [2]Department of Surgery, Prince of Wales Hospital, Sydney, Australia*

WEDNESDAY, JUNE 29	3:45pm - 5:15pm

Musculoskeletal System and Design — Azalea 2

Session Chair: Michele Grimm, *Wayne State, MI, United States*
Session Co-Chair: Brett Steineman, *Colorado State University, CO, United States*

3:45PM **Elucidating Mechanisms of Tendon Damage by Measuring Multiscale Unloaded Recovery following Tensile Loading** SB³C2016-800
Andrea H. Lee[1], Spencer E. Szczesny[2], Kristen L. Fetchko[1], Michael H. Santare[3], Dawn M. Elliott[1], *[1]Department of Biomedical Engineering, University of Delaware, Newark, DE, United States, [2]Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, United States, [3]Department of Mechanical Engineering, University of Delaware, Newark, DE, United States*

4:00PM **The Use of Individual Motion Units to Analyze In Vivo Total Thoracolumbar Motion in Healthy Older Adults** SB³C2016-717
Eileen S. Cadel[1], Sarah N. Galvis[1], William M. Eboch[2], Paul M. Arnold[3], Sara E. Wilson[2], Elizabeth A. Friis[2], *[1]Bioengineering Graduate Program, University of Kansas, Lawrence, KS, United States, [2]Mechanical Engineering, University of Kansas, Lawrence, KS, United States, [3]Department of Neurology, University of Kansas Medical Center, Kansas City, KS, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

4:15PM **Novel Instrumented Mouthguard Designs to Accurately Measure Head Kinematics for Traumatic Brain Injury** SB³C2016-696
Calvin Kuo[1], Lyndia C. Wu[2], David B. Camarillo[1, 2], *[1]Mechanical Engineering, Stanford University, Stanford, CA, United States, [2]Bioengineering, Stanford University, Stanford, CA, United States*

4:30PM **Effective Stiffnesses for the Human Buttocks and Thigh Regions Obtained Through in vivo Methods: Applications to Medical Seating** SB³C2016-124
Wu Pan, Zac Sadler, Lindsay Nault, Tamara Reid Bush, *Mechanical Engineering, Michigan State University, East Lansing, MI, United States*

4:45PM **Fatigue Testing of a Composite Meniscus Implant - What are the Limits?** SB³C2016-669
Jonathan J. Elsner[1], Maoz Shemesh[2], Adaya Shefy-Peleg[2], Eyal Zylberberg[2], Zahava Barkai[3], Eran Linder-Ganz[2], *[1]Research and Development, Active Implants, Cambridge, MA, United States, [2]Research and Development, Active Implants, Netanya, Israel, [3]Wolfson Applied Materials Research Center, Tel-Aviv University, Tel-Aviv, Israel*

5:00PM **Footwear Affects Muscle Activity during Ramp Walking** SB³C2016-685
Feng Wei, Andrew J. Crechiolo, Roger C. Haut, *Orthopaedic Biomechanics Laboratories, Michigan State University, East Lansing, MI, United States*

WEDNESDAY, JUNE 29 | 3:45pm - 5:15pm

Thermal Treatment and Hyperthermia — Azalea 3

Session Chair: Aili Zhang, *Shanghai Jiao Tong University, China*
Session Co-Chair: Zhenpeng Qin, *University of Texas at Dallas, TX, United States*

3:45PM **Development of a 3-D Whole Body Heat Transfer Model for Accurately Predicting Time of Death in Forensic Science** SB³C2016-149
Catherine Bartgis, Alexander LeBrun, Amirreza Saharkhiz, Ronghui Ma, **Liang Zhu**, *Mechanical Engineering, University of Maryland Baltimore County, Baltimore, MD, United States*

4:00PM **A Counterexample of Entropy-Enthalpy Compensation in Collagen Denaturation** SB³C2016-900
Neil T. Wright, *Mechanical Engineering, Michigan State University, East Lansing, MI, United States*

4:15PM **Contribution of Ultrasound Absorption in Nanoparticles for Hyperthermia Application** SB³C2016-765
Vishal Kumar[1], Surendra Devarakonda[2], Rupak K Banerjee[2], Ashok K Ganguli[1, 3], **Chandan Bera**[1], *[1]Institute of Nano Science and Technology, Mohali, India, [2]Mechanical and Materials Engineering Department, University of Cincinnati, Cincinnati, OH, United States, [3]Department of Chemistry, Indian Institute of Technology, Delhi, New Delhi, India*

4:30PM **Dynamic Bubble Formation in ADV Assisted HIFU with Preexisting Bubble Wall** SB³C2016-767
Ying Xin[1], **Aili Zhang**[1], Lisa X. Xu[1], Jeffery B. Fowlkes[2], *[1]Shanghai Jiao Tong University, Shanghai, China, [2]University of Michigan, Ann Arbor, MI, United States*

4:45PM **In Vitro and In Vivo Model for Assessing Irreversible Electroporation on Pancreatic Cancer** SB³C2016-770
Qi Shao[1], Connie Chung[1], Feng Liu[1], Kianna Elahi[2], Paolo Provenzano[2], Bruce Forsyth[3], John C. Bischof[1], *[1]Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States, [3]Boston Scientific, Marlborough, MA, United States*

5:00PM **Nanosecond Protein Thermal Inactivation by Plasmonic Nanoparticle Laser Heating** SB³C2016-745
Peiyuan Kang, **Zhenpeng Qin**, *Mechanical Engineering, University of Texas at Dallas, Richardson, TX, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	8:00am - 9:30am

Engineering Translation: Disease Models and Outcomes — Wilson B

Session Chair: Sharan Ramaswamy, *Florida International University, FL, United States*
Session Co-Chair: Ozan Akkus, *Case Western Reserve University, OH, United States*

8:00AM **3D in vitro Platform to Isolate Dormancy Capable Cancer Cells** SB³C2016-740
Julian A. Preciado, Eduardo Retagui, Molly Lefebvre, Samira Azarin, Emil Lou, Alptekin Aksan, *Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States*

8:15AM **Biomechanical Regulation of Angiogenesis by Cancer-Associated Fibroblasts** SB³C2016-97
M.K. Sewell-Loftin[1], Elizabeth L. Crist[1], B. Taylor Hughes[1], Samantha van Hove[2], Gregory D. Longmore[2, 3], Steven C. George[1], *[1]Department of Biomedical Engineering, Washington University in St. Louis, St. Louis, MO, United States, [2]Department of Cell Biology and Physiology, Washington University in St. Louis, St. Louis, MO, United States, [3]Department of Medicine, Oncology Division, Washington University in St. Louis, St. Louis, MO, United States*

8:30AM **Chondro-protective Effect of Zoledronate on In Situ Chondrocytes Damaged by Interleukin-1** SB³C2016-999
Mengxi Lv, Yilu Zhou, Shongshan Fan, Olivia Smith, Liyun Wang, X.Lucas Lu, *University of Delaware, Newark, DE, United States*

8:45AM **Photoclickable Peptide Microarrays for High Throughput Screening and Discovery in Regenerative Medicine and Disease Models** SB³C2016-1098
Michael L. Floren, *Department of Mechanical Engineering, University of Colorado Boulder, Boulder, CO, United States*

9:00AM **Characterization of Glioblastoma Growth Using Five Different Mathematical Models** SB³C2016-986
Mitra Shabanisamghabady, Martin L. Tanaka, *Engineering and Technology, Western Carolina University, Cullowhee, NC, United States*

9:15AM **Application of a Novel Biomechanical Fiber Model to Tissue Engineering for Improved Clinical Outcomes** SB³C2016-1055
Andrew B. Robbins[1], Silvia Minardi[2], Ennio Tasciotti[2], Alan D. Freed[3], Michael R. Moreno[3], *[1]Biomedical Engineering, Texas A&M University, College Station, TX, United States, [2]Methodist Research Hospital, Houston, TX, United States, [3]Mechanical Engineering, Texas A&M University, College Station, TX, United States*

THURSDAY, JUNE 30	8:00am - 9:30am

Design and Optimization of Cardiovascular Devices — Wilson C

Session Chair: Alan D. Freed, *Texas A&M University, TX, United States*
Session Co-Chair: Michael Moreno, *Texas A&M, TX, United States*

8:00AM **A Computational Framework for Optimization of Transcatheter Aortic Valve Leaflets** SB³C2016-993
Kyle E. Murdock[1], Kewei Li[2], Caitlin Martin[1], Wei Sun[1], *[1]Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Biomedical Engineering, Graz University of Technology, Graz, Austria*

8:15AM **A Computational Investigation of the Positioning of Transcatheter Aortic Heart Valves to Enhance Long Term Performance** SB³C2016-773
Orla M. McGee, Paul S. Gunning, Laoise M. McNamara, *Biomedical Engineering, NUIGalway, Galway, Ireland*

8:30AM **Computational Modeling of Optimization of Drug-Eluting Stents Under Multiple Mechanical Criteria** SB³C2016-882
Francois P. M. Cornat, Franz Bozsak, Abdul I. Barakat, *Laboratoire d'hydrodynamique LadHyX, Ecole Polytechnique, Palaiseau cedex, France*

8:45AM **Development and Evaluation of an Arborizing Catheter for Convection Enhanced Delivery** SB³C2016-849
Egleide Y. Elenes[1], Christopher G. Rylander[2], *[1]Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States, [2]Mechanical Engineering, The University of Texas at Austin, Austin, TX, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

9:00AM **A Virtual Coiling Algorithm to Simulate Endovascular Coil Deployment in Cerebral Aneurysm using Spring Based Geometric Constraint Model** SB³C2016-716
Rahul Sanal[1], Robert J. Damiano[1], Adnan H. Siddiqui[2], Jinhui Xu[3], Hui Meng[1], *[1]Department of Mechanical and Aerospace Engineering, State University of New York at Buffalo, Buffalo, NY, United States, [2]Department of Neurosurgery, State University of New York at Buffalo, Buffalo, NY, United States, [3]Department of Computer Science and Engineering, State University of New York at Buffalo, Buffalo, NY, United States*

9:15AM **Visco-Hyperelastic Modeling of the Penn State Pulsatile Pneumatic Pediatric VAD Membrane** SB³C2016-884
Bryan Good, Keefe Manning, *Bioengineering, The Pennsylvania State University, University Park, PA, United States*

THURSDAY, JUNE 30 | 8:00am - 9:30am

Injury: Brain I — Wilson D

Session Chair: Songbai Ji, *Dartmouth College, NH, United States*
Session Co-Chair: Reuben H. Kraft, *The Pennsylvania State University, PA, United States*

8:00AM **Modal Analysis of Human Brain Dynamics in Contact Sports** SB³C2016-1023
Mehmet Kurt, Kaveh Laksari, David B. Camarillo, *Bioengineering, Stanford University, Stanford, CA, United States*

8:15AM **Characterization of White Matter Using Asymmetric Indentation and Inverse Modeling in Large Strain** SB³C2016-53
Yuan Feng[1], Chung-Hao Lee[2], Lining Sun[1], Shengjun Fu[1], *[1]Mechanical and Electronic Engineering, Soochow University, Suzhou, China, [2]ICES, The University of Texas at Austin, Austin, TX, United States*

8:30AM **White Matter Injury Susceptibility Using Whole-brain Tractography: Concept Illustration** SB³C2016-69
Wei Zhao[1], James C. Ford[2], Thomas W. McAllister[3], Songbai Ji[1, 4], *[1]Thayer School of Engineering, Dartmouth College, Hanover, NH, United States, [2]Department of Psychiatry, Geisel School of Medicine, Dartmouth College, Hanover, NH, United States, [3]Department of Psychiatry, Indiana University School of Medicine, Indiana University, Indianapolis, IN, United States, [4]Department of Surgery and of Orthopaedic Surgery, Dartmouth College, Hanover, NH, United States*

8:45AM **A Bayesian Approach to Model Selection and Surrogate Modeling: Application to Traumatic Brain Injury Simulations** SB³C2016-1039
Sandeep Madireddy, **Kumar Vemaganti**, *Mechanical & Materials Engineering, University of Cincinnati, Cincinnati, OH, United States*

9:00AM **Subconcussive Head Impact Exposure for Concussed and Non-Concussed Division III College Football Athletes** SB³C2016-708
Alok S. Shah[1, 2], Brian D. Stemper[1, 2], James K. Murtha[1], Rachel A. Chiariello[1, 2], John R. Humm[1, 2], Ashley LaRoche[1], Michael McCrea[1, 2], *[1]Department of Neurosurgery, Medical College of Wisconsin, Milwaukee, WI, United States, [2]Neuroscience Research Center, Veterans Affairs Medical Center, Milwaukee, WI, United States*

9:15AM **Heterogeneity of Viscoelastic Behavior of Rat Brain** SB³C2016-1043
Soroush Assari, Golriz Kermani, Ali Hemmasizadeh, Mary F. Barbe, Kurosh Darvish, *Temple University, Philadelphia, PA, United States*

THURSDAY, JUNE 30 | 8:00am - 9:30am

ATH Plaque Imaging and Mechanics — Annapolis 1

Session Chair: Dalin Tang, *Worcester Polytechnic Institute, MA, United States*
Session Co-Chair: Lucas H. Timmins, *Georgia Institute of Technology, GA, United States*

8:00AM **A CT Based Model of the Fracture of Calcified Atherosclerotic Plaques** SB³C2016-1019
Brían L. O'Reilly, Patrick McGarry, Peter E. McHugh, *Biomedical Engineering, National University of Ireland, Galway, Ireland*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

8:15AM **Characterization of Fracture Behavior of Human Atherosclerotic Fibrous Caps Using a Miniature Single Edge Notched Tensile Test** SB³C2016-610

Lindsey A. Davis[1], Samantha E. Stewart[1], Christopher G. Carsten[2], Bruce A. Snyder[2], Michael A. Sutton[1], Susan M. Lessner[1], *[1]University of South Carolina, Columbia, SC, United States, [2]Greenville Health System, Greenville, SC, United States*

8:30AM **Deployment and Degradation of a Bioresorbable Stent: a Coupled Computational Model Between Stent and Artery** SB³C2016-777

Johanne Mensah-Gourmel[1], François Cornat[1], Antoine Lafont[2], Abdul I. Barakat[1], *[1]Hydrodynamics Laboratory - Ecole Polytechnique, Palaiseau, France, [2]Georges Pompidou European Hospital - Cardiology department - APHP - Paris Descartes University, Paris, France*

8:45AM **Imaging and Quantifying the 3D Collagen Architecture in Atherosclerotic Plaques** SB³C2016-940

Ali C. Akyildiz[1], Lambert Speelman[1], Chen-Ket Chai[2], Cees Oomens[2], Gustav Strijkers[3], Frank Gijsen[1], *[1]Biomedical Engineering Department, Erasmus MC, Rotterdam, Netherlands, [2]Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands, [3]Department of Biomedical Engineering & Physics, University of Amsterdam, Amsterdam, Netherlands*

9:00AM **Loss of Elastic Fiber Integrity Due to Fibulin-5 Deficiency Alters Aortic Elasticity, Central Hemodynamics, and Cardiac Function** SB³C2016-167

Jacopo Ferruzzi[1, 2], Paolo Di Achille[2], Pradyumn Agarwal[3], Federica Cuomo[3], C. Alberto Figueroa[3], Jay D. Humphrey[2, 4], *[1]Boston University, Boston, MA, United States, [2]Department of Biomedical Engineering, Yale University, New Haven, CT, United States, [3]Department of Biomedical Engineering, University of Michigan, Ann Arbor, MI, United States, [4]Vascular Biology & Therapeutics Program, Yale School of Medicine, New Haven, CT, United States*

9:15AM **Effects of Opening Angle, Axial Stretch and Circumferential Shrinkage on Blood Vessel Stress and Strain Calculations** SB³C2016-581

Liang Wang[1], Jian Zhu[2], Akiko Maehara[3], Jie Zheng[4], Chun Yang[1, 5], David Muccigrosso[4], Gary S. Mintz[3], Dalin Tang[1, 6], *[1]Mathematical Department, Worcester Polytechnic Institute, Worcester, MA, United States, [2]Department of Cardiology, Zhongda Hosiptial, Southeast University, Nanjing, China, [3]The Cardiovascular Research Foundation, Columbia University, New York, NY, United States, [4]Mallinckrodt Institute of Radiology, Washington University, St. Louis, MO, United States, [5]Network Technology Research Institute, China United Network Comm. Co., Ltd., Beijing, China, [6]Department of Mathemtics, Southeast University, Nanjing, China*

THURSDAY, JUNE 30 | 8:00am - 9:30am

Aneurysm Biomechanics — Annapolis 2

Session Chair: Ender A. Finol, *University of Texas at San Antonio, TX, United States*
Session Co-Chair: Jessica Shang, *University of Rochester, NY, United States*

8:00AM **Prediction of Abdominal Aortic Aneurysm shape evolution using Gaussian Process Implicit Surfaces** SB³C2016-56

Huan N. Do[1], Jongeun Choi[1, 2], Seungik Baek[1], *[1]Mechanical Engineering, Michigan State University, East Lansing, MI, United States, [2]Department of Electrical and Computer Engineering, Michigan State University, East Lansing, MI, United States*

8:15AM **A New Approach for Abdominal Aortic Aneurysm Local Growth Quantification** SB³C2016-783

Eleni Metaxa[1], Iordan Iordanov[1], Emmanuel Maravelakis[2], **Yannis Papaharilaou**[1], *[1]Institute for Applied and Computational Mathematics, Foundation for Research and Technology - Hellas, Heraklion, Greece, [2](2)Department of Environmental and Natural Resources Engineering, Technological Educational Institute of Crete, Chania, Greece*

8:30AM **Novel Growth and Remodeling Mechanisms May Explain the Unique Expansion Patterns and Evolving Mechanical Behavior of Abdominal Aortic Aneurysms** SB³C2016-1052

John S. Wilson[1], Christian Cyron[2], Jay D. Humphrey[3], *[1]Radiology, Emory University, Atlanta, GA, United States, [2]Mechanical Engineering, Technical University of Munich, Garching, Germany, [3]Biomedical Engineering, Yale University, New Haven, CT, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

8:45AM **Intrasaccular Hemodynamics, Wall Inflammation and Degenerative Changes of Cerebral Aneurysm Wall** SB³C2016-132

Juan Cebral[1], Eliisa Ollikainen[2], BongJae Chung[1], Fernando Mut[1], Visa Sippola[2], Behdam Jahromi[2], Riikka Tulamo[2], Juha Hernesniemi[2], Mika Niemela[2], Anne Robertson[3], Juhana Frosen[2, 4], *[1]Bioengineering, George Mason University, Fairfax, VA, United States, [2]Neurosurgery, Biomedicum & Helsinki University Hospital, Helsinki, Finland, [3]Mechanical and Material Science & Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States, [4]Neurocenter, Kuopio University Hospital, Kuopio, Finland*

9:00AM **Fluid-structure Interaction of a Ruptured Intracranial Aneurysm: Does Patient-specific Wall Thickness Matter?** SB³C2016-35

Philipp Berg[1], Samuel Voß[1], Sylvia Glaßer[2], Thomas Hoffmann[3], Simon Weigand[3], Gábor Janiga[1], *[1]Department of Fluid Dynamics and Technical Flows, University of Magdeburg, Magdeburg, Germany, [2]Department of Simulation and Graphics, University of Magdeburg, Magdeburg, Germany, [3]Department of Neuroradiology, University Hospital Magdeburg, Magdeburg, Germany*

9:15AM **Intra Aneurysmal Angiographic Analysis in Patients Towards Determination of Flow Diversion Efficacy** SB³C2016-1138

Ronak J. Dholakia, Chander Sadasivan, David J. Fiorella, Henry H. Woo, Baruch B. Lieber, *Neurological Surgery, Stony Brook University, Stony Brook, NY, United States*

THURSDAY, JUNE 30 | 8:00am - 9:30am

Computational Mechanics and Simulations — Azalea 2

Session Chair: Jonathan Vande Geest, *University of Pittsburgh, PA, United States*
Session Co-Chair: Andrew Feola, *Georgia Institute of Technology, A, United States*

8:00AM **Study of Two Arterial Wall Delamination Experiments** SB³C2016-635

Xiaochang Leng[1], Boran Zhou[2], Xiaomin Deng[1], Lindsey Davis[2, 3], Susan Lessner[2, 3], Michael Sutton[1, 2], Tarek Shazly[1, 2], *[1]Department of Mechanical Engineering, University of South Carolina, Columbia, SC, United States, [2]Biomedical Engineering Program, University of South Carolina, Columbia, SC, United States, [3]Department of Cell Biology & Anatomy, University of South Carolina, Columbia, SC, United States*

8:15AM **Individual-Specific Finite Element Model of the Rat Optic Nerve Head Under Elevated Intraocular Pressure Conditions** SB³C2016-107

Stephen A. Schwaner[1], Marta Pazos[2, 3], Hongli Yang[3], Elaine C. Johnson[4], John C. Morrison[4], Claude F. Burgoyne[3], C. Ross Ethier[1, 5], *[1]George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Ophthalmology Department, Hospital de l'Esperanca-Parc de Salut Mar. Institute Mar d'Investigacions Mediques, Barcelona, Spain, [3]Devers Eye Institute, Optic Nerve Head Research Laboratory, Portland, OR, United States, [4]Casey Eye Institute, Oregon Health and Science University, Portland, OR, United States, [5]Coulter Department of Biomedical Engineering, Georgia Institute of Technology/Emory University, Atlanta, GA, United States*

8:30AM **Lamina Cribrosa Disinsertions as a Mechanoprotective Strategy** SB³C2016-786

Andrew P. Voorhees[1], Ning-Jiun Jan[1, 2], John G. Flanagan[3], Jeremy M. Sivak[4], Ian A. Sigal[1, 2], *[1]Ophthalmology, University of Pittsburgh, Pittsburgh, PA, United States, [2]Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States, [3]Optometry and Vision Science, University of California Berkeley, Berkeley, CA, United States, [4]Ophthalmology and Vision Sciences, University of Toronto, Toronto, ON, Canada*

8:45AM **Magnetic Resonance Elastography of White Matter Brain Tissue Ex Vivo** SB³C2016-687

John L. Schmidt[1], Dennis J. Tweten[1], Andrew A. Badachhape[2], Ruth J. Okamoto[1], Joel R. Garbow[3], Philip V. Bayly[1, 2], *[1]Mechanical Engineering and Materials Science, Washington University, St. Louis, MO, United States, [2]Biomedical Engineering, Washington University, St. Louis, MO, United States, [3]Radiology, Washington University, St. Louis, MO, United States*

9:00AM **Numerical Constraint for Tracking Tagged Magnetic Resonance Images in Biomechanical Simulations** SB³C2016-1002

Arnold David Gomez[1], Deva Chan[2], Yuan-Chiao Lu[2], Dzung Pham[2], Philip Bayly[3], Jerry Prince[1], *[1]Electrical and Computer Engineering Department, Johns Hopkins University, Baltimore, MD, United States, [2]Center for Neuroscience and Regenerative Medicine, Henry Jackson Foundation, Bethesda, MD, United States, [3]Mechanical Engineering Department, Washington University in St. Louis, St. Louis, MO, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

9:15AM **A Parameterized Ultrasound-Based Finite Element Analysis of the Mechanical Environment of Pregnancy** SB³C2016-927

Andrea R. Westervelt[1], Michael Fernandez[1], Joy Vink[2], Chia-Ling Nhan-Chang[2], Miaoying Fan[2], Ronald J. Wapner[2], Michael House[3], Kristin M. Myers[1], *[1]Mechanical Engineering, Columbia University, New York, NY, United States, [2]Obstetrics and Gynecology Division of Maternal Fetal Medicine, Columbia University, New York, NY, United States, [3]Obstetrics and Gynecology Division of Maternal Fetal Medicine, Tufts Medical Center, Boston, MA, United States*

THURSDAY, JUNE 30 | 8:00am - 9:30am

Imaging and Modeling Physiological Microflows; Lymphatics, CSF, and Eyes — Azalea 3

Session Chair: James Moore, *Imperial College London, London, United Kingdom*
Session Co-Chair: Ryan Pedrigi, *University of Nebraska, NE, United States*

8:00AM **Contractile Activity in Branched Lymphatic Vessels** SB³C2016-1000

Samira Jamalian[1], Michael J. Davis[2], James E. Moore[1], *[1]Bioengineering, Imperial College London, London, United Kingdom, [2]University of Missouri School of Medicine, Columbia, MO, United States*

8:15AM **Investigation of the Pressure-length Relationship along a Lymphatic Chain with Modeling and Experiments** SB³C2016-828

Mohammad S. Razavi[1], Tyler S. Nelson[1], Rudolph L. Gleason[1, 2], **J. Brandon Dixon**[1, 2], *[1]Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Biomedical Engineering, Georgia Tech and Emory University, Atlanta, GA, United States*

8:30AM **Assessment of 4D Flow Accuracy for Quantification of Cerebrospinal Fluid Dynamics in the Cervical Spine: Comparison of in vitro Measurements and Numerical Simulation** SB³C2016-789

Soroush Heidari Pahlavian[1], Francis Loth[1], Suraj Thyagaraj[1], Alexander Bunck[2], Daniel Giese[2], Bryn Martin[3], *[1]Department of Mechanical Engineering, The University of Akron, Akron, OH, United States, [2]Department of Radiology, University Hospital of Cologne, Cologne, Germany, [3]Department of Biological Engineering, The University of Idaho, Moscow, ID, United States*

8:45AM **Quantifying Cerebrospinal Fluid Dynamics Using Real-Time Phase Contrast MRI** SB³C2016-51

Selda Yildiz[1], John Oshinski[2], Karim G. Sabra[1], *[1]Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Radiology & Imaging Sciences and Biomedical Engineering, Emory University, Atlanta, GA, United States*

9:00AM **Aqueous Humor Flow in the Posterior Chamber of the Eye with Iridotomy** SB³C2016-129

Mariia Dvoriashyna[1], Rodolfo Repetto[1], Jennifer H. Tweedy[2], *[1]Department of Civil, Chemical and Environmantal Engineering, University of Genoa, Genoa, Italy, [2]Department of Bioengineering, Imperial College London, London, United Kingdom*

9:15AM **Rheological Characterization of an Embryo Culture Liquid and Implications for Culture in Microfuidic Devices** SB³C2016-678

Irene Nepita[1], Alberto Lagazzo[1], Stefano Barone[2], Giovanni Besio[1], **Alessandro Stocchino**[1], Rodolfo Repetto[1], *[1]Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy, [2]Centro Procreazione Assistita, Ospedale della Versilia, Lido di Camaiore, Italy*

THURSDAY, JUNE 30 | 9:45am - 11:15am

Cardiovascular Cell and Tissue Engineering — Wilson B

Session Chair: Alisa Morss Clyne, *Drexel University, PA, United States*
Session Co-Chair: Pat Alford, *University of Minnesota, MN, United States*

9:45AM **Cardiac Contractility and Global Tissue Organization** SB³C2016-841

Meghan Knight, Nancy Drew, Linda McCarthy, **Anna Grosberg**, *UCIrvine, Irvine, CA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

10:00AM **Comparison of In Vitro Endothelial Wound Healing in Bare Metal vs. Drug-Eluting Stents** SB³C2016-89
Elizabeth Antoine, Abdul Barakat, *Mechanics, Ecole Polytechnique, Palaiseau, France*

10:15AM **Direction-dependent Collagen Disruption in Overstretched Cerebral Arteries** SB³C2016-734
Matthew I. Converse[1], Justin T. Ingram[2], Raymond G. Walther[1], Kenneth L. Monson[3], *[1]Mechanical Engineering, University of Utah, Salt Lake City, UT, United States, [2]Bioengineering, University of Utah, Salt Lake City, UT, United States, [3]Mechanical Engineering; Bioengineering, University of Utah, Salt Lake City, UT, United States*

10:30AM **Shear Stress Maintains Endocardial Phenotype in Induced Pluripotent Stem Cell Derived Endocardial Cells** SB³C2016-758
Mark Vander Roest, Camryn Johnson, Scott Baldwin, W. David Merryman, *Vanderbilt University, Nashville, TN, United States*

10:45AM **TGF-Beta 1 and Adipose-derived Mesenchymal Stem Cell Secreted Factors Aid in the Organization of Deposited Elastin Within 3D Fibroblast and Smooth Muscle Cell Constructs** SB³C2016-1022
Aneesh Ramaswamy, Justin Weinbaum, David Vorp, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

11:00AM **Valve Interstitial Cell Contractile Strength and Metabolic State are Dependent on its Shape** SB³C2016-686
Ngoc Lam, Timothy Muldoon, Narasimhan Rajaram, **Kartik Balachandran**, *University of Arkansas, Fayetteville, AR, United States*

THURSDAY, JUNE 30	**9:45am - 11:15am**

Safety and Biocompatibility in Medical Device Design — Wilson C

Session Chair: Lucas H. Timmins, *Georgia Institute of Technology, GA, United States*
Session Co-Chair: Michael Moreno, *Texas A&M, TX, United States*

9:45AM **Bearing Surface Damage Analysis of Anatomical and Reverse Total Shoulder Replacements: Retrieval Analysis Across Fixation Designs and UHMWPE Compositions** SB³C2016-1131
Louis G. Malito[1], Noah Bonnheim[1], Lulu Li[1], Taylor Lee[1], Steven Gunther[2], Tom Norris[3], Mike Ries[4], Lisa Pruitt[1], *[1]Mechanical Engineering, University of California, Berkeley, Berkeley, CA, United States, [2]Orthopedic Surgery, Martha Jefferson Hospital, Charlottesville, VA, United States, [3]San Francisco Shoulder, Elbow & Hand Clinic, San Francisco, CA, United States, [4]Tahoe Fracture and Orthopaedic Clinic, Carson City, NV, United States*

10:00AM **Wear Testing of an Innovative Design for Hip Resurfacing** SB³C2016-568
John B. Everingham, Jillian L. Helms, Kevin J. Warburton, Jeff Brourman, Steven Fox, Trevor J. Lujan, *Mechanical and Biomedical Engineering, Boise State University, Boise, ID, United States*

10:15AM **Evaluation of Laser Bacterial Anti-Fouling of Transparent Nanocrystalline Yttria-Stabilized-Zirconia Cranial Implant** SB³C2016-976
David L. Halaney, Yasaman Damestani, Natalie De Howitt, Javier E. Garay, Guillermo Aguilar, *Mechanical Engineering, University of California, Riverside, Riverside, CA, United States*

10:30AM **Polydopamine Based Insulating Coating for Shape Memory Alloy Biomedical Devices** SB³C2016-589
Mohammad Sahlabadi, Yao Zhao, Harold H Lee, Fei Ren, **Parsaoran Hutapea**, *Temple University, Philadelphia, PA, United States*

10:45AM **Addressing Iatrogenic Injury due to Traumatic Urethral Catheterisation** SB³C2016-831
Eoghan M. Cunnane[1], Niall F. Francis[2], Connor V. Cunnane[1], Rory O'C Mooney[1], John A. Thornhill[2], Michael T. Walsh[1], *[1]Mechanical, Aeronautical and Biomedical Engineering, University of Limerick, Limerick, Ireland, [2]Department of Urology, Tallaght Hospital, Dublin, Ireland*

11:00AM **Investigating the In Vitro and In Vivo Biocompatibility of a Novel Biodegradable Fe-316L Stent** SB³C2016-147
Jennifer Frattolin[1, 2], Richard Leask[3], Stephen Yue[4], Olivier F. Bertrand[1, 5], Rosaire Mongrain[1, 2], *[1]Department of Mechanical Engineering, McGill University, Montreal, QC, Canada, [2]Montreal Heart Institute, Montreal, QC, Canada, [3]Department of Chemical Engineering, McGill University, Montreal, QC, Canada, [4]Department of Mining and Materials Engineering, McGill University, Montreal, QC, Canada, [5]Interventional Cardiology Laboratories, Quebec Heart and Lung Institute, Laval University, Quebec City, QC, Canada*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	9:45am - 11:15am

Injury: Brain II — Wilson D

Session Chair: Brittany Coats, *University of Utah, UT, United States*
Session Co-Chair: JiangYue Zhang, *Johns Hopkins, MD, United States*

9:45AM **In Situ Estimation of Axonal Injury Strain Thresholds Following Tissue-level Tensile Stretch** SB^{3}C2016-955
Sagar Singh[1], Assimina A. Pelegri[2], David I. Shreiber[1], *[1]Biomedical Engineering, Rutgers, The State University of New Jersey, Piscataway, NJ, United States, [2]Mechanical and Aerospace Engineering, Rutgers, The State University of New Jersey, Piscataway, NJ, United States*

10:00AM **Simulated Blast-Induced Cavitation: An Invitro Study** SB^{3}C2016-996
Saranya Canchi, Yu Hong, Karen Kelly, Michael A. King, Ghatu Subhash, Malisa Sarntinoranont, *University of Florida, Gainesville, FL, United States*

10:15AM **Bandwidth Requirements for Wearable Head Impact Sensors** SB^{3}C2016-602
Lyndia C. Wu, Kaveh Laksari, Calvin Kuo, David B. Camarillo, *Bioengineering, Stanford University, Stanford, CA, United States*

10:30AM **In-Situ Head Acceleration Measurements for Playground Impacts Relative to Head Injury Metrics** SB^{3}C2016-747
Eric A. Kennedy, Greg P. Danchik, Chris D. DiDomenico, *Biomedical Engineering, Bucknell University, Lewisburg, PA, United States*

10:45AM **Development of Finite Element-Based Injury Metrics for Head Injury Prediction** SB^{3}C2016-866
Derek A. Jones, Jillian E. Urban, Ashley A. Weaver, Joel D. Stitzel, *Biomedical Engineering, Wake Forest University School of Medicine, Winston-Salem, NC, United States*

11:00AM **Sex Differences in the Dynamic Brain Response to a Mild Angular Head Acceleration** SB^{3}C2016-743
Deva Chan[1], Andrew Knutsen[2], Yuan-Chiao Lu[1], Sarah Yang[1], Philip Bayly[3], John Butman[4], Dzung Pham[1], *[1]Center for Neuroscience and Regenerative Medicine, Henry M Jackson Foundation, Bethesda, MD, United States, [2]Institute for Defense Analyses, Alexandria, VA, United States, [3]Mechanical Engineering and Materials Science, Washington University of St. Louis, St. Louis, MO, United States, [4]Radiology and Imaging Sciences, National Institutes of Health Clinical Center, Bethesda, MD, United States*

THURSDAY, JUNE 30	9:45am - 11:15am

Mechanics of Heart Valves — Annapolis 1

Session Chair: Michael Sacks, *The University of Texas at Austin, TX, United States*
Session Chair: Lik Chuan Lee, *Michigan State University, MI, United States*

9:45AM **Age-Dependent Differences in Mechanical Properties of Chemically Treated Bovine Pericardium** SB^{3}C2016-1115
Andres D. Caballero, Fatiesa Sulejmani, Wei Sun, *The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, United States*

10:00AM **Effects of Sagging Versus Stretched Leaflets on Bioprosthetic Heart Valve Durability** SB^{3}C2016-620
Nandini Duraiswamy[1], Parinaz Fathi[2], Stephen M. Retta[1], Jason D. Weaver[1], *[1]Center for Devices and Radiological Health, Food and Drug Administration, Silver Spring, MD, United States, [2]Oak Ridge Institute for Science & Education, Oak Ridge, TN, United States*

10:15AM **Stress-Relaxation Behaviors of Diseased Heart Valve Tissues** SB^{3}C2016-1093
Kaitlyn Barbour[1], Siyao Huang[2], **HY Shadow Huang**[2], *[1]Biomedical Eng., NC State, Raleigh, NC, United States, [2]Mechanical and Aerospace Eng., NC State, Raleigh, NC, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

10:30AM **Stress Fiber Contractile Behavior in Aortic Valve Interstitial Cells** SB³C2016-818
Yusuke Sakamoto[1], Rachel M. Buchanan[2], Johannah S. Adams[3], Farshid Guilak[4], Michael S. Sacks[1, 2], *[1]The Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX, United States, [2]Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States, [3]Departments of Orthopaedic Surgery and Biomedical Engineering, Duke University, Durham, NC, United States, [4]Departments of Orthopaedic Surgery, Biomedical Engineering, and Developmental Biology, Washington University, St. Louis, St. Louis, MO, United States*

10:45AM **Design of a Novel In Vitro Simulation of a Dynamically Contracting Mitral Valve Annulus** SB³C2016-702
Thomas F. Easley, Charlie H. Bloodworth, Ajit P. Yoganathan, *Georgia Institute of Technology, Atlanta, GA, United States*

11:00AM **Novel Irreversible Chemistry Produces Structurally More Stable Tissue Based Biomaterials** SB³C2016-1049
Hobey Tam[1], Will Zhang[2], Daniel Infante[1], Nathaniel Parchment[1], Michael Sacks[2], Narendra Vyavahare[1], *[1]Bioengineering, Clemson University, Clemson, SC, United States, [2]Biomedical Engineering, University of Texas, Austin, Austin, TX, United States*

THURSDAY, JUNE 30 | 9:45am - 11:15pm

Cerebral Aneurysm — Annapolis 2

Session Chair: Kristian Valen-Sendstad, *Simula Research Laboratory, Lysaker, Norway*
Session Co-Chair: David Steinman, *University of Toronto, ON, Canada*

9:45AM **A Simple and Rational Approach to Outflow Conditions in Cerebrovascular CFD Models.** SB³C2016-1026
Christophe Chnafa[1], Kristian Valen-Sendstad[2], Olivier Brina[3], Vitor Mendes Pereira[4], David Steinman[1], *[1]Mechanical & Industrial Engineering, University of Toronto, Toronto, ON, Canada, [2]Simula Research Laboratory, Centre for Biomedical Computing, Lysaker, Norway, [3]Department of Medical Imaging, Toronto Western Hospital, Toronto, ON, Canada, [4]Toronto Western Hospital, Toronto, ON, Canada*

10:00AM **Non-newtonian versus Numerical Rheology: Practical Impact of Shear-thinning on the Prediction of Stable and Unstable Flows in Intracranial Aneurysms** SB³C2016-579
Owais Khan[1], David A. Steinman[1], Kristian Valen-Sendstad[2], *[1]Mechanical and Industrial Engineering, University of Toronto, Toronto, ON, Canada, [2]Simula Research Laboratory, Kristian Valen-Sendstad, Lysaker, Norway*

10:15AM **Numerical Modeling of Post-surgical Flow in Basilar Artery Aneurysms** SB³C2016-609
Alireza Vali[1], Michael Lawton[2], David Saloner[3], Vitaliy Rayz[1], *[1]Neurosurgery, Medical College of Wisconsin, Milwaukee, WI, United States, [2]Neurological Surgery, University of California San Francisco, San Francisco, CA, United States, [3]Radiology and Biomedical Imaging, University of California San Francisco, San Francisco, CA, United States*

10:30AM **Comparison of Flow Conditions in Aneurysms at the Basilar Tip and Internal Carotid Artery Terminus** SB³C2016-110
Ravi Doddasomayajula[1], BongJae Chung[1], Farid Hamzei-Sichani[2], Christopher Putman[3], Juan Cebral[1], *[1]George Mason University, Fairfax, VA, United States, [2]Mt. Sinai Hospital, New York, NY, United States, [3]Inova Fairfax Hospital, Falls Church, VA, United States*

10:45AM **Hemodynamics in Developing Stages of Cerebral Aneurysms Using Spectral-Element Simulations and Comparison with PIV Experiments** SB³C2016-1008
Tanvi K. Kaushik[1], Yulia T. Peet[1], Priya Nair[2], David H. Frakes[2], *[1]School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, AZ, United States, [2]School of Biological and Health Systems Engineering, Arizona State University, Tempe, AZ, United States*

11:00AM **Aneurysmal Flow Modifications by Coils and Flow Diverters and Long-Term Treatment Outcome** SB³C2016-1081
Robert J. Damiano[1], Nicole Varble[1], Rahul Sanal[1], Jason M. Davies[2], Adnan H. Siddiqui[2], Hui Meng[1], *[1]Mechanical and Aerospace Engineering, University at Buffalo, Buffalo, NY, United States, [2]Neurosurgery, University at Buffalo, Buffalo, NY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	9:45am - 11:15am

Musculoskeletal Soft Tissue: Disc — Azalea 2

Session Chair: Amy Claeson, *University of Delaware, DE, United States*
Session Co-Chair: Grace D. O'Connell, *University of California, Berkeley, CA, United States*

9:45AM **Failure Properties of Annulus Fibrosus** SB³C2016-983
Noah Bonnheim, Benjamin Werbner, Grace O'Connell, *Mechanical Engineering, University of California, Berkeley, Berkeley, CA, United States*

10:00AM **A Probabilistic Finite Element Analysis of the Annulus Fibrosus Elastic Properties Influence on the Behavior of the Human L4-L5 and L5-S1 Segments** SB³C2016-127
Héctor E. Jaramillo[1], José J. García[2], *[1]Departamento de Energética y Mecánica, Universidad Autonoma De Occidente, Cali, Colombia, [2]Escuela de Ingeniería Civil y Geomática, Universidad Del Valle, Cali, Colombia*

10:15AM **A High Throughput Nucleus Pulposus Explant Culture System Preserves Tissue Integrity** SB³C2016-962
Timothy Jacobsen, Nadeen Chahine, *The Feinstein Institute for Medical Reseaerch, Manhasset, NY, United States*

10:30AM **Validation of a High Throughput Hydrostatic Pressure Bioreactor on the Nucleus Pulposus Biosynthesis** SB³C2016-1078
Bhranti Shah, Farzana Chowdhury, Nadeen Chahine, *Feinstein Institute for Medical Research, Manahasset, NY, United States*

10:45AM **Nucleotomy Alters Internal Strain Distribution of the Human Lumbar Intervertebral Disc** SB³C2016-1082
Amy A. Claeson[1], Brent L. Showalter[2], Edward J. Vresilovic[3], Alexander C. Wright[4], James C. Gee[4], Neil R. Malhotra[4], Dawn M. Elliott[1], *[1]Department of Biomedical Engineering, University of Delaware, Newark, DE, United States, [2]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [3]Department of Orthopaedics and Rehabilitation, Pennsylvania State University, Hershey, PA, United States, [4]Department of Radiology, University of Pennsylvania, Philadelphia, PA, United States*

11:00AM **Potential Involvement of Endplate Purinergic Signaling in Low Back Pain** SB³C2016-1117
Mary Boggs, John DeLucca, Dawn Elliot, Randall Duncan, *University of Delaware, Newark, DE, United States*

THURSDAY, JUNE 30	9:45am - 11:15am

Cryopreservation and Cryotherapy — Azalea 3

Session Chair: Nilay Chakraborty, *University of Michigan Dearborn, MI, United States*
Session Co-Chair: Sepideh Khoshnevis, *University of Texas at Austin, TX, United States*

9:45AM **Nanowarming of Arteris** SB³C2016-1089
Navid Manuchehrabadi, *University of Minnesota, Minneapolis, MN, United States*

10:00AM **Physiological Basis for Rational Cryotherapy Protocol Design** SB³C2016-737
Sepideh Khoshnevis[1], Robert M. Brothers[2], Kenneth R. Diller[1], *[1]University of Texas at Austin, Austin, TX, United States, [2]University of Texas at Arlington, Arlington, TX, United States*

10:15AM **Alginate Hydrogel Microencapsulation Inhibits Devitrification and Enables Large-volume Low-cpa Cell Vitrification** SB³C2016-582
Haishui Huang, *The Ohio State University, Columbus, OH, United States*

10:30AM **Development of an Isothermal Vitrification Matrix and Method for the Room Temperature Stabilization of Proteinaceous Cancer Biomarkers in Archival Human Sera** SB³C2016-839
Morwena J. Solivio, Goeun Heo, Alptekin Aksan, *Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States*

10:45AM **Dynamic Vapor Sorption in Trehalose/salt Mixtures: Effect of Composition on Retention of the Amorphous State** SB³C2016-168
Gloria Elliott, Babak Bagheri, Lindong Weng, Matthew Van Vorst, *Department of Mechanical Engineering, UNC Charlotte, Charlotte, NC, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

11:00AM **A Raman Microspectroscopic Technique to Quantify Residual Water in Desiccated Samples** SB³C2016-876
Quinn Osgood, Jason Solocinski, **Nilay Chakraborty**, *Mechanical Engineering Department, University of Michigan Dearborn, Dearborn, MI, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Biotransport Diagnostics and Therapeutics — Exhibit Hall A

1 **Probing the Interactions Between Mannobiose Molecules, Using Atomic Force Microscopy (afm).** SB³C2016-989
Komitige H. Perera, Saswati Basu, Preethii Chandran, *Biochemistry and Molecular Biology, Howard University, Washington, DC, United States*

2 **Increased Capture of Magnetic Microbeads Due to Switching of Electroosmotic Flow** SB³C2016-1067
Samuel A. Miller[1], William R. Heineman[2], Rupak K. Banerjee[1], *[1]Department of Mechanical and Materials Engineering, University of Cincinnati, Cincinnati, OH, United States, [2]Department of Chemistry, University of Cincinnati, Cincinnati, OH, United States*

3 **Evaluation of Sensitivity and Accuracy of Infrared Thermography for Melanoma Screening** SB³C2016-145
Yiyong Li[1], Alexander M. LeBrun[2], L. D. Timmie Topoleski[2], **Liang Zhu**[2], *[1]Mechanical Engineering, Beijing University of Aeronautics & Astronautics, Beijing, China, [2]Mechanical Engineering, University of Maryland Baltimore County, Baltimore, MD, United States*

4 **Validation of Image-assisted Modeling Approach to Design Heating Protocols in Magnetic Nanoparticle Hyperthermia** SB³C2016-24
Alexander M. LeBrun[1], Tejashree Joglekar[2], Charles Bieberich[2], Ronghui Ma[1], **Liang Zhu**[1], *[1]Mechanical Engineering, University of Maryland Baltimore County, Baltimore, MD, United States, [2]Biology, University of Maryland Baltimore County, Baltimore, MD, United States*

5 **Development and Characterization of Protein Nanoparticles Derived from Lung Extracellular Matrix** SB³C2016-682
Patrick A. Link[1], Sirish K. Desai[2], Nan Zhou[3], Da-Ren Chen[3], **Rebecca L. Heise**[1], *[1]Biomedical Engineering, VCU, Richmond, VA, United States, [2]J.R. Tucker High School, Richmond, VA, United States, [3]Mechanical and Nuclear Engineering, VCU, Richmond, VA, United States*

6 **Stiffness-Independent on-Chip Extraction of Cell-Laden Hydrogel Microcapsules from Oil Emulsion Into Aqueous Solution Based on Dielectrophoresis** SB³C2016-721
Mingrui Sun[1], Haishui Huang[2], Xiaoming He[1], *[1]Biomedical Engineering, The Ohio State University, Columbus, OH, United States, [2]Mechanical Engineering, The Ohio State University, Columbus, OH, United States*

7 **Point-of-Care Diagnosis by Nanoparticle Aggregation: Tuning the Sensitivity by Nanoparticle Size and Concentration** SB³C2016-1114
Peiyuan Kang, **Zhenpeng Qin**, *Mechanical Engineering, University of Texas at Dallas, Richardson, TX, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Cancer and Tumor Microenvironments — Exhibit Hall A

8 **In vitro Testing of Hydrogel Delivery for Potential Treatment for Pancreatic Cancer Lesions** SB³C2016-1125
Thomas L. Merrill, *rowan university, Glassboro, NJ, United States*

9 **Effect on Oligosaccharide Grafting on the Polyelectrolyte and Protonation Dynamics of Polyethylenimine** SB³C2016-1018
Saswati Basu, Danielle N. Miller, Stacy N. Apugo, Preethi L. Chandran, *Chemical Engineering, Howard University, Washington, DC, United States*

10 **Enhanced Microwave Hyperthermia of Cancer Cells with Fullerene** SB³C2016-724
Mingrui Sun, Xiaoming He, *Biomedical Engineering, The Ohio State University, Columbus, OH, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

11 **Isolation of Rare Tumor Cells Using Adhesion Rolling in a Microfluidic Chip with Inclined Wavy Surfaces** SB³C2016-749
Shunqiang Wang[1], Roy Ghosh[1], Ran He[1], Jie Yang[2], Yaling Liu[1, 3], *[1]Department of Mechanical Engineering & Mechanics, Lehigh University, Bethlehem, PA, United States, [2]School of Mechanics and Engineering, Southwest Jiaotong University, Chengdu, China, [3]Bioengineering Department, Lehigh University, Bethlehem, PA, United States*

12 **Analyzing Effects of Chemotherapeutic Drugs for the Prevention of Chemotherapy-Induced Alopecia** SB³C2016-1060
Likitha Somasekhar, Kunal Mitra, Carlos Martino, *Biomedical Engineering, Florida Institute of Technology, melbourne, FL, United States*

13 **Relationship Between Mechanical Stiffness and Multiple Cancer Cell Proliferation and Morphology in 3D Encapsulated Gelatin Methacrylate Hydrogels** SB³C2016-605
Sean Hennigan[1], Susan A. Pomilla[2], Melissa A. DePrato[1], John R. Beliveau[1], **Jason W. Nichol**[2], *[1]Biology and Biotechnology, Endicott College, Beverly, MA, United States, [2]Bioengineering, Endicott College, Beverly, MA, United States*

14 **A 3D Model of Breast Tumor- Endothelial Cell Interactions** SB³C2016-792
Swathi Swaminathan[1], Olivia Ngo[2], Alisa Morss Clyne[3], *[1]Mechanical Engineering and Mechanics, Drexel University, Philadelphia, PA, United States, [2]Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia, PA, United States, [3]Mechanical Engineering and Mechanics/ Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia, PA, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Bachelors Level Student Paper Competition I: Physiology & Diseases - Cellular & Tissue Mechanics - Biomaterial & Material Characterization — Exhibit Hall A

34 **Off-axis Biaxial Analysis of Synthetic Scaffolds for Hernia Repair** SB³C2016-587
Savannah Est[1, 2], Maddie Roen[1], Vivian Chi[2], Adrian Simien[2], Ryan Castile[1], Dominic Thompson[2], Corey R. Deeken[3], Spencer P. Lake[1], *[1]Department of Mechanical Engineering & Materials Science, Washington University in St. Louis, St. Louis, MO, United States, [2]Department of Surgery, Section Minimally Invasive Surgery, Washington University School of Medicine, St. Louis, MO, United States, [3]Covalent Bio, LLC, St. Louis, MO, United States*

35 **The Characterization of the Bone Marrow Mechanical Environment Using Poroelastic Models with Material Properties Determined From Micro-finite Element Modeling** SB³C2016-1057
Jason A. Shar[1], Thomas A. Metzger[2], Tyler Kreipke[2], Glen Neibur[2], Joshua Gargac[1], *[1]Engineering, University of Mount Union, Alliance, OH, United States, [2]AME, University of Notre Dame, Notre Dame, IN, United States*

36 **Anterolateral Capsule of the Knee Functions as a Sheet of Tissue based on Tissue Strain** SB³C2016-96
Stephanie L. Sexton[1], Daniel Guenther[2], Kevin Bell[1], Sebastian Irarrazaval[1], Ata Rahnemai-Azar[1], Freddie Fu[1], Volker Musahl[1], Richard Debski[1], *[1]University of Pittsburgh, Pittsburgh, PA, United States, [2]Hannover Medical School, Hannover, Germany*

37 **Methodology to Reduce Dimensional Variability in Tensile Testing of Soft Fibrous Tissue** SB³C2016-604
Madison E. Krentz, Jaremy J. Creechley, Trevor J. Lujan, *Mechanical and Biomedical Engineering, Boise State University, Boise, ID, United States*

38 **Ultrasound Measurement of Shape Change During In Vitro Inflation of an Arterial Bifurcation** SB³C2016-864
John P. Carruth, Ryan R. Mahutga, Christopher E. Korenczuk, Victor H. Barocas, *Biomedical Engineering, University of Minnesota - Twin Cities, Saint Paul, MN, United States*

39 **Three-Element Windkessel Model to Describe Pulmonary Vasculature Changes in Hypertensive Rat** SB³C2016-1031
Jesse W. Gerringer, Daniela Vélez-Rendon, Daniela Valdez-Jasso, *Bioengineering, University of Illinois at Chicago, Chicago, IL, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

40 **Analysis of the Effect of Saliva on the Degradation of Absorbable Sutures** SB³C2016-1075
Luke E. Riexinger[1], Jenna W. Briddell[2], Donna M. Ebenstein[1], *[1]Biomedical Engineering, Bucknell University, Lewisburg, PA, United States, [2]Otolaryngology, Geisinger Medical Center, Danville, PA, United States*

41 **Viscoelastic Properties of Human Patellar Tendons Measured Using Continuous Shear Wave Elastography** SB³C2016-606
Courtney T. Cox[1], Jennifer A. Zellers[1], Karin G. Silbernagel[1], Daniel H. Cortes[2], *[1]University of Delaware, Newark, DE, United States, [2]Penn State University, University Park, PA, United States*

42 **Determining Impedance in Pulmonary Vessels Using Four-Element Windkessel Models** SB³C2016-1133
Julie C. Wagner, Jesse W. Gerringer, Daniela Valdez-Jasso, *Bioengineering, University of Illinois - Chicago, Chicago, IL, United States*

43 **The Influence of Gel Stiffness on Growth Factor Gene Expression of Schwann Cells** SB³C2016-808
Carlisle R. DeJulius, Rebecca Kuntz Willits, *Department of Biomedical Engineering, The University of Akron, Akron, OH, United States*

THURSDAY, JUNE 30	**1:00pm - 3:15pm**

Poster Session I — Bachelors Level Student Paper Competition II: Imaging - Devices - Human Dynamics & Injury - Fluids & Microfluidics - Heat Transfer — Exhibit Hall A

44 **DTI Voxel-Wise Analysis of Mild TBI in Neonatal Pigs Following Non-Impact Head Rotation.** SB³C2016-941
Boston C. Terry[1], Gregory G. Scott[2], Osama Abdullah[1], Brittany Coats[2], *[1]Biomedical Engineering, University of Utah, Salt Lake City, UT, United States, [2]Mechanical Engineering, University of Utah, Salt Lake City, UT, United States*

45 **Characterizing a Novel Ex-Vivo Animal Knee Model: ACL Rupture and Meniscus Compressive Strength** SB³C2016-585
Nicole L. Zaino, Mark J. Hedgeland, Laurel Kuxhaus, Arthur J. Michalek, *Mechanical & Aeronautical Engineering, Clarkson University, Potsdam, NY, United States*

46 **Characterization of Particulate and Vapor Phase Nicotine in Electronic Cigarettes** SB³C2016-106
Mark C. Daley[1], James W. Baish[1], Dabrina D. Dutcher[2], Timothy M. Raymond[2], *[1]Biomedical Engineering, Bucknell Unviersity, Lewisburg, PA, United States, [2]Chemical Engineering, Bucknell Unviersity, Lewisburg, PA, United States*

47 **A Novel Imaging Technique to Quantify Surface Wear in Joint Replacement Devices** SB³C2016-583
Katherine Hollar[1], John Everingham[1], Jillian Helms[1], Daniel Ferguson[2], Trevor Lujan[1], *[1]Boise State University, Boise, ID, United States, [2]Global Inspection Solutions, Boise, ID, United States*

48 **Additive Manufacturing of Localized Microneedle Drug-Delivery System** SB³C2016-985
Sofia Chinchilla[1], Yangfeng Lu[1], Corey J. Schurko[1], Douglas C. Crowder[1], Bum-Joon Park[2], Jae-Won Choi[3], Yang H. Yun[1], *[1]Biomedical Engineering, University of Akron, Akron, OH, United States, [2]Molecular Biology, Pusan National University, Busan, Korea, Republic of, [3]Mechanical Engineering, University of Akron, Akron, OH, United States*

49 **Structural Interactions of the Vessel Wall and Stent Graft in Abdominal Aortic Aneurysm Treatment** SB³C2016-711
Ryan J. Pewowaruk, Victor H. Barocas, *Biomedical Engineering, University of Minnesota - Twin Cities, Minneapolis, MN, United States*

50 **A Flexible Method for Producing F.E.M. Analysis of Bone Using Open-Source Software** SB³C2016-967
Abhishektha Boppana[1], Ryan Sefcik[2], Jerry G. Myers[3], *[1]Biomedical Engineering, Case Western Reserve University, Cleveland, OH, United States, [2]Biochemistry, The Ohio State University, Columbus, OH, United States, [3]NASA Glenn Research Center, Cleveland, OH, United States*

51 **Investigation of Superposition in Microchannel Geometry for Inertial Particle Separation** SB³C2016-969
Utku M. Sonmez, Samir Jaber, Levent Trabzon, *Mechanical Engineering, Istanbul Technical University, İstanbul, Turkey*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

52 **A Fluid Dynamics Analysis of the Manifestation of Ebstein's Anomaly in the Right Ventricle** SB³C2016-1140
Alyssa L. Niquette[1], Shelly Lo[1], Adam Shore[2], Vittoria Flamini[1], Puneet Bhatla[3], *[1]NYU Tandon School of Engineering, Brooklyn, NY, United States, [2]NYU Langone Medical Center, New York, NY, United States, [3]NYU Langone Medical Center, Brooklyn, NY, United States*

53 **Internal-External Rotation Axis Locates Laterally Outside of Stifle Joints in the Dog** SB³C2016-1017
Tetsuya Takagi[1], Nobuo Kanno[2], Masakazu Shimada[2], Yasushi Hara[2], Satoshi Yamakawa[1], Richard E. Debski[3], Glen A. Livesay[4], Hiromichi Fujie[1], *[1]Faculty of System Design, Tokyo Metropolitan University, Tokyo, Japan, [2]Division of Veterinary Surgery Department of Veterinary Science Faculty of Veterinary Medicine, Nippon Veterinary and Life Science University, Tokyo, Japan, [3]Bioengineering department Faculty of Engineering, University of Pittsburgh, Pittsburgh, PA, United States, [4]Department of Biology & Biomedical Engineering, Rose-Hulman Institute of Technology, Terre Haute, IN, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Mechanotransduction and Sub-Cellular Biophysics — Exhibit Hall A

54 **Effect of Compaction on Stretch Sensitivity in Fibroblast-Populated Collagen Gels** SB³C2016-837
Kellen Chen, Jeffrey W. Holmes, *University of Virginia, Charlottesville, VA, United States*

55 **Role of P2r-er Ca2+ Signaling in Ca2+ Oscillations of In Situ Osteocytes in Response to Medium Intensity Focused Ultrasound** SB³C2016-1120
Minyi Hu, Jian Jiao, Daniel Gibbons, Yi-Xian Qin, *Stony Brook University, Stony Brook, NY, United States*

56 **Mechanical Trauma in Articular Cartilage Induces Rapid, Location-Dependent Chondrocyte Dysfunction** SB³C2016-819
Lena R. Bartell[1], Michelle M. Delco[2], Lawrence J. Bonassar[3], Itai Cohen[4], Lisa A. Fortier[2], *[1]School of Applied and Engineering Physics, Cornell University, Ithaca, NY, United States, [2]Department of Clinical Sciences, Cornell University, Ithaca, NY, United States, [3]Meinig School of Biomedical Engineering and Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, NY, United States, [4]Department of Physics, Cornell University, Ithaca, NY, United States*

57 **A Study for the Effects of the Mechanical Trapping of the Nucleus on Cellular Events Using a Micropillar Substrate** SB³C2016-569
Kazuaki Nagayama, *Department of Intelligent Systems Engineering, Ibaraki University, Hitachi, Japan*

58 **A Cell Migration Model Integrating the Mechanical Stress Generation and Sensing with Biochemical Signals** SB³C2016-639
hongyan yuan[1], Kevin K. Parker[2], *[1]University of Rhode Island, kingston, RI, United States, [2]Harvard University, Cambridge, MA, United States*

59 **Disturbed Cyclical Stretch of Endothelial Cells Promotes Nuclear Expression of the Pro-Atherogenic Transcription Factor NF-kB** SB³C2016-677
Ryan M. Pedrigi, Konstantinos I. Papadimitriou, Avinash Kondiboyina, Sukhjinder Sidhu, James Chau, Emmanuel M. Drakakis, Rob Krams, *Bioengineering, Imperial College London, London, United Kingdom*

60 **ElectroMechanical Coupling Behavior of Endothelial Cells** SB³C2016-1077
Khashayar Teimoori[1], Richard Khalily[2], Ali M. Sadegh[3], Marom Bikson[2], *[1]Mechanical Engineering Department, The City College of the City University of New York, New York, NY, United States, [2]Biomedical Engineering Department, The City College of the City University of New York, New York, NY, United States, [3]Mechanical Engineering, The City College of the City University of New York, New York, NY, United States*

61 **Thermodynamic Fluctuations Determine the Kinetics of Swell-burst Cycles of Giant Unilamellar Vesicles Under Osmotic Stress** SB³C2016-1118
Morgan Chabanon[1], James Ho[2], Atul Parikh[3], **Padmini Rangamani**[1], *[1]UCSD, La Jolla, CA, United States, [2]NTU, Singapore, Singapore, [3]UC Davis, Davis, CA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

62 **The Effect of Loading Frequency on Tenocyte Metabolism** SB³C2016-595
Chineye P. Udeze[1], Eleanor R. Jones[2], Graham P. Riley[2], Dylan Morrissey[3, 4], Hazel R. C. Screen[1], *[1]School of Engineering and Material Science, Queen Mary University of London, Mile End, United Kingdom, [2]University of East Anglia, Norwich, United Kingdom, [3]Sport and Exercise Medicine, Queen Mary University of London, London, United Kingdom, [4]Physiotherapy Department, Bart's Health NHS Trust, London, United Kingdom*

63 **Mild Traumatic Brain Injury Resulted in Increased Aquaporin-4 Expression - Relevance to Post-Injury Edema** SB³C2016-670
Nasya Sturdivant[1], Sean Smith[1], Syed Ali[2], Jeff Wolchok[1], Kartik Balachandran[1], *[1]University of Arkansas, Fayetteville, AR, United States, [2]National Center for Toxicological Research, Jefferson, AR, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Nano, Micro, and Multi-Scale Mechanics — Exhibit Hall A

64 **A Mechanostatistical Model for the Rapid Assessment of Femoral Neck Cortical Fracture Risk** SB³C2016-164
Xiaoming Wang[1], Raj Das[2], Peter Hunter[1], Justin Fernandez[1, 3], *[1]Auckland Bioengineering Institute, The University of Auckland, Auckland, New Zealand, [2]Department of Mechanical Engineering, The University of Auckland, Auckland, New Zealand, [3]Department of Engineering Science, The University of Auckland, Auckland, New Zealand*

65 **ElectroMechanical Coupling Behavior of Axon Microtubules** SB³C2016-720
Khashayar Teimoori[1], Ali M. Sadegh[1], Marom Bikson[2], *[1]Mechanical Engineering Department, The City College of the City University of New York, New York, NY, United States, [2]Biomedical Engineering Department, The City College of the City University of New York, New York, NY, United States*

66 **On Mechanics and Structure of 3D Randomly Cross-linked Fibrous Networks** SB³C2016-779
Hamed Hatami-Marbini, *Mechanical & Industrial Engineering, University of Illinois at Chicago, Chicago, IL, United States*

67 **Detailed Finite Element Modeling of Fiber-reinforced Tissues** SB³C2016-755
Bo Yang, Minhao Zhou, Grace D. O'Connell, *Mechanical Engineering, University of California, Berkeley, CA, United States*

68 **Micro-Structurally Motivated Constitutive Model for Human Skin** SB³C2016-52
Sheng Chen[1], A. Ni Annaidh[2], Sara Roccabianca[1], *[1]Mechanical Engineering, MIchigan State University, East Lansing, MI, United States, [2]School of Mechanical & Materials Engineering, University College Dublin, Dublin, Ireland*

69 **Computational Modeling of the Arterial Wall Based on Layer-specific Histological Data** SB³C2016-58
Tao Jin, Ilinca Stanciulescu, *Civil and Environmental Engineering, Rice University, Houston, TX, United States*

70 **Implications of Desiccation Induced Microheterogeneity on Protein Stability** SB³C2016-577
Sampreeti Jena[1], Raj Suryanarayanan[2], Alptekin Aksan[1], *[1]Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Department of Pharmaceutics, University of Minnesota, Minneapolis, MN, United States*

71 **Multidomain Particle Dynamics Simulator Engine** SB³C2016-155
Vi Q. Ha, *Mechanical Engineering, Univesity of Connecticut, storrs, CT, United States*

72 **FiberFit: A Validated Software Application to Measure Fiber Organization in Soft Tissue** SB³C2016-863
Azamat Tulepbergenov, **Erica Morrill**, Christina Stender, Roshani Lamichhane, Raquel Brown, Trevor Lujan, *Boise State University, Boise, ID, United States*

73 **Nonlinear Bending Dynamics of a Semiflexible Filament in 3D Brownian Fluctuation** SB³C2016-958
Jyothirmai J. Simhadri, Preethi Chandran, *Chemical Engineering, Howard University, Washington, DC, United States*

74 **Strain Determination in the Osteocyte Lacunae Using Finite Element Analysis** SB³C2016-797
Ganesh Thiagarajan, *Civil and Mechanical Engineering, University of Missouri Kansas City, Kansas City, MO, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	1:00pm - 3:15pm

Poster Session I — Medical Devices — Exhibit Hall A

95 **Using An Electroactive Polymer, Dielectric Elastomer, for Making Implantable Blood Pump** SB³C2016-49
Sheldon Ho, Yoke Yin Foo, Hareesh Gobada, Phan Thien Nhan, Jian Zhu, Choon Hwai Yap, *NUS, Singapore, Singapore*

96 **A Novel Self-expandable Retractor for Neuroendoscopy.** SB³C2016-719
Yang Xia[1], Zhong You[1], Puneet Plaha[2], Jingxian Yang[3], *[1]Engineering Science, University of Oxford, OXFORD, United Kingdom, [2]Department of Neurosurgery, John Radcliffe Hospital, OXFORD, United Kingdom, [3]Department of Pharmacy, Liaoning University of Traditional Medicine, Dalian, China*

97 **Fold-and-Go Single Knee Scooter** SB³C2016-830
Kevin Mozurkewich, Nicholas Colarossi, Muntha Issa, *Lawrence Technological University, Livonia, MI, United States*

98 **Customizable Surface-Coating Method for Bioprosthetic Valve Biocompatibility** SB³C2016-870
Monica M. Fahrenholtz, K. Jane Grande-Allen, *Bioengineering, Rice University, Houston, TX, United States*

99 **Design Optimization of a Hyaluronan-based Drug-delivery Device to Improve Ocular Retention** SB³C2016-879
Jourdan Colter[1], Nathaniel Cady[2], Hee-Kyoung Lee[3], Brenda Mann[3], Barbara Wirostko[3], Brittany Coats[1], *[1]Mechanical Engineering, University of Utah, Salt Lake City, UT, United States, [2]Colleges of Nanoscale Science and Engineering, SUNY Polytechnic Institute, Albany, NY, United States, [3]Jade Therapeutics Inc., Salt Lake City, UT, United States*

100 **Hemodynamic Effects of Asynchronous Pumping of the Penn State Pulsatile Pneumatic Pediatric VAD** SB³C2016-889
Bryan Good, Keefe Manning, *Bioengineering, The Pennsylvania State University, University Park, PA, United States*

101 **Performance Evaluation of a Developed Acoustic Impedance Device in Tumor Screening** SB³C2016-890
Ali Mohammadabadi[1], Qimei Gu[1], Alexander LeBrun[1], Mohamed Younis[2], Liang Zhu[1], *[1]Mechanical Engineering, University of Maryland Baltimore County, Baltimore, MD, United States, [2]Computer Science and Electrical Engineering, University of Maryland Baltimore County, Baltimore, MD, United States*

102 **The Effect of Simulated Anatomical Constraints on Buckling Loads of Cardiac Leads** SB³C2016-906
Donna Walsh[1], Ashok Williams[1], Nandini Duraiswamy[1], Oleg Vesnovsky[1], L.D. Timmie Topoleski[1, 2], *[1]Food and Drug Administration, Silver Spring, MD, United States, [2]Department of Mechanical Engineering, University of Maryland, Baltimore County, Baltimore, MD, United States*

103 **Clot Integration Factor for In Vitro Quantification of Stent-Retriever Deployment using Cone-Beam Computed Tomography** SB³C2016-929
Kajo van der Marel[1], Olivia W. Brooks[1], Robert M. King[1], Ju-Yu Chueh[1], Miklos Marosfoi[1], Erin T. Langan[1], Sarena L. Carniato[2], Raul G. Nogueira[3], Ajay K. Wakhloo[1], Matthew J. Gounis[1], Ajit S. Puri[1], *[1]Department of Radiology, University of Massachusetts Medical School, Worcester, MA, United States, [2]PreClinical Science, Stryker Neurovascular, Fremont, CA, United States, [3]Department of Neurology, Emory University School of Medicine, Atlanta, GA, United States*

104 **Design of a Cardiovascular Flow Mimicking Pump** SB³C2016-1009
Chris F. Brake, **Clifton R. Johnston**, *Mechanical Engineering, Dalhousie University, Halifax, NS, Canada*

105 **Simulation of Centrifugal Pump Thrombosis In Vitro** SB³C2016-1024
Susan Hastings[1], Shriprasad Deshpande[2], Scott Wagoner[2], Kevin Maher[2], David Ku[1], *[1]Mechanical Engineering, Georgia Institute of Technology, ATLANTA, GA, United States, [2]Pediatrics, Emory University School of Medicine, ATLANTA, GA, United States*

106 **Investigation of Forces and Moments During Minimally Invasive Total Hip Arthroplasty and the Likelihood of Intraoperative Fracture** SB³C2016-1058
Pooyan Abbasi[1], Dustin Greenhill[2], Andrew Star[2], Kurosh Darvish[1], *[1]Temple University, Philadelphia, PA, United States, [2]Temple University Hospital, Philadelphia, PA, United States*

107 **Magnetically Levitated Shear Inducing Device for the Testing of Cell Fragility** SB³C2016-1094
Oyuna Myagmar, Ramnath Raghunaithan, **Steven W. Day**, *Rochester Institute of Technology, Rochester, NY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

108 **Patient-Specific Assessment of Pre-TPVR Angioplasty Coronary Compression Using the Finite Element Method** SB³C2016-1139

Sara Amendola[1], Doff McElhinney[2], Puneet Bhatla[3], **Vittoria Flamini**[1], *[1]Mechanical and Aerospace, NYU Tandon School of Engineering, Brooklyn, NY, United States, [2]Medical Center, Stanford, Stanford, CA, United States, [3]Pediatrics, NYU Langone Medical Center, Brooklyn, NY, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Atherosclerosis & Aneurysms — Exhibit Hall A

129 **Modification of a Parallel Plate Flow Chamber for Analysis of Endothelial Response to Disturbed Flow** SB³C2016-944

Jason M. Sedlak[1], Alisa Morss Clyne[2], *[1]Biomedical Engineering, Drexel University, Philadelphia, PA, United States, [2]Mechanical Engineering and Mechanics, Drexel University, Philadelphia, PA, United States*

130 **Wall Shear Stress and Combined VH-IVUS and OCT Analysis of Coronary Plaque Composition** SB³C2016-951

David Molony[1], Lucas Timmins[1], Udit Joshi[1], Yasir Bouchi[1], Bill Gogas[1], Habib Samady[1], Don Giddens[2], *[1]Emory University, Atlanta, GA, United States, [2]Georgia Institute of Technology, Atlanta, GA, United States*

131 **An Explorative CFD Study on Stenosis-induced Flow Instabilities in the Carotid Artery** SB³C2016-668

Viviana Mancini[1], Jan Vierendeels[2], Daniela Tommasin[1], Simon Shaw[3], Abigail Swillens[1], Awais Yousaf[4], Stephen E. Greenwald[4], *[1]IBiTech-bioMMeda, Ghent University, Ghent, Belgium, [2]Ghent University, Ghent, Belgium, [3]Brunel University, London, United Kingdom, [4]Queen Mary University of London, London, United Kingdom*

132 **Co-localizations and Correlations of Established and Emerging Indicators of Disturbed Wall Shear Stress at the Normal Carotid Bifurcation** SB³C2016-140

Diego Gallo[1], David A. Steinman[2], Morbiducci Umberto[1], *[1]Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy, [2]Department of Mechanical & Industrial Engineering, University of Toronto, Toronto, ON, Canada*

133 **Longitudinal Study of Wall Shear Stress Over Atherosclerotic Plaques in Mice** SB³C2016-768

Ruoyu Xing, Astrid Moerman, Yanto Ridwan, Anton van der Steen, Frank Gijsen, Kim van der Heiden, *Erasmus MC, Rotterdam, Netherlands*

134 **Influence of Plaque Stifffness on Deformation and Flow of Arterial Stenosis Model for Percutaneous Transluminal Coronary Angioplasty** SB³C2016-658

Shunichi Kobayashi[1], Daiki Miyamoto[2], Hajime Kitami[1], *[1]Faculty of Textile Science and Technology, Shinshu University, Ueda, Japan, [2]Graduate School of Science and Technology, Shinshu University, Ueda, Japan*

135 **Effect of Deformation on Cerebral Aneurysm in Middle Cerebral Artery** SB³C2016-763

Suguru O. Omachi, Gaku Tanaka, Hao Liu, Ryuhei Yamaguchi, *Chiba University, Chiba, Japan*

136 **Numerical Simulation of Mechanics of Rupture in Abdominal Aortic Aneurysms Using Fluid-structure Interaction Methods** SB³C2016-980

Tejas Canchi[1, 2], Eddie Yin Kwee Ng[3], Esley Chin Hock Pwee[3], Dinesh Kumar Srinivasan[4], Sriram Narayanan[5], *[1]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore, [2]Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore, Singapore, [3]Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore, Singapore, Singapore, [4]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore, Singapore, [5]Department of General Surgery, Tan Tock Seng Hospital, Singapore, Singapore*

137 **How Sensitive are Hemodynamics in Intracranial Aneurysms to Different Blood Flow Waveforms?** SB³C2016-933

Michael J. Durka[1], Issac H. Wong[1], David F. Kallmes[2], Dario Pasalic[2], Juan R. Cebral[3], Pablo J. Blanco[4], Manoj Jagani[2], Anne M. Robertson[1], *[1]Department of Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA, United States, [2]Mayo Clinic, Rochester, MN, United States, [3]Department of Bioengineering, George Mason University, Fairfax, VA, United States, [4]Laboratorio Nacional de Computacao Cientifica, Petropolis, Brazil*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

138 **PCOM Aneurysms: Angio-Architecture, Hemodynamics and Geometry** SB³C2016-136
BongJae Chung[1], Ravi Doddasomayajula[1], Fernando Mut[1], Farid Hamzei-Sichani[2], Christopher Putman[3], Michael Pritz[1], Carlos Jimenez[4], Juan Cebral[1], *[1]Bioengineering & Krasnow Institute, George Mason University, Fairfax, VA, United States, [2]Interventional Neuroradiology, Mt. Sinai Hospital, New York, NY, United States, [3]Interventional Neuroradiology, Inova Fairfax Hospital, Falls Church, VA, United States, [4]Neurosurgery, University of Antioquia, Medellin, Colombia*

139 **Association of Hemodynamic Stresses with Thickness of Aneurysm Wall: A Case Study** SB³C2016-726
Hamidreza Rajabzadeh Oghaz[1], Jaco J. M. Zwanenburg[2], Hui Meng[1], *[1]University at Buffalo, Buffalo, NY, United States, [2]University Medical Center Utrecht, Utrecht, Netherlands*

140 **Comparison of Cerebral Aneurysm Flow Fields Obtained From Cfd And Dsa** SB³C2016-126
Juan Cebral[1], BongJae Chung[1], Fernando Mut[1], Fred van Nijnatten[2], Danny Ruijters[2], *[1]Bioengineering, George Mason University, Fairfax, VA, United States, [2]IGT Innovation, Philips Healthcare, Best, Netherlands*

141 **Objective Identification of the Yield Point from Tensile Testing of Aortic Tissues** SB³C2016-752
Madhavan L. Raghavan, Timothy K. Chung, Chaid D. Schwarz, *Biomedical Engineering, University of Iowa, Iowa City, IA, United States*

142 **Biomechanical Characterization of Six Murine Models of Thoracic Aortic Aneurysm and Dissection** SB³C2016-872
Chiara Bellini, Matthew R. Bersi, Jacopo Ferruzzi, Jay D. Humphrey, *Biomedical Engineering, Yale University, New Haven, CT, United States*

143 **A Novel Technique for Assessment of Mechanical Properties of Vascular Tissue** SB³C2016-662
Stefan Sanders, Frans van de Vosse, Marcel Rutten, *Eindhoven University of Technology, Eindhoven, Netherlands*

144 **Towards the Characterization of Carotid Plaque Tissue Toughness: Linking Mechanical Properties to Biological Content** SB³C2016-680
Hilary E. Barrett[1], Eoghan M. Cunnane[1], Eamon G. Kavanagh[2], Michael T. Walsh[1], *[1]Centre for Applied Biomedical Engineering (CABER) and Health Research Institute (HRI), University of Limerick, Limerick, Ireland, [2]Department of Vascular Surgery, University Hospital Limerick, Limerick, Ireland*

THURSDAY, JUNE 30	**1:00pm - 3:15pm**

Poster Session I — Cardiovascular Diagnostics and Devices — Exhibit Hall A

145 **Bifurcation Angle and Fractional Flow Reserve: A Multiscale Numerical Study of Coronary Bifurcation Lesions** SB³C2016-148
Catherine Pagiatakis[1, 2], Jean-Claude Tardif[2, 3], Philippe L. L'Allier[2, 4], **J. Frattolin**[2, 5], Rosaire Mongrain[1, 2], *[1]Mechanical Engineering, McGill University, Montreal, QC, Canada, [2]Montreal Heart Institute, Montreal, QC, Canada, [3]Faculty of Medicine, Université de Montréal, Montreal, QC, Canada, [4]Université de Montréal, Montreal, QC, Canada, [5]McGill University, Montreal, QC, Canada*

146 **Development of an Integrated Multi-Scale Simulation System with Multi-modal Data for Cerebral Circulation** SB³C2016-997
Marie Oshima[1], Zhao Zhang[2], Masaharu Kobayashi[1], Shigeki Yamada[3], Fuyou Liang[4], Shu Takagi[2], *[1]Interfaculty Intiative in Information Studies, The University of Tokyo, Tokyo, Japan, [2]Departoment of Mechanical Engineering, The University of Tokyo, Tokyo, Japan, [3]Department of Neurosurgery, Rakuwakai Otowa Hospital, Kyoto, Japan, [4]Department of Naval Architecutre and Ocean Engineering, Shanghai Jiao Tong University, Shanghai, China*

147 **Windkessel Approach for Blood Flow Responses: Application in Venous Ulcer Risk Assessment** SB³C2016-774
Wu Pan, Seungik Baek, Tamara Reid Bush, *Mechanical Engineering, Michigan State University, East Lansing, MI, United States*

148 **Patient-Specific CFD of Clinical Mitral Regurgitation as a Novel Method to Quantify Regurgitation Severity** SB³C2016-118
Muhammad Jamil[1], Kian Keong Poh[2], Choon Hwai Yap[1], *[1]Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore, [2]Department of Medicine, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

149 **Assessing Hemodynamic Response to Exercise for Patient with Left Ventricular Hypertrophy by Integrating Cardiovascular and Autonomic Nervous Systems** SB³C2016-93
Weiwei Jin[1], Fuyou Liang[2], Hao Liu[1, 2], *[1]Chiba University, Chiba, Japan, [2]Shanghai Jiao Tong University and Chiba University International Cooperative Research Center, Shanghai Jiao Tong University, Shanghai, China*

150 **Translating 4d-flow MRI to Clinical Practice** SB³C2016-1137
Kurt R. Sansom[1], Haining Liu[2], chun yuan[2], Alberto Aliseda[1], Gador Canton[2], *[1]Mechanical Engineering, University of Washington, WA, United States, [2]Vascular Imaging Laboratory, University of Washington, WA, United States*

151 **Patient-Specific Computational Fluid Dynamics Simulations of the Human Fetal Left Ventricle Based on 4D Clinical Ultrasound Imaging** SB³C2016-83
Changquan Lai[1], Guat Ling Lim[2], Muhammad Jamil[3], Citra Nurfarah Zaini Mattar[2], Arijit Biswas[2], **Choon Hwai Yap**[3], *[1]SIngapore MIT Alliance for Reseach and Technology, Singapore, Singapore, [2]Obstetrics and Gynecology, National University Hospital Systems, Singapore, Singapore, Singapore, [3]Biomedical Engineering, National University of Singapore, Singapore, Singapore*

152 **Impact of Idealized Versus Measured Velocity Profiles in Computational Models of Mass Transport in the Human Aorta** SB³C2016-593
Giuseppe De Nisco[1], Peng Zhang[2], Gianpaolo Usala[1], Diego Gallo[1], Xiao Liu[2], Xiaoyan Deng[2], Giovanna Rizzo[3], Umberto Morbiducci[1], *[1]Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy, [2]School of Biological Science and Medical Engineering, Beihang University, Beijing, China, [3]Research National Council, IBFM, Milan, Italy*

153 **Micro Matrix Encapsulation of Cell Aggregates for Injectable Delivery Augments Stem Cell Therapy of Myocardial Infarction** SB³C2016-731
Shuting zhao, Xiaoming He, *Biomedical Engineering, The ohio state university, Columbus, OH, United States*

THURSDAY, JUNE 30	**1:00pm - 3:15pm**

Poster Session I — Masters Level Student Paper Competition I: Physiology & Diseases - Cellular & Tissue Mechanics - Biomaterial & Material Characterization — Exhibit Hall A

188 **Early Production of Phospholipase A_2 Accompanies Spinal Neuroinflammation and Pain Following Nerve Root Compression** SB³C2016-641
Sonia Kartha, Jenell Smith, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

189 **Disorganized Layers within an Otherwise Aligned Fibrous Network Preserve Bulk Mechanics and Promote Strain Reconstitution in the Context of Radial Tears** SB³C2016-873
Sonia Bansal[1, 2, 3], Niobra M. Keah[1, 3], Feini Qu[1, 3, 4], Spencer E. Szczesny[1, 3], Alexander L. Neuwirth[1, 3], Robert L. Mauck[1, 2, 3], Miltiadis H. Zgonis[1, 3], *[1]McKay Orthopaedic Research Laboratory, University of Pennsylvania, Philadelphia, PA, United States, [2]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [3]Translational Musculoskeletal Research Center, Philadelphia VA Medical Center, Philadelphia, PA, United States, [4]University of Pennsylvania, School of Veterinary Medicine, Philadelphia, PA, United States*

190 **Long-term Exposure to Buffer Solution Alters Tendon Structure and Mechanics -Implications for Fatigue Studies** SB³C2016-1037
Babak N. Safa[1, 2], Kyle D. Meadows[2], Spencer E. Szczesny[3], Dawn M. Elliott[2], *[1]Mechanical engineering, University of delaware, Newark, DE, United States, [2]Biomedical engineering, University of delaware, Newark, DE, United States, [3]Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, United States*

191 **Effect of Ablation Pattern on Mechanical Function in the Atrium: A Finite-Element Study** SB³C2016-592
Thien-Khoi N. Phung, Patrick T. Norton, John D. Ferguson, Jeffrey W. Holmes, *University of Virginia, Charlottesville, VA, United States*

192 **Effects of Reproduction and Lactation on Maternal Bone Tissue Mechanical Properties at Different Length Scales** SB³C2016-885
Yihan Li[1], Peng Guo[1], Wei-Ju Tseng[1], Chantal M. J. de Bakker[1], Prashant Chandrasekaran[2], Yonghoon Jeong[3], Do-Gyoon Kim[3], Lin Han[2], X. Sherry Liu[1], *[1]University of Pennsylvania, Philadelphia, PA, United States, [2]Drexel University, Philadelphia, PA, United States, [3]The Ohio State University, Columbus, OH, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

193 **Methods to Determine Right Ventricular Performance in a Rat Animal Model of Pulmonary Arterial Hypertension** SB³C2016-1046

Daniela M. Velez Rendon, Jesse Gerringer, Gizzel Gomez, Erica Pursell, Daniela Valdez-Jasso, *Bioengineering, University of Illinois at Chicago, Chicago, IL, United States*

194 **Surface Modification of Electrospun gelatin/fibrinogen Scaffolds to Encourage Endothelial Cell Function** SB³C2016-162

Catalina Ardila[1], David Maestas[2], Victoria Lundine[2], Marvin Slepian[3, 4], Jonathan Vande Geest[5], *[1]Graduate Interdisciplinary Program of Biomedical Engineering, The University of Arizona, Tucson, AZ, United States, [2]Biomedical Engineering, The University of Arizona, Tucson, AZ, United States, [3]Sarver Heart Center, The University of Arizona, Tucson, AZ, United States, [4]Interventional Cardiology, The University of Arizona, Tucson, AZ, United States, [5]Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

195 **Swelling of Collagen-Hyaluronic Acid Co-Gels: An In Vitro Residual Stress Model** SB³C2016-942

David S. Nedrelow[1], Victor K. Lai[2], Spencer P. Lake[3], Bumjun Kim[1], Emily M. Weiss[1], Robert T. Tranquillo[4], Victor H. Barocas[1], *[1]Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Chemical Engineering, University of Minnesota, Duluth, MN, United States, [3]Mechanical Engineering and Materials Science, Washington University, St. Louis, MO, United States, [4]Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States*

196 **Longitudinal Assessment of Mouse Bone Microstructure by In Vivo µCT Imaging with Minimal Radiation Effects** SB³C2016-1035

Hongbo Zhao, Chih-Chiang Chang, Youwen Yang, Wei-Ju Tseng, Chantal M. J. de Bakker, X. Sherry Liu, *Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, United States*

197 **Pathological Engineering Study of Human Cerebral Aneurysms Three Dimensional Accumulation of Foam Cells Versus Hemodynamics** SB³C2016-1110

Kenta Suto[1], Takanobu Yagi[1, 2], Yasutaka Tobe[1], Takuma Murayoshi[1], Kiyofumi Takanishi[1], Mitsuo Umezu[1], Hirotaka Yoshida[3], Kazutoshi Nishitani[3], Yoshifumi Okada[3], Shigemi Kitahara[3], *[1]Center for Advanced Biomedical science (TWIns), Waseda University, Tokyo, Japan, [2](2)EBM corporation Ohmoriminami, Ohtaku, Tokyo, 143-0013 Japan, Tokyo, Japan, [3]Kitahara International Hospital Oowada-cho, Hachioji-shi, Tokyo Japan, Tokyo, Japan*

198 **Mathematical Modelling of Oxygen Transport in the Retina** SB³C2016-1007

Wouter J. Thijssen, Emilie Lunddahl, Andris Piebalgs, Xiao Y. Xu, *Chemical Engineering, Imperial College London, London, United Kingdom*

199 **Effect of Hydration on Intervertebral Disc Recovery** SB³C2016-754

Semih Bezci, Grace D. O'Connell, *Mechanical Engineering, University of California, Berkeley, Berkeley, CA, United States*

200 **The Role of IGF-1 in the Cytoskeletal Regulation of Gating of TRPV4 Channels in Articular Chondrocytes** SB³C2016-1101

Victor DeBarros[1], Joseph D. Gardinier[2], Lauren Hurd[3], Mary E. Boggs[1], Randall Duncan[4], *[1]Biological Sciences, University of Delaware, Newark, DE, United States, [2]Orthopedics/Bone and Joint Center, Henry Ford Health System, Detroit, MI, United States, [3]Molecular Diagnostics Laboratory, Nemours/AI duPont Hospital for Children, Wilmington, DE, United States, [4]Biological Sciences and Biomedical Engineering, University of Delaware, Newark, DE, United States*

201 **Image-based Analysis for Inverse Estimation of Muscle Fiber Forces in the Tongue** SB³C2016-1004

Narihiko Koike[1], Tsukasa Yoshinaga[1], Kazunori Nozaki[2], Satoshi Ii[1], Shigeo Wada[1], *[1]Osaka University, Toyonaka, Japan, [2]Osaka University Dental Hospital, Suita, Japan*

202 **Modeling the Viscoelastic Properties of Pulmonary Vessels in a Hypertensive Rat** SB³C2016-1020

Erica Pursell, Daniela Velez-Rendon, Daniela Valdez-Jasso, *University of Illinois at Chicago, Chicago, IL, United States*

203 **Biomechanical Consequences of Subchondral Bone Cysts - A Finite Element Analysis of the Equine Stifle Joint** SB³C2016-922

Lance F. Frazer[1], Kenneth Fischer[2], Elizabeth Santschi[3], *[1]Bioengineering, University of Kansas, Lawrence, KS, United States, [2]Mechanical Engineering, University of Kansas, Lawrence, KS, United States, [3]Clinical Sciences, Kansas State University, Manhattan, KS, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

204 **Confined Compression of a Hydrogel Composite for Nucleus Pulposus Tissue Engineering** SB³C2016-932
Thomas R. Christiani[1], Rachel Adams[2], Erin Signor[3], Alex Crudo[4], Patrick Myers[4], Dan Collins[4], Kathryn Wrinn[4], Michael Arigot[4], Alexandra Guido[4], Jennifer Vernengo[2], Jennifer Kadlowec[4], *[1]Biomedical Engineering, Rowan University, Glassboro, NJ, United States, [2]Chemical Engineering, Rowan University, Glassboro, NJ, United States, [3]Civil Engineering, Rowan University, Glassboro, NJ, United States, [4]Mechanical Engineering, Rowan University, Glassboro, NJ, United States*

205 **Flow Field Post-repair in Critical Aortic Valve Stenosis : Implications to Recurring Disease State** SB³C2016-909
Sana Nasim[1], Glenda Castellanos[1], Angie Estrada[1], Denise Medina[1], Makensley Lordeus[1], Lilliam Valdes-Cruz[2], Steven Bibevski[2], Frank Scholl[2], Benjamin Bosel[1], Arvind Agarwal[1], Sharan Ramaswamy[1], *[1]Florida International University, Miami, FL, United States, [2]Joe DiMaggio's Children's Hospital, Hollywood, FL, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Masters Level Student Paper Competition II: Imaging - Devices - Human Dynamics & Injury - Fluids & Microfluidics - Heat Transfer — Exhibit Hall A

206 **Comprehensive Hemdodynamics of Living Donor Liver Transplant** SB³C2016-101
David R. Rutkowski[1, 2], Scott B. Reeder[2, 3, 4], Luis A. Fernandez[5], Alejandro Roldán-Alzate[1, 2], *[1]Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, United States, [2]Radiology, University of Wisconsin-Madison, Madison, WI, United States, [3]Medical Physics, University of Wisconsin-Madison, Madison, WI, United States, [4]Biomedical Engineering, University of Wisconsin-Madison, Madison, WI, United States, [5]Surgery, UW Hospital and Clinincs, Madison, WI, United States*

207 **Patient Specific Computational Models to Optimize Surgical Correction for Flatfoot Deformity** SB³C2016-923
Brian A. Smith, Robert Adelaar, Jennifer Wayne, *Biomedical Engineering, Virginia Commonwealth University, Richmond, VA, United States*

208 **Determination of HIFU Induced Temperature Rise at Focal Location Using Numerical Approach** SB³C2016-1066
Sai Sameer Paruchuri[1], Surendra B. Devarakonda[1], Seyed Ahmad Reza Dibaji[1], Matthew R. Myers[2], Rupak K. Banerjee[1], *[1]Department of Mechanical Engineering, University of Cincinnati, Cincinnati, OH, United States, [2]Division of Applied Mechanics, Center for Devices and Radiological Health, US Food and Drug Administration, Cincinnati, OH, United States*

209 **Reproducibility of Mouse Trabecular Bone Microstructure at Multiple Skeletal Sites by In Vivo Micro Computed Tomography Imaging** SB³C2016-655
Chih-Chiang Chang[1], Hongbo Zhao[2], Youwen Yang[1], Chantal M. J. de Bakker[1], Wei-Ju Tseng[2], X. Sherry Liu[1], *[1]Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [2]University of Pennsylvania, Philadelphia, PA, United States*

210 **Patient Specific In Vitro Models for Hemodynamic Analysis of Congenital Heart Disease - Additive Manufacturing Approach** SB³C2016-757
Rafael Medero[1, 2], Sylvana García-Rodríguez[2], Christopher J. François[2], Alejandro Roldán-Alzate[1, 2], Petros V. Anagnostopoulos[3], *[1]Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, United States, [2]Radiology, University of Wisconsin-Madison, Madison, WI, United States, [3]Pediatric Cardiothoracic Surgery, University of Wisconsin-Madison, Madison, WI, United States*

211 **Drill-Specific Head Impact Exposure in Youth Football Practice** SB³C2016-814
Eamon Campolettano, Steve Rowson, Stefan Duma, *Virginia Tech, Blacksburg, VA, United States*

212 **The Food and Drug Administration's Nozzle Benchmark: In Theory, There is No Difference Between Theory and Practise. But, in Practice, There is.** SB³C2016-580
Aslak Bergersen[1], Mikael Mortensen[2], Kristian Valen-Sendstad[1], *[1]Simula Research Laboratory, Lysaker, Norway, [2]Department of Mathematics, University of Oslo, Oslo, Norway*

213 **Laboratory Evaluation of Wearable Head Impact Sensors** SB³C2016-887
Abigail M. Tyson, Steven Rowson, Stefan M. Duma, *Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

214 **Biomechanical Comparison of Youth and Adult Football Helmets: Standards Testing** SB³C2016-80
David W. Sproule, Steven Rowson, *Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, United States*

215 **Investigation of Flow Instability with Vascular Geometry at the Bifurcation of Middle Cerebral Arteries From Healthy Volunteers** SB³C2016-1106
Takuma Murayoshi[1], Takanobu Yagi[1, 2], Yasutaka Tobe[1], Kenta Suto[1], Kiyofumi Alex Takanishi[1], Mitsuo Umezu[1], Hirotaka Yoshida[3], Kazutoshi Nishitani[3], Yoshifumi Okada[3], Shigemi Kitahara[3], *[1]Center for Advanced Biomedical science (TWIns), Waseda University, Tokyo, Japan, [2]EBM corporation, Tokyo, Japan, [3]Kitahara International Hospital, Tokyo, Japan*

216 **Performance of Three Variable-length Intramedullary Nails: The Effect of the Length-adjustment Mechanism** SB³C2016-627
Mark Hedgeland[1], Alexander Martin Clark[2], Laurel Kuxhaus[1], *[1]Clarkson University, Potsdam, NY, United States, [2]Canton-Potsdam Hospital, Potsdam, NY, United States*

217 **A Phenomenological Model of Damage and Recovery in the Intervertebral Disc of the Cervical Spine due to Cyclic Loading** SB³C2016-928
Shruti Motiwale[1], Xianlin Zhou[2], Reuben H. Kraft[1], *[1]Department of Mechanical and Nuclear Engineering, The Pennsylvania State University, University Park, PA, United States, [2]CFD Research Corporation, Huntsville, AL, United States*

218 **Study of the Consistency of Wall Shear Stress in Healthy Major Human Cerebral Arteries** SB³C2016-1034
Kiyofumi A. Takanishi[1], Takanobu Yagi[1], Takuma Murayoshi[1], Kenta Suto[1], Mitsuo Umezu[1], Hiroki Yoshida[2], Kazutoshi Nishitani[2], Yoshifumi Okada[2], Yoshimi Kitahara[2], Akihide Yamamoto[3], Hidehiro iida[3], Hiroharu Kataoka[3], *[1]Center for Advanced Biomedical Science (TWIns), Waseda University, Tokyo, Japan, [2]Kitahara International Hospital, Tokyo, Japan, [3]National cerebral and cardiovascular centre, Osaka, Japan*

219 **A Finite Element Analysis of Augmented Glenoid Components** SB³C2016-15
Nikolas K. Knowles, G. Daniel G. Langohr, Louis M. Ferreira, George S. Athwal, *Biomedical Engineering, The University of Western Ontario, London, ON, Canada*

220 **Development of a Novel Fistula Occlusion Device** SB³C2016-584
Alyssa K. Rollando[1], Sara E. Wilson[2], Stephen C. Waller[3], Richard Gilroy[4], James M. Stiles[5], *[1]Bioengineering Graduate Program, University of Kansas, Lawrence, KS, United States, [2]Department of Mechanical Engineering, University of Kansas, Lawrence, KS, United States, [3]Department of Internal Medicine, University of Kansas Medical Center, Kansas City, KS, United States, [4]Department of Gastroenterology, Hepatology and Motility, University of Kansas Medical Center, Kansas City, KS, United States, [5]Department of Electrical Engineering and Computer Science, University of Kansas, Lawrence, KS, United States*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I — Cardiovascular Tissue Mechanics — Exhibit Hall A

227 **The Effect of Electropotenital on Nitinol Fatigue Life** SB³C2016-626
Shiril Sivan[1, 2], Matthew A. Di Prima[1], Jason D. Weaver[1], *[1]CDRH OSEL DAM, FDA, Silver Spring, MD, United States, [2]Oak Ridge Institute of Science and Education, Oak Ridge, TN, United States*

228 **Right Ventricular Adaptation to Pressure Overload Conditions in Mice** SB³C2016-652
Tik Chee Cheng[1], Diana Tabima[1], Zhijie Wang[1], Tim Hacker[2], Naomi Chesler[1, 2], *[1]Biomedical Engineering, University of Wisconsin-Madison, Madison, WI, United States, [2]Medicine, University of Wisconsin-Madison, Madison, WI, United States*

229 **Measurement of Aortic Stent Graft Coefficients of Friction** SB³C2016-60
Matthew G. Doyle[1, 2], Michael Lancaster[1], Leonard W. Tse[2], Thomas L. Forbes[2], Cristina H. Amon[1, 3], *[1]Department of Mechanical and Industrial Engineering, University of Toronto, Toronto, ON, Canada, [2]Division of Vascular Surgery, University of Toronto, Toronto, ON, Canada, [3]Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

230 **Effect of Sodium Hypochlorite on the Fatigue Performance and Corrosion Resistance of Nitinol Wires** SB³C2016-622
Erick J. Gutierrez[1, 2], Srinidhi Nagaraja[1], Shiril Sivan[1, 2], Jason D. Weaver[1], Matthew Di Prima[1], *[1]Center for Devices and Radiological Health, U.S. Food and Drug Administration, Silver Spring, MD, United States, [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN, United States*

231 **Integration of Opencascade and Improved Global Surface Interpolation Methods into Simvascular 2.0** SB³C2016-924
Adam R. Updegrove[1], Nathan M. Wilson[2], Shawn C. Shadden[1], *[1]Mechanical Engineering, University of California, Berkeley, Berkeley, CA, United States, [2]Open Source Medical Software Corporation, Santa Monica, CA, United States*

232 **Modelling the Evolution of Smooth Muscle Cell Stress Fibres following Stent Deployment in an Artery** SB³C2016-1065
Catherine A. O'Connor, Noel H. Reynolds, Patrick McGarry, *Biomedical Engineering, National University of Ireland, Galway, Galway, Ireland*

233 **Evaluating Left Ventricular Function Using Cardiac and Respiratory-Gated Volumetric Murine Ultrasound** SB³C2016-776
Arvin H. Soepriatna[1], Frederick W. Damen[1, 2], Pavlos P. Vlachos[1, 3], Craig J. Goergen[1], *[1]Weldon School of Biomedical Engineering, Purdue University, West Lafayette, IN, United States, [2]School of Medicine, Indiana University, Indianapolis, IN, United States, [3]Department of Mechanical Engineering, Purdue University, West Lafayette, IN, United States*

234 **Computational Analysis of Right-ventricular Fiber Distribution as a Compensatory Mechanism During Pressure Overload** SB³C2016-995
Arnold David Gomez[1], Huashan Zou[1], Osama M. Abdullah[1], Megan E. Bowen[2], Xiaoquing Liu[2], David A. Bull[2], Edward W. Hsu[1], Stephen H. McKellar[2], *[1]Bioengineering, University of Utah, Salt Lake City, UT, United States, [2]Division of Cardiothoracic Surgery, University of Utah, Salt Lake City, UT, United States*

235 **Image-Based Computational Modeling of the Ventricular Mechanics in Patients with Pulmonary Hypertension** SB³C2016-27
Ce Xi[1], Xiaodan Zhao[2], Liang Zhong[2], Martin Genet[3], Lik Chuan Lee[1], *[1]Michigan State Universiy, East lansing, MI, United States, [2]National Heart Center, Singapore, Singapore, [3]*École Polytechnique, Paris, France

236 **Comparison of Material Properties between the Main and Left Pulmonary Arteries of Congenital Heart Disease Subjects Using Cardiac Magnetic Resonance: A Feasibility Study** SB³C2016-990
Gavin A. D'Souza[1], Michael D. Taylor[2], Namheon Lee[2], Rupak K. Banerjee[1], *[1]Department of Mechanical and Materials Engineering, University of Cincinnati, Cincinnati, OH, United States, [2]The Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States*

237 **Decreased Wall Shear Stress in Isolated Regions of the Pulmonary Endothelium Could Impact Pulmonary Vascular Dysfunction on a Global and Cellular Level in Pulmonary Hypertension** SB³C2016-875
Vitaly O. Kheyfets[1], Michal Schafer[1], Joyce D. Schroeder[1], Jamie Dunning[1], Chris Podgprski[2], James Browning[3], Jean Hertzberg[3], Kendall Hunter[1], Kern Buckner[2], Robin Shandas[1], Brett Fenster[2], *[1]Bioengineering/Medicine, University of Colorado Denver|Anschutz Medical Campus, Denver, CO, United States, [2]Cardiology, National Jewish Health, Denver, CO, United States, [3]Mechanical Engineering, University of Colorado Boulder, Boulder, CO, United States*

238 **In Vitro Studies on Native to Engineered Heart Valve Tissue Integration** SB³C2016-938
Kristin Comella, Danique Stewart, Sasmita Rath, Sharan Ramaswamy, *Biomedical Engineering, Florida International University, Miami, FL, United States*

239 **Mathematical Modeling of Fluid--Structure Interaction in Bioprosthetic Heart Valves: Numerical Approximation and Experimental Validation** SB³C2016-1069
David Kamensky[1], Ming-Chen Hsu[2], John G. Lesicko[1], Mitchell A. Katona[1], Jordan L. Graves[1], Samuel J. Petter[1], Thomas J. R. Hughes[1], Michael S. Sacks[1], *[1]Institute for Computational Engineering and Sciences, University of Texas at Austin, Austin, TX, United States, [2]Mechanical Engineering, Iowa State University, Ames, IA, United States*

240 **In-vivo Analysis and Residual Strains in Semilunar Heart Valves** SB³C2016-905
Ankush Aggarwal[1, 2], Alison Pouch[3], Eric Lai[3], John Lesicko[2], Joseph H. Gorman[3], Robert C. Gorman[3], Michael S. Sacks[2], *[1]Swansea University, Swansea, United Kingdom, [2]University of Texas at Austin, Austin, TX, United States, [3]University of Pennsylvania, Philadelphia, PA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

241 **Multi-resolution Models of the Mitral Valve Leaflets for High Fidelity Biomechanical Simulations** SB³C2016-921
Amir H. Khalighi[1], Andrew Drach[2], Charles Bloodworth[3], Eric L. Pierce[3], Ajit P. Yoganathan[3], Robert C. Gorman[4], Joseph H. Gorman[4], Michael S. Sacks[5], *[1]Mechanical Engineering, University of Texas at Austin, Austin, TX, United States, [2]Instituite for Computational Engineering and Sciences, University of Texas at Austin, Austin, TX, United States, [3]Georgia Institute of Technology, Atlanta, GA, United States, [4]Gorman Cardiovascular Research Group, University of Pennsylvania, Philadelphia, PA, United States, [5]Biomedical Engineering, University of Texas at Austin, Austin, TX, United States*

242 **Determination of the Tensile Mechanical Properties of the Segmented Tricuspid Valve Annulus** SB³C2016-759
Fatima Al-Quaiti[1], Evelia Salinas[1], Lori Boies[1], Edward Sako[2], Shamik Bhattacharya[1], *[1]Engineering, St.Mary's University, San Antonio, TX, United States, [2]University of Texas Health Science Center at San Antonio, San Antonio, TX, United States*

243 **Inverse Modeling Based Estimation of In-vivo Stresses and Their Relation to Simulated Layer-specific Interstitial Cell Deformations in the Mitral Valve** SB³C2016-114
Chung-Hao Lee[1], Kristen Feaver[1], Will Zhang[1], Robert C. Gorman[2], Joseph H. Gorman[2], Michael S. Sacks[1], *[1]Institute for Computational Engineering and Sciences, Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States, [2]Gorman Cardiovascular Research Group, University of Pennsylvania, Philadelphia, PA, United States*

244 **Mitral Valve Leaflet Remodeling During Pregnancy: Implications for Modeling Valvular Adaptation** SB³C2016-803
Bruno V. Rego[1], Sarah M. Wells[2], Michael S. Sacks[1], *[1]Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States, [2]Biomedical Engineering, Dalhousie University, Halifax, NS, Canada*

THURSDAY, JUNE 30 | 1:00pm - 3:15pm

Poster Session I | Injury | Exhibit Hall A

258 **Cervical Spine Forces and Disc Herniation Risk During Standardized Rear-End Impact Testing** SB³C2016-930
Keith Button, Stephanie Rossman, Brian Weaver, Steve Rundell, *Explico Engineering Company, Novi, MI, United States*

259 **Changes of Total Finger Forces Due to Emulating Finger Amputations Using a Cylinder Handle Device** SB³C2016-1085
Diego F. Villegas[1], Jorge H. Escobar[1], Ricardo A. Quiros[1], Edna R. Buitrago[2], Ivan D. Quintero[2], *[1]Mechanical Engineering Department, Universidad Industrial De Santader, Bucaramanga, Colombia, [2]School of Medicine, Universidad Industrial De Santader, Bucaramanga, Colombia*

260 **Biomechanical Properties of the Neonatal Brachial Plexus** SB³C2016-827
Anita Singh[1], Shania Shaji[1], Maria Delivoria[2], Malaeb Shadi[2], *[1]Biomedical Engineering, Widener, Chester, PA, United States, [2]Pediatrics, Obstet. & Gynecol., Drexel College of Medicine, Philadelphia, PA, United States*

261 **Pulmonary Contusion Modeling in Reconstructions of Frontal Motor Vehicle Collisions** SB³C2016-858
James P. Gaewsky, Derek A. Jones, Ashley A. Weaver, Joel D. Stitzel, *Center for Injury Biomechanics, Wake Forest University, Winston-Salem, NC, United States*

262 **Sensitive Injury Detection in the Cervical Spine Using Acoustic Emission** SB³C2016-1027
Jay K. Shridharani, Brian R. Bigler, Courtney A. Cox, Maria A. Ortiz-Paparoni, **Anna E. Knight**, Cameron R. 'Dale' Bass, *Biomedical Engineering, Duke University, Durham, NC, United States*

263 **Comparison of Computed Tomography Imaging Measurements to Created Injuries Under UBB Loading Conditions** SB³C2016-586
Nathanael P. Kuo, Christopher J. Dooley, Constantine K. Demetropoulos, Kyle A. Ott, Andrew C. Merkle, *Research and Exploratory Development Department, Johns Hopkins University Applied Physics Laboratory, Laurel, MD, United States*

264 **An Investigations of Human Long Bone Fracture Patterns During Traumatic Amputations From Moving Railroad Equipment** SB³C2016-1092
Brian T. Weaver[1, 2], Mark Davison[2], Steve Rundell[2], Eric Meyer[3], *[1]Orthopedics Biomechanics Laboratories, Michigan State University, East Lansing, MI, United States, [2]Explico Engineering Co., Novi, MI, United States, [3]Biomedical Engineering, Lawrence Technological University, East Lansing, MI, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

265 **Development of a Combat Helmet Suspension System Computational Model: Implications for Pad Design and Injury Outcome** SB³C2016-978
Connor Bradfield, Quang Luong, Brian DeVincentis, John Clark, Adam Golman, Catherine Carneal, *Johns Hopkins Applied Physics Lab, Laurel, MD, United States*

266 **Development and Parametric Study of a 3-year-old Child Abdominal Finite Element Model** SB³C2016-1014
Haiyan Li[1], Ruirui Lu[1], Shijie Ruan[1], Shihai Cui[1], Chunxiang Wang[2], *[1]Tianjin University of Science and Technology, Tianjin, China, [2]Tianjin Children's Hospital, Tianjin, China*

267 **Dynamic Bending Response of the Unrestrained Femur in Underbody Blast Loading** SB³C2016-1102
Joshua G. Chen, Gwansik Park, Edward M. Spratley, Robert S. Salzar, *Mechanical and Aerospace Engineering, University of Virginia, Charlottesville, VA, United States*

268 **Scaling between Human and Porcine Models for Traumatic Brain Injury** SB³C2016-154
Siddiq Qidwai[1], Robert Saunders[2], *[1]Multifunctional Materials Branch, Code 6350, US Naval Research Laboratory, Washington, DC, United States, [2]Leidos Corporation, Arlington, VA, United States*

269 **Validation of a Porcine Head and Upper Torso Model** SB³C2016-156
Robert Saunders[1], Siddiq Qidwai[2], *[1]Leidos Corporation, Arlington, VA, United States, [2]U.S. Naval Research Lab, Washington, DC, United States*

270 **The Effect of Limited Fractional Anisotropy Representation on Brain Injury Predictions** SB³C2016-157
Shankarjee Krishnamoorthi[1], **Siddiq Qidwai**[2], *[1]NRL/ASEE Postdoctoral Fellowship, US Naval Research Laboratory, Washington, DC, United States, [2]Multifunctional Materials Branch, US Naval Research Laboratory, Washington, DC, United States*

271 **Simple Geometric Scaling to Transform Cervical Spine Injury Criteria From Males to Females Adequate?** SB³C2016-907
Narayan Yoganandan[1], Frank Pintar[1], Cameron-Dale Bass[2], Maria Ortiz[2], Hattie Cutcliffe[2], Jonathan Rupp[3], Amanda Agnew[4], Ashley Weaver[5], Scott Gayzik[5], Liming Voo[6], *[1]Neurosurgery, Medical College of Wisconsin, Milwaukee, WI, United States, [2]Duke University, Durham, NC, United States, [3]University of Michigan, Ann Arbor, MI, United States, [4]Ohio State University, Columbus, OH, United States, [5]Wake Forest University School of Medicine, Winston-Salem, NC, United States, [6]John Hopkins University, Laurel, MD, United States*

272 **A Study on the Mechanical Response of the Human Head during Single-Collision Car Crashes using Finite Element Analysis** SB³C2016-979
Parker Berthelson, *Mississippi State University, Mississippi State, MS, United States*

273 **Computational Fluid Dynamics Predictions of Pressure Loading on the Human Head in a Laboratory-Based Blast Test Methodology** SB³C2016-1041
Rubbel Kumar[1], Catherine Carneal[1], Ashish Nedungadi[1], Marina Carboni[2], Jonathan Cyganik[2], Michael Maffeo[2], *[1]JHU/APL, Laurel, MD, United States, [2]NSRDEC, Natick, MA, United States*

274 **A Computational Model of the Eye for Primary Blast Injury** SB³C2016-709
Bahram Notghi[1], Rajneesh Bhardwaj[2], Thao D. Nguyen[1], *[1]Mechanical Engineering, John Hopkins University, Baltimore, MD, United States, [2]Department of Mechanical Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India*

275 **Sustained Presentation of Neurotrophic Cues Following Traumatic Brain Injury Through Matrix Immobilized BDNF Fragment Peptides** SB³C2016-738
Christopher J. Lowe, David I. Shreiber, *Biomedical Engineering, Rutgers, the State University of New Jersey, Piscataway, NJ, United States*

276 **Comparison of Validation Data for Finite Element Models of the Human Head** SB³C2016-1103
Logan E. Miller, *Biomedical Engineering, Virginia Tech-Wake Forest University School of Biomedical Engineering and Sciences, Winston-Salem, NC, United States*

277 **Uncertainty and Similarity in Brain Strains Resulting From Shape Variation in Head Rotational Velocity Profile** SB³C2016-68
Wei Zhao[1], Songbai Ji[1, 2], *[1]Thayer School of Engineering, Dartmouth College, Hanover, NH, United States, [2]Department of Surgery and of Orthopaedic Surgery, Dartmouth College, Hanover, NH, United States*

278 **Registration, Regional Identification and Transfer of Data From Mri Scans to Finite Element Models** SB³C2016-590
Shankarjee Krishnamoorthi, Siddiq Qidwai, *US Naval Research Laboratory, Washington, DC, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	3:15pm - 4:45pm

Musculoskeletal Tissue Engineering: Micro to Macro — Wilson B

Session Chair: Matt Fisher, *North Carolina State University, NC, United States*
Session Co-Chair: Mariana Kersh, *University of Illinois, Urbana, IL, United States*

3:15PM **Anchorage-Independent Priming Increases Chondrogenic Potential of Human Mesenchymal Stem Cells** SB³C2016-1005
Andrea R. Tan[1], Daniel S. Donovan[2], Gerard A. Ateshian[1], J. Chloe Bulinski[3], Clark T. Hung[1], *[1]Biomedical Engineering, Columbia University, New York, NY, United States, [2]Orthopedic Surgery, Mt. Sinai-Roosevelt, New York, NY, United States, [3]Biological Sciences, Columbia University, New York, NY, United States*

3:30PM **Mechanical Control of Endochondral Bone Regeneration by Engineered Chondrogenic Mesenchymal Condensates** SB³C2016-151
Anna M. McDermott[1], Samuel Herberg[2], Hope B. Pearson[1], Devon E. Mason[1], Eben Alsberg[2], **Joel B. Boerckel**[1], *[1]Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, United States, [2]Biomedical Engineering, Case Western Reserve University, Cleveland, OH, United States*

3:45PM **Tissue Engineering Platform for Molecular Manipulation of Tenogenesis** SB³C2016-612
Chun Chien[1], Brian Pryce[2], Sara F. Tufa[2], Douglas R. Keene[2], **Alice H. Huang**[1], *[1]Orthopaedics, Icahn School of Medicine at Mount Sinai, New York, NY, United States, [2]Shriners Hospital, Portland, OR, United States*

4:00PM **The Effect of Cell Density on Prestress Development in Engineered Microtissues** SB³C2016-120
Mathieu A. J. van Kelle, Sandra Loerakker, Carlijn V. C. Bouten, *Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands*

4:15PM **Microfluidic-fabrication of Bundled Cellular Scaffolds by Phaseseparated Polymer Solution** SB³C2016-1032
Yukiko T. Matsunaga, *Institute of Industrial Science, The University of Tokyo, Tokyo, Japan*

4:30PM **Variations in the Relative Size of the Cruciate Ligaments and Menisci in the Porcine Stifle Joint throughout Skeletal Growth** SB³C2016-694
Stephanie G. Cone[1], Hope E. Piercy[1], Lynn A. Fordham[2], Jorge A. Piedrahita[3], Jeffrey T. Spang[4], Matthew B. Fisher[1, 4], *[1]Department of Biomedical Engineering, North Carolina State University and University of North Carolina - Chapel Hill, Raleigh, NC, United States, [2]Department of Radiology, University of North Carolina - Chapel Hill, Chapel Hill, NC, United States, [3]College of Veterinary Medicine, North Carolina State University, Raleigh, NC, United States, [4]Department of Orthopaedics, University of North Carolina - Chapel Hill, Chapel Hill, NC, United States*

THURSDAY, JUNE 30	3:15pm - 4:45pm

Reproductive Biomechanics — Wilson C

Session Chair: Kristin Myers, *Columbia University, NY, United States*
Session Co-Chair: Kristin Miller, *Tulane University, LA, United States*

3:15PM **Mechanical Properties of Pregnant Cervix from Mouse Models of Infection-Mediated and Hormone-Mediated Preterm Birth** SB³C2016-1011
Kyoko Yoshida[1], Alexandra Willcockson[2], Shanmugasundaram Nallasamy[2], Mala Mahendroo[2], Kristin Myers[1], *[1]Mechanical Engineering, Columbia University, New York, NY, United States, [2]Obstetrics and Gynecology, UT Southwestern Medical Center, Dallas, TX, United States*

3:30PM **Nonlinear Creep Behavior of Uterosacral and Cardinal Ligaments** SB³C2016-855
Adwoa Baah-Dwomoh, Ting Tan, Raffaella De Vita, *Virginia Tech, Blacksburg, VA, United States*

3:45PM **Exploring Differences in the Tensile Response of the Pregnant and Non-pregnant Mouse Cervix** SB³C2016-902
Carrie E. Barnum[1], Jennifer L. Fey[1], Brianne K. Connizzo[1, 2], Snehal S. Shetye[1], Michal A. Elovitz[3], Louis J. Soslowsky[1], *[1]McKay Orthopaedic Research Laboratory, University of Pennsylvania, Philadelphia, PA, United States, [2]Department of Biological Engineering, Massachusetts Institute of Technology, Boston, MA, United States, [3]Maternal and Child Health Research Program, Department OBGYN, University of Pennsylvania, Philadelphia, PA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

4:00PM **Effect of Elastin Digestion on the Biaxial Mechanical Response of the Murine Vagina** SB³C2016-703
Katy M. Robison, Derek J. Bivona, Kristin S. Miller, *Biomedical Engineering, Tulane University, New Orleans, LA, United States*

4:15PM **How much Additional Maternal Spatial Capacity do Forceps Require When Delivering the Fetal Head During Vaginal Birth?** SB³C2016-775
Paige V. Tracy[1], John O. L. DeLancey[2], James A. Ashton-Miller[3], *[1]Biomedical Engineering, University of Michigan, Ann Arbor, MI, United States, [2]Obstetrics and Gynecology, University of Michigan, Ann Arbor, MI, United States, [3]Mechanical Engineering, Biomedical Engineering, University of Michigan, Ann Arbor, MI, United States*

4:30PM **Use Inverse Finite Element Method to Determine the Impairments in Pelvic Floor Support Structure in Women with Pelvic Organ Prolapse** SB³C2016-847
Mark T. Gordon[1], James A. Ashton-Miller[2], John O. L. DeLancey[3], Luyun L. Chen[2], *[1]Bioengineering and Mechanical Engineering, California Baptist University, Riverside, CA, United States, [2]Biomedical Engineering Department, University of Michigan, Ann Arbor, MI, United States, [3]Obstetrics and Gynecology Department, University of Michigan, Ann Arbor, MI, United States*

THURSDAY, JUNE 30 | 3:15pm - 4:45pm

Solid Mechanics: Growth and Remodeling — Wilson D

Session Chair: Sara Roccabianca, *Michigan State University, MI, United States*
Session Co-Chair: Lik Chuan Lee, *Michigan State University, MI, United States*

3:15PM **Adventitial Remodeling in Hypertension Leads to Aortic Maladaptation and Loss of Function** SB³C2016-840
Matthew R. Bersi[1], Chiara Bellini[1], Jing Wu[2], Kim R. C. Montaniel[2], David G. Harrison[2], Jay D. Humphrey[1], *[1]Biomedical Engineering, Yale University, New Haven, CT, United States, [2]Medicine and Pharmacology, Vanderbilt University, Nashville, TN, United States*

3:30PM **Effects of Hemodynamic Changes on the Developing Dorsal Aorta of the Chick Embryo** SB³C2016-99
Gabriela Espinosa, Larry Taber, **Jessica Wagenseil**, *Washington University in St. Louis, St. Louis, MO, United States*

3:45PM **Flow-Rate-Controlled Remodeling of Glomerular Capillaries** SB³C2016-829
Lazarina Gyoneva[1], **Daniel Goodman**[1], Yoav Segal[1, 2], Kevin D. Dorfman[1], Victor H. Barocas[1], *[1]University of Minnesota, Minneapolis, MN, United States, [2]VA Medical Center, Minneapolis, MN, United States*

4:00PM **A Comparison of Phenomenologic Growth Laws for Myocardial Hypertrophy** SB³C2016-161
Colleen M. Witzenburg, Jeffrey W. Holmes, *Biomedical Engineering, University of Virginia, Charlottesville, VA, United States*

4:15PM **Experimental Investigation of Functional Forms Required for Modeling Degrading Acellular Tissue Engineered Vascular Grafts in a Predictive Growth and Remodeling Framework** SB³C2016-780
Piyusha S. Gade[1], Keewon Lee[1], Blaise N. Pfaff[2], Yadong Wang[3], Anne M. Robertson[4], *[1]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States, [2]Department of Chemical Engineering, Pennsylvania State University, Philadelphia, PA, United States, [3]Department of Bioengineering, Chemical and Petroleum Engineering, Surgery, University of Pittsburgh, Pittsburgh, PA, United States, [4]Department of Mechanical Engineering and Materials Science, Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

4:30PM **Histological and Biomechanical analyses of Human Abdominal Aortic Aneurysms** SB³C2016-1044
Mirunalini Thirugnanasambandam[1], Karthik Mikkineni[2], Satish Muluk[2], Oluwaseun R. Adeyinka[1], Ender Finol[1], *[1]Department of Biomedical Engineering, University of Texas at San Antonio, San Antonio, TX, United States, [2]Division of Vascular Surgery, Allegheny Health Network, Pittsburgh, PA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	3:15pm - 4:45pm

Characterization of Cardiovascular Tissues — Annapolis 1

Session Co-Chair: Jonathan Wenk, *University of Kentucky, KY, United States*
Session Co-Chair: Hai-Chao Han, *UTSA, San Antonio, TX, United States*

3:15PM **A Multi-Scale Mechanical and Cellular Argument for the Differential Performance of Coronary Artery Bypass Grafts** SB³C2016-937

David A. Prim[1], Boran Zhou[1], Laurel Carter[2], Vinal Menon[3], Jay Potts[3], Tarek Shazly[1], John F. Eberth[3], *[1]Biomedical Engineering, University of South Carolina, Columbia, SC, United States, [2]University of South Carolina School of Medicine, Columbia, SC, United States, [3]Cell Biology and Anatomy, University of South Carolina School of Medicine, Columbia, SC, United States*

3:30PM **Is There a Critical Time Point for Antihypertensive Treatment? Embryonic Antihypertensive Treatment Alters Arterial Stiffness in Elastin Haploinsufficient Mice** SB³C2016-982

Jungsil Kim[1], Victoria Le[2], Robert Mecham[3], Jessica Wagenseil[1], *[1]Mechanical Engineering & Materials Science, Washington University in St. Louis, St. Louis, MO, United States, [2]Biomedical Engineering, University of Texas, Austin, TX, United States, [3]Cell Biology & Physiology, Washington University in St. Louis, St. Louis, MO, United States*

3:45PM **Anatomically-driven Multiscale Model of Ascending Thoracic Aorta, with Application to Multidirectional Experiments** SB³C2016-917

Rohit Y. Dhume[1], Christopher E. Korenczuk[2], Victor H. Barocas[2], *[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

4:00PM **The Mitral Valve Chordae Tendineae: A Topological And Geometric Analysis** SB³C2016-852

Amir H. Khalighi[1], Andrew Drach[2], Charles Bloodworth[3], Eric L. Pierce[3], Ajit Yoganathan[3], Robert C. Gorman[4], Joseph H. Gorman[4], Michael S. Sacks[2], *[1]Mechanical Engineering, University of Texas at Austin, Austin, TX, United States, [2]University of Texas at Austin, Austin, TX, United States, [3]Georgia Institute of Technology, Atlanta, GA, United States, [4]University of Pennsylvania, Philadelphia, PA, United States*

4:15PM **Quantification of Biventricular Myocardial Strains from Cine Magnetic Resonance Images of Pulmonary Hypertensive Patients Using Hyperelastic Warping** SB³C2016-25

Ce Xi[1], Xiaodan Zhao[2], Liang Zhong[2], Martin Genet[3], Lik Chuan Lee[4], *[1]Michigan State Universiy, East lansing, MI, United States, [2]National Heart Center, Singapore, Singapore,* [3]École Polytechnique, Paris, France, *[4]Michigan State University, East Lansing, MI, United States*

4:30PM **A Novel Numerical-Experimental Inverse Modeling Approach to Investigate the Time-Evolving Three-Dimensional Mechanical Properties of Infarcted Myocardium** SB³C2016-735

David S. Li[1], João S. Soares[1], John G. Lesicko[1], Reza Avazmohammadi[1], Joseph H. Gorman[2], Robert C. Gorman[2], Michael S. Sacks[1], *[1]Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States, [2]Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States*

THURSDAY, JUNE 30	3:15pm - 4:45pm

Physiological Valves — Annapolis 2

Session Chair: Michael Sacks, *University of Texas, Austin, TX, United States*
Session Co-Chair: Lakshmi P. D. Dasi, *Ohio State University, OH, United States*

3:15PM **Developing Computational Fluid-Structure Models for the Lymphatic Valve** SB³C2016-881

John T. Wilson[1], Lowell T. Edgar[1], Raoul van Loon[2], James E. Moore[1], *[1]Bioengineering, Imperial College London, London, United Kingdom, [2]Swansea University, Swansea, United Kingdom*

3:30PM **Blood Clotting Potential and Hemodynamic Analysis of a Superhydrophobic Bileaflet Mechanical Heart Valve** SB³C2016-901

David Bark[1], Hamed Vahabi[1], Hieu Bui[2], Sanli Movafaghi[1], Arun Kota[1], Ketul Popat[1], Lakshmi Prasad Dasi[1], *[1]Mechanical Engineering, Colorado State University, Fort Collins, CO, United States, [2]Biomedical Engineering, Colorado State University, Fort Collins, CO, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

3:45PM **FSI Simulation of Intraventricular Flow in a Patient-Specific Left Ventricular Model with both Mitral and Aortic Valves** SB³C2016-1121
Andres D. Caballero, Wenbin Mao, Wei Sun, *The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, United States*

4:00PM **A Robust Framework for Building Attribute-Rich FE Models of Mitral Valve from Medical Images** SB³C2016-1003
Andrew Drach[1], Amir H. Khalighi[2], Robert C. Gorman[3], Joseph H. Gorman[3], Ajit P. Yoganathan[4], Michael S. Sacks[5], *[1]Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX, United States, [2]Mechanical Engineering, The University of Texas at Austin, Austin, TX, United States, [3]Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, United States, [4]Cardiovascular Fluid Mechanics Laboratory, Georgia Institute of Technology, Atlanta, GA, United States, [5]Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States*

4:15PM **Computational Assessment of Hemodynamic Parameters of Bicuspid Aortic Valve Aortopathy** SB³C2016-57
Kai Cao[1], **Philippe Sucosky**[2], *[1]Department of Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, United States, [2]Department of Mechanical and Materials Engineering, Wright State University, Dayton, OH, United States*

4:30PM **Importance of Including Papillary Muscles and Trabeculae in Cardiac Flow Simulations** SB³C2016-86
Jonas Lantz, Lilian Henriksson, Anders Persson, Matts Karlsson, Tino Ebbers, *Linkoping university, Linkoping, Sweden*

THURSDAY, JUNE 30 | 3:15pm - 4:45pm

Trends, Tips, and Tricks in Biomechanical Engineering Education — Azalea 2

Session Chair: Sarah Kieweg, *University of Kansas, KS, United States*
Session Co-Chair: Kristen Billiar, *Worcester Polytechnic Institute, MA, United States*

3:15PM **Student Learning of Biomechanics Topics by Embedding "Quantified Self" Motivated Problem Based Learning Modules in Biomedical Engineering Courses** SB³C2016-1116
Eric G. Meyer, Mansoor Nasir, *Biomedical Engineering, Lawrence Technological University, Southfield, MI, United States*

3:30PM **Introduction to Finite Element Modeling in a Guided Project-based Approach to Biomechanics Research** SB³C2016-992
Alexander Kotelsky, Amy L. Lerner, *Biomedical Engineering, University of Rochester, Rochester, NY, United States*

3:45PM **A New Educational Approach to Teaching Science and Engineering for K-12 Students** SB³C2016-860
Kritsakorn Chaumpanich[1], Michelle Johnson[2], Yingcai Xiao[1], Philip A. Allen[3], **Yang H. Yun**[4], *[1]Computer Science, Univeristy of Akron, Akron, OH, United States, [2]PLTW Biomedical Science, North High School, Akron, OH, United States, [3]Psychology, Univeristy of Akron, Akron, OH, United States, [4]Biomedical Engineering, Univeristy of Akron, Akron, OH, United States*

4:00PM **A Course in Maker Activities for a Master of Engineering in Design and Commercialization** SB³C2016-688
Brandon Kirkland, Ophelia Johnson, **Alan Eberhardt**, *UAB, Birmingham, AL, United States*

4:15PM **Best Practices in teaching biomechanics: Connecting Biomechanics Beyond the Classroom** SB³C2016-575
Laurel Kuxhaus, *Clarkson University, Potsdam, NY, United States*

4:30PM **When Theatre comes to Capstone Design: Oh How Creative They can Be...** SB³C2016-805
Ferris Pfeiffer[1], Suzanne Burgoyne[2], Rachel E. Bauer[2], *[1]Bioengineering/Orthopaedic Surgery, University of Missouri, Columbia, MO, United States, [2]Theatre, University of Missouri, Columbia, MO, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

THURSDAY, JUNE 30	3:15pm - 4:45pm

Cancer and Tumor Microenvironment — Azalea 3

Session Chair: Sihong Wang, *City College of New York, NY, United States*
Session Co-Chair: Hai Wang, *The Ohio State University, OH, United States*

3:15PM **Investigation of Biotransport in a Tumor with Non-Homogeneous Permeability Using a Non-Intrusive Polynomial Chaos Approach** SB³C2016-785
Miao Lu[1], Liang Zhu[1], Ronghui Ma[1], Maher Salloum[2], Meilin Yu[1], *[1]Mechanical Engineering, University of Maryland, Baltimore County, Baltimore, MD, United States, [2]Sandia National Labs, Livermore, CA, United States*

3:30PM **Adhesion and Invasion of Circulating Cancer Cells on Inflamed Endothelium** SB³C2016-848
Taylor J. Thompson, **Bumsoo Han**, *Mechanical Engineering, Purdue University, West Lafayette, IN, United States*

3:45PM **A Near Infrared Laser-activated "Nanobomb" for Breaking the Barriers to MicroRNA Delivery** SB³C2016-133
Hai Wang, Xiaoming He, *Biomedical Engineering, The Ohio State University, Columbus, OH, United States*

4:00PM **Conformal Nanoencapsulation of Allogeneic T Cells Mitigate Graft-versus-Host Disease but Retain Graft-versus-Leukemia Activity** SB³C2016-718
Shuting zhao, Xiaoming He, *Biomedical Engineering, The Ohio State University, Columbus, OH, United States*

4:15PM **Monitoring Tumor Response to Therapeutic TR4 Fusion Protein via in vivo Imaging** SB³C2016-67
Marianna Prokopi[1], Costas Pitsillides[2], Mahendra Deonarain[3], Konstantinos Kapnisis[2], Spyros Stylianou[4], George Kousparos[5], Christina Kousparou[1], **Andreas Anayiotos**[2], Agamemnon Epenetos[1], *[1]Trojantec Ltd, Nicosia, Cyprus, [2]Mechanical and Materials Science and Engineering, Cyprus University of Technology, Limassol, Cyprus, [3]ShyDen Biotechnology Ltd, Stevenage, Herts, United Kingdom, [4]Translational Genetics Team, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus, [5]Frimley Park Hospital, NHS Foundation Trust, Surrey, United Kingdom*

4:30PM **Development of a Tissue Engineered 3D Microfluidic Tumor Platform to Study Nanoparticle Transport** SB³C2016-1100
Manasa Gadde[1], Matthew R. DeWitt[2], Marissa N. Rylander[3], *[1]Biomedical Engineering, University of Texas at Austin, Austin, TX, United States, [2]Virginia Tech-Wake Forest SBES, Virginia Tech, Blacksburg, VA, United States, [3]Mechanical Engineering, University of Texas at Austin, Austin, TX, United States*

FRIDAY, JULY 1	9:45am - 11:15am

PhD Competition: Signaling & Remodeling — Wilson B

Session Chair: Triantafyllos Stylianopolous, *University of Cyprus, Cyprus*
Session Co-Chair: Trevor Lujan, *Boise State, ID, United States*

9:45AM **Reproduction Induces Adaptation of the Maternal Skeleton and Alters Patterns of Postmenopausal Bone Loss** SB³C2016-138
Chantal M. J. de Bakker, Allison R. Altman-Singles, Wei-Ju Tseng, Laurel Leavitt, Connie Li, X. Sherry Liu, *Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, United States*

10:00AM **Local Changes to the Growth Plate in Response to Injury** SB³C2016-691
Lauren M. Mangano[1], Meghan E. Kupratis[1], Katie Li[1], Eric Rapp[2], Louis C. Gerstenfeld[3], Elise F. Morgan[1, 2, 3], *[1]Biomedical Engineering, Boston University, Boston, MA, United States, [2]Mechanical Engineering, Boston University, Boston, MA, United States, [3]Orthopaedic Surgery, Boston University, Boston, MA, United States*

10:15AM **Vascular Smooth Muscle Cell Mechano-Adaptation Laws** SB³C2016-159
Kerianne E. Steucke, Zaw Win, Emily E. Walsh, Taylor R. Stemler, Patrick W. Alford, *Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

10:30AM **Cadherin-11 Excacerbates Maladaptive Remodeling After Myocardial Infarction** SB³C2016-1080
Alison Schroer, W. David Merryman, *Vanderbilt University, Nashville, TN, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

10:45AM **Positive and Negative Cues for Modulating Neurite Dynamics and Receptor Expression to Improve Peripheral Nerve Regeneration** SB³C2016-611

Melissa R. Wrobel, Harini G. Sundararaghavan, *Biomedical Engineering, Wayne State University, Detroit, MI, United States*

11:00AM **The RhoA/ROCK Pathway Mediates Nociceptive Signaling After Painful Ligament Loading** SB³C2016-32

Sijia Zhang, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

FRIDAY, JULY 1 | 9:45am - 11:15am

PhD Competition: Mechanosensing & Mechanics — Wilson C

Session Chair: Corinne Henak, *Wisconsin, WI, United States*
Session Co-Chair: Andrew Kemper, *Virginia Tech, VA, United States*

9:45AM **Chondrocyte Death and Mitochondrial Dysfunction are Mediated by Cartilage Friction and Shear Strain** SB³C2016-807

Edward D. Bonnevie[1], Michelle L. Delco[2], Naveen Jasty[1], Lena R. Bartell[3], Lisa A. Fortier[2], Itai Cohen[3], Lawrence J. Bonassar[1, 4], *[1]Mechanical Engineering, Cornell University, Ithaca, NY, United States, [2]Comparative Biomedical Sciences, Cornell University, Ithaca, NY, United States, [3]Applied Engineering Physics, Cornell University, Ithaca, NY, United States, [4]Biomedical Engineering, Cornell University, Ithaca, NY, United States*

10:00AM **Direct Osmotic Pressure Measurements in Articular Cartilage Demonstrate Non-Ideal and Concentration-Dependent Phenomena** SB³C2016-1010

Brandon K. Zimmerman[1], Robert J. Nims[2], Clark T. Hung[2], Gerard A. Ateshian[1, 2], *[1]Mechanical Engineering, Columbia University, New York, NY, United States, [2]Biomedical Engineering, Columbia University, New York, NY, United States*

10:15AM **N-Cadherin Adhesive Interactions Modulate ECM Mechanosensing and Fate Commitment in Mesenchymal Stem Cells** SB³C2016-640

Brian D. Cosgrove[1, 2, 3], Keeley L. Mui[4], Tristan P. Driscoll[1, 2], Steven R. Caliari[1, 3], Richard K. Assoian[4], Jason A. Burdick[1, 3], Robert L. Mauck[1, 2, 3], *[1]Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [2]Orthopedic Surgery, University of Pennsylvania, Philadelphia, PA, United States, [3]Translational Musculoskeletal Research Center, Philadelphia VA Medical Center, Philadelphia, PA, United States, [4]Pharmacology, University of Pennsylvania, Philadelphia, PA, United States*

10:30AM **A Multiphysics Model of the Pacinian Corpuscle** SB³C2016-95

Julia C. Quindlen[1], Henryk K. Stolarski[2], Martha Flanders[3], Victor H. Barocas[1], *[1]Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Civil Engineering, University of Minnesota, Minneapolis, MN, United States, [3]Neuroscience, University of Minnesota, Minneapolis, MN, United States*

10:45AM **Molecular Level Detection and Quantification of Collagen Mechanical Damage Using Collagen Hybridizing Peptides** SB³C2016-809

Jared L. Zitnay[1, 2], Yang Li[1], Zhao Qin[3], Baptiste Depalle[3], Shawn P. Reese[1, 2], Markus J. Buehler[3], S. Michael Yu[1], Jeffrey A. Weiss[1, 2, 4], *[1]Bioengineering, University of Utah, Salt Lake City, UT, United States, [2]Scientific Computing and Imaging Institute, University of Utah, Salt Lake City, UT, United States, [3]Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States, [4]Orthopaedics, University of Utah, Salt Lake City, UT, United States*

11:00AM **Collagen Degradation Alters Failure Properties & Matrix Reorganization During Tensile Loading** SB³C2016-92

Meagan Ita, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

FRIDAY, JULY 1	9:45am - 11:15am

PhD Competition: Tissue Mechanics & Modeling — Wilson D

Session Chair: Roger Haut, *Michigan State University, MI, United States*
Session Co-Chair: Megan Killian, *University of Delaware, DE, United States*

9:45AM **Multiscale Mechanics of Human Supraspinatus Tendon in Shear after Proteoglycan Depletion** SB³C2016-72
Fei Fang[1], Spencer P. Lake[1, 2, 3], *[1]Mechanical Engineering & Materials Science, Washington University in St. Louis, St. Louis, MO, United States, [2]Department of Biomedical Engineering, Washington University in St. Louis, St. Louis, MO, United States, [3]Department of Orthopaedic Surgery, Washington University in St. Louis, St. Louis, MO, United States*

10:00AM **Subject-specific vs. Averaged Structural Models of the Collagen Network in the Lumbar Facet Capsular Ligament** SB³C2016-918
Vahhab Zarei[1], Amy A. Claeson[2], Chao Liu[2], Taner Akkin[2], Victor H. Barocas[2], *[1]Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

10:15AM **Dynamic Imaging of Tendon Tissue Stress** SB³C2016-1042
Jack A. Martin[1], Alexander C. Ehlers[2], James R. Hermus[2], Matthew S. Allen[3], Daniel J. Segalman[3], Darryl G. Thelen[4], *[1]Materials Science Program, University of Wisconsin-Madison, Madison, WI, United States, [2]Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, WI, United States, [3]Department of Engineering Physics, University of Wisconsin-Madison, Madison, WI, United States, [4]Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, United States*

10:30AM **Tsai-Hill Maximum-Work Theory as a Failure Criterion for Fibrous Biological Tissues** SB³C2016-689
Christopher E. Korenczuk, Victor H. Barocas, *Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

10:45AM **Remodeling by Fibroblasts Alters the Rate-dependent Mechanical Properties of Collagen** SB³C2016-894
Behzad Babaei[1], Ali Davarian[2], Kenneth M. Pryse[2], William B. McConnaughey[2], Elliot L. Elson[2], Guy M. Genin[1], *[1]Department of Mechanical Engineering & Materials Science, Washington University in St. Louis, St. Louis, MO, United States, [2]Department of Biochemistry & Molecular Biophysics, Washington University in St. Louis, St. Louis, MO, United States*

11:00AM **A Permanent Set Constitutive Model for Exogenously Cross-linked Collagenous Tissues** SB³C2016-954
Will Zhang[1], Hobey Tam[2], Wei Sun[3], Naren Vyavahare[2], Michael S. Sacks[1], *[1]Department of Biomedical Engineering, Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX, United States, [2]Department of Bioengineering, Clemson University, Clemson, SC, United States, [3]Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States*

FRIDAY, JULY 1	9:45am - 11:15am

PhD Competition: Biomechanics of Injury — Annapolis 1

Session Chair: Brittany Coats, *University of Utah, UT, United States*
Session Co-Chair: Lakiesha Williams, *MIssissippi State, MS, United States*

9:45AM **Coronal Head Rotation and Rapid Corpus Callosum Tract Strain in Sports-Related Mild Traumatic Brain Injury** SB³C2016-971
Fidel Hernandez[1], Chiara Giordano[2], Svein Kleiven[2], David Camarillo[1, 3], *[1]Department of Mechanical Engineering, Stanford University, Stanford, CA, United States, [2]Department of Neuronic Engineering, KTH Royal Institute of Technology, Stockholm, Sweden, [3]Department of Bioengineering, Stanford University, Stanford, CA, United States*

10:00AM **Differences in the Ability of Bicycle Helmets to Reduce Risk of Head Injury** SB³C2016-1090
Megan L. Bland, Steven Rowson, *Virginia Tech, Blacksburg, VA, United States*

10:15AM **Spatio-Temporal Quantification of Cartilage Structural Changes in a Murine Model of Post-Traumatic Osteoarthritis** SB³C2016-966
Michael A. David, Avery T. White, Rachael Pilachowski, Ryan C. Locke, Melanie K. Smith, Christopher Price, *Biomedical Engineering, University of Delaware, Newark, DE, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

10:30AM **Principal Component Analysis of Friction Force Hysteresis Curves for Detecting Fatigue Failure and Generating Frictional S-N Curves for Articular Cartilage** SB³C2016-1071

Krista M. Durney[1], Robert J. Nims[1], James F. Boorman-Padgett[2], Jason T. Suh[1], Hyeon Jin Koo[1], Polina V. Smirnova[1], Gregory T. Salamone[1], Brian K. Jones[2], Sevan R. Oungoulian[2], Clark T. Hung[1], Gerard A. Ateshian[1, 2], *[1]Biomedical Engineering, Columbia University, New York, NY, United States, [2]Mechanical Engineering, Columbia University, New York, NY, United States*

10:45AM **Experimental Biomechanics of the Anterior Cruciate Ligament: Hyperelasticity and Viscoelasticity** SB³C2016-1063

Kaitlyn Mallett[1], Ellen M. Arruda[2], *[1]Mechanical Engineering, University of Michigan, Ann Arbor, MI, United States, [2]Mechanical Engineering, Biomedical Engineering, Program in Macromolecular Science and Engineering, University of Michigan, Ann Arbor, MI, United States*

11:00AM **Alterations in the Anterior Capsule Correlate with Impaired Joint Mechanics in a Rat Elbow Model of Post-Traumatic Joint Stiffness** SB³C2016-618

Chelsey Dunham[1], Ryan Castile[1], Leesa Galatz[2], Spencer Lake[1], *[1]Washington University in St. Louis, St. Louis, MO, United States, [2]Mount Sinai, New York, NY, United States*

FRIDAY, JULY 1 | 9:45am - 11:15am

PhD Competition: Cardiac & Vascular — Annapolis 2

Session Chair: Daniela Valdez-Jasso, *UI Chicago, IL, United States*
Session Co-Chair: Will Richardson, *Clemson, SC, United States*

9:45AM **Cellular Architecture Dictates Anisotropic Mechanical Properties of Vascular Smooth Muscle Cells** SB³C2016-629

Zaw Win, Justin M. Buksa, Patrick W. Alford, *Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

10:00AM **Analysis of Chromatin Mechanics During Cardiomyocyte Contraction Using Nuclear Spatial Strain Maps Reveals New Protective Mechanism** SB³C2016-751

Benjamin Seelbinder[1], Soham Ghosh[1], Sarah Calve[2], Corey P. Neu[1, 2], *[1]Mechanical Engineering, Universtiy of Colorado Boulder, Boulder, CO, United States, [2]Biomedical Engineering, Purdue University, West Lafayette, IN, United States*

10:15AM **Acute Effects of Cell Free Hemoglobin and Sickled Red Blood Cells on Pulmonary Vascular Impedance in Otherwise Healthy Mice** SB³C2016-772

David A. Schreier[1], Timothy Hacker[2], Diana Tabima[1], Naomi C. Chesler[1], *[1]Biomedical Engineering, University of Wisconsin-Madison, Madison, WI, United States, [2]Medicine, University of Wisconsin-Madison, Madison, WI, United States*

10:30AM **Virtual Evaluation of Surgical Revascularization Techniques in Coronary Artery Bypass Surgery** SB³C2016-904

Abhay B. Ramachandra[1, 2], Christopher Jensen[3], Andrew B. Goldstone[3], Joseph Y. Woo[3], Jack H. Boyd[3], Andrew Kahn[4], Alison Marsden[2], *[1]Department of Mechanical and Aerospace Engineering, University of California San Diego, La Jolla, CA, United States, [2]Institute for Computational and Mathematical Engineering, Department of Pediatric Cardiology, Stanford University, Stanford, CA, United States, [3]Department of Cardiothoracic Surgery, Stanford University, Stanford, CA, United States, [4]Department of Medicine, University of California San Diego, La Jolla, CA, United States*

10:45AM **Computation Investigation of Hydrogel Injection Characteristics for Myocardial Support** SB³C2016-94

Hua Wang[1], Christopher Rodell[2], Mandonna Lee[3], Neville Dusaj[4], Jason Burdick[2], Robert Gorman[3], Jonathan Wenk[1, 5], *[1]Department of Mechanical Engineering, University of Kentucky, Lexington, KY, United States, [2]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [3]Gorman Cardiovascular Research Group, University of Pennsylvania, Philadelphia, PA, United States, [4]Department of Chemistry and Physics, University of Pennsylvania, Philadelphia, PA, United States, [5]Department of Surgery, University of Kentucky, Lexington, KY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

11:00AM **Contribution of Glycosaminoglycans to Extracellular Matrix Fiber Recruitment and Arterial Wall Mechanics** SB³C2016-104

Jeffrey Mattson[1], Raphaël Turcotte[2, 3], Yanhang Zhang[1, 2], *[1]Mechanical Engineering, Boston University, Boston, MA, United States, [2]Biomedical Engineering, Boston University, Boston, MA, United States, [3]Center for Systems Biology, Advanced Microscopy Program, Wellman Center for Photomedicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States*

FRIDAY, JULY 1	9:45am - 11:15am

Undergraduate Design Competition - Rehabilitation & Assistive Devices

Azalea 2

Session Chair: Tamara Bush, *Michigan State University, MI, United States*
Session Co-Chair: Nicole Corbiere, *Clarkson University, NY, United States*

9:45AM **Substitute Voice Production via a Mechanically-Driven Arti icial Larynx** SB³C2016-130

Michael R. Baldwin[1], Kateri A. Kaminski[1], Janet A. Hrdina[1], Evan T. Cody[2], Erik A. Gillespie[1], Tyler T. Tuttle[1], **Byron D. E. Erath**[1], *[1]Mechanical and Aeronautical Engineering, Clarkson University, Potsdam, NY, United States, [2]School of Business, Clarkson University, Potsdam, NY, United States*

10:00AM **Wireless Instrumented Cane** SB³C2016-1095

Me'Lanae Garrett[1], Binod Shilpakar[1], Joel A. Whitney[1], Jon T. E. Williams[1], Radhakrishnan Srinivasan[2], Lakiesha Williams[2], *[1]Agricultural and Biological Engineering, Mississippi State University, Starkville, MS, United States, [2]Agricultural and Biological Engineering, Mississippi State University, Mississippi State, MS, United States*

10:15AM **Intrahospital Assistive Transportation Device for Mechanically Ventilated Pediatric Patients** SB³C2016-1047

Allison Fetz, Elysia Masters, Ravi Patel, Ameen Ozrail, John Williams, Gary Bowlin, Maris Brown, *Biomedical Engineering, University of Memphis, Memphis, TN, United States*

10:30AM **Adaptable, Affordable, and Reusable Interim Prosthetic Leg Solution in Response to Recent Medicare Coverage Changes** SB³C2016-615

Jason A. Shar, Andrew M. Milhoan, Nathan F. Levengood, Joshua Gargac, Matthew Volansky, *Mechanical Engineering, University of Mount Union, Alliance, OH, United States*

10:45AM **Improved Ankle Foot Orthosis for Clubfoot Treatment** SB³C2016-574

Angela Guardia[1], Alissa Adams[1], Brianna Bruni-Bossio[1], Alberto Palomino[1], Rex Wu[1], Kajsa Duke[2], *[1]Mechanical Engineering, University of Alberta, Edmonton, AB, Canada, [2]Mechanical Engineering - Biomedical Option, University of Alberta, Edmonton, AB, Canada*

11:00AM **Reaching Aid for Spinal Fusion Recipients** SB³C2016-834

Bijal Patel, **Casey K. Schiner**, Celia M. Staniak, Maryssa Mercer, Michele Grimm, Brian Mundo, *Wayne State University, Detroit, MI, United States*

FRIDAY, JULY 1	9:45am - 11:15am

PhD Competition: Devices, Microfluidics and Sensing

Azalea 3

Session Chair: James Baish, *Bucknell University, PA, United States*
Session Co-Chair: Luke Herbertson, *FDA, DC, United States*

9:45AM **Programming 'On-Demand' Delivery From Mechanically-Activated Microcapsules** SB³C2016-134

Bhavana Mohanraj, Miju Kim, Daeyeon Lee, George R. Dodge, Robert L. Mauck, *University of Pennsylvania, Philadelphia, PA, United States*

10:00AM **Analysis of Cell Spreading on Micropatterned Substrates using a Thermodynamically Consistent Non-Local Active Formulation** SB³C2016-1015

Eoin McEvoy[1], Tommaso Ristori[2], Sandra Loerakker[2], Vikram S. Deshpande[3], Patrick McGarry[1], *[1]Biomedical Engineering, National University of Ireland Galway, Galway, Ireland, [2]Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands, [3]Engineering, University of Cambridge, Cambridge, United Kingdom*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

10:15AM **An Experimental Canine Patent Ductus Arteriosus Occluder Based on Shape Memory Polymer Foam in a Nitinol Cage** SB³C2016-21
Mark A. Wierzbicki, Bradley H. Due, Landon D. Nash, Brandis Keller, Sonya G. Gordon, Matthew W. Miller, Duncan J. Maitland, *Texas A&M University, College Station, TX, United States*

10:30AM **Microfluidics for the Study of Oxygen Gradients at the Maternal Fetal Interface** SB³C2016-794
Yassen Abbas[1, 2], Carolin Oefner[2, 3], Graham J. Burton[2, 4], Ashley Moffett[2, 3], Michelle L. Oyen[1, 2], *[1]Engineering, University of Cambridge, Cambridge, United Kingdom, [2]Centre for Trophoblast Research, University of Cambridge, Cambridge, United Kingdom, [3]Pathology, University of Cambridge, Cambridge, United Kingdom, [4]Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom*

10:45AM **Thermal Contrast Amplification (TCA) Readers Improve the Limit of Detection for Influenza and Malaria Lateral Flow Assays** SB³C2016-1056
Yiru Wang[1], Zhenpeng Qin[1, 2], David Boulware[3], Iveth J. González[4], David Bell[3, 5], Warren Chan[6], Peter Chiodini[7], Roxanne Rees-Channer[7], John C. Bischof[1], *[1]Department of Mechanical Engineering, University of Minnesota - Twin Cities, Minneapolis, MN, United States, [2]University of Texas at Dallas, Richardson, TX, United States, [3]Department of Medicine Infectious Diseases and International Medicine, University of Minnesota - Twin Cities, Minneapolis, MN, United States, [4]Foundation for New Innovative Diagnosis, Geneva, Switzerland, [5]Global Good Fund, Bellevue, WA, United States, [6]Department of Chemistry, University of Toronto, Toronto, ON, Canada, [7]Hospital for Tropical Disease, University College London, London, United Kingdom*

11:00AM **Error and Uncertainty Quantification of a Commercial CFD Solver in an Intracranial Anenrusym** SB³C2016-1074
Nicole Varble[1, 2], Nikhil Paliwal[1, 2], Jianping Xiang[2, 3], Kristian Debus[4], Hui Meng[1, 2, 5], *[1]Mechanical and Aerospace Engineering, SUNY University at Buffalo, Buffalo, NY, United States, [2]Toshiba Stroke and Vascular Research Center, Buffalo, NY, United States, [3]Neurosurgery, SUNY University at Buffalo, Buffalo, NY, United States, [4]CD-adapco, Melville, NY, United States, [5]Biomedical Engineering, SUNY University at Buffalo, Buffalo, NY, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Thermal Treatment and Cryotherapy — Exhibit Hall A

15 **Blood Cooling Using Cryogenic Nitrogen** SB³C2016-638
Joseph Licwinko, Brian Dixon, *Mechanical Engineering, Rowan University, Glassboro, NJ, United States*

16 **Can We Use Apparent Thermal Conductivity to Include the Effect of Blood Perfusion? An Attempt to Predict Frozen Region During Cryosurgery** SB³C2016-766
Mohammed M. H. Shurrab, Haidong Wang, Takanobu Fukunaga, Kosaku Kurata, Hiroshi Takamatsu, *Mechanical Engineering, Kyushu University, Fukuoka, Japan*

17 **Development and Validation of a Brain Phantom for Therapeutic Cooling Devices** SB³C2016-1012
Ryan Packett[1], Philip Brown[1], Gautam Popli[2], Scott Gayzik[1], *[1]Biomedical Engineering, Wake Forest University, Winston Salem, NC, United States, [2]Neurosurgery, Wake Forest University, Winston Salem, NC, United States*

18 **Modulation of Ice Formation Characteristics Due to Addition of Trehalose in Cryoprotectant** SB³C2016-891
Jason Solocinski, Mian Wang, Quinn Osgood, **Nilay Chakraborty**, *Mechanical Engineering Department, University of Michigan Dearborn, Dearborn, MI, United States*

19 **A Novel Cryopreservation Approach Without Penetrating Cryoprotectants** SB³C2016-725
Haishui H. Huang, *The Ohio State University, Columbus, OH, United States*

20 **Enhancement of Cryopreservation outcome of Adipose Tissue Derived Stem Cells by Thermal Stress** SB³C2016-651
Mulla Shahensha Shaik, *Mechanical Engineering, Louisiana State University, Baton Rouge, LA, United States*

21 **Proliferation of Human Adipose Derived Stem Cells Cultured on Porous Poly (l-lactic Acid) Scaffolds Prepared by Thermally Controlled Methods** SB³C2016-43
Harish Chinnasami, Ram Devireddy, *Mechanical Engineering Department, Louisiana State University, Baton Rouge, LA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

FRIDAY, JULY 1	1:00pm - 3:15pm

Poster Session II — Ocular and Optofluidics — Exhibit Hall A

22 **Study of Ganciclovir Permeability Through Bovine, Rabbit & Human Alzhemeir Ex-vivo Ocular Tissues** SB³C2016-1099
Anita Penkova[1, 2], Komsan Rattanakijsuntorn[1], Satwindar Sadhal[1, 2], *[1]University of Southern California, Los Angeles, CA, United States, [2]Saban Research Institute, Children's hospital Los Angeles, Los Angeles, CA, United States*

23 **Intraocular Pressure Measurement Through the Laser Induced Cavitation Bubbles Dynamics** SB³C2016-761
Luis F. Devia-Cruz, Santiago Camacho-López, *Optics, CICESE, Ensenada, Mexico*

24 **Fluid Displacement During Droplet Formation at Microfluidic Flow-focusing Junction at Microfluidic Flow-focusing Junction** SB³C2016-722
Haishui H. Huang, *The Ohio State University, Columbus, OH, United States*

25 **Role of Intracranial Pressure in Optic Nerve Head Biomechanics** SB³C2016-713
Yi Hua, *Dept. of Mechanical & Materials Engineering, University of Nebraska-Lincoln, Lincoln, NE, United States*

26 **Finite Element Model of Ocular Accommodation Mechanism Based on Lens Pre-Tensioning and Ciliary Muscle Contraction** SB³C2016-572
Katherine R. Knaus[1], AnnMarie Hipsley[2], Silvia S. Blemker[1], *[1]University of Virginia, Charlottesville, VA, United States, [2]Ace Vison Group Inc., Akron, OH, United States*

27 **Riboflavin/uva Collagen Cross-linking Effects on Tensile and Compressive Properties of the Cornea** SB³C2016-799
Hamed Hatami-Marbini, *Mechanical & Industrial Engineering, University of Illinois at Chicago, Chicago, IL, United States*

28 **Regional Variations in the Mechanical Strains of the Human Optic Nerve Head** SB³C2016-804
Dan Midgett[1], Mohak Patel[2], Mary Pease[3], Christian Franck[2], Harry Quigley[3], Vicky Nguyen[1], *[1]Mechanical Engineering, Johns Hopkins University, Baltimore, MD, United States, [2]Engineering, Brown University, Providence, RI, United States, [3]Ophthalmology, Johns Hopkins University, Baltimore, MD, United States*

29 **An Image-Based Inverse Finite Element Method to Determine the Mechanical Properties of Human Trabecular Meshwork** SB³C2016-984
Anup D. Pant[1], Lawrence Kagemann[2], Ian Sigal[2], Joel Schuman[2], Rouzbeh Amini[1], *[1]Biomedical Engineering, The University of Akron, Akron, OH, United States, [2]Department of Bioengineering, Department of Opthalmology, University of Pittsburg, Pittsburgh, PA, United States*

30 **3D Characterization of Corneal Deformation Using Ultrasound Speckle Tracking** SB³C2016-936
Keyton Clayson, Elias Pavlatos, Jun Liu, *The Ohio State University, Columbus, OH, United States*

31 **The Impact of Ocular Pressures, Material Properties and Geometry on Optic Nerve Head Deformation** SB³C2016-637
Andrew Feola[1], Jerry G. Myers[2], Julia Raykin[1], Emily S. Nelson[2], Brian Samuels[3], C. Ross Ethier[1], *[1]Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]NASA Glenn Research Center, Cleveland, OH, United States, [3]Department of Ophthalmology, University of Alabama at Birmingham, Birmingham, AL, United States*

32 **Development of a Platform for Studying Astrocyte Mechanobiology: Compression of Astrocytes in 3D Collagen Gels** SB³C2016-868
John J. E. Mulvihill[1, 2], Lisa A. Schildmeyer[1], Julia Raykin[1], Eric J. Snider[1], Kavita Chinoy[1], Danny J. Kelly[2], C. Ross Ethier[1, 3], *[1]Wallace H. Coulter Dept. of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Mechanical and Manufacturing Engineering, Trinity College Dublin, Dublin, Ireland, [3]Atlanta VA Medical Center, Decatur, GA, United States*

33 **Characterization of the Mechanical Behavior of the Optic Nerve Sheath** SB³C2016-1054
Julia Raykin, Roy Wang, Taylor E. Forte, Andrew Feola, Brian Samuels, Jerry G. Myers, Emily S. Nelson, Rudy L. Gleason, C. Ross Ethier, *Georgia Institute of Technology, Atlanta, GA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

FRIDAY, JULY 1	1:00pm - 3:15pm

Poster Session II — Cardiovascular Tissue Engineering — Exhibit Hall A

75 **Connexin 43 Stability and Gap Junction Channel Functionality: the Role of Heparan Sulphate** SB³C2016-642
Solomon Mensah, Homa Homayoni, Ming Cheng, Brian Plouffe, Eno E. Ebong, *Bioengineering, Northeastern University, Boston, MA, United States*

76 **Phenotypic Changes of Stromal Vascular Fraction Cells for Use in a Tissue Engineered Vascular Graft** SB³C2016-861
Darren G. Haskett, *Department of Surgery, University of Pittsburgh, Pittsburgh, PA, United States*

77 **Influence of Subarachnoid Hemorrhage Factors on Vascular Smooth Muscle Cell Functional Phenotype in the Development of Cerebral Vasospasm** SB³C2016-865
Eric S. Hald, Zaw Win, Justin Buksa, Connor Timm, Patrick W. Alford, *Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

78 **Biomechanical Evaluation of Gelatin/Fibrinogen Electrospun Cylindrical Scaffolds Seeded with 3T3 Mouse Fibroblasts and Porcine Smooth Muscle Cells** SB³C2016-1064
Ehab Tamimi[1], Jamie L. Hernandez[2], Corina MacIsaac[2], Catalina Ardila[1], Jonathan P. Vande Geest[3], *[1]Graduate Interdisciplinary Program of Biomedical Engineering, University of Arizona, Tucson, AZ, United States, [2]Biomedical Engineering, University of Arizona, Tucson, AZ, United States, [3]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

79 **Quantify Patient-specific Coronary Vessel Material Property and Its Impact on Plaque Stress/strain Calculations Using Cine Ivus and 3D Fsi Models** SB³C2016-644
Xiaoya Guo[1], Jian Zhu[2], Liang Wang[3], Akiko Maehara[4], Jie Zheng[5], Chun Yang[6], David Muccigrosso[5], Gary S. Mintz[4], Dalin Tang[3], *[1]Southeast University, Nanjing, China, [2]Zhongda Hospital, Southeast University, Nanjing, China, [3]Worcester Polytechnic Institute, Worcester, MA, United States, [4]Columbia University, New York, NY, United States, [5]Washington University, St. Louis, MO, United States, [6]China United Network Comm. Co. Ltd., Beijing, China*

80 **Modeling Active Contraction of Left Ventricle Using Different Zero-load Diastole and Systole Geometries** SB³C2016-54
Longling Fan[1], Jing Yao[2], Chun Yang[3], Di Xu[2], Dalin Tang[4], *[1]Southeast University, Nanjing, China, [2]First Affiliated Hospital of Nanjing Medical University, Nanjing, China, [3]China Information Tech. Designing & Consulting Institute Co., Ltd., Beijing, China, [4]Math Sciences Department Worcester Polytechnic Institute, Worcestor, MA, United States*

81 **A Model to Determine the Effect of Axial Stretch on Lumen Collapse of Arteries** SB³C2016-857
Fatemeh Fatemi Far, Hai Chao Han, *Mechanical Engineering, University of Texas at San Antonio, San Antonio, TX, United States*

82 **Inhomogeneity of the Material Properties of Thoracic Aorta in Three Dimensions** SB³C2016-1033
Golriz Kermani, Ali Hemmasizadeh, Soroush Assari, Michael Autieri, Kurosh Darvish, *Temple University, Philadelphia, PA, United States*

83 **Mechanics of Heart Tube Formation in Chick Embryo** SB³C2016-65
Hadi S. Hosseini[1], Larry A. Taber[2], *[1]BME/Physics, Washington University in Saint Louis, Saint Louis, MO, United States, [2]BME, Washington University in Saint Louis, Saint Louis, MO, United States*

84 **Myocardial Wall Stiffening in a Mouse Model of Persistent Truncus Arteriosus** SB³C2016-1061
Christine Miller Buffinton[1], Kerra R. Mercon[1], Alyssa K. Benjamin[2], Asena Abay[3], Elise M. Buffinton[4], Roberta K. Blaho[3], Ashley N. Firment[5], Anne M. Moon[5], *[1]Mechanical Engineering, Bucknell University, Lewisburg, PA, United States, [2]Biology, Bucknell University, Lewisburg, PA, United States, [3]Biomedical Engineering, Bucknell University, Lewisburg, PA, United States, [4]Civil and Environmental Engineering, Cornell University, Ithaca, NY, United States, [5]Weis Center for Research, Geisinger Medical Center, Danville, PA, United States*

85 **Using Patient-Specific MRI-Based Right Ventricle Models with Different Zero-Load Diastole and Systole Geometries for Better Stress and Strain Calculations and Post-Surgery Outcome Prediction** SB³C2016-29
Dalin Tang[1, 2], Pedro del Nido[3], Chun Yang[1, 4], Heng Zuo[1], Xueying Huang[1, 5], Rahul H. Rathod[3], Alexander Tang[3], Zheyang Wu[1], Kristen L. Billiar[1], Tal Geva[3], *[1]WPI, Worcester, MA, United States, [2]Southeast University, Nanjing, China, [3]Harvard Medical School, Boston, MA, United States, [4]China Information Tech. Designing & Consulting Institute Co., Ltd, Beijing, China, [5]Xiamen University, Xiamen, China*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

FRIDAY, JULY 1	1:00pm - 3:15pm

Poster Session II — Tissue and Cellular Microenvironment — Exhibit Hall A

86 **Study on the Biosolubility of Calcined Bovine Bone Scaffold for Bone Tissue Engineering** SB³C2016-1141
Shigeo Tanaka[1], Naoki HIrooka[2], *[1]Institute of Science and Engineering, Kanazawa University, Kanazawa, Japan, [2]Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan*

87 **Molecular Spectroscopic Identification of the Water Compartments in Cartilage** SB³C2016-78
Mustafa Unal, Ozan Akkus, *Case Western Reserve University, Cleveland, OH, United States*

88 **Modeling Calcium Transients in Human Pluripotent Stem Cell-Derived Cardiomyocytes** SB³C2016-1108
Kevin Beussman, Marita Rodriguez, Adam Rakla, Ashley Emery, Nathan Sniadecki, *Mechanical Engineering, University of Washington, Seattle, WA, United States*

89 **Polycaprolactone Fibrous Scaffolds to Navigate Neural Stem Cells** SB³C2016-880
Nastaran Hashemi, *Iowa State University, Ames, IA, United States*

90 **Effect of Shear Stress on Glucose Metabolism in Pulmonary Arterial Hypertension** SB³C2016-810
Sarah Basehore, Alisa Morss Clyne, *Biomedical Engineering, Drexel University, Philadelphia, PA, United States*

91 **Impact of Membrane Cholesterol in the Monocyte Adhesion Cascade** SB³C2016-714
Amit K. Saha[1], Pawel Osmulski[2], Anand K. Ramasubramanian[1], *[1]Biomedical Engineering, University of Texas at San Antonio, San antonio, TX, United States, [2]Molecular Medicine, University of Texas Health Science Center at San Antonio, San antonio, TX, United States*

92 **Endothelial Cell Glycocalyx Modulates Shear-induced Tubule Formation** SB³C2016-119
Ping Zhao, Xiao Liu, Xiaoyan Deng, *School of Biological Science and Medical Engineering, Beihang University, Beijing, China*

93 **Decellularized Extracellular Matrix Electrospun Scaffold for a Novel Airway Smooth Muscle Model** SB³C2016-824
Bethany M. Young[1], Bryan A. Blakeney[2], Gretchen E. Schreyak[1], Robert A. Pouliot[1], **Rebecca L. Heise**[1], *[1]Biomedical Engineering, VCU, Richmond, VA, United States, [2]Physiology and Biophysics, VCU, Richmond, VA, United States*

94 **Numerical Investigation of Cell Migration** SB³C2016-1126
Xiaowei Zeng, Liqiang Lin, *Mechanical Engineering, University of Texas at San Antonio, San Antonio, TX, United States*

FRIDAY, JULY 1	1:00pm - 3:15pm

Poster Session II — Human Dynamics and Rehabilitation — Exhibit Hall A

109 **Biomechanical Analysis of Kicks in Soccer and Kicks in Football** SB³C2016-617
Allison M. Gerren, Tori Breitenbach, Jacob Forstat, Jonathan Fox, Mohamed Samir Hefzy, *The University of Toledo, Toledo, OH, United States*

110 **Assessing Kinematics and Kinetics of FES-rowing** SB³C2016-897
Adina Draghici[1], Glen Picard[2], J. Andrew Taylor[2, 3], Sandra Shefelbine[1, 4], *[1]Bioengineering, Northeastern University, Boston, MA, United States, [2]Cardiovascular Research Laboratory, Spaulding Rehabilitation Hospital, Boston, MA, United States, [3]Physical Medicine and Rehabilitation, Harvard Medical School, Boston, MA, United States, [4]Mechanical and Industrial Engineering, Northeastern University, Boston, MA, United States*

111 **Utilizing Bandwidth to Quantify Human Torso Motor Control Capability** SB³C2016-915
Shahab Karimi[1], Martin L. Tanaka[1], N. Peter Reeves[2], Sudhir Kaul[1], *[1]Engineering and Technology, Western Carolina University, Cullowhee, NC, United States, [2]Osteopathic Surgical Specialty, Michigan State University, East Lansing, MI, United States*

112 **Building a Better Quarterback: Using Biomechanics to Optimize Throwing Mechanics** SB³C2016-1127
Hunter Storaci[1], Andrew Robbins[1], Michael R. Moreno[1, 2], *[1]Biomedical Engineering, Texas A&M University, College Station, TX, United States, [2]Mechanical Engineering, Texas A&M University, College Station, TX, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

113 **Design of an Affordable Outdoor Add-on to a Manual Wheelchair for Developing Countries** SB³C2016-645
Swostik Dash, Vivek Sarda, Ashish Sharma, **S. Sujatha**, *Mechanical Engineering, Indian Institute of Technology Madras, Chennai, India*

114 **Relationship Between Force Applied & Velocity of Contraction of Air Muscles.** SB³C2016-1122
Aniruddha Phatak, *Rochester Institute of Technology, Rochester, NY, United States*

115 **Comparison of Humeral Head Osteotomy using Anatomic and Guide-Assisted Cuts** SB³C2016-1070
Emily A. West[1, 2, 3], Nikolas K. Knowles[1, 2, 3], Louis M. Ferreira[1, 2, 3], George S. Athwal[2], *[1]Biomedical Engineering, Western University, London, ON, Canada, [2]Roth|McFarlene Hand and Upper Limb Center, London, ON, Canada, [3]Lawson Health Research Institute, London, ON, Canada*

116 **A Testing Protocol for Evaluating and Classifying Spinal Orthoses** SB³C2016-76
Denis J. DiAngelo, John C. Simmons, Daniel M. Wido, *Orthopaedic Surgery and Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, United States*

117 **A Novel Distractive and Mobility-Enabling Lumbar Spinal Orthosis** SB³C2016-733
Daniel C. Hillyard, **Denis J. DiAngelo**, *Department of Orthopaedic Surgery and Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, United States*

118 **The Biomechanical Effects of Strap Options on Scoliosis Bracing Mechanics** SB³C2016-965
Chloe L. Chung[1], Derek M. Kelly[2], Jack R. Steele[3], **Denis J. DiAngelo**[1], *[1]The Department of Orthopaedic Surgery and Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, United States, [2]The Department of Orthopaedics, Campbell Clinic Orthopaedics and Le Bonheur Children's Hospital, Memphis, TN, United States, [3]Center for Orthotics and Prosthetics, Inc., Memphis, TN, United States*

119 **A.R.K. Brace: and Active Rehabilitation Knee Brace** SB³C2016-859
Jarrel Bobb[1], Kelly Chickering[2], **Patrick Donohue**[2], Mac Gallagher[3], Shannon Hartzell[4], Cole Lipman[2], M. Jake Miorin[2], Kailan Ottaway[2], Alexander A. Brown[2], *[1]Biology, Lafayette College, Easton, PA, United States, [2]Mechanical Engineering, Lafayette College, Easton, PA, United States, [3]Economics, Lafayette College, Easton, PA, United States, [4]Neuroscience, Lafayette College, Easton, PA, United States*

120 **Cable Actuated 3D Printed Exoskeleton: for Restoration of Hand Motor Function in Stroke Affected Patients** SB³C2016-616
Aaron J. Brice[1], Muxi Li[1], Stéphane Magnan[1], Jin Wang[1], Tyler Friesen[1], Yongsheng Ma[2], Ahmed Qureshi[2], Jonathon Schofield[2], *[1]Mechanical Engineering, University of Alberta, Edmonton, AB, Canada, [2]Mechanical Engineering, University of Alberta, Spruce Grove, AB, Canada*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Best Practices in Contemporary Biomechanical Engineering Education — Exhibit Hall A

121 **Enhancing Biomechanical Engineering Education Through Problem Based Learning** SB³C2016-1104
Alisa Morss Clyne, *Drexel University, Philadelphia, PA, United States*

122 **Project-based Biomechanics Laboratories: Theory and Practice** SB³C2016-1038
Kristen L. Billiar, Glenn R. Gaudette, *Biomedical Engineering, Worcester Polytechnic Institute, Worcester, MA, United States*

123 **Utilizing Problem-Based Learning to Teach Biomedical Engineering as a Chemical Engineering Elective** SB³C2016-684
Victor Lai, *Chemical Engineering, University of Minnesota - Duluth, Duluth, MN, United States*

124 **A Master of Engineerng in Design and Commercialization** SB³C2016-673
Alan Eberhardt, Brandon Kirkland, Ophelia Johnson, Joel Dobbs, Lee Moradi, *UAB, Birmingham, AL, United States*

125 **"Contemporary Issues in ... Bioengineering": A New Required Course Addressing Several Curricular Concerns** SB³C2016-826
Steven W. Day, Robert J. Stevens, *Rochester Institute of Technology, Rochester, NY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

126 **Recruiting and Supporting Transfer students to Mechanical Engineering Program at UMBC** SB³C2016-23
Liang Zhu[1], Dwayne Arola[2], Anne Spence[1], Carlos Romero-Talamas[1], Charles Eggleton[1], *[1]Mechanical Engineering, University of Maryland Baltimore County, Baltimore, MD, United States, [2]Materials Science and Engineering, University of Washington, Seattle, WA, United States*

127 **Experiences with Introducing STEM Clubs to K-12 Students: Perils, Pitfalls, and Pearls of Wisdom?** SB³C2016-821
Ferris Pfeiffer, *Bioengineering/Orthopaedic Surgery, University of Missouri, Columbia, MO, United States*

128 **Audio Response System for Active Learning in a Large Lecture Class** SB³C2016-61
Craig J. Goergen, *Biomedical Engineering, Purdue University, West Lafeyette, IN, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Cardiovascular Fluid Mechanics — Exhibit Hall A

154 **Hemodynamic Modifications and its Association with Outcome in Intracranial Aneurysms Treated using Flow Diverters** SB³C2016-798
Nikhil Paliwal[1], Jason Davies[2], Adnan H. Siddiqui[2], Hui Meng[1], *[1]Mechanical and Aerospace Engineering, University at Buffalo, the State University of New York, Buffalo, NY, United States, [2]Neurosurgery, University at Buffalo, the State University of New York, Buffalo, NY, United States*

155 **Flow Diverting Characteristics of Endoluminal and Intrasaccular Devices: A Comparison** SB³C2016-143
Fernando Mut[1], Pedro Lylyk[2], David Kallmes[3], Juan Cebral[1], *[1]Bioengineering, George Mason University, Fairfax, VA, United States, [2]Interventional Neuroradiology, Instituto Clinico ENERI, Buenos Aires, Argentina, [3]Radiology, Mayo Clinic, Rochester, MN, United States*

156 **Computational Modeling of Coiled Cerebral Aneurysms: Comparing Homogeneous Porous Medium Against Micro-CT Reconstructed Coil Volume in Aneurysmal Sac Hemodynamics** SB³C2016-1029
Michael C. Barbour[1], Patrick McGah[1], Christian Geindreau[2], Sabine Rolland du Roscoat[2], Kurt Sansom[1], Venkat Keshav Chivukula[1], Ryan P. Morton[3], John D. Nerva[3], Basavaraj V. Ghodke[4], Laligam N. Sekhar[3], Michael R. Levitt[3], Louis J. Kim[3], Alberto Aliseda[1], *[1]Mechanical Engineering, University of Washington, Seattle, WA, United States, [2]3SR Universite Grenoble Alps, Grenoble, France, [3]Neurological Surgery, University of Washington, Seattle, WA, United States, [4]Radiology, Harborview Medical Center, Seattle, WA, United States*

157 **Numerical Modeling of Flow Diverter Stent in Giant Cerebral Aneurysm** SB³C2016-771
Augusto F. Sanches, Eva Gutheil, *University of Heidelberg, Heidelberg, Germany*

158 **The Quantification of Blood Flow Patterns Induced by Endovascular Stent Grafts: An Experimental Investigation of The Effects of Oversizing and Compliance** SB³C2016-867
Amanda Colella Centazzo, *Mechanical Engineering, Dalhousie University, Halifax, NS, Canada*

159 **The Quantification of Blood Flow Patterns Induced by Endovascular Stent Grafts: An Experimental Investigation of the Effects of Oversizing and Compliance** SB³C2016-1013
Amanda Colella-Centazzo, **Clifton R. Johnston**, *Mechanical Engineering, Dalhousie University, Halifax, NS, Canada*

160 **A Preliminary Study to Determine If Arteriovenous Fistula Configuration Generates Helical Flow and If Helical Flow is A SurrogateMarker of Exposure to Disturbed Shear** SB³C2016-871
Connor V. Cunnane[1], Leonard D. Browne[1], Stephen P. Broderick[1], Craig Dunlop[2], Graeme J. Houston[3], Michael T. Walsh[1], *[1]Mechanical Aeronautical and Biomedical Engineering Department, University of Limerick, Limerick, Ireland, [2]Vascular Flow Technologies, Dundee, United Kingdom, [3]Cardiovascular and Diabetes Medicine, University of Dundee, Dundee, United Kingdom*

161 **A Real-Time Programmable Pulsatile Flow Pump for In-Vitro Cardiovascular Experimentation** SB³C2016-998
Rahul Raj Mechoor, Tyler M. Schmidt, Ethan O. Kung, *Mechanical Engineering, Clemson University, Clemson, SC, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

162 **Evaluation of Pulsatile and Continuous Flow Ventricular Assist Device Implementation in the Single-Ventricle Circulation: A Lumped-Parameter Modeling Study** SB³C2016-672
Tyler M. Schmidt[1], David N. Rosenthal[2], Olaf Reinhartz[2], Alison L. Marsden[3], Ethan O. Kung[1], The Modeling of Congenital Hearts Alliance (MOCHA) Investigators[4], *[1]Department of Mechanical Engineering, Clemson University, Clemson, SC, United States, [2]School of Medicine, Stanford University, Stanford, CA, United States, [3]Department of Pediatrics, Stanford University, Stanford, CA, United States, [4]Institute of Cardiovascular Sciences, University College London, London, United Kingdom*

163 **Apical Inflow Cannula Angle and Left Ventricular Size Impact LVAD Thrombosis Risk** SB³C2016-836
Venkat Keshav Chivukula[1], Patrick McGah[1], Anthony R. Prisco[2], Jennifer A. Beckman[3], Guilherme J. M. Garcia[2], Claudius Mahr[3], Alberto Aliseda[1], *[1]Mechanical Engineering, University of Washington, Seattle, WA, United States, [2]Biotechnology and Bioengineering Center, Medical College of Wisconsin, Milwaukee, WI, United States, [3]Division of Cardiology, University of Washington, Seattle, WA, United States*

164 **Native Cardiac Output and Surgical Implantation Configuration May Influence LVAD Thrombosis Risk** SB³C2016-838
Venkat Keshav Chivukula[1], Patrick McGah[1], Anthony Prisco[2], Jennifer Beckman[3], Guilherme Garcia[2], Claudius Mahr[3], Alberto Aliseda[1], *[1]Mechanical Engineering, University of Washington, Seattle, WA, United States, [2]Biotechnology and Bioengineering Center, Medical College of Wisconsin, Milwaukee, WI, United States, [3]Division of Cardiology, University of Washington, Seattle, WA, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II | Respiratory | Exhibit Hall A

165 **Acoustic Visualisation of Flow-Sound in the Respiratory Airway** SB³C2016-1001
Gabriel Pramudita Saputra[1], Kazunori Nozaki[2], Satoshi Ii[1], Chizu Habukawa[3], Shigeo Wada[1], *[1]Department of Biomechanical Science and Engineering, Graduate School of Engineering Science Osaka University, Osaka, Japan, [2]Division of Dental Informatics, Osaka University Dental Hospital, Osaka, Japan, [3]Department of Pediatrics, Minami Wakayama Medical Center, Wakayama, Japan*

168 **Influence of Standardization of Airway Geometry on Airflow and Particle Transport** SB³C2016-169
Toshihiro Sera[1], Hiroaki Kuninaga[2], Kazuaki Fukasaku[3], Hideo Yokota[3], Masao Tanaka[2], *[1]Kyushu Univ., Fukuoka, Japan, [2]Osaka Univ., Toyonaka, Japan, [3]RIKEN, Wako, Japan*

169 **Investigating Force Transfer During Parturition Using Experimental and Computational Methods** SB³C2016-599
Alexa Baumer[1], Roseanna Pealatere[2], Lisa J. Fauci[2], Megan C. Leftwich[1], *[1]The George Washington University, Washington, DC, United States, [2]Tulane University, New Orleans, LA, United States*

170 **A Mathematical Model of Vitreoschisis** SB³C2016-692
Krystyna Isakova[1], Jan Oscar Pralits[2], Outi-Leena Tammisola[1], Rodolfo Repetto[2], *[1]Faculty of Engineering, University of Nottingham, Nottingham, United Kingdom, [2]Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy*

171 **Digital Manufacturing and In Silico Modeling for Rational Design of Drug Delivery to the Central Nervous System** SB³C2016-953
Kevin Tangen[1], Ted Gabor[2], Lu Lu[2], Yayue Pan[2], Narasimhan Sriram[1], Andreas Linninger[1, 3], *[1]Bioengineering, University of Illinois at Chicago, Chicago, IL, United States, [2]Mechanical Engineering, University of Illinois at Chicago, Chicago, IL, United States, [3]Neurosurgery, University of Illinois at Chicago, Chicago, IL, United States*

172 **Integration of a Baroreflex Model into a Whole Body Physiology Engine** SB³C2016-888
Rachel B. Clipp, M. Cameron Thames, Jeffrey B. Webb, Rodney Metoyer, Zachary M. Swarm, Aaron M. Bray, *Applied Research Associates, Inc, Raleigh, NC, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

FRIDAY, JULY 1	1:00pm - 3:15pm

Poster Session II — Respiratory and Others Fluid Mechanics — Exhibit Hall A

173 **Aortic Regurgitation on Left Ventricular Diastolic Flow** SB³C2016-643
Ikechukwu (Ikay) Okafor[1], Vrishank Raghav[1], Gautam Kumar[2], Ajit Yoganathan[1], *[1]Georgia Institute of Technology, Atlanta, GA, United States, [2]Emory University, Atlanta, GA, United States*

174 **Computational Fluid Flow Modeling of a Pulmonary Vascular Phantom with Experimental Validation** SB³C2016-66
Alifer D. Bordones[1, 2], Matthew Leroux[1, 2], Vitaly O. Kheyfets[3], Ender A. Finol[1], *[1]Biomedical Engineering, University of Texas at San Antonio, San Antonio, TX, United States, [2]Graduate Program in Biomedical Engineering, University of Texas Health Science Center at San Antonio, San Antonio, TX, United States, [3]Bioengineering, University of Colorado Denver, Denver, CO, United States*

175 **Similarities and Differences Between Flow Mode of a Leukocyte and Circulating Tumor Cell in Microvessels** SB³C2016-742
Naoki Takeishi[1], Yohsuke Imai[2], Takami Yamaguchi[1], Takuji Ishikawa[2], *[1]Graduate School of Biomedical Engineering, Tohoku University, Sendai, Japan, [2]Division of Mechanical Engineering, Tohoku University, Sendai, Japan*

176 **Subject Specific Simulation of Entire Cerebral Arterial Tree: Implementation of Automatic Parametric Mesh Generation.** SB³C2016-171
Mahsa Ghaffari[1], Ben C. Schneller[1], Ali Alaraj[2], Andreas A. Linninger[1], *[1]Bioengineering, University of Illinois at Chicago, Chicago, IL, United States, [2]Department of Neurosurgery, University of Illinois at Chicago, Chicago, IL, United States*

177 **Hemodynamic Analysis on Correlations between Bicuspid Aortic Valve and Aneurysm Progression with an Integrated Model of Left Ventricle and Aorta** SB³C2016-1021
Takashi Fujiwara[1], Fuyou Liang[2], Koichi Sughimoto[3], Hao Liu[1], *[1]Graduate School of Engineering, Chiba University, Chiba, Japan, [2]School of Naval Architecture, Ocean & Civil Engineering, Shanghai Jiao Tong University, Shanghai, China, [3]Cardiovascular Surgery, Kitazato University Hospital, Kanagawa, Japan*

178 **Porcine Small Intestinal Submucosal Valve Dynamics in the Aortic Position** SB³C2016-856
Omkar V. Mankame[1], Makensley Lordeus[1], Lilliam Valdes-Cruz[2], Steven Bibevski[2], Frank Scholl[2], Sarah M. Bell[2], Ivan Baez[2], Sharan Ramaswamy[1], *[1]Biomedical Engineering, Florida International University, Miami, FL, United States, [2]Joe DiMaggio Children's Hospital, Memorial Regional Hospital, Hollywood, FL, United States*

179 **Comparison of Pediatric and Adult Blood Viscoelasticity** SB³C2016-88
M Keith Sharp[1], Mary E. Gregg[1], Guy Brock[2], George M. Pantalos[1], *[1]University of Louisville, Louisville, KY, United States, [2]Ohio State University, Columbus, OH, United States*

180 **Understanding the Fluid Mechanics of Aortic Regurgitation** SB³C2016-650
Samantha Houser[1], Ikechukwu Okafor[2], **Vrishank Raghav**[1], Ajit Yoganathan[1], *[1]Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, GA, United States*

181 **Abnormal Characteristics of Blood Flow in Human Left Atrium with Prior History of Embolic Stroke: Computational Fluid Dynamics Study** SB³C2016-659
Tomohiro Otani[1], Shigeo Wada[1], Hiroshi Ashikaga[2], *[1]Mechanical Science & Bioengineering, Osaka University, Toyonaka, Japan, [2]School of Medicine, Johns Hopkins University, Baltimore, MD, United States*

182 **Computational Modeling of Embolus Migration in the Human Inferior Vena Cava** SB³C2016-55
Kenneth I. Aycock[1], Robert L. Campbell[2], Brent A. Craven[3], Keefe B. Manning[1], *[1]Biomedical Engineering, The Pennsylvania State University, State College, PA, United States, [2]Mechanical and Nuclear Engineering, The Pennsylvania State University, State College, PA, United States, [3]Center for Devices and Radiological Health, U.S. Food and Drug Administration, State College, PA, United States*

183 **Shear Dependent Sickle Red Blood Cell Adhesion in Shear Gradient Hele Shaw Flow** SB³C2016-647
Erdem Kucukal, Umut A. Gurkan, *Mechanical and Aerospace Engineering, Case Western Reserve University, Cleveland, OH, United States*

184 **Velocity-Dilatation Formulation for Computational Fluid Dynamics in FEBio** SB³C2016-788
Gerard A. Ateshian[1], Jay J. Shim[1], Steve Maas[2], Jeffrey A. Weiss[2], *[1]Mechanical Engineering, Columbia University, New York, NY, United States, [2]Bioengineering, University of Utah, Salt Lake City, UT, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

185 **Production of Monodispere Silica Gel Microspheres for Bioencapsulation by Extrusion Into An Oil Crossflow** SB³C2016-653
Joey Benson[1], Lawrence Wackett[2, 3], Alptekin Aksan[1, 3], *[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Department of Biochemistry, Molecular Biology and Biophysics, University of Minnesota, Minneapolis, MN, United States, [3]BioTechnology Institute, University of Minnesota, St Paul, MN, United States*

186 **Bacterial Growth Inside Reversible Ca-alginate Beads Encapsulated in a Thin Silica Film** SB³C2016-853
Goeun Heo[1], Jonathan K. Sakkos[1], Sujin Yeom[2], Lawrence P. Wackett[2, 3], Alptekin Aksan[1, 3], *[1]Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Biochemistry, Molecular, Biology, and Biophysics, University of Minnesota, Minneapolis, MN, United States, [3]Biotechnology Institute, St Paul, MN, United States*

187 **Microbial Regeneration of Adsorbent Silica Gel for Sustainable Treatment of Environmental Pollutants** SB³C2016-608
Jonathan Sakkos[1], Lawrence P. Wackett[2], Alptekin Aksan[1], *[1]Mechanical Engineering, University of Minnesota, Minneapolis, MN, United States, [2]Biochemistry, Molecular Biology, and Biophysics, University of Minnesota, Minneapolis, MN, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Bone Mechanics — Exhibit Hall A

221 **Evaluation of BioDent Reference Point Indentation (RPI) Platform to Measure the Elastic Modulus in Mouse Bones** SB³C2016-795
Ganesh Thiagarajan, *Civil and Mechanical Engineering, University of Missouri Kansas City, Kansas City, MO, United States*

222 **Effects of Body Weight Supported Treadmill Training on Bone and Muscle Following Spinal Cord Injury** SB³C2016-910
Anita Singh[1], Bridgette Saverine[1], Gabrielle Gehron[1], Brittany King[2], Shania Shaji[1], Jennifer Kadlowec[2], *[1]Widener University, Chester, PA, United States, [2]Rowan University, Glassboro, NJ, United States*

223 **Orientation Dependent Strain Characterization of the Ultrastructure In Bone** SB³C2016-1136
Jitin S. Samuel, Xiaodu Wang, *University of Texas at San Antonio, San Antonio, TX, United States*

224 **A Coupled Reaction-Diffusion-Strain Model for Bone Growth in the Cranial Vault** SB³C2016-931
Chanyoung Lee, Reuben H. Kraft, *Department of Mechanical and Nuclear Engineering, Pennsylvania State University, University Park, PA, United States*

225 **Modeling Bone Formation with a Lab-on-a-Chip Platform** SB³C2016-63
Marnie M. Saunders, Spencer L. York, Estee L. George, Erica L. Grutkowski, Jennifer L. Smith, *Biomedical Engineering, The University of Akron, Akron, OH, United States*

226 **A Cellular Automata Model Verifying Osteoblastic Bone Formation In Vitro** SB³C2016-42
Estee L. George[1], Flora F. Opoku Asantewaa[2], Gabrielle K. Van Scoy[2], Alicia Prieto-Langarica[2], Marnie M. Saunders[1], *[1]The University of Akron, Akron, OH, United States, [2]Youngstown State University, Youngstown, OH, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Growth, Remodeling and Repair — Exhibit Hall A

245 **Acceleration of Critical Bone Defect Healing by Ultrasound Radiation Force in a Rat Tibial Model** SB³C2016-949
Yi-Xian Qin, Jingbo Liu, Tony Zhang, Xiaofei Li, *Biomedical Engineering, Stony Brook University, Stony Brook, NY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

246 **A Novel Structural Constitutive Model for Passive Right Ventricular Myocardium: Toward An Understanding of Remodeling During Pulmonary Hypertension** SB³C2016-137
Reza Avazmohammadi, Michael S. Sacks, *Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX, United States*

247 **Experimental Validation of a Subject-Specific Anisotropic Model of the Rotator Cuff to Predict Tear Propagation** SB³C2016-820
R. Matthew Miller[1], James Thunes[1], Volker Musahl[2], Spandan Maiti[1], Richard E. Debski[1], *[1]Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States, [2]Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, United States*

248 **Kinematic Evidence of Ring Apophysis Fracture During Cyclic Loading Typical of ADLs** SB³C2016-623
Nicole C. Corbiere[1], Stacey L. Zeigler[2], Kathleen A. Issen[1], Arthur J. Michalek[1], Laurel Kuxhaus[1], *[1]Mechanical and Aeronautical Engineering, Clarkson University, Potsdam, NY, United States, [2]Physical Therapy, Clarkson University, Potsdam, NY, United States*

249 **Effective Remodeling of Wall Content in Cerebral Aneurysms** SB³C2016-1028
Xinjie Duan, *Mechanical Engineering and Material Science, University of Pittsburgh, Pittsburgh, PA, United States*

250 **Modeling Soft Tissue Damage and Failure Using a Hybrid Particle/Continuum Approach** SB³C2016-71
Manuel K. Rausch[1], George E. Karniadakis[2], Jay D. Humphrey[1], *[1]Biomedical Engineering, Yale University, New Haven, CT, United States, [2]Applied Mathematics, Brown University, Providence, RI, United States*

251 **Temporal Healing Response of Achilles Tendons in Rodents Following Injury Depends on Surgical Treatment and Return to Activity Time** SB³C2016-84
Benjamin R. Freedman, Tyler R. Morris, Nabeel S. Salka, Joshua A. Gordon, Adam M. Pardes, Corinne N. Riggin, Courtney A. Nuss, Jennica J. Tucker, Pankti R. Bhatt, George W. Fryhofer, Daniel C. Farber, Louis J. Soslowsky, *McKay Orthopaedic Research Laboratory, University of Pennsylvania, Philadelphia, PA, United States*

252 **A Theoretical Evaluation of Potential Strategies for Enhancing Cellular Anabolism in the Extracellular Matrix of the Invertertebral Disc** SB³C2016-98
Shihab Asfour[1], Juan Pablo de Rivero Vaccari[2], **Francesco Travascio**[1], *[1]Industrial Engineering, University of Miami, Coral Gables, FL, United States, [2]Neurosurgery, University of Miami, Miami, FL, United States*

253 **In-Vitro Model of Healing Ligament** SB³C2016-727
Stephanie M. F. Tuft, Julia T. Oxford, Erica E. Morrill, Raquel J. Brown, Trevor J. Lujan, *Biology, and Mechanical and Biomedical Engineering, Boise State University, Boise, ID, United States*

254 **Adipose-derived Mesenchymal Stem Cells Stimulate Elastin Production by Adult Human Smooth Muscle Cells in a 3D Fibrin Scaffold** SB³C2016-1119
Kory Blose, Justin Weinbaum, David Vorp, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

255 **Effect of Three Dimensional Spheroid Culture on Bipotent Murine Liver Progenitor Cells** SB³C2016-165
Kenichiro Nishii, Erik Brodin, Taylor Renshaw, Rachael Weesner, **Jessica L. Sparks**, *Miami University, Oxford, OH, United States*

256 **Does Tissue Architecture Matter to Bulk Mechanics? Scrambled Embryos Suggest Not.** SB³C2016-862
Joseph H. Shawky, Lance A. Davidson, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

257 **Urinary Bladder Structure Remodeling Study with Multiphoton Imaging** SB³C2016-1030
Fangzhou Cheng[1], Jack Hornsby[2], Donna Daly[3], Florenta Kullmann[1], Lori Birder[1], Anne Robertson[1], Mark Thompson[2], Paul Watton[3], *[1]University of Pittsburgh, Pittsburgh, PA, United States, [2]University of Oxford, Oxford, United Kingdom, [3]University of Sheffield, Sheffield, United Kingdom*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

FRIDAY, JULY 1	1:00pm - 3:15pm

Poster Session II — Musculoskeletal Soft Tissue Mechanics — Exhibit Hall A

279 **The Contribution of Articular Cartilage Focal Defect Size and Location on Whole Knee Computational Models** SB³C2016-64
Benjamin C. Marchi, Rhima Coleman, Ellen M. Arruda, *Mechanical Engineering, University of Michigan, Ann Arbor, MI, United States*

280 **Determining the Relationship Between the Biomechanical and Biochemical Properties of Articular Cartilage Utilizing An Artificial Neural Network** SB³C2016-903
Joe T. Rexwinkle[1], Ferris Pfeiffer[2], Nikki Werner[3], Aaron M. Stoker[3], *[1]Mechanical Engineering, University of Missouri, Columbia, MO, United States, [2]Bioengineering/Orthopaedic Surgery, University of Missouri, Columbia, MO, United States, [3]Veterinary Medicine, University of Missouri, Columbia, MO, United States*

281 **Mechanical Properties of the Growth Plate in a Rat Model of Obesity** SB³C2016-926
Patrick Estep[1], Moriah Smoot[2], Shawn Gilbert[1], **Alan Eberhardt**[1], *[1]UAB, Birmingham, AL, United States, [2]University of Alabaama, Tuscaloosa, AL, United States*

282 **The Dynamics of Proteoglycan Loss in Articular Cartilage Following Mechanical Perturbation** SB³C2016-667
Lorenza Henao Murillo, Keita Ito, **Corrinus C. van Donkelaar**, *Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands*

283 **Tribological Rehydration 2: Insights into the Mechanics of Cartilage Recovery** SB³C2016-163
David L. Burris[1], Axel Moore[2], *[1]Mechanical Engineering, University of Delaware, Newark, DE, United States, [2]Biomedial Engineering, University of Delaware, Newark, DE, United States*

284 **Smoking and Smoking Cessation: Implications on the Degeneration of the Intervertebral Disc** SB³C2016-741
Shady Elmasry[1], Shihab Asfour[1], Juan Pablo de Rivero Vaccari[2], Francesco Travascio[1], *[1]Industrial Engineering, University of Miami, Coral Gables, FL, United States, [2]Neurological Surgery, University of Miami, Miami, FL, United States*

285 **Biomechanics of Muscle Tendon Junction and Tendon Bone Insertions** SB³C2016-1073
Sandhya Chandrasekaran, Ashley Saltzman, **HY Shadow Huang**, *NC State, Raleigh, NC, United States*

286 **The Effect of Ligament Stiffness on Shoulder Cartilage Pressure and Kinematics** SB³C2016-844
Hafizur Rahman, Mariana E. Kersh, *Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States*

287 **Anterior Cruciate Ligament Femoral Entheseal Shape and Insertion Angle are Risk Factors for Injury** SB³C2016-160
Callan M. L. Luetkemeyer, Ellen M. Arruda, *Mechanical Engineering, University of Michigan, Ann Arbor, MI, United States*

288 **Uninjured Supraspinatus Tendons in Rodents Do Not Exhibit Different Material Properties Across Sex** SB³C2016-674
Kelsey A. Robinson, Adam M. Pardes, Benjamin R. Freedman, Louis J. Soslowsky, *Department of Orthopaedics, University of Pennsylvania, Philadelphia, PA, United States*

289 **Simvastatin Does Not Adversely Affect the Mechanical and Histological Properties of the Achilles Tendon in a Diet Induced Hypercholesterolemia Rat Model** SB³C2016-778
Daniel S. Choi, Jennica J. Tucker, Louis J. Soslowsky, *University of Pennsylvania, Philadelphia, PA, United States*

290 **The Response to Stress Deprivation Differs Between the Interfascicular and Fascicular Matrix of Tendon** SB³C2016-664
Daniel T. Rowson, Martin M. Knight, Hazel R. C. Screen, *School of Engineering and Materials Science, Institute of Bioengineering, London, United Kingdom*

291 **Overlap Between Anterior Cruciate Ligament and the Anterolateral Meniscal Root Insertions: A Scanning Microscopy Study** SB³C2016-105
Brett D. Steineman[1], Samuel G. Moulton[2], Tammy L. Haut Donahue[3], Chase S. Dean[2], Robert F. LaPrade[2, 4], *[1]School of Biomedical Engineering, Colorado State University, Fort Collins, CO, United States, [2]Steadman Philippon Research Institute, Vail, CO, United States, [3]Mechanical Engineering, Colorado State University, Fort Collins, CO, United States, [4]The Steadman Clinic, Vail, CO, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

292 **Correlation of Supraspinatus Tendon Degeneration and Quantitative Ultrasound Measures** SB³C2016-710
Gerald A. Ferrer[1], R. Matthew Miller[1], Masahito Yoshida[2], Amir A. Rahnemai-Azar[2], Volker Musahl[1, 2], Richard E. Debski[1, 2], *[1]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States, [2]Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, United States*

293 **Energy Storing and Positional Human Tendons: Mechanics and Changes with Ageing** SB³C2016-81
Dharmesh Patel[1], Ewa M. Spiesz[1], Chavaunne T. Thorpe[1], Helen L. Birch[2], Graham P. Riley[3], Peter D. Clegg[4], Hazel R. C. Screen[1], *[1]School of Engineering and Materials Science, Queen Mary University of London, London, United Kingdom, [2]Institute of Orthopaedics and Musculoskeletal Science, University College London, London, United Kingdom, [3]School of Biological Sciences, University of East Anglia, Norwich, United Kingdom, [4]Department of Musculoskeletal Biology, University of Liverpool, Liverpool, United Kingdom*

294 **Effect of Collagen Fibril Alignment on Viscoelastic Mechanical Properties of Ligament** SB³C2016-109
Erica E. Morrill[1], Christina J. Stender[1], Raquel J. Brown[2], Trevor J. Lujan[1], *[1]Mechanical and Biomedical Engineering, Boise State University, Boise, ID, United States, [2]Biomolecular Research Center, Boise State University, Boise, ID, United States*

295 **Sex Differences in Achilles Tendon Properties Three Weeks After Injury in Rats** SB³C2016-144
George W. Fryhofer, Benjamin R. Freedman, Adam M. Pardes, Cody D. Hillin, Louis J. Soslowsky, *McKay Orthopaedic Research Laboratory, University of Pennsylvania, Philadelphia, PA, United States*

296 **Differences Between the Mechanical and Microstructural Properties of the Human ACL and PCL** SB³C2016-628
Ryan Castile[1], Nathan Skelley[2], Jon Wright[3], Robert Brophy[2], Spencer Lake[1], *[1]Mechanical Engineering, Washington University in St. Louis, St. Louis, MO, United States, [2]Washington University in St. Louis, St. Louis, MO, United States, [3]Beaumont Health, Royal Oak, MI, United States*

297 **Consequences of Meniscus Cracks in Uniaxial Tension** SB³C2016-911
John M. Peloquin[1], Julia Pezick[2], Pranita Muralidhar[2], Michael H. Santare[3], Dawn M. Elliott[2], *[1]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [2]Department of Biomedical Engineering, University of Delaware, Newark, DE, United States, [3]Department of Mechanical Engineering, University of Delaware, Newark, DE, United States*

298 **Effect of Age on the Mechanical Properties of the Porcine Temporomandibular Joint Disc** SB³C2016-152
Jesse Lowe, Alejandro Almarza, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

299 **In Situ Measurements of Hydraulic Permeability in Skeletal Muscles** SB³C2016-960
Michael Schenk, Lijian Peng, Xingyu Chen, **Shaopeng Pei**, X. Lucas Lu, Liyun Wang, *University of Delaware, Newark, DE, United States*

300 **Muscle Volume Prediction using Anthropometric Measurements and Population Derived Statistical Models** SB³C2016-117
Shasha Yeung, Justin Fernandez, Geoffery Handsfield, Cameron Walker, Thor Besier, Ju Zhang, *Auckland Bioengineering Institute, Auckland, New Zealand*

301 **Probing the Transition From Compaction to Fatigue in Human Articular Cartilage Under Cyclic Loading** SB³C2016-671
Jonathan T. Kaplan[1, 2], M. Hicham Drissi[3], Corey P. Neu[4], **David M. Pierce**[1], *[1]Mechanical Engineering/Biomedical Engineering/Mathematics, University of Connecticut, Storrs, CT, United States, [2]Biomechanics Research and Engineering, Natick Soldier RD&E Center, Natick, MA, United States, [3]Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, United States, [4]Mechanical Engineering, University of Colorado, Boulder, CO, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Joint and Spine Biomechanics — Exhibit Hall A

302 **Post-Operative Complications of Computer Assisted Total Knee Arthroplasty in Osteoporotic Femurs and Tibias: A Finite Element Study** SB³C2016-1129
Ruth Solomon[1], Andrew Sori[1], Shihab Asfour[1], Loren Latta[2], Ali Alhandi[2], Francesco Travascio[1], *[1]Industrial Engineering, University of Miami, Coral Gables, FL, United States, [2]Max Biedermann Institute for Biomechanics, Miami Beach, FL, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

303 **Computational Analysis on Post-Fusion Effects of Hardware Preservation of Removal on Osteoporotic Proximal Tibia Cartilage and Subchondral Bone** SB³C2016-812

Andrew Sori[1], Ruth Solomon[1], Shihab Asfour[1], Ronald Lindsey[2], Ali Alhandi[3], Loren Latta[3], Francesco Travascio[1], *[1]Industrial Engineering, University of Miami, Coral Gables, FL, United States, [2]Orthopaedic Surgery, University of Texas Medical Brach, Galveston, TX, United States, [3]Max Biedermann Institute for Biomechanics, Miami Beach, FL, United States*

304 **Effects of Tibiofemoral Compression on ACL Forces and Knee Kinematics Under Combined Knee Loads** SB³C2016-630

Kent T. Yamaguchi, Daniel Boguszewski, Justin Mathew, Keith Markolf, David McAllister, *Orthopedic Surgery, University of California Los Angeles, Los Angeles, CA, United States*

305 **Development of Clinically Relevant Constraint Measurement Using Modified Total Knee Replacement Implants** SB³C2016-956

Scott N. Anderson[1], Peter S. Walker[2], Ryan T. Willing[1], *[1]Mechanical Engineering, Binghamton University, Binghamton, NY, United States, [2]Langone Medical Center, New York University, New York, NY, United States*

306 **Nonlinear Multifactorial Influence of Ligament Properties on Rotatory Knee Stability: Novel Application of Bayesian Sensitivity Analysis** SB³C2016-1128

Mohammad Kia[1], Po-Hsu Chen[2], Thomas L. Wickiewicz[3], Andrew D. Pearle[3], Thomas Santner[2], **Carl W. Imhauser**[1], *[1]Biomechanics, Hospital for Special Surgery, New York, NY, United States, [2]Statistics, The Ohio State University, Columbus, OH, United States, [3]Orthopaedic Surgery, Hospital for Special Surgery, New York, NY, United States*

307 **Generating a Subject-specific Musculoskeletal Model of the Knee Using Motion Capture Data and Medical Imaging** SB³C2016-576

Mousa Kazemi, *ABI, Auckland, New Zealand*

308 **Evaluation of a Displacement-Driven Model for Assessing Patellofemoral Joint Contact Mechanics** SB³C2016-46

Jonathan A. Gustafson, Kyle A. Berkow, Richard E. Debski, Shawn Farrokhi, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

309 **Toward Patient-specific Computational Model of the Knee Joint** SB³C2016-90

Hongqiang Guo[1], Thomas Santner[2], Amy Lerner[3], Suzanne Maher[1], *[1]Hospital for Special Surgery, New York, NY, United States, [2]The Ohio State University, Columbus, OH, United States, [3]University of Rochester, Rochester, NY, United States*

310 **A Population Derived Mechanostatistical Model of the Human and Sheep Spine to Evaluate Spinal Fusion Implants** SB³C2016-654

Alex Swee, Vickie Shim, Justin Fernandez, *Auckland Bioengineering Institute, University of Auckland, Auckland City, New Zealand*

311 **Changes in Cervical Spine Intervertebral Disc Properties with Repetitive Axial Loading** SB³C2016-123

Brian D. Stemper[1, 2], Alok S. Shah[1, 2], Narayan Yoganandan[1, 2], Mingxin Zheng[3, 4], Brian Snyder[3, 4], *[1]Neurosurgery, Medical College of Wisconsin, Milwaukee, WI, United States, [2]Research Service, Zablocki VA Medical Center, Milwaukee, WI, United States, [3]Beth Israel Deaconess Medical Center, Boston, MA, United States, [4]Harvard Medical School, Boston, MA, United States*

312 **Treatment of Thoracolumbar Burst Fracture: A Biomechanical Analysis of Three Different Fixation Constructs** SB³C2016-746

Shady Elmasry[1], Shihab Asfour[1], Joseph Gjolaj[2], Loren Latta[3], Frank Eismont[2], Francesco Travascio[1], *[1]Industrial Engineering, University of Miami, Coral Gables, FL, United States, [2]Orthopaedic Surgery, University of Miami, Miami, FL, United States, [3]Max Biedermann Institute for Biomechanics, Miami Beach, FL, United States*

313 **Detecting Osteoporotic Vertebral Compression Fractures: BMD vs. Acoustic Emission Technique** SB³C2016-908

jihui li[1], Thomas Mazahery[1], Ronald Childs[1], Mark Theiss[1], Melanie Pham[2], *[1]Orthopaedics, Fairfax hospital, Falls Church, VA, United States, [2]Surgery, Eastern Virginia Medical School, Norfolk, VA, United States*

314 **Computer Simulation of Lumbar Flexion Shows In-Plane and Through-Plane Shear of the Facet Capsular Ligament** SB³C2016-22

Amy A. Claeson, Victor H. Barocas, *Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States*

315 **Shape Optimization of Lumbar Intervertebral Cages Featuring Different Cross-Section Shapes** SB³C2016-634

Chaochao Zhou[1], Khalid Sethi[2], Ryan Willing[1], *[1]Department of Mechanical Engineering, Binghamton University, Binghamton, NY, United States, [2]Senecka Spine, Binghamton, NY, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

316 **A Comparison of Normal and Osteoarthritic Humeral Head Size and Morphology** SB³C2016-17
Nikolas K. Knowles[1], Michael J. Carroll[2], Louis M. Ferreira[1], Jay D. Keener[3], George S. Athwal[2], *[1]Biomedical Engineering, The University of Western Ontario, London, ON, Canada, [2]The University of Western Ontario, London, ON, Canada, [3]Washington University, St. Louis, MO, United States*

FRIDAY, JULY 1 | 1:00pm - 3:15pm

Poster Session II — Other Solid, Tissue, Cellular and Molecular Biomechanics — Exhibit Hall A

317 **Evaluation of Polymeric Scaffolds Using a Vertical Layered Coextrusion for Topical Drug Delivery Applications and Comparison with Electrostatic Spinning** SB³C2016-621
Mohammad Mofidfar, Eric Baer, Gary E. Wnek, *Macromolecular Science and Engineering, CWRU, Cleveland, OH, United States*

318 **Synthesis and Characterization of Mesopore Forsterite Powder for Biomedical Application** SB³C2016-1053
Seyed Mehdi Mirhadi[1], **Fariborz Tavangarian**[2], *[1]Shahreza Branch, Islamic Azad University, Isfahan, Iran, Islamic Republic of, [2]Morehead State Univeristy, Morehead, KY, United States*

319 **PLA/ PLGA-coated Chitosan Micro-implants for Sustained Release of Methotrexate to Treat Vitreo-retinal Diseases** SB³C2016-172
Soumyarwit Manna[1], Marwan F. Al-Rjoub[1], Anna Donnell[2], Necati Kaval[2], James J. Augsburger[3], Zelia M. Correa[3], Rupak Banerjee[1], *[1]Mechanical and Materials Engineering, University of Cincinnati, Cincinnati, OH, United States, [2]Chemistry, University of Cincinnati, Cincinnati, OH, United States, [3]Ophthalmology, University of Cincinnati, Cincinnati, OH, United States*

320 **Investigating Collagen Methacrylamide, a Photocrosslinkable, Thermoreversible, Collagen-Based Hydrogel, for Regenerative Medicine** SB³C2016-946
Kathryn E. Drzewiecki, Juilee N. Malavade, David I. Shreiber, *Biomedical Engineering, Rutgers, The State University of New Jersey, Piscataway, NJ, United States*

321 **Detection of SK Channels on Neuronal Axons of Skchannels on Neuronal Axons** SB³C2016-33
Krithika Abiraman, Anastasios V. Tzingounis, George Lykotrafitis, *Univeristy of Connecticut, Storrs, CT, United States*

322 **Emulation of Muscular Thin Film Deflection Using Thermal Contraction: Comparison of Constitutive Models** SB³C2016-813
Victoria A. Webster[1], Santiago G. Nieto[2], Anna Grosberg[3], Ozan Akkus[1], Hillel J. Chiel[4], Roger D. Quinn[1], *[1]Mechanical Engineering, Case Western Reserve University, Cleveland, OH, United States, [2]Biomedical Engineering, Case Western Reserve University, Cleveland, OH, United States, [3]Biomedical Engineering, University of California, Irvine, Irvine, CA, United States, [4]Biology, Case Western Reserve University, Cleveland, OH, United States*

323 **Simulation of Strain Induced Damage During Delivery** SB³C2016-633
Olivier Mayeur[1, 2], Estelle JeanDitGautier[3], Pauline Lecomte[1, 2], Jean-François Witz[4], Chrystele Rubod[2, 3], Michel Cosson[2, 5], **Mathias J. Brieu**[1, 2], *[1]MSO, Centrale Lille, Villeneuve D'Ascq, France, [2]Lml - fre 3723, CNRS, Villeneuve d'Ascq, France, [3]Hopital Jeanne de Flandre, CHR Lille, Lille, France, [4]LML - FRE 3723, CNRS, Villeneuve D'Ascq, France, [5]Hopital Jeanne de Flandre, CHR Lille, Villeneuve D'Ascq, France*

324 **Elastin Fiber Network in Porince Epicardium: 3D Viscualization and Quantification** SB³C2016-823
Xiaodan Shi, Bryn Brazile, David Lee, Sourav Patnaik, Jim Cooley, Raj Prabhu, Lakiesha Williams, Song Zhang, Jun Liao, *Mississippi State University, Mississippi State, MS, United States*

325 **Determining the Effect of Elastin Digestion on the Regional Biaxial Mechanical Properties of the Murine Cervix** SB³C2016-695
Victoria Morris, **Cassandra Conway**, Kristin Miller, *Biomedical Engineering, Tulane University, New Orleans, LA, United States*

326 **Viscosity is a Necessary Component of Mechanical Characterization of Biological Tissue** SB³C2016-935
Andres Rubiano[1], Daniel Delitto[2], Song Han[1], Steven Hughes[2], Chelsey S. Simmons[1, 3, 4], *[1]Mechanical and Aerospace Engineering, University of Florida, Gainesville, FL, United States, [2]Department of Surgery, University of Florida, Gainesville, FL, United States, [3]Biomedical Engineering, University of Florida, Gainesville, FL, United States, [4]Division of Cardiovascular Medicine, University of Florida, Gainesville, FL, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

327 **Quantification and Comparison of Mechanical Properties of the Urinary Bladder Wall** SB³C2016-934
Antonella Massafra, **Sara Roccabianca**, *Mechanical Engineering, Michigan State University, East Lansing, MI, United States*

328 **A Mechanical Analysis of Compressible Collagen Hydrogels** SB³C2016-1135
Brooks Lane[1], Tarek Shazly[1, 2], John Eberth[1, 3], *[1]Biomedical Engineering, University of South Carolina, Columbia, SC, United States, [2]Mechanical Engineering, University of South Carolina, Columbia, SC, United States, [3]Cell Biology and Anatomy, University of South Carolina, Columbia, SC, United States*

329 **Stochastic Head Morphology Description for Uncertainty Quantification of TBI Prediction** SB³C2016-591
Kirubel Teferra[1], Siddiq M. Qidwai[1], Shankarjee Krishnamoorthi[2], *[1]Multifunctional materials branch, Code 6353, Naval Research Laboratory, Washington DC, DC, United States, [2]NRL/ASEE Postdoctoral fellowship, Naval Research Laboratory, Washington DC, DC, United States*

330 **Characterization of the Failure Responses of Skin: Comparison of Uniaxial and Equibiaxial Planar Mechanics** SB³C2016-649
Samantha Schumm, Meagan Ita, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

SATURDAY, JULY 2 | 11:45am - 1:15pm

Engineering the Cellular Microenvironment — Wilson B

Session Chair: Brendon Baker, *University of Michigan, MI, United States*
Session Co-Chair: Alice Huang, *Mount Sinai School of Medicine, NY, United States*

11:45AM **A Biomimetic Core-Shell Platform for Miniaturized 3D Cell and Tissue Engineering** SB³C2016-943
Pranay Agarwal, Jung K. Choi, Xiaoming He, *Biomedical Engineering, The Ohio State University, Columbus, OH, United States*

12:00PM **Differentiating Stem Cells Exhibit Molecular and Microenvironmental Heterogeneity at the Single Cell Level** SB³C2016-793
Claire M. McLeod[1, 2, 3], Allison J. Cote[1], Arjun Raj[1], Robert L. Mauck[1, 2, 3], *[1]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, United States, [2]Translational Musculoskeletal Research Center, Philadelphia VA Medical Center, Philadelphia, PA, United States, [3]Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, United States*

12:15PM **Anisotropically Stiff Micropillar Substrate for Controlling Cellular Alignment and Elongation** SB³C2016-750
Yunus Alapan[1], Mousa Younesi[1], Ozan Akkus[1, 2, 3], Umut A. Gurkan[1, 2, 3], *[1]Mechanical and Aerospace Engineering Department, Case Western Reserve University, Cleveland, OH, United States, [2]Biomedical Engineering Department, Case Western Reserve University, Cleveland, OH, United States, [3]Orthopaedics Department, Case Western Reserve University, Cleveland, OH, United States*

12:30PM **Non-swelling Micromolded Hydrogels Reveal That Matrix Degradability Controls Multicellularity of 3D Cell Invasion** SB³C2016-973
Brendon M. Baker[1], Britta Trappmann[1], Jason A. Burdick[2], Christopher S. Chen[1], *[1]Biomedical Engineering, Boston University, Boston, MA, United States, [2]Bioengineering, University of Pennsylvania, Philadelphia, PA, United States*

12:45PM **Schwann Cells Promote Penetration and Myelination of Regenerated Axons into Patterned Channels** SB³C2016-45
Chun Liu, **Christina Chan**, *Chemical Engineering and Materials Science, Michigan State University, East Lansing, MI, United States*

1:00PM **Tunable and Selective Nanofiber Degradation Regulates 3D Cell Migration** SB³C2016-631
Feini Qu[1, 2], Julianne L. Holloway[1, 2], Jason A. Burdick[1, 2], Robert Mauck[1, 2], *[1]University of Pennsylvania, Philadelphia, PA, United States, [2]Philadelphia VA Medical Center, Philadelphia, PA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

SATURDAY, JULY 2	11:45am - 1:15pm

Upper and Lower Extremity Joint Mechanics — Wilson C

Session Chair: Ken Fischer, *University of Kansas, KS, United States*
Session Co-Chair: Justin Fernandez, *The University of Auckland, New Zealand*

11:45AM **Fibrin Glue Increases the Strength of Conduit-Assisted Digital Nerve Repairs** SB³C2016-912
Patrick J. Schimoler[1, 2], Jessica Childe[2], Steven Regal[2], Alexander Kharlamov[2], Peter Tang[2], Mark Carl Miller[1, 2], *[1]Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA, United States, [2]Orthopaedic Surgery, Allegheny General Hospital, Pittsburgh, PA, United States*

12:00PM **The Effect of Lateralizing Joint Center of Rotation of Reverse Total Shoulder Arthroplasty on Adduction Range of Motion and Initial Implant Fixation: A Finite Element Study** SB³C2016-988
Josie Elwell[1], Joseph Choi[2], Ryan Willing[1], *[1]Binghamton University, Binghamton, NY, United States, [2]Guthrie Clinic, Sayre, PA, United States*

12:15PM **Premorbid Retroversion is Significantly Greater in Type B2 Glenoids** SB³C2016-16
Nikolas K. Knowles[1], Louis M. Ferreira[1], George S. Athwal[2], *[1]Biomedical Engineering, The University of Western Ontario, London, ON, Canada, [2]Surgery, The University of Western Ontario, London, ON, Canada*

12:30PM **Novel Method for Characterizing Loading Patterns of Knee Stabilizers Yields New Insight into the Function of the Anterolateral Ligament** SB³C2016-974
Robert N. Kent[1], Thomas L. Wickiewicz[2], Andrew D. Pearle[2], Carl W. Imhauser[1], *[1]Department of Biomechanics, Hospital for Special Surgery, New York, NY, United States, [2]Department of Orthopedic Surgery, Hospital for Special Surgery, New York, NY, United States*

12:45PM **Effects of Proximal Tibia Anterior Closing Wedge Osteotomy on ACL Force and Knee Kinematics** SB³C2016-75
Kent T. Yamaguchi[1], Daniel V. Boguszewski[1], Edward Cheung[1], Justin Mathew[2], Keith Markolf[1], David McAllister[1], Frank Petrigliano[1], *[1]Orthopedic Surgery, University of California Los Angeles, Los Angeles, CA, United States, [2]David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, United States*

1:00PM **Virtual Design of Modular 3D Printed Ankle Foot Orthoses** SB³C2016-661
Alessio Ielapi[1], Benedict Verhegghe[1], Miguel Vermandel[2], Jan Patrick Deckers[2], Malcolm Forward[3], Egle Vasiliauskaite[3], Matthieu De Beule[1], *[1]IBiTech-bioMMeda, Gent University, Gent, Belgium, [2]V!GO N.V. / S.A., Wetteren, Belgium, [3]Gait & Movement Analysis Laboratory, University Hospital Ghent, Gent, Belgium*

SATURDAY, JULY 2	11:45am - 1:15pm

Musculoskeletal Soft Tissue: Cartilage — Wilson D

Session Chair: Jennifer Wayne, *Virginia Commonwealth University, VA, United States*
Session Co-Chair: David M. Pierce, *University of Connecticut, CT, United States*

11:45AM **Indispensable Roles of Decorin and Biglycan in Cartilage Mechanical Function During Maturation** SB³C2016-964
Basak Doyran[1], Qingmei Yao[2], Samuel J. Rozans[1], Qing Li[1], Marian F. Young[3], Renato V. Iozzo[4], David Birk[2], Lin Han[1], *[1]School of Biomedical Engineering, Science and Health Systems, Drexel Univeristy, Philadelphia, PA, United States, [2]Department of Molecular Pharmacology and Physiology, University of South Florida, Tampa, FL, United States, [3]Molecular Biology of Bones and Teeth Section, National Institutes of Health, Bethesda, MD, United States, [4]Department of Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA, United States*

12:00PM **An Alternative Method to Characterize the Quasi-Static Material Properties of Murine Articular Cartilage** SB³C2016-744
Alexander Kotelsky, Chandler Woo, Mark R. Buckley, *Biomedical Engineering, University of Rochester, Rochester, NY, United States*

12:15PM **Bisphosphonate can Rescue the Damaged Articular Cartilage in vitro** SB³C2016-70
Yilu Zhou, Mengxi Lv, Marisa Bisram, Joshua Blotnick, Liyun Wang, X. Lucas Lu, *University of Delaware, Newark, DE, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

12:30PM **Tribological Rehydration I: A New Mechanism of Interstitial Fluid Recovery** SB³C2016-74
Axel Moore[1], David Burris[2], *[1]Biomedical Engineering, University of Delaware, Newark, DE, United States, [2]Mechanical Engineering, University of Delaware, Newark, DE, United States*

12:45PM **Mechanostatistical Cartilage Pellet Model to Evaluate Cartilage Growth in Scaffolds** SB³C2016-573
Christopher Miller, *Auckland Bioengineering institute, University of Auckland, Auckland, New Zealand*

1:00PM **Shear Testing of Human Articular Cartilage: Anistropy Apparent at Large But Not Small Shear Strains** SB³C2016-712
Franz S. Maier[1], M. Hicham Drissi[2], David M. Pierce[1], *[1]Mechanical Engineering/Biomedical Engineering/Mathematics, University of Connecticut, Storrs, CT, United States, [2]Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, United States*

SATURDAY, JULY 2 | 11:45am - 1:15pm

Morphogenesis, Remodeling and Repair — Annapolis 1

Session Chair: Nandan L. Nerurkar, *Harvard Medical School, MA, United States*
Session Co-Chair: Lance Davidson, *University of Pittsburgh, PA, United States*

11:45AM **Mechanical Regulation of Cell Behaviors During Convergent Extension of the Xenopus laevis Neural Plate** SB³C2016-1105
Deepthi S. Vijayraghavan, Emily E. Kieffer, Joseph H. Shawky, Lance A. Davidson, *Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States*

12:00PM **Meso-Scale Reorganization of Metabolic Brain Networks is Associated with Persistent Pain** SB³C2016-59
Megan Sperry, Sonia Kartha, Eric Granquist, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

12:15PM **Molecular Control of Differential Growth During Looping of the Embryonic Small Intestine** SB³C2016-832
Nandan L. Nerurkar, Cliff Tabin, *Genetics, Harvard Medical School, Boston, MA, United States*

12:30PM **Optimization of In Vitro Endothelial Cell Self-Assembly for Millimeter Scale Vasculogenesis** SB³C2016-878
Joshua T. Morgan, Jasmine Shirazi, Erica M. Comber, Peter A. Sariano, Jason P. Gleghorn, *Biomedical Engineering, University of Delaware, Newark, DE, United States*

12:45PM **Structural Analysis of Early Embryonic Aortic Arch Morhphogenesis** SB³C2016-895
Seyedehsamaneh Lashkarinia, Senol Piskin, Selda Goktas, **Kerem Pekkan**, *Koc University, İstanbul, Turkey*

1:00PM **The Effect of Dynamic Stimulation on Joint Morphogenesis of the Embryonic Chick Knee Joint** SB³C2016-14
Vikesh V. Chandaria, Niamh C. Nowlan, *Bioengineering, Imperial College London, London, United Kingdom*

SATURDAY, JULY 2 | 11:45am - 1:15pm

Pediatric Cardiology and Embryology — Annapolis 2

Session Chair: Alison Marsden, *UC San Diego, CA, United States*
Session Co-Chair: Ethan Kung, *Clemson University, SC, United States*

11:45AM **Quantifying Circumferential and Wall Shear Stress in a Developing Embryonic Heart Using Non-invasive Techniques** SB³C2016-893
David Bark[1], Deborah Garrity[2], Lakshmi Prasad Dasi[1], *[1]Mechanical Engineering, Colorado State University, Fort Collins, CO, United States, [2]Biology, Colorado State University, Fort Collins, CO, United States*

12:00PM **Buckling Configurations of the Extracardiac Total Cavopulmonary Conduit** SB³C2016-883
Gokce Nur Oguz[1], Senol Piskin[1], Erhan Ermek[1], Naz Altekin[1], Ahmet Arnaz[2], Kerem Pekkan[1], *[1]Mechanical Engineering, Koc University, Istanbul, Turkey, [2]Cardiovascular Surgery, Acıbadem Bakırköy Hospital, Istanbul, Turkey*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

12:15PM **In Vivo Measurements of Wall Shear Stress Environment in Fetus Umbilical Arteries and Veins** SB³C2016-34
Shier Nee Saw[1], Dawn Chia[2], Citra Nurfarah Zaini Mattar[2], Arijit Biswas[2], Choon Hwai Yap[1], *[1]Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore, [2]Department of Obstetrics and Gynecology, National University of Singapore & National University Health Systems, Singapore, Singapore*

12:30PM **Coronary Circulation in an In Vitro Multi-scale Model of Norwood Circulation** SB³C2016-91
Lauren E. Carter, Tim Conover, Tian-qi Hang, Richard Figliola, *Mechanical Engineering, Clemson University, Clemson, SC, United States*

12:45PM **Implementation of the Assisted Bidirectional Glenn in an Idealized Single Ventricle Model** SB³C2016-1091
Jessica K. Shang[1], Mahdi Esmaily-Moghadam[2], Tigran Khalapyan[3], Richard Figliola[4], Olaf Reinhartz[3], Tain-Yen Hsia[5], Alison L. Marsden[1], *[1]Pediatrics, Stanford University, Stanford, CA, United States, [2]Center for Turbulence Research, Stanford University, Stanford, CA, United States, [3]Cardiothoracic Surgery, Stanford University, Stanford, CA, United States, [4]Mechanical Engineering, Clemson University, Clemson, SC, United States, [5]Cardiothoracic Surgery, Great Ormond Street Hospital, London, United Kingdom*

1:00PM **Computational Fluid Dynamics of Fetal Right Ventricle Based on Patient-specific Ultrasound Images** SB³C2016-85
Hadi Wiputra[1], Changquan Lai[1], R. Nivetha[1], Khong Chun Chua[1], Joel Heng[1], Guo Lan[1], Guat Ling Lim[2], Citra Nurfarah Zaini Mattar[2], Biswas Arijit[2], Hwa Liang Leo[1], Choon Hwai Yap[1], *[1]National University of Singapore, Singapore, Singapore, [2]Department of Obstetrics and Gynecology, National University Hospital Systems, Singapore, Singapore*

SATURDAY, JULY 2 | 11:45am - 1:15pm

Rehabilitation Devices, Modeling, and Control — Azalea 2

Session Chair: Ted Conway, *Florida Institute of Technology, FL, United States*
Session Co-Chair: Laurel Kuxhaus, *Clarkson University, NY, United States*

11:45AM **The Synergistic Use of Haptic Feedback with an EMG Controlled Transfemoral Powered-Knee Prosthesis** SB³C2016-596
J. Miles Canino, Kevin B. Fite, *Mechanical and Aeronautical Engineering, Clarkson University, Potsdam, NY, United States*

12:00PM **Functional Evaluation of Exoskeleton Control Strategies for Treating Crouch Gait in Cerebral Palsy** SB³C2016-816
Zachary F. Lerner, Diane L. Damiano, Thomas C. Bulea, *Rehabilitation Medicine Department, National Institutes of Health, Bethesda, MD, United States*

12:15PM **A Methodology for the Quantification of Upper Limb Prosthetic Socket Interface Mechanics** SB³C2016-37
Jonathon S. Schofield[1], Jason P. Carey[1], Paul D. Marasco[2], Jacqueline S. Hebert[3], *[1]Mechanical Engineering, University of Alberta, Edmonton, AB, Canada, [2]Biomedical Engineering, Cleveland Clinic, Cleveland, OH, United States, [3]Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada*

12:30PM **A Mechanical Analog Model of Adolescent Idiopathic Scoliosis** SB³C2016-963
Chloe L. Chung[1], Derek M. Kelly[2], Jack R. Steele[3], **Denis J. DiAngelo**[1], *[1]The Department of Orthopaedic Surgery and Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, United States, [2]The Department of Orthopaedics, Campbell Clinic Orthopaedics and Le Bonheur Children's Hospital, Memphis, TN, United States, [3]The Center for Orthotics and Prosthetics, Inc., Memphis, TN, United States*

12:45PM **Mapping Hand Dysfunction: A Model for Use in Rehabilitation** SB³C2016-843
Joshua P. Drost[1], Hyokyoung Hong[2], Tamara Reid Bush[1], *[1]Mechanical Engineering, Michigan State University, East Lansing, MI, United States, [2]Statistics and Probability, Michigan State University, East Lansing, MI, United States*

1:00PM **Kinematic Evaluation of a Wearable Soft Robotic System for Continuous Passive Motion in Post Stroke Hand Rehabilitation** SB³C2016-833
Rita M. Patterson[1], Nicoleta Bugnariu[2], Timothy Niacaris[3], Mahdi Haghshenas-Jaryani[4], Carrigan Wei[4], Caleb Nothnagle[4], Muthu Wijesundara[5], *[1]Family Medicine and Osteopathic Manipulative Medicine, University of North Texas Health Science Center, Fort Worth, TX, United States, [2]Physical Therapy, University of North Texas Health Science Center, Fort Worth, TX, United States, [3]Orthopaedic Surgery, University of North Texas Health Science Center, Fort Worth, TX, United States, [4]Research Institute, University of Texas At Arlington, Arlington, TX, United States, [5]Osteopathic Manipulative Medicine, University of North Texas Health Science Center, Fort Worth, TX, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

SATURDAY, JULY 2	11:45am - 1:15pm

Hemodynamic Flows and Devices — Azalea 3

Session Chair: Richard Figliola, *Clemson University, SC, United States*
Session Co-Chair: Brandon Dixon, *Georgia Tech, GA, United States*

11:45AM **Computational Assessment of the Effect of Arteriovenous Graft Flow Rate on Vascular Access Hemodynamics in a Novel Modular Anastomotic Valve Device** SB³C2016-597
Andrew McNally[1], A. George Akingba[2], Philippe Sucosky[3], *[1]University of Notre Dame, South Bend, IN, United States, [2]Indiana University - Purdue University of Indiana, Indianapolis, IN, United States, [3]Wright State University, Dayton, OH, United States*

12:00PM **Effect of Transcatheter Aortic Valve Positioning on Paravalvular Leakage: A Patient-Specific Numerical Model** SB³C2016-753
Matteo Bianchi, Ram P. Ghosh, Gil Marom, Danny Bluestein, *Biomedical Engineering, Stony Brook University, Stony Book, NY, United States*

12:15PM **Image-Based Simulations Show Significant Flow Fluctuations in a Normal Left Ventricle.** SB³C2016-131
Christophe Chnafa[1], Simon Mendez[2], Franck Nicoud[2], *[1]Mechanical & Industrial Engineering, University of Toronto, Toronto, ON, Canada, [2]IMAG, University of Montpellier, Montpellier, France*

12:30PM **Hemodynamic Regulation of Tie1 in Aortic Valve Endothelial Cells** SB³C2016-756
Camryn Johnson, W. David Merryman, *Vanderbilt University, Nashville, TN, United States*

12:45PM **Patient-Specific CFD Simulations of Intraventricular Haemodynamics Based on 3D Ultrasound Imaging.** SB³C2016-121
Alessandra M. Bavo[1], Alison M. Pouch[2], Joris Degroote[3], Jan Vierendeels[3], Joseph H. Gorman[2], Robert C. Gorman[2], Patrick Segers[1], *[1]ELIS department, Ibitech bioMMeda, Ghent University, Gent, Belgium, [2]Gorman Cardiovascular Research Group, University of Pennsylvania, Philadelphia, PA, United States, [3]Department of Flow, Heat and Combustion Mechanics, Ghent University, Gent, Belgium*

1:00PM **Flap Motion and Flow Reversal Vary with Number of Tears in an In Vitro Model of Descending Thoracic Aortic Dissection** SB³C2016-683
Joav Birjiniuk[1], Lucas H. Timmins[1, 2], Mark Young[3], John N. Oshinski[1, 2], Ravi K. Veeraswamy[4], David N. Ku[5], *[1]Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States, [2]Radiology, Emory University School of Medicine, Atlanta, GA, United States, [3]Cardiac and Vascular Group, Medtronic, Inc., Santa Rosa, CA, United States, [4]Division of Vascular Surgery, Department of Surgery, Emory University School of Medicine, Atlanta, GA, United States, [5]Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, United States*

SATURDAY, JULY 2	1:30pm - 3:00pm

Mechanotransduction and Sub-Cellular Biophysics — Wilson B

Session Chair: Toshiro Ohashi, *Hokkaido University, Sapporo, Japan*
Session Co-Chair: Joel B. Boerckel, *University of Notre Dame, IN, United States*

1:30PM **Changes in Nuclear Stiffness of Nesprin-1 Depleted Fibroblasts Exposed to Cyclic Stretching** SB³C2016-760
Naoya Sakamoto[1], Kiyomi Sadamoto[2], Mai Ogawa[2], Masaki Takeuchi[2], Noriyuki Kataoka[3], *[1]Department of Intelligent Mechanical Systems, Tokyo Metropolitan University, Tokyo, Japan, [2]Department of Medical Engineering, Kawasaki University of Medical Welfare, Okayama, Japan, [3]Department of Mechanical Engineering, Nihon University, Fukushima, Japan*

1:45PM **Deletion of Cadherin-11 Increases Smooth Muscle Actin Expression But Prevents Contraction in Valve Fibroblasts** SB³C2016-1088
Meghan Bowler, W. David Merryman, *Vanderbilt University, Nashville, TN, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

2:00PM **Matrix Stiffness Enhances Vasculogenesis Through Cytoskeletal Activation of YAP and TAZ Mediated Gene Expression** SB³C2016-822

Devon E. Mason[1], Sherry L. Voytik-Harbin[2], Mervin C. Yoder[3], Joel D. Boerckel[1], *[1]Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, IN, United States, [2]Weldon School of Biomedical Engineering and Dept. of Basic Medical Sciences, Perdue University, West Lafayette, IN, United States, [3]Herman B Wells Center for Pediatric Research, Indiana University School of Medicine, Indianapolis, IN, United States*

2:15PM **Regulation of Valve Interstitial Cell Contractility and Metabolism by Mesoscale Architecture** SB³C2016-920

Ishita Tandon, Atefeh Razavi, Timothy Muldoon, Narasimhan Rajaram, Kartik Balachandran, *University of Arkansas, Fayetteville, AR, United States*

2:30PM **Strain-rate Dependent Mechanical Responses of the Aortic Valve Interstitial Cells** SB³C2016-950

Yusuke Sakamoto[1], Rachel M. Buchanan[2], Johannah S. Adams[3], Farshid Guilak[4], Michael S. Sacks[1, 2], *[1]The Institute for Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX, United States, [2]Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States, [3](2) Departments of Orthopaedic Surgery and Biomedical Engineering, Duke University, Durham, NC, United States, [4]Departments of Orthopaedic Surgery, Biomedical Engineering, and Developmental Biology, Washington University, St. Louis, St. Louis, MO, United States*

2:45PM **Myosin II Mediated Cortical Contractility Regulates Nucleus Pulposus Cell Osmotic Properties and Morphology** SB³C2016-959

Timothy Jacobsen, Paula Hernandez, Nadeen Chahine, *The Feinstein Institute for Medical Reseaerch, Manhasset, NY, United States*

SATURDAY, JULY 2 | 1:30pm - 3:00pm

Celebration for Vijay Goel: Spine Biomechanics — Wilson C

Session Chair: Denis DiAngelo, *University of Tennessee, TN, United States*
Session Co-Chair: Francesco Travascio, *University of Miami, FL, United States*

1:30PM **The Effect of Degeneration on the Six Degree of Freedom Mechanical Properties of Human Spine Segments** SB³C2016-646

John J. Costi[1], Dhara Amin[1], Dana Sommerfeld[2], Isaac Lawless[1], Richard Stanley[1], Boyin Ding[3], *[1]School of Computer Science, Engineering and Mathematics, Flinders University, Adelaide, Australia, [2]Institute of Biomechanics, TUHH Hamburg University, Hamburg, Germany, [3]School of Mechanical Engineering, The University of Adelaide, Adelaide, Australia*

1:45PM **The Resonance of the Thoracic Spine Under Whole Body Vibration is Non-Linear & Depends on Acceleration: An in Vivo Study Using a Rat Model** SB³C2016-82

Timothy Holsgrove, Martha Zeeman, William Welch, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

2:00PM **MRI Quantification of Human Spine Cartilage Endplate Geometry** SB³C2016-704

John DeLucca[1], John Peloquin[2], Lachlan Smith[2], Nichol Reisher[1], Alexander Wright[2], Edward Vresilovic[3], Dawn Elliott[1], *[1]University of Delaware, Newark, DE, United States, [2]University of Pennsylvania, Philadelphia, PA, United States, [3]Pennsylvania State University, Hershey, PA, United States*

2:15PM **Cervical Spinal Cord Stress: A Comprehensive Finite Element Model of the Cervical Spinal Cord** SB³C2016-698

Kirsten E. Stoner[1], Kingsely O. Abode-Iyamah[2], Douglas C. Fredericks[3], Matthew A. Howard[2], Nicole M. Grosland[1], *[1]Biomedical Engineering, University of Iowa, Iowa City, IA, United States, [2]Neurosurgery, University of Iowa, Iowa City, IA, United States, [3]Orthopaedics, University of Iowa, Iowa City, IA, United States*

2:30PM **Mechanisms of Cervical Spine Disc Injury Under Cyclic Loading: Experiments and Finite Element Analysis** SB³C2016-835

Sagar Umale[1], Narayan Yoganandan[1], Mike Arun[1], Brian Stemper[1], Brian Snyder[2], *[1]Neuroscience Research, Medical College of Wisconsin, Milwaukee, WI, United States, [2]Harvard Medical School, Beth Israel Deaconess Medical Center, Boston, MA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

2:45PM **A Finite Element Analysis of the Occipitoatlantal Capsular Ligaments as the Primary Stabilizers of the Adult and Pediatric CraniocervicalJunction** SB³C2016-62

Rinchen Phuntsok[1], Benjamin Ellis[1], Douglas Brockmeyer[2], *[1]Department of Bioengineering, University of Utah, Salt Lake City, UT, United States, [2]School of Medicine, Pediatric Neurosurgery, University of Utah, Salt Lake City, UT, United States*

SATURDAY, JULY 2 | 1:30pm - 3:00pm

Bone Biomechanics — Wilson D

Session Chair: Mariana Kersh, *University of Illinois, Urbana, IL, United States*
Session Co-Chair: Eric Kennedy, *Bucknell University, PA, United States*

1:30PM **The Development of a "Fuzzy" Yield Envelope for Trabecular Porcine Skull Bone Using Numerical Simulations** SB³C2016-1050

Allison N. Ranslow, Reuben H. Kraft, *Mechanical and Nuclear Engineering, Penn State University, University Park, PA, United States*

1:45PM **Design of Fatigue Test for Ex-Vivo Mouse Vertebra** SB³C2016-1025

Megan M. Pendleton[1], Joshua S. Alwood[2], Grace D. O'Connell[1], Tony M. Keaveny[1], *[1]Mechanical Engineering, UC Berkeley, Berkeley, CA, United States, [2]Space Biosciences Division, NASA Ames Research Center, Moffett Field, CA, United States*

2:00PM **Electric Properties of Cortical Bone are Strong Predictors of Bone Mechanical Properties** SB³C2016-77

Mustafa Unal[1], Fatih Cingoz[2], Cevat Bagcioglu[2], Yilmaz Sozer[2], Ozan Akkus[1], *[1]Case Western Reserve University, Cleveland, OH, United States, [2]The University of Akron, Akron, OH, United States*

2:15PM **Diagnostic Potential of Kirschner (K-) Wire and Reference Probe Indentation for the Prediction of Bone Mineral Density (BMD)** SB³C2016-1076

Eric A. Kennedy[1], Sarah C. Denning[1], Donna M. Ebenstein[1], Thomas R. Bowen[2], *[1]Biomedical Engineering, Bucknell University, Lewisburg, PA, United States, [2]Orthopaedic Surgery, Geisinger Health System, Danville, PA, United States*

2:30PM **Bioinspired Simulation of Polycrystalline Materials** SB³C2016-1096

Liqiang Lin, Xiaodu Wang, xiaowei Zeng, *Mechanical Engineering, University of Texas at San Antonio, San Antonio, TX, United States*

2:45PM **Characteristic X-ray Diffraction Method for Mechanical Analysis of Mineral and Collagen Phases in Bone Tissue** SB³C2016-781

Masahiro Todoh, Shigeru Tadano, *Faculty of Engineering, Hokkaido University, Sapporo, Japan*

SATURDAY, JULY 2 | 1:30pm - 3:00pm

Solid Mechanics: Biomechanics of Injury — Annapolis 1

Session Chair: Ian A. Sigal, *University of Pittsburgh, PA, United States*
Session Co-Chair: Timothy P. Holsgrove, *University of Pennsylvania, PA, United States*

1:30PM **Quantitative Comparison of Human Body and ATD Occupant Models in US-NCAP Test Simulations** SB³C2016-975

Berkan Guleyupoglu, Bharath Koya, Matt Davis, Scott Gayzik, *Biomedical Engineering, Wake Forest University School of Medicine, Winston Salem, NC, United States*

1:45PM **Upper Cervical Spine Loading Simulating Low-Speed Collisions Significantly Increases Facet Strains Compared to Equivalent Quasistatic Loading** SB³C2016-115

Timothy Holsgrove, Nicolas Jaumard, Nina Zhu, Nicholas Stiansen, William Welch, Beth Winkelstein, *University of Pennsylvania, Philadelphia, PA, United States*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

2:00PM **Injury-Based Advanced Automatic Crash Notification Algorithm Improves Motor Vehicle Crash Occupant Triage** SB³C2016-102
Samantha Schoell[1], Ashley Weaver[1], Jennifer Talton[2], Ryan Barnard[2], R. Shayn Martin[1], J. Wayne Meredith[1], Joel Stitzel[1], *[1]Wake Forest School of Medicine, Winston-Salem, NC, United States, [2]Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC, United States*

2:15PM **Damage Modeling of a Human Tibia and Fibula Fracture Caused by a Mixed Martial Arts Kick** SB³C2016-825
Andrew Lamont[1], **Vina L. Nguyen**[1, 2], Robbin Bertucci[1], Youssef Hammi[1], Mark F. Horstemeyer[1], Jun Liao[1, 2], Hongjoo Rhee[1], Lakiesha Williams[1, 2], Rajkumar Prabhu[1, 2], *[1]Center of Advanced Vehicular Systems, Mississippi State University, Starkville, MS, United States, [2]Department of Agricultural and Biological Engineering, Mississippi State University, Mississippi State, MS, United States*

2:30PM **Assessing the Ability of Hockey Helmets to Reduce Concussion Risk** SB³C2016-952
Bethany Rowson, Steven Rowson, Stefan M. Duma, *Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, United States*

2:45PM **Foul Tip Attenuation of Baseball Catcher Masks Using Head Impact Metrics** SB³C2016-625
Christopher Eckersley, Hattie Cutcliffe, Jay Shridharani, Cameron 'Dale' Bass, Terrance White, *Biomedical Engineering, Duke University, Durham, NC, United States*

SATURDAY, JULY 2 | 1:30pm - 3:00pm

Thrombosis and Cardiac Flows — Annapolis 2

Session Chair: Keefe Manning, *Pennsylvania State University, PA, United States*
Session Co-Chair: Shawn Shadden, *UC Berkeley, CA, United States*

1:30PM **Coagulation Cascade Model Reduction Using a Genetic Algorithm** SB³C2016-113
Kirk B. Hansen, Shawn C. Shadden, *Mechanical Engineering, University of California, Berkeley, Berkeley, CA, United States*

1:45PM **Macroscopic Predictions of Thrombus Growth in a Three-Dimensional Backward-Facing Step** SB³C2016-108
Joshua O. Taylor, Steven Deutsch, **Keefe B. Manning**, *Biomedical Engineering, The Pennsylvania State University, University Park, PA, United States*

2:00PM **Distal Emboli Following Cover Assisted Thrombectomy** SB³C2016-892
Juyu Chueh, Ajit S. Puri, Matthew J. Gounis, *Radiology, University of Massachusetts Medical School, Worcester, MA, United States*

2:15PM **Towards Non-invasive, Computational Modeling of the Transport of Thrombo-emboli and Athero-emboli along Arteries** SB³C2016-970
Debanjan Mukherjee, Shawn C. Shadden, *U.C. Berkeley, Berkeley, CA, United States*

2:30PM **A Shape Optimization Approach Applied to Intraluminal Thrombus Deposition in Abdominal Aortic Aneurysms** SB³C2016-939
Paolo DiAchile[1], George Tellides[2], Jay D. Humphrey[1], *[1]Department of Biomedical Engineering, Yale University, New Haven, CT, United States, [2]Surgery, Yale School of Medicine, New Haven, CT, United States*

2:45PM **Predicting False Lumen Thrombosis in 3D Patient-Specific Models of Type B Aortic Dissection** SB³C2016-636
Claudia Menichini[1], Zhuo Cheng[1], Richard G. J. Gibbs[2], Xiao Y. Xu[1], *[1]Department of Chemical Engineering, Imperial College London, London, United Kingdom, [2]Department of Surgery and Cancer, St. Mary's Hospital, Imperial College NHS Trust, London, United Kingdom*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

SATURDAY, JULY 2	1:30pm - 3:00pm

Human Dynamics of the Torso and Lower Extremities — Azalea 2

Session Chair: Joseph Iaquinto, *VA, Puget Sound, WA, United States*
Session Co-Chair: Tom Gardner, *Columbia University, NY, United States*

1:30PM **Muscle Activation in Cyclic Lifting with Trained Lumbar-Pelvic Coordination** SB³C2016-1086
Timothy D. Craig, Alice E. Riley, Neena K. Sharma, **Sara E. Wilson**, *Mechanical Engineering, University of Kansas, Lawrence, KS, United States*

1:45PM **The Determination of Free Torque on Athletic Turf Surfaces Using Insole Pressure Data** SB³C2016-1079
Brian T. Weaver[1, 2], Jerrod E. Braman[1], Roger C. Haut[1], *[1]Orthopedics Biomechanics Laboratories, Michigan State University, East Lansing, MI, United States, [2]Explico Engineering Co., Novi, MI, United States*

2:00PM **Knee and Ankle Biomechanics During Squatting with Heels On and Off the Ground, with and without Body Weight Shifting** SB³C2016-624
Jonathan Fox, Mohamed Samir Hefzy, Charles Armstrong, *The University of Toledo, Toledo, OH, United States*

2:15PM **A Method for Predicting Complete Ground Reaction Forces with Plantar Pressure Insoles during Level and Angled Walking** SB³C2016-851
Andrew J. Crechiolo, Feng Wei, Roger C. Haut, *Orthopaedic Biomechanics Laboratories, Michigan State University, East Lansing, MI, United States*

2:30PM **Knee Medial Tibial Cartilage Stress One and Five Years After Anterior Cruciate Ligament Reconstruction** SB³C2016-916
Ashutosh Khandha[1], Kurt Manal[2], Lynn Snyder-Mackler[3], Thomas S. Buchanan[4], *[1]Biomedical Engineering, University of Delaware, Newark, DE, United States, [2]Mechanical Engineering, University of Delaware, Newark, DE, United States, [3]Physical Therapy, University of Delaware, Newark, DE, United States, [4]Biomedical Engineering, Mechanical Engineering, University of Delaware, Newark, DE, United States*

2:45PM **The Effect of Soft Tissue Artifact on Kinematic Measurement - an Evaluation of Optical Marker Motion using Biplane Fluoroscopy.** SB³C2016-1097
Joseph M. Iaquinto[1], Matthew W. Kindig[1], David R. Haynor[2], William R. Ledoux[1], *[1]VA Puget Sound, Seattle, WA, United States, [2]University of Washington Medical Center, Seattle, WA, United States*

SATURDAY, JULY 2	1:30pm - 3:00pm

Hemodynamics, Lymphatics and Lung Therapy — Azalea 3

Session Chair: Nastaran Hashemi, *Iowa State University, IA, United States*
Session Co-Chair: Joshua Smith, *Lafayette College, LA, United States*

1:30PM **Cerebral Blood Flow Simulation for the Whole Mouse Brain** SB³C2016-1062
ben schneller[1], Mahsa Ghaffari[1], Sahar Ghanavati[2], john sled[2], andreas linninger[1], *[1]university of illinois at chicago, chicago, IL, United States, [2]University of Toronto, toronto, ON, Canada*

1:45PM **Directing Angiogenesis with Fluid Mechanics at Vessel Bifurcations** SB³C2016-1123
Ehsan Akbari, *Department of Mechanical and Aerospace Engineering, The Ohio State University, Columbus, OH, United States*

2:00PM **In Silico and In Vitro Modelling of Flow Behaviour in Lymphatic Vessels** SB³C2016-787
Sinéad T. Morley, David T. Newport, Michael T. Walsh, *MABE, University of Limerick, Limerick, Ireland*

2:15PM **Placenta-on-a-chip: A Novel Platform in Drug Testing and Toxicology Applications** SB³C2016-919
Nastaran Hashemi, *Iowa State University, Ames, IA, United States*

2:30PM **Preventing Upper Airway Collapse Using CPAP with and without Pressure Oscillations** SB³C2016-19

THE EFFECT OF DYNAMIC STIMULATION ON JOINT MORPHOGENESIS OF THE EMBRYONIC CHICK KNEE JOINT

Vikesh V. Chandaria, Niamh C. Nowlan

Department of Bioengineering
Imperial College London
London, UK

INTRODUCTION

Evolution has generated joint shapes highly specialised for joint function. Alterations or abnormalities in joint shape development can therefore severely compromise this ability. Mechanical stimulation has been identified as a critical variable during joint morphogenesis from both clinical case studies and animal models [1, 2]. It has been shown that under immobilised conditions developing joints in the chick embryo become fused across the joint site and appear simplified and flattened [3, 4]. By manually moving developing knee joints *in vitro,* it was demonstrated that the effects of immobilisation could be countered [5]. However, how variations of applied mechanical stimulation affects joint shape development remains poorly understood.

In this study we focused on exploring the effect of magnitude of movement on joint morphogenesis. It was hypothesised that joint shape would be affected by mechanical stimulation in a dose-dependent manner and that an increase in stimulation magnitude would lead to a more physiological joint shape. A novel *in vitro* explant culture setup was created using a compression bioreactor to apply 3 magnitudes of flexion to the developing chick knee (stifle) joint. After six days, cultured joints were compared between groups to estimate the impact of the amount of movement experienced.

METHODS

Chick embryos were harvested after 7 days of incubation at 37^{o}C. Hind limbs were separated from the main body and the soft tissues removed. Hind limb explants were positioned into customised bioreactor chambers where they were cultured *in vitro* for the duration of the study.

Culture conditions were similar to those used for chick femur explants by Kanczler et al, [6]. Each chamber was filled with serum free basal culture media alpha-MEM and supplemented with 1% Antibiotic/Antimycotic and 100uM Ascorbic Acid leaving the explants at an air-liquid interface. The culture medium was replenished every 24 hours.

For each embryo harvested the right hind limb was exposed to dynamic stimulation and the left hind limb was cultured under static conditions. Dynamic explants were loaded in compression with a sinusoidal waveform at an average rate of 4 mm/s for 2 hours, 3 times per day over a culture period of 6 days. Three experiments were performed applying 9±2.9, 14±4.0 and 22±5.0 (mean±SD) degrees of knee flexion. Observations of chick motility *in ovo* report an approximate mean knee flexion of 12 degrees, therefore the experiments resembled reduced, physiological and over stimulated groups respectively [7].

Differences in joint shape were analysed using virtual 3D reconstructions created using optical projection tomography (OPT) [8]. Cultured explants were stained with Alcian Blue and prepared for imaging using protocols from Quintana and Sharpe [9]. Shape profiles of the distal femoral condyles and proximal fibula and tibia were traced from the 3D models of each explant. Static and dynamic groups were compared to identify shape differences. Measurements of rudiment length and anterior posterior joint region size were also compared for each group.

RESULTS

The major effect of dynamic stimulation as compared to static culture occurred in the medial side of the joint. Under dynamic conditions the anterior-posterior width of the medial condyle and tibia were significantly larger than those produced under static conditions for all groups. The medial condyle was curved towards the posterior direction and protruded lower and closer to the tibia under dynamic stimulation

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

conditions compared to the shape profiles of static joints (data not shown).

Evaluation of the 3D models of the knee joints from the 3 stimulated groups revealed that, at the maximum 22±5.0 degrees of flexion, fusion of the joint on the lateral side had occurred merging the femur and fibula (Figure 1). This was consistent for all explants in this group.

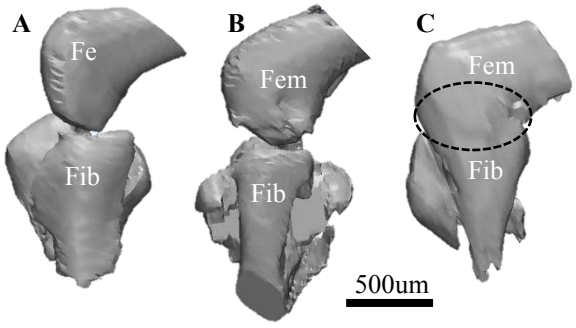

Figure 1: Lateral views of 3D knee joint models of explants cultured under A) reduced, B) physiological and C) over stimulated conditions. Dotted area indicates fusion between rudiments. Fem: Femur; Fib: Fibula

Outlines of the joint shape were overlaid to produce shape profile atlases for each group. The shape profiles of the lateral condyle, fibula and tibia did not show any obvious differences between the 3 magnitudes. The posterior curve of the medial condyle was seen in both the reduced and physiological groups but was absent in the over stimulated group (Figure 2). The migration of the medial condyle towards to the tibia in dynamic explants increased with the applied magnitude. However, the intercondylar fossa separating the two condyles was dramatically reduced in 3 out of 4 femora in the over stimulated group (Figure 2).

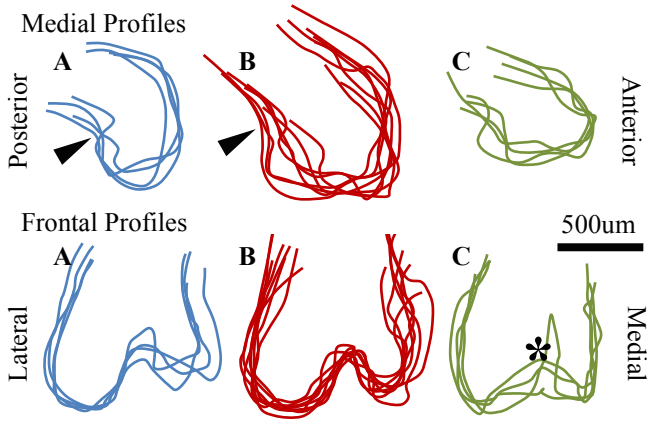

Figure 2: Shape profiles of the medial condyle of A) reduced B) physiological and C) over stimulated explants. Filled arrows illustrate the posterior bend; *indicated the missing intercondylar fossa.

Measurements were normalised for each group to their static controls to give the percentage difference caused by the applied stimulation. The percentage difference in rudiment length and joint region width compared to static explants increased with magnitude for all measurements made, with the exception of the lateral condyle which was smaller in dynamic joints compared to static explants for the reduced and physiological magnitudes (Figure 3).

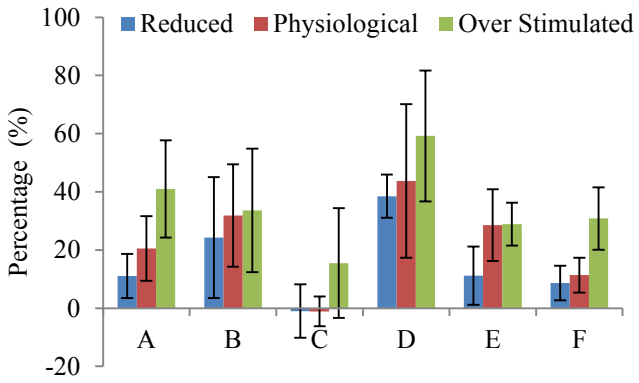

Figure 3: Percentage difference in A) Femoral length, B) Tibial Length, C) Lateral Condyle width, D) Medial Condyle width, C) Fibula width, E) Tibial width of dynamic joints compared with static controls. Error bars represent standard deviation.

DISCUSSION

This study has pioneered the exploration of how magnitude of movement affects prenatal joint shape development. After 7 days of incubation the lateral condyle is clearly distinguishable from the distal femur whereas the medial condyle has only slightly emerged [10]. Under normal circumstances this joint region would rapidly develop to create two equally sized femoral condyles as seen in mature joints. Therefore, it was expected that the medial condyle would produce major differences in our study. Our data supports this theory, that movement is necessary to signal the development of the medial condyle.

Although similar sized medial and lateral condyles were never achieved, the data revealed sensitivity to magnitude of movement. The under stimulated group produced smaller differences in size and a less prominent medial condyle suggesting reduced morphological progression compared to the average and over stimulated groups. The over stimulated group produced the largest differences in size; however the loss of the intercondylar fossa and simplified shape of the medial condyle implied too much stimulation could have had a negative influence on joint morphogenesis.

The data obtained in this study support our hypothesis of a dose-dependent relationship between joint shape and mechanical stimulation. These findings also demonstrate that this relationship is complex, and reveal the threshold above which dynamic stimulation is detrimental to the development of joint shape.

INTRODUCTION

Osteoarthritis induced glenoid bone loss can be classified by two common morphological erosion patterns: symmetric and asymmetric. An asymmetrically eroded glenoid has a bi-concave articular morphology that is retroverted by the glenoid erosion. In symmetrically eroded glenoids requiring joint replacement, the articular surface is typically reamed to match the curvature of the implant for full backside contact. This method, when used on asymmetrically eroded glenoids to correct the version angle, is referred to as eccentric reaming; however, the bi-concave articular morphology of the asymmetric glenoid may require substantial bone removal to facilitate implantation of standard glenoid components at the desired version angle.[2,4] This pathoanatomy therefore presents a challenging scenario for joint replacement in these complex cases.

To address these challenges, augmented glenoid components correct version with reduced removal of anterior bone by precluding the need for eccentric reaming. These claims are supported by recent studies which suggest that augments preserve underlying bone by volume.[2,4] The backside geometry of these components includes a posterior-step or wedge that is oriented along the vertical centerline. However, this is not consistent with recent studies which have shown that asymmetrical bone loss is not purely posterior, but rather is oriented in the posteroinferior direction.[1,3,5] Thus, aligning an augmented component with the type B2 erosion line may reduce bone removal and produce more congruent backside-to-bone contact, but likely at the cost of component malrotation.

While augmented designs address some aspects of the articular morphology of asymmetrically eroded type B2 glenoids, the knowledge base surrounding component fixation and load transfer is still largely based on the biomechanics of standard components with symmetrical erosion. Thus, given that recent literature has revealed significant differences between symmetrically versus asymmetrically eroded glenoids, there is a corresponding lack of data pertaining to the biomechanics that may alter load transfer through the component to the underlying bone. This study used finite element analysis to characterize augmented glenoid components based on three clinically relevant designs and two proposed designs with augments rotated to match the orientation of asymmetrical erosion, as previously reported.[3] All augmented designs were tested under varying simulated net joint loading directions and magnitudes, in order to quantify bone displacements, as well as contact area, and micromotion, at the implant-bone interface.

METHODS

Five augmented glenoid component designs were modeled to assess varying backside geometries (Figure 1). All implants were based on averaged characteristics of commercially available augmented implants and were constructed as CAD models with identical peg sizes/locations, geometrical shape, and articular and backside curvatures. Augment sizes were chosen to fully correct acquired retroversion while minimizing anterior reaming. The selected augments were: 7 mm posterior/parametric-step, 35° posterior/parametric-wedge, and 16° full-wedge. A 1 mm cement mantle surrounded each peg for complete peg fixation. The scapular models were created from a patient with advanced asymmetric glenoid erosion. Bone was discretized using tetrahedral elements and a heterogeneous distribution of cancellous bone properties were assigned based on CT intensity. Cortical elements were assigned homogenous properties. Scapular models were constrained on the medial boarder under loading. Net load vectors were applied to the articular surface of the augmented component by a simulated humeral component with a 4 mm mismatch in curvature. Loads of 500, 750 and 1000 N were applied to the center of the glenoid component and then varied 6° in all directions surrounding the central

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

position, for a total of 27 loading conditions. The compressive contact area, global posterior bone displacement (Figure 1), and micromotion were measured.

RESULTS

Compressive contact area represents the area of load transfer from the implant to the bone and was found to increase linearly with applied load and as the net joint load vector moved from anterior to posterior. Global bone displacements in the posterior region were found to increase in the stepped implants for posterior and posterosuperior directed loads, but were found to be relatively uniform for all other load magnitudes/directions, and for all other implants. Micromotion at the bone-implant interface was greatest for all implants under posteriorly directed loads. For posterior loads, the posterior-wedged implant showed much greater micromotions compared to the other implants. Micromotions were lowest with centrally directed loads, and moderate under anterior loading.

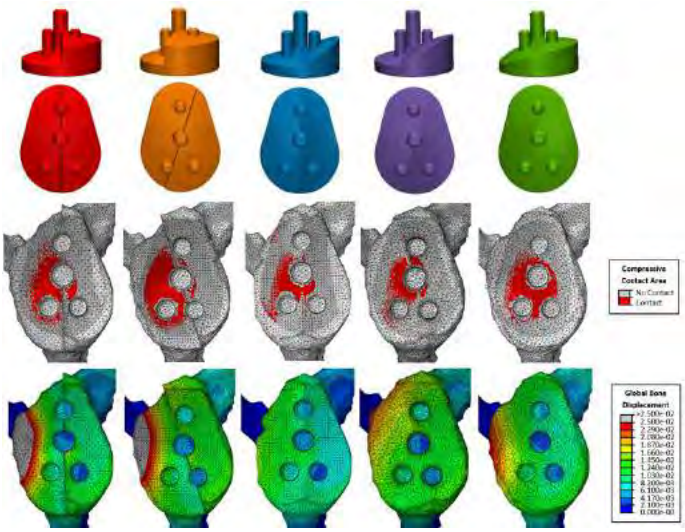

Figure 1: Finite element results for five augmented glenoid component designs – posterior-step (left column), parametric step (left-middle column), posterior-wedge (middle column), parametric-wedge (right-middle column) and full-wedge (right column). The compressive contact area represents the area of load transfer from the implant to the underlying bone. The global bone displacement is the magnitude of bone displacement in millimeters. Figures are for a 750 N compressive load directed six degrees posteroinferior in a right shoulder. Posterior is left, anterior is right for each glenoid.

DISCUSSION

This study addressed the under implant bone as the result of the biomechanical loading of augmented glenoid components under varying simulated joint loading. The loads chosen in this study represent the full range of net joint load vectors experienced *in-vivo.* The results suggest that compressive contact areas, global posterior bone displacements, and micromotion are largely a function of the magnitude and direction of the applied net joint load vector. The posterior-step implant showed relatively greater posterior bone displacement under posterior loading than the other two implants. This may be due to the increased bone removal required to facilitate the augmented component design. The wedged implants preserved more posterior bone, which likely decreased the global bone displacements observed in this region.

INTRODUCTION

Posterior glenoid erosion in osteoarthritis is believed to be initiated by posterior humeral head subluxation.[1] As the humeral head subluxates posteroinferiorly, it eccentrically erodes the posteroinferior aspect of the glenoid, leading to a bi-concave appearance. This pattern of erosion has been classified as a type B2 glenoid.[2] The aetiology of posterior glenohumeral instability and subluxation is unknown, and likely multifactorial. We postulate, based on clinical observations, that one possible factor in posteroinferior subluxation is greater than normal premorbid glenoid retroversion and inferior inclination.

The purpose of this study was to compare version and inclination of the anterior half of the glenoid in shoulders with type B2 osteoarthritis and age-appropriate normals (Figure 1). The objective was to determine whether type B2 glenoids exhibit greater retroversion or inferior inclination that may be causative factors in the development of posteroinferior subluxation. We hypothesized that type B2 glenoids would have greater anterior premorbid retroversion and inferior inclination, which may be contributing factors to posteroinferior humeral head subluxation.

METHODS

This study examined eighty scapulae, evenly distributed between two groups: osteoarthritis (OA) with type B2 glenoids and age-matched normals. The Walch type B2 OA group consisted of 15 left and 25 right shoulders (25 male, 15 female, mean age: 64±8 years), and the non-arthritic normal group consisted of 23 left and 17 right shoulders (25 male, 15 female, mean age: 68±16 years). Three-dimensional models of all shoulders were constructed from CT DICOM data. Points were placed on the anterior half of the glenoid articular surface, avoiding erosion, osteophytes and/or labrum calcification (Figure 2). A plane was fit to the set of points and custom code determined the version angle and inclination angle of the fit plane compared to the zero degree version plane – perpendicular to the validated scapular coronal plane. Interobserver reliability was used to validate anterior glenoid point selection by two observers using intraclass correlation coefficients (ICC) with a 2-way random effects model and absolute agreement (SPSS Statistics, IBM Software).

RESULTS

Comparing cohorts, the version of the anterior paleoglenoid region of type B2 glenoids (-14±6°) was significantly greater ($p<0.001$) than the anterior half of the non-arthritic normal glenoids (-5±5°). The statistical trends persisted when comparing males (n=25) and females (n=15) (males: B2 version = -15±6°; normal version = -6±6°, $p<0.001$) (females: B2 version = -11±5°; normal version =-5±5°, $p=0.004$).

There were no significant differences ($p=0.166$) in inclination angle between type B2 glenoids (0±6°) and non-arthritic normal glenoids (2±5°) when all shoulders were compared. This result persisted by sex (males: B2 inclination = 0±5°; normal inclination = 1±5°, $p=0.555$) (females: B2 inclination = 0±7°; normal inclination = 4±5°, $p=0.170$). Histograms illustrating the distribution of glenoid version and inclination are shown in figures 3 and 4, respectively.

Inter-observer reliability was excellent (ICC=0.954, 95% CI: 0.787 to 0.989) for version and excellent (ICC=0.938, 95% CI: 0.663 to 0.986) for inclination between the two observers.

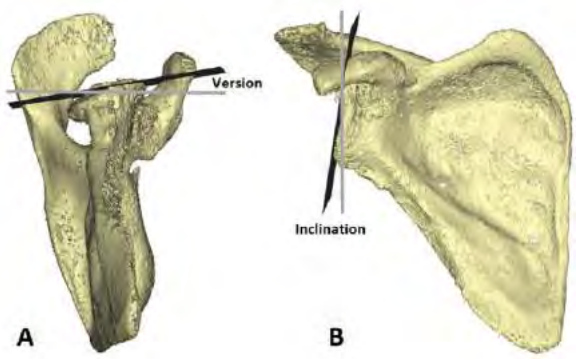

Figure 1: Inferior view of the zero degree version plane (grey) and plane fit to anterior points (black) used to determine the native anterior glenoid version angle or paleoglenoid version (A). Anterior view of the zero degree version plane (grey) and plane fit to anterior points (black) used to determine the native anterior glenoid inclination angle or paleoglenoid inclination (B). Note the difference between the paleoglenoid version and the eroded surface in this type B2 glenoid.

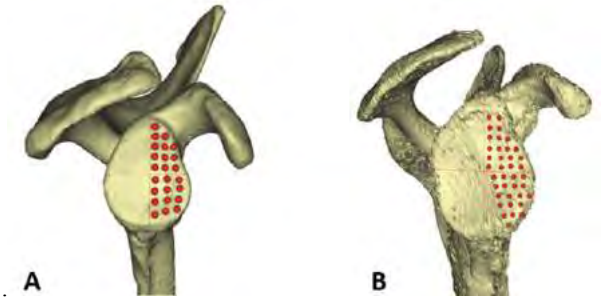

Figure 2: Points (red dots) placed on the anterior half of the glenoid used to calculate native anterior glenoid version and inclination. Point placement in a normal non-arthritic shoulder (A). Point placement on the paleoglenoid in a type B2 osteoarthritic patient (B). Note in the type B2 patient, points in the inferior region are placed to avoid erosion morphology.

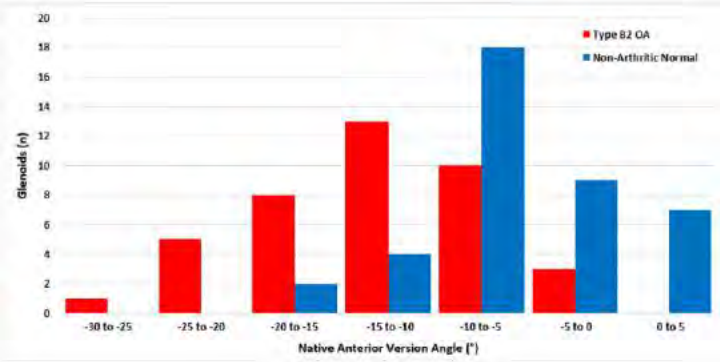

Figure 3: Distribution of the version angle of the anterior half of the glenoid. Negative values represent retroversion.

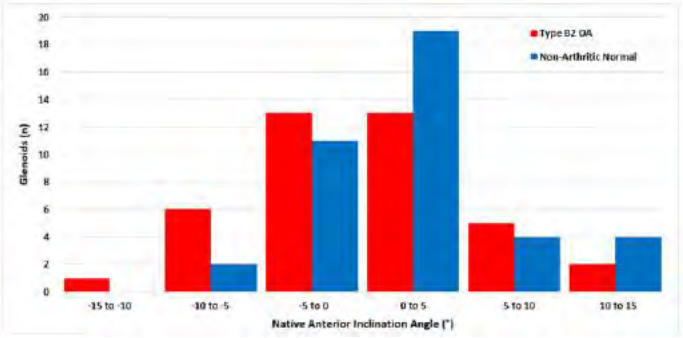

Figure 4: Distribution of the inclination angle of the anterior half of the glenoid. Negative values represent inferior inclination.

DISCUSSION

The results of this study suggest that patients who acquire posterior glenoid bone loss and associated retroversion, may have increased native glenoid retroversion when compared to non-arthritic normals. The anterior half of the glenoid in patients with type B2 glenoid erosion typically maintains articular cartilage, indicating that this region has not undergone bony erosion. Interestingly, there were no significant differences between glenoid inclination in the two groups. Assessing whether these similarities exist with larger cohort sizes may increase our understanding of the mechanisms of glenoid posterior erosion.

INTRODUCTION

Glenohumeral osteoarthritis (OA) causes progressive joint damage with extensive bone remodelling and osteophyte formation. As a result, it has been observed that OA humeral heads are morphologically different from normal humeral heads. However, little research has examined and compared the size and morphology of arthritic humeral heads to normal humeral heads.[7] Conversely, the arthritic glenoid has been well investigated.[6] Characteristic erosion patterns of the arthritic glenoid have been classified,[5] and regional variations in density, shape, orientation, and porosity have been reported.[1–4]

Although morphological changes to the humeral head are known to occur,[7] an anatomic characterization of the unique morphology of the osteoarthritic humeral head is lacking. As such, the purpose of this study was to evaluate and compare the size and morphology of normal and osteoarthritic humeral heads. Additionally, we sub-classified our osteoarthritic cohort as having symmetric or asymmetric (type B2)[5] glenoid erosion, in order to assess whether humeral head morphology varied by the type of glenoid erosion. We hypothesized that due to erosion the arthritic humeral head has a larger spherical diameter and is thinner, relative to the osteotomy plane, than normal humeral heads. This information may improve our understanding of glenohumeral pathoanatomy, posterior glenoid erosion patterns, and assist with implant design.

METHODS

One hundred fifty computed tomography scans of the shoulder were studied. Three-dimensional models were constructed for each shoulder using medical imaging software validated for anatomical measurements. The subjects were separated into three groups, (1) normal glenohumeral joint, (2) osteoarthritic joint with symmetric glenoid erosion, and (3) osteoarthritic with asymmetric (type B2) glenoid erosion. Each group comprised 50 non-paired shoulders (30 male and 20 female). The humeral head was virtually excised by one of two experienced shoulder surgeons. Three-dimensional point coordinates were collected on the articular surface of all humeral heads and a sphere fit algorithm was used to determine the diameter of each humeral head. To account for the curvature of non-spherical humeral heads, circle fits were performed along planes in the anteroposterior (A-P) and superoinferior (S-I) directions (Figure 1). The thickness of each humeral head was also determined as the perpendicular distance from the osteotomy plane to the intersection of the A-P and S-I planes on the articular surface.

RESULTS

The sphere fit diameter of the excised humeral head for the entire OA cohort (100 patients, mean diameter 59.3±8.7 mm) was significantly greater ($p<0.001$) than the normal cohort (50 patients, mean diameter 48.8±5.0 mm). This statistical trend persisted when examining males ($p<0.001$) and females ($p<0.001$) independently. However, when comparing symmetric to asymmetric glenoid erosion OA cohorts, no significant differences were observed for the sphere fit diameter.

Similarly, the humeral head circle fit diameters in the S-I and A-P planes were significantly greater ($p<0.001$) in the combined OA cohorts (59.4±8.7 mm and 56.4±9.8 mm, respectively) as compared to the normal cohort (51.0±5.1 mm and 47.1±5.0 mm, respectively). However, there were no significant differences ($p\geq0.099$) between the symmetric and asymmetric OA cohorts in S-I or A-P circle fit diameters. The mean

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

values of humeral head heights were 18.7 mm, 18.2 mm, and 18.2 mm for the normal, symmetric OA, and asymmetric OA cohorts, respectively. These values were not significantly different (p=0.382).

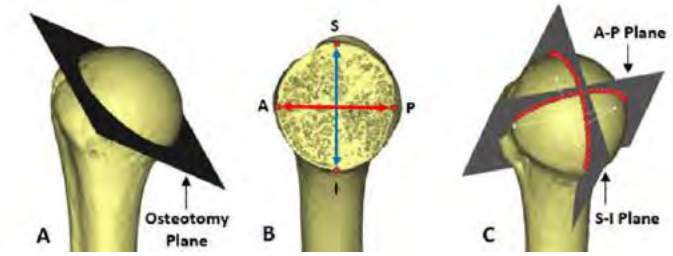

Figure 1: The osteotomy plane (A). Superior (S), inferior (I), anterior (A), and posterior (P) points on the humeral head-neck osteotomy plane. The blue arrow represents the S-I chord distance, and the red arrow represents the A-P chord distance (B). Points on the humeral head used for circle fitting in the S-I and A-P planes (C).

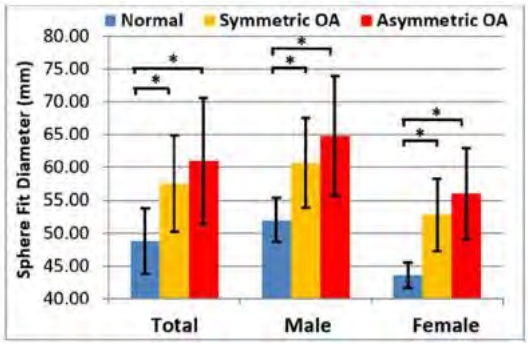

Figure 2: Mean sphere fit diameter of the humeral head articular surface for three cohorts. Significance is indicated by *, p<0.05.

DISCUSSION

Significant differences were observed between normal humeral head diameters and osteoarthritic humeral head diameters in two common glenoid erosion morphologies. The results of this study indicate that the size of the arthritic humeral head varies from the normal humeral head, but not as a function of the Walch classification between symmetric and asymmetric (B2) glenoids. The increased diameter associated with the osteoarthritic humeral head has unknown consequences for soft tissue stretching and associated soft-tissue balancing following total shoulder arthroplasty procedures. This information may have implications in our understanding of posterior erosion patterns and their treatments, as well as the design of humeral head replacement components.

PREVENTING UPPER AIRWAY COLLAPSE USING CPAP WITH AND WITHOUT PRESSURE OSCILLATIONS

ABSTRACT

Upper airway (UA) collapse occurs when the forces of the airway wall muscles become less than the forces generated from the airway negative pressures during the respiration process. Continuous Positive Airway Pressure (CPAP) treatment is considered the most effective treatment for patients diagnosed with moderate to severe obstructive sleep apnea (OSA). It provides a continuous flow of pressurized and humidified air to prevent airway collapse; however, there is a high rejection rate due to its high operating pressure. Using MRI scans, this paper investigates the effects of using the pressure oscillations (PO) superimposed on the CPAP to keep the airway open at lower pressure distributions inside the UA and consequently increase patients' comfort and reduce device rejection.

INTRODUCTION

As sleep onsets, the UA muscles relax causing the airway lumen to narrow which increases the resistance to airflow [1]. Further when an OSA patient sleeps in the supine position, the uvula and the tongue move towards the airway wall due to gravitational forces, reducing the air gap which increases the chance for airway obstruction and collapse [2]. These events occur hundreds of times every night resulting in restless sleep and many health implications such as diabetes, arrhythmia, stroke, hypertension, memory loss and cardiovascular disease [3]. The CPAP is considered the first line of treatment for patients diagnosed with moderate to severe OSA [4], however, there is a high patients' rejection rate due to its high operating pressure [5]. PO have been reported to increase the activity of the UA muscles [6], however, their effect on the performance of the UA when superimposed on the CPAP have never been previously investigated. Therefore this paper investigates the conditions of UA collapse in a group of apneic patients and presents the resulting pressure distributions inside their UA when the CPAP is used alone or with superimposed PO.

METHOD

While awake and in supine position, MRI data of the UA were collected for 10 non-smoking OSA patients (7 males and 3 females) with 42–66 years of age. Ethical approval was granted by The Auckland University of Technology Ethics Committee and consents were obtained prior to initiation of the study procedures. UA models from the nasopharynx to the hypopharynx were accurately constructed using 3D-DOCTOR software, then were imported to the ANSYS Workbench to conduct the simulations, Figure 1.

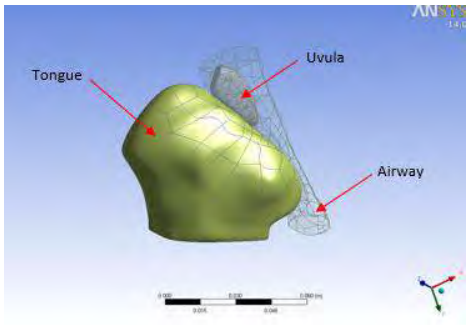

Figure 1: Entire UA model

The airway models were solved by the CFD methods using the Fluid-Flow (CFX) Modeller on the ANSYS Workbench. The interaction between the airflow and the deformations of the uvula and tongue was investigated by the Fluid-Structure Interaction (FSI)

methods using the Static-Structural Modeller on the ANSYS Workbench. The soft tissues were replaced by a hyper-elastic rubber enclosure, Figure 2, of 1 mm thickness, density of 1000 kg/m^3 and the temperature was set to 38^{o}C as that of the air coming from the lungs.

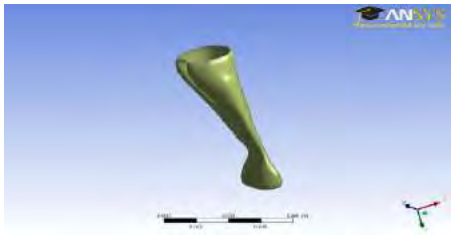

Figure 2: 1 mm thickness rubber enclosure

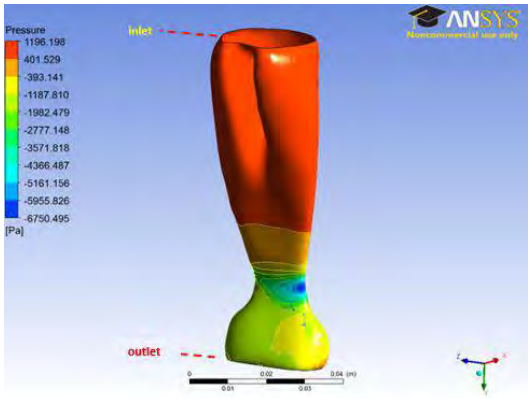
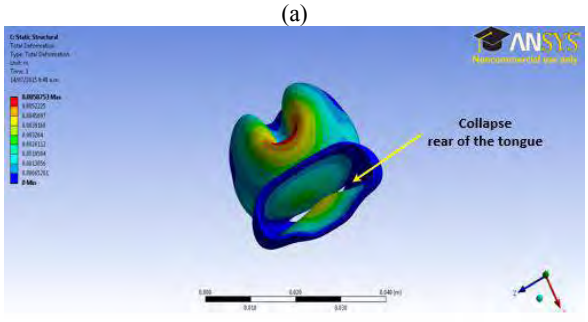
To investigate the effect of PO on the UA of an apnoeic subject, simulations were repeated until collapse was detected. CPAP was applied to keep the airway open and then PO were superimposed in such a way that the static pressure at the level of the nasopharynx is the same before and after using the PO.

RESULTS AND DISCUSSION

Standards RANS k-ε and RANS SST turbulence models were used; however the results of the latter model were more reasonable and therefore are presented in this paper. The boundary conditions were chosen to fulfil a pharyngeal pressure range of -1.4:1.5 kPa [7]. Collapse was detected during inspiration at the rear of the tongue when P_{in} = 1 kPa and P_{out} = -1.1 kPa, Figure 3. PO were applied at the inlet, with P_{in} = 0.9+0.1 Sin (2πf t) kPa, f=40 Hz.

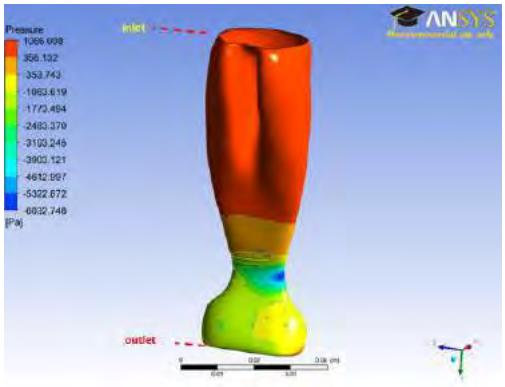


(a)

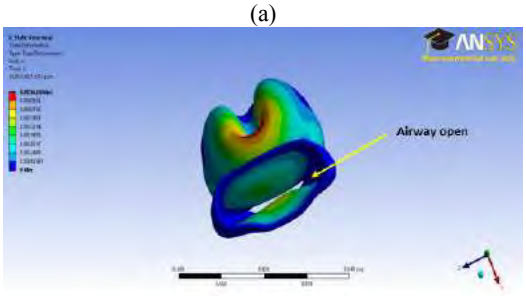


(b)

Figure 3: (a) pressure distribution and (b) bottom view of the airway during inspiration



(a)



(b)

Figure 4: (a) pressure distribution and (b) bottom view of the airway during inspiration showing open airway

These results show that the use of the PO has successfully kept the airway open at much lower pressure distribution compared to the use of the CPAP alone. Also, the use of the RANS SST turbulence model has resulted in more reasonable values compared to the RANS k-ε, and therefore it is recommended to be used in similar future studies.

INTRODUCTION

Tendon is composed of rope-like fascicles bound together by interfascicular matrix (IFM). Our previous work shows that the IFM is critical for tendon function, facilitating sliding between fascicles to allow tendons to stretch [1]. We have shown that this is particularly important in energy storing tendons such as the human Achilles tendon and equine superficial digital flexor tendon (SDFT), which can experience strains as high as 16% during intense exercise [2], and therefore require the capacity for considerable inter-fascicular sliding and recoil. This capacity is not required in positional tendons (e.g. equine common digital extensor tendon (CDET)). While the quasi-static properties of the IFM have been elucidated [1], the fatigue resistance of the IFM in functionally distinct tendons has not been established. The aim of this study was therefore to compare the fatigue properties of fascicles and IFM in two functionally distinct tendons. We tested the hypothesis that fascicles and IFM in the energy storing equine SDFT are more fatigue resistant than those in the positional CDET.

METHODS

The SDFT and CDET were harvested from the forelimbs of horses aged 3 to 7 years (n=5). For fascicle tests, individual fascicles were dissected from each tendon (n=8). For IFM tests, groups of 2 fascicles (bound together by IFM) were dissected from each tendon (n=12). Using a polarised light microscope and a dissection rig, the opposing end of each fascicle was cut transversely, leaving a 10 mm length of intact IFM (Fig.1).

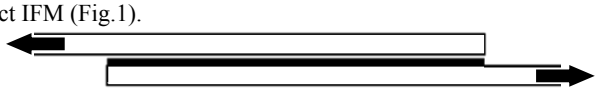

Fig.1 Schematic of IFM test. 2 fascicles (white) bound together by 10mm of IFM (black) were pulled apart, testing the IFM in shear.

Samples were gripped in individual loading chambers and secured in a mechanical test frame (Electroforce, TA instruments). A pre-load was applied to remove slack from the samples (0.1N for fascicles and 0.02N for IFM tests). One loading cycle of 1mm displacement was then applied (equivalent to 50% failure extension). The peak load measured at this displacement was recorded, and this load was subsequently applied to the fascicles in a cyclic manner at a frequency of 1 Hz until sample failure. Load and displacement data were recorded continuously throughout the test at a frequency of 100 Hz. In addition, the maximum and minimum load and displacement were recorded for each cycle.

For each test, the number of cycles to failure was recorded. The maximum and minimum displacement data were used to plot creep curves to failure (Fig. 2) and the gradients of the maximum and minimum displacement curves during secondary creep were calculated.

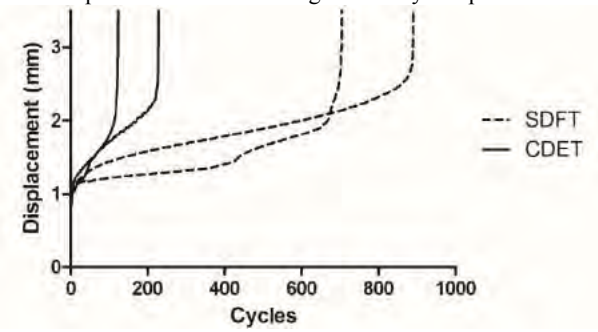

Fig.2. Typical creep curves for IFM samples in the SDFT and CDET.

For each sample, force extension curves were plotted and hysteresis calculated at various cycles throughout testing. Fascicle

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

elongation was calculated at cycle 10 and at the cycle prior to failure by subtracting the maximum extension at cycle 1 from the maximum extension in these cycles. It was not possible to calculate IFM elongation in the same manner, relative to the first cycle, as the low forces involved in this load controlled experiment required several cycles to fully stabilise.

Statistical significance was determined using Analysis of Variance (Minitab 17). A general linear model was fitted to the data, with donor and tendon type as factors. Data were tested for normality (Anderson–Darling test). Data that were not normally distributed were transformed (Box-Cox). Data are displayed as mean ± SD.

RESULTS

Fascicles and IFM from the SDFT resisted significantly more cycles before failure than those from the CDET (Table 1).

Table 1. Number of cycles to failure * indicates significant difference between tendon types (p<0.01).

	SDFT	CDET
Fascicles	2709 ± 4819	139 ± 157*
IFM	921 ± 1947	215 ± 145*

The gradients of the maximum and minimum creep curves for fascicle tests were significantly greater in the CDET than in the SDFT (p<0.001). For IFM tests, the gradient of the maximum creep curve was also significantly greater in the CDET than in the SDFT (p<0.01).

Initial fascicle elongation was greater in the CDET than in the SDFT (Fig. 3). However, in the last cycle prior to failure, fascicle elongation was greater in the SDFT than in the CDET (Fig. 3).

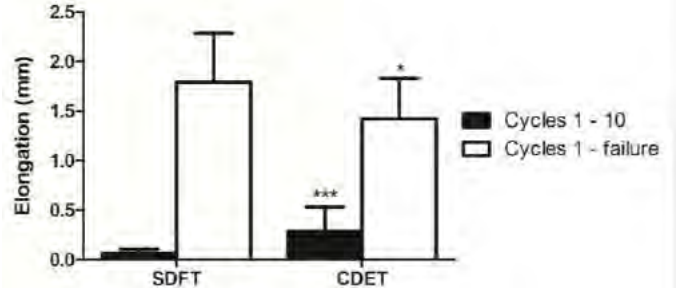

Fig.3. Fascicle elongation during fatigue testing. . * indicates significant difference between tendon types: *p<0.05; *** p<0.001.

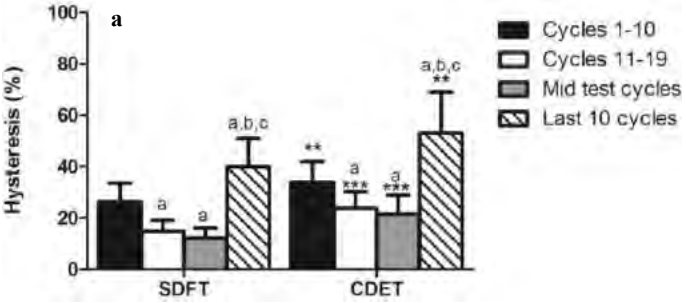
Hysteresis was significantly greater in CDET fascicles than in SDFT fascicles at all time points assessed. In both tendon types, hysteresis decreased over the course of fatigue testing but increased in the cycles prior to failure (Fig.4a). A similar pattern was observed in the IFM, with a trend towards greater hysteresis in the CDET, which reached significance at the mid-point of fatigue testing (Fig.4b).



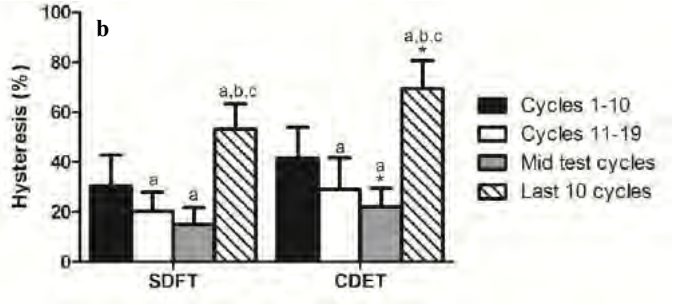


Fig.4. Hysteresis during fascicle (a) and IFM (b) fatigue testing. * indicates significant difference between tendon types: *p<0.05; ** p<0.01; *** p<0.001. [a] indicates significant difference relative to cycles 1-10 (p<0.05); [b] indicates significant difference relative to cycles 11-20 (p<0.001); [c] indicates significant difference relative to mid test cycles (p<0.001).

DISCUSSION

The data support our hypothesis, demonstrating that both fascicles and IFM in the energy storing SDFT are more fatigue resistant than those in the positional CDET. This is in agreement with previous studies which have shown lower levels of hysteresis and stress relaxation in fascicles and IFM in the SDFT compared to the CDET during cyclic loading [3].

When considering the fascicle response to fatigue loading, fascicles from the SDFT were able to resist almost 20 times more cycles to failure than those from the CDET, and exhibited lower hysteresis throughout fatigue testing. Interestingly, fascicles from the SDFT exhibited less elongation initially, but were able to elongate further before failure than those from the CDET.

The IFM exhibited surprisingly high fatigue resistance, which was greater in the SDFT than in the CDET. It is not possible to directly compare the fatigue resistance of fascicles and IFM due to differences in the testing methods used, but the results indicate that the IFM has a functional role within tendon and contributes significantly to tendon mechanical properties.

Previous studies indicate that fascicles from the SDFT have a helical substructure, allowing them to act as springs, which likely results in their superior fatigue resistance [4]. Specialisation of the IFM has also been observed in the SDFT, with localization of lubricin and elastin to this region [5]. Lubricin likely acts to aid sliding between fascicles, while elastin may provide the ability to recoil efficiently and contribute to improved fatigue resistance.

Taken together, these data indicate that both fascicles and IFM in the energy storing SDFT exhibit compositional and structural specialisations that likely contribute to superior fatigue resistance in the tendon as a whole. These data provide important advances into fully characterising structure-function relationships within tendon.

INTRODUCTION

Patent ductus arteriosus (PDA) occurs when a normal fetal connection between the aorta and main pulmonary artery (MPA) does not close following birth, leading to continuous left to right shunting of blood from the descending aorta to the MPA. This can lead to significant cardiac remodeling and complications [1, 2].

Surgical ligation, the traditional method of closure, is highly invasive and carries non-trivial risks [2]. In an effort to mitigate these risks, minimally invasive treatment methods were developed, such as the Amplatz® Canine Ductal Occluder (ACDO) (Infiniti Medical, LLC, Menlo Park, CA) (Figure 1A), a device composed of a dense nitinol mesh forming multiple disks used for positioning and stability. While effective, this device has limitations, including its large sized (≥4Fr sheath) delivery system, which limits the treatment of smaller canines with larger PDAs [3, 4] and high cost, indicating a clinical need for a device to address these issues.

The nitinol foam cage (NFC) prototype utilizes a low profile nitinol frame to aid in positioning and stability, and a shape memory polymer foam (SMP) foam to provide a tissue scaffold for occlusion and healing. SMPs are a class of materials, which through an entropy driven process, are capable of being programmed into a secondary shape and actuated to their primary shape when heated above their characteristic glass transition temperature [5]. These materials have been proposed for use in medical devices and embolic agents [6]. The NFC prototype (Figure 1 B&C) was constructed, and evaluated in mechanical, fatigue, and *in vitro* studies and compared to the mechanical properties and characteristics of the ACDO.

METHODS

NFC prototypes were fabricated and evaluated in multiple verification tests including: Axial fatigue, radial pressure, and benchtop *in vitro* tests evaluating device stability in simplified PDA models.

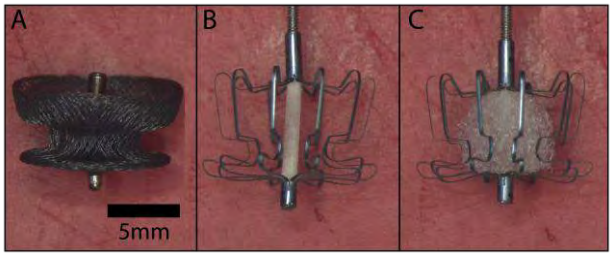

Figure 1: Device comparison. A: ACDO. B: NFC with foam compressed. C: NFC with foam expanded. Scale is the same across frames.

The NFC prototype, previously developed by Wierzbicki et. al [7], has been redesigned to address device stability issues of the original prototype. Briefly, devices were constructed by laser cutting slots into nitinol tubing (NDC, Fremont, CA) using an excimer laser (Resonetics, Nashua, NH). Following deburring and cleaning the laser cut tube, the NFC was attached to a custom fixture, compressed into the desired shape and set through heat treating at 550°C for twenty five minutes followed by a quench in water. A threaded release mechanism was laser welded to the proximal end to allow for repositioning and detachment from the delivery cable. A compressed 8mm diameter SMP foam was epoxied into the proximal portion of the tube.

A preliminary assessment of the fatigue characteristics was carried out by axially cycling the nitinol frame on a dynamic mechanical analysis unit (DMA Q800, TA instruments, New Castle, DE). Three NFC frames were cyclically extended by 1mm at a rate of 2Hz for one

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

million cycles, corresponding to approximately 6 days once implanted.

Radial force measurements were recorded using a J-Crimp™ RJA62 Radial Compression Station (Blockwise Engineering LLC, Tempe, AZ) attached to an Instron 5965 Test Frame (Instron, Norwood, MA). The radial force of the NFC was measured in 4, 6, 8, 10, and 11mm ampulla diameters and compared to that of the ACDO in all cases to assess the force that would be imparted to the ampulla wall, located on the aortic side of the PDA vessel.

Thin walled silicone models mimicking simplified PDA geometries including IIA, IIB, and wide ampulla (WA) models were created to evaluate delivery characteristics, and device migration. The devices, sized to occlude a 3mm MDD PDA, were tested in a gravity fed flow system (maximum head pressure of 240mmHg) with an adjustable pressure control valve. Seven different models were evaluated: 3mm and 5mm minimal ductal diameter (MDD) IIA, IIB, and WA, and a 3x4mm ovular MDD IIA model. The NFC was designed to occlude 3mm MDDs but the 5mm MDDs were tested to determine efficacy during undersized device deployment conditions. The devices were delivered into the system using a 4Fr sheath and tested at two pressures, physiological (100mmHg)[8], and elevated pressure (171±11 mmHg for 3mm MDD; 115±3 mmHg for 5mm MDD) developed by fully opening the pressure control valve. The devices were subjected to the physiological and elevated pressures for five minutes each to ensure that they would not migrate, or move from their desired deployed position. Images were recorded at one minute intervals and were analyzed for device motion following the experiment using ImageJ image analysis software (NIH, Bethesda, MD).

RESULTS

All three devices withstood one million cycles under a load of 0.019± 0.0012N throughout the test with no visible cracks or damage observed on the struts.

The radial force exerted by the NFC was lower than the ACDO for all diameters tested (Figure 2). The maximum and minimum force generated by the devices occurred in the 4mm and 11mm ampulla respectively.

The NFC and ACDO both exhibited negligible migration in the simplified models at both physiological and elevated pressures (Figure 3). The largest motion seen (0.3mm) was in the 3mm WA model.

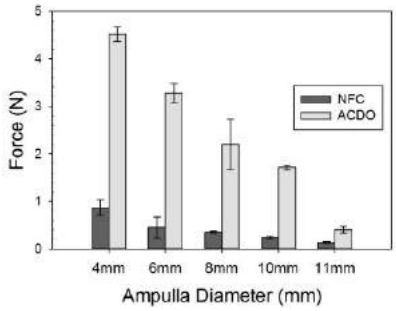

Figure 2: Radial Force of the NFC and ACDO in different ampulla diameters.

DISCUSSION

The fatigue results show that the prototype should not fracture or fail shortly after implantation. These promising results were achieved with minimal post-processing following laser cutting. While the device passed this metric, the final implant would be electropolished, a method to used improve surface finish, biocompatibility, and reduce stress concentrations, to further improve fatigue life, warranting further investigation.

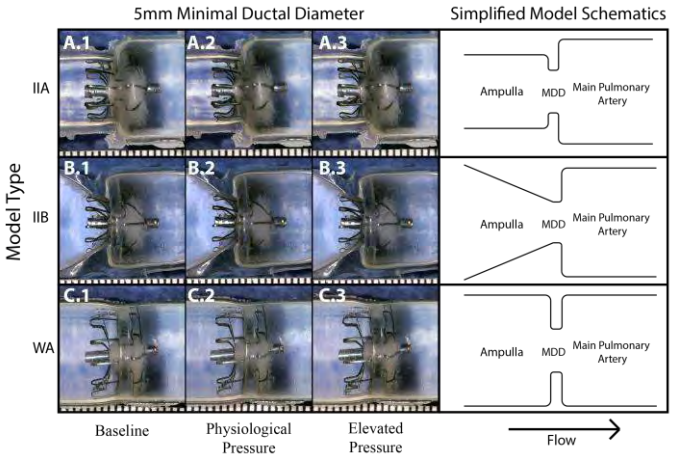

Figure 3: NFC *in vitro* device stability tests display negligible motion in all model types and MDD configurations. (A) IIA 5mm; (B) IIB 5mm; (C) WA 5mm. Images are taken (*.1) immediately after deployment; (*.2) after five minutes at physiological pressure gradient (100mmHg); and (*.3) after five minutes at an elevated pressure gradient (115±3 mmHg). Flow is left to right. Simplified model schematics are shown on the right illustrating the anatomy. Scale in mm.

The lower radial pressure exerted by the NFC compared to the ACDO shows that the device should not impart significant vessel trauma or rupture the ampulla wall. Despite the lower radial pressure, the NFC did not exhibit device migration, even in the WA models in which the struts did not contact the ampulla wall. Therefore, radial pressure alone is not a sufficient indicator of device stability. The oversized nitinol waist and ability for the device to catch on the taper prevented migration of both the NFC and ACDO. Additionally, the NFC withstood an elevated pressure gradient, similar to those that can develop acutely after closure. Finally, the softer nature may allow the NFC to better conform to irregular or ovular PDA geometries.

In addition to the positive *in vitro* tests, the low profile of the NFC could allow for a smaller delivery system (4Fr catheter, 0.038”ID) in comparison to the ACDO (4Fr sheath, 0.052” ID), based on compression limitation of the SMP foam and diameter of the nitinol tube, instead of a dense nitinol mesh.

The presented results and promising clinician feedback indicate that with minimal design refinement the NFC device could be used to treat canine PDA.

ACKNOWLEDGMENTS

We extend thanks to our colleagues in the Biomedical Device Laboratory for helpful discussion and support throughout this project.

COMPUTER SIMULATION OF LUMBAR FLEXION SHOWS IN-PLANE AND THROUGH-PLANE SHEAR OF THE FACET CAPSULAR LIGAMENT

Amy A. Claeson and Victor H. Barocas

Department of Biomedical Engineering
University of Minnesota – Twin Cities
Minneapolis, MN, USA

INTRODUCTION

Structurally and kinematically, the FCL is a complex tissue whose structure and functional responsibilities change with location along the spinal column. All FCLs contain two distinct materials that transition through the ligament thickness. Specifically to the lumbar FCL, the dorsal surface (i.e., the surface viewed from the posterior aspect and facing out from the joint space) consists of highly aligned collagen fiber bundles that preferentially align between the rigid articular facets. The ventral surface (anterior aspect), which interacts with the synovial fluid within the joint space, is rich with unorganized elastin fibers. The FCL has a convex curvature because it follows the geometry of the articular facets, and, because it is a capsule, it has multiple insertion sites across the facet joint. Articular facet kinematics drive FCL deformations that occur during all spinal motions (flexion/extension, lateral bending, and axial rotation), and which may be quite complex. Additionally, the contained synovial fluid constantly pressurizes the FCL. Therefore, the elaborate structure compounded with the kinematic response gives rise to complicated 3D deformations *in vivo*.

Previous studies have aimed to quantify three-dimensional (3D) deformations of the lumbar spine during flexion, but have fallen short of tracking the complex deformation of the FCL. Kozanek et al.[1] elucidated the kinematics of the articular facets, but did not characterize FCL deformation. A study by Ianuzzi et al.[2] extracted the 3D soft tissue deformations of the lumbar FCL in isolated spines, but calculated one tissue averaged principal strain to define the whole capsule deformation. A study from our group[3] quantified lumbar FCL deformations by optically tracking structural characteristics inherent to the FCL over a course of static bending. This work, however, only captured a portion of the capsule, and the deformations across the FCL emulated flexion, but were not indicative of true flexion. Thus, there exists a gap in our knowledge involving quantification of the full 3D deformations of the lumbar FCL during physiologic spine motions.

Realistic finite element (FE) models of the joint can provide complementary analysis when properly informed by experimental data. To construct a FE model of the lumbar FCL, three pieces of information are necessary: geometry, boundary conditions, and material properties. Figure 1 shows schematically how these inputs were obtained. Previously, our group published continuous *in vivo* vertebral kinematics during flexion/extension to quantify intervertebral margin strains[4]. Facet joint motion was extrapolated from vertebral kinematics in the sagittal plane. Also, we previously characterized the instantaneous material properties of healthy cadaveric L4-L5 FCLs using a hyperelastic model with two fiber distributions[5]. Thus, except for FCL geometry, the necessary information is available to undertake a computational analysis of lumbar FCL motion.

The goal of the current study was to quantify the continuous deformation of the lumbar FCL during flexion and extension by means of a realistic FE model.

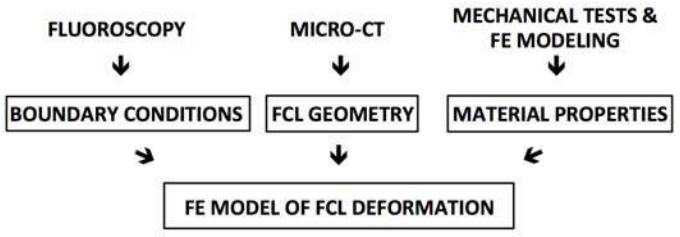

Figure 1. Finite element (FE) model construction

METHODS

Geometry Acquisition through micro-CT: A visually healthy cadaveric L3-L4 facet joint capsule was resected from the motion

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

segment and cleared of all posterior musculature. Radiopaque paint coated the dorsal surface to define the boundary of the radiolucent ligament. The coated facet capsule was imaged with a voxel resolution of 21.5μm, and the resulting image stack was segmented manually, smoothed, meshed and imported into the FEBio[6] software suite.

Material Model Specifications: Three material definitions were used in the model: two rigid bodies, one for each articular facet, and the material defining the ligament. The FCL material was defined with an eight-parameter hyperelastic strain-energy density function; a neo-Hookean ground matrix with two embedded fiber families described by an exponential strain-energy density function and a 2D von Mises distribution of fiber orientation. The parameters of this function were optimized[5] to minimize the error between the model output and experimental data of L4-L5 FCLs (n=6) under planar equibiaxial tension. The material was warped to the curved geometry of the current model (Figure 2) based on the direction (increasing, planar, decreasing) of the normal vectors of the surface elements.

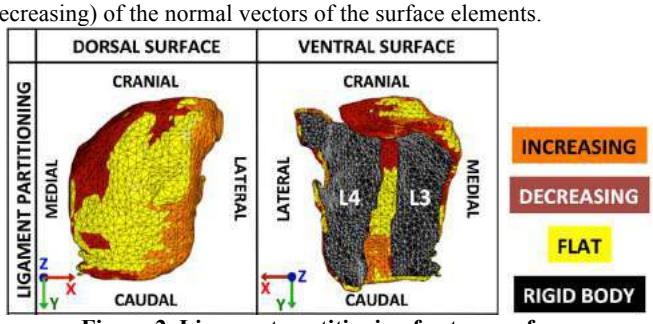

Figure 2. Ligament partitioning for two surfaces

Joint Kinematics in Spinal Motion: Kinematics of L3-L4 motion segments were extracted from left sagittal fluoroscopic data of ten healthy individuals during voluntary flexion. Further information regarding the fluoroscopic data sets and extraction of vertebral motion is given in Nagel et al.[5] The left lateral kinematics obtained were mirrored to mimic the kinematics of a right facet joint. The analysis of the sagittal plane fluoroscopy data yielded subject-specific kinematics (n=10) to be used as inputs to the FE model of a right FCL. Each of the ten sets of kinematics was used to simulate vertebral motion. Vertebral motion was prescribed to the rigid materials that define the L3 and L4 articular facets. Global coordinates are defined in Figure 2 with right lateral as +X, caudal as +Y, and ventral as +Z. In general, flexion induced ventral displacement ($+u_Z$), cranial displacement ($-u_Y$), and sagittal plane rotation ($-R_X$) for both vertebrae, which L3 rotating and displacing farther than L4 as the joint flexed. The ligament surface remained free, and during the simulation it deformed in response to displacements applied to the rigid articular facets.

RESULTS

Surface Strains during Simulated Flexion: Surface strains of the ventral and dorsal FCL (Figure 3) were generated by the relative rotation and displacement of the articular facets. The net effect of prescribed motion created compression in the Y direction, and the Z direction thickened because motion in this direction was unconstrained. In-plane shear (XY) strains were pronounced, and resulted from the caudal displacement of the L3 articular facet (black arrow) and fixed motion in the X direction. Dorsal surface strains were more diffuse than ventral surface strains because of a larger ligamentous area and greater deformability.

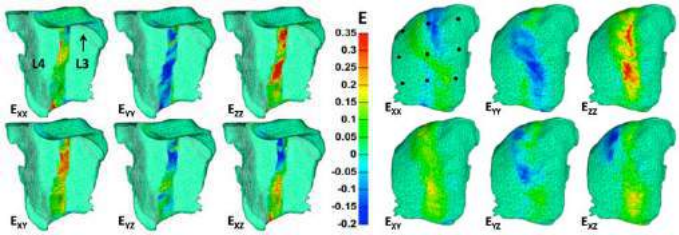

Figure 3. Ventral and dorsal surface strains

Surface Stresses during Simulated Flexion: Surface Cauchy stresses on the ventral and dorsal FCL (Figure 4) are generated by the structure and in-plane orientation of the embedded fiber families. Stresses are lower on the dorsal aspect compared to the ventral aspect because the fibers had more area to reorganize before acquiring tension. The two fiber families of the model were prescribed in the XY plane, and accordingly, σ_{XX}, σ_{YY}, and σ_{XY} exhibited the largest tensile stresses. Furthermore, through-thickness stresses, perpendicular to the fiber alignment, were smaller in value, but not negligible.

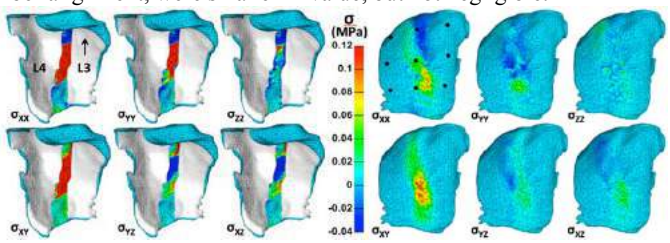

Figure 4. Ventral and dorsal surface Cauchy stresses (MPa)

DISCUSSION

A realistic finite element model of the lumbar facet joint during flexion elucidated the importance-of in-plane (XY) and through-plane (YZ, XZ) shear deformations on the ventral and dorsal surfaces of the FCL. The largest tensile strains were a function of unconstrained motion and the largest tensile stresses were a function of fiber direction. Human cervical, thoracic, and lumbar FCLs are densely innervated with proprioceptive, nociceptive, and mechanoreceptive nerve endings[7]. Based on our findings, the middle-body of the FCL would be a logical location for position- and pain-sensing nerve endings because of the large and readily occurring stress and strain values, at least in the case of lumbar flexion. Also, based on innervation and large deformations involved, the FCL may be sensitive to degenerative changes (osteophyte and enthesophyte formation[8]) and may play a role in low back pain. These ideas must be investigated further, both experimentally and theoretically, but our results suggest possible avenues for further exploration of lumbar FCL mechanobiology. Clearly, any such study should consider shear as well as tensile deformation.

This study considered only flexural motion, only one FCL of one (L3-L4) motion segment, and there was no accounting for individual variations in vertebral anatomy or ligament properties, except for our use of spine kinematic data from 10 different subjects.

In summary, we found large in-plane and through-plane shear deformations are in finite element simulations of a lumbar facet capsular ligament during flexion. Simulation results could inform future studies of lumbar FCL mechanobiology during realistic spinal flexion.

RECRUITING AND SUPPORTING TRANSFER STUDENTS TO MECHANICAL ENGINEERING PROGRAM AT UMBC

L Zhu (1), D. Arola (2), A Spence, (1), C Romero-Talamas (1), C Eggleton (1)

(1) Department of Mechanical Engineering
University of Maryland Baltimore County
Baltimore, Maryland, USA

(2) Department of Materials Science & Engineering
University of Washington
Seattle, Washington, USA

INTRODUCTION

Community colleges serve more than 46% of all professional engineers.[1] The recent economic recession has forced many students to start their college life in community colleges due to its affordability. Among the roughly 300,000 undergraduate students in Maryland in 2013, 49% of them enrolled in community colleges.[2] And of the community college students enrolled in Fall 2012, 37% were underrepresented minorities (6% Hispanics and 31% African American). In the six targeted community colleges in Maryland, 5.3% of the 9006 graduates were Hispanics and 22.8% are African American.[2] Therefore, regional community colleges serve a larger pool of underrepresented minorities to draw upon as transfer students to 4 year universities.

Despite substantial progress in the past several years, the percentage of Hispanic students in Mechanical Engineering (ME) at the University of Maryland Baltimore County (UMBC) is currently 3.7%, As indicated, regional community colleges have the essential student pool to diversify the ME Program at UMBC. Drawing from this pool could help produce engineers that are more reflective of the state's demographics. Offering scholarships to those students is a significant incentive to continue pursuit of a 4-year college degree. Therefore, having continuous improvement in the collaboration between UMBC and local community colleges will be essential. Identifying the most effective means to communicate educational opportunities at UMBC to local community college students is necessary to further bolster the transfer process.

Attracting talented students is only the first step. Keeping them engaged will be the next. Although UMBC has an existing student support structure and program elements currently in place, active mentoring of minority students is needed to address the diverse issues facing them in engineering fields. At the national level, among 20 engineering disciplines, ME ranks 16th in the enrollment of female students. That is unfortunate as ME currently has the largest undergraduate enrollment overall.[3] Numerous studies have demonstrated the success of interdisciplinary fields such as biomedical engineering in attracting talented female/minority students. One of the reasons may be related to the social relevancy of those curricula and how engineering can help humanity.

UMBC was awarded an NSF S-STEM grant in 2010 and a renewal in 2014. This paper is intended to report our approaches and educational outcomes of the Mechanical Engineering S-STEM Scholarship Program in the past six years at UMBC, with emphasis on recruiting and supporting transfer students that were attracted from local community colleges in the State of Maryland.

METHODS

We have decided not to rely on traditional recruitment methods to increase the rate of transfer students to UMBC. Our goal is to enhance collaborations with community colleges via the following approaches. We found that there was little interaction between the faculty at UMBC and the faculty and staff members in the local community colleges. Hence, over the past six years we visited community colleges on a regular basis, and also invited community college faculty members and their students to visit our campus. It was found that the major obstacle that students encountered is a lack of information on the transfer process and the responsible contact person on both campuses. Our department has re-designed the departmental website clearly describing the transfer process and requirements. There is at least one faculty member at each community college designated as our contact, and the faculty member can connect the students on their campus with faculty at UMBC. We also send our current S-STEM

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

scholars back to their community colleges to describe the ME program at UMBC, the S-STEM program, and to share their experiences.

Once the students are awarded an S-STEM scholarship, they are assigned a faculty member as their mentor so that they can have regular meetings with them to discuss their concerns. Since most of our students do not live on campus, we have established program activities for community building, including retreats, holiday parties, a room designated for S-STEM scholars, etc.

The Mechanical Engineering faculty members at UMBC have a strong research emphasis on bioengineering. However, there is a lack of interest in our undergraduate students to engage in research-related activities available in the department. To address this disconnect, we have developed a seminar series consisting of entry-level topics in bioengineering, with support from the S-STEM program. Faculty in the department actively invite outside speakers to give research seminars. Typically, three research seminars are scheduled each year and integrated into the regular Departmental series. We also help our students to locate internship opportunities and internal and external research experiences in research laboratories. In addition, the ME S-STEM Program provides funds to reimburse research expenses to faculty laboratories hosting our scholars, and to support our scholars to attend research conferences to disseminate their results.

RESULTS

In the past six years, we have supported 49 ME undergraduate students with diverse backgrounds, including 17% African Americans, 18% Hispanics, and 18% women, as shown in Figure 1. The connection with local community colleges and proactive recruitment strategy are particularly strong components of the program. Overall, 45% of the scholars are transfers from local community colleges. Among the 49 ME STEM scholars, 0 dropped out of college and only 5 scholars transferred to another major. None of the students who did not get a scholarship renewal are community students. The overall retention rate of our program is 89%, which is substantially higher than that of the control student group (ME department: 40%).

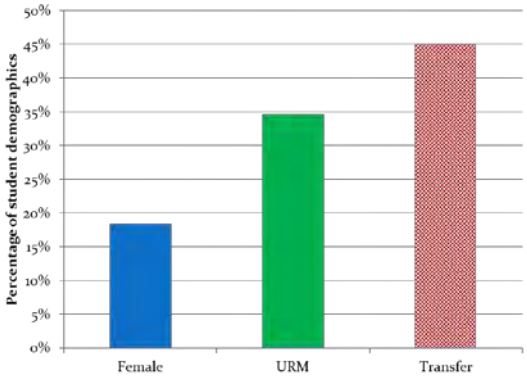

Figure 1: Percentage of underrepresented minority, female, and transfer students in the ME S-STEM program.

The scholars' attendance at all the activities (retreat, seminar, and mentor meeting) ranges from 87% to 95%. We implement regular email notices to students to remind them of various activities sponsored by the program. We have allowed students to make up their missed seminar by attending other research seminars. More than 90% of the students stated that they are satisfied or very satisfied with the research seminars and meetings with their assigned mentors.

Providing research seminars and facilitating internships are also effective. Despite the technical depth in the seminars and that half the scholars are freshmen or sophomores, the undergraduate students have found that the topics are easy to understand. They appreciate the opportunity and have suggested that we invite more researchers from industry/government agencies, and/or researchers who graduated from UMBC. Both suggestions have been implemented by our program. We have hosted 18 seminars in the past six years, among them 7 speakers are female or underrepresented minorities, 6 are UMBC graduates or affiliates, and 4 are from industry or a government agency. One encouraging result is the catalytic effort of the seminar on the undergraduate students. We have found some scholars have attended other research seminars even if it is not required. It is great to see that our scholars have invited their friends to attend the seminars. The scholars had an average of 1.2 internships and/or research experiences over their S-STEM experience; 61% had at least one internship and/or research opportunity.

35 scholars (average GPA at graduation: 3.5/4.0) had completed the BS degree in ME, 25% are pursuing graduate study in an STEM major and 69% are now working in an STEM industry, as shown in Figure 2. The 25% is much higher than the typical 10-15% of regular ME students who pursue graduate schools. We believe that this is partially due to our effort of incorporating research into education. No significant difference in the average GPA is found between scholars who transferred from community colleges and scholars who entered UMBC after they graduated from high school.

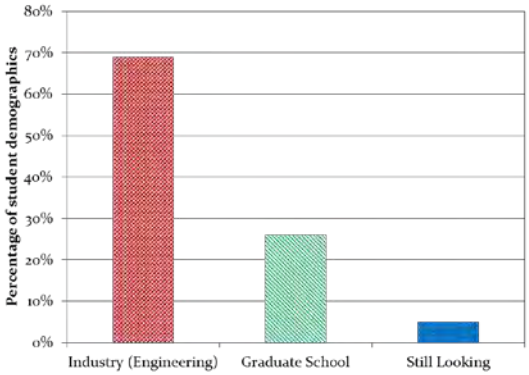

Figure 2. Placements of the 32 scholars who graduated from our program.

In summary, with the support of two NSF S-STEM grants, the UMBC Mechanical Engineering Department has established an S-STEM scholarship program that has supported 49 undergraduate students with diverse backgrounds. It has shown the success of recruiting community college students via implementing our approaches. The program outcomes of more than 80% retention rate and satisfaction rate have been achieved. 94% of the scholars who graduated from our program are either working in industry (69%) or in graduate school (25%). The high graduate school placement may reflect our efforts of incorporating research into education.

ACKNOWLEDGEMENTS

This research was supported by an NSF S-STEM grant DUE-1356440.

INTRODUCTION

Hyperthermia treatment using physical modalities has attracted a lot of attention in the past decades in cancer treatment. The amount of thermal damage to tumor cells is usually affected by the extent of temperature elevations in the tissue and its exposure time [1, 2]. Among all the thermal ablation techniques, magnetic nanoparticles have gained prominence in the last two decades for use in hyperthermia. Designing an optimal heating protocol to cause irreversible thermal damage to tumors while preserving the surrounding healthy tissue, relies on a wide range of heating parameters such as magnetic field strength, frequency, local concentration of nanoparticles and heating duration. The designed heating protocol also depends on the specific cell line, growth stage, and their surrounding tissue environment. Evaluating a designed heating protocol via using magnetic nanoparticles in animal models is the first step to test its efficacy in a biological environment, leading to validation of the theoretical modeling approach for future optimal designs in clinical settings.

In a previous study by our group [3], a heating protocol is designed to determine the heating time to induce complete thermal damage to PC3 tumors implanted on mice, with minimal collateral damage. The objectives of this study are to evaluate thermal damage by measuring tumor shrinkage over eight weeks and performing histological analyses after magnetic nanoparticle hyperthermia, and to evaluate whether the designed treatment protocol induces adequate thermal damage to tumors.

METHODS

22 Balb/c Nu/Nu female mice were used (25 ± 2.6 g) to test the efficacy of the designed heating protocol. Once the tumors reached a minimum diameter of 1 cm, the mouse was weighed and anesthetized using sodium pentobarbital (40 mg/kg, i.p.). The mouse was then placed on a water-jacketed heating pad to maintain the normal core body temperature. Some tumors were injected with 0.1 cc of the commercially available ferrofluid used previously at a rate of 3 μL/min, while other tumors were used as the control. After the injection, the needle was removed and the mouse was placed inside a two-turn water-cooled coil with the water-jacketed heating pad. The alternating magnetic field induced by the coil has a magnetic strength of approximately 5 kA/m and a frequency of 190 kHz [3]. The heating duration is based on our designed protocol.

Three groups (five tumors in each group) were tested for the tumor shrinkage: 25 minutes of heating (the Arrhenius integral $\Omega \geq 4$), 12 minutes of heating ($\Omega \geq 1$), and the control group with no ferrofluid injection but subjected to the alternating magnetic field for 25 minutes. After the heating experiment, the mouse was allowed to fully recover before it was then returned to the animal facility at UMBC, The tumor growth/shrinkage was measured daily over the next eight weeks using a Vernier caliper. Histological studies were performed via H&E staining following the heating experiment, and observation of thermal damage under light microscope. The protocol has been approved by the IACUC at UMBC.

RESULTS

The shrinkages/growths of the tumors in all three groups are list in Table 1. The tumors in the control group without heating almost doubts their size within 10 days, and at the end of the observation period of eight weeks, the volume increases more than 700%. In the undertreated group (with the Arrhenius integral $\Omega = 1$) the tumors shrink 85% within ten days, suggesting some positive outcomes in damaging tumor cells. Unfortunately, later the previously

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

disappearing tumors start to grow back. In the $\Omega = 4$ heating group (25 minute heating, fully treated), all tumors disappeared completely after the 3rd day, and the treatment site maintained the disappearance for the eight week observation period.

Table 1: Average tumor volumes in the three groups over the eight-week observation period.

	Day 0	Day 3	Day 10	Day 56
Control	307 mm^3	379 mm^3	532 mm^3	2618 mm^3
Undertreated	690 mm^3	384 mm^3	115 mm^3	1080 mm^3
Fully treated	655 mm^3	0	0	0

We further evaluate whether heating inhibits tumor growth, illustrated in Figure 1. The tumor growth rate in the control group is slower at the very beginning, then accelerating later with an average growth rate of approximately 67 mm^3/day. The growth rates in the undertreated group in weeks 3 – 8, when the tumors grow back, are noticed as approximately 35 mm^3/day. The results suggest that heating inhibits tumor growth, although that the thermal dosage in the undertreated group is not sufficient to obliterate the entire tumors. When one compares the shrinkage rates between the undertreated group and the fully treated group, it is evident that high thermal dosage in the $\Omega = 4$ group increases the shrinkage rate by 200%, therefore, accelerating the tumor shrinkage after heating.

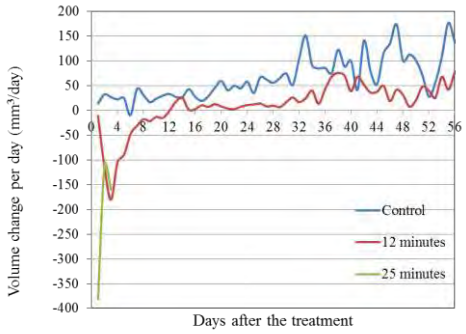

Figure 1. Tumor growth rates (mm^3/day) in the three groups over the observation duration of 56 days.

The top panel in Figure 2 provides the typical H&E staining of PC3 tumors with neither nanoparticle injection nor heating at the 25× magnification. The lower right hand side shows the tumor periphery noted by the light pink region of muscle. It is evident that there are necrotic regions in the untreated tumor. Under normal conditions, the presence of necrotic region in PC3 tumors is not uncommon, and it is most likely due to poor blood supply to those regions and/or the aggressive growing nature of the particular tumor. The typical H&E staining of PC3 tumor tissue in the sham group injected with ferrofluid, however, without heating is shown in the bottom panel in Figure 2. The PC3 tissue in the sham group still resembles normal PC3 cells. The reddish black area in the stain is a small deposition of the ferrofluid. It is shown that the presence of nanoparticles from the direct intratumoral injection does not seem to result in any additional cell necrosis to the tumor region. The tumor periphery still resembles normal PC3 cells with healthy fat and muscle layers.

Figure 3 shows the stained images of a tumor slice under 25× and 100× magnification after the tumor was heated for 25 minutes. It can be clearly seen that there are several areas of tumor cells containing no discernable nuclei and areas of cells detaching from their surrounding cells. The nuclei are significantly darker suggesting that the cells are pyknotic, a condensing of the nuclei that is pre-apoptotic or necrotic [4]. Cells in the immediate vicinity of the ferrofluid deposition region (dark red in the center of the image) are indiscernible as the cell structures have been completely destroyed and they appear "liquefied," much different than the region surrounding the ferrofluid in Figure 2. The muscle surrounding the periphery of the tumor also shows severe thermal damage due to heating, suggesting that heat penetration to the periphery regions is prevalent.

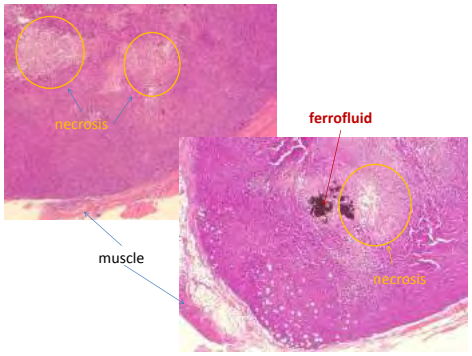

Figure 2. H&E staining images of tumors at 25× magnification for the control group without heating (top panel) and the sham group (bottom panel). The yellow circle shows the necrotic region.

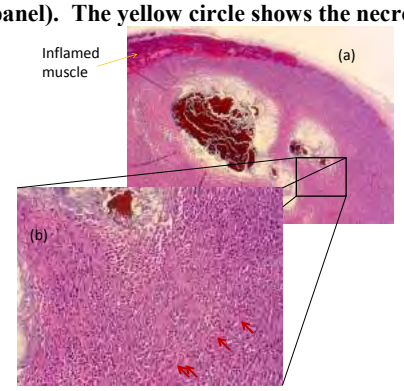

Figure 3. Histologic images of immediately resected PC3 tumors after 25 minutes of heating (a) 25× and (b) 100× magnification.

In summary, *in vivo* experiments have been performed to induce temperature elevations in implanted PC3 tumors in mice using magnetic nanoparticles following the same heating protocol designed in our theoretical study. It has been shown that the 25 minutes heating on tumor tissue is effective to cause irreversible thermal damage to PC3 tumors, while lowering the heating time results in an initial shrinkage, however, later tumor recurrence. On the other hand, the tumors in the control group without heating show approximately an increase of more than 700% in volume over the eight week observation period. In addition, results of the histological analysis suggest vast regions of apoptotic and necrotic cells, consistent with the regions of significant temperature elevations.

INTRODUCTION

Pulmonary hypertension (PH) is a disease resulting from a restricted flow in the pulmonary arterial circulatory system that is reflected by an increase in pulmonary vascular resistance. Without treatment, the disease can quickly lead to decompensated right heart failure and death. The quantification of RV function is essential for effective clinical management of PH patients. Recent studies have demonstrated that RV strains are associated with the right ventricular (RV) function, and is a potentially useful prognostic marker for the progression of disease in PH patients. Compared to the left ventricle (LV) that can be approximated by a truncated ellipsoid, *in vivo* quantitative assessment of strains in the RV is challenging because of its complex geometry and thin wall. Here, we overcome these challenges by the application of a hyperelastic warping technique [1] for quantifying biventricular regional strains in PH patients using regular cine magnetic resonance (MR) images.

METHODS

Cine MR images were obtained for the entire cardiac cycle in 5 PH patients (1 male and 4 females) and 5 age- and gender-matched healthy adults. Ventricular pressure was also measured in each PH patient by right heart catheterization.

Hyperelastic warping, an image registration technique, was applied to these images to compute the myocardial strains throughout the cardiac cycle. Briefly, a finite element (FE) representation of the biventricular unit in the template image (T) was constructed and then deformed into alignment with the corresponding object target image (S) during the registration process (**Fig. 1a**). The forces responsible for the registration deformation were derived from the differences in image intensity between the template image and the target images at different time points in a cardiac cycle. The deformation map is denoted by $\varphi(\mathbf{X}) = \mathbf{x} = \mathbf{X} + \mathbf{u}(\mathbf{X})$, where $\mathbf{x}$ are the current (deformed) coordinates corresponding to $\mathbf{X}$, and $\mathbf{u}(\mathbf{X})$ is the displacement field. The deformation gradient is given as:

$$\mathbf{F}(\mathbf{X}) = \frac{\partial \varphi(\mathbf{X})}{\partial \mathbf{X}} \ . \tag{1}$$

The local change in volume is directly related to $\mathbf{F}$ through the Jacobian ($J = \det \mathbf{F}$), and the right Cauchy-Green deformation tensor is defined as $\mathbf{C} = \mathbf{F}^{\mathbf{T}}\mathbf{F}$.

The registration of MR images can be posed as the minimization of an energy functional E that consists of two terms. This can be defined with respect to the current configuration as:

$$E = \int_{\beta} W(\mathbf{X}, \mathbf{C}) \frac{dv}{J} - \int_{\beta} U(T(\mathbf{X}), S(\varphi)) \frac{dv}{J}, \tag{2}$$

Here, W is a prescribed hyperelastic strain energy density function that provides regularization and/or some type of constraint on the deformation map, while U is an image energy density functional that depends on the image data in the template and target images and takes the form:

$$U(\mathbf{X}, \varphi) = \frac{\lambda}{2}(T(\mathbf{X}) - S(\varphi))^2, \tag{3}$$

where λ is a penalty parameter that enforces the alignment of the template model to the target image.

In Eq. (2), the first variation of W yields the standard weak form of the momentum equations for nonlinear solid mechanics, whereas the first variation of the functional U with respect to $\varphi(\mathbf{X})$ in direction η produces the image-based force term:

$$DU(\mathbf{X}, \varphi) \cdot \eta = -\lambda[(T(\mathbf{X}) - S(\varphi)) \frac{\partial S(\varphi)}{\partial \varphi} \cdot \eta]. \tag{4}$$

This term drives the deformation of the template based on the pointwise difference in the image intensities and the gradient of the target intensity evaluated at material points associated with the template. A Neo-Hookean potential with unit stiffness was used for W and the penalty parameter λ was adjusted until the deformation field converges.

The local circumferential direction was assigned using Laplace-Dirichlet Rule-Based (LDRB) algorithm (**Fig. 1b**), which ensures that the circumferential orientation varies smoothly and continuously throughout the entire myocardium [2]. The biventricular unit was divided into 3 material regions, namely, the left ventricular free wall (LVFW), the right ventricular free wall (RVFW) and the septum (**Fig. 1c**). The average circumferential strain was computed in each region.

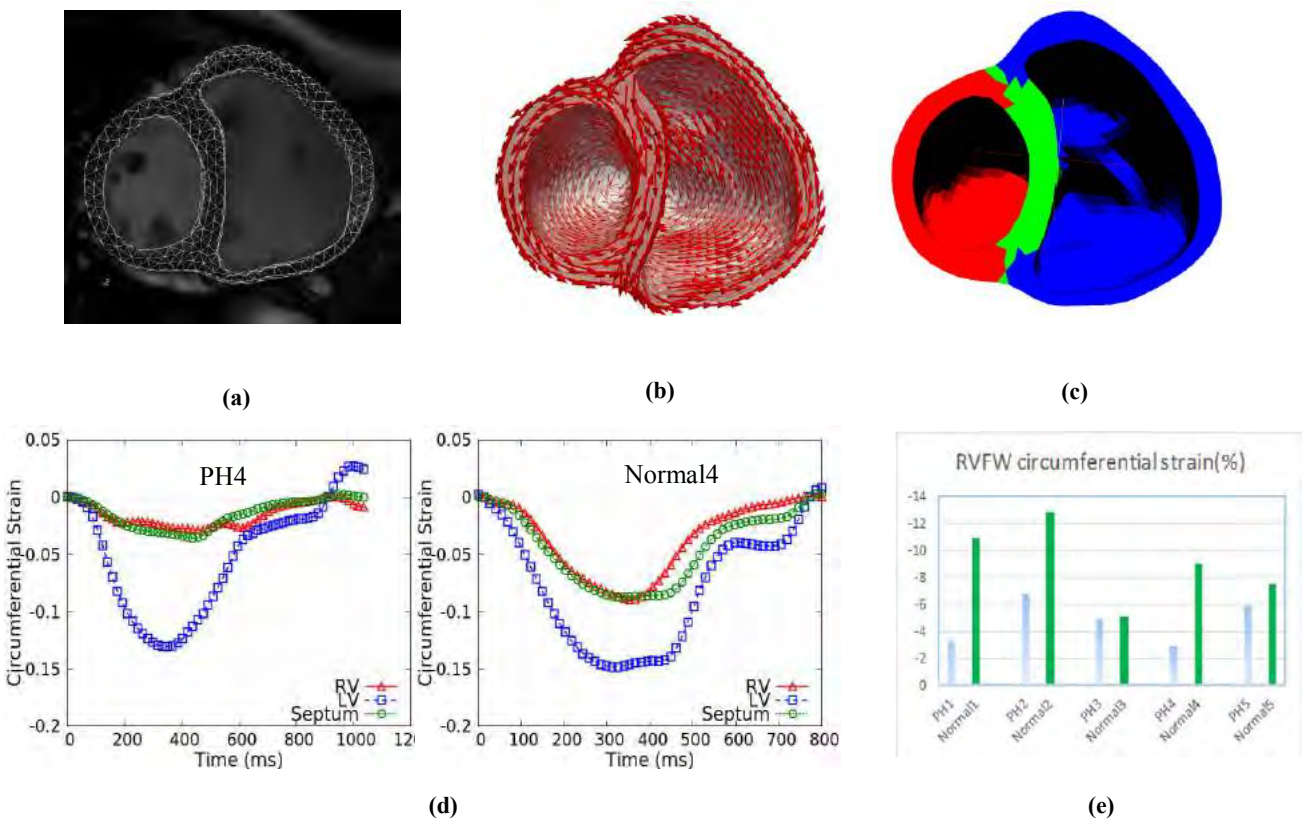

Figure 1. **(a)**: Segmentation of the biventricular unit in the template MR images. **(b)**: circumferential orientation in the biventricular unit. **(c)**: material regions (red: LVFW, green: Septum and blue: RVFW). **(d)**: regional circumferential strain vs. time over a cardiac cycle in a PH patient and a normal subject. **(e)**: comparison of RVFW circumferential strains between PH patients and healthy controls.

RESULTS

The average age of the PH patients was 50 ± 13 years. Peak RV systolic pressure was significantly higher in the PH patients (62.4 ± 9.0 mmHg) than normal range values (around 28 mmHg), and the RV end-systolic volumes were substantially higher in the PH patients than those in normal controls (128 ± 59 mL vs. 53 ± 16 mL). Global systolic circumferential strains of RVFW, LVFW and septum were quantified for the patients and controls (**Fig. 1d** and **Fig. 1e**). The results showed that all patients had a significantly depressed peak RVFW circumferential strain as compared to controls (-3.9 ± 1.8% (PH) vs -9.0 ± 3.0% (Normal), P=0.012), However, the LVFW and septum peak systolic circumferential strain predictions of PH patients were not statistically different from those of healthy controls (LVFW:-13.4 ± 5.0% (PH) vs -14.2 ± 2.4% (Normal), P=0.753; septum:-5.0 ± 3.0% (PH) vs -7.2 ± 2.0% (Normal), P =0.107).

DISCUSSION

In this study, we have used a deformable image registration technique known as hyperelastic warping to quantify the global circumferential strain of the biventricular unit constructed from MR images in patients with PH. Our findings show that the PH patients have significantly reduced RV peak systolic circumferential strains as compared with healthy controls. This result is consistent with a previous study, in which strain-encoded MR imaging is adopted to analyze RV peak regional strains in PH patients [3]. In their study, there are also significant reductions of the RV peak circumferential strain at the basal level in PH patients (-13.0 ± 4.8% vs. -20.4 ± 4.6%), which is qualitatively consistent with our findings. This may indicate that reduced RV circumferential strain could serve as a potentially useful indicator for the evaluation of global RV dysfunction in PH patients.

Besides RV strain, our study also shows that the LV and septum circumferential strains are reduced in PH patients. This finding is consistent with a previous study [4], which shows that patients with PH have significantly reduced septum circumferential strains (-17.6 ± 5.8% vs. -23.1 ± 4.87%; P<0.001) and LV circumferential strains (-11.9 ± 5.0% vs. -14.5 ± 6.1%; P<0.002). However, our finding shows that the differences of septum and LV circumferential strains between PH patients and normal controls are not statistically significant.

We are currently calculating the RV longitudinal strain in these patients so as to obtain a more comprehensive evaluation of the RV contractile dysfunction associated with PH.

INTRODUCTION

Pulmonary hypertension (PH) is associated with an elevated pressure in the pulmonary arterial system that can be due to idiopathic reasons or caused by other conditions (e.g., presence of ventricular septal defect). Prolonged PH produces functional, structural and geometrical changes in the right ventricle (RV). Without treatment, PH can quickly lead to decompensated RV failure and death. Currently, the prognosis of PH remains poor with about 15% mortality within 1 year on modern therapy. To the best of our knowledge, there are currently no in vivo studies that determine the impact of PH on the regional ventricular mechanics and mechanical properties in the human heart. To resolve the gap in our current understanding of PH, the overall goal here is to use image-based patient-specific computational modeling to quantify *in vivo* changes in the regional ventricular mechanics and mechanical properties in PH patients.

METHODS

Magnetic resonance (MR) images were obtained from PH patients as well as gender- and age-matched normal human subjects. Ventricular, atrial and artery pressure were measured in PH patients by right heart catheterization. On the other hand, ventricular pressure was estimated for the normal human subjects based on previous studies. Left and right ventricular (LV and RV) volumes were measured at different time frames in a cardiac cycle from the MR images based on the segmentation of the biventricular geometry. These measurements (as well as the pressure estimation for normal human subjects) were used to construct pressure-volume loops of the RV and LV for PH patients and normal controls.

A cardiac electromechanics model [2] was used to quantify the regional ventricular mechanics in a PH patient and a normal subject. Briefly, mechanics in a cardiac cycle was described by a Fung-type passive constitutive model and a cellular-based active stress constitutive model. In this model, the Cauchy stress tensor is given as follows:

$$\boldsymbol{\sigma} = -p\boldsymbol{I} + \frac{1}{det\boldsymbol{F}}\boldsymbol{F}\cdot\frac{dW(\boldsymbol{E};C)}{d\boldsymbol{E}}\cdot\boldsymbol{F^T} + \boldsymbol{\sigma}^a\left(\boldsymbol{s},\lambda_e,\dot{\lambda}_e;T_{ref}\right) \qquad (1)$$

In Eq. (1), W is the Fung-type strain energy function, $\boldsymbol{F}$ is the deformation gradient tensor, $\boldsymbol{E} = \frac{1}{2}(\boldsymbol{F^T F} - \boldsymbol{I})$ is the Green strain tensor, $\boldsymbol{\sigma}^a$ is an active stress tensor that is a function of (i): state variables $\boldsymbol{s}$ describing membrane channels and intracellular ionic concentration, and (ii): elastic myofiber stretch λ_e and rate of stretch $\dot{\lambda}_e$. In this model, the parameters C and T_{ref} are directly associated with the diastolic passive stiffness and ventricular contractility.

The unloaded biventricular finite element (FE) geometries for the PH patient and normal subject were reconstructed from the corresponding MR images at early diastole when the pressures were at the lowest. Pressure measurements in the LV and RV were used to prescribe the boundary conditions in the computational models. These models were divided into 2 distinct material regions, namely, LV (including the septum) and the RV free wall (RVFW) (**Fig. 1a**). Myofiber orientation was prescribed using a Laplace-Dirichlet Rule-Based algorithm [3]. Fiber helix angle with a transmural variation from 60° (endocardium) to -60° (epicardium) was assigned to the biventricular unit (**Fig. 1b**). Ejection phase was simulated by connecting the LV and RV volumes to a 3-parameter Windkessel model.

The parameters C and T_{ref}, as well as the peripheral resistance in the Windkessel model, were adjusted in the LV and RVFW to match the experimentally measured PV loops. Regional ventricular wall stresses and strains were computed for the PH patient and the normal subject. The differences of all quantified variables and parameters (e.g., regional ventricular strain and passive stiffness determined from FE modeling) were compared between the PH patient and normal subject. Regional differences between quantities obtained from LV and RV were also compared in each individual model.

RESULTS

We were able to match the measured PV loops in the RV and LV for the PH patient and normal subject (**Fig. 1c**). In the PH patient, the peak RV pressure was substantially higher than that found in the normal subject (65 mm Hg vs. 20 mmHg). End-diastolic volumes in the PH patient were also comparatively larger (LV: 160 ml vs.105 ml; RV: 275 ml vs. 100 ml). Ejection fractions were lower in the PH patient (LV: 38% vs. 69%; RV: 19% vs. 67%).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

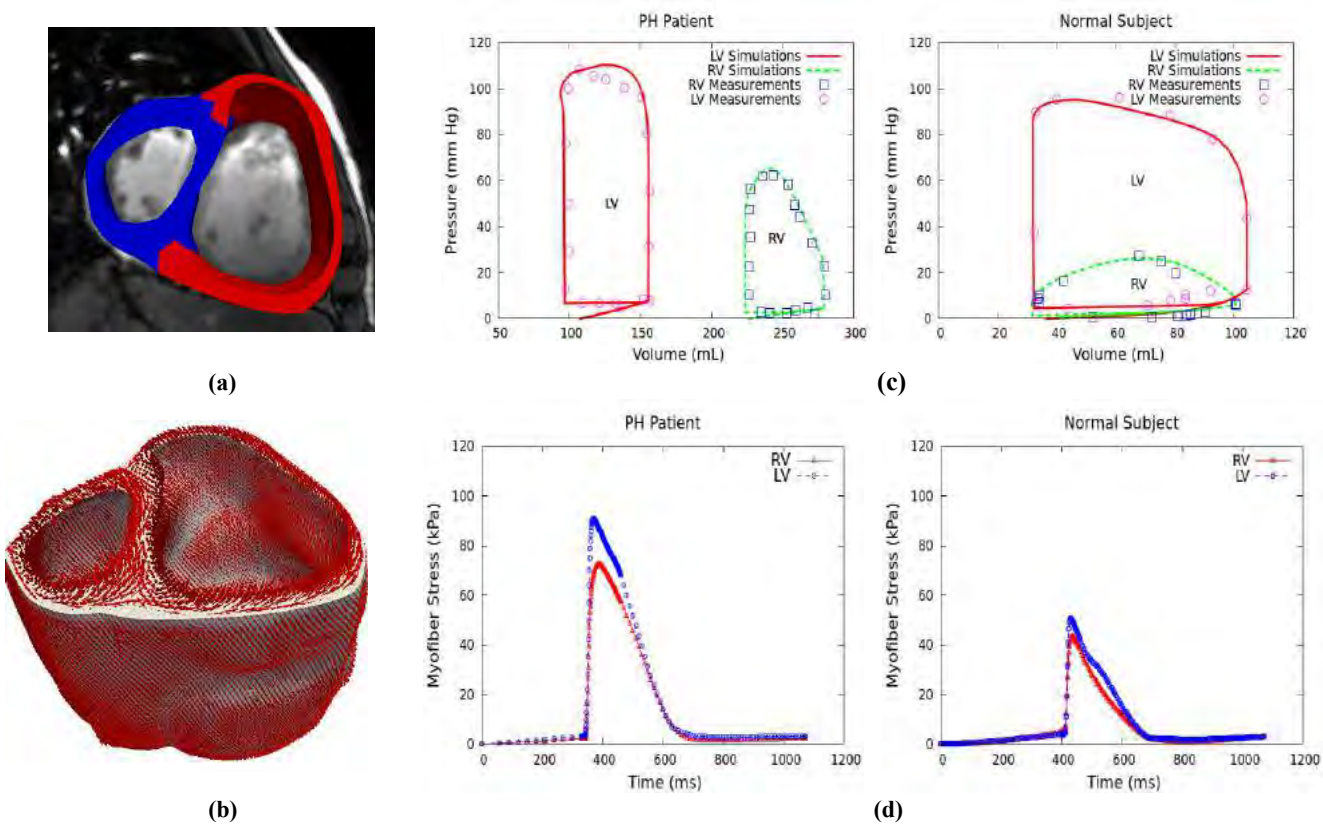

Figure 1. **(a)**: Two material regions in the biventricular unit: LV (blue) and RVFW (red). **(b)**: Myofiber orientation. **(c)**: Pressure-volume loops from experimental measurements and simulation results of a PH patient (left) and a normal subject (right). **(d)**: LV and RV myofiber stress vs. time over a cardiac cycle in the PH patient (left) and the normal subject (right).

To match the PV loops, the diastolic passive stiffness in the PH patient was found to be larger than that in the normal subject. Specifically, compared to the normal subject, the parameter C was found to be ~20 and ~60 times larger at the RVFW and LV in the PH patient, respectively. The RVFW to LV ratio of the parameter C was 1:1 in the PH patient and 3:1 in the normal subject.

On the other hand, the ventricular contractility was higher in the PH patient than in the normal subject. Compared to the normal subject, the value of T_{ref} was about twice as large. The RVFW to LV ratio of T_{ref} was slightly lower in the PH patient (0.43) compared to the normal (0.5). Peripheral resistance (afterload) in the RV was about 4 times higher in the PH patient. By contrast, we found no changes in the peripheral resistance in the LV between the PH patient and the normal subject.

Myofiber stress in the PH patient was significantly higher than that of the normal subject in the entire biventricular region (**Fig. 1d**). Peak myofiber stress in the RVFW and LV of the PH patient was almost 2 times of that in the normal subject (73kPa vs. 43kPa in the RVFW and 91kPa vs. 50kPa in the LV).

DISCUSSION

We have used an image-based cardiac electromechanics model to quantify the regional ventricular mechanics in a PH patient and a normal human subject in this study. Our findings indicate that the diastolic passive stiffness and the ventricular contractility of the PH patient are larger than those in the normal subject in both the LV and RVFW. The RVFW/LV contractility ratio (~ 0.5) is the same in the PH patient and the normal subject.

The increase in RVFW diastolic stiffness is consistent with a previous study [3], which shows that both collagen content and the passive tension of isolated cardiomyocytes from the explanted RV tissue samples of PH patients are increased when compared to those taken from normal controls. In that study, RV diastolic stiffness is also found to be significantly increased in PH patients and closely associated with the disease severity.

Although our finding that the contractility in the RV is increased runs somewhat contrary to the fact that PH is usually associated with severe RV systolic dysfunction, this finding is supported in that same study [3], which shows that the RV end-systolic elastance (a global measure) and the force-generating capacity of isolated RV cardiomyocytes (a local measure) are increased in PH patients compared to normal subjects. This finding is also observed in previous studies on rats. The increase in RVFW contractility is most likely a compensatory mechanism to the increase in afterload (peripheral resistance) in PH patients.

Last, our finding that the LV diastolic passive stiffness and ventricular contractility is also increased in the PH patient, suggests that the disease can affect the left heart as well. We are currently performing the same analysis on more PH patient data.

INTRODUCTION

Recent studies indicated that plaque rupture may be associated with: a) extreme mechanical stress/strain conditions; b) large lipid-rich necrotic cores; c) thin and weakening fibrous cap; d) cap inflammation; e) intraplaque hemorrhage; f) activities at molecular and cellular level which may be related to plaque rupture; and g) factors from genetic, diet, disease, behavior, chemical, mental stress, work conditions and others people think that may have linkage to plaque progression and rupture [1-5]. Extreme mechanical stress and strain conditions have been identified as a potential risk factor for plaque rupture [3]. However, accuracy of computational in vivo stress/strain calculations is affected by available in vivo image data. While it is believed that inflammation weakens plaque cap and may have considerable impact on cap stress and strain conditions, no single image modality is able to provide vessel geometry, plaque components and inflammation at the same time. Fayad et al and others have been developing multi-modality imaging technology using PET/CT (Positron Emission Tomography/ Computed Tomography) and MRI (magnetic resonance imaging) to identify inflammation in arteries [6,7]. Combining PET/CT with MRI, we are able to obtain plaque morphology with inflammation information on cap surface. This gives us the base for better modeling stress/strain predictions. The goal of this paper is to investigate possible impact of cap inflammation on plaque stress/strain and flow shear stress conditions, with plaque and inflammation data provided by PET/CT combined with MRI.

MRI AND PET/CT DATA ACQUISITION AND FSI MODELS

The data under consideration was acquired as part of a clinical trial imaging patients to assess arterial inflammation within the bilateral carotid arteries and ascending aorta. The 74 year old, male patient with coronary heart disease was imaged with Magnetic Resonance Imaging (MRI) and 18F-fluorodeoxyglucose (18F-FDG) PET/CT (Positron Emission Tomography/Computed Tomography) in separate imaging sessions approximately 12 days apart. For the MRI examination the patient was imaged in a head-first supine position. 2-D multi-contrast (T2-weighted, T1-weighted and proton-density weighted) dark-blood turbo spin-echo images of the bilateral carotids were acquired as part of a longer imaging study. The PET/CT was performed after the patient had fasted overnight, and 120 min after injection of 15mCi of 18F-FDG. A low-dose, non-contrast-enhanced CT scan was used for attenuation correction and anatomical information for the PET scan. The carotid arteries were imaged with a 15 min PET scan of one bed position in 3D mode. The MRI and PET/CT data were segmented and registered for modeling use (see Fig 1 for the registration of MRI with PET/CT) [6,7].

An MRI-PET/CT-based modeling approach is proposed to develop fluid-structure interaction (FSI) models for human carotid plaque assessment and quantify the effect of inflammation on plaque stress/strain conditions. For the 15-slice MRI/PET/CT data set acquired from the above procedures, inflammation was identified for S4-S10. The 3D FSI model was built following established procedures [Tang]. The artery wall was assumed to be hyperelastic, isotropic, incompressible and homogeneous. The nonlinear modified Mooney-Rivlin (M-R) model was used to describe the material properties of the vessel wall [BE38P 19, Tang2004]. Blood flow was assumed to be laminar, Newtonian, viscous and incompressible. Details of the FSI model were given in Tang, et al. [3]. Material stiffness for the fibrous cap was adjusted lower to reflect the cap weakening caused by cap inflammation. Setting stiffness ratio (SR) to be 1.0 for the baseline model, coefficients c_1 and D_1 in the M-R model were multiplied by SR=0.5, 0.25, and 0.1 to make the cap softer. The 3D FSI models were solved by a commercial finite element package ADINA (ADINA R & D, Watertown, MA, USA) using unstructured finite element methods

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

for both fluid and solid domains. Plaque cap stress, strain and flow shear stress data from all 4 cap stiffness variations corresponding to peak systolic pressure were recorded for analysis.

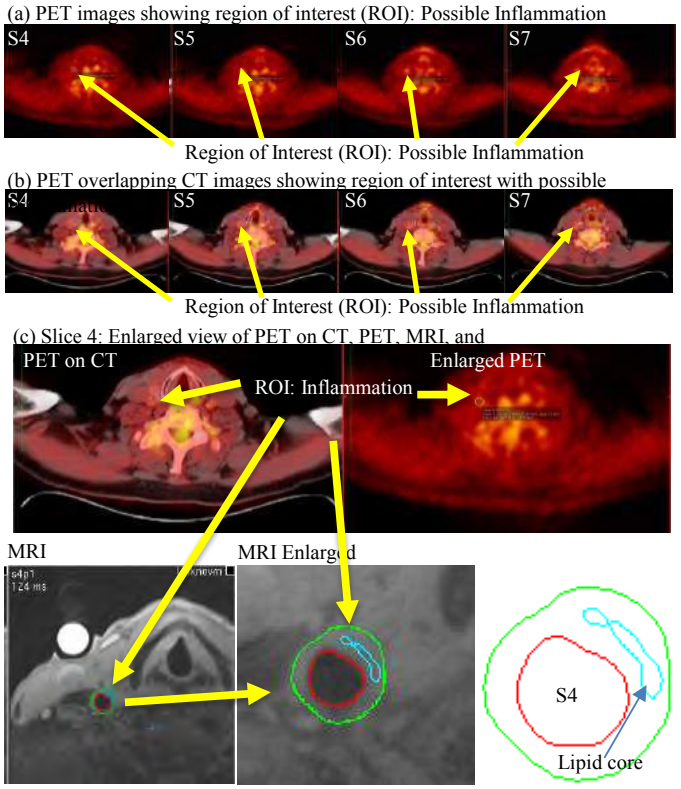

Figure 1. PET and CT images from S4-S7 with lipid-rich necrotic core and enlarged view S4 with MRI showing Region of Interest (ROI) with possible inflammation.

RESULTS

Figure 2 shows selected stress, strain and FSS plots from models with SR=1.0 and 0.1 respectively. Local maximum cap stress value without inflammation (SR=1.0) was 47.19 kPa. Corresponding to SR=0.5, 0.25, and 0.1, the local maximum cap stress values were 34.04, 27.69, and 18.95 kPa, respectively. The local maximum cap stress value reduced 60% from SR=1.0 to SR=0.1. Checking each slice, for example, looking at a S6, the local maximum cap stress value reduced from 62.79 kPa (SR=1.0 case) to 17.22 kPa (SR=0.1), a 72% decrease. On the other hand, local maximum stress values on S4 and S8 were much limited (<20%).

Our results also indicated that cap inflammation led to higher cap strain values. Cap strain variations caused by inflammation were much greater. Figure 2 (b) shows that the local maximum cap strain value without inflammation (SR=1.0) was 0.1065. Corresponding to SR=0.5, 0.25, and 0.1, the local maximum cap strain values were 0.1730, 0.2388 and 0.3178, which was 62.4%, 124%, and 195% higher than that of SR=1.0, respectively. The local maximum cap stress value reduced 60% from SR=1.0 to SR=0.1. Checking slice by slice, from S6, the local maximum cap strain value increased from 0.1392 with SR=1.0 to 0.4372, a 214% increase. Strain values on S4 and S8 increased less from SR=1.0 to SR=0.1. But the increases were still around 100%.

Cap inflammation has small impact on flow shear stress changes. Figure 4 (c) shows that flow shear stress (FSS) on a sagittal cut had an 8% increase from SR=1.0 model to SR=0.1 model. FSS mean values on the cap nodes changed from slice to slice, indication flow pattern changes. All FSS values stayed in a narrow range within their SR=1.0 values.

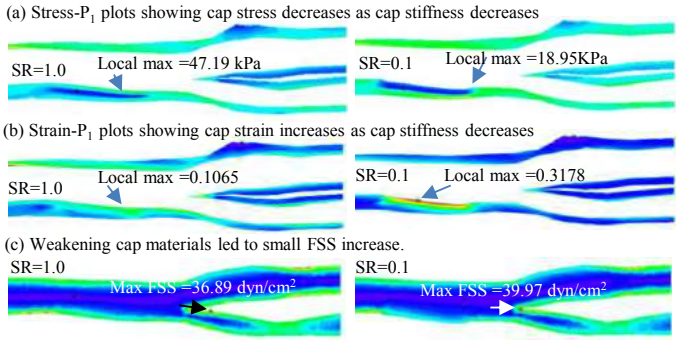

Figure 2. Stress, strain and flow shear stress plots from SR=1.0 and SR=0.1 models showing weakening cap materials led to decreased cap stress, increased cap strain, and small FSS changes.

DISCUSSION AND CONCLUSION

Significance of cap inflammation: huge impact on cap strain, reduced cap stress. Most investigations for atherosclerosis plaque rupture and vulnerability have been focused on flow shear stress and extreme cap stress conditions. Our findings in this paper indicated that inflammation may lead to lower cap stress and higher strain. That suggests our future effort should be focused more on cap strain conditions. Indeed, while stress is determined by both material stiffness and strain, strain is more an intrinsic condition of the plaque. Weakened plaque cap becomes softer and its lower stiffness reduces cap stress level. On the other hand, the increased strain may serve as a critical vulnerability indication. Needless to say, mechanical testing of plaque cap materials to find out its material strength would be a task for researchers in this field to provide threshold values to serve as base for model predictions.

Impact of plaque morphology and components. It is clear from this sample that the impact of inflammation on stress/strain is heavily dependent on the location and size of the plaque component, tissue type, and vessel material properties. This paper serves as a motivation to demonstrate the impact of inflammation on plaque mechanical conditions and the importance of further investigations.

INTRODUCTION

Accurate ventricle stress and strain calculations are of fundamental importance for cardiovascular research and investigations. From mechanical point of view, zero-stress ventricle geometry information is required for its stress/strain calculations. Ventricle modeling, especially ventricle active contraction modeling based on in vivo data, is extremely challenging because of complex ventricle geometry, dynamic heart motion and active contraction and relaxation where the reference geometry (zero-stress geometry) changes constantly in a cardiac cycle. Peskin pioneered heart modeling effort and simulated blood flow in a pumping heart with his immersed boundary method [1]. McCulloch et al. and Hunter et al. conducted comprehensive investigations for cardiac mechanics, and their papers and the Continuity package provide excellent review of the field [2,3]. In our previous papers, patient-specific MRI-based computational right ventricle/left ventricle (RV/LV) models (called 1G model thereafter) with fluid-structure interactions were introduced to assess outcomes of various RV reconstruction techniques with different scar tissue trimming and patch sizes [4-6].

Active contraction is caused by sarcomere shortening which leads to increased strain and stress. Due to sarcomere shortening, zero-load ventricle systole geometry is smaller than its zero-load diastole geometry. A new modeling approach using two different zero-load geometries (diastole and systole) was introduced in this paper (called 2G model thereafter) to properly model active contraction and relaxation and provide ventricle diastole and systole stress and strain calculations based on their respective zero-load geometries. The new morphological and stress/strain results from the new 2G models were used to identify potential predictors for post pulmonary valve replacement (PVR) outcome for Tetralogy of Fallot (TOF) patients.

MRI DATA ACQUISITION, MODELS AND METHODS

Cardiac MRI (CMR) data were acquired from 16 TOF patients before and after PVR surgery with patients' consent obtained. Data acquisition procedures were described in [7]. The patients were divided into Group 1 (n=8) with better outcome and Group 2 (n=8) with worst outcome based on their change in RV EF from pre- to post-PVR. RV EF was chosen due to its strong association with adverse clinical outcomes in patients with repaired TOF. Three-dimensional RV/LV geometry and computational mesh were constructed following the procedures described in [3]. An iterative pre-shrink process was applied to the in vivo minimum volume ventricular geometry to obtain the two zero-load geometries so that when in vivo pressure was applied, the ventricle would regain its in vivo geometry. As patient-specific fiber orientation data was not available, our 2-layer RV/LV models were constructed using fiber orientation angles given in [3,8].

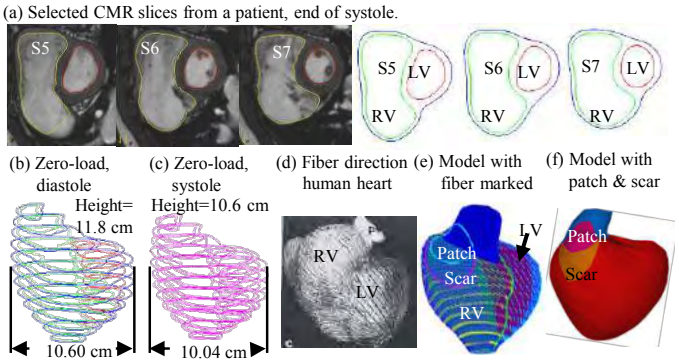

Figure 1: Selected CMR images of a TOF patient, 2-zero-load geometries, and the reconstructed 3D geometry with patch.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The anisotropic RV/LV computational models were constructed for the 16 patients and the models were solved by ADINA (ADINA R&D, Watertown, MA, USA) using unstructured finite elements and the Newton-Raphson iteration method. For each 3D CMR data set (9-14 slices), ventricular wall thickness (WT), circumferential curvature (C-cur), longitudinal curvature (L-cur), and stress/strain were calculated at all nodal points (100 points/slice). The "slice" values of those parameters were obtained by taking averages of those quantities over the 100 points for each slice and saved for analysis. Pairwise T-test and Linear Mixed Effect (LME) model were used to determine if the differences from the new and old models were statistically significant with the dependence of the pair-wise observations the clustering effects taking into consideration [6]. For group comparisons, continuous variables (RV volumes, WT, C-cur, L-cur, and stress and strain values) were summarized as mean ± SD and compared between the outcome groups using an unpaired Student t-test. Associations between pre-PVR RV parameters and the outcome (change in RV EF) were explored using Pearson correlation analysis. Logistic regression analysis was used to identify pre-PVR parameters that best predicted the primary outcome—RV EF response to PVR. The sensitivity and specificity of these parameters and their area under the receiver operating characteristic curve (AUC) were determined.

RESULTS

Our results included the following: a) differences between the 1G and 2G models; b) differences in morphological and mechanical risk parameters between the two patient groups using 2G models; c) post PVR outcome prediction results using the 2G models.

The overall results from the 16 patients indicated that peak-systolic (begin-systole from our model) stress from the 2G model was 28% higher than that from the 1G model (108.4 kPa vs. 84.7 kPa). The begin-diastole stress values from the two models were about the same (7.17 kPa vs. 7.32 kPa, 2% difference). Peak-systolic (begin-systole from our model) strain from the 2G model was 39.6% higher than that from the 1G model (0.606 vs. 0.434). The begin-diastole strain value from the 2G model was 23% lower than that from 1G model (0.048 vs. 0.062).

Comparisons of RV WT, C-curvature, L-curvature, and stress and strain values between Group 1 and Group 2 at begin-filling, end-filling, begin-systole, and end-systole indicated that RV stress is the only parameter with significant difference between the two groups. At begin-systole (maximal volume and pressure), mean RV stress of Group 2 was 57.4% higher than that of Group 1 (130.1 ±60.7 vs. 82.7±38.8 kPa; P=0.0042). Differences at other three time points were similar.

The logistic regression method was applied to all 255 possible combinations of the 8 candidate predictors to calculate their prediction accuracy for patient's group category. The 8 predictors are WT, C-cur, L-cur, RV volume, and stress at begin-systole, plus three stress variations from one time point to another: StressE-D is the difference between begin-systole and end-diastole stresses; StressE-F is the difference between begin-systole and end-systole stresses; and StressE-C is the difference between begin-systole and begin-diastole stresses. Strain was not taken as a predictor because it had no statistically significant difference between the two groups. Table 1 shows the 6 best combinations (out of 255) of RV parameters that correctly assigned patients to their ultimate outcome group and the prediction accuracy and ranking of the single predictors. Pre-PVR RV stress at begin-systole was the best single predictor among the 8 individual parameters with an area under the ROC curve of 0.782. The best combination of parameters was C-cur + RV volume + StressE-F with an area under the ROC curve of 0.855.

DISCUSSION AND CONCLUSION

Accurate stress/strain calculation is of fundamental importance for many cardiovascular research where mechanical forces play a role. The 2G modeling approach is setting up the right stage for diastole and systole stress/strain calculations using proper zero-load geometries. It should be noted that direct measurements of stress, strain, and sarcomere length are either extremely difficult or even impossible. Data from the literature or from ex vivo experiments (such as fiber orientation, sarcomere length contraction rate) have to be used to complete the computational models.

The current surgical approach to address chronic pulmonary regurgitation includes pulmonary valve replacement/insertion (PVR) with or without RV remodeling. However, while most patients demonstrate a variable degree of decrease in RV size, many do not experience an improvement in RV function and some show a decline after PVR [7]. It has remained unclear why some patients had experienced an improvement in RV EF whereas in others RV function had deteriorated. Our modeling and identified predictors provided a potential approach to identify patients and factors for possible surgical outcome improvements.

INTRODUCTION

To enable transmission of force from muscle to bone, tendon exhibits nonlinear, anisotropic, viscoelastic and dynamic properties. This mechanical function is modulated by *dynamic processes* that occur at the micro- and nanoscale during loading, specifically fiber uncrimping, fiber re-alignment, fibril deformation and fibril sliding. These mechanisms are thought to reduce strain on individual fibrils during the initial response to load and to prevent irreversible damage. The contribution of these dynamic processes to the mechanical response to load is thought to be dependent on region (insertion site versus midsubstance), alluding to the significance of extracellular matrix composition and structure in these processes. This matrix, comprised predominantly of collagen type I, is organized in a hierarchical manner spanning from the single collagen fibril to full tendon [1]. In addition to collagen I, the extracellular matrix contains quantitatively minor collagens and proteoglycans with glycosaminoglycans (GAGs). These elements all play a role in tendon mechanical function.

Despite previous studies [2-5], current explanations of load sharing are insufficient, suggesting that the mechanical behavior of tendons cannot be explained solely by composition and structure. Recent advances have allowed for the measurement of dynamic parameters, but only a limited number of studies have investigated the role of dynamic processes in structure-function relationships. Therefore, the purpose of this study was to investigate the role of composition, structure, and the dynamic response to load in predicting tendon mechanical properties using a multi-level statistical regression analysis mimicking native hierarchical collagen structure.

METHODS

Data analyzed in this study was gathered in a recent series of experiments [6, 7] measuring the multi-scale composition, structure, and mechanical response of mature supraspinatus tendons from wild type, collagen V heterozygous and tendon/ligament-specific collagen V null mice. The statistical analysis was "blind" to mouse genotype, allowing for the hypotheses to be tested by determining how variances in predictors affect mechanical properties, regardless of how those variances were achieved. Due to the destructive nature of many of the assays performed, it was not possible to obtain values for every parameter from a single specimen. Therefore, imputation was performed on the data set using the fully conditional specification method with 10 iterations for five imputations [8].

Summary statistics of all variables were examined to ensure that assumptions for linear regression were met. This study consisted of three sets of defined variables: (1) mechanical properties, (2) dynamic processes (fiber re-alignment & crimp, fibril deformation & sliding), and (3) composition/structure (cell morphology, fibril morphology, initial d-period and variance, extracellular matrix composition). Pearson correlation coefficients were first used to determine univariate relationships between predictor variables with significance at $p<0.05$. Multiple linear regression models were then used to quantify the relationships: (Regression A) between mechanical properties and dynamic processes, and (Regression B) between composition/structure and dynamic processes. A series of stepwise regression models using least-square estimation with forward elimination were used to predict these relationships, where variables were included in the model if they improved the model via an F test with significance set at $p<0.05$.

RESULTS

At the insertion site, glycosaminoglycan (GAG) content was positively correlated with total collagen (COL) content and negatively correlated with pyridinoline crosslinks (PYD) (not shown). COL was negatively correlated with PYD and positively correlated with fibril

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

density. Fibril density was also negatively correlated with PYD. At the midsubstance, fibril diameter and fibril density were negatively correlated.

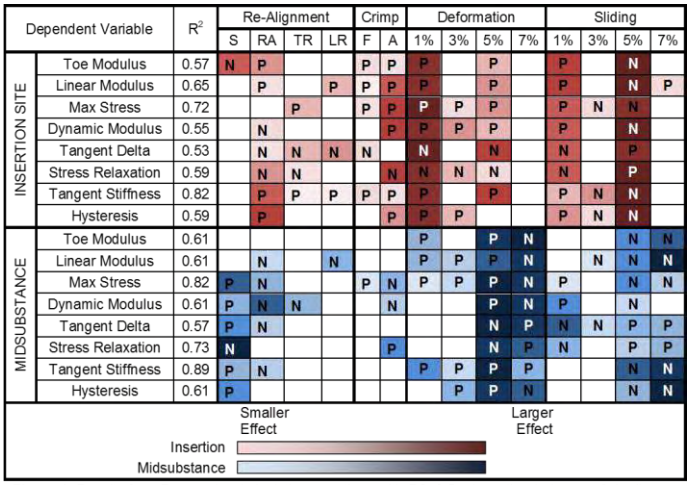

Figure 1. Results from Regression A depicting equations with R2>0.5, where the darkness of shading represents the importance of the contribution of each predictor. Note: S = strain required to re-align, RA = amount of re-alignment, TR = toe region re-alignment, LR = linear region re-alignment, F = crimp frequency, A = crimp amplitude; P = positive predictor, N = negative predictor.

Dynamic parameters were strong predictors of mechanical properties, with R^2 values reaching as high as 0.89 (Fig. 1). Tangent stiffness was the strongest predicted mechanical parameter in both regions. At the insertion site, mechanical parameters were well predicted by linear combinations of all four dynamic parameters, with fibril sliding and deformation making the largest contributions to the models. Fibril deformation at 1% and 5% applied strain were strong positive predictors of mechanics while deformation at 7% applied strain was not predictive. In contrast, the midsubstance mechanical parameters were best predicted by fibril deformation, with sliding and re-alignment playing more minor roles. Fibril deformation from 1-5% applied strain was a positive predictor of mechanics while deformation at 7% applied strain was a negative predictor. Finally, fibril sliding was a positive predictor at 1% applied strain and a negative predictor at higher strain levels in both regions.

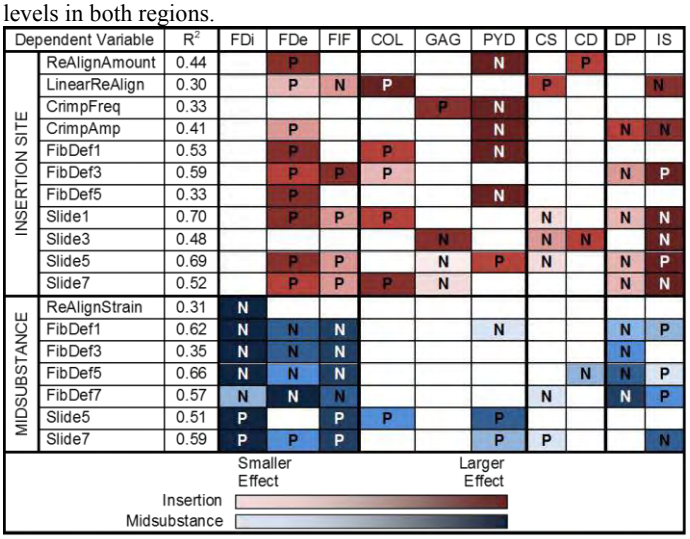

Figure 2. Results from Regression B depicting equations with $R^2 > 0.3$, where the darkness of shading represents the importance of the contribution of each predictor. *Note:* FDi = fibril diameter, FDe = fibril density, FIF = fibril irregularity, CS = cell shape, CD = cell density, DP = intial d-period, IS = initial variance of d-period; P = positive predictor, N = negative predictor.

Dynamic properties were moderately predicted by parameters of composition and structure, with R^2 values reaching 0.70 (Fig. 2). Deformation and sliding were the best predicted parameters, while re-alignment and crimp were only moderately predicted. Many parameters at the insertion site were strongly predicted by pyridinoline crosslinks content, fibril density, and initial d-period variance. Pyridinoline content was a negative predictor of re-alignment, crimp and deformation, but a positive predictor of sliding. Fibril density was a positive predictor of all dynamic processes. Initial d-period variance was a negative predictor of re-alignment and sliding. At the midsubstance, the strongest predictors of dynamic properties were fibril morphology (diameter, density, irregularity) and initial d-period length and variance. Fibril diameter and density were negative predictors of deformation and positive predictors of sliding. Initial d-period variance was a positive predictor of re-alignment, crimp, and deformation and a negative predictor of sliding. Initial d-period was a positive predictor of sliding and a negative predictor of deformation.

DISCUSSION

Mechanical properties were strongly predicted by dynamic processes, and the contribution of each process was location-dependent. The mechanical properties of the insertion site were predicted by all dynamic processes. Given that the insertion site experiences the highest strains [9], it likely utilizes re-alignment, uncrimping, and sliding in order to delay the onset of direct deformation to the fibrils/fibers. Due to the increased organization and structure at the midsubstance, this region of the tissue likely responds primarily through deformation of the fibrils and fibers themselves.

Dynamic processes were only moderately predicted by structure and composition. While increased crosslink density is thought to increase mechanical properties [10, 11], our models suggest that such an increase would reduce the dynamic responses. Since increased crosslink density may also increase the brittleness of collagen fibrils [12], this could result in early damage. Fibril diameter and density were strong predictors of dynamic function at the midsubstance, often both in the same direction, which is in contrast to results in univariate correlations. However, deformation was predicted negatively and sliding was predicted positively by both parameters, suggesting that they are negatively correlated to balance these two dynamic responses.

In conclusion, the mechanical properties at the midsubstance of the tendon are controlled primarily by fibril structure via fibril deformation and sliding. Conversely, mechanical function at the insertion site is more complicated, as it is controlled by many other important parameters via all four dynamic mechanisms. Overall, this study presents a strong foundation on which to design future experimental and modeling efforts in order to fully understand the complex structure-function relationships present in tendon.

INTRODUCTION

The field of tissue engineering aims to combine scaffolds, cells, and biological cues to create viable replacements for damaged biological tissue. Tendons and ligaments are an area of focus for tissue engineering research due the high incidence of injury and limited capacity for healing [1]. Surgical techniques to repair damaged tendons and ligaments are often inadequate at restoring function which further motivates the development a tissue engineered replacement [2].

Electrospinning is a technique that creates a non-woven mat of polymer nanofibers [3]. Modification of the electrospinning process can result in fibers that are aligned in a single direction, thus mimicking the anisotropy of collagen fibers found in tendons and ligaments [4]. A major drawback of conventional flat electrospun scaffolds is their failure to recapitulate the complex hierarchical structure of native tendons and ligaments.

Growth factors are often integrated into polymer scaffolds to encourage cell proliferation and differentiation. Connective tissue growth factor (CTGF) and basic fibroblastic growth factor (bFGF) have been shown to encourage fibroblastic differentiation of stem cells, as evidenced by cell proliferation, gene expression changes and increased matrix deposition [5,6]. Growth factors present some practical challenges including rapid inactivation and a short half-life in plasma [7]. Chemical conjugation of growth factors to polymer surfaces creates functionalized nanofiber scaffolds with attenuated growth factor release and a prolonged influence on cell behavior [8].

Our research group has developed a technique to create cylindrical bundles of aligned nanofibers that mimic the hierarchical structure of tendons and ligaments. Aligned nanofiber bundles have a modulus of ~50 MPa and a yield stress of ~20 MPa at 50% strain [9]. The goal of this work was to assess the influence of two chemically conjugated growth factors on the adhesion, proliferation and morphology of adipose derived stem cells grown on novel biomimetic aligned electrospun nanofiber scaffolds.

METHODS

Flat sheets of aligned nanofibers were fabricated using a 10% w/v solution of polycaprolactone that was prepared in a 3:1 v/v mixture of chloroform and methanol. The collector surface was a rotating aluminum drum located 10 cm from the needle tip and rotating with a linear velocity of approximately 12 m/s. Nanofibers were collected for 15 minutes resulting in a sheet approximately 20 µm thick. Sheets were then rolled to create cylindrical bundles of nanofibers approximately 0.5 mm in diameter and 175 mm length, with nanofibers aligned along the longitudinal axis (Figure 1). For further experiments nanofiber bundles were cut to 20 mm in length.

Either CTGF or bFGF were covalently conjugated to the nanofibers via a multi-step technique. First scaffolds were incubated in a 5% v/v aqueous solution of polyallylamine with simultaneous ultraviolet radiation for 25 minutes. Next scaffolds were incubated on a shaker plate in a solution of N-succinimidyl-3-maleimidoproprionate and N,N-dimethylformamide for 1 hour. Finally, the scaffolds were incubated in a 50 ng/mL solution of the designated growth factor for two hours. Between subsequent steps the scaffolds were rinsed to ensure no residual chemicals remained within the scaffold structure. Growth factor conjugation efficiency was assessed using X-ray photoelectron spectroscopy (XPS) conducted after each subsequent modification step to assess the accumulation of nitrogen.

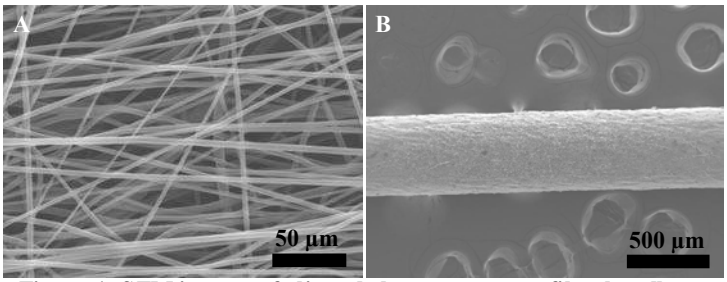

Figure 1: SEM images of aligned electrospun nanofiber bundles at (A) 20x and (B) 1000x magnification.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

After growth factor conjugation, scaffolds were sterilized using 70% ethanol and 30 minutes of exposure to ultraviolet light. Human adipose derived stem cells at passage 4 were seeded on scaffolds at a density of 10,000 cells/cm^2. Morphology and spatial organization of cells on seeded scaffolds were assed using scanning electron microscopy (SEM) after 1, 4, and 7 days of culture. Cell viability was measured at the same time points using a commercially available CellTiter Blue assay. Additionally cells were stained with 5-Chloromethylfluourescein Diacetate (CMFDA – live cells), rhodamine-phalloidin (actin – cytoskeleton), and 4'6-diamidino-2-phenylindole (DAPI – nucleus) to assess cell adhesion and proliferation.

RESULTS

After each conjugation step the relative percentage of nitrogen in the scaffold increased, indicating successful conjugation (Table 1). High resolution N1S scans were also taken and the results indicated an increase in the percentage level of nitrogen on the surface.

Table 1: Relative percentage of elemental nitrogen after subsequent modification steps.

	Nitrogen Composition
Unmodified	0%
After amine modification	1.5%
After maleimide modification	2.3%
After CTGF modification	3.5%
After bFGF modification	3.7%

Live cell counts based on fluorescence imaging showed the number of cells significantly increased over time in culture (Figure 2A) for all scaffolds. A culture period of 7 days for the presence of conjugated growth factors was required to significantly increase the number of cells on scaffolds compared to controls ($p<0.05$). The CellTiter Blue assay indicated that there were no cytotoxic effects for any scaffolds (Figure 2B). At days 4 and 7 the metabolic activity of cells on CTGF or bFGF scaffolds was significantly greater than the metabolic activity of cells on control scaffolds. At day 4 the metabolic activity of cells on CTGF scaffolds was significantly greater than that of cells on bFGF scaffolds; however no differences were seen between the two growth factor groups at days 1 and 7. SEM images showed that cells adhered, spread, and colonized on all scaffolds (Figure 3A). Additionally cells appeared to elongate along the direction of the nanofibers (along the longitudinal axis of the scaffolds) for all groups. Similarly by day 7 immunofluorescence images showed elongated cells covering the surfaces of all nanofiber bundle scaffolds (Figure 3B).

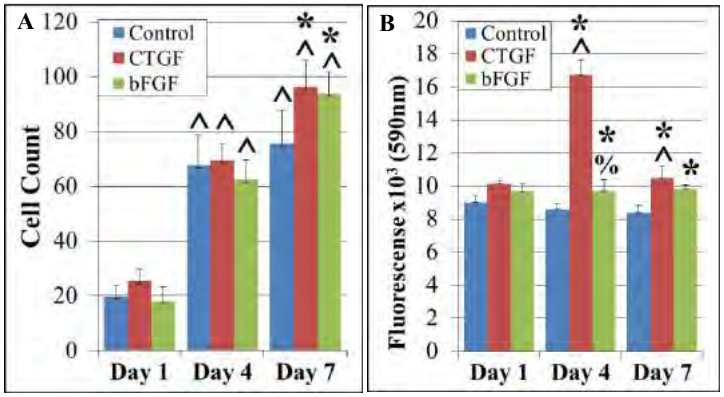

Figure 2: (A) Counts of cell nuclei. (B) Metabolic activity. * indicates significantly different from control. % indicates significantly different from CTGF. ^ indicates significantly different from previous time point ($p<0.05$).

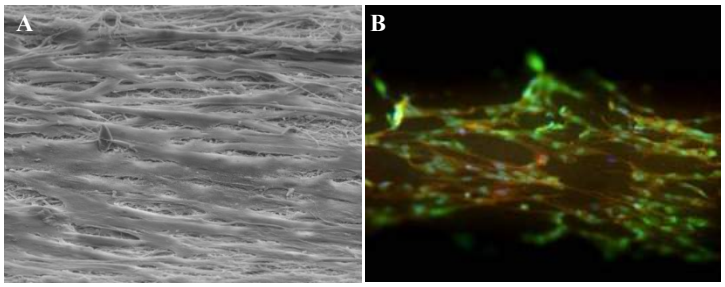

Figure 3: (A) SEM and (B) immunofluorescence images of cells on nanofiber bundles conjugated with CTGF after 7 days of growth.

DISCUSSION

Chemical modification of polycaprolactone can be reliably assessed using XPS. During the conjugation procedure the polymer nanofibers are first modified with amines, and correspondingly an increase in nitrogen is evident on the XPS spectra. Next maleimide linkers are conjugated to the surfaces, resulting in a further increase in amount of nitrogen. Finally, when either bFGF or CTGF are conjugated to the maleimide linkers the nitrogen percentage continues to increase. Since XPS is a depth sensitive technique the observed relative changes in composition indicates successful conjugation of bFGF and CTGF to the surfaces.

After 7 days in culture, counts of DAPI stained nuclei showed significantly higher numbers of cells on scaffolds conjugated with either CTGF or bFGF compared to control scaffolds. This indicates that although all scaffolds provided a favorable surface for cell growth, the scaffolds with conjugated growth factors encouraged additional cell proliferation.

Interestingly, results of the CellTiter Blue metabolic assay indicate higher rates of metabolic activity for cells on scaffolds with conjugated CTGF or bFGF compared to control scaffolds at both days 4 and 7. Additionally at day 4 cells on scaffolds conjugated with CTGF showed a significant spike in metabolic activity. The cause of the spike in metabolic activity is not completely know, however it could be indicative of other cellular processes [10]. The SEM images indicated that cells in all groups similarly aligned along the direction of the nanofibers. Although this could indicate that the presence of the growth factors have no influence on cell morphology, additional time in culture could result in further elongation of cells.

Overall these results indicate that the conjugation of either CTGF or bFGF to the polymer nanofibers that compose aligned electrospun nanofiber bundles significantly increased the proliferation of adipose derived stem cells. Future work will investigate the effects of the conjugated growth factors over longer time points to assess the deposition of collagen types I and III and sulfated glycosaminoglycans, indicative of fibroblastic differentiation.

INTRODUCTION

The cervical facet capsular ligament (FCL) encapsulates the bilateral spinal facet joints and is a common source of pain due to its innervation by pain fibers [1,2]. Excessive FCL stretch can induce morphological changes in its embedded nociceptors, altered expression of neurotransmitters in the dorsal root ganglion (DRG), and neuronal hyperexcitability in the spinal cord, all of which lead to pain [2-4]. In addition to trauma, inflammatory mediators, like nerve growth factor (NGF), in the facet joint can also initiate nociception [5]. Despite both mechanical and chemical stimuli to the FCL leading to pain, the molecular pathways are poorly understood, hampering effective treatments for facet and joint pain.

There is growing evidence that RhoA-mediated pathways are important in neuronal injury. Mechanical stress can up-regulate RhoA activity via adhesive interactions between cells and the extracellular matrix [6]. Active RhoA binds and activates Rho associated protein kinase (ROCK), triggering a host of downstream signaling cascades, including those involved in the pathogenesis of neural injury [7,8]. ROCK inhibition enhances axonal regeneration, attenuates morphological abnormality, reduces synaptic strength, and alleviates pain in inflammation and spinal nerve transection models [8-11]. Unlike mechanical loading, NGF is suggested to down-regulate RhoA activity [12]. As such, the RhoA/ROCK pathway is hypothesized to contribute to the onset of pain from FCL trauma, but not from NGF.

To test this hypothesis, RhoA activity was first measured in the DRGs from rats that underwent either a painful FCL distraction or painful NGF joint injection. Based on findings that RhoA activity is elevated *only* after the mechanical trauma to the facet joint, we used an in vitro neuron-collagen construct (NCC) system to further probe the role of the RhoA/ROCK pathway in nociceptive signaling due to loading. NCCs underwent biaxial loading to simulate FCL strains that induce pain in vivo. Expression of the pain-related neurotransmitter, substance P (SP), which is produced by afferents in the FCL [1], was measured after loading, in the presence or absence of a ROCK inhibitor to test if the RhoA/ROCK pathway mediates substance P.

METHODS

All animal procedures were IACUC-approved. Briefly, FCL distraction was imposed using bilateral tensile stretch across the C6/C7 facets (n=4) [13]. In a separate group of rats (n=6), 3μg of rat NGF was injected into the bilateral C6/C7 facet joints [5]. Sham rats with no FCL stretch (n=2) and rats with vehicle injection (n=3) were included as controls. Pain was assessed in the forepaw before (baseline) and 1 day after distraction or injection using von Frey filaments, and quantified as fold-change over baseline. DRG tissue at C6 was harvested at day 1 and RhoA activity was measured using an ELISA-based assay. The ratio of active to total RhoA was calculated relative to appropriate control group [14]. Differences in pain responses and RhoA activity between the groups were tested by separate t-tests.

NCCs were made using a solution of rat tail collagen I (2mg/ml) cast in a 12-well plate and punched into a cruciform shape with each arm being 6.25mm by 8mm. Embryonic (day 18) Sprague Dawley rat DRG explants were plated on the collagen gels and additional collagen was added 2 days later to encapsulate the DRGs. On day 5, NCCs underwent equibiaxial stretch to 1.5mm (~20% strain) [4] at 0.3mm/s using a 574LE2 planar biaxial testing machine (TestResources) (Fig. 1a). During loading, force-displacement data were recorded and a grid of markers on the NCC surface was tracked to measure the maximum principal strain (MPS) (Fig. 1). Unloaded gels were included as controls for RhoA activity and SP expression. RhoA activity relative to controls was measured at 30 minutes (n=3/group) or 6 hours (n=5/group) after loading to assess changes that could not be measured

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

in vivo due to the confounding effects of anesthesia. T-tests were used to detect differences in RhoA activity in loaded and unloaded NCCs.

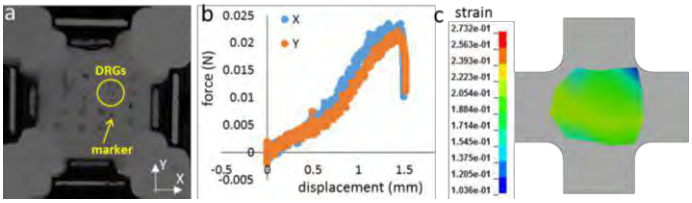

Fig. 1. (a) The biaxial test set-up with a loaded NCC, (b) force-displacement responses, and (c) a strain map.

To determine if the RhoA/ROCK pathway affects nociceptive signaling after loading, ROCK activity was inhibited (n=6) immediately after painful loading for 24 hours using 10μM of Y27632 (Selleckchem) [15]. SP expression was measured 1 day after loading. SP was also evaluated in NCCs that were loaded but not treated (n=6) and those not loaded either with (n=6) or without (n=5) Y27632 treatment. NCCs were immunolabeled for SP (1:500; Neuromics), and the average intensity per unit area of 5-10 axons from each DRG was measured by ImageJ and normalized to controls. Differences in SP expression between groups were detected by a two-way ANOVA with Tukey's test. To ensure consistent loading, the maximum force and MPS of treated and untreated NCCs were compared by t-tests.

RESULTS

Both FCL distraction and NGF injection induce pain at day 1, as evident in the lowered paw withdrawal thresholds relative to baseline ($p<0.05$); yet, there is no difference between the two groups (Fig. 2a). In contrast, only painful distraction, but not painful NGF injection, up-regulates RhoA activity at day 1 (Fig. 2b). RhoA activity in the DRG after FCL loading is 1.63±0.38 times ($p=0.046$) the level in the corresponding unloaded shams, which is also significantly greater than ($p=0.003$) normalized levels after the painful NGF injection (Fig. 2b).

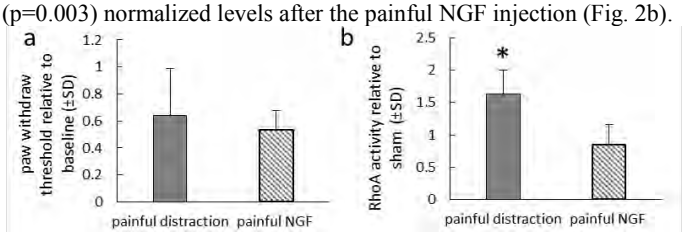

Fig. 2. FCL distraction & NGF joint injection induce (a) similar pain but (b) different DRG RhoA activity (*p=0.003) at day 1.

Similar to in vivo results (Fig. 2), stretch of the NCCs in vitro also up-regulates RhoA activity in the associated DRGs. RhoA activity after loading increases by 2.1±0.78 times at 30 minutes ($p=0.045$) and 1.8±0.84 times at 6 hours ($p=0.037$) over levels in unloaded controls. RhoA activity is not different between the two time points, indicating early and sustained activation of the RhoA pathway.

The increase in SP in the DRGs that is induced after painful NCC loading is prevented by inhibiting ROCK. The untreated and treated NCCs underwent comparable loading. The average MPS is 18.9±2.9% and 18.8±3.4% for the treated and untreated groups, respectively; the maximum force is not different between those NCC groups (Fig. 3). SP expression increases after loading ($p<0.01$) (Fig. 4). Y27632 treatment inhibiting ROCK in loaded NCCs significantly decreases SP expression ($p<0.01$) compared to the untreated group after the same loading, to levels lower even than in unloaded control NCCs (Fig. 4).

DISCUSSION

Mechanical loading of the FCL initiates a host of nociceptive responses in the DRG [3,4], which are associated with pain. Yet, the local mechano-transductive mechanisms that translate mechanical cues

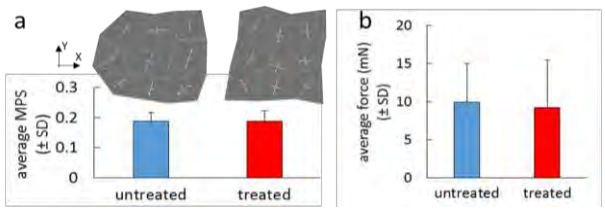

Fig. 3. Neither the (a) MPS direction & magnitude nor (b) maximum force differ between Y27632 treated & untreated NCCs.

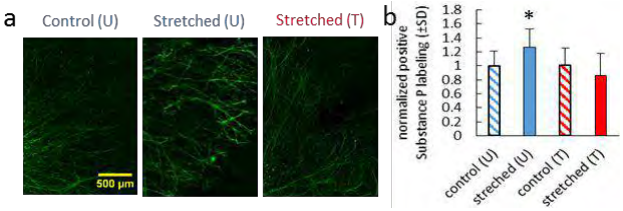

Fig. 4. (a) Images & (b) quantification of SP in Y27632 treated (T) & untreated (U) NCCs. SP in untreated stretched NCCs exceeds that in untreated controls & in treated stretched NCCs (*p<0.001).

into nociceptive signaling in the afferents remain unknown. This study shows that the RhoA pathway, which contributes to cellular force balance and underlies neuropathology [6-12], can be rapidly activated in DRG neurons by excessive sub-failure local strains (Figs. 2-4). The persistent early RhoA activation in vivo and in vitro suggests its potential role in initiating loading-induced facet pain. Despite the RhoA/ROCK pathway being associated with inflammatory pain induced by formalin injection in mice [8], excess intra-articular NGF in the facet joint that causes pain does not alter RhoA activity in the rat DRG (Fig. 2). As such, RhoA-dependent pathways are likely specifically involved in neuronal mechanotransduction of pain.

ROCK inhibition in vitro prevented the loading-induced increase in the expression of SP (Fig. 4), which has been directly related to facet pain [3]. ROCK is a promising target for neurological disorders [7] and this study further supports its potential for treating pain from neuronal trauma (Fig. 4). Yet, this in vitro model injures *both* the soma and axons of neurons; studies are needed to evaluate the effectiveness of ROCK inhibitors on alleviating facet pain from FCL trauma in vivo – a case where only axons undergo injury. Also, we did not probe the biomechanical mechanisms by which tissue deformation alters RhoA signaling in neurons. Since excessive FCL strains can induce collagen matrix reorganization [16], it is possible that integrin-mediated force transmission leading to RhoA signaling may cause FCL pain. Nevertheless, this study, for the first time, identified RhoA and ROCK as mediators of nociception after mechanical trauma to the FCL.

INTRODUCTION

Small-conductance calcium-activated potassium (SK) channels are a family of potassium channels that are voltage independent and are activated solely by intracellular calcium (Ca^{2+}) through constitutively bound calmodulin. SK channels exist within microdomains of Ca^{2+} sources that provides Ca^{2+} for its activation [1]. SK channels mediate afterhyperpolarization and thereby regulate neuronal excitability. The location and density of ion channels on neurons are important determinants of their functional and physiological impact. SK channels are expressed widely in the mammalian central nervous system. The three subtypes of SK channels, SK1, SK2 and SK3, have partially overlapping yet distinct distributions in the brain. Although all three subtypes are present in hippocampal CA1 pyramidal neurons, SK2 is the most abundant (Stocker 2000, Sailer 2004). SK2 channels reside primarily in dendrites and regulate dendritic integration, control the kinetics of excitatory post-synaptic potentials and are involved in long-term potentiation, and learning and memory [2-4]. In contrast, the expression of SK2 channels on the soma is much lower. However, it remains unclear if SK channels are present on axonal membranes. A recent study suggests that the neuronal excitability observed due to N and P/Q Ca^{2+} channel block could be due to the loss of SK channels in axons [5]. Other immunohistochemical studies indicate that SK3 channels are the subtype present in neuronal axons [6, 7].

To test whether SK channels are localized on axons, we used single molecule atomic force microscopy (AFM) combined with natural toxins. We exploited the selective block of SK channels by bee venom toxin, apamin, to detect SK channels on the axonal membrane. We primarily focused on detecting SK channels on the axon initial segment, which is ~20μm-40μm from the soma. The results presented here demonstrate that apamin-sensitive SK channels are distributed along the axon initial segment

METHODS

Primary culture of rat hippocampal neurons

E18 rat hippocampal tissue obtained from Brainbits (Brainbits LLC, Springfield, IL), was dissociated onto 30 mm diameter poly-D-lysine (Sigma) coated coverslips and grown in neurobasal media supplemented with B27, pencillin streptomycin and glutamax (Invitrogen).

Transfection

Neurons at 8-10 DIV were transfected with tau-gfp plasmid using Lipofectamine 2000 (Invitrogen) according to manufacturer instructions.

Atomic force microscopy measurements

Force-distance curves were obtained from Asylum MFP 3D-BIO (Asylum Research, Santa Barbara, CA). HEK293T cell measurements were performed in a solution containing (mM): 2.5 KCl, 144 NaCl, 10 HEPES, 22 D-Glucose and 2.2 $CaCl_2$, pH 7.2. Neuronal experiments were carried out in neurobasal media supplemented with 2% B27, 1% penicillin-streptomycin, 0.25% glutamax, and HEPES to maintain constant pH. All measurements and drug incubations were carried out at 37°C. Cells were identified using differential interference contrast microscopy, and a scan area of 1μm^2 with a lateral resolution of 31 nm was chosen. All force measurements were carried out at a nominal loading rate of 24,000 pN/s, calculated by multiplying the tip retraction velocity by the cantilever spring constant (pN/nm). The cantilevers used had a nominal spring constant of 30 pN/nm as

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

provided by the manufacturer, the exact values of which are obtained via a thermal noise based method implemented by the manufacturer. The approach and retraction velocities are held constant at 800 nm/s. Probes had nominal tip radii of 20 nm and nominal angle of 20°, as provided by the manufacturer.

Data processing and analysis

The distribution of SK2 channels on the cell surface was detected by recording spatially resolved unbinding force maps over 1 μm^2 areas using an apamin functionalized probe. Unbinding forces were extracted from each of the 1024 force curves generated from each test (Figure 1B). A MATLAB (Mathworks) program developed in our lab was then used to create unbinding force maps where each pixel represents an independent rupture force obtained from the retraction portion of the force-distance curve.

RESULTS

Atomic force microscopy cantilever functionalized with apamin was used to detect SK channels on the axonal membrane. The axon was identified by transfecting the rat hippocampal neurons with tau-gfp. Although both dendrites and axons are fluorescent, axons are clearly distinguishable by their distinct morphology. 1μm^2 scan areas were probed along the axon initial segment (~20µm-40µm from the soma) and we observed mean unbinding forces of 20±8.0pN in about 5.6% of the sampled sites (Figure 1B, red, n=6). In order to test the specificity of the unbinding force we repeated the experiments on cells pretreated with apamin. We observed a significant decrease in the frequency of the unbinding forces (0.58%, Figure 1B, blue, n=3). This data clearly demonstrates the specificity of single molecule AFM-based assay to identify SK channels on the axon. Next, we tested if the axonal SK channel expression was under the control of cAMP-PKA SK2 channel properties and cell-surface expression is regulated by cAMP dependent protein kinase A (PKA) activity [8-10]. To this end, we pretreated the cells with Rp-cAMP, a cAMP analog that prevents activation of PKA by cAMP. We found mean unbinding forces similar to that obtained at baseline but with higher frequency (µ=20±9pN, surface density = 10.1%, n= 5, Figure 1B, purple). This suggests that indeed axonal SK channels are under the control of cAMP-PKA.

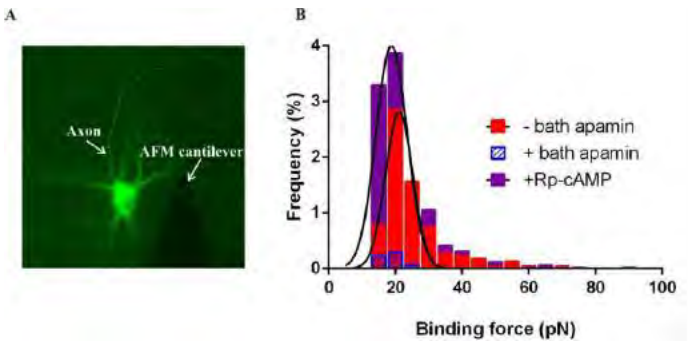

Figure 1: SK channels are present on neuronal axons and are regulated by cAMP

DISCUSSION

In this study, we show that SK channels are present in neuronal axons, particularly in the axon initial segment. Our study also provides insight into the role of cAMP in regulating the distribution of SK channels in neuronal axons.

IN VIVO MEASUREMENTS OF WALL SHEAR STRESS ENVIRONMENT IN FETUS UMBILICAL ARTERIES AND VEINS

Shier Nee SN. Saw (1), Dawn D. Chia (2), Citra Nurfarah Zaini CNZ. Mattar (2), Arijit A. Biswas (2), Choon Hwai CH. Yap (1)

INTRODUCTION

Endothelial cells (ECs) of the umbilical vessels are known to respond to wall shear stress (WSS) of blood flow and WSS is an important factor in controlling vascular growth and remodeling [1]. Umbilical vascular ECs are popular cell sources in mechanobiology studies, but detailed measurements of their native WSS environment is not comprehensively done. In diseases such as intrauterine growth restriction, where flow resistance in the placenta is high, understanding the WSS environment may provide clues for treatment / diagnosis.

In this study, we characterize WSS environment in human umbilical arteries (UAs) and umbilical vein (UV) using patient-specific 3D clinical ultrasound scans and computational simulations and found that umbilical arteries and veins have essential differences. Further, we investigated the effects of umbilical cord bending and found that the spiral shape of umbilical arteries played a role in maintaining constancy of flow resistance and WSS despite bending.

METHODS

28 pregnant women who underwent routine growth scan from 32nd to 33rd week of gestational age in the National University Hospital, Singapore were recruited with IRB approvals. Vascular cross-sectional areas were quantified through 3D reconstruction of the vascular geometry from 3D B-mode ultrasound images and flow velocities were quantified through pulse wave Doppler.

WSS in UA (τ_v) was obtained via Poiseuille's equation:

$$\tau_v = \frac{2\mu V_v^{US}}{R_v} \qquad (1)$$

where μ is the viscosity of fetal blood (0.005Pa.s), V_v^{US} is maximum flow velocity at the center of the parabolic profile measured from ultrasound and *Rv* is the radius of UV.

WSS in the UAs, due to its spiral geometry, could not be computed with Poiseuille's equation, and were computed based on an iterative scheme of CFD simulation. Each UA was modelled as a rigid helical pipe with physiological lumen diameter measured from ultrasound, helical pitch of 5cm and helical diameter of 17.4mm (Fig. 1a, b). Steady state simulation was performed. WSS results were obtained from the cross-sectional plane at the mid-length of UA. Bending of the umbilical cord was simulated by generating helical geometry spiraling around a bent centerline of the cord (Fig 1c).

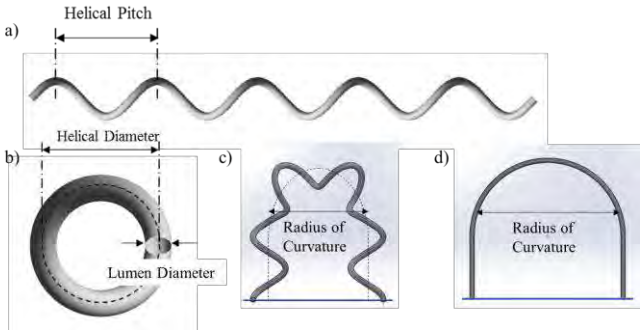

Figure 1(a) Geometry of helical geometry of UA used in CFD. (b) Transverse view of helical UA. (c) Helical UA after cord bending. (d) Straight UA after cord bending.

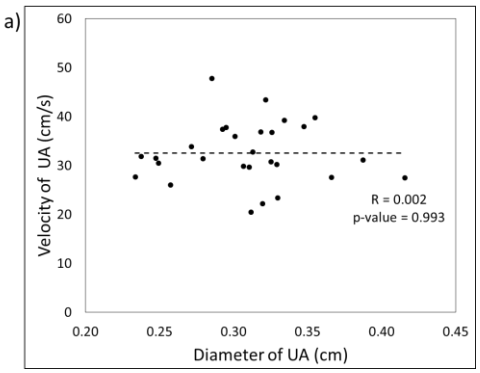
RESULTS

Ultrasound measurements showed that blood flow velocities in both umbilical arteries and veins were found to be relatively constant over different vascular sizes (Fig. 2a, 2b). CFD studies showed that UA's WSS remained relatively constant across vessel diameter (Fig. 2c) but UV's WSS showed a strong negative correlation with the vessel diameter (Fig. 2d).



Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

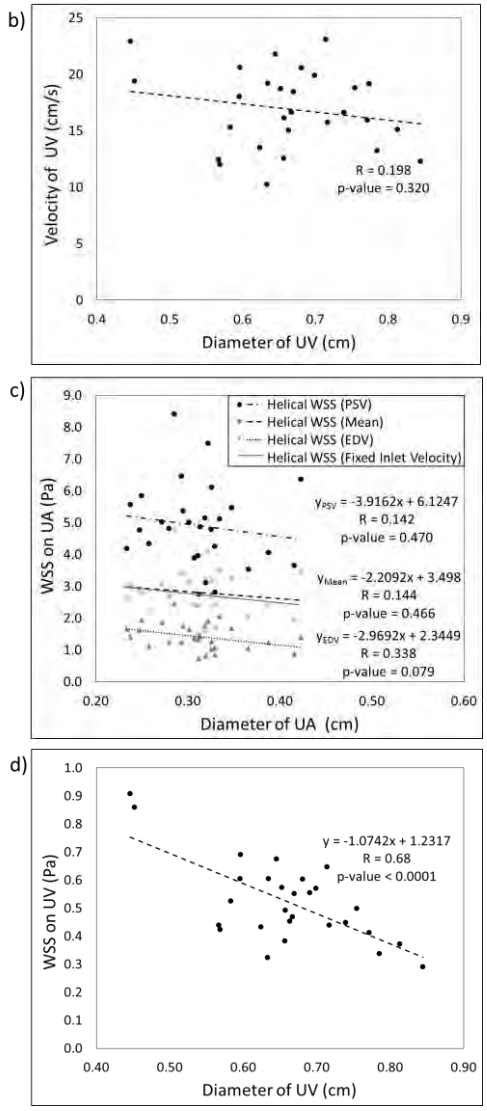


Figure 2. (a,b) Ultrasound measurements showed that blood velocities in the (a)UA and (b) UV are relatively constant over different vascular sizes. (c,d) Results of WSS computations for (c) UA and (d) UV. Since flow in UA was pulsatile, WSS for UA is plotted for peak systolic velocity (PSV), end diastolic velocity (EDV) and at the mean flow rate (Mean). Results showed relatively constant WSS over different sizes for UA, but not for UV. R is correlation coefficient. P-value determines the significance of coefficient of the regression line.

Typical secondary flow patterns and WSS spatial distributions are shown in Figure 3. Generally, velocities were skewed towards the outer wall of the helix (distal from the helical center), dean's vortices secondary flows were observed, and WSS were elevated on the outer wall of the helix but reduced in the inner wall.

Figure 4 shows the results of CFD of bent umbilical cords. Results are plotted as percentage change in resistance or WSS from the case of no umbilical cord bending to the case of umbilical cord bending. Cord bending was tested to various radii of curvatures. If the UA was straight and non-helical, both WSS and vascular resistance increased linearly with the inverse of radius of curvature of the bend. If the umbilical UA artery was spiral as it naturally is, however, bending of the umbilical cord did not significantly affect WSS or vascular resistance.

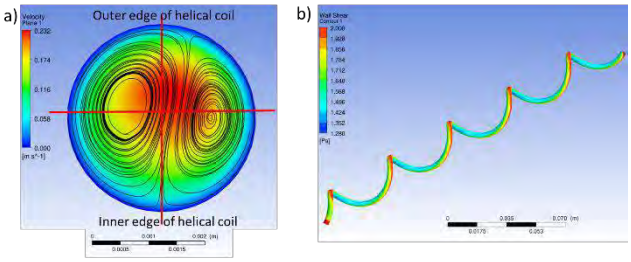

Figure 3 (a) In-plane streamlines and axial-velocity contour on the cross-sectional plane at mid-length of the UA model. (b) Wall shear stress contour on the UA.

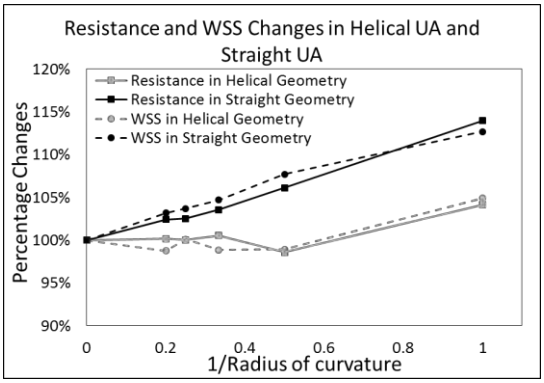

Figure 4 Comparison of resistance and WSS between helical UA and straight UA.

DISCUSSION

UA diameter's independence of WSS supports the hypothesis the vessel grows or regresses to maintain constancy in the shear stress environment. Nonetheless, this was not observed for UV. This might due to UV utilizes different cues for vascular remodeling. The constancy in flow velocity across vascular diameters suggests growth and remodeling according to rate of mass transport.

Umbilical cord coiling and bending occurs all the time in the womb, our study investigates the effect of coiling/bending of UA. Our results showed that bending of UA did not affect the WSS much, suggesting that helical geometry provides a more stable hemodynamic condition compared to straight bend geometry. Such a feature be the basis for the UA to sense hemodynamic flow rates without being interfered by cord bending.

INTRODUCTION

Although many numerical studies were carried out to improve the understanding of remodeling processes in intracranial aneurysms, almost all of them consider rigid vasculature. Only some groups take the interaction between blood flow and the surrounding vessels into account, but in most cases constant extrusions of the luminal surface are present [1,2]. Due to the lack of possibilities to precisely measure local wall thicknesses, corresponding studies are extremely rare. Cebral et al. [3] used the local wall shear stress (WSS) distribution of a rigid-wall simulation to estimate the local wall thickness, since it induces several pathophysiological processes in the vessel wall. A correlation between the wall thickness as well as its stiffness and the rupture site is presented. However, the real local wall thicknesses were still absent to validate the proposed approach.

The recent study focusses on a patient-specific intracranial aneurysm that was prepared ex vivo. Afterwards, microCT was used to acquire the inner and outer vessel surface. Computational Fluid Dynamics (CFD) in combination with fluid-structure interaction allows the examination of hemodynamic as well as structural parameters that influence the aneurysm wall. To compare the results with previous approaches, the luminal surface was extruded in normal direction and the simulation was repeated under identical conditions. Hence, this numerical study demonstrates a consequent step towards a better understanding of the thickness to stress relation and provides further insights regarding the rupture risk assessment of intracranial aneurysms.

METHODS

Image acquisition and vascular reconstruction

A complete Circle of Willis and adjacent vessels were harvested from a 33-year-old male person post mortem as part of a forensic examination and further investigated with the approval of the local ethics committee. The aneurysm, which was located at the anterior communicating (Acom) artery, was separated from the surrounding tissue and flushed with saline to remove intraluminal blood clots (see Figure 1). Since the aneurysm previously ruptured, the corresponding site was identified by a neuroradiologist.

To acquire the anatomy of the investigated aneurysm, a microCT scan was performed and the 3D model was manually reconstructed using MeVisLab 2.6.2 (MeVis Medical Solutions AG, Bremen, Germany). The results are displayed in Figure 1 and were revised by experienced neuroradiologists. To allow a comparison with the patient-specific vessel wall model the inner surface was extruded in normal direction by 300 μm.

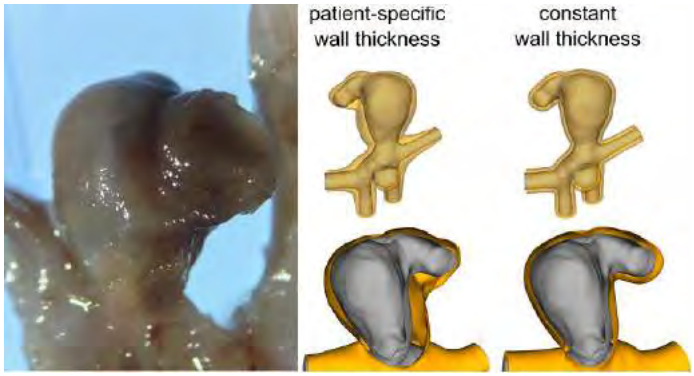

Figure 1: Ex vivo preparation of the Acom Aneurysm (left), patient-specific and constant vessel wall thickness from different perspectives (right).

Spatial discretization and hemodynamic simulation

The fluid and solid domains are represented by polyhedral as well as prism cells that possessed an adequate size to resolve the existing velocity gradients appropriately. This resulted in a total number of cells of approx.1.2 and 1.1 million for the patient-specific and the constant wall thickness, respectively.

Steady-state simulations were carried out using the finite-volume solver STAR-CCM+ V9.04 (CD-adapco, Melville, New York, USA). At the inflow cross-sections a mean velocity was applied that was previously measured in a healthy volunteer using 7T PC-MRI [4]. At both outlets a zero-pressure condition was applied. Blood was treated as a laminar, Newtonian fluid (ρ=1055 kg/m^3, η=4 mPa·s).

For the fluid-structure interaction a two-way coupling was chosen that considers the impact of pressure on the deformation and vice versa. The arterial wall was assumed to be homogenous with isotropic material properties and a commonly used linear elastic material behavior is considered. For the Young's modulus a value of 1 MPa was chosen and a Poisson ratio of 0.45 and a density of 1050 kg/ m^3 for the solid were defined, respectively.

RESULTS

Due to the page limit within this abstract only comparisons between displacement as well the stress distributions on the outer vessel wall surface are presented. As illustrated in Figure 2, the highest displacement is predicted in equivalent areas for the patient-specific and the constant wall thickness, respectively. However, the absolute values for the maximum displacement strongly deviate resulting in an over-estimation by the constant wall thickness approach.

Regarding the stress on the outer surface it can be noticed that due to the homogenous wall thickness in the artificial model almost no elevated values occur. In contrast, the patient-specific configuration shows spots of high stresses that are close to the identified rupture site.

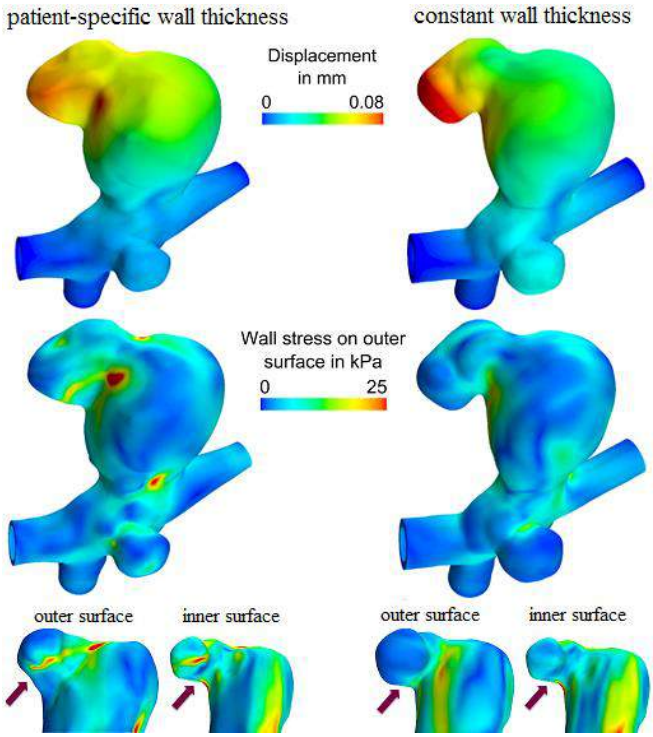

Figure 2: Comparison of displacement and wall stress for the patient-specific (left) and constant vessel wall (right) from different views. The rupture site is indicated with the arrow.

Further hemodynamic and structural parameters were analyzed in detail. Those as well as a quantitative comparison will be presented at the conference.

DISCUSSION

The consideration of a constant wall thickness to model fluid-structure interactions of intracranial aneurysms is a common approach since state-of-the-art imaging modalities are unable to capture cerebral vessel wall properties in vivo. In order to evaluate this method, locally varying wall thicknesses were acquired for an Acom aneurysm ex vivo. The comparison of both configuration reveals drastic differences regarding the analyzed parameters. Hence, assuming a constant vessel wall thickness might lead to wrong conclusions regarding the rupture probability of a certain aneurysm. Furthermore, using patient-specific data with locally varying wall thicknesses appears to be out of alternative to capture a realistic scenario.

Nevertheless, the presented approach still contains several limitations that need to be critically reflected. Firstly, the preparation might have led to some distortions of the geometry and hence a deviation to the in vivo configuration occurred. Secondly, since the aneurysm was harvested ex vivo, no patient-specific flow conditions were available and 7T PC-MRI data needed to be used. Thirdly, isotropic, homogenous, linear-elastic vessel walls were assumed due to the lack of material measurements. To overcome this issue, histologic analyses of the investigated aneurysm are carried out as presented in Figure 3 for two exemplary slices.

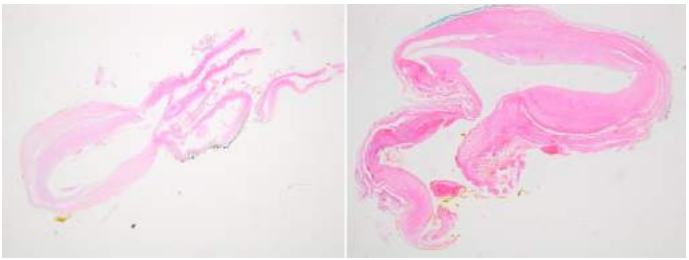

Figure 3: Two exemplary histologic slices to examine local wall thicknesses as well as the corresponding wall compositions.

Besides the mentioned limitations the presented study demonstrates the importance of acquiring patient-specific wall properties to understand the aneurysmal pathology. Further advances regarding the wall composition will be incorporated into the numerical studies and might lead to the assessment of reliable rupture risk criteria.

INTRODUCTION

Meniscal damage can be caused by age related degradation, obesity, overuse from athletic activities, and trauma[1]. Once damaged, the meniscus has limited healing ability due to its primarily avascular nature[2]. Meniscal allograft research has been investigated, but has been met with mixed results[3] and no long term data, leaving it a procedure with limited utility. Cell seeded scaffolds have been shown to allow the growth of meniscus like fibrocartilaginous tissue, but these scaffolds are limited mechanically[4]. There is a need for a permanent meniscal replacement with mechanical integrity similar to the native tissue. The objective of this study was to evaluate the time dependent compressive properties of a polystyrene (PS) - polyethylene oxide (PEO) diblock and PS-PEO-PS (SOS) triblock copolymer compared to the native meniscus. Specifically, it is hypothesized that this hydrogel can be tuned to have similar compressive modulus and cyclical relaxation profiles of the native tissue.

METHODS

The PS-PEO-PS triblock copolymer has been previously described[5]. The amount of triblock (SOS) was varied to determine the effects on mechanical behavior. Dry polymer was compressed at 500 psi for 5 minutes, cooled, and swollen in DI water. All mechanical tests were performed on a servo hydraulic test system (Bionic Model 370.02 MTS Corp, Eden Prairie, MN) using a 8.9 N load cell (Futek LSB200, Irvine, California) and were tested in a water bath to maintain hydration. Prior to indentation or cyclic compression tests, samples were preloaded to 12% strain over 1 second. Indentation relaxation tests were carried out for 300 seconds to allow for equilibrium and a spherical indenter tip (1.59 mm diameter) was used. Cyclical compression tests were performed on cylindrical disks 8mm in diameter mounted between two aluminum plates to assess the relaxation of the copolymer over 1,000 cycles at a frequency of 1Hz. Hertzian contact was used to assess both the instantaneous and equilibrium moduli of the indentation tests. Peak compressive force and displacements for each cycle were used to determine the compressive modulus for the cyclical results. Data from both the indentation relaxation and cyclical compression were compared to human meniscal values. Values for human menisci indentation (n=11) were taken from previous indentation relaxation work done by this group[6] and a preliminary cyclical compression test. Approval from Colorado State University Institutional Review Board was obtained for the human samples as well as consent forms from patients (age= 58 ± 4, BMI= 33 ± 6). Finally, to test the fatigue resistance of the hydrogel (6 mm) diameter plugs were swollen 1xPBS and subjected to 500,000 cycles at room temperature in a custom built bioreactor. Samples were compressed to 12% strain at a frequency of 1Hz. Data was recorded for 1,000 cycles every 24 hours for the duration of the test. Following the 500,000 cycles, samples were allowed to rest and were later subjected to an additional 1,000 cycles to evaluate recovery. Peak stress and strain were used to assess modulus, and values from the recorded 1000 cycles were averaged.

RESULTS

Increases in triblock percentage resulted in higher compressive modulus value, both instantaneously and at equilibrium (Figure 1). Instantaneous compressive modulus values were also within the range of healthy human menisci. There was a visible decrease from instantaneous to equilibrium modulus in all samples, with higher triblock SOS samples having a greater decrease. These decreases were at higher SOS content similar to those seen in the human samples

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

tested with the greatest decrease in SOS 93 around a 70% drop compared to the average meniscus decreasing around 83%. It is evident that these SOS triblock copolymers have similar compressive properties to that of the native meniscus.

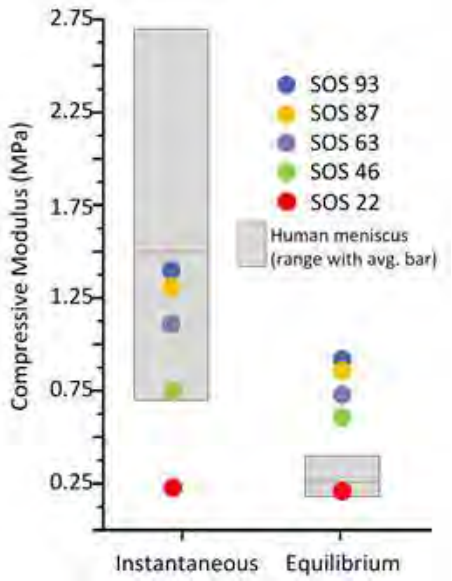

Figure 1: Indentation relaxation results

Two of the SOS triblock concentrations were used for cyclical testing (Figure 2). Similar to the differences seen in the static indentation testing, the human meniscus tended to relax more than the SOS triblock samples. Over the course of 1,000 cycles there was a total decrease of 40% in the human sample while the SOS 22 and SOS 46 relaxed 21% and 17%, respectively.

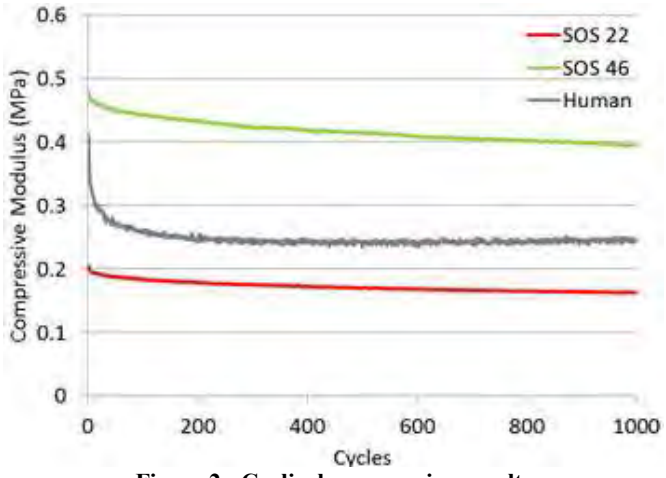

Figure 2: Cyclical compression results

A SOS triblock concentration of 61% was selected for the 500,000 cycle test. Initial modulus was similar to previous testing and there was minimal to no degradation over time. Over a half million cycles, the modulus varied between 0.4-0.5 MPa and recovered to within 1% of original modulus following a 12 hours rest period (Figure 3).

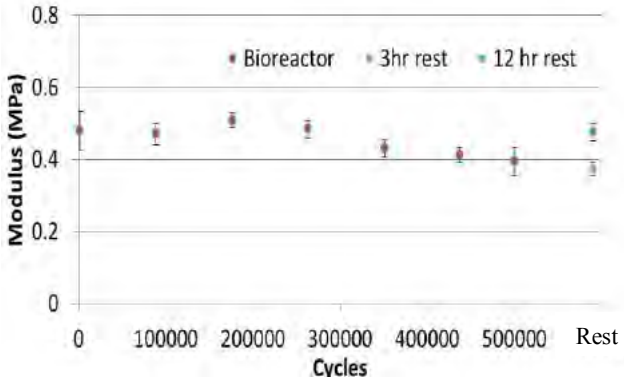

Figure 3: Cyclical fatigue results

DISCUSSION

This study proved that the compressive properties of the human meniscus can be mimicked with a SOS triblock copolymer. By increasing the triblock content, we are able to increase the compressive modulus while still maintaining a relaxation profile. The hydrogel is also able to maintain its mechanical integrity over the course of half a million cycles, which is further supported by the recovery of the gel after 12 hours of rest. This marks one of the first hydrogels of its kind to show mechanical integrity after repeated cycling.

Our group has been successful in creating a simple crescent shape with the same general dimensions of a sheep medial meniscus (Figure 4). Future work is underway to incorporated nylon fibers into the hydrogel to achieve anisotropy and similar tensile properties to the native human meniscus. Since load is distributed circumferentially in the native tissue, obtaining higher tensile strength will be necessary for this replacement to be viable. Additional testing will also be performed to determine more thoroughly investigate they hydrogels properties the long term wear of the 3D construct.

INTRODUCTION

One of the most influential factors for the use of upper limb (UL) prostheses is the socket design(1). The socket functions as the point of attachment between the prosthesis and the user's residual limb (RL). At this crucial junction, the soft tissue of the limb must interface with the rigid materials of the prosthesis. Sockets are designed to strategically compress areas of the user's limb to achieve suspension of the prosthesis and aid in movement control. Consequently, a prosthetic socket must be custom designed to accommodate the individual's morphology as to avoid discomfort and potential damage to the tissue. Achieving this task requires a high degree of expertise to manufacture a socket of suitable geometry that appropriately distributes interfacial pressures over the RL.

In clinical practice, the implications of proper design are well acknowledged and much of a prosthetist's effort will be specifically dedicated to socket fabrication(2). Yet surprisingly, UL socket fabrication relies heavily on heuristic practice as interfacial pressure distributions have yet to be comprehensively defined in literature. To date, Daly et al. present one of the only UL pressure measurement studies and report mean and maximum interface pressure(3). However, their work does not report the locations at which these pressures occur, limiting the translation of results into a design context.

At present 20-39% of UL prosthetic users abandon their device with socket discomfort highlighted as a major contributing factor(4). Development of novel prosthetic sockets specifically designed to optimize patient comfort may greatly increase device satisfaction. Yet, the absence of quantitative documentation impedes the ability of clinicians to innovate designs and fully appreciate the biomechanical implications on user comfort and potential tissue damage.

In lower limb prostheses, interfacial pressures have been well defined(2) facilitating quantitative design practices. Therefore, this work aims to evaluate and develop a methodology to adapt lower limb pressure measurement technologies for UL prostheses. Specifically, force sensing resistor (FSR) technology was evaluated under simulated biomechanical conditions of an UL prosthetic environment. The ability of this technology to define UL socket pressure distributions was then demonstrated in 2 participants with transhumeral (above elbow) amputation.

METHODS

FSRs are commercially available thin film polymer sensors commonly employed in lower limb prosthetic pressure measurement. Their versatility and thin profile make them attractive sensors for prosthetic applications. Yet FSRs have well known limitations such as sensitivity to temperature, curvature and substrate compliance(5,6). Prior to implementing these sensors in an UL prosthetic application, the effect of these unavoidable variables was first quantified and the results used to develop compensatory calibration practices. Varying levels of temperature (room: 21°C and body: 37°C), sensor curvature (5th percentile female wrist: 44mm diameter, 95th percentile male thigh: 215mm diameter, and flat) and surface compliance (human tissue analog and a rigid surface) were systematically assessed using a full factorial design-of-experiments approach. Two FSRs of 3 different models were evaluated (400, 402 and 406, Interlink Electronics). Calibration equations under 12 unique combinations of temperature, curvature and compliance were determined for each sensor. Root mean squared error was calculated and Main Effects ANOVAs used to determine statistical significance ($p<0.05$) of variables. Results were used to inform the design of calibration practices and a calibration

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

apparatus for the implementation of FSRs in an UL prosthetic environment.

The calibration practices and apparatus were used with 2 transhumeral amputee participants. A commercially available FSR-based prosthetic measurement system (9811E sensors and VersaTek System, Tekscan Inc) was employed to capture interfacial pressure on the RL. First, sensor location relative to each participant's anatomy was defined in 3-dimensional space using a FARO Edge Coordinate Measurement Machine. Participants then donned their prosthesis, positioned the prosthetic elbow at 90° flexion and statically held this position for 3 seconds. The corresponding interfacial pressures were captured. This pressure measurement data was then paired with the sensor location data in ParaView 5.0 software to reconstruct 3-dimensional pressure contour maps.

RESULTS

ANOVA results indicated that the calibration of all three FSR models was significantly affected by temperature, curvature and compliance (Table 1). The sensitivity to each variable differed for each sensor model. It was concluded that FSRs implemented in such biomechanical environments must therefore be calibrated as close to their intended use to minimize error.

Table 1: ANOVA Results- Temp, Curve, and Comp denote temperature, curvature and compliance respectively. Hyphenated variables denote interaction effects.

Model	Significant Variable	p-value
400	Temp-Comp	0.02
	Curve-Comp	<0.01
402	Comp	<0.01
	Curve-Comp	<0.01
406	Curve	<0.01
	Curve-Comp	<0.01

Correspondingly, the participant testing required a calibration apparatus capable of calibrating the Tekscan FSR sensors at the same temperatures, curvatures and tissue compliances as the UL prosthetic environment that they were to be used. An inflatable bladder system was developed that allowed for sensors to be positioned on the participant's RL at the time of calibration. The participant then placed their RL into a chamber where a bladder is inflated to a series of known calibration pressures around the RL (Figure 1). These pressures were input into the Tekscan Versatek system to facilitate its calibration algorithms.

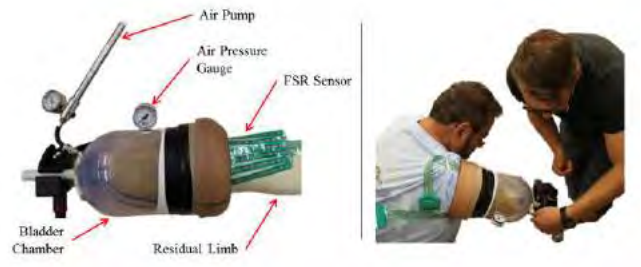

Figure 1: Calibration Apparatus- Shown both schematically and in use with a participant

Once calibrated and the pressure of donning the prosthesis was captured, FSR data was paired with the sensor location data. The resulting pressure contour maps are shown in Figure 2. In both participants, local regions of high pressure were found at the distal regions corresponding to the end of the residual humerus, and in the medial soft tissue close to the axilla.

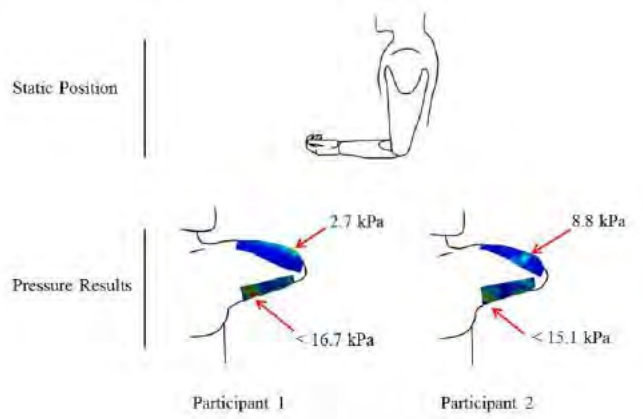

Figure 2: Resulting 3-Dimensional Pressure Contour Maps

DISCUSSION

UL prosthetic socket fit is a pivotally important factor in user acceptance and device satisfaction. Development of a well-fitting UL socket is a challenge that is fundamentally biomechanical in nature. Yet little quantitative work has been performed to define the interface mechanics of the socket and limb.

This work highlights a methodology that uses commercially available technology to quantify UL socket interface mechanics. This methodology takes compensatory steps to minimize error during calibration. Additionally, it is able to map pressure distribution patterns to the anatomy of the participant. This can provide crucial data to inform quantitative design and fabrication practices.

Follow-up work with an amputee population is warranted to comprehensively evaluate efficacy of the presented techniques. This methodology is directly translatable to research and clinical settings and has the potential to help guide analytically informed fabrication methods. More broadly, our work presents the first steps toward a departure from strictly experience-based practices, and holds the potential to improve the quality of patient care and UL prosthetic satisfaction.

THE RELATION BETWEEN SHEAR STRESS METRICS AND ATHEROSCLEROSIS: A FOLLOW-UP STUDY IN THE CAROTID ARTERIES OF ATHEROSCLEROTIC MICE

INTRODUCTION

Atherosclerosis is a cardiovascular disease characterized by the formation of plaque in large- to middle-sized arteries. It is generally accepted that low and oscillatory wall shear stress (WSS) favors the initiation and development of atherosclerosis. However, the slow progression time of atherosclerosis in humans makes it difficult to perform a quantitative analysis of the association between shear stress metrics in vivo on a within-subject basis. Therefore, in studies involving humans, shear stress patterns in a group of healthy subjects (providing baseline WSS metrics) are typically compared with plaque locations from a second group of subjects (suffering from atherosclerosis). To assess the correlation between WSS metrics and plaque location in such a cross-sectional between-group design, aggregation (averaging) of the datasets is needed. This aggregation possibly leads to an overestimation of the correlation between the baseline WSS metrics and the plaque location.

This study is the first to elucidate the relationship between shear stress and plaque location on a within-subject basis. To this end we performed a point-by-point quantitative comparison (based on surrogate sample data analysis) of baseline shear stress patterns (based on mouse-specific fluid-structure interaction simulations) and intermediate/end-stage plaque locations (based on a tracer for macrophage infiltration) in dedicated mouse models. We subsequently analyzed which WSS metric had the best correlation with plaque location, and compared the resulting correlations of the within-subject data to those based on aggregated datasets.

METHODS

At the age of 6 weeks four female ApoE$^{-/-}$ mice were put on a western type of diet to induce atherosclerotic plaque formation. The animals underwent an imaging protocol after 10, 15 and 20 weeks on the diet.

At the first imaging time point, the geometry of both carotid bifurcations was obtained by a gold-nanoparticle contrast- enhanced μCT scan (contrast agent: Aurovist 15nm). Ultrasound measurements were performed to generate mouse-specific boundary conditions for FSI simulations of the blood flow in the carotid arteries. Furthermore, the FSI model also included the in vivo prestress state of the arterial wall and the external tissue was modeled with springs. From these simulations several WSS metrics were calculated: time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI), relative residence time (RRT), transverse wall shear stress (transWSS), the dominant harmonic (DH) and the harmonic index (HI). A more detailed description of the FSI setup can be found in [1].

In the same mice, follow-up μCT scans were performed at weeks 15 and 20 (5 and 10 weeks after the baseline scan). As we have previously demonstrated that Aurovist particles from previous injections accumulate in the atherosclerotic plaques (or more precise in macrophages), a surface map of the presence of macrophages and thus plaque development was constructed [2].

We subsequently mapped both the WSS metrics and the macrophage infiltration (μCT) data to a common rectangular grid per branch for every bifurcation (see figure 1) using VMTK (www.vmtk.org) [3]. Afterwards statistical testing was performed on an individual branch level, an individual bifurcation level and a population bifurcation level. Spearman's correlation coefficient (ρ) and Pearson's correlation coefficient (r) were calculated. For the individual branch and bifurcation level statistical test, the surrogate sample data analysis was applied [4]. For this test two conditions have to be met for significance: (i) $p<0.05$ and (ii) the confidence bound (1-tailed equivalent of confidence interval) cannot include a zero

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

correlation value. At the population level, a t-test approach was followed after applying a Fisher r to z transformation. For a detailed description of the methodology the reader is referred to [5].

RESULTS AND DISCUSSION

In Figure 1, panel A displays the mapped values of RRT along the left carotid artery of a representative animal, calculated from FSI simulations using data measured at week 10. The highest values are found in the external carotid artery (ECA) and in the immediate vicinity of the bifurcation in the common (CCA) and internal (ICA) carotid artery. Panel B quantifies the presence of contrast agent (~macrophage infiltration) at week 20 within the arterial wall of the same animal. Visually, regions with a high RRT value and macrophage infiltration overlap in the ECA and close to the bifurcation.

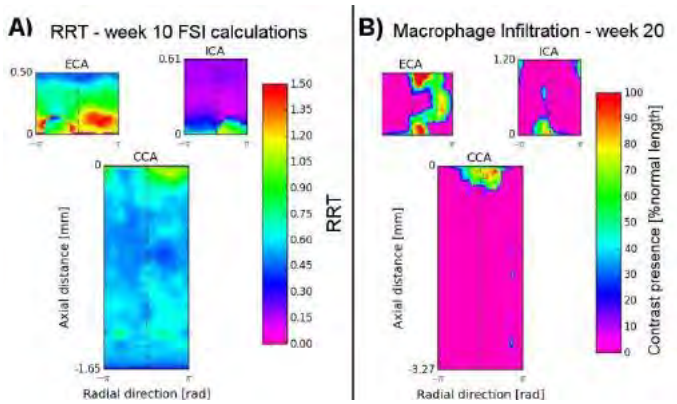

Figure 1: Representative case of a left carotid bifurcation splitted in its three main branches: CCA, ECA and ICA. (A) The relative residence time (RRT) calculated from mouse specific FSI simulations. At this time point no atherosclerotic plaques were discernable. (B) 10 weeks later the macrophage infiltration, as a marker of atherosclerotic plaque, was assessed using gold-particle enhanced μCT.

Maps as displayed in Figure 1 could be derived for 7 carotid bifurcations. When analyzing data at an individual branch level, no correlation was found between any of the hemodynamic wall parameters and the localization of contrast in the ECA and ICA. Only for the CCA, a significant correlation could be detected between RRT and presence of contrast in 4 out of 7 datasets (with similar results for OSI and TAWSS).

For the complete data set, the quantitative spatial correlation between the distribution of different wall shear stress metrics and the presence of contrast agents at week 20 is summarized in Figure 2. For each metric, the upper two symbols display the Spearman (ρ;diamond) and Pearson (r; triangle) correlation coefficients at bifurcation level taking into account the data from the 7 bifurcations. The highest correlations are found with RRT (positive correlation) and TAWSS (negative correlation). When analyzing aggregated datasets (lower two symbols; aggregate ρ: square; aggregate r: circle), the magnitude of the correlation tended to increase, with the highest value found for the Pearson correlation coefficient between aggregated maps of RRT and presence of contrast (r=0.575, P<0.001)

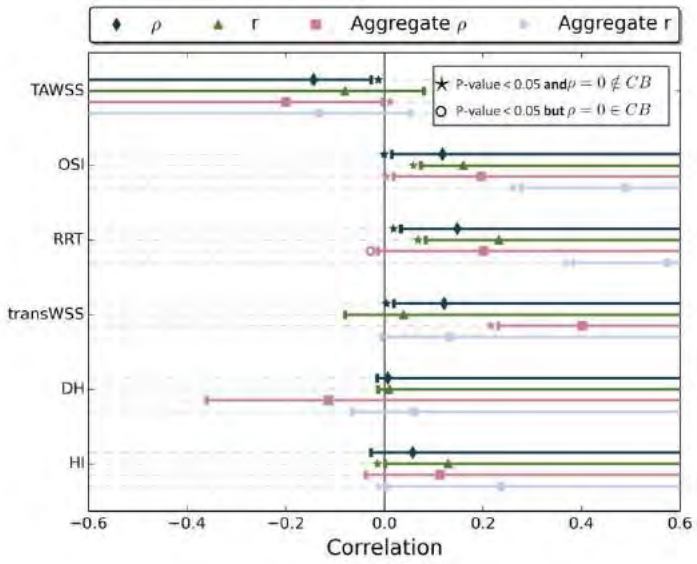

Figure 2: For the different shear stress metrics, the Spearman's (ρ) and the Pearson's (r) correlation coefficients are plotted together with the corresponding confidence bounds (CB). For the aggregated datasets, the correlation is overestimated.

CONCLUSION

We conclude that in the carotid bifurcation of the ApoE$^{-/-}$ mouse: (i) hemodynamic wall parameters are associated significantly with macrophage infiltration; (ii) the strongest spatial correlation between hemodynamics and atherosclerosis development was found for the relative residence time (RRT) and time averaged wall shear stress (TAWSS); (iii) data aggregating tends to overestimate the correlation.

INTRODUCTION

Bone remodeling is a tightly regulated multicellular process by which osteocytes, osteoblasts and osteoclasts function to maintain or modify bone; this is done by creating, destroying and monitoring the bone matrix [1]. Regulation by bone-forming osteoblasts and bone-resorbing osteoclasts is influenced by a variety of factors including genetic and metabolic diseases, metastases, medications and altered loading environments. Understanding the interactions among cells in the presence of these factors is critical to manipulate bone's inherent remodeling ability to cure osteoporosis, halt metastatic bone progression, improve implant longevity and develop functional tissue-engineered substitutes. While *in vitro* cellular systems have been used to study bone cell interactions, the results of the studies cannot be extended beyond the specific model, environment and conditions established in the experiment. As such, there is tremendous variation in experimental results across laboratories, and extrapolating findings back to the *in vivo* system is challenging. To advance research in the bone field will require the development of novel model systems that incorporate the multicellular interactions of the osteocytes, osteoclasts and osteoblasts and enable the systematic investigation of soluble signals, cell contact and cellular communication. The development of cellular automata (CA) and agent-based models (ABMs) of bone dynamics offers the potential to provide an approach that can reflect biologic complexity and parallel biologic discovery without relying on a governing state equation. The objective of this study, to develop a CA to model bone formation, or mineralization, of osteoblasts *in vitro*, is a first step in this resolve.

METHODS

Preosteoblastic MC3T3-E1 cells were chosen for their ability to form bone in culture under induction conditions. Cells were seeded onto polystyrene tissue culture wells and maintained. Upon reaching 100% confluence, the cells were induced to differentiate into osteoblastic (bone-forming) cells by the addition of L-ascorbic acid (vitamin C) and beta-glycerophosphate to the culture medium. For quantification of bone formation, assays that indicate the presence of bone were performed. These assays were von Kossa stains, which reveal the presence of phosphate, and alizarin red stains, which show calcium. The percent area of culture well covered by each stain was quantified at differing time points using measurement features in the ImageJ software. In this study, the time point of interest was 26 days; this is the time at which cells have reached their maximum bone-forming potential.

In a CA model, the state of each element within an n-dimensional matrix is updated randomly by use of rules or transition probabilities that depend on the current state of the element and the current state of elements in its neighborhood [2]. To develop the model, an initial matrix containing all zeros was formed to represent the cell culture well. By use of experimental data and a count of the initial number of mineral sites, a random number of elements n within an MxNx1 sub-matrix was chosen. To begin the simulation, each element was changed to a positive number generated from a normal distribution. At each time step (here time is measured in days), the value of each element in the matrix changed stochastically depending on the total amount of mineral formed by the cells in the neighborhood. Larger quantities of mineralization, then, represented by large values in the simulation matrix, increase the chance that the value of a nearby cell will become “bone-forming” in the next time step.

For the CA model, Monte Carlo simulations were run to determine the average area covered by bone at 26 days. To validate the model, permutation tests were performed by use of the computer software R [3], and experimental and simulated data were compared.

RESULTS

Alizarin red stains of cell culture wells after 26 days are illustrated in Figure 1; von Kossa stains, not shown, were similar. Results of the mathematical simulations are depicted in Figure 2. For the CA model, 10,000 Monte Carlo simulations were performed; nine are shown. Figure 3 represents a comparison of the average percent areas covered by mineral for each analysis (alizarin red, von Kossa, CA simulation). The CA simulation presents a 35.10% increase in the average area covered by mineral from the alizarin red analysis; the simulation presents a 35.76% increase in the average area covered by mineral from the von Kossa analysis.

Permutation testing gave a test statistic of 2.61% and a *P*-value of 0.6389. Thus, it was sufficiently evident that the two data sets, experimental and simulated, were not statistically different from one another. In other words, the mathematical model was proven to produce results in keeping with experimental results.

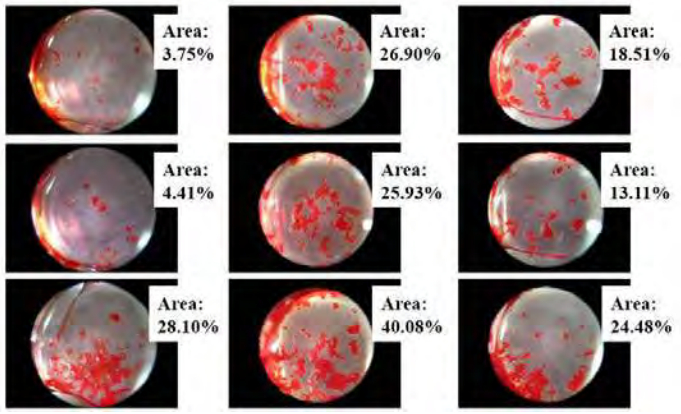

Figure 1: Experimental results of alizarin red analysis. Whole cell culture wells measure 1.9cm^2.

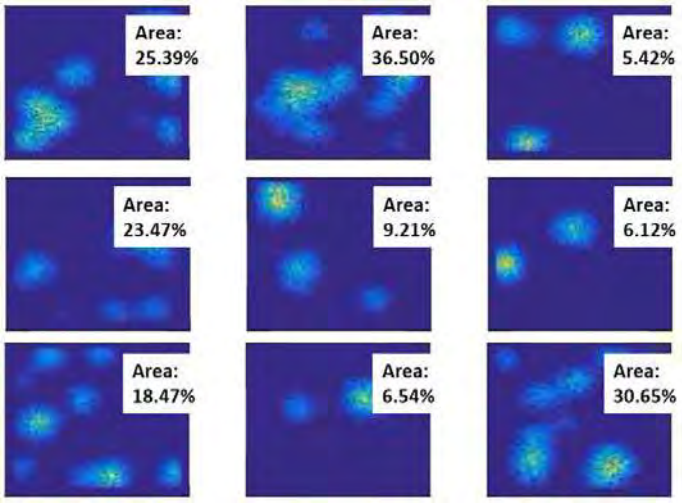

Figure 2: Simulation results. The scale for each image is 100*100 units. One unit is the mean length of one bone cell.

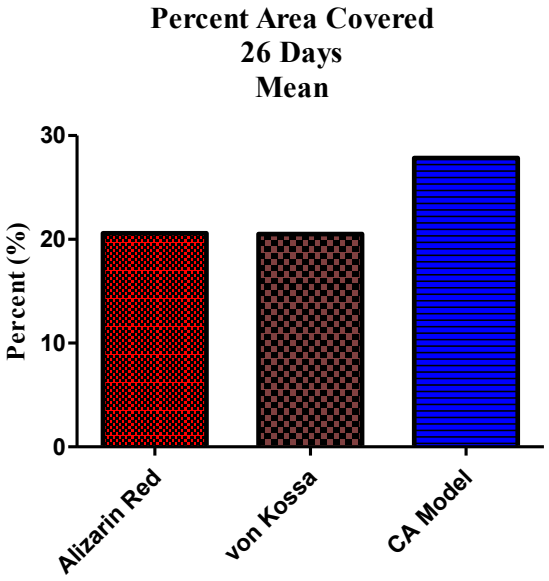

Figure 3: Average percent areas covered by mineral for each analysis. Results indicate the average percent area covered by alizarin red within experimental culture wells at 26 days was 20.6% (red); the average percent area covered by von Kossa was 20.5% (brown) and the average percent area covered for the CA model was 27.83% (blue).

DISCUSSION

This work is the first of a series of CA models which are being developed in order to better understand the mechanisms of bone formation and bone metabolism. This CA models with considerable accuracy the area covered by osteoblastic bone formation. In the future, the model will be expanded to incorporate elemental composition of mineral formed, concentration of alizarin red dye present within stained cultures, osteoblastic alkaline phosphatase activity (expressed during the formation of hard mineral) and the roles of biological markers/cytokines in bone formation/remodeling. As more data from *in vitro* studies are collected, the CA model will be further calibrated. Continued efforts will enable the development of an ABM that can incorporate multicellular interactions and reflect the contribution of the biologic milieu and the mechanical environment. Ultimately the goal is to develop an ABM capable of predicting bone remodeling as a function of environmental conditions.

INTRODUCTION

A tissue-engineered scaffold structurally mimics the intended tissue to be developed with adequate pore sizes for the stem cells to proliferate and differentiate. The initial scaffolds developed were primarily composed of ceramic compounds like hydroxyapatite, akermanite and tricalcium phosphate that are structurally rigid and resemble the mineral composition in bones. In recent years, many research works stressed on the advantages of using bio-compatible polymers such as poly (l-lactic acid) (PLLA), Polycaprolactone (PCL), poly (l-glycolic acid) (PLGA) as a scaffold material. Some of the prominent methods used to make polymer scaffolds are solvent casting, fiber bonding, membrane lamination and particulate leaching [1]. Absolute control over the 3D micro-structure of the scaffolds has been achieved by advanced methods such as computational topology design (CTD) and solid free-form fabrication (SFF) [2]. But these methods are very expensive when compared to TIPS, which could be easier to implement in large scale production.

The objective of this study was to (i) select suitable PLLA scaffolds for cell culture, (ii) to observe the viability of human adipose stem cells (hASCs) when cultured on these scaffold and (iii) to quantify the cellular growth inside the PLLA scaffolds selected. The future scope of this project is to make cryo-preservable bone-grafts for *in vivo* implantation into patients when needed.

MATERIALS AND METHODS

In thermally induced phase separation (TIPS) method, crystalline PLLA was dissolved in 1,4 Dioxane at 3, 7 and 10 (wt/vol)% to form a homogenous clear solution. These solutions were each frozen to a low temperature (-60°C), at 1, 10 and 40°C/min cooling rates (C.R.). The frozen solutions were lyophilized (freeze-dried) to remove the frozen solvent resulting in the final scaffold, which was 3D porous PLLA structure. The porous morphology of the scaffold was partly determined by the crystal formation of dioxane in the solution which was influenced by the applied freezing profile.

Porosity (%) of a scaffold was calculated at two positions (0-5 mm and 5-10 mm from bottom) by weighing a known volume of the scaffold and from the following formula:

$$Porosity\ (\%) = \left(1 - \frac{Scaffold\ Density}{Polymer\ Density}\right) \times 100 \quad (1)$$

Table 1: Porosities of the scaffolds made using the specified PLLA:Dioxane (wt/v) composition and the C.R.

PLLA: Dioxane	-1°C/min		-10°C/min		-40°C/min	
	(0-5) mm	(5-10) mm	(0-5) mm	(5-10) mm	(0-5) mm	(5-10) mm
3% (wt/v)	96.96%	96.89%	96.34%	96.75%	95.56%	95.50%
7% (wt/v)	94.16%	93.98%	93.92%	93.96%	91.81%	93.28%
10% (wt/v)	90.47%	89.46%	89.25%	89.69%	88.82%	88.39%

Figure 1: Cross-sectional SEM images of the micro-pore structures of the 7% (wt/vol) scaffolds cooled at (a) 1°C/min, (b) 10°C/min and (c) 40°C/min

Scaffold sections of 12mm diameter and 5mm height were coated with Platinum (15nm thick) using EMXS550X Sputter Coater. JEOL JSM-6610LV Scanning Electron Microscope was used to scan the samples and capture SEM images to qualitatively observe the pore structure and measure the pore sizes.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

INSTRON 5900 Series – Advanced Mechanical Testing Systems Compression tester was used to compress scaffolds of 12mm in diameter and 10mm in height to 20% of its initial height, while simultaneously recording the applied load and strain. Compressive modulus was calculated as follows:

$$Compressive\ Modulus = \frac{\left(\frac{Applied\ Load}{Cross\ sectional\ area\ of\ scaffold}\right)}{Compressive\ strain} \quad (2)$$

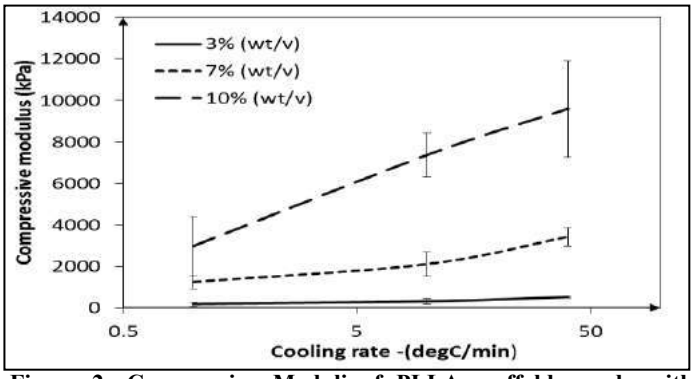

Figure 2: Compressive Moduli of PLLA scaffolds made with PLLA in Dioxane in 3, 7 and 10% (wt/vol) initially and also their variation with increasing cooling rate.

From the compression test results shows that 3% (wt/vol) scaffolds have very low modulus resulting in a weak scaffold that is difficult to manipulate during cell culture. Scaffolds cooled at 1°C/min showed irregular microporous structure. Therefore 7 & 10% (wt/vol) frozen at 10°C/min was selected for cell culture.

Cell Culture: Cryo-preserved hASCs were thawed and cultured in traditional Stromal Medium (SM) containing 90%(v/v) DMEM/F-12 (Gibco), 10%(v/v) Fetal Bovine Serum (Gibco), Penicillin - 90 IU/mL , Streptomycin – 90 µg/mL and Amphotericin B – 225 ng/mL. The PLLA Scaffolds were attached to the bottom of the 6-well plates using 1% Agarose (Sigma) as an adhesive. Equal number of hASCs was cultured simultaneously on both 3D porous scaffolds and 2D wells without scaffold as a control.

DNA Quantification: Number of cells on each sample at time point 0: ~10^5. The PLLA Scaffolds, homogenized with Dounce tissue grinder pestle (7 mL) (Sigma) as well as the control samples were incubated at 37°C with Lysis buffer (0.2 mg/mL Sodium Dodecyl Sulfate and 0.2 mg/mL Proteinase K) for 20 mins. The DNA present in the Lysis buffer was quantified using Quant-iT™ PicoGreen® dsDNA Assay Kit (Invitrogen) according to the manufacturer's protocol. The total DNA in each sample was normalized with the surface area exposed to SM in 1mm (150.80 mm^2), 5mm (263.89 mm^2) thick scaffolds and compared to 2D cell growth on control (962 mm^2).

Live/Dead Viability Assay: Number of cells on each sample at time point 0: ~10^4. Samples were incubated in staining solution of 2 µM Calcein AM and 4 µM Ethidium homodimer-1 (EthD-1) was prepared using LIVE/DEAD® Viability/Cytotoxicity Kit (Molecular Probes) stock solutions in DPBS for 20 mins at 37°C and were taken for fluorescence imaging using SteREO Lumar.V12 (Zeiss).

RESULTS

The proliferation of hASCs in scaffolds was measured by quantifying the amount of DNA in scaffolds and the viability was checked by fluorescence imaging after staining with live/dead dyes.

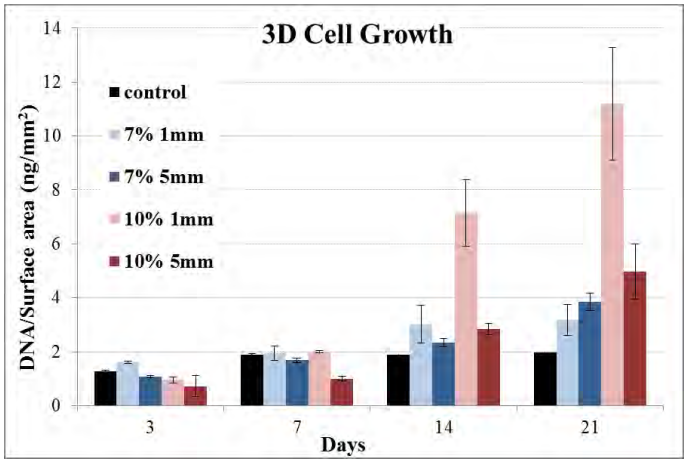

Figure 3: 3D cell growth measured by relative increase of DNA surface density (ng/mm^2) of scaffolds over control with time progression.

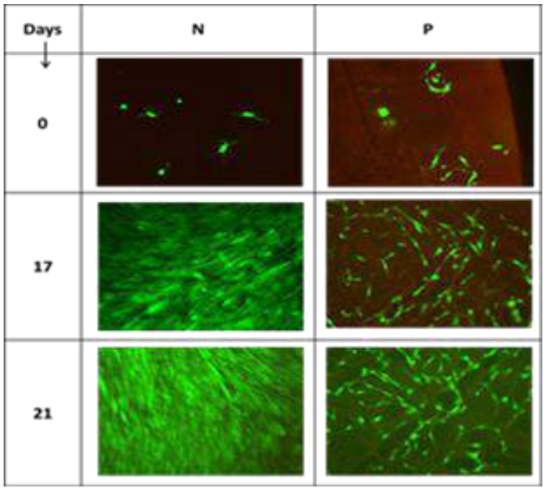

Figure 4: Live Cells (green) and dead cells (red) in Control samples (N) and PLLA Scaffolds (P) during time points 0, 17 and 21 days

DISCUSSION

Fig.3 shows DNA surface density increases with time in 3D scaffolds compared to 2D control where the cell growth stops at ~1.95 ng/mm^2 at day 7. This implies that cells are permeating through the scaffolds' micro-porous structure. 10% scaffolds show better cell growth than 7% even though the pore-sizes were comparatively low. This maybe because PLLA indeed promotes cell growth as seen in live/dead stain showing very little dead cell (similar to control). Therefore PLLA is also bio-friendly and shows no cytotoxicity to hASCs. The abundant growth in 10% 1mm scaffolds maybe because of better exposure to SM. Hence, either regular microstructure in scaffolds or simple increase in PLLA quantity could be favorable for cell growth, which will be investigated in future.

INTRODUCTION

Bioengineered scaffolds have the potential to enhance the organization of axon growth and guidance through the injury site after spinal cord injury [1-3]. Considerable progress has been made in enhancing the growth potential of injured adult axons, including aligning, lengthening, thickening, and myelinating the axons. Previously, we developed a pre-stretched anisotropic surface that successfully induced axon alignment and thickness of dorsal root ganglion (DRG) neurons and myelination [4].

Despite promising demonstrations in animal models, repair of long distance nerve injury with functional recovery is still challenging due to multiple factors, including axonal disruption, growth inhibitory molecules in the scar, lack of growth-promoting molecules, and incomplete remyelination [5-7]. Therefore, treatments to overcome these multiple deficits will require a multifaceted strategy, i.e. a multifunctional scaffold that can not only enhance axon growth and alignment but also deliver growth factors and promote myelination.

Schwann cells (SCs) are essential to the survival and function of neurons and play a vital role in the peripheral nervous system (PNS) by maintaining and aiding in the regeneration of axons [8]. It is known that SCs provide trophic support to promote the growth of axons from developing neurons [9]. SCs are also known to migrate into the central nervous system (CNS) and remyelinate the demyelinated axons after spinal cord injury (SCI). Due to their ability to secrete multiple growth factors, transplanting SCs hold promise as a therapeutic strategy for nerve regeneration.

We showed previously that the size of the channels of transplantable scaffolds strongly affects SC migration speed [10]. Here we explore axon growth in channels coupled with the migration of SCs, which offer trophic support to the regenerating axons. We designed a micropatterned channel platform using polydimethylsiloxane (PDMS) and co-cultured DRG neurons with SCs for 21 days to investigate the presence of migrating SC on the penetration and myelination of the axons into the channels. The effect of SCs on the axons were compared with nerve growth factor (NGF) released from a collagen gel and in different size channels.

METHODS

Patterned channel cell co-culture system fabrication

The micropatterned PDMS channels are prepared as [11], with two squares cut closely along with both ends of channels as an open area to seed cells. In order to create a sealed channel environment, the side of channel pattern is facing down and tightly attached to the PLL coated polystyrene substrate. Crosslinked collagen gel (375µl type I collagen + 27µl NaHCO3 + 50µl DMEM) was used as a glue to seal the edges, which helps to prevent the cells to be flushed outside the channel system.

Fluorescent imaging

The penetration of axons into channels was visualized through fluorescent live cell imaging, by adding 1µl of Fluo-4 into each well and incubate the cells at 37 °C for 30 mins. Fluorescent images were taken by a Leica DM IL inverted microscope (Bannockburn, IL) equipped with SPOT RT color camera (Diagnostics Instruments, MI) using a 10X objective.

Quantification of axon penetration depth

The axon penetration depth is defined as the furthest position the axons reach in each condition on each size channel. To quantify the axon penetration depth, a stage micrometer was first placed on objective to measure the diameter of the field viewed in eye pieces. The axon

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

penetration depth was quantified under the microscope according to the diameter and the size of channels. All the numbers are estimated values down to tens. 5 batches of biological replicates were quantified with each batch containing at least 4 identical replicates for each condition and each channel size.

RESULTS

Design of the patterned channel cell co-culture system

We co-cultured DRGs and SCs at opposite ends of the micropatterned channels (Figure 1a) and evaluated different size channels (50μm, 100μm, 150μm, and 200μm) as shown in Figure 1c. Freshly isolated DRGs were seeded at one end of the channels so that the cell bodies attached to the open area. As the axons grew and reached the start of the channels, they begin to penetrate into the channels, whereupon SCs were seeded at the other end of the channels to provide growth factors and migrate to the axons. As a positive control, in lieu of SCs, collagen gel pre-loaded with nerve growth factor (NGF) was added at one end of the channels as shown in Figure 1d, which provided growth factors to the axons extending from the other side. As a negative control, the one end of the channels, previously seeded with SCs or coated with NGF-containing collagen gel, was left blank (Figure 1b).

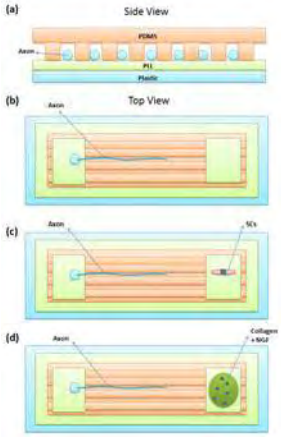

Figure 1: Schematic of micropatterned co-culture platform.
(a) Side view of the sealed channels. Polystyrene substrate is coated with a thin layer of PLL prior to overlaying the micropatterned PDMS. The sides of the channels are flush with the substrate to ensure a sealed channel environment for the axons to penetrate. (b) Top view of the platform. Freshly isolated DRG neurons are seeded in the open area at one end of the channels, with the regenerated axons penetrating into the channels. The open area on the opposite end of (Figure 1) the channels is left empty in the negative control group. (c) As the regenerated axons reach the end of the channels, SCs are seeded at the other end of the open area to promote axon penetration. (d) Collagen gel pre-loaded with NGF is alternatively added to the other end of the channels as a positive control.

Axon penetration depth and myelination under different conditions

We quantified the penetration depth after 21 days of culture of each group in each channel size as shown in Figure 2.

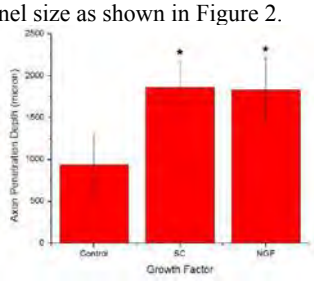

Figure 2. Quantification of axon penetration depth.
Comparison of penetration depth with all conditions and all channel sizes.

Both the SC and the positive control (NGF) group show much longer axons than the negative control group for all four channel sizes (Figure 2). However the difference between the SC and positive control group is not significant, but nevertheless differs with the channel size (data not shown). The addition of SCs minimized the effect of channel size. The results indicate that the addition of SCs or the NGF encapsulated gel effectively promote the penetration of the axons into the microchannels as compared to the negative control. However, the SCs group has the added benefit of enabling myelination of the axons (Figure 3). Findings from this study could inform the future transplantable scaffold design for nerve repair.

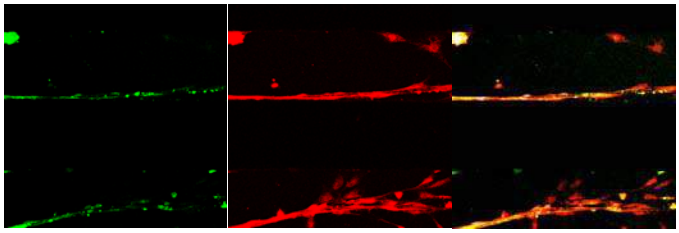

Figure 3. Quantification of myelination in the SC group.
Green is staining Tuj1 (indicator of axons), red is staining P0 (indicator of myelination) and yellow/orange is overlay of axons with SCs/myelination.

DISCUSSION

The addition of SCs offers two main advantages. First SCs are known to secrete growth factors that are beneficial to axon growth, and second migrating SCs decreases the diffusion distance to the axons thereby accelerating the delivery of the secreted growth factors. However, it is important to regulate the timing of SC addition since SCs could hamper the growth of the axons due to competition for nutrition as well as secretion of factors inhibitory to axon growth. Therefore, an ideal transplantable scaffold should be able to inhibit SCs from migrating towards the axons until after the axon growth period is completed. However, the scaffold should attract SCs towards the axons after their growth period to thereby myelinate the axon. To enable better control of SC migration, LbL self-assembled multilayers could be used in future to provide sandwich layers of compounds to repel and attract the SCs.

EVALUATION OF A DISPLACEMENT-DRIVEN MODEL FOR ASSESSING PATELLOFEMORAL JOINT CONTACT MECHANICS

Jonathan A. Gustafson (1), Kyle A. Berkow (1), Richard E. Debski (1), Shawn Farrokhi (1)

(1) Department of Bioengineering
University of Pittsburgh
Pittsburgh, PA, USA

INTRODUCTION

The use of computational models is a highly attractive solution for studying the effect of joint injuries and diseases on joint mechanics. Specifically, the knee is one of the most at-risk joints for developing osteoarthritis (OA), a debilitating joint disease that is a 50% lifetime risk at the tibiofemoral joint and afflicts 25% of the population at the patellofemoral joint [1]. A recent review on the use of computational models for assessing knee joint contact mechanics describes the potential clinical utility of these models while stressing the importance of understanding the assumptions and limitations of different modeling techniques [2].

Models employing both finite element analysis (FEA) and discrete element analysis (DEA) methods typically require estimations of muscle and soft-tissue forces along with load-based optimization techniques to drive the models. Displacement control of models can bypass several of these passive and active force assumptions utilized with current force-control methods; however, highly accurate kinematics are essential for implementing displacement-driven models, as described by Fregly and co-workers [3]. Theoretically, these displacement-driven models could be incorporated with highly accurate in vivo kinematic data collection techniques, such as biplane fluoroscopy, to estimate knee joint contact mechanics in patients with knee OA during functional tasks with the hopes of providing better rehabilitative and treatment options for this patient population.

The objective of this work was to develop a computational framework for employing DEA methods driven by knee joint kinematics of different degrees of tibiofemoral flexion using experimental data. We assessed the models knee joint contact mechanics at several joint positions and compared contact mechanics values to prior literature employing force-control methods.

METHODS

One fresh-frozen cadaveric knee was initially prepared by: 1) isolation of the quadriceps tendons, 2) affixing rigid registration blocks to the femur, patella and tibia for digitization, and 3) acquiring high resolution MRI scans of the extended, unloaded knee. Experimentally, a six degree of freedom knee jig was used to apply physiologic compressive loading to the tibiofemoral joint and tensile loading to the quadriceps tendons at tibiofemoral flexion angles of 0° - 60° with 5° of varying internal/external femoral rotation at 0° and 15° to simulate gait kinematics during loading response. Kinematic data was collected at each position using a mechanical digitizer (Faro Arm®, Lake Mary, FL; Single-point precision = 0.025 mm).

Inputs to the computational model included specimen-specific knee geometry, cartilage material properties, and experimental kinematics. Model geometry of the knee was developed from manual segmentation (Mimics®, Materialise, Leuven, Belgium) of bone, cartilage, and registration blocks from the MRI scans. Surface geometry was created from the segmentation process and imported into meshing software (Hypermesh, Altair Engineering Inc., Troy, MI). Tetrahedral, shell elements with an average element size of 1 mm were used to model the bones and cartilage.

DEA was utilized for computational analysis at each position by creating compression-only springs (E=4MPa, ν=0.42 [4]) at the centroid of each element of the segmented femoral and patellar cartilage surfaces [5]. Local coordinate systems built on the surface of the registration blocks were used to relate the position of the knee model from the MRI scans to each of the experimental positions in order to load the joint [6]. Contact pressure distributions were estimated using the following linear elastic modeling equation:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$P = \frac{(1-\nu)E}{(1+\nu)(1-2\nu)h}d, \quad (1)$$

where h is the undeformed surface to surface cartilage thickness and d is the spring deformation upon positioning the joint to its final, loaded state. Spring deformation was determined through a penetration analysis, where overlapping femoral and patellar cartilage elements were identified by computing the sign of the dot product of each element's outward normal and the vector connecting closest elements on each surface [4, 5]. Contact pressure was then calculated for each element (equation 1) and divided into medial and lateral patellar facet regions, defined by drawing a line through the inferior apex to the superior-most point on the base of the patella. The DEA algorithm was implemented using MATLAB (2015a, The Mathworks, Natick, MA).

RESULTS

Qualitatively, the contact pressure patterns between the varying femoral rotation angles were as expected, demonstrating increasing lateral facet pressure with increasing internal femoral rotation (**Figure 1**). Quantitatively, there was an increase of 5% contact area, 10% average contact pressure, and 5% peak contact pressure on the lateral patellar facet when going from an externally rotated femur to an internally rotated femur at 0° of flexion (**Table 1**). Additionally, there was a total increase of 276% contact area, 320% average contact pressure, 13% peak contact pressure when going from 0° to 60° of tibiofemoral knee flexion (**Table 2**).

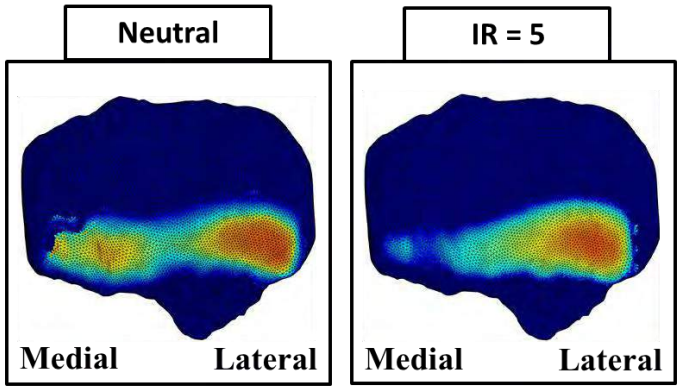

Figure 1: Patellofemoral pressure plots at 15° of flexion with 5° of femoral rotation (IR = Internal Rotation).

Table 1: Patellofemoral contact variables at 0° and 15° of flexion with 5° of femoral rotation (ER/N/IR = External/Neutral/Internal).

Position	Contact Area (mm^2) ER vs N vs IR	Avg. Pressure (MPa) ER vs N vs IR	Peak Pressure (MPa) ER vs N vs IR
Flexion = 0°			
Lateral Facet	144/149/151	0.50/0.45/0.55	5.09/4.22/5.34
Medial Facet	125/134/113	0.25/0.19/0.17	5.21/3.10/3.50
Flexion = 15°			
Lateral Facet	282/306/271	0.70/0.71/0.80	4.72/4.70/5.09
Medial Facet	301/304/230	0.57/0.55/0.30	4.13/3.90/3.27

Table 2: Patellofemoral contact variables from 30° - 60° of flexion

Position	Contact Area (mm^2)	Avg. Pressure (MPa)	Peak Pressure (MPa)
Flexion = 30°			
Lateral Facet	420	0.87	3.97
Medial Facet	415	0.80	3.82
Flexion = 45°			
Lateral Facet	509	1.03	3.92
Medial Facet	489	1.00	3.84
Flexion = 60°			
Lateral Facet	537	1.16	4.18
Medial Facet	526	1.09	3.92

DISCUSSION

This study assessed the utility of employing displacement-driven computational models in estimating patellofemoral joint contact mechanics. An important finding from this study is the models ability to differentiate between the different loaded positions. Specifically, the increase in contact area and contact pressure on the lateral patellar facet with increasing internal femoral rotation was expected and is significant. Patients with patellofemoral OA have demonstrated increased femoral rotation during walking [7]; thus, the model must be able to discriminate contact mechanics between small changes in femoral rotation to be used with kinematics collected in vivo.

The magnitude of our computational results is similar to prior studies [6, 8, 9]. Specifically, Fitzpatrick and co-workers report values for contact area, average and peak contact pressure between the range of 100 – 500 mm^2, 0.5 – 1.25 MPa, and 1.5 – 5 MPa, respectively [9]. Our model results for peak pressure are marginally higher, especially at the lower flexion angles (i.e. 0° and 15°), potentially due to the definition of cartilage to cartilage overlap, where in these lower flexion angles contact may be happening between cartilage and bone.

A number of limitations with the current study should be noted. First, results are indirectly compared with prior studies, which implemented different modeling techniques. However, these prior studies provide a benchmark for results from the current model. Additionally, cartilage is modelled as a linear, elastic material, though this assumption can be suitable under small durations of loading.

Future studies will perform direct validation of several knees in vitro as well as incorporate the use of these validated computational models with accurate 3D knee joint kinematics to estimate knee joint contact mechanics in patients with knee OA during dynamic activities in vivo. This study presents ground work for the potential use of displacement-driven models in assessing the effect of clinical intervention strategies for patients with knee OA.

INTRODUCTION

Inflammatory response in endothelial cells leads to increased vascular permeability by formation of intercellular gaps. In this work we use an engineeredbiomimetic blood vessel microfluidic model to characterize the dynamic nature of increase in vascular permeability and compare these results to traditional transwell insert permeability assays. The biomimetic blood vessel model has a monolayer of endothelial cells cultured under *in vivo* levels of flow. This endothelial monolayer was treated with thrombin, a serine protease that induce a rapid and reversible increase of endothelial cell monolayer permeability. Tracer molecule samples were collected in real time and analysed via spectroscopy to reveal the dynamic nature of inflammation induced permeability change.

METHODS

Fabrication and EC culture on bio-mimetic blood vessel model

Channels made of polydimethylsiloxane (PDMS) were photolithographically patterned and fabricated, and a monolayer culture of BAOECs was attained as explained in our prior work [28].The upper and lower channels are casted out of Sylgard 184 PDMS(Dow Corning Corp.).The upper and lower channels are casted out of PDMS. The upper channel is 20 mm long, 350 μm wide and 100 μm tall, and the lower channel is 5 mm long, 1000 μm wide and 100 μm tall. A polycarbonate (PC), track-etched thin clear membrane (Whatman, GE Healthcare) with 1 μm diameter pores is embedded between two PDMS channels. The bottom channel PDMS layer is bonded on to a thin glass slide by exposing the sides in contact to oxygen plasma. Upper PDMS channels is bonded to the membrane by using a thin PDMS mortar film. The upper channel bonded to the membrane is then bonded to lower channel after making sure the channels are aligned. After each step the components were placed in an oven at 60oC for an appropriate time to enhance bonding. Inlet and outlet ports were punched to provide access to upper and lower channels.

Cell seeded devices were placed in an incubator under standard culture conditions (37^{o}C and 5% CO^2) overnight to allow cell attachment and spreading on the membrane. On reaching confluence, the BAOECs were subjected to a physiologically relevant FSS of 12 dyne/cm^2. The flow was brought using a high precision and extremely low pulsation peristaltic pump (ISMATIPC-N series) and the entire setup was placed in standard culture conditions. Recirculation of media was not permitted while thrombin and tracer molecules were passed through the channels.

Thrombin treatment and cell permeability assay

BAOECs were treated with thrombin at 1 Unit (U)/ml concentration after being subjected to 6 hrs or more of flow in the microfluidic model. Thrombin induces an acute inflammatory response on endothelial cells and leads to profound increase in cell monolayer permeability. Thrombin was added to flow media along with the tracer molecule and the treatment was performed under flow on the apical side of the cells. For this the BAOECs were seeded at a density of 2×10^4 cells in the luminal chamber of ThinCert transparent insert for 12-well plates having a membrane with 1 μm pore diameter. Cells were cultured in DMEM with 10% of heat inactivated fetal bovine serum and, upon confluence the cells were treated with thrombin by replacing the medium in the luminal side with fresh DMEM (1% heat inactivated serum) supplemented with thrombin and tracer molecule.

Vascular permeability occurs through intercellular gap formation. We quantified the dynamics and kinetics of cell permeability caused by thrombin on BAOECs using the biomimetic blood vessel model. Fluorescent FITC sodium salt (376 Da), FITC-Dextran 4k Da and FITC-Dextran 70k Da molecular weight were used as tracer molecules. FITC sodium salt was flowed at 0.625 mg/ml and the FITC-Dextran molecules at 5 mg/ml. The desired tracer molecule was included in flow media along with thrombin in the luminal upper channel and the extent of tracer molecule permeation to the abluminal lower channel is a direct indication of the level of vessel permeability. This was monitored in real time by withdrawing 6 μl samples from the outlet of the lower channel every 10 minutes. These samples were analyzed photometrically using Infinite 200 PRO NanoQuant microplate readers at 490 nm excitation and 521 nm emission. The volume of buffer solution in the lower channel was maintained constant by adding 6 μl of PBS to the inlet before withdrawing the data sample. The abluminal media sample collected every 10 min for the transwell insert static cell case was also analyzed as described above.

RESULTS

On-chip cell culture

Characterization of endothelial cell culture on the biomimetic blood vessel microfluidic device has been detailed in our prior work The device has the upper channel arranged perpendicularly to the lower channel. The media, thrombin and tracer molecule are flowed in through the inlet of the upper channel (**Error! Reference source not found.**A).The porous PC membrane is cell culture friendly and provides the base for cell growth and proliferation as demonstrated before[28, 37-40]. Transport between the upper and lower channels is limited through the membrane pores present at an average density of $1.5*10^7/cm^2$. This high pore density and the 1 μm pore diameter (**Error! Reference source not found.**B) allow diffusion of tracer molecules through the membrane to the lower channel once it passes through the EC layer. As explained in **Error! Reference source not found.**C, thrombin and tracer molecule flow along

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with media and thus thrombin would act on the endothelial cell from the apical side. With the onset of cell-cell gap formation the tracer molecule would permeate through these gaps toward the lower channel. Thus the extent of vessel permeability can be quantified from the amount of tracer molecule in the lower channel.

An intact blood vessel endothelium is constantly exposed to FSS at its apical side due to blood flow. Therefore integrating in vivo levels of flow to the endothelial cell culture is important in limiting the chances of the cell monolayer undergoing phenotype drift and thus no longer reflecting in situ characteristics. Figure 1 D is a micrograph of F-actin stained flow aligned (12 dyne/cm2 FSS for 6 hrs) confluent BAOEC monolayer completely covering the base of the upper channel in our blood vessel model. The integrity and confluence of the cell layer was ensured to be optimal (at least 90% and comparable to Figure 1 D) through phase contrast microscopy before tests were performed.

Characterization of vascular permeability on biomimetic blood vessel model

Our platform is utilized to understand the increase in vessel permeability during an inflammatory state under physiologically relevant conditions. We used fluorescent tracer molecules of three different molecular weights and analyzed their diffusive permeability from the upper to the lower channel of the device, separated by the endothelial cell monolayer. The amount of tracer molecule transported to the lower channel will be a measure of vascular permeability based on its inflammatory response to thrombin treatment.

Endothelial barrier integrity was determined by real-time measurement of tracer molecule transport to the lower abluminal channel from the upper luminal channel, where the endothelial cells were grown to confluence on the semi-permeable membrane separating the two channels. FITC sodium salt, FITC-dextran 4kDa and FITC-dextran 70kDa were used as tracer molecules of different molecular weights and they were analyzed photometrically. Figure 2 A, B and C show the permeability curve for FITC sodium salt, FITC-dextran 4kDaand FITC-dextran 70 kDa respectively, along with the control case where the cells were not treated with thrombin. The data sample was collected from the lower abluminal channel every 10 min and the tracer molecule concentration was quantified by comparing the fluorescence intensity of collected data samples to a concentration calibration curve. It is observed that for all the tracer molecules the concentration in lower channel starts to increase acutely within 10 min of thrombin treatment and reaches the max value (0.09 mg/ml for FITC sodium salt, 0.34 mg/ml for FITC-Dextran 4kDa and 0.18 mg/ml for FITC-Dextran 70kDa) within 20-30 min. This means the permeability or gap formation of the endothelial cell monolayer initializes rapidly and reaches its maximum within 20-30 minutes. There is an increase of around 3.5 times in permeability for all the tracer molecules and this is a direct measurement of the change in endothelial cell-cell gap formation. Then a fall in abluminal concentration of tracer molecule is observed which plateaus to a minimum value at about 60-70 min. This signifies the decrease in endothelial cell permeability due to the reduction in intercellular gaps as a result of barrier recovery by the endothelial cells after the acute increase in permeability. FITC sodium salt and FITC-dextran (4 and 70 kDa) were included in flow media at different concentrations in the luminal channel for ease of photometrical detection and analysis.

Figure 2 C compares the concentration of the tracer molecules in the abluminal channel to their luminal concentration. For this, the concentration of tracer molecule in the abluminal channel is divided by the corresponding luminal concentration and compared with the thrombin treatment time. This normalizes the effect of doing the tests at different luminal concentrations to an extent and provides insights on how the size of the tracer molecule affects permeability. It is found that the permeability of tracer molecule across the endothelial cells decreased with increasing molecular weight. The lower molecular weight FITC sodium salt diffused faster and in larger quantity through the intercellular gaps than the higher molecular weight FITC-dextran 4kDa and 70 kDa. A reduction in diffusivity was observed with an increase in molecular weight of the tracer molecule.

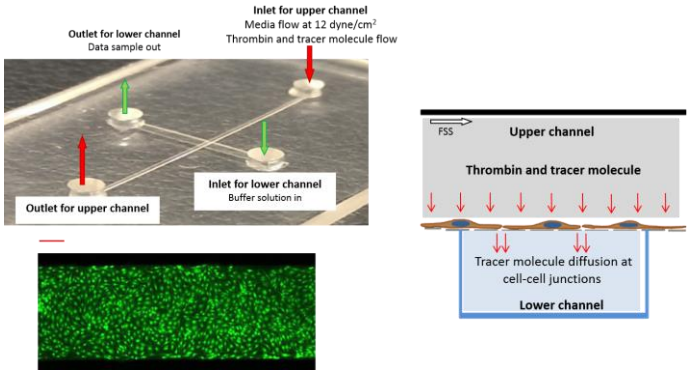

Figure 1: (A) Photograph of the bi-layer device showing the upper and lower channel separated by the semi-permeable membrane along with their inlets and outlets. The apical side of the EC layer face the upper channel and are exposed to media flow. Thrombin and tracer molecule are added to media to study blood vessel permeability under acute inflammation. Tracer molecule diffusion to lower channel is controlled by the extend of EC permeability under inflammation. The diffused data sample is collected from the lower channel. (B) Bright field image of the membrane with 1 µm diameter pores at an average density of 1.5*107/cm2. (C) Schematic depict EC growth on semi-permeable membrane, thrombin treatment from upper channel and tracer molecule diffusion through intercellular gaps. (D) Fluorescence labeled actin cytoskeleton (FITC-phalloidin) images of confluent BAOEC layer aligned to flow (12 dyne/cm2 FSS for 6 hrs) in the upper channel. Arrow shows flow direction (Scale bar: 100 µm)

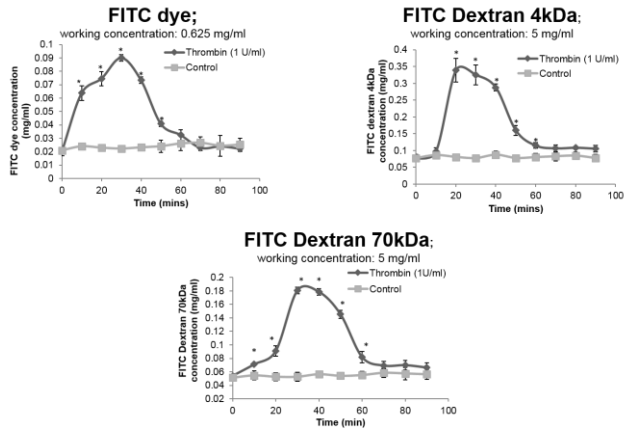

Figure 2: Permeability of the tracer molecule through the EC layer in the biomimetic device. (A) Permeability of FITC dye through the EC layer when treated with thrombin at 1 U/ml compared to control case. (B) Permeability of FITC dextran 4kDa through the EC layer when treated with thrombin at 1 U/ml compared to control case. (C) Permeability of FITC dextran 70kDa through the EC layer when treated with thrombin at 1 U/ml compared to control case. (D) Normalized comparison of FITC dye and FITC dextran 4 kDa permeability on the EC monolayer when treated with thrombin at 1 U/ml. FITC dye with a lower molecular weight has higher permeability compared to FITC dextran 4 kDa. Asterisks indicate values significantly different from control values ($p < 0.05$).

A MODEL FOR BIOLOGICAL FIBERS DERIVED FROM IMPLICIT ELASTICITY

Alan D. Freed

Department of Mechanical Engineering
Texas A&M University
College Station, TX 77845

INTRODUCTION

Collagen fibers are aggregate assemblages of collagen fibrils. Fibrils have a linear elastic response [1]. As a fiber becomes extended, individual fibrils get recruited and begin to bare traction [2]. The integral sum over this stochastic Poisson process [3] produces a stress-strain curve that starts out with a soft compliant response—nonlinear in stress—and finishes up with a stiff response—linear in stress. Applications of this strategy are computationally intensive [4]. In this paper an alternative approach is presented for describing an elastic biological fiber. The model was derived from thermodynamics and has been recently published by the author and his colleague [5].

FIBER MODEL

Consider two neighboring particles along the backbone of a fiber separated by a distance dX in some reference state that is free from traction. Under a state of traction, these particles become separated by a distance dx of which some fraction $d\xi$ represents a contribution caused solely by an unraveling of molecular configuration, e.g., a straightening of the crimp in collagen fibers. From these measures of length one can establish an overall stretch of $\lambda = dx/dX$, a stretch $\lambda^C = dx/d\xi$ where collagen carries the bulk of the traction, and a stretch $\lambda^E = d\xi/dX$ where an elastin network entangling the collagen carries the bulk of the traction. From the product rule, $\lambda = \lambda^C\lambda^E$ and $d\lambda = d\lambda^C\,\lambda^E + \lambda^C\,d\lambda^E$, the latter of which is coupled. This sum uncouples by dividing the equation through by the stretch λ, after which one gets $d\lambda/\lambda = d\lambda^C/\lambda^C + d\lambda^E/\lambda^E$ or $d\varepsilon = d\varepsilon^C + d\varepsilon^E$ which are logarithmic strain rates. Consequently, these strains add in the sense that $\varepsilon = \varepsilon^E + \varepsilon^C$ wherein $\varepsilon = \ln\lambda$, $\varepsilon^C = \ln\lambda^C$ and $\varepsilon^E = \ln\lambda^E$ are all true strain measures.

This additive decomposition in strain allows the work that is being done on a fiber, viz. $dW = \tau\,d\lambda$ wherein τ denotes the traction, to take on an equivalent form of $dW = \sigma\,d\varepsilon = \sigma\,d\varepsilon^C + \sigma\,d\varepsilon^E$ wherein $\sigma = \lambda\tau$ is the true stress of Cauchy. This stress acts on both strain increments. Consequently, the work being done becomes a sum of two separate work terms: $dW = dW^C + dW^E$ wherein $dW^C = \sigma\,d\varepsilon^C$ and $dW^E = \sigma\,d\varepsilon^E$.

Freed & Rajagopal [5] built their model for biological fibers in accordance with the graphic of Fig. 1. Like Carton et al. [6] and Maksym & Bates [7], we modeled elastin with a strain limiting material model. The difference being, their models were phenomenological in origin, whereas ours was derived rigorously from thermodynamics. To the strain attributed to elastin, in accordance with the above additive decomposition of strain, we add a linear strain accumulation attributed to collagen.

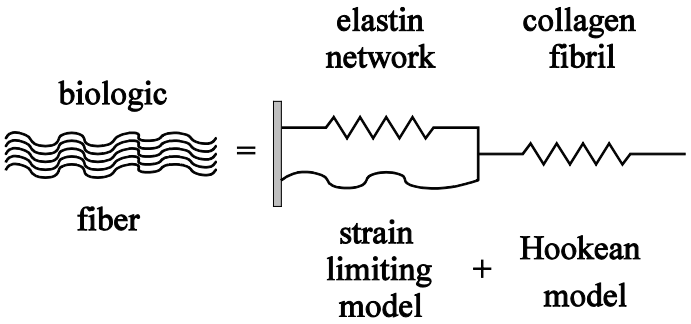

Figure 1: Schematic for modeling the elastic response of biological fibers. The elastin network is described by a strain limited spring, while the collagen is described by a Hookean spring.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

From an energetic perspective, and in accordance with the above decomposition of work, Freed & Rajagopal [5] modeled the strain contribution arising from a stressing of the collagen with a classic Gibbs potential, and we modeled the strain contribution arising from a stressing of the elastin with a novel, implicit, energy potential—an idea proposed by Rajagopal [8] in 2003—where here the energy potential depends upon both stress and strain. The stored energy potentials that we selected led to strain relationships of

$$\varepsilon^C = \frac{\sigma}{E^C} \quad and \quad \varepsilon^E = \frac{1}{\beta}\left(1 - \frac{1}{\left(1+(\beta-1)\sigma/E^E\right)^{\beta/(\beta-1)}}\right) \tag{1}$$

where strain $\varepsilon = \varepsilon^E + \varepsilon^C$ is described in terms of three material constants: E^C ($> E^E$) is the elastic modulus of the collagen fiber, i.e., the terminal stiffness, E^E (> 0) is the elastic modulus of the elastin network, i.e., the initial modulus, and $\beta = 1/\varepsilon^E_{max}$ (> 1) is a reciprocal to the limiting state of the molecular reconfiguration strain ε^E. These material constants can be acquired through a graphical procedure, as illustrated in Fig. 2.

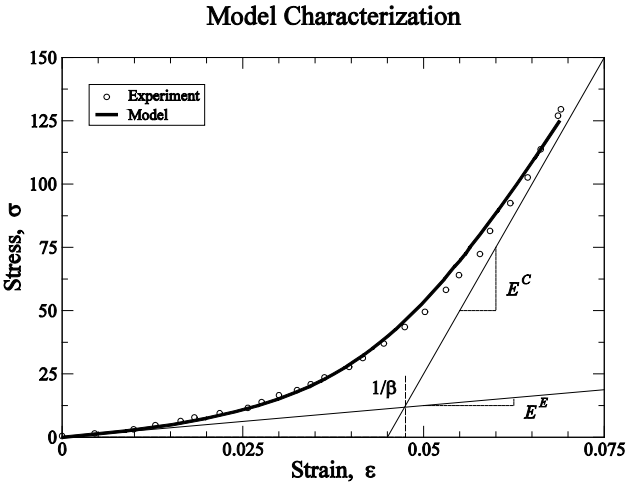

Figure 2: Illustration of graphical parameterization of model (1). E^C and E^E are the asymptotes for the tangent moduli at large and small strains, respectively, while 1/β is approximated well as the strain at the intersection of these two asymptotic lines.

RESULTS

The data presented in Fig. 2 are for a porcine chordae tendineae excised from a mitral valve [9]. The material constants for model (1), as drawn in Fig. 2, are: $E^C = 5000$ N/m, $E^E = 250$ N/m and $\beta = 21$. These parameters were obtained graphically. No computer optimization algorithm was employed, nor required. The model does an excellent job of describing these data.

DISCUSSION

Babu et al. [10] used the four-parameter, transversely isotropic model of Holzapfel et al. [11] where an exponential is employed to describe the strain response of the fiber. They used this model to describe the loading response of human aortas excised from sixteen individuals who suffered an aortic dissection, ages 7 to 71. They were unable to assign, with statistical significance, any dependence upon age to the parameters from the parametric fits of this model to their data. This led them to propose a phenomenological description of their data, which they described in terms of three parameters: E^C, E^E and σ^T. These are the same material parameters that the author derived from theory, as presented in Eq. (1), in that their transition stress σ^T equals our E^E/β.

The parameters of our material model (1) are unique, physical and intuitive. They are true material constants whose values will permit inferences to be drawn between different biologic materials, e.g., natural vs. engineered tissues. Furthermore, these material constants can be extracted from a tensile curve using simple graphical techniques.

In work that is underway, the elastic fiber model presented here has been extended into the viscoelastic domain. Also, multidimensional formulations based on this one-dimensional theory are being developed.

ACKNOWLEDGEMENT

The author would like to thank Prof. Jun Liao for making available the raw data from his thesis, as presented in Fig. 2.

INTRODUCTION

Current Ventricular Assist Device and Total Artificial Hearts are actuated based on continuous rotary pumps or hydraulic/pneumatic pumps. We propose to use an electroactive polymer, Dielectric Elastomer (DE), to fabricate these implantable blood pumps. DE is an advanced robotics material that sustains large deformations when given voltages, and has been recently hailed as "artificial muscles", as it is closest to natural muscles than alternatives, in terms of energy density and actuation magnitude. Due to its flexibility, high deformation capability[1], high energy density[2] and inexpensive nature[2], DE is explored for multiple applications such as linear actuators[3], generators[4] and microfluidic pump[2]. Much exploration is needed for application in macro-scale pump.

Using DE to make blood pumps allow reduction of device foot print, via removal of hydraulic/pneumatic systems, and allow a more organic shaped blood pump which can preserve natural fluid dynamics of the heart to reduce blood damage.

Traditional DE, fabricated with an acrylic polymer, VHB™ (3M Inc.)[3,4] suffers from high viscoelasticity[5], resulting in energy loss and damping of motion, compromising pumping performance at higher frequencies. In the current study, we investigate the use of a composite material in DE and show that it can generate higher flow rates and power outputs at frequencies close to the heart rate.

METHODS

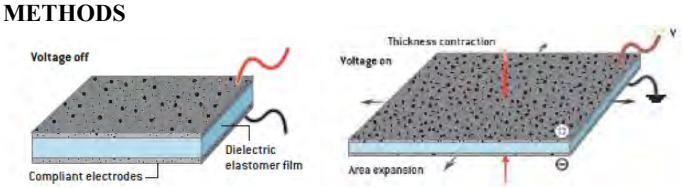

Fig 1. Dielectric Elastomer is actuation based on electrostatic attraction of soft electrodes

The non-composite DE was fabricated using one layer of 10mm thick VHB polymer (VHB4910, 3M Inc.), while the composite DE was fabricated using 2 layers of 5mm thick VHB polymer sandwiching a thin layer (0.16mm) of Latex membrane (Oppo 8001). Carbon grease was used as electrodes and was applied on both side on the DE. DE works on the principles of hydrostatic attraction between the soft electrodes for actuation (Figure 1).

A simplified DE fluid pump was fabricated by attaching a DE membrane to a PVC cylinder (56mm diameter). The DE membrane was subjected to 200% prestretch before attachment to the cylinder. The DE fluid pump was attached to a water reservoir via soft tubing of 2cm diameter and the water column is raised to about 80-120mmHg (figure 2). AC voltage was supplied to bring about cyclic expansion and then contraction of the DE membrane to cause pulsatile pumping (figure 2b). The pump was tested at various frequencies with increasing voltages until breakdown occur.

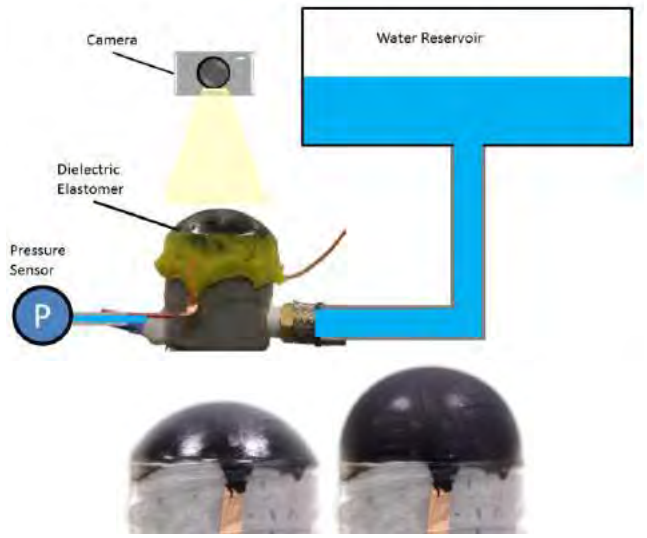

Figure 2: (a) Schematic of in-vitro flow setup to test the DE fluid pump. A large water reservoir was used to maintain a constant hydrostatic pressure. A pressure sensor measured localized transient pressure within the pump. (b) left: unactuated pump, right: actuated pump with voltage supplied.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

In the fluid pump, the breakdown voltage increased from 6kV in the non-composite DE to 10kV in the composite DE due to the change in dielectric strength and the increase in thickness.

Representative plots of volume of the non-composite DE pump over time are shown in figure 3, which demonstrates the role of viscoelasticity in reducing pump performance. With increasing pumping frequency, viscoelasticity limits the deformation motion of the DE membrane to cause reduction in the actuation volume (difference between maximum and minimum volumes). There is thus a need for a new material for better performance at higher frequencies.

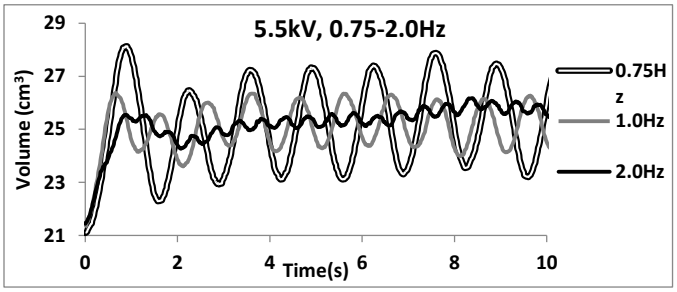

Figure 3: Plot of volume of non-composite (VHB) DE pump versus time between frequencies of 0.75Hz to 2Hz.

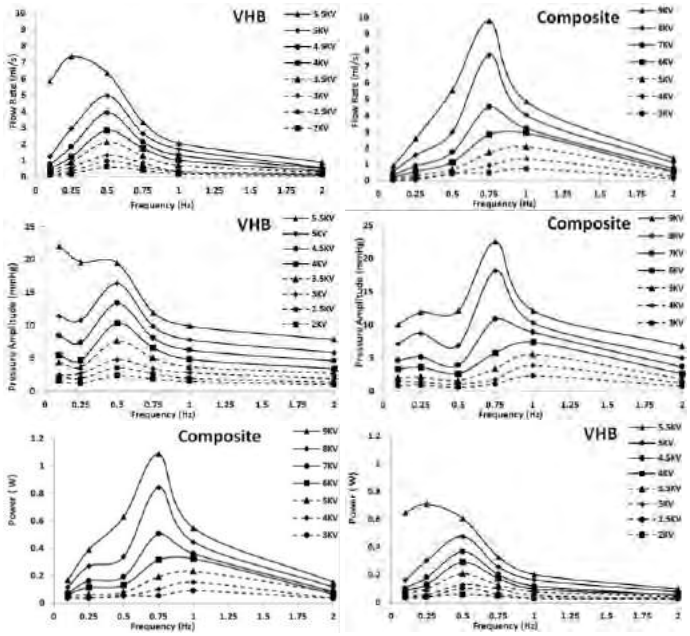

Figure 4: Comparison of DE fluid pump's net volumetric flow rate and pressure at frequencies and voltages before breakdown.

Figure 4 shows the comparison in the pumping performance between the traditional, non-composite DE fluid pump, versus the composite DE fluid pump. The resonance frequencies were found to be around 0.5 Hz for non-composite DE, but at around 0.75 Hz for composite DE. At the same time, the maximum flow rate achievable with the composite DE pump was 9.79 ml/s, which was higher than that in the non-composite DE pump (7.37 ml/s). At the higher frequencies of 0.75 Hz and above, the composite DE pump brought twice as much flow rate as the non-composite DE pump. For example, at 1 Hz, maximum achievable flow rate increased by 135% from 2.08 ml/s to 4.87 ml/s.

It is thus observed that through modifying the composition of the polymeric body of the DE, we could engineer its natural frequency to control resonance and yield much higher flow rate at higher frequencies. It is observed that pumping at the resonance frequency yields much higher performance than at non-resonance frequency indicating the importance of usage at the appropriate frequency and optimizing the composition to meet required frequency.

In terms of actuation pressure amplitudes generated by the DE fluid pump, as shown in figure 3b, both composite and non-composite DE pump generated similar pressure amplitudes, demonstrating maximum achievable pressure amplitudes of 22.1 mmHg and 22.6 mmHg respectively.

Finally, we observed that pump flow rates are greatly enhanced close to the resonance frequency, and were significantly higher than if the pump was operated not near to resonance frequency, underlying the importance of designing the natural frequency of the pump to specific applications.

DISCUSSION

To understand the role of viscoelasticity in causing this difference, we first note that actuation cycle of the DE membrane was such that the membrane expanded when the voltage was non-zero, and relaxed when the voltage was zero. Viscoelasticity, as a damping force on deformation, caused the DE membrane to relax towards its initial configuration gradually instead of immediately. At higher frequency, there is insufficient time during the relaxation phase for the membrane to relax completely before the next cycle started. Thus, the membrane could only oscillate between two very similar volume states, reducing the actuation amplitude and eventually leading to drastic drop in pumping performance for the non-composite DE pump.

The motivation for our selection of a composite of both VHB and latex was because of desirable qualities of both materials. On one hand, latex had very low viscous properties, and could down-moderate the high viscous properties of VHB in the composite. On the other hand, VHB was more elastic, and could sustain large deformations, but latex could not. DE pump made completely from latex yielded very poor results with negligible volume changes, due to the high stiffness of the latex and poor expansion capabilities under Maxwell stresses. A composite consisting of both materials was thus a good way to get the best of the two materials.

Heart failure is accountable for 2.8% of all deaths, and cost an estimated $32 billion per year in the US alone. There is much incentive and urgency to develop improved prosthetic hearts and cardiac assist devices to treat patients. With its properties that mimics natural muscles, DE is a promising material to use to fabricate the next generation implantable blood pumps and warrants investigations. DE also holds the promise of eventually developing into a more organically-shaped heart retaining the geometry and actuation motions of the natural heart.

ABSTRACT

The dynamic characteristics of human upper airway (UA) differ from healthy subjects to obstructive sleep apnea (OSA) patients. It is very difficult to find a common term of reference for comparison as many anatomical parameters are involved, such as air gaps at the rear of the mouth, volume of airway, uvula and tongue. This study investigates these characteristics in healthy subjects and OSA patients and introduces new common ground parameters for comparison. The objective of this study is to identify the causes of collapse by comparing between these characteristics in the two groups. MRI data of the UA were collected on 18 volunteers (8 healthy subjects and 10 OSA patients), and 3D models were constructed and simulated. Also, measurements of the UA were determined and compared in the two groups. The outcomes suggest that the apneic events are primarily caused by the large size of the tongue and uvula, and the air volume is not the main contributor to UA collapse. Finally for each subject's specifics, the natural frequencies of the uvula and tongue models are very close to one another, which suggests that they can be stimulated at the same time with approximately the same frequencies.

INTRODUCTION

OSA is the most prominent UA respiratory system disease [1]. It occurs due to obstruction in the UA region [2] and is characterized by repeated episodes of obstruction and collapse of the pharyngeal airway during sleep [3]. UA collapse occurs when the forces of the airway wall muscles become less than the forces generated from the airway negative pressures during the respiration process [4].

The tendency for UA obstruction increases when the patient sleeps in supine position, as gravitational forces pull the uvula and tongue towards the airway walls reducing the air gap between these tissues and the airway walls, which increases the chance for airway obstruction and collapse [5]. OSA can lead to many health implications such as hypertension, stroke and cardiovascular disease [6].

The dynamic characteristics of human upper airways differ from healthy subjects to OSA patients. Also, having a common term of reference for comparison is very difficult as many anatomical parameters are involved such as: volume of airway, uvula and tongue, and air gaps at the rear of the mouth. This study investigates these characteristics for healthy subjects and OSA patients and proposes new common ground parameters for comparison. The objective of this study is to identify the causes of collapse by comparing those characteristics between healthy subjects and OSA patients.

METHOD

While awake and in supine position, MRI data of the UA were collected for 18 non-smoking volunteers, consisting of 8 healthy subjects (4 males and 4 females) and 10 OSA patients (7 males and 3 females) with age of 31.12±10.10 and 55.00±8.22 years; respectively. BMI was 25.42±1.46 kg/m^2 for the healthy subjects; and 36.58±9.37 kg/m^2 for OSA patients. Ethical approval was granted by The Auckland University of Technology Ethics Committee and consents were obtained prior to initiation of the study procedures.

Three dimensional models for the UA including air, uvula and tongue were constructed from the MRI data using 3D-DOCTOR software and their sizes and the air gaps at the rear of the uvula and tongue and at the mid-sagital plane (MSP) were determined. Uvula and tongue models were simulated on the ABAQUS software to determine their natural frequencies. Figure 1 shows the region of interest and samples of the constructed models for air, uvula and tongue.

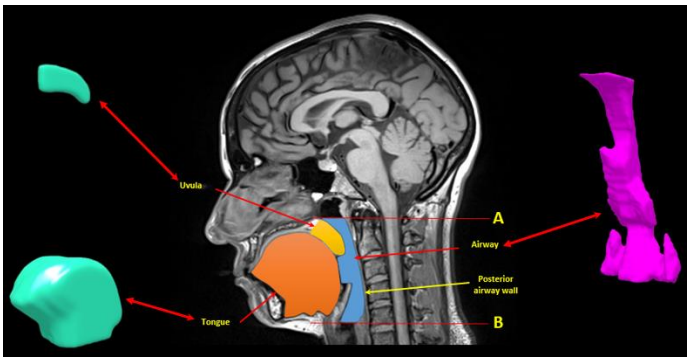

Figure 1: Region of interest expanding from the nasopharynx (A) to the hypopharynx (B); and samples of the constructed models

RESULTS AND DISCUSSION

Air gap at the rear of mouth: The values for the minimum air gaps at the rear of the uvula and tongue at MSP were 5.18±2.75 mm and 7.74±4.15 mm, respectively for healthy subjects; 6.43±1.19 mm and 8.22±2.10 mm, respectively for OSA patients. These results show that OSA participants have relatively larger air gaps at the rear of the mouth than the healthy participants.

Air Volume: For healthy subjects, the air volume was 12272.40±4161.57 mm^3 occupying 13.47±3.39% of the entire UA volume; while for OSA patients the air volume was 18830.10±8172.50 mm^3 occupying 12.76±4.31% of the entire UA volume. These results show that the participating OSA patients seem to have larger air volume than healthy subjects but with a slightly smaller percentage of the total UA volume.

Uvula Volume: For healthy subjects, the uvula volume was 1250.38±247.95 mm^3 occupying 1.57±0.23% of the total UA volume; while for OSA patients the uvula volume was 1942.90±234.03 mm^3 occupying 1.34±0.18% of the total UA volume. These results show that OSA patients have extremely larger uvulas than their healthy counterparts but with a slightly less percentage of the total UA volume.

Tongue Volume: For healthy subjects, the tongue volume was 66536.22±10097.45 mm^3 occupying 84.98±3.36% of the total UA volume; while for OSA patients the tongue volume was 124539.96±11917.40 mm^3 occupying 85.90±4.20% of the total UA volume. These results show that OSA patients have extremely larger tongues than their healthy counterparts (almost double the tongue volume of the healthy subjects), however the percentages are very close to each other.

VBMI: The above results may be misleading as the two participating groups have many differences such as body size, age range, ethnicities and weight categories. Therefore the changes in the volume and BMI were combined into a new parameter, namely VBMI which represents the ratio of an element volume (mm^3) to the BMI (kg/m^2). Values for VBMI of air, uvula and tongue for the healthy subjects and OSA patients are summarized in Table 1.

TABLE 1: VBMI for healthy and OSA subjects

VBMI	Healthy Subjects	OSA Patients
Air	486.25±175.32	527.65 ±226.61
Uvula	48.97±7.80	55.19±10.90
Tongue	2627.45±383.30	3716.00±479.50

Data in Table 1 shows that OSA patients compared with healthy subjects have: (i) slightly larger $(VBMI)_{air}$; (ii) larger $(VBMI)_{uvula}$ and (iii) much larger $(VBMI)_{tongue}$.

Natural Frequencies: For each subject specifics, the values for the first and second natural frequencies of the uvula and tongue models were very close to one another as shown in Figure 2, which indicates that both of these tissues can be stimulated at the same time with approximately the same frequencies. However, there were no significant differences in the obtained natural frequencies for the uvula and tongue models between the two participating groups.

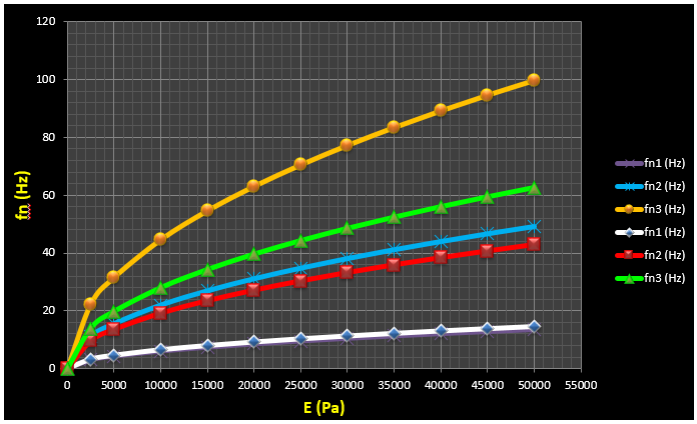

Figure 2: First natural frequencies of the uvula and tongue

These results suggest that the airway volume is not the main contributor to UA collapse, as OSA patients had significantly larger airways compared to the healthy subjects. However, the significantly large size of the uvula and tongue in the apneic group may be the main contributor to UA collapse.

AKNOWLDGEMENT

QUANTIFYING CEREBROSPINAL FLUID DYNAMICS USING REAL-TIME PHASE CONTRAST MRI

S. Yildiz (1), J. Oshinski (2), K. Sabra (1)

INTRODUCTION

Cerebrospinal fluid (CSF) undergoes periodic pulsations in the skull and the spinal canal primarily driven by the cardiac force [1-3] and respiratory force [2-5]. Earlier studies investigating CSF flow dynamics have demonstrated the impact of these forces invasively through spinal taps [2,6] and non-invasively through phase contrast (PCMRI). For instance spinals taps showed the impact of cardiac and respiratory forces as well as transient events such as coughing and sneezing on CSF dynamics. Phase contrast (PC) MRI studies [7,8] have primarily showed the influence of only the cardiac forces on CSF flow dynamics as most PCMRI studies used a conventional cine-phase cardiac-gated sampling technique which cannot quantify CSF dynamics that are not synchronized with the cardiac cycle, such as respiration or other short transient events like coughing or Valsalva maneuver. Understanding and quantifying respiratory mechanisms and such transient fluctuations of CSF flow dynamics requires the ability to perform *real-time* measurements of CSF flow along the spine and cranial cavity. Indeed, a very recent *real-time* MRI study [9] demonstrated the CSF flow velocity and directionality due to cardiac and respiration effects. However this previous study did not assess the accuracy of real-time measurements and the measurements were not made in the spinal subarachnoid space (SSS).

To address these limitations we aimed to continuously quantify CSF flow dynamics using a novel *real-time* phase contrast magnetic resonance imaging (RT-PCMRI) [10, 11] in order to explore the effects of respiration and transient events such as coughing and sneezing on CSF flow at the level of Foramen Magnum (FM). To date, this RT-PCMRI technique has only been used to perform real-time blood flow velocities across the heart chambers [11] but has not been used for *real-time* quantification of CSF velocities across the spinal canal.

METHODS

The study was approved by the institutional review board, and was performed after informed consent was obtained from each subject. Eight health subjects (four men and four women, mean age: 41 ± 13 years; age range: 27-60 years) with no neurological disorder or spinal trauma, allergic or respiratory disorders, pregnancy, and any contraindications for MRI, were enrolled in the study. MR images were acquired on a Siemens 3T scanner (Tim Trio, Siemens Healthcare, Erlangen, Germany) using multi-channel head and neck coils for subjects lying in supine. First, high-resolution sagittal T2-weighted fast spin echo MR images were collected to determine the location of FM. Transverse images were acquired at the FM using the conventional PCMRI and the RT-PCMRI sequence (e.g., see Fig. 1a). During the approximately 1-min RT-PCMRI acquisitions, subjects were instructed to perform deep diaphragmatic breathing, 20s breath-holding preceded and followed by deep diaphragmatic breathing, and forced contractions of perineum and abdomen during 20s breath-holding (for mimicking coughing and sneezing). Electrocardiogram (ECG), blood finger pulse and chest motion were also measured and synchronized with MRI acquisition.

In order to quantify the inter-subject variability for deep diaphragmatic breathing, the mean and standard deviation (N=8) of the following five set of dependent variables were calculated (see Table 1): maximum and minimum values of CSF velocity waveform (1) and the respiration component of this CSF velocity waveform (2); peak frequency of the respiration component (3) and cardiac component (4) of the CSF velocity waveform; and peak-to-peak amplitude ratio [r/c] of the respiration versus cardiac components (5).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

During deep diaphragmatic breathing (Fig. 1d), the slow oscillations (period ~10s) with large amplitude variations (up to 3cm/s) correspond to the continuous respiration forcing of the CSF flow during successive inhale and exhale cycles, while the superimposed rapid oscillations (period ~1s) with smaller amplitude variations (~1cm/s) are due to cardiac forces during successive systole-diastole cycles. This is confirmed in Fig. 1e showing that during the 20s long breath-hold (between t=10-30s), only the small cardiac fluctuations are visible as respiratory effects are suppressed (in agreement with previous findings from [15]) and that the respiratory forcing is enhanced between t=37-47s after the subject was instructed to take a few deep recovery breaths (causing CSF velocity up to 4cm/s). Finally, we found that large and abrupt changes in peak CSF velocity values can occur while the subject performs continuous perineum and abdominal contractions during breath-hold (see t=15-35s on Fig. 1e); this effect is likely due to the resulting abrupt intrathoracic pressures changes being communicated to the CSF via the venous system [12].

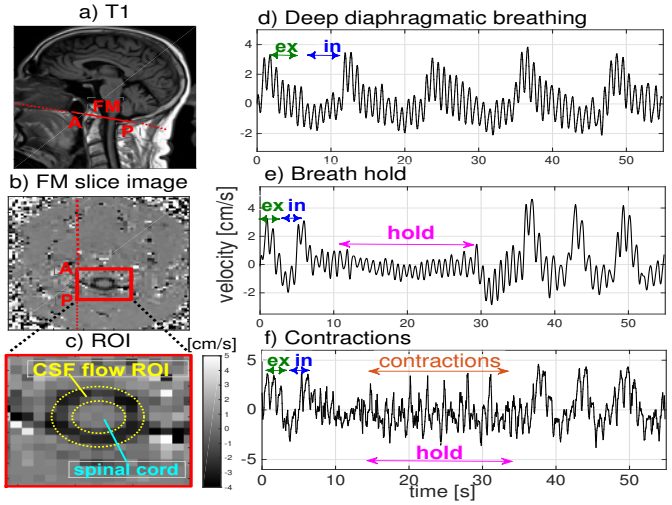

Figure 1: Sagital anatomical MRI image showing measurement slice at Foramen magnum (FM) (red line). b) Velocity distribution measured along this whole FM slice with RT-PCMRI at the time of peak exhalation. c) Zoom-in of (b) showing the annular region of interest (ROI) (yellow line) containing the CSF flow. d) Deep diaphragmatic breathing; cephalad (upward) direction with inhale (blue) and caudad (downward) with exhale (green). e) Breath hold. f) Contractions mimicking coughing/sneezing.

The inter-subject variability of CSF velocity measurements at the FM among eight subjects is shown in Table 1 in terms of (1) maximum and minimum measured velocities (2.09 ± 0.85 cm/s and -2.15 ± 0.82 cm/s), (2) maximum and minimum measured velocities for the respiration components (f<0.5Hz) (0.90 ± 0.62 cm/s and -1.06 ± 0.49 cm/s), (3) peak frequency for the respiration component of the CSF velocity waveforms (0.10 ± 0.04 Hz), (4) peak frequency for the cardiac component of the CSF velocity waveforms (1.19 ± 0.14 Hz), and (5) the peak spectral amplitude of the respiration vs. cardiac component [r/c] = 0.8 ± 0.33.

Table 1. Inter-subject variability (N=8) of CSF velocity measurements obtained with RT-PCMRI during deep diaphragmatic breathing.

In-vivo measurements		All (N=8)
Peak CSF Velocity	*max*	2.09 ± 0.85 cm/s
	min	-2.15 ± 0.82 cm/s
Peak CSF Velocity (respiration component only)	*max*	0.90 ± 0.62 cm/s
	min	-1.06 ± 0.49 cm/s
Estimated frequencies	*respiration*	0.10 ± 0.04 Hz
	cardiac	1.19 ± 0.14 Hz
Peak-to-peak spectral ratio [r/c]		0.8 ± 0.33.

DISCUSSION

RT-PCMRI measurements of CSF flow at the FM revealed a comparable contribution of cardiac pulsations and respiration on CSF velocity magnitude during deep breathing, breath-holding, and forced contractions. The observed modulations of the CSF velocity waveforms during deep breathing were consistent with measurements obtained in the brain and basal cisterns from a recent study using another RT-PCMRI technique [10].

Current routine clinical phase contrast MRI (PCMRI) measurements conducted for patients with Chiari Malformation (CM) are commonly done at level of the FM where their herniated cerebellar tonsils can hamper the normal CSF flow. Therefore, our RT-PCMRI technique measuring CSF flow velocity at FM can be applied to better understand the influence of respiratory mechanisms and transient events such as coughing and sneezing in populations with CM. Furthermore, on-going research suggests that the "glymphatic system", a functional waste clearance pathway between the CSF and the interstitial fluid (ISF) of the brain, is critical for maintaining CNS homeostasis and changes in the normal CSF circulation have been associated with the CNS diseases. Therefore, better understanding the mechanisms of CSF circulation is essential to support and improve the normal physiologic functions of the CNS.

In conclusion, we have demonstrated that RT-PCMRI technique provides a means to measure CSF flow modulations that are not repeatable cycle-to-cycle for each heartbeat, which are not-measurable with conventional cardiac-gated PCMRI.

ACKNOWLEDGEMENTS

The authors thank Xiaodong Zhong and Ning Jin for their assistance with the RT-PCMRI sequence, and Frank Loth and Suraj Thyagaraj for useful discussions on CSF dynamics and CM.

INTRODUCTION

Skin is the largest organ of the human body and it serves multiple purposes including providing protection from mechanical, biological and viral insults, and allowing regulation of heat and water exchange with the surroundings. As with most soft biological tissues, skin biochemical behavior is affected by the evolving mechanical behavior. For this reason, a model that describes the biomechanical characteristics of the tissue can be helpful in areas like plastic surgery, wound healing, and radiotherapy side effects.

The purpose of this work is to describe skin from the mechanical perspective by employing a constrained mixture theory approach, which has shown predictive capability in the cardiovascular field [1]. Specifically, in this model each distinct constituent (collagen fibers and elastin) was endowed independently with a constitutive descriptor and allowed to have a different natural (stress-free) configuration. This endows us to identify the independent contribution of each constituent to the overall mechanical behavior of this complex system.

METHODS

Skin can be described as a nonlinear, anisotropic, nearly incompressible elastic material. These characteristics can be explained by looking at the components of the tissue: families of collagen fibers aligned along preferential directions endow skin with its nonlinear, anisotropic behavior, while elastin give skin its elastic response [2]. Moreover, the presence of the Langer's lines shows that the constituents are experiencing a certain level of deformation in the in vivo, homeostatic state. For these reasons, we describe the mechanical behavior of skin employing a constrained mixture theory, inspired by the work done by Humphrey and colleagues in the field of cardiovascular mechanics [3-4].

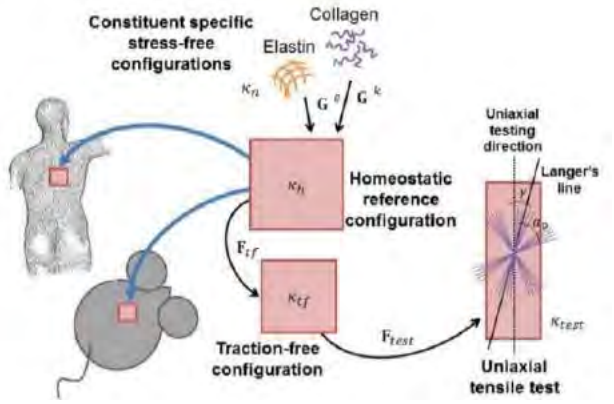

Figure 1. Schematic representation of the configurations of interest in the model.

Kinematics. We modeled the skin as a planar, three dimensional layer. Let the in vivo homeostatic configuration κ_h serve as a computationally convenient and biologically relevant reference configuration (Fig. 1). Moreover, let each constituent within the tissue possess a separate natural, stress-free configuration κ_n^α, where $\alpha = k, e$ for elastic fibers and $k = 1,2,3$ families of collagen fibers, respectively. Deformations between each natural configuration κ_n^α and the homeostatic configuration κ_h are defined by a constituent-specific deposition stretch tensor $\boldsymbol{G}^\alpha$.

Constitutive description. To describe the nonlinear, orthotropic behavior of skin we employ a mass averaged strain energy function (SEF) of the form

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$W = \phi^e W^e(\mathbf{F}^e) + \sum_{k=1}^{3} \phi^k W^k(\lambda^k). \quad (1)$$

where ϕ^α and W^α represent the mass fraction and the SEF for each constituent, respectively, with $\alpha = e, k$ for elastic fibers and families of collagen fiber ($k = 1,2,3$), respectively. We considered 3 collagen fibers families in this work, namely $k = 1$ for fibers in the direction of the Langer's line and $k = 2,3$ for symmetric diagonal fibers with respect to the Langer's line, see Figure 1. Elastin has been described by using a neo-Hookean constitutive model,

$$W^e(\mathbf{F}^e) = \frac{c^e}{2}(tr\mathbf{C}^e - 3), \quad (2)$$

where c^e represent a material parameter with the dimensions of stress and $\mathbf{C}^e$ represents the right Cauchy-Green tensor describing the deformation that affects the elastic network, i.e., $\mathbf{C}^e = (\mathbf{F}^e)^T\mathbf{F}^e$ with $\mathbf{F}^e = \mathbf{F}\mathbf{G}^e$. Collagen fibers mechanical behavior has been described by using a Fung-type exponential SEF

$$W^k(\lambda^k) = \frac{c_1^k}{4c_2^k}\left\{\exp\left[c_2^k((\lambda^k)^2 - 1)^2\right] - 1\right\}, \text{ for } \lambda^k > 1, \quad (3)$$

where c_1^k and c_2^k are material parameters, with the dimension of stress and dimensionless respectively, λ^kdescribes the stretch in the direction of k^{th} collagen fiber family defined as $\lambda^k = G^k\sqrt{\mathbf{M}^k \cdot \mathbf{C}\mathbf{M}^k}$, where $\mathbf{M}^k = \left(0, \sin\alpha_0^k, \cos\alpha_0^k\right)$ with angles $\alpha_0^1 = \gamma$, $\alpha_0^2 = \alpha_0 + \gamma$ and $\alpha_0^3 = -\alpha_0 + \gamma$. Material parameters for collagen fibers in compression are considered to be 20% of the tensile parameters.

Experimental data. Details on how the experiments were conducted can be found in [2-5]. Briefly, 43 samples from 6 human subjects were collected and mechanically tested by means of a quasi-static uniaxial tensile test. In this study, samples were grouped based on subject and inclination with respect to the Langer's line (i.e., $0°, 45°, 90°$) then averaged. The averaged datasets were used to estimate best-fit material parameters as a cohesive protocol.

Parameter estimation. We used a nonlinear least-squares regression to determine best-fit values of the material parameters by minimizing the error between theoretically predicted (subscript "th") and experimentally measured (subscript "exp") stresses.

RESULTS

Experimental data and model predictions are shown in Fig.2. Table1 shows best-fit values of the six material parameters for the constitutive model. Goodness of fit is showed in Table 1 in terms of the root mean sum-of-the-squares of the error (RMSE). Table 1 shows that the mechanical behavior of skin is dominated by the presence of collagen fiber, represented by the mechanical parameters of collagen being several orders of magnitude bigger than the one for elastin.

Due to the lack of histological quantitative information found in literature on the variation of content of constituents with age in skin as a first approximation we considered the mass fractions of both collagen and elastin equal to one. To refine this value, will be the subject of future studies. Deposition stretches for elastin and collagen, $\mathbf{G}^e$ and G^k respectively, cannot be measure or estimated easily experimentally. For this reason, we conducted a parametric study to assess the sensibility of the model to the deposition stretches values. Variation of $\mathbf{G}^e$ from 1.00 to 2.00 (i.e., in the direction of the Langer's line) has little effect on the accuracy of the prediction, measured as variation of RMSE. This could be due to the material parameter associated with elastin being small, however $\mathbf{G}^e$ will have an important effect on the estimation of pre-stress along the Langer's line. Due to lack of information on the pre-stress (i.e., deformation of the tissue upon excision) we set $\mathbf{G}^e = \boldsymbol{I}$, where is $\boldsymbol{I}$ the identity matrix. Following the work done by Humphrey and colleagues [3-4] we used a compressive deposition stretch, $G^k < 1$, to describe the fact that collagen fibers are coiled in the in vivo, homeostatic configuration. A parametric study showed that $G^k = 0.95$ gives the overall the lower value of RMSE for all the samples. Moreover, following [4], we model the compressive behavior of collagen fibers using the same SEF used to describe the tensile behavior, imposing the compressive parameters to be 20% of the tensile ones (i.e., average of values in Table 3 in [4]).

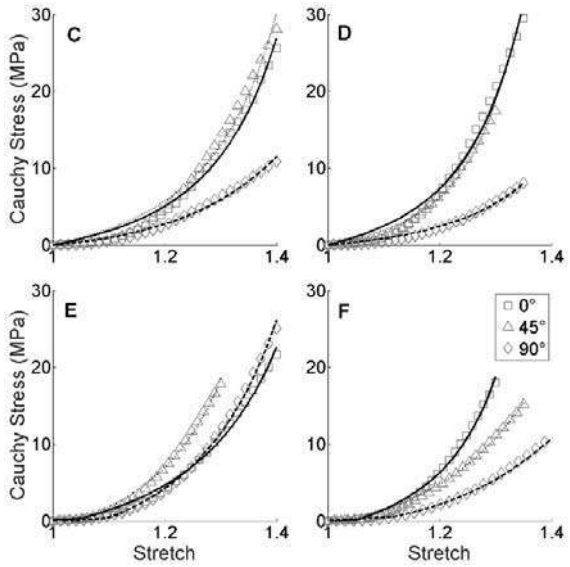

Figure 2: Experimental data as showed in [4], and model prediction.

DISCUSSION

To the authors' knowledge, we are the first to apply a constrained mixture theory approach to human skin. While further experimental data is required to verify the value of $\mathbf{G}^e$ and G^k determined numerically here, as well as the mass fractions ϕ^e and ϕ^k, a framework has been developed which can accurately represent the mechanical contributions of both elastin and collagen to the behavior of skin.

INTRODUCTION

Characterizing brain tissue is important to understand the mechanics of brain development, injury, and repair. Structurally, white matter tissue contains distinct myelin-sheathed axonal fiber bundles. This fiber-reinforced structure indicates that white matter is both structurally and mechanically anisotropic. A recent study using a combination of shear and indentation tests has demonstrated that a transversely isotropic model can be used to characterize the anisotropic behavior of white matter in small strain regime [1]. However, large deformation (>5% strain) commonly exists in many behaviors of soft biological tissues, especially in development and injury. Thus, the focus of this study is to further investigate the anisotropic behavior of white matter under large deformation.

Multiple testing methods have been proposed to characterize transversely isotropic materials, for example, shear-indentation tests [1] and extension-torsion tests [2], among others. However, the combination of two testing methods involves complicated tissue handling, transporting and testing processes. Therefore, a single experimental technique that allows for characterizing axonal fiber reinforced white matter is desired. Among typical mechanical testing methods, indentation has been widely adopted in studying many soft tissues, e.g. brain tissue [3] and corneal stroma [4]. Nevertheless, isotropic material models were typically adopted for parameter estimation in most of those studies, whereas studies using anisotropic material models are still lacking or restricted to certain tissue preparation and testing setup [5].

In this present work, we used asymmetric indentation to characterize white matter under large deformation. A minimal form of incompressible transversely isotropic (MITI) material model of both anisotropic invariants (I_4 and I_5) was employed. Three parameters of the model were estimated by an inverse finite element (FE) method.

METHODS

Tissue preparation: porcine brains (3-5 month old) were obtained from a local slaughterhouse 2 to 4 hours post-mortem. White matter tissues were dissected from the corpus callosum region similar to the method presented in a previous study [1]. Briefly, the flat corpus callosum region was exposed by cutting the tentorium. Using a circular punch, cylinder-shaped samples were produced from the central corpus callosum region where axonal fibers can be seen connecting the left and right hemisphere. A total of 12 samples were acquired. The average sample thickness was 3.3 mm with a diameter of 14 mm. During the experiment, samples were moisturized with phosphate-buffered saline solutions.

Asymmetric indentation testing: we used a custom-built asymmetric indentation device (Fig. 1) to measure the indentation force and displacement. A rectangular indenter, 2mm wide and 20 mm long, was used. To characterize white mater under large deformation, each sample was indented by 10% of its thickness parallel (0-deg) and perpendicular (90-deg) to the dominating fiber direction, with an average strain rate of ~0.2 s^{-1}. A custom-written MATLAB program was used for indenter control and data acquisition. Linear fitting was applied to the force-displacement curve in which portion the indenter velocity was constant.

Inverse modeling based material parameter characterization: to estimate the model parameters, the asymmetric indentation was simulated using commercial FE software (ABAQUS 6.12, Providence, RI, USA). The following MITI material model [1] was implemented in a user-material subroutine UMAT:

$$\psi = \frac{\mu}{2}[(I_1 - 3) + \zeta(I_4 - 1)^2 + \phi I_5^*], \quad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where μ is the shear modulus and ζ and ϕ are the anisotropic parameters related with invariant I_4 and I_5, $I_5^* = I_5 - I_4^2$. A quarter model was used due to symmetry of the sample and the indenter head. The metallic indenter head was treated as a rigid body, and a clamped boundary condition was prescribed at the bottom of the sample. The rigid indenter head was meshed with 23,600 R3D4 elements, while the quarter sample was meshed with 39,312 C3D4H elements. The friction coefficient between the indenter head and the sample was set to 0.5.

Parameter estimation was performed based on an inverse FE modeling approach by minimizing the objective function below:

$$f_{obj}(\mu,\zeta,\phi) = \left[\frac{1}{2}\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(F_{FE}^{i} - F_{exp}^{i}\right)^2}\right]_{0-deg} + \left[\frac{1}{2}\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(F_{FE}^{i} - F_{exp}^{i}\right)^2}\right]_{90-deg}, \quad (2)$$

where n=25 is the total number of indentation incremental steps, F_{FE}^{i} and F_{exp}^{i} are the predicted and experimentally measured indentation forces at increment i, respectively.

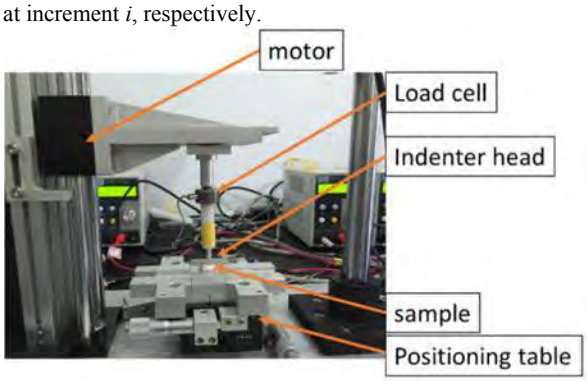

Figure 1. The custom-built asymmetric indentation device used to characterize white matter in large strain.

RESULTS

A representative force-displacement curve from the experiments is shown in Fig. 2. The average indentation stiffness for 0-deg testing configuration was 72.9 mN/mm, whereas the average indentation stiffness of 170.5 mN/mm was obtained for 90-deg testing configuration. A student *t*-test indicates a significant difference of indentation stiffness between the two testing configurations (p<0.001).

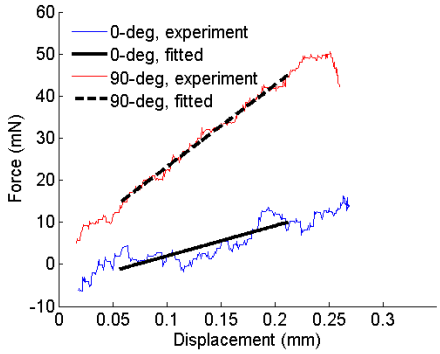

Figure 2. Measured and fitted force-displacement relationships of asymmetric indentation of the white matter.

Estimated parameters based on the inverse FE modeling are μ=0.15 kPa, ζ=3.84, ϕ=0.6 with f_{obj}=0.104. Numerical simulations of the indentation processes showed that the stress and deformation concentrated at the indenter-sample interaction region (Fig. 3).

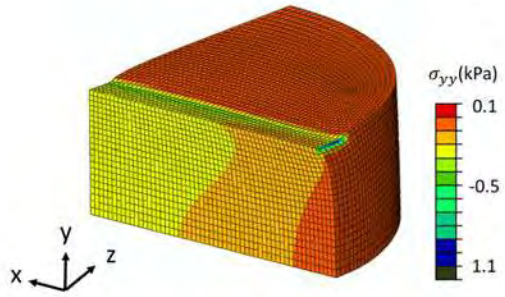

Figure 3 Predicted Cauchy stress component σ_{yy} from the FE simulation of 90-deg indentation.

DISCUSSION

The quantified indentation stiffness and the difference between the two testing configurations indicated a strong anisotropy of white matter tissue. This anisotropic property of porcine white matter in large strain regime agrees with the findings from indentation of lamb white matter in small strain regime [1].

This study characterized white matter tissue under large deformation, which is different from the previous study [1] and other indentation-based brain tissue characterization [3]. Under 10% indentation, we noticed that the indentation relationships were similar to those of 5% indentation strain. Moreover, a linear behavior during the indentation process was still observed. This linear behavior of white matter during the indentation process provides useful indications for brain tissue modeling in transit state.

We have demonstrated that with asymmetric indentation as a single experimental technique, the hyperelatic model parameters of the white matter can be estimated using an inverse FE modeling approach. Although, the characterization procedure in this work was limited to the elastic domain, where viscoelastic effect was not considered, the proposed techniques and acquired data will serve as a logical first step towards a complete characterization of white matter tissue and other transversely isotropic soft tissues.

INTRODUCTION

Modeling ventricle active contraction based on in vivo data is extremely challenging because of complex ventricle geometry, dynamic heart motion and active contraction and relaxation where the reference geometry (zero-stress geometry) changes constantly in a cardiac cycle. From mechanical point of view, zero-stress ventricle geometry information is required for its stress/strain calculations. Considerable progress in ventricle modeling has been made in recent years and excellent reviews are given by [1, 2]. Pezzuto and Ambrosi focus on the contraction of the left ventricle in a finite elasticity framework, adopting the "prolate ellipsoid" geometry and the invariants-based strain energy proposed by Holzapfel and Ogden [3]. In our previous papers, patient-specific Echo-based left ventricle (LV) models were introduced to quantify differences in morphology, mechanics and biology between patients with myocardial infarction and healthy volunteers [4, 5].

Active contraction is caused by sarcomere shortening which leads to increased strain and stress (called active strain and stress). At the beginning of active contraction, the zero-stress sarcomere length is shortened in a very short time duration while ventricle volume has no change, so in vivo sarcomere length does not change, which leads to ventricle strain and stress increases, equivalent to the active tension in models in [1, 2] for the stress part. Due to sarcomere shortening, zero-load ventricle systole geometry is smaller than its zero-load diastole geometry. A new modeling approach using two different zero-load geometries (diastole and systole) was introduced in this paper (called 2G model thereafter) to properly model active contraction and relaxation and provide ventricle diastole and systole material parameter values, stress and strain calculations based on their respective zero-load geometries.

3D ECHO DATA ACQUISITION, MODELS AND METHODS

Echo image data were acquired from 5 healthy volunteers. Details of the data acquisition procedures were described in [4]. The ventricle material was assumed to be hyperelastic, anisotropic, nearly-incompressible and homogeneous. As patient-specific fiber orientation data was not available from these patients, we chose to construct a two-layer LV model and set fiber orientation angles using fiber angles given in [2]. Modeling active LV contraction and relaxation is very difficult, Material stiffening and softening were achieved by adjusting parameter values at each Echo-time step (28 Echo frames per cycle) to simulate active contraction and expansion and match LV volume data. The least-squares method was used to find the equivalent Young's moduli (YM) for the material curves for easy comparison.

In our model construction process, an iterative pre-shrink process was applied to the in vivo minimum volume ventricular geometry to obtain the two zero-load geometries so that when in vivo pressure was applied, the ventricle would regain its in vivo geometry. To get the zero-load diastole geometry, we start with a 4% shrinkage, construct the model, and apply the minimum pressure to see if the pressurized LV volume matches the Echo data. If not, we adjust the shrinkage, re-made the model, pressurize it and check again. The process is repeated until LV volume matches Echo volume with error < 0.5%. For the zero-load systole geometry, assuming a 10-15% sarcomere shortening, we start with a 14% shrinkage. Different shrinkage rates were used for LV inner and outer surfaces so that mass conservation law was enforced. The same process was repeated until the pressurized LV volume under end-systole pressure matched the Echo-measured end-systole volume data. The anisotropic LV computational models were constructed for the 5 patients and the models were solved by ADINA (ADINA R&D, Watertown, MA, USA) using unstructured finite elements and the Newton-Raphson iteration method.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Maximum principal stress (Stress-P_1) and strain (Strain-P_1) were used for analysis and referred to as stress and strain. For each 3D Echo data set (11 slices), ventricular wall thickness (WT), circumferential curvature (C-cur), longitudinal curvature (L-cur), and stress/strain were calculated at all nodal points (100 points/slice). The "slice" values of those parameters were obtained by taking averages of those quantities over the 100 points for each slice and saved for analysis. Pairwise T-test and Linear Mixed Effect (LME) model were used to determine if the differences from the new and old models were statistically significant with the dependence of the pair-wise observations the clustering effects taking into consideration [6].

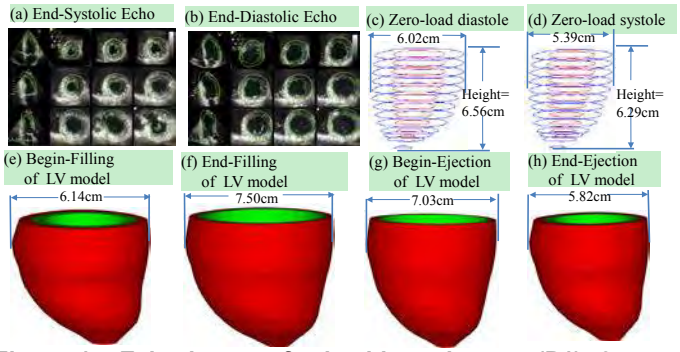

Figure 1: Echo image of a healthy volunteer (P1), 2-zero-load geometries, and the reconstructed 3D geometry.

RESULTS

Our results showed significant differences between the 1G and 2G models. For the 1G model, results at begin-filling (BF) and begin-ejection (BE) corresponding to minimum and maximum pressure and RV volume were obtained for comparison. For the 2G model, results at begin-filling (BF), end-filling (EF), begin-ejection (BE), and end-ejection (EE) were obtained for comparison. The traditional peak-systole, end-systole, end-diastole, and begin-diastole conditions correspond to our begin-ejection, end-ejection, end-filling, and begin-filling, respectively. They may be used interchangeably as needed.

Using the mean values of 1G models as the baseline values, at begin-filling, the mean YM value for the fiber direction (YM_f) from 2G model was 82% stiffer than that from the 1G model (342.33 kPa vs. 621.39 kPa). At begin-ejection, YM_f from 2G model was 54% softer than that from the 1G model (193.47 kPa vs. 86.10 kPa). Further analysis, begin-ejection YM_f was higher 6.8% that its end-filling value (86.10 kPa vs. 75.00 kPa), end-ejection YM_f was higher 70% that its begin-filling value (1056.05 kPa vs. 621.39 kPa). This indicated that the sarcomere length will shorten in isovolumic contraction and the sarcomere length will expand in isovolumic relaxation.

When comparing other parameters, the overall results indicated that peak-systolic (begin-systole from our model) stress from the 2G model was 39% higher than that from the 1G model (349.79 kPa vs. 251.23 kPa). The begin-diastole stress values from the two models were about the same (2.2748 kPa vs. 2.8165 kPa, 5% difference). Peak-systolic strain from the 2G model was 17% higher than that from the 1G model (1.0268 vs. 0.8812). The begin-diastole strain value from the 2G model was 117% lower than that from 1G model (0.0530 vs. 0.1149). Begin-diastole WT from the 2G model was 12% higher than that from the 1G model (1.1145 cm vs. 1.2059 cm). The Peak-systolic WT value from the 2G model was 11% lower than that from 1G model (0.7175 cm vs. 0.7952 cm). Peak-systolic C-cur and L-cur from the two models were about the same (0.6245 1/cm and 0.2794 1/cm vs. 0.6178 1/cm and 0.2931 1/cm, 1% and 4.9% difference respectively). The begin-diastole C-cur and L-cur from the two models were about the same (0.8971 1/cm and 0.3445 1/cm vs. 0.9042 1/cm and 0.3337 1/cm, 0.8% and 3% difference respectively).

DISCUSSION AND CONCLUSION

Ventricle remodeling, disease development, tissue regeneration, patient recovery after surgery and many other cell activities are closely associated with ventricle mechanical conditions. The 2-geometry modeling approach is setting up the right stage for diastole and systole stress/strain calculations using proper zero-load geometries. It should be noted that direct measurements of stress, strain, and sarcomere length are either extremely difficult or even impossible. Data from the literature or from ex vivo experiments (such as fiber orientation, sarcomere length contraction rate) have to be used to complete the computational models. In our previous study [5], we put forward a modeling approach to estimate in vivo ventricles material properties. At this point, the modeling approach was used investigate material property changes in a cardiac cycle, including diastole, isovolumic contraction, systole and isovolumic relaxation four phases.

INTRODUCTION

Pulmonary embolism is a common disease (annual incidence rate of approximately 1 per 1,000 [1]) that occurs when an embolus travels from the legs into the pulmonary arteries and occludes blood flow to the lungs. The disease is traditionally treated using anticoagulation therapy. When anticoagulants are ineffective or contraindicated, an inferior vena cava (IVC) filter may instead be placed to serve as a mechanical barrier to embolus passage. However, despite years of innovation, IVC filters still fail to capture all hazardous emboli [2].

Computational fluid dynamics (CFD) has been used previously to model the migration of arterial (e.g., [3-7]) and venous (e.g., [8]) emboli. Most computational models use empirical drag laws to calculate the forces on the emboli and are thus only valid for modeling small emboli (i.e., emboli smaller in volume than the volume of the computational cells in the discretized fluid domain). More advanced models have also been developed that resolve the fluid-structure interactions between the blood and rigid [8] or even deforming [7] emboli using the arbitrary Lagrangian-Eulerian method. However, these models, particularly those considering embolus deformation, are computationally expensive and are currently impractical for evaluating large numbers of emboli trajectories.

We have developed a novel model of embolus migration that uses a coupled fictitious domain/discrete element method (FD/DEM) [9, 10] to balance computational cost with computational accuracy. The model uses a single Eulerian mesh to simulate fluid-structure interactions between blood and the emboli, thus reducing the computational cost in comparison with other methods that require either dynamic mesh motion or remeshing of the fluid domain at each time step. Using this model, we simulate the migration and capture of rigid, spherical emboli in the IVC, and predict the embolus trapping efficiency of an IVC filter for emboli of various sizes and densities.

METHODS

The human IVC was modeled as a straight, cylindrical tube with rigid walls and a diameter of one inch (Fig. 1). Virtual placement of an IVC filter (G2 Express, Bard Peripheral Vascular, Tempe AZ) was simulated in the idealized IVC using our previously developed computational workflow [11]. Emboli were modeled as rigid spheres with diameters ranging from 3 to 7 mm in increments of 1 mm and embolus-to-blood density ratios of $\rho_p/\rho_f = 0.98$ (buoyant), $\rho_p/\rho_f = 1$ (neutrally-buoyant), and $\rho_p/\rho_f = 1.02$ (physiological; [12]).

A series of 128 simulations was performed for each combination of embolus diameter and embolus-to-blood density ratio, yielding a total of 1,920 simulations (5 x 3 x 128). For each of the independent simulations performed, the embolus starting position was randomized in a 30° slice of the IVC lumen to take advantage of symmetry (Fig. 1a). The initial velocity of each embolus was set to the corresponding velocity of the flow at the embolus starting position (Fig. 1b). For each set of 128 simulations, the trapping efficiency was calculated as the number of emboli trapped in the IVC filter divided by the total number of emboli simulated. An embolus was considered trapped if the embolus velocity decreased to below one micron per second.

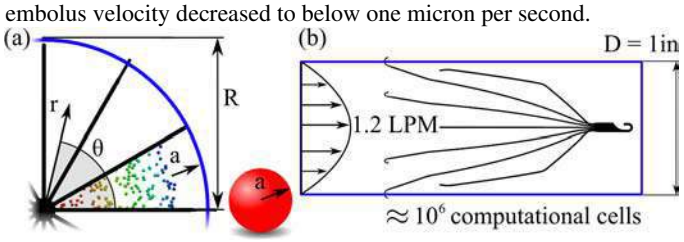

Figure 1: (a) Cross-sectional view of the IVC and placed IVC filter showing the starting positions for the virtual emboli. (b) Computational domain for the embolus migration simulations.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Steady, fully developed flow was specified at the inlet of the IVC at a flow rate of 1.2 LPM (Fig. 2b), corresponding to an average resting flow in the IVC [13]. Blood was modeled as a Newtonian fluid with a density of 1060 kg/m^3 and a viscosity of 3.5 cP. Gravitational effects were considered, with the gravity vector oriented opposite to the direction of the flow (i.e., representative of a patient standing upright). The presence of the IVC filter was modeled in the DEM to account for collisions between the emboli and the IVC filter. However, because preliminary CFD simulations showed that the IVC filter only had a negligible effect on the upstream flow, the presence of the IVC filter was not included in the flow solution for simplicity.

Embolus migration simulations were performed by solving the Navier–Stokes and Newton–Euler equations in a coupled fashion using a modified version of the resolved FD/DEM solver developed by Hager et al. [10]. This solver has been extensively validated against benchmark experimental data [10]. However, the original solver [10] considered only the translational motion of the spheres, neglecting rotational effects. Previous literature (e.g., [14]) has shown that rotational effects contribute to the migration of spheres across streamlines in shear flow, which may be important for accurately predicting embolus trajectories. Therefore, we modified the solver to include rotational effects (i.e., six degrees of freedom) by calculating the fluid-induced moments on the spheres and solving the equations for the conservation of angular momentum in the DEM solver.

RESULTS

Emboli are transported downstream with the flow and either pass through gaps in the IVC filter struts or are brought to rest and captured by the IVC filter. When an embolus is captured, a wake develops downstream of the trapped embolus (e.g., Fig. 2a). The volume of the wake increases with increasing embolus diameter.

Cross-streamline migration of the emboli occurs for all embolus sizes and all embolus-to-blood density ratios (e.g., Fig. 2b). Dense emboli ($\rho_p/\rho_f = 1.02$) migrate towards the centerline of the vessel, buoyant emboli ($\rho_p/\rho_f = 0.98$) migrate towards the vein wall, and neutrally buoyant emboli ($\rho_p/\rho_f = 1$) migrate towards an equilibrium position between the vessel centerline and the vein wall (≈0.6R).

Multiple embolus trapping locations are observed in the IVC filter (Fig. 2c). Emboli travelling near the vessel centerline are trapped in the center of the vessel lumen near the apex of the IVC filter. Other emboli are trapped either between two of the inner filter struts (i.e., the struts with hooks) or between two of the outer filter struts and one of the inner filter struts (Fig. 2c). Trapping locations shift upstream with increasing embolus diameter (Fig. 2c).

The embolus trapping efficiency of the IVC filter increases with increasing embolus diameter and density ratio (Fig. 2d). The embolus trapping efficiency reaches 100% for all embolus diameters when considering emboli with a density greater than that of blood due to the cross-streamline migration of the emboli towards the vessel centerline and the subsequent capture of the emboli at the filter apex (Fig. 2d).

DISCUSSION

Our simulations predict that the embolus-to-blood density ratio has a strong influence on embolus trajectories and the IVC filter trapping efficiency (Fig. 2d). Emboli that are denser than blood migrate towards the center of the vessel lumen, where capture is more likely to occur, while emboli that are buoyant migrate away from the center of the vessel lumen, where the gaps between the filter struts are larger and, thus, capture is less likely to occur. Previous studies of arterial blood flow (e.g., [6, 7]) have also predicted that embolus trajectories are sensitive to embolus density.

The simulations also predict multiple embolus trapping locations

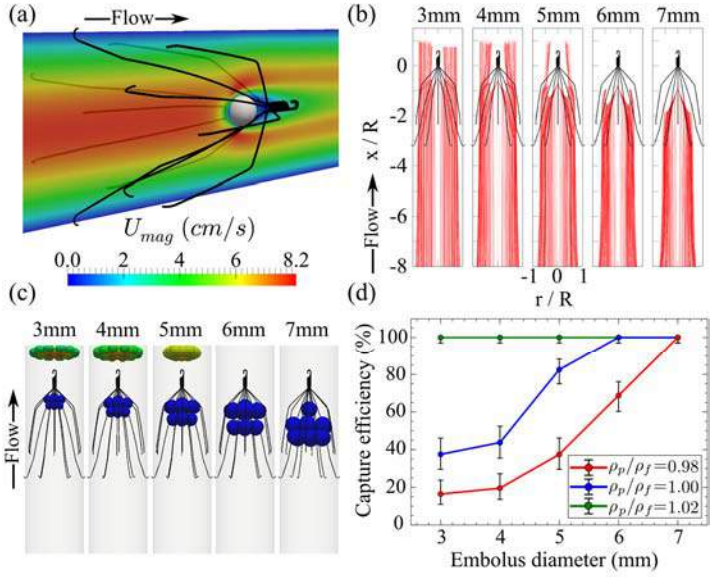

Figure 2: (a) Velocity magnitude contours for an example case with a 5mm embolus. (b) Trajectories for neutrally buoyant emboli. (c) Predicted trapping positions for neutrally buoyant emboli. (d) Predicted embolus trapping efficiencies for the filter.

for the IVC filter (Fig. 2c). Some studies have speculated that near-wall embolus trapping locations may increase the risk for intimal hyperplasia (e.g., [15]). Our model is the first that can predict embolus trapping locations and the subsequent IVC hemodynamics.

Some limitations should be noted. Emboli were modeled as rigid and spherical, while real emboli are compliant and usually cylindrical in shape. Thus, the IVC filter trapping efficiencies predicted in these simulations should be interpreted with care. However, spherical emboli likely represent the worst-case scenario for embolus capture, and therefore, merit study.

Furthermore, the simulations predict that 100% of the dense emboli are trapped in the IVC filter (Fig. 2d) due to their cross-streamline migration. We believe this result is due to the use of an idealized IVC geometry and a nominally placed IVC filter. Future simulations will consider patient-specific IVC morphology and tilted filter configurations for increased clinical relevance.

INTRODUCTION

An abdominal aortic aneurysm (AAA) is a form of vascular disease causing focal enlargement with about a 5% expansion rate of mean diameters per year [1]. Although the measurement of the maximum diameter provides an important factor for deciding the time of surgical treatment, recent studies suggest that the physician should consider other factors such as morphological changes and the patient with a small aneurysm should be examined with the interval of 6-36 months depending on the size. While advances in biomechanics provide state-of-the-art spatial estimates of mechanical stress distributions of AAAs, there are still limitations in modeling its shape evolution in time and the confidence regions. To date, there is no framework combining of biomechanics and the shape evolution to utilize a series of medical images that would aid physicians in detecting small aneurysms with high risk of rupture. Therefore, we define a problem as follows. Given a series of computer tomography scans (CT scans) of AAAs taken at different times, the model will predict the spatio-temporal evolution of AAAs at arbitrary time.

DATA AND METHODS

We used longitudinal data of 37 CT scan images from 7 different patients and the intervals of scan imaging were recorded. The resolutions of these CT scans are approximately 0.7 mm per pixel. This study was subject to internal review board (IRB) approvals at both Michigan State University and Seoul National University Hospital. Three dimensional (3D) models are reconstructed from CT scans using Mimics (Materialise, Leuven, Belgium) to get the longitudinal models using semi-automatic segmentation. Finally, we sample from the longitudinal models to create point cloud data sets, which are used as the observation to our proposed model.

For this study, we develop to model the spatio-temporal patient-specific geometrical evolution using a purely statistical framework. We adapt the Gaussian process implicit surfaces (GPIS) technique [2] that was originally applied for grasping and robot manipulation. The posterior mean of the GP represents our estimated object, and the posterior variance provides the uncertainty in the estimation.
An implicit surface potential (ISP) field is a continuous function:

$$f_t(\boldsymbol{x}) \begin{cases} = 0 \text{ if } \boldsymbol{x} \text{ is on the surface,} \\ > 0 \text{ if } \boldsymbol{x} \text{ is outside,} \\ < 0 \text{ if } \boldsymbol{x} \text{ is inside,} \end{cases} \quad (1)$$

where $\boldsymbol{x} \in \mathbb{R}^3$ is a coordinates vector in 3D space and t is a time index, i.e., $t \in [0, \infty)$ for a continuous stochastic process. Thus, $f_t(\boldsymbol{x}) = 0$ for all $\boldsymbol{x}$ belongs to the point cloud. The time-varying ISP field can be considered as a Gaussian process. A stochastic process is a Gaussian process if for all the choices $\{t_1, \dots, t_k\}$, the random variables $\{f_{t_1}, \dots, f_{t_k}\}$ are jointly Gaussian. Therefore, given a number of observations, the ISP field at arbitrary time has a predictive conditional Gaussian distribution. The development of the AAA surface can be inferred through the ISP field.

We investigate the implicit surface on a grid that is defined by the discretization of the space. We discretized the 3-D continuous space into n spatial sites $S := \{s^{[1]}, \dots, s^{[n]}\} \in \mathbb{R}^{n \times 3}$, where $n = h(x_{\max} - x_{\min}) \times h(y_{\max} - y_{\min}) \times h(z_{\max} - z_{\min})$. h is chosen such that n is a positive integer. The spatial limitations are determined from the training data set. The collection of the realized values of the ISP on the lattice is denoted as $z := (z^{[1]}, \dots, z^{[n]})^T$, where $z^{[i]} := z(s^{[i]})$. We make inference on the ISP field as a Gaussian process, i.e., $z \sim GP(\mu(\boldsymbol{x}, t), K(\boldsymbol{x}, t, \boldsymbol{x}', t'))$, where $\mu(.)$ and $K(.,.)$ are the mean and covariance functions. An example of an ISP field in 2-D space is shown in Figure 1. The boundary of the 2-D object will be a

closed contour in a plane. In particular, let the object be a disk with the radius of 2 and centers at (0, 0). Figure 1 shows the observations z from the locations that belong to the object's surface (black circles), inside the object (black crosses), and outside the object (black diamonds). Locations at which the ISP field values set zero are considered to be on-surface.

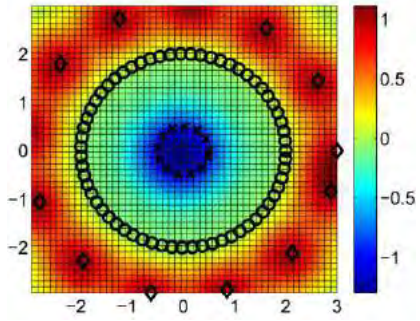

Figure 1. Example of an implicit surface for a 2-D object.

RESULTS

We use all the available scans from a patient *except* the most recent one as the training data, and run our prediction model on the date of the last scan to evaluate our method. Then, we compare the predicted results with the real scan. Figure 2 shows a 3D reconstruction using the PCL package [3] based on the real and the estimated point cloud from our proposed method. Figure 2 (b) shows the lattice with all the off-surface points are filtered out.

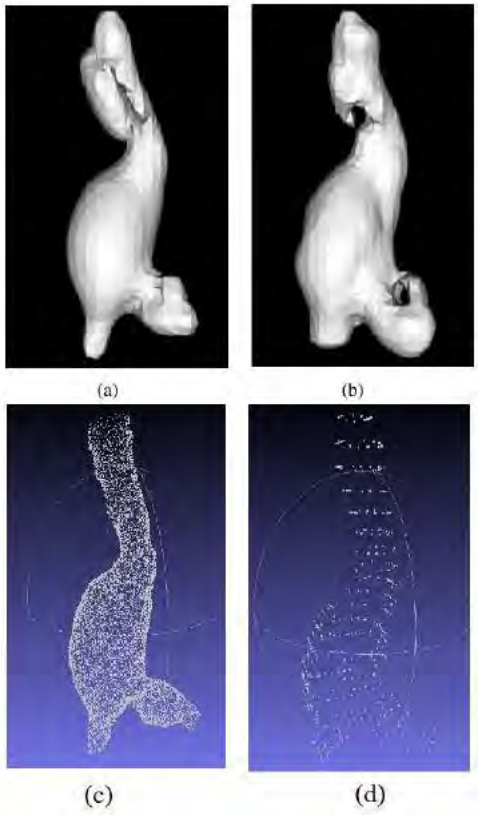

Figure 2. 3D reconstruction of (a) true and (b) estimated AAA surface using (c) true and (d) estimated point clouds.

One of the merits of our approach is that it provides the uncertainty in its prediction. In order to compute the confidence region, we generate the ISP fields on the grid by sampling from the multivariate Gaussian distribution with the posterior mean vector and covariance matrix in a Monte Carlo (MC) simulation with 100 runs. Then, we estimate 100 AAA surfaces that are corresponding to the realized ISP fields. With a sufficient number of MC runs, the set of surfaces forms the confidence region of the prediction. Each realization of the AAA surface from the posterior distribution is plotted with 2% occupancy in Figure 3. Therefore, spatial regions that appear brighter imply higher reliability of the prediction. The true point clouds are plotted in red dots. As shown in Figure 3, the confidence region covers the majority of the real AAA.

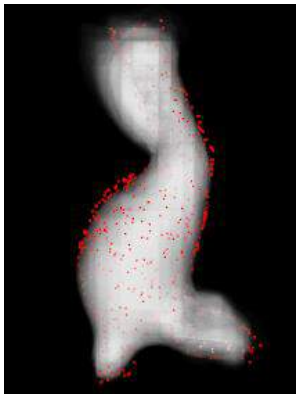

Figure 3. Confidence region: the real point cloud is plotted in red dots.

DISCUSSION

The goal of this paper is to provide a data-driven, nonparametric statistical framework using patient-specific data for improving the prediction results for aneurysm growth, hence assisting clinical management planning. The results of the case study showed excellent performance of our algorithms when they are compared to the true CT scan images.

To the best of our knowledge, this is the first study that predicts the AAA growth using available (patient-specific) CT scan data in a statistical perspective allowing uncertainty quantification in the prediction.

INTRODUCTION

The bicuspid aortic valve (BAV) is a valvular defect present in 1-2% of the general population. As compared to the normal tricuspid aortic valve (TAV) which consists of three leaflets, the most prevalent type-I BAV is characterized by one regularly sized leaflet and one larger leaflet. While 71% of type-I BAVs result from the fusion between the left- and right-coronary leaflets (LR subtype), 15% feature right- and non-coronary cusp fusion (RN subtype) and 3% present with non- and left-coronary cusp fusion (NL subtype). As compared to TAV patients, BAV patients have a much higher risk of developing secondary aortopathies such as aortic dilation. In addition, the particular leaflet fusion type affects the expression of dilation and thinning of the ascending aorta (AA) downstream of a BAV. While BAV aortopathy has been historically linked to a genetic predisposition, the abnormal BAV hemodynamics has emerged as a potential coincident etiology. Recent studies have revealed the existence of correlations between the locations of abnormalities in flow skewness, asymmetry, helicity and wall shear stress (WSS) in dilated BAV aortas and the sites of aortopathy development. However, the use of those metrics as predictors of disease initiation prior to dilation has not been thoroughly evaluated. Therefore, the objective of this study is to assess computationally the prognostic value of these hemodynamic parameters for BAV aortopathy, prior to dilation.

METHODS

Unified valve-aorta geometry: A realistic three-dimensional unified valve-aorta geometry was designed in SolidWorks 2014 (Dassault Systemes, Inc) and consisted of the aortic root and the aorta (**Fig. 1**). The non-dilated aorta geometry was created based on a series of computed tomography images of a human aorta. The aorta geometry included the ascending aorta and the aortic arch along with brachiocephalic (BCA), left common carotid (LCCA) and left subclavian (LSCA) arteries. Consistent with our previous valve models[1], the TAV geometry consisted of three identical leaflets attached to the root of the aortic sinus. Dimensional parameters for the aortic sinus and leaflets were obtained from published human aortic valve data. The LR-BAV was characterized by the presence of a normal non-coronary leaflet and a larger leaflet mimicking the two fused coronary leaflets. Consistent with previous morphologic studies, the non-coronary leaflet and the corresponding sinus occupied a circumferential span of 150°. The left- and right-coronary leaflets were assumed to be identical and the raphe was placed along the free edge of these two leaflets. The RN-BAV and NL-BAV anatomies were obtained by rotating the LR-BAV by 120° and 240°, respectively, with respect to the aortic root.

Material: The leaflet material was modeled as hyperelastic using a three-parameter incompressible Mooney-Rivlin model. This material model has been used successfully in a previous study to simulate physiologic hemodynamics through the aortic valve[1]. The aortic wall was approximated as a linear, elastic and isotropic material (elastic modulus: 2 MPa; Poisson's ratio: 0.45)[2]. Blood was modeled as an incompressible, homogeneous and Newtonian fluid (density: 1050 kg/m^3; dynamic viscosity: 0.0035 Pa·s).

Boundary conditions: Flow boundary conditions consisted of a physiologic ventricular pressure waveform varying between 0 and 130 mmHg at the inlet of the fluid domain and physiologic pressure waveforms at the four outlets of the aorta (BCA, LCCA, LSCA and descending aorta). The aortic wall was constrained in the axial direction at the inlet and outlet sections but was allowed to move in the radial and circumferential directions.

Hemodynamic characterization: Flow eccentricity was quantified in terms of the flow displacement (d) at the proximal and middle AA, which represents the radial distance between the center of the slice and the centroid of the region containing the top 15% of velocities at peak systole (**Fig. 2A**). Flow skewness was assessed in terms of the systolic flow angle (θ) between the net systolic flow velocity vector and the normal vector to the slice (**Fig. 2B**). Flow helicity was characterized in terms of the peak-systolic in-plane vorticity and positive helix fraction (PHF) defined as the ratio between right-handed helix and the totality of the rotating flux (**Fig. 2C**). The local magnitude and temporal characteristics of the longitudinal WSS (**Fig. 2D**) were assessed in terms of the temporal shear magnitude (TSM),

$$\mathrm{TSM} = \frac{1}{T}\int_0^T |\tau| dt \,,$$

and the oscillatory shear index (OSI),

$$\mathrm{OSI} = \frac{1}{2}\left[1 - \left(\left|\int_0^T \tau dt\right| \Big/ \int_0^T |\tau| dt\right)\right].$$

The TSM represents the time-averaged magnitude of WSS along the circumference of a slice over one cardiac cycle. The OSI characterizes the oscillatory nature or the directionality of WSS (OSI=0: purely unidirectional/pulsatile WSS; OSI=0.5: purely bidirectional/oscillatory WSS).

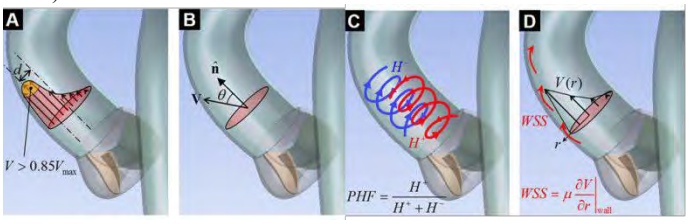

Figure 2: flow parameters: (A) flow displacement; (B) flow angle; (C) PHF; (D) WSS

RESULTS

Flow helicity: Flow in the TAV AA was shown to include both right-handed and left-handed helicity without a dominant helical flow pattern (PHF=0.51) (**Figure 3**). In contrast, flow in BAV AAs is mainly characterized by strong righted-handed helicity. Despite limited left-handed vortex near the periphery of the aortic wall, the LR-BAV is dominated by strong right-handed vortex at the anterior region (PHF=0.68). While the RN-BAV (PHF=0.71) and NL-BAV (PHF=0.72) generate vortex distributions qualitatively similar to the LR-BAV, they generate high vorticity over larger regions than those generated by the LR-BAV.

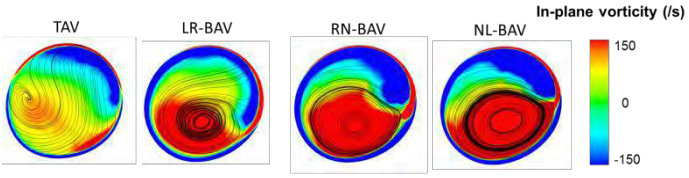

Figure 3: In-plane vorticity and streamlines

Flow eccentricity and skewness: The TAV generates essentially axisymmetric velocity fields in the proximal AA (θ=4.6°; d=1.3 mm). The flow velocity fields in all BAV AAs exhibit a higher degree of eccentricity towards the aortic wall (θ>11.2°; d>4.9 mm). While the flow captured in the middle segment of the TAV AA deviates slightly towards the periphery of the aortic wall due to the wall curvature (θ=5.5°; d=3.3 mm), the velocity fields predicted in all BAV AAs exhibit more skewness (θ>12.1°; d>6.8 mm).

TSM: The RN-BAV generates WSS levels (TSM=15.3 dyn/cm^2) similar to those predicted downstream of the TAV (TSM=15.4 dyn/cm^2) in the proximal AA, but the LR-BAV (TSM=19.9 dyn/cm^2) and RN-BAV (TSM=19.3 dyn/cm^2) AAs are subjected to WSS overloads. In the middle AA, the RN-BAV generates a WSS overload (TSM=19.5 dyn/cm^2) while the LR-BAV and NL-BAV generate sub-physiologic WSS levels (TSM=16.8 and 17.4 dyn/cm^2, respectively) relative to the TAV AA (TSM=18.9 dyn/cm^2).

OSI: While the TAV subjects the proximal AA to a bidirectional WSS distribution (OSI=0.37), the BAVs generate more pulsatile WSS environments (OSI<0.19). In the middle AA, while the TAV AA (OSI=0.17), RN-BAV AA (OSI=0.13) and NL-BAV AA (OSI=0.13) remain exposed to a relatively unidirectional WSS, the LR-BAV AA experiences a more oscillatory WSS (OSI=0.24).

DISCUSSION

This study reveals that the BAV generates abnormal aorta hemodynamics characterized by increased flow helicity, flow angle, flow displacement and disturbed regional WSS. These hemodynamic abnormalities are dependent on the valve cusp fusion and correlate with the sites on the aortic wall reported as vulnerable to dilation. Our results show that global flow metrics (i.e., PHF, flow angle and flow displacement) considered in past clinical measurements may not be sensitive enough to identify BAV patients and predict disease progression prior to dilation. Instead, WSS metrics (i.e., TSM and OSI) which are more challenging to measure by MRI, seem to exhibit superior predictive capabilities and to be better risk assessment markers for BAV aortopathy, prior to dilation and regardless of the BAV morphotype. These WSS metrics may be important in the development of new treatment strategies for monitoring and normalizing BAV flow in young patients prior to aortic dilation.

COMPUTATIONAL MODELING OF THE ARTERIAL WALL BASED ON LAYER-SPECIFIC HISTOLOGICAL DATA

T. Jin, I. Stanciulescu

Civil and Environmental Engineering
Rice University
Houston, TX 77005, USA

INTRODUCTION

Understanding the structure-function relationship of individual arterial wall layers provides insight into the pathophysiology of arterial wall diseases such as arteriosclerosis, allows for better predictions for the outcome of interventional treatments such as balloon angioplasty (Holzapfel et al., 2002), and advances various biomedical applications such as artificial heart valve (Durst et al., 2011; Hasan et al., 2014).

Uniaxial (in vitro) tension tests are widely used to study the mechanical behavior of different arterial wall layers. However, these tests are not sufficient for the construction of multi-dimensional models to predict the material behavior in physiological loading states. Conducting experiments that closely mimic the in vivo loading state would provide more valuable information, but such experiments often put higher demands on the equipment and human skills. On the other hand, developing numerical strategies involving layer-specific histological information may provide an effective and inexpensive choice to study the material behavior of different arterial wall layers under complex loading conditions.

In this work, we present two different constitutive modeling approaches for arterial walls, the embedded fiber (EF) approach belonging to the detailed modeling strategy and the angular integration (AI) approach belonging to the homogenized modeling strategy, to simulate the anisotropic behavior of individual arterial wall layers using layer-specific histological data. Both approaches take into consideration the influence of fiber dispersion introduced by fiber angular distribution (departure of individual fibers from the mean orientation) and fiber waviness. Through a comprehensive parametric study, we establish relationships between the phenomenological parameters used in the AI approach and those used in the EF approach that have straightforward physical meanings. These relationships are helpful to form a better understanding of the connection between the microscopic structure and the macro-mechanical functions of different arterial wall layers.

METHODS

Arterial walls are typically composed of three different layers in the thickness direction: intima, media and adventitia. Although each layer has different histological structure, they all can be modeled as fiber-reinforced materials with two families of collagenous fiber bundles symmetrically arranged in an isotropic soft ground matrix (Holzapfel et al., 2000; Holzapfel, 2006).

In the embedded fiber (EF) approach, a random walk algorithm (Spanos and Esteva, 2009; Jin and Stanciulescu, 2015) is implemented to generate the fiber microscopic arrangement. The fiber dispersion has two different causes, departure of individual fibers from the mean orientation measured by the initial angle and the fiber waviness represented by the relative angle. In order to directly incorporate the generated fiber microscopic structure into the numerical simulation, the embedded fiber approach is adopted. This approach assumes that fibers are embedded in the ground matrix and the two material components deform together, thus is essentially equivalent to the affine fiber kinematics (Lanir, 1983; MacKintosh et al., 1995; Agoram and Barocas, 2001; Storm et al., 2005). Figure 1 shows a rectangular arterial wall layer sample with two families of fibers synthetically generated by the random walk algorithm.

The angular integration (AI) approach follows a homogenization methodology that smears the two families of fibers into the ground matrix and treats the material as homogeneous. In the finite element formulation, the anisotropy introduced by fibers is considered at the constitutive level. The total strain energy is decoupled into two parts, the isotropic part representing the contribution from the ground matrix enhanced by the anisotropic terms representing the contributions from

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the two families of fibers. The fiber dispersion caused by departure of individual fibers from the mean orientation is considered by the Von Mises parameter, and the dispersion caused by fiber waviness is considered in this approach by introducing a correction term. The finite element formulation captures the anisotropy at the constitutive level with several phenomenological material parameters.

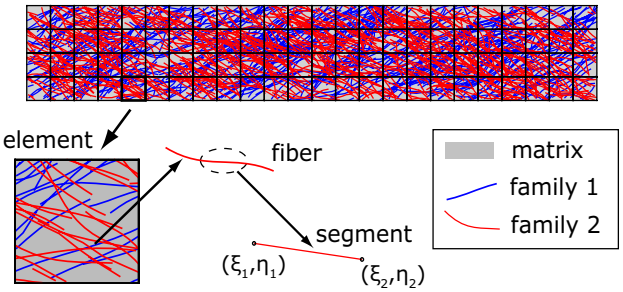

Figure 1: Synthetically generated arterial wall layer sample meshed with four-node quad element

RESULTS

Figure 2 shows the distribution of the generated initial angle of fibers in the intima layer and the resulted geometry of the two families of fibers generated by the random walk algorithm. Figures 3 and 4 show the comparison between the experimental data and the simulation results based on the AI and EF approaches. For both methods, the simulation results match the experimental data very well. Figure 5 shows the relationship between the parameters reflecting the fiber waviness in the EF and AI approaches.

DISCUSSION

In this paper we present two different modeling approaches, the embedded fiber (EF) approach and the angular integration (AI) approach, to simulate the anisotropic behavior of individual arterial wall layers using layer-specific histological data. Both approaches include the influence of fiber dispersion caused by fiber angular distribution (departure of individual fibers from the mean orientation), and take into consideration the dispersion caused by fiber waviness, which has not been previously considered. By comparing the numerical results with published experimental data of different layers of a human abdominal aorta, we show that both approaches can successfully capture the material nonlinearity and anisotropy. Furthermore, we establish the relationships between the AI phenomenological parameters and the EF parameters having straightforward geometrical or mechanical interpretations. Through a comprehensive parametric study, we demonstrate the validity and accuracy of these relationships. This study provides valuable insight for the calibration of phenomenological parameters used in the homogenized modeling taking into account the material microscopic arrangement. Moreover, it can facilitate a better understanding of individual arterial wall layers, which will eventually advance the study of the structure-function relationship of the whole arterial wall.

MESO-SCALE REORGANIZATION OF METABOLIC BRAIN NETWORKS IS ASSOCIATED WITH PERSISTENT TMJ PAIN

INTRODUCTION

Chronic pain affects over 100 million adults in the US with annual costs of $560-635 [1]. Temporomandibular joint (TMJ) disease is a common musculoskeletal disorder, second only to low back pain [2]. Osteoarthritis (OA) is the most common TMJ pathology; this low-grade inflammatory condition in the TMJ synovium has a complex and multifactorial etiology including pain [3]. In most patients TMJ pain resolves without needing further clinical action. Yet, for a subset of patients, chronic TMJ disorder develops, with physical, psychological, and pain symptoms [4]. The transition to chronic pain is due to sustained hyperexcitability in the central nervous system (CNS) that amplifies nociceptive signals from peripheral sources, increases spontaneous activity, and reduces activation thresholds, which can lead to changes in the spinal cord and brain circuitry [5].

Since the neuroplastic changes in the CNS vary in magnitude and regionally, complex network analysis is useful to begin to understand how such changes may relate to pain [6]. In fact, functional brain networks exhibit modified circuit connectivity during the transition to chronic neuropathic pain [7]. Limbic system circuitry changes have been noted with chronic pain after spared nerve injury in the rat, with increased connectivity *within* the limbic system, as well as between the limbic and sensorimotor regions [7]. Yet, little is known about the extent and time course of brain remodeling in *osteoarthritic* pain.

This study investigated the relationship between TMJ pain and the neuron-specific brain networks using acute/resolving and persistent pain models of TMJ pain [8]. Positron emission tomography (PET) imaging was used to investigate the global topological features of metabolic brain networks when pain is present. The structure of brain networks was also examined using community detection to investigate brain networks in the context of the different pain outcomes – persistent or acute/resolving pain.

METHODS

All procedures were IACUC-approved and used female Holtzman rats. TMJ OA was induced by separate magnitudes of mouth-opening load to induce pain that resolves within 7 days after loading (2N; n=7) or persistent pain after loading (3.5N; n=7) [8]. Steady mouth-opening was imposed daily for 60mins on 7 consecutive days under inhalation isoflurane anesthesia. Orofacial pain was measured during and after loading using von Frey filaments to quantify a withdrawal threshold as a measure of mechanical hyperalgesia [8]. Differences in pain were detected by a two-way repeated measures ANOVA with Tukey's test.

^{18}F-fludeoxyglucose (FDG)-PET images were acquired at day 0 (baseline) and day 7, which was 1 day after loading cessation for each rat. Prior to each imaging session, rats were anesthetized with isoflurane and ^{18}F-FDG given by a tail vein catheter. Then rats were transitioned to dexmedetomidine (0.075mg/kg) and allowed to rest for 1hr before imaging, providing time for radionuclide distribution. PET images were acquired using a small animal PET scanner, functionally similar to the Philips Mosaic; images were reconstructed and registered to Schwarz's FDG PET-specific stereotaxic rat brain template by Advanced Normalization Tools [9,10]. Image volumes were normalized to the visual cortex, which is an unaffected region.

To evaluate metabolic brain networks, registered PET images were parcellated into anatomic regions using the Schwarz rat brain atlas. Each brain region was represented as a node; edges connecting two nodes were defined by the Pearson correlation coefficient between the average FDG uptake in two brain regions for all rats [11]. All rats were combined to construct baseline and day 7 brain networks since the pain responses are similar in both groups at those days [8].

A variety of topological properties of each network was assessed: the *clustering coefficient* evaluated segregated information transfer, *efficiency* assessed integrative information transfer, *node strength*

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

computed the strength of network interconnectivity, and *modularity* quantified the degree to which the network can be subdivided into distinct groups. Modules were defined as those sets of nodes that are highly inter-connected [12]. Topological features were assessed by the Brain Connectivity Toolbox (BCT) in Matlab [13]. Differences in topological properties were measured with a pairwise t-test between corresponding nodes in each network. Also, changes in the community structure of the networks was estimated using the Louvain algorithm, also with the BCT. Because later pain patterns differ between the 2N and 3.5N groups [8], separate brain networks were also constructed for those groups at day 7; community detection identified changes in the *number* and *composition* of communities between the networks.

RESULTS

The withdrawal threshold significantly decreases ($p<0.001$) from baseline at day 7 for both groups (Fig. 1). Yet, after the rest-period with no loading (at day 14), sensitivity only remains in the 3.5N group ($p<0.001$), but returns to baseline in the 2N group (Fig. 1).

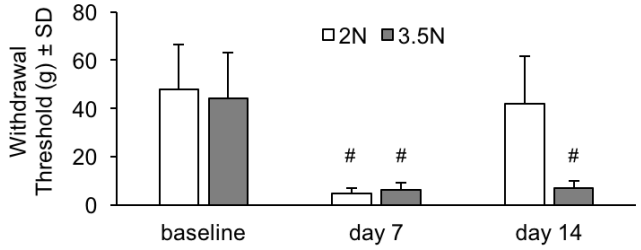

Fig 1. Orofacial sensitivity increases at day 7 (#p<0.001). But it only remains at day 14 in the 3.5N group (#p<0.001).

Evaluating the global topological properties reveals significant increases in the post-loading metabolic network at day 7 compared to baseline ($p<0.001$) for the mean clustering coefficient (0.61±0.05 baseline; 0.71±0.04 day 7), node strength (30.37±3.30 baseline; 34.31±2.82 day 7), and efficiency (0.60±0.05 baseline; 0.69±0.04 day 7). Network modularity significantly decreases ($p<0.0001$) at day 7 (0.050±0.001) from baseline (0.085±0.001). Despite differences in modularity, the networks consistently exhibit 3-modules at both baseline and day 7 (Fig. 2). Although there is consistency between those networks before and after loading, the composition of the subdivisions changes over time (Fig. 2). The sensory regions (somatosensory cortex, medulla, cerebellum) cluster more strongly at day 7 and the affective regions form two smaller subdivisions (Fig. 2).

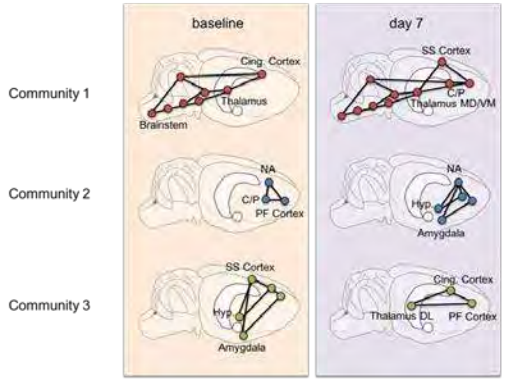

Fig 2. Metabolic network components in the brain reorganize following induction of TMJ OA (SS=somatosensory, NA=nucleus accumbens, Hyp=hypothalamus, C/P=caudate/putamen, PF=pre-frontal, DL=dorsolateral, MD=mediodorsal, VM= ventromedial).

The three-community structure is evident in the correlation network matrices for all rats at both days (Fig. 3). Considering the groups separately at day 7, a change in community structure emerges in the 3.5N group that is not evident in the 2N group (Figs. 1 & 3). The brain network in the 3.5N group shifts to two larger equally-sized communities (Fig. 3), but the 2N group maintains the three-modules.

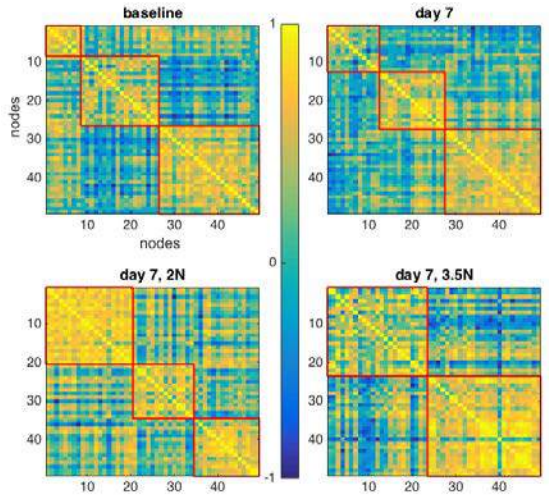

Fig 3. Correlation network matrices at baseline and day 7 show 3 communities (in red). At day 7, only 3.5N has a two-community structure. Color bar shows strength of connectivity (R).

DISCUSSION

This work shows metabolic brain networks are altered in TMJ OA pain and may predict the likelihood of pain becoming chronic (Figs. 1-3). The marked increases in the clustering coefficient, efficiency, and node strength between baseline (no pain) and day 7 (pain in both groups) suggests that select brain regions are becoming more tightly correlated with each other. Although the *global* topological properties used here strongly support brain networks being altered in this pain state, the *local* topological properties that may provide insight into sub-circuit modifications [7], were not evaluated.

Since the community structure is stable for acute pain (2N) but is altered when it persists (3.5N) (Figs. 1 & 3) these metrics may provide a diagnostic for pain prediction. Further, the transition to a two-module community structure in the chronic pain case [8] highlights the increasing correlation across local and remote brain areas, possibly indicating remodeling. This phenomenon is also seen in functional connectivity analyses of a host of clinical pain states [14]. Since we did not use fMRI or dynamic PET, our findings are restricted to correlation networks and did not evaluate functional connectivity. Nonetheless, findings highlight the possibility for networks from metabolic brain imaging to *predict* which cases will develop into persistent pain, which has tremendous clinical utility.

INTRODUCTION

An abdominal aortic aneurysm (AAA) is a pathological dilation of the abdominal aorta, which, if left untreated, will continue to grow and eventually rupture with a mortality rate of up to 90%, making AAAs the 13th leading cause of death in the United States [1]. Endovascular aneurysm repair is a minimally invasive procedure used to treat AAAs in which a stent graft (SG) is packaged in a sheath, delivered through the iliac artery, and unsheathed in the abdominal aorta. During the unsheathing process, SGs can unexpectedly rotate such that their deployed position differs from what was intended. For standard SGs, this rotation is generally a minor issue, which can result in kinking of the limbs or limb deployment on the opposite side to the surgical plan. However, for fenestrated SGs, which have fenestrations (holes) that are to be aligned with the branch vessels (renal arteries, superior mesenteric artery, and/or celiac artery), SG rotation can be a major problem, which can result in branch artery occlusion and potentially renal failure or bowel ischemia if not corrected.

We hypothesize that SG rotation during unsheathing is caused by an accumulation of rotational energy in the SG during delivery through iliac arteries that are tortuous, calcified, and/or stenotic, that is released during the unsheathing. To better understand this phenomenon, the overall goal of our research project is to develop finite element models of the delivery and deployment of standard and fenestrated SGs that take into account these rotational effects. Results from these simulations will be compared to ongoing experimental studies in our lab, in which SGs are delivered and deployed in arterial phantoms, as well as to clinical findings obtained as part of an ongoing prospective clinical study.

To develop models of SG delivery, we need to properly account for the friction between the packaged SG, its sheath, and the iliac artery to ensure accurate calculations of rotational energy accumulation. While a previous study [2] determined coefficients of friction for deployed SGs, there have been no studies that have measured these quantities in undeployed SGs. The objectives of this study were therefore to develop an apparatus to measure frictional forces and use these force measurements to determine the coefficients of friction between i) stents and the inner surface of the sheath (S-Sh$_i$), ii) graft fabric and the inner surface of the sheath (G-Sh$_i$), and iii) the outer surface of the sheath and a mock artery material (Sh$_o$-MA).

METHODS

An experimental apparatus (Fig. 1) was designed and built to measure the friction force between two materials. One material was fixed in position, and the other material was affixed to a moveable sled. A precision mass was affixed to the sled as well to ensure the contact of the two materials and to increase the normal force to a measurable level. The surfaces of both materials were wetted with saline solution to mimic *in vivo* conditions. A load cell was attached to the sled and to a motor via a nylon monofilament. The motor pulled the sled at 1 mm/s and the load cell recorded the frictional force between the two materials.

The SG used for the experiments was a standard Cook Zenith Flex SG (Cook Medical, Bloomington, IN, USA) which was separated into its polyester graft fabric and stainless steel stents by removing the sutures used to attach the stents to the graft fabric. The mock arterial material was chosen to be polyurethane, which was selected as a potential material for arterial phantoms to be used in ongoing SG delivery and deployment experiments. For each material pair (S-Sh$_i$, G-Sh$_i$, and Sh$_o$-MA), 20 trials were performed. To account for anisotropy of the graft fabric and the inner and outer surfaces of the sheath, experiments were conducted in both axial and circumferential directions for the G-Sh$_i$ and Sh$_o$-MA material pairs.

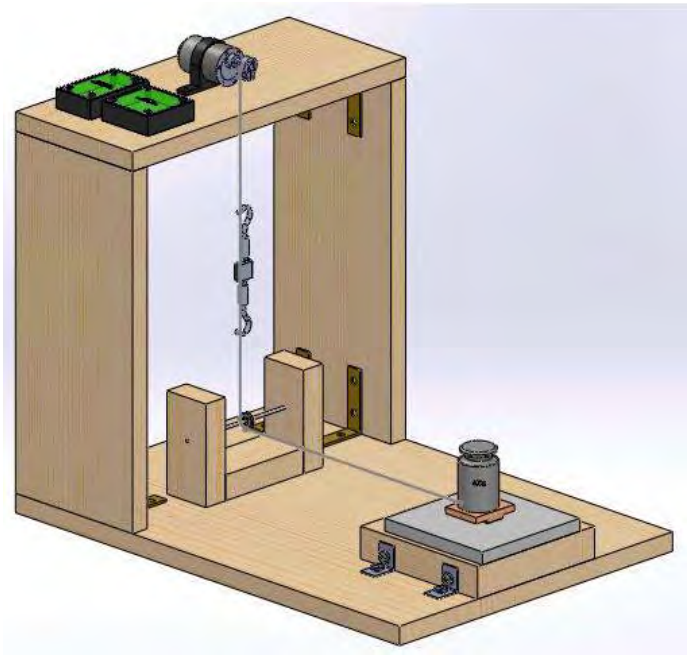

Figure 1: Schematic of experimental apparatus for measurement of friction forces between two materials.

For each material pair, static and kinetic coefficients of friction, μ_s and μ_k respectively, were calculated as

$$\mu_j = \frac{F_j - L}{N}, \quad (1)$$

where F_j ($j = s$ or k) is the average frictional force measured by the load cell, L is the weight of the load cell, and N is the normal force, measured as the weight of the sled assembly. The average static frictional force F_s for each material pair was calculated as the average of the maximum of the first 30-40 sample points for each of the 20 trials. The average kinetic frictional force F_k for each material pair was calculated by firstly averaging each of 120-160 sample points across the 20 trials and then fitting an average horizontal line through the resulting average data in the region following the peak.

RESULTS

Static and kinetic coefficients of frictions for the S-Sh_i, G-Sh_i, and Sh_o-MA material pairs are summarized in Table 1 for both axial and circumferential directions, where applicable. As expected, for all cases μ_s was found to be greater than μ_k. For both the G-Sh_i and Sh_o-MA pairs, the coefficients of friction in the circumferential direction were found to be greater than the corresponding values in the axial direction and in all cases, the differences were found to be statistically significant (p <0.05). The G-Sh_i material pair was found to have the largest coefficients of friction followed by the Sh_o-MA pair and the S-Sh_i pair. However, it should be noted that the values for the Sh_o-MA pair are dependent on the mock artery material used and could vary substantially with different materials.

The apparatus that we built for these experiments yielded consistent results across the 20 trials for each case with standard deviations of less than 14% over all tests. The apparatus is also easily reconfigurable to test different material pairs with different base piece configurations, allowing quick switches between a fixed material with a large surface, such as the mock artery material, to a fixed material with a small surface area, such as the inner surface of the sheath.

Table 1: Coefficients of friction for Cook Zenith Flex stent grafts

	stent-sheath (S-Sh_i)	**graft-sheath (G-Sh_i)**	**sheath-mock artery (Sh_o-MA)**
$\mu_{s,axial}$	0.058±0.0080	0.144±0.069	0.109±0.012
$\mu_{k,axial}$	0.044±0.0038	0.135±0.050	0.091±0.012
$\mu_{s,circumferential}$	--	0.157±0.004*	0.161±0.020*
$\mu_{k,circumferential}$	--	0.145±0.005*	0.131±0.008*

* Indicates statistically significant (p < 0.05) difference between directions.

DISCUSSION

The apparatus and protocols developed for the experiments needed to obtain coefficients of friction can and will be applied to other material pairs. Firstly, we will perform experiments with a material pair consisting of the outer surface of the sheath and porcine aortic tissue, as a surrogate for human iliac and aortic tissue. It is important to determine the coefficients of friction between the sheath and actual arterial tissue to estimate the coefficients of friction in the *in vivo* environment. Ideally, this would be done with human iliac artery tissue; however, the more readily available porcine aortic tissue will act as a reasonable surrogate.

Once we determine estimates of *in vivo* coefficients of friction, we will test a variety of mock artery materials in contact with the outer surface of the sheath to attempt to find one with comparable frictional properties. In parallel with this, we will be testing the mechanical properties of these mock artery materials to find a material that has comparable mechanical properties to those found in aged human iliac arteries as defined in Ref. [3]. We will use the results from these tests to select the optimal material that best matches iliac artery mechanical and frictional properties. By approximating both the mechanical and frictional behavior of human iliac arteries in our mock artery material, our experimental and computational studies will best reflect the *in vivo* environment enabling direct comparisons between experimental, computational, and clinical measurements of SG rotation following delivery through the iliac artery.

In conclusion, an experimental apparatus was designed and constructed to allow for the measurement of the frictional forces between two materials, and these measurements were then used to determine the static and kinetic coefficients of friction between these two materials. We presented coefficients of friction for three material pairs, stainless steel stents and the inner surface of a sheath, polyester stent graft fabric and the inner surface of a sheath, and the outer surface of a sheath and a mock artery material. These coefficients of friction are required for finite element simulations of stent graft delivery and deployment and have not been previously reported.

AUDIO RESPONSE SYSTEM FOR ACTIVE LEARNING IN A LARGE LECTURE CLASS

Craig J. Goergen (1)

(1) Biomedical Engineering
Purdue University
West Lafayette, IN, 47906

INTRODUCTION

Audience response systems allow teachers and students to dynamically interact by posing questions and collecting answers in real-time. This is especially important in large biomedical engineering lecture classes where encouraging active learning and class participation is important but difficult. The purpose of this report was to evaluate the effectiveness of a clicker system designed to improve learning outcomes in a cell biology course specifically designed for engineers with 282 enrolled students.

METHODS

Students enrolled in a Cell Biology course during the fall of 2013 (BIOL 230, Purdue University) were required to have and use an "i>clicker" or clicker as 3% of their overall class grade (Figure 1; [1]). This system requries a 900 MHz base with a 300 foot range for recording responses, customiziable software for displaying anwers (version 6.3), and each student to have their own clicker to answer questions. While short answer questions are possible with this system, only multiple choice questions with five possible answers were used during this class. A total of 282 students were enrolled in the course, the majority of whom were students majoring in biological, biomedical, chemical, and industrial engineering. Responses are reported for 8 lectures, with anywhere between 2 and 12 questions given per class for a total of 36 questions and an average of 4.5±3.4 questions per lecture. Attendance was determined as the maximum number or responses recorded for each lecture.

Figure 1: Both student (left) and instructor (right) versions of the iClicker 2 remotes [1].

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Figure 2: Base needed to collect responses. The system operates at 900 MHz base, has a 300 foot range, and is USB compatible.

RESULTS AND DISCUSSION

The number of students enrolled in the course and average attendance, total responses, and correct responses are displayed in Figure 1 below. Average attendance was 80.8% of total enrollment, a substantial improvement over previous years when clickers were not used. Most students who attended lecture used their clickers consistently to respond to the questions (98.2%). Of these responses, only 62.9% were correct, a rate that we believe challenges the students to think without making answers obvious.

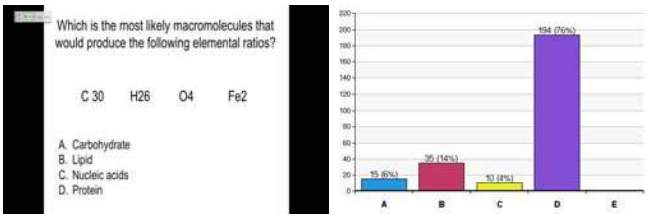

Figure 3: Example question (left) shown to the class and real-time student responses (right).

Indeed, much work has been done to determine the principles of good clicker questions that stimulate active engagement and engender fundamental understanding [2]. Development of questions focused on higher levels of learning is especially important for courses taken by engineering students that tend to be more focused on understanding of concepts versus rote memorization. Incorrect answers allowed us to slow the pace of the class and cover topics in more detail. Still, we are likely to change the grading of clicker questions in future years to provide incentives for answering questions correctly. It appeared most students made an honest effort to give correct answers, but we observed a small portion of the class that chose answers at random as points were awarded only for participation, thus negating any learning effect. In summary, an audience response or clicker system, if used effectively, can improve attendance, encourage active learning, and provide real-time feedback to instructors regarding the covered material. This type of clicker system can be effective in engineering courses if clicker questions are developed that encourage higher level thinking.

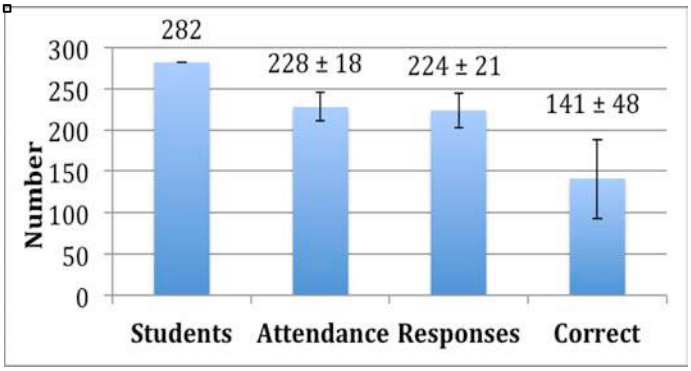

Figure 4: Student enrollment and average attendance, number of responses, and correct answers for each class session. With a course of 282 students, an average of 228±18 students attended each lecture, representing 80.8% of the total class. Responses were collected from 224±21 students, or 98.2%, of those who attended. Only 141±48, or 62.9%, of the responses were correct.

A FINITE ELEMENT ANALYSIS OF THE OCCIPITOATLANTAL CAPSULAR LIGAMENTS AS THE PRIMARY STABILIZERS OF THE ADULT AND PEDIATRIC CRANIOCERVICAL JUNCTION

INTRODUCTION

Traditional cadaveric biomechanical testing of the craniocervical junction (CCJ) demonstrates that the occipitoatlantal (OA) joint relies primarily on three ligamentous structures for stability: the tectorial membrane (TM), the transverse ligament (TL) and occipitoatlantal capsular ligaments (OACL). Most studies demonstrate that the TM plays the dominant role in stability, with the role of the TL and OACLs being less clearly defined. However, cadaveric biomechanical testing suffers from the inherent methodological flaw of sequential tissue disruption while trying to isolate a structure of interest. Stability studies involving isolated transection of OA structures have been performed, but are far less common, and do not adequately mimic the injury patterns seen in craniocervical trauma. The results from previous studies have held conflicting views on the role played by the TM in OA stability, with Werne et al. concluding it restricts CCJ extension and Oda et al. reporting it limits flexion [1, 2]. Tubbs et al. concluded the TM prevents impingement of the cervical canal by the odontoid [3]. Similarly, a finite element (FE) parametric study on ligament properties by Brolin et al. concluded that capsular ligaments had the most impact on joint motions [4]. Clearly, knowledge gaps exist in our understanding of OA stability. Furthermore, since all previous testing has been performed on adult cadavers, little is known about the inherent biomechanical properties of the developing CCJ.

To address these issues, we created a validated finite element model (FEM) of the normal pediatric CCJ, as well as adapted a previously published adult CCJ FEM [5, 6]. In this study, our goal is to examine the individual and combined contributions of the TM, TL and OACL on OA joint stability in both the pediatric and adult CCJ. Injury scenarios of the TM, TL and OACLs are examined in isolated and combined fashion. Specifically, we sought to explore the poorly understood role played by the OACL complex on adult and pediatric CCJ stability.

METHODS

Pediatric FE Model

The pediatric FE model was generated from CT scans of a 13 month old female (IRB# 00066287). We have reported on the surface generation, meshing, material properties, boundary conditions and the validation of the normal model in a previous study [4].

Adult FE Model

A previously validated adult FEM was used for adult injury simulations. The geometry for the model was generated from the CT scan of a single, fresh frozen female cadaveric spine (age: 64 year, height: 170 cm, weight: 74kg) [5]. The meshes from this model were imported into FEBio's preprocessor, PreView (http://febio.org/). Linear material properties were used for ligamentous structures (e.g. OACL, TM, and TL) as described in the pediatric model [4]. This normal model was reevaluated by comparing the flexion-extension ROM data obtained under physiological loads to Panjabi et al. flexion-extension experimental data, as well as the FE data reported previously by the model source (Fig. 1 Left) [5][7].

Sensitivity Studies (Ligamentous injury models)

Stability of the OA joint was evaluated for both the pediatric and adult FEMs. The intact normal FEMs were modified to evaluate the sensitivity of the models when damage to TM, TL and OACL were simulated.

Seven sets of scenarios were simulated for flexion-extension. These include 1) removal of TM, 2) TL, 3) removal of both TM and TL, 4) OACL injury model (i.e. reducing the stiffness of the OACL by orders of magnitude from 2.94 N/mm for pediatric and 29.4 N/mm for adult to 0.1 N/mm) 5) OACL injury model with TM, 6) TL, 7) and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

both TM and TL removed. Boundary conditions used for the models are the same as reported previously [4, 5]. A moment of 0.1 Nm was applied to all pediatric FE models. A moment of 1.5 Nm was applied to the adult FE model for validation, but only 0.5 Nm was applied to the injury models because the injury models behaved non-physiologically beyond this level of torque. FEBio was used for all analysis and post processing was completed using FEBio's post-processor, PostView. C0-C2 rotations were predicted for flexion-extension. Rotations are reported for normal models and percent increases from normal are reported for the injury models.

RESULTS

The flexion-extension ROMs predicted by the normal pediatric and adult models were within one standard deviation of previously reported data (Table 1 & Fig. 1, left) [5-7]. An isolated injury to the OACL caused the largest increase in flexion ROM (Table 2). Adult FEMs with isolated OACL injury showed a 30.5% increase in flexion (Fig.2 Top) and pediatric FEMs showed an 80.2% increase in flexion (Fig. 2 Bottom). Isolated TM, TL and TM-TL removal cases increased flexion ROM a maximum of 6%. For both pediatric and adult FEMs, an OACL injury combined with removal of TL, TM or both further increased flexion ROM from the isolated OACL injury by <5%. There was less than 1% increase in extension ROM for all pediatric injury models while adult FEMS showed over 30% increase in ROM.

Table 1. C0-C2 ROM data for normal adult and pediatric FEMs.

FEM	Load (Nm)	Flexion (degree)	Extension (degree)
Adult	1.5	28	29.8
Pediatric	0.1	23.5	16.4

Table 2. C0-C2 ROM % increase from normal (Table 1) FEMs for OACL, TM, TL, TM-TL injuries and OACL combined (+) injury cases.

Injury Simulations	FEM	Flexion (%)	Extension (%)
OACL Injury	Adult	30.5	30.7
	Pediatric	80.2	<1
TL removed	Adult	5.8	< 1
	Pediatric	4.9	< 1
TM removed	Adult	2.9	< 1
	Pediatric	4.4	< 1
TM-TL removed	Adult	5.8	< 1
	Pediatric	5	< 1
OACL + TL removed	Adult	31.4	35.4
	Pediatric	84.7	<1
OACL + TM removed	Adult	31.3	32.6
	Pediatric	83.6	<1
OACL + TM-TL removed	Adult	31.6	41.6
	Pediatric	84.8	<1

DISCUSSION

The results of this study show that the OACL plays a major role in contributing to the ROM and stability of both the adult and pediatric CCJ. In contrast to other studies, we found the TM and TL to be relatively small contributors to the stability [8, 9]. In extension, the adult model was far more sensitive to the OACL injury than the pediatric model. This could be due to the flatter facets in the pediatric C0-C1 condyle (Fig 1. Right) compared to the relatively more round and congruent adult facets [10, 11]. The FEMs in this study used linear material properties to save computational time and obtain converged results. These materials provide realistic predictions for normal adult and pediatric flexion-extension ROMs and previous studies of the lumbar spine have used a similar approach [12].

MODELING BONE FORMATION WITH A LAB-ON-A-CHIP PLATFORM

Marnie M. Saunders, Spencer L. York, Estee L. George, Erica L. Grutkowski, Jennifer L. Smith

Department of Biomedical Engineering
The University of Akron
Akron, OH, USA

INTRODUCTION

A lab-on-a-chip (LOC) is a miniaturized platform that has the ability to integrate multiple functional elements to construct a complete analytic microsystem. A LOC removes spatial and temporal limitations lending to its applicability in the biological sciences, such as in genomics, proteomics, clinical diagnostics, and drug discovery. LOCs are equipped to culture small numbers of cells under precisely regulated conditions with the consumption of minimal amounts of reagents. This benefit has led to a substantial degree of work being aimed at developing these systems to mimic tissues, organs, and organ systems.

While many areas of research have adopted this technology to great benefit, the bone field has been slow to appreciate the opportunities that these systems provide. Presently, much of what is known about the response of bone cells to mechanical stimulation has been gathered from *in vitro* mechanotransduction studies. These systems are not able to adequately mimic the physiologic environment of the bone or integrate many of the fundamental elements known to be crucial in mechanotransduction. The incorporation of the three cell types (osteocytes, osteoclasts and osteoblasts) on the same platform removes spatial and temporal limitations. That is, bone cells possess vastly dissimilar lifecycle timescales, with osteocytes and osteoclasts differing by years. With respect to spatial limitations, physiologically each cell type is rarely observed in the same location simultaneously. And, the LOC platform can be designed to enable quantification of functional outcomes. As such, we believe the LOC technology offers opportunities to bridge the gap between *in vitro* experiments and animal models.

Here, we laid the groundwork for a LOC bone remodeling platform. We fabricated the platform and subjected osteocytes to short-term mechanical stimulation quantifying the soluble effects of conditioned medium on osteoblast bone formation.

METHODS

The platform was designed from a mask devised in AutoCad and fabricated using Prototherm 12120 high-resolution stereolithography in a 0.05mm build. A platform configuration of three separate wells was utilized to isolate the cell types and investigate soluble activity. The well size of the configurations was approximately 7mm. PDMS was poured on the surface of the mask of the LOC contained within a leveled, Plexiglas chamber machined in-house. After curing for 24 hours, the PDMS was removed and covered to prevent accumulation of dust and other particles. Before use with cell culture, the product was sterilized. The streamlined equipment and process for the manufacture of the LOC ensured accurate reproducibility between batches. It was critical to maintain the appropriate thickness given the mechanical characterization was completed as a function of well thickness.

Osteocytes Osteocytic, MLO-Y4 cells were seeded at an initial density of $3*10^4/cm^2$ and grown to 85-90% confluence cultured in minimum essential alpha medium (α-MEM, Gibco) supplemented with 5% fetal calf serum (Hyclone), 5% fetal bovine serum (Hyclone), and 1% penicillin/streptomycin (Invitrogen). Cells were maintained in culture (5% CO_2 and 37°C) in $25cm^2$ flasks coated with rat tail collagen type I (CTI) (BD Bioscience). Flasks were coated using a $5\mu g/cm^2$ CT1 solution in 0.2M acetic acid (Sigma) for 1hr, prior to rinsing in Dulbecco's phosphate buffered saline solution with calcium and magnesium (Hyclone). Osteocytes were maintained in culture on the CTI-coated PDMS (10:1 mixture ratio) for a minimum of

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

72hr to establish typical morphology and phenotype prior to loading.

Osteocyte loading was applied for 15min using a platform developed in-house. Physiologic loading (≤10% strain) was generated using a platen distention of 3804μm; physiologic/supraphysiologic loading (15-19% strain) was generated using a platen distention of 5720μm [1]. CM was collected following a 90 min post-load incubation.

Osteoblasts MC3T3-E1 cells were seeded on polystyrene at an initial density $2.5*10^3/cm^2$ and grown to 100% confluence cultured in minimal essential alpha medium (MEMα, Gibco) supplemented with 10% fetal bovine serum (Hyclone) and 1% penicillin/streptomycin (Invitrogen). Cells were induced to differentiate at 100% confluence with a cocktail containing 50μg/ml ascorbic acid (AA) and 10mM β-glycerophosphate (BGP) in culture medium. Cells were fed with 90% switch medium (medium with BGP and L-ascorbic acid (AA)) and 10% CM every 3rd day for 26 days. Bone formation was quantified using standard alizarin red (calcium) and von Kossa (phosphate) staining.

RESULTS

The fabricated platform is shown in Figure 1. While a picopump (Harvard Apparatus) may be hooked up to the LOC to circulate fluid within and between the wells, initial work was completed with static cultures.

Shown in Figure 2, is a typical SEM image of polystyrene-seeded osteoblasts prior to CM addition. A typical outcome is shown in Figure 2b for the physiologic and physiologic/supraphysiologic CM results. The CM from physiologic loading resulted in a 36% increase in bone formation. Typical quantitative results are plotted in Figure 2c and 2d for alizarin red extraction at physiologic loading levels and the percent area covered for physiologic/supraphysiologic loading levels. In both experiments, CM experiments are compared to controls (Neg 1 – cells cultured in medium containing osteocytes/ no mechanical stimulation, Neg 2 – cells cultured in osteocyte medium (no cells) and Pos 1 – cells cultured in osteoblast medium). For alizarin red extraction, calcium concentration was 23%, 25% and 20% higher from cells treated with CM from physiologic levels of stimulation in comparison to Neg 1, Neg 2 and Pos controls, respectively. In contrast, physiologic/supraphysiologic levels of stimulation resulted in a reduced area of calcium positive nodules with Neg 1, Neg 2 and Pos controls exhibiting a 116%, 46% and 2% increase in area coverage over the osteoblasts treated with the CM. In comparing the physiologic to the physiologic/supraphysiologic experiments, alizarin red extraction was decreased 17%, percent area coverage of alizarin red was decreased 15% and percent area coverage of von Kossa was decreased 17% in the physiologic/supraphysiologic samples. Given a limited volume of medium available from the initial stimulatory trials, rigorous statistics were not completed. A minimum n of 3 is represented.

DISCUSSION

We advocate for the development of LOC bone remodeling platforms. These systems have the potential to accurately represent complex multicellular interactions in a highly controlled and reproducible environment. As a proof-of-concept, we developed a platform and subjected osteocytes to a brief bout of stimulation (15min) at normal and elevated mechanical levels. Soluble factors from that brief loading bout were then assessed

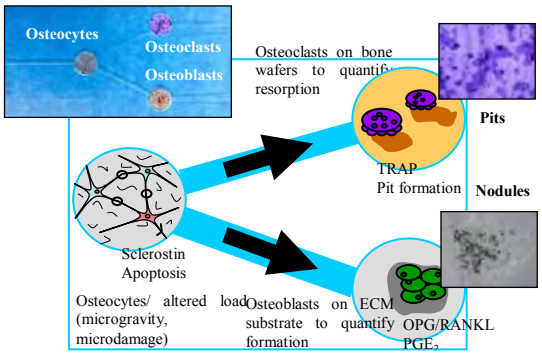

Figure 1: LOC fabrication and development. Cartoon rendering of the LOC platform to study soluble interactions in bone remodeling. The actual platform is shown in the inset with osteocytes stained for viability, osteoclasts stained with toluidine blue on wafers (only osteoblasts discussed here) and osteoblasts stained with alizarin red to identify calcium deposits.

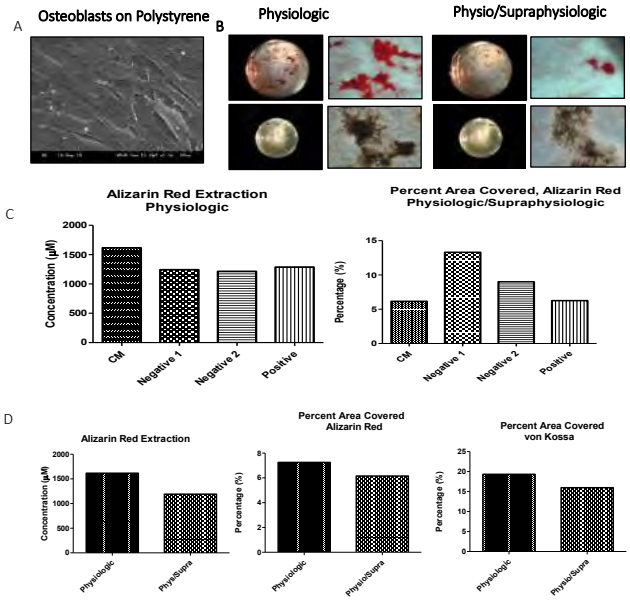

Figure 2: Physiologic levels of short-term osteocyte mechanical stimulation resulted in increased bone formation in comparison to physiologic/supraphysiologic levels.

for their effects on bone formation. Physiologic levels increased formation over physiologic/supraphysiologic levels. Given the brief bout of loading the 36% increase in formation is sufficient to demonstrate proof-of-concept. Additional testing is needed to further assess the soluble factors, cell contact and cell communication. The synthesis of data from these studies will begin to allow us to understand the elegant and intricate process of bone remodeling.

INTRODUCTION

Articular cartilage focal defects are a common knee pathology that has been linked to the progression of degenerative soft tissue diseases, like osteoarthritis (OA). OA affects approximately 15% of the adult American population [1] and typically presents initially as a decline in cartilage integrity, eventually developing into through-thickness lesions. Focal defects occur most frequently on the femoral cartilage, about 60% based on previous arthroscopy studies, with an average area of 2.1 cm^2 and corresponding range of 0.5 – 4 cm^2 [2]. While focal defects predominately appear in weight bearing and high wear regions, with prolonged joint use focal defects without intervention tend to expand [3] and show signs of cartilage degeneration in the neighborhood around the original focal defect [4]. It has been shown that the presence of focal defects influences both near and fear field strains during sliding contact typical of normal gait using bovine cartilage explants [5]. However, the general and coupled contribution of focal defects within whole joints has not been fully explored.

This work attempts to fundamentally quantify the role of articular cartilage focal defect size and location in joint mechanics by illustrating the impact of defects on both local tissue deformation and global joint kinematics. Tibial and femoral cartilage strain distributions were determined first for native, healthy anatomies during a simulated gait cycle and compared to models containing various femoral cartilage focal defects within a whole knee model built using geometrically and physiologically accurate representations of important tissue structures. Cartilage strains located on and adjacent to the perimeter of focal defects were calculated. We show the tremendous influence of focal defects on tissue deformation, manifesting in alterations in deformation of cartilage with and without focal defects, and joint motion.

METHODS

A three dimensional finite element (FE) model was developed using a combination of computerized tomography and magnetic resonance digital images from a healthy adult female with no history of knee injury or tissue disease. The joint motion and deformation of individual tissue structures were examined during a simulated stance phase of normal gait in an explicit FE framework using a general purpose FE code, Abaqus v6.13 (SIMULA, Providence, Rhode Island, United States). The stance phase was approximated by a linear time varying load, equal to roughly one body weight (F_{max} = 800 N) applied at the distal tibia; the anterior/posterior (A-P) and medial/lateral (M-L) translations of the tibia were constrained numerically at the ankle, while rotations of the tibia about the ankle remained free. The proximal femur was translationally fixed and rotationally free at the hip. Friction was modeled generally among structures in the joint, where the relationship between the coefficient of friction and the relative shear slip rate was derived from relevant experimental studies of cartilage to cartilage contact [6].

The whole joint model included key soft and hard tissue structures, including bones (femur, patella, tibia, and fibula), ligaments, muscles, tendons, articular cartilage, and menisci. Constitutive descriptions for each tissue type were developed from appropriate experimental evidence available in the literature. Bones were modeled supposing rigid behavior due to the negligible contribution of deformable bones on total deformation [7]. The menisci were assumed to be transversely isotropic, linear elastic [8]. The trans-knee muscles, muscle tendons, auxiliary ligaments, and meniscal horn attachments were constructed using uniaxial elements, each with independent, potentially nonlinear constitutive descriptions [9]. The constitutive responses of the major ligaments—the anterior cruciate ligament, posterior cruciate ligament, medial collateral

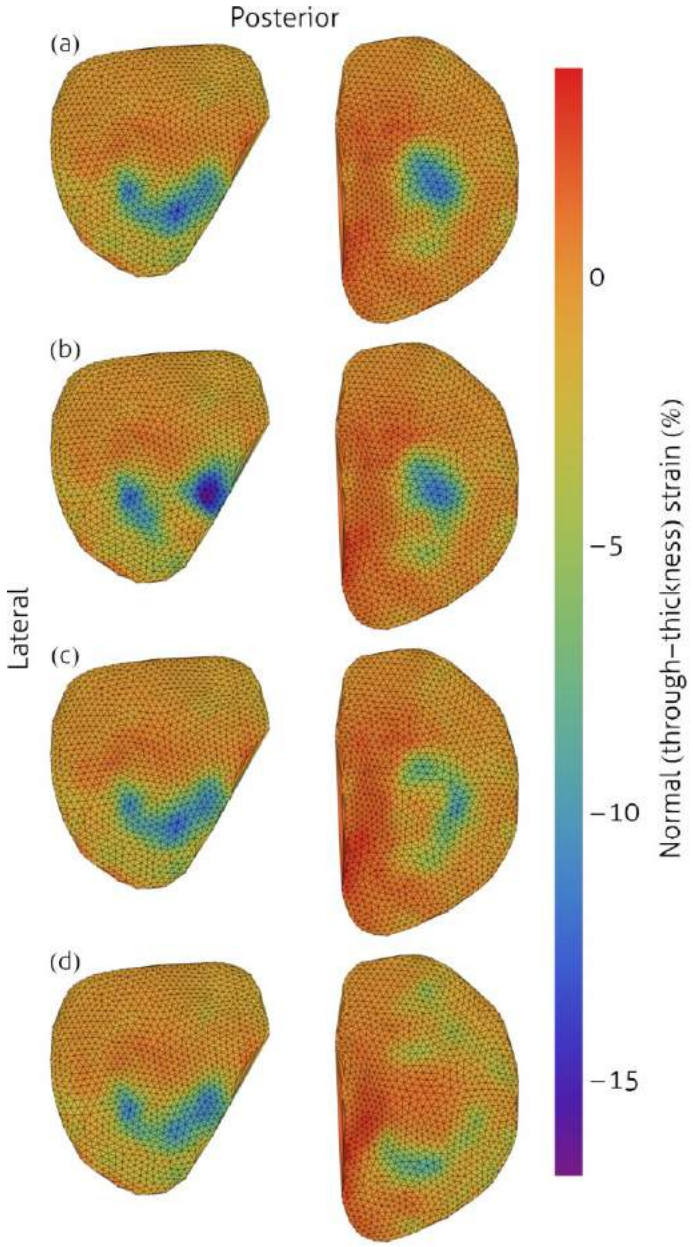

Figure 1: Surface normal strains of tibial articular cartilage that is (a) anatomically native, contains a small femoral focal defect located (b) laterally or (c) medially, or (d) an averaged sized femoral medial defect.

ligament, and lateral collateral ligament—were modeled using a transversely isotropic form of an isotropic eight-chain model of rubber elasticity [9-11]. Tibial and femoral cartilages were assumed to have spatially heterogeneous mechanical property fields that were constructed using the transversely isotropic eight-chain model [12,13]; sparse experimental moduli distributions were completed by a smooth and continuous interpolation scheme. Focal defects were included on the femoral condyles assuming a cylindrical defect shape (defect sizes and locations: 0.5 cm^2 (medial and lateral) and 2.1 cm^2 (medial)).

Table 1: Effect of focal defect size and location on joint motion.

	Relative anterior tibial translation (mm)	Relative interior tibial rotation (°)	Knee flexion (°)
Native	0.742	3.26	1.42
Lateral – Small	0.899	2.59	2.05
Medial – Small	-0.455	2.51	1.09
Medial – Average	2.88	-5.36	-0.494

RESULTS

Figure 1 illustrates normal (through-thickness) strain distributions located on the tibial cartilage corresponding to femoral cartilage with (Fig. 1b-d) and without (Fig. 1a) focal defects at the time of maximum loading. From Fig. 1 it is clear that the presence of focal defects, Fig. 1b-d, fundamentally alters, with respect to Fig. 1a, the evolution of strain within the joint capsule. A small lateral defect increases the maximum thought-thickness compressive strain (from 13.5% to 16.8%), shifting the maximum strains on the lateral plateau medially toward the center of the tibia. Small and averaged sized medial defects decreased the maximum observed compressive strains to 12.7% and 11.4%, respectively. There was also a noticeable decrease in the dispersion of compressive strain on the medial tibial plateau, Fig. 1c-d, as compared to the intact joint.

Altering cartilage integrity not only affects local tissue deformation, but also global joint kinematics—presented in detail in Table 1. As the size of the defect increased on the medial condyle, the directions of relative internal tibial rotation and knee flexion flipped with respect to both the native knee and small sized defect models. A decrease in the amount of relative internal tibial rotation was observed corresponding to each of the small sized defect models. The presence of a small medial defect resulted in relative tibial motion opposite to the anticipated anterior tibial translation (ATT), while increasing the defect size drastically increased the observed ATT.

DISCUSSION

Whole joint computational biomechanics models have the potential to generate clinically meaningful insights and inform optimal, patient-specific treatments by illustrating the highly coupled and nonlinear behavior of joints with complex anatomies and pathologies. The size and location of cartilage focal defects leads to alternations in local deformations in tissues with and without defects, as well as changes in the measured joint kinematics. These deviations motivate the clinically observed, widespread effects of focal defects on surrounding tissues [3-5] and offer to further the understanding of potentially dangerous articular cartilage focal defects that may require surgical intervention.

INTRODUCTION

In the embryo, the heart is initially a simple tubular structure that undergoes complex morphological changes as it transforms into a four-chambered pump. This work focuses on the mechanisms that create the heart tube (HT). The early embryo is composed of three relatively flat primary germ layers called endoderm, mesoderm, and ectoderm. Precardiac cells located within bilateral regions of the mesoderm called heart fields (HFs) fold and fuse along the embryonic midline to create the HT. This folding is part of a more global folding of the endoderm and mesoderm, which essentially comprise a bilayered epithelial plate. The right and left halves of this plate fold symmetrically to bring their upper edges into contact along the midline, where they fuse (see Figure 2F-H). In a region near the fusion line, these layers then separate to generate the primitive HT and foregut, which then extend vertically. The anterior intestinal portal (AIP) is the opening at the caudal end of the foregut, which descends as the HT lengthens (Figure 2B-D) [1-3].

The biomechanical mechanisms that drive this folding are poorly understood. Here, we consider folding and extension of the endo-mesodermal plate, excluding separation of the layers. Our central hypothesis is that folding is caused by differences in growth between the endoderm and mesoderm, while subsequent extension is driven by contraction along the AIP. The feasibility of this hypothesis is examined using experiments with chick embryos and finite-element modeling.

METHODS

Experimental Method

Fertilized white Leghorn chicken eggs were incubated at 38°C rof approximately 22-33 hours until the appropriate Hamburger and Hamilton stage (HH5 to HH9) was reached [4]. Whole embryos using a filter paper carrier method [5]. To inhibit contraction, embryos were cultured in media containing blebbistatin (myosin II inhibitor; 100μM) for 18h (from HH5 to HH10).

Finite-Element Models

Three-dimensional models were created using ABAQUS (D. S. Simulia). The initial geometry consists of a flat plate including two layers representing the mesoderm and endoderm (Figure 1).

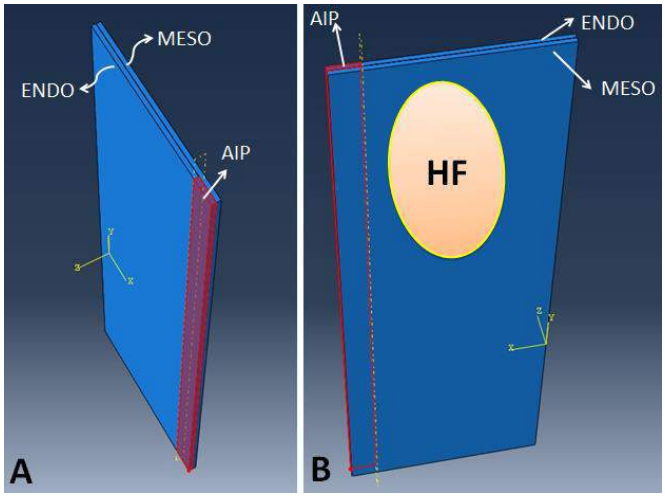

Figure 1: Initial model geometry for embryo at stage HH5. (A, B) Ventral /Dorsal view. ENDO = endoderm; MESO = mesoderm; HF = heart field; AIP = presumptive anterior intestinal portal.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Only half of the embryo is modeled with symmetry conditions specified along the plate edge at the embryonic midline. Rollers are specified along the lower edge, and the other edges are initially free. After folding brings the upper edge to the midline, fusion is simulated by converting the free boundary condition into a symmetry condition. After fusion occurs, the AIP contracts tangent to the plate edge.

Nonlinear material properties were taken from previous studies [3, 6]. Growth and contraction (negative growth) were simulated using the theory of Rodriguez et al [7], where the total deformation gradient is given by

$$\mathbf{F} = \mathbf{F}^{*}.\mathbf{G} \qquad (1)$$

In which **G** is the growth tensor and **F*** is the elastic deformation gradient tensor. The growth tensor defines the stress-free configuration for each material element after it grows. Here we take

$$\mathbf{G} = G_x e_x e_x + G_y e_y e_y + G_z e_z e_z \qquad (2)$$

With $\dot{G}_z = 0$, $\dot{G}_x < \dot{G}_y$ for both layers, $\dot{G}_{ENDO} < \dot{G}_{MESO}$, and $\dot{G}_y < 0$ for AIP contraction.

RESULTS

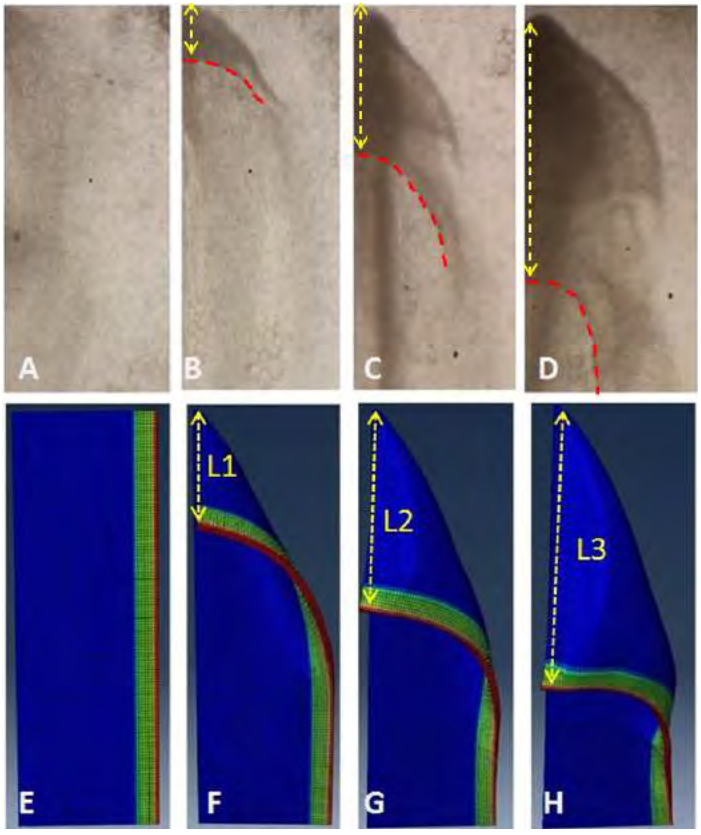

Figure 2: (A-D) Heart development in early chick embryo at stages HH5, HH7, HH8, and HH9. Red dashed lines outline AIP. (E, F) Computational model for initial folding of mesoderm-endoderm plate. (G, H) AIP contraction stretches the combination HT and foregut.

In embryos exposed to blebbistatin, initial folding and AIP descension occurred normally. However, after HFs partially fused to create the upper part of the HT, fusion and AIP descension stopped, and the HT failed to grow longer. These results suggest that cytoskeletal contraction is required only for the later stages of HT formation.

In the model, a larger biaxial growth rate in the mesoderm compared to the endoderm causes the bilayered plate to bending ventrally, as the upper edge moves toward the midline, where it 'fuses' with the other half (Figure 2E,F). This folding creates the upper section of the HT, as well as the foregut pocket bordered by the AIP [8, 9]. After this phase completes by stage HH7, contraction along the arch-shaped AIP pulls the lower edge of the plate downward, stretching the two layers. All of these results are consistent with experimental data for control embryos (Figure 2), as well as embryos treated with blebbistatin.

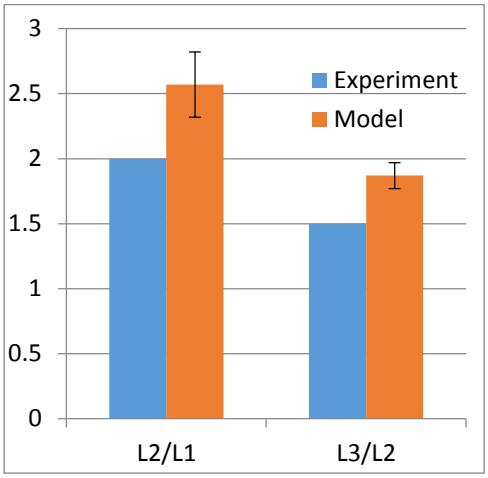

Figure 3: Comparison of experimental measurements (n= 4) and model results for length ratio of fused midline at different stages. L_1, L_2 and L_3 are shown in Figure 2.

DISCUSSION

As one test of the model, we measured the change in length of the midline of the folding epithelial plate above the AIP in both cultured embryos and the model. Figure 3 shows reasonable agreement between model and experiment at different stages of development. In conclusion, the results of our experimental and theoretical study support our hypothesis for folding and extension of the endo-mesodermal plate. Future work is warranted to further test this idea.

INTRODUCTION

Pulmonary hypertension (PH) is a chronic progressive disease characterized by a higher than normal pressure in the main pulmonary artery, caused by an increase in resistance in the distal vasculature. Computational fluid dynamics (CFD) can be used to identify metrics representative of the stage of PH disease. Nevertheless, experimental validation of CFD models is often not pursued due to the geometric complexity of the model or shortcomings in the reproduction of the required flow conditions. The goal of this research was to validate experimentally a CFD model of a pulmonary artery phantom using a stereo particle image velocimetry (PIV) technique.

METHODS

The patient-specific pulmonary artery geometry was reconstructed from chest computed tomography angiography (CTA) images, which were segmented using the application Mimics (Materialise, Belgium). The lumen of the phantom was built up to the first bifurcation of the left pulmonary artery by means of a MakerBot Replicator Z18 3D printer (Makerbot, Brooklyn, NY) using a polylactide resin filament (Makerbot, Brooklyn, NY). Following a lost-core technique, liquid silicone (Applied Silicones, Inc., Santa Ana, CA) was poured on the rapid prototype, cured for 24 hours and dissolved using dichloromethane [1].

The ensuing silicone phantom was connected to a flow loop with in-line electromagnetic flow meters and pressure transducers at the inlet and each outlet. Fully developed flow was achieved by extending the inlet cross-section ten hydraulic diameters using a matching diameter connector constructed with stereolithographic techniques. Similar connectors were used for the phantom outlets. The blood-mimicking fluid (BMF) used in the experiments consisted of water, glycerol, sodium iodine, sodium thiosulphate, and aluminum thiosulphate. The measured density of the BMF was 1.245 g/cm^3 (at 22.4 ºC) and viscosity of 4.17 cP. The bench-top experiment was operated at constant flow rate conditions with a Reynolds number of 877, which is typical of time-averaged flow conditions in the human main pulmonary artery. A stereo PIV system (LaVision, Germany) was used for flow visualization and velocity quantification at select planes of interest within the phantom [1].

The phantom geometry was modified for the computational simulations using CAD editing software at the inlet and outlets to ensure fully developed flow. This can prevent potential numerical errors to be transferred to the vessels and it can reduce inconsistencies between the experimental and computational flows [2-4]. To ensure the results obtained are independent of the mesh size, a wall shear stress (WSS) based grid convergence analysis was performed [5]. The CFD modeling was carried with the solver Ansys Fluent (Ansys Inc., Canonsburg, PA) using an unsteady algorithm. The boundary conditions involved a constant flow rate at the inlet, a no-slip condition at the walls and a pure resistance structured-tree outflow boundary condition at the three outlets. Velocity contours, WSS and flow rates obtained with the CFD simulations were compared to the counterparts from the PIV flow visualization experiments.

RESULTS

CFD simulations were performed on the patient-specific pulmonary model with a Reynolds number, viscosity and density of the fluid matching those used with the PIV experiments. The BMF was considered incompressible and Newtonian, with an inlet velocity of 9.16 cm/s and a flow rate of 95 mL/s, obtained after a Reynolds number similarity analysis was performed. The vascular resistance was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

calculated for each outlet and adjusted following an iterative process until the flow measured at the right pulmonary artery (RPA) and left pulmonary artery (LPA) matched those measured in the PIV experiment. Table 1 describes the volume flow rates calculated from the CFD simulations and measured in the experimental setup.

Table 1: Volume flow rates predicted by CFD simulation of the pulmonary model and measured in the PIV experiment.

Pulmonary model branch	Q_{CFD} (cm^3/s)	Q_{PIV} (cm^3/s)	Relative difference with respect to Q_{PIV} (%)
MPA	95.00	94.97	0.03
RPA	36.08	36.28	0.55
LPA	39.32	39.22	0.25
TA	19.59	22.28	12.07

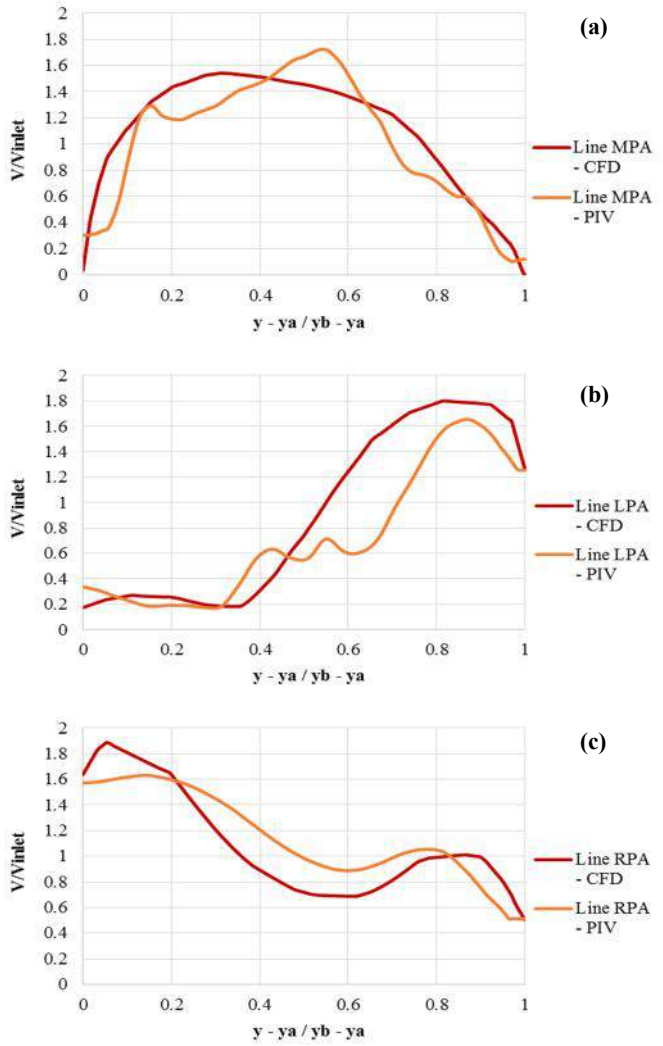

Figure 1: Non-dimensional velocity profiles obtained through a CFD simulation and PIV experiment along the cross-sections shown in Fig. 2(a) at each major pulmonary artery branch – (a) MPA, (b) LPA, and (c) RPA.

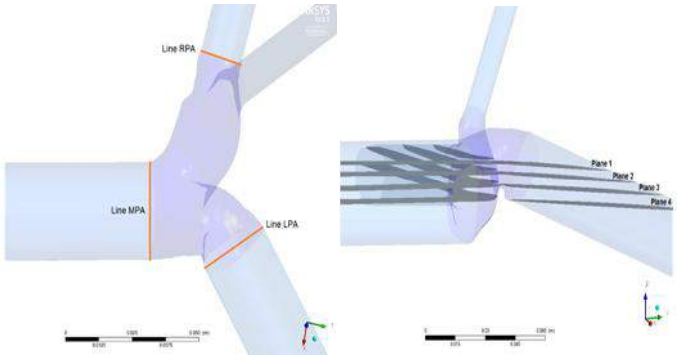
Hemodynamic parameters such as wall shear stress (WSS) and flow field velocity vectors were also computed. Figure 1 presents a comparison between velocity profiles obtained in the CFD simulations and the PIV experiments. There is good agreement in all velocity profiles based on relative RMS errors for cross-sections at the MPA, RPA, and LPA of 0.2133, 0.3396, and 0.2047, respectively. Four planes of visualization, shown in Fig. 2(b), were chosen to compare the average velocity at each plane, as described in Table 2.



(a) **(b)**

Figure 2: (a) Location of the cross sections at each major branch used to compare the velocity profiles; (b) planes of visualization for the comparison of the average velocity predicted by CFD simulations and the PIV experiments.

Table 2: Average velocities at the visualization planes predicted by the CFD simulation and PIV experiment.

Plane	Average V_{CFD} (cm/s)	Average V_{PIV} (cm/s)	Relative difference with respect to V_{PIV} (%)
1	10.08	11.25	10.40
2	9.47	10.90	13.11
3	9.13	9.70	5.87
4	7.95	8.81	9.76

DISCUSSION

There are small differences between the CFD and PIV predicted average velocities, which could be the result of discrepancies in the geometry of the computational domain relative to the physical dimensions of the flow phantom. An exact agreement between the computational and experimental results should not be expected considering the impossibility of constructing a perfect pulmonary phantom. These differences can be attributed to the simplifications and assumptions made in the numerical simulations, surface roughness of the phantom's lumen, mismatch in the precise location of the planes of interest between the computational and experimental models, and the use of structured tree outflow boundary conditions in the CFD model, which lacked the precise intraluminal pressure measurements at each outlet. In addition, the silicone phantom, which was assumed to have a rigid wall in the CFD simulations, was observed to have a finite compliance in the PIV experiments.

INTRODUCTION

The Notch signaling pathway has been associated with breast, cervical and lung cancer, neuroblastomas and acute T-cell lymphoblastic leukemia and is strongly implicated in tumorigenesis. [1] Notch genes encode large single pass transmembrane proteins that regulate cell fate. Upon activation, Notch undergoes cleavage, releasing its intracellular domain NICD and translocates into the nucleus for transcriptional activation of its downstream target genes. [2] Discovery of this pathway has prompted many pharmaceutical companies to develop novel anti-Notch therapeutics. We (Trojantec Ltd) have generated a novel fusion protein TR4 that inhibits the Notch pathway at the transcriptional level and can potentially reduce tumor growth *in vivo*. TR4 consists of the truncated version Mastermind-like (MAML) that behaves in a dominant negative fashion and inhibits Notch activation and the cell penetrating peptide Antennapedia (Antp). The fusion protein is able to translocate into the cell nucleus and suppress Notch activation thus reverting the transformed phenotype, inhibiting the anchorage dependent growth and inducing apoptosis in highly metastatic epithelial human breast cancer cells.

Utilizing a state-of-the-art *in vitro* pharmacokinetics and toxicology program, in combination with innovative imaging techniques such as *in vivo* flow cytometry and whole body fluorescence reflectance imaging, we have investigated the pharmacokinetic and pharmacodynamic behavior of the TR4 protein in order to define its mode of action and establish safety and efficacy in treating tumors in animal models of breast adenocarcinoma.

METHODS

A comprehensive *in vitro* and *in vivo* pharmacokinetics study that included apoptotic, toxicology and immunogenicity assays was undertaken through administration of various concentrations of TR4 in 10 immuno-competent mice in order to determine the effects of TR4 and define the mechanism(s) of action. Blood samples were collected for toxicological assays and to monitor the immune response by ELISA whereas major organs were excised for immunohistochemistry to determine tissue toxicity and induction of apoptosis.

The dynamics of the TR4 fusion protein were investigated in animal cancer models, through the successful conjugation of the TR4 to proprietary fluorescent markers (Cy5.5). Molecular modeling studies were performed to identify appropriate conjugation sites on the TR4 molecule to ensure no loss of the membrane transfer capabilities of the fusion protein. A group of fluorescent dyes was prepared, with maleide groups appropriate for bioconjugation to thiols on the TR4 molecule. TR4-Cy5.5 conjugates were chosen based on their optical properties (absorption 600-650 nm, emission 650-700 nm) and suitability for the *in vivo* imaging study. Conjugated TR4 was purified using proprietary methods to ensure protein solubility and avoid excessive aggregation and was further tested to ensure that the protein retained the ability to translocate in breast cancer cells.

The *in vivo* pharmacodynamic behavior of the fluorescent TR4-Cy5.5 was investigated using fluorescence-based *in vivo* flow cytometry and whole body imaging. These molecular imaging techniques have the ability to monitor and quantify fluorescently labeled vehicles in circulation, to detect and image the biodistribution and incorporation of therapeutic agents in cells and organs of both healthy and tumor-bearing mice, as well as to provide a quantifiable assessment of tumor growth over time. Following intravenous administration of the TR4-Cy5.5 in non-tumor bearing mice (n=5) the non-specific uptake of the protein by circulating blood cells was assessed via *in vivo* flow cytometry, while the biodistribution of the protein accumulating in different organs/tissues was imaged using whole body reflectance imaging. The accumulation of TR4 in various

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

major organs (liver, kidney, lung and brain) was further verified by Western blot analysis.

An orthotopic mouse model for breast cancer disease was developed via injection of $7x10^6$ MDA-MB-231 GFP labeled cells in SCID mice, in order to enable the imaging and assessment of tumor growth *in vivo*. Animals that expressed a detectable fluorescent signal from established orthotopic tumors were selected and divided into two (n=5) groups: untreated (control) and treated with TR4 (day 0). Mice were monitored for 2 weeks via *in vivo* imaging and were then euthanized at the end of the experiment (day 14).

RESULTS

The pharmacokinetics studies indicated that TR4 did not induce any overt toxicity, notable death of cells, organ dysfunction, or any toxic manifestations that were predicted materially to reduce the life span of the animals. The immunogenicity tests indicated that animals do not raise an antibody response against the injected TR4 protein. Finally, no murine antibodies against full-length TR4 were detected by ELISA in mice serum.

TR4-Cy5.5 conjugates prepared via molecular modeling studies (Fig. 1A) and selected based on their optical characteristics (Fig. 1B) were first validated *in vitro* for their membrane translocation ability (Fig. 1C) prior to their use for the *in vivo* part of the study.

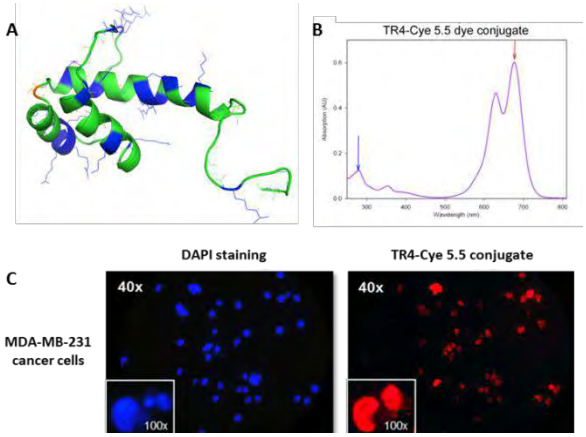

Figure 1: (A) The TR4 model containing 24 arginine residues (green), 9 lysine residues (blue) and 4 cysteine thiol residues (orange). (B) UV-vis spectra showing the quality of the conjugation and the peak absorbance shifts. (C) Cell penetration of TR4-Cy5.5 in MDA-MB-231 cancer cells.

In vivo flow cytometry in mice, injected i.v. with the TR4-Cy5.5 conjugates, showed that free, non-internalized protein was rapidly cleared from circulation, as the background (noise) signal collected from the blood vessels did not substantially increase. Furthermore, fluorescently labeled circulating cells that may have internalized the TR4 protein were not detected at any time point. Whole body imaging showed that TR4-Cy5.5 accumulated in some of the major organs/tissues imaged and was cleared within 24 hrs via the gastrointestinal tract (Fig. 2A-B). This is in agreement with the Western blotting analysis of excised liver and kidney (Fig. 2C).

Assessment of tumor burden via *in vivo* imaging demonstrated a reduction in tumor growth over time in mice treated with TR4-Cy5.5 compared to untreated mice (Fig. 3). The figure shows an overall increase of less than 50% in the relative intensity of fluorescence signal in the treated mice (right panel) compared to a 3-fold increase in signal and thus tumor size in untreated mice by day 14 (left panel).

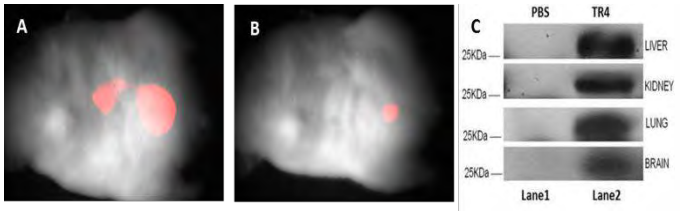

Figure 2: The TR4 protein biodistribution at (A) 2h and (B) 24h post injection. (B) Western blot analysis of excised mouse liver, kidney, lung and brain.

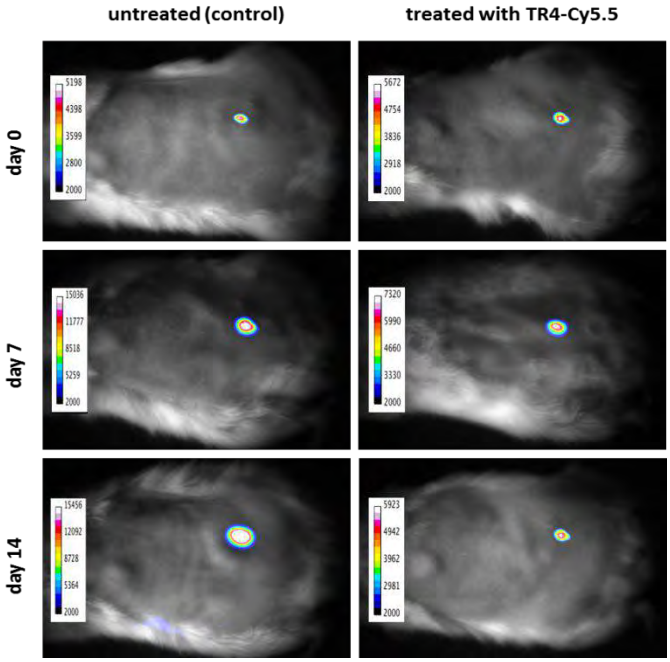

Figure 3: Tumor response in untreated (control) and treated with TR4-Cy5.5 mice at day 0, 7 and 14 post injection (representative images of the n number of mice tested).

DISCUSSION

In this report we have performed preclinical studies to validate TR4 as a promising therapeutic strategy for breast adenocarcinoma. The dynamics of the drug molecule have been investigated in an *in vivo* setting in order characterize its therapeutic efficacy in an animal tumor model. Mechanisms of action have been investigated via the application of innovative imaging modalities with the aim of guiding the technology closer to the market by completing the necessary preclinical studies in order to optimize the TR4 fusion protein as a novel therapy for invasive cancer disease.

INTRODUCTION

Traumatic brain injury (TBI) remains a major socioeconomic public health problem. The importance of head rotation for inducing brain strains and the resulting diffuse axonal injury is well-recognized [1,2]. Because rotational velocity ($\boldsymbol{v}_{rot}$), as opposed to rotational acceleration ($\boldsymbol{a}_{rot}$), is more strain-relevant [3–6], recent brain injury criteria have explicitly incorporated peak magnitude of $\boldsymbol{v}_{rot}$ to assess the risk and severity of TBI (e.g. RIC, PRIC, [7] and BrIC [6]).

Still, these kinematics-based injury criteria do not inform regional brain strains. To better understand the rotation-strain causal relationship, Yoganandan et al. employed a 2D finite element (FE) head model to study the significance of idealized $\boldsymbol{a}_{rot}$ profile shapes and acceleration-deceleration separation time on regional brain strains [8]. With more realistic $\boldsymbol{a}_{rot}$ profiles and a 3D head FE model, Post et al. observed a substantial influence of $\boldsymbol{a}_{rot}$ shape on brain strains [9].

In contrast, Ji and Zhao [3] found that brain strains were insensitive to $\boldsymbol{a}_{rot}$ peak magnitude ($\boldsymbol{a}_{rot}^{p}$) or shape in monophasic, acceleration-only rotation. Virtually identical peak strains were obtained when simulating head rotations of the same $\boldsymbol{v}_{rot}$ peak magnitude (v_{rot}^{p}) and impulse duration (Δt), regardless of their differences in $\boldsymbol{a}_{rot}$ shape (triangular, sine, or haversine, with $\boldsymbol{a}_{rot}^{p}$ difference by up to 21.5%). Longer Δt but identical v_{rot}^{p} in an acceleration-only rotation led to a decrease in strains [3,5,10], likely due to the increase in strain energy dissipation resulting from the brain's viscoelastic properties. These findings confirm that both v_{rot}^{p} and Δt are important to brain strains.

However, despite the general notion that $\boldsymbol{v}_{rot}$ is more strain-relevant, no study appears to exist that investigates how its shape, beyond v_{rot}^{p} and Δt, affects brain strains. To this end, we conducted this study to evaluate the uncertainty and similarity in $\boldsymbol{v}_{rot}$-induced strain responses as a result of shape variation in $\boldsymbol{v}_{rot}$ temporal profile.

METHODS

We used the 58 reconstructed NFL cases [11] to extract $\boldsymbol{v}_{rot}$ profile shapes. First, all $\boldsymbol{a}_{rot}$ profiles were filtered using an SAE 180 low-pass filter [4]. The x-components of these $\boldsymbol{a}_{rot}$ profiles were then numerically integrated (zero initial velocity or integration constant) to allow simulating uniaxial coronal head rotations (from left to right). The complete largest $\boldsymbol{v}_{rot}$ peak capturing rotation from onset to full stop was identified for each case (**Figure 1a**). Profiles with negative $\boldsymbol{v}_{rot}^{p}$ were negated to maintain a left-to-right rotation (**Figure 1b**). Profiles that did not record a full stop were discarded (**Figure 1c**). This led to a total of 44 $\boldsymbol{v}_{rot}$ profiles. They were further scaled to maintain an identical $\boldsymbol{v}_{rot}^{p}$ and Δt, corresponding to the average values from all the retained $\boldsymbol{v}_{rot}$ profiles (23.4 rad/s and 46.3 ms, respectively; **Figure 1d**). The scaling allowed isolating the shape of $\boldsymbol{v}_{rot}$ profiles for investigation.

All brain strain responses were simulated using the Dartmouth Head Injury Model (DHIM). Element-wise peak maximum principal strain regardless of the time of occurrence (ε^{p}) was determined. To facilitate comparison, the group average ε^{p} from the 44 simulated responses ($\overline{\varepsilon^{p}}$) was computed for each element to serve as a reference. For each ε^{p}, a volume-weighted average percentage error (err%) was defined to measure the magnitude difference relative to $\overline{\varepsilon^{p}}$:

$$err = \sum_{i=1}^{n} \left\| \left(\varepsilon_i^{p} - \overline{\varepsilon_i^{p}} \right) / \varepsilon_i^{p} \right\| \times V_i \Big/ \sum_{i=1}^{n} V_i \qquad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where ε_i^p and $\overline{\varepsilon_i^p}$ are the ε^p and $\overline{\varepsilon^p}$ values of the i^{th} element (n elements in total), and V_i is its volume. To evaluate the similarity in ε^p distribution or "pattern", Pearson correlation coefficients between each ε^p and $\overline{\varepsilon^p}$ were calculated. All responses were spatially resampled on a regular grid at a resolution of 2 mm to generate strain-encoded coronal images for illustration and comparison.

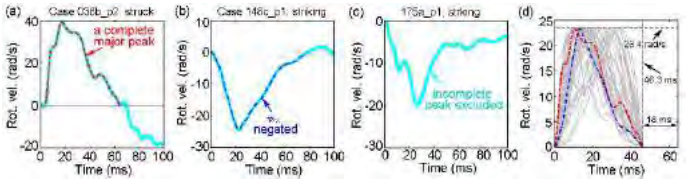

Figure 1: Illustration of $\boldsymbol{v}_{rot}$ profile selection and scaling for impact simulation. The largest $\boldsymbol{v}_{rot}$ peak capturing head rotation from onset to full stop was first identified (a) and (b). Those not capturing a full stop were discarded (c). The selected $\boldsymbol{v}_{rot}$ profiles were then scaled to maintain an identical v_{rot}^p and Δt (d; those from (a) and (b) highlighted).

RESULTS AND DISCUSSION

The average err% between ε^p and $\overline{\varepsilon^p}$ was 10.14±0.04% (range 4.29–17.89%). **Figure 2** shows the element-wise minimum, average, and maximum ε^p along with the standard deviations. They were not necessarily from a specific head impact, but represented element-wise "ranges" and "typical" responses. The four head impacts that led to the most similar and most different ε^p relative to $\overline{\varepsilon^p}$ were identified according to err% and correlation coefficient, respectively (**Figure 3**).

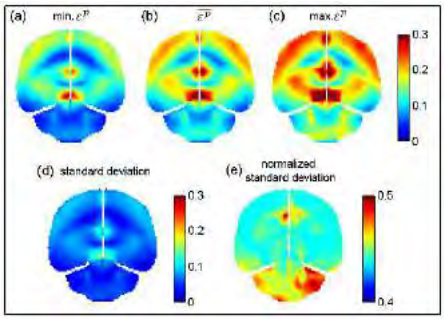

Figure 2 The minimum (a), average (b), and maximum (c) ε^p along with the standard deviation (d) (further normalized by the corresponding $\overline{\varepsilon^p}$ (e)) on a representative resampled coronal plane. Note that these responses are not necessarily from a given specific head impact.

The average element-wise differences between the maximum and minimum ε^p relative to $\overline{\varepsilon^p}$ was 47.9±17.0% (range 17.0–150.3%; **Figure 2**). In terms of CSDM, a variation of up to 23.9% was observed at a strain threshold of 0.1. These disparities suggest the shape of $\boldsymbol{v}_{rot}$ profiles is an important contributor to brain strain magnitude. Because only a limited number of uniaxial coronal head rotations were simulated, the observed uncertainty represented a lower bound of that expected in arbitrary, real-world head impacts. These findings are important to assess the effectiveness of kinematics-based injury metrics that indirectly rely on brain strains.

Despite the uncertainty in strain magnitude, the pattern of high/low strain exposures remained largely unchanged, regardless of the $\boldsymbol{v}_{rot}$ profile shapes (**Figure 3**; average correlation coefficient of 0.98±0.01, range 0.95–0.99). Such consistency in strain pattern may allow using targeted brain regions (vs. whole-brain) as the basis to develop a potentially more effective injury metric in the future. The targeted or more vulnerable regions can be determined via pre-computation [3,10].

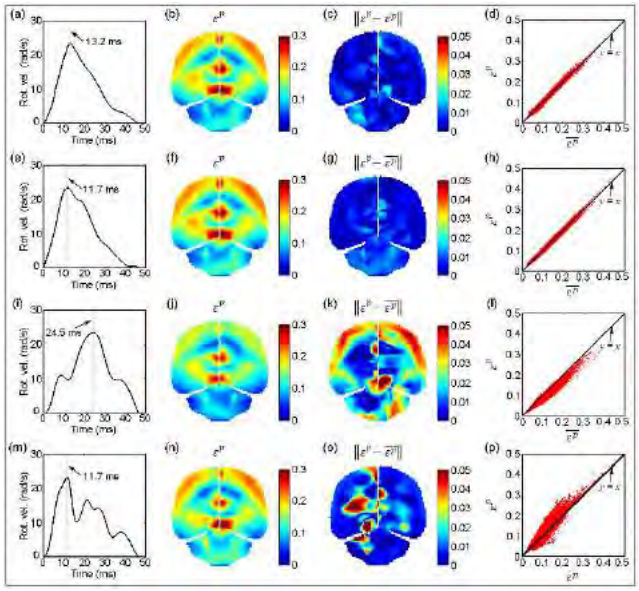

Figure 3 Comparison between ε^p and $\overline{\varepsilon^p}$. Left to right: $\boldsymbol{v}_{rot}$ profiles, ε^p, absolute difference between ε^p and $\overline{\varepsilon^p}$, and element-wise comparison between ε^p and $\overline{\varepsilon^p}$. Top to bottom: impacts leading to the smallest err%, the largest correlation coefficient, the largest err%, and the smallest correlation coefficient, respectively.

The two $\boldsymbol{v}_{rot}$ profiles that led to the most similar strain responses relative to $\overline{\varepsilon^p}$ in terms of err% and correlation coefficient (4.16% and 1.00 (p=0), respectively) also had similar shapes in $\boldsymbol{v}_{rot}$ profile (**Figure 3**). This observation suggests that a response-guided approach using group averaged brain strains may offer a useful, alternative method to "inversely" identify and characterize "typical" head impacts (vs. to operate directly on acceleration profiles [12,13]).

CONCLUSIONS

The shape of $\boldsymbol{v}_{rot}$ profile significantly affects brain strain magnitude, but not the pattern under uniaxial head rotations with identical peak $\boldsymbol{v}_{rot}$ magnitude and impulse duration. These findings offer important insight into the uncertainty or confidence in kinematics-based brain injury metrics. Further, they suggest the potential of using strains in targeted, more vulnerable regions (vs. whole-brain) to improve injury prediction performance in the future.

INTRODUCTION

Finite element models of the human head estimate impact-induced regional brain mechanical responses (e.g. strain and stress) that are believed to initiate injury [1] but are not feasible to measure *in vivo*. Therefore, they are important in the study of the biomechanical mechanisms of traumatic brain injury (TBI).

Most model-based TBI studies employ isotropic variables such as maximum principal strain (ε_{ep}), despite the fact that white matter (WM) structural anisotropy is well-known. These isotropic measures are unable to fully characterize WM axonal shearing or elongation along fibers; however efforts to incorporate WM structural anisotropy into injury analysis are now emerging [2]. Initial evidence has shown that elongation along WM fiber directions (termed as "fiber" or "axonal" strain, ε_n) improves injury prediction performance compared to ε_{ep} [3,4]. To-date, however, these studies have been limited to averaged fiber directions at coarse elements [4,5] or image voxels [3].

Evaluating WM fiber strains at a finer spatial resolution has the potential to further improve injury prediction performance. This is because a single, averaged fiber direction is unable to accurately describe the structural anisotropy in regions of crossing fibers or complex fiber configurations (occurring in as much as 63–90% of human brain WM [6]).

WM tractography from diffusion MRI identifies brain anatomical connections that form the substrate for information transfer between functionally eloquent cortical areas. High-resolution sampling points along the tractography fibers (or "streamlines" representing them) enable a more accurate estimation of WM fiber orientations than those using less accurate or precise averaging.

This study is aimed at developing a technique to evaluate ε_n using anatomically constrained whole-brain tractography [8]. A novel injury susceptibility index was also proposed to quantify injury vulnerabilities of discrete WM voxels and individual neural tracts. As an initial step, this study focuses on comparing a new tractography-based technique with our previous voxel-based approach for ε_n evaluations.

METHODS

Brain strain responses corresponding to axial, coronal and sagittal (anterior-posterior direction) rotations were selected from an existing pre-computed brain response atlas (pcBRA; [7]). The pcBRA employs triangulated rotational acceleration (a_{rot}) impulses as inputs. The selected brain responses corresponded to peak a_{rot} of 4.5 krad/s^2 and impulse duration of 10 ms (identical to those used in our most recent study [8]). Whole-brain tractography was generated via ExploreDTI using pre-season DTI scans corresponding to the same individual used to create the Dartmouth Head Injury Model (DHIM). The accumulated peak tractography-based ε_n (ε_n^p), regardless of time of occurrence, was then calculated at all sampling points based on a Lagrangian strain tensor [3]. A fiber sampling point was considered "injured" when its ε_n^p exceeded a given threshold, and a voxel-wise injury susceptibility index (φ_{voxel}) was defined as the fraction of "injured" sampling points within the voxel as shown in equation (1),

$$\varphi_{voxel}(\varepsilon_{thresh}) = \frac{\#\ of\ injured\ sampling\ points\ within\ the\ voxel}{total\ \#\ of\ sampling\ points\ within\ the\ voxel}. \quad (1)$$

To calculate a tract-wise injury susceptibility index (φ_{tract}), identifying an anatomically constrained neural tract is necessary. For illustration, three sub-regions of the corpus callosum (CC) were localized by registering the JHU-ICBM-81 WM atlas [9] with the T1-weighted MRI corresponding to the DHIM. Fibers traversing each CC sub-region were identified by testing if fiber sampling points fell inside the anatomical boundary. We then defined, φ_{tract} analogously to φ_{voxel} as the fraction of "injured" WM fibers:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\varphi_{tract}(\varepsilon_{thresh}) = \frac{\#\ of\ injured\ fibers\ for\ the\ given\ neural\ tract}{total\ \#\ of\ fibers\ for\ the\ given\ neural\ tract}. \quad (2)$$

The values of φ_{voxel} and φ_{tract} are percentages ranging from 0% (no injury) to 100% (fully damaged).

RESULTS

The voxel- and tractography-based ε_n^p distributions were largely similar but the latter appeared smoother (**Figure 1)**. This was because the tractography-based approach used much finer resolution sampling points to compute an average ε_n^p at each WM voxel.

Binary injury maps were also compared (**Figure 2**). For the voxel-based method, a voxel was considered "injured" if the corresponding ε_n^p exceeded a given threshold. For the tractography-based approach, voxels with φ_{voxel} >50% were considered as "injured". The two techniques produced discordant voxel-wise injury distributions, especially when ε_{thresh} was high (the average dice coefficient of the three rotations dropped from 0.81 to 0.66 when ε_{thresh} increased from 0.09 to 0.18).

Figure 3 shows φ_{tract} as a function of ε_{thresh} for each CC sub-region. Consistent with φ_{voxel} (**Figure 1g-i**), axial and sagittal rotations were the most and least damaging, respectively. The directional dependency of φ_{tract} was evident. At the "optimal" ε_{thresh} of 0.18, the largest φ_{tract} of 96.8% was observed in the genu for an axial rotation. The largest values for coronal and sagittal rotations were 25.3% and 8.3%, respectively, in the CC main body (**Figure 3**).

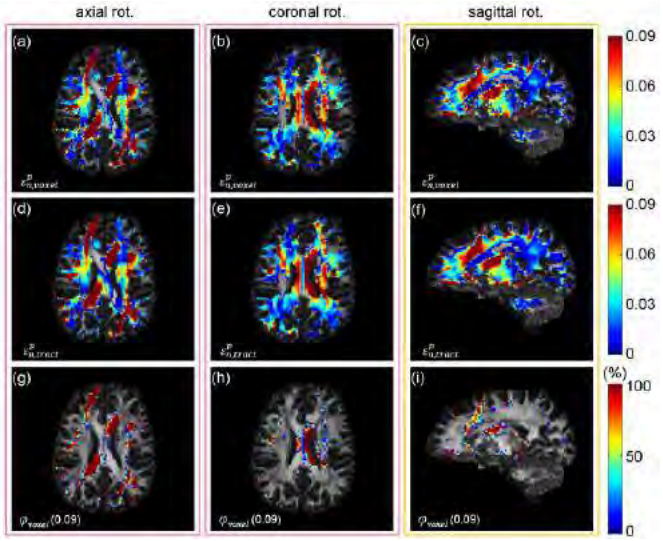

Figure 1 Maps of ε_n^p using the voxel- (top) and tractography-based (middle row) approaches, along with φ_{tract} maps (bottom) on a selected MRI in axial, coronal, and sagittal rotations (from left to right).

DISCUSSION AND CONCLUSION

We have developed a tractography-based technique to evaluate WM fiber strain [8]. The technique was compared with a previously developed voxel-based method, as illustrated using rotations in three directions and three CC sub-regions. Maps of ε_n^p were largely similar across methods, suggesting a certain fundamental concordance between the two methods. However, their binary injury maps based on voxel-wise ε_n^p or φ_{voxel} differed significantly. Because of the much finer spatial resolution used in the tractography-based method, "graded" injury susceptibility may provide a confidence measure for local structural integrity (larger φ_{voxel} indicates higher likelihood of injury).

A unique capability of the tractography-based method was to enable injury assessment for functionally important neural tracts, which was not possible with the voxel-based analogue. As neural tracts connect cell bodies and transmit information between them [10], it is reasonable to assume any damage along axons, regardless of location, would lead to functional impairment [11]. This logic led to the tract-based φ_{tract} to quantify the vulnerabilities of WM neural pathways.

The current study focused on introducing the use of whole-brain tractography to better evaluate WM fiber strain. Future studies using real-world brain injury cases will reveal whether the new injury predictors can improve injury predictive power in a practically useful way. In addition, they may allow assessment of relative vulnerabilities of neural pathways and identification of the most vulnerable ones in real-world head impacts.

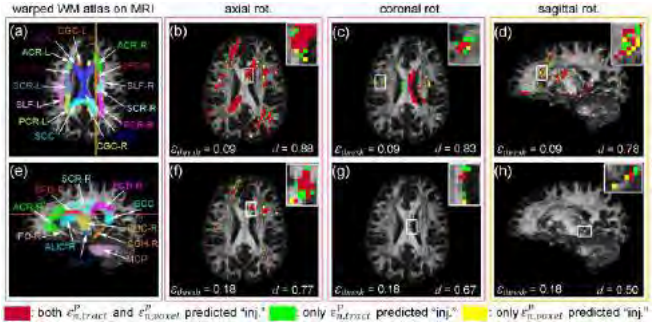

Figure 2 Binary injury maps for the voxel- and tractography-based approaches overlaid on an axial (axial (b and f) and coronal (c and g) rotations) and a sagittal (sagittal rotation (d and h)) MRI along with the ICBM-81 WM atlas warped onto the individual's anatomical MRI (a and b). Dice coefficient (*d*) was reported for each MRI.

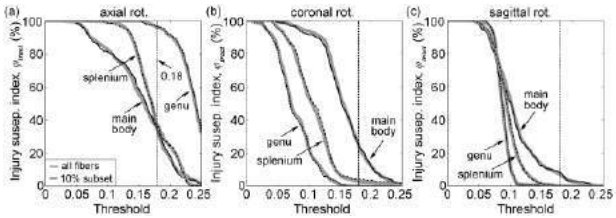

Figure 3 Tract-wise φ_{tract} as a function of ε_{thresh} for each CC sub-region in (a) axial, (b) coronal, and (c) sagittal rotations. The results from the 10% randomly selected fiber sample were virtually identical to those from the full set.

BISPHOSPHONATE CAN RESCUE THE DAMAGED ARTICULAR CARTILAGE IN VITRO

INTRODUCTION

Osteoarthritis (OA) could result from the traumatic damage to the diarthrodial joint, such as the meniscus rupture, anterior cruciate ligament tear, and trauma induced joint bleeding. Few therapeutic techniques are now available to prevent post-traumatic OA (PTOA). Using PTOA animal model, a few studies found that systematic administration of bisphosphonates (BPs) can significantly slow down the development of OA after traumatic damages, including dislocation of meniscus, ACL transaction, and carrageenan-induced inflammation [1]. BPs are a class of commercial drugs widely used for the treatment of bone loss by the dysfunction of osteoclasts [2]. Little knowledge is available about the promising rescue effects of BPs on PTOA. A few studies conjectured that BPs protect the cartilage through the prevention of bone loss after joint trauma [3-4].

In this study, we tested a bold hypothesis that the chondro-protective function of BPs could be related to their direct regulation of the metabolic activities of chondrocytes, which further preserve the integrity of the cartilage solid matrix. Using a long-term *in vitro* culture model, the effect of bisphosphonates on cartilage explants with no subchondral bone attached was investigated.

METHODS

Cartilage explants were harvested from the femoral condyle head of 3-month old calf knee joints using a biopsy punch (diameter: 3mm), as illustrated in Fig. 1. The superficial-middle zones of cartilage (height: 2 mm) were obtained using a custom-designed cutting tool. All cartilage samples were cultured in serum supplemented medium (DMEM, 10% FBS, 1% P/S) for 1 week to simulate the traumatic damage on cartilage caused by joint bleeding. Previous studies from ours and other groups showed that the mechanical integrity of cartilage explants was significantly impaired after long-term exposure to serum medium [5-6]. Damaged samples were then separated into two groups (N=10) and cultured in chemically defined serum-free medium (DMEM, 1% ITS, 50 μg/mL L-proline, 0.9 mM sodium pyruvate, and 50 μg/mL ascorbate 2-phosphate [7]) with or without the supplement of 1 μM zolendronic acid (ZA, Zometa® from Novartis Pharmaceuticals Corporation, an FDA approved BP). The samples were cultured in rescue medium for 4 weeks. Mechanical and dimensional properties of cartilage explants were measured longitudinally on days 2, 8, 15, and 29. The equilibrium Young's modulus and dynamic compressive modulus of samples were determined using unconfined compression tests. GAG content of samples was measured at the end of the 4-week culture using dimethylmethylene blue dye-binding assay. The Mann-Kendall test was performed to analyze the trend of parameters with culture time.

RESULTS

Mechanical Properties: During the 4-week culture, mechanical properties of cartilage explants decreased in the control group (Fig. 2A-2B), while samples in the ZA supplemented medium maintained the mechanical modulus at a relatively constant level (Young's modulus: 0.21~0.25 MPa, dynamic modulus: 4.70~5.53 MPa), and significantly higher than those of corresponding controls. The Mann-Kendall test showed that the difference gap between the two groups increased with culture time (confidence factor > 95%). Young's modulus of the samples in the ZA group became significantly higher than the control after a 15-day culture (Fig. 2A). The dynamic modulus started to show a difference between the two groups after merely 8 days (Fig. 2B).

Biochemical Analysis: After the 4-week culture, GAG content of cartilage in the control group (Fig. 2C) was significantly lower than that in the ZA treated group (3.59% vs. 4.06%).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Dimensional Analysis: The 1-week culture in serum supplemented medium increased the height of cartilage explants by 60% (from the initial 2 mm to 3.2 mm). Increase of height slowed down after switching into serum-free medium (40.6% after 4 weeks). No significant difference was detected in thickness between the control and ZA-treated groups (Fig. 2D). Diameter of the explants (Fig. 2E) increased in both groups, but samples in the ZA group swelled significantly less after 29 days. Thus the volume of explants in the ZA group is significantly smaller than that of control (Fig. 2F). The Mann-Kendall test showed that the difference gap between the two groups increased with culture time (confidence factor > 95%).

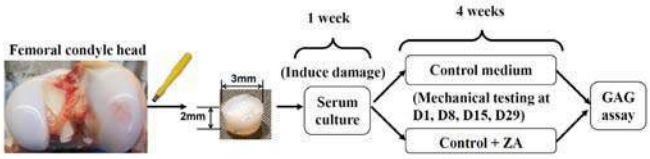

Figure 1: Cartilage explants were harvested from the femoral condyle head, followed by a 1 week culture in serum medium (DMEM+10% FBS). Samples were then separated into 2 groups, control and ZA supplemented group, for another 4-week culture. Mechanical properties were measured longitudinally on days 1, 8, 15, and 29.

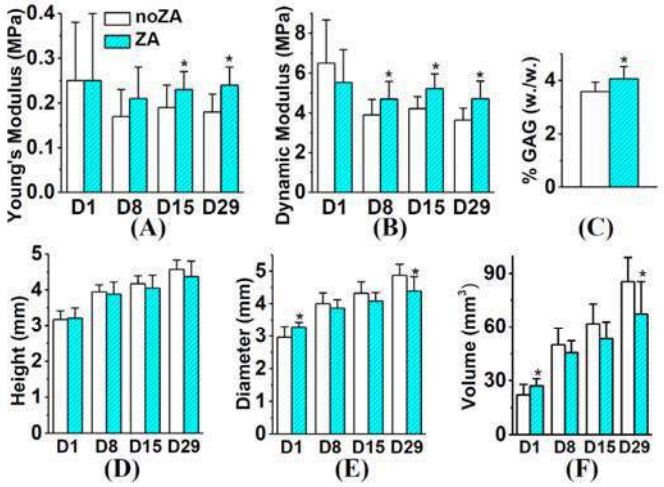

Figure 2: (A) The equilibrium Young's modulus and (B) dynamic modulus of cartilage explants were determined longitudinally by unconfined compression tests on days 1, 8, 15, and 29 (n = 10). Samples were cultured in chemical defined medium with no dexamethasone. (C) GAG content of cartilage explants was determined at the end of the 4-week culture. Geometric dimensions of the cylindrical explants were measured longitudinally including the (D) height, (E) diameter, and (F) volume of cartilage explants. (* $p<0.05$)

DISCUSSION

As an FDA approved drug for two decades, bisphosphonates could represent a new therapeutic medicine for the prevention of PTOA. This concept-proof study showed that BPs can directly regulate the metabolic activities of chondrocytes in a beneficial direction. Besides revealing the chondro-protective mechanisms of BPs, the results also provided us extra confidence for studying BPs for PTOA. This new evidence, however, does not necessarily conflict with the conjecture that the chondro-protective effect of bisphosphonate is related to its inhibition of bone loss. BPs might protect the cartilage after joint trauma through both mechanisms, i.e., preventing bone loss and regulating chondrocytes activities.

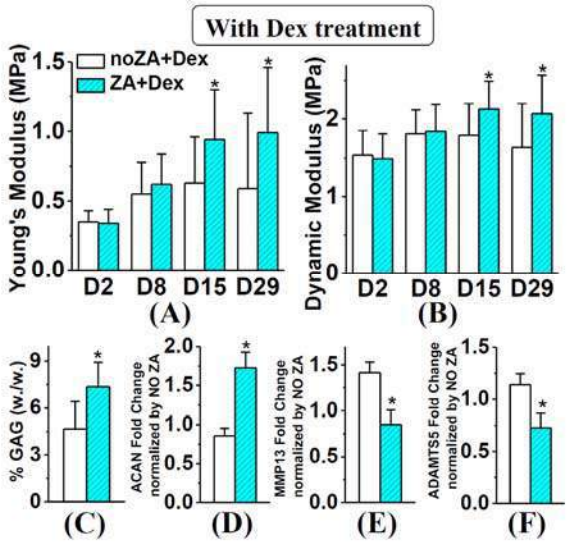

Figure 3: (A) Equilibrium Young's modulus and (B) dynamic modulus of cartilage explants were determined longitudinally on days 2, 8, 15, and 29 in serum-free culture supplemented with dexamethasone. (C) GAG content after 4-weeks culture. Gene expression of chondrocytes after 2-week culture: (D) Aggrecan, (E) MMP-13, and (F) ADAMTS5.

In our previous study [7], we investigated the effect of ZA on cartilage explant with the addition of dexamethasone in the culture medium, in which ZA showed similar chondro-protective effects in terms of the mechanical modulus (Fig. 3A-B), GAG content (Fig. 3C) and the gene expression of chondrocytes (Fig. 3D-F). Dexamethasone has a strong chondro-protective effect by upregulating the anabolic genes and suppressing the catabolic genes in chondrocytes. In the present study, dexamethasone was removed from the culture medium, and the beneficial effects of bisphosphonate were retained. Therefore, it is clear that BPs can directly regulate the metabolic activities of chondrocytes.

ZA treatment increased the GAG content in cartilage explants. As the GAG chains are negatively charged, more GAG generates higher osmotic swelling pressure in the solid matrix [8]. However, explants in the ZA group swelled less than the control group. This implies that the collagen networks in ZA treated samples should be much stronger than those in control medium, which is reflected by the mechanical testing results (Fig. 2A-2B) and MMP gene expression (Fig 3E). Therefore, ZA protects the mechanical integrity of the solid matrix in cartilage.

INTRODUCTION

Biological soft tissues resist loads under physiological conditions remarkably well. Nonetheless, they can fail due to disease or simply age; examples range from torn ligaments [1] to arterial dissections [2]. Because soft tissues have complex geometries and complex, non-linear material properties, computational methods are essential to the study of soft tissue damage and failure. However, traditional approaches, such as the Finite Element Method, are limited.

Here, we test the utility of a novel mixed particle/continuum approach to the study of soft tissue damage and failure. Specifically, we combine traditional continuum damage mechanics with Total Lagrangian SPH (Smoothed Particle Hydrodynamics) to model soft tissue damage and discontinuous failure, respectively. While SPH was originally conceived for applications other than solid mechanics, recent improvements have made the method a promising alternative to the Finite Element Method in a number of applications [3].

The purpose of this work is to demonstrate SPH's potential advantage for damage and failure modeling with an example of a generic, anisotropic soft tissue sample subject to finite deformations.

METHODS

SPH for Solid Mechanics. In SPH, physical quantities at point $\boldsymbol{X}_i$ are smoothed over the "particle's" immediate neighborhood within the domain of interest:

$$\hat{g}(\boldsymbol{X}_i) = \int f(\boldsymbol{X})\widehat{W}(\boldsymbol{X}-\boldsymbol{X}_i,h)\mathrm{d}\boldsymbol{X}, \tag{1}$$

where $\widehat{W}$ is referred to as the smoothing kernel. Spatial discretization is further performed by approximating the above integral expression by a finite sum over discrete neighboring points $\boldsymbol{X}_j$ within the smoothing length *h*. Thus,

$$g(\boldsymbol{X}_i) = \sum_{j\in S} f_j\, V_j W(\boldsymbol{R}_j,h), \tag{2}$$

where $f_j = f(\boldsymbol{X}_j)$, V_j is the volume associated with each neighboring particle, and $W(\boldsymbol{R}_j,h)$ is the kernel weight as a function of particle distances, with $\boldsymbol{R}_j = \boldsymbol{X}_j - \boldsymbol{X}_i$. The gradient of $g(\boldsymbol{X})$ follows from,

$$\nabla_{\boldsymbol{X}} g(\boldsymbol{X}_i) = \sum_{j\in S} f_j\, V_j \nabla_{\boldsymbol{X}} W(\boldsymbol{R}_j,h). \tag{3}$$

Because the standard SPH method lacks 0th order and 1st order completeness, two ad-hoc corrections are performed, viz.,

$$\tilde{\nabla}_{\boldsymbol{X}} g(\boldsymbol{X}_i) = \sum_{j\in S} (f_j - f_i)\, V_j \mathbf{A}^{-1}\nabla_{\boldsymbol{X}} W(\boldsymbol{R}_j,h), \tag{4}$$

where,

$$\mathbf{A} = \sum_{j\in S} V_j\, \nabla_{\boldsymbol{X}} W(\boldsymbol{R}_j,h)\otimes\boldsymbol{R}_j. \tag{5}$$

Given this basic framework, we explicitly solve the local strong form of the equilibrium equations in referential form,

$$m_i\ddot{\boldsymbol{x}}_i = \boldsymbol{f}_i^{\,int} + \boldsymbol{f}_i^{\,ext}, \tag{6}$$

by first approximating the deformation gradient,

$$\boldsymbol{F}(\boldsymbol{X}_i) = \sum_{j\in S} \boldsymbol{r}_j \otimes V_j \mathbf{A}^{-1}\nabla_{\boldsymbol{X}} W(\boldsymbol{R}_j,h), \tag{7}$$

where $\boldsymbol{r}_j = \boldsymbol{x}_j - \boldsymbol{x}_i$. Next, assuming the existence of a strain energy density function ψ, we derive the first Piola-Kirchhoff stress tensor according to,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\boldsymbol{P}(\boldsymbol{X}_i) = 2\boldsymbol{F}(\boldsymbol{X}_i)\frac{\partial \psi(\boldsymbol{X}_i)}{\partial \boldsymbol{C}(\boldsymbol{X}_i)}. \quad (8)$$

Finally, we calculate the particle forces $\boldsymbol{f}_i^{int}$ from the divergence of $\boldsymbol{P}(\boldsymbol{X}_i)$ using above expressions and ad-hoc corrections,

$$\boldsymbol{f}_i^{int} = \sum_{j \in S} V_i V_j \left(\boldsymbol{P}_i \mathbf{A}^{-1} \nabla_{\boldsymbol{X}} W(\boldsymbol{R}_j, h) - \boldsymbol{P}_j \mathbf{A}^{-1} \nabla_{\boldsymbol{X}} W(\boldsymbol{R}_i, h) \right). \quad (9)$$

Thus, once the internal and external forces are known, the acceleration can be updated for each particle according to equation (6) and integrated twice via the Leap-Frog scheme to obtain the current nodal positions.

Damage and Failure Modeling. We assume that our test material behaves according to following strain energy density function [4],

$$\psi(\boldsymbol{C}, \boldsymbol{M}) = \frac{\mu}{2}(I_1 - 3) + \mu \ln J + \frac{\lambda}{2}(\ln J)^2 + \frac{k_1}{4k_2}[\exp(k_2(I_4 - 1)^2) - 1], \quad (10)$$

where $I_1 = \boldsymbol{C}:\boldsymbol{I}$, $I_4 = \boldsymbol{C}:\boldsymbol{M}\otimes\boldsymbol{M}$, $J = \det\boldsymbol{F}$, and $\boldsymbol{M}$ is the direction vector of structural fibers embedded in a neo-Hookean ground substance. Isotropic continuum damage is further modeled by employing an approach first proposed by Simo in which the original strain energy function ψ is modified by a reduction factor $(1 - D)$, where D is the damage variable [5,6]. Therefore,

$$\psi(\boldsymbol{C}, \boldsymbol{M}, D) = (1 - D)\psi_0(\boldsymbol{C}, \boldsymbol{M}) \text{ and } \boldsymbol{S} = 2(1 - D)\frac{\partial \psi_0}{\partial \boldsymbol{C}}. \quad (11)$$

In our examples, the damage evolution is prescribed through following exponential law,

$$D = \begin{cases} \exp\left(\left((\lambda_m - \lambda_{crit})/\tau\right)^2\right) - 1 & \lambda_m \geq \lambda_{crit} \\ 0 & \lambda_m < \lambda_{crit} \end{cases}. \quad (12)$$

Here τ and λ_{crit} are material specific damage parameters and λ_m is the largest previously experienced maximum principal stretch, $\lambda_m(t) = \max_{s\in(-\infty,t]} \lambda(s)$.

Once, the damage variable D reaches a value of one, the material is considered fully damaged. Continuum methods have no capacity to model material behavior beyond this point. However, knowing the behavior of soft tissue following damage and failure may be important as new surfaces, for example, could be subject to applied tractions and loads. Because in SPH particle connectivity is determined based on a list of neighboring particles, we model strong discontinuities following irreversible tissue damage, such as crazing or rupture, by a simple modification to this list.

RESULTS

To verify the implementation of equations (1) - (12), we simulated simple uniaxial and biaxial tensile tests of an anisotropic soft tissue strip and, compared to the analytical solution, found a maximum error of less than 1%.

Further, to demonstrate the ability of our novel hybrid approach to model strong material discontinuities that occur during damage and failure of soft tissue, we also modeled the response of a cylindrical, anisotropic soft tissue sample to clamped uniaxial extension, see Figure 1. Because rupture initializes at focal material points, we assigned the critical damage parameter λ_{crit} for each particle according to a normal distribution. The figure illustrates the damaged soft tissue sample with fibers oriented in horizontal direction at six time points between the reference configuration and catastrophic failure.

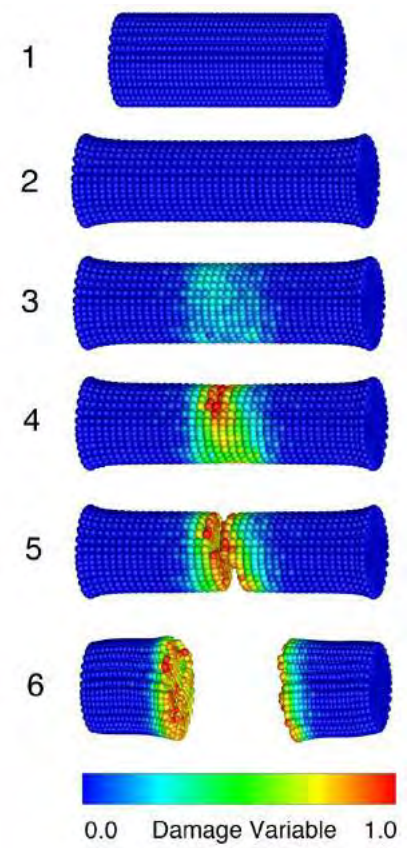

Figure 1: Example of a cylindrical tissue sample under clamped uniaxial extension to failure. Shown is the evolution of the damage variable at six time points: 1) reference configuration, 2) before damage, 3) initial damage in areas of highest stress, 4) first particles reach damage values of one, 5) particles disconnect to form a rupture surface, 6) full rupture.

DISCUSSION

SPH suffered from a number of short-comings which have limited its use in solid mechanics and specifically soft tissue mechanics. However, recently introduced correction steps have improved the accuracy of SPH as shown in our verification problems. Furthermore, as we demonstrated, SPH may provide advantages over more established methods, especially where catastrophic failure such as crazing, dissection, and rupture is modeled. Of course, this is only a first step toward establishing SPH as a reliable numerical method for soft tissue mechanics and specifically damage and failure, however, we believe further research is warranted.

INTRODUCTION

The evaluation of tendon composition and structure could facilitate an understanding of how tendon behavior changes as tissue properties are modified in injury and aging. Unfortunately, studies evaluating the contribution of tissue constituents with small quantities (e.g., proteoglycans (PGs)) have yielded inconsistent results. PGs, composed of a core protein attached to glycosaminoglycan (GAG) chains, have been observed in high-resolution micrographs; some studies have utilized computational modeling to suggest that these PGs maintain tendon mechanical integrity by bridging adjacent collagen fibrils [1-3]. Experimental studies report conflicting results: tensile mechanics were unchanged after partially enzymatic depletion of GAGs, while tendons from PG-null mice showed inferior failure loads and dynamic mechanics in an age-dependent manner [1,4-6]. While these studies have focused on tensile loading, the contribution of PGs to the mechanical response of tendons under other loading scenarios has not been as well addressed [1-6]. In particular, understanding the role of PGs under shear loading would be beneficial since shear is likely to cause more sliding between collagen fibers and could better explore the possibility of force transfer assisted by PGs side-chains. Damage to the oft-injured supraspinatus tendon (SST) may be partially due to shearing through the tendon thickness [7,8], so tissue constituents that govern the shear response may play a critical role in SST mechanics. In this study, we examined if PGs influence the multiscale mechanics of human SST, using micromechanical shear testing with two-photon microscopy before and after enzymatic digestion.

METHODS

Biomechanical testing. SSTs (n=10) were obtained from fresh frozen human cadaver shoulders (age: 70.8±21.4 years), with torn tendons excluded. 10×8 mm (LxW) full-thickness samples were cut from three distinct SST regions (Fig. 1A, A: anterior, M: medial, P: posterior), corresponding to previous studies [8,9]. After leveling surfaces on a microtome, samples were incubated for 30 min in a 100 μg/ml 5-DTAF solution to stain collagen [10]. Following PBS washes, samples were mounted in a micromechanical test device secured to the stage of a Zeiss two-photon confocal microscope system. Four adjacent squares (100×100μm) were photobleached at three locations (bursal to joint) at a depth of ~50μm after applying a 0.005N pre-load. Incremental stress-relaxation shear testing was applied (Fig. 2B), and multi-channel z-stacks were collected as described previously [10,11]. Then, clamps were locked and one set of samples (n=5/region) was randomly selected for treatment with Chondroitinase ABC (ChABC) solution (described below), while the other set (n=5/region) was incubated in PBS. Following incubation, all samples were retested with the same shear loading protocol and two-photon images acquired.

ChABC treatment and GAG quantification. The efficiency of ChABC on SST was examined in concentration- and time-dependent testing. Results (not shown) indicated an optimal treatment of 0.2 units/ml ChABC buffer for 8 hours. Due to the relatively large size of samples and the method used for mounting samples within the test device, the depth to which ChABC could penetrate into the tissue and digest PGs was also evaluated. For these preliminary tests, bovine deep digital flexor tendons (DDFTs) were used for their easy accessibility. Samples (n=8) of similar size were cut from the proximal region of four bovine DDFTs [10,11]. Samples were glued to shear clamps and the clamp-sample assemblies were incubated in either ChABC solution (n=4) or PBS (n=4) for 8 hours. Five small tissue pieces weighing 40-50 mg each were evenly taken from locations along the thickness of each sample using a freezing stage sledge microtome. Total GAG amount in digested samples was quantified using a 1,9-Dimethylmethylene Blue Assay and normalized by GAG quantity in a corresponding control sample [12].

Data analysis. Peak/equilibrium stresses, and local matrix-based strains were calculated as in previous studies [10,11]. Rotation was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

defined as the angle change between the deformed horizontal photobleached lines and the image x-axis (Fig. 1E). Normalized stresses were computed as shear stresses after ChABC treatment/PBS incubation normalized by the last step peak stress of the corresponding samples before treatment/incubation (control). Mechanical differences between control and treated samples were evaluated by paired *t*-tests, while unpaired *t*-tests were used to evaluate local matrix-based strains and rotations. One-way ANOVAs with Bonferroni post-hoc tests were used to find differences across the three SST regions. Significance was set at $p < 0.05$. Data are shown as mean ± SD.

RESULTS

ChABC treatment caused a gradient distribution of GAGs in tendon, with 20.0±13.0% left on the surface of samples and 69.0±5.9% in the middle (Fig.2A). Shear stress values were similar for all regions,

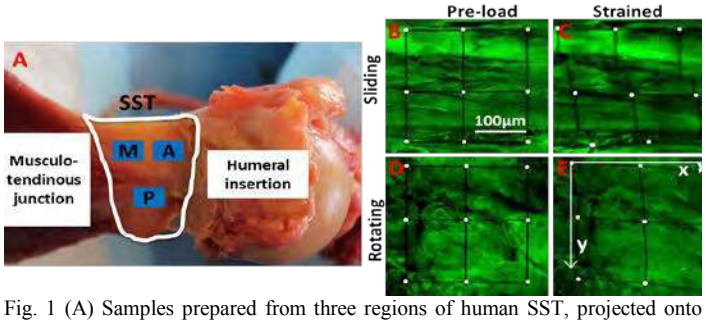

Fig. 1 (A) Samples prepared from three regions of human SST, projected onto the joint side of the tendon. Compared to pre-load images (B,D), sliding between fibers (C) and rotation of fibers (E) are shown in two-photon microscopy images.

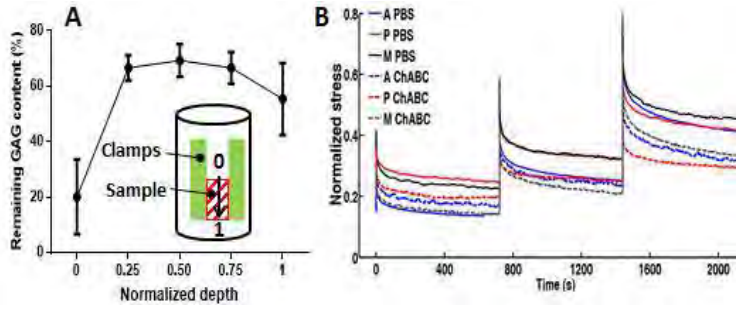

Fig. 2 (A) Remaining GAG content along the depth; inset shows a sample (red block) attached to clamps (green blocks) incubated in ChABC solution. The normalized depth is defined as 0 (top) to 1 (bottom). Averaged stress-time curves (B) of PBS incubated and ChABC treated groups, normalized by corresponding control stresses.

and stress profiles decreased more for ChABC-treated samples than PBS-incubated samples (Fig. 2B). Control samples (i.e., before digestion) exhibited larger peak and equilibrium stresses than treated samples in all three SST regions; digestion decreased peak and equilibrium stresses by an average of 30.7 and 27.2%, respectively (Fig. 3A&B), although these differences were not significantly different. On the microscale, areas of both organized and disorganized collagen were found in most SST samples, showing microstructural heterogeneity. For loaded samples, breaking and rotation of photobleached lines were found in all regions (Fig. 1C&E), demonstrating fiber sliding and reorganization. Local matrix-based strains were similar before and after treatment, and were generally smaller than clamp strains (Fig. 3C), demonstrating strain attenuation. Rotation increased with increasing applied strains (Fig. 3D).

DISCUSSION

Although not attaining statistical significance, digested SSTs exhibited decreased stresses, and even smaller normalized stresses

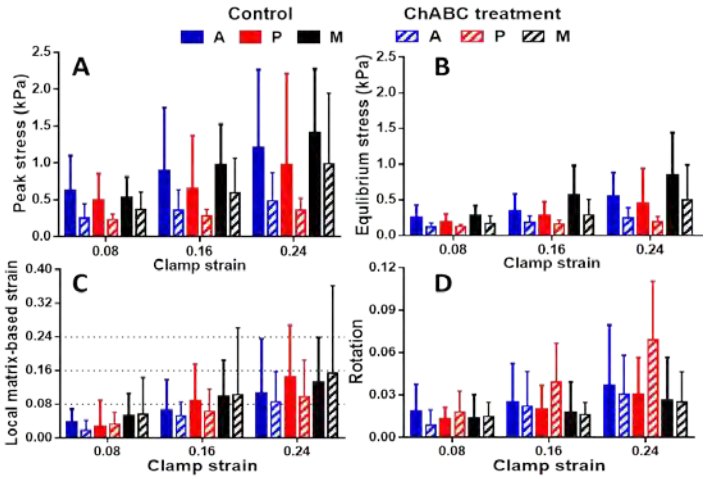

Fig. 3 Peak (A) and equilibrium (B) stresses of SST samples before (control) and after (ChABC) treatment. Similar local matrix-based strains (C) and rotations (D) across different regions, and even between control and treated samples.

than PBS incubated SSTs under shear loading. These results suggest that PGs provide force support under shear loading. The high variability of tendon stress values may be due to the wide age range and (assumed) varied loading history of cadaveric human tissue tested in this study; evaluation of additional samples could raise differences observed herein to the level of statistical significance. Our study also illustrates the limited penetration of ChABC inside SST to digest GAGs, indicating the limitation of the enzyme-treated approach to examine the role of tissue constituents [1,6]. Mechanical results of digested samples were compared to data from PBS-incubated samples to account for effects due to tendon swelling. Similar microscale strain across all three regions and even between control and treated tendons may be due to SST high microstructural heterogeneity (i.e., disorganized collagen fibers). Sliding between collagen fibers and fiber reorganization appear to be the physical mechanisms on the microscale-level that regulate tendon behavior under shear. Previous studies reported fiber elongation and sliding in tendon as deformation mechanisms under tensile loading [13,14]. One limitation of this study was that PGs were only partially digested, particularly in the middle of samples, which limits the magnitude of the effect by ChABC treatment. By analyzing multiscale mechanical behavior of SST under shear loading before and after PG digestion, this study provides insight into the role of tissue constituents of relatively small amounts in tendon, which may help predict how non-tensile mechanics are altered with degeneration/injury-related changes to compositional properties of tendons.

MODULATION OF ICAM-4 ADHESION RECEPTORS ON SS-RBCS REVEALED BY ATOMIC FORCE MICROSCOPY

INTRODUCTION

Painful vaso-occlusive episodes in sickle cell disease (SCD) are largely due to abnormal adherence among red blood cells (RBCs), leukocytes, platelets, and the endothelium [1]. Adhesion receptors expressed on RBCs regulate RBC adherence to the endothelium and to blood cells. ICAM-4 is an adhesion receptor interacting with αvβ3, an integrin expressed on endothelial cells and platelets [2].

Here, we employ atomic force microscopy (AFM) to detect the distribution of active ICAM-4 molecules on the RBC membrane and measure the unbinding force between ICAM-4 and αvβ3.

METHODS

Human subjects and blood preparation

Homozygous SCD (SS) patients were eligible to participate if they were at least 18 years old and at steady state. Additionally, they were not on treated with hydroxyurea and had no blood transfusion in the past three months. Blood samples were obtained from fresh-drawn, heparin-anticoagulated venous blood of qualified volunteers. The whole blood was centrifuged at 145×g for 5 min at 4 ℃ to separate the RBCs. The plasma and buffy coat were extracted and discarded. Then the RBCs were washed three times with Alsever's solution and stored at 4 ℃.

Ligand and reagents

Human integrin αvβ3 protein was obtained from Millipore (Billerica, MA). Alsever's solution, epinephrine (Epi), forskolin (FSK), KT 5720, Rp-Adenosine 3′,5′-cyclic monophosphorothioate triethylammonium salt (Rp-cAMPS), bovine serum albumin (BSA), valsartan were purchased from Sigma-Aldrich (St. Louis, MO). St-Ht 31 inhibitor peptide and St-Ht 31P control peptide were purchased from Promega (Madison, WI).

Probe functionalization

Silicon nitride probes (Bruker AFM Probes, Camarillo, CA) were first aminated with 2% v/v 3-aminopropyltriethoxysilane (APTES) in acetone for 10 min, then rinsed with deionized (DI) water. Probes were soaked in 0.5% glutaraldehyde (solution in DI water) for 30 min to attach the flexible glutaraldehyde molecule linker, then rinsed again with DI water and incubated in 100 μg/mL αvβ3 solution. After 30 min, the probes were rinsed again with DI water and immersed in BSA for 1 min to block remaining aldehyde groups. Probes were stored in PBS at 4℃ and used in three days.

AFM setup and data recording

Experiments were performed using the MFP-3D-BIO AFM (Asylum Research, Santa Barbara, CA), which was mounted on an inverted microscope (Zeiss Axiovert A1). Through the microscope we were able to position the AFM cantilever on a chosen RBC (Fig. 1a). The nominal spring constant of the applied cantilever was 30 mN/m. RBCs were pretreated with biomedical reagents and incubated at 37℃ (30 min: epinephrine, FSK, KT 5720, Rp-cAMPS, valsartan; 2h: St-Ht 31, St-Ht 31P).

Adhesive interactions were quantified by recording force-distance curves between a αvβ3-functionalized cantilever and ICAM-4 receptors at 32×32 points homogeneously distributed in 1μm^2 area of the RBC membrane. Each curve comprised a complete approach and retraction cycle. An unbinding force was measured as the abrupt drop to zero in the retraction path. The approach and retraction speeds were controlled at 800 nm/s, which gave an effective loading rate of 24 000 pN/s. Furthermore the unbinding forces were plotted as a force map

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

displaying the spatial distribution of the active ICAM-4 receptors on the RBC surface (Fig. 1b). Therefore, we were able to measure changes in the expression of force maps due to modulation of the density of activated ICAM-4 molecules in the presence of biochemical reagents that interfere with the cAMP-dependent PKA pathway.

Statistical analysis

The unbinding forces between αvβ3 ligands and ICAM-4 receptors were measured using frequency (%) distribution and box-and-whisker plots. In the frequency distribution plots (not shown here), each bin represented the number of unbinding forces within the bin width. We found that the mean value of the unbinding forces did not depend on the employed reagents. Collective frequency (CF, %), denoting the surface density of active ICAM-4 receptors, was defined as the number of curves with nonzero forces divided by the number of all curves in each experimental condition, accumulating all tested cells. The collective frequencies from different groups were reported as mean ± SE and illustrated by box-and-whisker plots then compared using non-parametric statistical test. The results were considered significant if $p<0.05$.

RESULTS

Here we show at the single molecule level that in SS-RBCs the interaction between ICAM-4 and αvβ3 is strongly mediated by cAMP-dependent PKA-signaling pathway (Fig 1c). Stimulation of β2-adrenergic receptors (β2-ARs) activates the Gas proteins, which are associated to G protein-coupled receptor (GPCRs), and stimulate adenylyl cyclase (AC). AC catalyzes the conversion of ATP to cAMP which then activates PKA that binds to A-kinase anchoring proteins (AKAPs) causing activation of ICAM-4 [3]. First, we performed experiments on SS-RBCs without reagents to measure the baseline unbinding frequency (BF) of ICAM-4. Then we used epinephrine, a catecholamine that stimulates the β2-ARs resulted in a significant increase in the average BF from 10.08±0.85% to 21.41±2.27%. Next, we used forskolin (FSK), a strong AC activator, which raised the average BF to 26.55±2.68%. In order to confirm that the modulation was acting via PKA, we used known PKA inhibitors KT 5720 and Rp-cAMPS which respectively decreased the average BFs to 8.94±0.83% and 6.49±0.96%. Furthermore, following treatment of the SS-RBCs with St-Ht31 (a peptide which inhibits binding of PKA to AKAPs), the average BF decreased to 5.33±0.88%. As a negative control, we used St-Ht31P which did not alter the frequency. To investigate whether AKAP inhibition would block ICAM-4 activation, we treated SS-RBCs with St-Ht31 and FSK subsequently. Indeed, we observed that AKAP inhibition prevented forskolin-mediated ICAM-4 and αvβ3 adhesion.

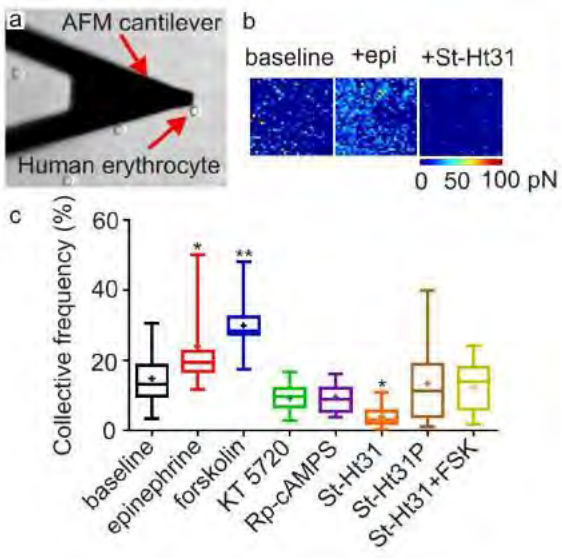

Figure 1: (a) Representative optical microscopy image showing human RBCs and an AFM cantilever. (b) Adhesion force maps. (c) Box-and-whisker plot of the collective frequency of detected ICAM-4 receptors on SS-RBCs after treatment with biochemical reagents modulating the cAMP-dependent PKA pathway. Significance relative to baseline is denoted as * such that $p < 0.05$ and ** such that $p < 0.005$.

DISCUSSION

In this study, we have demonstrated at the single molecule level that the activation of ICAM-4 receptors on SS-RBC membrane is critically dependent on the cAMP-dependent PKA pathway.

TRIBOLOGICAL REHYDRATION I: A NEW MECHANISM OF INTERSTITIAL FLUID RECOVERY

Axel C. Moore (1) and David L. Burris (1,2)

(1) Department of Biomedical Engineering
University of Delaware
Newark, DE, USA

(2) Department of Mechanical Engineering
University of Delaware
Newark, DE, USA

INTRODUCTION

It is now generally accepted that the primary lubrication mechanism of articular cartilage is derived from the deformation induced pressurization of interstitial fluid [1]. The pressurized fluid stiffens the matrix, supports load, shields the solid matrix, and reduces friction by ~2 orders of magnitude [2]. However, interstitial pressure also drives fluid from the tissue resulting in the loss of interstitial fluid, pressure, and lubrication over time.

The apparent fact that interstitial pressure is self-defeating has raised concerns that interstitial lubrication cannot possibly contribute to joint lubrication in the long-term. However, *in-vivo* joint-space and contact stress measurements prove that interstitial fluid, pressure, and lubrication are retained indefinitely in healthy joints [3]. Caligaris and Ateshian offered the first direct insight into why joints retain interstitial fluid [4]. They showed that interstitial lubrication can be retained indefinitely if the contact migrates across the cartilage as is the case in natural joints. They proposed that migration helped retain interstitial fluid, pressure, and lubrication by moving before the fluid could respond.

However, this migration theory fails to explain how cartilage recovers fluid following inactive periods of sitting and standing. *In-vivo* studies have shown that interstitial fluid is recovered during activity [5], thus enabling long-term sustainability. It is proposed that cartilage recovers fluid because articulation intermittently exposes the contact to the synovial bath where it can freely imbibe fluid; to our knowledge, this remains the only explanation for cartilage recovery. Here we present the first direct evidence of an alternate mechanism of fluid recovery. Cartilage lost, retained, and recovered interstitial fluid in a rapid, predictable, and controllable manner without ever exposing the contact area to the bath. This study demonstrates a fundamentally new mechanism, which we call tribological rehydration.

METHODS

Cartilage samples, Ø 19 mm osteochondral cores, were taken from the femoral condyles of mature bovine stifles. Immediately after removal, samples were rinsed, soaked in phosphate buffered saline (PBS), and refrigerated for less than 5 days, a time frame that produces no statistically significant changes in properties [6]. The cartilage was placed in stationary contact (SCA [4]) against an optically smooth/flat glass slide in a PBS flooded contact. All friction experiments used a reciprocation track length of 20 mm, speeds of 0, 10, and 60 mm/s, a normal force of 5 N, and a measured contact diameter of 5 ± 0.4 mm. Normal force, friction force, and compression were measured *in-situ*.

RESULTS

The friction coefficient (μ) and compression are plotted versus time in Figure 1. The original 19 mm diameter sample started below μ = 0.01 and equilibrated near μ = 0.02, an observation that appears at odds with interstitial lubrication theory [4]. Due to the sample diameter (19 mm) being much larger than the contact diameter (5 mm), the contact produced a convergent wedge, *i.e.* a means for fluid entrainment and hydrodynamic pressurization. To test this effect, the sample was cut to Ø 12 mm then to Ø 6 mm; the test was repeated on the same sample at each size condition.

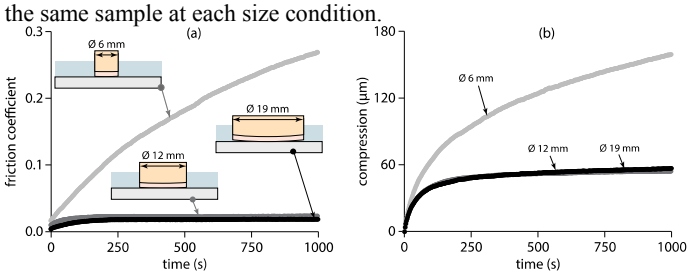

Figure 1. (a) Friction coefficient and (b) compression of a single representative cartilage sample cut to varying size (19, 12, 6 mm diameter) and reciprocated at 60 mm/s. The sample surface was convex with a curvature radius of 21.5 mm in the direction of sliding.

The friction response to SCA sliding only transitioned to high friction when the sample size approached the contact diameter, which eliminated the hydrodynamic convergence zone; this observation appears to suggest that low sustained friction coefficients of larger

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

sizes can be attributed to hydrodynamic fluid films [7]. However, the compression measurements in Figure 1b are inconsistent with this hypothesis.

When the sample was significantly larger than the contact, cartilage maintained a strain of ~5%, which is consistent with that found in healthy active joints [3]. When the sample size approached the contact size, fluid exudation (compression) persisted and friction increased as expected for the SCA testing configuration [4]. The fact that the effect dissipates when the convergence zone is compromised suggests that hydrodynamic effects arrest or compete with the exudation process.

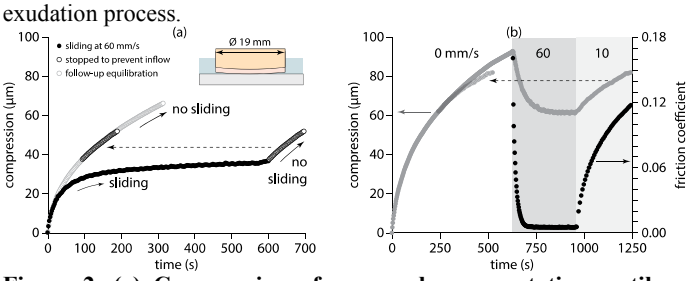

Figure 2. (a) Compression of a second representative cartilage sample versus time in a start-stop SCA test configuration. The sample was loaded to 5 N and slid at 60 mm/s. Reciprocation was stopped at 600 s to provide a period of static equilibration. The sample was then unloaded and soaked for 1 hour to restore interstitial fluid and equilibrated again under static loading at 5 N. (b) Compression and friction versus time for a third representative sample of 19 mm diameter in a stop-start test configuration. Following a period of static equilibration, the sample began sliding at 60 mm/s until reaching a dynamic equilibrium; at which point the sliding speed was reduced to 10 mm/s.

Follow-up experiments were conducted to elucidate the dynamics of the exudation and recovery processes. A second representative 19 mm diameter sample was slid at 60 mm/s for 600 seconds and then stopped; the compression of this sample is shown as a function of time in Figure 2a. In this case, exudation ceased at a compression asymptote of ~40 μm (~5% strain) during sliding, but resumed once sliding stopped. Following re-equilibration by soaking in PBS, the sample was compressed statically at 5 N to obtain the static equilibration response. Comparisons to the original test results produced two noteworthy observations. Firstly, the initial compressive response during sliding was identical to the initial response under static loading, which suggests that the competing effects of hydrodynamic pressurization were negligible initially. Only after ~15 μm of compression did the curves diverge, suggesting that significant deformations are required to produce competitive hydrodynamic pressures (the integration of deformation and hydrodynamics is the defining feature of elastohydrodynamics or EHD). Secondly, the static exudation response following sliding overlays nearly perfectly onto the control equilibration response, suggesting that the exudation response is strain dependent and history independent. Since sliding speed has no theoretical connection to interstitial exudation in the SCA configuration, these results suggest that, at dynamic equilibrium, EHD pressurization during sliding drove fluid into the surface at a rate equal to that of exudation.

Figure 2b illustrates the recovery of interstitial fluid following static loading and gross exudation. In this case, a representative sample was compressed by 90 μm over 600 seconds of static loading. On the first sliding cycle at 60 mm/s the friction coefficient was $\mu = 0.16$. Thereafter the friction coefficient and compression decreased monotonically with continued sliding and eventually reached asymptotes of $\mu \sim 0.005$ and $\delta \sim 65$ μm (~5% strain), respectively.

Following equilibration at 60 mm/s, the sliding speed was reduced to 10 mm/s to test the hypothesis that inflow becomes less competitive with exudation when hydrodynamic pressures decrease at lower speeds. The reduced sliding speed caused an immediate increase in friction (from 0.005 to 0.02) and compression rate; as the overlay in Figure 2b illustrates, the compression rate at 10 mm/s was less than that under static conditions, which indicates that EHD pressurization at lower speeds remains finite but is less competitive with exudation. In general, increased speeds caused thickening and decreased friction, while decreased speeds caused compression and increased friction; this observation is consistent with the hypothesis that exudation from interstitial lubrication is offset by inflow from external EHD pressurization, which is strongly speed dependent [8]. We call the EHD-driven inflow mechanism 'tribological rehydration' and we define the 'convergent-SCA', as a SCA in which there is a clear convergence zone for hydrodynamic pressurization.

DISCUSSION

The results of this study demonstrate that cartilage can recover interstitial fluid and lubrication in a convergent-SCA. This fact cannot be explained by the existing hypothesis, which is that cartilage recovers fluid when joint articulation exposes the compressed area to the bath. This study suggests a new mechanism, tribological rehydration, in which fluid drawn into the contact by sliding is pressurized elastohydrodynamically and subsequently forced into the porous articular surfaces to restore hydration.

Because joints and other migrating contacts possess entrainment zones for hydrodynamic pressurization, it is difficult to determine if migration, bath exposure, or tribological rehydration is primarily responsible for observations of recovery and retention of interstitial fluid during activity. To our knowledge this paper is the first to demonstrate these important physiological phenomena under conditions that isolate a single mechanism, tribological rehydration.

EFFECTS OF PROXIMAL TIBIA ANTERIOR CLOSING WEDGE OSTEOTOMY ON ACL FORCE AND KNEE KINEMATICS

INTRODUCTION

Rupture of the anterior cruciate ligament (ACL) is one of the most common ligamentous injuries of the knee. Although many patients have a good outcome after ACL reconstruction, there are a number of individuals that experience continued instability secondary to a failed or stretched-out graft. Some individuals go on to have multiple failed ACL revision reconstructions. While effect of tunnel placement, graft selection, and fixation technique have been evaluated relating to a successful ACL reconstruction, there is a lack of basic science research evaluating the effect of changing the anatomy of the knee on ACL reconstruction surgery. There is increasing evidence that the posterior tibial slope (PTS) of the tibial plateau, and in particular PTS differences between the medial and lateral compartments, may play a role in ACL injury [1-3]. In theory, contact force on a steeper PTS would translate the tibia anteriorly, and an increased slope of the lateral plateau would cause additional anterior subluxation of the lateral plateau, producing an internal tibial rotation. Thus, some clinicians have begun treating select ACL revision reconstruction cases with a PTS-reducing osteotomy with the hope of reducing force acting on the ACL graft [4-6]. While it is known that anterior tibial translation and internal tibial rotation increase ACL force [7], there remain questions as to the biomechanical role of the PTS on knee kinematics and the resulting force generated in the ACL. To date there have been no biomechanical studies evaluating the effect of such a procedure on the human knee. Our hypothesis was that a proximal tibia closing wedge osteotomy to reduce the PTS will alter tibiofemoral kinematics and reduce ACL force.

METHODS

Seven fresh-frozen knee specimens with a mean age of 23 years (range: 18-34 years) were used for this study. For all knees, the distal tibia and proximal femur were potted in PMMA. Using an established technique [7], the femoral attachment of the ACL was mechanically isolated and attached to a calibrated load cell in order to directly measure resultant ACL force. Using a 6-DOF robot, each knee was flexed from 0°-50° while maintaining 200N of tibiofemoral compression force (TFC) in combination with the following forces and/or torques: 1) 45N anterior tibial force (AF); 2) 5Nm valgus moment (VM); 3) 2Nm internal torque (IT); and 4) 45N AF + 2 Nm IT + 5Nm VM. After testing each normal knee, a proximal tibia anterior closing wedge osteotomy was performed to decrease the PTS by 10° (Figure 1). The wedge of bone was removed 20mm distal to the tibial plateau. With the posterior cortical bone acting as a hinge, the plateau was lowered (reducing the PTS) and secured with a rigid external fixator. The osteotomized knee was then re-tested for each loading condition. Resultant ACL force and knee kinematics were recorded for each test. Statistical analysis was performed between normal and osteotomized knees with paired t-tests at every 5° of flexion. Significance level was set at $p < 0.05$.

Figure 1. Closing wedge osteotomy procedure: A) remove the wedge of bone, B) closed the tibial plateau, C) secure with an external fixator, and D) add PMMA for additional support.

RESULTS

The osteotomy produced 10° of tibiofemoral hyperextension and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

shifted the tibia 6.7mm posteriorly, 2.3° internally, and 3.3° valgus. Compared to the normal knee, in the absence of IT, the osteotomy significantly reduced resultant ACL force ($p<0.04$; Figure 2a-b). However, with the application of IT, ACL force was not reduced (Figure 2c-d). After osteotomy, relative anterior translation was significantly reduced with only an applied VM ($p<0.02$; Figure 3b), while anterior translation increased beyond 35° flexion under the combined loading condition ($p<0.04$; Figure 3d). After osteotomy, relative internal rotation was only significantly reduced with an applied VM ($p<0.02$; Figure 4b), while all other loading conditions showed significant increases in internal rotation ($p<0.05$; Figure 4a,c,d). After osteotomy, relative valgus rotation was not altered with an applied AF (Figure 5a), but showed significant decreases for all other loading conditions ($p<0.03$; Figure 5b-d).

DISCUSSION

Our results show that a PTS-reducing osteotomy significantly reduced ACL force under TFC when combined with AF or VM. However, we found no significant differences in ACL force under all conditions when IT was applied. We postulate that these effects are due to the resulting altered kinematics, most notably, the observed increase in internal tibial rotation and decrease in valgus rotation. Though we found that the PTS-reducing osteotomy is effective reducing force in the ACL in the absence of internal torque, the osteotomy shows little benefit under combined loading conditions simulating forces known to increase ACL injury risk. In summary, while a PTS-reducing osteotomy may reduce force across an ACL graft during non-strenuous knee motion, its protective effect may be lost during rigorous activity such as athletic knee "cutting" motions.

A TESTING PROTOCOL FOR EVALUATING AND CLASSIFYING SPINAL ORTHOSES

Denis J. DiAngelo (1), John C. Simmons (1), Daniel M. Wido (1)

INTRODUCTION

Back braces are used to treat a variety of spine-related problems (e.g., disc degeneration, spinal stenosis, weakness with aging, injury and scoliosis). Due to the substantial differences between these conditions and the individual needs of each patient, numerous spinal orthoses have emerged to provide varying degrees of mobility, rigidity, and positional control. However no scientific data or testing methodology exists to determine the structural properties of an orthosis or how well back orthoses work for treating specific disease or injury modalities. The selection process is often random and empirical [1,2]. A mechanical analog of the upper torso and lower spine was developed and integrated into a robotic testing platform to determine the structural properties and load carrying capacities of a commercially available lumbar spine orthosis. The spinal loading mechanics of typical daily living activities were simulated.

METHODS

Human Analog and Spinal Orthosis. A life size upper torso, lumbar spine and pelvic girdle assembly (the human analog) was designed that emulated the mechanical properties of the human spine. The biomimetic lumbar spine consisted of individual components having shape, size and material properties comparable to human lumbar spine motion segments. The biomimetic spine was partially concealed by the pelvic girdle assembly during testing. However, the hip/girdle assembly did not make contact with the spine or base load cell (Fig. 1A). A commercially available dynamic stabilizing orthosis (DSO) (Orthotrac Pneumatic Vest^{TM}, Kinesis Medical, Minneapolis MN) was "worn" by the human analog during orthosis testing (Fig. 1B). The orthosis used pneumatic air cylinders to apply a distractive force across the spine and was conceptually designed to provide flexion/extension and lateral stability.

Testing Platform. The human analog was mounted in a multi-axis robotic testing platform (Fig. 1) that included two six-axis load cells mounted to the upper gimbal assembly and lower base plate. The upper load cell (ULC) measured applied forces and moments while the base load cell (BLC), attached to the base of the spine, simultaneously captured forces and moments transferred through the lower spine. The resultant mechanics of the spine (Fx', Fz', BM') in Fig. 2 were analyzed at the L5-Sacrum disc plane (SDP). Differences in the two load cell readings transformed to the SDP represented the portion of the torso forces and bending moments carried by the orthosis.

Testing Protocol. The robot was programmed to actuate the human analog through ranges of physiologic flexion and extension under upper torso loading conditions. The following postural conditions were simulated: vertical orientation, initiation of motion (up to 5deg) and extended ranges of motion (10deg extension through 28deg flexion). The applied loading conditions simulated upper torso weight, i.e., up to 400N vertical compression, 20Nm flexion, and 10Nm extension. Measurements of the loads acting at the lower lumbar spine (compression, shear, and rotational moments) were used to determine the biomechanical function of the orthoses including its load-sharing and structural stiffness properties. The pneumatic pressure settings of the orthosis were increased to accommodate increased torso loads (i.e., 10, 20, 20 and 30 PSI for torso loads of 100, 200, 300, and 400N respectively).

RESULTS

The compressive loads acting at the SDP for the different torso weights are shown in Table 1. For the applied load conditions of 100 and 200 N (with orthosis pressures of 10 and 20 PSI), the majority of the applied load was carried by the orthosis and transferred to the pelvic girdle assembly. However, for the 300 N torso load with the orthosis pressure held to 20 PSI, 224N of the torso load was carried by the brace (i.e., 75% of the applied load). When the orthosis pressures were increased an additional 10 PSI to 30 PSI and the applied torso load increased to 400 N, the brace loads were 294N or 74% of the applied load.

The bending moment mechanics of the DSO during the initiation of flexion and extension movement is shown in Fig. 3. Throughout extension the majority of the applied bending moment was transferred to the spine. During flexion, the brace moment support progressively increased. The percentage of the applied bending moment carried by the brace at end limits of extension and flexion is provided in Table 2. At 5 degrees of flexion and applied load condition of 300N and 18Nm flexion moment approximately 63% of the flexion moment was supported by the brace. At 3 degrees of extension and applied loads of 300N and 7.1Nm extension moment, 18% of the applied bending moment was support by the brace. The slope of the curve represents the rotational stiffness properties. The flexion stiffness was 1.25Nm/deg and the extensional stiffness was 0.09Nm/deg.

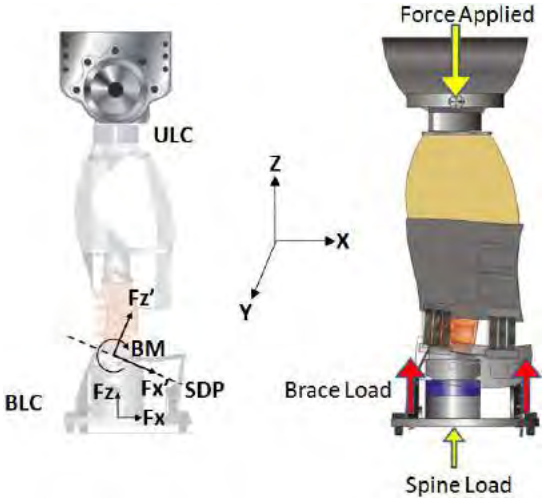

Figure 2. Force Analysis. Applied loads were controlled at ULC. Loads transferred through the lower spine were measured at the BLC. The ULC and BLC forces were transformed to the sacral disc plane and compared.

Table 1: Compressive Load Response of DSO

Applied Load (N)	Brace Load (N)	Brace Effect as Percent of Applied Load (Brace/Applied*100)
100	86	86%
200	206	103%
300	224	75%
400	294	74%

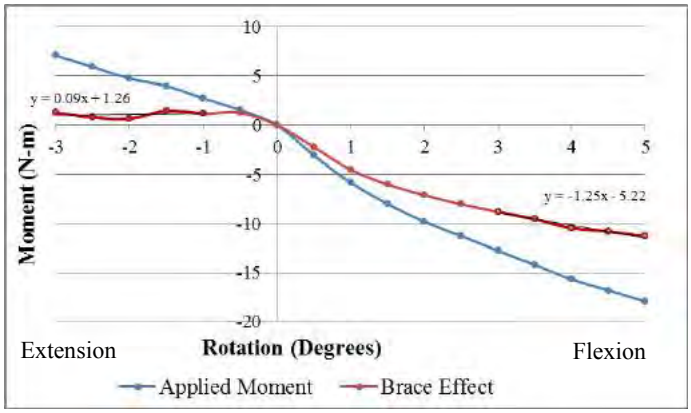

Figure 3. Bending Moment Mechanics During Extension and Flexion Testing for 300N Applied Load.

Table 2: The Brace Effect on Applied Moment for 300N Applied Load

Degrees of Rotation	Applied Moment (Nm)	Brace Effect (Nm)	Brace Effect as Percent of Moment (Brace/Applied*100)
At 3deg Extension	7.1	1.3	18%
At 5deg Flexion	18	11.3	63%

DISCUSSION

For all tests, motion was confined to the sagittal plane and the spinal loading mechanics were analyzed at the L5-S disc plane. The mechanical analog lumbar spine was validated under flexion and compression loading only. During the rotational tests (i.e., 3deg extension and 5deg flexion) only the force components of the gravitational torso mechanics were simulated but not the in vivo spinal bending moment. The applied moment was a function of the biomimetic spine's structural stiffness properties as well as the DSO. In summary, the unique biofidelic testing platform and biomimetic human analogue were able to assess the beneficial and/or adverse clinical function and biomechanical capacity of a spinal orthosis. Outcomes from this study provide the basis for developing a technical standard for evaluating, ranking and classifying lumbar spine orthoses.

INTRODUCTION

Skeletal fragility is a major social-health problem affecting the lives of millions of people. Accurate assessment of fracture risk would help timely inception of therapy or help avoid unnecessary treatments. Bone mineral density-based diagnosis cannot assess bone fragility with high accuracy, calling for information on other measures that affect bone strength. During the past two decades, the electrical properties of bone have gained an increasing attention since their measurements may hold potential for the diagnosis of bone quality. Although many earlier studies focused on the electrical properties of cortical bone as a function of moisture level and/or measurement direction of bone [1] to the best of our knowledge, the interrelationship between electrical and mechanical properties of cortical bone was not investigated. Furthermore, the contributions of individual bone composition including unbound water, bound water, organic matrix and mineral to electrical properties of cortical bone are still unclear. In this perspective, it would be valuable to perform a systematic investigation about the interrelationship between electrical and mechanical properties of cortical bone, and the role of bone composition in this interrelationship as a first step toward developing a potential diagnostic method for assessing bone quality. Therefore, this study was intended to investigate associations of electrical properties of cortical bone with mechanical properties and bone composition of cortical bone.

METHODS

This study was planned in three experimental phases. In the first phase, the correlations between electrical (i.e., impedance, conductivity and dielectric constant) and mechanical properties (i.e., toughness, elastic modulus and ultimate strength) of cortical bone (35x3x1.1 mm, N=24) were assessed. In the second phase, the contributions of unbound water, bound water, organic matrix and mineral to electrical properties of bone was investigated. In the third phase, the associations of different bound water compartments (mineral vs. collagen bound) with the electrical properties of cortical bone were assessed. In this way, we sought to assess the interrelationships between electrical and mechanical properties of cortical bone, and the potential role of different water compartments in this interrelationship. Briefly, following biomechanical testing, bone samples were probed by sequential heat treatment process: 1) dehydration at 40 °C for 48 h to remove unbound water, 2) dehydration at 200 ^{o} C for 30 min to evaporate bound water in bone samples, 3) heat treatment at 1000 ^{o} C for 30 min to remove the organic phase. Electrical impedance (at the frequency range of 5 kHz-2 MHz) of bone (7x3x1.1 mm) was immediately measured in wet state and after each step of heat treatment episode to record the change in electrical impedance by a LCR meter and associated text fixture. From the known impedance magnitude (|Z|) and phase angle (θ), the parameter values of the circuit model can be extracted as follows:

$$R = |Z|/\cos\theta \quad (1)$$

$$C = -\sin\theta/(2\pi f|Z|) \quad (2)$$

By using these calculated values, the electrical and dielectric properties of a bone sample can be obtained as follows:

$$\sigma = \frac{1}{R}(l/A) \quad (3)$$

$$\varepsilon' = \frac{C}{\epsilon_o}(A/l) \quad (4)$$

where σ and ϵ' are the electrical conductivity and dielectric constant, respectively, and the ϵ_o is the vacuum permittivity. The l and A are the length and the measured surface area of samples. In parallel with thermal analysis and electrical measurement, the Raman spectra were also collected immediately after each heat treatment episode to

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

confirm completion of elimination of corresponding bone composition. The contributions of collagen- and mineral-bound water to electrical properties were further investigated by our novel Raman spectroscopy-based method [2]. Electrical parameters obtained after each heat treatment episode were compared using one-way ANOVA followed by Tukey's post-hoc test. Linear regression analyses were performed between electrical properties and mechanical properties of bone and between electrical properties and bound water amount. Statistical significance was set at $p< 0.05$.

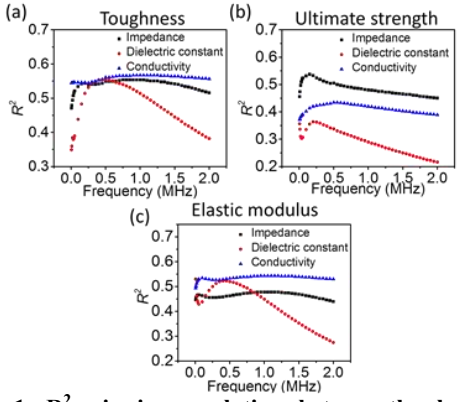

Figure 1: R^2 pairwise correlations between the electrical properties and (a) toughness, (b) ultimate strength and (c) elastic modulus of bone as a function of frequency.

RESULTS

The linear correlations between impedance, conductivity and mechanical properties are less susceptible over the wide range of the frequency while the correlations between dielectric constant and mechanical properties were strongly dependent on the frequency (Fig. 1). Dielectric constant at 0.5 MHz displayed the highest correlation with toughness and elastic modulus (R^2=0.56 and R^2=0.52, respectively) (Fig. 1a and 1c) while the correlation peaked at 0.2 MHz (R^2=0.36) for ultimate strength (Fig. 1b). Bone impedance and conductivity at around 1 MHz displayed the highest correlation with both toughness (R^2=0.56 and R^2=0.57, respectively) (Fig. 1a) and elastic modulus (R^2=0.48 and R^2=0.54, respectively) (Fig.1c) while the correlations of the impedance and conductivity with ultimate strength peaked at 0.2 MHz (R^2=0.54) and at 0.5 MHz (R^2=0. 43), respectively (Fig. 1b). Fig. 2 shows that the average changes in electrical properties were predominantly associated with unbound and bound water in bone. The elimination of organic matrix in bone only affected the conductivity at all frequency ranges (Fig. 2c) and affected the impedance at only low and middle frequency ranges (Fig. 2a). The correlations of specific impedance with collagen- and mineral bound water peaked at 0.75 MHz (R^2=0.45) and at 1.25 MHz (R^2=0.45), respectively (Fig.3a). For dielectric constant, the highest correlation was observed at 0.5 MHz (R^2=0.58), and 0.75 MHz (R^2=0.56) for collagen- and mineral-bound water, respectively (Fig. 3b). For conductivity, the highest correlation was observed at 1 MHz (R^2=0.55), and 2 MHz (R^2=0.62) for collagen- and mineral-bound water (Fig. 3c).

DISCUSSION

For the first time in the literature, our results show that electrical properties of cortical bone have strong correlations with the mechanical properties. The highest correlations between electrical and mechanical properties of cortical bone are typically found at the frequencies of 0.2, 0.5 and 1 MHz. At these specific frequencies, our results also indicate that unbound and bound water compartments are the major determinant of the electrical properties. Our findings provide first evidence that collagen- and mineral-bound water may contribute differentially to the electrical properties of bone (Fig.3). For example, mineral-bound water predominantly determines conductivity behavior of cortical bone at high frequencies.

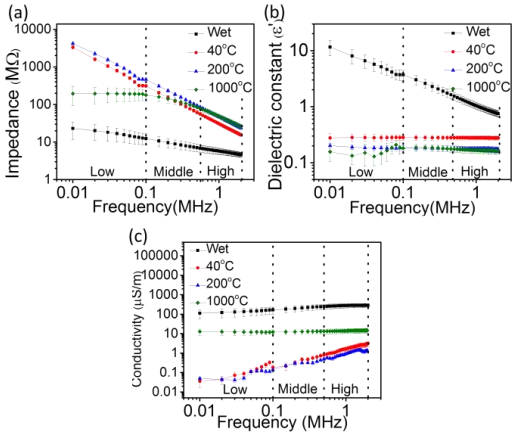

Figure 2: Average changes in (a) impedance, (b) dielectric constant and (c) conductivity of cortical bone samples during sequential heat treatment as a function of frequency at low (≤100 kHz), middle (100-500 kHz) and high (≥500 kHz) frequencies.

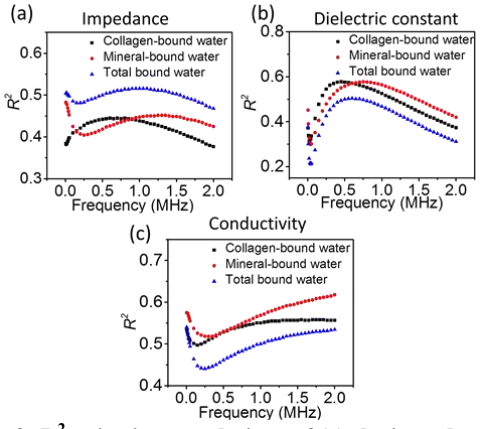

Figure 3: R^2 pairwise correlations of (a) the impedance, (b) dielectric constant and (c) conductivity with the corresponding amount of total bound, collagen- and mineral-bound water in the bone estimated by Raman spectroscopic analysis.

Since water amount of bone is associated with multiple factors, including porosity, mineralization, collagen crosslinks, collagen quality and non-collagenous proteins which are all interrelated [3], this may be elucidation why the associations between electrical and mechanical properties are mainly determined by the amount of unbound and bound water compartments. In conclusion, the significant correlations among electrical and mechanical properties and water compartments suggest that measurement of electrical properties as a tool to assess bone strength. The findings also underline the necessity for developing techniques to measure these electrical properties *in vivo* to improve the current diagnosis of those who may be at risk of bone fracture due to aging and diseases.

INTRODUCTION

Osteoarthritis (OA) is a debilitating musculoskeletal disease characterized by degeneration of articular cartilage and affects the lives of millions of people. Since cartilage has a limited ability for self-repair, it is crucial to detect early stage OA to increase the success of treatment. Therefore, a great amount of effort has been focused on developing non-destructive methods for early detection of OA. The cartilage matrix mainly contains water (70-80 wt. %), type II collagen (15-25 wt. %), and proteoglycan (PG) (5-10 wt. %) [1]. The majority of water in cartilage exists in a mobile-like state (also referred as unbound) as a result of electrostatic equilibrium between water molecules and glycosaminoglycan (GAG) chain(s). The rest of the water is bound to collagen and PG phases of cartilage with various degrees of affinity. Early stage of OA is characterized by a damaged collagen network, loss of PG and an increase in water content by up to 10% [2]. Although measurement of water content in the cartilage holds a great potential for early detection of OA, there is a dearth of nondestructive methods for studying the hydration status of cartilage. MRI-based methods are among the few available non-destructive methods for analyzing water content in cartilage; however, the sensitivity of MRI analyses to detect small changes in water content and cartilage matrix in early stages of OA is limited due to the partial-volume averaging effects [2]. Thus, a broader range of methods is needed to infer the hydration status of cartilage. Raman spectroscopy is one of the few nondestructive methods to assess hydration status of cartilage with the unique advantages on determination of type of water with various energy levels and the moiety to which water molecules are bound to [3]. However, to date, OH-related Raman bands of cartilage have not been studied by Raman spectroscopy since the most commercial Raman spectroscopy systems lack sensitivity into the OH-stretch range (3100-3800 cm^{-1}). Recently, we developed a custom designed short-wave infrared (SWIR) Raman spectroscopy system and successfully identified the water fractions of bone with the moiety to which water molecules are attached to [3]. In the present work, for the first time in the literature, Raman OH-stretch band of cartilage was investigated to identify water fractions in cartilage as a first step developing new non-destructive method for early diagnosis of OA.

METHODS

A refined analysis of the water content in biological tissues is challenging with standard Raman systems because of protein related background fluorescence. Furthermore, the CCDs of most commercial Raman systems lack sensitivity in the OH-stretch range since the Raman scattered photons of the OH range shift deeper into the infrared region. Therefore, we built a custom short-wave infrared (SWIR) Raman system to survey the OH-stretch range while accommodating the background fluorescence. Our custom SWIR system involved excitation at 847 nm (Axcel Photonics) at ~40 mW on the sample and signal collection using a shortwave InGaAs IR spectrometer (BaySpec, Inc., CA, USA) optimized for 1000-1400 nm wavenumber range that is suited for OH-stretch vibrations [3]. Bovine articular cartilage plugs (diameter: 4 mm, N=6) were excised from knee joints of freshly slaughtered animals. Since Raman OH stretch band originates from the hydroxyl groups of proteins, water molecules (bound, loosely bound and unbound) and contribution from the NH-stretch of proteins, a sample treatment protocol was developed so as to probe the contributions of different sources to the bands of interest. Water compartments were interrogated by a sequential dehydration process: 1) drying in ambient conditions for 60 min, 2) oven drying at 40° C for 48 h, 3) hydrogen-deuterium (H/D) exchange up to 7 days [3]. Raman spectra were recorded immediately after each treatment. The low energy air- and oven-drying employed in this study is expected to

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

remove the mobile-like water and have minimal effect on tightly bound water compartments. The long term H/D exchange beyond oven drying provides information on the rate of dissociation of different moieties of bound water through observation of the disappearance of OH-related Raman peaks. The remaining part after H/D exchange is expected to be associated with organic matrix [3]. Bulk water spectra were recorded as another reference. The collected spectra were fitted through second derivative method to identify each peak locations.

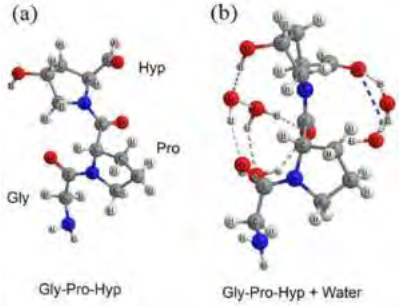

Figure 1: The optimized equilibrium structure of molecular models of (a) Gly-Pro-Hyp amino acid sequence and (b Gly-Pro - Hyp amino acid sequence of collagen with five water molecules.

Raman bands of glycine-proline-hydroxyproline (Gly-Pro-Hyp) amino acid sequence of collagen were generated computationally (Fig. 1) via ChemBio 3D Ultra software. Simulations were run with and without the surrounding water molecules to further verify the assignment of the experimentally observed Raman bands. Overall, the sequential water removal protocol and computational analysis allowed the interpretation of the locations of Raman bands associated with mobile-like, loosely and tightly bound water as well as organic matrix.

RESULTS

The presented spectral data result from the average of three Raman spectra taken at different locations. The spectral range of 2700-3100 cm^{-1} manifests CH-stretch that is predominantly associated with the matrix phase of cartilage whereas the OH-stretch extends across 3100-3800 cm^{-1}. The cartilage spectra were scaled to obtain the same intensity at the CH-stretch peak (Fig. 2a). Therefore, changes in the Raman intensities were normalized by the amount of matrix. Direct comparison of Raman spectra of bulk water with wet and oven-dried cartilage samples indicated the prominence of mobile water related intensity in cartilage which accounted for ~90% of the Raman intensities (Fig. 2a). The results of H/D exchange demonstrated that remaining Raman signal was associated with tightly bound water compartments and organic matrix (~10%) (Fig.3a). Using secondary derivative method and computational analysis together, six peaks in OH-stretch bands of wet cartilage were revealed (Table 1). Among these peaks, ~3630 and 3655 cm^{-1} are solely associated with unbound (mobile-like) water compartments since these peaks were no longer visible in the spectra even after air-drying for 1h (Fig. 2b and Table 1). The peaks centered at ~3200 (the range of 3180-3260 cm^{-1}), 3435 and 3520 cm^{-1} in wet cartilage seem to be the combination of mobile-like, bound water compartments and the OH of matrix proteins (Fig. 2b and 3b-c). More specifically, the peaks at ~3254, 3315, 3330, 3430, 3455, 3470 and 3490 cm^{-1} are associated with different bound water compartments with various energy levels (ranging from loosely to tightly) (Table 1). The peak centered at ~3345 cm^{-1} is associated with NH-stretch band of collagen and ~3450 cm^{-1} is associated with OH group of hydroxyproline, also confirmed by molecular dynamics. The remaining peaks at ~3190 and ~3515 cm^{-1} may be associated with PG matrix since it is the only candidate for these peaks.

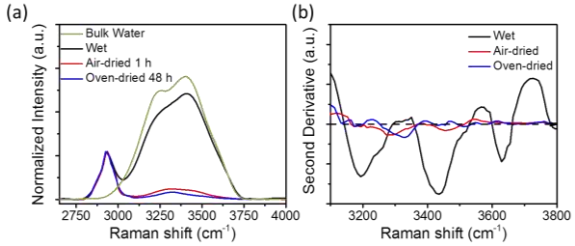

Figure 2: (a) Raman bands of wet and dehydrated samples, (b) second derivative spectra during sequential dehydration.

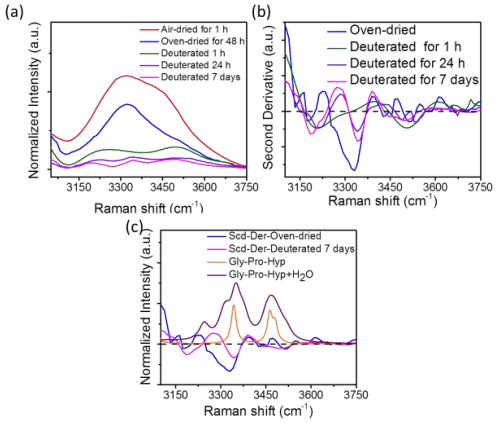

Figure 3: (a) Raman bands of deuterated samples, (b) second derivative spectra as water exchanges with deuterium oxide over time, (c) comparison of computationally obtained Raman spectra with second derivative spectra of oven and deuterated samples.

DISCUSSION

For the first time in the literature, OH-stretch band in cartilage was investigated to identify the water compartments which are mobile-like (removable by prolonged drying at low temperature), and semi-bound and tightly bound (removable by deuterium following prolonged drying) to the matrix of cartilage. It was found that the OH-stretch band in wet cartilage represents mainly mobile-like water molecules (~90%). Identified water compartments in cartilage by Raman spectroscopy in this study collectively indicate that assessment of water content by Raman spectroscopy can be used as a potential diagnostic approach in early OA. Immediate next step in this project will be identifying the associations of these peaks with mechanical behavior of cartilage as well as assessing the variations of these peaks between arthritic and healthy human cartilage.

Table 1: Raman peaks in cartilage

	Wavenumbers (cm^{-1})					
Wet	~3200	~3260	~3435	~3520	~3630	~3655
Air dried	~3180	~3215	~3285	~3345	~3460	
Oven dried	~3180	~3254	~3330	~3430	~3455	~3520
Deuterated 1 h	~3210	~3315	~3470	~3510		
Deuterated 24 h	~3205	~3340	~3490	~3530		
Deuterated 7 days	~3190	~3345	~3450	~3515

BIOMECHANICAL COMPARISON OF YOUTH AND ADULT FOOTBALL HELMETS: STANDARDS TESTING

David W. Sproule and Steven Rowson

Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, Virginia, USA

INTRODUCTION

Of the estimated 5 million people that participate in organized football each year, approximately 70% are youth players between the ages of 6 and 13 [1]. Currently, youth helmets, which are intended for players younger than 14 years old, undergo an identical impact testing protocol and are held to the same performance criteria as adult helmets in the NOCSAE safety standard. Although NOCSAE is in the process of developing a test standard specific to youth helmets [2], there are many challenges in determining how a youth helmet standard should differ from the adult standard.

Several studies investigating head impact exposure in youth football players of various age groups have demonstrated that the number of head impacts and severity of impact increases with age. Although high severity impacts occur less frequently in younger players, impact magnitudes greater than 80 g were recorded in all age groups [3]. While the front of the helmet is the most commonly impacted location in adult and youth players, youth players experience a greater proportion of impacts to the side of the head, which is likely attributed to weaker necks and relatively heavier helmets [3].

Head mass and size are about 95% of adult size at 3.5 years old and stay relatively constant until around age 10, when the head size gradually increases to 100% around age 16 or 17 [4]. However, children have a larger head-to-body ratio than adults, which is accompanied by reduced neck and shoulder musculature [5]. Other concerns specific to the susceptibility of concussion in youth are an immature CNS, thinner cranial bones, a larger subarachnoid space in which the brain can move, and differences in cerebral blood flow [6].

Developing youth-specific helmets has proven challenging given the differences in head impact exposure, anthropometry, and physiology. Furthermore, no data are currently available on the relative impact performance of youth and adult helmets. This study aims to evaluate the relative impact performance of youth and adult helmets during standards testing, which will provide insight towards the development of a youth-specific standard.

METHODS

A total of 256 tests were conducted to evaluate differences between youth and adult helmets. Helmets were selected on the condition that a specific model was available in both adult and youth versions. This criterion included 8 helmets on the market: Riddell 360, Schutt Air XP Pro, Schutt DNA Pro+, Rawlings NRG Impulse, Riddell Speed, Riddell Speedflex, Schutt Vengeance DCT, and Xenith X2E.

Matched tests were conducted using a NOCSAE style drop test for the youth and adult helmets. This series of drop tests consisted of 4 impact locations (front, side, rear, and top) and 4 drop heights (24, 36, 48, and 60 inches) [7], resulting in 16 tests for each helmet. For each test, a triaxial accelerometer at the center of gravity of the NOCSAE headform was sampled at 20,000 Hz and filtered to SAEJ211 specification (CFC 1000). Peak linear acceleration and Severity Index (SI) were calculated for each impact. Differences between youth and adult models were compared for each impact configuration and evaluated using a paired t-test. Significance was set as $p<0.05$.

RESULTS

Of the 8 helmets tested, 3 were found to have significant differences in peak linear acceleration. These were the Schutt Air XP Pro ($p=0.028$), Schutt DNA Pro+ ($p=0.004$), and the Riddell Speed ($p=0.006$) (Table 1). A negative difference indicates that the youth helmet had a lower peak acceleration than the matched adult helmet. In each of the significant cases, the youth helmets performed better.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Table 1: Average difference ± standard deviation for linear acceleration and Severity Index. Peak linear acceleration and Severity Index were significantly lower for the Schutt DNA Pro+. Peak linear acceleration was also significantly lower for the Riddell Speed and Schutt Air XP Pro.

Model	Linear Acceleration Difference (g)	P-value	Severity Index Difference	P-value
360	0 ± 6	0.901	0 ± 21	0.932
Speed	-4 ± 5	0.006*	-8 ± 18	0.077
Speedflex	-1 ± 5	0.625	-2 ± 13	0.499
Air XP	-4 ± 6	0.028*	-12 ± 28	0.119
DNA	-7 ± 8	0.004*	24 ± 18	<0.001*
Vengeance	-1 ± 13	0.769	11 ± 45	0.329
Impulse	-2 ± 6	0.262	-11 ± 41	0.317
X2E	0 ± 3	0.781	4 ± 10	0.116

In terms of Severity Index, youth and adult versions were only significantly different for the Schutt DNA Pro+ (p=<.001) (Table 1). The maximum observed Severity Index values were 518 for the youth helmet and 618 for the adult helmet. Both peak values occurred at the top location in the Rawlings NRG Impulse from the 60 in. drop height.

Adult helmets generally performed better in rear impacts, and youth helmets better in the top, side, and front locations. Higher drop heights were associated with larger differences (Figure 1).

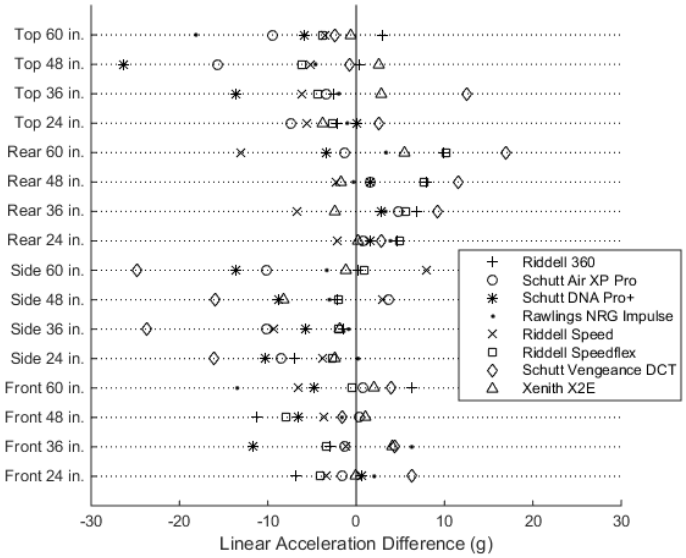

Figure 1: Differences for each test scenario for each helmet model. Points to the left of zero indicate better performance by the youth helmet and points to the right indicate better performance by the adult helmet. Individual differences between youth and adult helmet varied by impact location and drop height.

DISCUSSION

Although 3 helmet models produced significant differences, it is important to put these differences in context of injury risk. For example, the average difference seen in the Schutt DNA Pro+ would relate to less than a 5% reduction in concussion risk in adults [7]. Overall, helmet performance for youth and adult helmets were very similar. While individual differences varied by impact location and drop height, average differences were low, with standard deviations overlapping no difference.

All adult helmets tested had a polycarbonate plastic shell and all youth helmets had an acrylonitrile butadiene styrene (ABS) plastic shell, with the exception of the Rawlings NRG Impulse, which utilizes polycarbonate for both youth and adult models. Generally, the youth helmets performed slightly better in all tests, which is likely attributed to the alternate shell material. The ABS plastic used in youth helmets is a cheaper and lighter material, however it has decreased durability. This is recognized by helmet companies as the warranties offered for youth helmets are typically shorter than warranties for adult helmets. Since both youth and adult helmets performed similarly, the benefit of an adult helmet is a more durable shell, and the advantage of the youth helmet is that it is about 5% lighter (excluding facemask) due to the shell material.

In NOCSAE's draft of proposed youth standards, more tests are suggested at each location. Additionally, the 4.88 m/s (48 in.) impact has a lower threshold of 600 SI along with the 1200 SI threshold for all tests. A mass limit of 1.3 kg, including all accessories, is also proposed for this standard [2]. Currently, all of the youth football helmets that were tested would meet the impact criteria. However, all would fail the 1.3 kg mass limit. For the youth helmets in this study the average mass was 1.3 kg without a facemask, and 1.7 kg including a facemask.

This study has several limitations. The first of which is that only one sample was used for each helmet. Secondly, rotational acceleration, known to contribute to concussion risk, was not evaluated [1]. Third, it is still unknown which impacts are the most important. Future studies should use both on-field head impact data and laboratory tests to better inform standards testing.

This study quantified the relative performance of matched youth and adult football helmets using methods similar to the NOCSAE certification process. These data have direct applications to future youth specific football helmet standards.

INTRODUCTION

The primary function of tendon is to transmit forces from muscle to bone. However, some tendons, such as the human Achilles tendon and equine superficial digital flexor tendon (SDFT) also store and release energy during locomotion, and are consequently known as energy storing tendons. These energy storing tendons have specialised properties but are prone to injury (1,2,3).

Specialised properties of tendons have been most studied in equine tendons. Mechanical properties of equine tendons have shown higher failure strains in the SDFT than in the common digital extensor tendon (CDET; a positional tendon) during *in vitro* testing, indicating specialisation of the tendon to meet its secondary function (4). Subsequent microstructural studies have found that the inter-fascicular matrix (IFM) exhibits lower stiffness in the SDFT than the CDET, and is also better able to withstand cyclic loading, potentially facilitating the additional extension and energy storing capacity of the SDFT, through fascicle sliding and recoil (4,5). In the equine SDFT, ageing leads to stiffening of the IFM, and reduced functionality of the IFM is linked to compromised tendon function (5).

Knowledge of tendon microstructure and the related micro-mechanics is currently limited in human tissues. Human tendons are generally smaller than those in the equine model, but also have different functional roles, potentially leading to differences in the properties and significance of the IFM. This study investigates the mechanical properties of the IFM and fascicular matrix (FM) of three functionally distinct human tendons (Achilles, anterior tibialis, and posterior tibialis), and additionally, explores the effect of ageing on IFM and FM mechanics, and how this influences bulk tendon mechanical behaviour. It is hypothesised that the IFM of the Achilles tendon is more elastic to facilitate energy storage, but this specialisation is lost with ageing.

METHODS

The mechanical properties of three lower leg tendons were compared; the Achilles tendon (an energy storing tendon), the anterior tibialis tendon (a positional tendon), and the posterior tibialis tendon (a positional tendon with a minor energy storing function). All tendons were obtained with ethical approval. Matched samples from each tendon type were compared, and samples categorised into two age groups: middle-aged tendons (46-57 years old; 3 donors) and old-aged tendons (87-94 years old; 4 donors).

FM and IFM samples were prepared from each tendon for mechanical testing. Fascicles of approximately 40mm length were dissected for FM testing and the diameter of each specimen measured using a laser micrometer. The FM specimens were then pre-loaded to 0.02N, pre-conditioned with 10 loading cycles between 0 and 2.5% strain at 1Hz, and then pulled to failure at a strain rate of 5%/second. For IFM testing, fascicle pairs (i.e. two adjoining parallel fascicles) were isolated from the same region of each tendon as used to isolate FM specimens. The opposing ends of the fascicle pairs were dissected such that 10mm of IFM was left intact between the two fascicles, enabling the IFM to be tested in shear by pulling the opposing fascicle ends in a uniaxial manner (4). The IFM specimens were pre-loaded to 0.02N, pre-conditioned with 10 loading cycles between 0 and 0.25mm at 1Hz, and then pulled to failure at a rate of 1mm/second.

RESULTS

FM test data were used to calculate the ultimate tensile strength (UTS), failure strain and max modulus (Table 1), whilst IFM test data

Table 1: Mechanical properties of the FM in three human tendons (data shown as mean ± standard error). The properties of the FM remain similar between tendon types, however ageing significantly affects the Achilles tendon and the posterior tibialis tendon.

FM

	Achilles Tendon		Posterior Tibialis Tendon		Anterior Tibialis Tendon	
Property	Middle-Aged	Old-Aged	Middle-Aged	Old-Aged	Middle-Aged	Old-Aged
UTS (MPa)	27.2 ± 2.8	43.3 ± 3.2 #	26.3 ± 7.2	60.1 ± 6.5 * #	35.2 ± 3.9	38.3 ± 2.5
Failure Strain (%)	14.9 ± 0.6	12.6 ± 0.3 * #	13.5 ± 1.5	15.3 ± 0.7	14.1 ± 0.7	14.4 ± 0.3
Max Modulus (MPa)	332.1 ± 31.4	645.6 ± 48.3 #	402.9 ± 92.3	736.3 ± 62.5 c #	444.2 ± 42.5	511.5 ± 48.1 b
Hysteresis (%)	55.2 ± 2.3	45.7 ± 1.1 * #	58.0 ± 2.3	52.7 ± 1.7	58.2 ± 1.7	55.3 ± 1.1 #
Stress Relaxation (%)	17.8 ± 2.0	15.6 ± 1.9	18.1 ± 2.7	17.9 ± 1.7	19.7 ± 3.5	19.9 ± 1.1

*Key for significant difference (P<0.05): # = between age groups, * = between tendon types, a = compared to Achilles tendon, b = compared to posterior tibialis tendon, and c = compared to anterior tibialis tendon.*

were used to calculate the ultimate tensile force (UTF), extension at failure and max stiffness. Hysteresis and stress or force relaxation were also calculated from the initial 10 cycles for both FM and IFM samples.

The mechanical properties of the FM from middle-aged tendons showed no significant difference between tendon types. Comparing middle-aged and old-aged tendons, the mean UTS significantly increased with ageing in both the Achilles tendon and posterior tibialis tendon, which resulted in a significantly greater mean UTS in the old-aged posterior tibialis compared to both the Achilles and anterior tibialis tendons (Table 1). Ageing also showed a significant increase in the mean max. modulus of the Achilles tendon and posterior tibialis tendon, and a significant reduction in the mean hysteresis of the Achilles tendon and anterior tibialis tendon (Table 1).

Concerning the IFM from middle-aged tendons, no significant differences were observed in the mean failure extension or max. stiffness between tendon types. However, the mean UTF of the Achilles tendon IFM (1.6N) was significantly higher than the posterior tibialis tendon (0.4N) and anterior tibialis tendon (0.8N), while the mean force relaxation of the Achilles tendon IFM (17.0%) was significantly lower than the posterior tibialis tendon (37.4%) and notably lower than the anterior tibialis tendon (28.0%). Ageing was also seen to affect the IFM of the Achilles tendon only, significantly decreasing the mean UTF (figure 1a) and increasing the percentage of force relaxation (figure 1b).

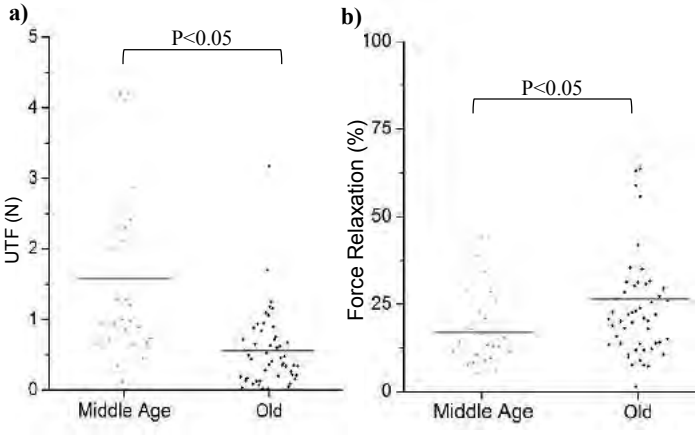

Figure 1: a) Mean UTF and b) mean force relaxation of the Achilles tendon IFM. Dots indicate data points and horizontal lines indicate the mean. Old-aged tendons show significantly decreased UTF (P<0.05), while percentage force relaxation increased (P<0.05).

DISCUSSION

This is the first study to look at microstructure and mechanics across a range of functionally distinct human tendons. The mechanical properties of the FM of all three tendon types were similar, suggesting that the structures which contribute to the energy storing function, and consequently tendon specialisation, are positioned outside the FM. However, it is interesting to note that ageing significantly affected the properties of the FM in the Achilles and posterior tibialis tendon only. Both of these tendons have a degree of energy storage, indicating structural or compositional changes with age in energy storing tendons only, which could lead to the increased injury risks in the elderly.

It has been previously demonstrated that the IFM in equine tendons possesses the ability to recover from cyclic loading, particularly in the energy storing SDFT, where the IFM has a greater capacity for recovery than the positional CDET. Furthermore, ageing reduced elasticity of the IFM in the equine SDFT (4,5). The current data provides further evidence that the IFM has considerable mechanical strength, being able to withstand loads in excess of 1N in the Achilles tendon. The IFM of the Achilles tendon was also found to exhibit higher failure forces and behave more elastically than that of the other tendons; properties which are beneficial for energy storage. Ageing was found to only effect the IFM of the Achilles tendon and not the other tendon types, reducing failure force and increasing viscoelasticity, bringing values closer to those of the posterior and anterior tibialis tendons, suggesting a potential loss of energy storing capabilities.

The SDFT and Achilles tendon are structurally different as, unlike the SDFT, the fascicles in the Achilles tendon are further grouped into higher order bundles. A bundle describes a group of fascicles originating from a distinct triceps surae muscle belly, demarcated by a surrounding matrix known as the inter-bundle matrix (IBM). As the Achilles tendon is shorter than the equine SDFT, it is likely the majority of sliding in the Achilles tendon occurs between the bundles, in the IBM. Further mechanical tests will therefore be performed to ascertain the properties of the IBM and its contribution to the extensibility mechanisms in the Achilles tendon and the effect of ageing. Mechanical tests on quarter tendons will also provide a reference to compare the contribution of FM, IFM and IBM to the overall mechanical properties.

THE RESONANCE OF THE THORACIC SPINE UNDER WHOLE BODY VIBRATION IS NON-LINEAR & DEPENDS ON ACCELERATION: AN IN VIVO STUDY USING A RAT MODEL

INTRODUCTION

Low back and neck pain is common in the general population [1], is a leading cause of disability [2], and accounts for 70% of all years lived with disability due to a musculoskeletal disorder [3]. Whole body vibration (WBV) at the resonance of the spine has been suggested to damage the underlying structures of the spine [4]; even a single WBV exposure is sufficient to induce sustained pain and neuroinflammation in a rat model [5]. However, the effect of WBV on pain, injury, degeneration, or its therapeutic effects are not well-defined.

Helicopter pilots are subject to vibrations along the spine's long-axis, and there is evidence suggesting that such vibrations can occur at resonance during routine flights [6]. In fact, the resonant frequency for seated subjects has been defined at 4-5Hz [7-9], with the resonance along the long-axis of the spine in other species being estimated at 4.5Hz in rabbits [10] and 8-9Hz in rats [5]. Those studies exposed subjects to vibrations of either a single root mean squared (RMS) acceleration or a single peak-to-peak (PTP) displacement, and the human spine exhibits a 'softening' non-linear effect with the resonant frequency decreasing as the RMS acceleration increases [8]. Yet, the resonance has not been investigated for sinusoidal vibration, which is commonly used to replicate occupational vibration exposure [5,9,11], nor has it been characterized over the wide range of frequencies that may be encountered during occupational WBV exposures [7].

A rat model of WBV has been established to study the biomechanical, behavioral, and biological effects of vibration [5,11,12]. WBV exposures with a PTP displacement of 5.0mm and frequency of 8Hz were found to produce greater behavioral sensitivity (i.e. pain) than exposures with a PTP displacement of 1.5mm and frequency of 15Hz, despite both exposures having approximately the same RMS acceleration [5]. Accordingly, this study aimed to define the resonant frequency of the rat spine at different PTP displacements in order to understand the mechanical effects of displacement and acceleration on the resonance of the spine.

METHODS

All procedures were IACUC-approved. Two groups of male Holtzman rats (Envigo) were exposed to sinusoidal WBV under isoflurane inhalation anesthesia. Rats were positioned prone on a platform using straps placed behind the shoulders and above the pelvis [5], enabling application of WBV along the long-axis of the spine. The platform was attached to a shaker (K2007E01; The Modal Shop); uniaxial accelerometers (7521A2; 120 Hz; Dytran) were affixed to the platform and also strapped to the thoracic spine [5].

One group of rats (n=8; 353±11g mass) was exposed to vibrations of 1.5mm and 5.0mm PTP displacements to match those used in previous studies [5,11,12], and a second group (n=8; 426±12g mass) was exposed to vibrations of 0.435mm, 0.735mm, and 2.5mm PTP displacements in order to define the resonant frequency over a wider range of exposures. Vibration at each displacement was performed from 3-15Hz, at 1Hz intervals. Due to the power capacity of the shaker, for the 2.5mm and 5.0mm amplitudes, the maximum frequency was limited to 12Hz and 9Hz, respectively. For each displacement, the WBV was performed in increasing frequency. Each frequency was applied for 1min, with a period of approximately 2mins between each exposure to minimize any residual effects of the previous test(s).

Accelerometer data were filtered with a 5th-order Butterworth filter (Matlab2010; Mathworks). The transmissibility was calculated at each frequency for each PTP displacement by dividing the RMS rat acceleration by the RMS platform acceleration [5]. The resonant frequency for each PTP displacement was defined as the frequency with the greatest transmissibility. To assess the effect of resonance on transmissibility, the transmissibility at the resonant frequency was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

compared to the transmissibility at all other frequencies using repeated-measures ANOVAs and Bonferroni post-hoc test. A power regression using the RMS acceleration at each resonant frequency was used to determine the relationship between those two parameters.

RESULTS

For all PTP displacements, the transmissibility at 3Hz is consistently below 1.0, which is likely to be due to those accelerations being close to the level of noise detected by the accelerometers. As the frequency increases, the calculated transmissibility is consistent with theoretical transmissibility curves. Increasing the PTP displacement of WBV reduces the resonant frequency (Fig. 1). This reduction in resonant frequency also corresponds to an increase in RMS acceleration (Fig. 2).

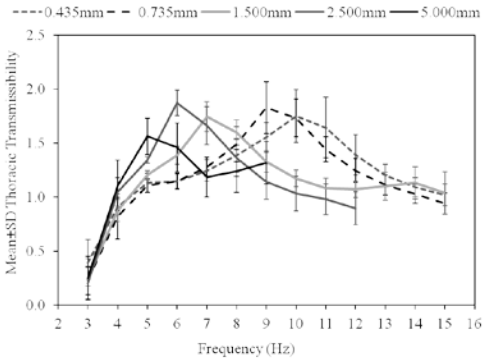

Fig. 1. Thoracic transmissibility, showing that the resonant frequency decreases as the PTP displacement increases.

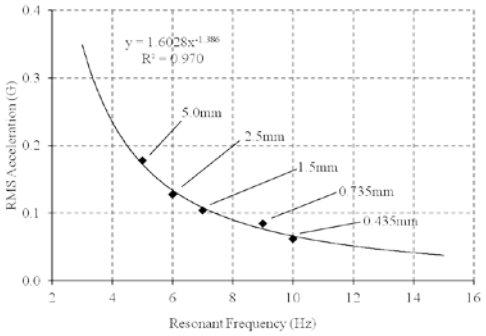

Fig. 2. Power regression of the RMS acceleration at the resonant frequency for each of the PTP displacements.

For PTP displacements of 2.5mm, the transmissibility at resonance is 6Hz (Fig. 1) and is significantly greater than all other frequencies ($p<0.03$). At PTP displacements of 1.5mm and 0.735mm, the transmissibility at resonant frequencies of 7Hz and 9Hz, respectively are significantly greater than at all other frequencies ($p<0.01$) with the exception of one frequency (8Hz for 1.5mm; 10Hz for 0.735mm) adjacent to the resonant frequency ($p>0.85$). This suggests that the resonance is likely between those values. For 5.0mm PTP displacements, the transmissibility at 5Hz is significantly greater ($p<0.031$) than all but 6Hz and 9Hz, suggesting the true resonance is between 5Hz and 6Hz, and that a secondary resonance may exist at approximately 9Hz. The transmissibility curve is more rounded for 0.435mm PTP displacements, and the peak transmissibility at 10Hz is not different from transmissibilities at 8Hz, 9Hz, or 11Hz ($p>0.2$), despite being greater than at all other frequencies ($p<0.013$).

An analysis using power regression of the RMS acceleration in relation to the resonant frequency closely fits the data (Fig. 2), with an R^2 value of 0.970 fit by the equation $y=1.6028x^{-1.386}$.

DISCUSSION

This study demonstrates that resonance can occur over a wide range of frequencies commonly encountered during occupational WBV [9], and that the resonant frequency of the rat spine is non-linear (Figs. 1 & 2). These findings are consistent with the non-linear 'softening' of the human spine that has been reported with random vibrations with increasing RMS acceleration [8]. By using sinusoidal WBVs and determining the resonance over a range of PTP displacements, the current study also provides a means of predicting the resonance for specific vibration signals. Although these findings are specific to the rat, the approach can be extended for other species.

The statistical analysis of transmissibility suggests that at some of the PTP displacements, the true resonance actually exists *between* the discrete frequency exposures used here. Investigating those exposures may further improve the fit of the power curve. Nevertheless, the curve already closely fits the current data (Fig. 2), so the added benefit may be limited. The PTP displacement of 5.0mm led to a secondary maximum transmissibility at 9Hz (Fig. 1); which may be a secondary resonant frequency, as has been previously reported in human subjects in-vivo [8]. However, since this was only evident at one PTP displacement (5.0mm), it also may be due to confounding effects of using the strap to fix the accelerometer to the rat at the highest accelerations used in our study (RMS 0.576G). Also, the different shape of the transmissibility curve for the PTP displacement of 0.435mm may mean that resonance is increasingly difficult to determine as the RMS acceleration decreases; this challenge is consistent with the shape of the power regression (Fig. 2). Together, these findings suggest that for low accelerations, resonance may occur over a wide range of frequencies with very little change in RMS acceleration.

The complex interactions of the parameters of a vibration signal with the tissues of the spine not only complicates the experimental use of WBV, but also may explain the lack of consensus around which conditions may be harmful and which may be beneficial [4]. Low-amplitude, high-frequency vibrations are generally used therapeutically [4,13], but have also been shown to lead to osteoarthritis and disc degeneration in a murine model [13]. Our results provide a link between the RMS acceleration and resonance, which can be used to predict the most detrimental vibrations in terms of acceleration and PTP displacement. In addition, these data may be used to inform further studies of occupational WBV in the rat and other species, as well as in the translation of such work to the human. Those studies will ultimately improve the effectiveness of systems designed to prevent pain and injury, and may also improve the safety of therapeutic vibration devices.

INTRODUCTION

Congenital cardiovascular malformations occurs in 0.6-1.9% of the population, some with devastating consequences [1]. Studies in small animal embryos have shown that abnormal blood flow mechanics may play a role in causing these defects [2]. It is thus important to understand how mechanical forces influence prenatal cardiovascular development, so as to develop suitable treatments. Such an understanding may also enable novel fetal surgeries to be performed to rectify congenital cardiovascular defects.

Currently, although congenital malformations are detectable prenatal, intervention can only be given after birth, at which time, the regenerative ability of the fetus would have been lost, and the defect is complete in its formation. Fetal surgery intervenes at an earlier time point to restore normal blood flow mechanics and coax the fetal body to remodel away from the defect. Fetal heart surgery had already been performed for the Hypoplastic Left Heart Syndrome using minimally invasive techniques [3], and this technique had been rapidly adopted since.

To improve our understanding of human fetal cardiovascular fluid mechanical environment, we developed a technique to perform patient-specific computational fluid dynamics (CFD) simulations of human fetuses, based on 4D clinical ultrasound scans. We applied the technique on 3 human fetuses at 20 weeks of gestation to study the fluid dynamics of their left ventricles.

METHODS

4D ultrasound scans of human fetuses at 20 weeks of gestation was performed at the National University Hospital Systems, Singapore, with appropriate IRB approvals and consent. Ultrasound scans were performed in the Spatio-Temporal Image Correlation (STIC) mode to ensure sufficient temporal resolution. The 4D images over one cardiac cycle were exported as 29 image stacks corresponding to 29 time points and the left ventricle blood space was segmented using an open-source software VMTK.

Ventricular wall motion was quantified using a polar coordinate system (θ,ϕ,r) from the centroid of the left ventricle, by specifying the radial distance from the centroid to the wall:

$$r(\theta,\phi,t) = \alpha(\theta,\phi)\Omega(t) + r_0(\theta,\phi) \qquad (1)$$

where Ω is the characteristic waveform of wall motion over time, α is the amplitude of wall motion, and r_0 is the initial condition. Ω is specified using pulsed-Doppler ultrasound measurements of the inflow at the mitral valve and outflow at the aortic valve, from the literature, while α and r_0 were obtained through the segmentation from our ultrasound images. A 2D polynomial fitting was applied to α for smoothing as well as to obtain a continuous mathematical description of wall position.

	I	II	III
Heart Rate (bpm)	147	147	156

Table 1. Characteristics of the 3 fetal hearts and their CFD model.

Dynamic mesh CFD was performed with ANSYS Workbench® (Ansys Inc.), using a user-defined-function for programming wall motion. Boundary conditions were such that the mitral inlet was a zero-pressure inlet during diastole and a wall during systole, while the aortic

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

outlet was a zero-pressure outlet during systole and a wall during diastole. Non-newtonian fluid following the Carreau viscosity model was specified (η_0=0.0056Pa.s, η_∞=0.0035Pa.s). Simulations were performed for 4 cardiac cycles to remove initial condition artifacts.

RESULTS

Table 1 shows the characteristics of the 3 fetal hearts studied. Figure 1 shows cross-sections of the raw images, their 3D segmentations, and the CFD mesh at various time points. Figure 2 shows the results of the simulations, with vorticity visualized in 3D using the Lambda-2 criteria, and with wall shear stress plotted using surface color contours.

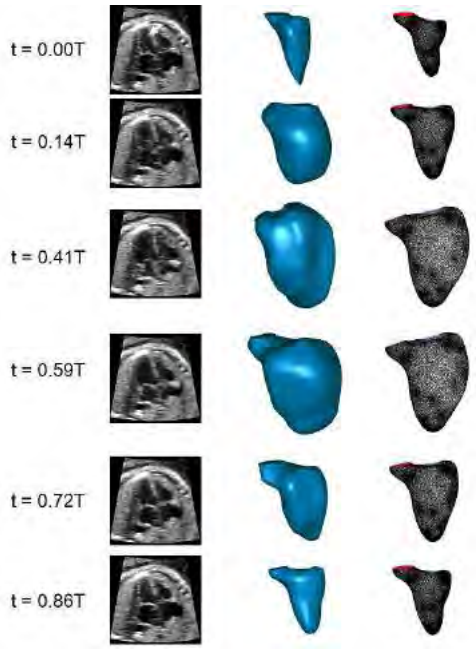

Figure 1. Ultrasonic 4-chamber view (first column), 3D surface reconstruction (second column) and simulated mesh (third column) of a fetal left ventricle over time. The left ventricle is indicated by a white arrow in the ultrasound image at t = 0.00T. T refers to the period of 1 cardiac cycle.

The dominant feature of the fluid dynamics of the 20 weeks human fetal left ventricle is the formation of 2 vortex rings during diastole, corresponding to the E- and A- wave. In the fetus, the A-wave is much stronger than the E-wave, thus resulting in a larger vortex ring during late diastole. The vortex rings were observed to move towards the apex while interacting with the ventricular wall, bringing about complex secondary hairpin vortices around the primary ring, as well as higher shear stresses, in the range of 0.5-5Pa, where the vortex ring approached the vicinity of the wall. At the same time, vorticity is being dissipated away via diffusion and stretching phenomenon. However, since the fetal heart rate is about 2.5 times higher than adult human heart rate, there was insufficient time for the vortex rings to completely dissipate, resulting in remnant vorticity structures being ejected from the heart into the aorta, providing the aortic outflow with some helicity.

DISCUSSION

Our results showed that just like in adult hearts, the human fetal left ventricle also featured dual vortex rings corresponding to the E- and A-wave. A worthy future work would be to experimentally confirm the presence of these vortex rings via clinical measurements. In adult hearts, vortex rings characteristics were hypothesized to contain information on the health of the heart. We hypothesize that the same apply to the fetal hearts as well, where vortex ring features may inform clinicians of abnormalities.

In the human fetal heart, it has been hypothesized that fluid wall shear stresses are important stimuli for proper growth of the cardiac ventricles, and the lack of flow in the left heart has been thought to be the factor causing the Hypoplastic Left Heart Syndrome. Here, our results showed the vortex ring to be the driving force for elevated wall shear stresses on the left ventricular wall, suggesting these ventricular vortex rings are important to developmental health.

There are some limitations to our study, including the absence of mitral valve and papillary muscles in the simulations, and the lack of wall twisting in our ventricular wall motion. Our future work include resolving these limitations, as well as studying diseased fetal hearts.

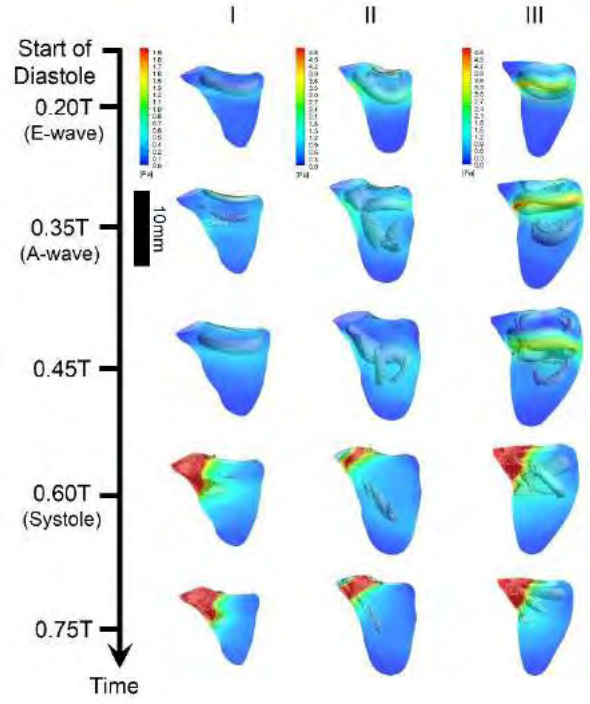

Figure 2. Wall shear stress distribution in the left fetal ventricular wall and the isosurfaces of vortex rings plotted with the lambda-2 criterion. T = duration of 1 cardiac cycle.

CONCLUSION

We developed a technique for patient-specific CFD simulations of the human heart chambers, and for the first time, performed patient-specific CFD of three 20-weeks human fetal left ventricles.

TEMPORAL HEALING RESPONSE OF ACHILLES TENDONS IN RODENTS FOLLOWING INJURY DEPENDS ON SURGICAL TREATMENT AND RETURN TO ACTIVITY TIME

Benjamin R. Freedman, Tyler R. Morris, Nabeel S. Salka, Joshua A. Gordon, Adam M. Pardes, Corinne N. Riggin, Courtney A. Nuss, Jennica J. Tucker, Pankti R. Bhatt, George W. Fryhofer, Daniel C. Farber, Louis J. Soslowsky

INTRODUCTION

Achilles tendon ruptures affect over 8 in 100,000 people each year in North America [1]. Unfortunately, optimized treatment and rehabilitation protocols throughout the healing process for Achilles tendon ruptures remain unknown [2]. Despite the higher costs and risks for complication, operative treatment has been believed to result in superior function and lower re-rupture rates compared to non-operative treatment [3]. However, recent reviews have suggested that outcomes for Achilles tendon ruptures are not necessarily improved with surgical treatment [3].

The effect of loading environment on Achilles tendon healing has been evaluated only for relatively short time points of healing (~14-21 days [4, 5]). Although early weight bearing has been suggested to be equally effective as immobilization [6] – and, in some cases, beneficial for Achilles tendon healing in humans [7] – the benefit of return to activity (RTA) following various periods of immobilization is unknown.

The objective of this study was to investigate the effects of surgical repair and RTA on joint function and Achilles tendon mechanical, structural, and histological properties after 1, 3, and 6 weeks of injury. We hypothesized that non-repaired tendons and early RTA would result in a superior healing response.

METHODS

Sprague Dawley rats (n=216) received 2 weeks of treadmill exercise training (up to 60 minutes at 10m/min) (IACUC approved) prior to blunt mid-substance transection of the right Achilles tendon and surgical removal of the right central plantaris longus tendon. Animals were then randomized into repaired (Modified Kessler approach) (n=108) or non-repaired (n=108) groups, and all hind limbs were immobilized in plantarflexion. These groups were further divided into animals with RTA after 1- (RTA1), 3- (RTA3), or 6- (RTA6) week cast immobilization (**Figure 1**). Functional evaluation (n=18/group) of passive ankle joint range of motion (ROM) and stiffness for dorsiflexion and plantarflexion was completed using a custom torque cell and accelerometer-based device on anesthetized animals. Quantitative gait assessment was performed prior to surgery and 3, 4, and 6 weeks after surgery.

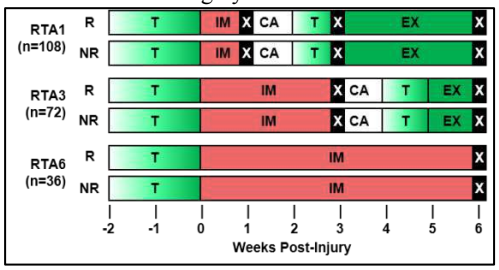

Figure 1: Study Design. Animals were treadmill trained (T) for two weeks. Following injury, animals were divided into repaired (R) and non-repaired (NR) groups, and were returned to activity (RTA) after 1- (RTA1), 3- (RTA3), or 6- (RTA6) weeks of cast immobilization (IM). *CA- cage activity; EX- exercise; X-sacrifice.*

All *ex vivo* assays were performed following sacrifice at 6-weeks post injury. After sacrifice, the Achilles tendon-foot complex was carefully removed *en bloc*, fine dissected, measured for cross sectional area (CSA), and secured in fixtures. Tendons were loaded at 1N in a PBS bath while a series of sagittal B-mode high frequency ultrasound images (HFUS) were acquired using a 40MHz scanner (Vevo 2100, MS550D; VisualSonics) (n=9-11/group). Echogenicity and collagen fiber alignment were evaluated from the HFUS images for the injury

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

region. Tendons were then mechanically tested and imaged (n=9-11/group) with a protocol consisting of stress relaxation (6% strain), a low-load dynamic frequency sweep (0.1 to 10 Hz), and fatigue testing (~10-75% of ultimate failure load) at 2Hz using a sinusoidal waveform until failure (Instron Electropuls 3000). Percent relaxation, |E*|, tanδ, toe and linear modulus, hysteresis, cycles to failure, and laxity were computed from mechanical and optical data. Cellularity and cell shape were evaluated using hematoxylin- and eosin-stained paraffin sections.

To evaluate the role of RTA on tissue healing 6-weeks post injury for RTA1 and RTA3 groups, 6-week post-injury data were normalized to either 1-week or 3-week post-injury data. Data were analyzed with parametric or non-parametric two-way ANOVAs (treatment and RTA), with post hoc Fisher's tests or Mann Whitney U-tests.

RESULTS

RTA3 groups had decreased dorsiflexion (**Figure 2A**) and plantarflexion ROM compared to RTA1 groups at 6-weeks post injury. These decreases in ROM occurred in concert with increased toe stiffness (not shown). No changes in quantitative ambulatory measures (vertical force (**Figure 2B**), braking force, propulsion force, lateral force, step width, stride length, or velocity) were found.

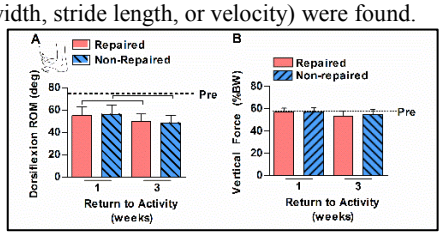

Figure 2: Ankle ROM and Gait. RTA was a significant factor (p<0.05) on dorsiflexion ROM (A), but not vertical force (B) after 6-weeks of healing. Data shown as mean ± SD. *Lines- significant differences (p<0.05). "Pre"- pre-surgery values.*

At 6-weeks post injury, longer periods of immobilization resulted in decreased CSA for all groups, and non-repaired tendons had decreased CSA for all RTA periods (**Figure 3A**). Delayed RTA decreased the number of cycles to failure in non-repaired tendons only (**Figure 3B**). For RTA1 and RTA3 groups, non-repaired tendons withstood a greater number of cycles to failure than repaired tendons. In addition, the linear modulus was elevated in non-repaired RTA1 and RTA3 tendons (**Figure 3C**). Treatment (but not RTA) was a significant factor for toe-modulus, dynamic modulus, hysteresis, and laxity (not shown). On HFUS imaging, delayed RTA was associated with increased fiber organization in repaired tendons. Increased echogenicity (a surrogate measure of matrix density) was observed with delayed RTA for both repaired and non-repaired tendons. Treatment was a significant factor on cell shape, but not cellularity.

Rates of property change following RTA were dependent on RTA time. RTA1 groups affected the rate of change of tissue CSA, toe modulus, fiber alignment, and echogenicity. Compared to RTA6 tendons, RTA1 groups had increased rate of CSA increase (**Figure 4A**), decreased rate of toe-modulus increase for repaired tendons, increased rate of disorganization in repaired tendons, and decreased rate of echogenicity increase (**Figure 4B**). RTA1 groups had no effect on the rates of change for percent relaxation, transition strain, or the linear modulus; however, rates for these properties did differ between treatments. In contrast, RTA3 groups affected the rates of change of only two properties; rates of CSA increase and echogenicity increase were both increased (**Figure 4C,D**). RTA3 groups did not affect the rate of change for percent relaxation, toe modulus, transition strain, fiber alignment, or linear modulus; however, these rates did differ in some cases between treatment groups.

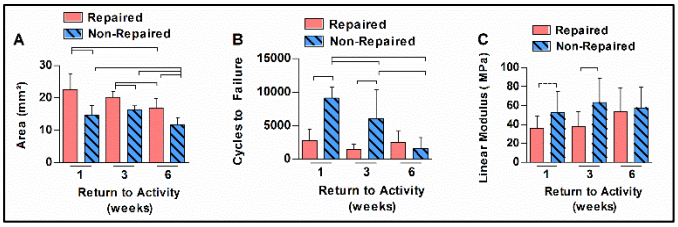

Figure 3: Mechanical Testing. Repair was a significant factor on tendon CSA (A), linear modulus (B), and cycles to failure (C) (p<0.05). RTA was a significant factor on tendon CSA and cycles to failure (A,C) (p<0.05). Data shown as mean ± SD. *Lines- significant differences (p<0.05); Dashed lines- trends (p<0.1).*

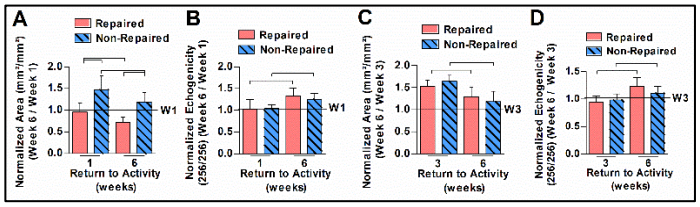

Figure 4: Effect of RTA. RTA1 and RTA3 groups had a significant effect on the rate of change of tendon CSA (A,C), but not the linear modulus (B,D). Data shown as mean ± SD. *Lines- significant differences (p<0.05); Dashed lines- trends (p<0.1).*

DISCUSSION

Achilles tendon healing following a variety of common clinical treatment methods was evaluated 6-weeks post injury in a rat model. Functional benefits of RTA1 groups identified on Achilles tendon healing include elevated range of motion and decreased ankle toe stiffness closer to pre-injury values. Although tendons with delayed RTA had higher echogenicity and alignment compared to other groups, they also had lower CSA, which likely limited the capacity of the more aligned tendon to withstand fatigue loading. Ultrasound evaluation detected changes in healing capacity between groups with different RTA strategies. Surgical treatment was a significant factor for mechanical properties, particularly the number of cycles to failure for RTA1 and RTA3 groups.

This study provides insight into how RTA affects healing. RTA1 groups maximize the effect of RTA with CSA, toe modulus, alignment, and echogenicity all affected. RTA3 also affected the rate of CSA and echogenicity increase, but did not affect tissue alignment or toe modulus. Taken together, these data highlight the capacity to tailor specific mechanical and structural property changes with RTA alone. Future work will evaluate the biological changes that may also be affected by RTA and the long-term effects of these treatment and return to activity protocols.

INTRODUCTION

Congenital Cardiovascular Malformation (CCM) affects 0.6-1.9% of the population [1] and is the leading cause of birth-defect related death. Many have shown that abnormal hemodynamics condition can affect the development of animal embryonic hearts to cause CCM [2]. It is thus important to understand how blood flow mechanics affects embryonic cardiovascular development. Such an understanding may be used for predicting CCM, and for planning fetal cardiovascular surgery. Fetal heart surgery is fast becoming the norm [3].

We recently developed a new technique to elucidate human fetal heart fluid dynamics, using 4D clinical ultrasound scans, and performing patient-specific Computational Fluid Dynamics (CFD) simulations of these human fetal hearts [4]. In the current study, we applied this technique to 2 human fetal hearts at 20-week gestation to elucidate the fluid mechanics within the right ventricle, and we have also performed energy balance analysis to understand whether the diastolic vortex rings play a role in conserving kinetic energy of flow from one cycle to the next.

In adult hearts, it is known that the right ventricle wall exhibits peristaltic-like contractile wave which moves from near the tricuspid inlet to the pulmonary outlet [5]. We analyzed wall motion from our images and found that such a peristaltic motion also exists in the 20-week human fetal hearts.

METHODS

4D ultrasound images of two 20 weeks old human fetal hearts were obtained using the Voluson 730 ultrasound machine (GE Healthcare Inc.) under STIC (Spatio-Temporal Image Correlation) mode. Images were exported as a 3D stack of images over 29 time points.

The images were first re-sampled along multiple slices from the tricuspid inlet to the pulmonary outlet. The luminal cross-sectional area of the right ventricle was segmented using custom written lazy snapping algorithm over all time points, over all slices. The results were examined for any contraction delay from the ventricular wall near the inlet to that near the outlet to quantify the right ventricular peristalsis.

The right ventricle chambers were segmented in 3D using the open-source program, VMTK, for 3D segmentation, for CFD analysis. The motion of the ventricle wall was first defined in polar coordinates, as the radial distance (r_{model}) between the centroid of the right ventricle to the wall endothelial surface:

$$r_{model}(\theta, \phi, t) = \alpha(\theta, \phi)\Omega(t) + r_0(\theta, \phi) \quad (1)$$

where Ω is the characteristic waveform over time, r_0 is the initial condition of the radius parameter, α is the amplitude of changes in radius over one cycle, θ and ϕ are angle coordinates and t is time.

Ω was formulated using Pulsed-Wave Doppler ultrasound velocity reading at the tricuspid inlet and the pulmonary outlet, from the literature, and was described mathematically via a 1D Fourier transformation of the data points. A mathematical description of α was obtained through a 2D Fourier Transformation of the radius amplitudes measured from the 3D segmentation. These equations were utilized to control dynamic mesh wall motion in the CFD simulations.

CFD simulation is done with FLUENT 16.0 (ANSYS Inc.). The boundary conditions were such that during diastole, the outlet was a zero velocity wall and the inlet was a zero pressure inlet, and that during systole, the outlet was a zero pressure outlet and the inlet was a zero velocity wall. Non-Newtonian fluid following the Carreau model was utilized, and the simulations were performed for 4 complete cardiac cycles to remove initial condition artefacts.

RESULTS

From the quantification of the luminal cross-sectional areas, we found that the maximum cross-sectional area occurred earlier in the cross-sections nearer to the tricuspid inflow, and later in the cross-sections nearer to the pulmonary outflow. The total delay from the inflow region to the outflow region was approximately 73ms and 49ms (17.5% and 12.9% of cardiac cycle) for the 2 hearts (Figure 1). These indicated that the initiation of contraction occurred first in the myocardium nearer to the tricuspid inflow and spread linearly towards myocardium near to the pulmonary outflow, suggesting that the right ventricular peristalsis occurred in fetal hearts just like in adult hearts.

Figure 2 shows the results of wall motion modeling for use in CFD. Results showed a good match with the 3D reconstruction from the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

ultrasound images.

Figure 3 shows the results of the simulations, in terms of the spatial pressure variations and wall shear stresses on the walls of the fetal right ventricle, and the vortex dynamics within the ventricle.

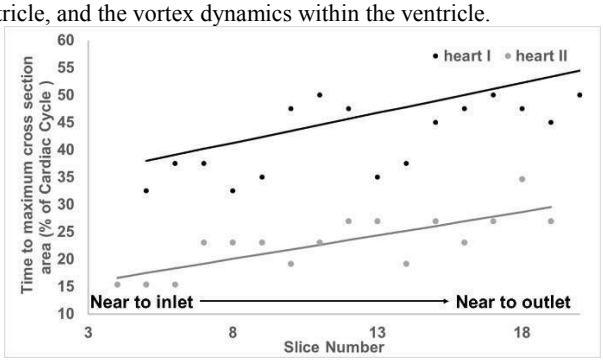

Figure 1: Time maximum luminal cross-sectional area at different cross-section slices from the tricuspid inlet to the pulmonary outlet shows a linear trend, showing that contraction occurred in a "peristaltic" wave.

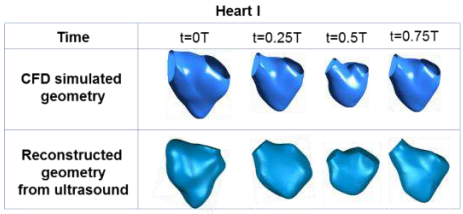

Figure 2: Ventricle wall motion programmed in CFD matches segmentations from ultrasound images well.

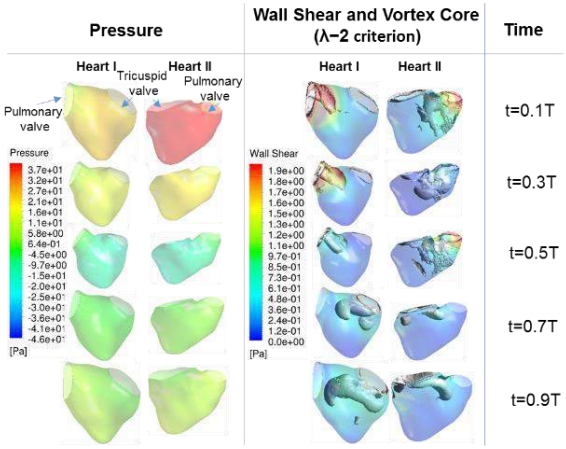

Figure 3: Results of the CFD simulation in the 20 weeks fetal right ventricle. The wall pressures, wall and the vortex dynamics in the ventricle are illustrated at various time points in the cardiac cycle.

The human fetal ventricular fluid dynamics appeared to be dominated by the formation of two vortex rings during diastole, corresponding to the E- and the A-wave. These vortex rings carried a downward momentum towards to the apex. In the fetus, the A-wave is much stronger than the E-wave, unlike in adults. As a result, the A-wave vortex was larger and had higher momentum than the E-wave vortex. Consequently, the second vortex caught up with first vortex and combined into a single vortex. Furthermore, the vortices do not dissipate fully at the end of diastole, and appeared to conserve kinetic energy of flow into the following systole. The vortex structures persist and were ejected through the pulmonary valve during systole, giving the pulmonary outflow a helical flow pattern.

It was also observed that the location of high wall shear stress coincides with the location of high vorticity, as the vortices generated velocity tangential to the heart wall, which led to elevated wall shear stresses (0.7-1.2 Pa). During systole, fast moving outflow through the pulmonary valve also created high wall shear stresses (1.5-2.9 Pa) in the outflow tract.

Figure 4 shows our quantification of kinetic energy (KE) of right ventricular flow. Elevations of KE was observed during systolic outflow and during both the E- and A-wave of diastolic inflow. The results showed that an average of 24% of the peak kinetic energy from diastole is transferred to the subsequent systole.

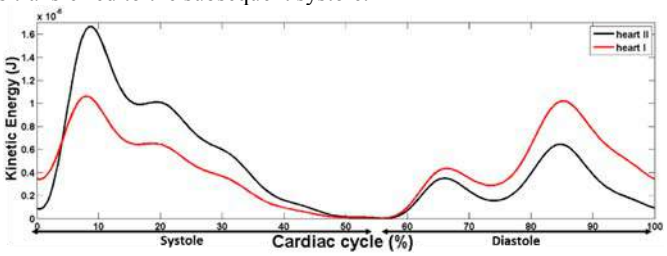

Figure 4: Kinetic energy within the right ventricle chamber at different time points.

DISCUSSION

Our studies have revealed that right ventricular peristalsis occurs in the human fetal heart, just like in adult hearts. We hypothesize that this peristaltic motion, which squeezes on the blood at the inlet first and outlet later, provides higher efficiency in draining blood from the ventricle during systole. We are currently investigating this notion via CFD simulations.

For the first time, we performed patient-specific CFD simulations of the human fetal right ventricle based on 4D clinical ultrasound imaging. Our simulations revealed interesting fluid dynamics in the human fetal right ventricle, where two independent vortex rings were observed to merge over the course of diastole. We hypothesize that the characteristics of these vortices can be used as markers for heart diseases, like that proposed for adult hearts.

Many studies have demonstrated that fluid forces can affect the development of embryo in both animals [2] and human [3]. Understanding the fluid forces, such as pressures and wall shear stresses, imposed onto the human ventricular walls may be important to understanding the pathway at which fluid forces influences development. Interestingly, our results showed that the ventricular vortices were driving forces behind the elevation of shear stresses during diastole. It is thus important to further study their features.

Additionally, it has been hypothesized that ventricular vortices have the function of preserving energy from diastolic inflow for the subsequent systolic outflow, as an evolutionary trait to reduce energy expenditure of the heart function. In our study we observe that a significant part (24%) of the kinetic energy after diastole is carried over to systole, corroborating with this energy conservation hypothesis.

INTRODUCTION

The blood flow in the left ventricle (LV) is normally very complex, with intricate flow patterns on both small and large scales. The flow in the LV is driven by the myocardial motion and strongly interacts with valves, papillary muscles and also the protruding surfaces, trabeculae, which constitute parts of the innermost surface in the LV. Computed tomography (CT) is able to provide information about the heart and coronary arteries with geometrical details on sub-millimeter levels. While CT is unable to measure flow, the high-resolution geometry can instead be used in numerical models to compute the flow. Such models often simplify the endocardial surface, and papillary muscles and trabeculae have often been neglected.

The overall goal of this study was to develop a novel and efficient computational model for computing hemodynamics of physiologically realistic hearts. The flow was computed in the left atrium, ventricle, and parts of the ascending aorta, and the model included patient-specific wall motion, valves, trabeculae, and papillary muscles. To investigate the importance of computing the flow in a realistic heart geometry, a comparison with a smoothed geometry, resembling models often found in literature, was performed.

METHODS

Coronary CT angiography was performed on a 76 year old male with a dilated left ventricle. No significant stenoses were present in the coronary arteries and left ventricular function was considered to be normal. Image acquisition was performed using a third generation dual source CT (Siemens SOMATOM Force, Siemens Medical Solutions, Forcheim, Germany). In-plane image resolution was 512x512 pixels and the reconstructed resolution was 0.35x0.35x0.25 mm^3 and 20 time frames per cardiac cycle. From the 4D CT data, a map of the patient-specific wall motion was obtained through a non-parametric diffeomorphic image registration algorithm [1]. Approximately 500 000 vertices were located on the model wall and a one-to-one vertex correspondence between the time frames described the wall motion over the entire cardiac cycle. Besides a baseline model where the trabeculae and papillary muscles were included, a smoothed model was also included where the ventricular surface was smoothed and the papillary muscles were removed, see Figure 1. The dynamics of the valves could not be resolved with sufficient detail by the CT measurement, but the open and closed positions could be extracted. In order to resolve the geometrical details of the ventricle, the total number of mesh cells was on the order of 12 million anisotropic cells. Automatic remeshing was triggered during the simulation when the mesh quality became too poor

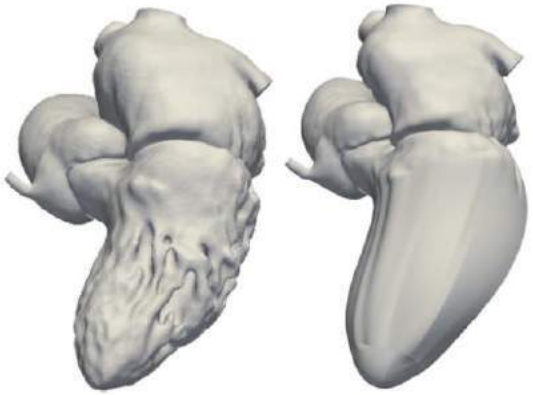

Figure 1. Left: reference geometry with trabeculations and papillary muscles, right: smoothed model.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

or when the topology changed. The meshing strategy was fully automated and capable of handling the folding and unfolding of the complex trabeculated structures. The flow simulation was performed using ANSYS CFX 16.0, and the wall motion was specified from the image registration process. Pressure boundary conditions were applied at the pulmonary veins and ascending aorta. The time step was 1e-4 s and intermediate meshes at each time step were computed during run time using a fast cubic interpolation FORTRAN-subroutine [2] to ensure that both velocity and acceleration of the wall were continuous and smooth.

RESULTS

A cross-sectional plane through the atrium, LV and aortic sinuses was used to display velocity magnitude and vectors at three different phases during the cardiac cycle, see Figure 2. During systole (time = 0.1T) the flow field is similar between the models, with a high velocity region in the left ventricular outflow tract and through the aortic valve. This could be expected since both geometries were similar in that region and the LV stroke volume and ejection fraction was almost the same. The velocity in the apical region is lower in the baseline model than the smoothed model. During diastole the flow patterns appeared different between the baseline and smoothed models; the smoothed model had a high velocity flow in the mid region while the flow was more stagnant in baseline model. Instead the papillary muscles seem to divert the flow and created a large vortex in the middle of the LV, which was not as prominent in the smoothed model. The LV filling pattern in this patient was asymmetrical, with a mitral jet directed towards the lateral side of the ventricle. Thus, a large vortex formed behind the anterior mitral leaflet, and was allowed to expand in the ventricle, while the flow on the posterior side strongly interacted with the wall.

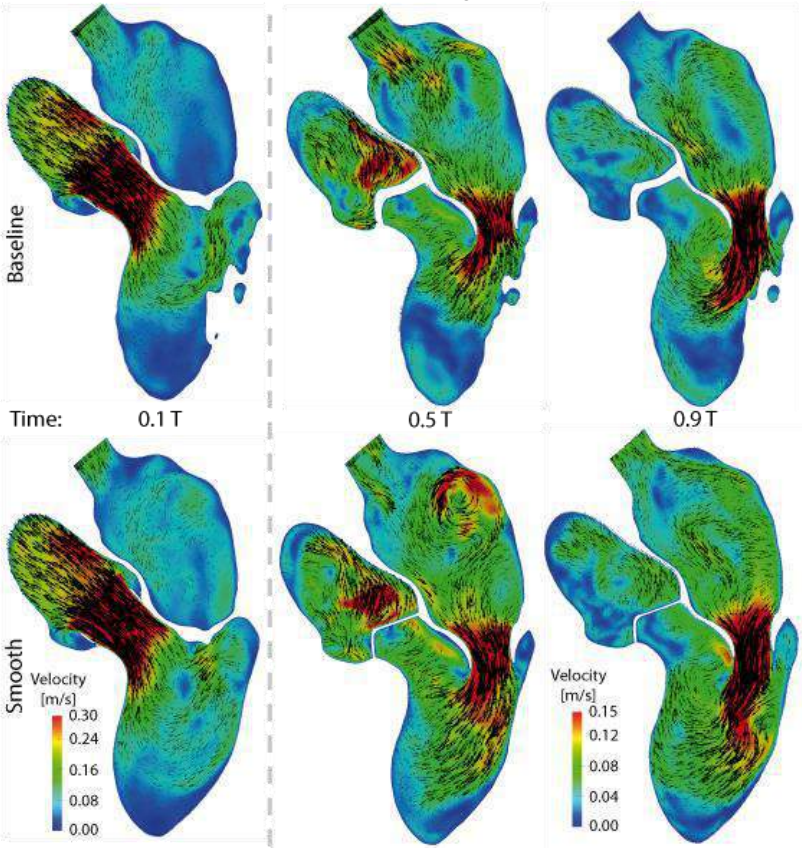

Figure 2. Flow field in the baseline model with trabeculations and papillary muscles (top) and in the smoothed model (bottom). Timing is indicated as fraction of cardiac cycle (T).

DISCUSSION

In the present study, a framework for computing patient-specific hemodynamics in physiologically realistic hearts was developed and applied to a patient with a dilated left ventricle. The framework only required time-resolved CT images of the heart. The model included papillary muscle motion and the folding and unfolding of left ventricular trabeculae, and the results indicated that these are important aspects to consider when computing cardiac blood flow. In addition, the model also included the atrium, ventricle, valves, aortic root and part of the coronary arteries and ascending aorta, which has, to the authors' knowledge, never been achieved before in a computational flow model. The simulation time was the same for both models, even though the baseline model included more geometrical details. Thus, the framework was able to handle complex geometrical LV features without any additional computational cost.

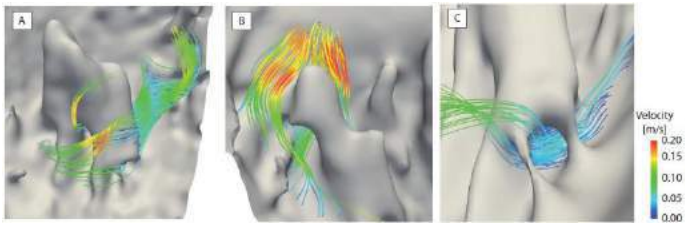

Figure 3. Visualization of particle traces near the papillary muscles and trabeculated structures. A: anterior papillary muscle, B: posterior papillary muscle, C: geometrical structure below the anterior papillary muscle.

Compared to simplified models commonly found in literature, the blood in the physiological model interacted strongly with papillary muscles and trabeculae which in turn affected the computed flow field. Specifically, the simulations showed that the complex flow patterns in the LV were affected by the blockage effect posed by the papillary muscles, which effectively reduced the amount of energetic flow that reached the apical part of the heart. The interstitial spaces in the trabeculated surface could promote stagnant blood flow, as regions of high residence time could be found in such structures. As such, the presented results suggest that over-simplified models are unable to capture details that could have important physical implications. From a clinical perspective, the framework developed here opens up for the possibility to artificially add pathologies such as myocardial infarction or hypertrophy to the model. The wall motion can be turned off or tuned, the size of LV can be changed, and the valves can allow for regurgitant flow.

In conclusion, the novel framework developed in this study enables the inclusion of geometrical features on a scale that has never been achieved before. In addition, the feasibility, as well as importance, of including the motion of papillary muscles and trabeculae in computational models of cardiac hemodynamics was demonstrated.

INTRODUCTION

Hemodynamic forces, especially wall shear stress (WSS), are well documented to affect atherosclerotic plaque formation[1,2]. This study explores the effects of the directionality of pulsatile WSS on the gene expression of endothelial cell grown on the bottom of a Petri dish subjected to orbital flow on a shaker platform. A 3D computational fluid dynamics (CFD) model[3] quantified the oscillating WSS. WSS magnitude was relatively uniform temporally and spatially at low orbital speed. At higher orbital speeds, it remained fairly uniform near the center of the dish and fluctuated significantly near the side walls. An extension to Stokes' second problem was used to validated the CFD model. Atherogenic gene expression was measured under the same flow conditions in the presence of leukotrienes (LTB_4) and lipopolysaccharide (LPS), since the role of LTB_4 and LPS are implicated in several inflammatory diseases[4]. Statistical analysis showed that expression of I-CAM and E-Selectin was significantly influenced by directional oscillatory shear index (DOSI), but not by WSS magnitude.

METHODS

1. Multiphase CFD model

ANSYS Fluent was used to model the flow. The unsteady laminar fluid motion in the orbiting dish was simulated with a multiphase volume of fluid (VOF) model in which the two fluids across the interface share the same stress and velocity boundary conditions.

2. Determination of velocity and WSS – Analytical approach

Stokes' second problem was extended to orbital motion of the plate, which gives the velocity of the fluid relative to the plate as

$$\mathbf{V}(z,t) = U\exp\left(-\sqrt{\frac{\omega}{2\upsilon}}z\right)\left[-\sin\left(\omega t-\sqrt{\frac{\omega}{2\upsilon}}z\right),\cos\left(\omega t-\sqrt{\frac{\omega}{2\upsilon}}z\right)\right]+U(\sin\omega t,-\cos\omega t) \quad (1)$$

where $U = R\omega$ is the dish velocity magnitude, R is orbital radius, ω is orbital speed, $\nu = \mu/\rho$ is kinematic viscosity, μ is absolute viscosity, ρ is density, z is the vertical coordinate and t is time. Using the dish velocity magnitude, wall shear stress is

$$\vec{\tau}_w = R\sqrt{\frac{\rho\mu\omega^3}{2}}(\cos\omega t+\sin\omega t,\sin\omega t-\cos\omega t) \quad (2)$$

3. Directional Oscillatory Shear Index

Directional Oscillatory Shear Index (*DOSI*) was used as a measure of bi-axiality [3]. *DOSI* is given by

$$DOSI = 1 - (OSI_2/OSI_1) \quad (3)$$

where OSI (Oscillatory Shear Index) components are given by[5]

$$OSI_1 = 1-\left|\int_0^T\tau_1 dt\right|\Big/\int_0^T|\vec{\tau}_w|dt \quad , \quad OSI_2 = 1-\left|\int_0^T\tau_2 dt\right|\Big/\int_0^T|\vec{\tau}_w|dt$$

where principal direction 1 is that of the larger of the two oscillations, and $\overrightarrow{\tau_w}$ is the two-dimensional WSS vector.

4. Cell culture and shear stress applications

Human umbilical vein endothelial cells (HUVECs) were grown at controlled radial locations. The dishes were placed on an orbital shaker platform to generate pulsatile flow. Two sets of plates contained HUVECs in the presence of media containing either LTB_4 (100 nM) or LPS (100 ng/ml) or both. One set of dishes was exposed to shear stress and another was grown under stationary conditions. Changes in gene concentration were calculated using Real Time PCR method. The effects of DOSI and shear magnitude on the atherogenic genes were analyzed at 20% and 85% radial locations of the dish.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

5. *Statistical Analysis*

ANOVA was used to identify the effects on gene expression of DOSI and shear magnitude with the model given by

$$Y_{ijk} = \mu_{mean} + G_i + T_j + I_i + (GT)_{ij} + (GI)_{ij} + D_{ijk} + M_{ijk} + (DG)_{ijk} + (DT)_{ijk} + \varepsilon_{ijk} \quad (4)$$

where μ_{mean} is the general mean effect, G_i, T_j and I_k, are the additional effects due to the *i*th gene, *j*th treatment and *k*th individual (replicate) respectively. $(GT)_{ij}$ is the interaction effect between gene and treatment, $(GI)_{ik}$ is the interaction effect between gene and individual. D_{ijk} and M_{ijk} are the values of *DOSI* and shear magnitude. $(DG)_{ijk}$ and $(DT)_{ijk}$ are the interaction effects of *DOSI* with gene and treatment respectively. ε_{ijk} is the random error component for the *i*th *DOSI*, *j*th treatment and *k*th replicate.

RESULTS

1. *Validation of 3D CFD model with analytical solution*

Agreement between CFD and the analytical solution for simplified inertial flow was within 1% for velocity components (Figure 1), which establishes the accuracy of the model.

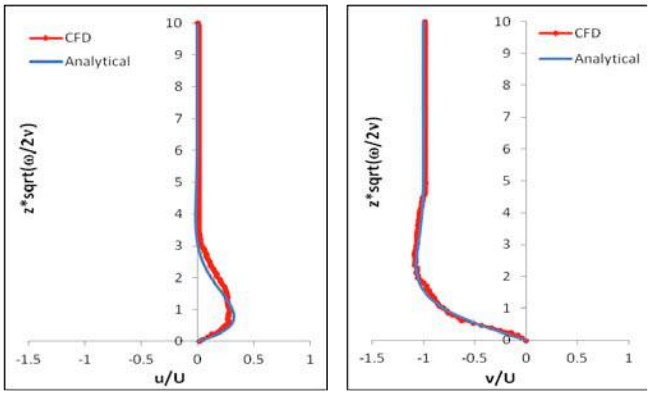

Figure 1. Normalized velocity components for analytical and CFD models.

2. *Oscillatory WSS for experimental conditions: DOSI*

Highest WSS was observed near the vertical wall and lower shear was observed near the center of the dish (Figure 2). WSS ranged from 0-9 dyne/cm^2 at 85% of the radius, and 0-1 dyne/cm^2 at 20% radial location, respectively. *DOSI* was calculated (Table 1) on the basis of principal axes. The first principal direction was the direction of the resultant of the two (radial and tangential) shear components. The second principal direction is perpendicular to the first.

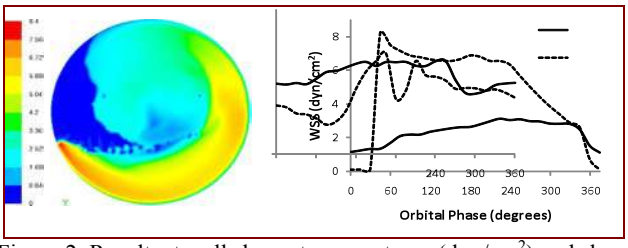

Figure 2. Resultant wall shear stress contours (dyn/cm^2) and shear waveforms at different radial locations.

Table 1. *DOSI* at different radial locations

Radial location (%)	OSI_{tan}	OSI_{rad}	DOSI
20	0.892	0.620	0.305
85	0.986	0.06	0.994

3. *Impacts of shear stress on atherogenic gene expressions in the presence of LTB_4 and LPS*

I-CAM expression was significantly lower at high *DOSI* in the presence of LPS only, while E-Selectin was significantly lower at high *DOSI* regardless of treatment (Figure 3). ANOVA (Table 2) further reinforced the significance of *DOSI* on those gene expressions by the strength of its interactions with other atherogenic factors.

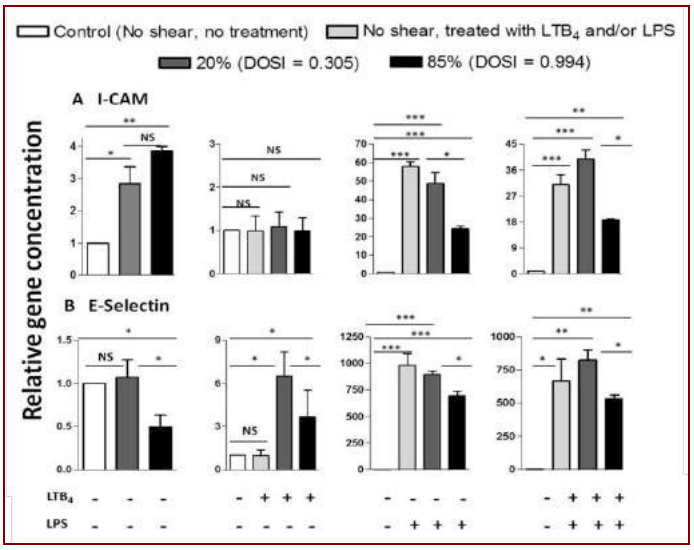

Figure 3. Effects of *DOSI* and shear magnitudes on gene expressions (I-CAM, E-Selectin) at different radial locations. Statistical significance : $*p < 0.05$, $**p < 0.01$, and $***p < 0.001$, respectively.

Table 2. ANOVA of gene expression – Statistical significance (p) of *DOSI*, shear magnitude, and treatment by Eqn. 4.

Gene (G)	Treatment (T)	DOSI (D)	Magnitude (M)	GT	DG	DT
<0.001	<0.001	<0.01	NS	<0.001	<0.001	<0.001

DISCUSSION

This study demonstrated the validation of computational and analytical models of oscillating shear and velocity components in an orbiting Petri dish. Further, the model was used to quantify pulsatile WSS to understand the effects of WSS directionality on cell function, in particular, expression of genes involved in atherosclerosis. The ANOVA model characterizes the main and interaction effects of the genes (ICAM, E-selectin, IL-6), treatment (LTB_4, LPS), *DOSI* and shear magnitude. The significance of *DOSI* and its interactions within the fitted model reveal the significant individual impact of bi-axiality and its interactive effects with the other factors in altering the cellular gene expression. So *DOSI*, as an index of bi-axial oscillatory shear, characterizes its impact either singly or in consort with a variety of other cofactors on different types of responses. This study suggests that the directionality of shear modulates gene expression and, thus, may influence the formation of atherosclerotic plaque.

INTRODUCTION

Driven by the increasing number of surgical cardiac procedures performed and by the advancement in surgical techniques, mechanical circulatory support has become progressively more viable and more frequently utilized as a treatment option for pediatric patients [1,2]. While methods of providing circulatory support have improved significantly over the years, complications with hemolysis and thrombus formation still persist as serious concerns. Numerous investigations have demonstrated that shear-induced hemolysis, mechanical stress, and device surface contact associated with mechanical circulatory support can lead to thromboembolism, bleeding, and infection [3-5]. In order to better understand and more effectively study these complications, Bachmann *et al.* established the importance of using a fluid that simulates the properties of blood during *in vitro* testing of pediatric ventricular assist devices [6]. Viscoelasticity of whole blood, even in normal subjects, varies over a wide range due to the strong influence of hematocrit, plasma viscosity, and protein concentrations. These physiological factors influence the viscoelasticity of blood, and thus the flow dynamics through assist devices, and should also be taken into consideration during blood pump design and performance testing [7-8]. This study compares blood rheology between adult and pediatric cardiac surgery patients to improve the understanding of design criteria for pediatric devices.

METHODS

Informed consent was obtained from parents of pediatric patients scheduled for cardiac surgical procedures at the Kosair Children's Hospital, Louisville, KY, and from adult patients scheduled for cardiac procedures at Jewish Hospital, Louisville, KY. The research protocol and consent forms were approved by the Institutional Review Board at the University of Louisville and the Norton Healthcare Research Office. The focus of the pediatric study was to be on patients weighing less than 25 kg based on the specifications of the NHLBI Pediatric Assist Device Program [9]. The age, weight, most recent hospital hematological data, and surgical procedure to be performed were recorded at the time of blood sample collection. Each sample was obtained from an indwelling catheter at the time of surgery and was immediately placed into a 3 mL EDTA blood collection tube and iced until analyzed by a Vilastic-3 viscoelasticity rheometer (Vilastic Scientific, Inc., Austin, TX) within two hours of collection. Viscous and elastic components of complex viscoelasticity were measured in a capillary tube of 0.504 mm radius and 6.33 cm length at temperature of 37^{o}C and frequency of 2Hz over a range of shear strain from 0.15 to 25 (shear rate 1.8 to 251 s^{-1}). Spun hematocrit was also determined.

Samples were collected from 35 adult and 35 pediatric patients. Viscosity and elasticity measurements were reviewed to insure physiological validity. Patient data sets were removed when elasticity was higher than viscosity (5 adult and 4 pediatric samples). Samples that were more than 3 standard deviations were removed as outliers (2 adult and 2 pediatric samples). Viscosity and elasticity were interpolated to get values at strain rates of 0.2, 1, and 5, corresponding to the rheology of erythrocyte aggregates, individually suspended cells, and oriented, layered cells, respectively.

Analysis used the natural logarithms of viscosity, elasticity, and strain values, as the natural log transformation of these variables produced an approximately linear relationship. The model takes the form:

$$y_{ij} = \beta_0+u_{0i}+(\beta_1+u_{1i})x_{1ij}+\beta_2x_{2ij}+\beta_3x_{3ij}+\beta_4x_{1ij}x_{2ij}+\beta_5x_{1ij}x_{3ij}+\beta_6x_{2ij}x_{3ij}+\varepsilon_{ij}$$

where y_{ij} represents the logarithm of (centered) viscosity or elasticity measurement from subject i on observation j, x_1 is log strain, x_2 is hematocrit, x_3 is subject age, and ε_{ij} are independent and identically distributed N(0, σ) error terms.

RESULTS AND DISCUSSION

Only the viscosity results are presented here. A preliminary model was fit that included fixed effects of age, hematocrit, strain, age-by-strain, hematocrit-by-strain, and hematocrit-by-age interactions. A likelihood ratio test for the significance of the random coefficient for log strain was highly significant ($p < 0.0001$),

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

indicating substantial variation in slopes among subjects. A significant age-by-strain interaction indicates that increasing age decreases the average slope of the log strain effect on log viscosity. Negative log strain and log strain-by-age coefficients suggest that age increases the effect of strain on viscosity. A similar relationship exists between hematocrit and strain. The hematocrit-by-age interaction was not significant (p-value 0.4439), indicating the effect of hematocrit on viscosity is independent of age, and was subsequently removed from further models.

To determine whether the effect of age was linear, a model was built with categorical age quartiles and strain as fixed effects. The large difference observed between the second and third quartiles in the estimated coefficients for the age main effect and age-by-strain interaction, along with the similarity in the third and fourth quartile estimates suggested a difference in age effect and its interaction with strain occurring in the third quartile. To pinpoint where the distinction occurred, fitted strain coefficient values, representative of the slope of subjects' log strain versus log viscosity curves, from a model including only strain as a predictor variable were plotted against subject age (Figure 1, top). The regression line and loess curve in Figure 1 illustrate the the age-by-strain interaction. A similar plot of the fitted intercepts against age was produced to detail any trend in the strain main effect as age increased (Figure 1, bottom). The inflection points of the loess curves in these graphs occur in the 14-36 age range. As puberty is a biologically plausible phase, fourteen was selected as the cut point and further analysis focused on differences between juveniles (defined as subjects aged fourteen and under) and adults.

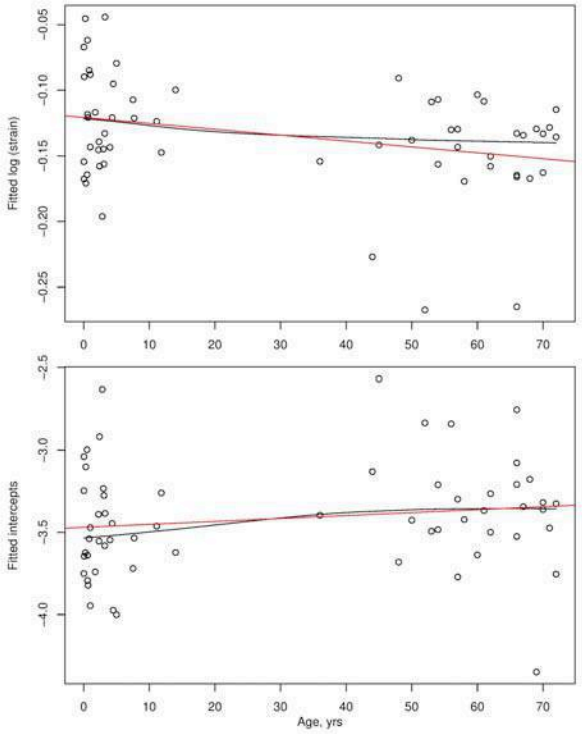

Figure 1. Top: Fitted log strain and intercept values plotted against age from modeling outcome of viscosity as a function of log strain. Top: The points represent fitted log strain values from a linear mixed model of log viscosity as a function of log strain, including a random intercept and random coefficient for log strain. The red line represents the linear model and the black line the smoothed loess curve.

Bottom: The points represent fitted intercept values from a linear mixed model of log viscosity as a function of log strain, including a random intercept and random coefficient for log strain. The red line represents the linear model of the fitted intercepts as a function of age. The black line is the smoothed loess curve of the age-intercept function.

To reflect this difference between juveniles and adults, the age-by-strain interaction was replaced by separate adult-by-strain and juvenile-by-strain interaction terms, with adult status being an indicator variable (taking value 1 for subjects > 14 and 0 otherwise) and the juvenile term simply the juvenile age. The inclusion of two strain-by-age interaction terms allows the slope of log strain to vary depending on juvenile or adult status. The juvenile-by-strain interaction is a linear term that modifies the log-strain slope per year increase in age up to age 14, while the adult-by-strain interaction is a constant modifier of the log-strain slope for all subjects over age 14. While the juvenile-by-strain interaction was not significant, it is included in the model as it is biologically implausible that the observed difference in slope of log strain between juveniles and adults begins suddenly at a certain age.

An important outcome of this analysis is that the likelihood ratio test for the combined effects of both age-by-strain interaction terms was significant (p-value 0.0177). The new model incorporating these interactions, therefore, facilitates improved design of cardiovascular devices across diverse patient groups.

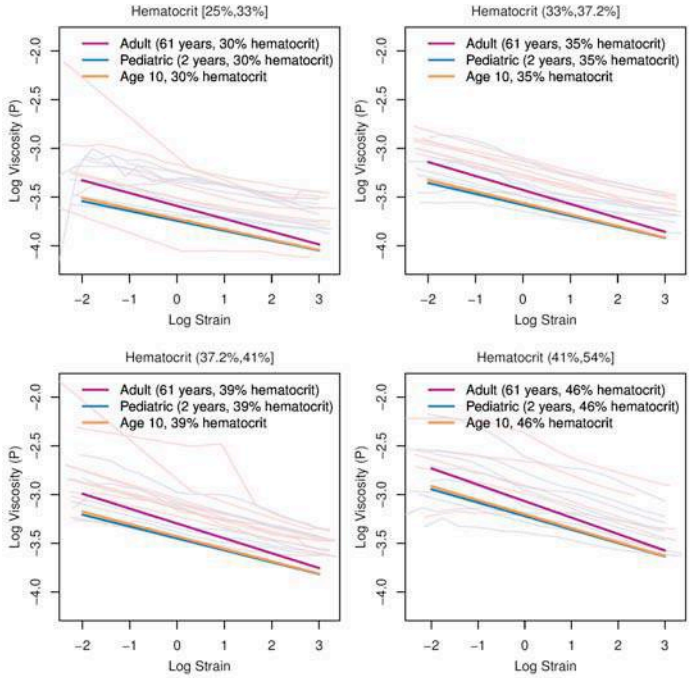

Figure 2. Comparable log viscosity response for pediatric and adult subjects at given hematocrit values. The solid lines represent log viscosity values for adult and pediatric subjects at the respective hematocrit percentiles as predicted by our final model. Each panel represents the midpoint of its respective hematocrit quartile. Pediatric lines were modeled at age 2, while adult lines were modeled at age 61.

COMPARISON OF *IN VITRO* ENDOTHELIAL WOUND HEALING IN BARE METAL VS. DRUG-ELUTING STENTS

Elizabeth E. Antoine, Abdul I. Barakat

Hydrodynamics Laboratory (LadHyX)
Department of Mechanics
Ecole Polytechnique
Palaiseau, France

INTRODUCTION

The pathological complications of atherosclerosis, namely heart attacks and strokes, are the leading cause of mortality in the world. While the use of endovascular stents to open blocked arteries is broadly successful, stent deployment triggers a complex set of biological responses leading in some cases to in-stent restenosis (ISR) or late stent thrombosis (LST). Understanding the biological pathways involved in these and other stent pathologies under physiological conditions remains a major challenge. Although *in vivo* studies and computational models provide invaluable information about the biology of atherosclerosis and inform stent design strategies, the availability of *in vitro* devices for controlled studies of atherosclerosis and validation of numerical work remains critically limited [1,2].

Implantation of a stent in an artery leads to endothelial cell (EC) denudation which disrupts communication between ECs and smooth muscle cells (SMCs) necessary for homeostasis. EC-SMC interactions in response to wounding have been studied in classical monolayer cultures; however, the similarity of such experiments to *in vivo* conditions is limited. Furthermore, in most cases stent deployment is not possible in *in vitro* devices and therefore effects specific to stenting such as localized sustained drug release cannot be reproduced.

At SB^{3}C 2015 we presented the design and development of an *in vitro* artery within which a stent can be deployed and cellular response studied. Here we revisit this system, presenting a robust methodology for quantification of endothelial wound healing and investigating differences in wound healing after deployment of a drug-eluting stent (DES) compared with a bare metal stent (BMS).

METHODS

The *in vitro* artery was assembled as described previously [3]. Briefly, collagen I from rat tail tendon was combined with 200,000 cells/mL bovine aortic SMCs (Tebu-Bio) labeled with a red fluorescent marker (Vybrant CM-DiI, Fisher) and polymerized in an annular shape in a polymer tube (Figure 1**a**). Bovine aortic ECs (Georges Pompidou Hospital, Paris) labeled with a green fluorescent marker (Vybrant DiO, Fisher) were seeded on the lumenal surface of the collagen. The device was perfused (Figure 1**b**) over 72 hours with stepwise-increasing flow of culture medium (DMEM supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin, Invitrogen) to condition the endothelial monolayer and finally obtain pulsatile flow conditions hydrodynamically similar to human coronary artery flow (Reynolds number = 360, Womersley number = 16) (Figure 1**c**).

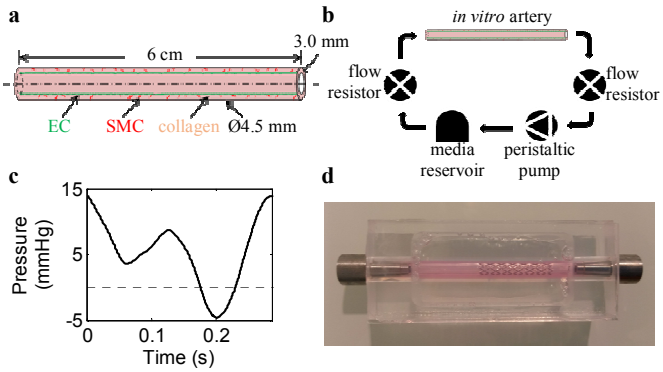

Figure 1: The *in vitro* artery. (a) Schematic. (b) Flow components used to generate pulsatile coronary flow. (c) Pressure trace under coronary flow conditions. (d) Photograph of stented *in vitro* artery.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

After preconditioning and perfusion at the final flow condition for 18 hours, either a BMS (Tsunami Gold, Terumo) or a biolimus-eluting stent with biodegradable polymer coating (Nobori, Terumo) was inserted in the *in vitro* artery (Figure 1**d**). Each stent, nominally designed for a 3.0 mm artery, was overexpanded 10% to 3.1 mm to ensure retention in the *in vitro* artery during and after catheter removal.

Cell migration was recorded after stent deployment using time-lapse imaging on an epifluorescent microscope (Ti-E, Nikon) and 4X magnification (1.66 µm/pix). Phase contrast and fluorescence images were acquired every 30 minutes using a motorized stage to acquire a grid covering the entire *in vitro* artery (Figure 2). The camera was focused at the nearest plane tangent to the lumen in order to best record endothelial motion. Image acquisition and stitching were performed using either ImageJ plugins (NIH) or NIS Elements (Nikon).

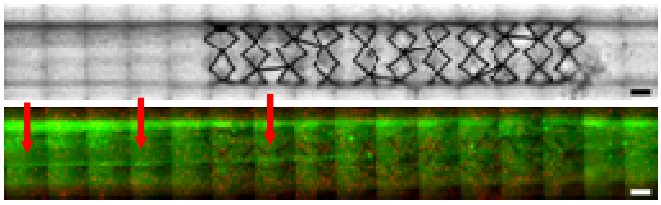

Figure 2: *In vitro* artery immediately after deployment of the BMS. (top) phase contrast. (bottom) overlay of endothelium (green) and smooth muscle (red). Arrows indicate denuded region. Scale bar: 1 mm. Flow: left to right.

Endothelial wound healing analysis was performed in MATLAB. First, two regions of interest (ROIs) of similar size were selected, each containing a well-defined section of wound: one ROI upstream of the stent and one ROI within the stent (Figure 3, images). Whole-image shifts in the time-lapse sequence were corrected using a PIV-based image registration scheme. Because the wound boundary is poorly defined due to variation in individual cell position as well as heterogeneous cell fluorescence, bulk analysis was performed on profiles obtained by averaging the fluorescence intensity in the FITC (endothelial) channel along the length of the wound (Figure 3, profiles). Subsequently, each profile was normalized to reduce the influence of lighting variations. The speed of wound healing was computed robustly using parametric variation in the intensity threshold used to estimate boundary position as well as the number of frames (time points) used in linear regression for slope estimation. This parametric variation provided 54 "replicates" for each wound boundary within each ROI (upstream and in-stent). Comparisons were performed using ANOVA and Tukey's post-hoc test.

RESULTS

Catheter insertion and stent deployment resulted in large patches of denuded lumen (Figure 2**,** arrows) for both stented arteries. Although endothelial cells migrated to fill the wounds in both cases, qualitatively their behavior differed significantly between the BMS and the DES artery. In the BMS artery, endothelial front advancement was organized, appearing to be group motion with a well-defined trajectory into the wound (Figure 3). In contrast, endothelial cells in the DES artery appeared to migrate independently of one another and with less directionality. Furthermore, endothelial cells appeared less healthy and were more apt to detach from the lumen in the DES case, resulting in a sparser endothelium 24 hours after stent deployment.

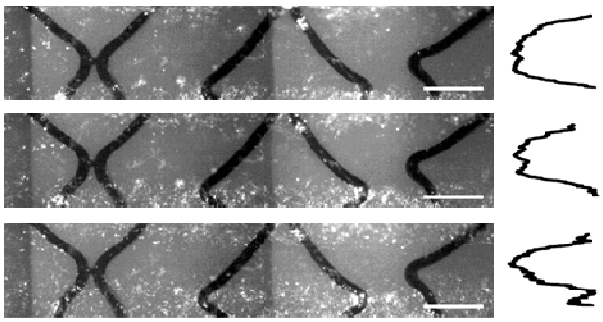

Figure 3: Wound healing in an in-stent ROI of the BMS-implanted *in vitro* artery. Top to bottom: 0, 5, and 10 hours post-stent. The mean intensity profile is used to estimate the rate of endothelial wound healing. Scale bar: 500 µm.

Quantification of the speed of wound healing (Figure 4) revealed that the endothelium repaired itself considerably faster ($p<0.0001$) in the BMS *in vitro* artery (15.0 ± 0.5 µm/h) than in the DES *in vitro* artery (0.63 ± 0.02 µm/h) (mean ± SEM, $p<0.0001$). While the wound healing speed was not significantly different between the BMS upstream and in-stent regions ($p\sim0.8$), a small yet significant ($p<0.0001$) decrease was found within the DES (0.43 ± 0.02 µm/h) compared with the artery section upstream (0.84 ± 0.02 µm/h). All results reported are mean ± SEM.

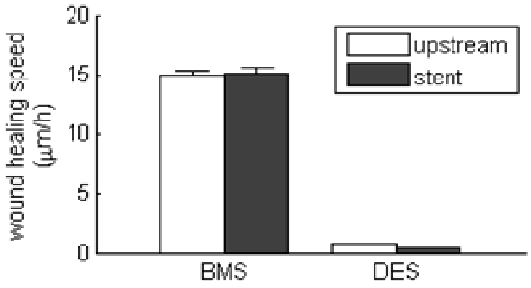

Figure 4: Comparison of endothelial wound healing in BMS- vs. DES-implanted *in vitro* arteries. Error bars indicate the standard error of the mean.

DISCUSSION

We successfully deployed a BMS and a DES in a novel *in vitro* artery platform and quantified the rate of endothelial wound healing in each. We identified significant inhibition to wound healing in the DES-implanted *in vitro* artery, a result which is consistent with *in vivo* data. The endothelial response quantified here will be combined with the accompanying analysis of SMC migration to better understand EC/SMC interaction in response to stent deployment.

INTRODUCTION

In vivo animal models and *in vitro* tissue explant studies have indicated that increased joint translation, contact stress, and impact force are associated with increased likelihood of cartilage degeneration [1, 2]. The holy grail of orthopedics is to translate this emerging body of knowledge to clinical care: in theory, a deeper understanding of a patient's joint mechanics could be used to assess the risk of joint tissue degeneration after injury. Finite element (FE) models of cadaveric specimens are created from inputs that include joint geometry, tissue properties, and joint kinematics [3], and comparisons between the outputs from FE and the corresponding cadaveric models can be made [4]. However, for patient-based models it is impossible to measure joint tissue properties and thus to compare FE model outputs with physical model outputs. To realize the vision of creating patient-specific FE models requires researchers to determine if realistic models can be created based only on clinically derived inputs.

The goal of this study was to establish key inputs for the development of patient-specific FE models of the knee joint. To satisfy this goal, we applied a statistically-augmented FE approach to three human cadaveric knees for which full geometric and kinematic data was available. Two sets of conditions were simulated: (I) FE Inputs were varied to represent all possible combinations of a 'normal' patient population (II) clinically measurable FE Inputs were fixed at specific values while other inputs were varied over `normal` values (called *patient derived inputs,* or PDIs). By assessing the *range* of contact mechanics outputs for conditions I vs. II, we quantified the decrease in model output uncertainty due to fixing specific PDIs.

METHODS

Three knee-specific FE models were created from MR scans of cadaveric knees. Articular cartilage and menisci were modeled as elastic materials, and menisci were assumed to be transversely isotropic. Kinematic inputs derived from physical simulations of gait on each knee were input: anterior-posterior translation, medial-lateral translation, varus-valgus angle, internal-external angle, flexion-extension angle, and axial force, applied to the mid-point of the femoral epicondylar axis [4].

Condition I: A set of 21 FE runs was made for each knee in which the values of meniscus and cartilage tissue properties, meniscal insertion position, length, and stiffness, and body mass index were varied to represent all possible combinations of the 'normal' patient population (Table 1). The combinations of input values for each FE run were determined using a space-filling algorithm [5]. An additional 180 FE runs was added using a grid pattern approach to ensure adequate coverage of the design space [4]. Condition II: *Patient derived inputs,* PDIs: Subsequent to the above analysis, inputs to the FE model that could be readily quantified in a clinical setting were identified: BMI (which can be quantified in an office setting) and position of meniscal-bony insertion points (which can be extracted from MR scans). For each knee, all other inputs (Table 1) were allowed to vary across the range for normal knees, but the PDIs were fixed at five combinations: (1) BMI, IP_a, IP_p: 22, -2.4, -2.4, respectively (2) BMI, IP_a, IP_p: 22, -2.4, 2.4 (3) BMI, IP_a, IP_p as 27, 0, 0, (4) BMI, IP_a, IP_p as 32, 2.4, -2.4 (5) BMI, IP_a, IP_p as 32, 2.4, 2.4.

The output from each FE run was the percent of load acting through the cartilage-cartilage (C-C) contact region on the tibial plateau, which was predicted at additional input combinations based on a MATLAB driven Gaussian Process interpolator [6, 7]. Percent load in the C-C zone was computed at three points in the gait cycle where the axial force magnitude peaked: 4, 14 and 45% (peaks 1, 2 and 3, respectively) of the gait cycle. Main effect sensitivity indices (SIs) [8] were computed for the nine variables for condition I. Results

for peak 2 of the gait cycle are presented herein.

Table 1. FE model input variables and their ranges. For IP_a and IP_p +ve value indicates more anterior, -ve value indicates more posterior.

Input Variable	*Lower Bound*	*Upper Bound*
Body Mass Index (**BMI**) [9]	22	32
Anterior-Posterior position of the bony insertion point of the anterior meniscal attachments, $\mathbf{IP_a}$ (mm) [10]	-2.4	2.4
Anterior-Posterior position of the bony insertion point of the posterior meniscal attachments, $\mathbf{IP_p}$ (mm) [10]	-2.4	2.4
Circumferential modulus of the meniscus, $\mathbf{E_{cm}}$ (MPa) [11]	80	220
Radial/axial modulus of the meniscus, $\mathbf{E_{rm}}$ (MPa) [11]	11.5	35
Elastic modulus of the articular cartilage, $\mathbf{E_c}$ (MPa) [12]	11.5	35
Stiffness of the meniscal attachments, $\mathbf{S_{ma}}$ (N/mm) [13]	140	220
Length of the anterior meniscal attachments, $\mathbf{L_a}$ (mm) [13]	10	17
Length of the posterior meniscal attachments, $\mathbf{L_p}$ (mm) [13]	6	11

RESULTS

When the mean values of all 9 input parameters were used, the three knee-specific FE models had very different contact stress distributions (**Fig. 1**), which were similar to that recorded from the experimental testing of each knee [4].

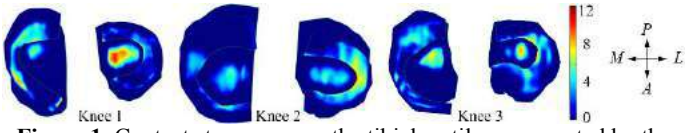

Figure 1. Contact stress map on the tibial cartilage computed by the knee-specific FE models at peak 2 of the gait cycle for 3 knees.

Condition I: When all possible ranges of meniscal and cartilage tissue properties, meniscal fixation characteristics, and BMI inputs were considered, the range of percent load in the C-C zone was wide and variable across knees (see group 0 in **Fig. 2**). Condition II: Fixing the three PDIs at specific values decreased the range of percent load in the C-C zone for each knee. The amount by which it was reduced was variable across knees.

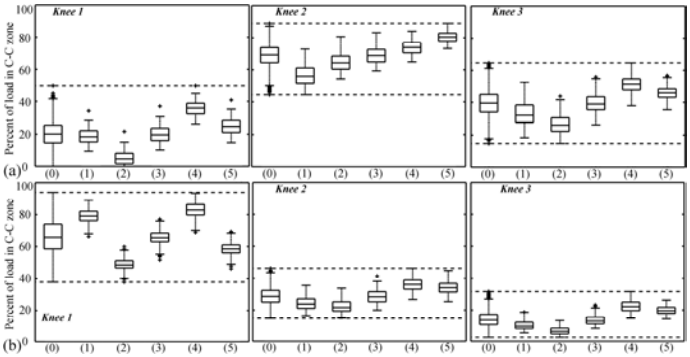

Figure 2. Range of percent of load in C-C zone of the medial (a) and lateral (b) compartments at peak 2 of the gait cycle. On the y-axis, group (0) represents the output from condition I, where all nine variables span the range of normal patient population, groups (1-5) represent the outputs where PDIs were fixed.

To understand which of the nine input variables were responsible for changes in the range of the percent load in the C-C zone for each knee, the main effect sensitivity indices were estimated (**Fig. 3**). Of the nine inputs studied, five (BMI, IP_a, IP_p, E_{cm}, and E_{rm}) had the most profound and consistent effects, while the other four variables (i.e. E_c, S_{ma}, L_a, and L_p) had minimal effect. The effect of each input was highly variable between knees and compartments. For both medial and lateral compartments of knee 1, the three PDIs accounted for ~60% of variation of the percent of load in the C-C zone; while for knees 2 and 3, the three PDIs accounted for ~40% of the variation. Of note, for all knees for all conditions, increasing BMI and moving IP_a in an anterior direction increased the percent of load in the C-C zone. While increasing E_{cm} and E_{rm}, and moving IP_p in the anterior direction decreased the percent of load in the C-C zone.

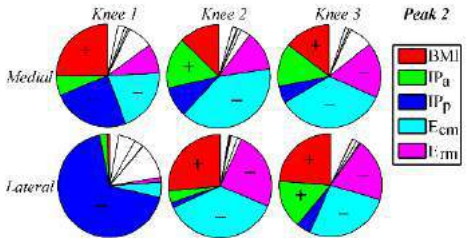

Figure 3. Pie charts representing the main effect sensitivity indices of the input variables for the percent load in the C-C zone of medial compartment at peak 2 of the gait cycle. The '+' sign indicates that increasing the input increases the percent of load in the C-C zone. Simultaneously moving IP_a in an anterior direction and IP_p in the posterior direction both increased the percent of load in the C-C zone.

DISCUSSION

Our goal was to establish key inputs for the development of patient-specific FE models. We computed the range of possible outputs for two conditions: condition I where inputs were allowed to represent variability in a normal patient population, and condition II where three inputs that could be clinically quantified, PDIs, were fixed, but all other inputs could vary. The output (percent of load in the C-C zone) was highly variable between knees *and* compartments, illustrating the importance of patient-specific geometry and kinematics in dictating the response of the model. But, for a particular compartment of each knee, the range of outputs was significantly reduced (between a third and a half), when PDIs were included. Our analysis indicates in the best case scenario, where geometry, kinematics, BMI, and meniscal insertion points are known, an FE model can be used to calculate the percent load in the C-C zone with an uncertainty range of 10-30%. In future studies, we aim to apply this approach to the study of patients undergoing meniscal surgeries.

CORONARY CIRCULATION IN AN *IN VITRO* MULTI-SCALE MODEL OF NORWOOD CIRCULATION

INTRODUCTION

Hypoplastic Left Heart Syndrome (HLHS), a congenital heart disease where the left ventricle and ascending aorta are underdeveloped, is commonly treated by a set of 3 surgeries. The first of these surgeries is the Norwood. In this surgery, the reconstructed aorta is anastomosed to the right ventricle, thus allowing systemic blood flow. To oxygenate the blood, options such as the modified Blalock-Taussig (mBT) are chosen to divert some of the systemic blood flow to the pulmonary circulation and create a balance between the two. In the case of the mBT, a shunt is connected from the brachiocephalic trunk to the pulmonary artery (PA).[1]

The coronary circulation is the means by which the heart receives oxygenated blood. The coronary artery descends from the ascending aorta into the myocardium to supply oxygen, and deoxygenated blood returns to the right atrium via the coronary sinus. In the case of HLHS patients with an mBT shunt, retrograde flow from the coronary circulation to the pulmonary circulation via mBT shunt is a common problem during diastole.[1] This shunt steal of coronary blood can lead to detrimental issues such as myocardial ischemia leading to right ventricular dysfunction.[2] Hence, it is essential to understand the relationship between mBT shunts and coronary blood flow so that these damaging circumstances can be avoided.

Multi-scale computational models of the Norwood circulation have modeled the coronary circulation and the effects of varying mBT shunts on coronary[2,3,4] and cerebral perfusion[3]. To our knowledge, limited work has been done in developing an *in vitro* multi-scale model of the same kind. This may be due to the intricate nature of the heart and its effect on the coronary flow. The contraction during systole and relaxation during diastole of the myocardium around coronary vessels provides a varying resistance to blood flow through the coronary circulation. Although the computational models have presented evidence of the effects the mBT shunt has on Norwood circulation, *in vitro* multi-scale models are commonly used for validation studies of such computational models. Therefore, the objective of this study is to implement the coronary circulation into a pre-existing *in vitro* model of the Norwood circulation so that phenomena such as shunt steal can be studied.

METHODS

An *in vitro* mock circulatory system (MCS) coupling a three-dimensional (3D) test section of the aorta with a lumped parameter network (LPN) describing the global hemodynamics of the Norwood patient's circulation was previously validated.[5] The coronary circulation and circulation values are based on a previous multi-scale model.[4]

As shown in Fig. 1, the expanded MCS's LPN is separated into four sub-circulations: upper body, lower body, pulmonary, and coronary. Each is composed of physical elements modeling the resistance, compliance, and inertance of that particular area. The system's driving mechanism is a ventricular assist device (Berlin Heart), which provides the patient-specific input to the 3D aortic test section. The system can be tuned to patient-specific values.

In particular to this system, the coronary circulation features the single ventricle pressure (SVP) signal in conjunction with the compliance, C_{ACE}, that dictates how the pressure, P_{ACE}, responds. The physical *in vitro* representation of this is an active compliance element (ACE) made up of a hydraulic and pneumatic chamber, and a connecting compliant diaphragm. The SVP signal is applied pneumatically to the air-filled chamber. The high systolic and low diastolic pressures of this signal act through the diaphragm into the hydraulic chamber connected to the LPN. P_{ACE} is accordingly raised

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

or lowered due to this signal, such as when the myocardium tightens and relaxes around the coronary vessels.

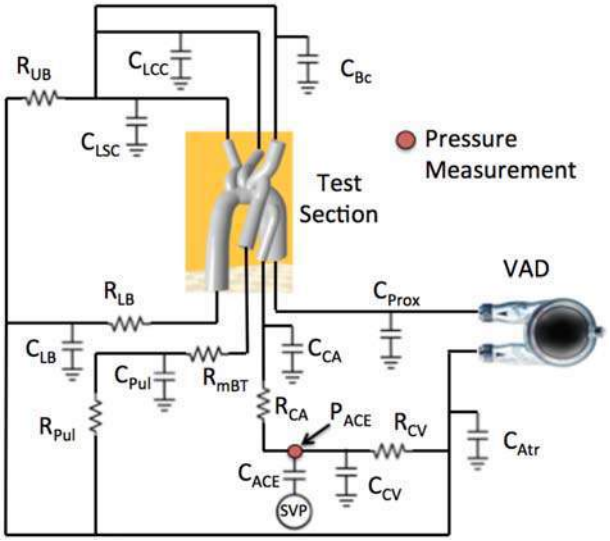

Figure 1: MCS of the coupled LPN and 3D test section that is pneumatically powered by a ventricular assist device (VAD). R, resistance; C, compliance; Prox, proximal; Bc, brachiocephalic artery; LCC, left common carotid; LSC, left subclavian; UB, upper body; LB, lower body; mBT, modified Blalock-Taussig shunt; Pul, pulmonary; CA, coronary artery; ACE, active compliance element; SVP, single ventricle pressure; CV, coronary vein; Atr, atrium.

Initial testing of the *in vitro* system was done in which a 3D test section[3] was introduced into the system under parameters described by Lagana et al.[4] The results were compared to those from a newly developed complete LPN model of the system in Fig. 1. Flow and pressure measurements from the experimental model closely matched those from the LPN model, thus verifying the *in vitro* setup represented the LPN. Further tests were completed with patient specific 3D test sections and hemodynamic parameters. The MCS was validated by recapitulating physiological flow and pressure measurements.

RESULTS

Preliminary testing of the coronary circulation's ACE was completed to ensure a proper SVP signal could be generated to create the appropriate response at P_{ACE}. In these tests, pneumatic pressure signals of the ACE were compared to SVP signals from the LPN and clinically obtained ventricle pressure waveforms. As shown in Fig. 2, a physiological SVP was achieved. Further, the response of the P_{ACE} is in accordance to previous studies that found decreased coronary flow during systolic ventricular contraction.[3] The increase in SVP (Fig. 2) corresponds with the onset of systole. Concurrently, P_{ACE} increases, which opposes flow through the coronary circulation. At the onset of diastole when SVP decreases, P_{ACE} also decreases, allowing flow to continue through the coronary circulation. These signals were achieved at a mean coronary flow rate of 0.08 ± 0.02 L/min, which corresponds to the mean flow found in previous studies.[4]

Further testing of the entire MCS was then conducted and results closely matched those of the LPN model and clinical data.

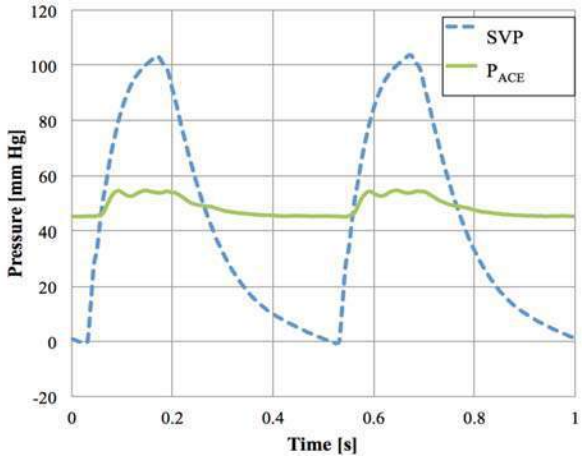

Figure 2: The SVP signal made in the ACE and the corresponding pressure measured at the connection of the ACE and *in vitro* LPN, P_{ACE}. Mean coronary flow of 0.088 ± 0.018 L/min.

DISCUSSION

The previous standard of testing coronary circulation of Norwood patients relied on multi-scale computational models.[3,4] Most *in vitro* systems did not include coronary circulation due to its complexity. However, it is believed that *in silico* models cannot be validated by clinical data; that there must be an *in vitro* MCS to bridge that connection.

Preliminary results show that an *in vitro* MCS including the coronary circulation is feasible for studying Norwood hemodynamics. Additionally, the ACE coupled with the SVP is instrumental in modeling the myocardium's interaction with coronary vessels to accurately dictate coronary flow and pressure. In the future, this expanded *in vitro* system can be used to study the effects of varying patient physiologies, such as coarctation and the effects of shunt size.

The combination of aortic coarctation and the mBT shunt in Norwood patients has been shown to result in shunt steal.[3] Shunt steal can be harmful because it corresponds to decreased coronary flow, and thus decreased oxygen delivery to the heart. In Norwood circulation, the right ventricle is already having to support both systemic and pulmonary blood flow. Decreased coronary oxygen supply can change the elastance of the heart, resulting in less cardiac output and less oxygenated blood to the body. This would result in a damaging cyclic reaction where the heart continues to not receive enough blood and becomes more and more weak.[2] Shunt steal has also been linked with decreased cerebral perfusion.[3] And so, expanding on this new *in vitro* MCS will be pertinent in developing an even greater understanding of how the various Norwood surgical options can present positive or negative hemodynamics.

The results show that an *in vitro* multi-scale model of Norwood circulation, including the coronary, is possible and can be used to study the coronary steal phenomenon.

COLLAGEN DEGRADATION ALTERS FAILURE PROPERTIES & MATRIX REORGANIZATION DURING TENSILE LOADING

INTRODUCTION

The spinal facet joints are a common source of pain, which can be induced by degeneration due to either aging or injury [1,2]. Degeneration of spinal tissues is associated with changes in tissue composition [3], including enzymatic tissue degradation via increases in collagenase protein and mRNA [2]. Collagenase activity in degenerative states can degrade collagen, which is the main component of the facet capsular ligament (FCL) [3,4]. Although enzymatic digestions simulating tissue degradation alter the mechanical properties of tissue [5], the effect of collagen degradation on ligament mechanics is not well defined. Also, it is unclear how collagen degradation affects failure responses and if, and how, a loss of collagen alters how a collagen matrix reorganizes under load.

FCL loading that induces microstructural damage and pain coincides with anomalous collagen matrix reorganization [6-8]. That microstructural damage occurs before any tissue rupture and is associated with decreased tissue stiffness and ligament laxity [6,8,9]. Further, the regional strains at microstructural damage correspond to those that induce pain in vivo and activate neurons embedded in collagen networks in vitro [7,8]. Although collagen degradation occurs in degeneration-induced pain [2,3], the effects of that degradation on ligament mechanics and/or the potential for injury is not known.

Accordingly, collagen degradation is hypothesized to lower the macroscopic failure properties and also to alter matrix reorganization during tensile loading. To test this hypothesis, an in vitro collagen gel model was modified using bacterial collagenase to enzymatically degrade collagen. First, the effect of digestion time on collagen loss was assessed. From that work, a digestion time that appreciably decreases collagen density while leaving the collagen gel intact was identified and used in a second study that quantified failure mechanics, local strain, and matrix reorganization under tensile distraction.

METHODS

To assess the effect of collagenase digestion time on collagen gel degradation, compositional experiments analyzed collagen loss after 10mins or 35mins. Gels were formed in 24-well plates with 800µl rat tail collagen I solution at 2mg/ml (Corning) and allowed to gel overnight at 37ºC (n=4). Bacterial collagenase (Sigma C0130) was dissolved in DMEM (2mg/ml) and heated for 30mins at 37ºC [10]. After digestion in 2.5ml of collagenase solution for the designated time, gels were washed in PBS; separate groups were lyophilized or post-fixed for immunolabeling of collagen (n=4). Matched gels were digested in DMEM for 10mins or 35mins to serve as controls (n=4).

To quantify collagen loss, dry weights (DW) were measured after lyophilization for 24hrs at <0.12mBar and -43ºC. To measure collagen changes by immunolabeling, gels were blocked, incubated overnight at 4°C with collagen antibody (anti-mouse, Abcam, 1:400), and then incubated for 2hrs with Alexa Fluor 488 (1:1000). Images (n=5) were taken throughout each gel at 40X using a Zeiss LSM510 confocal microscope. Collagen labeling was quantified using densitometry and t-tests compared the digest and control groups at each time point.

Based on that work, the effect of collagen degradation on tensile failure, local strain, and matrix reorganization was evaluated with gels digested for 35mins. Gels were formed in dog-bone molds with 5ml collagen I (2mg/ml) [7,11] and digested in collagenase or bathed in DMEM as controls (n=4/group). Gels were washed before mounting in an Instron5865 [7]. A grid of markers was tracked by a Phantom v9.1 camera (Vision Research) at 500fps to quantify strains. Polarized light imaging was acquired during loading at 500fps to generate alignment maps of collagen fibers that were used to calculate the circular variance (CV) which measures the spread of fiber angles [6,7,12].

Gels were distracted to failure at 0.5mm/sec. Force and displacement data were collected at 1kHz and synchronized with video

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

data for strain and CV calculations. Force data were digitally filtered [9] and force-displacement curves used to define failure, which was the maximum force during loading (Fig. 1). Stiffness was defined as the slope of the loading curve at 20-80% of maximum force (Fig. 1) [13]. The maximum principal strain (MPS) at failure was computed using the marker displacements and LS-DYNA, with the peak MPS recorded at failure [7]. CV values were calculated both before loading (reference) and at failure to compare collagen matrix reorganization after digestion but before loading, and at failure. Lower CV values indicate a more random fiber orientation and higher values indicate preferential fiber alignment [7,12]. T-tests compared all measures separately between the digest and control gels.

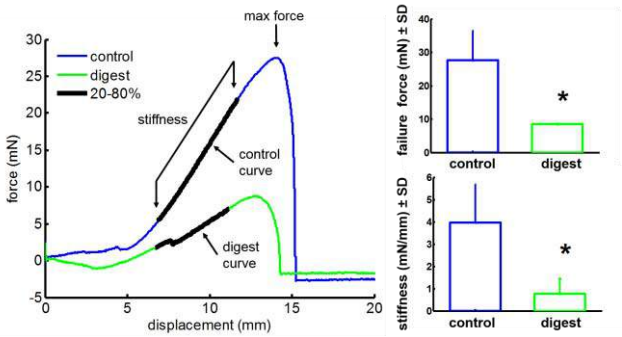

Fig. 1. Representative force-displacement curves. Failure force and stiffness are lower for digest than control gels (*p<0.03).

RESULTS

Collagen loss was detectable after 35mins, but not 10mins, of digestion with significantly less (p=0.03) collagen immunolabeling only in 35mins digest gels (Fig. 2). The decreased collagen labeling corresponds to lower DW of 28.6% and 40.0% after 10mins and 35mins, respectively. Before loading, macroscopic defects like small tears and thinning of the gel were evident only after digestion and not in control gels (Fig. 2). Despite those defects, no differences in the collagen fiber orientation was detected between digest (0.0007±0.0010) and control (0.0012±0.0010) gels before loading.

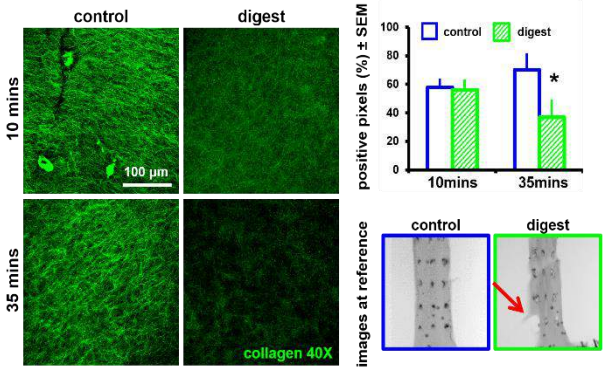

Fig. 2. Representative confocal images of immunolabeled gels prior to distraction show decreased collagen (*p=0.03) & macroscopic structural defects (red arrow).

The failure force was significantly lower (p=0.022) in digest gels (8.48±0.29mN) than controls (27.70±8.74mN) (Fig. 1). Tensile stiffness was similarly decreased (p=0.025) by 75.6±44.8% after digestion (Fig. 1). However, the displacement at failure was not altered (control: 8.60±4.06mm; digest: 6.72±5.3mm), nor was peak MPS. But, the dramatic increase in fiber alignment at failure that was observed in controls was not evident in digested gels (Fig. 3). In fact, the difference in CV at failure between groups was significant (p=0.045).

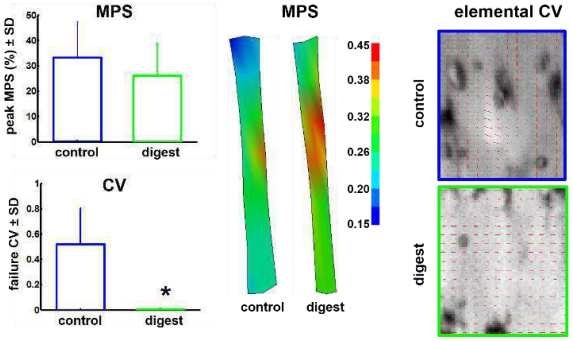

Fig. 3. Collagenase digestion does not alter the peak MPS at failure but does prevent the increase in CV that is evident in control gels, which is significant (*p=0.045).

DISCUSSION

Collagen degradation decreases failure force and stiffness but does not change failure strains (Figs. 1 & 3). Although the peak MPS is not altered by digestion, collagen matrix kinematics are different, with less reorganization at failure (Fig. 3). Both groups fail at displacements (~7-9mm) that initiate neuronal activation and at strains exceeding a transition for collagen fiber kinematics in this same collagen gel system [7]. Those same strains also correspond to pain in vivo [8,13]. Taken with the literature, our results suggest that a substantial loss in collagen may not alter the regional strains in a degraded ligament and that similar mechanotransductive signaling may be initiated under the same biomechanical conditions regardless of the extent of tissue degradation. However, because pain is evident with degeneration in the absence of excessive tissue loading [2,3], biochemical mediators or other non-mechanical factors may contribute to degeneration-associated pathology.

Transient FCL tension that causes pain also decreases ligament stiffness and fiber realignment in vivo [8]. Yet, in our study, collagen degradation does *not* cause fiber realignment (Fig. 3), suggesting that collagen degradation alters how the matrix responds to loading. Since collagenase preferentially degrades *unstrained* collagen fibers [10] and unloaded gels were digested, a greater degree of collagen degradation is expected here than for a degenerated ligament in vivo. Yet, since FCL injury induces both degeneration and laxity [2,3,8], degeneration may alter the loading state of a ligament in vivo and cause some fibers to be strained more than others, which would also cause unstrained collagen fibers to degrade more quickly than strained fibers [10]. Such an inhomogeneous biomechanical environment has implications for neurons in unloaded regions of a ligament. As such, imposing tension after digestion of pre-loaded gels would reveal any changes in the global and/or regional mechanics [10]. Nonetheless, this work begins to define how collagen degradation affects global and local mechanics, and highlights potential pathomechanisms by which degenerative processes may mediate biomechanical and physiological responses.

INTRODUCTION

Dynamic exercise influences the cardiovascular system in various ways, especially for patients with cardiovascular diseases (CVD). As a usual tool to quantify the dynamic exercise, exercise test is often utilized in clinical field to evaluate the severity of CVD. In reality, both myocardial infraction and death have been reported to occur at an incident rate of 1/2500 during the test [1], and a simulation-based exercise test for patients with CVD can be affective to avoid such risk. Pervious numerical studies have been carried out to investigate how the patients with CVD respond to exercises, whereas, the exercise data were either obtained based on the experiment, or simply by adjusting the resistance in arterial system [2–4]. Here we have designed a virtual exercise test by developing an integrated computational model, which coupled the cardiovascular system (CVS) and the autonomic nervous system (ANS). As a case study for CVD, we performed the simulation-based exercise test on patients with left ventricular hypertrophy (LVH), one of the chronic cardiac diseases with an annual mortality rate of 2.1% [5]. In this study, we compared the hemodynamic features between healthy subjects and patients with LVH during cycling exercise to assess hemodynamic response to exercise with and/or without LVH as well as to discuss their functional discrepancy.

METHODS

A double-closed-loop model for hemodynamic prediction and cardiovascular regulation that involves a CVS model, an ANS model, and an exercise model has been established. The CVS model is a time-domain closed-loop lumped model, which consists of 4 cardiac chambers and 266 arteries. The CVS model and the ANS model are coupled in terms of blood pressure, heart rate, cardiac contractility, arteriolar resistance, and compliance and unstressed volume of veins. Descriptions of the governing equations associated with the CVS and ANS models in detail can be found in our previous study [6].

In the exercise mode, the input is set to be the intensity of exercise which is determined by oxygen intake, and also relates to workload. The outputs of the exercise model influence both the CVS model and the ANS model. The blood pressure in the CVS model is influenced dynamically by muscle pump, mechanovasodilation, and metabovasodilation; the ANS model is affected by a combination of resetting of operating pressure threshold of the arterial baroreflex, central command model, and summary of mechanoreflex, metaboreflex and baroreflex. To provide a peek of the exercise model, modeling equations for the muscle pump are illustrated below.

$0 \le t_{im} \le T_{con}$:

$$p_{im} = p_{imp} \cdot sin\left(\frac{\pi}{2} \cdot \frac{t_{im}}{T_{con}}\right) \quad (1)$$

$T_{con} < t_{im} \le T_{rel}$:

$$p_{im} = p_{im}|_{T_{con}} \cdot sin\left(\frac{3\pi}{2} \cdot \frac{t_{im} - T_{con}}{T_{rel} - T_{con}}\right) \cdot \left(1 - \frac{t_{im} - T_{con}}{T_{rel} - T_{con}}\right) \quad (2)$$

$without\ muscle\ pump$:

$$p_{im} = 0 \quad (3)$$

where t_{im} [s] is a moment during muscle contraction-relation cycle; T_{con} [s] is the duration of muscle contraction; T_{rel} [s] is a specified moment before the end of a contraction-relaxation cycle; p_{im} [mmHg] is the extravascular pressure; p_{imp} [mmHg] is the peak value of p_{im}, which is dependent on the oxygen intake [7].

The LVH model is based on the previous study [8]. Peak systolic and diastolic wall stress σ_s [kPa] and σ_d [kPa] are related to the wall thickness in left ventricle, therefore the maximum and minimum values of the elastance in left ventricle can be presented as follow:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$e_{lv,max} = \frac{\frac{\sigma_s h(2r+h)}{r^2}}{LVESV - V_d} \quad (4)$$

$$e_{lv,min} = \frac{\frac{\sigma_d h(2r+h)}{r^2}}{LVEDV - V_d} \quad (5)$$

where $e_{lv,max}$ [mmHg · ml^{-1}] and $e_{lv,min}$ [mmHg · ml^{-1}] are the maximum and minimum values of the elastance in left ventricle, respectively; h [cm] is the wall thickness in left ventricle; r [cm] is the cavity radius in left ventricle; $LVESV$ [ml] and $LVEDV$ [ml] are the end systolic and end diastolic volume in left ventricle, respectively; V_d [ml] is a volume axis related to the end-systolic *P-V* relation in left ventricle.

RESULTS

Mean blood pressure (MBP), heart rate, and cardiac output in healthy subjects and patients with LVH during the rest and the exercise are illustrated in Figure 1, 2, and 3, respectively. During the exercise, MBP increased in healthy subjects, while barely changed in patients with LVH. The difference of heart rate between healthy subjects and patients with LVH is relatively small during the exercise (rest: 10%, exercise: 4%). Meanwhile, the increase of heart rate form the rest to the exercise is extensive, and the increased amount is relatively small in patients with LVH (healthy subjects: 36%, patients: 27%). The increase of cardiac output from the rest to the exercise is relatively low in patients with LVH (healthy subjects: 35%, patients: 14%). Therefore, cardiac output for healthy subjects and patients with LVH is close during the rest, while decreased in patients with LVH during the exercise. In addition, the simulated data for both healthy subjects and patients with LVH during the rest are consistent with the experimental results in the previous study [9].

DISCUSSION

The simulated results of MBP and heart rate obviously show a trend in the increased stiffness of blood vessel and workload of the heart, along with the decreased cardiac function in the patients with LVH. We further observed that the insufficient blood supply in the patients with LVH during the exercise, indicating that the dynamic exercise may endanger the patients. This points to the importance of a virtual exercise test as a useful tool to reduce the burden of the patients during clinical testing. On the other hand, the major limitation in this study is the lack of clinical data for constructing a patient specific model, which will be our future work. Despite of this, the current study demonstrates the potential of utilizing the detailed mathematical exercise model to quantify and assess the severity of CVD in concert with including LVH.

INTRODUCTION

The material properties of myocardium are an important determinant of global left ventricular (LV) function in both health and disease. In vivo studies have demonstrated that hydrogel injections can mitigate the adverse effects of myocardial infarction. More importantly, the stiffness of these injections can be tuned to minimize wall thinning and ventricular dilation. The current investigation combines experimental data and finite element (FE) modeling to correlate how injection stiffness and volume influence myocardial wall stress and wall thickness. The results indicate that increased injection stiffness reduced LV myofiber stress. Also, stiffer hydrogel injections maintained an increased level of LV wall thickness. Overall, this study may predict that stiffer and bigger hydrogel injection can reduce MI bulging during LV remodeling.

METHODS

In order to evaluate the effects of hydrogel injections on myocardial wall stress, FE models of the LV with two different injection volumes were generated (150μL and 300μL). The size and shape of the hydrogel injections were based on MRI of injected explant tissue (Table 1). The geometry of the LV wall was based on experimental measurements from the ovine hearts. Since the model was meant to mimic the initial time frame after infarction, it was assumed that 30 minutes post-MI the myocardial properties around the injections would be roughly unchanged [2]. The myofiber orientation was assigned to vary linearly from epicardium to endocardium using the angles of -37 degrees to 83 degrees, respectively. For the control case, the undeformed wall thickness was approximately 1.3cm. For the models with hydrogel injections, the control model was modified to include a 4 x 4 pattern of 16 injections around the free wall (Figure 1).

The material response of the myocardium was represented using a nearly incompressible, transversely isotopic, hyperelastic constitutive law, which was defined using the following strain energy function:

$$-(e \quad 1) + -(J \quad 1) \qquad (1)$$
$$(E \qquad) + \quad (E \qquad)$$

where E_{ij} are the deviatoric components of the Green-Lagrange strain tensor relative to the myofiber coordinate system (f=fiber direction, s=cross-fiber in-plane direction, n= transverse-fiber

direction) and J is the determinant of the deformation gradient. The diastolic material parameters were assigned to be C = 0.51 kPa, b_f = 22.84, b_t = 3.45, and b_{fs} = 12 [1], while the bulk modulus was κ = 1e10^3 kPa. The material response of the hydrogel injections was represented using a nearly incompressible, isotopic, hyperelastic constitutive law, which was defined using the following strain energy function:

$$W_{injection} = \frac{E}{2(1+\nu)}\,\mathrm{tr}(\mathbf{E}^2) + \frac{E}{6(1-2\nu)}\,\ln(J)^2 \qquad (2)$$

where $\mathbf{E}$ is the deviatoric Green-Lagrange strain tensor. The material parameters for Young's modulus (E) were assigned in a range between 0.1kPa to 100kPa, while the Poison ratio (ν) was assigned a value of 0.499. A pressure of 10 mmHg was assigned as a boundary condition on the endocardial wall in each of the FE models.

RESULTS

Figure 2a shows that when the injection stiffness is 0.1kPa the transmural distribution of stress is nearly unchanged compared to the control. For hydrogel stiffness of 25kPa, the 150µL injection reduced the myofiber stress by roughly 18.9% at the epicardium, 0% at mid-myocardium, and 21.6% at endocardium compared to the control (Figure 2b). While, the 300µL injection reduced the myofiber stress by roughly 31% at the epicardium, 10.6% at the mid-myocardium, and 34.7% at endocardium compared to the control (Figure 2b). For hydrogel stiffness of 100kPa, the 150µL injection reduced the myofiber stress by roughly 39.2% at the epicardium, 18.3% at mid-myocardium, and 38.7% at endocardium compared to the control (Figure 2c). While, the 300µL injection reduced the myofiber stress by roughly 56.8% at the epicardium, 36.5% at the mid-myocardium, and 55.2% at endocardium compared to the control (Figure 2c).

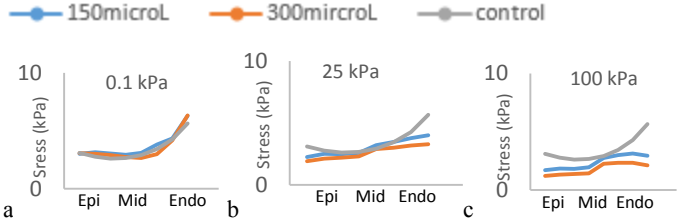

Figure 2: (a-c) End-diastolic transmural distribution of myofiber stress using stiffness 0.1kPa, 25kPa and 100kPa hydrogel injection between 150µL injection and 300µL injection.

Additionally, the results of average myofiber stress in the myocardium surrounding the 150µL and 300µL injection, using different hydrogel stiffness, is shown in Figure 3. When the injection stiffness is increased, the myofiber stress was decrease. It should be noted that the slope of the trend lines decreased after 50kPa, indicating that the influence of stiffness begins to level off. Figure 4 shows the average wall thickness as a function of injection stiffness. When the injection stiffness increased, the wall thickness was increased. The average wall thickness at end-diastole for the control was approximately 1cm, while the thickness for the 150µL injection with 25kPa stiffness was 1.1cm and 300µL was 1.2cm. For the case of 150µL injection with 100kPa stiffness, the thickness was 1.2cm while 300µL was 1.3cm. This is primarily driven by the fact that the stiffer injections maintained their original shape during deformation, which allowed the LV wall to remain thick (Figure 5c and 5f). However, it can be seen that the 0.1kPa injection effectively collapse as the LV wall is loaded by the pressure on the endocardium (Figure 5a and 5d).

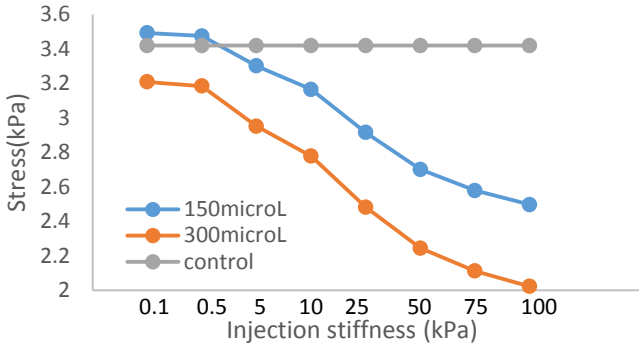

Figure 3: Average end-diastolic myofiber stress surrounding the injection as a function of injection stiffness and volume.

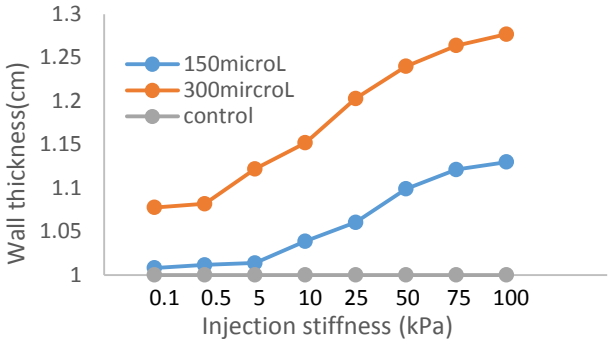

Figure 4: End-diastolic myocardial wall thickness in the injection region as a function of injection stiffness and volume.

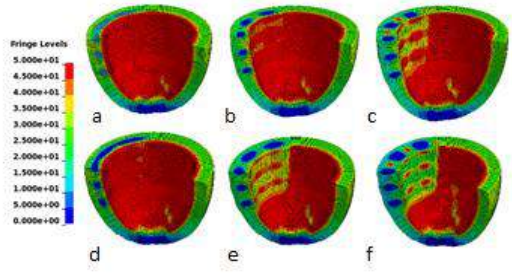

Figure 5: (a-c) The LV myofiber stress distribution around 150 µL injections and (d-f) 300 µL injections with stiffness values of 0.1kPa, 25kPa and 100kPa.

DISCUSSION

FE models were generated using experimentally measured LV and injection geometry. The modeling results show a clear reduction of myofiber stress based on the hydrogel injection volume. Additionally, by turning the stiffness of the hydrogel, greater reductions in stress can be achieved. The current results indicated that stiffer, bigger hydrogel injections could reduce myofiber stress further. These improvements taper after a stiffness of 50kPa.

INTRODUCTION

Mechanoreceptors located throughout the body transduce mechanical stimuli into neural signals that produce sensations such as touch and pain [1]. The Pacinian corpuscle (PC), located within the skin, responds to 50-1000 Hz vibrations [2]. The PC structure allows transmission of vibrations through its layers (lamellae), ultimately resulting in deformation of the centrally-located nerve fiber (neurite) and neuronal action potentials. The mechanisms by which mechanical stimuli pass through the PC lamellae to the nerve fiber, and by which neurite deformation induces neural response, remains unknown. This work combines a mechanical model of the PC with an electrochemical model of nerves to simulate the entire tactile response of the system.

The PC shows two distinct neural responses to mechanical stimulation: high-pass filtration of oscillating stimuli [3,4] and rapid adaptation to sustained stimuli [5]. Attempts have been made to address these observations separately [6,7] and to determine the relationship between PC structure and its unique mechanical response. No study has been able to unify these observations to answer the fundamental question of how the PC responds to mechanical stimulation, which requires a multiphysics and multiscale analysis. In this work, we examined the filtering and adaptation properties of the PC via a single mechanically and electrochemically unified model.

METHODS

A three-stage model was developed, consisting of three separate models applied in series. The input to Stage 1 was a mechanical stimulus applied to the PC outer surface, which supplied inner core deformation to Stage 2. The output of Stage 2 was the neurite membrane strains, which were input into Stage 3 to control stretch-gated channel dynamics. The output of Stage 3 was the neural response to the specific stimulus applied in Stage 1. A schematic of the three-stage model is shown in **Figure 1**.

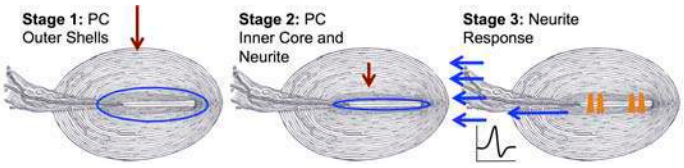

Figure 1: Three-stage dynamic model used in study.

Stage 1: Outer core spherical shell mechanical MATLAB model: A detailed model was developed of the alternating fluid and lamellar layers in the outer core, whose structure is hypothesized to control the PC's high-pass filtering [2,6]. The mechanics of the lamellae were modeled with the equations of equilibrium for spherical shells, and the fluid was modeled as a thin lubricating layer. Alternating layers of fluid and solid were coupled in a finite-element model. A 30-layer model was assigned parameters obtained from a previous study [7]. The elastic modulus of each lamella was 500 kPa, with layer thicknesses of 0.1-0.4 μm, and the fluid viscosity was 7 mPa-s. Oscillating pressure was applied to the outer shell at 1-10^8 Hz. Sustained pressure was applied with square wave displacements generated via a Fourier series and applied to the outer shell. The displacements of each shell were obtained in the simulations.

Stage 2: Inner core and neurite mechanical COMSOL model: A second mechanical model was created to account for the complex morphology of the PC neurite. Simulations of the inner core and neurite were performed in COMSOL's frequency domain mode to compute neurite mechanics in response to vibrations of the inner core.

The inner core was modeled as a sphere, and the neurite was modeled as a cylinder with five filopodia (2 central, 3 distal). The domain was modeled as an isotropic linearly elastic material with a Young's modulus of 7kPa [8], a Poisson's ratio of 0.49, and density of 1000 kg/m^3. Damping was modeled by an isotropic loss factor of 0.2.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The outer boundary of the inner core received a prescribed displacement equal to that of the innermost shell in Stage 1. Simulations were run at 30-1000 Hz.

Stage 3: Electrochemical neurite model: A model was created in NEURON to convert strain on the neurite membrane into opening of stretch-gated cation channels at the base of the filopodia [9]. Stretch-gated channel opening was approximated by an increase in injected current at each location on the membrane. Current proportional to the strain measured at the base of each filopodia in the COMSOL model was inserted at the base of the corresponding dendrite in the NEURON model. Simulations were run for 1000 ms. Membrane potential and action potential firing rate were calculated.

RESULTS

Stage 1: Simulations were run for spheres of different sizes to observe the effect of shell number on the frequency response. The number of layers was increased from 2 to 30 shells. The displacement amplification is shown for different frequencies and PC sizes in **Figure 2**. The model showed characteristic high-pass behavior in models with more than 10 shells.

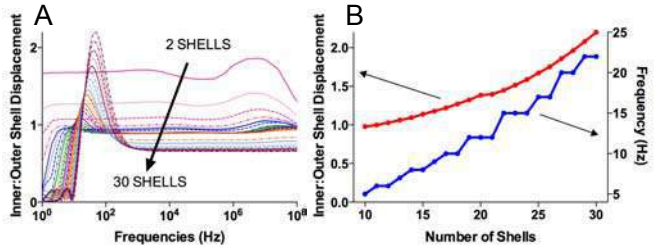

Figure 2: (A) Ratio of inner to outer maximum displacements vs. frequency for spheres of 2-30 shells. (B) Peak displacement and frequency at peak displacement for spheres of 10-30 shells.

The inner and outer shell displacements during the square wave simulations are shown in **Figure 3**. The PC mechanically adapts in response to the sustained pressure, as the inner core displaces only during the onset and offset of the stimulus, as seen experimentally [5].

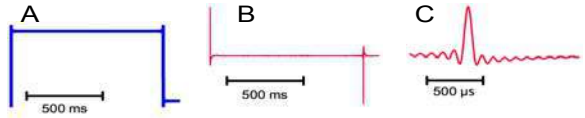

Figure 3: (A) Outer and (B) inner shell displacements in square wave simulations from summation of 0.5-1000.5 Hz simulations. (C) Inner displacement zoomed-in on stimulus onset response.

Stage 2: **Figure 4** shows the first principal strain of the neurite alone at the peak displacement during a 150 Hz simulation. High strain occurred near the filopodia at the distal end of the neurite (Location I).

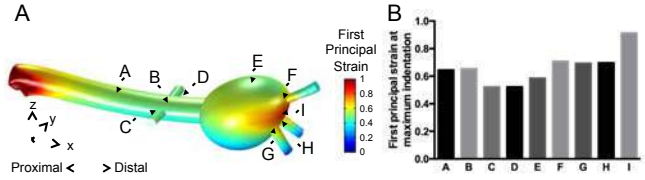

Figure 4: First principal strain on neurite surface at maximum displacement. The graph in (B) plots value at the locations in (A).

Stage 3: The firing rate in response to current injection proportional to the Stage 2 neurite strains was calculated. **Figure 5A** shows experimental [3] firing rates recorded from PCs stimulated with sinusoidal indentations at increasing displacement. The plots in **Figure 5** have been color-coded to show similarities between experiments and simulated neurite firing rates obtained from the NEURON model (**Figure 5B**). In both cases, the intermediate frequencies show the highest sensitivity (i.e., respond to the smallest amplitude stimuli).

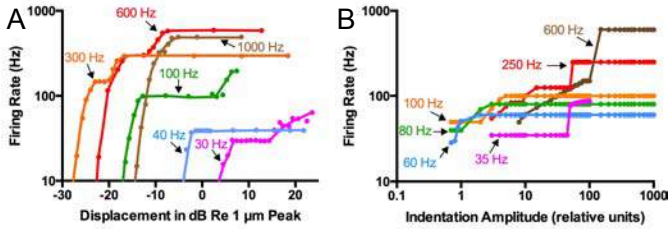

Figure 5: (A) Experimental [3] and (B) simulated data of neurite firing rates resulting from displacements at various frequencies.

DISCUSSION

The Stage 1 results show that incorporating the layered PC structure introduces the high-pass filtering response into the model, as suggested previously [2,6]. The results of Stage 2 complement previous studies [9] that suggest that mechanogated cation channels at the base of the neurite's filopodia would be well positioned to transduce temporal, and possibly spatial, information. This study presents new information that the distal, rather than the central, filopodia are better positioned for mechanosensation.

The Stage 1 sustained indentation simulations show that the outer core adapts mechanically to a square wave displacement. Previous studies showed that the intact PC fires action potentials only at stimulus onset and offset [5], an effect that disappears upon removal of the PC capsule [10]. Those studies proposed that the PC adaptation rate is dependent on the mechanical properties of the lamellae. This work supports that hypothesis and concludes that adaptation can arise entirely from the PC mechanics without neuron adaptivity.

A strength of this work is that it is the first model (1) to include the entire mechano-to-neural transduction process of the PC by combining three stages that deal with specific mechanisms of this transduction, (2) to simulate PC response to both vibratory and sustained indentation, and (3) to account for both the structure of the PC core and the morphology of its neurite.

A limitation of this work is that the neural model in Stage 3 must be tuned to match experimental observation better. The simulated and experimental results in **Figure 5** showed similar trends at high frequencies, but the simulated PC did not follow the experimental trend at lower frequencies. Second, the mechanics of the inner core are unknown, so neurite properties were used in Stage 2. Also, the spherical shape of the Stage 1 model could be transformed to an ellipsoid, which would allow the study of directional tuning of the PC.

The detailed mechanical and neural models created in this study allow for characterization of the mechano-to-neural transduction of the PC. By understanding this process in the PC, we can also begin to characterize the mechanosensation of other receptors and nerve endings to eventually understand how hundreds of receptors in a single hand interact to send detailed sensory feedback to our somatosensory cortex and create our sensation of touch.

INTRODUCTION

Knee injuries are one of the most common reasons for physician appointments. The most commonly injured ligament in the knee requiring surgery is the anterior cruciate ligament (ACL) [1]. ACL reconstruction is the sixth most common orthopedic surgical procedure in the US, with an estimated 150,000 ACL reconstructions performed annually [2]. Normal structure and function of the knee was restored in only 37% of the patients undergoing ACL reconstruction [3]. However, injuries of the anterolateral capsule are often under diagnosed in conjunction with ACL injuries, which can lead to decreased rotational stability of the knee and early arthritis.

Significant clinical interest exists in the structure and function of the anterolateral capsule. A ligamentous structure inserting midway between Gerdy's Tubercle and the tip of the fibular head was recently described [4] and it has been found to serve as a secondary stabilizer in the ACL-deficient knee [5]. However, this structure is integrated into the anterolateral capsule. Traditionally, ligaments transmit tensile loads along their length and are stretched along their longitudinal axis, resulting in a relatively uniform strain pattern in their midsubstance. The purpose of this study was to determine the magnitude and direction of the strain in the anterolateral capsule in response to external loads applied to the ACL deficient knee throughout a range of flexion angles. Our hypothesis was that the direction of the strain in the anterolateral capsule does not align with the proposed ligamentous structure. Knowledge of the function of the anterolateral capsule can lead to development of an injury model and more informed choices of repair.

METHODS

Seven fresh frozen cadaveric knees (mean age 53.7 years, range 46-59 years) were dissected until the anterolateral capsule was clearly visible. Twenty-four black markers were placed on the mid-substance of the anterolateral capsule in a 4 x 6 grid, approximately 1 cm superior to Gerdy's tubercle and the LCL insertion and 5 mm anterior to the LCL origin and insertions. The specimens were then mounted into a robotic testing system (MJT Model FRS2010, Chino, Japan). The femur was rigidly fixed relative to the lower plate of the robotic testing system and the tibia was attached to the upper end plate of the robotic manipulator through a 6-degree-of-freedom universal force/moment sensor (UFS, ATI Delta IP60 (SI-660-60), Apex, NC). The robotic testing system was used to apply loads to the knee at 3 flexion angles and a motion capture system (Spica Technology Corporation, Haiku, HI) was utilized to track motion of the strain markers attached to the surface of the capsule. The externally applied loads were: anterior tibial load (134N), external rotation torque (7 Nm), internal rotation torque (7Nm), and posterior tibial load (134N). The loading conditions were applied at 30°, 60°, and 90° of knee flexion for the ACL deficient knee.

The magnitude and direction of the maximum principal strain in the midsubstance of the anterolateral capsule were computed by comparing the positions of the strain markers in a non-strained reference configuration to the loaded configurations using ABAQUS (Dassault Systems, Velizy-Villacoublay, France) (Figure 1). The direction of the maximum principal strain of each element was quantified using Image J software (National Institute of Health, Bethesda, MD). The angle between the direction vectors representing each element in the anterolateral capsule and the anterolateral ligament proposed by Claes et al. was determined in a counterclockwise manner from the ligament [4]. The angles of each element were averaged per

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

loading condition and flexion angle for the seven specimens and then the mean of the angles of the seven specimens was calculated. Angles were in the range of 0-180° [6]. One tailed paired t-tests with significance set at $p < 0.05$ were used to compare the angles with 0°.

To compare the magnitude of the strain distribution within the anterolateral capsule at each flexion angle and loading condition, histograms were generated for the magnitude of the maximum principal strain at the centroid of each element for each specimen, flexion angle, and loading condition. The magnitudes of the maximum principle strain were compared between flexion angles and loading conditions as histograms normalized with bins from 0 to 90% strain at increments of 5%. The histograms could then be compared to the uniform strain distribution expected for a typical ligament based on the variance and kurtosis.

RESULTS

The average angles calculated between the direction vectors of the maximum principal strain and the proposed ligament's direction vary depending on loading condition (Figure 2). The mean angles ranged between 38° and 129.9°. All angles were significantly different than 0°.

The histograms for strain magnitude did not represent normal distributions and varied and between specimen, loading condition, and flexion angle. Overall, the mean kurtosis was 1.296±0.955 and the mean variance was 0.015±0.008 (Figure 3). The variance is linked to the spread of the strain magnitudes between bins and the kurtosis indicates the prevalence of strain magnitudes over the range of bins.

DISCUSSION

The direction of the strain does not align with the proposed ligament, supporting our hypothesis. The average direction vectors over all specimens and loading conditions were significantly different from 0°. The direction vectors were varied throughout the entire capsular mid-substance. (Figure 1). For a typical ligament, the distribution of the direction vectors would have been consistently close to the longitudinal direction of the proposed ligament [4] and had little variation.

The magnitudes of the maximum principal strain also did not act in a ligamentous fashion. A histogram of the magnitude of the maximum principle strain of a traditional ligament would have a high kurtosis and the variance would be low. However, compared to expected values for a typical ligament, the anterolateral capsule kurtosis was lower than expected and the variance was higher. The magnitudes of the maximum principle strain were not uniformly distributed (Figure 3).

Mapping the three-dimensional direction vectors into two dimensional space in order to calculate the angles with the proposed ligament introduced some variability. Thus, in the future, a statistical comparison between multiple observers orienting the direction vectors will be compared to determine repeatability.

In conclusion, the angle and the magnitude of the maximum principal strain in the anterolateral capsule during four loading conditions suggest that the anterolateral capsule functions more like a sheet of tissue than a traditional ligament. Knowledge of the behavior of the capsule can help to improve injury prevention models and repair procedures for the anterolateral capsule.

INTRODUCTION

During tumor progression, angiogenesis occurs to develop enhanced vascular networks to deliver nutrients to the ever expanding tumor tissue. As a hallmark of tumor progression, angiogenesis has long been targeted in anti-cancer therapeutic strategies with varying amounts of effectiveness (1). This is due, in part, to a limited understanding of biomechanical regulation of blood vessel growth in the tumor microenvironment. Much research has been dedicated to soluble signaling factors, including vascular endothelial growth factor (VEGF), but it is only recently that biomechanical factors have been appreciated as regulators of angiogenesis. Cancer-associated fibroblasts (CAFs) have been described as important stromal regulators of tumor progression, playing a role in ECM remodeling, blood vessel growth, and tumor metastasis (2). CAFs differ from normal fibroblasts by demonstrating a myofibroblast-like phenotype. Recent work has shown that CAFs demonstrate higher tensile forces when plated on 2D polyacrylamide gels when compared to normal fibroblasts (3). CAFs have also demonstrated mechanosensitive behavior, specifically responding to stiffness cues from the ECM via YAP signaling (4). Additionally, mechanical forces have been shown to initiate epithelial-to-mesenchymal transformations (EMT), which is remarkably similar to the process used to form tip cells in angiogenesis (5). While much is known about the soluble signaling factors regulated by CAFs, less is understood regarding the complex biomechanical behaviors of these cells and how that may alter angiogenesis in the tumor microenvironment. Together, this prompted our global hypothesis that CAF-mediated strain may play a previously underestimated role in the development of tumor associated vascular networks specifically by increasing the activation of tip cells to enhance and direct angiogenesis in the tumor microenvironment.

METHODS

Our lab has developed a 3D *in vitro* tissue engineered model of the vascularized tumor microenvironment (6-7). Using this model, we embedded a 1:1 ratio of umbilical cord blood derived endothelial cells and either normal breast fibroblasts (NBFs) or CAFs in a fibrin gel and cultured for 7 days. Gels were then fixed and stained for CD31 to identify blood vessel growth. Images were taken corresponding to the center of each gel using an inverted microscope. Vessel length was measured with AngioTool, with four replicates per condition. Fibrin concentration was altered to vary gel stiffness. For inhibition studies, the VEGF pathway was inhibited using a small molecule VEGF-receptor inhibitor (SU-5402, Abcam) supplemented in the media after 3 days of culture. Mechanical strain induced by NBFs and CAFs was determined using a custom designed bead tracking algorithm in MATLAB. Fibroblasts only were seeded at $2.5x10^6$ cells/mL in 10mg/mL fibrin gels containing fluorescent beads (FluoSpheres, 1μm diameter). Cells were allowed to grow overnight before analysis. Bead movement was tracked over the course of 1h in an environmental chamber maintained at 37^{o}C on an Olympus IX83 inverted microscope. Images were collected over 100μm z-stack, with a slice at every 0.5μm. A minimum of 50 beads per sample were analyzed. Bead displacement was interpreted as ECM deformation or strain induced by either NBFs or CAFs.

RESULTS

CAFs support the development of blood vessel networks in 3D fibrin gels, while NBFs do not (Figure 1). This is consistent for all concentrations of fibrin tested. Increasing the fibrin concentration above 2.5mg/mL enhances vessel growth supported by CAFs,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

although no affect is seen upon further increase. NBFs do not support vessel formation regardless of fibrin gel concentration. A VEGFR inhibitor fails to completely suppress blood vessel growth supported by CAFs (Figure 2). CAFs exhibit significantly higher gel deformations, as measured by fluorescent bead displacement, compared to NBFs (Figure 3A). The distribution of deformations is heterogeneous for both cell types (Figure 3B).

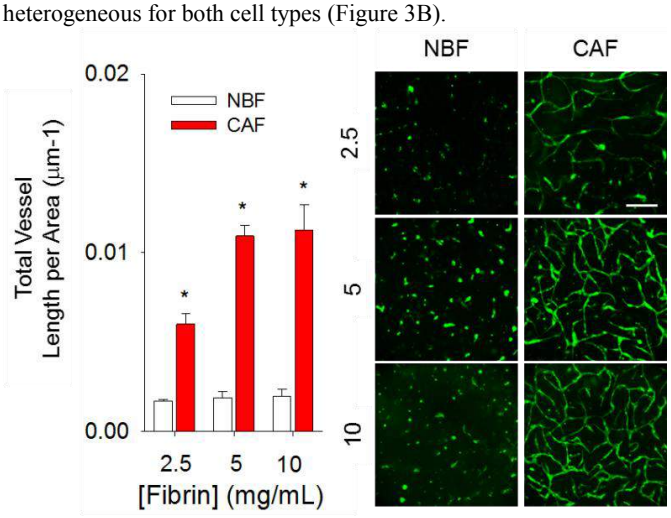

Figure 1: Blood vessel growth in fibrin gels is supported by CAFs but not NBFs. Increased stiffness of fibrin gels above 5mg/mL did not significantly affect blood vessel formation. . * p < 0.001 vs. NBF at same concentration; scale bar = 250μm.

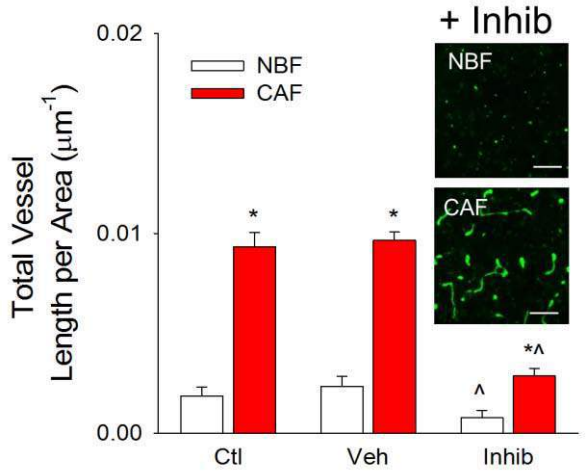

Figure 2: Inhibiting VEGF receptors suppresses, but does not eliminate, blood vessel formation supported by CAFs. Insets show treated samples. * p < 0.001 vs. NBF at same treatment; ^ p < 0.001 vs. NBF-Ctl scale bar = 250μm.

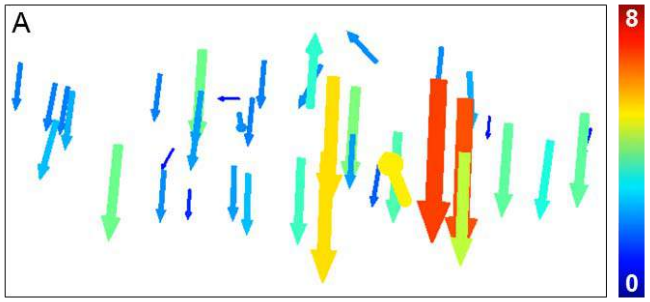
DISCUSSION

The role of CAFs in tumor progression and angiogenesis is complex and needs to be further studied. These studies show CAFs but not NBFs support vascularization in our 3D tissue model. Our results also indicate that fibrin concentration, which correlates with gel stiffness, demonstrates little effect on blood vessel formation. While increasing fibrin concentration also increases integrin signaling, this can be viewed as "effective gel stiffness" interpreted by the cell (8). This enhanced integrin signaling may play a role in the increase in blood vessel growth seen between 2.5 and 5mg/mL fibrin gels. Increased vessel formation in CAF samples in the 5 and 10mg/mL fibrin gels supports the idea that CAF biomechanics are an important factor in tumor associated angiogenesis. Furthermore, the VEGFR inhibitor studies indicate that CAF supported vascularization may not occur solely through the VEGF pathway. Additionally, we have developed an algorithm capable of tracking bead displacements generated by cells growing in 3D fibrin gels. Our studies show that CAFs have a significantly higher average magnitude of ECM deformation compared to NBFs.



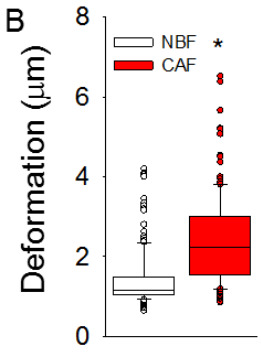


Figure 3: A) Representative image of bead displacement vectors shows CAF induced deformations in 3D fibrin gels. Color and size of arrow correspond to magnitude. Displacements induced by NBFs are much smaller and difficult to visualize so are not shown here. B) Distribution of bead displacement magnitudes for NBFs and CAFs. * p < 0.001.

Future studies will examine the mechanistic pathways important in CAF biomechanical regulation of blood vessel growth in the tumor microenvironment. Additionally, we will investigate the ECM deformations generated by CAFs and NBFs during blood vessel growth using our optimized bead tracking algorithm. Results from these studies will elucidate biomechanical factors associated with CAFs that are important for angiogenesis during tumor progression. Ultimately, we believe this work will provide information to develop novel anti-cancer treatment strategies by inhibiting angiogenesis.

INTRODUCTION

Intervertebral disc (IVD) homeostasis results form a balance between anabolic and catabolic activity of cells in the extracellular matrix (ECM) of the tissue. When catabolism overcomes anabolism, the IVD degenerates [1]. A possible strategy for restoring degenerated IVDs may consist in enhancing the cellular anabolism in the ECM of the disc. However, anabolic processes in IVD are complex and not entirely understood. This prevents the development of successful anabolic therapies for degenerated IVD.

Insulin-like growth factor-1 (IGF-1) plays a central role in IVD homeostasis, stimulating cell proliferation and biosynthesis of the ECM in a dose-dependent fashion [2, 3]. IGF-1 is either endogenously produced by disc cells, or exogenously delivered *via* plasma from the liver. Once in the IVD, this molecule binds to IGF-1 cell surface receptors (IGF-1R), initiating the signaling cascade that leads to the production of new ECM [4]. Hence, in order to enhance ECM anabolism in IVD, increased binding of IGF-1 to its receptor is highly desirable.

The interaction between IGF-1 and its receptor is only one of the many competing reversible chemical reactions occurring in the disc. For instance, IGF-2, delivered *via* plasma to the IVD can also bind to IGF-1R. However, such interaction has no downstream consequences in terms of ECM biosynthesis. Similarly, no downstream effects occur when either IGF-1 or IGF-2 bind to IGF-2R. Moreover, IGF molecules can be 'sequestered' by IGF-binding proteins (IGFBP). Particularly, IGF-1 and IGF-2 can reversibly bind to five IGFBPs (i.e., IGFBP-(1-5)). In addition, IGF-2 has a high affinity for IGFBP-6 [4]. The results of these reversible reactions are bound complexes that prevent IGF-1 and IGF-2 from interacting with their cell receptors. It has been proposed that the presence of IGFBP extends the half-life of IGF in the IVD [5, 6, 8].

The objective of this study is to theoretically examine possible strategies to enhance binding of IGF-1 to its receptor, with the ultimate goal of providing guidelines for the development of drug delivery approaches to cure IVD degeneration.

This is done *via* a novel pharmacokinetic model of IVD homeostasis that is capable of describing the role of IGF-1 in disc anabolism. More specifically, the model is deployed to test several approaches to increase IGF-1 binding to the IGF-1R. This is based on the use of inhibitors of competing signals or on the delivery of stimulants. The amount of complex obtained by IGF-1 binding to IGF-1R (i.e., IGF-1/IGF-1R) is used as a biological marker to quantify the level of anabolic activity in the IVD.

METHODS

The model is based on previous diffusive-reactive theoretical frameworks describing the role of IGF-1 in the homeostasis of cartilaginous tissues [5-10]. The IVD is schematized as composed of 3 regions: the nucleus pulposus (NP) in the center, surrounded by the annulus fibrosus (AF), and enclosed within the cartilage endplates (CEP). Molecular solutes (i.e., IGF-1, IGF-2, IGFBP-(1-6), and bound complexes) are delivered to the IVD via the vascular network surrounding the AF and in contact with the CEP, and diffuse through the ECM of the disc [8-10]. Disc cells in the ECM express surface receptors (i.e., IGF-1R and IGF-2R) to which growth factors bind, and can also endogenously produce IGF-1 [8]. The interactions of IGF-1 with its cell receptor and the other competitors are schematically reported below (Figure 1). Model parameters are taken from previous studies [5-10].

A straightforward mechanism to stimulate IGF-1/IGF-1R formation is to increase IGF-1 concentration in the plasma. However,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

high levels of IGF-1 in plasma have been associated to cancer. Hence, it would be desirable to seek for alternative strategies.

In this study, four strategies are simulated. For each one of them, the values of IGF-1/IGF-1R formed in each compartment of the disc (i.e., NP, AF, and CEP) are normalized with respect to baseline values attained when no treatment is performed on the disc.

In the first strategic approach, stimulants for increasing the expression of IGF-1R in disc cells may be delivered. This is supposed to increase the availability of binding sites for both growth factors, thus increasing the amount of IGF-1/IGF-1R formed. This is simulated in the model by parametrically increasing the concentration of IGF-1 receptors in disc cells. In the second approach, binding proteins IGFBP-(1-5) are exogenously delivered, since they increase the half-life, and consequently the bioavailability, of IGF-1 in the ECM. This is simulated by parametrically increasing the concentrations of such proteins at disc boundaries. A third method would be the delivery of an inhibitor of IGFBP-6 in order to prevent the formation of an IGF-2/IGFBP-6 bound complex and reduce the half-life (bioavailability) of IGF-2, which competes with IGF-1 in binding to IGF-1R. This is implemented by parametrically reducing the boundary-concentration of IGFBP-6. The last approach would consist of delivering an inhibitor of IGF-2, thus preventing this growth factor to compete with IGF-1 in binding to IGF-1R. This is implemented by parametrically reducing IGF-2 boundary-concentrations.

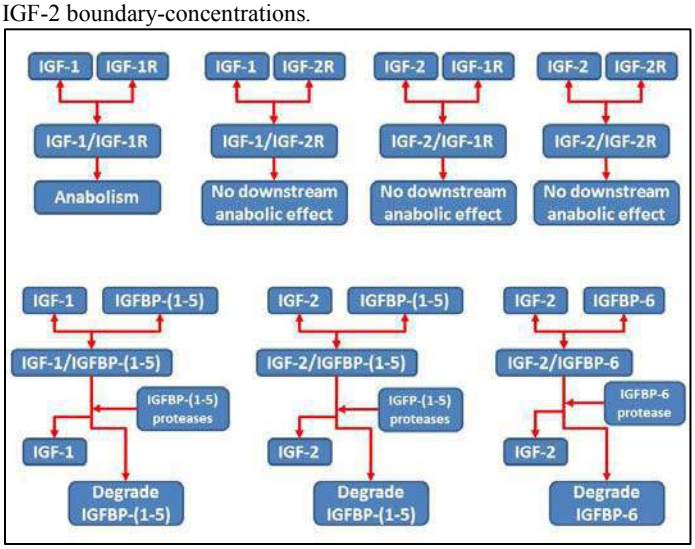

Figure 1: Schematic of competing binding reactions among growth factors IGF-1 and IGF2, binding proteins IGFBP-(1-6) and cell receptors IGF-1R and IGF-2R.

RESULTS

For the four therapeutic approaches simulated, steady-state average concentrations of IGF-1/IGF-1R complex have been reported and normalized to the scenario when no treatment is added to the disc (Figure 2).

The highest increases in the IGF-1/IGF-1R complex-formation are found when IGF-2 is inhibited (Figure 2d). Such type of approach is especially effective for promoting bound complex-formation at the CEP. In contrast, stimulation of IGF-1R expression has similar effects across all disc regions (Figure 2a). The low increases are observed when modulating the concentration of IGFBPs. Doubling plasma concentration of IGFBP-(1-5) only increases the formation of IGF-1/IGF-1R in the NP by about 20% (Figure 2b). Even smaller effects are observed when IGFBP-6 is inhibited. Accordingly, changes in IGF-1/IGF-1R are less than 10% in all disc regions (Figure 2c).

DISCUSSION

A new pharmacokinetic model for IVD homeostasis was deployed for investigating potential therapies for disc degeneration based on increasing anabolism in the ECM of the disc.

Anabolism in IVD was modeled as the result of IGF-1 binding to its cell surface receptor IGF-1R. However, several other competing interactions among proteins and receptors in the ECM of the disc simultaneously occur, which limit the formation of the IGF-1/IGF-1R complex. The therapeutic approaches herby investigated aimed at modulating the bioavailability of proteins and receptors in the disc to favor the interaction of IGF-1 with IGF-1R.

It was found that increased anabolism can be obtained by inhibiting IGF-2, since this growth factor competes with IGF-1 in biding to IGF-1R. However, a significant increase in IGF-1/IGF-1R mainly occurs at the CEP, and it requires a reduction of up to 25% of IGF-2 when compared to the normal physiological concentration. Stimulation of IGF-1R expression also increases anabolism, but major changes occurs only if IGF-1R concentration is increased 1.5- to 2-fold. Modulation of IGFBPs bioavailability produced minor changes in IGF-1/IGF-1R formation. Similar results have been reported in a theoretical analysis on cartilage homeostasis [5].

In conclusion, this study suggests that drug delivery protocols for IVD regeneration should be combinatorial by tackling simultaneously as many factors involved in disc anabolism as possible.

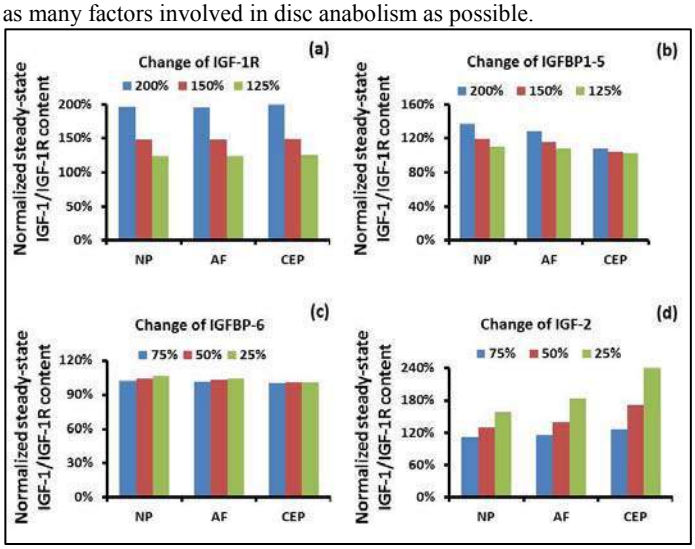

Figure 2: Effect of therapeutic approaches on the availability of IGF-1/IGF-1R: (a) stimulation of IGF-1R; (b) delivery of IGFBP-(1-5); (c) inhibition of IGFBP-6; (d) inhibition of IGF-2.

INTRODUCTION

Congenital heart defects (CHD) account for almost a quarter of birth defect related infant deaths and are diagnosed in 8 out of every 1000 live births, often leading to further development of cardiovascular disease in adulthood [1]. Since it is well established that hemodynamic forces influence cardiovascular development, several groups have used surgical interventions to alter blood flow and induce cardiovascular defects in chicken embryos. The chick embryo is particularly well suited for direct physical manipulations, therefore eliminating unintended effects common to biochemical treatments. Two common interventions, outflow tract banding (OTB) and vitelline vein ligation (VVL), are frequently used to increase and decrease blood flow velocity, respectively [2]. Previous studies have shown that these alterations result in remodeling of the heart, aortic arches, and capillary plexus, but have not investigated their impact on large, elastic artery development.

The chick embryo's dorsal aorta (DA) is the first intraembryonic vessel to form, later developing into the adult descending aorta. Its passive mechanical properties are determined by the deposition of elastin and collagen, beginning at about Hamburger-Hamilton stage (HH) 29 or embryonic day (E) 6 [3-4]. We hypothesize that hemodynamic changes will affect the structure and development of the DA. We used Doppler velocimetry to measure blood velocity and immunofluorescence to examine the DA's wall structure and components in embryos under control and VVL conditions. These data will further our understanding of the relationship between hemodynamics and vessel maturation, supplementing current knowledge of vascular CHDs and directing efforts in the field of arterial tissue engineering.

METHODS

Fertilized White Leghorn chicken eggs were incubated blunt side up for approximately 70 hours at 37°C yielding embryos at HH 18-19. The embryo was exposed by creating a small window in the shell above the air cell and removing the membranes above the areas of interest. Control embryos were sealed with tape, while experimental embryos had the right vitelline vein ligated using a 10-0 monofilament suture prior to sealing.

A 20-MHz pulsed Doppler flowmeter probe (Iowa Doppler Products) was placed on the DA at the level of the sinus venosus to measure blood velocity along the DA centerline of control and VVL embryos at HH 18-19, 22-23, 25-26, and 28-29. A custom Matlab program was used to calculate the heart rate and peak velocities. Additionally, a Vevo 2100 ultrasound system (VisualSonics) was used to measure DA blood velocity for control embryos at HH 30-31 and 33-34. Corresponding VVL embryo measurements are forthcoming.

Immunofluorescence was used to characterize DA lumen area, wall area, and fiber alignment in whole embryo cryosections for controls. These sections were taken transversely at levels corresponding to the heart, liver, and mesonephros. Dimensional measurements were performed using ImageJ (NIH) and alignment was determined using its Directionality plugin. Circular statistics were employed to assign an R-value to the fibers, where R=1 indicates perfect alignment. Isolated control and VVL DAs at HH 36-37 were also stained to determine the percent quantities of elastin, collagen, and cells in the arterial wall. A Matlab script was developed to quantify these measurements. Statistical significance in comparisons between controls and VVLs was determined using unpaired, two-tailed t-tests with unequal distributions.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

These results are the first to include blood velocity measurements in the chick embryo DA using ultrasound, a more reliable technique for late developmental stages (Figure 1). They confirm that VVL immediately reduces blood velocity, but is quickly normalized. Additional ultrasound data will show whether or not this normalization persists though day 8. Heart rate is unaffected by the ligation.

We determined that the lumen area, wall area, and elastic fiber orientation all increase over time in control embryos, but also observed substantial thinning along the length of the DA (Figure 2). At HH 36, we found that VVL DAs show a significant decrease in elastin content, while maintaining the same collagen and cell volume fractions (Figure 3).

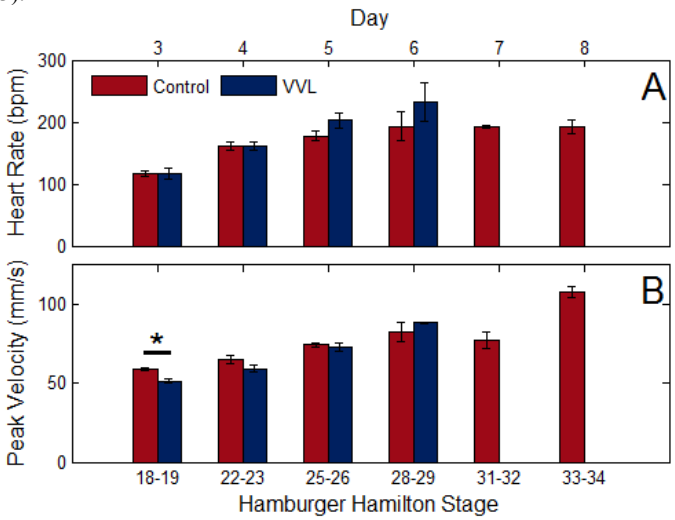

Figure 1: Heart rate (A) and peak velocity (B) of control and ligated embryo DAs. *=P<0.05 compared to control.

DISCUSSION

Doppler measurements along with analysis of immunofluorescence micrographs show that ligation causes a modest, but significant, 13% reduction in DA blood velocity. Despite this small and short-lived change, elastin content in the DA wall of ligated embryos is dramatically decreased by almost 65%. These results suggest that decreased blood flow hinders elastin lamellar development and support our hypothesis.

Dimensional measurements of control DAs provide a standard to which VVL DAs can be compared in future work. Corresponding measurements in VVL DAs are forthcoming. This data will be used to ascertain whether or not the compositional changes due to ligation are also accompanied by structural changes.

Given the uncertainty associated with immunofluorescence, further quantification will be performed using RT-PCR. This will not only measure the expression of matrix genes, but also genes associated with smooth muscle cell phenotype and endothelial cell shear stress response. Future work will also include mechanical testing, which will provide valuable information showing how hemodynamics can affect the mechanical properties of the maturing DA.

INTRODUCTION

Liver transplantation is a successful and definitive treatment for patients with liver failure. Yet, over the last two decades, there has been a short supply of organs from deceased donors. This has motivated the implementation of living donor liver transplantation (LDLT), a therapy that has produced results comparable to traditional liver transplants.[1,2] However, little is known about the effects that LDLT has on the liver hemodynamics of the donor. To investigate these effects, studies have been conducted to examine alterations due to surgery in the underlying fluid dynamics of blood flow using in vitro experiments, numerical simulation, and clinical studies[3]. In order to implement a methodology that provides further insight into the hemodynamic alterations, this study employs patient specific 4D Flow MRI, in vitro physical model experiments, and computational fluid dynamics simulation in living donor portal venous models before and after the LDLT procedure. Additionally, the validity of the in vitro and simulation analysis methods is examined through a comparison of each method at the same operating conditions.

METHODS

In this IRB-approved and HIPAA-compliant study, a LDLT donor (33 year-old female, 68 kg) was imaged after written informed consent before and within one month after surgery. The subject was scanned after at least 5 hours of fasting to avoid variability in splanchnic flow[4]. The study was conducted on a clinical 3T scanner (Discovery MR 750, GE Healthcare, Waukesha, WI) with a 32-chanel body coil (NeoCoil, Pewaukee, WI). 4D velocity mapping was achieved using a cardiac-gated time-resolved 3D radially undersampled phase contrast acquisition (5-point PC-VIPR)[5] with increased velocity sensitivity performance[5,6]. Radial 4D flow MRI image parameters included: imaging volume: 32x32x24cm spherical, 1.25mm acquired isotropic spatial resolution, TR/TE=6.4/2.2ms. The subject received 0.05 mmol/kg of gadoxetic acid (Eovist, Bayer Healthcare, Wayne, NJ). Pre- and post-surgery 4D flow MRI imaging protocols were identical.

The vessels of the patient liver were segmented using MIMICS (Materialise, Leuven, Belgium) from PC angiograms (Figures 1a. and 2a.). Using Ensight (CEI, Apex, NC), cut-planes were manually placed in the Splenic Vein (SV), Superior Mesenteric Vein (SMV), and the Left (LPV), Right (RPV), and Main portal Veins (PV), where flow measurements were taken.

The segmented pre- and post-surgery liver models were prepared for in vitro flow experiments using 3-matic (Materialise, Leuven, Belgium). The models were then fabricated using selective laser sintering (DTM Sinterstation 2500CI ATC with 30 Watt coherent laser and 3 axis M3ST scanning system). The printed models (Figures 1b. and 2b.) were connected to a perfusion pump (Stockert SIII Heart-Lung Machine) using surgical tubing. Fluid was pumped through the models at rates of 1 and 2 liters per minute, and flow measurements were recorded at each inlet and outlet vessel using a flow probe (Transonic PXL Flowsensor). The in vitro set-up was then taken to a magnetic resonance scanner, where the same flow experiments were conducted. The 4D Flow MR data were then analyzed using cut planes in Ensight (CEI, Apex, NC), as done in the in vivo case analysis.

The same segmented pre- and post- surgery liver models that were used for the in vivo analysis and in vitro model fabrication were also prepared for numerical simulation using the mesh generation software ICEM (ANSYS). The computer models were then imported to Fluent (ANSYS) and computational fluid dynamics simulations were conducted at the same conditions present in the in vitro model experiments. Results from the simulations were analyzed in Ensight in the same manner as the in vitro experimental results.

RESULTS

Comparison of the in vivo 4D Flow MRI results showed an increase in the average and maximum fluid velocity throughout the portal venous system in the post-surgery case compared to the pre-surgery case. This relationship held true in the in vitro experiment and CFD simulation results as well. A visual representation of this phenomenon can be seen though a comparison of the pre- and post-surgery in vitro experiment streamlines (Figure 1c. and figure 2c.) and the CFD simulation velocity vectors (Figure 1d. and Figure 2d.). The CFD simulation results also displayed an increase in the pressure gradient across the portal venous system in the post-surgery models.

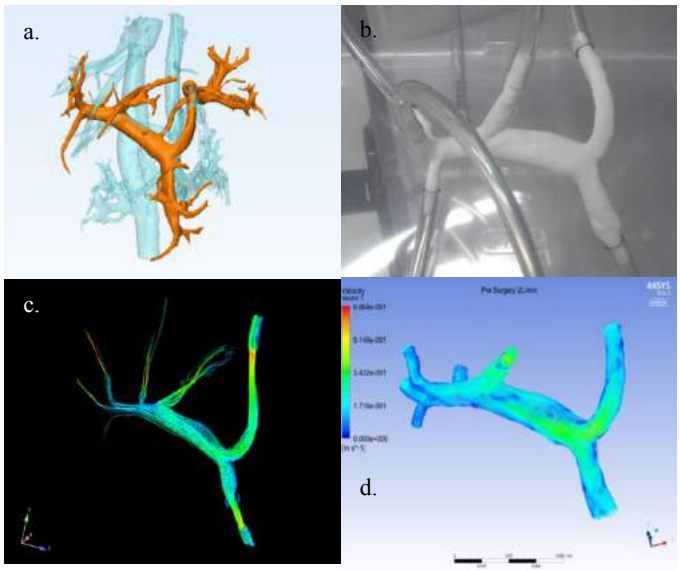

Figure 1: Pre-Surgery portal vein described as follows: a) In vivo segmented model, b) In vitro 3D printed experimental model, c) In vitro experiment velocity streamlines, d) CFD simulation velocity vectors.

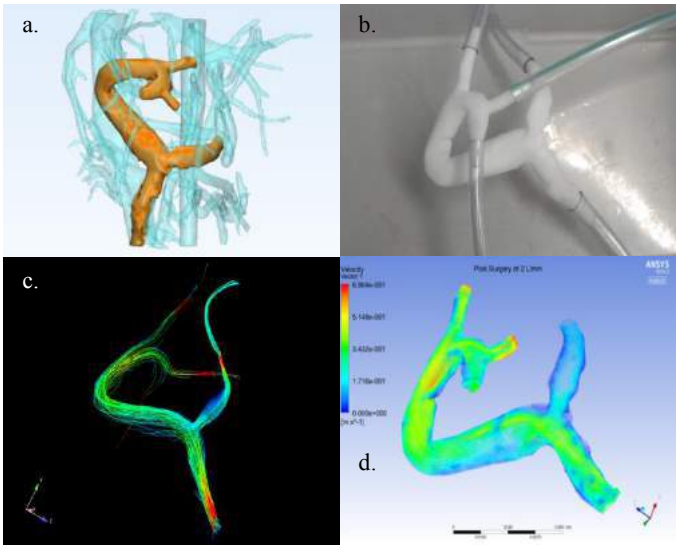

Figure 2: Post-Surgery portal vein described as follows: a) In vivo segmented model, b) In vitro 3D printed experimental model, c) In vitro experiment velocity streamlines, d) CFD simulation velocity vectors.

In addition to the post-surgery increase in velocity and pressure gradient, an increase of fluid flow in both the Left Portal Vein (LPV) and Superior Mesenteric Vein (SMV) was observed in the post-surgery models compared to pre-surgery conditions. Again, these results held true for each analysis method.

Lastly, when comparing the results of the in vitro experiments and CFD simulations from the same case, the difference between the flow values remained within 5% on all vessels, except for the SMV and SV in the pre-surgery models, which produced a 8% difference. The in vitro and CFD simulation flow values displayed a 10 to 15 percent difference from the flow probe measurements.

DISCUSSION

Living donor liver transplant has been a successful treatment for liver failure. However, the health and safety of the donor post-transplant is of paramount importance, and there remains insufficient data. Given the difficulty of assessing in vivo liver function and the inability to predict how a specific procedure will alter liver hemodynamics, further work is needed. To develop a methodology to better predict this outcome, this study employed MRI in vivo flow analysis, in vitro experiments, and computational fluid dynamics simulations.

In the transplant case examined in this study, the right lobe of the liver was resected, eliminating the RPV. Thus, the results that displayed an increase in fluid velocity throughout the portal vein were expected due to the decrease in total portal vein volume. The increase in LPV flow was also expected, as after surgery the LPV provided the only path for blood flow. However, what could not be predicted through physical examination was the magnitude of the change in blood flow through each of the PV branches and the change in pressure that these alterations would induce.

The methods used in this study successfully measured the hemodynamic changes that could not otherwise be predicted. The pressure gradients were quantified and visual representations of the fluid flow paths were provided so that a comparison could be made between pre- and post- surgery anatomical configurations. In addition, the use of multiple methods of analysis provided a process to validate the flow quantification data of each method against the others.

The capability to predict the hemodynamic changes induced by a surgery before it occurs may be of great value in the surgical planning process. In future studies, the methods described here will be expanded to multiple cases so that more insight may be gained on their validity and utility.

INTRODUCTION

Advanced Automatic Crash Notification (AACN) algorithms have shown promise in improving the trauma triage process by predicting occupant injury severity using vehicle telemetry data to recommend a transportation decision (trauma center versus non-trauma center). Current AACN algorithms such as OnStar and URGENCY incorporate model variables such as crash direction, delta-v, multiple impacts, belt use, vehicle type, age, and sex [1-2]. Both algorithms use Abbreviated Injury Scale (AIS) metrics to define severely injured patients. Although AIS-based metrics are most commonly used, other methods of injury scoring have been developed to better discriminate severely injured patients.

The objective of this study was to develop an AACN algorithm and evaluate its performance in making optimal occupant triage decisions using an injury-based approach. In addition, a benefits analysis was conducted to estimate the reduction in undertriage (UT) and overtriage (OT) if the algorithm was implemented nationwide.

METHODS

The developed AACN algorithm uses measurements obtainable from vehicle telemetry to predict risk of overall occupant injury and recommend a transportation decision for the occupant, particularly whether transport to a Level I/II trauma center is recommended. A list of injuries associated with a patient's need for treatment at a Level I/II trauma center was determined using an injury-based approach based on three facets (severity, time sensitivity, and predictability). Severity was scored based on mortality risk ratios (MRRs) obtained from the National Trauma Data Bank (NTDB) [3]. Time sensitivity was scored using expert physician survey data which incorporated the recommended treatment location and a rank of urgency for treatment [4]. Predictability was scored using two components: an occult score and a transfer score. The occult score is a measure of the likelihood that an injury is missed using expert survey data from physicians and emergency medical services (EMS) professionals. The transfer score is a measure of the likelihood that an injury is present in patients that require transfer from a non-trauma center to a Level I/II trauma center using the National Inpatient Sample (NIS) database [5].

Scores of each of these facets (severity, time sensitivity, and predictability) were computed for each of the 240 frequent motor vehicle crash AIS 2+ injuries and normalized on a zero to one scale in which scores closer to one were more severe, more time sensitive, and less predictable. The AACN algorithm inputs include a Target Injury List and 38,970 National Automotive Sampling System-Crashworthiness Data System (NASS-CDS) 2000-2011 occupants used to train and evaluate the algorithm (Figure 1). The Target Injury List is determined by multiplying the severity, time sensitivity, and predictability scores by a weighting coefficient and then summing these values to produce an injury score. Injuries meeting or exceeding a variable injury score threshold are included on the Target Injury List (Figure 1). The Target Injury List is not a static list and is capable of being varied in order to optimize the algorithm.

The AACN algorithm uses multivariate logistic regression to predict an occupant's risk of sustaining an injury on the Target Injury List from the following model variables: longitudinal delta-v (in frontal and rear crash modes), lateral delta-v (in near side and far side crash modes), number of quarter turns (in rollover crash mode), belt status, multiple impacts, and airbag deployment. The algorithm features five tunable variable parameters allowing for extensive optimization. These include severity, time sensitivity, and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

predictability multipliers, an injury score and risk threshold. The severity, time sensitivity, and predictability multipliers are coefficients used to weight each injury's contribution to the injury score. Above the injury score threshold, an injury is included on the Target Injury List. The risk threshold is the tolerable risk for any target injury. At or above this threshold, the algorithm recommends triage to a Level I/II trauma center (Figure 1). The AACN algorithm transportation decision for each NASS-CDS occupant is compared to a dichotomous representation of their Injury Severity Score (ISS). Occupants with ISS 16+ should be transported to a Level I/II trauma center. AACN algorithm optimization minimized UT and OT with the goal of producing UT < 5% and OT < 50% as recommended by the ACS [6].

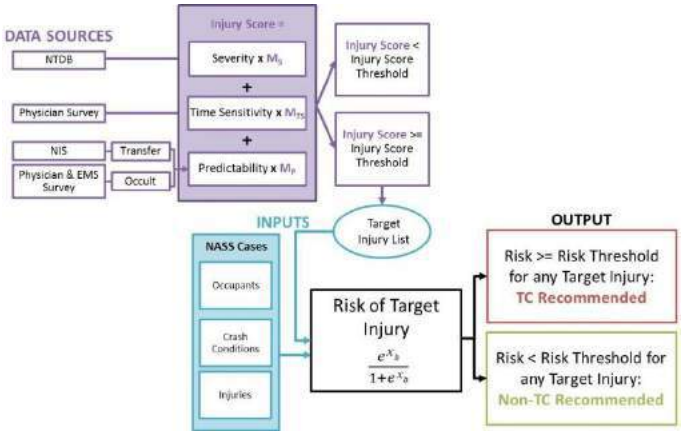

Figure 1: Overview of AACN algorithm.

RESULTS

The resulting OT and UT metrics for the optimal variable parameters are listed in Table 1. UT rates for far side and near side met the 5% ACS recommendation. OT rates for frontal, rear, far side, near side, and rollover all met the 50% ACS recommendation.

Table 1: Over/under triage rates (OT/UT) and true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN) for the AACN algorithm by crash mode.

Crash Mode	OT	UT	TP	FP	TN	FN
Frontal	49.7%	5.9%	903	10451	10312	57
Rear	44.0%	7.0%	40	1470	1154	3
Far side	48.7%	2.9%	232	1727	1642	7
Near side	47.9%	4.6%	559	1723	1581	27
Rollover	49.7%	16.0%	871	3040	3005	166

DISCUSSION

The AACN algorithm was developed with an injury-based approach that examined three injury facets to identify injuries necessitating treatment at a Level I/II trauma center. Large hospital and survey datasets containing information on injuries, mortality risk, treatment urgency, and hospital transfers were used in conjunction with large crash datasets with crash, vehicle, occupant, and injury data. The algorithm has been rigorously optimized and has demonstrated improved UT rates compared to other AACN algorithms in the literature and OT rates meeting ACS recommendations. These results are encouraging as the algorithm uses only crash characteristics that are obtainable from vehicle sensors, whereas the majority of published algorithms use variables such as age or gender that are not obtainable directly from the vehicle. The AACN algorithm appears to be doing "more with less" than several algorithms to which it has been compared and shows great promise as an improved approach for triaging patients. Since the AACN algorithm uses only data elements specified in Part 563 regulation, it could be readily incorporated into new vehicles to inform emergency personnel of recommended occupant triage decisions [7].

Benefits of an existing AACN algorithm were estimated using the differential between the number of MVC occupants correctly triaged using the AACN algorithm compared to actual triage decisions for real-world occupants. Actual triage decisions were extracted from NASS-CDS 2000-2011 to compare each occupant's ISS (≥ 16 vs < 16) versus the occupant's actual triage destination (trauma center or non-trauma center). Analyses included 47,361 unweighted occupants representing 9,763,984 weighted occupants with complete information on the crash mode (frontal, far side, near side, rear, rollover), hospital destination (trauma center or non-trauma center), and a valid ISS.

The weighted analysis of 12 years of NASS-CDS data revealed an UT rate of 20% and an OT rate of 54% among real-world MVC occupants across all crash modes. If the triage rates from the AACN algorithm were applied to these occupants by crash mode, the UT and OT rates would be reduced to 11% and 34%, respectively. Across a 12 year period, this would result in an UT improvement for 32,959 (44%) occupants and OT improvement for 1,947,620 (38%) occupants for an estimated total of 1,980,579 occupants who would now be triaged correctly with the AACN algorithm. Thus, with nationwide implementation of the AACN algorithm, we estimate a potential benefit of improved triage decision-making for 165,048 occupants annually (one-twelfth of the 1.98 million occupants). Annually, this translates to more appropriate care for 2,747 seriously injured occupants and reduces unnecessary utilization of trauma center resources for 162,302 minimally injured occupants.

The projected reduction in UT for the U.S. population attributable to AACN has important implications for decreasing MVC mortality and morbidity, while reduction of OT will lead to better hospital resource utilization and decreased healthcare costs. The AACN algorithm developed in this study will aid emergency personnel in making the correct triage decision for an occupant after a MVC, and once incorporated into the trauma triage network it can reduce response times, increase triage efficiency, and improve overall patient outcome.

INTRODUCTION

Skeletal muscle consists of approximately 75% fluid [1] in addition to muscle fibers and extracellular matrix and can thus be characterized as a biphasic material. Other biphasic biological tissues such as cartilage utilize fluid content to lubricate joints and distribute loads under compression [2]. Yet the biphasic properties of muscle, specifically permeability, are often overlooked in experimental and modeling studies. The role that permeability plays in skeletal muscle mechanics is unclear. Permeability is often neglected in computational models of skeletal muscle, or simply approximated using viscoelastic modeling. The goals of this work were to 1) characterize skeletal muscle permeability by direct experimental measurement, and 2) identify how various permeability implementations affect finite element analyses of skeletal muscle.

METHODS

Four New Zealand White Rabbits ~2.5 kg in weight, either male or female, were euthanized with Colorado State University Institutional Animal Care and Use Committee approval. The biceps femoris muscles were harvested from the left or right hind limb and all experimental work was completed within 6 hours post mortem to reduce the effects of rigor mortis [3]. Cylindrical samples for permeability testing were removed from the muscle mid-belly using a custom fabricated drop cutter with high profile histology blades spaced 4 mm apart and a biopsy punch 8 mm in diameter. Since skeletal muscle exhibits transverse isotropy [3, 4], samples were obtained in the longitudinal and the transverse directions.

Each sample was directly evaluated in a permeation test device similar to previously published work [5]. In short, this device applied a known flow rate (0.5 mL/min) with a syringe pump to phosphate buffered saline across a tissue sample while measuring the pressure difference across the sample. Additionally, since permeability is typically a function of tissue strain [5], samples were compressed axially (12.5% and 25%) to replicate transverse or longitudinal compression or compressed laterally (25% and 50%) to simulate longitudinal stretch. Pressure (ΔP), flow rate (Q), specimen dimensions (L_0 and A), and strain (ε) were utilized to calculate the permeability of the tissue [5] (Equation 1). A paired t-test was utilized to compare permeability values between longitudinal and transverse samples and a general linear model was utilized to determine if permeability varied with strain level ($p<0.05$ for both analyses).

$$k = \frac{QL_0(1-\varepsilon)}{A\Delta P} \quad (1)$$

To identify the effect of permeability on muscle behavior, a 3D finite element (FE) model representing muscle tissue was developed using FEBio (febio.org) to simulate passive stretch and transverse compression. This model consisted of a cuboid with a cross section of 4 mm x 4 mm and a length of 20 mm, with muscle fibers running parallel to the length of the cuboid. To represent the transversely isotropic behavior of skeletal muscle [3, 4] as well as biphasic behavior, a poroelastic fiber reinforced coupled Mooney-Rivlin constitutive model was implemented. For finite element implementation strain-dependent permeability is a function of the volume ratio J, the undeformed void ratio φ_0 (0.19 for skeletal muscle [1]), and material properties k_0, M, and α (Equation 2, [5]).

$$k(J) = k_0\left(\frac{J-\varphi_0}{1-\varphi_0}\right)^{\alpha}\exp\left[\frac{M}{2}(J^2-1)\right] \quad (2)$$

To study how a biphasic approach affects model behavior, four permeability conditions were utilized in separate simulations. First, a solid analysis (no permeability) was used as the simplest approach ("Solid"). Next, a constant, isotropic permeability was calculated from experimental data for a baseline biphasic model ("Constant"). Finally,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

two separate fits of Equation 2 to the experimental data to were utilized to generate anisotropic and strain dependent responses ("Fit I" and "Fit II"). Fit I is a conservative strain dependent formulation while Fit II is a case of extreme strain dependence (Table 1 and Figure 1).

The model was subject to two different loading conditions in separate analyses, longitudinal strain and transverse compression. Each condition consisted of a quick ramp phase from 0-10% strain over 1 second and 300 seconds of relaxation followed by a constant rate load to 50% strain at 1% second^{-1}. This evaluated how various permeability implementations affect transient muscle behavior under tensile and compressive conditions. The mean Cauchy stress over the whole model was calculated for comparison between simulations.

RESULTS

The mean permeability value for all samples was 7.41×10^{-11} m^4/N-s with a standard error of 2.22×10^{-11} m^4/N-s. There was no statistical effect of either strain level (p=0.398) or orientation (p=0.158) on skeletal muscle permeability.

Table 1: Permeability implementations for the FE simulations. The Solid analysis had no biphasic parameters, the Constant analysis had a single permeability value, and finally the Fit analyses had fully anisotropic strain dependence with different parameter values.

	k_0 (m^4/N-s)		M (-)		α (-)	
	Long	Trans	Long	Trans	Long	Trans
Solid	N/A	N/A	N/A	N/A	N/A	N/A
Constant	7.41 E-11		N/A	N/A	N/A	N/A
Fit I	1.1 E-10	4.2 E-11	0.63	0.16	0.097	0.97
Fit II	5.0 E-10	4.0 E-11	10	1	2	0.5

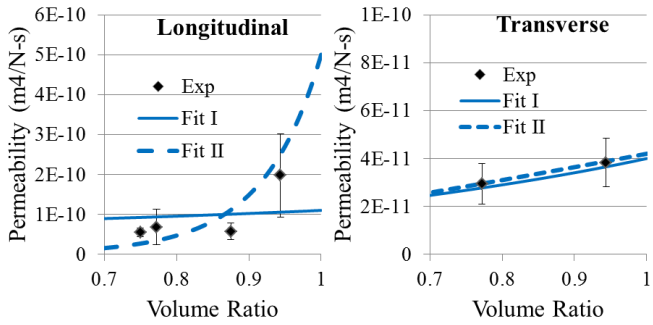

Figure 1: Permeability experimental data (diamonds with standard error bars), Fit I (solid line) for conservative strain dependence, and Fit II (dashed line) for extreme strain dependence.

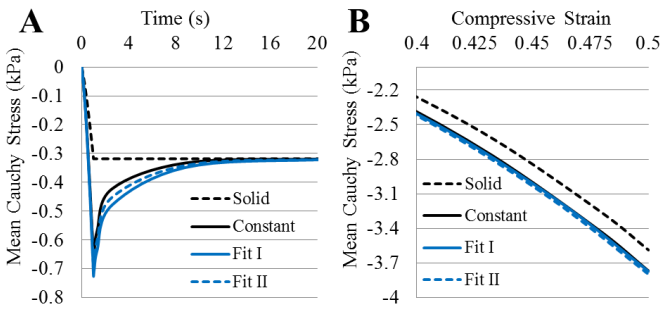

Figure 2: Model outputs for each of the four simulations under compression for ramp and relaxation (A) and constant rate (B).

Utilizing a biphasic approach affected tissue behavior (Figure 2 and Table 2). While variations in strain dependence and anisotropy affect results, they played less of a role than simply defining a constant, isotropic permeability. More specifically, inclusion of a biphasic analysis versus a solid analysis greatly affects the transient response of the tissue under compressive conditions, as evident by the increases in peak stresses in the biphasic analyses (Figure 2A and Table 2). Additionally, under tensile transient conditions, inclusion of a biphasic approach affected model output to a greater extent than anisotropic strain dependent permeability (Table 2).

Table 2: Percent differences between mean Cauchy stress of model outputs when compared to the Constant analysis at two different model instants: after a fast ramp strain of 10% and at 50% strain. Bold represents the highest percent error between analyses. The Solid analysis experienced the highest percent difference (up to 52%) for three of the four measurements.

	Solid		Fit 1		Fit 2	
	Tension	Comp	Tension	Comp	Tension	Comp
10% strain peak	**2.1%**	**52%**	0.62%	8.6%	0.035%	4.3%
50% strain	0.067%	**4.8%**	0.19%	0.11%	**0.24%**	0.82%

DISCUSSION

This work provided, to the authors' best knowledge, the first direct measurement of skeletal muscle permeability. The observed permeability values from this work reflect a difference of roughly 4-5 orders of magnitude over other biological tissues such as cartilage or ligament [2, 5]. This is not surprising since low muscle permeability would resist muscle deformation, thus significantly reducing contractile capabilities.

Additionally, this work provides insight into how various assumptions about muscle permeability affect tissue behavior from a computational standpoint. Statistical results showed no dependence of permeability on strain level or orientation, while modeling results agreed that utilizing an anisotropic, strain dependent permeability formulation typically had a minor effect on behavior. Model calculated stresses had good agreement with previously published experimental work under both compression [3] and tension [4], which gives greater confidence in these results.

However, the differences between a biphasic analysis and a solid only analysis should not be ignored, especially in an instance where compression occurs (Table 2). Thus a simple biphasic analysis (isotropic, constant permeability) should be utilized for skeletal muscle models involving compression, particularly under highly transient conditions. Future work should be conducted to identify how skeletal muscle models with complex geometries or contact are affected by a biphasic approach.

INTRODUCTION

Elastic and collagen fibers are well-known to be the major load-bearing extracellular matrix (ECM) components of the arterial wall. Despite the important mechanical role of glycosaminoglycans (GAGs) in other tissues such as cartilage, GAGs are only recently gaining attention in mechanical studies of arterial tissue. The goal of this study was to study the mechanical and structural contributions of GAGs to the arterial wall. Biaxial tensile testing was paired with multiphoton microscopic imaging of elastic and collagen fibers in order to establish the structure-function relationships of porcine thoracic aorta before and after enzymatic GAG removal.

METHODS

Sample Preparation: Descending porcine thoracic aortas were obtained from a local abattoir and cleaned of loose connective/fatty tissue. Approximately 20 mm sized square samples (n=6) were cut so that one edge is parallel to the longitudinal direction and the other edge is parallel to the circumferential direction of the artery.

Enzymatic GAG Removal Treatment: To enzymatically remove GAGs in arterial tissue, a protocol adapted from Lovekamp et al. [1] was used by adding heparinase to the treatment. Briefly, samples were treated in 100 mM ammonium acetate buffer, pH 7.0, 2-5 U/mL hyaluronidase, 0.025 U/mL chondroitinase ABC, 0.25 U/mL heparinase and gently agitated for 24 hours at 37°C to remove GAGs. Samples were then rinsed and mechanically tested in 150 mM phosphate buffered saline (PBS).

Mechanical Testing: A custom designed biaxial tensile testing device was used to mechanically test the tissue samples before and after GAG removal. Tissue deformation, was measured by tracking four carbon marker dots on the tissue during a tension control protocol using a custom LabVIEW program. Samples were hooked on each edge and connected to the linear positioners with sutures. A preload of 5 ± 0.050 N/m was applied in order to straighten the sutures connecting the tissue to the device. Samples were loaded with 10s half-cycles at 50 N/m until a consistent preconditioning response was achieved. Then the samples were subjected to an equibiaxial loading condition of 400 N/m to characterize the anisotropic mechanical behavior. To examine the viscoelastic behavior of arteries and the effect of GAG removal, a 400 N/m equibiaxial loading was reapplied with a 2s rise time and held at a constant stretch for 900s for the stress relaxation test. To quantify the effect of GAG removal on stress relaxation, normalized stress relaxation curves are obtained by normalizing to the peak stress. Percent stress relaxation is taken as the decrease in normalized value for the end of the test at 900s.

Multiphoton Microscopy and Image Analysis: To understand the contribution of GAGs to the structure and function of the arterial wall, and the interaction of GAGs with other ECM constituents, mechanical loading was paired with multiphoton imaging of tissue with GAGs removed following methods detailed by Chow et al. [2] to allow for comparison with untreated tissue. The adventitial side was imaged to a depth of 60 μm, whereas the medial side was imaged to a depth of 40 μm and maximum intensity projections of the Z-stacks were made. Images were cropped from 360x360 μm^2 to 110x110 μm^2 regions with optimal fiber coverage, which were used for analysis. Samples were imaged from 0 to 40% equibiaxial strain in 5% increments. These images were then used in the analysis of fiber straightening and recruitment in response to mechanical loading. Adventitial collagen fiber waviness was quantified with NeuronJ by measuring the end-to-end distance (L_o) and total fiber length (L_f), to define a straightness parameter, $P_s = L_o / L$, which is equal to 1 for a straight line. This manual

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

tracing method cannot be applied to the more intricate elastic and collagen fiber network in the media. Therefore, fractal analysis was also used as a broad measure of fiber recruitment following the protocol described by Chow et al. [2].

RESULTS AND DISCUSSION

Equibiaxial testing results show that the treated samples stiffening at lower strains than untreated samples (Figure 1).To quantify the changes in mechanical properties due to GAG removal, initial and stiff slopes were determined by linear fit to the regions of stress-strain curves from 0-20 kPa and 180-200 kPa, respectively. Transition stress/strain was then calculated as the intersection of the bilinear curve fit to the initial and stiff regions of the stress-strain curves (Fig. 1) [3]. For treated samples, the transition points of the circumferential (p=0.04) and longitudinal (p=0.002) directions are at significantly lower strain measurements, indicating earlier stiffening behavior of the arterial wall. However, the initial and stiff slopes for each direction are not significantly different after treatment (all p>0.1), suggesting GAG removal results in earlier stiffening, but not absolute stiffening.

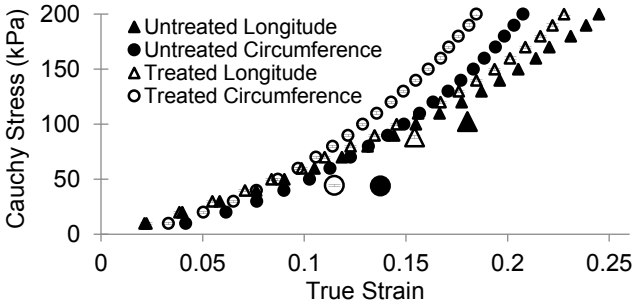

Figure 1: Averaged stress-strain curves of untreated and treated aorta. Treated samples have transition points (larger symbols) at significantly lower strain (p<0.05).

Results of multiphoton imaging (Fig. 2) show that after removing GAGs, adventitial collagen fibers are straighter and recruited at lower levels of strain, supporting the finding of lower transition point from straighter fibers that are recruited at lower levels of strain. Waviness of adventitial collagen fibers was quantified with the straightness parameter (Fig. 3). At 0% strain, the straightness parameter for adventitial collagen fibers of tissue with GAGs removed was significantly higher than for untreated tissue from Chow et al. [2]. While delayed collagen fiber engagement behavior, i.e., fibers do not show significant straightening until around 20% strain, was observed in the adventitial collagen from untreated tissue, this behavior is absent from the treated tissue. In fact, removing GAGs (P_s=0.92) has a similar effect on the waviness of adventitial collagen fibers to applying between 20% (P_s=0.90) and 25% (P_s=0.94) strain to untreated tissue [2]. A possible explanation is that GAGs inflated from the repulsive charges and swelling pressure may contribute to collagen fiber waviness, so removing GAGs would allow the collagen fibers to be straighter.

Fractal analysis further revealed that in addition to adventitial collagen fibers, medial collagen and elastin fibers in the treated samples are also recruited at low levels of strain and show small changes after being fully recruited (Fig. 3). These results are consistent with the finding that the ECM fibers appear to be straighter and are engaged earlier than the untreated tissue. Previous histology studies suggest that GAGs fit within wavy collagen fibers perpendicular to the local fiber direction, similar to a laterally supported Euler column [4]. Such interactions may contribute to the entanglement of fibers, and provide support to fibers. Moreover GAGs can delay fiber engagement in the direction of mechanical loading. As a result of GAG removal, these fibers can engage earlier in response to mechanical loading.

Figure 2: Representative multiphoton images of adventitial collagen at 0 (left), 20 (middle) and 40% strain (right). The circumferential direction is horizontal. Images are 110×110 μm.

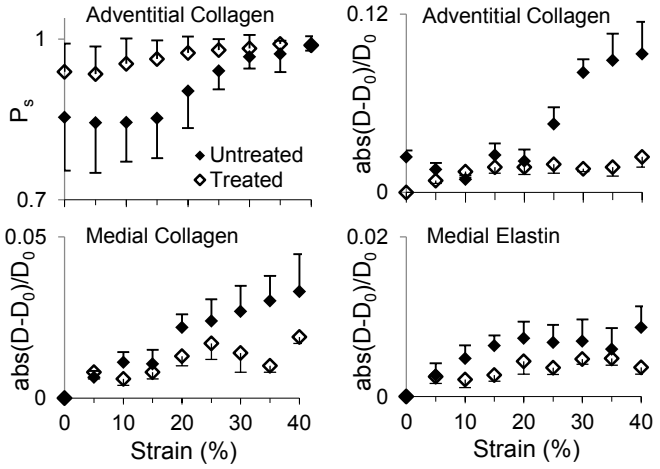

Figure 3: Straightness parameter (P_s) and fractal analysis (abs(D-D_0)/D_0) shows that GAG removal results in straighter fibers that are recruited at lower levels of strain, where D and D_0 are the average fractal number for the deformed and undeformed state, respectively.

Stress relaxation tests were performed to examine the contribution of GAGs to the viscoelastic behavior of arteries. Removing GAGs significantly reduce the percent stress relaxation from 8.77% to 7.14% (p=0.01) and 9.90% to 7.83% (p=0.03) in the longitudinal and circumferential directions, respectively. The finding of decreased stress relaxation after removing GAGs suggests that GAGs contribute to the viscoelastic behavior of arteries.

GAGs serve many functions in development, maintenance, and repair of a variety of tissues. An increase in GAG depleting enzymes such as those used in this study are noted in conditions such as hyperglycemia and hyperlipidemia that are prevalent in diabetes and atherosclerosis. Overall, our study suggests that despite the relatively low mass fraction of GAGs in arterial tissue, GAGs play an important role in contributing to the structural and mechanical properties of the arterial wall, and GAGs should be considered in addition to elastic and collagen fibers when studying arterial function.

INTRODUCTION

Reconstructions of the anterior cruciate ligament (ACL) attempt to restore knee function after ACL injuries and studies have demonstrated the efficacy of ACL reconstructions to significantly improve knee integrity [1]. However, recent investigations have highlighted concern over iatrogenic injury of anterior meniscal root insertions caused by reaming of replacement ACL tibial bone tunnels, specifically the anterolateral meniscal root (ALMR) insertion.

Recently, the ALMR has been described to insert underneath the lateral portion of the ACL with 41% of the ACL insertion area overlapping an average of 63% of the ALMR insertion [2]. Investigations of ACL reconstruction tunnel reaming demonstrated an average injury area of at least 25% of the original ALMR insertion and significantly decreased ultimate tensile strength of the attachment [3, 4]. While these studies begin to describe the risk of ALMR injury during ACL reconstruction and the complex relationship between the insertions, further investigation of how the insertions interact is necessary to understand and define the three-dimensional relationship of these two structures.

The purpose of this study was to investigate the microstructural relationship between the tibial ACL and ALMR insertions using scanning electron microscopy (SEM) of coronal and sagittal sections and quantify the overlap of the two insertions. It was hypothesized that the maximum percentage of tibial ACL insertion overlapping with the ALMR insertion would be the same in both the coronal and sagittal planes.

METHODS

Institutional review board approval was not necessary for this study because de-identified cadaveric specimens are exempt from review at our institution. Ten cadaveric knees, five males and five females, mean age 52.7 (range, 33-63), mean BMI 22.4 (range, 15-34), and no history of knee injury were used. Care was taken to isolate and preserve the entire ACL and ALMR throughout the dissection before a rectangular bone block was cut to include the tibial ACL and ALMR insertions.

Samples were prepared for SEM using standard methods [5]. Briefly, the samples were placed in fixative (2.5% glutaraldehyde) for 48 hours at room temperature. The samples were then submerged in 10% formic acid to decalcify at room temperature. Following decalcification, the samples were immersed in a 1% tannic acid solution buffered with 0.05 M cacodylate (pH 7.2) for 4 hours and then rinsed in distilled water for 24 hours. Samples were then dehydrated in ascending concentrations of ethanol and cut into 2 mm sections. Five specimens were cut into coronal sections with the ALMR insertion fibers running approximately parallel to the section plane and the remaining five specimens were cut into sagittal sections with the ACL fibers running parallel to the section plane. Once sectioned, the samples were placed into ascending concentrations of hexamtheyldisilazane (HMDS) and dried in a vacuum desiccator. Samples were mounted with conductive tape, coated with a 10 nm layer of gold, and scanned using a JSM-6400 scanning electron microscope (JEOL, Peabody, MA) in the secondary electron emission mode (SEI) with an accelerating voltage of 15 kV.

To evaluate the relationship between the tibial ACL insertion and the ALMR insertion in the coronal plane, sections taken from the middle of the ALMR insertion were imaged. In the sagittal plane, imaged sections were taken closer to the lateral side of the ACL insertion to incorporate the ALMR insertion. Each section was imaged at high magnification (up to 1,500X) to view fiber direction and to identify the entirety of the ACL and ALMR insertions. Lower magnification (15X) images were taken across the entirety of each sample and stitched

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

together for quantitative analysis of the insertion relationship using ImageJ software (NIH, Bethesda, MD).

To further understand the relationship between the two insertions, the percentage of the tibial ACL that interacts with the ALMR insertion instead of inserting into subchondral bone was determined (Figure 1). For each sample, the length of the ACL visibly inserting into subchondral bone was initially determined by measuring the boundary between the ligament-bone interface for indirect fibers and insertion tidemark of the direct fibers described in previous literature [5]. The length of the ACL insertion visibly overlapping with the ALMR insertion was also measured. The two length measurements were then used to calculate the percentage of overlap between the two insertions. Measurements were taken from the stitched SEM images using ImageJ software.

A two-sample, equal variance Student's t-test was performed on the coronal and sagittal percentages of overlap with significance determined as $p < 0.05$.

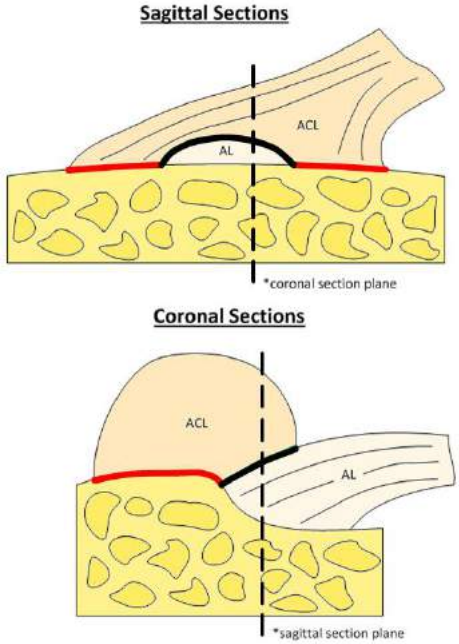

Figure 1: Schematic of method used to analyze the percentage of tibial ACL insertion interacting with the ALMR insertion fibers instead of inserting into subchondral bone. Solid red = ACL into subchondral bone; solid black = interaction between ACL and ALMR; dashed black = sections taken of other plane.

RESULTS

Macroscopically, the ALMR inserted underneath the lateral side of the ACL in all ten specimens. The relationship between the tibial ACL and the ALMR insertions was also clearly visible upon forming the coronal and sagittal sections. Microscopically, the tibial ACL insertion displayed an intimate relationship with the ALMR insertion as they transitioned into bone in all specimens. Direct four-phase fibers of the tibial ACL insertion were also identified directly adjacent to the ALMR insertion as they attached onto the tibial plateau in the coronal plane (Figure 2).

After identifying the insertion fibers of the tibial ACL and ALMR, the percentages of the ACL insertion overlapping with the ALMR insertion were calculated for each section in both planes. The tibial ACL insertion overlapped the ALMR insertion in the coronal and sagittal sections with a mean percentage of 40 ± 8% and 43 ± 9%, respectively. There was no significant difference in the percentage of insertion interaction between the coronal and sagittal sections ($p = 0.32$).

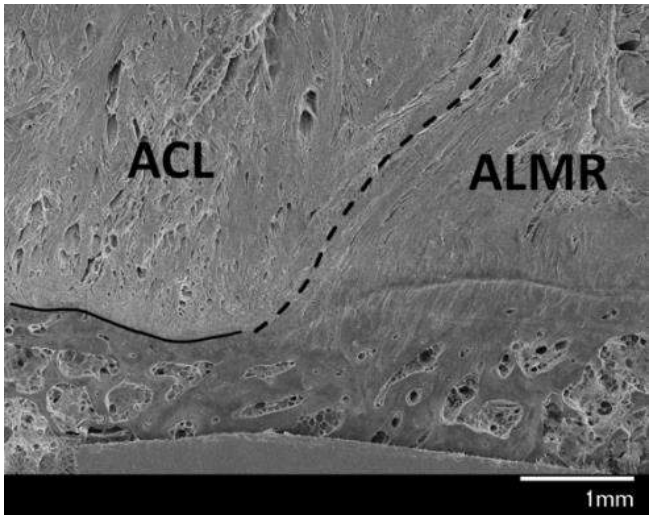

Figure 2: SEM image of insertion relationship in coronal plane. Note the direct fibers of the ACL insertion with the tidemark (solid line) separating the uncalcified fibrocartilage layer from the calcified fibrocartilage layer directly adjacent to the ALMR insertion. The dashed line represents the interaction between the ACL and ALMR. 15X; Working distance = 25 mm.

DISCUSSION

This study investigated the relationship between the tibial ACL and ALMR insertions using SEM and quantified percentages of interaction in the coronal and sagittal planes. The results of this study suggest that a significant portion of the tibial ACL insertion in the coronal and sagittal planes overlaps with the ALMR insertion instead of inserting directly into subchondral bone. There was no significant difference between the targeted maximum percentage of insertion interaction in the coronal and sagittal planes, which suggests the ALMR equally interacts with the tibial ACL insertion in both planes.

The clinical implications of this finding are currently unknown; however, acceptance of a guide pin placed laterally in the tibial ACL insertion may have even more significance than previously thought. During ACL reconstruction, reaming over a laterally misplaced guide pin could lead to complete or functional detachment of the anterior horn of the lateral meniscus after tunnel reaming, potentially leading to iatrogenic injury and development of osteoarthritis over time.

The goal of an ACL reconstruction should be to place a tibial tunnel within the center of the direct fibers of the insertion, described as the most structurally important attachment fibers [6]. The direct fibers of the tibial ACL were found medially adjacent to the ALMR insertion in the central coronal plane. This intricate relationship and overlap complicates the placement of a tibial tunnel for an ACL reconstruction. Therefore, thorough investigation of the tibial ACL direct fibers with respect to the location of the ALMR insertion fibers is warranted.

INTRODUCTION

Electronic cigarettes, colloquially known as e-cigs, are rapidly increasing in popularity among both users and non-users of traditional cigarettes[1,2,3]. Unfortunately, knowledge of their relative health hazards is sparse despite this popularity.

Unlike conventional cigarettes, which deliver nicotine along with known carcinogens via smoke from the combustion of tobacco, electronic cigarettes operate by vaporizing an e-liquid, consisting of propylene glycol, vegetable glycerin, flavoring agents, and nicotine[1]. Heating the e-liquid generates an inhalable aerosol that delivers these ingredients into the user's respiratory system, simulating the experience and nicotine delivery of traditional cigarettes. While the basic components of e-liquids, excluding nicotine, are generally considered safe for human consumption, findings show significant presence of heavy metals and carcinogens in electronic cigarette vapor[4,5]. For these reasons, many nations including the United States are proposing regulations to control health risks[1].

However, there are relatively few studies on electronic cigarettes, resulting in gaps in necessary knowledge. Given their intended use to deliver nicotine to the bloodstream, the dosage amount and rate are of interest to regulators. Previous studies show that users' nicotine levels increase more slowly as compared to conventional cigarettes[6]. One possible explanation for this is a difference in the manner in which nicotine is delivered. Nicotine in the vapor phase, large particles, and small particles will be delivered to different areas of the respiratory system[7,8]. The disparity in absorption rate is thought to be because nicotine is rapidly delivered to the body via the pulmonary route while it is considerably slower when administered orally or dermally[9,10].

This study was designed to determine the mass and distribution of nicotine available to users from electronic cigarettes between particulate and vapor phases to account for observed differences in absorption.

METHODS

The first task of the investigation was to effectively capture both the vapor and particulate phase nicotine separately while precisely controlling puff parameters. An Arduino-controlled device regulated the puff duration, puff intervals, number of puffs, and electronic cigarette voltage. For this investigation, each sample consisted of 30 puffs separated by 30 seconds each. Puffs lasted for 3 seconds with a flow rate of 35 ml/s with the heater coil in the electronic cigarette being turned on 1 second prior to air flow. A KangerTech™ T3'D Dual Coil Clearomizer with ZigZag™ Dragonberry flavor 18 mg nicotine/mL e-juice was utilized for all sampling.

Puffs were sampled through a 4.7 cm diameter quartz filter and then 3 inch and ½ inch long open-cell polyurethane foam (PUF) filters each with a 2 inch diameter (Figure 1). Prior to use, the quartz filters were rinsed three times with deionized water via vacuum filtration and dried in a high temperature oven overnight. The PUF filters were rinsed three times in excess methanol and allowed to air dry. Additionally, the mass of the clearomizer was taken before and after each trial. This process was repeated a total of three times for each voltage: standard (3.7 V), high (4.8 V), extreme (5.5 V).

Once the electronic cigarette emission samples were collected, the quartz and ½ inch PUF filters were placed in 25 mL of methanol and the 3 inch PUF filters were placed in 150 mL of methanol and sonicated for 60 seconds. A small aliquot of each solution was taken to be analyzed by Gas Chromatography Mass Spectrometry (GC-MS).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

An Agilent 7890A GC with an Agilent HP-5MS capillary column and an Agilent 5975C VL MS were utilized. A 1 µL volume was injected and run using a method previously used for detecting urinary nicotine[11]. The peak attributed to nicotine appeared at 8.42 minutes.

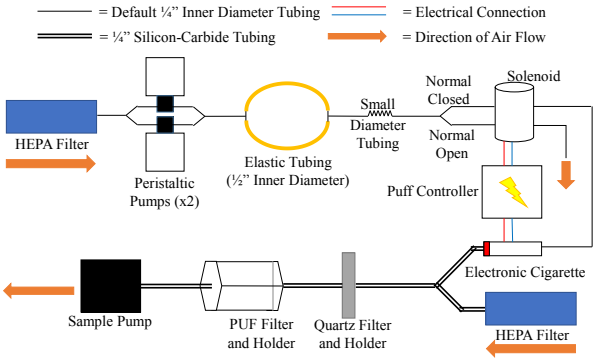

Figure 1: Flow diagram of emission sample collection.

A standard curve was created using solutions prepared from ≥99% pure nicotine in methanol in order to associate chromatographic peak area to nicotine concentration. The total mass captured by the filter was calculated by multiplying concentration by solution volume. If nicotine vapor breakthrough was detected, as indicated by detected nicotine on the ½ inch PUF filter, the trial was excluded due to sample loss.

Nicotine from the quartz filters was considered particulate and nicotine from PUF filters was considered to be vapor phase. A theoretical amount of total nicotine available was also calculated by assuming that the e-liquid had a density equal to an average of propylene glycol and glycerin, and a nicotine content of 18 mg/mL as labeled. The theoretical mass of nicotine available, m_{theor}, is found from:

$$m_{theor} = \frac{\Delta m \cdot C}{\rho} \quad (1)$$

where Δm is the change in clearomizer mass, C is the concentration of nicotine, and ρ is the density.

RESULTS

The theoretical and experimental amounts of nicotine were determined for each voltage setting with the power calculated from the measured resistance of the coil (Figure 2).

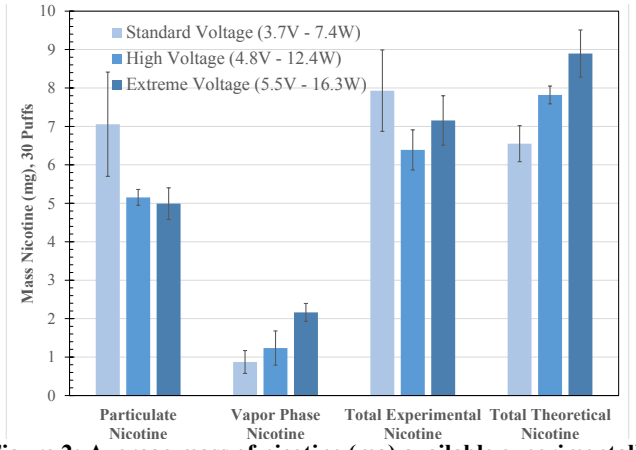

Figure 2: Average mass of nicotine (mg) available experimentally from the particulate and vapor phases as well as the total nicotine available theoretically and experimentally, with average deviation.

The total mass of theoretical nicotine as well as the experimental vapor phase nicotine available increased with power. The amount of experimental particulate phase nicotine available was larger at the standard power and approximately the same at both the high and extreme powers. Since the total experimental nicotine was simply the sum of the vapor and particulate phases, it was the highest at the standard voltage and lower at both the high and extreme voltage, increasing approximately with vapor phase nicotine. With the exception of the standard voltage, experimentally available nicotine was less than the theoretically available nicotine. This lack of mass balance may be due to the portion of e-liquid observed in the tubing near the electronic cigarette's mouthpiece, which was unaccounted for in either the vapor or particulate phases.

DISCUSSION

As predicted, nicotine from electronic cigarettes is distributed between the particulate and vapor phases (Figure 1). A majority, regardless of power, is found in the particulate phase. The associated particle size would determine where in the respiratory tract this nicotine would be available[7,8]. It is unclear why particulate phase nicotine is more abundant at standard power, but the overlap in average deviation between total experimental and theoretical mass at standard power suggests a mass balance is achieved at this lower power. This same mass balance was not achieved at the high or extreme powers due to the lower mass of particulate phase nicotine.

As vapor phase nicotine increases with power, a larger portion of the nicotine is available for rapid absorption in the lungs. This means, that at higher powers, electronic cigarettes can better simulate rapid rise in plasma nicotine levels produced by traditional cigarettes[10]. The increase in total available nicotine also means that a higher level of blood nicotine levels can be achieved. This combination supports previous findings that later generation electronic cigarettes, which operate at higher powers, cause more rapid nicotine absorption[6].

For the high and extreme voltages, the total theoretical nicotine was larger than the total experimental nicotine, indicating a portion would not be distributed throughout the respiratory system. Instead, it is possible that a portion is simply mechanically splattered into the mouth and absorbed orally. The e-liquid observed in the tubing directly following the mouthpiece seems to account for this possibility. A portion of the nicotine may have also been chemically converted.

The proposed distribution of bioavailable nicotine between the mouth, upper airways, and lungs explains the nicotine absorption pattern of electronic cigarettes as compared to traditional cigarettes.

INTRODUCTION

Glaucoma is the second most common cause of blindness worldwide, and is characterized by the death of retinal ganglion cells (RGC) which carry vision information to the brain [1]. A key risk factor in glaucoma is elevated intraocular pressure (IOP). IOP induces stress and strain in the tissues of the optic nerve head (ONH), which is thought to contribute to retinal ganglion cell axon insult. The ONH is a region in the posterior eye with complex tissue morphology, including a passage in the sclera (connective tissue shell of the eye) known as the scleral canal. RGC axons pass through a web of connective tissue (lamina cribrosa) that spans this canal as they exit the eye and converge to form the optic nerve (Fig 1). Data suggest that the ONH is the main site of axonal damage in glaucoma and that ONH biomechanics is important in glaucoma [2], motivating previous modeling studies of the human ONH [3]. However, there is a need to better understand ONH biomechanics of animal models used in glaucoma research.

The rat is a well-accepted animal model for glaucoma. Such studies using the rat are based on elevation of IOP and observation of resulting biological and structural changes in the ONH. However, rat ONH biomechanics have not been characterized, and there are significant structural differences between the rat and human ONH, including the lack of a connective tissue lamina cribrosa spanning the rat neurovascular scleral canal (Figs 2 and 3), the presence of a vascular plexus between the optic nerve and the sclera of the neurovascular canal, and the presence of a separate, inferior arterial canal. Digital 3D histomorphometric reconstructions of the rat ONH (Fig 2) are now available, making eye-specific finite element (FE) modeling of the rat ONH possible [5]. We present herein the first eye-specific FE models of the normal rat ONH under elevated IOP conditions, with the goal of understanding rat ONH mechanobiology.

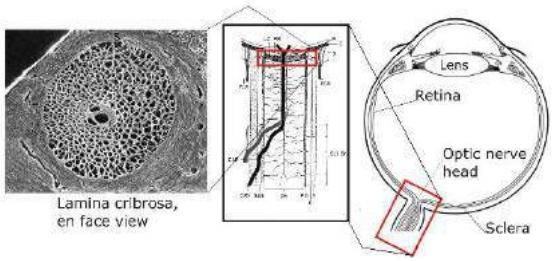

Figure 1: From left to right: electron microscopic image of the lamina cribrosa, schematic of the ONH, and schematic of the eye anatomy [4]. All three represent human anatomy.

METHODS

A finite element model was constructed from manual delineation of a normal rat ONH within a digital 3D histomorphometric reconstruction, created as follows. Following perfusion fixation, the ONH from a normotensive rat eye was embedded in paraffin and serial sectioned. After each cut, the block face was stained and photographed. All images were aligned and stacked into a digital 3D reconstruction [5]. Digital radial and transverse cross sections of the reconstruction were viewed in order to delineate key ONH tissues (Fig 2). Points were manually placed on the borders of the sclera, nerve, central retinal artery (CRA), central retinal vein (CRV), perineural vascular plexus (PNVP), and inferior arterial canal (IAC). CAD software (Rhino) was used to fit NURBS surfaces to 3D point clouds, creating an ONH geometry for FE modeling using Abaqus. Tissues were treated as isotropic, nearly-incompressible, neo-Hookean materials and assigned properties (Table 1) from previous modeling studies of the human ONH [3] since little information about rat-specific tissue properties is currently available.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

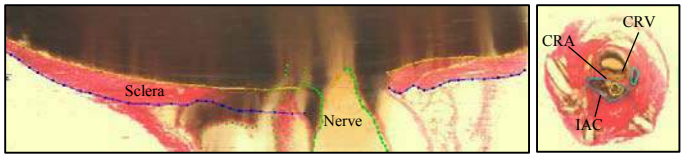

Figure 2: Radial (left) and transverse (right) digital sections of a rat ONH with manual delineations of tissues (colored dots).

The model was meshed using 10-node, hybrid tetrahedral elements (C3D10H in Abaqus). Approximately 350,000 elements were used. Pressure was applied to the anterior surface of the model (interior ocular surface) to simulate IOP. Because the eyes were perfusion fixed while experiencing an IOP of approximately 10 mmHg, pressures applied to the model represent a change in IOP from a reference state at 10 mmHg. Arterial and venous pressures were applied to the CRA and CRV lumens. Boundary conditions were applied using a submodeling approach as follows. A generic posterior eye (GPE) model was created by embedding simplified ONH tissue geometries in a semi sphere of 6.41 mm diameter and 0.2 mm thickness and applying IOP up to 30 mmHg. The geometric best fit match between the GPE and the ONH models was found, and displacements from matching locations of the GPE model were applied to the edges of the local ONH model as boundary conditions.

	Young's Modulus (MPa)	Poisson's Ratio
Sclera	3.0	0.49
Nerve	0.03	0.49
CRA	0.3	0.49
CRV	0.3	0.49
PNVP	0.1	0.49
IAC	0.1	0.49

Table 1: Material properties of model components

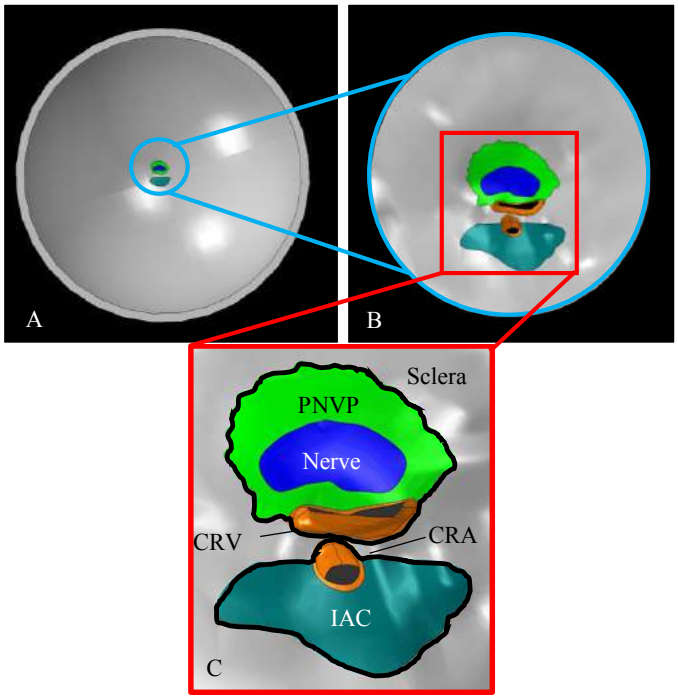

Figure 3: Generic posterior eye model (A), and local ONH model (B, C). Central retinal artery (CRA), central retinal vein (CRV), perineural vascular plexus (PNVP), inferior arterial canal (IAC).

RESULTS

As a proof of principal, we modeled an applied pressure of 20 mmHg (simulating an IOP of 30 mmHg), and CRA and CRV blood pressures of 70 and 20 mmHg (Figure 4). Within the optic nerve, the site of axonal damage, the model predicted 95th percentile first principal strain (logarithmic) and stress of 19.1% and 8.5 kPa, respectively. This strain value exceeds that predicted in the human: 95th percentile first principal strain of ~7.5% in the prelaminar nerve at an even higher IOP of 50 mmHg [3]. Higher strains in the rat nerve are expected due to the absence of structural support from a lamina cribrosa which is present in the human.

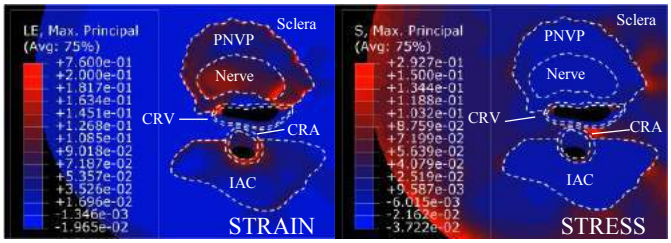

Figure 4: First principal strain (logarithmic) and stress (MPa) in the ONH. Central retinal artery (CRA), central retinal vein (CRV), perineural vascular plexus (PNVP), inferior arterial canal (IAC).

DISCUSSION

We present an initial FE model of the biomechanics of the rat ONH. The results of this study are promising, as an FE model utilizing complex, individual-specific ONH geometry was successfully solved under elevated IOP loading conditions. Future work is underway and includes the following. 1) Although we expect that rat tissue material properties are relatively similar to values in the human, values specific to the rat will be obtained and used. 2) Although we have included a significant portion of the rat ONH morphology, additional tissues are being added to the model in order to capture even more of the complex rat ONH geometry. 3) We will model additional individual-specific ONH geometries (including from contralateral experimental glaucoma eyes [6]) to evaluate biomechanical effects of rat-to-rat ONH morphology variation and of glaucomatous structural changes. These models will allow us to relate regionally specific stress and strain levels to biological outcomes in rat glaucoma models, which will in turn provide better context for interpreting outcomes of past and future rat studies, thus improving our understanding of glaucoma pathogenesis.

INTRODUCTION

The efficacy of blood-contacting devices has improved significantly over the years; yet, thrombosis still remains a co ncern with current device technology. To help better understand and predict thrombus deposition and growth, many thrombosis models have been developed for use in computational fluid dynamics (CFD) simulations. However, due to the convoluted and multi-scale nature of the thrombotic process, the most thorough models need to track tens of species and consider dozens of coupled reactions, making them too computationally expensive to use in the complex, three-dimensional flows associated with blood-contacting devices. Additionally, they often rely on *a priori* knowledge to dictate locations of initial thrombus deposition and/or are not rigorously validated due to a lack of *in vitro* or *in vivo* thrombus growth data.

One of the primary causes of device-induced thrombosis is disrupted blood flow through the device [1]. Specifically, regions of high shear stress can activate platelets, while regions of low wall shear stress (WSS) promote thrombus deposition. A thrombosis model for use in blood-contacting devices must be able to simulate the entire thrombotic process; platelet activation, platelet adhesion, and thrombus growth; at both high and low shear conditions, relying purely on the fluid dynamics of the system to dictate locations of thrombus deposition.

METHODS

A single-scale thrombosis model, initially developed by Fogelson [2], is modified to predict macroscopic device-induce thrombosis. The model considers bulk concentrations of platelets, non-activated (ϕ_n) and activated (ϕ_a), and adenosine diphosphate (ADP – a platelet agonist), and terms for mechanical platelet activation and WSS-dependent thrombus deposition and growth are added. The concentrations of activated platelets and ADP are calculated with Eqns (1) and (2), respectively.

$$\frac{\partial \phi_a}{\partial t} + (\boldsymbol{u}\cdot\nabla)\phi_a = D_a\nabla^2\phi_a + \{[A_C(ADP)]\phi_n + [A_M(\phi_f,\tau)](\phi_a+\phi_n)\} \quad (1)$$

$$\frac{\partial ADP}{\partial t} + (\boldsymbol{u}\cdot\nabla)ADP = D_{ADP}\nabla^2 ADP + R_{ADP}\{[A_C(ADP)]\phi_n + [A_M(\phi_f,\tau)](\phi_a+\phi_n)\} \quad (2)$$

Mechanical platelet activation (A_M) is quantified through an Eulerian power law model – Eqn (3) – adapted from Soares *et al*. [3].

$$A_M(\phi_f,\tau) = (1-\phi_f)C^{\frac{1}{\beta}}\beta\phi_f^{\frac{\beta-1}{\beta}}\tau^{\frac{\alpha}{\beta}} \quad (3)$$

Thrombus deposition and growth is quantified through the use of a scalar aggregation intensity (ε), quantified using Eqn (4), which relies on a novel WSS-dependent weighting function, P_{TSP} in Eqn (5), to determine locations of deposition and the subsequent rate of thrombus growth. P_{TSP} is based on a thrombus susceptibility potential (TSP) metric developed to quantify the risk of thrombosis in pulsatile blood pumps [4].

$$\frac{\partial \varepsilon}{\partial t} = \alpha_\varepsilon P_{TSP}(\tau_w)\phi_a^2 - \beta_\varepsilon(\tau_w)\varepsilon \quad (4)$$

$$P_{TSP}(\tau_w) = \begin{cases} 1 \; for \; |\tau_w| \le \tau_{low} \\ 1 - \frac{|\tau_w|}{\tau_{high}} \cdot \frac{e^{\frac{|\tau_w|-\tau_{low}}{\tau_{high}-\tau_{low}}}-1}{e^1-1} \; for \; \tau_{low} < |\tau_w| < \tau_{high} \\ 0 \; for \; |\tau_w| \ge \tau_{high} \end{cases} \quad (5)$$

Lastly, a growing thrombus is coupled to the velocity field through the use of a modified Brinkman term, *F*, in the Navier-Stokes equations, Eqn (6).

$$\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = -\frac{1}{\rho}\nabla p + \nu\nabla^2\boldsymbol{u} - \nu F(\varepsilon)\boldsymbol{u} \quad (6)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Many model parameters are taken from literature, but some are estimated from an *in vitro* study of thrombus growth in a BFS using magnetic resonance imaging (MRI) [5]. The governing equations are solved using the open-source CFD toolbox OpenFOAM in a 3D BFS domain (Fig. 1). Steady flow, resulting in a laminar upstream Reynolds number of 490, is imposed at the inlet to match the experimental conditions [5], and 10 ms time steps are used to simulate thrombus growth for 30 min. The computational domain matches the dimensions of the *in vitro* model and consists of 2.15 million cells.

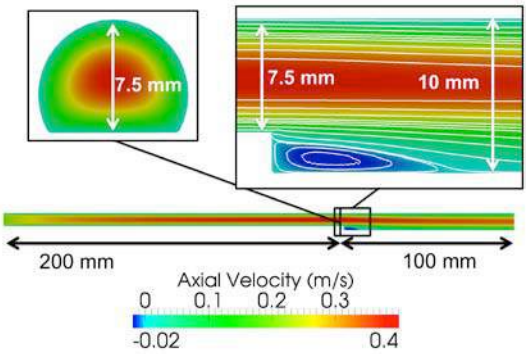

Figure 1: Axial velocity distribution in the BFS domain. An axial slice through the centerline is displayed in the bottom of the image, with two regions selected for enlargement. In the upper left, a transverse cross section just upstream of the step is displayed. In the upper right, a portion of the axial centerline near the step is displayed, with contour lines used to illustrate flow recirculation. Additionally, the velocity scale is non-linear to accentuate regions of flow reversal (dark blue).

RESULTS

Simulated thrombus growth begins near the step, in the region of separated flow, and thus low WSS, produced by the sudden expansion and at the reattachment point (see Fig. 2). The two distinct thrombi merge between 5 and 10 min into the simulation and continue to grow into the lumen. Thrombus growth reaches the step height after approximately 20 min (Fig. 2D), and by 30 min, nearly the entire initial region of flow separation is filled with thrombus.

Fig. 3 provides a quantitative look at simulated thrombus growth, and direct comparisons between the CFD and *in vitro* [5] results. Both thrombus height and length are normalized by the step height, 2.5 mm, and the trend for thrombus height shows excellent agreement with the MRI data, as quick initial growth approaches a normalized asymptotic height near one (Fig. 3A). However, the thrombus appears to initially lengthen much too quickly, but this is due to the fact that some deposition occurs near the reattachment point within the first few minutes of the simulation. There is nice agreement between the predicted and *in vitro* length at 25 minutes, but the predicted length is much longer at 30 minutes than that determined with MRI: 7.5S and 4.7S, respectively (Figure 3B). Nevertheless, if simulated thrombus length is extrapolated toward 60 minutes, it appears the simulation and MRI results will again agree.

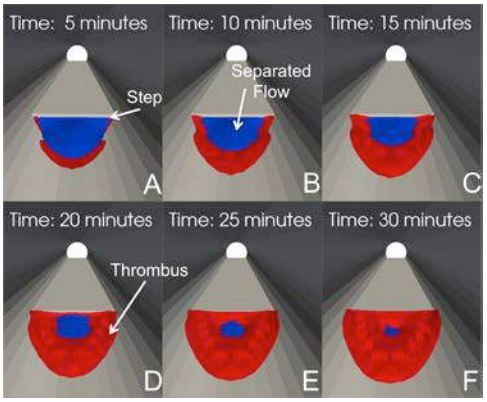

Figure 2: Simulated thrombus growth for (A) 5 minutes, (B) 10 minutes, (C) 15 minutes, (D) 20 minutes, (E) 25 minutes, and (F) 30 minutes of blood flow.

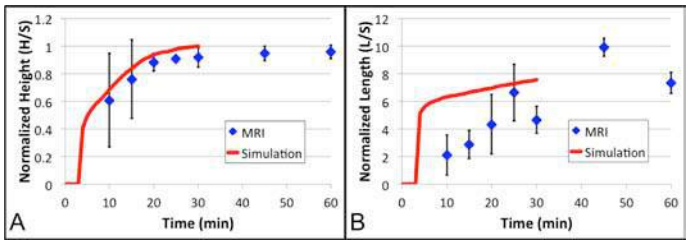

Figure 3: Simulated thrombus (A) height and (B) length compared to the MRI results of Taylor *et al.* [5], and both thrombus height (H) and length (L) are normalized using the step height (S). Error bars denote the 95% confidence intervals of the MRI data.

DISCUSSION

A thrombosis model is used in a three-dimensional BFS domain, and the present simulations represent the first three-dimensional growth simulations of a thrombus on spatial and time scales relevant to medical devices. The simulations show great promise toward the eventual application to medical device development, as thrombus deposition location, general shape, and height trends all agree well with the *in vitro* thrombus data [5]. However, additional work is still needed to ensure thrombosis model accuracy under more clinically relevant flow conditions, such as pulsatile or turbulent flow. Importantly, the three-dimensional simulation results provide evidence that the reduction of the thrombotic process to the present governing equations is appropriate in situations relevant to device-induced thrombosis, as simulated thrombus growth agrees, at least macroscopically, with the *in vitro* whole blood experiments [5], and thus the full thrombotic network.

INTRODUCTION

The mechanical behavior of ligament is governed by the organization and composition of its fibrous protein network. To stabilize joints, ligaments resist deformation by storing energy (elastic properties) and dissipating energy (viscoelastic properties). The structural origin of these mechanical properties is either the fibrillar network or the ground substance of the extracellular matrix. Type I collagen is the primary load bearing constituent of ligament, however it is unknown what features of the collagen fibrillar network are required to successfully describe the viscoelastic mechanical behavior. A focus has been placed on measuring collagen material features such as fiber orientation, fiber dispersion (or alignment index), fiber diameter, and number of intersections [1,2]. Typically, healthy ligament contains very aligned (low dispersion) collagen networks, however, it can also exhibit disordered or multiaxial fiber networks [3,4]. Disorganized collagen networks are also prevalent throughout granulation tissue and scar tissue and may be connected to inferior mechanical properties observed in repaired ligament [5,6]. Multi-scale analysis of tendon has shown that fiber sliding was the largest contributor to stress relaxation [7], however the connection between viscoelastic properties and fibril organization in ligament tissue remains unclear.

Understanding the relationship between structure and function of collagen networks can give insight into pathologies associated with damaged ligament and assist in treatment development. The objective of this study is to determine if correlations exist between collagen fibril orientation distribution and the viscoelastic behavior of ligament.

METHODS

Overview. Forty ligament specimens from ten adult bovine hooves were mechanically tested in uniaxial tension under cyclic loads. Collagen fibril microstructure was imaged using confocal microscopy and analyzed using the fast Fourier transform (FFT) to quantify the fibril orientation distribution. Regression analysis was performed to determine relationships between the fibril orientation distribution and mechanical properties of the specimens.

Test Protocol. The lateral collateral sesamoid ligament (LCSL) and palmar annular ligament (PAL) were harvested from ten bovine hooves. Fascicle orientation in the LCSL tissue was visibly aligned, whereas the PAL tissue contained more disorder. Dog-bone shaped specimens were prepared in both the transverse (trv) and longitudinal (lng) directions of primary loading. Mechanical testing was performed using an Instron E10000. After preconditioning and a 2-minute rest period, the specimen was pulled to 5% or 8% clamp strain for transverse and longitudinal samples, respectively. Stress relaxation was measured for a 2-minute interval; viscoelastic testing proceeded with ten 1 Hz sinusoidal cycles oscillating from 4 to 6% clamp strain for transverse samples and 7 to 9% clamp strain for longitudinal samples. Data from the last four cycles was used for mechanical analysis [8].

Confocal Imaging and Image Processing. At the conclusion of testing, the samples were sliced to 50 μm using a cryostat at -20°C. The 405 nm laser of a confocal microscope, in coordination with ZEN software, was used to capture the autofluorescence of collagen fibrils by utilizing the 63x objective lens [9]. Three z-stack projections were obtained for all LCSL longitudinal specimens (Figure 1A) and all PAL specimens (Figure 1B), for a total of 90 z-stacks.

Image analysis was performed to determine the fibril orientation distribution for each specimen. Each z-stack projection was first filtered using ImageJ and saved as an 8-bit grayscale image. FiberFit, an FFT software program developed internally, was used to quantify the fibril orientation distribution. The preferred fibril orientation, θ_p and fibril dispersion, k were used to define the semi-circular von Mises distribution (P) for each collagen network. In addition, we defined a third term called

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the fiber contribution factor (*FCF*). In Figure 1C, the fibril stretch λ and von Mises distribution P are plotted with respect to the spatial orientation θ. The light gray shaded region represents the fibrils in tension ($\lambda \geq 1$). The dark-gray area, where the fibrils are in tension represents the *FCF*. The remaining fibrils are in compression and, therefore are assumed to not resist tensile deformation.

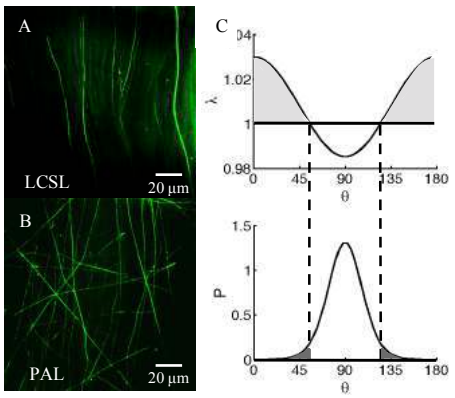

Figure 1. Collagen fibril networks captured with confocal microscopy: (A) LCSL and (B) PAL tissue. (C) Graphical representation of FCF calculation.

Statistical Correlations. A MANOVA was used to test for differences in microstructural properties (θ_p, k, and *FCF*) and mechanical properties (dynamic modulus, stress relaxation, and phase shift) across groups; the four groups were defined by the loading direction (longitudinal or transverse) and ligament (LCSL or PAL) ($p_{critical} = 0.05$). Microstructural properties that showed significance between groups were used as predictors for regression models.

RESULTS

Microstructural Properties. The PAL and LCSL tissues had significant differences in preferred orientation and *FCF* (Table 1). For the transverse specimens, the average preferred orientation was further from the loading axis in the LCSL specimens when compared to the PAL specimens ($p = 0.048$). In addition, the aligned LCSL tissue had a lower *FCF* than the disordered PAL tissue ($p = 0.001$). There were no differences observed between PAL and LCSL specimens for the longitudinal loading direction.

Table 1. Microstructural parameters from confocal images

Specimen Type	Fibril Dispersion Mean $k \pm$ SD	Preferred Fibril Orientation Mean $\theta_p \pm$ SD (°)	Fiber Contribution Factor (*FCF*)
LCSL Lng.	5.58 ± 5.04	4.8 ± 14.1	0.95 ± 0.05**
LCSL Trv.		94.8 ± 14.1*	0.15 ± 0.12*
PAL Lng.	3.21 ± 3.03	4.8 ± 18.6	0.92 ± 0.06**
PAL Trv.	1.24 ± 0.79	2.6 ± 56.3	0.58 ± 0.25*

Note: 0° is along the loading axis. * = significant difference from all other groups, ** = significant difference from both transverse groups

Mechanical Properties. The dynamic modulus and stress relaxation results reflected the microstructural results. In the transverse loading direction, the disordered PAL tissue had a higher dynamic modulus and stress relaxation than the more aligned LCSL tissue ($p = 0.002$ and $p < 0.0005$), however the phase shift did not show any differences (Figure 2A-C). In the longitudinal loading direction, there were no differences between the PAL and LCSL tissues.

Regression Analysis. Using *FCF* as a predictor gave moderate correlations for the transverse loading direction. The *FCF* describes 20% of the variation in dynamic modulus, 22% of the variation in stress relaxation, but only 7% of the variation in phase shift (Figure 2D-F).

DISCUSSION

This study investigated the correlations between microstructural collagen organization and ligament mechanical behavior. Using confocal imaging and FFT analysis, fibril orientation distribution parameters were quantified and regression analysis revealed several important correlations. There were only moderate correlations between the *FCF* and viscoelastic properties, except for the phase shift, which did not show a correlation. The dynamic modulus and stress relaxation both followed the same trends as the elastic modulus, suggesting a relationship between elastic and viscoelastic mechanical properties.

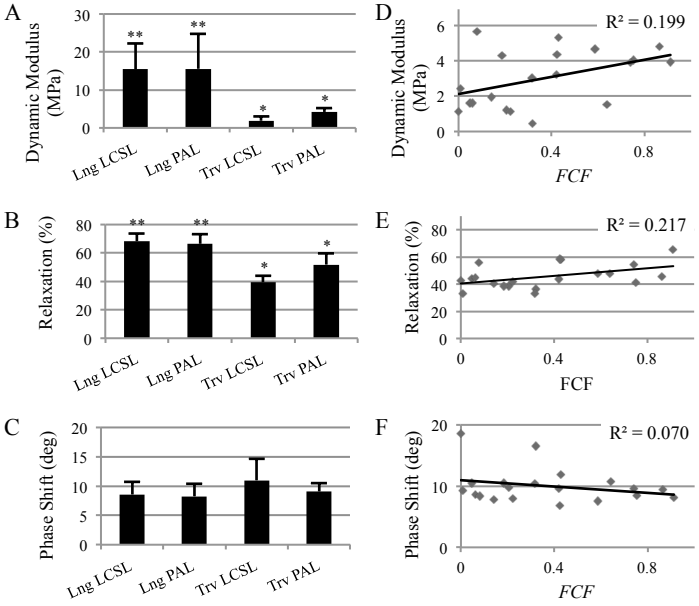

Figure 2. Viscoelastic properties of LCSL and PAL specimens: (A) dynamic modulus, (B) stress relaxation, and (C) phase shift with corresponding correlations (D-F).

Note: * = Significant difference from all other groups, ** = significant difference from both transverse groups

It is important to note that for the bovine ligament specimens used in this study, the fibril dispersion was not significantly different among testing groups and required the novel *FCF* term to see differences in microstructure. The results from this study indicate that both the fibril dispersion and orientation are important when describing mechanical properties of ligament tissue. While moderate correlations were present, this study also suggests that other microstructural properties may be required in order to accurately predict ligament mechanical behavior. This may include specimen specific fiber density or average fiber diameter.

This study had limitations. Bovine ligament was used instead of human ligament. However, published mechanical properties are similar [10,11]. In the described imaging methodology, both collagen and elastin were captured under autofluoresence. While elastin only makes up about 5% of ligament dry weight, it still likely influences the calculated microstructural parameters [12]. Additionally, only one strain rate was used for viscoelastic analysis.

In summary, this study suggests that viscoelastic mechanical behavior of ligament cannot be described solely using the orientation distribution of its collagen fibril network. However, it is clear that both the orientation and dispersion of fibrils are important parameters to include in constitutive models describing energy dissipation mechanics of collagenous soft tissues.

INTRODUCTION

Cerebral aneurysms is a common disease affecting a significant portion of the population (estimated at 2-5%) [1]. Rupture of an intracranial aneurysms have devastating consequences with high mortality and disability rates. Consequently, many physicians often preventively treat incidentally discovered aneurysms. However, the treatment risk can exceed the low natural risk of rupture of incidental aneurysms [2]. Therefore, it is important to precisely distinguish high risk aneurysms for immediate treatment from low risk aneurysms which could be conservatively followed.

Several patient, demographic and behavioral characteristics have been investigated as possible risk factors, including gender, age, family history, smoking and hypertension, population, etc. According to past studies, the most important aneurysm-specific rupture risk factors are size and location [3]. In particular, aneurysms in the posterior circulation have been shown to have in general higher rupture risk than aneurysms in the anterior circulation. The cause of this difference in rupture risk is largely unknown [4]. Since aneurysm evolution is thought to be governed by a progressive degradation and weakening of the wall in response to abnormal hemodynamics [5], it is reasonable to ask whether differences in the aneurysm hemodynamics, induced by different configurations and geometries of vessels of the anterior and posterior circulations, could help explain the different rupture rates.

The purpose of this study was to test this hypothesis by comparing the hemodynamic environments of aneurysms at the tip of the basilar artery (posterior circulation) and aneurysms at the internal carotid artery bifurcation (anterior circulation). These two locations were selected because they are anatomically similar, i.e. the terminal bifurcation of a major feeding artery, but one in the anterior circulation and the other in the posterior circulation.

METHODS

We have developed a database of intracranial aneurysms imaged with 3D rotational angiography (3DRA). This database contains 3DRA images and anonymized clinical information including rupture status, size and location, gender and age, etc. of approximately 1800 intracranial aneurysms. All aneurysms from our database located at either the tip of the basilar artery (BAtip) or the terminus or bifurcation of the internal carotid artery (ICAbif) were included in the study.

A total of 117 aneurysms were studied, 63 at the BAtip (27 ruptured, 36 unruptured, rupture rate=43%), and 54 at the ICAbif (11 ruptured, 43 unruptured, rupture rate=20%).

Computational fluid dynamics (CFD) models of all 117 aneurysms were constructed from the corresponding 3DRA images. Pulsatile simulations were carried out by numerically solving the 3D unsteady Navier Stokes equations assuming Newtonian viscosity and rigid walls. The simulations had a minimum mesh resolution of 200 μm and a time resolution of 0.01 sec and were run for two cardiac cycles. A number of flow variables were then computed from the results of the second cycle to characterize the aneurysm flow conditions [6, 7].

To test whether aneurysms at the BAtip have different hemodynamic environments than those at the ICAbif, and if ruptured and unruptured aneurysms have different flow conditions at each of these two location, the set of flow variables used to characterize the intracaccular flow environment were compared between these groups using the Mann-Whitney U test. Differences were considered statistically significant if $p<0.05$ (95% confidence).

RESULTS

The distribution of ruptured and unruptured aneurysms at the BAtip and ICAbif are presented in Fig.1(a). A 2x2 contingency table

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

analysis based on the Fisher exact test confirmed that there is a statistically significant association between the location at the BAtip or the ICAbif with aneurysm rupture (p=0.0107).

Comparisons of flow variables between all aneurysms at the BAtip and at the ICAbif are presented in Fig.1(b). Similarly, comparisons of flow variables between ruptured and unruptured aneurysms at the BAtip and ICAbif are shown in Fig.1 (c) and (d), respectively. The bars in these graphs represent the ratio of mean values of variables of the BAtip group over mean values of the ICAbif groups. Variables that are significantly different between these groups are marked with a *.

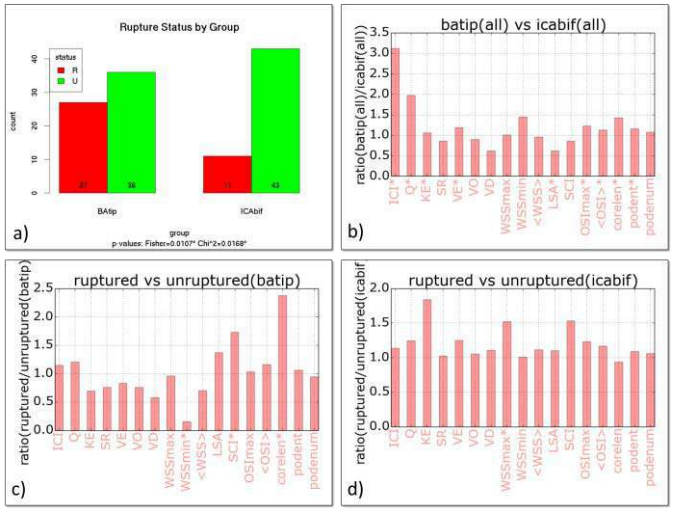

Fig. 1: Distribution of ruptured and unruptured aneurysms at the BAtip and ICAbif (a). Comparison of flow variables between BAtip and ICAbif aneurysms (b) and between ruptured and unruptured aneurysms at the BAtip (c) and the ICAbif (d).

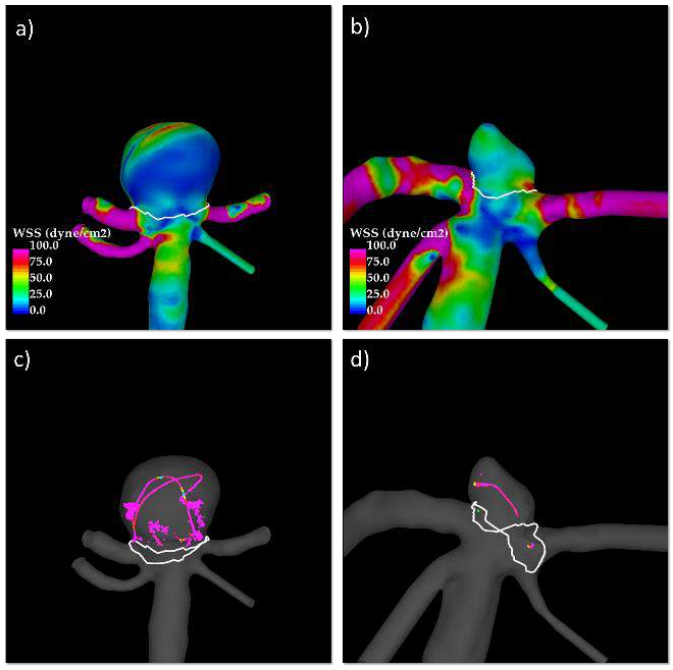

Fig. 2: BAtip: concentrated WSS (a) and complex flow (c) in ruptured aneurysm; diffuse WSS (b) and simple flow (d) in unruptured aneurysm.

On average, aneurysms at the BAtip had more concentrated inflow jets (ICI, p<0.001), larger inflow rates (Q, p<0.001), larger maximum oscillatory shear index (OSI, p=0.003), more complex flows (corelen, p=0.033) and smaller areas under low WSS (LSA, p<0.001) than aneurysms at the ICAbif (Fig.1 b).

Ruptured aneurysms at the BAtip had more concentrated wall shear stress distributions (SCI, p=0.011), more complex flows (corelen, p<0.001) and smaller minimum WSS (p=0.012) than unruptured aneurysms at this location. On the other hand, ruptured aneurysms at the ICAbif had larger maximum WSS (WSSmax, p=0.017) than unruptured aneurysms at this location.

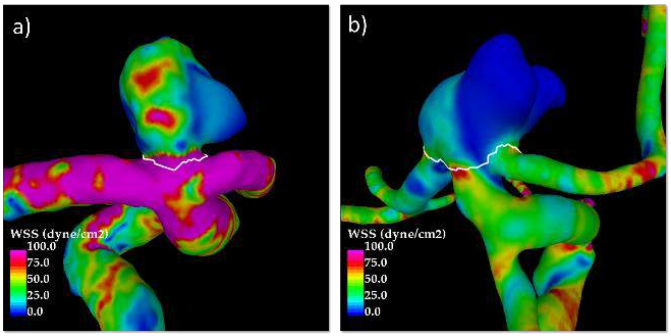

Fig. 3: ICAbif: high maximum WSS in ruptured aneurysm (a); low maximum WSS in unruptured aneurysm (b).

Examples of ruptured and unruptured aneurysms illustrating the statistically significant differences between ruptured and unruptured aneurysms at the BAtip and ICAbif are presented in Fig. 2 and 3, respectively.

DISCUSSION

According to our series, aneurysms at the basilar tip have a rupture rate larger by a factor of 2.15 than aneurysms at the internal carotid bifurcation.

Compared to aneurysms at the ICA bifurcation, aneurysms at the basilar tip have different hemodynamic environments, characterized by higher flow conditions (higher inflow rate into the aneurysm, more concentrated inflow jets, more unstable and oscillatory flow patterns, and smaller areas under low wall shear stress). These differences are likely due to the different configuration (bifurcation asymmetry, bifurcation angles, etc.) and geometry (curvature, tortuosity, tapering, etc.) of the internal carotid and basilar arteries.

At each of these two locations, a different set of flow variables associated with rupture. This observation suggests that at both locations hemodynamics may play an important role in the evolution and rupture of aneurysms, but the underlying mechanisms may be different.

MECHANICAL EFFECTS OF DYNAMIC BINDING BETWEEN TAU PROTEINS ON MICROTUBULES DURING AXONAL INJURY

INTRODUCTION

The unique viscoelastic nature of axons is thought to underlie selective vulnerability to damage during axonal injury. In particular, dynamic loading of axons has been shown to mechanically break microtubules and create axonal swellings at the time of injury. Alternatively, under slow pulling rates, axon has been shown to resist large tensile strain without any evidence of microtubule rupture or cytoskeletal damage. In our previous work[1] we presented a computational model for uniaxial tension of axon where a bundle of microtubules were interconnected by tau proteins and the applied load was transferred through the sliding and stretching of the microtubules, regulated by the tau proteins. There we showed that the viscoelastic behavior of the tau proteins could increase the chance of the microtubule rupture at the time of the injury[1]. Although the mentioned model was successful to predict the rate dependent behavior of the axons observed in experimental studies, here in the next step we present a more comprehensive model where by including the rupture of the connections between the linking tau proteins, the pathway of the load transfer within the axon can be obstructed and correspondingly the axon response can be altered. In this model$_2$, under different pulling rates, we monitor the rupture of the connections between the attached tau proteins and the tensile force exerted on the microtubules and at the end, present conditions leading to the rupture of the microtubules or the complete disassembly of the microtubule bundle. By including the rupture of the interconnecting elements within the axon, our current model can provide a picture of the damaged axon following traumatic brain injury where distinct regions including ruptured microtubules and disassembled microtubule bundles can be distinguished explicitly.

METHODS

Our axon model consists of staggered array of MTs with length L, outer and inner radii 12.5 nm, 7 nm enclosed by the axon lipid membrane. Tau proteins are bonded to the outer surface of the MTs at their MT binding domains while the distance between the adjacent tau proteins on a single MT is 30nm. Also the zipper bond dimer configuration is adopted for the connection between the tau proteins belonging to neighboring MTs. To include the viscoelastic response of the tau proteins, we modeled the tau proteins with two parallel springs, representing the backbone stiffness and the rate-dependent stiffness that arises from the intramolecular bonds within the tau protein.

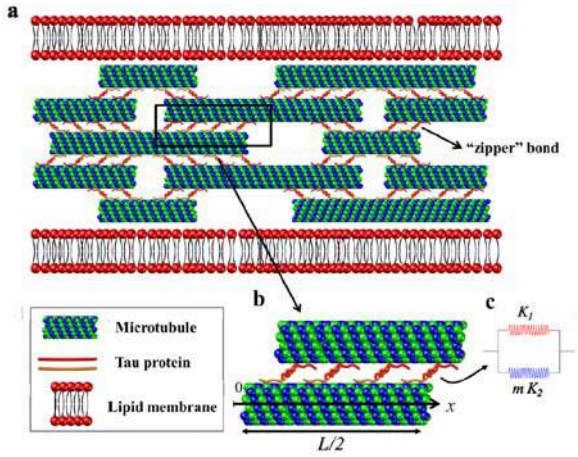

Fig. 1. (a,b) Axon model consists of MTs and tau proteins enclosed by axon lipid membrane. (c) A mechanical element for the tau proteins.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

While the connection between the two tau proteins can rupture at a critical force, floating end of a free tau protein can still reattach to the tail of the next available tau protein and reengage in the load transfer mechanism if the applied loading rate is sufficiently slow (quasi-static loading). As illustrated in Fig. 2, this recruitment process of the free tau proteins can be repeated until the ends of the adjacent MTs pass each other.

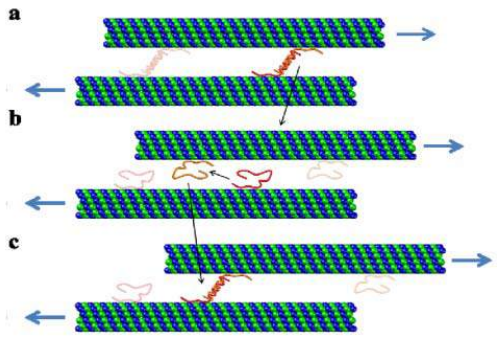

Fig. 2. (ac) Recruitment of the free tau proteins after rupture incorporated in our model when the loading rate is sufficiently slow (quasi-static loading).

RESULTS

MT rupture is sensitive to strain rate compared to strain

As shown in Fig. 3, under dynamic loading rates (1–50 sec-1), MTs are under a significantly larger force (almost 3–4 times) than the quasistatic rate. In this case, the large force can lead to the rupture of the MTs and the subsequent interruption of the cargo transport similar to the observations for the axons injured by TBI. For the unruptured MTs, due to the large extension of the tau proteins, the zipper bond connecting tau proteins start to break. Eventually by the rupture of the majority of the interconnections, the unruptured MT bundle disassembles and the force-strain curve displays a rapid drop as the axon loses its load bearing capacity completely.

For the quasi-static loading the axon behavior is considerably different. While the force exerted on the MTs is significantly small compared to the dynamic loading, with the help of the reformation process (explained in Fig. 2), the free tau proteins can still reengage in the load transfer mechanism and avert the drop of the force. As a result, we observe a slow decline in the force as well as the concentration of the connected tau proteins with strain.

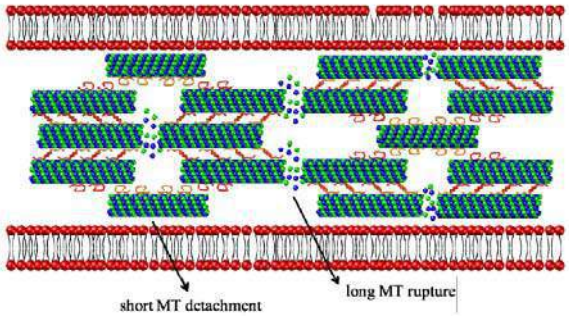

Fig. 3. (left) The force exerted on the MTs at different strain rates. The MT length is 200μm in both figures.

The pattern of the MT bundle disassembly depends on the strain rate

By increasing the applied tensile strain, the connections between the attached tau proteins start to rupture. As shown in Fig 4 the model predicts that under the fast loading rate, the rupture of the tau-tau bonds starts from the ends of the MTs and progresses sequentially toward the interior points. In the contrary under slow loading rate, these bonds rupture simultaneously and cause a rapid drop in the stiffness of the axon at a threshold strain.

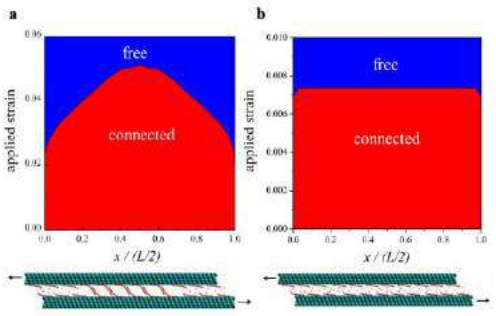

Fig.4. Breaking of the tau-tau connection by (a): fast (50 sec-1) and (b): slow (quasi-static) loading rates. MT length is 50μm.

Following TBI, the long MTs inside the axon break while the short MTs detach from the MT bundle.

For varying lengths of for the microtubules under a fast pulling rate, we obtained the force exerted on the microtubules with strain. Our model predicts that the long MTs inside the axon experience large tensile forces while the short MTs undergo relative sliding with respect to the neighboring MTs without any significant force. On the other hand, the tau proteins attached to long MTs undergo different degrees of elongation depending on their position relative to the MT ends while, the tau proteins connecting the short MTs are extended equally to accommodate the relative sliding. As a result, while the large force on the long MTs would eventually break the MT, the large sliding of the short MTs would result in the MT disassembly from the rest of the MTs by an instantaneous rupture of the interconnection bonds between the tau proteins. Based on this prediction, our model presents a picture of the damaged axonal cytoskeleton by injury. In this picture (Fig 4) the long microtubules are broken while the short microtubules are detached from the microtubule bundle and remain unaffected.

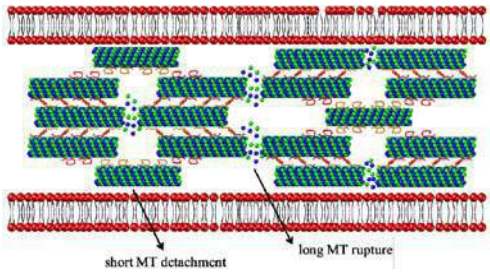

Fig. 5. Predicted damaged picture of the axon following TBI.

Discussion

In this study we presented a computational model to explain the axonal pathology observed in traumatic brain injury. While the fast loading rates rupture the long microtubules inside the axon, the slow loading rates cause disassembly of the unruptured microtubules.

INTRODUCTION

Tendon injury is a common clinical problem characterized by slow recovery and high recurrence after treatment. Adult tendon heals via fibrosis (scarring), and this failure to re-establish native tendon structure is likely the leading cause of injury recurrence. Improving tendon healing to a regenerative, tenogenic state is therefore a crucial research priority. In a previous study, we showed that neonatal mice may harbor a unique regenerative capacity [1]. Lineage tracing further revealed that neonatal and adult tendons heal via distinct cellular mechanisms; while the cells driving neonatal regeneration are recruited from intrinsic tenocytes, the cells driving adult fibrosis are completely derived from extrinsic cells [2]. To date, considerable evidence in the literature suggests that adult tendon healing results in impaired ultrastructure and mechanical properties, however the functional outcomes of neonatal tendon healing have not been fully investigated. The objective of the current study was therefore to determine long-term structural and functional properties of tendon after neonatal and adult injury.

METHODS

Achilles tendons of postnatal day P5 (neonate) or P112 (adult) ScxGFP mice [3] were transected at the mid-substance and left unrepaired, in accordance with IACUC, while contralateral tendons were used as non-injured controls. For consistency, all surgeries were carried out on the right hindlimb. To determine matrix ultrastructure, transmission electron microscopy (TEM) was carried out for d56 transverse sections (n=3), and collagen fibril diameters measured using Image J. To determine mechanical properties, tensile testing was carried out on d56 samples (n=12). Briefly, tendons were preloaded to 0.05N for ~1 min, followed by ramp to failure at 1%/sec in PBS at room temperature. Gait analysis was performed on injured and non-injured mice at d3 and 14 after injury using the Digigait Imaging System with treadmill speed of 5 cm/s (n=5). Parameters were normalized to Stride length to minimize variations due to mouse size. Neonatal tendons were also harvested at d3, 7, 14, and 28 after injury for RNA isolation (Trizol-chloroform), cDNA synthesis and qPCR amplification with SYBR Green (n=5-7). Expression data was quantified relative to standards generated from E14.5 embryonic limbs, and normalized to GAPDH. In situ hybridization (ISH) and immunostaining was carried out on d 14 cryosections. For statistics, qPCR data were analyzed using two way ANOVA with Tukey's posthoc with timepoint and injury as independent variables (Systat). Mechanical and gait data were analyzed using paired t-tests. Significance was set at $p<0.05$.

RESULTS

We previously showed that neonatal tendons regenerate a *ScxGFP*+ 'neo-tendon' structure following complete transection, in contrast to adult tendons, which heal via formation of *ScxGFP*-negative tissue (**Fig 1**). Immunostaining for laminin and αSMA (two myofibroblast markers) showed strong positive staining throughout the newly formed tissue in adults and weak punctate staining in the 'neo-tendon' in neonates at d14 after injury (not shown). Real time qPCR analysis showed enhanced expression of tendon markers after neonatal injury, with detectable differences in *Scx* and *Tnmd* by d14 ($p<0.05$) while *Mkx* expression was not significantly increased until d28 ($p<0.05$) (**Fig 1**). ISH using a probe against *Scx, Col1a1,* and *Tnmd* detected expression in both control tendon and injured 'neo-tendon' by d14 (not shown). **Collectively, these results suggest that neonatal tendons heal via tenogenesis while adult tendons heal via fibrosis.**

To determine structural properties, we used TEM imaging to assess collagen fibril diameter. Overall, collagen fibril diameter was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

highly reduced in injured tendon from both neonatal and adult groups compared to respective controls. While control tendons showed a heterogeneous distribution of fibril diameters across a wide range of sizes, fibril diameters in injured tendon were far more homogeneous. However, the fibril population of the neonatal injury group showed a shift toward fibrils of larger sizes (~3x the number of >60 nm fibrils) compared to adult injury tendons which had a higher population of lower sized fibrils (2x the number of <60 nm fibrils) (**Fig 2**).

Interestingly, while the matrix of injured tendons appeared immature, tensile properties of neonatal injured tendons were fully restored by d56, with no difference in maximum load or stiffness ($p>0.1$) (**Fig 3A**). In contrast, adult tendon stiffness remained lower after injury. Using gait analysis as an additional assay for function, we identified parameters associated with injury using d3 adult injured mice. These parameters include %Swing, %Brake, and %Propel, all of which were significantly different between the left and right hindlimbs of injured mice (**Fig 3B, C**). Notably, no difference was ever detected between hindlimbs of non-injured age-matched mice. While %Swing was recovered in both injury groups by d14, %Brake and %Propel remained significantly abnormal. However, the difference between left and right hindlimbs was much reduced in the neonatal group compared to adult for both parameters, suggestive of rapid recovery (%Brake: 25% vs 50% diff; %Propel: 17% vs 25% diff). **Taken together, our functional data suggests that neonatal tendons heal more rapidly compared to adult tendons with restoration of tendon properties.**

DISCUSSION

In this study, we test the regenerative capacity of neonatal tendon and show that mechanical properties are restored following complete transection in neonates, in contrast to adult tendon, in which mechanical properties are permanently impaired [4, 5]. We further demonstrate that neo-tendon differentiation after injury begins at d14, coincident with upregulation of tenogenic markers *Scx* and *Tnmd*. Delayed expression of *Mkx* is consistent with its role in collagen maturation during development [6]; however, the overall small size of fibrils after injury suggests that additional factors that regulate matrix maturation may not be present. This is supported by recent data in which ectopic Mkx expression in MSCs resulted in only a modest increase in fibril diameter [7]. This dichotomy suggests that Mkx may be necessary but not sufficient for matrix maturation. Finally, although gait parameters are not fully recovered at d14, we already observed more rapid recovery compared to adult at this early timepoint; evaluating later timepoints is the focus of ongoing work.

COAGULATION CASCADE MODEL REDUCTION USING A GENETIC ALGORITHM

Kirk B. Hansen and Shawn C. Shadden

Department of Mechanical Engineering
University of California, Berkeley
Berkeley, CA, US

INTRODUCTION

The coagulation cascade is a complex system of biochemical reactions involving dozens of reactive species. It is mathematically modeled by a system of ordinary differential equations (ODEs) for the well-mixed case, or by advection-diffusion-reaction partial differential equations (PDEs) for the flow-mediated case. Due to the many species that must be tracked, numerical problems introduced by the high Schmidt and Peclet numbers inherent to intra-arterial mass transport problems, and a wide range of temporal scales, computational modeling of these types of problems is often prohibitively expensive, especially for three-dimensional, unsteady, patient-specific cases [1]. These models also require the knowledge of a large number of parameters (e.g. 42 reaction rates and 34 initial conditions in the well-known Hockin-Mann model [2]), many of which are impossible to ascertain on a patient-specific basis.

Previous researchers have shown that thrombin generation curves can be reproduced by significantly simplified models [3, 4]. These models, however, ignored intermediate species that may be important in incorporating additional aspects of clot formation, e.g. activated and non-activated platelets. The parameter fitting methods were also not reported. In this work, we develop a framework for coagulation cascade model reduction using genetic algorithm optimization techniques.

METHODS

The reduced-order model chosen for this work describes the tissue-factor-initiated extrinsic pathway to thrombin generation, and is based on the model suggested by Wagenvoord et al. [3]. A schematic of the model is shown in Fig. 1. The model includes eight biochemical species, although only seven are solved for as the tissue factor concentration is considered known. The reactions between the species are controlled by seven rate constants. Although Wagenvoord et al. suggested the use of Michaelis-Menten kinetics, linear reactions were found to be sufficient and are used in this work for simplicity. For example, the ODE for thrombin generation is

$$\frac{d[\mathrm{IIa}]}{dt} = k_0[\mathrm{Xa}][\mathrm{II}] + k_1[\mathrm{Va{:}Xa}][\mathrm{II}] - k_2[\mathrm{IIa}]. \qquad (1)$$

By employing a reduced-order model, the reactions actually represent systems of reactions, and thus the kinetic rate constants are unknown. These rate constants are found by fitting the reduced-order ODE system results to those obtained with the Hockin-Mann model [2].

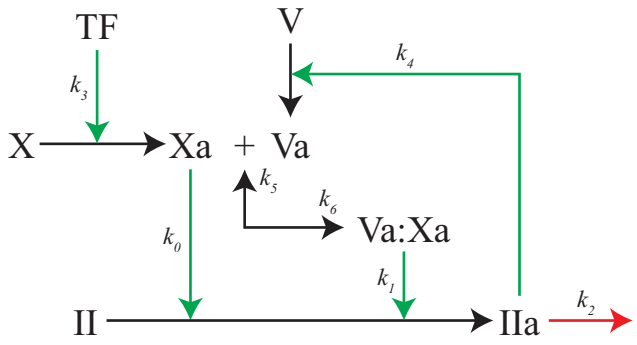

FIGURE 1: REDUCED-ORDER EIGHT-SPECIES MODEL OF THE TISSUE FACTOR (TF) INITITIATED EXTRINSIC COAGULATION CASCADE TO THROMBIN (IIa) PRODUCTION.

To fit the reduced-order model results to those from the full model, a cost function was defined as

$$\Phi = \sum_{i=1}^{n_{\text{species}}} \sum_{j=1}^{n_{\text{tsteps}}} w_i \left[\tilde{c}_i(t_j) - c_i(t_j)\right]^2, \qquad (2)$$

where w_i is a weight for species i, t_j is the time at timestep j, and $\tilde{c}_i$ and c_i are the concentrations of species i obtained using the Hockin-Mann and reduced-order models, respectively. The weighting function is used to normalize the influence of each species by its maximum concentration. It can also be used to assign a greater weight to species that are deemed more important; in this work a five-times greater importance was assigned to thrombin concentration.

The cost function defined in Eq. (2) was minimized using a continuous, unbounded genetic algorithm. All operations were performed on the logarithms of the rate constants both to ensure positiveness and to allow them to evolve by orders of magnitude. Initial guesses for the rate constants were taken from the Hockin-Mann model. A population of 300 was initially seeded with Gaussian

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

distributions around the guesses. Tournament selection, uniform crossover, and Gaussian mutation were performed for each of 500 generations to evolve the population. The crossover and mutation steps utilized an adaptive algorithm to facilitate convergence to the best-fit solution [5]. Genetic algorithms do not guarantee convergence to a minimum value, so the algorithm was run ten times.

RESULTS AND DISCUSSION

Time evolution curves for each species are shown in Fig. 2. The reduced-order results for all species show a good fit to those obtained with the Hockin-Mann model. The thrombin (factor IIa) generation curve, which was weighted five times more than the others, shows excellent agreement.

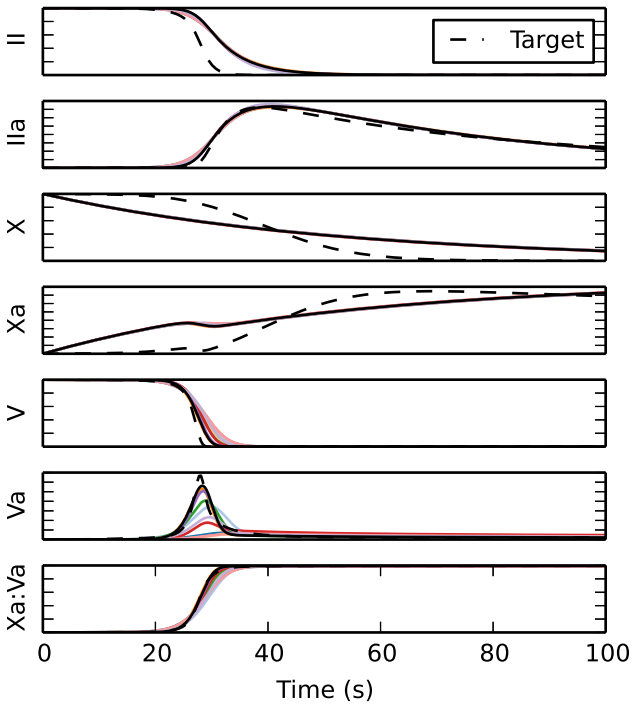

FIGURE 2: RESULTS FROM TEN RUNS OF THE GENETIC ALGORITHM. THE DASHED LINE IS THE OUTPUT OF THE HOCKIN-MANN MODEL, AND THE BLACK SOLID LINE IS THE BEST FIT.

These results indicate that such a reduced-order model is capable of describing the coagulation cascade. While other researchers have found that thrombin generation curves can be accurately reproduced by reduced-order models, this is the first work that has shown that an optimized model can replicate the other key species as well. This is significant, as it allows for the incorporation of additional biophysics with the coagulation model. For example, some reaction rates are dependent on the local availability of binding sites on activated platelets. Properly modeling the evolution of species involved in these reactions allows for the coupling of platelet activation and coagulation cascade submodels, whereas a coagulation cascade model optimized only to reproduce a thrombin generation curve would produce erroneous results.

The reduced-order model provides an improvement over more comprehensive models such as Hockin-Mann for two key reasons. First, by reducing the number of species equations from 34 to 7, the required computational cost is reduced by nearly a factor of five. This cost reduction could be significant when incorporated into thrombosis models that are already computationally expensive. Second, the number of rate constant parameters is significantly reduced, in this case from 42 to 7. This reduces the severely underconstrained nature of trying to fit such a model to limited patient-specific data.

INTRODUCTION

Recent studies have showed unsatisfying recurrence of severe mitral regurgitation 3-5 years after initial surgical repair, suggesting that surgery-induced excessive tissue stresses and the resulting tissue failure are related to the success of surgical repair for treating mitral valve (MV) diseases [1-3]. Moreover, the underlying biomechanical behaviors of soft tissues and cellular mechanobiological responses are critical in design of individual-optimized surgical repair strategies with improved long-term durability. Therefore, quantification of the regional tissue stresses, characterization of the MV leaflet mechanical behaviors, and quantification of the mitral valve interstitial cell (MVIC) deformations at normal and surgically repaired conditions are the main focus of this work. In this study, we used an enhanced finite element (FE) based inverse modeling method combined with the in-vivo kinematics for estimating the valvular stresses. This work sheds light on proper linking of in-vitro mechanical testing data with clinical in-vivo modeling and will ultimately help in gaining insight into the primary drivers for MV remodeling in response to surgical repair.

METHODS

Sonocrystal data acquisition, key kinematic states, and in-vivo deformation analysis: Previously, we have used 3D echocardiography for acquiring the in-vivo sonocrystal data of the ovine mitral valve anterior leaflet (MVAL) in large animal studies using six 35-40kg male adult Dorset sheep [4]. Sonomicrometry positional data were taken at an acquisition interval of 5 ms (Fig. 1a) and transvalvular pressure was monitored over cardiac cycles (Fig. 1b). The 3D positional data were then used for the subsequent analysis of MVAL deformations and strains as well as the inverse modeling based estimation of the in-vivo valvular stresses. Here, we adopted the notations for each kinematic state (Fig. 1c): in-vitro reference state (β_0) for biaxial mechanical testing, in-situ unloaded state (β_1), in-vivo reference state (β_2) associated with onset ventricular contraction, and pressure-loaded state (β_t). Based on the population-averaged positions (n=6) of the four corner fiducial markers at various states, in-surface deformation gradient tensors ${}^1_0\mathbf{F}$, ${}^2_1\mathbf{F}$, and ${}^2_0\mathbf{F}$ were quantified using one single 4-node bilinear finite element.

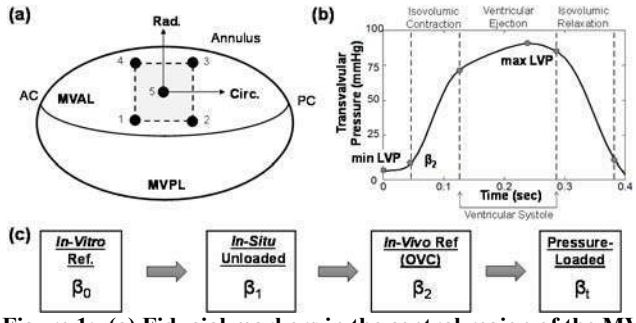

Figure 1: (a) Fiducial markers in the central region of the MV anterior leaflet, (b) typical pressure profile over the cardiac cycle, and (c) key states for analyzing the deformation and strain.

Estimation of the in-vivo functional valvular stresses: The inverse modeling technique developed previously [5] was modified into a two-stage FE simulation to account for the measured deformation gradient ${}^2_0\mathbf{F}$ between states β_2 and β_0 in the in-vivo parameter quantification. Briefly, the MVAL FE model with discretized 1,600 (40x40) shell elements was allowed to deform freely with the inversion of ${}^2_0\mathbf{F}$ employed throughout the tissue to simulate the shrinking process from the in-vivo reference state to the in-vivo

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

reference state. The inverse modeling was performed to quantify the in-vivo mechanical properties of the MVAL by accounting for the pre-strains (from β_0 to β_2) and simulating MV deformations over the cardiac cycle (from β_2 to β_t) with prescribed transvalvuar surface pressure (Fig. 1b) and time-varying boundary displacements. The in-vivo valvular stresses were then estimated using the optimal parameters obtained from the genetic algorithm based global optimization. Note that a simplified structural constitutive model, linking the 2nd Piola-Kirchhoff stress tensor **S** and the Green strain tensor **E**=(**C**-**I**)/2 with fiber unit vector **N**=[cos(θ), sin(θ)]^T, was used in the inverse modeling pipeline, which consists of five parameters (matrix neo-Hookean parameter η_m, two collagen fiber parameters c_0 and c_1, and the preferred fiber direction μ_Γ and fiber splay σ_Γ):

$$\mathbf{S}(\mathbf{E}) = \eta_m(\mathbf{I} - C_{33}^{-1}\mathbf{C}^{-1}) + \int_{-\pi/2}^{+\pi/2} \Gamma(\theta;\mu_\Gamma,\sigma_\Gamma)\, c_0(e^{c_1\mathbf{N}\cdot\mathbf{E}\mathbf{N}} - 1)\mathbf{N}\otimes\mathbf{N}d\theta \quad (1)$$

Liking with cellular deformations: Following the previously developed down-scale modeling approach [6], one representative volume element (RVE) model of the MVIC microenvironment was constructed for each of the four tissue layers, *atrialis*, *spongiosa*, *fibrosa* and *ventricularis* layers, by accounting for layer respective compositions and microstructural information. In brief, the measured deformation gradients ${}^1_0\mathbf{F}$ and ${}^1_2\mathbf{F}$ were incorporated as boundary displacements on the RVE model to quantify the layer-specific MVIC deformations at both in-vitro and in-vivo reference states. Here, a dimensionless indicator—nucleus aspect ratio (NAR), which is the ratio of the circumferential dimension to the transmural dimension, was used for quantifying the layer-specific MVIC deformations.

RESULTS

Averaged positions with their variations of the fiducial markers at various states were obtained from the sonocrystal data (Fig. 2a) with their respective quantified deformation gradients between any two states (Fig. 2b), demonstrating fairly isotropic pre-stretches (λ_C=1.323 and λ_R=1.346) exhibited in the MVAL tissues from the in-vitro reference state (β_0) to the in-vivo reference state (β_2).

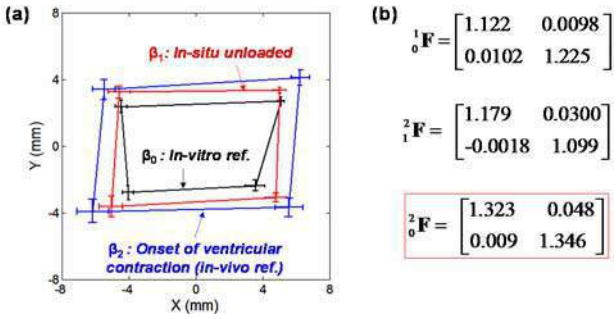

Figure 2: (a) Averaged positions of the fiducial markers at various kinematic states, and (b) quantified deformation gradient tensors.

Using the quantified in-vivo mechanical properties based on the inverse modeling approached and incorporating the analyzed deformation gradient ${}^2_0\mathbf{F}$, the functional valvular stresses along the circumferential and radial directions at the in-vivo and in-vitro reference states were estimated (Fig. 3a-b). The amount of the pre-stresses for the MVAL tissues was also determined from the FE-based numerical calculations (σ_C=30.4 kPa, σ_R=20.4 kPa).

By applying the tissue-level deformations as boundary displacements on the MVIC microenvironment model, the layer-specific NARs were for the first time quantified from the FE simulations of each RVE model for the four MVAL tissue layers. Interestingly, we found substantial discrepancy between the predicted extracellular (ECM) deformation and cellular deformation (Fig. 4a) and larger values of NAR and d(NAR)/dt in the fibrosa layer (Fig. 4b-c), which is the primary load-bearing layer consisting of dense collagen fiber networks along the circumferential direction.

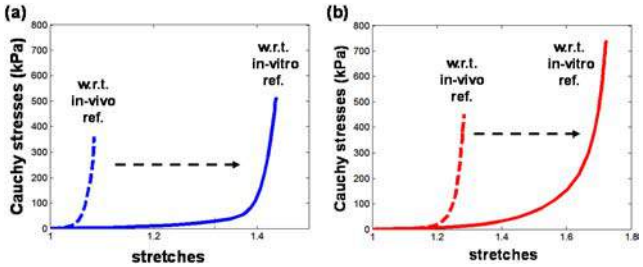

Figure 3: Predicted functional stresses of the MVAL tissues at β_2 and β_0 in the (a) circumferential and (b) radial directions.

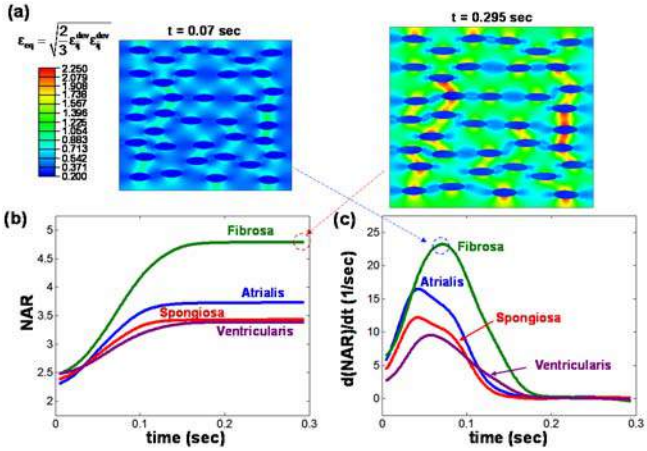

Figure 4: (a) Predicted von Mises equivalent strain (ε_{eq}) profiles of the fibrosa RVE model at the highest deformation rate (0.07 sec) and at the largest deformation (0.295 sec). (b-c) Predicted layer-specific MVIC deformations and rates with respect to state β_0.

DISCUSSION

The estimated pre-stresses were relatively small compared to the estimated in-vivo functional stresses. The results also indicated that the long toe-region of the MV stress-strain relation, typically observed in in-vitro mechanical testing data, is completely taken up by the pre-strain in the in-vivo functional state. Moreover, the novel predicted in-vivo MVIC deformations demonstrated substantial layer-specific variations in the deformation level and rate during isovolumetric contraction. Finally, the proposed modeling approaches are currently applied for estimating repair-induced changes of the MV stresses and MVIC deformations with various annuloplasty ring designs, and the acquired information will be integrated with the computational framework for organ-level simulations of the MV closing behavior [7], which will ultimately help in developing optimal therapeutic strategies with best restoration of MV functionality and improved durability.

UPPER CERVICAL SPINE LOADING SIMULATING LOW-SPEED COLLISIONS SIGNIFICANTLY INCREASES FACET STRAINS COMPARED TO EQUIVALENT QUASISTATIC LOADING

INTRODUCTION

Between one-quarter and one-third of people exposed to low-speed rear-end collisions experience neck injury [1], and 15-40% of those injuries will develop into chronic neck pain, which can extend to the head, shoulders, and arms [2]. In 35-60% of people with chronic neck pain, the cervical facet joint is its source [3-5], with the C2/C3 and C5/C6 levels most common for trauma and idiopathic origin [3-5].

The facet capsule has both low- and high-strain threshold units, which discharge at 10% and 47% strain, respectively [6]. Some low-threshold units are likely to play a role in proprioception, but capsular strains as low as 19% have been shown to induce behavioral sensitivity in the absence of any facet capsule ligament failure [7]. Although facet strain has been related to injury from dynamic loading exposures, the regional strain magnitudes, and their relationships to facet kinematics during such loading is not known.

Despite a high prevalence of injuries from dynamic neck loading and the large proportion of injuries being attributed to the upper cervical spine [3-5], the full-field strain responses of the C2/C3 facet capsule are not known. Further, the facet's behavior during potentially injurious exposures has not been contextualized relative to vertebral kinematics. This study investigated the response of the C2/C3 facet joint to dynamic flexion-extension loading using a human cadaveric model, and compared the vertebral rotations and full-field capsular strains at C2/C3 with those responses during quasistatic loading to determine if, and how, dynamic loading increases the risk of C2/C3 facet capsule injury and whether the vertebral rotations in the upper cervical spine are alerted compared to normal physiological loading

METHODS

Fresh frozen, ligamentous specimens from the occiput (Occ) to the C3 vertebra (n=6), were acquired by appropriate methods and procedures for our institution. Specimens were potted in a two-part fast curing polymer (Smooth Cast 300; Smooth-On, Inc.) combined with self-tapping screws and Kirschner wires to aid fixation. A surrogate replicating the mass and moment of inertia of the human head [8] was affixed to the occiput, and the C3 vertebra was rigidly fixed to an actuation cradle coupled to a servo-hydraulic MTS test machine (Fig. 1a). The cranial end allowed movement only in the sagittal and axial planes. Tracking markers were placed on the head, C1 and C2, the cradle, and to the surface of the C2/C3 facet capsule.

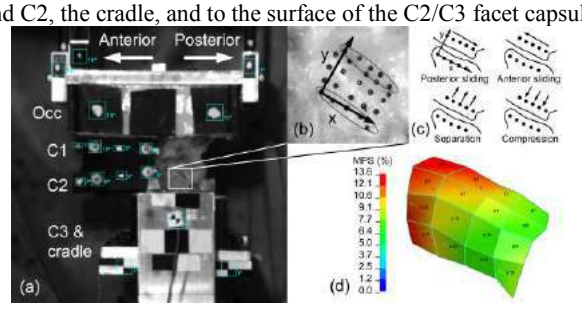

Fig. 1. Sagittal view (a) of an occiput-C3 specimen, with tracking markers. The C2/C3 facet capsule was imaged (b) to measure facet kinematics (c); 3D reconstructions were used for MPS (d) and SS.

Quasistatic flexion/extension loading was applied over physiological ranges of motion (ROMs) before and after dynamic loading to provide comparison data and to assess the effect of dynamic loading on neck kinematics. The vertebral motions and C2/C3 three-dimensional (3D) deformations of the facet capsule surface were acquired during all tests. Quasistatic testing was performed by manually guiding the head through flexion/extension with the C3 vertebra held stationary. For dynamic loading, the head was held in the neutral position using an electromagnet and was released upon actuation of C3 via the cradle. To simulate the rotation of the C3

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

vertebra during low-speed rear-end and frontal collisions [9], dynamic tests were imposed at 100°/s to 6.1° in each of flexion and extension. A high-speed camera (V4; Vision Research) tracked the vertebral kinematics in the sagittal plane. Two additional cameras (Miro eX1; Vision Research) tracked the capsule markers (Fig. 1b) to measure the C2/C3 kinematics (Fig. 1c) and linear strain across the facet [10]; and enabled the 3D reconstruction of the capsule. Using that reconstruction, the maximum principal strain (MPS) and shear strain (SS) on the surface of the C2/C3 facet capsule was estimated (Fig. 1d), using images at 20ms prior to actuation as the reference (0% strain) condition. All image data were synchronized and captured at 1kHz.

The quasistatic tests for each specimen were compared at 1° increments of global ROM from 16° of flexion to 13° of extension. Comparisons of the rotation at each cervical level (Occ/C1, C1/C2, C2/C3) relative to the global ROM were made using two-way repeated measures ANOVAs. Wilcoxon signed-rank tests compared the MPS and SS of the C2/C3 level at 10ms intervals over 150ms during dynamic loading with those strains at equivalent rotations during quasistatic loading.

RESULTS

The intervertebral rotations during quasistatic loading were not altered at any level by the dynamic loading (Occ/C1 p=0.997; C1/C2 p=0.999; C2/C3 p=0.714). The average respective acceleration and deceleration of the MTS actuator during dynamic tests was 2.8±0.8g and 2.8±0.8g in flexion, and 1.8±0.2g and 2.8±0.3g in extension. Dynamic flexion initially produced extension at C2/C3 (maximum 2.2±0.7°), which was reversed when actuation stopped, forcing the C2/C3 joint into flexion (maximum 2.4±2.1°). The opposite response was produced in dynamic extension, with C2/C3 rotation first peaking in flexion (1.4±1.1°) and then moving into extension (maximum 1.5±1.0°). The maximum and minimum rotation in dynamic tests was generally less than rotation during quasistatic tests.

Both the MPS and SS were inhomogenous in both dynamic and quasistatic loading (Fig. 2). The location of the peak MPS was in the center and towards the anterior aspect of the facet capsule in dynamic flexion (Fig. 2), and in the center and towards the posterior aspect of the capsule in dynamic extension. The direction of the peak MPS was orientated approximately along the facet joint, particularly in the region of the capsule where the peak MPS was sustained (Fig. 2a).

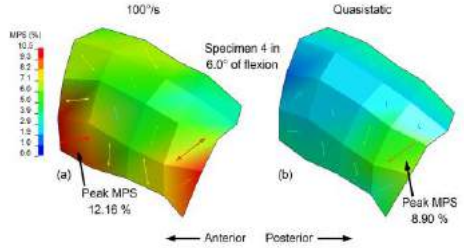

Fig. 2. Inhomogeneous MPS at its peak during dynamic flexion and for quasistatic loading at equivalent C2/C3 vertebral rotation.

Strain during dynamic flexion continued to increase after C3 rotation stopped, peaking at 12.5±4.6%. Quasistatic loading produced significantly lower (p=0.028) MPS (7.6±4.4%) at equivalent C2/C3 rotations (Fig. 3a). In contrast, dynamic extension produced peak strains during the actuation of C3, and did not alter the MPS at equivalent quasistatic C2/C3 rotations (Fig. 3a). The maximum SS was significantly greater in both dynamic flexion (p=0.028) and extension (p=0.028) compared to quasistatic loading at equivalent C2/C3 rotations (Fig. 3b); yet, minimum shear strains were not different.

Posterior-anterior facet sliding exhibited similar behavior, with the facet undergoing posterior sliding during actuation in dynamic flexion, changing to anterior sliding at approximately the time that actuation stopped; the reverse occurred in dynamic extension. Peak posterior-anterior sliding of -1.1±0.5mm in dynamic flexion and 1.2±0.5mm in dynamic extension were significantly greater than during equivalent quasistatic C2/C3 rotations (p≤0.043). There was more facet compression in dynamic flexion than equivalent quasistatic loading (p=0.027); yet, the magnitudes were small and all within 0.5mm of separation and 0.6mm of compression. The maximum linear strain across the facet joint of 3.9±1.5% in dynamic flexion and 2.8±1.2% in dynamic extension was lower than the peak MPS from the full-field analysis. No differences were detected between the linear facet strain in dynamic and quasistatic loading (p>0.35).

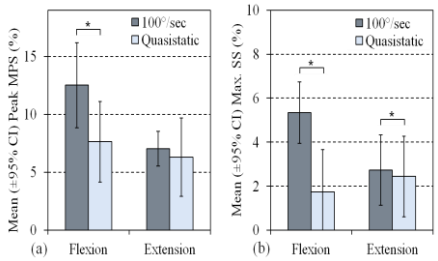

Fig. 3. Peak MPS & maximum SS in dynamic (100°/sec) flexion is greater (*p=0.028) than in quasistatic loading.

DISCUSSION

Dynamic flexion simulating a low-speed, rear-end collision increases the C2/C3 facet capsule strains compared to quasistatic loading at equivalent joint rotations (Fig. 3). Since vertebral rotations during dynamic loading remain within physiological ROMs [11], the increased strains may be due to abnormal local joint motions. The inertia of the head when C3 stops moving altered the flexion/extension behavior of C2/C3. In dynamic flexion this inertial effect produced increased peak MPS, maximum SS, and maximum anterior facet sliding compared to equivalent quasistatic loading.

Full-field capsular strain analysis shows that both MPS and SS were inhomogeneous (Fig. 2). Peak MPS during dynamic flexion approached the magnitude that has been reported to lead to pain (19.4±11.4%) from facet capsule stretch in the rat [7], suggesting the potential for tissue injury. Assessing linear facet strain [10] did not reveal differences between dynamic flexion and quasistatic loading, suggesting that full-field strain measurements of the capsule more accurately identify local responses within the facet capsule, and may, be better for predicting the risk of injury, pain and/or other pathophysiological dysfunctional responses due to traumatic exposure.

Combining these data with microstructural analyses of the tissues could help fully define how such loading exposures occur, and what conditions pose the greatest risk of injury. The results also indicate that the deceleration following a rear-end collision is critical for altering facet mechanics and generating the peak strains, which provides a potential for injury mitigating designs and approaches.

INTRODUCTION

Knowledge of subject-specific muscle volumes can be used to estimate muscle forces and joint loads, patient strength, and to properly scale computational muscle models. Historically in biomechanics, cadaver data were used to make these estimates, but muscle volumes vary significantly between cadavers and *in vivo* imaging [1]. Cadaver data are limited due to dehydrated muscle in fixed static poses and are usually not of healthy populations. In vivo imaging studies to date have been limited in population size, thus calling into question the ability to generalize these data to large, diverse clinical populations. Hence, there has been a drive towards population based modeling from large image datasets.

Current methods for predicting muscle volumes use either manual or semi-automated segmentation, both of which require manual user intervention and are not practical for large populations. Previous studies using model-based muscle volume predictions used only a few anatomical inputs, such as muscle lengths, shapes and belly cross sections; have been based on manually segmented datasets from Magnetic Resonance Imaging (MRI), which is less abundant clinically than Computed Tomography (CT) data; and have used only athletic humans which may not be applicable to sedentary populations [1-4].

The aim of this study was to develop a population-based statistical tool to rapidly predict lower limb muscle volume from sedentary and non-sedentary population data. This model was designed to be fast, utilize simple anthropometric inputs and be validated against manually segmented MRI data. Statistical models allow for quick muscle volume prediction, which can be used to compute subject-specific muscle forces, and can be used to compare biomechanics between populations.

METHODS

CT image data was obtained with ethical approval (applications EC9/2007 and EC10/2007) from the Victorian Institute of Forensic Medicine (VIFM), the University of Melbourne. Data were from thirty healthy individuals with no pathologies. Half of the subjects were male with an average age of 56 ± 26 years, weight of 65 ± 13 kg and height of 167 ± 6 cm, while the female subjects had an average age of 50 ± 25 years, weight of 66 ± 17 kg and height of 160 ± 6 cm.

Total muscle volumes were acquired by semi-automatically segmenting the CT images to extract total lower limb muscle volume from the top of the iliac crest to the malleoli. The algorithm used image filtering (adjusted to the population set) to define bulk muscle boundaries, and voxel clustering to segment the bulk muscle volume. Once the total muscle volume was extracted, individual muscle volumes were calculated using known leg muscles proportions [1,3].

Partial Least Squares Regression (PLSR) [5] was used to model the relationships between total muscle volume and anthropometric measurements, thereby creating a total muscle volume predictor. Measurements used were height, weight, sex, age, leg length, thigh length, shank length, thigh girth, shank girth, and Anterior Superior Iliac Spine (ASIS) distance, which is the distance from the left pelvic ASIS point to the right pelvic ASIS point. The PLSR predictor was validated firstly using a 'leave-one-out' analysis, and secondly using manually segmented muscle volumes from an independent MRI study [1]. The 'leave-one out' analysis predicted each subject's muscle volume using a predictor trained on all other subjects' data, and compared the prediction to the subject's segmented volume. The second validation used a predictor trained on all 30 subjects to predict

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the muscle volumes of a separate dataset of MRI subjects with known anthropometry and muscle volume [2]. In a further analysis, step-wise regression (using the Akaike Information Criteria (AIC) fitness criterion [6]) was used to determine the optimal subset of anthropometric parameters needed to predict muscle volume using linear regression [6]. Figure 1 highlights the general methodology for this study.

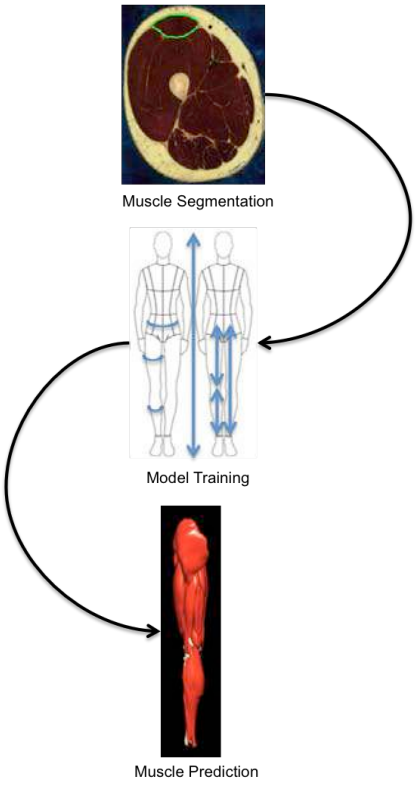

Figure 1: Muscle volume prediction framework

RESULTS

The R^2 prediction error from the 'leave-one-out' analysis was 0.96 using all anthropometric measurements, 0.84 when only given height, and 0.90 when given height and weight. For the MRI dataset, the PLSR-predicted and segmented muscle volumes yielded an average R^2 of 0.91 using all anthropometric measurements.

The optimal step-wise regression model yielded an adjusted R^2 of 0.93 using seven anthropometric measurements (Table 1). The most significant anthropometric measurements were shank girth, sex, leg length, age, and shank length, in that order. Height and thigh girth were insignificant components in the optimal model, while ASIS distance, weight, and thigh length were discarded by the stepwise regression.

Table 1: Results of anthropometric parameters significance.

Parameters	Estimate	Std. Error	t value	Pr(>|t|)	Signif. Code
Sex	3190209	786464	4.056	0.00365	**

Age	-56171	20985	-2.677	0.02807	*
Leg Length	33566	8722	3.849	0.00489	**
Thigh Girth	-17864	16039	-1.114	0.2977	
Shank Length	12567	5076	2.476	0.03837	*
Shank Girth	101960	21048	4.844	0.00128	**
Signif. Codes:	0 '***'	0.001 '**'	0.01 '*'	0.05 '.'	0.1 ' '

DISCUSSION

The PLSR model was able to explain 91% of the variation in muscle volume when all parameters were included through evaluation against a second MRI study. This offers confidence in the PLSR model, which can only improve with larger population training sets.

The results of this study show that sex, leg length and shank girth are the most important variables for predicting muscle volume. This suggests there is a significant difference between the muscle volumes of the lower limb in females and males. It also suggests that shank girth is important, which could be due to lower fat-to-muscle ratio in the shank area (as opposed to thigh areas).

An interesting result was the 2 non-significant covariates in Table 1, thigh girth and height. This suggests that, since height is highly related to leg length, with either contribution the other is made redundant. The fact that thigh girth was not significant in the step-wise regression suggests that in the general population, thigh girth is more dependent on body fat percentage than muscle volume.

These findings offer a better understanding of muscle volume anthropometric dependencies. It presents ability to quickly generate lower limb muscle volumes for population analysis and muscle force predictions scaled by muscle volume. This in turn will help clinical analysis of musculoskeletal joint loadings.

ACKNOWLEDGEMENTS

The authors of this study would like to thank the MedTech Core seed project for funding this study, the VIFM and Dr Jacqui Hislop-Jambrich for providing the CT images.

PATIENT-SPECIFIC CFD OF CLINICAL MITRAL REGURGITATION AS A NOVEL METHOD TO QUANTIFY REGURGITATION SEVERITY

INTRODUCTION

Mitral regurgitation (MR) is a highly prevalent cardiovascular disease which is estimated to affect significant number of people[1, 2]. MR results from incomplete closing of the mitral leaflets. Correct assessment of MR severity is crucial in utilizing the protocols needed for prognosis, disease management and patient outcome.

Doppler echocardiography is routinely used to quantify the MR severity. It can potentially provide the information about type and mechanism of regurgitation, anatomical features, extent of regurgitation and reparability assessment. Current gold standard is the 2D proximal isovelocity surface area (PISA) method which is based on the conservation of mass principle. As the fluid is squeezed through the orifice, it forms a series of concentric hemispherical shells of decreasing surface area and increasing velocities. Known limitations of the 2D-PISA method include heavy user dependency, poor repeatability, sensitivity to orifice shape and the need for the angle correction[3].

In this study, we propose a novel method of MR assessment, which relies on the curve fitting between 3D clinical color Doppler data of the regurgitation and data from patient-specific CFD of the same valve. We first demonstrate the feasibility of performing patient-specific CFD of mitral regurgitation based on clinical ultrasound scans. Subsequently we performed experimental assessment of our new technique and found it to be more precise, and in some cases, more accurate, than 2D PISA.

METHODS

Patient-specific CFD of mitral regurgitation was performed as follows: 3D B-mode ultrasound scans of the mitral valve and 3D color Doppler images of regurgitant jet were obtained from the National University Hospital, Singapore. Images were exported as a stack of images and was segmented with VMTK, an open-source software. (www.vmtk.org). The regurgitation jet segmentation was subtracted from the mitral valve segmentation to create the regurgitation orifice (Figure 1). CFD simulation of the regurgitation was then performed for this patient-specific geometry using an assumed physiological pressure gradient of 120 mm of Hg.

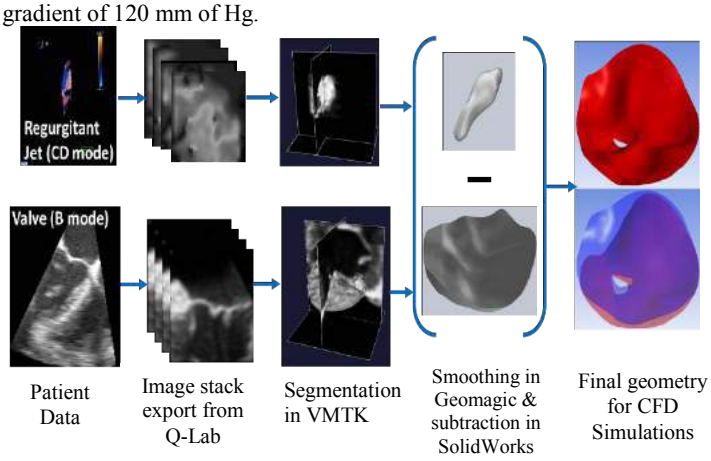

Figure 1: Schematic of methods used to perform patient-specific CFD of mitral regurgitation based on ultrasound scans.

The above CFD technique was then applied to quantify mitral regurgitation by curve fitting of the resulting CFD velocities in the flow convergence zone to the 3D clinically imaged Color Doppler data of the same valve. Our technique is summarized as follows:

Step 1: Obtain 3D color Doppler velocities (V_{us}) and 3D B-mode data of the valve from clinical ultrasound scan.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Step 2: Run CFD of regurgitation at an assumed flow rate (Q_{CFD}) to obtain velocities (V_{CFD}) at the same points as ultrasound data.

Step3: Finding the mean ratio between numerical and Ultrasound velocities: $Mean\ Ratio = \frac{1}{N}\sum_{all\ points}(V_{CFD}/V_{US})$

Step 4: Rescaling Q_{CFD} to obtain the predicted regurgitation flow rate:

$$Q_p = \frac{Q_{CFD}}{Mean\ Ratio} \qquad (1)$$

To validate our proposed method, we set up a steady flow loop to simulate the mitral regurgitation in vitro (Figure 2). Detachable plate with orifice allowed for incorporation of different orifice shapes. For this study, a circular and a slit orifice were experimented with. Experiments were performed at 5-7 different flow rates and a research 3D ultrasound machine (SonixTablet, Ultrasonix Inc) was used to obtain the ultrasound Color Doppler data. Simulations were ran with Ansys Workbench (Ansys Inc.), and the above 4 step technique was used to compute regurgitation flow rate. The results were compared to the truth flow rates obtained via physical measurements.

Figure 2: The experimental flow loop setup. White arrows show the flow direction.

RESULTS

Figure 3 shows the CFD results of patient specific real valve geometry under physiological pressure gradient. Results from our proposed method were compared with 2D-PISA method.

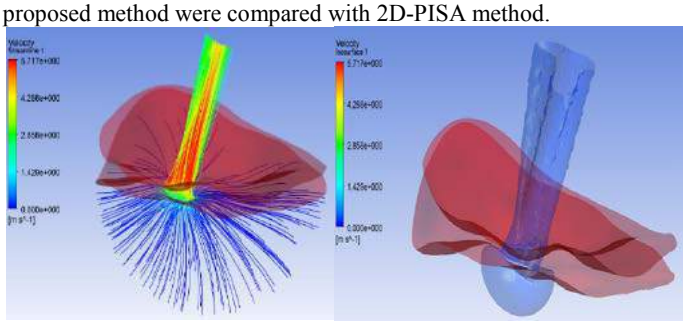

Figure 3: Streamlines (left) and iso-velocity surface (right) of the flow convergence zone CFD results based on ultrasound scans of a mitral regurgitation patient

Fig. 4 compares the results of proposed method with 2D-PISA method for circular orifice. As can be seen that our method accurately predicts the regurgitant flow rate (<5% error) while 2D-PISA incurs large inaccuracies especially at higher flow rates. For slit orifice our method had comparable accuracy with that of 2D-PISA method. However, in both orifices, our method had better precision, as can be observed by the smaller standard deviations.

(b)

Figure 4: Comparison of predicted flow rate for circular (a) and slit orifice (b) between 2D-PISA method and proposed method

DISCUSSION

Our work can show that ultrasound-based CFD is a r ealistic technique that can be used to aid patient diagnosis. In the current study, we show that such simulations can be used for improved quantification of the mitral valve regurgitation flow rates, but other applications such as understanding the energy losses of blood flow, turbulent stresses imposed on bl ood to cause blood damage, and the shear stresses imposed by blood on the mitral valve, can be realized as well.

Our new method for quantification of mitral regurgitation showed promise, in the two simplified orifices tested, our technique showed excellent accuracy for circular orifice (<5 %, better than 2D PISA) and comparable accuracy 2D PISA for the straight slit orifice (mean error of <9 %), and our technique showed consistently higher precision. These could be explained by considering that our technique uses the curve fitting of an entire velocity field instead of a single PISA radius measure for flow rate quantification, rendering it less sensitive to localized noise and imaging errors.

Our future work includes in vitro testing of the new technique with more orifice shapes, such as a realistic 3D printed valve geometry, and in vivo testing of the efficacy of our technique in diagnosis and prognosis of mitral regurgitation patients.

ENDOTHELIAL CELL GLYCOCALYX MODULATES SHEAR-INDUCED TUBULE FORMATION

P. Zhao, X. Liu, X.Y. Deng

Key Laboratory for Biomechanics and Mechanobiology of the Ministry of Education, School of Biological Science and Medical Engineering, Beihang University, Beijing, China.

INTRODUCTION

Angiogenesis, the process of blood vessels form from existing ones, is the most common form of vessel formation during development and in adulthood. Abnormal or immature angiogenesis has been implicated in more than 70 disorders such as obesity, asthma, diabetes, cirrhosis, multiple sclerosis, endometriosis, AIDS, bacterial infections and autoimmune disease so far, and the list is ever growing [1]. Sprouting angiogenesis, known as the major form, involves a series of cellular events including basal membrane degradation, endothelial cell proliferation and migration, tube formation and pericyte recruitment.

Although the detailed mechanism leading to pathological angiogenesis remains unknown, flow-induced stress has shown significant impact on vessel growth. Early studies by Clark et al. [2] demonstrated that small blood vessels exposed to high shear stress sprouting while vessels tend to regress after a decrease or a halt in the flow. Recent investigations indicate shear stress on endothelium regulate endothelial cell (ECs) morphology and function, hence affect angiogenesis. Kang et al. [3] found that the distance of endothelial cell invasion into three-dimensional collagen matrices was proportional to the magnitude of shear stress. An in vitro study by Tressel et al. [4] reported that laminar shear stress inhibits endothelial cell migration and tubule formation, two important functions in blood vessel formation..

The responses of ECs to shear stress have been investigated extensively. However, how shear stress is sensed and transmitted into chemical signals and thereby regulates neovascularization is still uncertain. Previously, various membrane molecules and cellular microdomains were proposed as mechanosensors of endothelial cells, including integrins, G proteins, growth factor receptors, caveolae, ion channels, adhesion proteins and the cytoskeleton [5]. Recent researches on the glycocalyx have verified its pivotal role in the shear stress–sensing mechanism.

Endothelial glycocalyx layer (EGL), coating at the luminal surfaces of vascular endothelium, is a bush-like structure composed of heparan sulfate (HS), chondroitin sulfate (CS), and hyaluronic acid (HA) [6]. Theoretical study indicates that flow-induced shear stress can hardly act on ECs directly but is transmitted to the cells largely by the EGL [7]. Experimental studies demonstrated that glycocalyx modulates cell proliferation, migration and shear-induced nitric oxide release of vascular endothelium in response to fluid shear stress [8]. All of these functions are essential in sprouting angiogenesis.

Therefore, we hypothesizes that as a mechanotransducer, the endothelial glycocalyx may sense the change of shear stress, hence affect the sprouting angiogenesis. To test the hypothesis, we investigate the tubule formation of endothelium exposed to shear stress in a parallel-plate flow chamber.

METHODS

A parallel plate flow chamber was employed to expose human umbilical vascular endothelial cells (HUVECs) monolayers to a physiological level of shear stress (15 dyn/cm^2) for 24 hours. Heparinase II (Hep.II) was applied to selectively degrade heparan sulfate on the ECs surface. Then, cells were used in Matrigel tubule formation assay and total tubule length was compared among the following four groups of cells: 1) untreated with no flow, 2) Hep.II treatment with no flow, 3) untreated with flow of 15 dyn/cm^2 exposure, and 4) Hep.II treatment with flow of 15 dyn/cm^2 exposure.

RESULTS

Tubule formation was observed using a phase contrast microscope at 5x magnification (Fig. 1) and total tubule length was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

quantified using AngioTool. Results show that flow-induced shear stress significantly suppressed endothelial tubule formation in cells without Hep.II treatment, whereas the suppression was reduced in sheared, enzyme treated cells. No difference of total tubule length was found between enzyme treated and untreated cells in static state (Fig. 2).

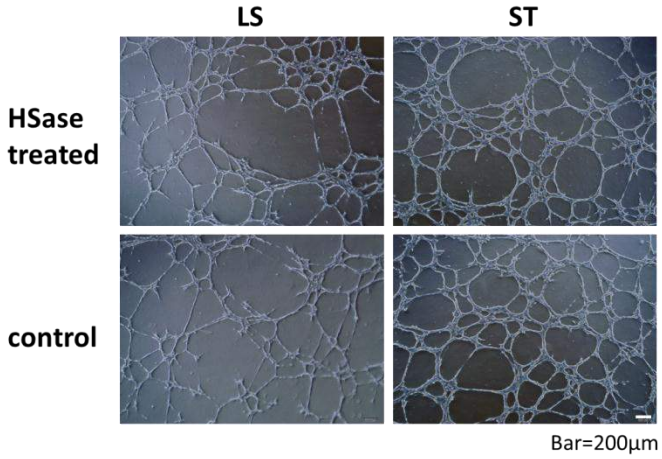

Figure 1: Endothelial cells tubule formation on Matrigel. Enzyme treated and untreated cells showed different capacity of tubule formation in laminar shear (LS) and static state (ST).

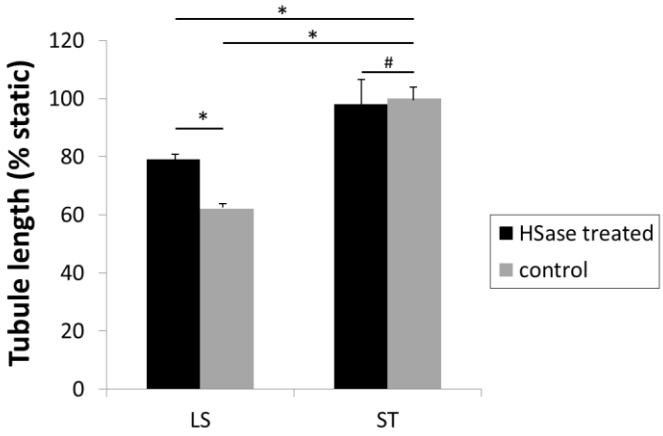

Figure 2: Shear stress inhibits endothelial cell tubule formation. (mean±SD, *P<0.05, #P>0.05)

DISCUSSION

Since angiogenesis involved in so many diseases, controlling angiogenesis has become an important therapeutic target nowadays. Among the numerous factors, shear stress is considered as a strong stimulus to angiogenesis, but the specific mechanism is unclear. Recent studies have shown that the endothelial glycocalyx acting as a mechanotransducer, play important role in fluid shear stress transmission and transduction. In the present work, we try to detect the relationship between glycocalyx and angiogenesis. To this end, one of the classic assays for angiogenesis study, endothelial cell tubule formation which focuses on the ECs differentiation was observed.

We found that laminar shear stress could suppress ECs tubule formation, indicating flow-induced shear stress may inhibit angiogenesis, which is consistent with the observation by Tressel et al [4]. Meanwhile, our results showed that without flow imposing on the cells, Hep.II treatment alone could not decrease tubule formation, implying the integrity of glycocalyx does not affect angiogenesis directly. However, compared to cells in static control, enzyme treatment can significantly reduce the suppression caused by shear stress. Therefore, the suppression of tubule formation induced by shear stress may partially be mediated by glycocalyx.

THE EFFECT OF CELL DENSITY ON PRESTRESS DEVELOPMENT IN ENGINEERED MICROTISSUES

INTRODUCTION

Many cells used in soft tissue engineering exhibit a contractile phenotype. These cell-generated contractile forces lead to the development of tissue prestress. In heart valve tissue engineering in particular, prestress can lead to leaflet retraction, which in many cases results in failure of the valve. In addition, tissue prestress changes the apparent stiffness of the biological material. To successfully mimic the properties of native tissues in engineered tissues, it is therefore important to understand what biological factors determine the level of tissue prestress. In the current study, the effect of cell density on cell-generated forces and resulting tissue prestress was investigated using a high-throughput microfabricated tissue gauge (µTUG) setup, allowing for the culture of contractile microtissues.

METHODS

Microtissue Culturing

First, the µTUG setup was fabricated from polydimethylsiloxane (PDMS). Each setup consist of 80 microwells, each embedding 4 compliant microposts (Figure 1a). Next, cells with a contractile phenotype were suspended in a collagen-based gel and centrifuged into the µTUG setup. Within a few hours, the cells compacted the surrounding matrix around the microposts and formed a microtissue (Figure 1b)[1]. Initial seeding densities of 0.5, 1 and 2 million cells per 80 microwells were used. The microtissues were cultured up to 24 hours after seeding.

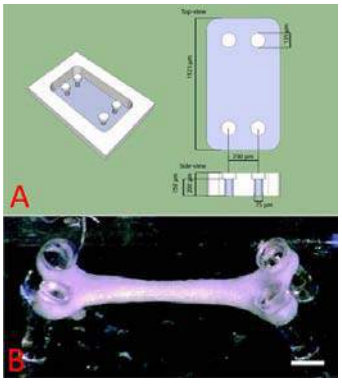

Figure 1: A) µTUG design B) Microtissue compacting microposts[1]

Microscopy

Both brightfield and confocal microscopy was used in order to:

1. Count the number of cells per microtissue:

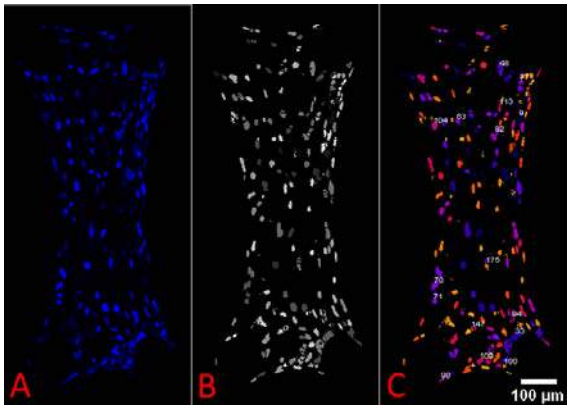

Figure 2: Process of obtaining the number of cells per microtissue

Microtissues were DAPI stained and Z-stack images were made using confocal microscopy (A). After preprocessing, these images were segmented using a 3D-watershed algorithm (B). Finally, the amount of cells per microtissue was determined by counting the number of separate components in the entire 3D segmented images (C).

2. Quantify microtissue forces:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

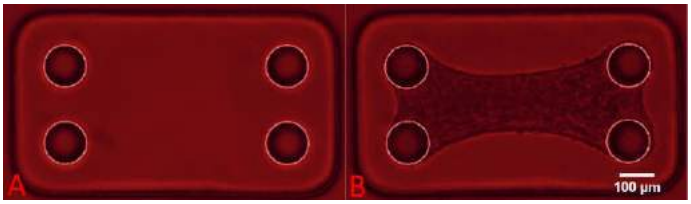

Figure 3: Force quantification using brightfield images

Brightfield images were taken of the empty microwells before seeding (A), and after a microtissue had formed in the well (B). Next, the displacement of the top of the microposts was determined by finding the center of the 4 strongest circles (red) in the reference image, and the image containing the microtissue. A spring constant for the microposts was determined using finite element analysis [N/m] which was then used to determine the total microtissue force.

3. Determine the tissue's cross-sectional area (CSA):

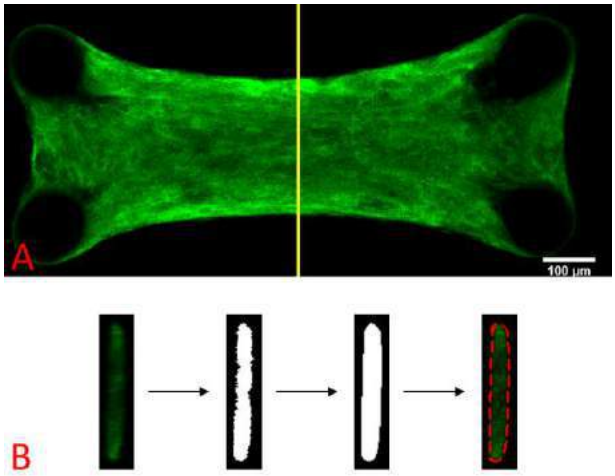

Figure 4: CSA of a collagen-stained microtissue

The collagen of each microtissue was stained with CNA[2], after which it was subjected to confocal life imaging (A). The obtained Z-stack images were rotated such that their main orientation coincides with the long axis of the image. Next, the amount of pixels of each later slice were obtained. Finally, using a convexhull of the smallest lateral slice, the microtissue CSA was determined (B).

RESULTS

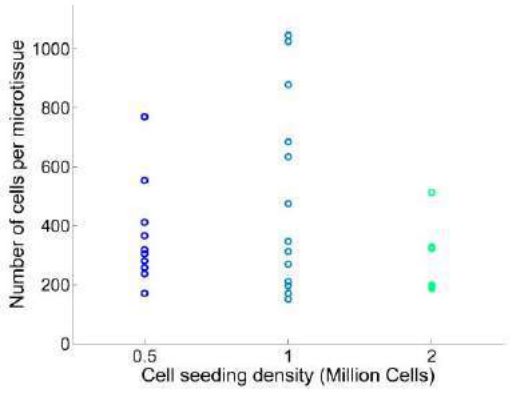

Figure 5: Cell seeding density against the number of cells per microtissue

First, figure 5 shows that the initial seeding density (per 80 µTUGs) was not the major determinant of the final amount of cells in each microtissue. Second, there appeared to be a large discrepancy between the number of cells per microtissue (±150 – 1050 cells).

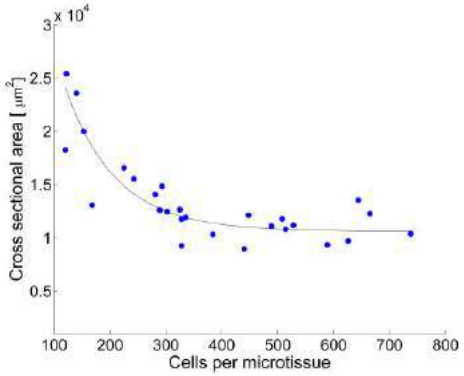

Figure 6: Microtissue cell number against cross sectional area [µm^2]

Furthermore, the tissue CSA decreased with the number of cells up to ±300 cells per microtissue. However, for higher cell numbers, the microtissue CSA does not depend on the number of cells (figure 6).

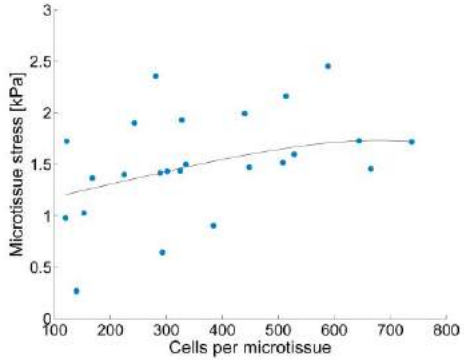

Figure 7: Microtissue cell number against microtissue stress (kPa)

Finally, microtissue stress was determined using the microtissue force and CSA. An increase in cell number results in a higher microtissue stress (figure 7).

DISCUSSION

Surprisingly, the number of cells seeded in 80 microwells, turned out to have no effect on the number of cells ending up in each individual microtissue. There appeared to exist a biphasic relation between the number of cells and the CSA of the microtissues. A similar inverted relationship existed between microtissue cell density and stress. A potential explanation for this result is that there exists a preferred tissue prestress which can only be achieved with a certain minimal amount of cells. This study shows the importance of considering tissue prestress and actual cell density in tissue engineering applications.

INTRODUCTION

The combined use of computational simulations and clinical images can provide interesting insights and advance the analysis and interpretation of intraventricular haemodynamics. In previous studies, the cardiac fluid-dynamics have been simulated with a prescribed geometry approach, imposing the patient-specific motion of the ventricle as a boundary condition [1-6]. Different approaches can be adopted to include the mitral valve (MV) in the model. The first technique is the use of an on/off procedure, with the MV open upon ventricular filling and closed during systole [1,2]. A more advanced choice includes the projection of the valvular orifice open area on the valvular plane, to model the gradual opening of the leaflets [3,4]. Nevertheless, the 3D valve leaflets have a great impact on the haemodynamics of the region and on the clinical interpretation of the results of the model [4,5]. In only a few studies, the moving MV was introduced in the model as a shell structure in an immersed boundary framework [5, 6]. However, in [5] the motion of the LV is not directly derived from clinical data.

The goal of this paper is to present a CFD-based model to study the intraventricular flows in a patient-specific framework, overcoming some of the limitations listed above. From a geometrical point of view, the fully three-dimensional moving mitral valve and left ventricle were included in the simulation. Their kinematics were retrieved from high resolution segmented clinical preoperative real-time transesophageal ultrasound (rt-TEE US) images. From a methodological point of view, the described model had been especially designed for a CFD simulation with an Arbitrary Lagrangian-Eulerian (ALE) description of the fluid domain.

METHODS

The *a priori* knowledge of the position of the LV and MV structures was available from preoperative rt-TEE images. The MV and LV were segmented in all the available frames using a previously described method that combines multi-atlas label fusion and deformable medial modeling to obtain volumetric geometrical models [7], resulting in a set of triangulated surfaces (of the LV and MV) throughout the cardiac cycle, which were used as reference surfaces to prescribe the motion. The 3D, time-dependent position of the MV and LV was transferred to the fluid solver with adequate interpolation schemes. In particular, third-order natural splines were used for the time interpolation and an adaptive scheme based on the three nearest neighbor points was used for the space interpolation, to decouple the reference meshes from the computational mesh. A constant zero pressure was imposed at the inlet (atrium) and a pressure of 100 mmHg was imposed at the aortic outlet during systole. The aortic surface outlet was converted into a wall during diastole to account for the presence of the closed aortic valve, with an on/off procedure. The calculation was performed in Fluent 15.0 (Ansys), solving the Navier-Stokes equations using the arbitrary Lagrange-Eulerian approach. The dataset used for this study was obtained from a female patient undergoing surgery for treatment of aortic valve stenosis. Written informed consent was obtained from the patient and the study was approved by the local ethical committee.

RESULTS

In figure 1a the flows at the mitral and the aortic surface are shown, while in figure 1b the flow field is reported, during systole and diastole. During systole (panels i-iii), the flow was accelerated by the ventricular contraction and was almost immediately aligned with the major direction of the blood (i). After the peak of systole (ii) the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

ventricle shrunk to its lowest volume configuration while the blood decelerated until complete standstill (iii). No significant vortex structure was detected in this phase. During diastole, the typical two-peak-shaped transmitral flow was recorded (fig. 1a, solid line). The flow streamlines were mainly aligned with the valvular leaflets during the entire phase (panels iv-vi). The presence of the valve provided the orientation to the blood flow into the LV. In fig. 1b, panels iv-vi, the vortex structure is also visualized. The vortex arose from the free edge of the valve (iv), travelled lower into the ventricular cavity (v) and dissipated when impacting the lateral wall (vi).

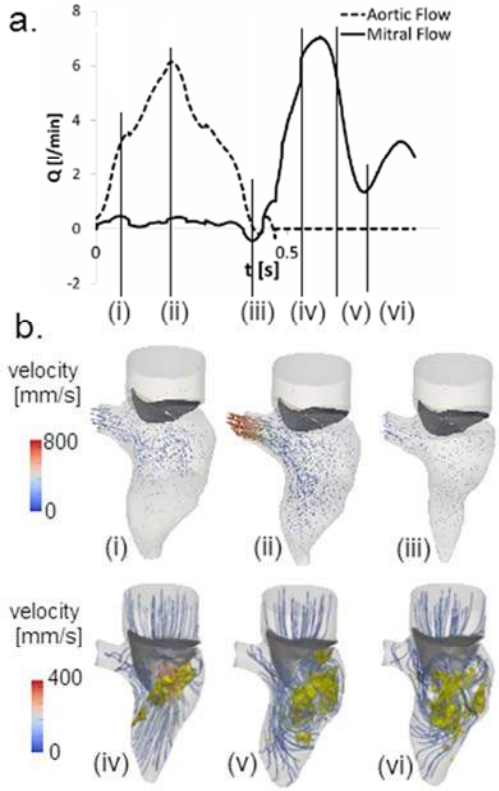

Figure 1: (a) flow curves at the mitral and aortic surfaces. (b) Systolic flow field: velocity vectors. (c) Diastolic flow field: velocity streamlines and vortex structure.

The model allowed to verify the complexity of the intraventricular flow, in particular during diastole. In fig. 2 (a-b) two views of the LV at the same time point (t=0.6s) are displayed. Together with the formation of a larger primary vortex structure (V1), a secondary vortex structure V2 was generated in the proximity of the septal wall. Additional tests could also be performed with the model, as a proof of concept. In fig. 2 (a and c), the flow field at t=0.6s is reported in the model including the MV (a) and in the model where the MV has been previously removed (b), to highlight the effect of the presence of the valvular leaflets. In the latter case, the presence of the MV was included with the on/off procedure, as done for the aortic valve.

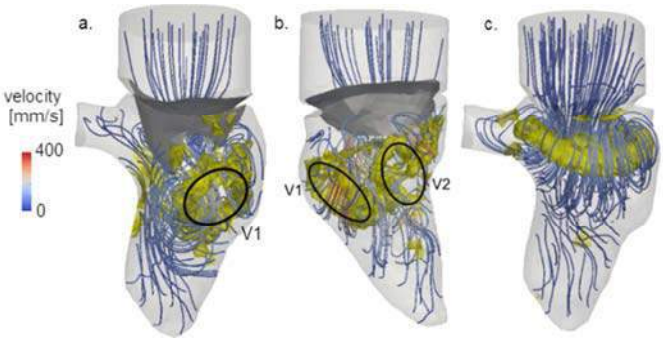

Figure 2: (a) diastolic flow field at t=0.6s, (b) back view at t=0.6s, (c) diastolic flow field at t=0.6s without the mitral valve.

DISCUSSION

Thanks to the use of rt-TEE images as a reference, the described model resulted in a patient-specific CFD model of the left ventricle, which included the presence of the moving ventricular wall and the fully three-dimensional moving mitral valve. The results obtained were in good agreement with the expected haemodynamics of the region (fig.1). The chosen algorithms for the interpolation resulted in a valid kinematics of the LV and MV, leading to realistic flow patterns. As indicator of potential pathologies, the vortex structure was identified during the cardiac cycle. Of paramount importance was the presence of the 3D valve [5]. In fact, during diastole, the flow was oriented according to the valvular leaflets into the ventricular cavity, impacting the lateral wall of the LV. The absence of the valve, on the contrary, resulted in a central blood jet during diastole, which generated a much broader vortex, located in a higher position in the LV (fig. 2a, 2c).

In conclusion, in this work we described a CFD model with imposed moving boundaries of a patient-specific left ventricle, including the three-dimensional mitral valve. The model was based on segmented rt-TEE ultrasound images, which allowed for a patient-specific model and provided the *a priori* knowledge of the position of the structures of interest. The described modeling choices for the interpolation provided a realistic kinematics of the LV and MV, leading to a high quality flow field analysis. The model allowed to analyze the intraventricular haemodynamics throughout the entire cardiac cycle, of particular importance were the results obtained in the diastolic phase, where it was possible to monitor the vortex formation and development.

INTRODUCTION

Pressure ulcers occur as a result of (prolonged) mechanical loading. They represent a common complication in the management of a range of patients and can be considered as an indicator of quality of healthcare. In many cases, pressure ulcers are avoidable [1]. Currently the proposed mechanisms for pressure ulcer formation are: 1) ischemia, 2) direct deformation, 3) ischemia-reperfusion injury, and 4) lymphatic blockage [2]. To understand how these processes induce pressure ulcer formation controlled experiments can unravel the specific temporal and spatial effects of each of these mechanisms. In the past a combined experimental-numerical approach has been used. A load was applied via an indenter to the tibialis anterior muscle (TA) of the hind leg of Brown-Norway rats. The experiment was monitored with magnetic resonance imaging (MRI), providing data on changes in tissue geometry and physiology. By correlating finite element analysis (FEA) and T_2-weighted MRI a threshold level of applied deformation energy was identified above which damage occurred [3]. However, this study was limited to a local 2D analysis directly under the indenter. The aim of the current study was to determine the global effects of loading muscle tissue by extending the analysis to 3D. The experimental protocol was adapted accordingly and 3D FEA was performed.

METHODS

Experimental: The TA of Sprague- Dawley rats (♀, n=7) was loaded for 2 hours using an indenter with a spherical head (diameter: 3 mm, Fig 1). Before, during and after loading MRI was performed using a 7T Bruker small animal scanner with a 86mm excitation coil and 20mm diameter receiver coil. Anatomy and geometry was determined by T_1 weighted MRI and physiological changes with T_2 mapping MRI (FOV 25x25x20 mm, MTX 256x256x20, T_1: TE/TR 11.50/800.0 ms, T_2: TE 6.95-180.7 ms, 26 echos).

Damage/T_2-analysis: T_2-maps ware obtained by fitting the MR signal (S) voxelwise to equation (1). The TA was manually drawn on the T_2-scans ro represent the region of interest (ROI). Voxels were accepted for analysis if the $R^2 > 0.8$ and SNR > 4. Slices were accepted for further analysis if >90% of the voxels in the ROI fulfilled the previous criteria. The mean and standard deviation of the mean (SD_μ) were determined for the ROI in the T_2-map prior to loading. Voxels were considered elevated (damaged) if they exceeded a threshold (Th) (2). Regions > 3 adjacent voxels were used for analysis. The leg was divided into 3 regions of 4 slices: distal to, underneath and proximal to indentation. The results per region were averaged over the analyzed slices

$$S = S_0 e^{\frac{-TE}{T_2}} \quad (1)$$

$$Th = \mu_{T_2} + 3 \times SD_{\mu_{T_2}} \quad (2)$$

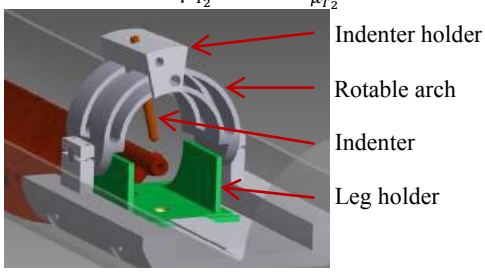

Fig. 1: The experimental set-up. The hind limb of the rat is fixated with a cast in the holder. The optimal indenter position is obtained by rotating the arch and the indenter holder. The indenter is applied manually.

FEA: Animal specific FEA was performed (n=5). Skin and bone contours were determined from the T_1 scans before and during loading using the GIBBON toolbox [4] (Fig 2A-B). The orientation and endpoint of the indenter were obtained from the T_1 scans during loading. The start point of the indenter was obtained by giving an offset to the indenter in its direction to make sure the start point was outside the contours of the model. Essential boundary conditions were the movement of the indenter and the bone. To match the experiment a rigid cast was simulated (Fig 2C). The model was solved in Abaqus 6.14 using the Ogden material law. To determine the elements of the TA, the ROI before indentation was interpolated on the original model using a natural neighbor algorithm.

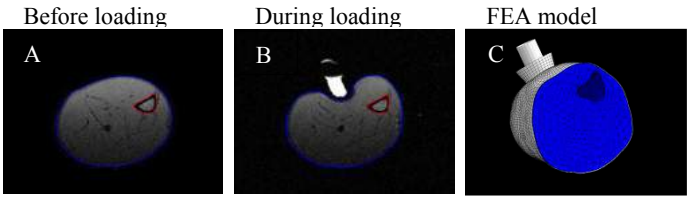

Fig. 2: T_1 images before (A) and during (B) loading. The skin contour is shown in blue and the bone contour in red. C) The front view of a reference state of one finite element model. Soft tissue in blue, the cast and indenter in white.

RESULTS

A structured increase in T_2-value was found after indentation (Fig 3). The region of indentation consistently has the highest volume of elevated T_2-values (Fig 4). High strain energies were found in the regions with the most T_2-elevation (Fig. 3 K,N). However, in regions with low strain energy values, namely the proximal and distal regions, T_2-elevation was also evident (Fig 3,J,L,M,O).

DISCUSSION

This study shows that the effects of mechanical loading extends outside the region of indentation. The loading threshold for deformation damage found previously [3] was clearly exceeded in all experiments in the current study. However, these experiments show that the linear relationship previously found does not extend to regions outside indentation. This may be explained as follows. An increase in T_2-value represent an increase in free water, which occurs due to oedema formation and/or intracellular fluid leakage [5], both considered early signs of tissue damage by the authors. In the destruction phase of muscle injury, transection of muscle fibers creates a release of intracellular fluid [6]. The buildup of fluid within the muscle can potentially diffuse between the muscle fibers, explaining the propagation of T_2-elevation. A previous study has shown that 24 hours after loading T_2-elevation highly correlated with a loss of cross striation and infiltration of inflammatory cells [7]. This indicates the applicability of T_2-values as an early sign of muscle damage. To further map the physiological changes occurring in regions outside of indentation histology needs to be performed.

CHANGES IN CERVICAL SPINE INTERVETEBRAL DISC PROPERTIES WITH REPETITIVE AXIAL LOADING

INTRODUCTION

High rates of neck pain in military personnel may be attributable to vibrational environments that can subject the cervical spine to repetitive axial loading. Those types of environments can be experienced in military helicopters, fixed-wing aircraft, and fast boats. For example, the rate of recurrent neck pain in military helicopter pilots was reported to be approximately 30% [1], compared to 14% in the general population [2]. Additionally, the effect of axial vibration can be exaggerated with the use of helmets and helmet-mounted instrumentation that can increase the inertial load on the cervical spine. Non-specific neck pain could be attributed to progressive subfailure changes in cervical spine biomechanics associated with fatigue of the spinal soft tissues. Characterizing these changes is important for the development of environment-specific exposure limits. However, previous efforts to determine the fatigue response of spinal tissues have focused on the onset of tissue failure [3] or characterizing the effect of spinal implants [4]. Therefore, the objective of the current study was to characterize the effect of repetitive compressive loading on cervical spine biomechanics in an experimental study incorporating Post-Mortem Human Subjects (PMHS), focusing on the influence of spinal level and loading rate.

METHODS

Cervical spine intervertebral disc segments were used to quantify the progressive change in compressive stiffness during repetitive loading. Cervical spines were obtained from fresh/frozen PMHS with mean age of 55±11 years and sectioned into C2/3, C4/5, and C6/7 motion segments. The posterior elements were then removed at the pedicle, resulting in intervertebral disc segments that consisted of adjacent vertebral bodies, the intervertebral disc, and the anterior and posterior longitudinal ligaments. The cranial and caudal aspects of the specimens were potted in polymethylmethacrylate (PMMA) to facilitate fixation to the loading apparatus.

Each specimen was subjected to five sets of 10,000 compression cycles (total 50,000 cycles) between 0 and 150 N using a sine wave function. All testing was conducted in a physiologic saline bath at 37 deg C to simulate in vivo conditions. Cyclic compressive loading was applied to the specimen using an electrohydraulic testing device (MTS Systems Corporation, Eden Prairie, MN). The protocol consisted of five consecutive sets of 10,000 cycles separated by an approximately 60-minute rest period between sets. Cyclic compression testing was conducted at either 2 or 4 Hz.

Axial force was measured at 100 Hz using a uniaxial load cell mounted to the piston of the electrohydraulic testing device. Piston displacement was measured at 100 Hz using a linear variable differential transducer (LVDT). Displacement of the piston was quantified for each 150-N cycle and slope of the force versus displacement trace was used to compute compressive stiffness. Stiffness magnitudes were then compared between spinal levels, cycles, and loading rates using multiple factor repeated measures Analysis of Variance (ANOVA). Pairwise comparisons were conducted for significant main effects using Bonferroni adjustment to account for multiple comparisons.

RESULTS

Twenty-one cervical spine intervertebral disc segments (8 C2/3, 6 C4/5, 7 C6/7) obtained from 12 PMHS were subjected to 50,000 cycles of compressive loading. Eleven specimens were tested at 2 Hz and 10 specimens were tested at 4 Hz. Stiffness progressively increased throughout the testing period, with consistent set-to-set behavior characterized by a sharp increase in stiffness during the first 1,000 cycles followed by a more gradual increase for the remaining

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

9,000 cycles of each set (Figures 1, 2). Multi-factor ANOVA revealed that compressive stiffness was significantly dependent upon loading rate ($p<0.0001$), cycle ($p<0.0001$), and spinal level ($p<0.0001$). Post hoc analysis revealed that each spinal level demonstrated significantly different stiffness profiles compared to every other spinal level ($p<0.001$). The C6/7 spinal level demonstrated the greatest stiffness and the C2/3 level generally demonstrated the lowest stiffness. Post hoc analysis of cycle-by-cycle stiffness demonstrated that stiffness magnitudes during the first 10,000 cycles were significantly different from all other sets ($p<0.01$) and that stiffness during the last 10,000 cycles was significantly different than the first 30,000 cycles ($p<0.05$). In general, stiffness values during the first set were lower than the subsequent sets.

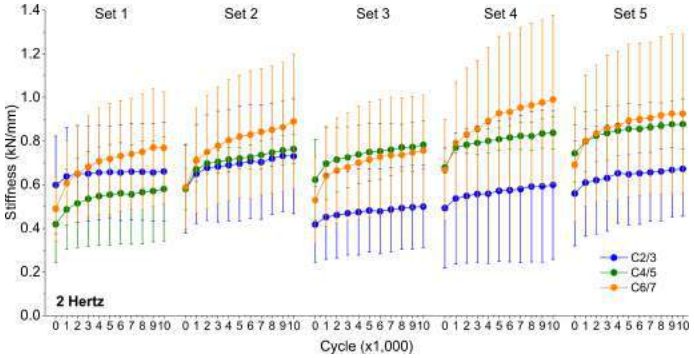

Figure 1: Compressive stiffness of intervertebral disc segments during 2 Hz repetitive loading.

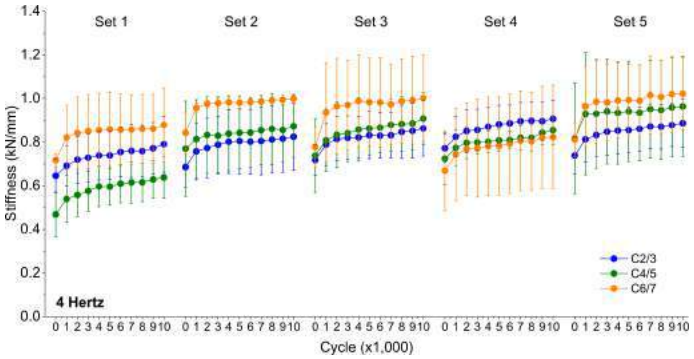

Figure 2: Compressive stiffness of intervertebral disc segments during 4 Hz repetitive loading.

The change in stiffness (N/mm/cycle) for each 10,000-cycle set was mathematically modeled using a bilinear approximation, with the first regression characterizing the slope of increasing stiffness for cycles 1 to 1,000 and the second regression characterizing the slope of increasing stiffness for cycles 1,001 to 10,000. ANOVA analysis demonstrated that the slope of stiffness change during the first 1,000 cycles was significantly dependent on spinal level ($p<0.05$) but not cyclic testing rate, with a greater increase in compressive stiffness occurring at the C6/7 spinal level than the other tested levels (Figure 3). However, the slope of stiffness change during the last 9,000 cycles was significantly dependent on both spinal level and cyclic testing rate (Figure 4). Statistically significant increases in stiffness for both spinal level and cyclic loading rate were driven primarily by the large increase in C6/7 stiffness during the last 9,000 cycles for the 2-Hz cyclic loading rate.

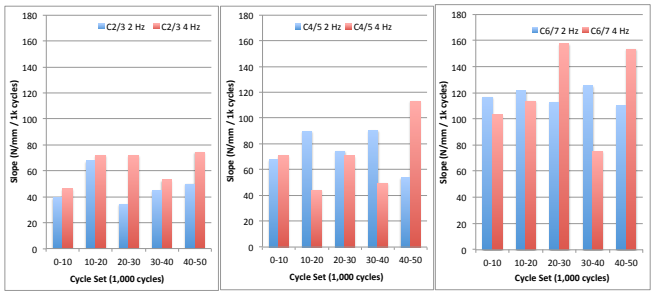

Figure 3: Slope of increasing stiffness during the first 1,000 cycles of each set of cyclic compressive loading.

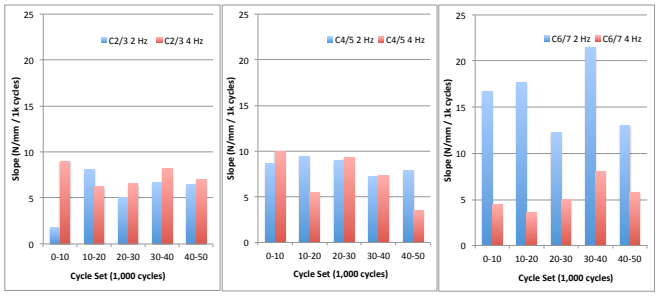

Figure 4: Slope of increasing stiffness during the last 9,000 cycles of each set of cyclic compressive loading.

DISCUSSION

Results of this study characterized the change in compressive stiffness of the cervical intervertebral disc during cyclic loading designed to mimic the types of inertial loading experienced in vibrational environments. Although testing was conducted below the threshold for injury, level-based differences may imply a greater likelihood for injury at the C6/7 level compared to other tested levels due to greater initial stiffness and a greater effect of cyclic loading evident by the increased slope of the regression fit over the last 9,000 cycles of each set. Increased propensity for lower cervical spine injury is consistent with studies quantifying injury in automotive environments [5] and may focus future analyses of exposure limits to vibrational environments. Another important factor not accounted for in this analysis may be an effect of gender, wherein prior studies have indicated significantly different mechanical response of spinal disc segments between men and women [6]. Given an increased combat role for females in the military, delineation of possible gender effects in fatigue response of the spine remains of focus of this ongoing research. Future research in this area will also focus on characterizing the effect of loading rate/duration and increased helmet mass on the fatigue response of the cervical spine intervertebral disc.

EFFECTIVE STIFFNESSES FOR THE HUMAN BUTTOCKS AND THIGH REGIONS OBTAINED THROUGH *IN VIVO* METHODS: APPLICATIONS TO MEDICAL SEATING

W. Pan (1), Z. Sadler (1), L. Nault (1) TR. Bush (1)

(1) Mechanical Engineering
Michigan State University
East Lansing, MI, USA

INTRODUCTION

Soft tissue mechanical properties are necessary for both human body modeling and devices that interact with people. In particular, the human gluteus and thigh regions are of great interest for the study sitting biomechanics which has applications in medical seating (wheelchair design), automotive safety, office chairs, and pressure ulcer studies [1], [2]. Many studies have evaluated tissue properties of the skin; muscle and bone separately through *in-vitro* methods [3], [4]. However, data that defines the tissue properties of the entire tissue system *in vivo* are not currently available. The goal of this study was to determine the soft tissue stiffness in the human gluteus and thigh regions. To accomplish this goal, we also developed a method that enables data collection and measurement of stiffnesses for these sensitive and difficult to test regions.

METHODS

A hand-held indenter was developed by attaching a 5 x 5 cm block system to a six-axis load cell (MC3A, AMTI, USA) (Fig 1 a). The indenter also had reflective markers attached so that the movement could be captured by a 3D motion capture system (Qualisys, USA) and deflection computed. Additional markers were attached to the participants' hips and knees so the body location in space could be obtained.

Since a focus of this work was for seating applications, it was necessary for the data to be gathered in a seated position. Other positions that may have been easier to test, such as lying in a prone position, would not obtain the same tissue tensions; in seating the pelvis and knees are rotated causing a tension that is not present in the prone position. Therefore, a custom chair was built to allow indentation tests to be performed while participants were seated (Fig 1 b,c,d). The seat pan included two removable boards allowing the indenter to reach different regions on the thigh from underneath. The chair was also elevated so that the motion cameras could capture data from the indenter while positioned under the chair.

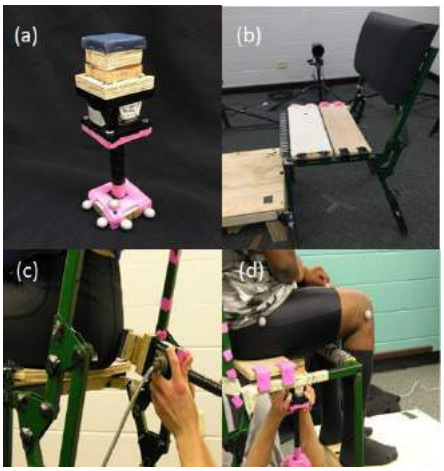

Figure 1: Tissue stiffness test set up: (a) indenter with load cell and motion capture markers (b) customized test chair with removable seat pan sections (c) testing on the lower gluteus (d) testing on the proximal thigh

Six different body regions on the right side were tested including: the top region of gluteus, lower gluteus, under the Ischial Tuberosity (IT), as well as proximal, middle and distal thigh (Fig. 2). The force was applied manually at a constant rate through the use of a metronome until a physiological barrier was felt and then it was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

released. Each location was tested three times and a minimum of 5 mins between each trial was provided for tissue recovery.

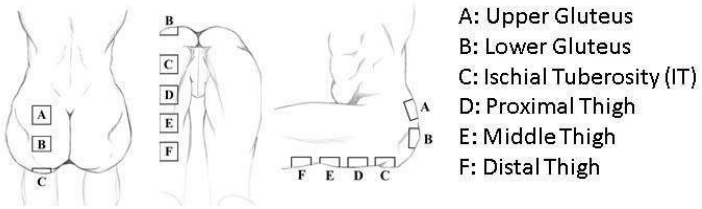

Figure 2 Six test regions on gluteus and thigh

Using the forces from the load cell, initial contact and maximum forces were identified; these corresponded to the initiation of deflection and maximum deflection. Since the motion and force data were synchronized, the indenter movement could be matched with the force data. Displacement for the thigh regions was calculated with respect to the vector between the hip and knee joints and gluteus displacement was with respect to the marker on the greater trochanter. These data were analyzed with a custom written MATLAB code.

RESULTS

Ten men and ten women were tested, however only the male data are presented and discussed here. The ten male participants had an average age of 20.9 yr (SD 1.7 yr), their average height was 170.5cm (SD 2.7 cm), and the average weight was 76.5kg (SD 3.6 kg).

The force-displacement relationships for all test participants for all three trials were then plotted together. Figure 2 shows an example of the stiffness plot for upper gluteus and middle thigh region. It can be seen that upper gluteus region is stiffer than the tissue in the middle thigh. This trend held true with the highest stiffness occurring along the back of the buttocks and the stiffness decreasing from the IT region to the distal thigh region.

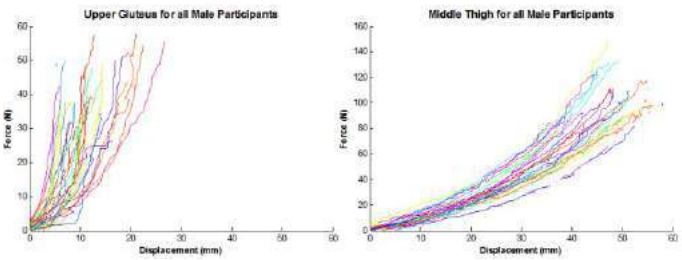

Figure 2: Tissue force-displacement data for the upper gluteus region (left) and the middle thigh region (right).

For seating, we are most concerned with the final deflections, as the tissues are fully loaded in this position. As a preliminary estimation of stiffness for the seated condition, we applied linear regression analysis to the last 1/3 of the stiffness data for all 6 regions for each of the test trials. These average stiffness results are listed in Table 1. Current work is being conducted to use strain energy and inverse Finite Element Methods to classify the entire curve for other applications.

Results indicate a clear trend that the tissues in the gluteus are stiffer than the tissue in the thigh region. The stiffness of the tissue in region D was slightly deviated from the trend, which was due to the testing region being in between a supporting bar of the chair and the front seat pan, causing the tissue to be in higher tension and present an increased stiffness.

Table 1: Average *in-vivo* tissue stiffness for human gluteus and thigh regions for the last one third of each force-deflection curve.

Region*	A	B	C	D	E	F
Average (N/mm)	7.45	7.145	6.65	7.37	4.16	3.09
SD (N/mm)	3.35	4.38	3.63	4.18	1.56	0.71

Note: region A—upper gluteus; B—lower gluteus; C—ischial tuberosity; D—proximal thigh; E—middle thigh; F—distal thigh

DISCUSSION

Human skin and muscle are a multi-layer material and exhibit complex material behavior. However, it is usually difficult to differentiate each layer's mechanical properties during *in vivo* testing. Thus, we have taken a systems approach by determining an effective stiffness that can represent the entire set of tissue.

The *in vivo* stiffness data collected for the human gluteus and thigh are extremely valuable for developing human body model and advancing the study of seating mechanics. These data will be used to develop a better understanding of how the tissue interacts with the seat cushion, and in turn lead to improved human body models and medical seating. In addition, these data will be beneficial for designing prosthetic limbs and sockets that have interface regions with material properties that are closer to actual human tissue material properties. Furthermore, these data could be used for establishing more accurate human tissue models for pressure ulcers research.

One potential limitation of this work is that the population of the test participants was generally young and active, so the obtained data represents this group. To better understand the tissue stiffness in across the general population, a more diverse participant group will be needed with variations in age and BMI.

Future reports will include results from the female participants and a population with higher BMI. Furthermore, inverse Finite Element Methods and strain energy approaches will be used to fully classify the entire force-deflection curve.

ACKNOWLEDGEMENTS

INTRODUCTION

Quantifying the flow dynamics in cerebral aneurysms is important to understand the mechanisms responsible for aneurysm progression and rupture and develop improved aneurysm risk assessment procedures (diagnosis) as well as for understanding and evaluating endovascular interventions such as flow diversion (treatment).

Many studies have used computational fluid dynamics (CFD) to model the flow in cerebral aneurysms to study rupture as well as flow diversion treatments. On the other hand, attempts at measuring the *in vivo* flow fields have been made with phase-contrast magnetic resonance as well as dynamic angiographic velocimetry [1]. The latter technique is attractive because it can be used during the angiographic evaluation of the aneurysm or during its endovascular treatment.

Previous studies have shown the potential clinical value of the angiography-based flow quantification and have compared the results to Doppler ultrasound and synthetic angiograms generated from CFD simulations [2, 3]. The purpose of our study was to further evaluate the angiography-based flow field quantification by comparing against patient-specific CFD models with angiographic aneurysm patient data.

METHODS

A total of 15 cerebral aneurysms imaged with 3D rotational angiography (3DRA) and 2D digital subtraction angiography (DSA) at 60 frames per second were studied. The DSA images were acquired from two different viewpoints trying to minimize the overlap between the aneurysm and the surrounding vessels. In two patients only a single view was acquired (total 28 views for all 15 patients).

Two dimensional flow fields in the aneurysm and connected vessels were reconstructed from the corresponding DSA images using a previously developed optical flow technique [1]. The mean aneurysm flow amplitude (MAFA) was calculated from the DSA images in the aneurysm region as in previous studies [4].

Patient-specific CFD models were constructed from the 3DRA images and ran with pulsatile flow conditions derived from DSA-based flow measurements in the parent artery. The mean aneurysm flow velocity (VEL) was computed as the spatial average of the CFD velocity magnitude over the aneurysm region and over time.

Since the DSA and 3DRA images were acquired relative to the same reference frame, the CFD flow fields were projected to the same views used in the DSA acquisitions. Both the DSA and CFD flow fields were averaged over the cardiac cycle, and the CFD flow fields were further averaged along the line of sight. The DSA and CFD flow fields were then compared visually by plotting streamlines in the projected 2D images, and quantitatively using a similarity measure defined as:

$$s = \frac{1}{N} \sum_{i \in ROI} \boldsymbol{a}_i \cdot \boldsymbol{b}_i / (|\boldsymbol{a}_i||\boldsymbol{b}_i|) \qquad (1)$$

where $\boldsymbol{a}_i$ and $\boldsymbol{b}_i$ are the velocity vectors in the two flow fields, ROI the region of interest, N the number of pixels in ROI, and the . operator denotes the dot product. This quantity measures the similarity of the directions of the two vector fields. A similarity of 1 means a perfect match, random input would yield 0, and opposing fields would give -1.

RESULTS

The average similarity of all DSA and CFD flow fields was s=0.66. Restricting the comparison to the vessel (i.e. excluding the aneurysm region) resulted in an average similarity of s=0.78. Considering only the aneurysm regions, the average similarity was s=0.37.

In 8/15 patients (53%) there was at least one view in which the CFD and DSA flow fields agreed with a similarity s>0.5. Four examples

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

are shown in Fig. 1. In these cases, the main intra-aneurysmal vortex structures are seen in both fields.

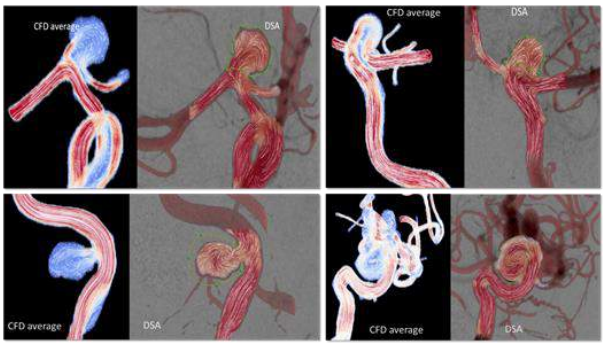

Fig. 1: Average CFD and DSA flow fields in good agreement.

An important issue affecting the results of the DSA flow quantification is overlap between the aneurysm and surrounding vessels. Two examples are shown in Fig.2. In the first case (top), the overlap is emphasized by computing the maximum intensity projection (MIP) along the line of sight (left most picture), and can be seen to affect both the projected CFD and the DSA flow fields. In the second case (bottom), the aneurysm wraps around the parent vessel making it impossible to find a view without vessel overlap. Nevertheless, the main vortex structure inside this aneurysm is well captured by the DSA flow.

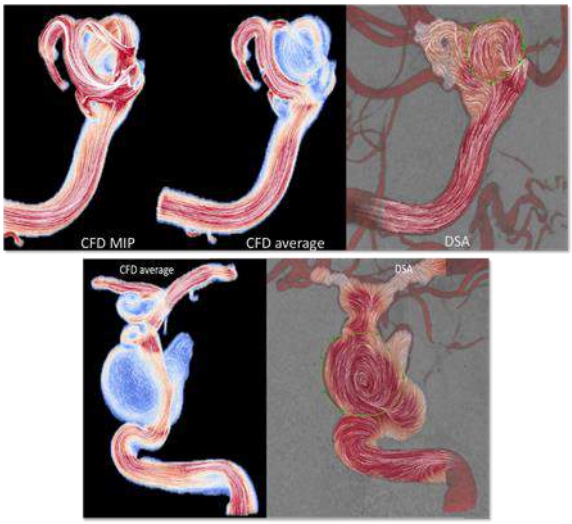

Fig. 2: CFD and DSA flow fields in cases with overlapping vessels.

In 7/15 patients (47%) the DSA and CFD flows did not agree (s<0.5). Some of these disagreements were due to vessel overlaps as explained before, but in other cases a "sink" effect was observed in the DSA field where the flow is directed towards the center of the vortex instead of around it. Two examples of are presented in Fig.3. In the first case (top), it can be seen that within the aneurysm the DSA flow points radially towards the center of the vortex seen in the CFD flow. In the second case (bottom), the DSA flow seems to go over the vortex center seen in the CFD field. This effect could be due to under sampling in the DSA quantification. This may happen when the time interval between DSA images is comparable to the time it takes for a particle to travel around the vortex core. For example a particle that is initially seen at the aneurysm inflow would be seen in the next frame close to the exit, and thus the trajectory would look like those of the bottom case of Fig. 3. It may also occur when the cardiac wave length is large compared to the aneurysm perimeter.

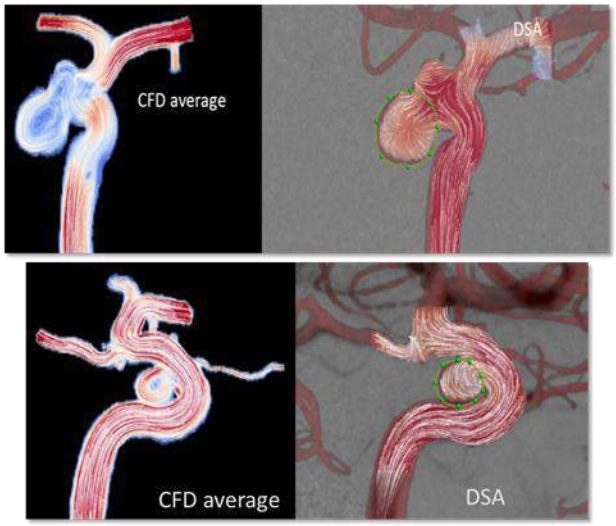

Fig. 3: Cases where a "sink" effect can be seen in the DSA flow.

The mean aneurysm velocity (VEL) and MAFA values are compared in Fig. 4 (left). After discarding views with significant vessel overlaps (red dots) regression analysis shows a linear correlation between VEL and MAFA (R=0.80, p<0.0001). However, the relative difference between VEL and MAFA increases with VEL (fig. 4, right) which is consistent with the notion of under sampling for a fixed frame rate when the aneurysm velocity increases.

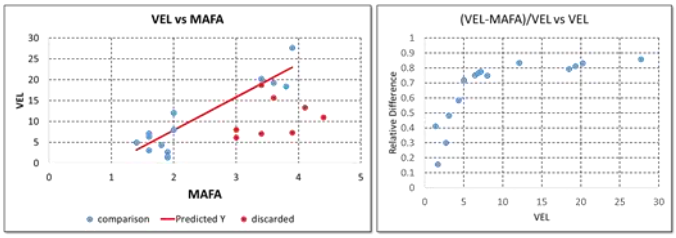

Fig. 4: Relation between MAFA and mean aneurysm velocity (left), and relative difference (right).

DISCUSSION

In general there was good agreement between DSA and CFD flow fields. In the aneurysm, where the flow can be quite complex the agreement was not as good as in the vessel. In some cases a "sink" effect was observed that could be due to under sampling. Further study is necessary to understand this effect. Vessel overlap has a strong influence on DSA flow results and should be avoided, however sometimes it is not possible to find views without overlapping vessels.

The MAFA value previously defined seems to be linearly correlated with the mean aneurysm velocity, which suggests that it could be a good parameter to evaluate aneurysms or treatments. However, the difference between the MAFA and the mean aneurysm velocity increases with the velocity. Increasing the framerate of the DSA measurements could improve both the agreement of the MAFA with the mean aneurysm velocity and resolve the "sink" effect.

INTRODUCTION

The uncertainty in loads, geometry and material properties is present in the biomechanics of the spine. However, few probabilistic analysis [1–5] have been performed to obtain a more accurate estimate of the influence of such uncertainties in the mechanical response of the spine [6,7]. Considering that there may be substantial variations of the mechanical properties of biological tissues among individuals, this paper presents probabilistic finite element (FE) analyses intended to assess the effects of the variations of the elastic constants of the annulus fibrosus (AF) on the biomechanics of the lumbar spine. In particular, the range of motion (ROM) of the L4-L5 and L5-S1 segments loaded under flexion, extension, lateral bending and axial rotation was analyzed for different combinations of the elastic properties of the AF.

METHODS

We extracted the geometries of the L4-L5 and L5-S1 AFs from a realistic FE model [8]. To take into account the high stiffness of the vertebrae with respect to that of the AF, the endplates were considered to be rigid. The AF was represented as a homogeneous hyperelastic matrix reinforced with two families of fibers [9,10] oriented at ±30° [11–13] with respect to the transverse plane. Consistent with previous studies, a Yeoh energy function W_m was used for the matrix while a the hyperelastic function W_f was used for the fibers, as follows,

$$W_m = c_1(I_1 - 3) + c_2(I_1 - 3)^2 + c_3(I_1 - 3)^3 \quad (1)$$

$$\mathrm{W_f} = \frac{\mathrm{a_1}}{\mathrm{a_2}}\left[\mathrm{e}^{\mathrm{a_2}(\mathrm{I_4}-1)^2} + \mathrm{e}^{\mathrm{a_2}(\mathrm{I_6}-1)^2}\right], \quad (2)$$

where c_1, c_2, c_3, a_1 and a_2 are material constants; I_1 is the first invariant of the deviatoric Green deformation tensor, and I_4 and I_6 are the deviatoric invariants associated with the two families of fibers. A subroutine Uanisohyper of the program Abaqus 6.14.2 (Dassault Systemes SA, USA) was developed to implement the Equations (1) and (2). A set of 100 combinations of constants a_1 (mean=0.23 MPa, DS=0.15) and a_2 (mean=7.44 MPa, DS=7.5) was determined randomly using Excel (Microsoft, USA) according to a normal distribution and experimental measurements accomplished by Cortes et al. [14]. The constants c_1, c_2, and c_3 were equal to 0.035 MPa, 0.00065 MPa and 0.00045 MPa, respectively [8].

For each AF, the caudal endplate was fully restricted while a pure moment ramped from 0 to 8 N-m was applied to the cranial endplate in each of flexion, extension, lateral bending, and axial rotation movements. A convergence analysis was performed to develop a final mesh of 9472 eight-node hybrid hexahedral elements (C3D8H).

The ROM was selected as the output variable and compared with experimental data. The ROM was plotted as a function of a_1 and a_2 and various surface equations were fit to the response using a nonlinear least squares algorithm. The cumulative probability and the probability density functions were obtained using Origin 8.5 software (Northampton, UK). The ROM sensitivity to each of the input random variables (a_1, a_2) was calculated according to the equation proposed by Thacker et al. [5]. The coefficient of variation (CV) for the ROM was calculated in order to obtain a measure of data dispersion.

RESULTS

The ROM dispersion (Fig. 1) for the segment L4-L5 was greater in axial rotation (CV=14.6%) and extension (CV=12.6%) followed by lateral flexion (CV=8.7%) and flexion (CV=6.3%). For the L5-S1 segment (Fig. 2) the greater dispersion was observed in axial rotation (CV=14.0%), followed by lateral flexion (CV=11.5%), extension (CV=10.6%) and flexion (CV=5.6%). The percentages of points within the experimental range for the L4-L5 disc were 100%, 50%, 48.3%, and 25.7% in flexion, lateral flexion, extension, and axial rotation, respectively. For the L5-S1 disc, these percentages were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

95.9%, 94.2%, 38.0%, and 15.8% in flexion, axial rotation, lateral flexion, and extension.

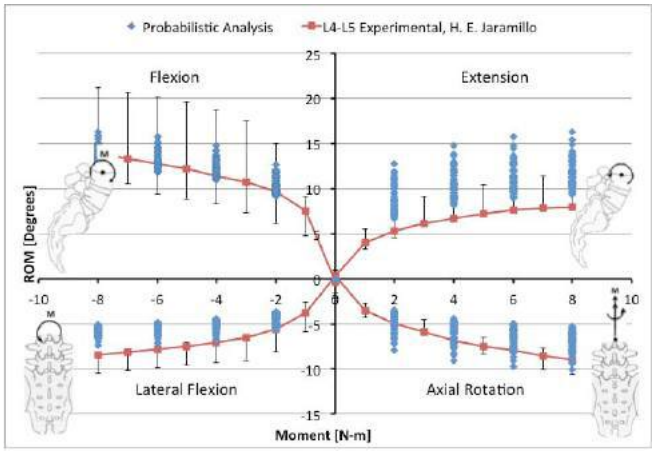

Figure 1: Results of parametric analyses for the L4-L5 disc compared with experimental ROM

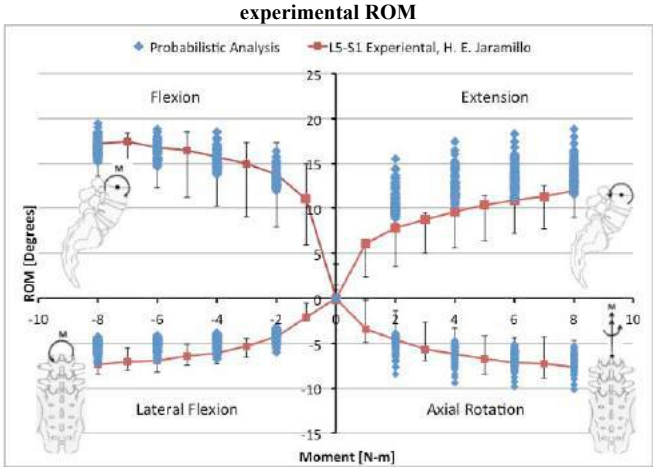

Figure 2: Results of parametric analyses for the L5-S1 disc compared with experimental ROM

The ROM response surfaces for the two segments were similar. The Equation (3) provided the best fit to the computational points:

$$\mathrm{ROM} = \mathrm{Zo} + \mathrm{Be}^{\left[-\frac{a_1}{C}-\frac{a_2}{D}\right]}, \quad (3)$$

where Zo, B and C are constants obtained during the fitting procedure. These constants were between 5% and 31% higher for the L5-S1 segment than the L4-L5 segment, while D showed an opposite trend in extension, lateral flexion and axial rotation (Table 1). From this fitting process, the averages of coefficients of determination (R^2) were 0.974 for the L4-L5 disc and 0.966 for the L5-S1 disc.

Table 1: Constants of Equation (3) that fit the computational response (M=8 N-m)

	Movement	Z_0 [Deg.]	B [Deg.]	C [MPa]	D	Chi-Square	R^2
L4-L5 Disc	Flexion	11.6	7.2	0.45	17.5	0.015	0.980
	Extension	8.4	12.6	0.42	16.0	0.043	0.980
	Lateral Flexion	4.7	4.5	0.43	15.4	0.005	0.979
	Axial Rotation	4.5	8.7	0.48	16.1	0.045	0.955
L5-S1 Disc	Flexion	13.9	8.6	0.59	19.6	0.023	0.975
	Extension	10.2	13.6	0.54	15.5	0.050	0.977
	Lateral flexion	3.6	5.3	0.58	17.1	0.024	0.935
	Axial Rotation	4.6	9.1	0.53	14.4	0.021	0.978

The ROM was about 26 and 38 times more sensitive to a_1 than to a_2. In their order, the ROM was more sensitive to the input variables in extension, flexion, axial rotation and lateral bending. The ROM probability density function analyzed at 8 N-m showed that the L5-S1 ROM has a higher probability to be lower in lateral flexion and higher in flexion, extension and axial rotation, with respect to the L4-L5 ROM.

DISCUSSION

The high level of uncertainty of the mechanical properties of the AF produced a significant dispersion in the biomechanical response, which cannot be fully described with a deterministic model [4].The proposed analytical surface showed an excellent fit (R^2=0.98) to the probabilistic ROM points. Hence, the equations of these surfaces may be used to expedite the calibration process of the AF of FE lumbar models.

A relatively high percentage of the theoretical ROM points (97.9% in flexion, 32.0% in extension, 44.0% in lateral flexion and 59.9% in axial rotation) were within the experimental ranges. This suggests that the values of a_1 and a_2 reported by Cortes et al. [14], which were used as a point of departure to select the set of input data, are reliable to be used in probabilistic analysis and in the calibration of the AF properties. Higher differences in some movements with respect to the experimental data may have been due to the adopted homogeneous properties, as other studies have documented [14–18] that elastic constants variations in the circumferential and radial directions may have more effect in some movements than others. Further analyses should be accomplished to address this issue.

Some FE models [12, 19, 20] include the AF properties without performing a calibration using experimental data. As the AF is one of the main elements to support spine loads, the calibration of its properties should be the first step during the validation of a spine segment model. A bad calibration of the AF can generate overload in other elements of the segment such as the ligaments and facet joints. The sensitivity analysis suggests that a_1, which is the constant that defines the initial slope of the stress-strain curve for the fibers, should be calibrated before a_2. With respect to the movements, it is indicated to calibrate flexion first, followed by extension, lateral bending and axial rotation.

INTRODUCTION

Elastic fibers, composed primarily of elastin and fibrillin-rich microfibrils, impart important mechanical properties (i.e., elastic recoiling, energy storing) to skin, vasculature, and lung tissue [1]. With high elastin content (58-75% of dry weight) in arteries and skin, decreased mechanical integrity results from degeneration and disease that disrupt elastic fibers in these tissues [2]. Although connective tissues such as intervertebral disc and ligament have much fewer elastic fibers, reduced mechanical strength has been attributed to depletion of elastic fibers [3, 4]. Tendons also contain small amounts of elastic fibers, but an understanding of their contribution to tendon mechanical behavior is lacking. The aim of this study was to measure the uniaxial tensile mechanics of supraspinatus tendons (SSTs) from unaffected (*Eln*+/+, WT), elastin haploinsufficient (*Eln*+/-, HET), and elastin knockout mice with a bacterial artificial chromosome (BAC) encoded human elastin gene (*Eln*-/-, hBAC-KO) [5, 6]. SSTs function in a complex loading environment, are often torn, and are difficult to repair, thus motivating efforts to understand how tissue properties relate to mechanical function. Histological, biochemical, immunostaining, and ultrastructural analysis of SSTs were also performed to provide structural and compositional data to further investigate structure-function relationships and the role of elastin in tendon mechanics.

METHODS

Biomechanical testing. Humerus-SST complexes were dissected from 3-month-old WT (n=6), HET (n=8), and hBAC-KO (n=10) C57BL6 male mice. A non-contact laser scanning system was used to measure cross-sectional area (CSA). Samples were placed in custom clamps, submerged in a PBS bath, and mounted onto a tensile testing machine [7]. After applying a 0.1 N pre-load, samples were loaded in uniaxial tension at 0.5-0.75%/sec until failure. Camera images were collected for strain calculation.

Biochemical analysis. After mechanical testing, tendons were separated from the humerus and pooled into groups of three by genotype for biochemical analysis. Similar to previous studies [8], a ninhydrin-based assay and nonequilibrium competitive enzyme-linked immunosorbent assay were used to determine quantities of total protein and desmosine, a marker of elastin. Elastin amounts were converted from desmosine and normalized by total protein.

Histology, immunostaining, and transmission electron microscopy (TEM). For histological analysis, each humerus-SST complex was fixed in 10% neutral buffered formalin and decalcified in 14% EDTA. Samples were then dehydrated with 70% ethanol, embedded in paraffin, sectioned at 5 μm, and stained with hematoxylin and eosin (H&E), Verhoeff-Van Gieson (VVG), and picrosirius red. Elastin distribution was also visualized by immunostaining. Fresh-frozen sections of SST from each genotype were cut at 5 μm on a cryostat. Sections were fixed with cold methanol and treated with hyaluronidase to improve immunodetection of elastin. Sections were blocked with 1% fish gelatin, then incubated with primary [9] and secondary antibodies. After washing, sections were mounted with DAPI aqueous medium. TEM analysis was also conducted to examine the distribution of elastic and collagen fibers on the nanoscale. The tendon midsubstance was cut from the humerus, fixed in 0.1M sodium cacodylate, post-fixed in 1.25% osmium tetroxide, dehydrated in alcohol, and embedded in Poly/Bed® 812 resin. Samples were cut in transverse and longitudinal orientations at 90 nm and stained with uranyl acetate and lead citrate.

Data Analysis. The minimum CSA along the tendon length was selected for computing stress and modulus. Linear modulus was computed from the linear region of stress-strain curve. Maximum force and stress were calculated as the loading point at failure. Engineering strains were calculated by tracking marks on tendon surface with a custom MATLAB program. All data are presented as mean±standard deviation. Comparisons across genotypes of different parameters (i.e.,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

CSA, maximum stress, linear modulus, elastin content) were performed with one-way ANOVA and Bonferroni post-hoc tests. Significance was defined as $p<0.05$.

RESULTS

Maximum stresses (Fig. 1A), linear modulus (Fig. 1B), stiffness (Fig. 2A), and CSA (not shown) of SSTs were statistically different by genotype, with decreased values from WT to HET to hBAC-KO. While collagen content was similar among different genotypes (not shown), elastin content in HET was 42.7% less than WT, and, surprisingly, hBAC-KO had 200% of elastin in WT (Fig. 2B).

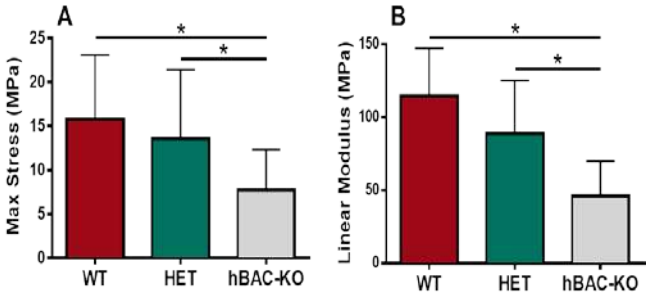

Fig. 1. Maximum stress (A) and linear modulus (B) were statistically different across genotype, with significantly smaller values in hBAC-KO mice. *$p<0.05$.

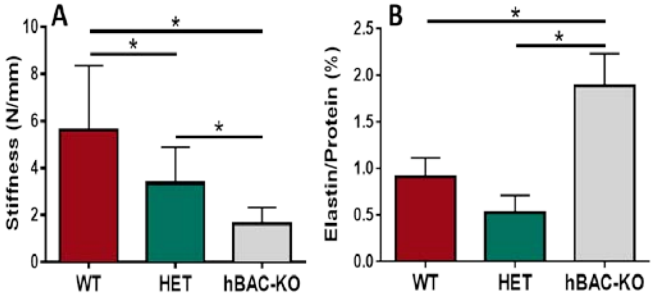

Fig. 2. Stiffness (A) and elastin content (B) for tendons from each genotype (mean ± standard deviation). *$p<0.05$.

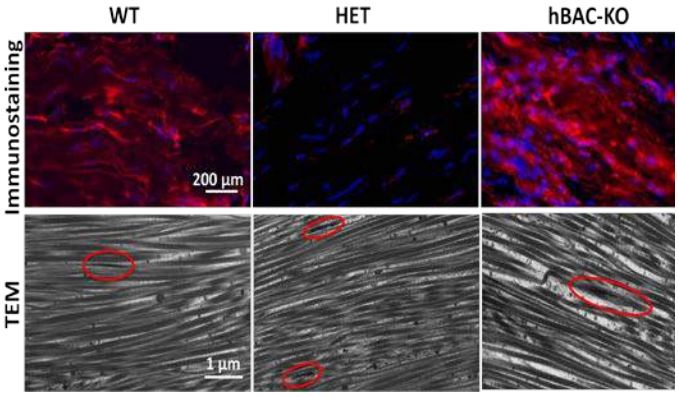

Fig. 3. Immunostaining images (top) show elastin (red) and nuclei (blue) in tendon sections. TEM micrographs (bottom) show elastin (denoted by red ellipses) in longitudinal sections of each genotype.

Consistent with the biochemical data, immunostaining images showed moderate levels of elastin in WT tendons, much less staining in HET, and dramatically increased elastin in hBAC-KO (Fig. 3). VVG staining provided additional evidence of increased elastin in hBAC-KO tendons (not shown). Elastic fibers were aligned along collagen fibrils in TEM micrographs, and no obvious structural differences were observed in different genotypes (Fig. 3). H&E staining showed fairly consistent collagen structure and cellularity between genotypes (not shown). Collagen crimp pattern shown by picrosirius red staining varied across the entire tendon and even among different tendons of the same genotype.

DISCUSSION

This study demonstrates that elastin, even in relatively small quantities, contributes to the mechanical properties of tendon, which is consistent with previous studies that showed decreased stress under both transverse tensile and shear loading for elastase-treated ligaments [3,4,11]. Elastin, and corresponding elastic fibers, may help to support load, facilitate stress/strain transfer among collagen fibers, and/or maintain the mechanical integrity of tendon [10] Compared to WT, HET tendons followed the pattern that inferior mechanics correspond to less elastin in a dose-dependent manner. However, hBAC-KO tendons exhibited larger elastin quantities yet smallest maximum stress and linear modulus values, which conflicts with this concept. Results for hBAC-KO may be due to improper assembly of elastic fibers encoded by the human elastin gene, such that these elastic fibers are not involved in supporting force during loading; this hypothesis needs further evaluation by differentiating human and mouse elastin-gene encoded elastic fibers. Contrary to results of the current study, arterial walls from both HET and hBAC-KO mice were stiffer than those of WT mice in a previous study [6]. These differences may be due to very different relative amounts and distributions of elastin and collagen in vessels compared to tendon. The mechanics of elastin-deficient vessels are defined by the stiffer collagen network, while elastin depletion in tendon may limit force transfer along collagen, thereby weakening the mechanical response. Compared to elastin depletion via elastase [3,4,11], gene-modified animal models with protein reductions could be a better approach to examine the role of elastin, since elastase has been reported to change tissue structure and other components [11]. The animal models used in this study can isolate the effect of elastin-deficiency on tendon mechanics separate from that of other tissue constituents, however compensatory mechanisms in genetically manipulated models are always a possibility. These results suggest that elastin, as part of properly-formed elastic fibers, provides mechanical strength in a disproportionate degree relative to its small quantity in tendon, further improving the understanding of tendon composition-function relationships.

ACKNOWLEDGEMENTS

We thank Qi Wu and Ivan Stoilov for their contribution to biomechanical testing and biochemical analysis, respectively. We also thank Dr. Jessica Wagenseil for providing mice.

INTRODUCTION

Iridotomy is a procedure in which a hole is surgically created in the iris to allow aqueous humour to flow from the posterior to the anterior chamber. It is done in cases in which there is a concern that this flow might otherwise not occur freely (e.g. pupillary block). The problem of the choice of the optimal size and location of an iridotomy is still poorly understood. In the biomechanical literature there are a number of works about aqueous flow, however very few consider the effect of iridotomy. Fleck [1] proposed a basic mathematical model of aqueous flow through an iridotomy in the case pupillary block, using Poiseuille formula to calculate the pressure drop across the iridotomy hole. Silver and Quigley [2] studied aqueous flow in the iris-lens channel driven by aqueous production in the ciliary body and they also considered the presence of an iridotomy.

We extend these works and study aqueous flow in the posterior chamber of the eye due to aqueous production and miosis (e.g. pupil contraction). We also consider the cases of partial and complete pupillary block. We develop and solve a mathematical model of the fluid dynamics of an iridotomy, and use it to comment on the effect of the location and size of the hole and investigate the pressure and stress on the surrounding tissues, which we show are usually within safe levels. We propose a mathematical theory, which allows us to solve the problem semi-analytically. This gives us insight into the pressure difference between anterior and posterior chambers and allows us to predict conditions that can lead to angle closure glaucoma. During miosis our results indicate there could be a strong jet through the hole, which could, in turn, damage the cornea.

METHODS

Since the posterior chamber is long and thin, we use lubrication theory to simplify the Navier-Stokes equations and assume miosis can be modeled as quasi-steady. This implies that we keep the domain fixed and impose a given velocity distribution $\boldsymbol{v}$ on the iris.

We work in spherical coordinates (r, θ, φ) and denote by R the radius of the lens and $h(\theta)$ height of the posterior chamber. Then, the simplified equation for the pressure is

$$\frac{1}{12\mu}\nabla_h \cdot (h^3 \nabla_h p) = v_r + \\ + \frac{h}{2(R+h)}\nabla_h \cdot \left((R+h)\mathbf{v_h}\right) - \frac{1}{2}\nabla_h h \cdot \mathbf{v_h}, \qquad (1)$$

where μ is dynamic viscosity, v_r is r component of the velocity of the iris, p is independent of r and 'h' is a subscript indicating that only the (θ, φ) components are considered with $r = R + h$ fixed.

We assume that the volumetric flux through the iridotomy hole is proportional to the pressure drop across the hole and compute it using Dagan's formula [3]. The iridotomy is modeled as a point sink, thus, in order to avoid singularity of the pressure there, we work in terms of a suitably regularised pressure, which is defined as follows

$$p_{\text{reg}} = p - \frac{6\mu Q}{\pi h_i^3} ln \frac{\tan\left(\frac{\theta'}{2}\right)}{\tan\left(\frac{\theta_d}{2}\right)}, \qquad (2)$$

where Q is volumetric flux through the iridotomy, h_i is a height of the posterior chamber at the point of the iridotomy, θ' is a distance in θ component from the point of the hole, θ_d is radius of the iridotomy divided by R.

Therefore, equation (1) has to be solved for the unknown regularized pressure (2) and for the flux through the iridotomy Q. The solution is obtained using a second order finite difference scheme and realistic shapes of the posterior chamber, which are inferred from

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

ultrasound scan images. The resulting linear system is solved with modified reduction method.

RESULTS

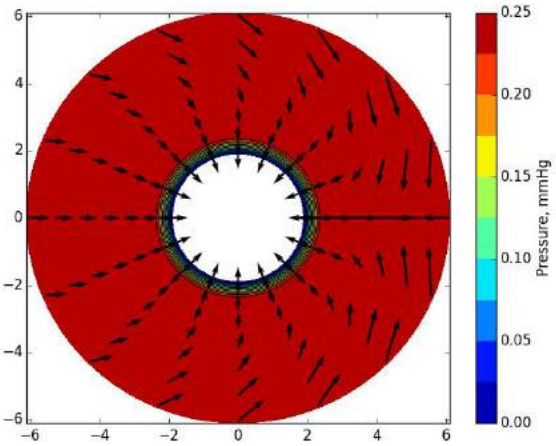

Figure 1: Predicted flow in posterior chamber from ciliary body (outer boundary) to pupil (central hole) showing calculated pressure (colorbar) and depth-averaged velocity vectors (arrows). The iridotomy has diameter 50 μm and is located at a distance of 5 mm to the right of the pupil. 29% of the total volumetric flux passes through the iridotomy.

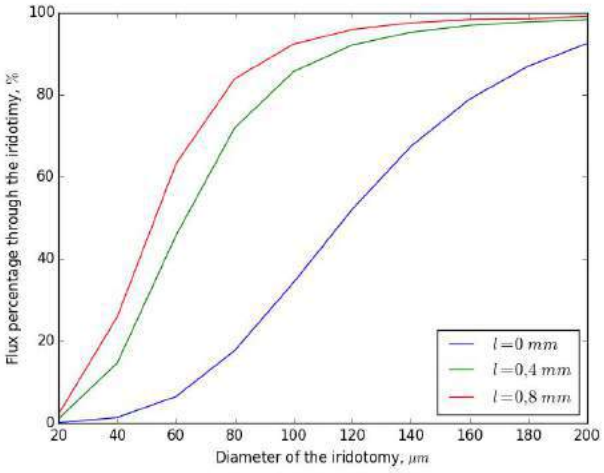

Figure 2: Percentage of the total volumetric flux that passes through the iridotomy for different lengths of iris-lens channel *l*. The height of the iris-lens channel is fixed at 7 μm. The red curve is for a channel of length 0.8 mm, the green one 0.4 mm and the blue one has the height 7 μm only at the pupil (channel length 0). The iridotomy is located at a distance 4.5 mm from the center of the pupil.

In this section by the term "pressure" we mean the pressure difference between the anterior and the posterior chamber. We calculated the pressure distribution and the velocity field in the posterior chamber of the eye for different pupil diameters, iridotomy diameters, length of the iris-lens channel and with and without miosis; an example is shown in figure 1. We note that the pressure along the domain remains almost constant, except for the iris-lens channel, where it rapidly drops from about 0.25 mmHg to 0 mmHg at the pupil.

Figure 2 shows the percentage of flux through the iridotomy with respect to the total flux, as a function of the diameter of the iridotomy. Each curve corresponds to a different value of the iris-lens channel (a region with a height from 3 to 7 μm [2]). The results show that geometry of the posterior chamber (in particular the height and length of the iris-lens channel) and the diameter of the iridotomy significantly influence the pressure distribution and flow. On the other hand, the location of the iridotomy on the iris does not have a significant effect. The pressure drop from the posterior to the anterior chamber is below 1 mmHg during aqueous production, if the iridotomy is bigger than 20 μm in diameter.

During miosis different velocity distributions on the iris give different volumetric fluxes through the iridotomy. However, the overall percentage of the flux that passes through the iridotomy remains almost unchanged. For a given geometry there is a value of the iridotomy for which the velocity of the aqueous jet passing through the iridotomy is maximal. This velocity is much higher during miosis than when the iris is stationary.

In the case of pupillary block an iridotomy with a diameter of at least 20 μm is needed to avoid dangerously high pressures. Partial pupillary block (the case when some region of the pupil is blocked for the outflow) causes the dangerously high pressures only with if the blocked region is more than 90%. However, with the presence of a small iridotomy with diameter 15 μm the pressure drops to less than 1 mmHg.

DISCUSSION

The ideal size and location of an iridotomy is influenced by various geometrical and fluid mechanical factors. We find the most significant ones are the size of the hole, the width and height of the narrow iris-lens channel and the possible presence of complete or partial pupillary. For certain iridotomy diameters, we cannot rule out the possibility that the jet velocity through the iridotomy during miosis might become large enough so as to cause corneal damage.

INTRODUCTION

The human larynx contains two vocal folds that, when driven by air expelled from the lungs, undergo self-sustained oscillations, thereby producing sound. [1] Laryngeal cancer and other diseases can necessitate the removal of the larynx (laryngectomy), rendering conventional voiced speech production impossible. On a global scale, there are approximately 160,000 cases of laryngeal cancer each year. Of those cases, roughly 80,000 receive laryngectomies. The United States comprises ~3,000 annual procedures. While the past 15 years have shown a decrease in laryngectomies in the United States, there is increasing occurrence in Latin America, Asia, Southern Europe, and Eastern Europe. [2]

Following laryngectomy, a handheld artificial larynx (AL) is employed to restore voice. An AL produces sound from a driven striker that impacts a diaphragm, causing the diaphragm to vibrate. When the diaphragm makes contact with the neck, sound is transmitted through the tissue and into the oral cavity, producing sound that is then modulated by the lips and tongue to form intelligible speech. [3] Unfortunately, ALs produce harsh and monotonic sound with significant background noise, resulting in suboptimal voice production. These drawbacks are further compounded by the fact that AL's are electrically powered and as such, prohibitively expensive (O($1,000), which limits deployment to developed countries.

Prior research regarding AL development has explored neural control for hands-free and on-demand sound production yielding ALs that are activated electromyographically; that is, the user is able to activate the AL and modify pitch using signals arising from muscle activation. [4] Other efforts have improved AL output sound quality by utilizing inverse filtering of the frequency response functions (FRF) of the throat, which allows the AL output to be optimized for the FRF of a human throat through modification of the AL input signal. [5] While these advances serve to greatly improve AL performance they do not address the issue of high cost, which prohibits their widespread deployment to developing countries.

The objective of this study is to develop a mechanically-driven artificial larynx (i.e. mechanolarynx (ML)) at a price that will facilitate access to patients in developing countries. Device design is driven by end-user feedback to determine features of greatest importance. A system dynamics model was employed in order to determine the key design variables that impact oscillation frequency (pitch), and loudness.

PRODUCT DESIGN

The conceptual design of the ML follows basic wind-up mechanics. Figure 1 provides a schematic and Table 1 lists the relevant parts. A constant torque spring, wound by use of an external knob (Part No. 5 and 18, respectively), acts as the energy storage device. A constant torque spring ensures constant amplitude and frequency, thereby providing constant voice pitch for the user until the spring winds down. A gear and pawl system holds the wound spring until a button is pressed, releasing it. Releasing the button causes the mechanism to stop the spring from unwinding. As the compressed spring begins to unwind, it transmits energy to a gear train (Part No. 10-12, 14), causing a knocker (No. 13) to periodically impact a rigid membrane (No. 2), which is mounted into the AL head with a circumferential rubber O-ring (No. 3), to provide compliance and allow it to vibrate.

Initially, the design comprised of two flexible membranes in series, similar to that of current ALs; however, it was found that the device could be simplified to the knocker, and one membrane. This concept was validated by attaching a knocker with 2 heads to an electric motor running at 83Hz. The flexible

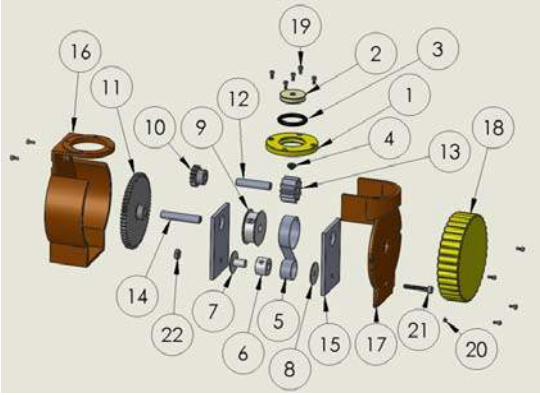

Figure 1: Exploded schematic of the mechanolarynx.

membrane was impacted at 166 Hz, successfully producing voice when pressed to the user's throat.

User feedback established that the device should operate at approximately 120Hz with 10s of phonation time. In order to determine parameters needed to achieve these characteristics, the vibration of the membrane was modeled as a spring-mass damper system with a constant force input (from the knocker), with the time history of the vertical motion given as:

$$y = Ae^{-\beta t}\cos(\omega_d t + \phi) + \left(\frac{F}{\omega Z_m}\right)\sin(\omega t - \theta)$$

where ω_d is the driving frequency, Z_m is the mechanical impedance, F is the amplitude of a sinusoidal-varying constant force input, and ω is the resonance frequency ($\omega = \sqrt{k/m}$) – m is equal to the mass and k is equal to the spring constant. Beta, β, is the temporal absorption coefficient, phi, ϕ, and A, are the phase angle and the amplitude respectively and are determined by initial conditions, and theta, θ, is the phase angle of the forcing function.

The model predicts that a rubber O-ring spring constant of ~ 21.6 N/m and a fixed 1.5 g membrane mass will yield a fundamental frequency of 120 Hz. Along with a 4-headed knocker, and a gear ratio of 10:1, a carbon steel constant torque spring with diameter of approximately 5cm and an arbor diameter of 2.54 mm will be implemented. The spring will have a spring constant of 3.6 g/mm, a width of 1.3cm and thickness of 0.08mm. It is estimated that the spring will provide 3.4 N-m of torque with an unwind speed of 3 rev/sec. This will yield a phonation time of > 10 seconds, with the knocker frequency impacting the membrane at its fundamental frequency.

BUDGET & MARKET ANALYSIS

Table 1 includes a parts list for the proposed AL design and the anticipated prototyping costs. Costs are based on commercial pricing. While the raw material prototype cost for the ML is ~$15.00, additional costs for the prototype development include material for the 3D printer, machining labor, an electrical motor for benchtop validation, prefabricated gear trains, and anticipated overruns of fasteners, springs, etc. As such, the prototype budge is estimated to be ~$250.00

Final production costs are estimated at $5.40/device allowing a for a reasonable target price point of $20.00. Based on the aforementioned global statistics it is estimated that there

Table 1: ML part list with prototype and production costs.

Part Name	Prototype Cost	Production Cost
(1) Outer head	$0.76	$0.10
(2) Inner head	$0.35	$0.05
(3) O-ring	$0.03	$0.02
(4) Impact cone	$0.15	$0.03
(5) Constant torque spring	$7.60	$3.15
(6, 9) Rotating spring cylinders	$0.74	$0.09
(7, 8) Static spring shaft and cap	$0.45	$0.07
(10, 11) Gears	$0.46	$0.30
(12, 14) Gear shafts	$0.34	$0.23
(13) Knocker	$0.50	$0.08
(15) Spring mounting plate	$0.81	$0.11
(16, 17) Casing	$1.38	$0.19
(18) Winding dial	$0.97	$0.13
(19, 20, 21, 22) Fasteners	$0.84	$0.45
Subtotal	**$15.38**	**$5.40**

are approximately 1.2 million potential customers. An initial target of 10,000 units in the first year would capture a conservative market share of ~1.0%. Assuming a compounding market share of ~1.40 annually will enable capturing ~25% of the market over the next 10 years. A production schedule of 10,000 units in the first year would generate revenue of $146,000. A 25% market share within 10 years would result in selling 20,000 units on an annual basis, producing $292,000 in gross profit annually.

This profit is not sufficient, however, to reasonably finance staff salaries, infrastructure, utility and manufacturing start-up costs. Therefore, the strategy that will be employed is to license the design to an existing biomedical firm (e.g. InHealth). Consequently, a provisional patent will be filed to protect intellectual property, and a Limited Liability Corporation (LLC) is being established through collaborations with the Clarkson University Shipley Center for Entrepreneurship.

Nevertheless, the ML design is novel in that it provides speech through a simple mechanical system that does not require the use of batteries or electricity, thereby satisfying a demonstrated market need. This simple design results in a device that is able to produce outcomes similar to those of an EL but at a fraction of the cost of currently available devices.

IMAGE-BASED SIMULATIONS SHOW SIGNIFICANT FLOW FLUCTUATIONS IN A NORMAL LEFT VENTRICLE

Christophe Chnafa (1,2), Simon Mendez (2), Franck Nicoud (2)

(1) Biomedical Simulation Laboratory, Department of Mechanical & Industrial Engineering, University of Toronto, Toronto, Ontario, Canada.

(2) Institute of Montpellier Alexander Grothendieck, University of Montpellier Montpellier, France.

INTRODUCTION

The hemodynamics of the left ventricle (LV) conveys information regarding the heart function. Observation of LV flow may thus reflect the presence of an existing pathology. In addition, there is substantial evidence that the LV hemodynamics can be responsible for the initiation of ventricular remodeling through mechanosensitive feedbacks modulating cardiomyocytes architecture and thus cardiac function [1]. Therefore, accurate assessment of the intraventricular flow is of paramount importance to get further comprehension of the role played by the hemodynamics in normal and abnormal LV.

Previous in vivo studies have been heavily based on velocity data obtained thanks to phase-contrast cardiovascular magnetic resonance (CMR) imaging. However, cycle-to-cycle variations and instabilities in the flow cannot be observed with CMR velocity mapping as the spatio-temporal resolution is relatively low and the measurements are not real-time but rather provide a mean cycle.

Used with caution, image-based computational fluid dynamics (CFD) can retrieve all the scales of the instantaneous flow, hence being able to capture disturbed flows. However, pioneering CFD studies focused only on the large-scale features of the flow i.e. the jets and the large recirculating cell. Apart from a few studies that mentioned the potential presence of flow instabilities, little focus has been given to the disturbed nature of the LV flow, despite its potential importance. However, using a new CMR method to evaluate the intensity and the localization of velocity fluctuations, Zajac et al.[2] recently confirmed the presence of non-negligible in vivo levels of "turbulent" kinetic energy in abnormal and normal LVs.

We emphasize that in addition to be controversial, the nature of the flow in normal heart does not comply with the canonical definition of developed turbulence, which makes even the definition of intracardiac "turbulence" problematic. Nevertheless, non-periodic, 3D fluctuations may appear, given the Reynolds number of order 5000, the flow domain complexity and the pulsatile nature of the flow.

The purpose of this study is to elucidate if a normal LV could harbor flow instabilities, to analyze them and to describe the potential consequences of their presence.

METHODS

Large-eddy simulations were preformed to compute 35 cardiac cycles using the in-house YALES2BIO solver developed at IMAG (www.math.univ-montp2.fr/~yales2bio) in a patient-specific left heart model obtained from CMR images. The 4D image set consists in 20 3D images of spatial resolution $5.0\times1.1\times1.1$ mm^3, which correspond to $21\times256\times256$ voxels. The subject was 26 years old and his cardiac cycles lasted on average T = 750 ms. The model includes the valves, atrium, ventricle, papillary muscles and ascending aorta. The deformations of the heart all along the heart cycle match the CMR exam thanks to an image registration technique [3].

The heart geometry is discretized using ten million tetrahedral elements. The average edge length is close to 0.55 mm during diastole. The time step, based on a Courant-Friedrichs-Lewy stability number of 0.9, varies from 0.2 ms during the beginning of diastole to 0.5 ms during diastasis.

RESULTS

The LV large-scale flow features i.e., the blood ejection, the two vortex rings for the E and A waves and the recirculating cell, are well retrieved (Fig. 1, only diastole is shown here) in accordance with the numerous observations performed in vivo, in silico, and in vitro. However, the present results reveal also large velocity fluctuations during diastole (Fig. 2).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The largest fluctuations are predominantly located in the first third of the LV and their frequency content reaches 200 Hz (Fig. 3).

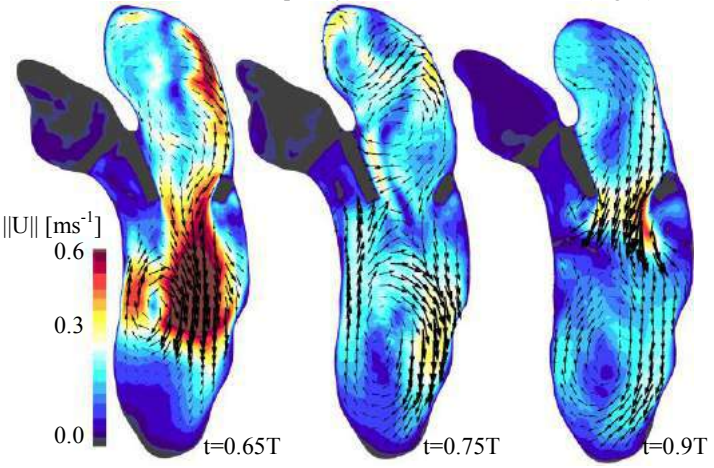

Figure 1: Phase-averaged diastolic velocity field and magnitude over a plane through the left heart. Valves are depicted in black

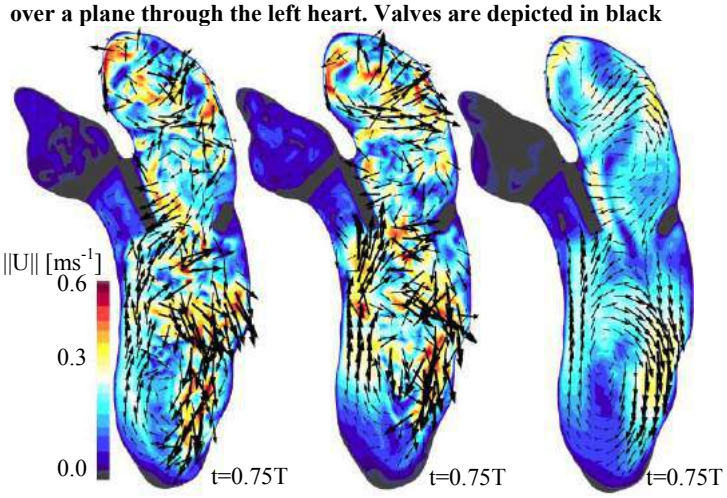

Figure 2: Left and middle plots: typical instantaneous velocity fields at 0.75 T for two consecutive heart cycles. Right plot: phase-averaged velocity field over thirty heart cycles at 0.75 T.

DISCUSSION

Our results question the common idea of laminar flow in the normal LV. Imposing the flow to be laminar (as often done in CFD for the LV) may be sufficient to retrieve main large-scale hemodynamic features, namely jets, recirculating cell, and ejection. However, a transitional or turbulent state features small-scale phenomena that cannot be retrieved under the laminar hypothesis. Therefore, our results suggest that the laminar assumption often made implicitly should be reconsidered in LV CFD if one wants to simulate all the flow features.

It is worth noting that any CFD study where flow instabilities are not properly represented cannot address the prevalence of LV bruits. Among the sounds usually reported, the S3 bruit (detected in one third of asymptomatic individuals younger than 40 [4]) is a brief sound harboring a main frequency content in the range of 10-100 Hz and occurring at the end of the E wave, 120-200 ms after the start of diastole. It is widely reported that "vibrations" occurring during the deceleration of the E wave generate this sound. These "vibrations" may be generated by the interaction of the flow instabilities with the LV tissue. While we do not directly prove that the reported fluctuations are responsible for the S3 bruit, we show here that flow fluctuations obtained in the present calculations are in the same frequency range as the S3 bruit.

As shown in vivo by Zajac et al.[2] a certain level of fluctuations intensity can be a sign of cardiac dysfunction. Nevertheless, in light of their results and ours, it seems that velocity fluctuations in LV flows are actually not a synonym of pathological flows: they should not be considered as an absolute proof of a pathological state.

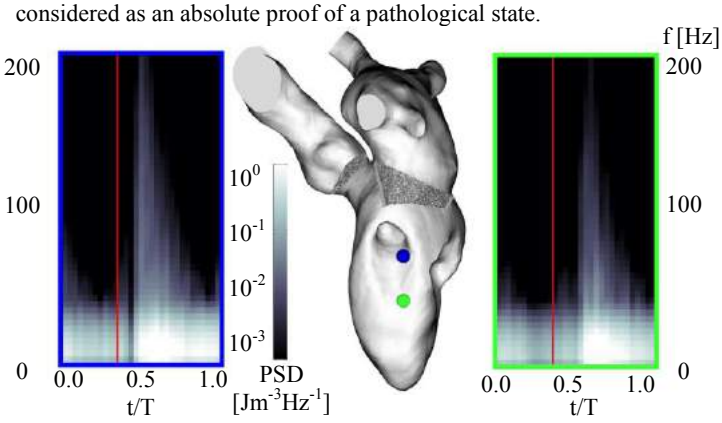

Figure 3: Time-frequency representation of the Power Spectral Density (PSD) of the velocity fluctuations at two locations. Each vertical slice of a spectrogram exhibits the frequency spectrum of the flow at a specific time. Red lines on spectra delimit systole (0 to 0.34 T) from diastole (0.34 to 1.0 T).

As CMR is widely used to explore the LV flow, the prevalence of fluctuations in normal LV serves as a reminder that time-resolved velocity fields measured with CMR are not instantaneous. Blood flow patterns and derived quantities correspond to mean flow fields, not the actual flow seen by the cells. While the same mean flow as CMR is retrieved, Fig. 2 shows how different the instantaneous flow may be.

These fluctuations amplify the forces exerted by the blood on the LV wall cells and can potentially trigger mechanosensitive feedbacks [1]. It has been shown in vitro that even weak flow stimuli can induce modifications of gene expression, which may result in its functional modification. Although the remodeling mechanisms of the LV are not completely understood and that the relevance of these fluctuating velocities compared with the mean flow field remains to be defined, fluctuations can be expected to play an important role in myocardial function and adaptations.

In conclusion, as the nature of the flow directly affects the characteristic time scales and local levels of flow stresses, it can be speculated that our findings point toward new directions for future clinical research, complementing conventional studies focusing on the mean flow field for the assessment of the cardiovascular flow and the heart mechanosensitive feedbacks.

INTRODUCTION

Intracranial aneurysms are common, they affect 2-3% of the population, and have devastating consequences if they rupture [1]. Fortunately, aneurysm rupture is quite rare and many aneurysms never rupture. Because the risk of interventions can outweigh the natural risk of rupture, it is important to discriminate between rupture prone aneurysms and those that are very unlikely to rupture.

Aneurysm enlargement is thought to be governed by a progressive degradation and weakening of the wall induced by abnormal hemodynamics [2]. The strength of the wall depends on its structure (cellular content and collagen fiber architecture). Histological changes of the wall, mainly inflammation and decelullarization, have been previously observed in ruptured and rupture prone aneurysms [3]. However, the causes of this degenerative remodeling of the wall are largely unknown.

Previous studies have identified hemodynamic differences between ruptured and unruptured aneurysms that suggest that hemodynamics may affect the structure of the wall and its strength [4,5].

Thus, the purpose of this article is to present recent results regarding associations between intrasaccular flow characteristics of cerebral aneurysms and wall inflammation and other degenerative changes of the aneurysm wall [6].

METHODS

A total of 20 patients with intracranial aneurysms undergoing surgical clipping were studied. Pre-operative 3D computed tomography angiography (CTA) images were used to build patient-specific computational fluid dynamics (CFD) models. Pulsatile simulations were carried out by numerically solving the 3D unsteady Navier Stokes equations assuming Newtonian viscosity and rigid walls. The numerical simulations had a minimum mesh resolution of 200 μm and a time resolution of 0.01 sec and were run for two cardiac cycles. A number of hemodynamic variables were then computed from the results of the second cycle to characterize the aneurysm flow conditions, as in previous studies [7].

During surgery, tissue samples were resected from the aneurysm domes and analyzed with histology and immunohistochemistry. Specifically, the 20 samples were analyzed for the presence of inflammatory cells (CD45 staining), lipid accumulation (ORO staining), and the presence of organized thrombus (HE staining), as in previous studies [6, 8].

To test the hypothesis that abnormal wall shear stress (WSS) is associated with inflamed walls, the number of CD45+ cells was compared between aneurysms with low WSS (<4.5 dyne/cm^2), high WSS (>18 dyne/cm^2), and medium WSS (between 4.5 and 18 dyne/cm^2). Similarly, flow variables were compared between aneurysms with high wall inflammation (CD45+ counts > 100), low wall inflammation (CD45+ counts < 10) and mild wall inflammation (CD45+ counts between 10 and 100). The statistical comparisons between these aneurysm groups were carried out using the one-sided Wilcoxon test due to the small sample size. Differences were considered statistically significant if $p<0.05$ (95% confidence).

RESULTS

Comparisons of mean flow variables (averaged over the aneurysm region and over time) between aneurysms with different levels of wall inflammation are presented in Fig.1 (top). For simultaneous display and comparison, the flow variables in this graph have been scaled to the maximum, corresponding to the high CD45 group.

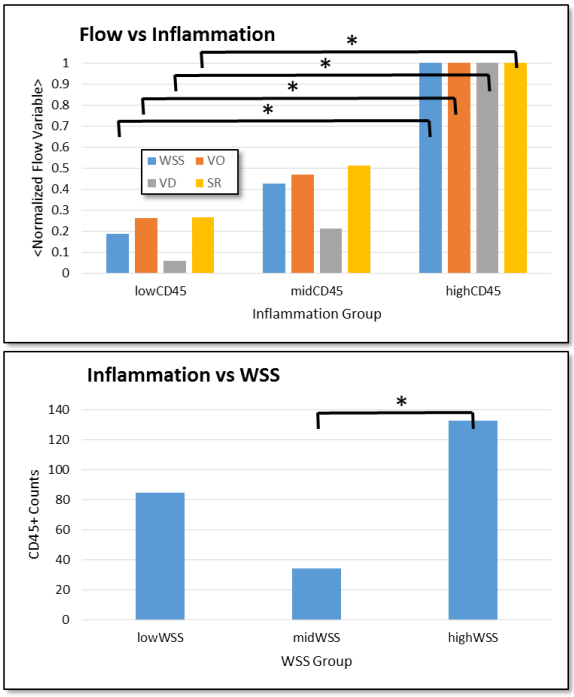

Figure 1: Hemodynamics and Wall Inflammation. Top: mean wall shear stress (WSS), vorticity (VO), viscous dissipation (VD) and shear rate (SR) in walls with low, middle and high inflammation. Bottom: Number of inflammatory cells (CD45+) in aneurysms with low, middle and high WSS.

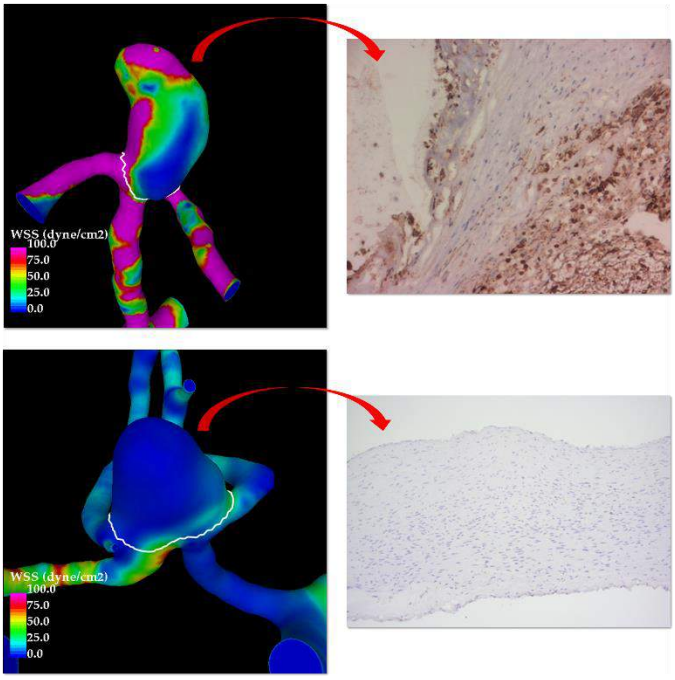

Figure 2: Example aneurysm with high WSS (top-left) and high wall inflammation (top-right), and aneurysm with low WSS (bottom left) and low wall inflammation (bottom right). Visualizations show peak systole WSS.

In our study, no association between flow variables and aneurysm rupture reached statistical significance. On the other hand, increased wall inflammation was associated with rupture (CD45+, p=0.031).

Aneurysms with high inflammation (high CD45+ group) had significantly larger wall shear stress (WSS, p=0.032), vorticity (VO, p=0.046), viscous dissipation (VD, p=0.046) and shear rate (SR, p=0.046) than aneurysms with low inflammation (low CD45 group).

Similarly, aneurysms in the high WSS group had significantly larger numbers of inflammatory cells than aneurysms with WSS in the middle range (Fig.1 – bottom). Aneurysms in the low WSS group also had larger number of inflammatory cells than aneurysms in the mid WSS group but this trend did not reach statistical significance.

Additionally, high vorticity (p=0.034), viscous dissipation (p=0.020), and shear rate (p=0.034) were also associated with endothelium damage, which in turn associated with wall inflammation (p=0.034). Although organized luminal thrombosis associated with inflammation (p=0.018), organized thrombosis was associated with low minimum WSS (p=0.034) but not with the flow conditions that associated with inflammation.

DISCUSSION

In our series, inflammation associated with aneurysm rupture. As such, inflammation could be considered a potential biomarker for rupture, which could potentially be imaged clinically.

Our results indicate that there is a connection between intrasaccular flow characteristics with inflammation and other histological changes of the aneurysm wall. Inflammation associated with increased wall shear stress, vorticity, viscous dissipation and shear rate, i.e. a high flow environment. Interestingly, high levels of wall inflammation were also observed in a few samples with low wall shear stress, suggesting that both abnormally high and low WSS may induce degenerative changes to the wall. However, in general high and low wall shear stress levels associated with different histological changes of the aneurysm wall, possibly suggesting different pathways or mechanisms of wall degeneration.

The current study supports the idea that image-based CFD models could be used to identify unruptured intracranial aneurysms at higher risk of developing wall inflammation, and since inflammation is associated to rupture, these aneurysms would require more careful observation or preventive treatment.

INTRODUCTION

Cancer stem-like cells (CSCs) have attracted a great deal of attention as the target of cancer therapy due to their high resistance to chemotherapy and capability of initiating and/or reinitiating tumor growth. The miR-34a, originally studied as a p53 target, has been identified as a key negative regulator of the variant CD44 receptors overexpressed on the prostate CSCs.[1] However, as with many other genetic materials, the use of free miR-34a as a medicine is limited by extracellular barriers including its unstable molecular structure in the environment including air, rapid clearance in blood, and poor intracellular uptake. Recent advances in nanotechnology make it possible to overcome the extracellular barrier by encapsulating the genetic materials in nanoparticles to shield them from the enzymatic environment outside the cells and increase their half-life in circulation.[2] However, nanoparticles are usually taken up by cells via endocytosis, which results in the intracellular barrier that can easily degrade the genetic materials released from the nanoparticles. Therefore, the major challenge to nanoparticle-mediated delivery of miRs is to achieve endosomal/lysosomal escape and ensure effective release of the miRs into the cytosol where they perform their biological functions. To overcome this challenge, we present a novel strategy by using a near-infrared (NIR) laser to activate "bomb-like" nanoparticles for endosomal/lysosomal escape and cytosolic gene delivery.

METHODS

To prepare HLPP or HLPP-IAR nanoparticles, various amounts of PLGA, DPPC (lipid), and PF127 were dissolved in 2 ml of methylene chloride. After adding 0.4 ml of DI water either with or without ICG (0.25 mg/ml), ammonium bicarbonate (10 mg/ml), miR-34a (0.25 mg/ml), and chitosan (1 mg/ml), the immiscible solutions were emulsified by sonication for 1 min. Then, this first emulsion and 4 ml of chitosan-PF127 and HA solution (in DI water) were emulsified by sonication for 2 min. After rotary evaporation to remove the organic solvent, the nanoparticles were collected by centrifugation at 1620g for 10 min at room temperature and washed twice with DI water.

In vivo antitumor efficacy and systemic toxicity. After tumors reached ~5 mm in diameter, mice were treated intravenously via the tail vein with 100 μl saline or blank HLPP nanoparticles, free miR-34a (1.5 mg/kg body weight), HLPP-IA nanoparticles (ICG: 1.5 mg/kg body weight), HLPP-AR nanoparticles (miR-34a: 1.5 mg/kg body weight), and HLPP-IAR nanoparticles (miR-34a: 1.5 mg/kg, ICG: 1.5 mg/kg body weight) at day 1, 7, 14, and 21. At 12 h after each the intravenous injection, NIR irradiation at 0.7 W/cm^2 for 2 min was applied on the tumors. Tumor growth was monitored every two days. The tumor volume (V) was calculated as: $V = (L \times W^2)/2$, where L is long diameter and W is short diameter determined using a caliper. The mice were euthanized at day 30 after the first injection. Tumors, livers, lungs, hearts, spleens, and kidneys were collected, formalin fixed, paraffin embedded, and haematoxylin&eosin (H&E) stained for further histological analysis.

RESULTS

Ammonium bicarbonate (NH_4HCO_3) could be thermally triggered to generate carbon dioxide (CO_2) and ammonia (NH_3) gases. Therefore, we hypothesized that the endosomes/lysosomes could be broken open if the ammonium bicarbonate encapsulated inside the nanoparticles turns into gases when heated up. We synthesized the nanoparticles using five different materials approved by the U.S. Food and Drug Administration (FDA) for medical use: poly (D,L-lactide-co-glycolide) (PLGA), Pluronic F127 (PF127), chitosan, hyaluronic acid (HA), and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

dipalmitoyl phosphatidylcholine (DPPC).[3] Three agents are encapsulated inside the nanoparticles including miR-34a for gene therapy of prostate CSCs, indocyanine green (ICG) for NIR laser activated photothermal effect, and ammonium bicarbonate for gas generation under heating. We prepared the nanoparticles using a modified/improved double-emulsion method (**Figure 1A**). First, aqueous solution containing ICG, ammonium bicarbonate, miR-34a, and chitosan was emulsified with organic solvent containing PF127, PLGA, and DPPC to form a water-in-oil structure where ICG, ammonium bicarbonate, and miR-34a were encapsulated in the hydrophilic core dispersed in organic solvent. Unlike conventional double-emulsion approach that uses PVA as the stabilizer during the second emulsion, a mixture of chitosan-PF127 and HA was used instead in this study for surface modification with HA for targeting CSCs.[4]

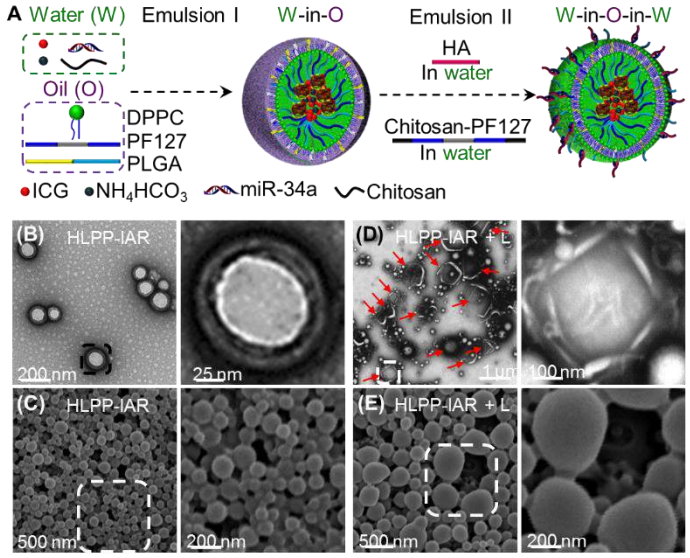

Figure 1: A schematic illustration and characterizations of the "bomb-like" effect of the nanoparticles.

Typical transmission (TEM) and scanning (SEM) electron microscopy images of the miR-34a, chitosan, ammonium bicarbonate, and ICG-laden HLPP (HLPP-IAR) nanoparticles are shown in **Figure 1B** and **1C**, respectively. The HLPP-IAR nanoparticles have a uniform size, spherical morphology, and core-shell structure. Chitosan was mixed with miR-34a before encapsulation, which significantly increases the encapsulation efficiency to more than 85% from ~45% without chitosan. Interestingly, for the HLPP-IAR nanoparticles: their size decreased to <100 nm when heated from 22 °C to 37 °C and mostly increased to >300 nm with further heating to 43 °C (**Figure 1D**). Some of the large particles might break up into small nanoparticles as shown in **Figure 1E**. The former is desired for tumor targeting at the body temperature while the latter can be used to break open the endosome/lysosome (~150-200 nm in diameter) and release the encapsulated miR-34a into the cytosol.

As shown in **Figure 2A**, overlap between the HLPP-IAR nanoparticles (red) and endosomes/lysosomes (green) is evident in the 2D cultured cancer cells, which gives the bright yellowish appearance when merged. In contrast, with NIR laser irradiation, the overlap was minimal and the miR-34a (red) distributed throughout the cytosol (bottom, w/ laser), indicating the NIR laser triggered escape of the nanoparticles from the endosomes/lysosomes. We next investigated the biodistribution in mice of the HLPP-IAR nanoparticles to understand the enhanced in vivo antitumor capacity. As shown in **Figure 2B**, highly enhanced fluorescence of ICG was observable in tumor at 6 h after intravenous injection of the HLPP-IAR nanoparticles, compared to free ICG. Lastly, we tested the safety and efficacy of the HLPP-IAR nanoparticles for gene therapy of prostate cancer using human prostate tumor grown in nude mice. Except for the saline and HLPP groups, all the other groups were with NIR laser irradiation at 12 h after intravenous injection of the gene formulations. As shown in **Figure 2C**, the HLPP-IAR nanoparticles with laser irradiation (HLPP-IAR+L) exhibited outstanding antitumor capacity and significantly reduced the tumor volume during the entire observation period. It is the "nanobomb" effect due to the combination of both ICG and ammonium bicarbonate with NIR that breaks the intracellular barrier to deliver the miR-34a specifically into the cytosol where the miR-34a performs its function to destroy tumor. The size and weight of the tumors harvested from the HLPP-IAR+L group on day 30 were significantly less than that from the other groups.

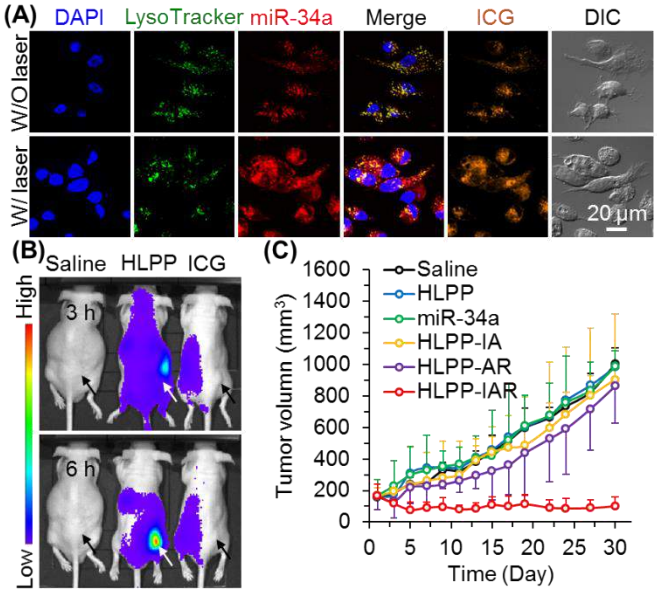

Figure 2: NIR Laser controlled endosomal and lysosomal escape and cytosolic release of miR-34a and its impact on excellent antitumor efficacy and safety *in vivo*.

DISCUSSION

Although the tissue penetration of the NIR is limited to less than ~1 cm and multiple polymers are needed for preparing the nanosystem, NIR could be delivered into deep tissue using minimally invasive approaches and the preparation of the nanosystem using the double-emulsion method is straightforward. Therefore, the present study demonstrates the great potential of the NIR laser-activatable "nanobomb" for microRNA delivery to augment cancer therapy.

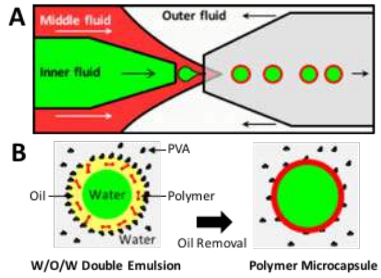
INTRODUCTION

Stimuli-responsive drug delivery systems have several advantages, including local delivery, maintenance of drug concentrations within a therapeutic range, and preservation of activity. One desirable feature for these systems is self-regulation, wherein physiology controls release via stimuli-sensitive triggers (e.g. temperature, pH, or enzyme activity [1]). However, to date, few systems exist that take advantage of the mechanical environment to tune release [2]. Tissues within the body experience mechanical perturbation across multiple force magnitudes and length scales, from mechanotransduction at the cellular level [3] to the dynamics of whole joints. These forces provide feedback to regulate cell biology and maintain tissue integrity, but can also, at supra-physiologic levels, initiate degeneration [4]. Current strategies to repair degenerated tissues include combinations of cells, scaffolds, and growth factors; however, maturation of such engineered tissues in a demanding mechanical environment may require additional factors, and most delivery systems for such factors are operative over time scales based on material degradation rather than based on the physical environment. To address this, we developed and characterized a novel mechano-activated microcapsule (MAMC) technology for "on-demand" drug delivery based on mechanical inputs as a new approach to regenerative medicine.

METHODS

MAMCs were fabricated using a glass capillary microfluidic device [5] to form a monodisperse Water/Oil/Water (W/O/W) double emulsion. For proof-of-concept, the inner aqueous phase contained FITC-dextran (2 MDa) and was sheathed by an oil phase consisting of poly(lactic-co-glycolic) acid (PLGA 50:50 + Nile Red 0.001% w/v) to form the microcapsule shell. Shell thickness and outer diameter were tuned by controlling the sheath flow rates and polymer concentration **(Fig 1)**. To demonstrate mechano-activation, a layer of MAMCs was subjected to increasing load (~500 MAMCs, parallel plate compression test, n=3/load). Intact microcapsules served as negative controls, and microcapsules compressed to 5N served as positive controls. Following compression, MAMCs were imaged by confocal microscopy to determine the empty fraction. The slope of the % empty vs. load curve was determined for each formulation. To determine the impact of degradation on release, MAMCs were incubated at 37^{o}C in PBS, and mechano-activation was evaluated after 1 (1hr), 3, 7, and 14 days. Confocal 3D volume reconstructions and scanning electron micrographs were also obtained. Mechano-activation was further



PLGA Conc. (w/v %)	Inner (mL/hr)	Middle (mL/hr)	Thickness (t, μm)	Outer Diameter (D, μm)	t/D
(C) 0.9	1	5	0.5	76	0.006
(D) 1.8	2	6	0.65	105	0.006
(E) 2.7	2	6	1.01	105	0.009

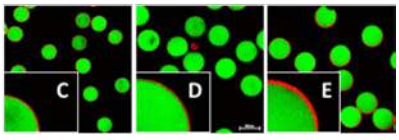


Figure 1. (A-B) Schematic of double emulsion microcapsule generation using a glass capillary microfluidic device. (C-E) Fabrication parameters (polymer concentration and flow rates) determine MAMC dimensions.

assessed in 3D constructs by embedding MAMCs in a 30% w/v photo-crosslinked poly(ethylene glycol) diacrylate (PEGDA) hydrogel whose stiffness was comparable to native articular cartilage. Using a custom confocal-mounted compression device [6], MAMC-laden hydrogels were compressed in unconfined compression and their deformation and rupture were tracked (0-20% strain, steps of 4%, followed by compression until hydrogel failure).

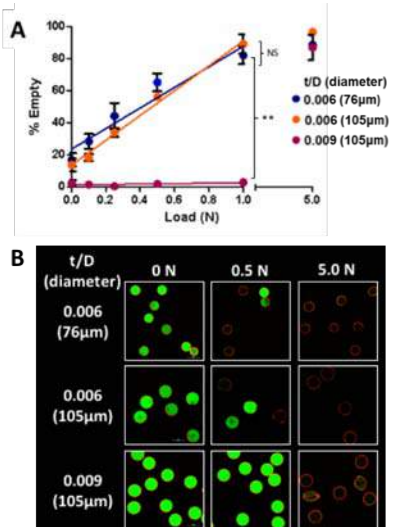

Figure 2. Mechanical release profiles of MAMCs containing dextran (green) with labeled shells (red). (A-B) MAMCs deform and fracture with increasing load, dependent on the t/D ratio (slopes differ: **p<0.01).

RESULTS

Mechanical testing of MAMCs demonstrated that microcapsule rupture and release depended on the shell thickness to diameter ratio (t/D), with a decreasing ratio resulting in MAMCs with increased sensitivity to load (**Fig 2**). MAMCs with matched t/D ratios, but different shell thicknesses and diameters, showed similar mechano-activation profiles. In these model microcapsules, PLGA was chosen due to its biocompatibility; however, polymer degradation might impact MAMC response. Indeed, PLGA MAMCs showed increased sensitivity to load after seven days of incubation at 37°C (**Fig 3**), and by day 14 had lost structural integrity. Confocal reconstructions and SEM confirmed the spherical, intact shape of naïve MAMCs, with failure in compressed MAMCs illustrated by ruptured morphology of the shell wall (**Fig 3C**). In 3D constructs, MAMCs deformed with increasing gel compression, becoming ellipsoid at 20% and rupturing at 60% strain (hydrogel failure, **Fig 4**).

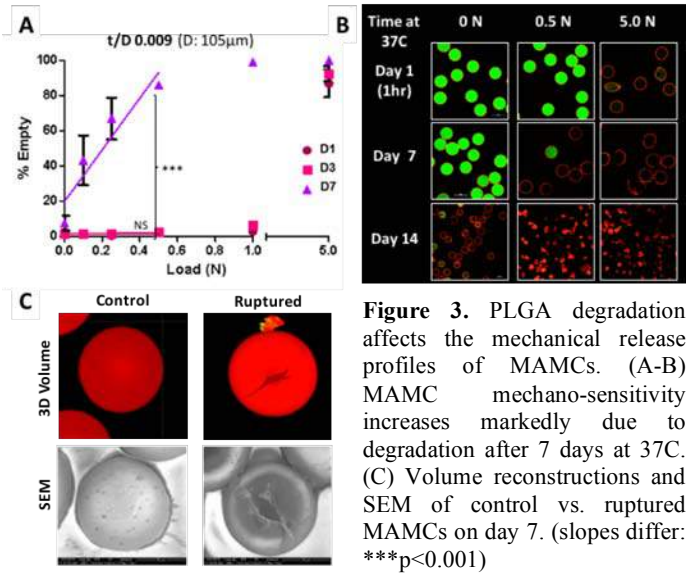

Figure 3. PLGA degradation affects the mechanical release profiles of MAMCs. (A-B) MAMC mechano-sensitivity increases markedly due to degradation after 7 days at 37C. (C) Volume reconstructions and SEM of control vs. ruptured MAMCs on day 7. (slopes differ: ***p<0.001)

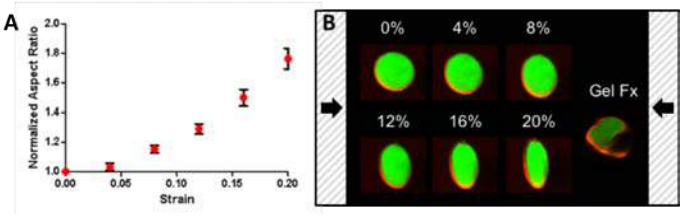

Figure 4. Micro-compression of MAMCs embedded within hydrogels show MAMC deformation (aspect ratio) with hydrogel compression (A-B). MAMCs ruptured only upon hydrogel fracture (n = 11 MAMCs/ 3 hydrogels).

DISCUSSION

This study demonstrated the production of tunable mechano-activatable microcapsules (MAMCs) whose failure characteristics depend on the physical properties of the microcapsule. As shown here, both the shell thickness to diameter ratio and polymer degradation process affect MAMC sensitivity to mechano-activation. We also observed MAMC deformation and release within 3D constructs (i.e. mimicking MAMCs in engineered tissues for repair of a cartilage defect). Controlling the MAMC and surrounding matrix properties within this model will enable tuning of release in response to physiologic loading scenarios. Ongoing studies are exploring the effects of long-term dynamic loading on MAMC release profiles in concert with efficacy studies to demonstrate the chondrogenic effects of bioactive molecules (e.g. TGF-β) released from MAMCs in an engineered cartilage system.

As we continue to characterize this novel technology, we envision the creation of a suite of MAMCs with different physical and compositional properties that are programmed to release within particular physiologic or supra-physiologic loading scenarios. By combining cohorts of microcapsules with different rupture thresholds, release events can be programmed sequentially to stimulate tissue repair in an autonomic manner. Applications for this technology include direct injection for release during passive loading with rehabilitation, prophylactic injection prior to the start of high impact activities, as well as MAMCs embedded within engineered tissues to stimulate growth and repair in a manner that is dictated by the evolving mechanical properties of the newly formed tissue. Importantly, these applications are not limited to one tissue or loading scenario, due to the tunable nature of the MAMCs, and as such this technology is a valuable platform for self-regulated drug delivery across the musculoskeletal system.

INTRODUCTION

Because of the devastating consequences of cerebral aneurysm rupture, physicians often perform prophylactic interventions. However, interventions still carry significant risks that can exceed the natural risk of rupture [1]. Thus, it is important to improve aneurysm evaluation to treat only high risk aneurysms avoiding unnecessary interventions.

Numerous patient and behavioral characteristics have been investigated as possible risk factors, including gender, age, family history, smoking and hypertension. According to past studies, the most important aneurysm-specific rupture risk factors are size and location [2]. However, it is well known that small aneurysms do rupture [3]. On the other hand, the posterior communicating artery (PCOM) is a common site for aneurysm development and aneurysms at this location have larger risks than those at other locations such as the middle cerebral artery or other segments of the internal carotid artery [4]. Therefore, often clinicians need to decide whether to treat or not PCOM aneurysms, but do not have reliable parameters to guide or support their decisions.

The purpose of this study was to propose a new angio-architecture classification of PCOM aneurysms and to test if the proposed classes have different rupture rates as well as hemodynamic and geometric characteristics that could be used to improve aneurysm evaluation.

METHODS

We have constructed a database of over 1800 aneurysms imaged with 3D rotational angiography (3DRA). This database contains 3D images and anonymized clinical information such as rupture status, aneurysm location and size, patient gender and age, etc.

All PCOM aneurysms in our database (n=275, 127 ruptured, 148 unruptured) were included in the current study. Computational fluid dynamics (CFD) models of all PCOM aneurysms were constructed from the 3DRA images. Pulsatile simulations were carried out by numerically solving the 3D unsteady Navier Stokes equations assuming Newtonian viscosity and rigid walls. The simulations had a minimum mesh resolution of 200 μm and a time resolution of 0.01 sec and were run for two cardiac cycles. A number of flow variables were then computed from the results of the second cycle to characterize the aneurysm flow conditions [5,6].

All PCOM aneurysms were classified into different angio-architecture types depending on the location of the aneurysm orifice with respect to the ICA-PCOM bifurcation, as shown in Fig. 1. Rupture rates as well as geometric and hemodynamic variables were statistically compared between the different angio-architectures.

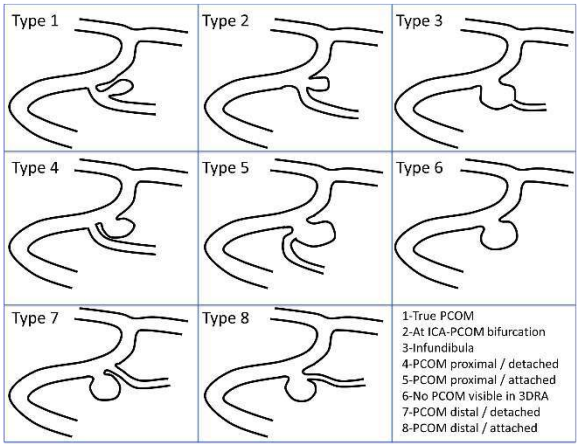

Fig. 2: Angio-architectures of PCOM aneurysms.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

The distribution of all ruptured and unruptured aneurysms of our database, subdivided by location, is presented in Fig.2a) (ACA= anterior cerebral artery, ACOM= anterior communicating artery, ICA= internal carotid artery, MCA= middle cerebral artery, PCOM= posterior communicating artery, BA= basilar artery, VA= vertebral artery, PCA=posterior cerebral artery). This graph shows that PCOM location has the second largest proportion of ruptured aneurysms after ACOM. Fig. 2b) shows the distribution of ruptured and unruptured PCOM aneurysms by size, showing that the majority of ruptured PCOM aneurysms are between 3-10mm, i.e. are relatively small.

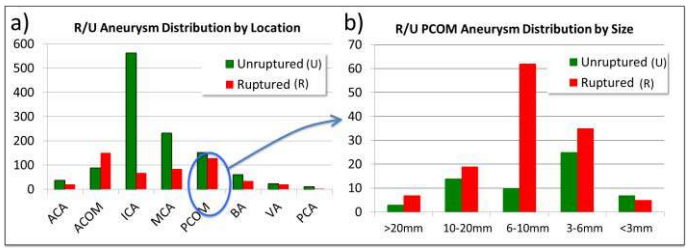

Fig. 2: Distribution of ruptured and unruptured aneurysms of our database by location (a), and PCOM aneurysms by size (b).

In our series, no PCOM aneurysms were found in types 7 or 8. The distribution of ruptured and unruptured PCOM aneurysms by angio-architecture is presented in Fig.3a), showing that type 2 (G2= aneurysms with orifices involving both the ICA and the PCOM) have the largest rupture rate. Grouping types 1-2 (G12=aneurysms with orifices involving the PCOM artery) and types 3-6 (G36=aneurysms with orifices involving only the ICA) yields the ruptured/unruptured distribution presented in Fig.3b), showing that group G12 has a larger rupture rate (62%) than group G36 (38%). Contingency table analyses using the Chi-Square test (and Fisher test for 2x2 tables of Fig.3b) indicate that the associations between angio-architecture and aneurysm rupture are statistically significant ($p<0.0001$).

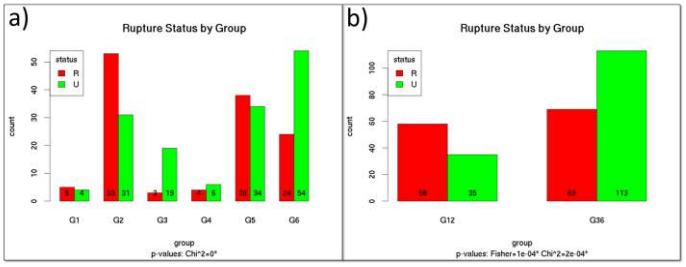

Fig. 3: Number of ruptured and unruptured aneurysms in each angio-architecture class (a), and by merging types 1-2 (G12) and types 3-6 (G36) (b).

Comparisons of geometric and flow variables between aneurysms of groups G36 and G12 are presented in Fig.4 a) and b), respectively. These graphs shows the ratio of mean variables of the G12 group over the mean values of the G36 group. Statistically significant differences ($p<0.05$, 95% confidence) according to the unpaired Wilcoxon test are indicated with an * next to the variable names. Aneurysms in G12 (larger rupture rate) had significantly larger aspect ratio (AR, p=0.0236), larger maximum wall shear stress (WSSmax, p=0.0077), more concentrated WSS distributions (SCI, p=0.0048), larger oscillatory shear index (OSImean, p=0.0164), and more unstable flow patterns (podent, p=0.025).

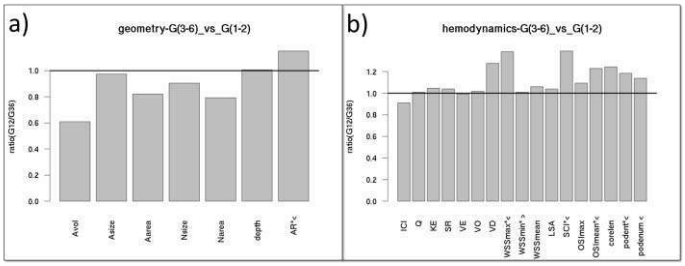

Fig. 4: Comparison of geometric (a) and hemodynamic (b) variables between aneurysms of groups 1-2 and 3-6.

DISCUSSION

In this study we proposed a new PCOM aneurysm classification strategy based on different angio-architecture classes that take into account the location of the aneurysm orifice and the origin of the PCOM artery with respect to the aneurysm sac. Aneurysms in the different angio-architecture classes have different rupture rates. The association between angio-architecture and aneurysm rupture suggest that angio-architecture could be considered a potential PCOM aneurysm risk factor that could help improve evaluation of aneurysms at this location.

Our study identifies type 2 (at the ICA-PCOM bifurcation apex) as the angio-architecture with the largest rupture rates, and type 6 (lateral aneurysms with no visible PCOM) with the lowest rupture rate. Grouping types 1-2 and 3-6 reveals that aneurysms with orifices involving the PCOM (G12) have higher rupture rate and that these aneurysms have different hemodynamic environments than aneurysms with orifices on the ICA (G36). The hemodynamic environments associated with the higher rupture rate angio-architecture are characterized by increased maximum wall shear stress, more concentrated WSS distributions and more unstable and oscillatory flow patterns.

The current study suggests that the proposed angio-architecture classification could be used to identify PCOM aneurysms at higher risk of rupture, and that the observed differences in hemodynamic environments could help explain the different rupture rates associated with the various angio-architectures.

A NOVEL STRUCTURAL CONSTITUTIVE MODEL FOR PASSIVE RIGHT VENTRICULAR MYOCARDIUM: TOWARDS AN UNDERSTANDING OF REMODELING DURING PULMONARY HYPERTENSION

Reza Avazmohammadi, Michael S. Sacks

Center for Cardiovascular Simulation,
Institute for Computational Engineering and Sciences

INTRODUCTION

The right ventricular (RV) is recognized to play a key role in development of cardiopulmonary disorders such as pulmonary arterial hypertension (PAH) [1]. From mechanistic point of view, PAH imposes a pressure overload on the RV free wall (RVFW), leading to elevated wall stress. This leads to progressive hypertrophy and remodeling, and ultimately in mechanical failure of the right heart [2]. Our recent studies [3, 4] have demonstrated substantial remodeling occurs in the RVFW under PAH. These observations highlight the need for a constitutive model for RV myocardium under remodeling conditions.

Our objective in the present work is to develop a structural constitutive model of the viable, passive RV myocardium that extends previous approaches by accounting realistic 3D distribution of the myocardium constituents. The model incorporates the novel transmural distribution of myo- and collagen fiber orientation as separate architecture of each fiber type, and accounts for the collagen fiber recruitment. We utilized extant tissue structural information and comprehensive mechanical data, available from recent works on the murine experimental studies [3, 4], to estimate parameters. A novel aspect of the present approach is the incorporation of the effects of fiber-fiber interactions.

METHODS

Mechanical testing and structural quantification data. Details of the experimental methods have been previously presented [3]. Briefly, viable RV myocardium specimens (n=5) were isolated from the rats and attached to the biaxial mechanical testing device [3]. Myofiber and collagen fiber orientation distributions were determined (n=3) by analyzing transmural histological sections.

Biomechanical Modeling. The RVFW is primarily composed of two major fiber types: the myo- and collagen fibers. For the collagen fibers, we make a distinction between two sub-groups: the "thick" perimysial fibers observed to be approximately aligned with the myofibers [3], and "fine" endomysial collagen fibers that surround individual myofibers and connect to the thicker collagen fibers. Assuming that the constitutive behavior of each constituent can be described by a pseudo-hyperelastic strain energy function, the total energy function of the myocardium can be written as

$$\Psi(\mathbf{E}) = \phi^{mat}\,\Psi^{mat}(\mathbf{E}) + \phi^{myo}\,\Psi^{myo}(\mathbf{E}) + \phi^{col}\left[\Psi^{col}(\mathbf{E}) + \Psi^{m\text{-}c}(\mathbf{E})\right] \quad (1),$$

where $\mathbf{E}$ is the Green-Lagrange strain tensor, Ψ^{mat}, Ψ^{myo} and Ψ^{col} are the strain energy functions associated with the matrix phase, myofibers and (thick) collagen fibers, respectively, and $\Psi^{m\text{-}c}$ refers to the energy contribution of interaction between the myo- and (thick) collagen fibers which is intended to (at least partially) capture the mechanical contribution of the "fine" collagen fibers. Also, ϕ denotes the volume fraction of respective phases. The final expression for 2nd Piola-Kirchhoff stress tensor $\mathbf{S}$ derived from proposed energy terms in (1) reads as

$$\mathbf{S} = \partial\Psi / \partial\mathbf{E} - p(2\mathbf{E}+\mathbf{I})^{-1} = \phi^{mat} k^{mat}\,\mathbf{I} - p(2\mathbf{E}+\mathbf{I})^{-1} + 1/H \times$$

$$+\left[\phi^{myo} k_1^{myo} \int_0^H \int_{-\pi/2}^{\pi/2} \Gamma^{myo}\,(1 - 1/\sqrt{I_4})\; e^{\left[k_2^{myo}(\sqrt{I_4}-1)^2\right]}\;(\mathbf{N}\otimes\mathbf{N})\; d\Theta\, dZ\right.$$

$$\left.+\,\phi^{col} k^{col} \int_0^H \int_{-\pi/2}^{\pi/2} \Gamma^{col} \int_{\lambda_{lb}}^{\lambda_{ub}} (D(\lambda_s)/\lambda_s^2)(1-\lambda_s/\sqrt{I_6})\, d\lambda_s\;(\mathbf{M}\otimes\mathbf{M})\, d\Phi\, dZ\right.$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$+\phi^{col} k_1^{m-c} \int_0^H \int_{-\pi/2}^{\pi/2} \int_{-\pi/2}^{\pi/2} \int_{\lambda_{lb}}^{\lambda_{ub}} \Gamma^{myo} \Gamma^{col} D(\lambda_s) \left\{ (\varphi_1 - \varphi_2) / \lambda_s^2 (\mathbf{M} \otimes \mathbf{M}) \right.$$

$$\left. + \left\{ \varphi_1 - \left[k_2^{m-c} (I_6 / \lambda_s^2 - 1) + 1 \right] \varphi_2 \right\} (\mathbf{N} \otimes \mathbf{N}) \right\} d\lambda_s \, d\Phi \, d\Theta \, dZ], \quad (2)$$

where k's are material constants associated with each phase, $D(\lambda_s)$ is the recruitment function for (thick) collagen fibers with lower and upper bounds λ_{lb} and λ_{ub}, $\mathbf{M}$ and $\mathbf{N}$ denote myo- and collagen fiber directions (see Figure 1), respectively, H is the normalized thickness of the RVFW, Z denotes the transmural direction, Γ's are transmural distribution functions for fiber orientation, p is unknown hydrostatic pressure, and $\mathbf{I}$ is the identity tensor. Also, $\varphi_1 = \exp[k_2^{mc}(I_4 + I_6 - 2)]$ and $\varphi_2 = \exp[k_2^{mc}(I_4 - 1)]$ with kinematical invariants $I_4 = 2\mathbf{N}\cdot(\mathbf{EN}) + 1$ and $I_6 = 2\mathbf{M}\cdot(\mathbf{EM}) + 1$.

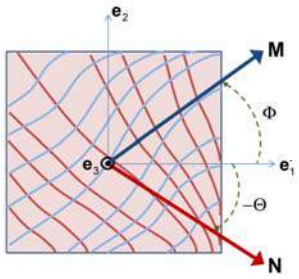

Figure 1: Ensembles of myo- and collagen fibers with uniform orientations, characterized by unit vectors $\mathbf{N}$ and $\mathbf{M}$.

A novel feature of the constitutive model (2) is that it accounts for the interaction between all ensembles of myo- and undulated collagen fibers (represented by the expression following k_1^{m-c}). Finally, the measurement data of (3-D) orientation distribution of myo- and collagen fibers (Γ^{myo} and Γ^{col}) were used directly in our model to fit the multi-protocol stress-strain data available from biaxial tests.

RESULTS

The model fit the mechanical data very well, with the lowest $r^2 \approx 0.92$. The average (n=3) transmural distribution functions for myo- and collagen fiber orientation exhibit strong 3-D dispersion throughout the RVFW (see Figure 2) . Figure 3 shows representative

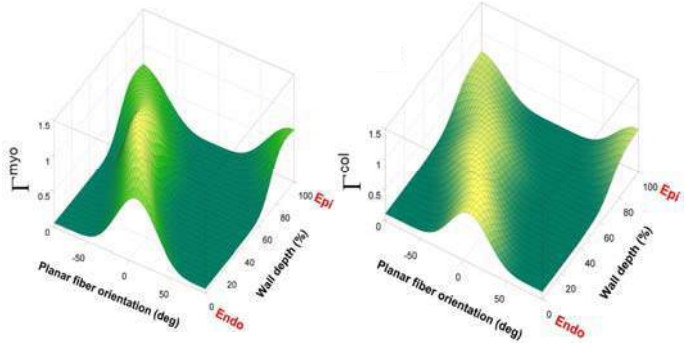

Figure 2: 3-D transmural distribution of myo- and collagen fiber orientation in RVFW.

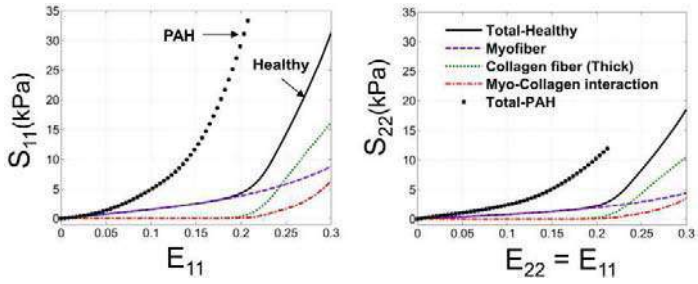

Figure 3: Contributions of fibers and interaction among them in the in-plane stress components under equibiaxial loading path. The results for the case of PAH [3] are included for comparison.

results for mechanical contribution of myo- and collagen fibers and the interaction among them in the in-plane stress components in healthy murine RVFW under equibiaxial loading condition. In this figure, we also included corresponding experimental results (for the total stress) for the case of PAH-induced (hypertensive) RVFW [3].

DISCUSSION

In this work, we took an essential step towards the modeling the biomechanical behavior of RV myocardium by formulating a structurally-consistent constitutive model for the passive RVFW that incorporates the full 3-D orientation distribution of myo- and collagen fibers and accounts for interactions among fiber types.

RVFW tissue exhibited pronounced stress stiffening along the mean fiber direction. Histological study revealed that local material axes of the RVFW are not generally orthogonal, and therefore, the behavior of the RVFW is not locally orthotropic. This is in contrast to the assumption of locally orthotropic behavior in constitutive modeling of the left ventricular myocardium often used in the literature [5]. The results of our model supported the hypothesis that, in the low strain regime, the behavior of the RVFW is governed by myofiber response alone, beyond which undulated collagen fibers and their interactions with myofiber begin to gradually contribute to the behavior as their recruitment proceeds. Once fully straightened, the collagen fibers become a major contributor to the RVFW behavior. Moreover, our results suggest that there is a substantial mechanical coupling between myofibers and thick collagen fibers. We inferred that this coupling could be in part due to the existence of a rather dense network of fine collagen struts running across myofibers and thicker collagen fibers. Finally, the comparison between results for healthy and hypertensive murine RVFW showed a substantial increase in the tissue stiffness and a decrease in the strain range within which the collagen fibers are recruited. To fully understand and characterize these changes, our next step is to implement the constitutive model for PAH data which will provide insights into the relationships between micro-scale hypertrophy and remodeling events and macro-scale biomechanics of RV myocardium during PAH.

REPRODUCTION INDUCES ADAPTATION OF THE MATERNAL SKELETON AND ALTERS PATTERNS OF POSTMENOPAUSAL BONE LOSS

Chantal M.J. de Bakker, Allison R. Altman-Singles, Wei-Ju Tseng, Laurel Leavitt, Connie Li, X. Sherry Liu

INTRODUCTION

Reproduction and lactation cause substantial changes in the maternal skeleton. During lactation, a woman's bone mineral density (BMD) has been found to decline by up to 1-1.5% per month [1], while in rodents around 30% of bone volume fraction (BV/TV) is lost over the course of 3 weeks of lactation [2,3]. Although reproductive bone loss has been well characterized, the extent of recovery post-weaning and the long-term effects of these dramatic skeletal changes are less clear. Pregnancy- and lactation-induced bone loss has been shown to undergo a partial but incomplete recovery after weaning [2,3]. However, clinical studies have found that reproductive and lactation history have no detrimental effect on post-menopausal risk of fracture [4,5]. This suggests that the changes in skeletal architecture induced by reproduction may constitute a structural adaptation rather than deterioration. Additionally, the altered bone architecture and biology following reproduction may confer protective effects post-menopause. This study aims to define the adaptations undergone by maternal trabecular bone as a result of reproduction on two timescales: (1) immediately after pregnancy, lactation, and weaning, and (2) over the long-term, including postmenopausal effects. We hypothesized that reproduction and lactation lead to a modified maternal bone phenotype, where the skeleton undergoes a partial recovery post-weaning, resulting in adaptation to physiological loading, and increasing its resistance to postmenopausal, estrogen-deficiency-induced bone loss.

METHODS

All animal experiments were approved by IACUC. *Short-term effects at multiple skeletal sites:* Rats (aged 6-7 mo at sacrifice) were divided into 4 groups: Virgin (n=6), Pregnancy (n=6, euthanized at parturition), Lactation (n=5, euthanized after 2 wks of lactation), and Weaning (n=5, euthanized 2 wks post-weaning). The proximal tibiae, L4 vertebrae, and femoral midshafts were μCT scanned *ex vivo* at 10.5 μm resolution (vivaCT 40, Scanco Medical) for analysis of bone structure. Femurs were loaded to failure in 3-point bending to assess stiffness and peak load. *Long-term and postmenopausal effects:* Rats were assigned to 4 groups: Virgin OVX (n=4), Reproductive OVX (n=4), Virgin Control (n=10), and Reproductive Control (n=7). Reproductive rats underwent 3 cycles of pregnancy, lactation, and weaning starting at age 3 mo. At age 12 mo, OVX groups underwent ovariectomy (OVX) surgery to induce estrogen deficiency, and their proximal tibiae were scanned by *in vivo* μCT [6] at 0, 4, 8, and 12 wks post-OVX (10.5μm, vivaCT 40). Rats were sacrificed at age 14-19 mo, and L4 vertebrae and femurs were harvested and scanned by μCT. Femoral stiffness and peak load were measured via 3-point bending.

RESULTS

Short-term effects at multiple skeletal sites: The two trabecular sites examined, L4 and tibia, showed 67% and 84% reduced trabecular bone volume fraction (BV/TV), respectively, in post-lactation rats, relative to controls (Fig 1B). This recovered partially after weaning, and in post-weaning rats, the BV/TV of L4 and the proximal tibia were 27% and 40% lower than virgin controls. Additionally, the tibia underwent significant and irreversible deterioration in trabecular number (Tb.N; Fig 1C) and connectivity density (Conn.D; data not shown), while there were minimal changes in these parameters at L4. Reproduction resulted in an irreversible 10-12% reduction in cortical area (Ct.Area; Fig 1D) at the femur midshaft. However, whole-bone stiffness and peak load were not different between reproductive and virgin rats (Fig 1E,F). *Long-term and postmenopausal effects:* Prior to OVX surgery, reproductive rats had 36% and 31% lower BV/TV, 46% and 24% lower Tb.N, and 67% and 34% lower Conn.D than virgins at the proximal tibia and L4 vertebra, respectively, indicating long-lasting effects of reproduction on trabecular bone. Bone-loss patterns

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

post-OVX were dramatically different between reproductive and virgin rats. At the tibia, reproductive rats underwent a 51% decrease in BV/TV, but underwent no changes in Tb.N or Conn.D (Fig 2). In contrast, tibial BV/TV of virgin rats decreased by 76%, and virgins also showed 50% and 86% reductions in Tb.N and Conn.D, respectively ($p<0.05$). Even more striking, there was no difference between Reproductive OVX and Reproductive Controls in BV/TV, Tb.N, and Tb.Th at L4 (Fig 3), indicating no OVX bone loss in reproductive rats at this site. In contrast, Virgin OVX rats had 36% lower BV/TV and 23% lower Tb.Th at L4 relative to Virgin Controls. Comparisons between Reproductive and Virgin OVX rats at 12 weeks post-OVX indicate no remaining differences between groups in BV/TV at both the tibia and L4. Structural and mechanical testing of the femur midshaft indicated no significant differences among groups in Ct.Area, stiffness, and peak load.

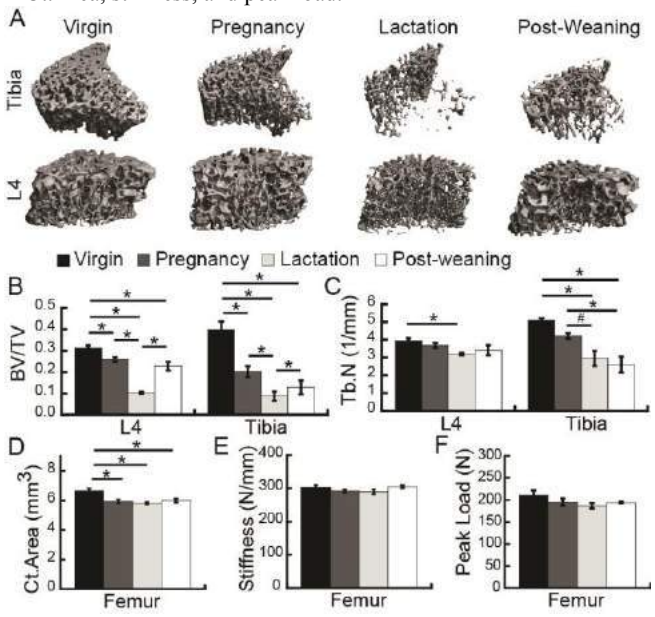

Figure 1: Reproductive effects at multiple skeletal sites. (A) 3D renderings, (B) BV/TV and (C) Tb.N indicate variable effects of reproduction on trabecular bone at the tibia and L4. (D) Cortical area, (E) stiffness, and (F) peak load at the femur midshaft indicate structural deterioration of reproductive bone, but no impact on mechanical competence (*: $p<0.05$, #: $p<0.1$).

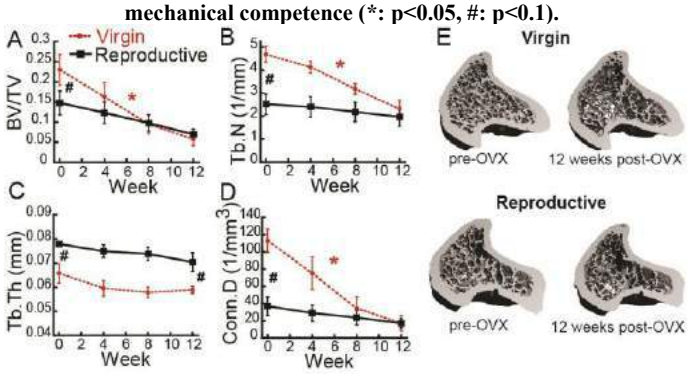

Figure 2: Effects of OVX on (A) BV/TV, (B) Tb.N, (C) Tb.Th, and (D) Conn.D in rats with and without a reproductive history. Figure 3: Effects of OVX on (A) BV/TV, (B) Tb.N, (C) Tb.Th, and (D) 3-D renderings of L4 in reproductive and virgin rats. *: $p<0.05$.

DISCUSSION

Similar to previous studies [3], reproduction had differential effects depending on the skeletal site, indicating that pregnancy, lactation, and weaning induced a redistribution of bone mass, which resulted in an altered cortical and trabecular phenotype in post-reproductive animals. This redistribution may be due to variations in the balance between the metabolic and structural functions of the bone. The mechanical integrity of the highly load-bearing regions, such as the vertebral trabeculae and the femoral cortex, were largely preserved. On the other hand, trabecular bone at the proximal tibia (which is surrounded by a dense cortex) plays a less crucial role in the bone's load-bearing function, which may help to explain its dramatic deterioration. Effects of reproduction on trabecular bone were long-lasting, as evaluation of the tibia and L4 after 3 reproductive cycles, but prior to OVX, indicated a reduced trabecular bone quality at both sites in reproductive rats relative to virgins. However, reproductive rats appeared to compensate for structural deficiencies through an adapted response to OVX: Although both groups lost bone at the tibia post-OVX, virgin rats underwent substantial deterioration of trabecular structural integrity while reproductive rats underwent minimal changes in trabecular architecture, indicating that post-reproductive bone was more resistant to estrogen deficiency-induced bone loss. Even more striking, reproductive rats underwent no changes in trabecular bone quality at L4, while virgin rats underwent dramatic structural deterioration at this site after OVX. At both the tibia and L4, there were no differences between reproductive and virgin rats in BV/TV, Tb.N, and Conn.D at 12 weeks post-OVX, which may help to explain the paradox that reproductive history does not negatively impact postmenopausal fracture risk [4,5], despite its long-lasting skeletal effects. Additionally, the lack of deterioration in bone quality post-OVX in reproductive rats at the load-bearing vertebral trabecular bone suggests that reproductive history may enhance the bone's mechano-sensitivity, resulting in reduced bone loss at load-bearing sites. Taken together, short-term and long-term results indicate, that although reproduction significantly changes bone structure, these alterations may constitute adaptations rather than deteriorations, and the post-reproductive skeleton appears to be mechanically equivalent, but better able to withstand postmenopausal bone loss than that of virgins.

Co-localizations and Correlations of Established and Emerging Indicators of Disturbed Wall Shear Stress at the Normal Carotid Bifurcation

INTRODUCTION

In arterial bifurcations the preferential development of atherosclerosis has been attributed to the atherogenic role played by low and oscillatory wall shear stress (WSS) on endothelial cells (ECs). This theory is challenged by evidences underlining how the ECs are exposed to a complex hemodynamic milieu that can be only partially described by the low/oscillatory WSS [1]. In fact, the established descriptors quantifying low and oscillatory WSS, proposed over the years as potential indicators and localization factors of vascular wall dysfunction, are significant but moderately weak predictors of vascular wall dysfunction. Discrepancies can be observed when comparing low/oscillatory WSS distribution with location of regions with lesion prevalence [1]. The endeavor to explain these discrepancies led to findings on ECs sensing of flow direction. In particular, there is evidence for a relation between flow directionality and ECs mechanotransduction pathway [2]. In this context, two different quantitative approaches for the characterization of WSS multidirectionality have been recently proposed, quantifying the WSS component orthogonal to the temporal mean WSS vector [1], or the WSS vector component aligned along the main flow direction [3]. However, an in depth, quantitative analysis of the extent of the co-localization of regions of low/oscillatory and multidirectional WSS at the luminal surface of the carotid bifurcation is still lacking.

Here we explore the relationship between the recently-proposed descriptors quantifying WSS multidirectionality and "established" WSS-based hemodynamic descriptors in a representative sample of subject-specific computational models of ostensibly normal carotid bifurcations. To do so, we quantitatively assess the co-localization of those descriptors at the luminal surface, aiming at providing connections (if any) among the peculiar hemodynamic features captured by the different descriptors.

METHODS

Data from this study are a subset (N=46) of the Vascular Aging – The Link That Bridges Age to Atherosclerosis (VALIDATE) study. The carotid geometry of each participant was acquired from contrast-enhanced angiography. Inlet/outlet velocities of each participant were acquired from phase contrast MRI to ensure patient-specific boundary conditions. As detailed elsewhere [4], lumen geometries were reconstructed from the thoracic segment of the common carotid artery (CCA) to above the bifurcation. The distributions at the luminal surface of five WSS-based descriptors were computed in the 46 cases. Three descriptors are "established" WSS-based descriptors, namely time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI) and relative residence time (RRT). Two additional descriptors quantifying WSS multidirectionality are considered. The first is transWSS, defined as the time-averaged WSS component in the direction normal to the mean WSS vector direction along the cardiac cycle [1]. The second is the time-averaged value of the projection of the WSS vector along the main flow direction (WSS_{ax}), locally identified as the direction of the tangent to the vessel's centerline [3].

For OSI, RRT and transWSS threshold values were calculated corresponding to the 80th percentile value of the descriptor distribution of the combined surface of all models. For TAWSS, threshold values related to the 20th percentile were considered. Negative values were considered for WSS_{ax}, thus highlighting regions where WSS_{ax} direction is opposed to the main flow direction. For a given model, disturbed flow was quantified as its relative surface area (SA) exposed to OSI, RRT, or transWSS above (TAWSS and WSS_{ax} below) respective thresholds, normalized by the SA to the total surface area of the model clipped at CCA3, ICA5 and ECA2 (as in Figure 1). In this way, it was possible to characterize disturbed shear in each

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

carotid bifurcation by means of scalar values, hereafter denoted as TAWSS20, OSI80, RRT80, transWSS80, and WSS_{ax}^{-}, representing the fraction of the luminal surface exposed to "disturbed" shear.

The analysis of the co-localization of the considered indicators of disturbed shear can be thought of as consisting of two components. One component is correlation, evaluated through the Spearman rank correlation coefficient r for each of the 10 unique pairings of wall descriptors. The second component of co-localization analysis is co-occurrence, and consists in the evaluation of the spatial overlap of the SAs exposed to OSI, RRT, or transWSS above (TAWSS, WSSax below) respective thresholds. Co-occurrence of the two generic descriptors i and j was evaluated for each case by the similarity index (SI):

$$SI_{ij} = \frac{2 \times (SA_i \cap SA_j)}{SA_i + SA_j} \quad (1)$$

SI_{ij} ranges from 0 (SAs by the two descriptors have no spatial overlap) to 1 (SAs are equivalent and perfectly spatially overlapped). The distribution of the SI for two generic WSS-based descriptors was characterized in terms of median (Me) and median absolute deviation (MAD), to measure the dispersion.

RESULTS

An explanatory visualization of the identified SAs in a representative carotid bifurcation is shown in Figure 1. The correlations among the SA exposed to descriptors above or below the respective threshold show that the ranking of cases is similar for TAWSS20 and OSI80 (positive correlation, r=0.54). Strong positive correlations are observed also between RRT80 and both TAWSS20 and OSI80, as expected from RRT definition. WSS_{ax}^{-} is moderately positively correlated with OSI80 and transWSS80 (r=0.46 and r=0.53, respectively). A significant albeit weak negative correlation is found between transWSS80 and TAWSS20 (r=-0.43).

From the quantitative analysis of co-occurrence, evaluated in terms of SI distribution for the 10 pairings of WSS-based descriptors (Table 1), it emerges that the SA exposed to low WSS values co-localizes with the area exposed to high OSI (even though with a marked dispersion, MAD=0.13) and strongly with the area characterized by high RRT. The SI values between high transWSS and low TAWSS are very low, suggesting that the average WSS component orthogonal to the mean WSS direction is not characterized by low WSS values. It also emerges that regions of flow reversal are moderately co-localized with low WSS regions (Me=0.46). Considering OSI, it emerges that OSI co-localization with RRT is slightly weaker than TAWSS versus RRT, indicating that RRT is mainly biased by low WSS values rather than high OSI values. In addition, OSI co-localizes weakly with transWSS (Me=0.13), implying that OSI captures mainly oscillations along the mean WSS direction, rather than along the direction orthogonal to it. In this sense, OSI and WSS_{ax}^{-} are moderately co-localized (Me=0.56), suggesting that a relevant part of the WSS oscillation accounted for by OSI is aligned with the main flow direction, in regions where flow reversal is predominant. The two descriptors of WSS multidirectionality, transWSS and WSS_{ax}^{-}, are weakly co-localized (Me=0.14), implying that in areas of flow reversal the WSS component orthogonal to the mean WSS direction is low.

DISCUSSION

It is worth noting that OSI per se does not distinguish between uniaxial pulsatile flow and multidirectional flow, but insights into OSI nature at the carotid bifurcation are given here. High OSI at the carotid bifurcation is likely due to pulsatile flow with flow reversal in the axial direction, since high OSI co-localizes with negative WSS_{ax} and not with transWSS. The very weak or null co-localization observed between transWSS *vs*. the other descriptors likely reflects the fact that transWSS is highest at the bifurcation apex (Figure 1), while the other descriptors concentrate at the carotid bulb and around the bifurcation expansion. Interestingly, the use of transWSS in the study of onset of atherosclerosis at the carotid bifurcation seems to be questionable from our results, as the bifurcation apex, where transWSS concentrates, is not a common location where atherosclerosis is observed. It is likely that the different WSS features captured by the considered descriptors might have to be concurrent, in light of atherosclerosis initiation. Alternatively, the considered descriptors are just an "echo" of the complex mechanism that encompasses the vascular response.

In conclusion, the results of the present study suggest that, for the carotid bifurcation, the hemodynamic disturbances captured by the recently-proposed descriptors based on WSS multidirectionality are different from those given by low TAWSS and high OSI. Regions of low TAWSS and high OSI are not co-localized with high transWSS regions, and weakly with negative WSS_{ax} regions. In general, for practical purposes we suggest that the two categories of WSS descriptors ("established" descriptors, based on low and oscillatory WSS, and multidirectional WSS descriptors) represent different hemodynamic disturbances with different impact on ECs homeostasis, depending on the specific arterial district. However, the role of multidirectional WSS on carotid bifurcation pathophysiology needs to be clarified and further research is encouraged. Potentially, the considered descriptors could be part of WSS phenotypes more effective in localizing the map of vascular atherosclerotic lesions.

INTRODUCTION

High-flow nasal cannula (HFNC) therapy has become ubiquitous in hospital settings as a form of respiratory support. During HFNC therapy, an oxygen/air blend is administered through nasal cannula at a high constant flow, intended to meet or exceed patient inspiratory flow rates. The exact mechanics of the therapy are not fully defined [1]. In particular, the airway pressures developed during HFNC therapy are of great interest, with an increase in positive end-expiratory pressure (PEEP) seen as a potential benefit in airway support and alveolar recruitment [1,2]. The present research focused on evaluating airway pressures in the application of HFNC therapy to infants.

Due to the invasive nature of acquiring the desired airway pressure and breathing pattern data, in vivo experiments in a clinical setting are challenging to perform [3]. Our work explored in vitro bench testing on realistic airway models as a promising method to investigate the physical phenomena involved in determining tracheal pressures during HFNC therapy.

METHODS

Ten realistic nasal airway replicas were previously built using rapid prototyping based on CT scans of infants ranging in age from 3 to 18 months [4]. The airways were deemed to be normal and healthy. For this study, each airway replica was supplied typical HFNC flow rates equivalent to 1 L/kg/min and 2 L/kg/min [1], with the weight of each subject calculated based on recorded age and sex [5,6].

Breathing was simulated using an ASL-5000 lung simulator (Ingmar Medical, PA). The lung was modeled as a single compartment, with the resistance being set individually for the inspiration (21 cm H20/L/s) and expiration (25 cm H2O/L/s) portions of the breath. The compliance of the lung model was set to 12 ml/cm H2O. The uncompensated residual capacity (URC) was set to 0.2 L. These URC, compliance, and resistance settings were predefined in the lung simulator's Infant Bronchiolitis breathing script and were held constant through all measurements. Experiments were performed in all ten replicas at breathing frequencies of 29 and 40 breaths per minute. A control measurement was taken for each airway replica at either breathing frequency, in which high flow was not supplied, and the cannula was not inserted. In these control measurements, simulated patient effort was adjusted individually for each replica in order to achieve tidal volume of 7 ml/kg, based on average tidal volume measured in infants with bronchiolitis [7].

The HFNC therapy was provided using a Precision Flow (Vapotherm Inc, MD). Temperature was regulated by the device to 37 degrees Celsius, and the fraction of inspired oxygen was set to 0.21. The same cannula (Pediatric Small; Vapotherm Inc, MD) was used for all 10 subjects. Subsequent data were obtained for dry air delivered using a mass flow controller (M-100; Alicat, AZ), where the outer diameter of the cannula prongs was slightly enlarged by wrapping with Parafilm (Bemis NA, WI). This procedure increased the outer diameter at the midpoint of the cannula prongs from 3.75 mm to 4.5 mm and 5.25 mm.

For data analysis, an annular area was defined as the difference between the cannula obstruction area and the total nostril area. A non-dimensionalized PEEP, K, was defined as

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$K = P/((\rho U^2)/2)(\quad (1)$$

where K is an Euler number, P is PEEP, ρ is the density of the gas, and U is the average velocity of the air through the annular area.

Reynolds numbers were calculated using the hydraulic diameter of the annular area as the characteristic length.

RESULTS

The peak expiratory pressures, positive end-expiratory pressures, and average inspiratory pressures were determined for all trials using the non-modified cannula (Table 1).

TABLE 1. AVERAGE PRESSURES VALUES

	Control	1 L/kg/min	2 L/kg/min
Peak Expiratory Pressure @ f=29 min^{-1} (cm H_2O)	1.4 ± 0.8	3.4 ± 0.9	8.0 ± 2.8
Peak Expiratory Pressure @ f=40 min^{-1} (cm H_2O)	1.6 ± 0.9	3.7 ± 0.8	8.2 ± 2.5
PEEP @ f=29 min^{-1} (cm H_2O)	-0.02 ± 0.01	1.7 ± 0.7	6.1 ± 2.5
PEEP @ f=40 min^{-1} (cm H_2O)	-0.03 ± 0.01	1.7 ± 0.6	6.3 ± 2.4
Average Inspiratory Pressure @ f=29 min^{-1} (cm H_2O)	-0.5 ± 0.4	0.7 ± 0.8	4.9 ± 2.5
Average Inspiratory Pressure @ f=40 min^{-1} (cm H_2O)	-0.9 ± 0.7	0.4 ± 0.9	4.5 ± 2.4

f = breath frequency
PEEP = positive end-expiratory pressure
Values expressed as mean ± standard deviation (n=10).

The non-dimensional pressure was calculated using the PEEP values for all the experimental trials as well as the additional occlusion trials (Figure 1). The data indicates that the non-dimensionalized PEEP increases with the annular area. A least square regression provides a linear relationship of with an R^2 value of 0.68.

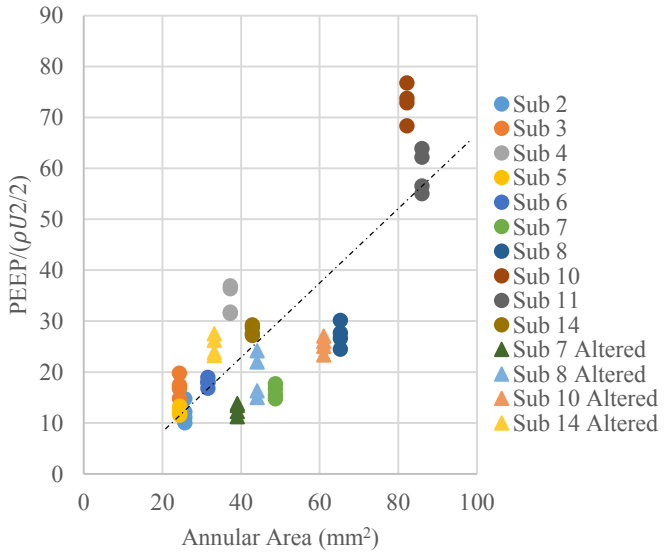

Figure 1: Non-Dimensionalized PEEP vs Annular Area

The Reynolds number was also calculated at PEEP for all the trials. The data indicates a downwards trend in non-dimensionalized pressure drop as the Reynolds number increases for each subject (not shown).

DISCUSSION

There is a significant increase in pressures from the 1 L/kg/min data to the 2 L/kg/min data. At the 2 L/kg/min level, the PEEP values are elevated to potentially clinically significant values for the majority of the subjects. For the 1 L/kg/min trials, no subjects achieve a clinically significant PEEP. Potential clinical significance was defined as being greater than 4 cm H_2O, the lower threshold in continuous positive airway pressure (CPAP) therapy (2).

There is a clear correlation between the annular area and the non-dimensionalized PEEP. Such a correlation allows delivered PEEP to be estimated based on a subject's nostril area, the outer diameter of the nasal prongs, the gas flow rate delivered through the nasal cannula, and the gas density.

INTRODUCTION

Cerebral aneurysms is a devastating disease with high mortality and morbidity rates [1]. Endoluminal flow diverters have been used successfully to treat large aneurysms with wide necks that cannot be treated with traditional techniques such as coils [2]. However, they may fail in preventing the blood flow from entering the aneurysm in the event, for example, of mal apposition against the vessel wall [3]. Intrasaccular flow diverters, although developed for the treatment of bifurcation aneurysms, may overcome this difficulty since they are released inside the aneurysm sack.

The purpose of this study was to compare the flow diversion effects of endoluminal and intrasaccular flow diverters in a saccular aneurysm.

METHODS

A cavernous aneurysm that was treated with an endoluminal flow diverter, and that remained open at a 6 month follow up was selected for this study (see Figure 1). A patient-specific model of the aneurysm and surrounding vessels was created from a 3D angiography taken prior to treatment [4].

Detailed models of the pipeline embolization device (PED) used for the treatment, and of an intrasaccular device (WEB) were created and virtually deployed. The virtual deployment process starts by computing a centerline at the location where the device will be released. Using this centerline, a cylindrical support surface is created and expanded until it completely touches the wall or the maximum allowed diameter has been reached. The "inflated" support surface is then used to obtain the device in its final "deployed" state, by means of a mapping process which takes into account foreshortening effects [5].

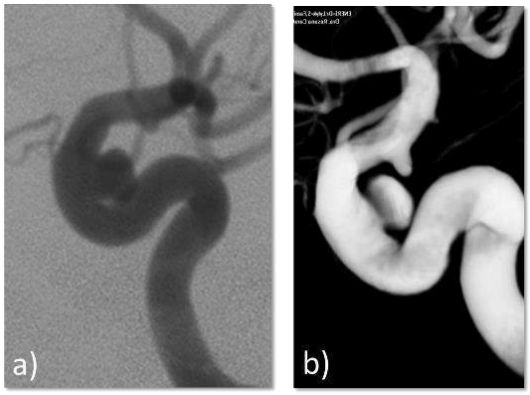

Figure 1: a) DSA before treatment, b) DSA at 6 months after treatment with PED

For this study, a set of three centerlines were computed: one following the parent vessel across the aneurysm neck (endoluminal), and two entering the aneurysm (intrasaccular) with slightly different angles in order to study two possible WEB deployment "scenarios". Since the intrasaccular devices are closed at the ends (as opposed to the endoluminal devices which are open ended), the support surface corresponding to such devices need to be closed before doing the mapping. For that purpose, each of the end sections of the cylinders was extruded toward its centroid following a user-given profile. Figure (2) shows an example of the deployment technique applied to the intrasaccular device in the reference configuration.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Four pulsatile computational fluid dynamics (CFD) simulations were performed using immersed unstructured grids [4]: 1) pre-treatment (PRE), 2) post-treatment with PED, 3) post-treatment with WEB (scenario 1) and 4) post-treatment with WEB (scenario 2).

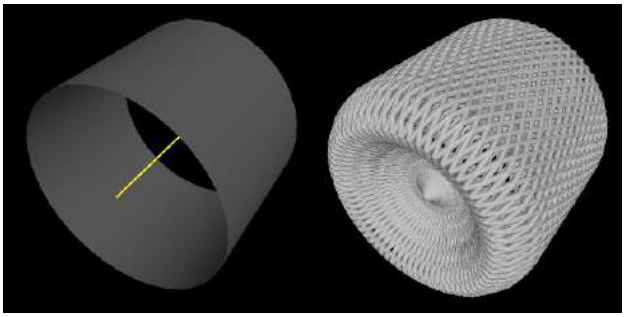

Figure 2: Virtual deployment: centerline and support surface (left), and device mapped on the support surface (right).

RESULTS

A comparison of the inflow streams at the peak systole before and after device implantation is presented in Figure 3. As it can be seen from the plots, the endoluminal device failed to substantially reduce the flow into the aneurysm because of mal apposition against the wall. On the other hand, both implantations of the intrasaccular device achieved a significant inflow reduction.

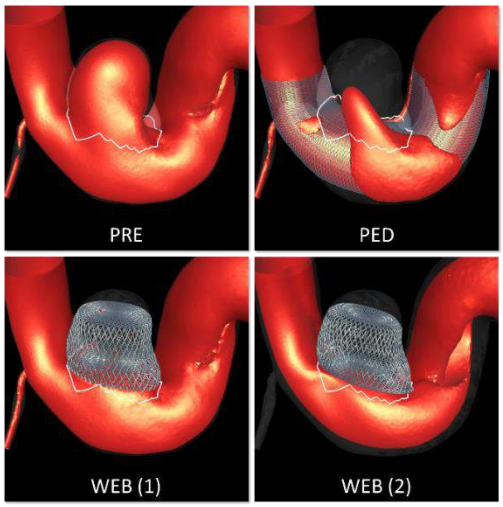

Figure 3: Inflow stream before and after device implantations.

The distribution of wall shear stresses (WSS) at the peak systole are shown in Figure 4. In this case, the endoluminal device performed better in protecting the wall at the neck of the aneurysm by means of flow redirection. In contrast, the intrasaccular device failed in preventing the blood flow from hitting the aneurysm neck, thus leaving this region unprotected, as in the pre-treatment case (see arrows).

A summary of the aneurysmal flow changes obtained for each of the device implantations is presented in Figure 5. The main hemodynamic variables that were considered for the comparison are: Mean Inflow Rate (Q), Mean Velocity (VEL), Mean Vorticity (VOR), Mean Viscous Dissipation (DISSIP), Mean Shear Rate (SR) and Mean Wall Shear Stress (WSS). As it can be seen, the intrasaccular device outperformed the endoluminal device in both scenarios. However, the WSS was better controlled by the endoluminal device due to its flow redirection effect.

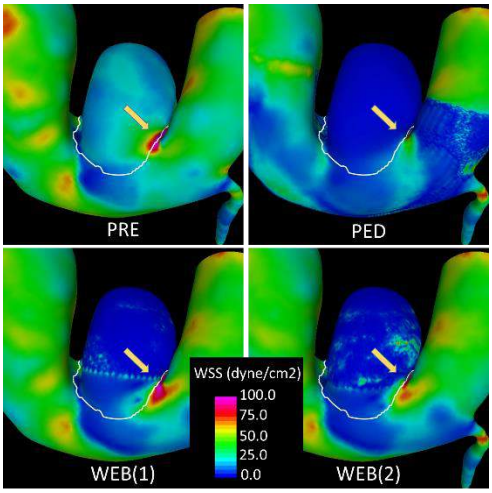

Figure 4: Wall Shear Stresses (WSS) before and after device implantations.

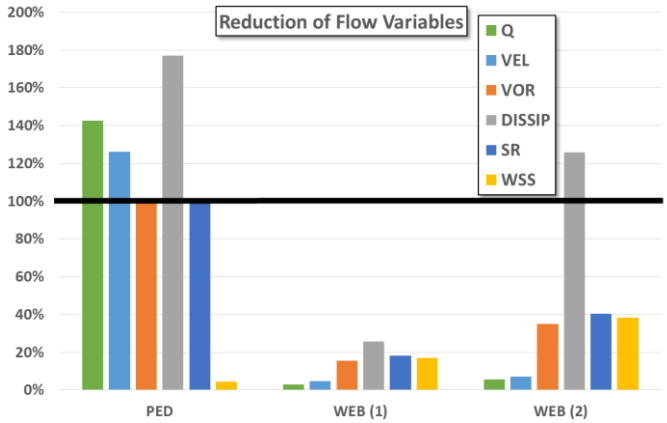

Figure 5: Changes in aneurysmal flow variables after implantation of PED or WEB devices.

DISCUSSION

Endoluminal flow diverting devices may result in poor hemodynamics performance due to mal apposition against the wall when deployed on irregularly shaped parent arteries. Intrasaccular flow diverters, although originally developed for bifurcation aneurysms, may solve this problem if the ostium is completely covered. However, while these devices may be more efficient in preventing the blood flow from entering the aneurysm sack, they may leave parts of the aneurysm neck exposed to the parent artery main flow.

In the case studied, the intrasaccular device had substantially larger flow diversion effects than the endoluminal device, suggesting that in this case a faster and complete occlusion of the aneurysm could have been achieved.

SEX DIFFERENCES IN ACHILLES TENDON PROPERTIES THREE WEEKS AFTER INJURY IN RATS

G.W. Fryhofer, B.R. Freedman, A.M. Pardes, C.D. Hillin, L.J. Soslowsky

McKay Orthopaedic Laboratory
University of Pennsylvania
Philadelphia, PA, USA

INTRODUCTION

Achilles tendon ruptures are common injuries that result in significant pain and disability. Clinical studies demonstrate the risk of Achilles tendon rupture to be much lower in women compared to men, with as many as 84% of ruptures occurring in men [1]. It is not known if sex-related differences in injury may be extended to include differences in Achilles tendon healing, as well. Therefore, the objective of this study was to determine if sex or hormone-related differences are present in Achilles tendon healing following acute tendon rupture, in order to better inform sex-specific treatment recommendations. We hypothesized that healing female Achilles tendons would exhibit superior mechanical properties compared to healing male tendons; however, there would be no difference in the functional performance of male and female ankle and hindlimb. This study also includes a group of females that have undergone ovariectomy (OVX) to mimic ovarian hormone deficiency, and we hypothesized that tendons from OVX females would exhibit inferior mechanical properties and contribute to inferior ankle functional performance compared to non-OVX female Achilles tendon.

METHODS

Study Design: Male (400-450g), female (250-300g), and ovariectomized (OVX) female (250-300g) Sprague Dawley rats were used in this study. One group of animals was sacrificed as uninjured animals at ~19wks of age (n=12 each per M/F/OVX). The other group received 2 weeks of treadmill exercise training (up to 60 min/day at 10m/min) to ensure that animals could complete our rehabilitation protocol to be used following injury. Following exercise training, animals underwent surgical removal of the right central plantaris longus tendon and blunt transection of the right Achilles tendon mid-substance (n=16 per M/F/OVX, IACUC-approved). For OVX animals, ovariectomy was performed 4 weeks before Achilles tendon surgery (previous studies in female rats have demonstrated significant alterations in bone morphology and muscle mass as early as two and four weeks after ovariectomy [2, 3]). Following surgery, the right hindlimb of each animal was immobilized in full plantarflexion for 1 week, followed sequentially by 1 week of cage activity and 1 week of gradually increasing treadmill time (up to 60 min/day at 10m/min). All animals in the surgical group were euthanized at 3 weeks post-injury. *In vivo* Functional Evaluation: Passive ankle joint range of motion (ROM) and stiffness were measured using a custom torque cell and accelerometer-based device on anesthetized animals [4]. Ground reaction forces of the right hindlimb were also measured using an instrumented walkway equipped with a load cell [5]. *Ex vivo* Mechanical Testing: After euthanasia, the Achilles tendon-foot complex was carefully removed *en bloc*, fine dissected, measured for cross sectional area, and secured in fixtures. Tendons were imaged and mechanically tested (n=10/group) with a protocol that included stress relaxation (6% strain), low-load dynamic frequency sweep (0.1 to 10 Hz), and fatigue testing (~10-75% of ultimate failure load) at 2 Hz using a sinusoidal waveform until failure (Instron Electropuls 3000). Data Analysis: Functional ankle ROM and rotational stiffness (bilinear fit of torque-angle data for dorsiflexion and plantarflexion) were calculated. For mechanical testing data, Achilles tendon percent relaxation, dynamic modulus, dynamic stiffness, tanδ, hysteresis, laxity, and linear modulus were also computed [6]. To account for sex- and hormone-related differences in baseline properties, properties obtained for injured animals were normalized by group using values obtained from uninjured animals. One-way ANOVAs were performed for each *normalized* variable of interest at 3 weeks post-injury and, if found to be significant ($p < 0.05$), were followed by post-hoc t-tests (M vs. F, F vs. OVX) with Bonferroni corrections ($p < 0.025$).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

At 3 weeks post-injury, relative dorsiflexion and plantarflexion ROM were superior in females compared to males; relative plantarflexion ROM was also superior in females compared to OVX (**Fig 1**). Females had relative plantarflexion toe-stiffness values closer to pre-injury values compared to both males and OVX; relative plantarflexion linear-stiffness was increased from pre-injury values in females compared to males, but similar to OVX. OVX had relative dorsiflexion toe-stiffness values closer to pre-injury values compared to females; there were no other differences in relative dorsiflexion stiffness between groups.

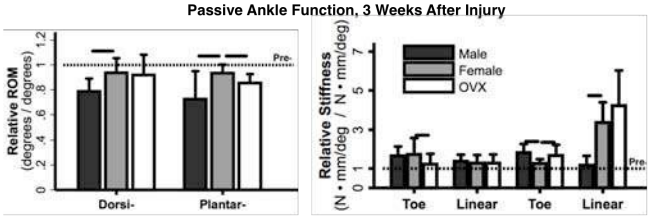

Figure 1: Ankle joint passive range of motion (ROM) and stiffness at 3 weeks post-injury in male (black), female (grey), and OVX (white) animals. Sex was a significant factor for relative ROM, toe-stiffness, and linear-stiffness at 3 weeks post-injury. Solid lines denote significance (p<0.025). Dashed line indicates "Pre"-injury baseline.

Active ankle function was also assessed at 3 weeks post-injury by measurement of relative ground reaction forces. Males exerted maximum relative braking force closer to pre-injury values compared to females (**Fig 2**). Females exerted relative lateral, braking, and vertical forces closer to pre-injury values compared to OVX.

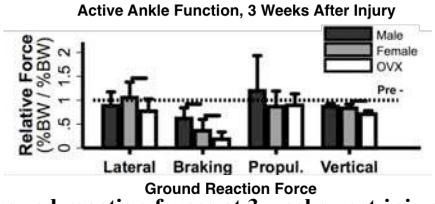

Figure 2: Ground reaction forces at 3 weeks post-injury. Sex was a significant factor determining active ankle functional performance. Solid lines denote significance (p<0.025).

Mechanical testing was performed on uninjured tendons and on tendons 3 weeks post-injury. In injured tendons, relative CSA, percent relaxation, strain (1Hz), hysteresis (50% fatigue life), and linear modulus were closer to pre-injury values in males compared to females (**Fig 3**). Females were closer to pre-injury values for relative tanδ (0.1Hz, 10Hz) and dynamic stiffness vs. males. Compared to females, OVX were closer to pre-injury values for relative hysteresis (50% fatigue life) and laxity (95% fatigue life). No other differences were present for relative stress, strain, tanδ, laxity, or cycles to failure.

DISCUSSION

Achilles tendon functional and mechanical properties were evaluated in males, females, and OVX three weeks after tendon injury.

With respect to active ankle functional measures, males performed "better" (i.e. closer to uninjured levels) than females, and females performed better than OVX. OVX has been associated with behavioral changes, including decreased cage locomotor activity [7]. Therefore, it is possible that the decreased relative ground reaction forces observed in the OVX group at 3 weeks post-injury may be the result of continued behavioral adaptation in the setting of recent ovariectomy. The functional data also suggest that the effect of male sex yields better functional outcomes 3 weeks post-injury compared to females, which mirrors clinical observations [8]. Such an interpretation of male functional advantage is challenged, however, by the results of passive functional testing, in which females had better relative ROM and better relative plantarflexion toe-stiffness than male and OVX, despite their "worse" relative plantarflexion linear-stiffness.

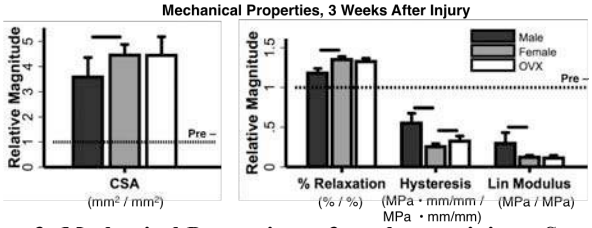

Figure 3: Mechanical Properties at 3 weeks post-injury. Sex was a significant factor determining relative cross-sectional area (CSA), % relaxation, hysteresis (at 50% fatigue life), and linear modulus. Solid lines denote significance (p<0.025).

Mechanical testing data reveal the post-injury properties of male tendons to be superior to those of female tendons. Relative percent relaxation and hysteresis in male tendons closer to baseline indicate that male tendons are able to return stored elastic energy in a manner more similar to uninjured tendon. Similarly, the increased relative linear modulus of injured male tendons compared to female tendons indicates that male tendons may more effectively transmit stress from muscle to bone. OVX does not appear to be a significant factor in determining tendon mechanical properties 3 weeks after injury, which is consistent with observations from a similar study of tendon healing at later time points [9]. Finally, the increased relative CSA in females compared to males may reflect a sex-related difference in scar formation and inflammatory response; increased testosterone levels associated with male sex could allow for a decreased inflammatory response in males compared to females [10].

This study does have some limitations. Despite steps to maximize human relevance through the use of clinically translatable immobilization and rehabilitation protocols, some elements of the study may not reflect a human environment. In addition, the data for injured tendons in this study were obtained at a relatively early phase of the recovery process, and it is likely that the functional and mechanical properties measured here will continue to evolve over time. And finally, without additional biological data, we are currently unable to provide a mechanism to explain why, compared to males, females exhibit inferior Achilles tendon healing at 3 weeks post-injury despite their relative protection against tendon injury at baseline. We are particularly interested in potential differences in the inflammatory response between sexes. Further work is needed to study tendon properties at later time points and to identify biological mechanisms to explain these sex-related differences in Achilles tendon healing.

INTRODUCTION

It is well known that blood perfusion rate in tissue has a profound influence on its temperature. Based on the Pennes bioheat equation[1], local blood perfusion rate can act as either a sink or a source, depending on whether the local tissue temperature is higher or lower than the arterial temperature of 37°C. The thermal effect of local blood perfusion rate has been investigated in the past to extract its value based on transient temperature measurements[2-5]. All of the previous research has demonstrated that dynamic responses of skin temperature after heating or cooling may be sensitive to local blood perfusion rate in the targeted tissue region.

This study focused on evaluating approaches to increase sensitivity for screening melanoma using the temperature profile of the skin surface. It has been suggested that melanomas may have higher blood perfusion demands, due to their more aggressive nature and higher metabolism, than the surrounding skin. A 2-D heat transfer model consisting of a melanoma lesion embedded in a cylinder of tissue was developed. The model was used to investigate potential temperature differences between the melanoma lesion and its surrounding tissue, when the skin was initially subjected to a convection boundary and later subjected to a constant heat flux. Experiments were also performed using an infrared camera to record the skin surface temperature profile. The effect of the unknown emissivity of the skin and the influence of the surrounding environment on the recorded temperature reading were investigated.

METHODS

The computational thermal model consisted a melanoma (10 mm in diameter and 5 mm in thickness) embedded in a tissue cylinder (100 mm diameter and 60 mm height) (Figure 1). The geometries were selected because a large mole is one of the risk factors leading to melanoma, and the tissue cylinder was sufficiently large that the boundary conditions at the bottom and side surfaces did not affect the temperature field of the melanoma significantly. The top surface was initially subjected to a convection boundary condition (convection coefficient h =6 W/m^2 ^{o}C and air temperature T_{air}=20°C) under thermal neutral conditions. The boundary condition was changed to a combination of free convection and a constant heat flux impacting on the surface q_o''. The side surface of the tissue cylinder was adiabatic and the bottom surface had a prescribed constant temperature of 37°C.

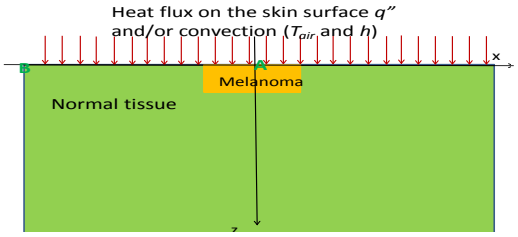

Fig. 1. Schematic diagram of the 2-D axisymmetric geometry of a melanoma embedded in a tissue cylinder.

The Pennes bioheat equation[1] was used to simulate the steady state or transient temperature field inside both the melanoma and the normal tissue, and is written as:

$$\rho c \frac{\partial T}{\partial t} = k\nabla^2 T + q_m + \omega\rho c(37 - T) \qquad (1)$$

where k is thermal conductivity, ω is the local blood perfusion rate, ρ is density, c is specific heat, and q_m is metabolic heat generation rate. Simulation of the transient temperature field was carried out by COMSOL 4.3 software. Sensitivity to meshing and time steps was examined to ensure that the maximum temperature changed by less

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

than 1% when the size of the elements and/or time step were decreased by 50%.

An infrared camera (Fluke Ti100, Everest, WA) was used to evaluate temperature uncertainty associated with an unknown skin surface emissivity. A temperature image of a skin surface requires inputs of both the emissivity and the environmental temperature. In this study, a thermal image of a skin surface was recorded both indoors and outdoors. The images were analyzed to assess the effects of the value of the emissivity on the temperature reading at a skin location.

RESULTS

All the properties used in the model are given in Table 1. Note that the blood perfusion rate of the melanoma was an order of magnitude larger than that of the normal tissue.

Table 1 Thermal and physiological properties of normal skin tissue, melanoma, and blood.

	ρ (kg/m^3)	c (J/kg°C)	k (W/m°C)	q_m (W/m^3)	ω (1/s)
Tissue	1000	3800	0.5	342	0.0003
Melanoma	1000	3800	0.5	2280-9120	0.002-0.008
Blood	1000	3800	0.5	n/a	n/a

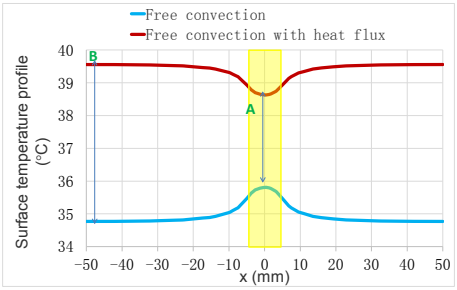

Fig. 2. Steady state surface temperature profiles under thermal neutral conditions (blue) and when the surface is subject to heating (red).

The steady state surface temperature profiles predicted by the model (Figure 2) shows the elevated temperature in the melanoma surface (blue line) due to its large blood perfusion rate (0.008 (1/s)), compared to that in the normal tissue (0.003 (1/s)). Under thermal neutral conditions, the temperature difference between them was approximately 1.03°C. Once the surface was subject to a constant heat flux of 140 W/m^2, the normal tissue temperature (location B) increased from 34.8 to 39.4°C (4.6°C), however, the temperature increase at the melanoma center was limited to only 2.8°C (from 35.8°C to 38.6°C). Therefore, the temperature elevation due to surface heat flux may be less profound to the larger blood perfusion in the melanoma lesion.

Figure 3 compares the transient temperature rises at a normal tissue location (location B in Figure 2) and at the center of the melanoma (location A in Figure 2) to evaluate how fast the temperature rises in the melanoma. It took several hours to establish a steady state. Examining the rise curves, 50% of the temperature rise occurred after heating for only 500 seconds. The temperature rise rate of the first 500 seconds at location B is 10%-47% higher than that at location A when the melanoma blood perfusion rate varied from 0.002-0.008 (1/s). Clinically, the skin surface with the melanoma lesion could be exposed to a heater to induce local temperature rises. However, it would not be feasible to wait several hours to establish the 2nd steady state (the red line in Figure 2).

The major challenge of implementing the approach is the unknown emissivity values of melanoma and normal skin. It has been shown that normal skin emissivity varies from 0.95 to 0.99, depending on skin tone. Many infrared cameras on the market use an equation to predict temperature that requires the emissivity value, as that given below, modified from Bernard *et al.*[6]:

$$T = \sqrt[4]{\frac{q_{ck}}{\sigma\varepsilon} - \frac{1-\varepsilon}{\varepsilon} T_{amb}^{\ 4}} \qquad (2)$$

where q_{ck} is the heat flux received by the camera and ε is the emissivity of the surface. The ambient temperature T_{amb} affects the reading only when the surface is not a blackbody surface. Figure 4 gives the deviation of the temperature reading from that when ε is selected as 1, based on inputs of ε and T_{amb} to the recorded infrared image of human skin using the infrared camera. In a room temperature environment (T_{amb} = 22.5°C), changing ε from 1 to 0.96 resulted in an uncertainty of 0.5°C. The potential error is more profound when T_{amb}=8.6°C, with a deviation of 0.83°C. The results from the camera reading are consistent with those predicted by Equation 2.

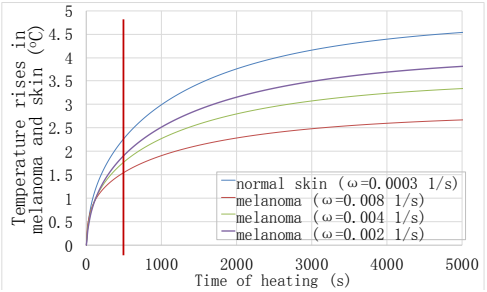

Fig. 3. Temperature rise curves after the skin is exposed to a constant of heat flux of 140 W/m^2.

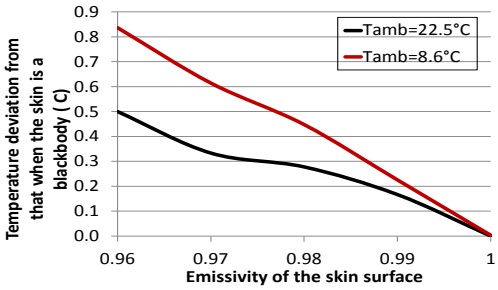

Fig. 4. Effect of skin emissivity and ambient temperature on the temperature reading of a skin location given by the Fluke camera.

In summary, the developed 2-D heat transfer model suggests that a normal temperature profile can be used to screen melanomas that have a large blood perfusion rate. A temperature rise rate after a surface heating is more sensitive and therefore better able to distinguish melanoma from normal tissue. However, caution is needed to interpret experimental results because the emissivity may not be known. The temperature reading error can be as large as 0.5°C in a normal room temperature environment, and the error is bigger (0.8°C) when the image is taken in a cooler environment.

INTRODUCTION

Coronary artery disease (CAD) is the leading cause of death worldwide. The current trend in disease treatment has witnessed an innovative shift from permanent metallic stents to the implementation of biodegradable scaffolds. Clinicians and scientists agree that there are three general requirements for biodegradable stent feasibility: (1) its mechanical properties are similar to those of stainless steel 316L, the industry's gold standard for stent design; (2) the stent material is biocompatible, and its degradation products are non-cytotoxic and; (3) it has a controlled corrosion rate, with little degradation occurring during vessel remodeling (approximately 3–6 months), but completely degraded within 12–24 months [1]. The combination of these properties has yet to be realized in a single stent, however.

Therefore, a novel biodegradable metallic amalgamate for stent application has been proposed [2]. Cold-gas dynamic spraying (CGDS), with iron and stainless steel 316L powders, is utilized to fabricate a nanostructured biomaterial. This reduction in grain size leads to an improvement of the material's strength, fatigue and wear properties. In this study, the biocompatibility of the proposed Fe-316L stent is investigated through *in vitro* and *in vivo* tests. Cell viability was assessed by MTT assay on flat specimens [3], while stent deliverability and biocompatibility were evaluated through an *in vivo* animal stent implantation.

METHODS

Commercially available iron and stainless steel 316L powders (SandVik Osprey, United Kingdom) were mixed in a 4:1 weight ratio. Coatings were sprayed on 5 mm diameter cylindrical rods using cold spray, as shown in Figure 1(a-b). The rods were then heat treated at 1150°C in a tube furnace with oxidation control. To reduce coating thickness to approximately 0.25 mm, the specimens were ground utilizing centreless grinding (Figure 1(c)). Electrical discharge machining was utilized to separate the coating from the substrate, as shown in Figure 1(d). Lastly, femto laser cutting produced the desired stent cell design, followed by electropolishing (Figure 1(e)). The finalized stent was 0.8 cm in length, with a strut thickness of 145 μm.

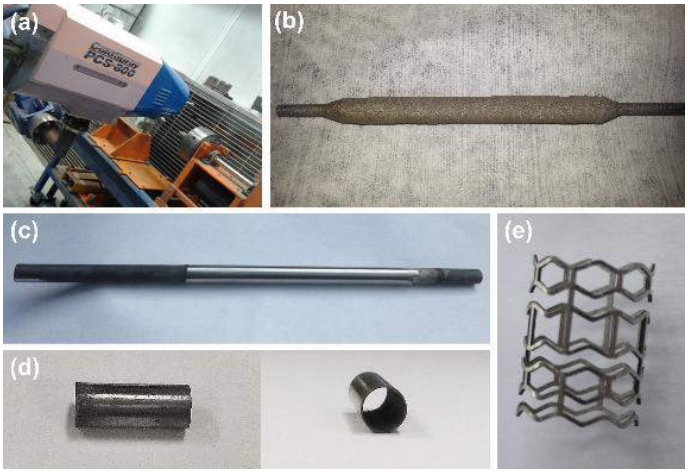

Figure 1: Stent manufacturing process: (a) cold-gas dynamic spraying, (b) coated specimens, (c) centreless grinding, (d) EDM, (e) femto laser cutting and electropolishing.

The biocompatibility of the proposed Fe-316L biodegradable was assessed through two investigations. First, a cell viability test was conducted, where endothelial cells from the human abdominal aortic artery, with added MTT (Sigma-Aldrich, M5655), were grown on the surface of 80Fe-20SS and SS316L flat specimens. A media only control

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

was also analyzed. After 24 hours, images were taken using a stereo microscope at 225x magnification. Cell viability was then determined by MTT assay, which measures the metabolic activity of cells. The specimens were incubated in a MTT solution (0.5 mg mL^{-1}) for 4 hours at 37°C. After incubation, the change in the absorbance was measured by spectrophotometer at 540 nm. The tests were conducted in triplicate.

A preliminary animal study was also conducted at AccelLAB (AccelLAB Inc., Canada) to assess stent deliverability and biocompatibility *in vivo*. Two Fe-316L stents were crimped on 5 mm diameter balloon catheters, and subsequently expanded in the left and right femoral arteries of an adult swine specimen. Four weeks post-insertion, the specimen was euthanized and the stented arteries were removed for histological examination and testing.

RESULTS

The biocompatibility of the Fe-316L stent was assessed by means of two different investigations; first, a cell viability test, and second, a preliminary *in vivo* study. The efficacy of endothelial cells to grow and proliferate on the 80Fe-20SS surface was evaluated by MTT assay. Stereo images of the specimen surface were taken after 24 hours. Oxidoreductase enzymes found in living cells will reduce MTT, a yellow tetrazole, to purple formazan. As evident by the purple pigmentation in Figure 3(a), cell growth was observed along the amalgamate's surface. When analyzing the results of the MTT assay (Figure 3(b)), it was found that the average mitochondrial activity of the 80Fe-20SS specimen was similar to that of 316L. Statistical analysis was performed utilizing Bonferroni's Multiple Comparison Test, where it was determined that the mitochondrial activity of the 80Fe-20SS was not significantly different from 316L.

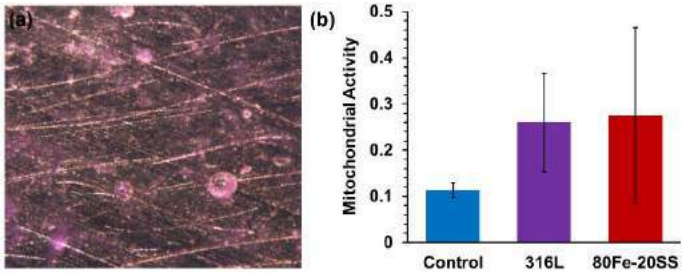

Figure 2: (a) Stereo image of 80Fe-20SS, and (b) mitochondrial activity of the tested specimens with cells (mean ± SD, n = 3).

A preliminary *in vivo* study was also conducted to further assess the biocompatibility of the proposed stent. The crimped stents were successfully expanded within the swine femoral arteries, and were visible under angiography and x-ray (Figure 3).

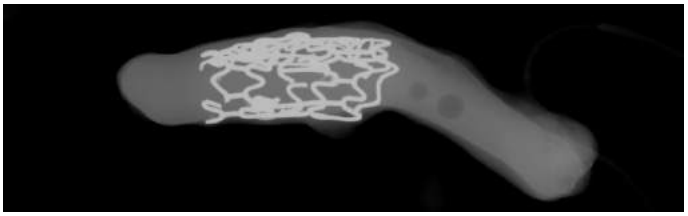

Figure 3: X-ray of expanded stent

The stented femoral arteries were removed from the swine specimen after four weeks for histological examination. When analyzing the cross-section of the stented artery, it was observed that no significant thrombus formation had developed after implantation (Figure 4(a)). In addition, degradation of the stent was also evident, where Fe^{2+} ions appear to diffuse into the surrounding arterial tissue (Figure 4(b)).

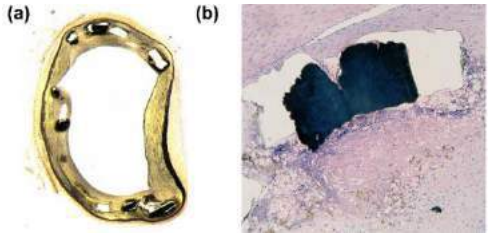

Figure 4: (a) Cross-section of the stented artery four weeks post-insertion, and (b) the degradation of a strut after four weeks.

DISCUSSION

In order for biodegradable stents to become a viable clinical alternative to permanent metallic stents, a critical requirement is that the material is biocompatible, and its degradation products are non-cytotoxic. Therefore, *in vitro* and *in vivo* tests were conducted to assess the biocompatibility of the proposed 80Fe-20SS biodegradable stent.

In order to facilitate vessel healing and remodeling post-insertion, it is critical that cells are able to grow, proliferate, and remain viable on the stent surface [4]. This was established through the cell viability test, where it was found that endothelial cells grew and proliferated on the 80Fe-20SS surface. In addition, the average mitochondrial activity of the amalgamate was similar to the gold standard of stent design, 316L.

For the MTT assay investigation, the test was conducted in triplicate, and the standard deviation showed a large variability in the mitochondrial activity of both 316L and 80Fe-20SS specimens. In particular for the 80Fe-20SS specimens, this variability may be a result of interference caused by specimen degradation during testing. The degradation products may cause interference with spectroscopy, which is employed to quantify the formazan colour shift induced by mitochondrial activity. If a significant degree of degradation occurred, this may introduce some error within the results, which is a limitation of the work. In future studies, more conclusive cell viability tests should be conducted, which avoid degradation product interference.

While this limitation may have an effect on the conclusive nature of the cell viability results, the biocompatibility of the proposed Fe-316L stent was evident during *in vivo* testing. Histological examination demonstrated that the 80Fe-20SS amalgamate did not induce a thrombogenic response *in vivo*. There was no significant evidence of thrombotic tissues, inflammation or neointimal proliferation. This animal study also established the ability of the stent to degrade *in vivo*. As shown in Figure 4(b), degradation products (Fe^{2+} ions) were found in the surrounding arterial tissue. This is critical to clinical implementation, as *in vitro* corrosion tests are often conducted in an environment that strays from a true physiological representation, which leads to an overestimate of the stent's degradation ability.

In the presented work, the biocompatibility of the proposed 80Fe-20SS biodegradable stent was assessed. The preliminary *in vitro* and *in vivo* results support the use of cold-gas dynamic spraying to fabricate a biocompatible metallic amalgamate for biodegradable stent application.

INTRODUCTION

Despite the designation of fractional flow reserve (FFR) as the gold-standard clinical diagnostic index for the functional evaluation of coronary lesions, it is used in less than 10% of all catheterization labs prior to percutaneous coronary intervention (PCI) [1]. The computation of FFR using numerical methods [2] is increasing in popularity, however there is much reservation in its clinical use. Interventional cardiologists thus still rely heavily on angiography to evaluate coronary lesion severity, despite its poor correlation with ischemic considerations [3]. Consequently, in order to improve the accuracy of the current diagnostic procedures, an understanding of the relative influence of geometric characteristics (of the stenoses and the arteries) on the induction of ischemia is required.

A notable proportion of all PCIs involves the treatment of coronary bifurcation lesions (CBLs). The study of CBLs is important because procedures are high risk and accurate angiographic evaluations are difficult to obtain due to complex bifurcation geometry [4]. Furthermore, CBLs are subject to haemodynamic interactions that complicate their dynamics and thus their clinical manifestation. To date, a systematic evaluation of the factors affecting CBL functionality (quantified by FFR), has not been executed.

Clinically, bifurcation angle is an important parameter because it influences the outcome of PCI [5]. Whereas in healthy bifurcations, the angle has been shown to affect the flow patterns in the daughter vessels [6], its effect on the clinical manifestation of CBLs remains unknown. Therefore, the objective was to compute and compare the FFR of different CBL configurations with varying angulations.

METHODS

A geometric multiscale (MS) computational fluid dynamics (CFD) model of an idealized left main coronary artery (LMCA) bifurcation was developed [7] and used to compute the flow-based FFR (ratio of the diseased to healthy flow), in each daughter vessel (Figure 1).

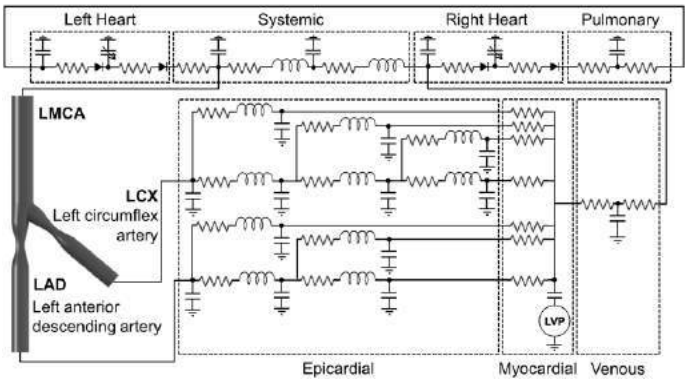

Figure 1: MS model of the LMCA bifurcation.

Four multilesional CBL configurations based on the Medina classification [7], four stenosis severities and five bifurcation angles were considered (total of 80 simulations, examples provided in Figure 2). The transient, incompressible and Newtonian Navier Stokes equations modelling the 3D fluid domain were solved using ANSYS Fluent (Canonsburg, PA, USA). Average uniform pressure boundary conditions were applied at the inlet and outlets and were calculated at each timestep from the nonlinear system of ordinary differential equations describing the dynamics of the 0D model. The heterogeneous coupling between the two models, achieved using a partitioned approach [8], was implemented directly within ANSYS by a fully-automated, in-house user-defined function written in C.

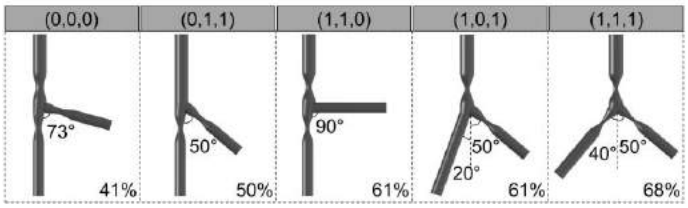

Figure 2: Examples of the CBL configurations, stenosis severities and bifurcation angles employed in the study.

RESULTS

For all configurations, when the angle of the LCX was varied between 50° and 90° relative to the centerline of the LMCA, differences in FFR were not observed in either of the daughter vessels, over the entire range of stenosis severities (Figure 3); the maximum relative difference in FFR between the angles was 1.0% and was recorded within the LAD of the (1,1,1) configuration with a 68% diameter reduction.

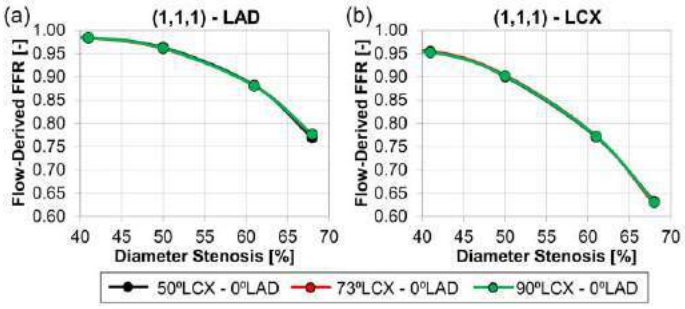

Figure 3: Effect of varying LCX angle on FFR within the (a) LAD and (b) LCX for the (1,1,1) configuration.

When the angle of the LAD was varied between 0° and 20°, for all configurations and diameter reductions, a negligible difference in FFR was observed (up to 1.7%) in both the LAD and the LCX (Figure 4). Interestingly, when further increasing the angle to 40°, configurations with a stenosis in the supplying vessel, namely the (1,1,0), (1,0,1) and (1,1,1) cases, resulted in an observable decrease in the LAD FFR and an increase in the LCX FFR, relative to the 0° geometry (Figure 4).

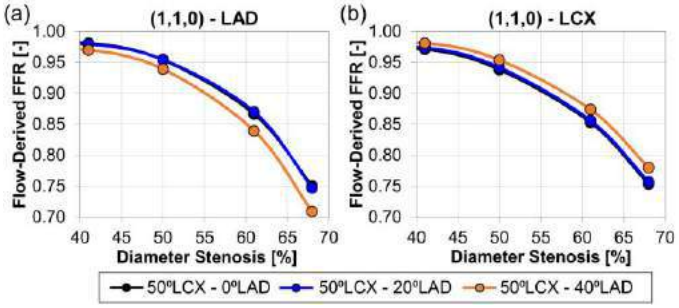

Figure 4: Effect of varying LAD angle on FFR within the (a) LAD and (b) LCX for the (1,1,0) configuration.

More specifically, the maximum relative difference in FFR, computed to be 5.7%, occurred in the LAD of the (1,1,0) configuration at a 68% diameter reduction. The corresponding increase in LCX FFR was on the order of 3.4%. The relative differences in FFR corresponded to absolute differences in FFR of 0.04 and 0.02 in the LAD and LCX respectively. The relative and absolute differences in FFR for the (1,0,1) and (1,1,1) configurations were of similar magnitude to that of the (1,1,0) configuration. Finally, in the (0,1,1) case, the relative difference in FFR with varying LAD angle remained below 1.0%.

DISCUSSION

Bifurcation angle displays significant interpatient variability, correlates with localized flow patterns in healthy daughter vessels [6] and influences the outcome of PCI. Although it is a key geometric parameter with important clinical implications, the presented work was the first, to the best of the authors' knowledge, to study its effect on CBL functionality.

In clinic, absolute differences of 0±0.04 have been recorded between successive FFR measurements [9]; as such the differences computed in the current study with varying angle were within the reported clinical variance, even for an LAD angle of 40° which displayed the most notable discrepancy compared to the remaining cases. The observed differences in the 40° LAD case are interestingly attributed to a shift in the carina towards the centerline of the LMCA, rather than to the change in bifurcation angle. In the configurations where the supplying vessel was diseased, there was a high momentum jet emerging from the neck of the LMCA stenosis which, due to the shift of the carina, resulted in an increase in flow to the LCX. This observation is supported by the fact that the decrease in LAD FFR was coupled with an increase in the LCX FFR. In addition, within the (0,1,1) configuration, negligible differences in FFR relative to the other angles were observed for the 40° LAD geometry.

Interventional cardiologists still rely on angiography to diagnose coronary lesions [1] despite its inability to identify the presence of ischemia. An understanding of the influence of geometric parameters on FFR could improve diagnostic accuracy of imaging techniques and thus better substantiate the decision to perform PCI. This idea is especially important in the case of CBLs, where PCI is high risk. In this study, by implementing a geometric MS CFD model, the functionality (FFR) was computed and systematically compared between different bifurcation angles in multilesional CBL configurations with varying stenosis severity. Although *in vivo,* coronary morphology is curved and tortuous, idealized geometries were employed in the simulations. The use of simplified geometries lends well to studies of parametric nature; in this study, it allowed to isolate the effect of a single geometric parameter on CBL functionality. This idea will also prove to be beneficial in future works where other geometric parameters (ex. lesion length) will be investigated so as to obtain a comprehensive view on CBL dynamics, although patient-specific geometry should eventually be utilized for corroboration purposes.

In summary, in the context of the current model, the results of the study indicate that bifurcation angle has a negligible effect on the functionality of CBLs.

DEVELOPMENT OF A 3-D WHOLE BODY HEAT TRANSFER MODEL FOR ACCURATELY PREDICTING TIME OF DEATH IN FORENSIC SCIENCE

C Bartgis (1), A M LeBrun (1), A Saharkhiz (1), R Ma (1), L Zhu (1)

(1) Department of Mechanical Engineering

Baltimore, Maryland, USA

INTRODUCTION

Determining postmortem interval is vital to the study of forensic science. Knowing the time of a murder can be used to exonerate or incriminate a person of interest. In the past two centuries, multiple approaches have been developed to determine postmortem interval using biochemical markers as well as physical measurements.[1] In additional to using biochemical markers appearing after death, body temperatures are normally measured to determine the time of death. The Algor Mortis approach provides a simple two-segment linearly declining temperature curve and uses a fixed temperature decay rate for the 1st 12 hours (~0.78°C/hr) and another decay rate for the 2nd 12 hours (~0.39°C/hr). Other approaches state that the temperature delay follows an exponential function with a time constant. A more accurate method was proposed to implement a correction factor into a body weight dependent formula to take into consideration of the number of layers of clothing, whether the air is still or moving, whether the clothing is dry or wet, etc.[1] Unfortunately, none of the methods have considered all the factors that may influence the cooling processes of the body.

This study is focused on developing a whole body heat transfer model to simulate not only the time decay after death, but also the temperature distribution of the body before the death. The steady state temperature field is also used to quantify the lumped thermal resistance between the skin and the environment based on an assumed thermal equilibrium before the death. From this initial temperature distribution, temperature decay curves at various body locations will be simulated postmortem and a curve fitting formula describing the cooling process will be tested for practical use.

METHODS

The whole body model shown in Figure 1 is based on a female having a height of 1.68 meters and a weight of 68 kilograms. The body is composed of five main sections: legs, arms, neck, torso, and head. For each section, a layer of skin, a layer of fat, and a region of muscle are the major components. In the torso, the internal organs are modeled as an embedded rectangular region that also has higher metabolism and blood perfusion rate than that of muscle. The Pennes bioheat equation, modified from the traditional heat conduction equation with extra source/sink terms describing the thermal effect of local blood perfusion rate ω and metabolism q_m, is used to simulate the temperature fields before and after death:

$$\rho_t c_t \frac{\partial T_t}{\partial t} = k_t \nabla^2 T + \omega \rho_a c_a (T_a - T_t) + q_m \qquad (1)$$

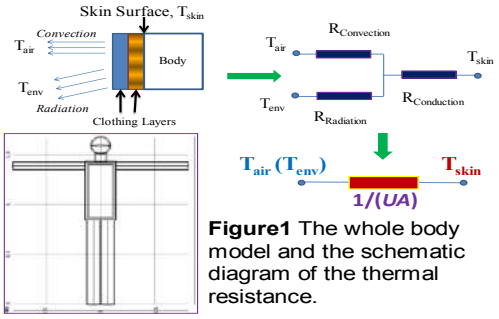

Figure1 The whole body model and the schematic diagram of the thermal resistance.

How easy to cool a body relies on thermal resistance between the skin surface and the environment (air). Combining the three resistances shown in Figure 1 and assuming that $T_{env}=T_{air}$, one can lump them into a single resistance $1/(UA)$, where U is the overall heat transfer coefficient describing thermal barrier between the skin and the air, and A is surface area of the body. We assume that the person would have proper clothing, move under the sun or in shade, etc., so that he/she feels thermally comfortable. The value of U is adjusted so

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

that a weighted average temperature of the body equals the arterial temperature at 37°C, when the body establishes a thermal equilibrium with the environment. The weighted average temperature is derived from the Pennes bioheat equation, and is defined as

$$\overline{T}_t = \iiint_V \omega T_t dV \Big/ \iiint_V \omega dV \qquad (2)$$

Eq. 1 without the last two source terms and the same overall coefficient U will then be used again in the postmortem simulation of temperature decays at various body locations.

RESULTS

Properties such as the density ρ, thermal conductivity k, and specific heat c, are listed in Table 1.[2] Table 2 shows how the air temperature affects the overall heat transfer coefficient. A smaller U associated with cold air temperature situations implies that the person wearing more clothing. When the air temperature decreases from 30°C to 10°C, the overall heat transfer coefficient decreases almost 80% from 5.5 to 1.2 W/m^{2}C, suggesting that the thermal resistance increases more than 350%. The last row of Table 2 gives the weighted average body temperature, which is very close to the arterial temperature of 37°C.

Table 1. Material properties of different tissue regions

Material	Skin	Fat	Muscle	Brain	Internal Organs
k (W/mK)	0.47	0.21	0.642	0.49	0.592
ρ (kg/m^3)	1085	900	1000	1080	1000
c (J/kg)	3680	3500	3500	3850	3500

Table 2. Overall heat transfer coefficient U and the calculated weighted average body temperature $\overline{T}_t$

T_{air} (°C)	10	15	20	25	30
U (W/m^2°C)	1.2	1.5	2	3	5.5
$\overline{T}_t$ (°C)	37.00	37.00	37.00	36.99	37.00

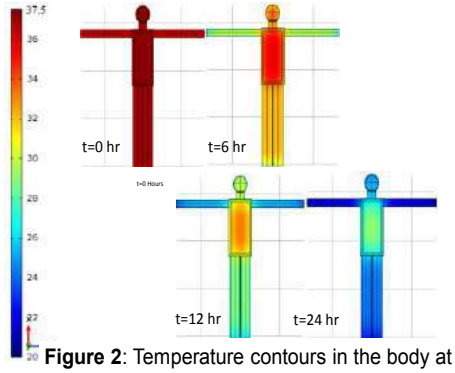

Figure 2: Temperature contours in the body at various time instants after death.

The upper left image in Figure 2 shows a cross sectional temperature field before death, with the hottest temperature in the body located in the internal organs and the brain, approximately 37.3°C, 0.3°C higher than the arterial blood of 37°C. The steady state temperature is slightly lower in the muscle regions and is the lowest in the skin region. The steady state temperature field agrees very well with previous simulations and literatures.[3] The other three images in Figure 2 illustrate how the body is cooled when subject to an air temperature of 20°C after death. One can see that the extremities cool at the most rapid rate, followed by the head, and the internal organs cool the slowest among all the body regions. After 24 hours the only noticeable temperature difference above the air temperature is located in the internal organs. The deep brain region has a temperature very similar to that in the internal organ before death; however, due to the small size of the head, its temperature decays faster than that of the internal organs.

In this study we propose a formula for practical use to fit the temperature decay curves, the formula is given below:

$$\Theta(t) = \frac{T(t) - T_{air}}{T_{initial} - T_{air}} = \begin{Bmatrix} 1 & t < t_{delay} \\ \exp\left[-\frac{t - t_{delay}}{\tau}\right] + & t \geq t_{delay} \end{Bmatrix} \qquad (3)$$

where t is the time, $\Theta(t)$ is the normalized temperature at a location, T_{air} is the environmental temperature, $T_{initial}$ is the initial temperature at the same specific location. The temperature is normalized so that Θ only varies between 1, when time is zero, and 0, when time is infinite. Based on our preliminary study, one finds that there is an initial period of t_{delay}, when the temperature at the tissue location is almost unchanged from its the initial temperature $T_{initial}$. After t_{delay}, the temperature decay is proposed to follow an exponential function. The R^2 values of all curve fittings are larger than 0.998.

At the head center, the fitted t_{delay} varies slightly around 1.6 hours for all the air temperatures, while t_{delay} is longer at the center of the internal organs, varying from 2.4 to 2.9 hours. The time constants for both locations are shown in Figure 3. The time constant τ provides the measurement window after death to be between 8 hours to 31 hours if the brain site is used, while τ increases 60%-95% at the internal organ site. The time constant is larger when the body is exposed to colder air, since a person usually wears more clothing when it is cold outside to keep the body warm and comfortable. Assuming that after death, the body has the same clothing as that before the death, the larger thermal resistance due to clothing in colder air would slow down heat conduction from the body core to the skin, leading to a slower cooling rate of the body.

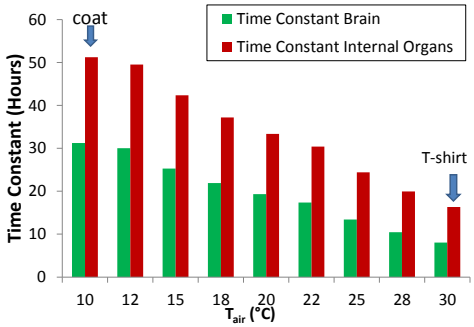

Figure 3:Effects of the air temperature and body location on the time constant.

In summary, we have articulated the limitations of current practices of determining post mortem time in practice, and elaborated the rationales of simulating temperature cooling curves based on development of rigorous 3-D whole body heat transfer models. The results given in this study has demonstrated the accuracy of determining the overall heat transfer coefficient or the thermal resistance between the skin and air via an indirect approach assuming thermal equilibrium. The curve fitting techniques used in this study have been tested to understand how the air temperature affects the overall heat transfer coefficient, the initial time delay, and the time constant associated with the body cooling.

INTRODUCTION

Synergistical bacterial species can perform more varied and complex transformations of chemical substances than either species alone, but this is rarely used commercially because of technical difficulties in maintaining mixed cultures. Typical problems with mixed cultures on scale are unrestrained growth of one bacterium, which leads to suboptimal population ratios, and lack of control over bacterial spatial distribution, which leads to inefficient substrate transport. To address these issues, we designed and produced a synthetic ecosystem by co-encapsulation in a silica gel matrix, which enabled precise control of the microbial populations and their microenvironment. As a case study, two greatly different microorganisms: *Pseudomonas sp.* NCIB 9816 and *Synechococcus elongatus* PCC 7942 were encapsulated. NCIB 9816 can aerobically biotransform over 100 aromatic hydrocarbons, a feat useful for synthesis of higher value commodity chemicals or environmental remediation. In our system, NCIB 9816 was used for biotransformation of naphthalene (a model substrate) into CO2 and the cyanobacterium PCC 7942 was used to provide the necessary oxygen for the biotransformation reactions via photosynthesis (Figure 1). A mathematical model was constructed to determine the critical cell density parameter to maximize oxygen production, and was then used to maximize the biotransformation rate of the system. Experimental results showed that the system was able to support the oxygen demand of the biotransformation reactions, and performed better than oxygenation by external supplementation. It is proposed that this was due to micron-scale proximity of the co-encapsulated bacteria, which was verified by confocal microscopy.

METHODS

Silica gel synthesis and encapsulation of bacteria

Tetraethyl orthosilicate (TEOS) was hydrolyzed by stirring 2 h at a 1:5.3:0.0013 molar ratio of TEOS:water:HCl. The pH of the SNPs was adjusted to 7.4 by adding 1M hydrochloric acid. After pH adjustment, PBS was added to further stabilize the pH of the SNPs and improve overall cytocompatibility of the solution. Bacteria suspension was added to SNP/PBS solution, and hydrolyzed TEOS was added to the SNP/PBS/bacteria solution by pipetting a few times to obtain a homogeneous sample. Final volume of the gels consisted of 40% of silica precursors (TEOS + SNP) and 60% of (PBS + Bacteria suspension).

Oxygen generation/consumption and naphthalene biotransformation rate measurement

Oxygen generation and consumption rates of the silica gel encapsulated bacteria were measured by using an Oxygraph Oxytherm System (Hansatech Instruments Ltd., United Kingdom). Silica gels were made into cylindrical 200 µL test pieces by mixing the reagents and bacteria suspension in a 96-well plate. After gelation, a thin copper wire was used to extract the test pieces (radius = 0.32 cm and height = 0.62 cm) and suspend them in the reaction chamber during measurement. For oxygen production measurements with cyanobacteria containing gels, 3 mL of PBS was added to the chamber and the LED was turned on to provide light to the cyanobacteria. For oxygen consumption measurements with NCIB 9816 containing gels, 3 mL solution of PBS saturated with naphthalene was added to the chamber.

For biotransformation rate measurements, NCIB 9816 and PCC 7942 were mixed gently via vortexing prior to encapsulation. Silica gels with co-encapsulated cells were synthesized (500 µL volume, height = 0.15 cm) in septa sealed, glass vials. After gelation, 9 mL of saturated naphthalene + BG11 solution was added on top of the gel, ensuring that the vial was completely filled before sealing (except for the samples with additional 4 mL of headspace). Then, the samples were placed on a shaker setup and naphthalene concentrations in the solution were measured intermittently, as described in [1].

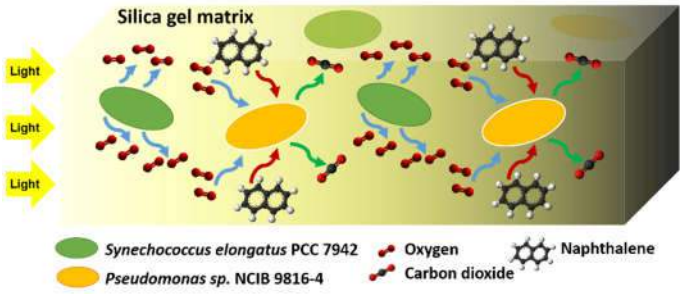

Figure 1 – Silica gel encapsulated synergistic bacteria

RESULTS

Modeling of oxygen generation by silica gel encapsulated PCC 7942

Light intensity varies through the gel as both the silica gel and the encapsulated bacteria within contribute to light attenuation (At) via absorption and scattering, and can be modeled by a modified Beer-Lambert law as follows:

$$At(\rho, x) = \frac{-(C_1\,\rho + C_0(1-\rho))}{C_S}x \quad (1)$$

where attenuation coefficient C_1 represents the contribution of cells to light attenuation, C_0 represents the contribution of the gel to light attenuation, C_S represents the contribution of the back-scattering effects,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

ρ is the cell density (of the photosynthetic bacteria), and x is the pathlength of light in the gel.

Coefficients of Eq. 1 were determined experimentally by measuring light transmittance through silica gel with encapsulated PCC 7942 at different cell densities, as well as with free PCC 7942 in suspension (C_1 = 116.42 mL/(mL cells-cm) and C_0 = 0.089 1/cm). Using Eq. 1, transmittance (T) at a distance x from the gel surface for encapsulated PCC 7942 was determined as:

$$T(\rho, x) = exp(-At) = exp(-(C_1\,\rho + C_0(1-\rho))x) \quad (\mathbf{2})$$

Based on Eq. 2, two volume elements (Figure 2a) for cells encapsulated in a silica gel of uniform cross-section (UCS) and non-uniform (cylindrical) cross-section (NUCS) were defined. For UCS, a differential volume can be defined as:

$$dV = A\,dx$$

where A is the uniform cross-sectional area (the differential volume definition and the derivation of the following equations for NUCS is not discussed here). Oxygen generation rate of cyanobacteria is known to be linearly correlated with light intensity up to a saturation limit where photo-inhibition effects start damaging the oxygen evolution complex [2]. The system was designed to operate below the saturation limit, so the net oxygen generation rate ($d\dot{q}$) in the differential volume was defined as:

$$d\dot{q} = (k_{gen}\rho_C T(\rho_T, x) - k_{con}\rho_C - k_{deg}\rho_N)dV \quad (\mathbf{3})$$

where $\boldsymbol{k_{gen}}$ is O_2 generation rate constant per unit volume of PCC 7942, $\boldsymbol{k_{con}}$ is O_2 consumption rate constant per unit volume of PCC 7942, $\boldsymbol{k_{deg}}$ is O_2 consumption rate constant during naphthalene transformation per unit volume of NCIB 9816. The net oxygen generation rate in the volume was then obtained by integrating Eq. 3 over the whole volume, and incorporating the consumption by the NCIB 9816, as shown in Eq. 4:

$$\dot{Q} = \int_{x=0}^{x=L} (k_{gen}\rho_C T(\rho_T, x) - k_{con}\rho_C - k_{deg}\rho_N)A\,dx \ \text{(UCS)} \quad (\mathbf{4})$$

The results obtained from the mathematical model were verified experimentally. Cell density (ρ_C) was varied from 1% to 30% [v/v] in the silica gel with PCC 7942 to determine how ρ_C affected oxygen generation rate. The net oxygen generation rate of the whole gel increased with increasing ρ_C up to a certain point, then slightly decreased (Figure 2b). The maximum oxygen generation rate of 3.7 ± 0.7 nmoles/min was achieved at ρ_C = 20% [v/v]. Base oxygen consumption rate constant of PCC 7942 (k_{con}) was measured in the absence of light as 22.1 ± 1.7 nmoles/(min.mL-cells). Incorporating k_{con} and other known experimental parameters for encapsulated cells into Eq. 4, k_{gen} was determined as 721.74 nmoles/(min.mL-cells), and C_s was determined as 1.88 with a fit as shown in Figure 2b (red line). For comparison, a model that did not incorporate the back-scattering effects is also shown in Figure 2b (blue line). The model with the back-scattering effects was then used to optimize the relative densities of the co-encapsulated cells for naphthalene biotransformation.

Optimization of the co-encapsulation matrix and synergistic biotransformation study

The goal of the optimization study was to maximize the biotransformation rate of naphthalene to CO_2 while minimizing the required amount of cells. We proposed that under optimal operating conditions, the system is to have neither an oxygen surplus (*i.e.* excess PCC 7942) nor an oxygen deficit (*i.e.* excess NCIB 9816). This design requirement was satisfied by solving Eq. 4 for $\dot{Q} = 0$, which yielded a non-linear ρ_C vs. ρ_N curve (Figure 2c). It can be seen that ρ_C increased with increasing ρ_N, up to ρ_N = 0.4% [v/v] where a ρ_{cr} value of 40% [v/v] was reached. If ρ_N is increased beyond this critical point, additional PCC 7942 cannot provide more oxygen for the biotransformation reactions, yielding an oxygen deficit ($\dot{Q} < 0$).

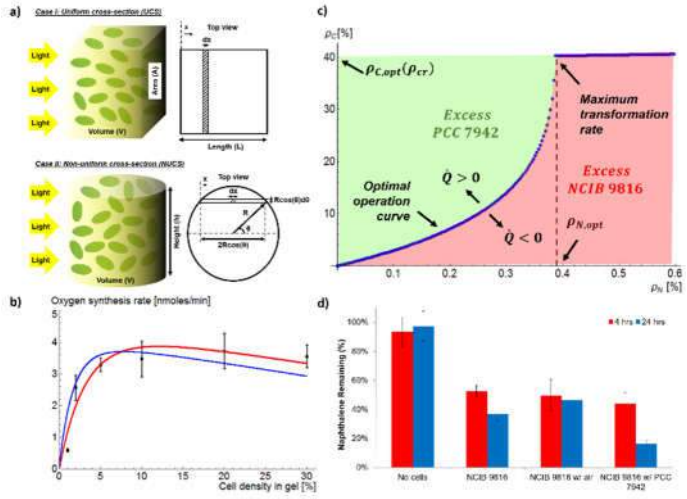

Figure 2 – Oxygen generation modeling and naphthalene biotransformation optimization results

Naphthalene biotransformation experiments with silica gel co-encapsulated cells were tested with four cases: (I) No cells: Silica gel without cells, (II) NCIB 9816: Silica gel encapsulated NCIB 9816, (III) NCIB 9816 with air: Silica gel encapsulated NCIB 9816 with additional headspace which provides additional oxygen for biotransformation reactions and (IV) NCIB 9816 with PCC 7942: Silica gel co-encapsulated NCIB 9816 and PCC 7942. In Case I, naphthalene concentration decreased only slightly over 24 hours (Figure 2d), verifying that the disappearance of naphthalene due to effects other than biotransformation was minimal. For cases II, III and IV, naphthalene concentrations were comparable after 4 hours at 52.3 ± 4.1%, 49.8 ± 10.9% and 43.9 ± 7.6% respectively. These values indicated that when a sufficient amount of dissolved oxygen was present in the solution, oxygen generation by encapsulated cyanobacteria did not make a difference. At 24 hours, the naphthalene concentrations in cases II and III were still comparable, whereas the naphthalene concentration for case IV was measured as 16.3 ± 2.3%, which was significantly lower than cases II and III. This indicated that dissolved oxygen was depleted in solution sometime between 4 and 24 hours, and after the depletion of dissolved oxygen, PCC 7942 provided oxygen to further drive the biotransformation reactions. Experimental results also verified that oxygenation via co-encapsulated PCC 7942 (Case IV) was more efficient than providing oxygen externally (Case III).

INTRODUCTION

Long bone morphogenesis is initiated by condensation of mesenchymal cells in the early limb bud and progresses through chondrogenic differentiation and subsequent hypertrophy, forming the cartilaginous anlage that serves as a template for endochondral bone formation [1]. This process is remarkably efficient, forming a vascularized, hierarchical architecture capable of longitudinal growth. This endochondral ossification process is also recapitulated in fracture healing through callus formation and has inspired biomimetic tissue engineering paradigms that aim to replicate development for postnatal tissue regeneration [2,3].

Strikingly, the process of endochondral ossification in both development and fracture healing is controlled by extrinsic mechanical stimuli. *In utero*, chemical or surgical induction of muscular paralysis inhibits longitudinal and volumetric bone growth through reduced chondrocyte proliferation and delayed ossification [4]. Similarly, in fracture healing, compressive interfragmentary motion is necessary for cartilaginous callus formation and endochondral healing [1]. However, the role of mechanical loading in endochondral bone defect regeneration has not been investigated.

Here we report the necessity of *in vivo* mechanical loading for functional bone regeneration through endochondral ossification of human mesenchymal stem cells, self-assembled in high-density sheets with growth factor-releasing gelatin microspheres to replicate the chondrogenically primed mesenchymal condensate found in early endochondral bone development [1]. This approach eliminates the typical need for lengthy chondrogenic pre-differentiation *in vitro*, and enables direct investigation into the temporal interactions between endochondral lineage specification and mechanical stimulation *in vivo*.

We hypothesized that the timing and magnitude of mechanical loading *in vivo* would control cell differentiation and endochondral ossification for functional regeneration of large bone defects.

METHODS

Chondrogenically-primed engineered mesenchymal condensates were created by seeding hMSCs mixed with recombinant human transforming growth factor-β1 (TGF-β1)-bound gelatin microspheres (GM) on 12 mm transwell plates (3μm pore size) at a density of 2 x 10^6 cells/well [5]. High density cell sheets were self-assembled for 2 days *in vitro* prior to histology and message-level gene expression analysis or implantation. Each sheet received 600 ng TGF-β1.

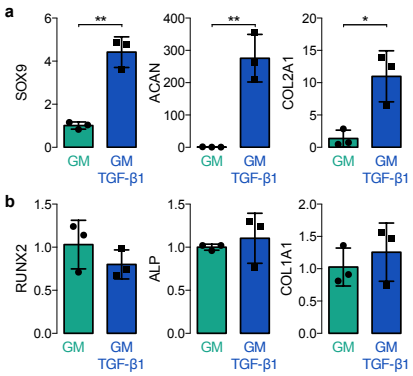

Figure 1: Engineered mesenchymal condensates at day 2 *in vitro*. (a) mRNA expression of chondrogenic markers SOX9, Aggrecan (ACAN), and Collagen 2A1 (COL2A1). (b) mRNA expression of osteogenic markers RUNX2, Alkaline phosphatase (ALP), and Collagen 1A1 (COL1A1). For each, expression is normalized to GAPDH and growth factor-free gelatin microsphere-containing controls (GM). * p < 0.05, ** p < 0.01; Student's t-test.

Critical sized 8 mm segmental bone defects were created in 14 week-old male RNU nude rat femora and stabilized with custom fixation plates that allow controlled transfer of ambulatory loads *in vivo* [6]. The experimental design featured three groups: control limbs (stiff) were stabilized with fixation plates that limited load transfer (k_{axial} = 214 N/mm). Early loading limbs were stabilized by axially compliant fixation plates (k_{axial} = 8.4 N/mm) that allowed load transfer immediately upon implantation (early). Delayed loading limbs were stabilized by the same compliant plates initially implanted in a locked configuration to prevent loading, but after four weeks the plates were surgically unlocked to enable load transfer (n = 9-10 per group).

In all three groups, each defect received three high-density cell sheets, contained within perforated electrospun polycaprolactone nanofiber mesh tubes [6] for a total of 6 x 10^6 cells and 1.8 μg TGF-β1

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

per defect. Bone regeneration was longitudinally evaluated *in vivo* by radiographs and microCT, with post-mortem analysis at week 12 by high-resolution (20 μm voxel size) microCT, torsional testing to failure, and histology. Mechanical properties were compared to age-matched un-operated limbs (n = 7). To distinguish between cell-mediated and growth factor-mediated bone regeneration, an additional stiff fixation plate group was included featuring the same cell sheets, except the cells were devitalized by three freeze-thaw cycles immediately prior to implantation (n = 6).

Bridging rate was evaluated by chi-square test for trend, and differences between groups were assessed by Student's t-test or ANOVA with Tukey's post-hoc tests ($\alpha = 0.05$). Error bars are shown as SD (Figs. 1-3) or interquartile box with min/max whiskers (Fig 4).

RESULTS

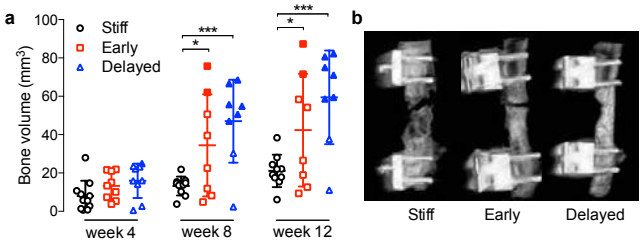

Figure 2: Longitudinal evaluation of bone formation *in vivo*. (a) Bone volume quantification. Shaded data points indicate radiographic bridging of the defect at that time point. (b) Representative 3D reconstructions of bone formation at week 12. * p < 0.05, *** p < 0.001; ANOVA with Tukey's post-hoc test.

Histological (data not shown) and gene expression analysis (Fig. 1) of hMSC sheets at day 2 *in vitro* demonstrated chondrogenic, but not osteogenic, priming of engineered mesenchymal condensates at the time of implantation.

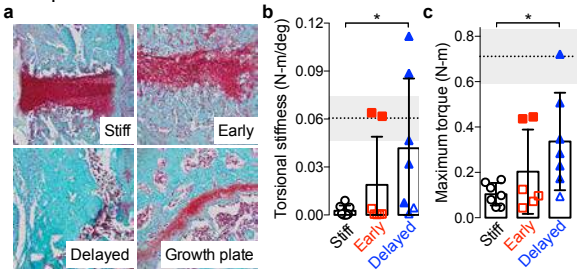

Figure 3: Post-mortem analysis. (a) Safranin-O/fast green histological staining of glycosaminoglycans (red; images at 10x). (b) Torsional stiffness. (c) Maximum torque at failure. Dotted lines and shaded regions indicate mean ± SD of age-matched intact bone properties. Shaded data points indicate radiographically bridged samples. * p < 0.05; ANOVA with Tukey's test.

In vivo, the delayed loading group was the only to exhibit a significantly increasing trend in radiographic bridging over 12 weeks ($p < 0.001$, data not shown). There was no difference in bone volume between loading groups at week 4, but by week 8, 4 weeks after loading was initiated in the delayed group, both early and delayed loading groups were significantly greater than the stiff group, and these differences persisted over 12 weeks (Fig. 2).

Post mortem microCT analysis and histology revealed a cortex-like shell with internal trabeculae (data not shown) in all three groups, but also gaps of unmineralized cartilage tissue in stiff and early loading samples, with characteristics similar to growth plate cartilage (Fig. 3a). Mechanical testing (Fig. 3b,c) revealed significantly higher torsional stiffness and maximum torque in the delayed loading group compared to the stiff plate controls. Only the delayed group had mechanical properties not significantly different from intact femora ($p > 0.05$, $\beta = 0.71$). In both bone volume and mechanical testing, a bimodal response was observed in the early loading group, consistent with persistence of cartilage tissue in non-mineralized gaps.

Comparison of regeneration in constructs containing TGF-β1 with MSCs either alive or devitalized prior to implantation showed significantly lower regeneration in constructs with devitalized cells at week 12 (Fig. 4).

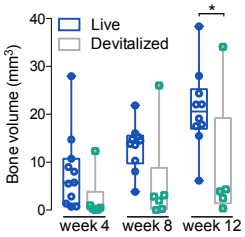

Figure 4: Bone formation *in vivo* induced by constructs containing live cells, or cells devitalized prior to implantation. Both groups feature stiff fixation plates. *p < 0.05; ANOVA with Tukey's test.

DISCUSSION

We present a tissue engineering approach that recapitulates the early mesenchymal condensation necessary for endochondral bone morphogenesis through spatiotemporal control of growth factor-mediated MSC self-assembly and demonstrate the necessity of *in vivo* mechanical stimulation for functional regeneration through the endochondral pathway. Bone regeneration progressed by endochondral ossification as demonstrated by histological and morphological analysis in all three groups, but mechanical loading enhanced bone formation and functional regeneration, in a manner dependent on magnitude and timing. Both load initiation during chondrogenic differentiation at the time point of implantation and loading delayed until after the onset of ossification significantly enhanced bone formation, but only delayed loading restored functional mechanical properties to the regenerated limbs. The early-loaded group exhibited a bimodal distribution with both responders and non-responders compared to the more uniform distribution seen with delayed loading. Despite a significant increase in bone volume, few samples in the early loading group achieved radiographic defect bridging over 12 weeks, with regions of persistent non-mineralized cartilage tissue. In the early group, the large strains applied during the differentiation process may have induced pseudarthrosis, resulting in a cartilaginous nonunion with morphological similarity to the native growth plate. Importantly, the endochondral regeneration response was not dependent only on the delivered growth factor, but required delivery of live cells.

Taken together, these data demonstrate that the timing and magnitude of *in vivo* mechanical loading on engineered mesenchymal condensates directed tissue formation and enhanced functional bone regeneration through endochondral ossification in a manner mimetic of bone morphogenesis.

INTRODUCTION

It is currently estimated that roughly 10 million Americans have temporomandibular joint disorders (TMDs). These TMDs encompass a variety of conditions, such as structural abnormalities of the TMJ, which can be accompanied by severe pain. The causes for TMDs are varied, and can include trauma, parafunction, unstable occlusion, functional overloading, and increased joint friction. Patients with TMD can show symptoms of persistent pain affecting normal life activities, such as malocclusion, facial asymmetry, locked jaw, and the deterioration of tissues around the joint space.

Roughly 80% of TMD patients are women between the ages of 20-40, which necessitates an effective, long term clinical treatment for TMDs. The current clinical treatment for patients with irreparable TMJ disc damage is the use of autogenous tissue sources, which resorb over time, making them ineffective for long term treatment required. In an effort to create site appropriate therapies, tissue engineering has been used to create implants that can remodel into tissues that possess near-native properties. [1]

Before the efficacy of such treatments can be assessed, however, the native mechanical properties of a healthy TMJ disc must be understood. To this end, several studies have been performed investigating the tensile and compressive properties of skeletally mature pigs, but no study has looked into age-dependent mechanical properties of growing pigs.[2-3] Since in-vivo tissue engineering studies involve implanting devices into pigs that are skeletally immature and growing, it is necessary to determine what effects age would have on native discs. Therefore, the objective of this study is to determine the tensile and compressive mechanical properties of the native porcine TMJ disc at 3, 6, and 9 months of age. We hypothesize that there will be an age dependent effect, with mechanical properties increasing with age.

METHODS

Female porcine heads (n=9) from 3, 6, and 9 month animals were procured from a local abattoir and both TMJ discs were excised immediately. For tensile testing, anterior-posterior samples were collected from the intermediate zone of the TMJ disc, and a dogbone shape was created in the tissue by punching two holes about 2 mm apart with a 8 mm dermal biopsy punch. Each anterior-posterior sample was cut using a cryotome to produce multiple 300-400 micrometer sections per disc, which were kept in sequential order. Samples were then allowed to equilibrate in phosphate buffered saline in individual wells of a 6 well plate for at least one hour.

The samples were tested for tensile properties using an Instron 5565 mechanical testing apparatus. The ends of each sample were gripped using 400 grit sandpaper in a pneumatic clamp. Samples were preloaded to 0.2 N. After the preload was applied, 20 cycles of 5% strain were applied at 10 mm/min for preconditioning. The samples were then pulled to failure at a strain rate of 10 mm/min. Samples were analyzed for the peak stress (stress at first rupture in the tissue), strain (clamp to clamp strain at first rupture in the tissue), and modulus (slope of stress-strain behavior from 5-10% strain). These parameters were collected for all the inferior-superior sections of each individual disc, and averages from each disc were used to collect an aggregate value for each parameter.

For compression testing, 4 mm dermal punches were taken from the punched tissue collected to create a dogbone shape in each disc. The discs were allowed to equilibrate in phosphate buffered saline for at least one hour. Each sample was then tested in unconfined stress relaxation compression in a water bath at 37 ^{o}C. Samples were preloaded to 0.05 N. 10 cycles of 10% strain were applied at a strain rate of 9%/min for preconditioning. The samples then had a stress relaxation compressive load applied at a strain rate 9%/min from 0-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

30% strain, in 10% increments. The tissue was allowed to relax for 30 min between each step. Samples were analyzed for peak stress (stress at ending of ramping phase), and modulus (last 20% of the stress/strain curve of the ramping phase).

RESULTS

For tensile stress (Figure 1), no significant differences ($p<0.05$) were seen between the 3 month (3.91 ± 1.81 MPa), 6 month (5.24 ± 1.69 MPa), and 9 month (4.57 ± 1.60 MPa) age groups. For tensile modulus (Figure 2), no significant differences ($p<0.05$) were seen between the 3 month (28.62 ± 9,16 MPa), 6 month (38.25 ± 10.09 MPa), and 9 month (29.84 ± 8.27 MPa) age groups.

For compressive stress (Figure 3), significant differences ($p<0.05$) were seen between the 3 month (65.1 ± 49.6 MPa), and 9 month (80.4 ± 34.5 MPa) age groups. For compressive modulus (Figure 4), significant differences ($p<0.05$) were seen between the 3 month (710 ± 456 MPa) age group and both the 6 month (1108 ± 512 MPa), and 9 month (893 ± 294 MPa) age groups.

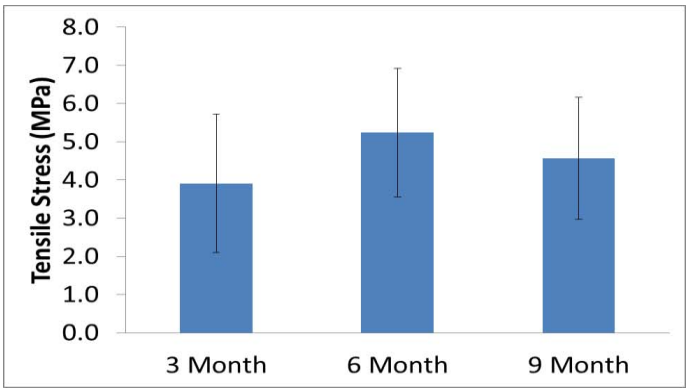

Figure 1; Tensile stress at tissue failure for 3, 6, and 9 month old pigs (n=9).

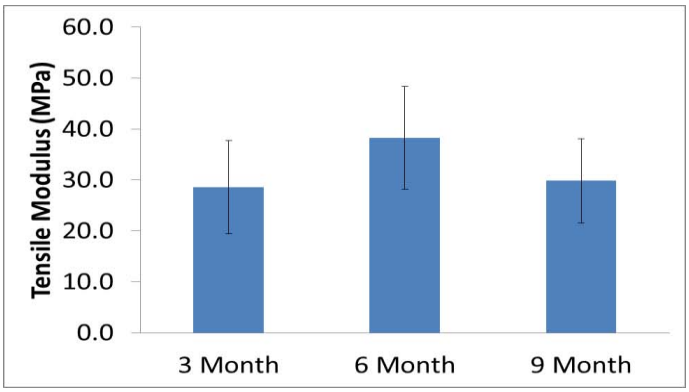

Figure 2; Tensile modulus for 4-8% of stress-strain curve for 3, 6, and 9 month old pigs. (n=9).

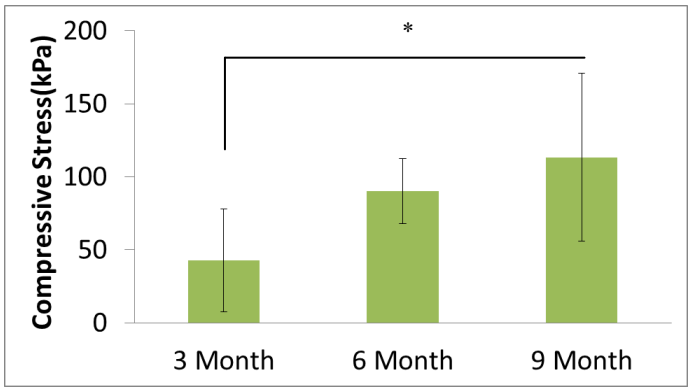

Figure 3; Compressive stress at 30% strain for 3, 6, and 9 month old pigs (n=9).

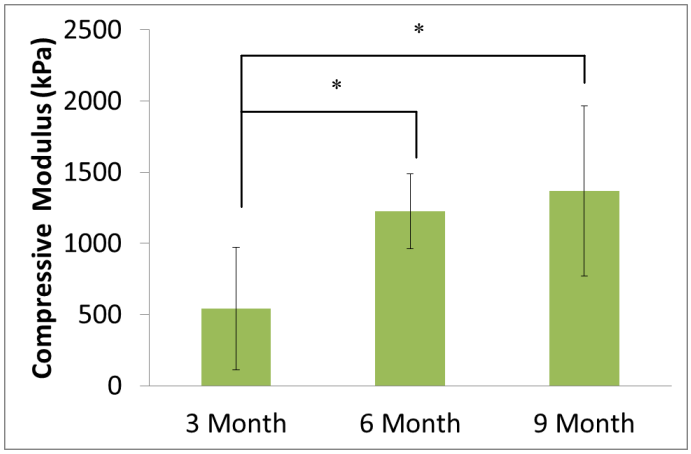

Figure 4; Compressive modulus of the last 20% of the loading curve at 30% strain for 3, 6, and 9 month old pigs (n=9).

DISCUSSION

As shown in these results, the compressive properties of the porcine TMJ disc do change over time, whereas the tensile properties do not. The variation in these trends show that depending on the type of mechanical testing being performed for an in vivo test, it is important to include age-matched controls. Otherwise, differences observed between end stage experimental groups and early native pigs may be confounded by age-induced mechanical property differences.

SCALING BETWEEN HUMAN AND PORCINE MODELS FOR TRAUMATIC BRAIN INJURY

Siddiq M. Qidwai (1), Robert N. Saunders (2)

INTRODUCTION

The motivation to study the causes and mechanisms of traumatic brain injury (TBI) is quite evident from the news, events, and investigative reports and studies being published in mass media and scientific journals over the last decade. The issue has attained such gravity and momentum that all manners of *in vitro*, *in vivo*, *ex vivo*, *in silico*, and surrogate methods and techniques have been incorporated to study it [1]. Indeed, the complexity of a stress wave propagating through a highly heterogeneous biomaterial system such as the head and neck complex with its intricate interfaces and diverse materials, multi-phase components, and multi-scale and multi-physics mechanisms, demands a multi-prong approach. Thus, live animal models, e.g., pigs are also now being used as surrogates based on certain physiological and morphological reasons to study TBI in humans [2, 3]. However, ethical considerations, cost, and insufficient granularity of data are concerns that reduce the viability of this approach. This is where computational modeling may both complement and supplement experimentation.

There are two challenges associated with the use of computational models of animals, or pigs as is the case in this study. The first is validation, which is the universal bane of most models, especially in biomechanics because of the difficulties in accruing consistent and accurate granular data. The second is the applicability of data from porcine modeling, or even porcine testing, on humans. In this study, we investigate the later challenge based on the notion that we already have a validated model (being reported in a companion paper). Thus, development of scaling or correspondence rules that link the pig and human together is considered in this study, with specific focus on blast induced TBI.

The procedure followed for the overall study is straightforward: 1) create the human and porcine computational models of the head, 2) validate the models, 3) simulate the two models under the same impact scenarios, and 4) compare and analyze injury prediction to formulate scaling or correspondence rules.

METHOD

The development and validation of the porcine head and upper torso model are described in relatively greater details in the companion paper. That same approach has also been used for the human head and neck model. Thus, we only describe the first two steps of the aforementioned procedure briefly here. Gray-scale magnetic resonance imaging (MRI) scans with a resolution of 1 mm were procured for both species. For the pig, CT scans with a resolution of 0.6 mm were also obtained. The human subject was a 50th percentile Caucasian male of 26 years age, whereas the porcine subject was a 36.5 kg mini-Yucatan pig. Then, through careful image-to-voxel transformation, all major components of the head have been included in the geometric models, as well as heart and lung for the porcine upper torso. Material models for each component have been chosen and calibrated based on the latest available data over the loading regime of interest (quasi-static to 1000/s). The hybrid finite element mesh, created from the voxel data, is composed of linear and quadratic tetrahedral elements, which are placed according to the compressibility of the associated material regions. The two finite element models are shown in Figure 1. For validation, the human head model has been tested against four well-known experimental studies related to the automotive sector (e.g., [4, 5]). Similarly, the porcine head and upper torso model has been validated against blast tube injury response data obtained elsewhere (e.g., [3]).

For the next step in the development of scaling rules, the finite element models are simulated under the same frontal blast loading conditions. A planar Friedlander pressure wave profile based on the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

peak magnitude and pulse duration of an in house open-field test is used as the template (see Figure 2). A parametric study based on peak pulse magnitudes of 37, 50, and 62 psi with the same duration is carried out. The boundary conditions are set to least disrupt the similarity in loading conditions although some discrepancy is inevitable at later times in the loading when reflections from the boundaries reach the brain. Pressure, maximum shear stress (or Tresca stress) and principal strain are used as predictors of injury, with threshold values of 235 kPa, 7.8 kPa, and 5%, respectively [6].

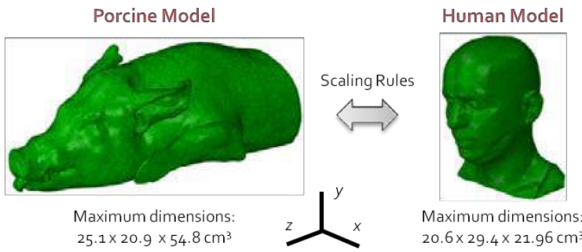

Figure 1: Finite element models of the porcine and human subjects.

RESULTS

Even at the minimum applied peak pulse of 37 psi, the human brain exhibits the onset of TBI. In Figure 2, the predicted injured volume as a function of blast time is shown for the three injury measures, with an additional threshold for pressure at 173 kPa added for educational purposes (as it is suggested as a measure of mild TBI in the literature). It is noted that only pressure-induced TBI is observed for the humans, whereas the porcine brain shows no severe injury.

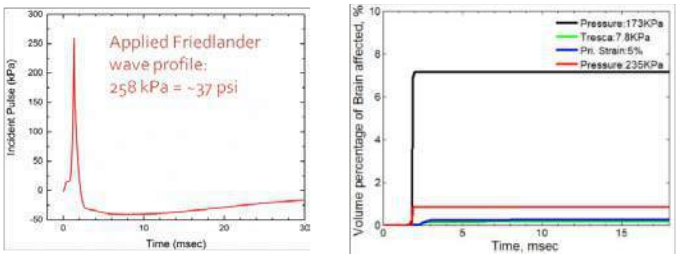

Figure 2: (Left) Friedlander pulse profile for a peak magnitude of 37 psi; (Right) Predicted TBI by percent volume of the human brain as a function of time based on pressure, shear and strain.

This particular trend continues for the peak magnitudes of 50 psi and 62 psi. In the top row in Figure 3, the spatial extent of TBI based on the pressure threshold of 235 kPa is shown in red color for the human brain. The porcine brain again exhibits no severe injury; mild TBI is probable though based on the threshold of 173 kPa. This is demonstrated by the comparative evolution of the injured volumes of the human and pig as a function of blast time in the bottom row of Figure 3. All other injury measures predicted no injury.

DISCUSSION

It is obvious from these results that frontal blast insult predominantly induces only pressure-based TBI up to significantly large insults (at least 62 psi) in humans. The mini-Yucatan pig remains unaffected, however. It appears from the closer inspection of the simulation data that the pig skull acts as a pathway for the frontal blast transmission away from the brain. This implies that blast impacts from oblique or transverse orientations may be better to yield TBI in pigs. Work is already underway with initial results for the porcine model showing the onset of pressure-based PSI at only 40-50 psi range under side-on blast impact. Also, the frontal blast parametric study has been extended to include 80, 100 and 120 psi peak magnitude pulses. Already, at 80 psi, the onset of pressure based TBI has been observed in pigs. Thus, one can note the scaling pattern that is developing for frontal impact, i.e., higher insults are needed to cause TBI in pigs than in humans.

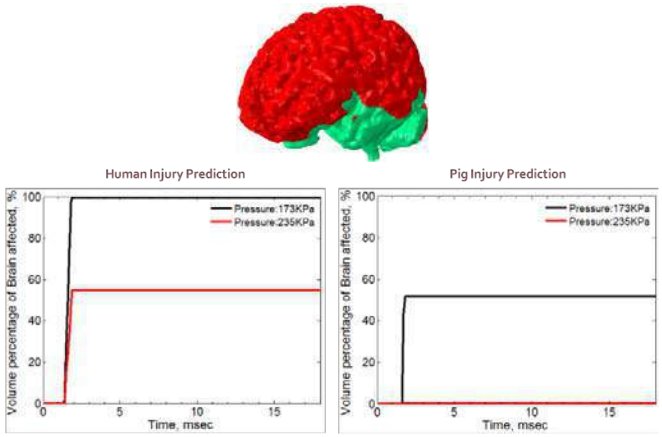

Figure 3: (Top) Spatial extent of pressure-induced TBI (235 kPa threshold, in red color) in human brain under 62 psi peak pressure frontal blast insult; (Bottom) Comparison of pressure-induced TBI as a function of time for both human and pig models.

The absence of injury as predicted by shear and strain is quite interesting. Does it mean that blast insults cannot really cause these modes of injury or is it that their appearance in significant manner may only happen at higher insults or insults from orientations other than the front? It will also be interesting to see if similar injury patterns, both in terms of location and volume, appear at different applied insults in human and pigs because that would be pertinent to developing meaningful scaling rules for various classes of injury. All these issues are under consideration as this study is continuing and we hope to answer a majority of them in the near future.

An important note of caution is necessary here. The success of developing scaling rules is predicated on the notion that the threshold values and the predicting variables are indeed accurate and reliable. This is an area of research that needs to be paid more attention by the community.

MULTIDOMAIN PARTICLE DYNAMICS SIMULATOR ENGINE

Vl Q. Ha (1), George Lykotrafitis (1)

Storrs, CT, USA

INTRODUCTION

In this work, we introduce a lightweight, fast-paced, and easily customizable C++ particle dynamics simulator engine that is designed to run on large-scale parallel distributed-memory computing clusters. The simulator uses message passing interface (MPI) for parallel computing operations. It is easily customizable and provides a highly intuitive user interface by using contemporary pragmatic object-oriented pointer systems that allows easily access to suitable components of the molecular dynamics (MD) engine. Modern MD simulator programs are limited to primary employing spatial distribution. Here we introduce a simulator engine that offers three interacting domain that can be modularly programmed: spatial domain, network domain and continuum domain.

METHODS

Spatial distribution allocates particles to processors according to their positions to attain high efficient short-range MD computations. The simulator utilizes the linked list method to construct a robust cell list algorithm. The spatial decomposition algorithm and cell list method allow extremely fast paced and efficient computations of large-scale short-range MD simulations of particles interacting within a cut off radius. In addition, specific long-range interactions are realized via the introduction of a second interaction domain, the global network domain. The global network registers particles as nodes and connects them via edges. This allows efficient interaction between particles regardless of their spatial position or the processors they reside within the cluster. The third interaction domain that we introduce is the continuum space domain. In the current version of the code, the simulator employs an explicit finite difference algorithm to solve the diffusion equation. The continuum domain allows communication between particles or between particles and the environment via diffusion. Particles from the network domain, spatial domain, and the continuum domain are able to interact with one another. For example, calculations of the chemotaxic response of particles moving in the spatial domain and subjected to a chemical concentration gradient in the continuum domain are perfectly feasible. The introduction of particles, nodes and their interactions are easily programmable. The simulator provides tools to program each particle or a defined group of particles individually.

RESULTS

The simulator can be employed in numerous biological cases. The spatial domain allows users to simulate short-range MD simulations. Users can also easily simulate more complex scenarios such as diffusion of cell membrane proteins. The network domain allows user to simulate long distance protein-protein interactions while the continuum space allows simulation of chemical diffusing in the environment.

Users have the option to create any combinations of provided domains in the simulation. Users can easily assign multiple domains of the same type or completely turn a domain off to avoid unnecessary memory consumption. For example, particles from a spatial domain interact in two continuum domains with two independent diffusing chemical. An example is provided below. Another example is simulating mixture of molecules of different sizes and properties by creating several spatial domains with different cut off radius in other to avoid impairment of computational efficiency.

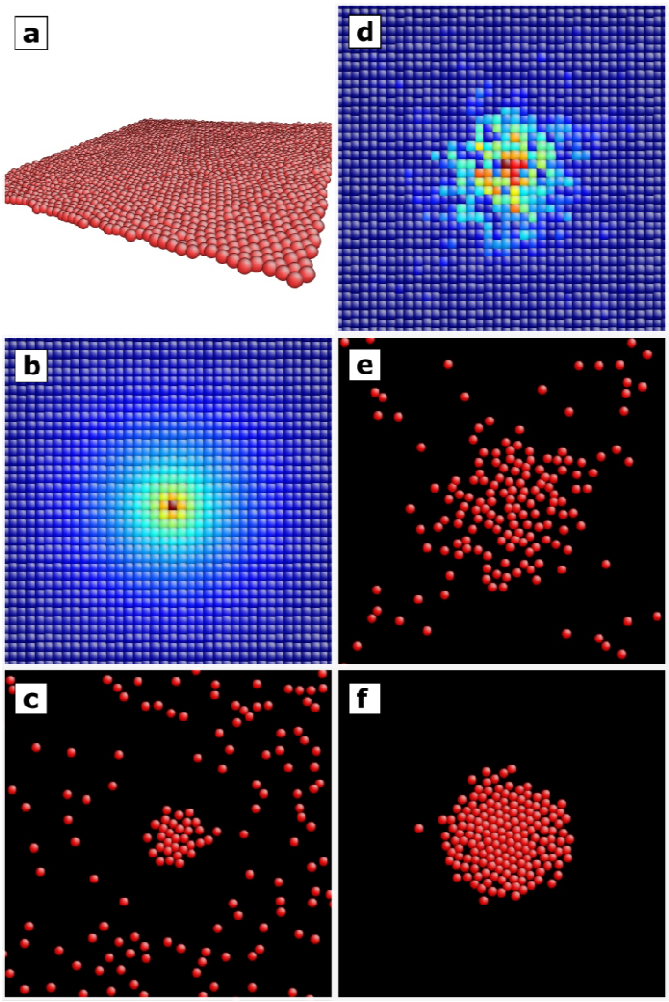

Figure 1. A simulation of the cytoskeleton and membrane of the red blood cell (RBC) is presented (a). Two simulation cases are performed to demonstrate the significance of LTB_4 as a relay signal that amplifies neutrophil chemotaxis to wound sites. Case 1: Neutrophils interacting with 1 continuum domain (b) which has a constant source of fMLP, shown at equilibrium. Local Neutrophil reacts to this by migrating towards the wound site (c), however, distanced Neutrophil are unable to acknowledge the wound, since they cannot detect the weakened signals of fMLP. Case 2 : Neutrophils interacting with 2 continuum domains (b) a constant source of fMLP and (d) an LTB_4 domain emitted by Neutrophils. When a Neutrophil Cell detects fMLP, it will locally produce LTB_4 of proportioned concentration. (e) shows the early stage of Neutrophil migration and produced LTB_4 signals (d) as it detects fMLP. By being chemotaxically attracted to LTB_4 produced by neighboring Neutrophils, the system emerges a collective migration behavior (f), where distanced Neutrophils also migrate to the wound site via chemotaxis.

DISCUSSION

Two examples are provided in this paper to demonstrate the function of the simulation engine (Figure 1).

1) The membrane of the red blood cell (RBC) is being modeled (Fig. 1a). The membrane comprises a phospholipid bilayer represented as a single layer of particles and a spectrin network. Each phospholipid bilayer particle represents a patch of a phospholipid bilayer of 5nm diameter. The particles interact with each other via a potential that depends on the relative distance and the orientation of the particles [1-3]. The potential is not spherically symmetric but it forces the particles to form a thermally oscillating 2D membrane sheet. The cytoskeleton of the RBC membrane comprises spectrin filaments that are connected at actin junctions forming a canonical hexagonal. In this simulation, the spectrin filaments are replaced by the worm-like chain potential (WLC) applied between two actin junctions. The model is discussed in detail in [1, 4]. Each actin junction is modeled as a network node. Two nodes that are connected by a spectrin filament may belong to different processors. Each actin junction also dynamically interacts with the phospholipid bilayer. Each spectrin filament of the cytoskeleton is represented as a network connection (edge) between the nodes.

2) A simulation of Neutrophil aggregation during wound healing is presented (Fig. 1b-f). Neutrophil recruitment to inflammation sites often shows extremely coordinated chemotaxis and cluster formation. Upon injury, chemoattractants such as formyl peptides (fMLP) are emitted from bacteria. Neutrolphil near the wound site are able to detect the secreted fMLP signals and subsequently release a secondary chemoattractant leukotriene B_4 (LTB_4) to stimulate neighboring neutrophils. Our simulation demonstrates that LTB_4 plays a very powerful role in neutrophil activation and migration to fMLP by serving as a signal-relaying molecule that regulates and amplifies neutrophil chemotaxis to fMLP [5-7]. In the simulation Neutrophil are modeled as particles in a spatial domain interacting with two continuum domains: fMLP chemical domain and LTB_4 chemical domain. Neutrophils migrate along both the gradient of concentration of fMLP and LTB_4 simultaneously. In addition, Neutrophils emit LTB_4 concentration proportional to the fMLP it detects (Fig. 1d-f). It is shown by the simulation that the lack of LTB_4 emission will severely hinder neutrophil chemotaxis to the wound site (Fig. 1b,c).

INTRODUCTION

A RAND report estimates that nearly 20% of deployed service members experience some level of traumatic brain injury (TBI) [1]. Blast events account for as much as 70% of these injuries and is the primary cause of mild TBI (mTBI) [1]. The exact injury mechanisms in mTBI are not well understood and for obvious reasons, the blast events cannot be replicated on *in vivo* human subjects. Thus, in order to better understand mTBI, researchers rely upon computational simulations of human and animal testing combined with physical and physiological scaling procedures. One such animal that has been studied due to its similarities to the human size and physiology is the pig [2]. To bridge the gap between simulations of human subjects and animal testing, computational models of animal subjects have also been created to make comparison. Using computational models of animals is significantly less expensive than conducting a large number of tests on animals as the computational models can be validated against a smaller number of experiments and then applied to an extensive set of problems. A number of complications arise when creating, verifying, and validating these computational models. The models must first have a high level of detail in the geometry, and second, the constitutive description of the materials must be accurate when compared to experiments. Lastly, the validation process has to be performed against a limited amount of data that is available in the literature, which potentially impedes the iterative corrective development such complex models need.

METHODS

The high level of geometric detail can be obtained by using high-resolution magnetic resonance imaging (MRI) and computed tomography (CT) scans of the subject and converting the 3-D voxels into a finite element mesh. This process has been implemented to obtain the geometry of a porcine head and upper torso as shown in Figure 1. The 0.6-mm resolution CT scans and 1-mm resolution MRI scans allowed for a high fidelity model geometry to be constructed, which includes all major organs and features. These are the: skin, eyes, cranium (inner and outer table and diplöe), facial bones and muscles, falx cerebri, tentorium cerebelli, air sinuses, cerebro-spinal fluid (CSF), ventricles, meninges (dura mater and pia-arachonoid), cerebrum and cerebellum (gray and white matter), brain stem, muscles, and spinal column (cervical vertebrae, intervertebral disks, and spinal cord).

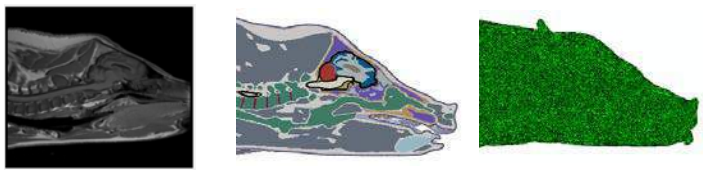

Figure 1. Transformation of porcine CT and MRI scans into a 3-D geometric model and then conversion to a finite element mesh.

Constitutive behavior of the organs is determined by collecting the latest available data in literature over the loading regime of interest (quasi-static to 2000/s strain rates). Material parameters are obtained using a global optimization scheme that compares the experimental curves to a hyper-viscoelastic functional form, e.g., in the case of the brain component, which is able to capture both large strain hyperelastic and rate-dependent viscoelastic behavior. The process of data collection through calibration is briefly illustrated in the top row in Figure 2 where the data for grey matter is obtained, extracted, and then conditioned. The first two images in the bottom row of Figure 2 show the respective efficacy of two optimization schemes at both low

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

and high strain rates while the third image demonstrates the predicted behavior at a variety of strain rates of interest.

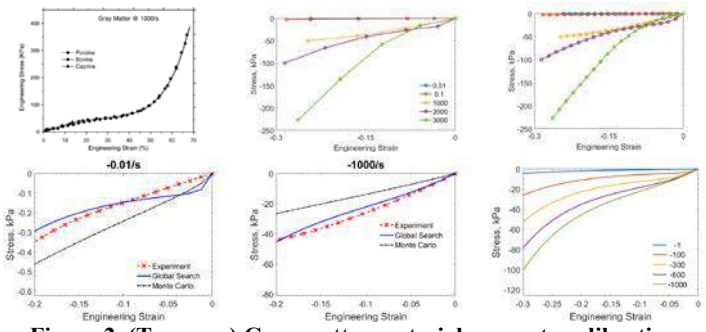

Figure 2. (Top row) Grey matter material property calibration process moving from published data [3] to (Bottom row) a model that closely approximates the behavior under both high and low rates.

There are several ongoing challenges in validating the computational pig model against a limited amount of data. In this study, the porcine model is being validated against two types of data sets: 1) high-rate blast tube data and 2) low-rate magnetic resonance elastography (MRE) data. The former has already been utilized in the validation process, whereas the later data is currently being generated by collaborators. The high-rate blast data involving porcine subjects is obtained from [3, 4]. In both tests, a pig is subjected to a side-on blast wave with its torso protected from the blast.

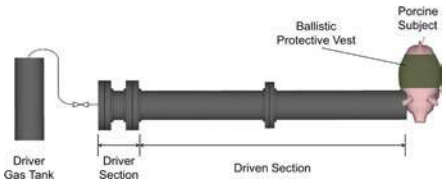

Figure 3. Test setup of [3] using shock tube to apply a side-on pulse to a porcine subject.

In the first case [3], the blast wave is applied using a shock tube as shown in Figure 3. For the simulations, the applied load is assumed to be an ideal Friedlander wave with peak overpressure and positive phase durations specified in the study. Both kinematic and kinetic responses are measured inside and outside of the cranium as shown in Figure 4. In the second case [4], the blast is produced by an explosive charge in a blast tube. The wave generated by this charge is provided by the original authors and applied to the computational porcine model. Unlike [3], the data measured in [4] is purely kinetic, which only allows for a partial validation.

Figure 4. Kinetic and kinematic sensor location on the pig from the test setup in [3].

MRE tests on porcine subjects are currently underway and will be able to provide small strain measurements over the entire brain. Incorporating the MRE strain data into the validation process allows the model to be compared against both low and high-rate kinematic data as well as blast-level kinetic data, for a comprehensive validation process.

RESULTS AND DISCUSSION

The results of the initial validation attempt against the kinetic data of [3] are shown in Figure 5. The external pressure response measured compared to what was simulated shows good agreement after the initial peak pulse in the comparison on the top. The absence of the peak pressure in the simulation is found to be due to volumetric locking of the linear tetrahedral elements used in the skin. We also notice a delay in the intracranial pressure in the bottom plots, which is likely due to contact conditions around the brain. In light of these results, a second iteration of the model composed entirely of quadratic elements for the removal of volumetric locking and modified contact conditions has already been performed and simulations are being run. Regardless, the preliminary results indicate that the model is effectively capturing the prominent features of both internal and external pressure responses well.

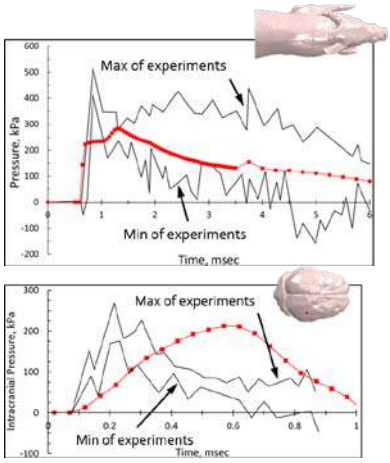

Figure 5. Preliminary side-on blast results compared to the test of [3].

The process detailed above does highlight the challenges associated with the validation of complex models when the experimental data is scarce; however, as shown here, a car eful progressive use of it may nonetheless lead to the objective. As the model is being improved based on data from [3], true validation will be attempted against the larger set of unused data from [4] and the MRE test results in the near future.

THE EFFECT OF LIMITED FRACTIONAL ANISOTROPY REPRESENTATION ON BRAIN INJURY PREDICTIONS

INTRODUCTION

Traumatic brain injury (TBI) is currently one of the leading causes of disability in the warfighters returning from the battlefield. Amongst various types of impacts that may lead to TBI, the interaction of an explosive blast wave with the head is arguably the most complex event due to its global effect on the brain. Modeling has already been used to investigate blast wave propagation in the human head to varying degrees of success. One of the most critical drawbacks in these efforts, however, relates to the incomplete material description of the brain, or more specifically the description of its spatially varying anisotropy.

Magnetic resonance imaging (MRI)-based diffusion tensor imaging (DTI) and magnetic resonance elastography (MRE) techniques have demonstrated in the last several years that the human brain cannot be construed as a simple, homogeneous isotropic material. It is in fact composed of the highly heterogeneous white matter, which in turn is made of fiber tracts of different morphologies surrounded by an isotropic matrix, and the tightly bound, hierarchical cortical columns or gray matter in the outer regions. The gray matter is also present in the internal brain regions intermixed with the white matter to various levels of geometric complexity. Thus, this material anisotropy has to be taken into account if an accurate description of wave propagation from any impact and its effect on the brain needs to be described.

DTI essentially describes the anisotropic diffusion behavior of water in the brain represented by the so-called fractional anisotropy (FA) data, which is then used to construct fiber tractography (morphology and size of fiber bundles). The range of FA values chosen to be included determines the completeness of anisotropic representation; for example, typically $FA < 0.2 = FA_{cri}$ is assumed to be isotropic and anything greater anisotropic. MRE, in contrast, is a relatively recent and rapidly developing technology that is being used to assess the mechanical properties of biological soft tissues. MRE obtains stiffness information of the tissue by evaluating the propagation of mechanical waves.

The present work aims to understand the effect of the partial inclusion of fractional anisotropy in the models as described by the DTI and MRE data, i.e., fiber tractograghy and associated material anisotropy, respectively, on the accuracy of brain injury predictions. This is achieved by accommodating partial to complete description of the fiber tractography and degree of material anisotropy in a series of simulations of the same human head model under blast loading, and comparing predicted locations and levels of TBI.

METHODS

The first part of this work is focused on developing the procedures for transferring the relevant DTI data (fiber orientation tensor) and utilizing the MRE data (derived small strain elasticity stiffness tensor), obtained in house, from unrelated subjects to a previously validated high fidelity finite element (FE) model of the human head, also developed using MRI. (Details of registration of the structured MRI data to an unstructured finite element mesh are discussed in a companion paper.)

Once the MRI data is matched with the FE head model, the DTI data describing material principal orientations are transferred for each finite element using a linear invariant based tensor interpolation scheme [1]. The degree to which fiber tractography is accounted for in the model is controlled by the range of FA values chosen to be included. For an assumed value of FA_{cri} say 0.5 the scheme would eliminate fiber bundle orientation and thus material anisotropy from larger regions of white matter than for the traditional choice of $FA_{cri} = 0.2$. The implication is that all material having less than FA_{cri} value is isotropic.

Having defined the brain material orientation this way, the Hookean stiffness data from the MRE scans is transferred to the FE model using the nearest neighbor interpolation. The FE model uses anisotropic hyper-viscoelastic material description to capture large rate-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

dependent deformation of the brain tissue under blast insult. To relate the Hookean stiffness data with anisotropic data, initially viscous effects are ignored and the relevant hyperelastic parameters are determined by minimizing the differences in the internal energy of the brain using both the Hookean stiffness tensor and the hyperelastic strain energy function. A schematic of the procedure is shown in Fig 1.

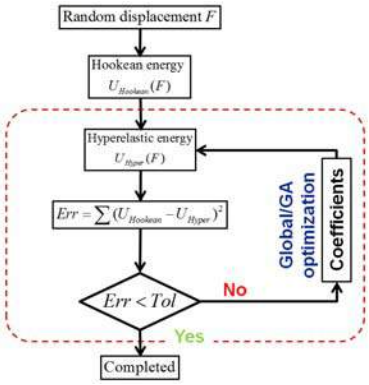

Figure 1: Optimization routine used to compute parameters in hyperelastic material model using small strain MRE data.

The viscous part of the material model is then computed by fitting the full hyper-viscoelastic model to the available experimental rate-dependent data [2] using the parameters obtained in the previous step. Various heuristic and non-heuristic optimization algorithm schemes were explored to achieve this. Lastly, the isotropic regions of the brain, i.e., those regions with FA < FA_{cri}, are modeled with an isotropic two-term Ogden hyper-viscoelastic description based on the data from [2] directly. Currently, a parametric study is being performed where FA_{cri} value is varied from 0.2 to 1 in increments of 0.1. The minimum value represents a fully anisotropic representation of the brain, whereas the maximum one describes a fully isotropic one.

RESULTS AND DISCUSSION

Fig. 2 describes the ability of the developed procedure in transferring the DTI data from an unrelated subject to the existing human head FE model. It shows the volumetric histogram of FA values from the original MRI data and the interpolated FE data. For lower values of FA, the volumetric differences are significant. One potential explanation for this is the fact that there is a substantial difference in the brain volumes of the MRI subject and the FE mesh subject and the isotropic volume (typically FA < 0.2) being large in both cases, it shows the most effect at lower values. Despite this discrepancy, the quality of results is not compromised severely because it is the higher values of FA that define white matter anisotropy, which are captured sufficiently both from volume and tractography standpoints.

Fig. 3 shows the comparison of anisotropy in terms of fiber tractography (orientations) included in the FE model of the brain when different values FA_{cri} are chosen as thresholds for anisotropy. Similarly, Table 1 shows the anisotropic brain volume percentage as a function of ranges of FA that are being included in the parametric study. It can be inferred from the spatial differences in Fig. 3 and volume magnitudes in Table 1 that the mechanical response of the brain to blast loading will be affected by the choice of FA_{cri}.

The parametric FE study based on ranges of FA values is under progress now. The blast loading is being applied from the front of the head and is defined by a planar Friedlander pressure wave based on data obtained from an in-house field test. Injury predictors based on invariants of stresses, strains and translational/rotational accelerations will be computed for all these models. The injured brain volume percentage will be calculated based on thresholds available in the literature, and compared. The results from these simulations will be used to provide a rational basis for choosing the FA range(s) prudentially, and they will be applicable to studies related to all impact types, especially blunt impacts incurred in recreational and vehicular incidents.

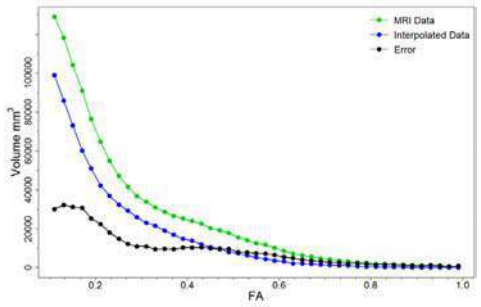

Figure 2: Comparison of volume histogram for FA values between the original MRI data and the interpolated data in the FE mesh. The error is simply computed as the difference.

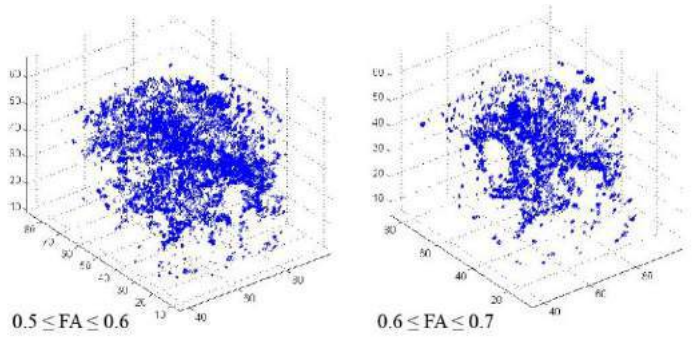

Figure 3: Comparison of interpolated orientation data in the FE model of the brain for different FA ranges

Table 1: Comparison of anisotropic brain volume as function of FA ranges

FA Range	Anisotropic brain volume	FA range	Anisostropic brain volume
≥ 0.2	31.2%	≥ 0.6	1.61%
≥ 0.4	8.8%	≥ 0.8	0.19%

DISORDER AS A BIOMECHANICAL PATTERN FORMING MECHANISM THAT GUIDES SYMMETRIC VERTEBRATE BODY ELONGATION

INTRODUCTION

Throughout vertebrate trunk elongation, prospective mesodermal cells arrive at the posterior tailbud in an epithelium. These cells undergo an epithelial-to-mesenchymal transition (EMT), which represents a transition from ordered to disordered motion and disperse symmetrically into the left and right paraxial mesoderm (*1-3*). This symmetric dispersion is necessary to prevent scoliosis, i.e. an abnormal lateral curvature of the spine.

The tailbud is the posterior leading edge of the growing vertebrate embryo consisting of motile progenitors of the axial skeleton, musculature and spinal cord as well as bipotential neural/mesodermal stem cells (Fig. 1A and B) (*4-9*). Prior studies in zebrafish established that cell migration, not cell proliferation, is the primary driver of body elongation (*10-13*). Here, we devise a simple theoretical model of collective cell migration within a finite tailbud-like geometry to assess the importance of the disordered cell motion for development.

METHODS

Using 4-D confocal imaging, cell segmentation and cell tracking, we mapped the cell flow of the paraxial mesoderm and its progenitors during trunk elongation. The dataset from each embryo averages ~2500 tracks per time-point and 55 time-points. We divided the tracks into four tailbud regions based on morphology and patterns of gene expression to facilitate statistical comparison of different regions of the tailbud (Fig. 1A-D)(*14, 15*).

Here, we quantitatively examine the possible mechanisms of symmetric trunk elongation. We develop a theoretical model of cell migration in the tailbud. Following a coarse-grain methodology commonly used in physics and biology to study bird flocks (*16, 17*), bacterial swarms (*18, 19*), and cell migration (*20, 21*), we represent cells as self-driven particles that interact via an adhesion-repulsion potential and tend to align their motion with that of their neighbors (*16, 17, 20, 22-25*). Using this framework we then systematically study how the dynamics and symmetry of the trunk elongation process depend on the dynamical behavior of the individual cells within the tissue and the interaction among them. Finally, we examine the in vivo data to test whether the theory aligns with the biology.

RESULTS

A key theoretical prediction that emerges from our model is that the variability in the alignment of the individual cell motion with the average direction of its neighbors is a critical cellular parameter that must be regulated at the EMT in order to avoid trunk elongation defects. We call this parameter *angular noise*. If there is not enough angular noise, the overall motion becomes highly ordered and cells start swirling on either side of the axis, breaking trunk symmetry. If there is too much angular noise, the motion becomes overly disordered, and the rate of trunk elongation is reduced. We qualitatively confirm these theoretical predictions by examining experimental data using the same quantitative metrics used to analyze the numerical simulations. As in our model, wild-type embryos exhibit fluctuations between sinstral and dextral biases in the cell flow. Disordered cell motion in the PZ destabilizes these biases in the flow such that they even out over time and lead to bilaterally symmetric trunk elongation. Analysis of Cadherin 2 mutants and embryos with reduced Wnt signaling further support our model. We conclude that the dynamical regulation of cell motion from an ordered regime (epithelium) to a disordered regime (mesenchyme) in the posterior tailbud is critical for the embryo to achieve both rapid and bilaterally symmetric trunk elongation.

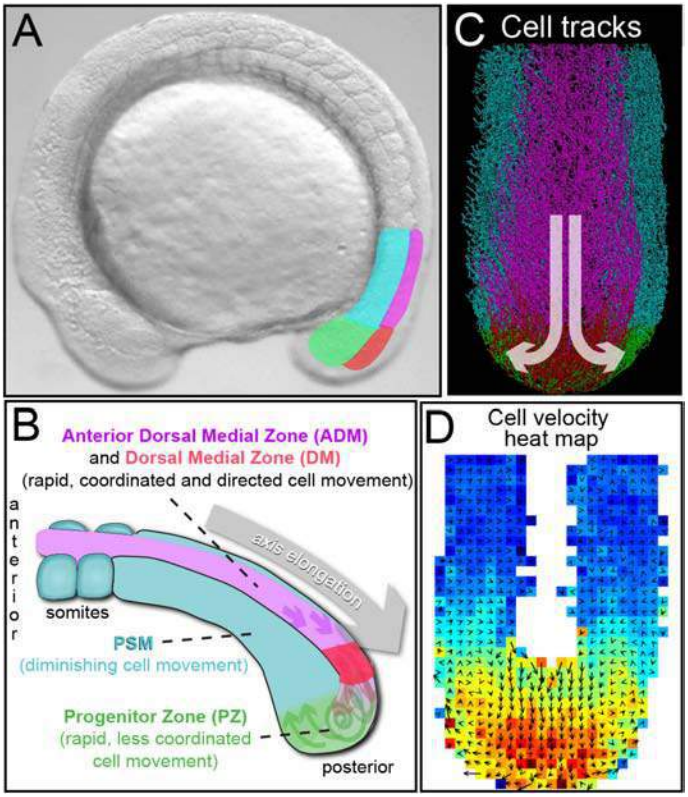

Figure 1: Cell flow in the zebrafish tailbud. (A) A 16-somite stage embryo with the tailbud domains colored as in B and C. **(B)** A schematic summary of tailbud cell motion. EMT occurs as cells migrate from the DM (red domain) to the PZ (green domain). **(C)** A dorsal view of the cell tracks in the tailbud. Arrows indicate the general bilaterally symmetric direction of cell flow. **(D)** Cell motion visualized by projecting the 3D cell velocities into 2D and averaging over 10 mm^2 sectors. Warmer colors indicate higher average velocities. Note that the ADM has been removed.

DISCUSSION

We find that localized disorder in cell motion ensures organism level order. The localized disorder is created by an epithelial to mesenchymal transition in the posterior of the elongating vertebrate embryo. The transition continues post-gastrulation as the vertebrate trunk is being formed and has been observed in zebrafish, mouse and chick. Mesodermal progenitors undergo EMT, enter a zone of disordered cell motion and then segregate bilaterally into the left and right paraxial mesoderm. These cells will then undergo an MET during somite formation and ultimately contribute to the vertebral column and musculature. Why do these cells undergo a transient transition to a mesenchyme in all vertebrate embryos and why is there a zone of disordered cell motion at the posterior tip of these embryos? We find that the answer arises from the fundamental fact that EMT represents a transition from an ordered to disordered tissue morphology. The ordered epithelium allows cells to efficiently migrate to the growing posterior tip of the embryo. If the tissue is prematurely disordered, we find that the rate of elongation is stunted. However, the transition to a disordered state is necessary for these cells to evenly disperse along the left and right sides of the paraxial mesoderm. We find that if the cells remained too ordered, a vortex forms in the cell flow and trunk elongation loses bilateral symmetry leading to scoliosis.

Over the past few decades, we have learned that embryos expend much effort in pattern formation to guide normal development. Pattern formation is fundamentally an ordering process. What we find here that regulated localized intercellular *disorder* is an integral part of a pattern forming mechanism. Moreover, this mechanism crosses scales from local cellular disorder to organism level symmetry. Thus, our study answers a vexing problem in vertebrate development and conceptually introduces a counter intuitive relationship between disorder and pattern formation.

INTRODUCTION

Vascular diseases, such as hypertension, can alter the forces on vascular cells, leading to growth and remodeling of the vessel wall [1]. It has been suggested that vascular smooth muscle cells (VSMCs) adapt themselves and their environment in response to mechanical perturbation to maintain a 'target stress' [2,3]. While extracellular matrix remodeling is important long term, early vessel adaptation is the result of changes in contractility [4]. VSMCs are the active mechanical component of the vessel wall and are known to respond to mechanical perturbations by altering phenotype, active contraction, proliferation, and hypertrophy [1, 5-6].

Tissue-scale vascular growth and remodeling can be described using the linearized form of Fung's growth law:

$$\dot{G} = A(\sigma - \sigma_o). \quad (1)$$

Where $\dot{G}$ is the growth rate with respect to time, σ is the current stress state, σ_o is the target stress, and A is a constant [2,3], though other forms have been suggested [7]. However, mechano-adaptation of individual vascular cells has not been directly measured or characterized. **Here, we have measured and determined VSMC mechano-adaptation laws with biologically meaningful parameters using traction force microscopy methods. The result will provide increased insight to vascular pathologies and improve current multi-scale vascular models.**

METHODS

Cell Culture. Passage 5-7 human umbilical artery VSMCs purchased from Lonza were used for all experiments. VSMCs were cultured in Medium 199 in 5% CO_2 at 37^{o}C. Constructs were seeded at 15cells/mm^2 and in serum free media 24h prior to applying strain.

Construct Fabrication. Fibronectin (FN) was micropatterned on polyacrylamide gels doped with fluorescent microspheres and constructed on clean elastomer membranes secured in steel clamps as depicted in figure 1A. Briefly, FN was incubated on micro-raised rectangular features (26μmx184μm) on polydimethylsiloxane stamps for 1h. Then, the stamp feature-side was placed in conformal contact with coverslips for 30m. Clean and secured elastomer membranes were treated with 10% benzophenone [8]. A pre-polymer solution of 10% acrylamide, 0.13% bis-acrylamide, and 1% red 0.2μm fluorescent beads was degassed and then 0.2% tetramethylethylenediamine, 1M hydrochloric acid to a pH of 7.0-7.4, 10ug/ml N-hydroxysuccinimide-acrylic ester, and 0.05% aminopropylsilane was added [9]. Quickly, 10μl of this solution was placed on the elastomer membrane and the FN patterned coverslip was placed face-down on the droplet. The polyacrylamide gels were cured and rehydrated allowing the coverslip to be removed. The polyacrylamide gels were passivated in 4% bovine serum albumin.

Traction Force Microscopy Experiments. A linear motor was used to apply either 10% or 20% strain at 2% strain/s along the patterned VSMCs' longitudinal axis. Images of the fluorescent beads immediately below the VSMCs and bright field images of the cells were taken on an Olympus IX81ZDC confocal microscope (fig. 1B) at 0h, 4h, 8h, 24h, and 48h post-stretch. Images were acquired pre-treatment (reference state) and 5m post-treatment with 0.1% sodium dodecyl sulfate (SDS). All experiments were conducted in serum free Medium 199.

Cell Force Analysis. Substrate displacements were determined by comparing SDS post-treatment fluorescent bead images to the pre-treatment image reference state using published particle image

velocimetry software in ImageJ (fig. 1B) (fig. 2A) [10]. Bead displacements and known polyacrylamide gel properties were used to calculate traction forces using an unconstrained FTTC algorithm in ImageJ [10]. Cell Cauchy stress was calculated using a force balance and the cross-sectional area of the cell.

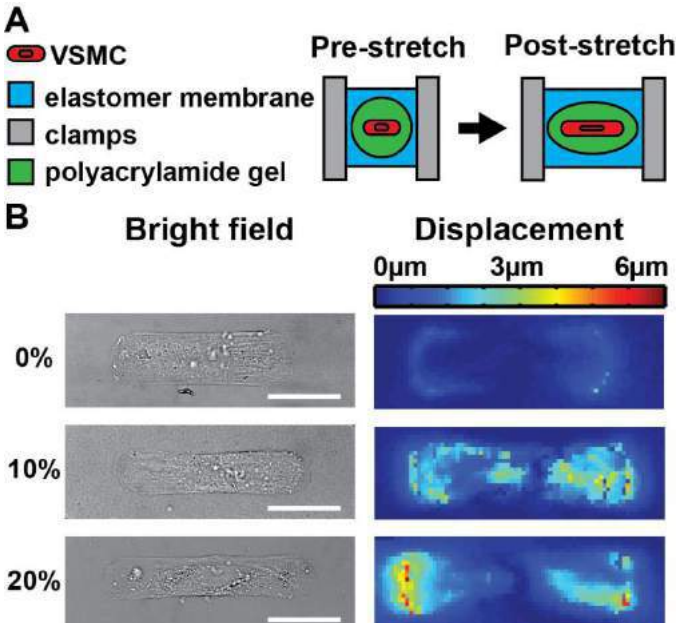

Figure 1: Chronic strain traction force microcopy method. A. Top-down schematic of FN patterned VSMC on chronic strain construct. **B. Left:** Bright field images of VSMC at 0h stretched to 0%, 10%, or 20% applied strain. Scale bar: 50μm **Right:** Displacement field of respective VSMC bright field images at 0h as determined from comparing pre-treatment reference state to SDS post-treatment state.

Mechano-adaptation Law Determination. Experimental Cauchy stress data (fig. 2B) was used to fit both the standard growth law (fig. 2C) and a growth law incorporating hyper-restoration (fig. 2D) using a custom MATLAB script. Briefly, the data was fit to equation 1 for the standard growth law and the hyper-restoration model fit equation 1 and the following equation:

$$\dot{\sigma_o} = -\beta(\sigma - \sigma_o). \quad (2)$$

Where $\dot{\sigma_o}$ is the rate of change of target stress and β is a constant. The strain energy density was assumed to be Neo-Hookian.

RESULTS

We applied a step-change in strain of 0%, 10%, or 20% to micropatterned VSMCs and tracked the evolution of their traction stresses. Immediately post-stretch, cell strained 10% and 20% exhibited greater than a 2-fold increase in stress compared to controls (0%). By 48h, the 10% and 20% constructs approach the control values as predicted by equation 1 (fig. 2B). We fit a standard growth law (Eq. 1) and hyper-restoration growth law (Eq. 1 and Eq. 2) to the data and found that neither optimally fit the data, but that the more dynamically adaptive hyper-restoration law fit the data better than the standard law.

DISCUSSION

Here, we developed a system to measure the temporal stress behavior of VSMCs in response to an applied chronic strain to experimentally determine a VSMC mechano-adaptation law. Our data contains features of the standard targeted growth law, such that initially stress increases with applied strain and approaches the homeostatic stress. However, the resulting fit (fig. 2C) fails to capture the temporal changes in stress. We applied hyper-restoration theory [7], which was better able to capture the experimental results (fig. 2D). To improve the fit, we will examine the role of VSMC biological pathways in mechano-adaptation to generate a robust VSMC mechano-adaptation law with additional biologically meaningful parameters. Ultimately, this will further our understanding of vascular disease initiation and progression and improve multi-scale vascular disease models.

ANTERIOR CRUCIATE LIGAMENT FEMORAL ENTHESEAL SHAPE AND INSERTION ANGLE ARE RISK FACTORS FOR INJURY

Callan M. Luetkemeyer, Ellen M. Arruda

Mechanical Engineering Department
University of Michigan
Ann Arbor, Michigan, USA

INTRODUCTION

Anterior cruciate ligament (ACL) tears are the most common knee ligament injury, occurring more than 200,000 times per year in the United States [1]. These injuries are especially common in female athletes, who are two to five times more likely to sustain an ACL tear than their male counterparts [2]. Complete tears of the ACL often require surgical reconstruction and increase the susceptibility to knee osteoarthritis within 10 years of the injurious event [3]. Clinically, the most common location for an ACL tear is at or near the femoral insertion [4], but the reasons for this region's susceptibility are not yet well understood. In recent histological studies, Beaulieu and colleagues identified six human ACL femoral enthesis shapes based on the order and concavity of tidemark profiles in addition to measuring the angle of attachment of the ACL [5,6]. We hypothesized that the differences observed in profile and attachment angle would have important implications on the strain field in the ACL. Therefore, the objective of this study was to identify which of these aspects of geometry of the femoral attachment may increase ACL injury risk.

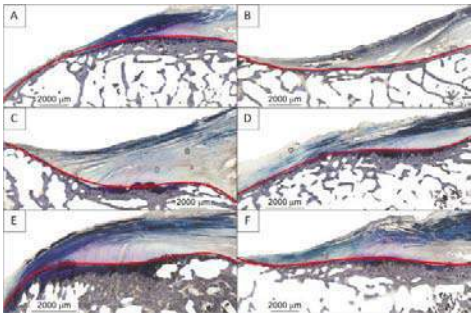

Figure 1: Entheseal shape categories identified by Beaulieu et al.

METHODS

The ACL femoral enthesis was modeled as a body of width (2D) or diameter (3D) w rigidly attached to a fixed boundary, $y=A(x)$, representing the enthesis. This boundary characterized the entheseal shape at the junction of the calcified and uncalcified fibrocartilage, and it had an overall slope of a/w, such that the insertion angle of the enthesis (ϕ) was 13 degrees or 7 degrees, representing the average angle of attachment for men and women, respectively [6]. The opposite edge of the body ($y=L$) represented the ligament proper, and it was assumed to undergo a uniform displacement δ.

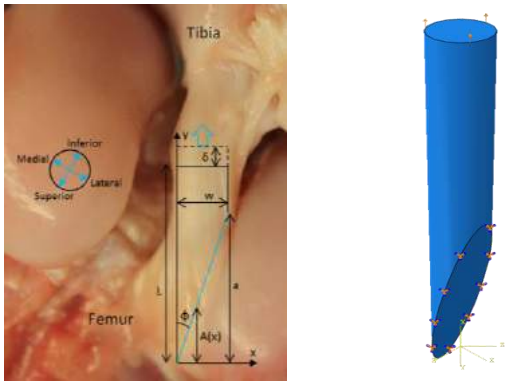

Figure 2: (Left) Schematic showing the geometry and variables used to create the models. (Right) Finite element model with boundary conditions.

The Lagrangian and von Mises strain fields were calculated using a simplified 2D model, and these were compared to the logarithmic

and von Mises strain fields computed using a 3D finite element model rendered in ABAQUS 6.13 (Abaqus, Inc.), utilizing a Holzapfel constitutive relation [7] fit to experimental data.

RESULTS

Shear strain was dramatically affected by both the shape of attachment and angle of insertion, which consequently influenced the von Mises strain. For the male insertion angle of 13 degrees, the convex shape (A) reduced the maximum von Mises strain by more than 23% compared to a linear (no curvature) shape, while the concave shape (B) increased the maximum von Mises strain by nearly 25%.

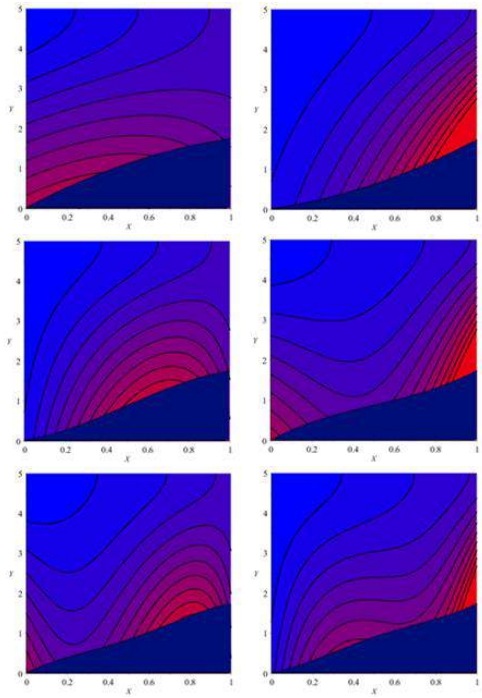

Figure 3: Example von Mises strain fields computed with the 2D model for shapes A-F. Red represents high strain and blue, low. Navy blue represents bone.

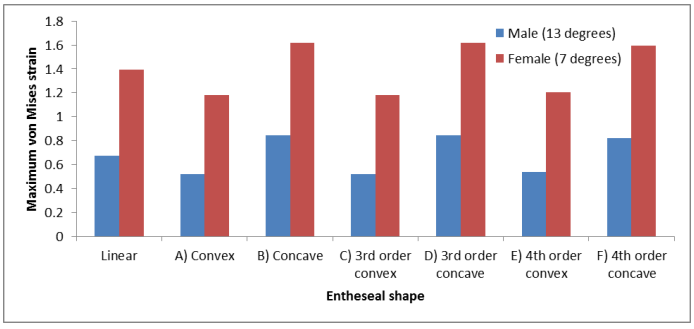

Figure 4: The maximum von Mises strain for male and female attachment angles, calculated with the 2D model for shapes A-F and linear.

Entheseal shapes A, C and E reduced the maximum von Mises strain compared to a linear shape, while shapes B, D and F increased maximum strains. Not surprisingly, a smaller attachment angle increased shear strain, thus increasing the maximum von Mises strain for all shapes. The 3D finite element model produced similar results.

DISCUSSION

Shapes with convexity of the bone near the inferior corner of attachment (A, C and E) are the most advantageous tidemark profiles, while shapes with concavity in that region (B, D and F) may put an athlete at greater risk for ACL injury. This is because the convex shapes effectively reduce the local shear strain near the most vulnerable point of attachment by locally increasing the attachment angle there. These results lend insight into why most ACL failures occur at the femoral enthesis, and suggest that failure may initiate at the inferior aspect. The acute attachment angle produces a considerable amount of shear strain in the ligament near the attachment. The more acute the attachment angle, the greater the von Mises strain, and thus, the more likely it is to fail. While shear strain clearly plays a critical role in ligament mechanics, most studies have focused on the tensile properties of ligaments. More research is needed to characterize their shear properties and to determine the role of shear in ligament failure.

Most importantly, these results may help explain why women are more susceptible to ACL injury. Not only do women, on average, have a more acute angle of attachment, but they are also more likely to have one of the less advantageous entheseal shapes. Grouping the shape data by gender, we found that nearly half of all female sections in the Beaulieu et al. study (43%) had shapes B, D or E, while less than 20% of the male sections possessed one of these less advantageous shapes. Injury risk related to smaller attachment angle may also provide a mechanistic understanding of the correlation observed between injury risk and smaller notch width [8], as a smaller intercondylar notch width would necessarily require a smaller insertion angle.

Both models used in the study have limitations. Neither model took into account the fact that the enthesis is functionally graded. However, while the gradient in stiffness of the enthesis does mitigate the stress/strain concentration, it does not eliminate it. Both models also assumed a regular geometry and single bundle, which is a physiologic simplification. Additionally, both models assumed a simple uniform displacement. The strengths of this study lie in using realistic attachment angles and amplitudes of concavity/convexity. In addition, the finite element model incorporated three-dimensional effects, anisotropy, and a realistic Poisson's ratio of nearly one half. Thus, the results of this study still provide realistic conclusions; concavity of entheseal shape and smaller insertion angle of the femoral ACL enthesis are risk factors for ACL injury. These results provide a mechanistic explanation for why women are more susceptible to these injuries.

INTRODUCTION

The heart grows in response to both normal developmental and pathologic changes in hemodynamic loading. In general, a left ventricle (LV) subjected to chronic pressure overload (PO) exhibits concentric growth (thickening of individual myocytes and the heart wall), and one experiencing chronic volume overload (VO) exhibits eccentric growth (lengthening of myocytes and dilation of the cavity).

In the past 20 years there has been considerable effort to simulate growth within the heart; predictive models of growth could be important tools in planning treatment and designing novel therapies for a range of diseases. However, no direct comparisons of the various published models have been performed. In this work, we compare seven growth laws in order to determine if they are capable of predicting both eccentric and concentric growth following perturbations in mechanics characteristic of VO and PO.

METHODS

During the cardiac cycle, peak stretches occur in the circumferential and longitudinal directions at end-diastole, associated with significant radial thinning. Thus, to provide a simple test-bed for comparing different growth laws, we simulated cyclic equibiaxial stretch of a thin slab of myocardium between prescribed end-diastolic (ED) and end-systolic (ES) stretches, and observed the predicted growth responses when ED and ES stretches were altered to match reported values from *in vivo* PO and VO studies.

We established normal values for ED and ES stretch relative to the unloaded state by comparing reconstructed sarcomere lengths in beating hearts to their values in unloaded arrested hearts [1, 2]. Thus, the baseline ES and ED stretches were 1.05 and 1.30, respectively for both the fiber and cross-fiber directions. For the radial direction, baseline ES and ED stretches were 0.90 and 0.59. For growth laws in which stress was an input (i.e. L&T and GCG) the constitutive equation provided was used to calculate stress. The input set-points (Table 1) for each growth law were modified such that repeated cycling between normal ED and ES stretches induced zero growth.

Table 1: Growth Laws Compared and Modified Input Set-Points

Law	Original Input Set-Point	Modified Input Set-Point
L&T [3]	$\sigma_{set,f} = \sigma_{set,c} = \sigma_{set,r} = 0$ mmHg	$\sigma_{set,f} = \sigma_{set,c} = 1.07$ mmHg $\sigma_{set,r} = -1.02$ mmHg
KFR [4]	$s_{hom} = 0.13$	$s_{hom} = 0.30$
KUR [4]	$s_{hom} = 0.13$	$s_{hom} = 0.30$
GEG [5]	$F_{g,f,max} = 1.50$ $\lambda^{crit} = 1.01$	$F_{g,f,max} = 1.50$ $\lambda^{crit} = 1.30$
GCG [5]	$F_{g,c,max} = 3.0$ $p^{crit} = 0.0120$ MPa	$F_{g,c,max} = 3.0$ $p^{crit} = 0.0124$ MPa
ART [6]	${L_{s,0}}^1 = 1.44\ \mu m$ $L_{s,max,adapt} = 2.30\ \mu m$ $L_{s,min,adapt} = 1.75\ \mu m$	${L_{s,0}}^1 = 1.85\ \mu m$ $L_{s,max,adapt} = 2.40\ \mu m$ $L_{s,min,adapt} = 1.95\ \mu m$
KOM [7]	$E_{f,set} = \mathrm{N/A}$ $E_{cross,set} = \mathrm{N/A}$	$E_{f,set} = 0.341$ $E_{cross,set} = 0.0555$

Next, experiments in which PO or VO were induced were considered [8-14]. To avoid potentially confounding effects of growth normalizing the inciting stimulus, only studies that recorded ED and ES dimensions *prior to appreciable change in LV mass* were considered. ED dimension increased significantly with VO ($p=0.02$), but was unchanged with PO ($p=0.23$). ES dimension increased significantly following PO ($p=0.01$) and was slightly depressed following VO ($p=0.05$). Accordingly, both fiber and cross-fiber ES and ED stretches were set to 1.19 and 1.31 for PO and 1.01 and 1.40 for VO simulations, respectively. Radial ES and ED stretches were 0.71 and 0.58 for PO and 0.98 and 0.51 for VO, respectively.

All growth laws considered (Table 1) utilize the framework of

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

[15], in which material is added or removed through a growth deformation, F_g, changing the local stress-free configuration. The overall deformation is given by $F_{eg} = F_e F_g$; only the elastic deformation, F_e, contributes to stress. For each law, after ES and ED stretches were set, the growth inputs were computed and F_g was calculated. Since F_{eg} was constant, a new F_e could be computed. Alternating periods of stretch and growth were simulated until a steady-state was achieved or growth diverged ($F_g > 20$ or $F_g < 0.05$).

RESULTS

Since VO is known to provoke LV dilation, fiber growth was expected. L&T, KFR, GEG, and KOM all predicted the same level of steady-state fiber growth in response to simulated VO (Fig. 1A). Interestingly, these laws predicted very different patterns of growth in the cross-fiber and radial directions. ART predicted fiber growth and radial and cross-fiber atrophy but did not achieve a steady-state. GCG predicted no growth.

Since PO triggers wall thickening *in vivo*, radial growth was expected. KOM predicted a large degree of steady-state radial growth ($F_{g,r} = 1.13$) in response to simulated PO (Fig. 1B). ART predicted radial and cross-fiber growth and fiber atrophy, but again did not achieve a steady-state. GCG predicted maximal radial growth (limited to 3.0 by law). Steady-state radial growth levels were very low for L&T, KFR, and KUR and were unlikely to produce the degree of thickening typically observed during PO. Finally, GEG exhibits no radial growth, but instead grew in the fiber direction.

Next, we computed the ratio of fiber to radial growth from each simulation, and compared them to the range of reported values for changes in myocyte length-to-width ratio following *in vivo* PO and VO [16-19]. The steady-state growth ratios predicted by KOM for both PO and VO simulations closely resemble experimental values. Since ART did not reach a steady-state, we halted the PO simulation at the point when the predicted growth ratio best matched the reported mean. When the VO simulation was stopped at the same point, ART yielded a growth ratio close to the reported mean. Similarly, for GCG we halted the PO simulation when the growth ratio matched the reported mean. When the VO simulation was stopped at the same point, GCG fell outside the experimental range. The steady-state growth ratio predicted by GEG matches reported values well following VO and poorly following PO. L&T overestimates the steady-state growth ratio during PO and greatly underestimates it during VO. Finally, by definition, KUR and KFR yield isotropic growth.

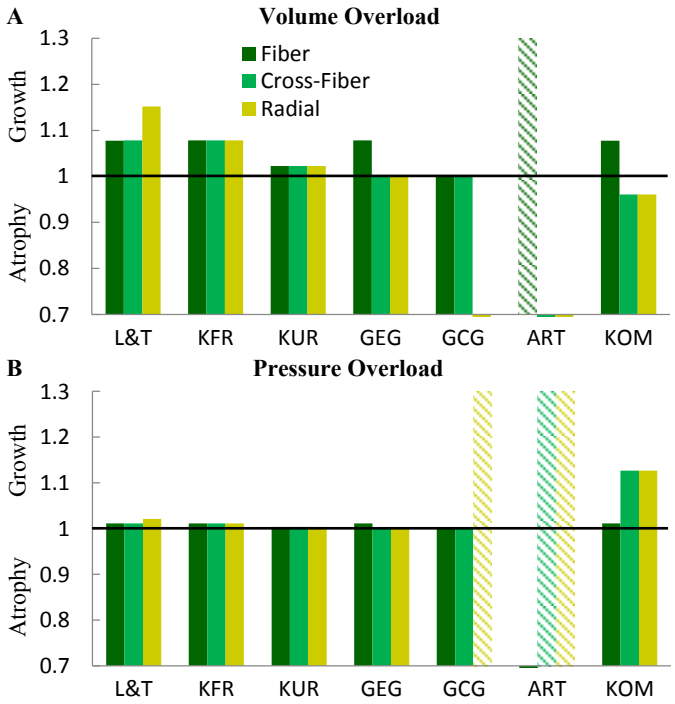

Fig. 1: Growth stretches induced by VO (A) and PO (B).

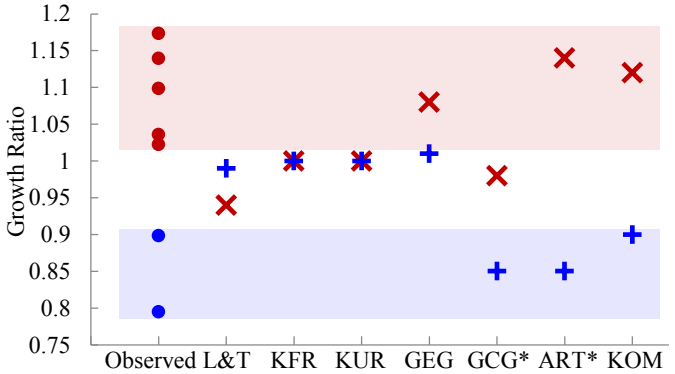

Fig. 2: Growth ratios for experiments where PO and VO were induced are column one [16-19]; red and blue boxes emphasize their range. Growth ratios for PO and VO simulations are indicated by (+) and (×), respectively. (*) indicates simulations stopped prior to divergent growth ($F_g > 20$ or $F_g < 0.05$).

DISCUSSION

The published laws that were most successful in capturing growth following PO and VO in our study employed two different inputs: KOM employed strain components in two different directions, while ART used stretches computed at different time points during the cardiac cycle. In theory, laws based on a single input could still predict different patterns of growth for VO and PO if that input increased for VO and decreased for PO (or vice versa). However, many of the single-input laws considered here (L&T, KFR, KUR, and GEG) employed end-diastolic stretch or stress, which increase in VO and are unchanged in PO. Thus, most of these laws were able to capture the VO response to some extent, but not the PO response.

In our simulations, some laws did not reach steady-state. In some cases this was partly due to the simplified nature of our simulation; we fixed the overall ED and ES stretches at literature-derived values rather than letting them evolve with growth (as was done in [5]). In order to ensure a steady-state, some laws explicitly limit growth to a maximum value (e.g. GEG), while others impose a diminishing growth rate (e.g. KOM). However, the broader question of whether growth always resolves the inciting stimulus *in vivo* remains open.

INTRODUCTION

Surface modification of biomaterials is a popular method in tissue engineering for increasing the biocompatibility of a polymer. It is known that the chemical and physical structure of the scaffold surface is the principal characteristic responsible for the attachment, viability, and biological response of cells in the biomaterial [1]. Endothelial cells (EC) are present in the most inner layer of the vasculature and are responsible for vasoregulation and the control of blood coagulation, making them important for vascular tissue engineering applications [2]. In order to mimic the antithrombogenic endothelium, it is important that the biomaterial surface promotes viability and proper function of endothelial cells. A healthy endothelium is able to produce protective molecules such nitric oxide (NO) whose principal role is the modulation of vascular dilator tone [3]. Also, functional EC are able to respond to elevated doses of interleukin-β (IL-1 β) by increasing the production of the intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), both implicated in leukocyte/EC interactions in inflammation [4]. Importantly, a healthy endothelium limits platelet adhesion and aggregation in the vascular surface and inhibits the expression of plasminogen activator inhibitor-1 (PAI-1), a prothrombotic protein [5].

In this work gelatin/fibrinogen electrospun flat scaffolds were surface modified by thermoforming, coating with ECM proteins, and including polycaprolactone (PCL) in the electrospun solution. Human cord blood derived endothelial cells (hCB-ECs) were seeded in the surface modified scaffolds and a growth, inflammatory response, eNOS production, and platelet activity were evaluated.

METHODS

Gelatin extracted from porcine skin and fraction I bovine fibrinogen were mixed at 80:20 ratio w/w respectively (80:20 G-F). Electrospun sheets with this composition have been previously shown to promote porcine vascular smooth muscle (SMC) cell adherence and proliferation [6]. This blend was dissolved in HFP to create a 10% (w/v) solution. The polymeric solution was electrospun onto glass cover slips attached to a metallic target to create fine fibers. The resultant flat sheets were crosslinked in 25% glutaraldehyde vapor, which was then removed in a ventilated oven. A second polymeric blend consisting in 50% 80:20 G-F and 50% PLC in HFP was electrospun as described above. All the resultant flat scaffolds were sterilized and surface modified by either coating with a mixture of 2.5 ug/ml Collagen IV and d 2.5ug/ml Fibronectin, or by thermoforming in a water bath at 45°C for 5 min and then applying pressure in between 2 glass slides to smooth the surface. A third experimental group consisted of a combination of both coating and thermoforming. hCB-ECs were seeded at a density of $1x10^5$ cells/scaffold and cultured for 7 days. To assess cell viability, cell nuclei were stained with DAPI, and Alexa Fluor® 568 phalloidin was used to visualize f-actin. Scaffolds and cells were imaged with a laser scanning multiphoton microscope. By this qualitative assessment of viability, a surface treatment was selected and the following experiments were performed to evaluate cell function. eNOS production was evaluated by in-cell ELISA using mouse to human eNOS primary antibodies and rabbit anti mouse secondary antibodies HRP conjugated. Absorbance was measured at 450 nm. For inflammatory response, cultures were stimulated with 0.5 ng/ml of IL-1β for 3 days and the production of ICAM-1 and VCAM-1 was measured by in-cell ELISA using mouse to human ICAM-1 and VCAM-1 primary antibodies and HRP secondary antibodies as described above. Platelet activation was studied by a platelet activity state (PAS) assay, a prothrombinase based experiment; calculating the platelet activation rate (PAR) obtained from the slope of the PAS values after 2h [7]. The PAS values were normalized against fully activated platelets (obtained by sonication). The normalized value represents the fraction of thrombin

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

that is produced by the sonicated platelets. All the assays were performed under static conditions. Significant difference was found using one way ANOVA.

RESULTS

Multiphoton images qualitatively show variation in growth of hCB-ECs in the different surface modified constructs. 50% PCL-50% 80:20 G-F electrospun scaffolds thermoformed and coated demonstrated the best results in cell growth, having an almost complete coverage of the scaffold surface in 7 days (**Figure 1**). hCB-ECs seeded in the chosen surface modified scaffold increased the production of ICAM-1 and VCAM-1 when stimulated with IL-1β (**Figure 2**). Intracellular eNOS was detected after 7 days in culture. Also, platelets had lower activation when hCB-ECs were growing in these selected constructs (**Figure 3**).

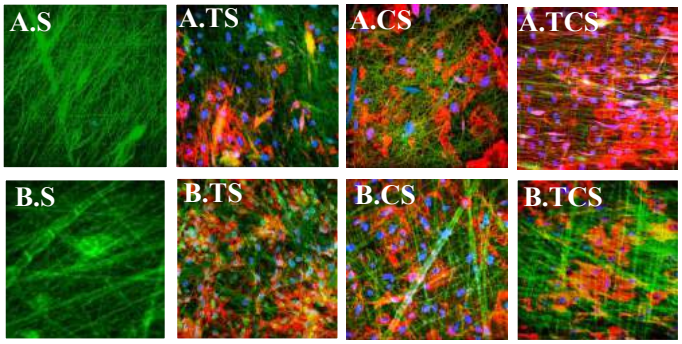

Figure 1: Multiphoton imaging of seeded scaffolds in an xy plane. Blue: Cell nuclei, Green: electrospun fibers, Red: f-actin. A) 50%PCL-50% □0:20 G-F. B) □0:20 G-F.- S. Scaffold non-treated, TS=Thermoformed, CS=Coated, TCS=Thermoformed and coated.

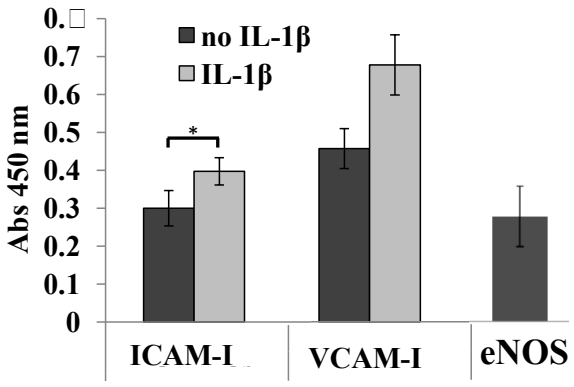

Figure 2: Inflammatory response and intracellular eNOS production of hCB-ECs growing in 50%PCL-50% □0:20 G-F thermoformed and coated. To stimulate inflammatory response IL-1β was added to the culture media. Error bars are standard deviation, n=4, □p□0.05.

DISCUSSION

The results indicated that surface topology and chemistry of the scaffolds have an effect on EC viability. Specifically, hCB-ECs show a better growth when the electrospun constructs were thermoformed to smooth the surface and also coated with ECM proteins present in the

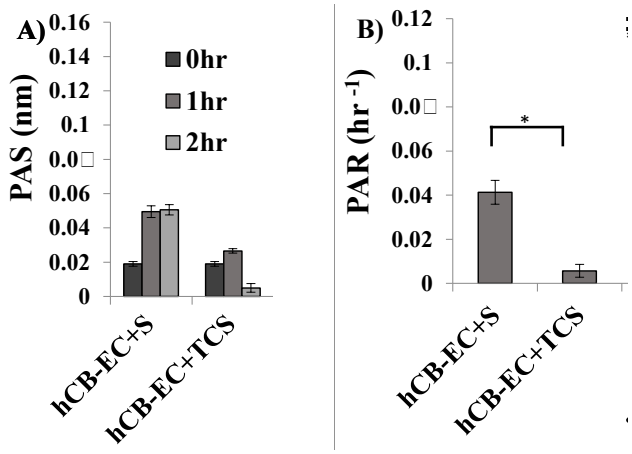

Figure 3: (A) Platelet activity state (PAS) and (B) platelet activation rate (PAR) of platelets on hCB-EC growing on nontreated 50%PCL-50% □0:20 G-F (S), and thermoformed and coated scaffolds (TCS). Error bars are standard deviation, n=4, □p□0.05.

vessel lamina such as collagen IV and fibronectin. The presence of PCL made the thermoforming process easier, which is the presumed reason why 50%PCL-50% 80:20 G-F electrospun scaffolds that were thermoformed and coated had a better cell coverage. Although the experiments were performed in static conditions, comparable levels of intracellular eNOS were detected in the hCB-ECs which can be an indication that the EC phenotype is conserved. hCB-EC function was also evaluated by the assessment of inflammatory response. Cells growing in the selected scaffold upregulated the production of ICAM-1 and VCAM-1 as occurs in a healthy endothelium when proinflammatory cytokines, such as IL-1β, are present. Antithrombogenic function was also evaluated using a platelet activation assay. It was shown that platelet activation state and rate decreased in both hCB-ECs when the constructs were surface modified. As a conclusion, 50%PCL-50% 80:20 G-F electrospun scaffolds thermoformed and coated encourage hCB-ECs growth, and the vasoregulatory, inflammatory, and antithrombogenic functions are well maintained.

INTRODUCTION

Cartilage is a porous hydrated tissue and this fact has vital implications for joint function. During contact, interstitial fluid pressurizes to support load and provide hydrostatic lubrication; this 'interstitial lubrication' effect simultaneously explains the high stiffness and low friction of joint surfaces [1]. Like a punctured tire, loaded cartilage inherently leaks pressurized fluid and eventually 'deflates', resulting in the loss of load-carrying and lubrication capabilities. Remarkably, however, healthy joints do not 'deflate' as expected for reasons that remain uncertain.

Caligaris and Ateshian [2] showed that lubrication could be maintained indefinitely when a glass sphere migrated against cartilage and proposed that the contact moved before interstitial fluid could flow. Similarly, Eckstein *et al.* showed that joints maintained thickness during exercise but thinned during inactivity [3]. Ekholm and Ingelmark showed thickening when activity resumed and concluded that 10 minutes of activity was sufficient to recover the fluid lost during 30 minutes of non-weight-bearing rest [4]. To our knowledge, the accepted and only existing theory to explain this recovery phenomenon involves the passive imbibition of cartilage when exposed to the bath during articulation.

Here, we review recent experimental results that require an alternate explanation of interstitial fluid recovery by cartilage. Cartilage lost, retained, and recovered interstitial fluid in response to sliding in stationary contact areas (SCAs) that eliminated migration and bath exposure as potential contributors. The goals of this paper are to 1) elucidate the mechanism responsible for this 'tribological rehydration' phenomenon, 2) evaluate the extent to which tribological rehydration likely contributes to the recovery of whole joints, and 3) highlight important health-care implications of the results.

METHODS

Three 19 mm diameter osteochondral cores were taken from three mature bovine femoral condyles; more than 20 samples have been tested to confirm generality of these results. The samples were lubricated by saline (PBS), loaded to 5 N, and slid (0, 10, or 60 mm/s over a 20 mm long track) against a large glass flat to eliminate migration and intermittent bath exposure as potential contributors to the retention and recovery mechanics. The contact area was limited to 5 mm in an effort to ensure a convergence zone for hydrodynamic pressurization as illustrated in Figure 1a; we sub-classify this as the convergent SCA or cSCA. Normal force, friction force, and compression were measured *in-situ*.

RESULTS

Figure 1a illustrates the effect of sample size on the compression response of cartilage during sliding. The smallest sample size produced the time-dependent creep response expected of the SCA sliding configuration. Larger samples limited compression to ~60 μm. These results suggest that the presence of a convergence zone for hydrodynamic pressurization helped arrest the anticipated exudation response.

Figure 1b illustrates the recovery response to sliding following 600 seconds of static loading. Sliding at 60 mm/s led to an initial friction coefficient of $\mu \sim 0.16$ and thickening of the cartilage. With continued sliding, friction and compression decreased in concert until reaching steady states at $\mu \sim 0.005$ and $\delta \sim 65$ μm, respectively.

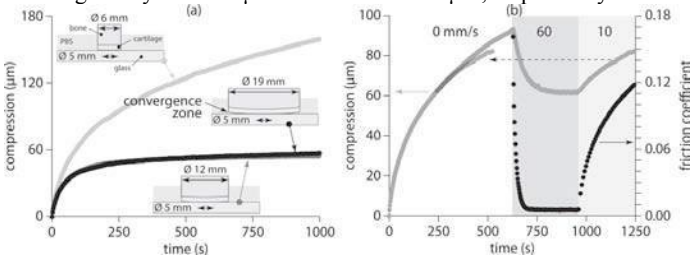

Figure 1. (a) compression of a single representative cartilage sample cut to varying size (19, 12, 6 mm diameter) and reciprocated at 60 mm/s as a function of time. (b) Compression and friction versus time for a second representative sample of 19 mm diameter in a stop-start test configuration. Following a period of static equilibration, the sample began sliding at 60 mm/s until

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

reaching a dynamic equilibrium; at which point the sliding speed was reduced to 10 mm/s.

DISCUSSION

The results of this study demonstrate that cartilage can retain and recover interstitial fluid and lubrication. Previous observations of similar phenomena in migrating contacts were attributed to the facts that: 1) migration provides insufficient time for flow [2] and 2) migration enables passive imbibition during intermittent bath exposure [4–6]. The cSCA used in this study excludes both. Therefore, the retention and recovery phenomena observed here require a new mechanism, which we call 'tribological rehydration'.

In light of this alternate hypothesis of cartilage recovery, it is appropriate to revisit conclusions regarding the recovery mechanisms in joints. Linn's measurements (Figure 2a) best-illustrate the loss and recovery mechanics of a typical joint (canine ankle) [6]. As shown in Figure 2b, removing potential contributions from migration and bath exposure using the cSCA had no obvious detrimental effect on recovery efficacy, which suggests that the recovery of Linn's ankle, and joints in general, are more likely attributable to tribological rehydration than migration or free swelling.

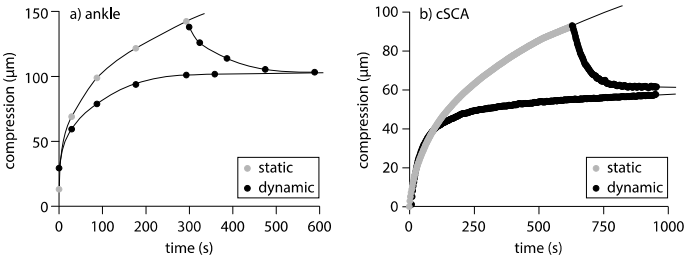

Figure 2. Comparison between Linn's results [6] and those from comparable experiments with the cSCA. The figures demonstrate striking resemblance despite grossly different loads, contact areas, reciprocation lengths, material properties, and testing configuration (whole joint (a) versus cSCA (b)).

The comparison in Figure 2 suggests that tribological rehydration is an important physiological process and the results from this study provide important clues into the underlying mechanics. First, the effect was eliminated when reduced sample size eliminated the convergence zone for hydrodynamic pressurization. Secondly, the effect was reduced when sliding speed was reduced. These facts strongly suggest that the recovery response was driven by hydrodynamics.

Joints are widely believed to be lubricated by hydrodynamic fluid films [7], which implies a broader belief that the hydrodynamic pressures developed during joint articulation must reach physiological contact pressures (1-10 MPa) [8]. This study supports the importance of hydrodynamics while simultaneously raising doubt about the importance of fluid films. The high initial friction in Figure 1b is the best evidence that hydrodynamic pressurization does not necessarily lead to the formation of fluid films. Instead, friction decreased with decreased compression, which suggests that pressurized fluid flowed into the surface to restore interstitial lubrication rather than between surfaces to create a lubricating fluid film.

The main disadvantage of hydrodynamic fluid film lubrication, particularly when applied to the diarthrodial joint, is film collapse during inactivity. Hydrostatic lubrication requires no relative motion and is associated with even lower friction coefficients. The main disadvantage of hydrostatic lubrication is the complexity of the fluid pressurization and supply system [9].

By integrating these seemingly disparate lubrication systems, Nature appears to have eliminated the disadvantages of each. When cartilage is hydrated, interstitial fluid is automatically pressurized by contact thereby providing hydrostatic lubrication [1]. Cartilage also effectively acts as a fluid reservoir, maintaining reasonable pressures over normal periods of inactivity (*e.g.* 10-60 minutes) [1]. However, because pressurized fluid escapes the cartilage as it does any hydrostatic bearing, the lack of a fluid supply is an obvious problem. This study shows that cartilage is resupplied with fluid during activity and suggests that external hydrodynamic pressurization pushes fluid back into articular surfaces to restore hydration and to prepare surfaces for subsequent inactivity.

This concept supports previous assertions that porous surfaces are not well-suited for the generation of fluid films [1]. If surfaces are in direct frictional contact, as we believe they are under most circumstances, then boundary films must be critical for wear prevention at locations of contact. Thus, we propose that 1) boundary films primarily prevent wear, 2) interstitial lubrication primarily reduces friction and protects boundary films by substantially reducing their load-carrying burden, and 3) hydrodynamics are primarily responsible for maintaining and restoring interstitial lubrication.

This cooperative joint lubrication system has important health-care implications. First, it suggests a completely different approach to joint replacement. Currently, designers either acknowledge direct unmitigated contact between surfaces and use polymers for tolerance to contact [10], or they use smooth, hard and well-defined surfaces in an effort to separate surfaces with hydrodynamic fluid films [11]. This study suggests that Nature uses neither approach. Secondly, it implies that activity is the engine by which the joint prevents the otherwise inevitable collapse of cartilage as a functional load-bearing tissue. This fact may help explain recent and counterintuitive findings that runners have reduced risk of joint disease [12]. It also helps reinforce the U.S. Surgeon General's call for increased physical activity to reduce risk of major health problems, including joint disease [13].

INTRODUCTION

Femoral neck fractures associated with ageing and disease are a leading cause of morbidity. As the cortex of the bone bears most of the load in daily activities, fracture usually initiates in cortical bone and thus is the focus of this study.

By informing an accurate hip and femur geometry derived from the Visible Human [1] with Haversian-level models of cortical bone, experimentally determined muscle forces from gait analyses, and spatially-varying porosity data in the femoral neck, it is possible to construct a database of femoral neck strains after strain adaptation through finite element (FE) simulations for different known load intensities. A statistical method can then be used to call upon this database to rapidly estimate strains from new load scenarios.

The objective of this study was to develop a multiscale mechanostatistical FE cortical bone model, combined with Frost's remodelling rules and cutting cone behaviour. The model estimates physiologically adapted regional femoral neck strains as a result of walking and running gaits to build a database of load-strain scenarios. Partial least squares regression (PLSR) [2] is trained on a set of mechanics simulations to rapidly estimate strains for new load scenarios, avoiding additional expensive simulations.

METHODS

The framework for the multiscale model is shown in Figure 1, indicating the flow of information across the scales.

Macroscale: Gait-relevant skeletal muscle and bones were segmented from the Visible Human Male data and meshed with hexahedral 5 mm elements with walking- and running- level muscle loads [3], extracted at toe-off stance, under the assumption that the model is adapted to walking loads. Loads were transferred from the acetabulum to the mesoscale proximal femur model (the region of interest), and were recorded for subsequent simulations.

Mesoscale: Load was transferred from the macroscale to the proximal femur, resulting in strains in the femoral neck cortex. Eigenvectors associated with the maximum principal strains in the cortical elements were used as estimates for the fibre directions for the definition of a transversely isotropic cortical bone material. Spatially varying porosities were assigned to the cortical bone elements according to a periodic B-spline function with parameters determined from experimental data [4] for subjects who had, and had not experienced an intracapsular (femoral neck) fracture. These were then converted into bone densities via an empirical relation [5].

Microscale: Porosities assigned to the cortical bone mesoscale elements were used to section cuboid blocks, containing representative Haversian structures, off a healthy region of cortical bone obtained through voxel meshing of μCT images. Each mesoscale cortical element was assigned microscale cortical bone blocks with matching porosities. The microscale models have local coordinates globally aligned with fibre directions determined in the mesoscale. Elements in the microscale models were assigned densities calculated from the corresponding mesoscale cortical element density, and a porosity value was determined from this density. These porosities were converted to to element-wise transversely isotropic material properties [6] in the microscale. Strains passed down to the elements were used to evolve density via Frost's mechanostat and cutting cone behaviour directed by high-strain regions, driving material property adaptations. Load cycles were applied for 3 simulated months. These properties were then passed back up the mesoscale for the reapplication of loads.

PLSR: The simulation of various loads on microscale models and the resultant homogenised material property adaptations were stored in a database, and PLSR was used to call upon this database to quickly

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

estimate homogenised material properties for unsimulated loads passed down from the mesoscale. Element-wise material properties in the mesoscale cortical elements were rapidly estimated. From the different macroscale loads applied, high strain regions were rapidly identified and noted for fracture risk.

RESULTS

The cortical bone remodelling and cutting cone algorithms changed the material properties of the cortical bone and new Haversian canals tunnelled in the estimated fibre directions in the microscale models. PLSR from the various different loads rapidly predicted homogenised material properties with low errors.

Spatially varying porosities in the cortical bone informed significant differences in strain magnitudes across the geometry of the femoral neck cortical bone. For the model emulating the case of subjects who did not suffer intracapsular fracture, walking loads showed no significant change in material properties in the cortical layer, while adaptation from running loads increased bone strength for a short while. The strength increase quickly plateaued. For the case of subjects who have suffered intracapsular fracture, walking loads also showed no significant change in material properties; however, strain magnitudes are much higher for many more regions of the femoral neck cortex. These two load cases are highlighted in Figure 2.

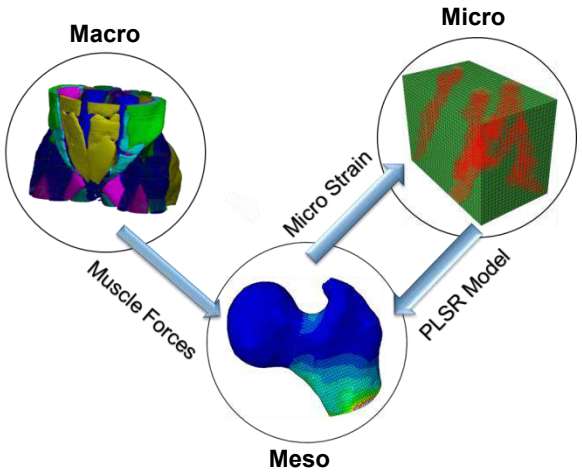

Figure 1: Framework for multiscale model.

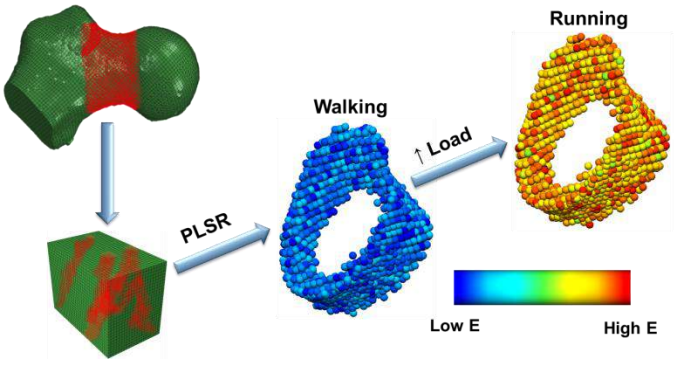

Figure 2: Remodelling adaptation to increased loads (*E*: Young's Modulus)

DISCUSSION

Microscale: For the non-fracture case, material property changes in the microscale model showed no change for walking-level loads and an increase in general bone strength in the fibre direction for running-level loads as an appropriate physiological adaptive response to increased strains in the non-fracture case. These strength changes plateaued fairly quickly due to the 'fading memory' effect proposed in [7]. For the intracapsular fracture case, many microscale models showed strains breaching the damage zone of the mechanostat, present in running-level loads; stronger bone maintained or increased their strength, while more porous bone received damaging strains causing a decrease in bone strength. For both cases, Haversian canal tunnelling occurred towards the direction of highest applied strain, maintaining the fibre directions estimated in the mesoscale. PLSR was shown to be a good rapid estimator of homogenised material properties in the microscale models.

Mesoscale: Microscale changes were reflected in the mesoscale femoral neck model. Walking and running level loads showed no noticeable fracture risk indicated by high strain regions in the femoral neck cortex for the case without intracapsular fracture. Walking level loads also did not show an increase in high strain regions in the post-fracture case. However, running-level loads resulted in high strains in some femoral neck areas, notably in some regions with high porosities which bear high loads. This indicates that the porosity variation implemented and the resultant strain patterns were in agreement with the stress distributions of mid femoral neck during normal and traumatic loading [8], and was a good estimator for fracture risk.

EFFECT OF THREE DIMENSIONAL SPHEROID CULTURE ON BIPOTENT MURINE LIVER PROGENITOR CELLS

Kenichiro Nishii (1), Erik Brodin (1), Taylor Renshaw (1), Rachael Weesner (1), Jessica L. Sparks (1)

(1) Chemical, Paper and Biomedical Engineering Department
Miami University
Oxford, OH, United States

INTRODUCTION

Adult livers harbor bipotent hepatic progenitor cells (HPCs) that can become either biliary cells or hepatocytes [1]. In diseased livers, HPCs can mount a proliferative response followed by a remodeling phase. During this HPC-mediated regenerative process, the HPCs recapitulate aspects of liver development and morphogenesis. This regenerative response, termed the ductular reaction, can repair the injured liver and restore healthy tissue [2]. However, in many cases the regenerative response is misregulated, resulting in scarring and increased risk of primary liver cancer [3]. The mechanisms that dictate whether the regenerative response will lead to repair or misrepair are still unknown. There is a need to better understand the mechanisms controlling the liver regenerative response.

In order to address this issue, physiologically realistic cell culture environments are essential. The objective of this study was to develop and test a three-dimensional culture system for bipotent hepatic progenitor cells. To better mimic in vivo conditions, we sought to create a 3D culture system capable of applying interstitial flow to cultured cells and spheroids, with estimated target shear stresses in the range of 1-15 dynes/cm^2 [4]. In addition, the system incorporates an extracellular matrix (ECM) gel formed from hyaluronic acid, collagen III, and laminin, components of the hepatic progenitor cell niche.

METHODS

Study Design. Bipotent murine oval liver (BMOL) cells, a well-established hepatic progenitor cell line [5], were used for the experiments. Cells were studied under four conditions: traditional 2D culture on tissue culture plastic (2D); 3D spheroid culture using hanging drop culture conditions (3D); 2D cultured cells suspended in ECM (ECM2D); and 3D spheroids suspended in ECM (ECM3D). For each culture condition, two types of media were compared: Williams' E medium (WE) (Fisher, Waltham, MA) prepared with 2% fetal bovine serum and supplemented as described previously for routine BMOL cell culture [5]; and serum-free InSight Liver Maintenance medium (IS) (InSphero, Brunswick, ME) developed for 3D spheroid culture applications. Quantitative reverse-transcriptase PCR (qRT-PCR) was used to evaluate the effect of culture condition (2D, 3D, ECM2D, ECM3D) and media type (WE, IS) on BMOL gene expression. GAPDH and PPIA were reference genes, and target genes were ALB, CK19, HNF4α, HNF6, and SOX9. Each experiment was done in triplicate, and all technical replicates were done in triplicate.

Cell Culture. Cells from the BMOL cell line were obtained from Dr. Janina Tirnitz-Parker [5]. BMOL cells were cultured in 25 cm^2 culture flasks (Fisher) for at least 2 weeks for cell stabilization after they were thawed from Lq N_2. Culture medium was changed every other day, and cells were passaged every 4 days through trypsinization. For 2D culture, BMOL cells were cultured in a flat bottom 6 well cell culture plate for 48 hours before the gene analysis. For 3D culture, an InSphero GravityPLUS hanging drop culture plate (InSphero, Brunswick, ME) was used to make spheroids. BMOL cells were cultured in the GravityPlus plate for 4 days and transferred into a GravityTRAP plate (InSphero, Brunswick, ME). The spheroids were cultured in the GravityTRAP for 48 hours before the analysis. ECM was prepared from Hystem hydrogel (ESI Bio, Alameda, CA) at a concentration of 5 mg/mL (corresponds to 0.5%), collagen III (Sigma, St. Louis, MO) at 1 mg/mL (0.1%), laminin (Sigma, St. Louis, MO) at 1mg/mL (0.1%). The ECM components were dissolved in Tris buffered NaCl (pH≈7.3), followed by PEGDA (ESI Bio, Alameda, CA) cross linker addition at 5 mg/mL (0.5%) concentration. The ratio between the ECM solution and cross linker was 4:1. 2D cultured cells and 3D spheroids were suspended in the ECM and cultured for 48 hours before the analysis.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Analysis. Microscopy images were taken after each culture condition with a Zeiss AXIO Vert A1 light microscope (Zeiss, Atlanta, GA). RNA was extracted with a Maxwell 16 instrument and Maxwell 16 LEV simplyRNA tissue kit (Promega, Madison, WI), and RNA integrity was assessed with an Agilent 2100 Bioanalyzer and Agilent RNA 6000 Pico kit (Agilent Technologies, Santa Clara, CA). Quantitative RT-PCR gene expression analysis was conducted using a CFX Connect Real Time PCR Detection system (Bio Rad, Hercules, CA) and qBasePlus (Biogazelle, Zwijnaarde, Belgium) was used for statistical analysis of the results (ANOVA, significance level 0.05). Expression was normalized to the two reference genes (GAPDH, PPIA) using the delta delta Ct method.

Chamber Design. The flow chamber design was adapted from Ng and Swartz [6] with modifications in dimensions and ECM components (Figure 1). Cover glass on the top and bottom was cleaned with 0.1M NaOH followed by functionalization with (3-Aminopropyl) trimethoxysilane and glutaraldehyde (Sigma, St. Louis, MO). Pressure applied to the hydrogel was monitored by measuring the height of the fluid column. Permeability (K) and shear stress (τ) applied to the encapsulated cells were estimated from equations (1) and (2) from [6]:

$$K = \frac{Q\mu ln(r_o/r_i)}{2\pi h \Delta P(t)} \ [m^2] \qquad (1)$$

$$\tau = \frac{Q\mu}{2\pi r h}(K)^{-\frac{1}{2}} \ [Pa] \qquad (2)$$

where Q is fluid flow rate in [m/s], μ is viscosity of perfusion media [Pa·s], r_i and r_o and are inner and outer radius of the ECM hydrogel ring [m], h is height of the ECM hydrogel [m], $\Delta P(t)$ is pressure difference at time t [Pa]. For this experiment, 0.0012 Pa·s (=1.2 cP) was used for the media viscosity for both perfusion media. 3.4 mm and 9.15 mm were used for r_i and r_o, and 1.6 mm for h. Each experiment was done in triplicate.

RESULTS

Cells spheroids showed increased intercellular attachment and more uniform spheroid geometry in IS media compared with WE media (Figure 2). RNA integrity results are listed in Table 1. In some trials, the amount of RNA obtained was too low to perform the integrity evaluation (shown as N/A in Table 1). Accordingly, results for the ECM2D WE and ECM2D IS conditions were excluded from further analysis due to insufficient RNA quality. qRT-PCR results are shown in Table 2, with the 2DWE condition as the control. The average pressure drop across the ECM gel was 1428 Pa. Mean permeability was K_{ave}=1.48x10^{-11}±1.34x10^{-11} m^2, and mean shear stresses were $\tau_{i,ave}$=1.16±0.68 Pa, $\tau_{o,ave}$=0.43 ±0.25 Pa.

*Statistically significant difference ($p<.05$) compared to control

DISCUSSION

Hepatic progenitor (BMOL) cells were successfully grown in spheroid culture, and expression levels of six target genes were characterized to determine the effects of spheroid culture on gene expression. HNF6, a biliary marker, was significantly elevated in BMOL cells in 3D culture, for both media types and with and without the presence of ECM (Table 2). HNF6 was also slightly elevated in the 2DIS condition compared with the 2DWE control; this represented the only statistically significant difference attributed to media type alone. HNF4a, expressed in hepatocytes, was slightly decreased in two of the four 3D culture conditions (3DIS, ECM3DWE). Importantly, Table 2 results suggest that the BMOL cells maintained bipotent progenitor cell status in 3D culture. This is supported by the observed co-expression of ALB, a hepatocyte marker, and CK19, a marker of biliary and progenitor cells, and by the consistent expression of SOX9, an indicator of stem/progenitor status. Chamber results demonstrate that the ECM gel, which mimics hepatic progenitor niche components, has a permeability consistent with other collagen I-based interstitial flow systems [6] and can produce approximate shear stresses within the targeted range of 0.1-1.5 Pa (1-15 dynes/cm^2). Future work will use this system to investigate BMOL cell response to interstitial flow.

INTRODUCTION

In cerebral aneurysms treated by coil embolization, incidences of and complications from recurrence – or the reentry of blood into the coiled aneurysm sac – are not insignificant. Identifying the mechanism underlying cerebral aneurysm recurrence will improve patient selection for coil embolization treatment, as well as impact coil device design. Coil mass compaction inside a cerebral aneurysm is a plausible mechanism, but quantitative evidence to support it as the presumptive mechanism is lacking, since the supporting evidence usually collected are visual inspections of 2D angiograms. Growth of the aneurysm sac is an alternative recurrence mechanism; in an earlier study we reported sac growth may be equally as or more important than coil compaction as a recurrence mechanism. [1] In a similar study with four patients, De Craene et al. [2] reported that all showed longitudinal sac growth while only one patient showed coil compaction. Caution is warranted in drawing conclusions from both studies because, in addition to having small study populations, neither demonstrated the fidelity of the image-processing methods by using non-recurrence controls. The aims of this study were three-fold: 1) to develop an objective image analysis approach to assess the incidences of cerebral aneurysm growth and coil compaction, 2) to evaluate the user sensitivity in the developed approach and 3) to independently assess the association of sac growth and coil compaction with recurrence in human subjects.

METHODS

To independently assess aneurysm growth and coil compaction in patients who underwent coil embolization treatment of their aneurysm and later presented with recurrence, three-dimensional rotational angiography (3DRA) scans were retrieved from four time points: pre-first treatment (1-), post-first treatment (1+), pre-second treatment (2-), and post-second treatment (2+). Note that patients with recurrence are routinely coiled a second time. In contrast, the 3DRA scans obtained for the control patients (also coil embolization patients, but those that did not present with recurrence during follow-up) were from three time points: 1-, 1+, and 2- (since these patients do not undergo a second coiling treatment). The collected 3DRA scans were then used to create 3D models of the aneurysm sac, contiguous vessels, and aneurysm coil mass for each study time point using a dedicated image analysis pipeline. This pipeline was built using Vascular Modeling Toolkit (VMTK) 1.0.0 libraries (D.Steinman-L.Antiga © 2004-2012); additionally, some new VMTK libraries were also developed such that automated image segmentation and automated aneurysm isolation could be implemented. These new libraries have since been incorporated into VMTK 1.2. Afterward, the volumes of the following structures were computed from the representative aneurysm and coil mass models: the aneurysm sac volume at the 1- time point (V_{S1-}), the aneurysm sac volume at the 1+ time point (V_{S1+}), the aneurysm sac volume at the 2- time point (V_{S2-}), the aneurysm sac volume at the 2+ time point (V_{S2+}), the coil mass volume at the 1+ time point (V_{C1+}), and the coil mass volume at the 2- time point (V_{C2-}), as illustrated in Figure 1. Volumetric sac growth, V_{SG}, was computed as the difference in sac volume between follow-up and initial presentations. Given the four study time points, there can be two sac volumes at initial presentation (V_{S1-}, V_{S1+}); similarly there can be two sac volumes at follow-up (V_{S2-}, V_{S2+}). In theory these volume pairs should be equal but in practice small differences exist due to factors like differences in image artifacts and in aneurysm isolations relative to the parent vessel. An independent investigation showed that such differences did not impact our findings. [3] As a result, aneurysm sac growth can be defined as the difference in the sac volume between the 2+ and 1- presentation:

$$V_{SG} = V_{S2+} - V_{S1-} \quad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Therefore, $V_{SG} > 0$ indicates growth of the aneurysm sac. Next volumetric coil mass growth, V_{CG}, was computed as the difference in the coil mass volume between the 2- and the 1+ presentation:

$$V_{CG} = V_{C2-} - V_{C1+} \quad (2)$$

Therefore, $V_{CG} < 0$ indicates compaction of the coil mass. To document the sensitivity of the image analysis pipeline to the investigator a second user, blinded from the first, used it to calculate aneurysm and coil volumes for a subgroup of eight recurrence patients. The volumes computed by each investigator were compared. To assess the association of sac growth and coil compaction with recurrence, paired Wilcoxon tests (statistical significance at $p<0.05$, one-tailed) were conducted to test the hypotheses that $V_{SG} > 0$ and $V_{CG} < 0$ for the recurrence and control cohorts.

RESULTS

Three-dimensional rotational angiography (3DRA) scans were retrospectively collected for 15 recurrence aneurysms and 12 non-recurrence control aneurysms (consecutively chosen) that were initially completely coiled by a single neuroradiologist between July 2009 and September 2012 at The University of Iowa Hospitals and Clinics (UIHC). The study was approved by Institutional review board (No. 201210828). The developed image analysis pipeline was used to compute the aneurysm sac and coil volumes for all aneurysms. A second blinded investigator used the pipeline to compute aneurysm sac and coil volumes for a subgroup of eight recurrence patients. The aneurysm and coil volumes estimated by the two blinded investigators were found to agree quite strongly, with coefficients of determination for the aneurysm sac and coil mass volumes of 0.998 and 0.999 respectively, see Figure 2. Note that imaging data was available to calculate V_{SG} in all 15 subjects within the recurrence cohort and all 12 subjects in the control cohort; however, imaging data was only available to calculate V_{CG} in 9 of 15 aneurysms in the recurrence cohort and 9 of 12 aneurysms in the control cohort. Therefore aneurysm sac growth was found to exist with statistical significance in the recurrence cohort (min, median, max V_{SG} = -0.044, +0.083, +0.580 cc; $p<0.05$). In contrast, sac growth was not found to exist with statistical significance in the control cohort (min, median, max V_{SG} = -0.009, +0.001, +0.024 cc; $p>0.05$). Coil compaction was not found to occur with statistical significance in either the recurrence (min, median, max V_{CG} = -0.265, +0.004, +0.359 cc; $p>0.05$) or control cohorts (min, median, max V_{CG} = -0.013, 0.000, +0.008 cc; $p>0.05$). It is noteworthy that the control cohort had smaller aneurysms at initial presentation compared to the recurrence cohort (sac size median = 10 versus 6.5 mm; $2p<0.05$ by Mann-Whitney U-test).

DISCUSSION

We have developed a new and objective image analysis pipeline to estimate aneurysm and coil mass volume growth. Unlike previous studies the aneurysm population in this study was free of any selection bias as it included all aneurysms that presented with recurrence at the UIHC between July 2009 and September 2012 for which 3DRA scans were available. This is the first study to include control aneurysms. The automated image analysis pipeline was shown to be objective and insensitive to the investigator. Details of our developed pipeline and analyses may be found in our recent report [3].

Aneurysm sac growth was found to be associated with recurrence in this study with sensitivity and specificity. Coil compaction was not found to be associated with recurrence. These findings are consistent with De Crane et al.'s earlier report [2] and also with a recent report by Abdihalim et al. [4]. Nevertheless this study has limitations. For instance, it is a single-center, single-practitioner experience. The sample size, though largest to date, is limited; aneurysms in the control cohort are smaller than those in the recurrence cohort (which was inevitable because size is independently associated with recurrence risk).

Contrary to conventional wisdom, this study found little association between recurrence in coil embolized cerebral aneurysms and coil compaction; particularly, aneurysm sac growth was found to be the predominant etiology of recurrence. This suggests that a growing aneurysm may also be at a high risk for recurrence and hence better treated by other modalities; this also suggests that it would not be prudent to presume the existence of coil compaction in embolized aneurysms that present with recurrence. Coil designs targeted toward minimizing compaction may only have modest impact in reducing incidences of recurrence.

INTRODUCTION

Central artery stiffness has emerged over the past decade as a clinically significant indicator of cardiovascular function and initiator of disease. Loss of elastic fiber integrity is one of the primary contributors to increased arterial stiffening in normal aging and in pathologic conditions such as hypertension and aortic aneurysms. The current clinical gold standard metric of central artery stiffness is the carotid-to-femoral pulse wave velocity (*cf*-PWV). Despite showing a steady increase with age [1] and being associated with increased risk of cardiovascular events [2], *cf*-PWV represents a global measure of arterial stiffness that integrates individual contributions of the heterogeneous arterial segments separating the carotid and the femoral arteries. Detectable changes in local mechanical properties of the aorta have been shown to precede measurable changes in *cf*-PWV and blood pressure, hence suggesting that altered hemodynamics could be a consequence, not a cause, of irreversible degenerative processes [3]. Therefore, local measures of arterial stiffness could delineate regional variations in central artery function, perhaps enabling earlier diagnosis and thus preemptive treatment.

Motivated by the need to associate local changes in aortic geometry and properties with global changes in cardiovascular function, we characterized aortic wall mechanics, central hemodynamics, and left ventricular function in wild-type ($Fbln5^{+/+}$) and fibulin-5 deficient ($Fbln5^{-/-}$) mice. Arteries from $Fbln5^{-/-}$ mice are characterized by a severe fragmentation of medial elastic lamellae [4], which renders them more tortuous [5]. Based on a novel combination of *in vitro* and *in vivo* data on regional aortic mechanics, we suggest that fibulin-5 deficiency results in a preferential lengthening and loss of elasticity of the ascending thoracic aorta, which in turn underlies increased pulse wave velocity and compromised left ventricular function.

METHODS

Adult $Fbln5^{+/+}$ (n = 13) and $Fbln5^{-/-}$ (n = 13) mice of both sexes were subjected to ultrasound imaging using the Visualsonic Vevo 2100 system. Echocardiographic examination of the left ventricle (LV) was followed by assessment of arterial diameters (via M-Mode imaging) and blood velocities (via pulsed-wave Doppler). These measurements were performed at four locations of interest within the central vasculature: ascending thoracic aorta (ATA), suprarenal abdominal aorta (SAA), infrarenal abdominal aorta (IAA), and common carotid artery (CCA). B-Mode scans of the ATA from a long axis view allowed monitoring the cyclic changes in both luminal diameter and axial length. A 1F Millar pressure catheter was then inserted via the right carotid artery and used in combination with ultrasound imaging to measure invasively blood pressure in the ATA and pressure-volume relationships in the LV. Finally, micro-CT scans were collected to measure the tortuosity of the $Fbln5^{-/-}$ central vasculature.

Echocardiographic data from the LV were analyzed by a trained cardiac sonographer, whereas vascular ultrasound data were analyzed automatically using both commercial and custom software. Briefly, the biaxial motion of the ATA was quantified from B-Mode cine loops using the VevoStrain and custom MATLAB software to reconstruct waveforms of luminal diameter and axial length. In addition, a graphical user interface (GUI) was developed to extract regional waveforms of luminal diameter and blood velocity via image analysis. Luminal edges were detected from M-Mode stacks by means of the Canny methods [6] and Doppler velocities were extracted using automatic tracing in the Visualsonic software. Aortic pulse transit time (PTT) was calculated as the time delay between proximal and distal velocity waveforms and used, in combination with the aortic path lengths (L) from micro-CT scans, to approximate aortic pulse wave velocity as PWV = L / PTT.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The *in vivo* mechanical behaviors of the most proximal (ATA) and most distal (IAA) aortic segments were estimated by combining knowledge of intrinsic material properties [7] with noninvasively measured deformations. The complex mechanical properties of each aortic segment are described by a single scalar quantity – the elastic stored energy W – from which one can compute biaxial stress and stiffness. We adopted the following functional form

$$W = \frac{c}{2}\left(I_C - 3\right) + \sum_{i=1}^{4} \frac{c_1^i}{4c_2^i}\left(\exp\left[c_2^i\left(IV_C^i - 1\right)^2\right] - 1\right), \quad (1)$$

where $I_C = \text{tr}\,\mathbf{C}$, $IV_C^i = \mathbf{C} : \mathbf{M}^i \otimes \mathbf{M}^i$, and $\mathbf{C} = \text{diag}[\lambda_\vartheta^2, \lambda_z^2, \lambda_r^2]$. It should be noted that the principal stretches λ_ϑ and λ_z were calculated from the average waveforms extracted from ultrasound, whereas [c, c_1^i, c_2^i] and $\mathbf{M}^i$ represent, respectively, values of the material parameters and collagen fiber orientations reported in [7].

RESULTS

Micro-CT images confirmed the elevated arterial tortuosity of fibulin-5 null aortas reported previously [5] whereas mean aortic PTTs were found to be similar across genotypes and sexes, thus suggesting that PWV is higher in *Fbln5*$^{-/-}$ mice primarily due to longer aortas. Central blood pressure was characterized by normal systolic pressures but increased pulse pressures, primarily due to lower diastolic values. On the cardiac side, systolic LV function measured both non-invasively and invasively was essentially preserved, despite lower cardiac outputs in male *Fbln5*$^{-/-}$ mice. Diastolic LV function, measured via transmitral Doppler, was instead significantly impaired in *Fbln5*$^{-/-}$ mice of both sexes. These results suggest that the fibulin-5 mutation results in a cardiovascular phenotype consistent with accelerated aging.

Regional measurements of local distensibility from M-Mode images showed differences in luminal diameters of ATA and SAA (with *Fbln5*$^{-/-}$ aortas being smaller than normal) while IAA and CCA were undistinguishable from wild-types. Regardless of size, circumferential deformations during the cardiac cycle were maintained nearly normal, despite a trend towards lower cyclic strains in the ATA. These findings were confirmed by the speckle-tracking analysis of ATA biaxial motion from B-Mode scans (Figure 1-a). *Fbln5*$^{-/-}$ ATAs were found to have significantly smaller diameters and to be significantly longer than controls, independent of sex (Figure 1-b,c). In addition, they preserved a normal range of axial strains induced by cardiac contractions, possibly thanks to an adaptive axial lengthening.

Mechanical properties calculated under *in vivo* deformations showed that *Fbln5*$^{-/-}$ aortas – both ATA and IAA – experience significantly reduced stresses (particularly in the axial direction) despite maintaining nearly normal values of biaxial stiffness. Instead, calculations of W over a single cardiac cycle showed that *in vivo* elastic energy storage was compromised in the ATA (Figure 1-d) but not in the IAA. Thus, loss of elasticity due to mutation in the fibulin-5 gene seems to alter biaxial mechanical properties preferentially in the ATA.

DISCUSSION

Loss of elastic fiber integrity is a degenerative process that occurs gradually with aging and that is accelerated by hypertension. Herein, we employed the *Fbln5*$^{-/-}$ mouse model to evaluate the effects of a severe elastopathy on local arterial mechanics and its relationship with central hemodynamics and cardiac function. Our approach relies on a unique combination of *in vitro* biaxial data on regional mechanics with *in vivo* ultrasound data on cyclic deformations, which also accounted for the effects of perivascular support. We focused our estimations of *in vivo* arterial mechanics solely based on passive elasticity, despite the need to consider also the effects of contractility and viscoelasticity in the future. Our results showed higher central pulse pressure and signs of diastolic dysfunction in *Fbln5*$^{-/-}$ mice, consistent with other studies [4,8]. In addition, we found that increased PWV in the *Fbln5*$^{-/-}$ model is a result of a preferential lengthening of the thoracic aorta and not a product of early wave reflection, as proved by normal PTTs. *Fbln5*$^{-/-}$ arteries seem to preserve normal cyclic strains during the cardiac cycle, thus loss of cyclic energy storage (i.e., loss of cushioning function) in *Fbln5*$^{-/-}$ ATAs is a result of intrinsic differences in material properties. The present study demonstrates that by impairing storage of elastic energy in the ascending aorta, arterial stiffening impairs global cardiovascular function and can potentially contribute to diastolic heart failure.

DYNAMIC VAPOR SORPTION IN TREHALOSE/SALT MIXTURES: EFFECT OF COMPOSITION ON RETENTION OF THE AMORPHOUS STATE

Babak Bagheri, Lindong Weng, Matthew Van Vorst, Gloria D. Elliott

Department of Mechanical Engineering and Engineering Science, University of North Carolina at Charlotte, Charlotte, NC, USA

INTRODUCTION

Trehalose has been widely used in the pharmaceutical and food industries to stabilize dried products because of its high viscosity and low molecular mobility in the glassy state[1]. The glassy state is a metastable state that will eventually convert to a crystal, at a rate dependent on the environmental temperature and humidity level. Sugar crystallization, however, can have a detrimental effect on preserved materials, so additives are sometimes used to stabilize the glassy state either by increasing the glass transition temperature (T_g) or by interfering with the crystallization process[2,3].

In previous molecular modelling work we observed that trehalose and sodium phosphate (Na_2HPO_4) mixtures yielded a higher T_g than pure trehalose because marginally self-aggregated HPO_4^{2-} ions established a strengthened hydrogen-bonding network with trehalose molecules[4]. In contrast dihydrogen phosphate ($H_2PO_4^-$) ions served only as plasticizers, resulting in a lower T_g of the mixtures than trehalose alone, creating large-sized ionic pockets, weakening interactions, and disruption of the original hydrogen-bonding network amongst trehalose molecules. This work inspired us to also look at the effect of sugar-salt molecular interactions on water uptake and the persistence of the amorphous state at high humidity levels. Because we had observed in previous work that choline (Ch^+) $H_2PO_4^-$ was a good stabilizer for proteins[5] we investigated mixtures of trehalose with NaH_2PO_4 and Na_2HPO_4, as well as ChH_2PO_4 and $ChHPO_4$, in order to understand their effectiveness at suppressing crystallization and retaining the desired glassy form.

METHODS

A stock solution of 30.8 wt% trehalose (1.3 M), made in 1X TE buffer (1X Tris-EDTA buffer, pH 8.0, consisting of 10 mM Tris-HCl and 1 mM EDTA), was used to prepare solutions with varying amounts of phosphate salts (salt to trehalose molar ratio (R) of 1:4.8, 1:2 and 1:0.7). Compositions of salts with trehalose in buffer solution were made by combining aliquots of the trehalose stock solution together with the appropriate mass of salt in order to achieve the desired molar ratios of salt to trehalose in the final volume of 1X TE buffer.

To investigate moisture sorption in different trehalose/salt compositions, a closed environment that maintained a stable relative humidity over the test duration was prepared. Supersaturated salt solutions of sodium bromide (prepared by following ASTM Protocol E 104-02) are capable of producing an environment with constant relative humidity of 61%.[6] This composition was prepared and placed in Kilner glass jars with rubber seals and clamps or Mason glass jars with screw caps to create controlled humidity vessels (1 L, total height of 159 mm, mouth diameter of 89 mm).

To create the glassy samples, a 100 μL droplet of the solution studied was pipetted on the treated side of Thermanox coverslips (Nunc, Thermo Fisher Scientific, Rochester, NY, Dia. 22mm) inside a custom-made 11% RH environmental chamber, which was then placed on a custom turntable for microwave assisted drying at 11% RH and 23.5±1.5 °C (SAM 255, CEM Corp., Matthews, NC). The end moisture content was determined to be below 0.105 gH_2O/gdw, which is known to produce a T_g higher than room temperature in the case of aqueous trehalose solutions.[2] The dried samples were then transferred from the 11% RH environment into the fixed relative humidity jar of 61% RH. Other studies have shown that amorphous trehalose crystallizes in environments with 44% RH and higher.[2] The dynamic vapor sorption (DVS) method was then used to monitor moisture sorption in the microwave-processed trehalose samples before and after crystallization (crystals detected visually in samples).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The gravimetric method was used to determine the dry weight of samples with different compositions (expressed in terms of mass of water per mass of dry solids). The dry weight of different compositions was determined by pipetting small volumes of solution onto a glass fiber absorbent pad (CEM Corp., Matthews, NC) and then baking in a convection oven (VWR International, West Chester, PA) for 48 hours at 95 °C.[7,8] The sample was then cooled in a desiccator containing phosphorus pentoxide (P_2O_5) which maintained the humidity near 0% RH. By recording the initial wet mass and the bake-out dry mass, the percent dry weight of each composition was obtained, and used for subsequent determination of water contents in processed samples.

RESULTS

Figure 1 shows the moisture absorption kinetics in amorphous trehalose with or without ChH_2PO_4. The absorption profile of pure trehalose illustrates that the amorphous sample took up water until an adequate amount was absorbed to enable the formation of trehalose dihydrate (~0.105 gH_2O/g trehalose), which is consistent with previous findings.[2] For pure trehalose samples, the formation of trehalose dihydrate crystals was observed at day 1. When ChH_2PO_4 was added to trehalose, the onset of sugar crystallization was delayed in proportion to the amount of salt in solution (Ex. 7 days for the salt:sugar ratio of 1:0.7). Initially the compositions absorbed more than the needed amount to crystallize, but upon crystallization, the moisture content in the sample gradually decreased to ~0.105 gH_2O/gdw during the following 18 days. The initial moisture uptake increased as the ChH_2PO_4 concentration increased. Pure ChH_2PO_4 was observed to be very hygroscopic. Interestingly, given that trehalose/ChH_2PO_4 samples picked up more moisture at 61% RH than pure trehalose, the higher volume of moisture and therefore the plasticizing effect of water did not promote the formation of trehalose dihydrate crystals.

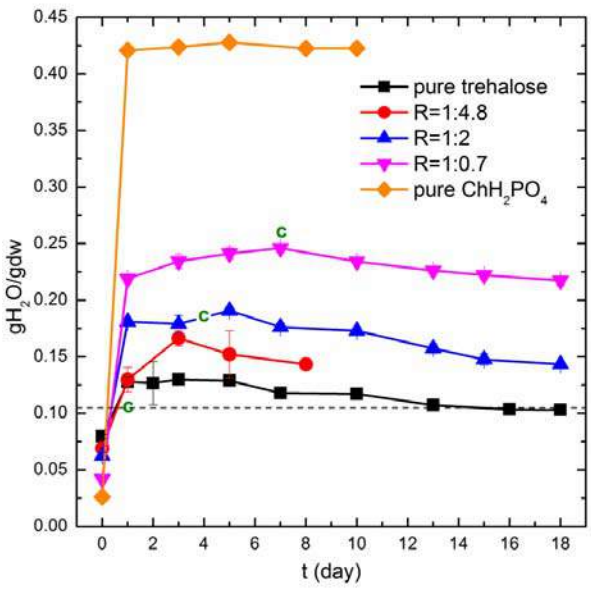

Figure 1. Moisture absorption kinetics in amorphous trehalose/ChH_2PO_4 systems of different ratios of ChH_2PO_4 to trehalose. The onset of crystallization as observed visually is indicated with the letter c.

Of all the salts tested, Ch_2HPO_4 was most effective at suppressing crystallization. No crystals were observed in trehalose/Ch_2HPO_4 samples after 15 days (1:0.7 molar ratio) at 61% RH. We observed that the crystallization suppression efficacy increased with increasing concentration of salt in the mixture for all salts tested, with the exception of compositions containing NaH_2PO_4 in which samples at all molar ratios crystallized within the same time period as pure trehalose (1 day).

DISCUSSION

The present study demonstrated that Ch_2HPO_4 is a promising agent for crystallization suppression in trehalose glasses. In relatively high salt mass fractions of choline hydrogen phosphate the crystallization of trehalose was delayed for a considerable period of time (>2 weeks). The samples absorbed a considerable amount of water compared to pure trehalose, suggesting that the mechanism of crystallization suppression was associated with hindered nucleation and not increased glass transition temperature.

INTRODUCTION

Pulmonary airways consist of tapered, curved, branching tubes of a range of length and diameter, which become narrower, shorter, and more numerous as they penetrate deeper into the lung. The trachea divides into right and left main bronchi, which in turn bifurcate into lobe, then segmental bronchi. This complex geometry can affect respiratory function.

Airway geometry has been studied using measurements of mammalian-lung cast models [1, 2]. Recently, 3D anatomical data of the human conducting airways were measured using high-resolutions computed tomography (CT) images [3]. Furthremore, 3D airway tree models were generated into the lung lobes by the specific algorithms [4 ,5], and have been used widely for pulmonary biomechanics [6, 7]. However, there are some differences in the airway geometry even among healthy subjects,

In this study, we focused on central airways and investigated the influence of standardization of airway geometry on pulmonary function, in particular, airflow and particle transport.

METHODS

In this study, thorax CT images of the four healthy male subjects (A1, A2, A3, and A4) were obtained. The voxel size was approximately 0.5mm or 1.0 mm. The study protocol was approved by RIKEN Ethics Committee.

The airway regions were segmented the 3D region-growing method using Amira software (Visage Imaging, Germany). The generation of the segmented airway was 6 as a function of Weibel generation [1]. After segmentation, the airway skeleton and branching points were calculated without the topology using a 3D thinning algorithm (Amira software, Visage Imaging, Germany). As the results, the Euclidian distance to the nearest boundary was stored at every skeleton voxel as local diameter, that is, the diameter of a sphere superimposed on the duct.

Based on the airway skeleton of four subjects, the averaged skeleton was calculated. All airway models consisted of 45 airway segments. The origin was defined as the branching point of trachea and main right and left bronchi, and each segments were averaged from the origin. Each segment was moved based on the averaged starting branching point of the segment, thereafter the coordinates and the Euclidian distance of all segment voxels were averaged. Finally, the averaged airway model was obtained from the averaged skeletons and Euclidian distances using an inverse 3D thinning algorithm (Amira software, Visage Imaging, Germany).

In this study, we evaluated the steady inspiratory flow and particle transport in each airway model and the averaged model. Assuming laminar and incompressible airflow, the governing equations are expressed as:

$$\nabla \cdot u = 0 \tag{1}$$

$$\rho\left(\frac{\partial u}{\partial t} + u \cdot \nabla u\right) = -\nabla p + \mu \nabla^2 u \tag{2}$$

where u represents the velocity, p is the pressure, μ is the dynamic viscosity (1.81×10^{-5} g/mm/s), and ρ is the density (1.2×10^{-6} g/mm^3).

In particle deposition in the alveolar region, the governing equations are expressed as:

$$\frac{\pi}{6}{D_p}^3\rho_p\frac{dU_p}{dt} = \left(\frac{\pi}{8}C_D\rho{D_p}^3\left|U - U_p\right|\left(U - U_p\right) + \frac{\pi}{6}{D_p}^3\left(\rho_p - \rho\right)g\right. \tag{3}$$

$$C_D = \left(\frac{24}{Re_p}\left(1 + 0.15{Re_p}^{0.678}\right)\right. \tag{4}$$

where U is the air velocity, Up is the particle velocity, ρ_p is the particle density, D_p is the particle diameter, C_D is the drag coefficient, and Re_p is the particle Reynolds number [8]. In this simulation, we assumed that acting forces on particles were convection and gravity, not Brownian

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

forces. For particle diameters of D_p = 1.0 ~ 10.0 μm, ρ_p was set equal to the density of water (1.0 g/cm^3). In this study, we evaluated the escape particles through the airway model. The fraction of escape particles was calculated as the ratio of the number of escape particles to the initial number of particles.

To define the boundary condition, we focused on the heterogeneous ventilation and obtained the CT images at functional residual capacity and after tidal volume. The flow rate was determined from volume change of each lobe and applied at each distal bronchus as boundary condition.

An unstructured mesh with tetrahedral volume elements were generated in each airway models, for a total of approximately ~ 6 M cells. These equations (1 - 4) were solved using OpenFOAM (OpenCFD Ltd.).

RESULTS

Qualitative comparison of the individual and averaged models is presented in Fig. 1, and the averaged airway model exhibits macroscopic geometrical characteristics of the individual model. Table 1 shows the airway characteristics, and also shows the direct averaged values calculated from the individual models. The averages do not completely match the direct average, and particularly the volume was smaller slightly.

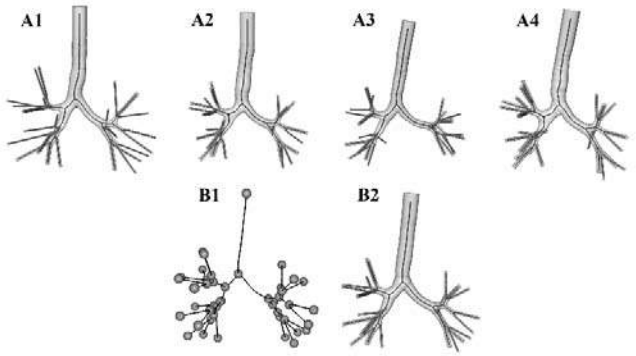

Figure 1: The surfaces of the individual airway models (A1, A2, A3, and A4), and averaged airway skeleton (B1) and model (B2). Black lines indicate airway skeleton. Spheres (B1) are branching points.

Table 1: The geometric characteristics of the individual airway models (A1, A2, A3, and A4) and averaged airway model

	A1	A2	A3	A4	Averaged model	Direct average
Volume [cm^3]	98.1	79.5	63.4	86.6	76.3	80.8
Height [cm]	24.5	22.3	20.3	22.6	20.6	22.1
Width [cm]	21.6	17.3	17.6	17.3	18.0	18.4
Length [cm]	14.2	10.7	11.4	10.2	10.5	11.4

Figure 2 shows the qualitative comparison in streamline of the individual and averaged models. Although there are small differences at the distal bronchi and the bifurcation among individual models as well as between average and individual models, the macroscopic flow patterns in the averaged model are good agreement with individual models.

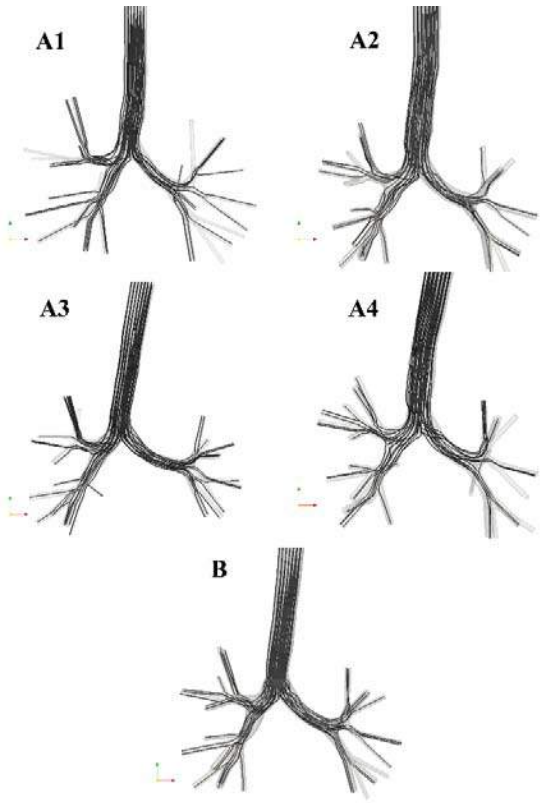

Figure 2: The streamlines in the individual airway models (A1, A2, A3, and A4) and averaged airway model (B).

Regarding the particle transport, in individual models, the fractions of escape particles were ranged 14.4 ~ 24.8 % in right lung and 42.7 ~ 50.6 % in left lung, respectively. In averaged model, the values were 29.5 % and 42.9 %, respectively.

DISCUSSION

In this study, the averaged model of the central airways was developed from four healthy airways using 3D skeleton, and preserved the geometrical characteristics of individual airways. The reduction in volume of the averaged model may be caused by the exclusion of the fake segments in average processes. The irregularity of the surface can induce the fake segments, in particular around branching points.

We investigated numerically whether the averaged model can predict pulmonary function, in particular, airflow and particle transport. Regarding the fraction of escape particles, the averaged model did not anticipate the individual models, because the particle transports may be influenced strongly by the bifurcation geometry. However, our results indicate that the airflow and particle transports in averaged model can estimate the individual phenomena macroscopically.

INTRODUCTION

Current computational fluid dynamic (CFD) have played an important role in simulating cerebral hemodynamics in various cerebrovascular diseases. This include future aneurysm hemorrhage assessment, understanding hemodynamics changes post intervention and understanding flow and wall shear stress changes in parent vessels and inside cerebral aneurysms post flow diverting stents. Yet such CFD simulations have limitations related to basic assumptions that affect results of such simulations. These include assumptions related to inflow and outflow boundary conditions and simulation on a short segment of the arterial tree. In this paper, we will introduce a pipeline for subject-specific hemodynamic simulation of entire intracranial arterial tree using a fully automatic parametric mesh generation and subject-specific boundary conditions assignment.

METHODS

Magnetic resonance angiograms (MRA) were acquired on volunteer subjects, and Hessian-based vessel filter and image processing techniques are carried out for cerebral angioarchitecture reconstruction [1]. After image filtration, we extract the vessel centerline and radius to reconstruct the vascular skeleton, Figure (1).

Current mesh generation methods require user interaction and cannot be used for very large vascular tree with hundreds bifurcation. We used a fully automatic hexahedral parametric mesh generation techniques to represent complex cerebral tress with smooth virtual surface and low mesh density. An in-house meshing algorithm is developed to automatically decompose the skeleton, generate and index parametric mesh from image-based data [2].

Regional volumetric cerebral blood flow is measured at selective large vessels using phase contrast MR angiography (PC-MRA) using commercially available NOVA software (VasSol Inc). Flow rate were measured for Inflow arteries including left and the right internal carotid arteries (LICA and RICA) and basilar artery (BA); and outflow arteries including the anterior cerebral arteries (LACA and RACA); middle cerebral arteries (LMCA and RMCA) and posterior cerebral arteries (LPCA and RPCA). Inflow measurements were directly used as inlet boundary conditions. The unsteady hemodynamic simulations were carried out using computational fluid dynamic solver ANSYS Fluent 15.0 (ANSYS Inc., Canonsburg, PA). Rigid wall assumption is used for the hemodynamic simulation.

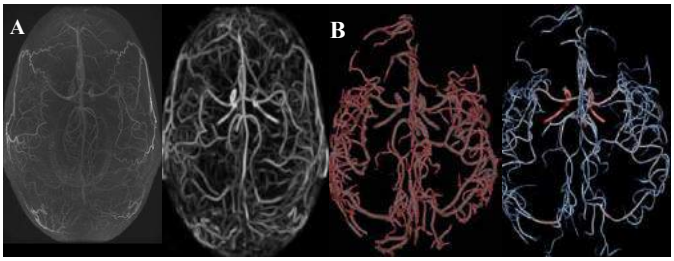

Figure 1: Image filtration and geometrical descriptor extraction of cerebrovascular tree. A) Hessian-based filters were implemented for suppressing signals from non-vascular tissues. B) Vascular skeleton, centerline and radius are extracted using VMTK software.

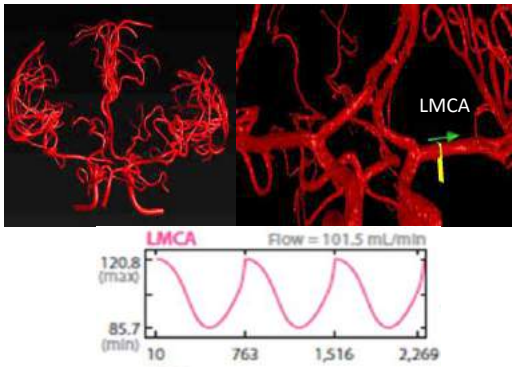

Figure 2: Regional blood flow measurement using PCMRI and Nova software. The flow direction and the slice plane perpendicular to the longitudinal axis of a vessel segment showing where the measurement was made in LMCA.

RESULTS

Figure (2) shows an example volumetric flow measurement using NOVA. The perpendicular plane to the longitudinal axis of LMCA segment is generated to measure time-dependence flow rate. Inflow measurements were converted to velocity profile to be used as inlet boundary conditions in our simulations. Then outlets are labeled based on their anatomical region in the six groups of LMCA, RMCA, RPCA, LPCA and LACA, RACA Figure (3B). For validation purpose, pressure boundary conditions in these six anatomical regions are adjusted to match results with NOVA measurement.

Figure (3A) illustrates a schematic view of Circle of Willis anatomy with hypoplastic Left Pcom. Subject specific arterial map is generated and color coded in eight anatomical regions, Figure (3B). Vascular skeleton was decomposed into Bifurcation (Bif), Bifurcation to Bifurcation (Bif-Bif) and Bifurcation to Terminal (Bif-Term). Then, Bezier curve approximation is used for smooth centerline generation and parameterization. Figure (3D-F) show the distribution of pressure and wall shear stress and vorticity along cerebral arterial tree, respectively.

DISCUSSION

In this study, we developed the largest subject specific intracranial modeling with automated mesh generation techniques and physiological boundary conditions. Using a large cerebral tree model, we can assess local and global effect of any endovascular intervention in upstream and downstream vessels. There are a multitude of quantifiable flow effects that can be studied within the hemodynamics of an aneurysm, including velocity, pressure, vorticity, helicity, wall shear stress, oscillatory shear index, and various flow structures and characteristics. Furthermore, vascular skeleton can be used for morphological feature analysis such as anastomosis and subject specific vascular map can be used for both surgical and educational purpose.

In conclusion, we introduce a pipeline for development the largest cerebrovascular model for hemodynamic analysis. Patient specific blood flow measurement and modeling will broaden the application of CFD analysis among neurosurgeons. Subject specific hemodynamic analysis is a promising procedure for assessment of different endovascular treatments such as stenting, angioplasty or bypass surgery.

INTRODUCTION

At present, Methotrexate (MTX), a *hydrophilic* antimetabolite chemotherapeutic drug is being used for the management for vitreo-retinal (VR) diseases, such as intraocular lymphoma, uveitis, retinal detachment and proliferative vitreoretinopathy. Serial intravitreal injections containing ~ 400 µg of MTX is being administered in clinical practice, which results in rapid clearance of the hydrophilic MTX with a short half-life of 14.3 hours (1). In order to maintain therapeutic efficacy, repetitive intravitreal injections of MTX are administered, which often results in collateral trauma, complications and ocular toxicity. It is expected that a sustained release drug delivery device (micro-implant), which maintains a therapeutic release rate of *0.2-2.0 µg/day* of MTX for a period of a month or more would avoid the possible complications associated with an injection (2).

Currently, no sustained release devices for hydrophilic drugs, such as MTX, in the VR domain have been reported. The *challenge* to fabricate a sustained release device for hydrophilic drugs is that they do not blend well with existing FDA approved lipophilic materials, such as poly-lactic acid (PLA) and poly-(lactic-co-glycolic) acid (PLGA), which is a copolymer of PLA and poly-glycolic acid (PGA). Due to the similar hydrophilic nature, chitosan (CS), a biocompatible and biodegradable polymer, is used as a matrix to blend MTX. Since both CS and MTX are hydrophilic in nature, MTX is expected to be released rapidly out of the CS-MTX micro-implant. Therefore, a lipophilic surface modification of the CS-MTX micro-implant is required to cause sustained release of MTX.

In a prior study, a PLA-coated CS-MTX micro-implant was fabricated which was able to administer therapeutic release rate of MTX for 50-70 days (3). In this study, PLGA copolymer and PLA has been used for improved control of MTX release rate. The *objective* of this study is to characterize the influence of a) PLA:PGA copolymer ratio in PLGA and b) the molecular weight of PLA on the MTX release rate, swelling and structural stability of the micro-implants.

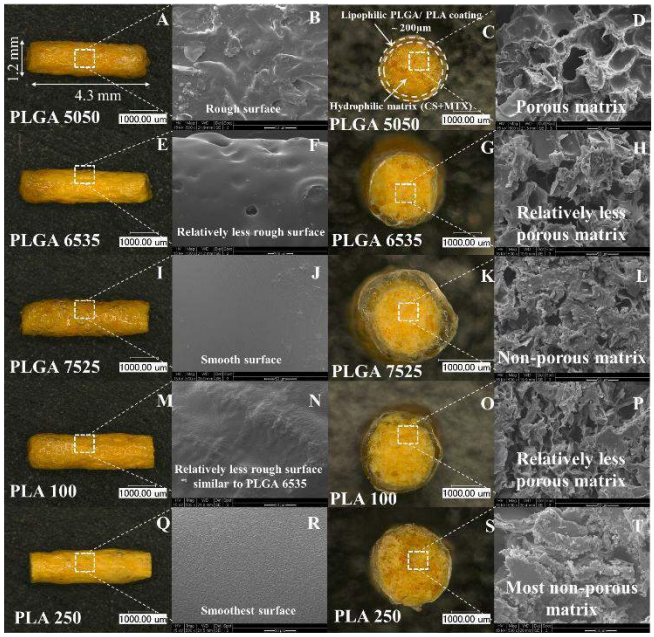

Figure 1: Optical microscopy and SEM images of the top view And the cross-sectional view of the CS-MTX micro-implants coated by PLGA 5050 (A.,B.,C.,D, respectively); PLGA 6535 (E.,F.,G.,H, respectively); PLGA 7525 (I.,J.,K.,L., respectively); PLA 100 (M.,N.,O.,P, respectively); and PLA 250 (Q.,R.,S.,T, respectively)

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

METHODS

MTX is blended with CS (M.W: 50,000-190,000) in dilute HCl to obtain a mixture containing 40% w/w MTX. The CS-MTX mixture is injected into Tygon tubing (1/16 in I.D) and *freeze-dried* to obtain CS-MTX fibers, which are cut into desired length (~ 4 mm) (3). For lipophilic surface modification, the CS-MTX micro-implants containing ~ 400 µg of MTX, are *dip coated* with fixed concentrations of different PLGA combinations (PLGA 5050, PLGA 6535 and PLGA 7525, where PLA: PGA – 50:50, 65:35, 75:25, respectively; M.W: 54,400 – 103,000) and PLA combinations (PLA 100 and PLA 250 of MW: 102,000 and 257,000, respectively). Fourier transform infrared spectroscopy (FTIR) are employed to characterize chemical bonding of the coating with the CS-MTX matrix. The comparative assessment of a) the MTX release rate and b) the swelling of the different PLA / PLGA coated CS-MTX micro-implants is conducted to investigate the effect of the lipophilic surface modification on the sustained release of MTX. The MTX release rate study and the swelling analysis are conducted by placing the PLA / PLGA-coated CS-MTX micro-implants (n = 3, for each type of coating) in a vial containing 5 ml of phosphate buffered saline (pH 7.4) in a water bath at 38°C. Samples are assayed at predetermined time intervals for a) MTX release rate using UV-Visible Spectrophotometer (MTX characteristic peak-258 nm) and b) swelling (% weight difference) of the micro-implant.

RESULTS

Morphology and Structure. The length and cross-sectional diameter of the micro-implants are 4.3 mm and 1.2 mm, respectively. The *porosity* of the micro-implant surface and matrix is reduced with an increase in a) PLA content in PLGA and b) molecular weight of PLA (Fig. 1). FTIR results show the characteristic peaks of CS and MTX (3355 cm^{-1} and 3284 cm^{-1} for O-H and N-H stretching) and that of PLA / PLGA (2996 cm^{-1} and 2943 cm^{-1} for stretching of alkyl groups; 1747 cm^{-1} for carbonyl stretching and 1180 cm^{-1} for C-O stretching) are restored in the PLA / PLGA coated CS-MTX micro-implant (Fig. 2). This confirms that there is *no chemical bonding* between the PLA / PLGA coating and the CS-MTX matrix.

MTX Release. The mean release rate of the coated CS-MTX micro-implants is 5.4 ± 0.1 µg/day (PLGA 5050), 5.7 ± 0.5 µg/day (PLGA 6535), 3.4 ± 0.6 µg/day (PLGA 7525), 3.3 ± 0.3 µg/day (PLA 100) and 1.8 ± 0.1 µg/day (PLA 250) (Fig. 3). The total release duration of MTX from the coated CS-MTX micro-implants is 82 days (PLGA 5050), 82 days (PLGA 6535), 138 days (PLGA 7525), 138 days (PLA 100) and 150 days (PLA 250). The half-life ($t_{1/2}$) of MTX release from the coated micro-implants is 11.3 days (PLGA 5050), 11.8 days (PLGA 6535), 24.9 days (PLGA 7525), 18.6 days (PLA 100) and 100.3 days (PLA 250), when the release data is fitted to the *first-order* equation.

Swelling Analysis. The peak swelling of the CS-MTX micro-implants coated with PLGA 5050, PLGA 6535, PLGA 7525, PLA 100 and PLA 250 is observed to be 6.2 times (30th day), 7.4 times (82nd day), 6.2 times (114th day), 2.2 times (22nd day) and 2.1 times (22nd day), respectively (Fig. 4).

CONCLUSIONS

It is observed that with an increase in a) PLA content in PLGA and b) molecular weight of PLA, the mean release rate of MTX and swelling of the micro-implant reduces, stability improves and the overall release duration of MTX increases. Therefore, the lipophilic surface modification of the CS-MTX micro-implant surface is important for improving and optimizing the release duration of MTX.

INTRODUCTION

Hip osteoarthritis is a debilitating and irreversible disease that gradually degenerates the articular cartilage in the hip joint. In the United States, the lifetime risk to develop hip osteoarthritis is 25% in humans, and this disease also affects 50% of some canine breeds. The standard treatment for humans and animals with hip osteoarthritis is a total hip replacement (THR). Although THR has been successful at reducing pain and returning patients to a moderate activity level, THR is not ideal for younger patients, as implant life is relatively short (10-15 years) and there is a limited number of revision surgeries due to invasive bone removal during surgery. Another option for patients with hip osteoarthritis is Hip Resurfacing, where surgeons "resurface" the hip joint by fitting it with a cup and ball. Hip Resurfacing, introduced in 2006, better mimics the natural hip anatomy and has three functional benefits: lower cost, optimized bearing dimensions that improve mobility, and bone preservation that extends implant lifespan [1]. Despite these advantages, Hip Resurfacing has not been widely adopted due to complications related to metal wear debris generated by friction between the metal ball and metal cup [2]. Metal wear debris could be eliminated by using an ultrahigh-molecular-weight polyethylene (UHMWPE) plastic liner in the cup, but this solution has not been viable due to the high wear rates of UHMWPE combined with inherent size constraints of the cup and ball geometry. However, new material processing techniques have been developed to increase cross-linking in the UHMWPE microstructure, which greatly increases wear resistance. These advances in material engineering could potentially enable polymer liners to be used in Hip Resurfacing.

The objective of this research is to determine the wear behavior of a hip resurfacing implant for canines that uses a highly cross-linked UHMWPE liner. This implant is the first of its kind, and is composed of a thin titanium acetabular shell with a press fit highly cross-linked UHMWPE liner that articulates on a cobalt chromium (CoCr) femoral head (Fig. 1A). The wear behavior of this implant will be measured during the simulation of over one million cycles of canine hip motion. These wear tests will give veterinarian surgeons confidence to implant this new hip resurfacing device in canines, and results from this work will support translation of this technology to human application.

METHODS

Materials. Six acetabular liners (three control, three wear) of 24mm diameter highly cross-linked UHMWPE were tested. The acetabular liners were irradiated with 75kGy in vacuum with annealing. (Securos Surgical, Fiskdale, MA). Titanium shells were cemented into the holding fixtures of the wear simulator with the liners press fit into the shells (Fig. 1B). Femoral heads were press fit and cemented onto a separate holding fixture (Fig. 1C). The 24 mm CoCr femoral heads were coated with titanium niobium nitride (Ti-Nb-N) and had a surface roughness of ~0.77 microns (Fig. 1A-B).

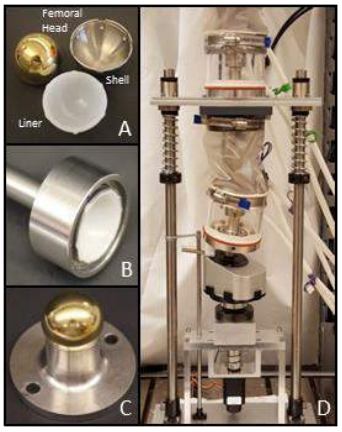

Figure 1: Implants and Hip Simulator (A) Implant components, (B) Shell in fixture, (C) femoral head in fixture, (D) hip simulator.

Hip Simulator Details. Wear tests were performed using a custom hip wear simulator (Fig. 1D). The simulator is a single axis orbital bearing machine (OBM) designed to produce canine hip

kinematics for an average sized German Shepard [3]. The simulator consists of two chambers each housing one implant. The top chamber serves as a load soak control, while the bottom chamber is loaded and rotated for wear testing. Vertical load was applied through the top implant fixture and transferred onto the bottom implant with a mechanical actuator (Instron, Norwood, MA; E10000). The implants were loaded at 10 N during the swing phase and at a peak of 211 N during the stance phase. The total range of flexion and axial rotation in the wear tested implant was +/-10° C with the max load reached at roughly 45% of the canine gait cycle. These two waveforms have been shown to closely match canine gait patterns [3]. The range of abduction does not correlate well with canine gait due to limitations inherent in the OBM simulator design, but this is shown to not greatly affect the resulting wear patterns [3].The implants in each chamber were lubricated with HyClone bovine calf serum, diluted with deionized water to a protein concentration of 2.0–2.5 g/100ml. Additional deionized water was added to replenish fluid lost from evaporation and small leaks in accordance with international standards for wear testing of total hip replacements (ISO 14242-3). The bovine serum was heated in external tanks and circulated through each chamber using a peristaltic pump. The bovine serum was changed every 550,000 cycles.

Testing Procedure. The implants were tested for a total of 1,100,000 cycles, broken into four stages of 275,000 cycles. Tests were conducted at 2 HZ. The peak load and tank temperature was sampled every 550 cycles to ensure that the implants were loaded consistently (± 5N) and that the circulating lubricant remained within the proper range (38.3 ± 1.67 °C). The motor position, load, and actuator displacement were sampled at the beginning, middle, and end of each testing phase to ensure the motor and load remained in phase.

Gravimetric wear analysis was performed every 275,000 cycles (ISO 14242-2). Prior to testing, liners were initially weighed after presoaking in diluted bovine serum for 48 hours. During testing, implants were removed from their test chamber and were immersed in an ultrasonic cleaner for 4 cycles: 10 minutes with deionized water, 10 minutes with detergent, 10 minutes with deionized water, 3 minutes in deionized water. Liners were then dried with a nitrogen gas jet, soaked in isopropyl alcohol for 5 minutes, then dried again with the nitrogen gas jet, and finally dried for 30 minutes in a vacuum desiccator. Each liner was weighed 3 times with a microbalance (Metter, Toledo OH; AT201, resolution = 0.1 mg). The net weight loss was calculated by adding the weight gain of the load-soak control liners to the weight loss of the wear tested liners (ISO 14242-2). An ANOVA test was performed to determine statistical difference in net mass loss between testing stages.

RESULTS

The average total wear rate and average total mass loss for the liners was 1.3 mg/10^6 cycles and 1.4 mg, respectively (Table 1). There was no significant difference seen in the net mass loss between testing stages ($p<0.52$; Fig. 2). No liners, shells, or femoral heads had any catastrophic failure due to cracking or any significant visual damage from wear.

TABLE 1. Average Wear Rate and Total Wear for each Testing Trial

Trial	Average Wear Rate a_G (mg/10^6 Cycles)	Corrected Net Mass Loss W_T (mg)
1	0.9	1.5
2	2.0	1.7
3	1.0	1.2
Average	1.3+/-0.6	1.4+/-0.3

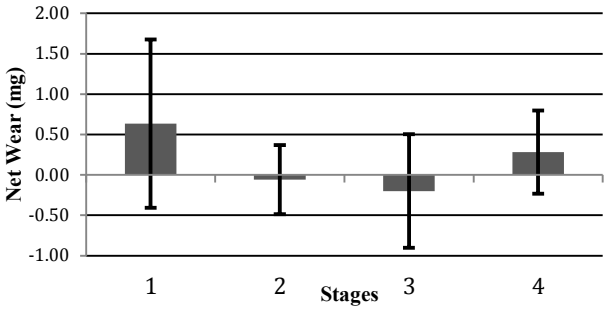

Figure 2: Net Mass Loss per Stage (each stage = 275,000 cycles)

DISCUSSION

This study introduced a novel hip resurfacing device and found that this device withstood wear testing with minimal amounts of weight loss and no visible signs of failure. This device is innovative since it is the first to incorporate a polymer liner into a hip resurfacing design. The liner is very thin, with a thickness of 1.5 mm, compared to an average thickness of 8 mm in UHMWPE liners used in human THR implants [4]. The thin liner is necessary due to geometric constraints inherent in hip resurfacing, where there is a large femoral head and a limited amount of acetabulum bone for implant fixation. Because of the thin liner, it was important to determine if the liner would crack or wear through during long-term testing. Our results indicate a successful design that may be ready for canine implantation and eventual translation to human patients.

The wear rate per million cycles for the highly cross-linked UHMWPE liner used in this study was similar to wear rates for similar liners used in human THR studies [5][6]. For example, Saikko et al. found wear rates of 2.4 mg per million cycles, which was 54% greater than our wear rate. Although canine implants experience 5x less load than human implants, the similar amount of wear can likely be attributed to the high surface roughness of the femoral heads used in this study (0.77 μm) compared to the "worst-case" surface roughness used by Saikko et al. (0.14-0.184 μm) [7]. Therefore, the roughness of the femoral heads used for testing the canine liners can be considered extreme, and the actual wear in canines would likely be less. Weight gain was seen in stage three (Fig. 2). While not expected, other studies have observed weight gain in cross-linked polymer liners [5][6].

This study had limitations. First, implants were tested for only 1.1 million cycles; comparable human studies tested for upwards of 3 million cycles [5][6]. However, the life expectancy of a canine is only 9-13 years so the required implant life is much shorter. Second, no analysis was done on the size or shape of the wear debris. Wear debris that are too small (< 10 μm diameter) can provoke an adverse inflammatory response that can lead to osteolysis and subsequent implant loosening [8]. The bovine serum used as lubricant in this study has been stored for future wear debris analysis.

This is the first study to report wear testing of a canine hip implant. The canine hip replacement market has an annual growth of 5%, and it is hoped that the technology introduced in this study can reduce the high out-of-pocket cost incurred to canine owners. This technology may also benefit human healthcare, since the development of a hip resurfacing device that eliminates metal wear debris would be an appealing procedure for younger patients.

INTRODUCTION

The nucleus is the largest and stiffest organelle in eukaryotic cells [1] and is exposed to the mechanical forces transmitted through the cytoskeleton from outside the cell and the intracellular tension generated by the actin-myosin contractile cytoskeleton via nuclear membrane proteins [2]. The nucleus itself has been proposed to act as a cellular mechanosensor, and the changes in nuclear shape or its deformation possibly affect the regulation of cell functions. Recently, we demonstrated the mechanical deformation and trapping of the intracellular nucleus using polydimethylsiloxane (PDMS)-based microfabricated substrates with an array of micropillars, and found that the cell proliferation was dramatically inhibited by cultivation on the micropillar substrates, even though remarkable deformation of nuclei was observed [3]. In the present study, we further investigated the effects of nuclear deformation on the physiological function, such as cell migration, DNA synthesis, and contractile differentiation of vascular smooth muscle cells (SMCs).

METHODS

Porcine aortic SMCs were used as the test model. Micropillar array substrates were fabricated by replica-molding [4]. In this study, we designed the PDMS micropillar array substrates with a hexagonal arrangement and with a pillar diameter, length, and center-to-center spacing of 3, 9, and 9 μm, respectively. The Young's modulus of the PDMS substrate was ~1.6 MPa [3], which was of the same order of magnitude as extracellular matrices such as elastin (~0.6 MPa [5]) surrounding SMCs *in vivo*.

Both micropillar array substrates and the flat substrates made of the same lot of PDMS were placed in the glass-bottom culture dishes. The surfaces of both substrates were exposed to oxygen plasma (5 mA, 10 Pa) for 2 min using a plasma generator (SEDE-P, Meiwafosis, Tokyo, Japan). All surfaces of both the pillar and flat substrates were coated with fibronectin (50 μg/ml) to allow cell adhesion. SMCs were cultured on these two substrates in DMEM supplemented with 10% FBS at 37ºC.

To investigate the effects of the mechanical trapping of the nucleus on cell migration, we obtained time course images of the cells cultured on the flat and micropillar substrates for 24 h at 5-min intervals using a microscope imaging system with a compact CO_2 incubator. Then, we measured and compared the cell proliferation and DNA synthesis on the both substrates using BrdU assay. To investigate the effects of the nuclear deformation on smooth muscle contractile differentiation, changes in the expression level of α-smooth muscle actin following the cultivation on the micropillar substrates was measured. We also investigated the distribution of intranuclear DNA and lamin A/C which is the main component of nuclear lamina by using confocal microscopy.

RESULTS AND DISCUSSION

Typical fluorescent images of SMCs cultured on the PDMS pillars and flat substrates are shown in Figure 1. SMCs elongated well on the flat substrates, and their nuclei had elliptical shapes with smooth surfaces (Fig. 1A). The cells also spread completely between the fibronectin-coated pillars, leading to strong deformations of their nuclei (Fig. 1B). The nuclei in SMCs were entirely inserted into the grooves between the pillars and they appeared to be "trapped" mechanically on the array of pillars, although they remained in an elongated shape (Fig. 1B). Such nuclear deformation did not affect cell viability; the viabilities of SMCs on the pillar substrate were greater than 98%. These results demonstrated that the SMC nuclei had the ability to deform in response to the micropillared surface.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Such mechanical trapping of the SMC nuclei with the micropillars significantly inhibited cell migration (Fig. 2), and they also prominently inhibited DNA synthesis (Fig. 3). It has generally been suggested that contact inhibition of cell proliferation occurs when a cell culture reaches confluence [6]. However, the proliferation of SMCs was significantly inhibited in the micropillar substrates even though the cells did not reach the confluent state. We also found that not only the migration and cell proliferation of SMCs but also their contractile protein expression was dramatically inhibited by cultivation on the micropillar substrates (Fig. 4). A detailed image analysis with confocal microscopy revealed that expression of lamin A/C was significantly decreased in the region deforming along the pillar surfaces (Fig. 5C), and underlying DNA distribution became more heterogeneous (Fig. 5D). These results may indicate that lamin A/C has a role of mechanosensor to detect an excessive deformation of nucleus, and they switch the cell state from an "active phase" to a "resting phase".

A chemo-mechanical free-energy-based approach to model durotaxis and extracellular stiffness dependent contraction and polarization of cells

Vivek B. Shenoy (1), Hailong Wang (1), Xiao Wang (1)

(1) Department of Materials Science and Engineering,
University of Pennsylvania

INTRODUCTION

Cytoskeletal tension is fundamental to many cellular processes such as cell motility, cytokinesis, tissue morphogenesis, and remodeling, as well as pathologic processes such as tumor growth, metastasis, and fibrosis. Cells modulate their contractility and adapt to different tissue-specific and extra cellular environments in both normal and pathological settings. Stiffness of the extra cellular environment plays a crucial role in determining the contractility of cells. Because of the coupled nature of the mechanical and biochemical signaling processes, progress in understanding how they interact to control cell contractility and more importantly, cell shape has proved challenging. Predictive quantitative models that link biochemical signaling pathways that control recruitment of molecular motors leading to changes in contractility with the mechanics of the extracellular environment can provide a means to interpret and predict cell functions in normal and pathological conditions.

However, most of the current models do not treat these chemo-mechanical processes in a consistent and unified manner [1-3]. A key drawback of these models reviewed do not consider the chemical, mechanical and interfacial contributions to the free energy of a given shape and polarization of a cell, and thus are not able to predict which configuration (for example, spindle shaped or spherical) is favored from an energetic perspective. It is also well known that cells migrate towards regions of larger mechanical stiffness, a process referred to as durotaxis. However, the energetic driving forces for this process have not been quantitatively studied to date. Given the key role that cytoskeletal tension plays in physiological processes, it is important to develop a mathematical description that treats the mechanics of the cell and the ECM and the biochemistry of stress fiber formation on an equal footing.

METHODS

We develop a unified framework to study contractility and polarization of cells as a function of the stiffness of their surroundings by considering the chemical free energy available from the assembly of stress fibers and the mechanical energy due to the deformation of cells and the extracellular matrix [4]. The key kinematic variables that describe the cell are the strain and the contractility tensors and the free energy of the cell-matrix system is expressed in terms of these variables. We explicitly include a term that couples the stress and contractility tensors, thus are able to capture how the contractility of the cell can change in response of mechanosensitive signaling pathways (Fig. 1).

$$U(\rho,\epsilon) = \frac{K}{2}\epsilon^2 - \int_0^{\varepsilon} \sigma d\varepsilon + \frac{\beta}{2}(\rho-\rho_0)^2 - \alpha \int_0^{\rho} \sigma d\rho + \rho\varepsilon. \qquad (1)$$

By using the principles of non-equilibrium thermodynamics, we relate the rate of myosin recruitment and cross-bridge sliding to variations of the free energy with respect to contractility and the active strain. We show that the rate of change of contractile strain is linearly related to stress, providing derivation of the Hill law based on considerations of free energy, rather than phenomenology. We then show that the overall free energy of cells is lowered in stiffer environments due to recruitment of myosin motors, providing a means to evaluate the thermodynamic driving force for durotaxis. By comparing the predictions of our simulations with experiments on cells deformed using the atomic force microscope we obtain estimates of the chemo-mechanical coupling parameters. We also study how the free energy and polarization of cells depend on their shape in 3D matrices, on 2D substrates and on micropost arrays. The chemo-mechanical parameters we have derived can be used to quantitatively model cell sorting, motility and morphogenesis in complex 3D environments.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

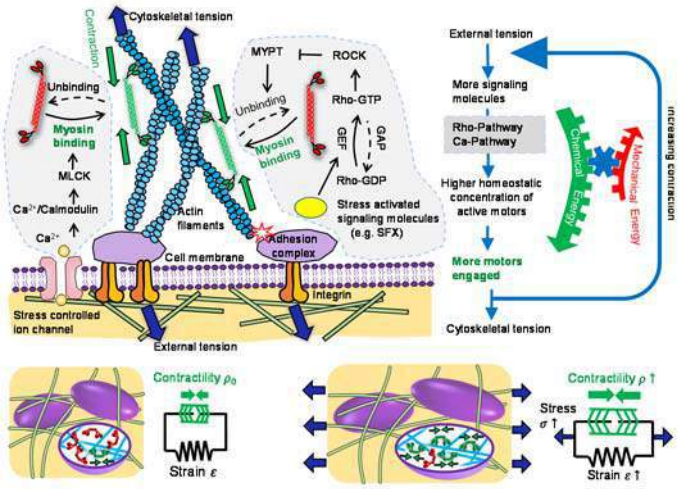

Figure 1: Schematic depiction of the chemo-mechanical coupling and stress-dependent feedback mechanisms in our model.

RESULTS

We consider three examples to validate our 3D chemo-mechanical model, namely, cells on a bed of microposts [2] (Fig. 2), cells on 2D substrates [5] (Fig. 3) and cells in 3D matrices (Fig. 4). In all of these examples, our focus is on the elucidation of the variations of the chemical and mechanical free energies as a function of the stiffness of the posts, substrates and matrices.

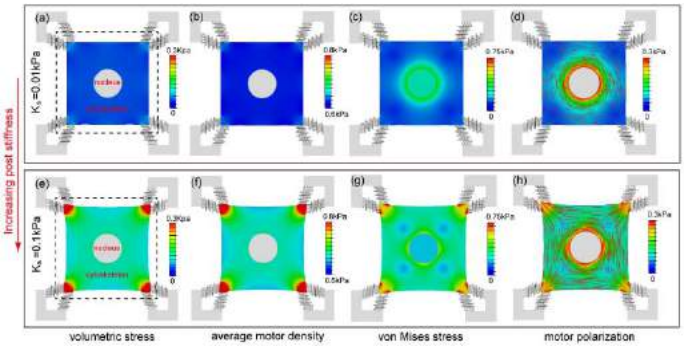

Figure 2: The steady-state distributions of the volumetric stress, average motor density, von Mises stress, and motor polarization with various post stiffnesses.

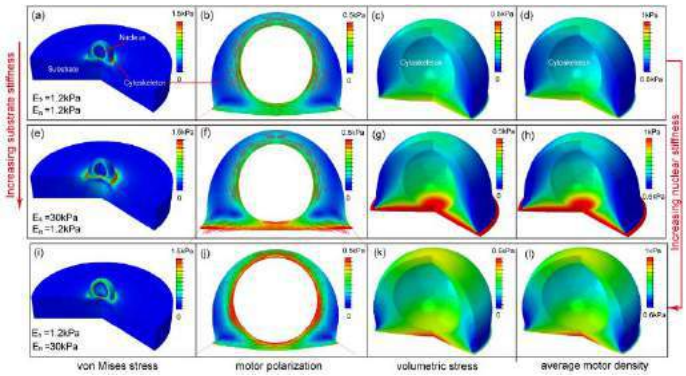

Figure 3: The steady-state distributions of the von Mises, motor polarization, volumetric stress, and average motor density of cytoskeleton for varying substrate and nuclear stiffnesses.

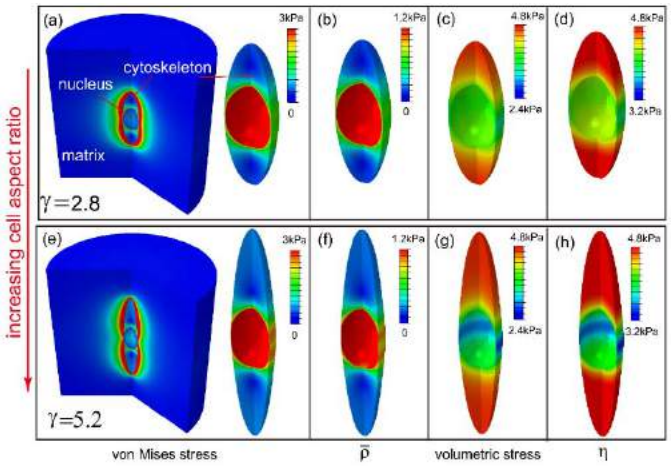

Figure 4: The steady-state distributions of the von Mises stress, motor polarization, volumetric stress, and average motor density of cytoskeleton for various cell aspect ratio.

These observations provide the basis for durotaxis, where cells preferentially migrate towards stiffer regions of the extracellular environment. Our models also explain, from an energetic perspective, why the shape of cells changes in response to the stiffness of the surroundings. The effect of cell shape on the shape of the nucleus has also been studied.

DISCUSSION

We have developed a model that explicitly includes stress dependent recruitment of molecular motors to develop a chemo-mechanical description of polarization and strain in contractile cells. The basic variables that describe the model are the strain tensor and the contractility tensor that depends on the spatial distribution of the molecular motors. In contrast to previous models, we do not keep track of individual fibers, but capture the effect in a coarse-grained sense; the principal direction of the contractility tensor with the largest principal value gives the orientation of the stress-fibers and the difference between the largest and smallest principal values of contractility gives the polarization of the cells. We have derived the free energy of the cell in terms of these variables. The free energy includes the elastic strain energy of the cytoskeleton, the mechanical work done by the molecular motors and the chemical free energy of motor recruitment. The dynamic laws for the evolution of the active strain and the contractility tensor are derived based on the second law of thermodynamics. In this manner, we are able to recover the well-known Hill relation for active stresses in tissues, based on fundamental principles of irreversible thermodynamics rather than phenomenology.

FINITE ELEMENT MODEL OF OCULAR ACCOMMODATION MECHANISM BASED ON LENS PRE-TENSIONING AND CILIARY MUSCLE CONTRACTION

INTRODUCTION

Accommodation of the human eye transitions from distant to near focus through deformation of the lens. This lens change is caused by contraction of the intraocular ciliary muscle, relieving tension on the lens through the suspensory zonule fibers, allowing the thickness and surface curvature of the lens to increase [1]. The ring-shaped ciliary muscle is composed of three uniquely oriented fiber groups (longitudinal, radial, and circular) that contract toward the center and anterior of the eye [2]. The deformation of the ciliary due to the contraction of the different muscle fibers translates a change in tension to the surface of the lens through the zonule fibers, whose complex patterns of attachment to the lens and ciliary dictate the resultant changes in the lens during accommodation [3]. Ciliary muscle contraction also applies strain at its connections to the sclera, the white outer coat of the eye, and the choroid, the inner connective tissue layer between the sclera and retina.

As people age, they develop presbyopia and lose accommodative ability, leaving people over the age of 50 with an almost complete lack of focusing ability for near vision [1]. Although scientists have studied accommodation for centuries the functional mechanism is not well understood. Most presbyopia research has focused on property changes of the aging lens without examining the accommodative mechanism as a whole, basically ignoring the complicated role of the ciliary muscle. Without understanding the interactions of the muscle, lens, and other structures that alter the eye's optic power, treatments for presbyopia that effectively restore this ability cannot be successfully developed. This lack of understanding is also in part due to the limited data, especially *in vivo* or dynamic, of healthy human eyes; most current measurement techniques require isolating or disturbing some portion of the accommodative system and are limited to cadavers or monkey models [3,4]. These data provide a disjointed comprehension of the accommodative mechanism and the implications of age-related changes to eye structure.

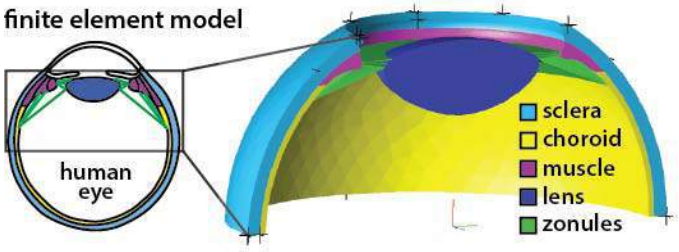

Figure 1: FEM of ocular structures involved in accommodation

A computational model is critical to understanding how the complex movements of the ciliary muscle drive the lens changes necessary for accommodation, and to understand how age-related changes lead to presbyopia. Most previous models focused solely on the actions of lens and zonules, simplifying ciliary movement to a single displacement, and simulating the transition from the accommodated state where the lens is un-stretched but the muscle is contracted, to the unaccommodated state where the muscle is at rest and the lens is stretched. This method depends on a simplified arrangement of the zonule attachments and also ignores the complex behaviors of the ciliary muscle, whose movements are constrained by its attachments to the sclera and choroid. The goal of this study was to develop a multi-component finite element (FE) model of the accommodative mechanism that includes the ciliary muscle, lens, zonules, sclera, and choroid [Fig. 1], to characterize the role of complex ciliary muscle action in producing the lens changes required for accommodative function.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

METHODS

Representative 3D geometry of the resting ocular structures was defined computationally based on extensive review of literature measurements and medical images of the anatomy of the young adult eye. AMPS software (AMPS Technologies, Pittsburgh, PA) was used for geometric meshing, defining material properties and boundary conditions, and to perform finite element analysis. The ciliary muscle and zonules were represented as a transverse isotropic material with orientations specified to represent the complex fiber directions [5]; computational fluid dynamic simulations were used to produce fiber trajectories, which were then mapped to the geometry. The lens began in the relaxed configuration and was stretched through pre-tensioning of the zonule fibers to the unaccommodated position and shape. Unaccommodated lens position was reached when zonules were shortened to 77% of their starting length [Fig. 2]. Then accommodative motion was simulated by active contraction of the fibers of the ciliary muscle, using a previous model of skeletal muscle that was modified to represent the specific dynamics of the ciliary muscle [5]. Model results of lens and ciliary anterior movement and deformed thickness at the midline and apex, respectively, were validated through comparison to literature measurements of accommodation [4]. To investigate contributions of the different fiber groups to the action of the ciliary muscle, the simulation was repeated with each fiber group activated in isolation while the other groups remained passive.

RESULTS

Model results of displacement and deformation of the lens and ciliary muscle fell within the range of literature values for accommodation of a young adult human [Fig. 3]. Pre-tensioning of the zonules prior to muscle contraction was necessary for the model to produce appropriate lens deformation. The contraction of specific fiber groups contributed disproportionately to different aspects of lens change in accommodation [Fig. 3]. Contraction of the radial fibers contributed most to anterior movement of the lens (fiber contraction responsible for anterior lens movement was 44% longitudinal, 73% radial, and -18% circular), and circular fibers contributed most to thickening of the ciliary at the apex lens (fiber contraction responsible for ciliary apex thickening was 27% longitudinal, 21% radial, and 52% circular), which leads to lens thickening and increased curvature.

DISCUSSION

This model provides novel insight into the interactions of the components of the accommodative mechanism through incorporation of decades of previous research. The model results were effectively validated with existing data; these comparisons are bounded by the limitations of current measurements, they suggest new experiments for future study of accommodation. New appreciation of ciliary muscle function gained through simulations of its specific actions motivates hypotheses for targeted therapies for presbyopia. Moving forward, we plan to use this model to systematical investigate the effect of age-related changes to the eye of the action of the ciliary muscle to determine major influences of presbyopia the accommodative mechanism. We will also test hypothesized therapies effectiveness at restoring normal function to the presbyopic eye.

INTRODUCTION

Articular cartilage is a specialized tissue that operates within a hostile biomechanical environment. As with the majority of musculoskeletal tissues, cartilage is able to sense its mechanical environment and adapt accordingly to the physical requirements of the body. It is well evidenced from in vivo and in vitro experimental models that it requires regular mechanical stimulation within a window of "reasonable" physiological loading to stimulate growth and maintain its functional integrity, with loading outside of this range deleterious to its general structure and composition [1]. This is an indication that there is a quantified correlation between loading circumstances and tissue remodeling, comparable to the mechanostat growth/loss model for bone.

The inherent complexity in assessing the remodeling response to physical stimuli and the broad range of spatial scales involved, make it highly challenging to assess cartilage mechanobiology experimentally. As such, the precise events, their sequence and the mechanisms associated with the contribution of joint loading history to cartilage remodeling have yet to be fully eluded too and properly quantified. The computational modeling of cartilage remodeling presents a means of separating the myriad of internal and external mechanisms influencing the development of functional engineered cartilage and seeking out dominant underlying factors [2].

However research in this area is sparse and traditionally models have been deterministic in nature. They therefore do not readily account for random variation in experimental parameters and initial circumstances. Statistical methods are widely used in the musculoskeletal modeling discipline and their use in simulating mechanically mediated cartilage remodeling presents a means of overcoming current shortcomings. Presented here is a novel experimentally informed population based statistical model to predict cartilage pellet growth in scaffolds. Its function is to determine cell and protein spatio-temporal distributions based upon the system input conditions and localized mechanical environment.

The potential uses of such a model are extensive; the intention is that it be used as the building block for an overall multi-scale mechanobiological framework, whose aim is to simulate mechanically mediated tissue remodeling within patella-femoral joint implanted tissue engineered constructs, see Figure 1.

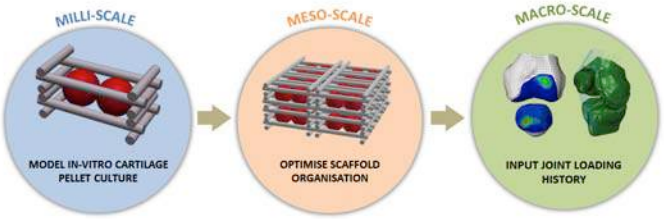

Figure 1: Schematic Diagram of Multi-scale Cartilage model.

METHODS

Data concerning the fusion of cartilage pellets within 3D scaffold architectures was used to construct the model (see Figure 1, far left). Inverted scope microscopy, histology, and biochemical analysis were performed to investigate the contribution of cell co-culture on chondrogenic differentiation, the formation of functional cartilaginous tissue and pellet interaction within the scaffold.

Four experimental groups were considered; the AC (Articular Chondrocyte) and the MSC (Mesenchymal Stem Cell) groups used pellets containing those cell types exclusively. The MSC-AC group used a pellet populated with either; whilst the pellets of the mix group were populated with a combination of both cell types.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Histological images were used to gather information concerning the 2D distribution of cells and glycosaminoglycan (gag) within cultured pellet configurations. A semi-automated GUI was used to extract cell location, whilst gag distribution was gathered by assuming a linear relationship between image intensity and gag concentration, see Figure 2. The positioning of both fields are described based on the normalized distance from the pellet periphery and the angle made with the horizontal axis, this was to take into account pellet geometrical changes. Pellet shape progression was determined by fitting a pair of ellipses to the inverted scope images.

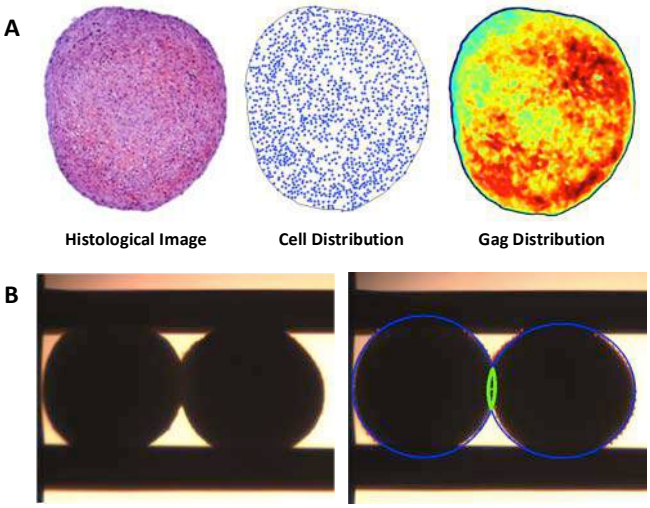

Figure 2: Examples of (A) Extracted Cell & Gag Distributions and (B) Pellet Geometry Determination.

A combination of univariate and multivariate inverse transform sampling methods were used to generate sets of pseudorandom initial pellet configurations. These were then translated to Abaqus FE software. Mass diffusion analyses were performed, where the governing equations are an extension of Ficks-law (1), to determine spatio-temporal alterations in distribution. Gag and cell movement were modeled individually with spatially varying diffusion coefficients directing movements between adjacent elements, cell proliferation and gag synthesis were accounted for via positive or negative body concentration fluxes for relevant elements. The diffusion coefficient distributions were also generated randomly based on those estimated directly from experimental data.

$$J = -D \cdot \left(\frac{\partial c}{\partial x} + sk_p \frac{\partial p}{\partial x}\right) \quad (1)$$

The generated datasets were used as the predicted and observable variables to train a partial least squares regression (PLSR) machine-learning model [3]. An iterative optimization scheme was used to attain a statistical model best able to approximate the diffusion coefficient profile that resulted in the culture outcome for the extracted experimental data. The impact of hydrostatic pressures on the diffusion of cell and gag fields throughout the pellet system was also analyzed through the inclusion of the pressure gradient term in the governing equations for a number of external loading circumstances.

In addition to the methodology discussed, an eigenvector morphological analysis was performed to reveal different cell phenotypes and alternate cell states.

RESULTS

The statistical model was able to estimate diffusion coefficient profiles for the experimental circumstances that when inputted into the Abaqus mass diffusion model, predicted the culture outcome for the experimental case reasonably well. The model predicted temporal alteration to a high degree of accuracy, however the spatial variation was predicted poorly when proliferation was excluded and only diffusive migration was accounted for. Figure 3 is an example of the evolution of the gag distributions over the seven-day culture period, with blue and red parts of the image corresponding to low and high concentrations respectively.

The addition of the hydrostatic pressure term to the FE model had a significant impact on culture outcomes. Even at small loads, the pattern of applied loading was observed to heavily determine the spatial evolution of the cell and gag distributions, with both fields preferentially migrating to areas of small relative pressures.

The cell morphology analysis allowed for cell phenotype and those undergoing apoptosis to be readily determined based on the roundness and size of cells respectively. Thus permitting a better quantification of cell type and state than existing image classifications.

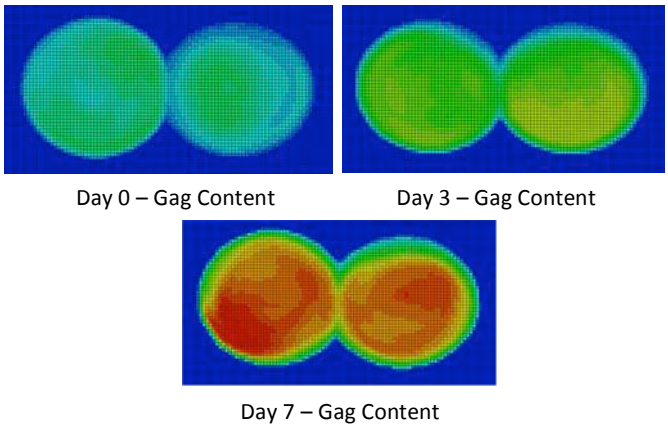

Figure 3: Example of Gag Diffusion Over Seven Days of Culture.

DISCUSSION

The observation that the model predicted better temporal than spatial distribution of cell and gag concentration when proliferation was omitted from the governing equation, suggests that cell genesis and gag synthesis play a strong role in the evolution of the cartilage pellet experiment. The model demonstrated a complimentary role in cartilage experimental evaluation by highlighting the significant effect of hydrostatic pressure on culture outcomes that are difficult to perform experimentally.

Furthermore, the model lends itself naturally to inclusion within a multi-scale framework; acting as a building block for subsequent investigation. Cell and Gag distribution can be related to material properties and hydrostatic pressure accounted for in the statistical procedure to evaluate loading independent of normal culture behavior. Coupling the model with larger scale FE models will permit material optimization to be carried out and the effect of joint loading history on remodeling to be analysed.

INTRODUCTION

Clubfoot, the most common congenital deformity of the feet in newborns, affects about 1 in 1000 children [1]. Children born with clubfoot have misaligned bones in their lower extremities due to short muscles causing their feet curl in adduction and plantar flexion. Clubfoot is corrected through a treatment consisting of manipulation, casting, minor surgery, and bracing [2]. The first three parts of the treatment aim to bring the feet to a correct anatomical position and last approximately 3 months. The corrected feet require bracing for a period of approximately 4 years to prevent the feet from returning to their deformed position.

Ankle foot orthoses (AFOs) are the braces commonly used for clubfoot treatment. The purpose of a clubfoot AFO is to maintain the feet at specific, physician-prescribed angles of abduction (rotation of the foot outwards) and dorsiflexion (flexion of the foot upwards).

Existing clubfoot AFOs consist of a pair of boots connected by a rigid bar. Limitations of these systems are: comfort, as the straps often cause rubbing or abrasion; difficulty in donning and properly securing the child's feet; expensive retail prices of around $600 (CAD); and bars that are typically rigid, therefore restricting independent motion of the feet and inhibiting natural crawling motion of the child.

Our design team was approached by a client requiring the development of a new orthosis to correct the deficiencies in current devices while providing a more affordable brace option. Upon examination of the flaws in current designs, three main design objectives were identified: i) the bar must allow mobility to facilitate the child's crawling, and its length must be adjustable to match the child's growth throughout the entire treatment; ii) the boots must be able to be put on and secured more efficiently while proper abduction and dorsiflexion angles of the foot are maintained, for which the client favored alternatives to the existing belt straps; iii) the design must have a more affordable retail cost than existing designs, consequently a predefined criteria from the client was that 3D printing techniques be used where possible.

PRODUCT DESIGN

The design was divided into three main areas: the bar, the boot, and the mechanism that attaches the bar to the boot (Figure 1).

The bar design consists of two aluminum 6061 T6 pieces. Each piece has two bolt holes on the inside end and 4 bolt holes on the outside end. The inside holes are used to connect the two bars together in either a pinned or locked configuration. The pinned configuration allows movement to facilitate a more natural crawling motion. The outside holes on the bar permit incremental length adjustments to match the shoulder width of the child for comfort. The bar is designed to span the average change in shoulder width undergone by a child from ages 0 to 4 so it can be used for the entire duration of the treatment.

The attachment mechanism was designed to serve two main purposes. First, to attach the boot and bar assemblies. Second, to set the abduction angle. It consists of a top and a bottom clip. Seventy degrees of abduction, in 10 degree increments, can be achieved by changing the positions of the top and bottom clips relative to one another. Typically, the prescribed angle of abduction does not change throughout the course of treatment. The range from 0-70 degrees allows flexibility to achieve the spectrum of angles a doctor may prescribe. The top clip connects to the bottom of the boot with a quick release mechanism which facilitates the process of inserting and removing the boots from the bar. Both the top and the bottom attachment mechanism clips are 3D printed as single Acrylonitrile-Butadiene-Styrene (ABS) pieces.

The boot is also printed as one ABS piece. It features three Nylon webbing straps, which are used to maintain foot position. These are secured using Velcro and a quick release buckle. These straps are easier to secure and more comfortable than belt straps typically used in clubfoot AFOs. The underside of the boot has a compartment compatible with the top attachment mechanism to quickly secure it to the bar.

INNOVATION

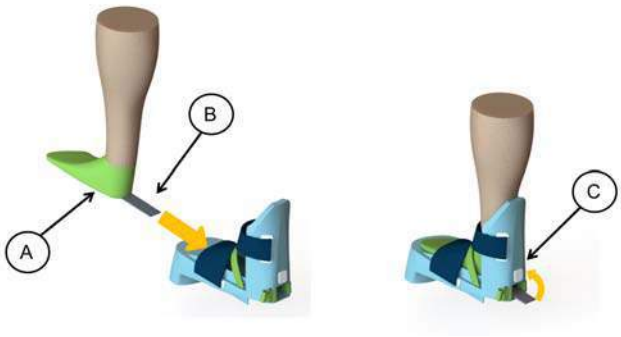

Figure 2: Sock-tab function; A: sock, B: Velcro tab and C: Velcro connection

Conventional clubfoot braces are difficult to properly put on and secure. Upon careful review of existing designs, two main difficulties were identified: proper insertion of the foot within the boot and maintaining correct foot placement while securing the boot.

These difficulties require attention because placement of the feet within the boots is needed for effective treatment. To ensure proper dorsiflexion and abduction, the child's heel needs to be in complete contact with the back of the boot. A sock-tab accessory was designed to address this issue. The sock-tab is simply a sock with a Velcro tab sewn at the heel (Figure 2). This tab can be pulled through an opening at the heel of the boot to easily align the heel at the back of the boot. The Velcro strip on the tab attaches to a corresponding Velcro piece on the back of the boot, keeping the foot in place while the boot straps are secured. This accessory eases the process of inserting the foot, allowing inexperienced people such as family members or babysitters to put on the boots.

FEASIBILITY ANALYSIS

Anthropometric data of the strength of children was used to define worst case loading scenarios for the device. The analysis varied depending on the material of the part being analyzed. The microstructure of 3D printed materials is anisotropic because of the linear printing pattern of the polymer jet; therefore, the mechanical properties of the 3D printed part will be orthotropic. Parts manufactured using commercial 3D printers are printed as a shell and are filled with infill. The latter does not bear a significant portion of the load; therefore, the structures must be interpreted as shells. To account for the shell-like structure, the maximum stresses were scaled using correction factors that accounted for the effect of the change in the geometry on the particular loading scenario. The values of the maximum stresses were determined using hand calculations and FEM simulations. The nominal stresses were then scaled using the correction factors to obtain the corrected stresses, and then compared to the material's failure stress.

The distortion energy failure criterion for ductile materials was used for the analysis of the aluminum bar. The maximum stresses for the different loading scenarios were determined to ensure that the bar will not be loaded more than at an acceptable stress level, much less than the yield strength.

All loading scenario stresses for the bar and 3D printed pieces were below the failure stress. Therefore, the device should not fail under anticipated loading conditions.

BUDGET & MARKET ANALYSIS

The budget for the prototype was required to be under $100. All components were donated from various departments of the University of Alberta and our client so no funds were spent making the prototype. However, a detailed breakdown of the expected part costs can be seen in Table 1.

Table 1: Breakdown of Part Costs for Clubfoot Orthosis

Parts	Quantity.	Total Price (CAD$)
Attachment components (screws, nuts, washers etc.)	22	1.07
Buckle	2	3.80
Velcro	6	0.92
Straps	6	1.68
Adhesive Foam	2	0.44
Bar	2	22.05
Top Attachment	2	2.11
Bottom Attachment	2	7.35
Boot	2	29.08
Total	-	**68.50**

The client plans to deal with customers directly in the Edmonton and Calgary area using a website to place orders. The product is currently being tested by the client and user feedback is being collected. Our client intends to use crowd funding through an organization such as Kickstarter to source funds and potentially start making early sales. This would also enable the start of early production. The client has connections with patient populations diagnosed with clubfoot, a clubfoot clinic, and some orthotists to whom he can pitch the product. The initial scale of manufacture for the product is of 1000 units. At this scale, the material and manufacturing costs of the orthosis amount to $69.00. The average retail cost of the current products on the market is $580.00; this allows for substantial flexibility in our products' final retail cost which is to be determined by the client. The largest investment cost will be the accrual of a 3D printer. The 3D printer that was selected by the client costs $55,000. The large price is a consequence of the quality desired in the product.

ACKNOWLEDGEMENTS

BEST PRACTICES IN TEACHING BIOMECHANICS: CONNECTING BIOMECHANICS BEYOND THE CLASSROOM

Laurel Kuxhaus

Mechanical & Aeronautical Engineering
Department
Clarkson University
Potsdam, NY, USA

INTRODUCTION

Engineering students must attain technical proficiency in their chosen discipline. Developing this proficiency often relies on analysis of 'textbook problems' which are typically simplified versions of real-life scenarios. As such, students perceive this disconnect between their classroom studies and real-world problems. Making the connections between classroom content and life outside the classroom is both challenging and essential. Furthermore, instances of academic dishonesty are reduced when students can identify the importance of classroom topics to their lives, as these types of activities increase students' intrinsic motivation for learning. [1]

Topics covered in biomechanics classes have clear application to life outside the classroom, from injury prevention and healing to the mechanics of pulmonary circulation. However, transferring the skills learned in the classroom to real-life applications can pose a barrier for students. For example, students will likely not perform a full finite element model to analyze their grandmother's pending hip replacement (though they may be interested in reading about the results of such models.) This abstract presents some ready-to-implement activities to connect biomechanics content directly to students' experiences outside of the classroom.

METHODS

The activities described here were employed to foster connection between content learned in the classroom to students' lives outside the classroom. All can be integrated into a typical classroom setting without radical disruption of an existing course syllabus and schedule. The author has implemented these in her undergraduate biomechanics class, which typically attracts 30-35 students, primarily from Mechanical and Chemical Engineering. These activities are intended to be customized to individual classrooms as needed. Each activity is described, and followed by observations from implementation and some suggested variations.

Popular Press Assignment

Description: The goal of the popular press assignment is for students to connect popular media reporting of biomechanical studies to the source of the findings. Ultimately, students compare the peer-reviewed scientific article to the media report.

Students start with a news article that reports a finding from a biomechanical study that has been published recently (that is, within the current semester.) The story can be from any media source; popular sources include the NY Times, IFL Science, and cnn.com. The article must contain sufficient information about the authors and/or the peer-reviewed publication to find the source article. Students must then find the peer-reviewed article (or articles) referenced in the news story.

After reading both, students must write a short (one-page) essay summarizing the scientific findings and comparing/contrasting the peer-reviewed article with the news report thereof. Students are asked to consider the accuracy and completeness of the news story.

Following this analysis, students share their observations in small group discussions (3-4 students per group.) The class discussion concludes with one person from each group summarizing their story for the class, and a tally of how many of the group's stories "got it right", "sort of got it right", and "were pretty much wrong." Students were assessed based on their written essay (including documentation of their news story and journal article), and participation during the in-class discussion.

Observations and Variations: Students are generally able to complete this assignment; common pitfalls include procrastination (which may

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

not allow sufficient time for an Interlibrary Loan article to arrive) or difficulty in finding an article (searching for "knee replacements" may yield better news results than "biomechanics"). The general conclusion is that popular media reporting of biomechanics studies gets most of the facts right, though is often incomplete. Possible variations on this activity include having the students format their essay as a letter to the editor, with a concluding statement about the media's responsibility to ensure accuracy when reporting about biomechanics. [1]

TED-style Talks

Description: With the widespread popularity of TED (Technology, Entertainment, and Design) Talks, [2] this format is nearly ubiquitous in the consciousness of today's college students. Hallmarks of TED talks include engaging presenters with minimal visual aids and clear take-home messages. The topics of TED talks vary widely. Asking students to give a TED-style talk encourages connection to the world outside of the classroom. This activity is particularly well-suited to an end of semester time (such as: during a scheduled Final Exam period.)

In the author's class, students gave TED-style talks subject to the following constraints: 1) the length had to be 4:00-4:30 minutes (so that all students could present within the allotted time); 2) the topic could be anything, so long as there was at least one reference to a specific biomechanics example somewhere; 3) students were permitted one static (animation-free) PowerPoint slide, from a template that included a countdown timer. Logistically, slides were assembled in a random order (with the next speaker's name appearing on the slide) and set to auto-advance at the end of the maximum allotted time. Students were encouraged to be creative in both their topic selection and delivery.

Students were assessed on both their preparation and delivery. An in-class worksheet guided students through a brainstorming activity to explore possible topics and get feedback from their peers. Additional aspects of student assessment included preparing their PowerPoint slide by the specified deadline, and documenting two instances of practicing their talk (at least once with a video recording, and at least once in front of another person). The presentation delivery was evaluated on its timeliness, the effectiveness of the visual aid, elocution and eye contact, and creativity. A panel of judges from the community without expertise in biomechanics was invited to select awardees for Best Overall Presentation and one Honorable Mention. Students also voted for an Audience Choice award.

Observations and Variations: From the instructor's perspective, this activity was worthwhile; students were highly engaged and motivated to give a strong presentation, and the topics of the talks were extremely diverse. Some students built their talks around biomechanics (such as: the history of high heels and gait); others had a more motivational appeal (such as: what one's legacy should be), or high relevance to college student life (such as: binge drinking). The most common, though rare, pitfalls were a short presentation or a nervous presenter. Most students reported that the required practice helped them stay within the time limits. Anecdotally, students reported that they found this activity worthwhile and more enjoyable than preparation for a standard exam. Most had not previously recorded themselves giving a presentation, and were surprised at their own mannerisms and stage presence. Possible variations of this assignment might include narrowing the topic further (e.g., requiring it to be relevant to sports performance), or modifying the format. For example, Ignite talks [3] place more emphasis on the display of visual aids.

Short Writing Exercises (can be used in class, on exams, or other)

Description: As previously-described [4], and inspired by "Emergency Assessments" [5], this technique encourages students to connect their course-related experiences to their present and future lives outside the classroom. Students write in response to a prompt, such as:

> *You've applied for a job as a technical consultant for the next Batman movie. They liked your application and have called you in for an interview. The person doing the hiring says "I see that you have taken a course in Biomechanics. How will a background in that make you a better member of our crew?" What will you reply?* (modified from [5])

Observations and Variations: Students seem to find these exercises enjoyable; some have commented that questions like this are helpful to think about in anticipation of job interviews. Pitfalls in this activity are rare, though some students are unfamiliar with Batman. The writing prompt can vary; possible ideas include asking students to design a web page for a summer biomechanics camp for middle-school students (see [1, 4]), or name particular search tools (e.g., PubMed) and search terms that they might use to help an elderly relative learn what to expect from an anticipated hip replacement.

DISCUSSION

All of these activities foster intrinsic motivation for learning, and therefore are challenging for students to plagiarize. [1] In addition to fostering intrinsic motivation [1], these activities develop lifelong learning skills. In the Popular Press Assignment, students observe firsthand the inaccuracies inherent with news reporting of scientific results and the importance of critically reviewing such stories. Students may continue to seek source material throughout their lifelong learning. The TED-style talk assignment fosters good presentation preparation by requiring students to view a practice of their own talk, and then practice again. Students may continue to use this technique to prepare presentations in the workforce. Short writing exercises encourage both reflective thinking and connection to extracurricular activities. Additional activities, such as Journal Clubs can also help students connect classroom knowledge to other aspects of their lives; most students in a biomechanics journal club have discussed their journal club articles outside of the classroom. [6] These activities are also beneficial to the instructor; reading student responses can inform future classroom discussions.

In conclusion, these activities encourage students to connect their classroom experiences to their extracurricular lives. All can be implemented into existing courses with little disruption of the structure.

ACKNOWLEDGEMENTS

The author thanks her students for their willingness to try these activities in class.

GENERATING A SUBJECT-SPECIFIC MUSCULOSKELETAL MODEL OF THE KNEE USING MOTION CAPTURE DATA AND MEDICAL IMAGING

INTRODUCTION

Kinematics and load sharing of the knee joint are essential to understanding the mechanical etiology of knee disorders such as osteoarthritis. Tibiofemoral kinematics are controlled by a complex combination of soft tissue constraints and articular contact [1]. Kinematics and load sharing at the tibiofemoral joint can be predicted using computational models generated from medical imaging data [2]. Accounting for subject-specific geometry alters the lengths and moment arms of soft tissues crossing the joint, improving the prediction of *in vivo* joint contact forces compared to 'scaled' generic geometry [3]. However, creating musculoskeletal models from medical imaging data is time consuming and costly, thus limiting their uptake in a clinical setting. Furthermore, there is typically a 'disconnect' in model geometry between musculoskeletal models used to estimate muscle forces and finite element models used to estimate cartilage deformation.

Rigid-body musculoskeletal models typically ignore cartilage deformation due to its small strain compared to the large transformation of the joint segments. It is also common for rigid body models to treat the joint as a mechanical hinge, ignoring cartilage contact. Understanding the influence of body motion on cartilage stress and potential pathology requires deformable, finite element contact models [4]. However, finite element models developed from medical imaging data often rely on rigid-body models for estimates of loads and boundary conditions and only include anatomical information from the imaging field of view.

For computational models to have a clinical impact they must have a consistent representation of patient geometry. Therefore, we need to bridge the gap between rigid-body and finite element models. In addition, the models need to be rapidly generated from routine clinical data.

We present an integrated workflow to rapidly generate subject specific knee models from motion capture and small field-of-view imaging data, implemented in an open source software framework, the Musculoskeletal Atlas Project (MAP)[1] [5]. The workflow can generate models for rigid-body modelling, finite element simulations, and statistical modeling.

METHODS

Our workflow used statistical shape models to combine motion-capture data with MR images of the knee to generate subject specific bone and cartilage meshes 3D magnetic resonance images of the knee (slice thickness: 1.5 mm, pixel size: 0.55 × 0.55 mm, field of view: 12 × 12 cm) from 23 subjects in the supine position with the knee at full extension were segmented using a custom Matlab script. The boundaries of the bony segments (femur, tibia-fibula, and patella) and the articular cartilage surfaces were digitized. Reflective markers were placed on anatomical landmarks and recorded using a motion capture (mocap) system. Using a lower limb statistical shape model [6], marker data and segmented surfaces were fused using a custom MAP Client workflow. Whole-bone surface meshes were predicted from mocap marker locations, while parts of the meshes within the field of view of the MR image were fit to the segmented bone surfaces. Tendon and ligament attachment regions were digitized from a reference subject and embedded on the bone meshes as material points. Thus attachment regions were customized for each subject during mesh fitting. Articular cartilage thickness 'fields' were

[1] https://map-client.readthedocs.org/en/latest/

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

calculated from the distance between segmented bone surface and corresponding articular cartilage surfaces. Each field was sampled from a dense distribution of material points in the cartilage region on the bone mesh. For each material point, the distance between the closest segmented articular surface and bone surface points along the material point normal vector were considered as cartilage thickness. Segmented and ligamentous attachment zones were embedded on each bone mesh by projection and calculation of their mesh material coordinates. We performed principal component analysis (PCA) to assess variations [7] on the shape and cartilage thickness for all bone and cartilage layers of the knee. We assessed the accuracy of our predicted bone surface geometry by calculating the distance between the closest points on the fitted mesh and the segmented point clouds.

RESULTS

Twenty-three knee models were generated using the MAP-Client workflow, each taking ~22 minutes using a single CPU PC. Each model was composed of femur, tibia-fibula, and patella surface meshes (mean errors of 1.45±0.37, 1.82±0.32 and 1.54±0.78 mm, respectively; distribution in figure 1), tibiofemoral and patellofemoral cartilage thickness fields, and ligament insertion zones (Figure 2).

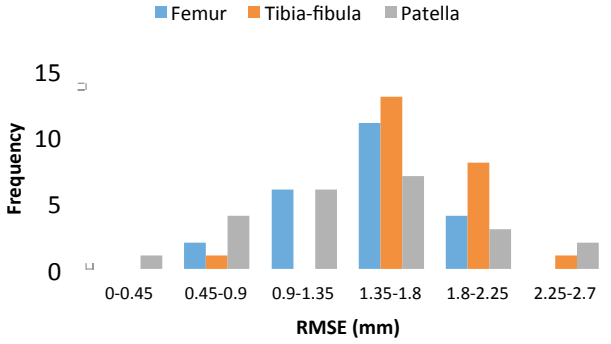

Figure 1: Local fitting error (RMSE) for all subjects.

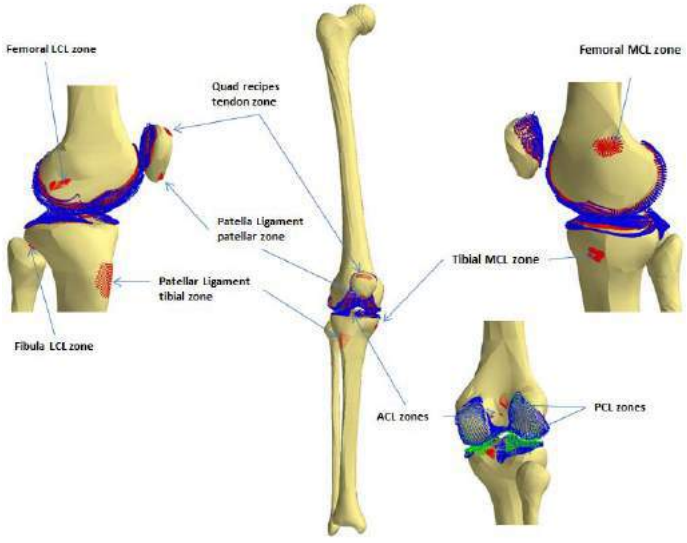

Figure 2: 3D knee model of subject # 1 developed from MRIs and motion capture data. Each model is composed of whole bone surface meshes, cartilage thickness fields (blue), attachment zones (red) and segmented point clouds (green).

DISCUSSION

The presented workflow generated subject-specific knee joint models with embedded muscle and ligament attachments as well as articular cartilage thickness. The models were used to train a statistical shape model of the knee joint for further predictive application. The bone meshes were generated with accuracy close to voxel size of the image. However, it remains to be seen whether these models can adequately predict kinematics and contact pressure in loaded and unloaded joints at various degrees of knee flexion. To achieve this, a deformable knee joint contact model has been developed, using our generated knee models. In addition, the generated models have been used to train a statistical shape model of the knee. This shape model will be used to efficiently generate complete knee model geometries from sparse data.

Our population-based models also have application to use in motion retraining procedures or evaluate of the implant designs and surgical procedures.

INTRODUCTION

Freeze-drying and desiccation are widely-applied processes to increase the shelf life of food products, enzymes, vaccines and cells. Lyoprotectants are chemicals in the presence of which proteins have been known to retain their stability and native conformation in the face of freezing and drying induced stresses. Disaccharides such as trehalose and sucrose are used as lyoprotectants. The sugar matrix formed by disaccharides, upon vitrification, surrounds the protein and slows down its degradation kinetics. Trehalose especially is favored due to its non-reducing nature, resistance to hydrolysis and high glass transition temperature.

It is very important for the lyoprotectant to be retained amorphous during freeze-drying or air drying. Crystallization or phase separation would render it completely ineffective [1]. Trehalose by itself crystallizes only after prolonged annealing. But recent studies have reported trehalose crystallization while freezing and drying in the presence of readily crystallizing solutes such as mannitol [2].

In the present study, we have explored the effects of desiccation on the physical form of trehalose and its ability to stabilize bovine serum albumin (BSA) during desiccation.

METHODS

Solutions were prepared gravimetrically with ultrapure water. Bovine serum albumin (MW 66.5 kDa, ≥99% Purity, Sigma-Aldrich, St. Louis, MO) and D-(+)- trehalose dihydrate (MW 378.33 kDa, 99.9% pure, Sigma-Aldrich, St. Louis, MO) were used as received.

Fourier Transform Infrared (FTIR) Spectroscopy was used to study the composition of the dried samples at different spatial locations. For analysis, solutions containing 20% (w/w) trehalose in water with an albumin to trehalose ratio of 1:3 (6.67% w/w albumin) were used. This resulted in an albumin mass concentration of 66.6 mg per ml of water.

100 nL of the experimental solution was sandwiched between two CaF2 windows. The windows were propped apart with shims and transferred to the infrared microscope attached to the FTIR spectrometer (Thermo-Nicolet Continuum equipped with a Mercury Cadmium Telluride detector, Thermo Electron, Waltham, MA) equipped with an FDCS 196 (Linkam Scientific Instruments Ltd., UK) freeze-drying cryostage. A constant vacuum of 40 Torr was applied inside the cryostage. During acquisition of spectra we chose a resolution of 4 cm^{-1}, and a total of 128 IR scans were averaged per spectrum in the 4000−930 cm^{-1} wavenumber range. The IR spectra were analyzed using OMNIC (Thermo-Nicolet) software.

RESULTS

Gradual removal of water by application of vacuum resulted in sample vitrification. This was reflected in the shifts in the peak locations of the amide II at 1550 cm^{-1} and the ν-(C-O) peak at 1150 cm^{-1} for BSA and trehalose, respectively. Light microscopy images of the sample clearly showed an interface that gradually advanced from the outer periphery to the center of the sample (Figure 1). It separated the sample into an inner vitrified zone and an outer zone, which was completely dry. IR spectra of the dry regions showed a significantly reduced signal intensity (low signal to noise ratio) due to the absence of water. Spectra obtained carefully from the interface clearly indicated crystallization of trehalose (Figure 2). This was evident from the bifurcation of the ν-(C-H) peak (2970-2910 cm^{-1}), and the ν-(C-O-C) peak (1010-975 cm^{-1}) [3].

Second derivative analysis of amide II peak revealed two peaks. The peak at 1526−1504 cm^{-1} was assigned to intermolecular and antiparallel β-sheet structures, while the band at 1560−1530 cm^{-1} was assigned to a combination of α-helix and β -sheet structures [4]. The % beta sheets defined as (Beta Sheet)/(Alpha Helix + Beta Sheet) was calculated by taking the ratio of the integrated areas of the two peaks obtained from Amide II, as mentioned above. It was observed that spectra obtained from the interface yielded considerably higher percent of beta sheets than the spectra taken from the vitrified interior (Figure 3).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The position of the amide II band can be used to determine the extent of association (hydrogen bonding) and the hydration level of BSA [5]. Amide II in the spectra taken from the vitrified interior was located at (1547-1548 cm^{-1}), which was comparable to the amide II location in spectra taken of the wet sample before desiccation. On the other hand, amide II in spectra obtained from the interface was located at much lower wavenumbers (1544-1545 cm^{-1}).

On fixing the aperture at a given location in the sample with continuous spectra acquisition, distinctive changes in the spectra were observed. The ν-(C-O) peak at 1150 cm^{-1} originates from vibrational stretching of the glycosidic linkage connecting the two glucose pyranose rings in trehalose. Therefore, this peak position was used to determine the flexibility of the glycosidic linkage of trehalose [6]. With the gradual approach of the interface and removal of water, the glycosidic peak shifted to lower wavenumbers until trehalose completely crystallized (Figure 4).

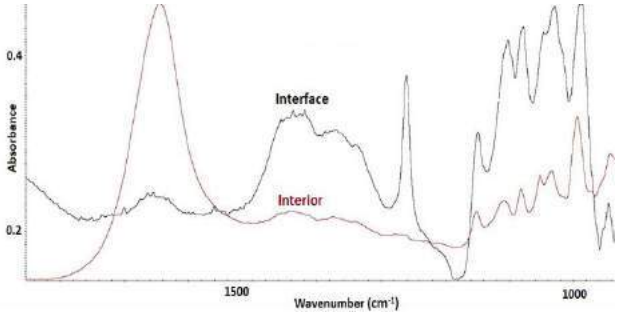

Figure 2: Fingerprint region of overlaid IR spectra obtained from the interface and the vitrified interior.

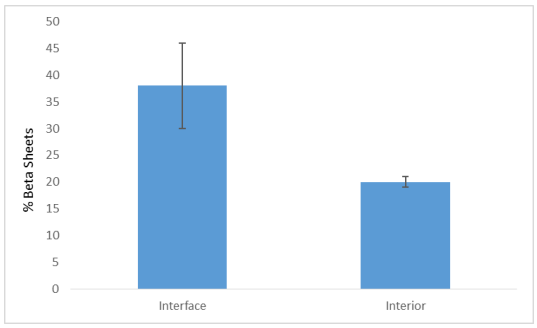

Figure 3: % intermolecular and antiparallel beta sheets calculated using second derivative of Amide II (n = 6).

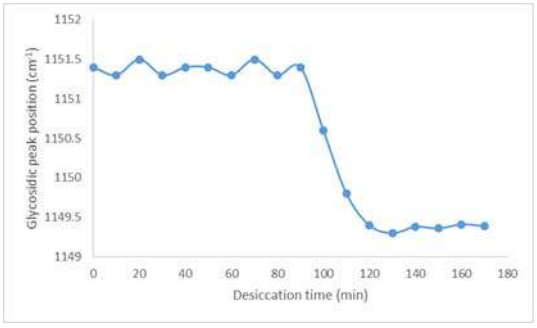

Figure 4: Trehalose glycosidic peak position at a fixed location in the sample as a function of drying time.

DISCUSSION

Desiccation of a solution containing trehalose and BSA resulted in a heterogeneous end product with portions of the sample being completely dry (crystallized trehalose) and others being vitrified (viscous matrix). Upon vitrification, there was a pronounced strengthening in inter-molecular association and local hydrogen bonding. On complete dehydration, these vitrified regions underwent trehalose crystallization. Removal of water resulted in "stiffening" of the trehalose molecule about its glycosidic linkage, followed by trehalose crystallization at the interface. BSA distributed near the interface where trehalose crystallization occurred, showed significantly lower levels of hydration and higher percentage of intermolecular and anti-parallel beta sheets than the BSA in the vitrified interior, clearly indicating unfolding of secondary structure and a possibility of aggregation.

INTRODUCTION

One of the hallmarks of biological tissues is their capability to grow and remodel in response to changes in their environment. It has been hypothesized that this occurs to maintain a certain mechanical homeostasis, yet there is no consensus as to which mechanical quantity is the driving factor behind tissue growth and remodeling [1]. A deeper knowledge of this mechanical homeostasis will greatly benefit the field of tissue engineering as well as our understanding of healthy and pathological tissue development.

Currently, we aim to study the mechanical tissue homeostasis in growing tissues by quantifying the evolution of stress and stretch is to be quantified. To this end, multiple tests on a single sample are required over time and, therefore, most of the common biomechanical tests such as biaxial tensile tests are not applicable. The presence of cell traction-induced prestretch further complicates testing [2,3].

In order to real-time estimate the mechanical properties of growing tissues, we developed a nondestructive mechanical test and inverse analysis method, which aims to overcome issues that are typically encountered when mechanically characterizing biological tissues, such as tissue thickness and prestretch.

METHODS

Circularly constrained tissue-engineered samples were exposed to a dynamic hydrostatic pressure to induce tissue growth and remodeling. Ultrasound (Esaote MyLab 70 with a 7.5 MHz linear transducer) is used to noninvasively visualize the samples during deformation (Figure 1). A custom image processing script was developed in Matlab to automatically obtain the tissue thickness, profile displacement, in-plane stretches and curvatures (Figure 1).

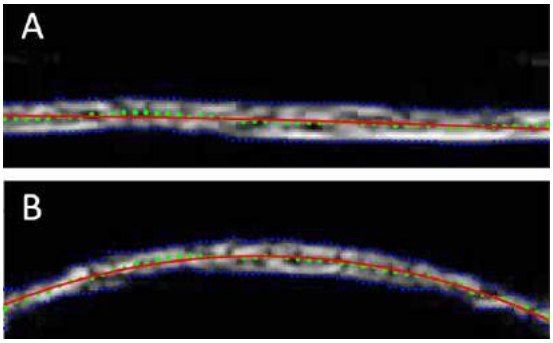

Figure 1: Ultrasound images and profile tracking of an engineered tissue at 0.0 kPa (A) and at 4.5 kPa (B).

The inverse analysis to estimate the material parameters comprises two steps. The first step is computationally cheap yet its accuracy is limited by the assumptions made in shell theory (i.e. limited thickness) and does not account for prestretch. Therefore, the parameter estimation of this step is used as an initial estimate in step 2, which is computationally costly yet provides a more accurate solution.

In the first step, classical shell theory is used to compute the in-plane principal tensions T_1 and T_2 (Figure 2A) directly from the experiment, as only pressure (p) and principal curvatures (κ_1 and κ_1) are required:

$$T_1 = \frac{p}{2\kappa_2}$$
$$T_2 = \frac{p}{\kappa_2}\left(1 - \frac{\kappa_1}{2\kappa_2}\right) \quad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

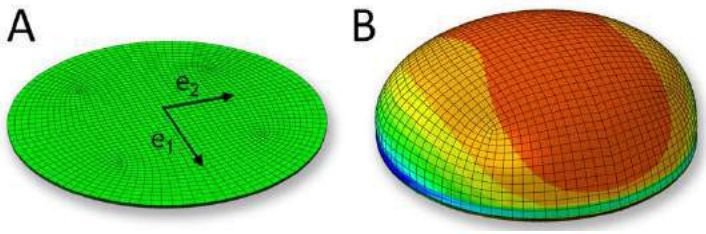

Figure 1 Finite element model of the bulge test before (A) and after (B) pressure application.

The in-plane tensions can also be obtained by calculating the integral of the in-plane Cauchy stress (σ_1 and σ_2) through the sample thickness t:

$$T_1^{\text{est}} = \int_{-t/2}^{t/2} \sigma_1(\lambda_1, \xi)\, dz$$
$$T_2^{\text{est}} = \int_{-t/2}^{t/2} \sigma_2(\lambda_2, \xi)\, dz \quad (2)$$

where $\lambda_{1,2}$ are the in-plane stretches as function of tissue depth [4] and ξ is a set of material parameters. A trust-region algorithm was used to minimize the difference between $T_{1,2}$ and $T_{1,2}^{est}$ and hence obtain an initial estimate of the material parameters.

In the second step, a full inverse finite element (FE) method is employed, where the estimate from the first step is used as initial estimate to dramatically decrease computational time. The experimental setup was mimicked with a FE model in Abaqus (Figure 2) using quadratic brick elements. The material parameters are estimated by minimizing the difference between the measured and simulated profile displacement. A fiber-reinforced material model was used, where the matrix contribution is modeled by a Neo-Hookean material and the fiber component by a Holzapfel model with either an isotropic or anisotropic fiber distribution [5,6].

In order to validate the proposed method, virtual experiments were generated by performing FE simulations (Figure 2) with different sample thicknesses (0.1, 0.2, 0.3, 0.4 and 0.5 mm) and prestretch magnitudes (1.0, 1.1, 1.2 and 1.3 at a thickness of 0.1 mm). The sample diameter was set at 10.0 mm and a pressure of 8.0 kPa was gradually applied while displacement at the outer nodes was suppressed.

RESULTS

The first step of the parameter estimation of the virtual experiments yielded parameter sets that were close to, yet did not match the input parameters exactly (Figure 3). For both the isotropic (not shown) and anisotropic samples, the analytical method over-estimated the stiffness of the material, which became more severe when a prestretch was introduced in the samples (Figure 3B).

By using these parameter sets as initial estimates in the full inverse FE method, the estimated parameters matched the input parameters exactly for all sample thicknesses and prestretches (Figure 3). When performing the full inverse FE method with a random initial estimate rather than with the outcomes from the analytical estimation, the number of increments until convergence increased two-fold, while in two cases convergence was not even reached.

DISCUSSION

Previous studies have commonly employed either analytical or inverse FE approaches to estimate the material parameters from a mechanical test. In the current method, we combined these two approaches to retain the advantages of both while eliminating their disadvantages. The analytical approach significantly reduces the computational cost and instability of the full inverse FE method by

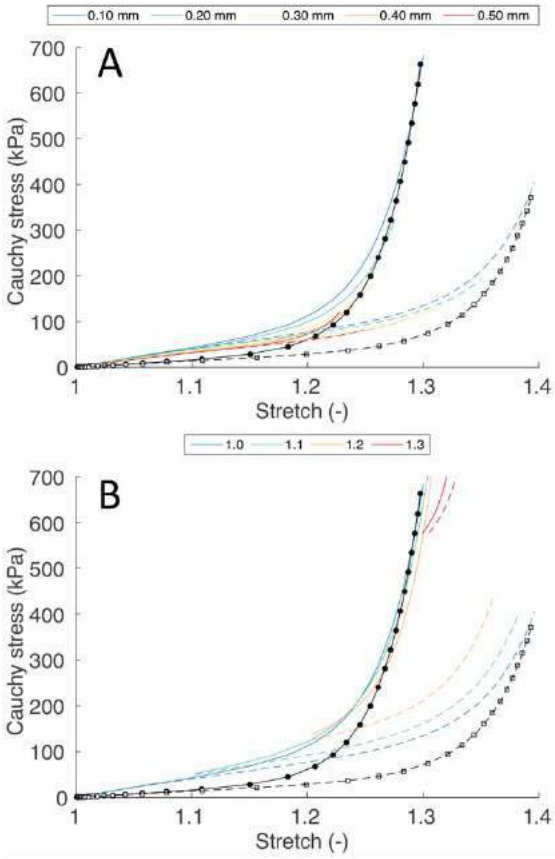

Figure 3: Estimated stress-stretch curves for anisotropic virtual simulations with various thicknesses (A) and prestretches (B). The circular and square markers indicate the true behavior in the fiber and cross-fiber direction, respectively; and the lines indicate the estimated behavior of the shell analysis (colored) and all finite element fits (in black, overlapping each other).

providing a rapid initial estimate; while the full inverse FE method is capable of a more accurate parameter estimation than the shell analysis on its own.

Currently, experiments are being performed to validate this method with rubber and tissue-engineered samples and compare the results with biaxial tensile tests. The tissue prestretch in tissue-engineered samples is still to be measured, yet is known to be stable over time [2].

In conclusion, we presented a method to characterize the mechanical behavior of isotropic and anisotropic planar tissues, which can be used to track the mechanical properties of growing tissues over time. A combination of experimental and inverse methods was employed that is nondestructive and is not limited by prestretch or excessive tissue thickness.

NON-NEWTONIAN VS. NUMERICAL RHEOLOGY: PRACTICAL IMPACT OF SHEAR-THINNING ON THE PREDICTION OF STABLE AND UNSTABLE FLOWS IN INTRACRANIAL ANEURYSMS

INTRODUCTION

Risk associated with treatment options of incidentally detected, asymptomatic, unruptured intracranial aneurysms can often exceed the natural risk of aneurysm rupture[1]. Image-based computational fluid dynamics (CFD) is arguably a robust tool to estimate hemodynamic forces, particularly variants of wall shear stress (WSS), and to investigate their role in initiation, growth, and rupture of intracranial aneurysms[2]. Although plausible correlations between various hemodynamic metrics and aneurysm rupture status have been derived from retrospective image-based CFD studies, criticism has been raised regarding the use of CFD in aneurysm rupture risk assessment[3], partially aimed towards CFD-modeling assumptions and uncertainties.

The effect of non-Newtonian vs. Newtonian rheology models on aneurysm CFD has been investigated in previous studies[4,5], but there exists no consensus regarding its impact. One challenge in interpreting these findings is that there is usually little context of what constitutes a 'significant' impact of rheology model on hemodynamic predictors of rupture status. Further, a key deficiency in the majority of these and other non-Newtonian aneurysm CFD studies is that they typically rely on low-order stabilized numerical schemes, previously termed normal-resolution (NR)[6], that introduce artificial numerical viscosity to avoid numerical instabilities. Therefore, it is difficult to distinguish between the effects of numerical viscosity versus non-Newtonian viscosity, and which of the two has a dominant effect on the hemodynamic indices.

The effects of added numerical viscosity have shown to inevitably predict laminar and stable flow patterns at the reported temporal and spatial resolutions[6]. This latter point is important, as recent CFD studies using a high-resolution (HR) solution strategy have highlighted the presence of "turbulent-like" flows that alter the hemodynamic stimuli. Since these HR simulations used Newtonian rheology for blood, it is not completely understood how the shear-thinning non-Newtonian rheological models would alter the "turbulent-like" flow instabilities. The aim of the present study was two-fold: 1) To investigate the effect of non-Newtonian rheology in intracranial aneurysms using an HR strategy with models previously shown to exhibit flow instabilities; and 2) To contextualize the practical impact of non-Newtonian rheology against artificial numerical viscosity introduced by common-place NR solution strategies.

METHODS

We focused on three previously published middle cerebral artery (MCA) aneurysm cases that exhibited flow patterns that were stable (case8), mildly unstable (case9), or highly unstable (case16)[7]. These models were meshed to have ~800,000 elements with 4 boundary layers. Pulsatile simulations were run with 5600 time-steps per cardiac cycle. We applied a cross-sectional average velocity of 0.37 m/s resulting in cycle-averaged flow rates of 1.11, 1.93, and 2.12 mL/s. A fully developed Womersley velocity profile was applied at the inlet, and zero pressure was specified at the outlets. A second-order accurate, minimally dissipative energy-preserving CFD solver was used with linear tetrahedral elements[7]. Newtonian blood viscosity and density were assumed to be 3.690 mPa-s and 1.056 g/cm^3, respectively. We then ran the exact same simulations using a modified-Cross viscosity model to simulate the shear-thinning properties that dominate blood's non-Newtonian behavior, using published parameters. To contextualize the effects of non-Newtonian rheology against solver strategy, we performed the same Newtonian simulations using the exact same meshes and a typical NR solver. To be consistent with the literature and our previous refinement study, for the NR simulations, we reduced the temporal resolution to 1400

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

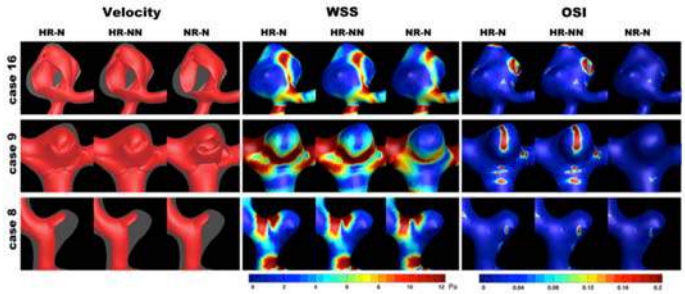

Figure 1: Qualitative impact of Newtonian (N) vs. non-Newtonian (NN) rheology and solution strategy on isosurfaces of time-averaged velocity, and surface distributions of WSS and OSI. HR refers to "high-resolution" and NR refers to "normal-resolution" CFD strategy.

time-steps/cycle (i.e $dt = 0.7ms$). We used a first-order accurate discretization in time to mimic the default and recommended settings in most widely used commercial CFD solvers. This solution strategy involves adding artificial numerical viscosity to stabilize the solution to account for numerical stability criteria not being met at this temporal resolution[8]. The impact of non-Newtonian rheology and solution strategy was qualitatively evaluated via volumetric maps of cycle-averaged velocity and shear rates, and surface maps of WSS magnitude, and oscillatory shear index (OSI). For quantitative evaluations we computed the following: dome-averaged WSS and dome-maximum WSS (MWSS), both normalized to parent artery WSS, and dome-averaged OSI.

RESULTS

Qualitative results of time-integrated quantities are shown in **Figure 1**. First focusing on velocity isosurfaces from Newtonian vs. non-Newtonian HR simulations (HR-N vs. HR-NN), we observe negligible visual differences for velocity for all cases. However, when comparing Newtonian HR vs. NR solutions (i.e., HR-N vs. NR-N) differences are evident, particularly for case 16 and 9, models that have previously been shown to exhibit high frequency fluctuations. Now looking at the qualitative WSS maps, it is evident that there are negligible differences between HR-N and HR-NN. However, differences are evident between HR-N and NR-N for cases 9 and 16, due to the different velocity pattern and shifted impingement region, respectively. Finally, for OSI, there again are negligible differences between HR-N and HR-NN. In contrast, OSI has been completely suppressed by the NR-N simulations. These qualitative results indicate that, for time-integrated quantities and frequency content, non-Newtonian rheology has *relatively* negligible impact on the hemodynamic environment when compared to solution strategy.

More practically, the quantitative impact of rheology vs. solution strategy on proposed scalar metrics of rupture status is shown in Figure 2. As seen from the plot, non-Newtonian rheology has relatively negligible impact on WSS, MWSS and OSI metrics when compared to solution strategy. WSS and MWSS scalars are noticeably reduced due to NR-N scheme, particularly for cases 9 and 8. Similar trends are observed for OSI; however, in this case the rank ordering of cases is altered by the NR-N approach, owing to the steep reductions in OSI for cases 9 and 16. These results indicate that quantitative scalar metrics are sensitive to solution strategy but not non-Newtonian rheology.

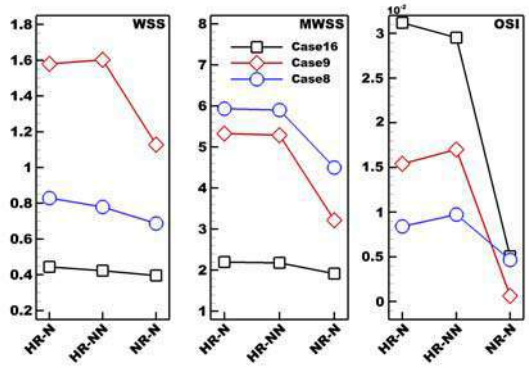

Figure 2: The quantitative impact of rheology and solution strategy on selected reduced hemodynamic indices, as indicated at the top right corner of each plot.

DISCUSSION

Based on our results, it seems evident that CFD solution strategy has greater impact on hemodynamic parameters compared to non-Newtonian rheology. To better understand why our conclusions differ from those of Xiang et al.[5], we note that those authors based their conclusions on normalizing WSS and viscosity values from the non-Newtonian simulations by the respective point-wise values from the Newtonian simulations, which they denoted WSS* and viscosity*, respectively. Indeed, as shown in Figure 3, results viewed in this way seem to suggest non-negligible overestimation of WSS (i.e., WSS* < 1) and similar overestimation of viscosity (i.e., viscosity* > 1), coinciding, as expected, with regions of low shear rate also highlighted in Figure 3. For example, focusing on the bleb-like region of case 16, marked in red circle, the Newtonian and non-Newtonian WSS values in this region were 0.45 Pa and 0.32 Pa, respectively, giving WSS* ~ 0.7 and suggesting a ~40% overestimation of WSS by the Newtonian simulation. However, one could argue that such differences in already-low WSS regions have questionable physiological or mechanobiological relevance.

INTRODUCTION

Cardiovascular diseases are burdening the healthcare systems and the costs are expected to rise in the years to come[1]. Although systemic risk factors have been associated with higher prevalence of cardiovascular diseases, it has been shown that blood flow induced abnormal wall shear stress is correlated with disease development at specific locations. However, in contrast to traditional engineering disciplines, geometries, boundary conditions, flow conditions, and fluid properties are not necessarily well defined in biomedical engineering because many studies are retrospective. Additionally, one often has to rely on medical image segmentation[2] that can involve a significant amount of manual labor that may introduce noise and variability. Verification and validation is therefore especially important and the U.S. Food and Drug Administration (FDA) therefore devised a benchmark of a *standard model of a generic medical device, consisting of a nozzle with a conical change in diameter at one end of the throat, and a sudden change at the other end*.

The first round of experiments and computational fluid dynamic (CFD) simulations showed an acceptable agreement for low and high Reynolds number flows; however, large discrepancies were found for the weakly transitional flows with a Reynolds number of 3500[3]. The aim of this study is therefore twofold: 1) To validate our open-source CFD solver *Oasis*[4] against experimental data, 2) Investigate the Reynolds number flows that showed the largest variability (Re = 3500).

METHODS

The computational domain was chosen to be -0.12 to 0.20 m, relative to the sudden expansion. Meshes were created using ICEM-CFD (Ansys Inc., Canonsburg, PA, USA) with 4 boundary layers. In total 4 meshes where produced consisting of 5, 10, 17 and 28 million tetrahedron cells, refereed to as 5M, 10M, 17M, and 28M, respectively. We chose to specify a constant node spacing to ensure that the meshes can be reproduced. The time step was kept fixed at $\Delta t = 10^{-5}$ s for all simulations which was based on setting the Courant number to ½ for the 28M mesh. The initial conditions were set to zero and we specified a parabolic inlet velocity profile, no-slip at the wall, and zero pressure at the outlet. CFD simulations were performed using our open-source finite element method-based solver, *Oasis*[4], where special care has been taken to ensure a second-order accurate temporal and spatial discretization so that the numerical solution of the Navier-Stokes equation is energy kinetic preserving and minimally dissipative[5].

We recorded the velocity as a function of time along the centerline in multiple points. We then decomposed the instantaneous velocity u_i in to the time averaged velocity $\bar{u}$ and the fluctuating velocity u', i.e., $u_i = \bar{u} + u'$. The power spectral density was computed based on $|u'|$ using Welch's method, Hann windowing function, and 8 segments with 50% overlap. The kinetic turbulence is defined as $k(t) = \frac{1}{2}(u'^2 + v'^2 + w'^2)$.

RESULTS

Figure 1 (top) shows the instantaneous velocity magnitude in a plane at time 1.0 s. Figure 1 (bottom) shows velocity traces, turbulent kinetic energy, and power spectral density from 1.0 - 1.1s in rows a, b, and c, respectively. Focusing now on sub-plot 1a and 1b, there are high frequent but low amplitude fluctuations in the 5M simulation, which are confirmed by 1c. Looking at plot 2a and 2b, just

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

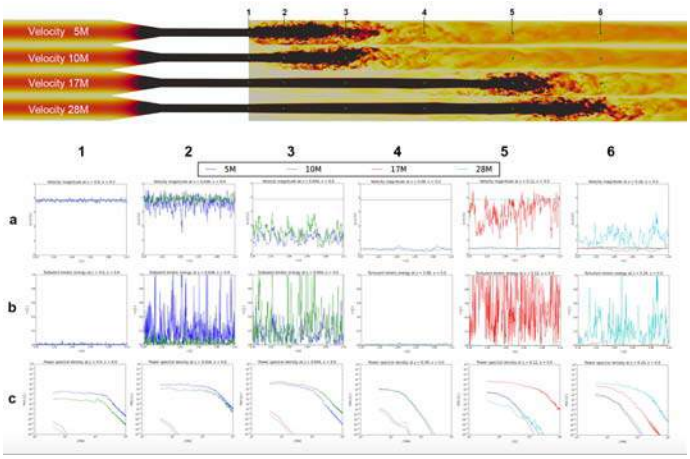

Figure 1: Top of the figure are instantaneous velocity fields at t = 1.0 s. The first row (a) is velocity traces, second (b) is the turbulent kinetic energy, and the last row (c) is the power spectral density of $|u'|$, all from 1.0 to 1.1 s.

downstream of the sudden expansion, the 5M and 10M simulations are clearly unstable, and the velocity at the centerline is high. In plot 2c, the 5M and 10M simulations show that there is a large amount of turbulent energy at a wide spectra as opposed to 17M and 28M. Further downstream in plot 3a we can see that the centerline velocity magnitude is reduced for 5M and that the fluctuations are less high frequent in 3b. This is reflected by 3c where the high frequency components contain slightly less energy, while 10M contains slightly more. On the other hand, 17 and 28M are almost unchanged. Further downstream in plots 4a and 4b both 5 and 10M develop equally; the centerline velocity is stable and contains only small and low frequent fluctuations. In plot 4c, the 17M and 28M simulations show that the instabilities are growing whereas the energy of the 5M and 10M flows are decreasing due to dissipation. Now, 10 diameters downstream of the sudden expansion, the 17M jet breaks down and can be viewed in plot 5a and 5b. The energy spectra plot 5c shows that the 28M simulation also have increased instabilities. In the last column of Figure 1 we can se that the centerline velocity of 5M, 10M, and 17M now have close to the same magnitude, although 17M have larger fluctuations. The jet in the 28M simulations has at this point started to break down, as shown in plot 6a, 6b, and 6c, and the power spectral density of the 17M simulations has also lost width.

DISCUSSION

One of the objectives of the study was to validate our solver against experimental data. However, our results would seem to suggest that we have falsified it instead. Before concluding firmly that our solver is erroneous, let's consider a few aspects of the benchmark case and our approach.

First of all, it is evident from Figure 1 (sub-plot 1c) that the two coarsest simulations predict an unstable flow developing in the inner pipe, whereas the fine simulations predict stable flow. This fundamental difference has a profound impact on the flow as the jet enters the large pipe. The coarse, already unstable, simulations break up immediately, whereas the fine simulations remain laminar for 10-15 diameters downstream before transition occurs. The coarse simulations are in acceptable agreement with the experiments, but what is correct?

To shed some light on our results we turn to linear stability theory. A linear stability analysis amounts to computing the leading eigenvalues of the linearized Navier-Stokes operator, as well as the corresponding eigenmodes, representing the perturbations to the laminar base flow. The growth rate (i.e., the eigenvalues) of the perturbations reveal whether or not the flow is linearly stable. A leading positive eigenvalue represents an unstable mode and a negative eigenvalue represents a stable mode. To perform the analysis on the FDA case we used the open source spectral element code Semtex (http://users.monash.edu.au/~bburn/semtex.html). Since we were mainly interested in whether or not the flow in the inner pipe should be unstable, we split the domain at position 1 in Figure 1, and performed two analyses, one for the inlet section and one for the outlet. The analyses reveal that all eigenvalues in the first pipe, diverging inlet section, and inner pipe are all negative, which indicates a stable and laminar region, whereas the outlet section contains positive eigenvalues and thus unstable eigenmodes. Having said that, linear stability theory doesn't provide definite proof and is often very conservative compared to experiments.

Now looking at the results from a numerical point of view, the first thing to notice is the presence of noise in the 5 and 10M simulations shown in plot 1c, which is absent at higher mesh resolutions. This noise represents deviation from the stable and symmetric 2D laminar solution, caused by an asymmetry in the tetrahedral mesh. A tetrahedral mesh will always introduce skewed elements and a completely symmetric mesh in a pipe is only possible to achieve using cylinder coordinates. Furthermore, a coarse mesh will lead to more asymmetry and noise than a fine mesh, which is what we observe. What is interesting, though, is that noise (and any other instability) will either grow or decay, depending on the Reynolds number. Reynolds actually addressed this himself for pipe flow and reported that transition varied between Re 1800 and 13,000 depending on how carefully the noise was controlled[6]. Conceptually, we can of course do the same by putting some physics back in CFD by breaking symmetry at the inlet. We therefore added white noise with magnitude 0.001m/s at the inlet velocity in the angular direction at the inlet of the 17M simulation. The noise grew in the inner pipe and gave phenotypically similar results that match those from the experiments and our coarse simulations. The amount of noise[7] that is needed to get an unstable flow typically scales with 1/Re. We therefore added the same noise also to the Re 500 and 6500 simulations using the 17M mesh. As expected, at these Reynolds numbers, the flows were completely unaffected by noise; the Re 500 case was still stable and breakdown of the Re 6500 jet was unchanged.

The impact of our study is debatable but can potentially explain the *discrepancies in transition*[8] between 'sterile' CFD and experiments that are inherently 'noisy', and offer a plausible explanation for the reported discrepancies in the original challenge for Re 3500.

INTRODUCTION

Mechanical forces play an important role in atherosclerotic plaque progression and rupture. Image-based computational models have been introduced to obtain plaque stress, strain and flow shear stress conditions to identify risk factors and mechanisms associated with plaque progression and rupture. For models constructed from in vivo data, residual stress defined as the stress in the blood vessel under no-load state remains to be an issue. Model construction normally starts from no-load state geometry, but in vivo blood vessels are under pressure, axially stretched, not in no-load state. Furthermore, blood vessel under no-load state is still not stress-free [1].

Researchers have proposed several modeling techniques to deal with the residual stress issue and have demonstrated that residual stress has a significant influence on stress/strain distribution under in vivo conditions. Using an opening angle method in human carotid model to quantifying residual stress, Delfino et al. claimed that the circumferential stress throughout the wall is much more uniform with residual stress was included [2]. Ohayon et al. showed that peak strain in the thin fibrous cap was overestimates by a factor of as much as four if residual stress was not considered [3]. In an in vivo MRI data study, Huang et al. indicated that stress-P_1 and strain-P_1 at the plaque cap increased 23.7% and 25.9%, respectively, under 10% axial stretch and patient-specific circumferential shrinkage [4]. Speelman et al. adopted a backward incremental method to account for the initial stress under in vivo state, and found abdominal aortic aneurysms (AAA) wall stresses as computed with initial stress considered were higher than without initial stress [5].

It should be noted that stress distribution in vivo concerns not only the classically-known opening angle, but also axial shrinkage and circumferential (radial) shrinkage. In this paper, a 3D computational model was constructed using a three-step procedure: a) wrap a stress-free circular sector to form a cylinder to obtain residual stress; b) pressurize the cylinder to in vivo pressure; c) stretch the cylinder axially to its "in vivo" state. Eight models were constructed to investigate the effects of opening angle, axial stretch and circumferential shrinkage on stress distribution under physiological conditions.

METHODS

Blood vessel geometry: the cross-section of the blood vessel under zero-stress state is induced from the ideal geometry in vivo state based on incompressibility of the material and the assumption that the circumference of the middle line of the vessel wall remains un-changed. The cross section of the blood vessel in vivo was assumed to be circular with inner diameter 3.343 mm and wall thickness 0.436 mm which were taken from human coronary IVUS data. The vessel in vivo length was 20 mm (pre-stretch length 18.18 mm, with 10% axial stretch gave 20 mm). The zero-stress state of the blood vessel is a circular sector with an opening angle 120 degree based on the real human coronary data in previous work of Kural et al. [6]. Figure 1 shows the geometries of the blood vessel at zero-stress state and no-load state.

Structure model and boundary conditions: 8 3D computational structure models were constructed with various combinations of wrapping, axial shrink/stretch and circumferential shrinkage/ pressurization (see Table 1). The blood pressure applied on the lumen is 70-130mmHg. The Mooney-Rivlin material model was used to describe the material properties of the blood vessel tissue. The strain energy density function is:

$$W = c_1(I_1 - 3) + c_2(I_2 - 3) + D_1 e^{\{D_2(I_1-3)-1\}} + \frac{K_1}{2K_2} e^{\{K_2(I_4-1)-1\}} \quad (1)$$

where I_1, I_2 are the first and second invariants of right Cauchy-Green

deformation tensor **C.** Parameter values in the Mooney-Rivlin model was selected to fit our b iaxial testing data using a human coronary sample. The parameter values were: c_1= -1312.9 kPa, c_2=114.7 kPa, D_1=629.7 kPa, D_2=2.0, K_1=35.9 kPa, K_2=23.5 in this work.

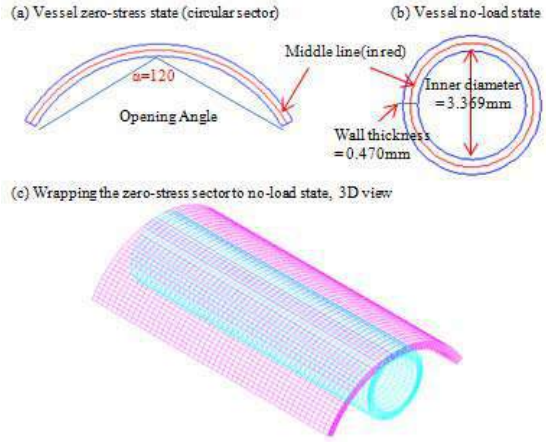

Figure 1: the geometries of th e cross-section of th e blood vessel under no-load state and in vivo state, and 3D geometry.

Table 1: 8 model cases and their descriptions.

Models	Description
M1(base)	With wrapping, 10% axial stretch, with radial shrinking
M2	With wrapping, 10% axial stretch, no radial shrinking
M3	With wrapping, no axial stretch, with radial shrinking
M4	With wrapping, no axial stretch, no radial shrinking
M5	Without wrapping, 10% axial stretch, with radial shrinking
M6	Without wrapping, 10% axial stretch, no radial shrinking
M7	Without wrapping, no axial stretch, with radial shrinking
M8	Without wrapping, no axial stretch, no radial shrinking

RESULTS

Circumferential shrinkage determination: Using trial-and-error method to find out when lumen and wall shrinkage are set to -0.78% and -2.3%, respectively, blood vessel will fully recovered into in vivo state after pressurized and 10% axial stretch.

Models comparison: Figure 2 and Figure 3 give the stress-P_1/strain-P_1 distribution of all 8 models on a given plane-cut at pressure=130mmHg. Table 2 lists the average values of stress-P_1 and strain-P_1 on the lumen at the same pressure condition for each model. According to table 2, the circumferential shrinkage does not have much influence on s tress/strain distributions, given the lumen/wall shrinkage is small in this study. The wrapping process will decrease the average stress on lumen because the lumen will be compressed and out-boundary will be stretched during the wrapping process. And if the axial stretch is not considered, stress-P_1 will decrease about 120% when wrapping process is involved and 28% when wrapping process is not involved.

Table 2: Average value of s tress-P_1/strain-P_1 on lumen at mi n pressure=70 mmHg of all 8 models are listed.

Model cases	Average Stress-P_1	Average Strain-P_1
M1(baseline)	66.87kPa	0.1051
M2	69.85kPa	0.1051
M3	-13.95kPa	0.0010
M4	-10.54kPa	0.0069
M5	148.6kPa	0.1051
M6	143.8kPa	0.1051
M7	108.0kPa	0.1094
M8	102.4kPa	0.1071

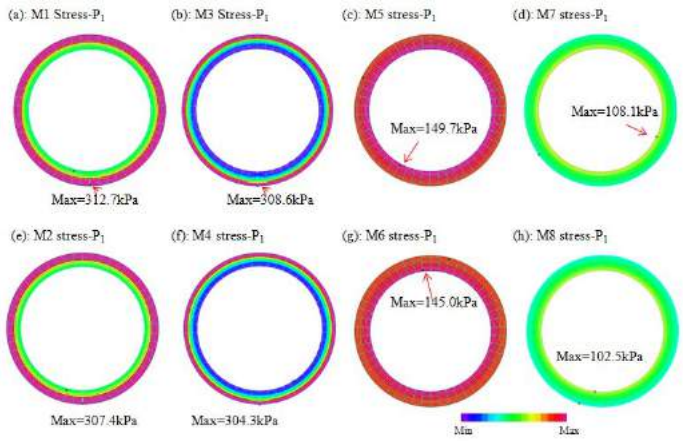

Figure 2: the plots of unsmoothed stress distribution of all models on a plane-cut at pressure=130 mmHg.

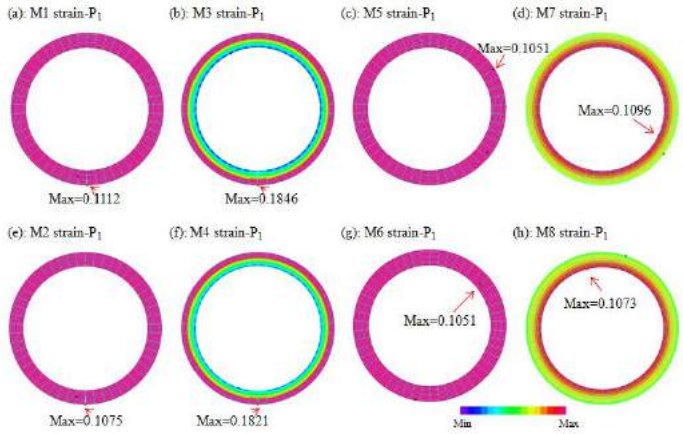

Figure 3: the plots of unsmoothed strain distribution of all models on a plane-cut at pressure=130mmHg

DISCUSSION

The stress distribution on l umen will be reduced when residual stress in blood vessel is taken into consideration while axial stretch will increase the stress distribution on the lumen. Circumferential shrinkage have little influence on stress/strain distribution given the lumen/wall shrinkage in this study is so small.

INTRODUCTION

Cryopreservation of stem cells is important to meet their ever-increasing demand by the burgeoning cell-based medicine. The conventional slow freezing for stem cell cryopreservation suffers from inevitable cell injury associated with ice formation and the vitrifi cation (i.e., no visible ice formation) approach is emerging as a new strategy for cell cryopreservation. A major challenge to cell vitrifi cation is intracellular ice formation (IIF, a lethal event to cells) induced by devitrifi cation (i.e., formation of visible ice in previously vitrified solution) during warming the vitrified cells at cryogenic temperature back to super-zero temperatures. Consequently, high and toxic concentrations of penetrating cryoprotectants (i.e., high CPAs, up to ≈8 M) and/or limited sample volumes (up to ≈2.5 μL) have been used to minimize IIF during vitrification. It is revealed that alginate hydrogel microencapsulation can effectively inhibit devitrifi cation during warming. The data show that if ice formation were minimized during cooling, IIF is negligible in alginate hydrogel microencapsulated cells during the entire cooling and warming procedure of vitrifi cation. This enables vitrifi cation of pluripotent and multipotent stem cells with up to ≈4 times lower concentration of penetrating CPAs (up to 2 M , low CPA) in up to ≈100 times larger sample volume (up to ≈250 μL, large volume).

METHODS

Cell encapsulation by microfluidics: To produce alginate hydrogel microcapsules, the core fluid consisting of 2% (w/v) purified sodium alginate and 0.5 M trehalose either with or without stem cells (cell density 2.5 × 106 cells ml^{-1}) was introduced into the non-planar microfluidic device. The presence of trehalose in the core fluid can pre-dehydrate the cells, which may help to suppress intracellular ice formation during cryopreservation. The shell fluid was prepared by dissolving purified sodium alginate (2%, w/v) in 0.25 M aqueous D-mannitol solution to achieve an osmolality of 280 mOsm determined by a micro osmometer (Advanced Instruments). The carrier oil emulsion was made using a method reported by us previously. All these solutions were introduced into the microfluidic device using syringe pumps (Harvard Apparatus). The flow rates of core, shell and carrier fluids were 75 μl, 75 μl, and 7 ml per hour, respectively.

Vitrification by plastic straw (PS): To minimize the contact time to the hypertonic vitrification solution of PS (VSP) and enhance the diffusion of 1,2-propanediol (PROH) into cells, the encapsulated or non-encapsulated cells were incubated in their medium with 2 M PROH for 30 min at 4 °C, and then transferred into VSP within 1 minute before vitrification. For vitrification, the sample-laden PS was plunged into liquid nitrogen and held for 3 min that is long enough to cool the sample to the temperature of liquid nitrogen. The samples were then warmed back to room temperature by taking the PS out of liquid nitrogen and plunging them into 1x PBS with 0.2 M trehalose at room temperature. The cell suspension post vitrification was one-step unloaded from the PS into cell culture medium with 5 μM of calcein AM and 5 μM of ethidium homodimer (Invitrogen) to stain live and dead cells, respectively. After incubation at 37 °C for 10 min, the live and dead cells stained green and red, respectively, were checked and counted under fluorescence microscopy to determine cell viability.

Cryomicroscopy study of inhibiting devitrification by alginate hydrogel microencapsulation: A total of 4 μl cell culture medium (either with or without 1.5 M PROH and 0.5 M trehalose) containing alginate hydrogel microcapsules was loaded into the sample crucible of the Linkam cryomicroscopy system and sandwiched with a coverslip (9 mm in diameter) to obtain a thin solution film for taking clear images during both cooling and warming. The samples were first cooled to -60 °C rapidly at 60 °C min-1, held for 2 min, warmed back at 60 °C min-1 to either -7 °C (without CPA) or -15 °C (with CPA), and held at the respective temperature for 20 min for annealing to observe ice formation/growth inside and outside the microcapsule under both polarized and phase contrast light microscopy.

RESULTS

The quantitative and qualitative data of cell viability of mouse embryonic stem cells (mESCs) and human adipose-derived stem cells

(hADSCs) post vitrification using the PS together with VSP are shown in Figures 1. These data show that most of the microencapsulated cells could survive while almost all non-encapsulated cells are killed during the vitrification procedure. They demonstrate that IIF induced by devitrification during warming kills most non-encapsulated cells and alginate hydrogel microencapsulation can effectively protects the encapsulated cells by inhibiting devitrification to minimize IIF. We have performed this experiment for many times (>10) and the results are consistent. However, the survived cells must be capable of functioning normally in order to ascertain the effectiveness of our low-CPA (2 M penetrating CPA) vitrification approach with the PS developed in this study. Therefore, further studies were performed to examine the functional properties including stemness and capability of guided (or directed or coaxed) differentiation of the mESCs and hADSCs before and after the low-CPA vitrification with PS.

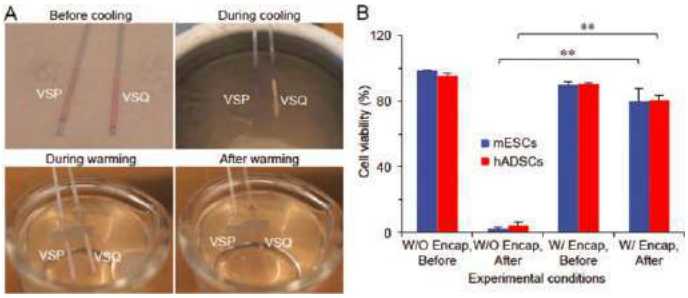

Figure 1: Low-CPA vitrification of stem cells with conventional plastic straw (PS). (A) Typical images showing the vitrification of VSP during cooling with PS and devitrification of the vitrified VSP during warming with the PS. VSP: Vitrification solution for PS which is the culture medium of mESCs or hADSCs with 2 M PROH (penetrating) and 1.3 M trehalose (non-penetrating). (B) Viability of mESCs and hADSCs either with (w/) or without (W/O) alginate hydrogel encapsulation (Encap) before and after vitrification in VSP. **: $p < 0.01$.

We further investigated the capacity of inhibiting devitrification by alginate hydrogel microencapsulation using cryomicroscopy. Figure 2 shows the size and morphology of visible ice crystals outside the alginate hydrogel microcapsule in the bulk solution, at -60 °C (at the end of cooling) and at -7 or -15 °C (during warming) of mESC medium either without (Figure 2A) or with (Figure 2B) CPA (1.5 M PROH and 0.5 M trehalose) under phase (grayscale) and polarized (color) light microscopy. The blue and pink regions in the polarized microscopy images indicate ice crystals of different crystallographic orientations. For medium without CPA, fine ice crystals (FICs, single asterisk) suddenly form around -20 °C during cooling and do not change much with further cooling to -60 °C. During warming, however, the FICs outside the microcapsules grow and merge into large ice crystals (LICs, double asterisks) at -7 °C (after 20 min annealing) with their boundaries being clearly visible as whitish curves in the phase image (Figure 2A). More importantly, the aforementioned growth of FICs into LICs during warming outside the microcapsules does not occur inside the alginate hydrogel microcapsule at all according to Figure 2B: no visible ice formation is observable inside the microcapsule throughout the entire cooling and warming procedure. This confirms the exceptional capability of alginate hydrogel microcapsules in inhibiting devitrification during warming, which should contribute to the high viability and intact functionality of the microencapsulated stem cells post vitrification using PS.

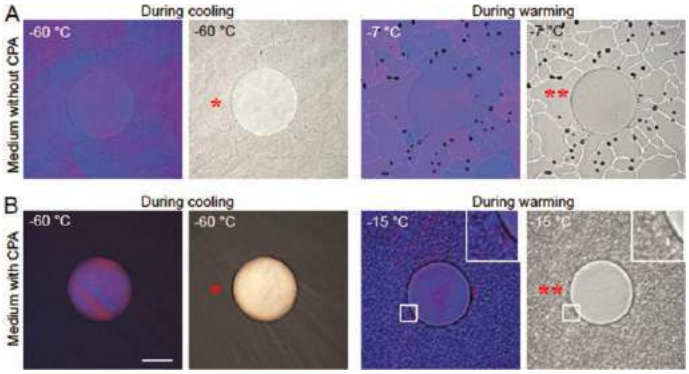

Figure 2: Alginate hydrogel microencapsulation inhibits devitrification during warming. Polarized (color) and phase contrast (grayscale) images at -60 °C at the end of cooling and at -7 and -15 °C during warming with annealing for 20 min for an alginate hydrogel microcapsule in mESC medium without (A) and with (B) CPA (1.5 M PROH and 0.5 M trehalose), respectively. No visible ice formation inside the microcapsule is observable during both cooling and warming while the fine ice crystals (FIC, *) outside the microcapsules in the bulk solution merge into large ice crystals (LIC, **) during warming. Scale bar: 100 µm.

DISCUSSION

In the alginate hydrogel microcapsule, by contrast, devitrification during warming is effectively inhibited. As a result, IIF in the microencapsulated cells is minimized during warming and a high cell viability post vitrification ensues. Of note, although the capability of alginate hydrogel microencapsulation in inhibiting devitrification may depend on the thermal profile of the device used for vitrification, it was verified over a wide range of warming rate between 100,000 °C/min and 2000 °C/min in this study. This is probably because the hydrogel network of the polymer can effectively dampen the movement of water molecules to prevent devitrification from occurring, due to its immense viscosity at subzero temperature and/or the polymer can bind to the surface of invisible nascent ice crystals to inhibit their growth. Further investigations are certainly needed to identify the exact mechanisms that are responsible for the exceptional capability of inhibiting devitrification by the alginate hydrogel microencapsulation.

INTRODUCTION

The prevention of premature failure in joint replacement devices has been an ongoing challenge for engineers and physicians. Joint replacement devices are now being designed with highly cross-linked polymers that improve wear resistance of the bearing surfaces to increase implant longevity [1]. In order to assess the wear performance of advanced materials, the amount and location of bearing wear must be accurately measured and analyzed. The conventional methods used to locate wear on the bearing surface include micro computed tomography (μCT) and coordinate measuring machines (CMMs) [2,3]. Imaging with μCT offers good spatial volume resolution, but is limited by cost, operator subjectivity and complexity [4]. Accuracy can be improved using CMMs, which provide highly-accurate three dimensional (3D) renderings of implant surfaces by using a stylus to probe thousands of points on the bearing surface. CMMs are limited by inter-operator error and manual operation [4, 5]. Therefore, a need exists to develop a novel imaging technique that accurately and automatically quantifies the topology of the bearing surface. This technology would help detect regions of abnormal wear and could shorten the time required for clinical studies of new implants.

A novel approach to measuring wear in joint replacement devices is to use a 3D structured-light scanner. A 3D structured-light scanner uses projected light patterns and cameras to quickly and accurately model the 3D geometry of physical objects. These imaging devices are typically used for quality control in manufacturing and reverse engineering of complex components. The objective of this research is to verify that wear on joint replacement devices can be detected using a 3D structured-light scanner. This study will first validate the accuracy of the 3D scanner and will then use the 3D scanner to detect wear in a hip resurfacing implant made with a highly cross-linked wear resistant polymer for the bearing surface.

METHODS

Setup and Calibration. The 3D structured-light scanning system consisted of two cameras, a projector, and a rotary table (LMI Technologies, Delta, Canada) (Fig. 1). The system was setup with two low-profile camera lenses angled at 45 degrees. A 4.5 x 3.5 x 3 cm space was calibrated using a 2 mm calibration card positioned at various angles relative to the two cameras. The card was imaged when it was tilted left, right, close, and far to the cameras. A total of 30-50 calibration grid positions were required for a successful calibration space. A rotary table was used to make scanning objects more efficient, since it was able to align meshes as it captured 360 degrees of scans at user-defined increments. The rotary table was calibrated by placing the 2 mm calibration card on the rotary table at an angle that approximated the object of interest (e.g. hip implant). For a successful alignment of the rotary table, the calibration card was visible through five pre-set rotations.

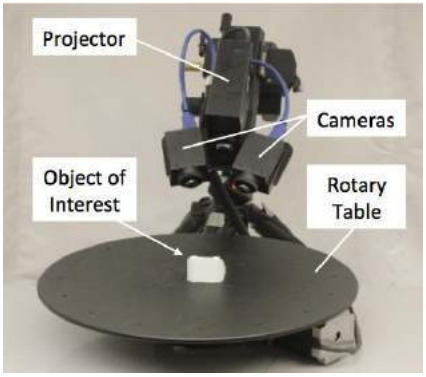

Figure 1: 3D Scanner Components

Verification. To verify the accuracy of the 3D scanner, a brass and opaque plastic reference block were machined with known recesses of 0.05, 0.04, 0.03, 0.02, and 0.01 mm (Fig. 2). Brass and plastic were chosen as materials because brass could be machined to

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

excellent tolerances and the plastic was chosen to mimic the natural low-light reflectance of the opaque polymers used in total joint replacements. Prior to scanning, each reference block was sprayed with a light coating of white foot powder. This further reduced the light reflectance and enhanced the quality of the scan. Each block was then scanned in 8 increments of 45 degrees. The software associated with the 3D scanner, FlexScan 3D, was then used to measure the recess depth. Three points were selected on the non-machined surface to create a plane. Points were then selected on the recessed surfaces and the shortest distance between these points and the plane was calculated. This procedure was repeated 8 times for each recessed surface, for a total of 40 measurements on each block. Error was measured as the difference between the predicted and known recess depth, divided by the known depth. Significant differences were determined with an ANOVA.

Figure 2: Reference Blocks

Application. After verifying accuracy, the 3D scanner was then used to measure wear in a highly-crosslinked ultra-high-molecular-weight polyethylene liner that was used as a bearing surface in a hip resurfacing implant for canines (Figure 3A). These liners had a thickness of 1.5mm ± 0.05mm. For this project, two plastic liners were

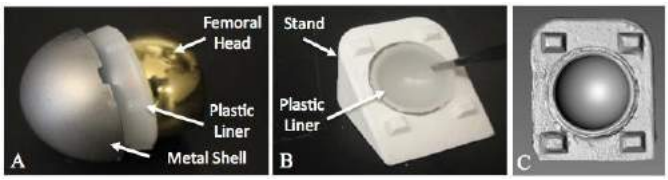

Figure 3: Hip Implant. A) Implant components. B) Alignment stand for plastic liner. C) 3D scan of stand and liner.

subjected to 1,100,000 cycles of loading in a canine hip simulator. The hip simulator is a single axis orbital bearing machine designed to reproduce canine hip kinematics (peak load = 211 N, 2 Hz). The plastic liners received 3D scans before and after cyclic loading. These scans included filling and smoothing algorithms, and took approximately 25 minutes.

In order to have a repeatable frame of reference to measure wear between the two time points, the plastic liner was inserted on a custom stand fabricated with a 3D printer (Fig. 3B). The stand and liner were sprayed with white powder-based spray and scanned at 18 increments of 20 degrees. Using FlexScan 3D, the post-wear image was first aligned to the pre-wear image and then the stand's 3D geometry was selected to refine image registration. The software merged the two images, with the average deviation of the stand surface between scans being 0.038 mm (Figure 3C). It's important to note that the stand was aligned independently of the plastic liner. Therefore, any deviation in the implant liner surface between scans was due to wear. Average differences in wear for the liner surface was measured, as well as average differences in wear for the central region of the liner.

RESULTS

The scanner was able to detect 40 μm changes in the surface topology of the brass and plastic reference blocks with an error less than 13% and 10%, respectively (Fig 4A). Error increased for smaller recesses ($p=0.004$), and this error exceeded 40% when measuring indents of 20 μm or below. The scanner was more accurate when scanning brass than plastic ($p<0.01$).

The central region of the canine hip liner had 30% more wear than the average wear rate of the liner (Fig. 4B, Fig. 5). The greatest liner wear depth was 0.3 mm, which was ~20% of the liner thickness.

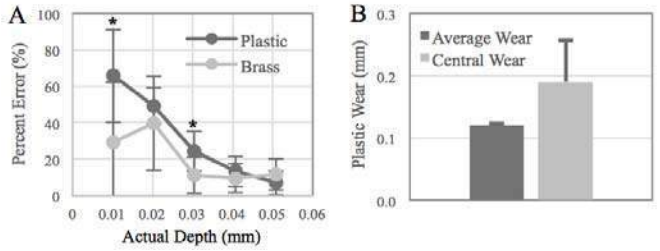

Figure 4: 3D scanner results. A) Accuracy (*= significant difference between brass and plastic). B) Wear of hip implants.

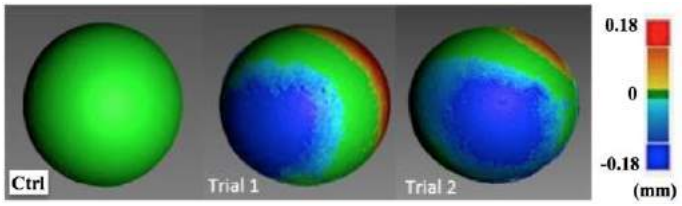

Figure 5: Wear observed in a non-tested implant (Ctrl) compared to implants that receive one-million loading cycles (Trial 1-2)

DISCUSSION

Wear in canine hip liners was successfully imaged and measured using a 3D structured-light scanner. Wear was localized near the central region of the plastic liner, and had a depth of penetration less than 20% of the implant thickness. To our knowledge, this is the first time a 3D structured-light scanner has been used to measure wear in a joint replacement device.

A structured-light scanner has advantages as an imaging technique for wear measurement. First, the structured light scanner can detect changes of 30 μm or more with reasonable error. The accuracy reported for μCT and CMM is 300 μm and 190 μm, respectively [4]. Second, the 3D scanner is relatively fast and automated, taking under 30 minutes to create a 3D representation of a liner. CMMs take roughly the same amount of time [5], but the process requires operator intervention, which is less efficient and reduces measurement objectivity. Third, the 3D scanner is cost-effective relative to microCT and high-end CMM instruments.

A limitation of 3D structured-light scanners is the need to apply powder-based spray during scanning, as this powder can potentially interfere with weight measurements and wear testing. Therefore, it is recommended that powder be applied only after gravimetric testing is completed. The accuracy of the method is also dependent on a repeatable protocol to remove and insert the liner into the stand (Fig. 3B). For this study, a metal shell component (Fig 3A) was cemented into the stand to improve the repeatability of this process.

This study found that structured-light scanners can be used to assess wear in joint replacement devices. These imaging systems can be used to identify abnormal wear patterns and assist the design of durable devices that enhance implant longevity.

INTRODUCTION

Fistulas are a pathological tunnel between two organs within the body [1]. Fistulas most commonly occur between the gastrointestinal tract or biliary system and the skin or between two abdominal cavities, for instance the bowel and bladder [2]. The exact prevalence of fistulas in the US populations is unknown due to its under-reporting, however, enterocutaneous fistulas effect approximately 2% of all bowel surgeries [2]. Unrepaired fistulas lead to significant morbidity and are associated with prolonged hospitalization and costs. Sepsis may accompany gastrocutaneous fistulas with a mortality rate as high as 85% [3]. As a function of the challenges, morbidity, potential mortality and costs associated with fistulas the medical field continues to search for better solutions to this challenging clinical dilemma.

Fistulas are difficult to repair and the only current method is invasive surgery that removes some of the surrounding and potentially otherwise healthy tissue [4]. Some patients are not surgical candidates because of other health complications [5].

Mechanical closure methods include clips and plugs. Comprehensive studies on the application of clips are extremely limited and a vast majority of the available literature is reliant on individual case studies [6]. Approximately 50% of all clips fail due to poor clip position, early detachment and densely epithelialized tissue [6]. Plugs are the newest advancement in fistula repair. They can be made of synthetic silicones or bioabsorbable xenografts. They are currently being used exclusively for anal fistulas. Despite the recent innovation, plug extrusion occurs in between 10-41% of cases and only heals 49% of fistulas in twelve months [7, 8].

Various forms of glues have been explored as a non-surgical closure method with limited success to date; typically because of the inability to maintain a precise location once injected [9]. Before curing, one glue, cyanoacrylate with a low viscosity, easily flows through the catheter for placement of an occlusive plug, but unfortunately continues to flow once within the fistula of interest potentially causing occlusion downstream. Decreasing the cure time is possible with additives; however, additives often clog the injection catheter causing it to stick to the delivery device or cause premature obstruction of the fistulous tract leaving an enteric hole inadequately treated to prevent recurrence of the fistula. In summary, closure precision remains especially important in the eradication of fistulas.

Considering the poor treatment options available for fistulas, it is imperative to create a device that is minimally invasive and offers better quality of life for these patients. The preliminary design work presented here hopes to form the foundation for a more effective fistula occlusion technology. The aims of this project are to create a method to control placement of ferromagnetic glue deployed from a catheter.

METHODS

The goal of this specific portion of the fistula occlusion device was to develop a prototype that could move magnetically responsive material. In future studies, the steel balls, used here for simplicity, will be replaced with ferromagnetic glue.

Prototypes were built on 20 cm of the distal end of Angiodynamics Soft-Vu Berenstein 5F catheters. This would allow for the eventual deployment of the electromagnetic glue through the 0.97 mm lumen. The solenoid was built on the last 2 cm of the catheter. To create the core of the solenoid alternating layers of iron paint (Modern Metals Metalic Oxidizing Iron Paint, 49.97% wt) and iron wire (0.35mm) were applied. Three types of each experimental group were built according to the specifications shown in Table 1. These materials were chosen from previous prototype iterations utilizing the Taguchi method.

After drying, an external coil was constructed using coated copper wire with a diameter of 0.33 mm wrapped tightly approximately 50 times around the iron core. This coil was connected to the power supply in order to create the magnetic field.

To verify the presence of a magnetic field, each prototype was set in a slim track and secured. A 1.5 mm steel ball was placed 3 mm away from the distal end of the solenoid and the power supply was turned on. The current through the external coil was increased until the magnetic field pulled the steel ball towards the solenoid.

RESULTS

Nine prototypes (three of each construction) were built using the described method. Each prototype moved the ball within the limits of the power supply, no more than 10A of current. Preliminary results indicate that solenoids on this scale can be used to move magnetically reactive materials. Initial results indicate that this design may provide a viable control mechanism for the deployment of electromagnetic glue. It was expected that there would be a relationship between the iron core weight and the required current to move the ball. However, the results were inconsistent between trials and prototype groups indicating an issue with either alignment, resolution of the power supply or variability in the construction. Reliability needs to be addressed in the experimental set up before making sweeping conclusions. This demonstrates that magnetic force can be achieved at this scale. However, it is yet to be determined if that magnetic force is sufficient for the application.

DISCUSSION

This work represents the beginning of a body of work to develop a device to repair fistulas. This study was limited by the resolution of the available power supply and the ability to control the alignment of each prototype into the track. Researchers could also not control for friction within the track, although all attempts were made to reduce friction as much as possible. Further steps in the development of this device include quantifying the magnetic force supplied by each prototype to determine the most appropriate for the application. This will likely be done in an inverted scenario so friction can be neglected and the force opposing the magnetic field will be gravity.

Additionally, the electromagnetic glue will need to be characterized. This is important so that the flow patterns are understood when being deployed. Although previous research indicates the applicability of fibrin glue to this scenario, it is unknown if the addition of ferrous particles will alter its composition too much. Evaluating different glue ratios in combination with solenoid catheters will help to fine-tune the design parameters of both components.

The method of creating a solenoid-catheter described here provides a promising foundation for future iterations of the device. Further verification is needed before conclusions can be drawn regarding the usefulness of the design.

CHARACTERIZING A NOVEL EX-VIVO ANIMAL KNEE MODEL: ACL RUPTURE AND MENISCUS COMPRESSIVE STRENGTH

Nicole L. Zaino, Mark J. Hedgeland, Laurel Kuxhaus, Arthur J. Michalek

Mechanical and Aeronautical Engineering
Department
Clarkson University
Potsdam, NY, USA

INTRODUCTION

The knee is a complex part of the body, function of which is critical to quality of life, but is prone to injury, with 200,000 anterior cruciate ligament (ACL) injuries annually [1]. Accurate knee models assist surgeons in practicing new reconstruction techniques, and are crucial to the advancement of technology and rehabilitation. Animal knee models are often suboptimally sized or have differently-shaped menisci. Many models excel in one aspect compared to the human knee, but not all, thus an improved ex-vivo animal model is needed that better mimics the human knee in all aspects. We evaluated the cervine (white-tailed deer) knee with the expectation that it would be a closer model to the human knee compared to current animal models, due to similar body weight. To evaluate the cervine knee, we measured its range of motion, cross-sectional area and rupture strength of the ACL, bony morphometry, and compressive properties of the meniscus.

METHODS

Twelve fresh frozen left hind legs (5 male, 7 female, 2.7±0.5 years old) from white tailed deer were obtained (Nolt's Custom Meat Cutting, Lowville, NY, and Twiss' Custom Meat Cutting, Potsdam, NY). Passive range of motion was measured before transecting the joint capsule, medial and lateral collateral ligaments, and posterior cruciate ligament after meniscus removal. The femur and tibia were then potted in Bondo (Auto Body Filler, 3M, St. Paul, MN). Throughout testing specimens were kept moist with 0.159 M saline.

The cross-sectional area of the ACL was measured using a dental impression material (Jeltrate Plus, Dentsply, York, PA). The knee was held at 140° (included joint angle) under approximately 8 N of tension during the measurement (Figure 1A). A positive cast was transected at mid-length and photographed twice next to a ruler with a microscope camera (AmScope Inc., Irvine, CA). Images were analyzed using ImageJ (Figure 1B). Our validation showed that this technique was accurate with a random error of ±4%, and a +3% bias.

The rupture strength of the ACL was measured in a hydraulic axial load frame using a custom fixture (MTS 809 Axial/Torsion Test System, MTS Systems Corp., Eden Prairie, MN). Force and displacement data were collected at 100Hz. The knees were secured at an included joint angle of 140°, then distracted in displacement control at a constant rate of 3.33mm/s until failure following pre-conditioning (10 cycles, 5-7mm amplitude, at 20mm/minutes).

Peak stress was computed for the midsubstance failure specimens. Differences between male and female specimens were compared using two-tailed t-tests. Median ACL rupture strength was assessed using a Kaplan-Meier survival estimator in order to account for specimens which did not fail in midsubstance. Following ACL rupture the articulating surfaces were photographed next to a ruler. Morphometry was measured using ImageJ: femoral bicondylar width, intercondylar notch width, intercondylar notch height, (Figure 1C) and tibial plateau slope angles (medial and lateral).

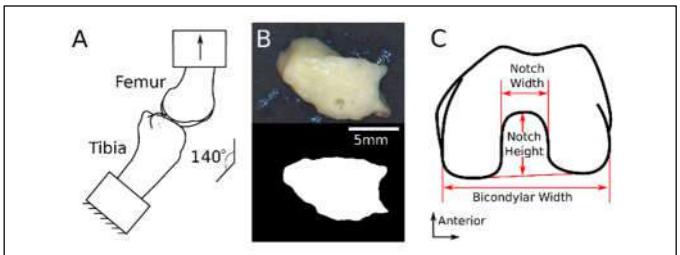

Figure 1: (A) ACL rupture test (B) cross-sectional area and imaging (C) tibial morphometry

To further validate the deer as an ex-vivo knee model, the structure and function of the menisci were analyzed. Cryosections (40µm thick, Microm HM560, ThermoScientific, Kalamazoo, MI)) from the central portion of the axial-radial plane, mounted on coated glass slides, (MAS-GP, Matasunami Glass, Osaka, Japan) were counterstained with Sararanin O (Sigma-Aldrich, St. Louis, MO) to visualize proteoglycans and Methyl Blue (Sigma-Aldrich, St. Louis, MO) to visualize collagen. Brightfield imaging was performed using an inverted microscope (Olympus IMT2, Olympus Scientific, Waltham, MA) using a 2x objective and digital camera.

Unconfined compression tests were performed on ten specimens in a custom-built axial testing machine. 5mm cylindrical plugs of tissue were prepared (2.5mm thick) and compressed between 100 grit sandpaper and a smooth glass plate. Stress-relaxation tests (3-28% strain) were performed at 2%/s and held for 180 seconds. Reaction forces were measured at 100 Hz.

RESULTS

The cervine knee appears similar to the human knee (Figure 2A,B). The femur and tibia are principally connected with anterior and posterior cruciate ligaments, and both medial and lateral collateral ligaments. The joint capsule contains two menisci (Figure 2C) and a patella. Visually, the ACL shows clear evidence of a double-bundle structure. The range of motion was 147°±10° without a significant difference between male and female specimens ($p=0.26$). Mean measured ACL cross-sectional area was 44.75±18.3mm^2, slightly smaller than reported human ACL measurements. Most measured morphometry parameters were greatly similar between deer and humans. The medial and lateral tibial slope measurements were closer to human values than other quadrupeds. There were no significant differences found in the measured bony parameters between our male and female specimens ($p>0.19$ for all parameters).

The cross-section of the cervine meniscus appears similar to the human meniscus. (Figure 2D) There are large collagen fiber bundles in the axial, radial, and circumferential directions, with high density in the peripheral "red zone". Proteoglycan density is greatest in the "white zone". Equilibrium compressive modulus was 70 ±25kPa.

All specimens failed during the rupture test at a stress of 50±18MPa (Table 1). ACL rupture occurred in 5 specimens through tearing at mid-substance, which was evident mechanically as a linear increase in reaction force with increasing joint extraction followed by a pair of sudden force drops indicating failure of the two ACL bundles (Figure 2E). The remainder experienced avulsion fractures, including 1 tibial avulsion and 6 Salter-Harris type fractures across the distal femoral epiphyseal plate [2]. All but one of these specimens also had visible evidence of partial tearing of the posterior bundle of the ACL.

DISCUSSION

The goal of this study was to identify an optimal ex-vivo animal model for ACL rupture and repair research. An improved ex-vivo model will offer a testing platform for orthopaedic implants, a training analogue for surgeons, and will accelerate translation of results from the laboratory to the clinic.

The deer knees had a high degree of morphological similarity to those of humans. In cervine (as with other quadrupeds) the patellar trochlea is deeper and extends further proximally up the femur than in humans. White-tailed deer do not have a fibula, so the lateral collateral ligament is attached directly to the tibia. Among the currently-used ex-vivo knee models some have a full fibula, some have no fibula, and some have a vestigial proximal fibula element. Tibial plateau slope and notch are commonly associated with ACL rupture risk in humans which is important when finding a valid animal model [10].

Table 1: Deer, human[3,4,5], sheep[6,7], & pig[8,9] comparison

	Bicondylar Width (mm)	Notch Width (mm)	Notch Height (mm)	Lateral tibial slope (deg)	Medial tibial slope (deg)	Rupture Force (N)
Deer	53.5 ±3	14.7 ±2.5	16 ±2.5	17.6 ±4.7	16.7 ±2.1	2150 ±397
Human	66 ±5	19.2 ±3.4	31.4 ±3.6	7.8 ±3.9	6.2 ±3.7	2160 ±157
Sheep	47.2 ±1.8	10.8 ±1.2	13.9 ±3.4	--	--	605 ±256
Pig	42.9 ±2.4	8.5 ±1.2	--	34.9 ±4.4	29.5 ±4.5	1720 ±196

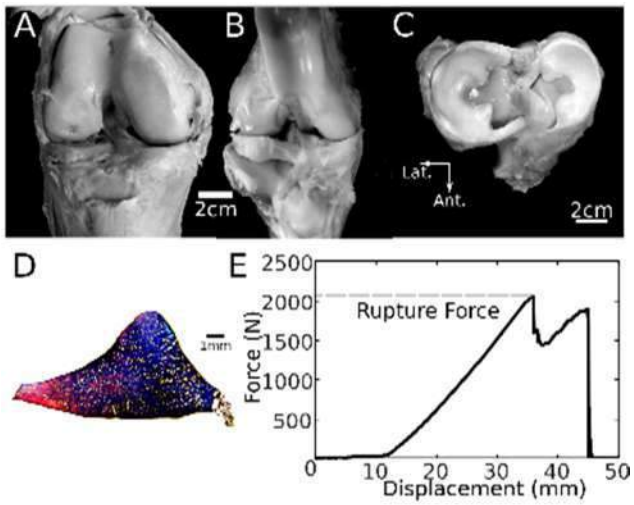

Figure 2: Comparison of anterior aspects of intact (A) human and (B) deer knees. (C) Superior view of cervine tibial plateau with menisci. (D) Meniscus cross-section counterstained with Safranin O. and Methyl Blue. (E) Typical force displacement trace for ACL rupture test showing two rupturing events

Similarities in morphology extend to the soft tissues. ACL structure, cross section, and rupture strength are comparable to those in humans, as are meniscus geometry, composition, and compressive stiffness. The specimens in this study were wild so exact ages could not be determined with high certainty. The use of these skeletally immature specimens accounts for the Salter-Harris fractures during the ACL rupture testing [2]. Overall, our results suggest the white-tailed deer to be an optimal ex-vivo animal model of the human knee.

COMPARISON OF COMPUTED TOMOGRAPHY IMAGING MEASUREMENTS TO CREATED INJURIES UNDER UBB LOADING CONDITIONS

Nathanael P. Kuo, Christopher J. Dooley, Constantine K. Demetropoulos, Kyle A. Ott, Andrew C. Merkle

Research and Exploratory Development Department
Johns Hopkins University Applied Physics Laboratory
Laurel, Maryland, USA

INTRODUCTION

Improvised explosive devices have accounted for a significant number of injuries over the last decade. Military vehicles have evolved to become more resistant to these types of attacks, but the massive amount of energy imparted during under-body blast (UBB) events still results in debilitating injuries to vehicle occupants. These events are characterized by short duration, high amplitude accelerative loading delivered through the vehicle structure, both directly to the occupants and through the seat system [1]. This type of loading may generate a range of injuries, including spinal injuries concentrated in the thoracolumbar junction and the lumbar spine [2-5]. Spinal injuries are of particular concern due to their debilitating nature and long term effects.

Prior biomechanics research on spinal injury has primarily focused on component level testing. Classically, bone quality measurements, such as quantitative computed tomography (qCT) and dual-energy x-ray absorptiometry (DEXA), have been used as specimen selection criteria to ensure that a tested postmortem human surrogate (PMHS) specimen falls within a representative range based on medical data. Studies have investigated individual vertebral bodies [6], three vertebra segments [7], and larger functional units [8]. These studies highlight mechanical parameters and mechanisms that are predictive of vertebral body failure. Yet, it is unclear if the current bone quality measurements sufficiently predict localized fracture risk.

This study leverages a unique data set to investigate if pre-test computed tomography (CT) imaging identifies individual vertebral bodies or functional segments that are at an increased risk for compression fracture under high rate vertical loading.

METHODS

For this study, specimen variability was minimized through tight restrictions on anthropometry and bone quality. The targeted specimen was between 18 and 80 years of age with anthropometry within one standard deviation of the 50th percentile military male and a DEXA Lumbar T-score between -1.0 and 2.5. The average specimen was 72 ± 3 years of age, weighed 82.5 ± 10.6 kg, and had a total stature of 177.6 ± 6.4 cm. Average specimen body mass index was 26.2 ± 3.1 and Lumbar T-Score was 1.2 ± 0.1. Specimens with prior traumatic injuries to the spine, skull, or long bones were excluded from the study, as were specimens with spinal degeneration such as bridging osteophytes and degenerative disc disease.

Twelve whole body PMHS specimens were tested on the Vertically Accelerated Load Transfer System (VALTS) at the Johns Hopkins University Applied Physics Laboratory. The VALTS is a custom designed, pneumatically driven system constructed to recreate UBB conditions, which are characterized by their short duration and high velocity. Tests included in this data set were conducted at different input conditions using a rigid floor and seat (**Table 1**). Specimens 6, 8, 9 and 12 had personal protective equipment, including a vest and helmet. Specimens 11-12 were tested with a pad system installed on the rigid seat.

Whole body CT scans were taken prior to testing with a slice thickness of 0.625 mm. Individual vertebrae in the pre-test CT were analyzed to determine average Hounsfield unit (HU) intensities at three levels using an analysis technique adopted from Schrieber et al. [9]. The three elliptical regions of interests (ROI) per vertebral body were manually delineated on axial slices of the CT scan: one immediately inferior to the superior endplate, one in the middle of the vertebral body, and one immediately superior to the inferior endplate (**Figure 1**). Each ROI was drawn as large as possible while avoiding

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

cortical bone, and the mean intensities were calculated for each ROI. All three mean intensities were then averaged to compute a final mean HU intensity for each vertebral body. We conducted the above analysis using FIJI [10], which is a distribution of the freeware image analysis software known as ImageJ [11].

RESULTS

Vertebrae L5 to T5 were analyzed to compute mean body HU intensities from the CT scans of the twelve specimens (**Table 2**). After each specimen was tested, a licensed medical examiner evaluated each PMHS specimen for vertebral body fractures (bolded and boxed values) by both CT and anatomical dissection.

A one-tailed t-test was also conducted between the mean HU intensities of the six fractured vertebral bodies and those of the remaining bodies to test the hypothesis that the mean of the population of all fractured bodies is less than that of the unfractured bodies. The resulting p-value was 0.048. Significance was set at $p < 0.05$.

Additionally, a two-tailed t-test was conducted between the mean HU intensities of the fractured vertebral bodies from T5 to T10 and the intensities of those fractured from T11 to L5. A significant p-value of 0.0184 resulted from the test, suggesting that fractured vertebral bodies attached to the sternum via the ribcage (T5 to T10) have a different mean HU intensity compared to the other levels evaluated (T11 to L5).

DISCUSSION

It is important to note that there are limitations in our data analysis. First, our dataset is small with only twelve specimens and six total vertebral body fractures. While these numbers are sufficient to make some statistical conclusions, more data is needed to build a stronger case. The testing conditions for the specimens in our dataset also vary, and may prove to be confounding variables in our experiments. Finally, we did not calibrate bone density against a radiographic phantom in this work, as Schrieber et al. [10] also did not incorporate a phantom in their methods. We hope to investigate the effects of incorporating a phantom in the future. Despite these limitations, the low resulting p-values provide reasonable confidence for our statistical conclusions. Moreover, this data set represents a large number of specimens when compared to similar studies.

In this study, we have demonstrated that vertebral bodies that are prone to fracture generally have lower mean HU intensities than non-fractured vertebral bodies. This fact may prove valuable in the prediction of vertebral body fracture risk, both in experimental specimens, and potentially, in patient populations.

INTRODUCTION

Hernias remain one of the most common ailments to affect men and women. In the late 1950s, surgical mesh materials were first used to reinforce a defect during surgery [1]. Today, there are over 50 prosthetic meshes available for hernia repair [1]. With the multitude of available options, surgeons are faced with the problem of how to pick which mesh is best for each patient. During surgery, meshes are typically placed in the most convenient orientation for the surgeon, which may not provide the best match of the mesh to the properties of the implantation site. If the mechanics of the mesh are not compatible with the surrounding tissue, mismatch can occur, which could lead to complications (e.g., mesh failure and/or hernia recurrence).

To better describe properties of synthetic meshes, we developed a set of standard characterization techniques and a classification system [2,3,4]. We found that meshes exhibit dramatically different mechanical properties (e.g., stiffness, nonlinearity, hysteresis). In addition, many meshes exhibit considerable mechanical anisotropy, which has important implications for dictating how these materials will be loaded once implanted within the abdominal wall. As the forces within the body are multidirectional, it is essential to classify prosthetic hernia reinforcements in a variety of orientations. Therefore, the purpose of this study was to provide a more complete mechanical analysis of a variety of commercially available prosthetic meshes for hernia repair. Twenty different meshes were subjected to equibiaxial tensile tests at both 90° and 45° orientations, and results were analyzed for relative strength, strain behavior, anisotropy, and nonlinearity.

METHODS

Twenty different commercially available meshes were evaluated in this study, which were grouped according to whether or not they included a barrier coating. Samples (n = 5/mesh type) were prepared by cutting 45mm x 45mm square pieces of each mesh at 90° and 45° orientations. 90° was denoted as orthogonal alignment of the warp and weft direction of the mesh, and is the orientation when removed from packaging. To obtain 45° samples, meshes was rotated 45° from the warp/weft alignment, and cut into 45mm x 45mm squares.

Samples were marked with 4 equidistant dots for strain tracking, then soaked in 0.9% saline for 15 minutes to hydrate adhesion barriers. For testing, meshes were subjected to three different loading protocols for both the 90° and 45° orientations: a 1-3 direction strip biaxial test, a 2-4 direction strip biaxial test, and an equibiaxial test. For 90° samples, the warp of the mesh was oriented along the 1-3 axis, while the 45° samples had the mesh's stiffest direction along the 1-3 axis. Each mesh was pre-loaded to 0.1 N, then stretched to a 2.5mm displacement (~12.5% strain) over 5 seconds for 10 cycles, with data collected for the 10th cycle. Digital images were acquired for strain calculations.

Force values were divided by the width of the channels within each grip to convert to membrane tension values. Tension-displacement data from each test type (equibiaxial, 1-3 strip, 2-4 strip) were averaged across samples from each mesh to characterize the mechanical anisotropy, nonlinearity, and relative strength of each type of mesh at each orientation (90° and 45°). Peak tensions along each axis (i.e., T_{13} and T_{24}) were evaluated to compare relative mesh strength. For the ratio T_{13}/T_{24}, values close to 1 indicate isotropy, whereas values >1.5 indicate significant anisotropy. Data for the 1-3 and 2-4 strip tests were analyzed similarly. Images were analyzed to compute orthogonal strains of both the 90° and 45° orientations along the 1-3 and 2-4 axes of each mesh during biaxial and strip tests (E_{11} and E_{22} strains, respectively).

RESULTS

Peak tension values varied dramatically across all mesh types for all directions for both the 90° and 45° orientations (not shown). Meshes

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

oriented in either direction with a barrier coating tended to have higher peak equibiaxial tensions than those without a coating. Likewise, peak equibiaxial tensions in the 90° direction were higher than peak tensions in the 45° orientation for almost every mesh, indicating the mechanical impact of the warp/weft direction. Ratios of the 1-3 and 2-4 actuator peak tensions exhibit a large variation in the degree of anisotropy across samples (Figure 1). For the majority of the samples, the 90° orientation was observably more anisotropic when compared to the ratio of the same mesh in the 45° orientation.

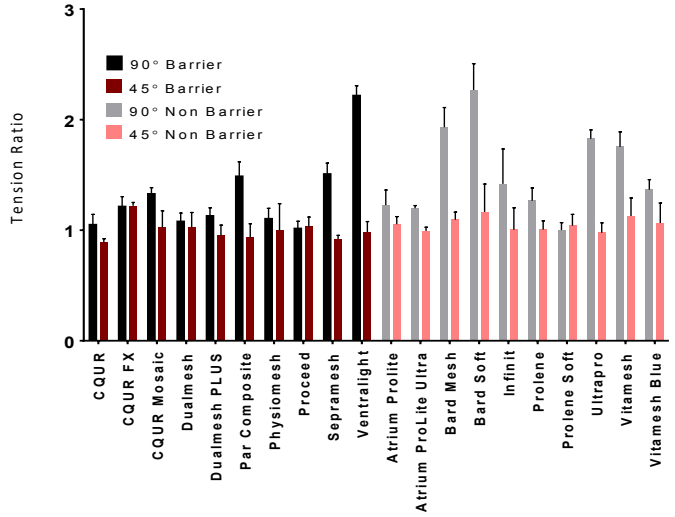

Figure 1: Ratio of peak tensions (F_{13}/F_{24}) in equibiaxial tests. Tension ratios provide a measure of mechanical anisotropy: several samples are isotropic (ratios of ~1) while others were highly anisotropic (ratios >1.5). Meshes oriented in the 45° were significantly more isotropic than those in the 90° orientation.

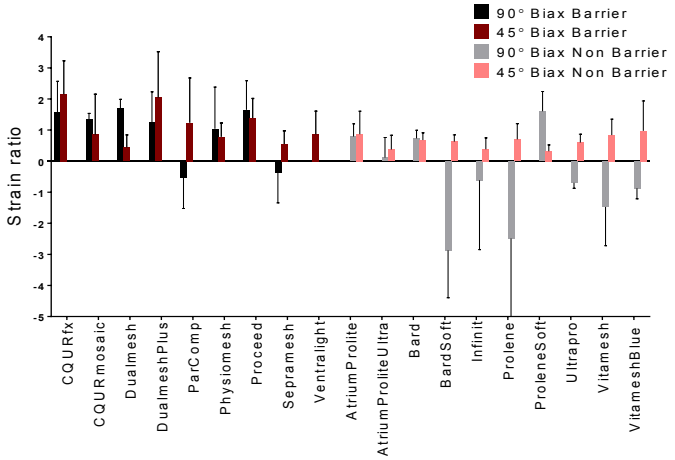

Figure 2: Ratio of peak strains (E_{11}/E_{22}) in equibiaxial tests. These ratios provide an approximation of the Poisson effect, and in turn, deformation anisotropy: some samples had ratios close to 1 and are considered isotropic while others were highly anisotropic. Meshes oriented in the 45° direction had ratios closer to 1 and were more isotropic than those in the orthogonal orientation.

Likewise, peak equibiaxial strain varied greatly across samples, with strain values ranging from almost -5% to 10% strain (not shown). There was no clear difference between peak equibiaxial strains of barrier and non-barrier groups. The ratio of peak equibiaxial strains (Figure 2) supports these observations, with very few samples having ratios close to 1, meaning there is a high prevalence of anisotropy in mesh deformation behavior across samples in both orientations. Similar to the tension ratios, the 90° orientation exhibited higher values for each mesh than the 45° orientation, indicating a higher degree of anisotropy in the orthogonal orientation. Likewise, it can be observed that the non-barrier meshes show several negative strain ratios with large magnitudes, which are not present in the barrier group. These high negative ratios are caused by a significant Poisson effect for meshes tested at angles not aligned to the warp/weft direction. The strip biaxial tests further confirmed the high variability among mesh samples as well as the wide ranges of strength and anisotropy of mechanics and deformation when the 1-3 strip peak values were compared to the 2-4 strip peak values (not shown).

DISCUSSION

The directions and magnitudes of forces present on a hernia defect within the body and the corresponding requirements for a successful prosthetic mesh are not well understood. As observed in this study, there is great mechanical variability amongst commercially available meshes. Likewise, there is a significant degree of anisotropy across the range of meshes, and even further, an observable difference between the anisotropy of barrier and non-barrier meshes.

While the magnitudes of the forces on biological abdominal wall are unknown, it is known that the forces on a hernia defect are present from all directions. If a mesh is highly anisotropic, there may be a greater risk of surgical failure. However, some meshes when tested at a 45° orientation displayed more isotropic behavior, meaning it may be advantageous for a surgeon to place meshes strategically depending on the patient's defect rather than what is most convenient.

A barrier coating is meant to prevent adhesion to the abdominal wall. However, results of this study suggest that a coating may also have the added effect of contributing to a more isotropic mesh, which may promote mechanical success in addition to preventing adhesion.

In order to provide the most successful hernia repair to a patient, a surgeon should consider not only the size and placement of the mesh, but the mechanical characterization of the mesh as well. As shown by the variability in the data, certain meshes may be more appropriate depending on the forces they will encounter within the body than others. In some cases, an isotropic mesh will be more successful, while other conditions for a specific patient may dictate a more anisotropy mesh. While further study of prosthetic meshes, in addition to better characterization of properties of the human abdominal wall, are needed, the results of this study provide valuable data that may aid clinicians in optimizing mesh selection for specific patients and repair conditions.

INTRODUCTION

Traumatic brain injury (TBI) is currently one of the leading causes of disability in the warfighters returning from the battlefield. While the exact mechanism of TBI is yet to be determined, it is often sustained during the interaction of blast with the head. Accurate modeling of this interaction can improve the understanding of TBI and aid in developing mitigating strategies by providing insights on the biomechanical measures like stress, strain, and pressure experienced by the tissue during such loading. Computational modeling has been used to understand the interaction between the human head and blast wave (e.g., [1]-[3]), however such modeling efforts do not account for the inherent variations in blast magnitude, human head size, shape and associated biological material properties. Hence such deterministic head models are not equipped to take into account the effect of variations on the occurrence and extent of TBI. The present work aims to compare blast-induced traumatic brain injury (TBI) response variation in warfighters by accounting for uncertainty or variations in insults, and warfighter characteristics (material and geometry). Blast simulations incorporating variations in four major inputs (blast magnitude, head volume, skull stiffness and brain shear stiffness) are performed. For each instance the injury response is evaluated by calculating the injured brain volume based on various injury thresholds for TBI. The comparison of injury responses allows development of effective mitigation strategies for actual representative population groups. The findings are also useful in understanding the effect of inherent variability among population groups in various other scenarios including blunt impact, vehicular collision and falls.

METHODS

A previously validated high fidelity geometric model [1] of the human head developed at Naval Research Laboratory is used for generating each instance of simulation. These individual instances are generated by applying affine transformations (generated by matching FE model to available human templates), changing the material property, or changing the blast magnitude (or a combination of these). The original geometry was developed using magnetic resonance imaging (MRI) scans of a human head (average 50th percentile Caucasian male of 26 years age). The 1-mm resolution scans provided a high fidelity head geometry, and captured all the important components (see Fig. 1(a)). Experimentally observed behavior of constituents, such as the hyper-viscoelasticity of the brain, rate-dependence of skull response, and incompressibility of CSF, dictated the choices of material models. This original validated head model is referred to as the 50th Percentile case.

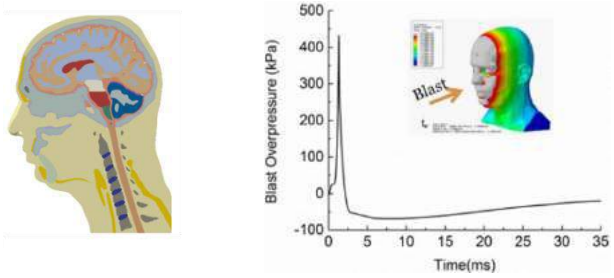

Figure 1: a) Interior structure of the model, b) Applied Friedlander wave profile and loading direction.

The blast loading on the 50th percentile case is simulated by applying a planar Friedlander pressure wave on the exposed surfaces of the head (see Fig. 1(b)). The individual model instances are created by accommodating variations in four major inputs. The magnitude of

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

variation of each input is based on the available data in literature (e.g., [[4, 5]), and is presented in Table 1. As a first step three distinct levels for each input variation are considered, requiring 81 separate blast simulations to be analyzed. Design of experiment techniques are therefore used to reduce the simulations set size. Specifically, a preliminary Taguchi L9 orthogonal design array is used to reduce the requirement to 12 distinct cases. For comparison, the injured brain volume percentage is calculated based on five different injury measures (stress and strain invariant) with thresholds obtained from the literature (see Table 2).

Table 1: Input variation used for various instances.

Input	Variation (%)
Blast magnitude	± 20
Head volume	± 25
Skull stiffness	± 20
Brain shear stiffness	± 20

Table 2: Injury measures and associated thresholds. Measure	Value	Injury
Pressure (kPa)	> 235	Severe TBI
	> -100	50% probability of DDM
Effective stress (kPa)	33	50% probability of severe DAI
Shear stress (kPa)	7.8	50% probability of mild TBI
Principal strain (%)	15	50% probability of mild TBI CSDM
Effective strain (%)	35	50% probability of severe DAI

RESULTS

From the predicted injury volume the main effect plot which compares the change in injured volume with variation in individual parameters is shown in Fig 2. The main effect plot was generated as follows. For a given value of blast magnitude, say nominal value, the other three parameters (head volume, skull and shear stiffness) were varied and the injured volumes were calculated and its mean was also calculated. The same is repeated for low and high values of blast magnitude. This results in 9 different values which are plotted. The mean values are connected by dotted lines and this is used to draw inferences on the influence of blast magnitude on injury volume. The same procedure is repeated for all the other variables and different injury measures.

Looking at the main effect plot for stress based criterion (Fig 2. (a)-(d)) the following are inferred:

1. Increasing the shear modulus leads to increase in injury volume as predicted by Tresca and Mises measures; however, it has minimal effect on pressure based criterion.
2. Change in volume has minimal effect on all injury measures.
3. Increase in blast magnitude and decrease in skull stiffness leads to increase in all injury measures.

In the case of principal strain based criterion (Fig 2. (e)) the inferences are similar to those observed with stress invariants except that a decrease in shear modulus leads to increase in injury measure. With an effective strain based criterion (Fig 2. (f)), the inferences are similar to those of principal strain except that now head volume affects injury measure.

DISCUSSION

The results indicate that the response of injury measure with variation in input is not always intuitive. A single factor can be either positively correlated or negatively correlated, or not correlated to the injured volume. The addition of variability in input shows different outcomes for injury measures when changing certain parameters. The effect plots showcase the challenge of using currently suggested injury measures in the literature. The deterministic simulations so far have been focused on comparing and evaluating injury measures. These results highlight the shortcomings of a single simulation performed on an average human head, and strongly motivate the case for accounting for variability and reevaluation of injury measures suggested in literature in the same context.

INTRODUCTION

Shape memory alloy (SMA) materials, such as Nickel Titanium (NiTi), can generate stress and strain during phase transformation induced by thermomechanical stimulation. Therefore, they may be used to construct active actuating devices for various biomedical applications such as smart needles [1,2]. Since temperature rise during the operation of SMA devices may damage the surrounding tissue, it is important to thermally shield such devices.

We propose to use polydopamine (PDA) [3, 4] as an insulating coating for NiTi-based smart needles. PDA is a biomolecule (dopamine) derived polymer, that can form conformal coating on various materials including NiTi. It is hypothesized that the surface temperature of the PDA coated needle can be reduced by the low thermal conductivity of PDA and the thermal resistance of the PDA/NiTi interface.

Our preliminary experiments conducted in ambient air at room temperature showed that the coating reduced the surface temperature by 45%. In this paper, we will present the thermal insulating performance of the PDA coating on NiTi wires. An experimental setup where the wire is embedded inside a gel phantom [5] has been developed to simulate needle-tissue interaction. Effects of the coating thickness (material thermal resistance) and the number of layers (interfacial thermal resistance) will be discussed. Experimental data will also be compared with finite element analysis (FEA) results.

METHODS

In this study, PDA films were applied onto NiTi wires using a dip coating method. Coating was conducted in mild base solutions at room temperature. Samples with different PDA layer thickness and total number of layers were fabricated. The thickness of the PDA coating was controlled by varying the coating time.

Thermal properties of the PDA were studied using differential scanning calorimetry and thermogravity analysis. Coating morphology and thickness were examined by scanning electron microscopy (SEM) and atomic force microscopy (AFM).

To study the thermal insulation performance, NiTi wires with and without PDA films were inserted into a gel phantom [5]. Electrical current was applied through the wires, and the temperature distribution in the gel surrounding the wires was measured using thermalcouples and infrared imaging.

On the other hand, finite element analysis (FEA) was performed to study the temperature distribution, where the thermal properties of the materials were obtained from experimental measurements (i.e. differential scanning calorimetry).

RESULTS

The NiTi wires can be coated with PDA, and the thickness varies from tens to hundreds of nanometers. The thickness of the coating on the wire can be observed using SEM (Fig 1). Fig. 1(a) shows a bare NiTi wire surface without PDA coating. The grain boundaries can be clearly identified. Fig. 1(b) shows a PDA-coated NiTi wire surface, where a continuous film was observed and the grain boundaries became blurry to distinguish .Fig. 1(c) is a backscattered electron image of the cross-section of a coated NiTi wire. Fig. 1(d) shows a combined secondary/backscattered electron microscopy image of the cross-section of a PDA-coated NiTi wire, where the PDA coating can be idenfitied.

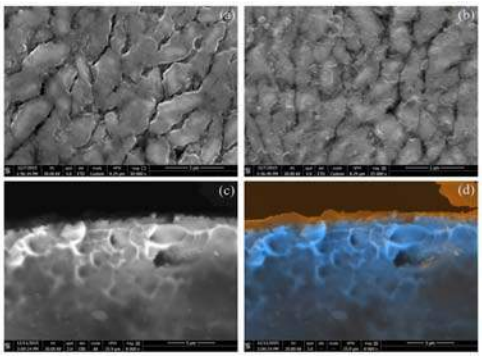

Figure 1: SEM images of NiTi wire with and without PDA coating. (a) NiTi wire without PDA coating. (b) NiTi wire with PDA coating. (c) The cross-section of NiTi wire (brighter) with PDA coating (darker film). (d) The overlay image of secondary/backscattered electrons of PDA coating (orange) on the surface of NiTi alloy (blue).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

A preliminary study using NiTi wires with diameter of 0.25 mm was performed. The uncoated and coated wires were tested using the test setup as shown in Fig. 2. The NiTi wire was dipped inside of the PDA solution which was made by adding dopamine hydrochloride into Tris buffer. The NiTi wires were activated using Joule heating by applying current as a ramp function and wire temperature was measured using k-type thermocouples. Note in this experiment, the wire was exposed to the ambient air.

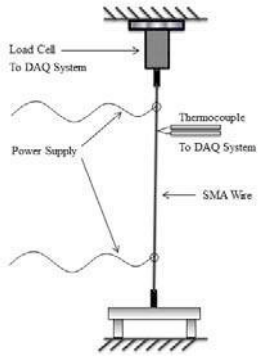

Figure 2: Schematic of test setup to measure the surface temperature on the coated and uncoated wires by using thermocouples.

In this preliminary study, a series of experiments on coated and uncoated wires were performed. As shown in Fig. 3, the average surface temperature is about 80-82 ºC on the uncoated wires and 47-48 ºC on the coated wires. This represents a 45% reduction of temperature when the wires were coated by PDA.

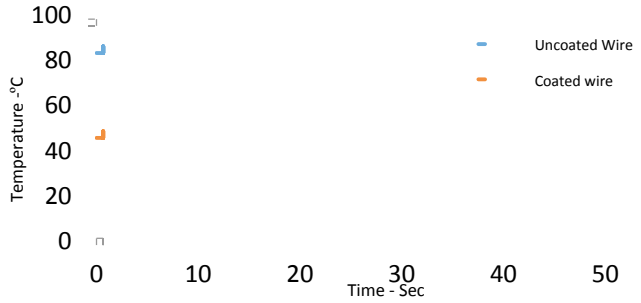

Fig. 3. The surface temperature as a function of time on coated and uncoated NiTi wires tested in ambient air.

In order to simulate the influence of the temperature change of the wire on tissues, an experimental setup was developed such that the wires are embedded in a gel phantom. Fig. 4(a) shows the experimental setup, which is used in this study. The gels is made of PVC in combination with a softener, and wire placed inside the gels in a way which all its part is in full contact with the gel. As a result of the good connection, conduction is believed to be the major mechanism of heat transfer. Fig. 4(b, c, d)) represent the temperature distributions around the uncoated NiTi wire inside the gels. As it shows in Fig. 4, the temperature decreases when moving away from the NiTi wire.

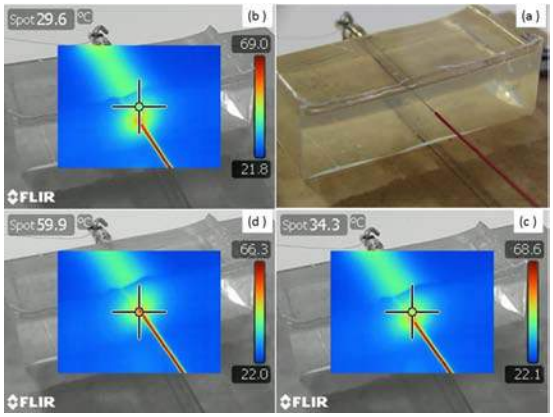

Figure 4: Temperature distribution near an uncoated Ni-Ti wire measured using an IR camera. (a) Experimental setup. (b), (c), (d) temperature distribution around the wire at different distances .

DISCUSSION

Our preliminary results (Figure 3) indicate the PDA coating can effectively reduce the surface temperature of an activated NiTi wire. Two mechanisms may be responsible for this effect: low thermal conductivity of the PDA film, and the NiTi/PDA interface. Detailed study will be carried out to evaluate the contribution of the two factors to determine which is the major contributor to the enhanced thermal resistance.

On the other hand, finite element analyses (FEA) will be used to study the thermal distribution on the interface of the wires and tissues. The FEA results will be used to optimize the coating parameters including the thickness and number of NiTi/PDA interfaces.

REGISTRATION, REGIONAL IDENTIFICATION, AND TRANSFER OF DATA FROM MRI SCANS TO FINITE ELEMENT MODELS

INTRODUCTION

With advances in imaging technology, magnetic resonance imaging (MRI) and diffusion tensor magnetic resonance imaging (DT-MRI) data have proven to be very useful in multiple ways. The generated images chiefly provide detailed anatomical information for prognostic purposes, but computational modelers have found them to be as advantageous. Computational analysts typically face two-pronged challenges in handling MRI-based scans: (i) registration, i.e., alignment of data, and (ii) transfer of data to the numerical model using consistent interpolation techniques. The finite element (FE) models used for modeling the brain are typically deterministic in nature, whereas the human head is subject to variability. Hence, the main issue of registration is the need to transform the MRI data into the FE model coordinate system and match (through translation, shear and scaling) the topologies. The DT-MRI data representing the white matter fiber tractography essentially requires the same treatment with more robust considerations for the mapping due to the tensorial complexity of fiber orientations.

Manual registration of regions in the brain is error prone and also prohibitive in terms of time spent. In a very effective study on automatic registration with head and brain as the focus, Klein et al [1] evaluated 14 different nonlinear algorithms (FLIRT, AIR, ANIMAL, ART, Diffeomorphic Demons, FNIRT, IRTK, JRD-fluid, ROMEO, SICLE, SN and 4 different SPM5 based methods), and identified three schemes as the most effective ones. However, the transformation methods analyzed in their study are applicable to transferring data from one MRI structured dataset to another structured dataset and not from an MRI dataset to an unstructured dataset as in an FE mesh. To address this gap we layout one method here, which can be used to transfer data between structured datasets as well as between non structured data sets. We cast the problem into a point cloud matching problem and compute an affine transform which maps given source and target point clouds. We demonstrate the scheme by registering and transferring data between MRI's and also from MRI to an FE mesh. Then using the transformed dataset we interpolate diffusion tensor data from MRI to the same FE mesh.

METHODS

In the proposed scheme, we do not match MRI's to each other or the FE model described by the mesh, based on topology or topological features. For each voxel, a point is generated at its center and, in turn, the point cloud this generates represents the brain captured by the MRI. In the case of an FE mesh a similar point cloud can be generated from the nodal locations or integration points within each element, or elemental centroids. In our work we use the elemental centroid. Now the problem is matching up point clouds, which is routinely performed in disparate tasks such as surface reconstruction and optimal path planning.

Iterative Closest Point (ICP) [2] is a computational scheme for registration of 3D shapes including free form curves and surfaces. A typical ICP algorithm only involves rotation and translation. A finite version of the same called as FICP involves scaling, rotation and translation. The scaling part is crucial when trying to match up point clouds where the bounding box sizes are not close enough. The basic steps involved in point cloud matching are

1. For each point in the source point cloud the closest point in target point cloud is computed.
2. An affine transformation is applied to the entire source point cloud and the distance between each affine transformed source point and closest target found in step 1 is accumulated.
3. The accumulated distance function is minimized to get the next set of affine transformation coefficients.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

4. The procedure is repeated till the accumulated distance error is minimized as defined.

The FICP routine library implemented in Matlab [3] was used in the following work.

DT-MRI measurements were conducted on a healthy 29 year old male; the accumulated data is used as the structured target data. The brain atlas developed by Oishi et al [4] is used as the structured source data. This particular atlas is chosen because 189 unique brain regions are identified in it, which is useful for injury analysis purposes in later studies. Lastly, the unstructured target data is obtained from an in-house FE model of a human male of 26 year age.

RESULTS

Fig 1(a) shows the initial exterior point cloud of the target and source scans, and 1(b) shows the final point cloud generated after applying the affine transformation by FICP.

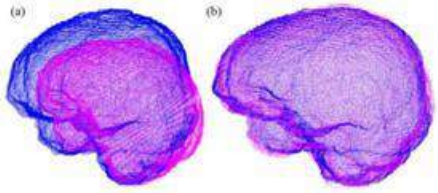

Figure 1: The exterior point cloud of the source and target scans: a) brain atlas, i.e. the source, is blue and target in magenta, b) Superposed transformed source point cloud over the target cloud.

The goodness of the fit was evaluated using error metrics used in [1] and the values obtained are tabulated in Table 1. A value of 1 means perfect total overlap, mean and union overlap, whereas 0 implies the same for volume similarity, false positive and false negative. In another post-processing step, for each target voxel the nearest source point within a cube of 3 units centered at the target voxel was identified and given the same region as the target voxel. The resultant target data with regions assigned is shown in Fig 2.

Table 1: Values of error metrics.

Volume Similarity	Total Overlap	Mean Overlap	Union Overlap	False Positive	False Negative

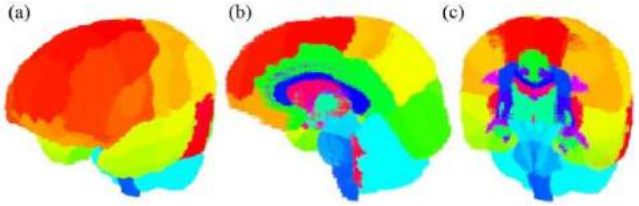

Figure 2: Target scans with 189 regions color coded displayed similar to color coded brain atlas scans.

For the process to match structured dataset to unstructured dataset, the exterior of the FE model of the human brain was extracted. However, the detailed mesh includes folded features in the brain namely the sulci, which are not present in the exterior of the source MRI scan. To circumvent this issue only the convex hull of the mesh was chosen as the target cloud. As the convex hull was sparse, for every point on the hull a closest neighbor was also generated on the hull. Fig 3 shows these point clouds and the final transformed point clouds.

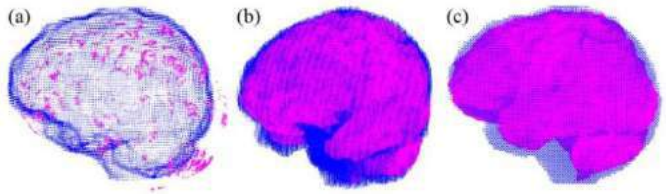

Figure 3: (a) Blue denotes the MRI exterior point cloud and magenta the convex hull + neighbors of the FE mesh. Two views of the transformation are shown in (b) and (c).

To evaluate the fit for the second transformation, diffusion tensor data from the DT-MRI scans was interpolated to the FE model using the Log Euclidean interpolation method (details withheld for brevity). The primary diffusion tensor directions are plotted for both the MRI scan and the interpolated data in the FE scan in Fig. 3. For the sake of visual comprehension, only vectors for a partial range of fractional anisotropy (FA) values are displayed here.

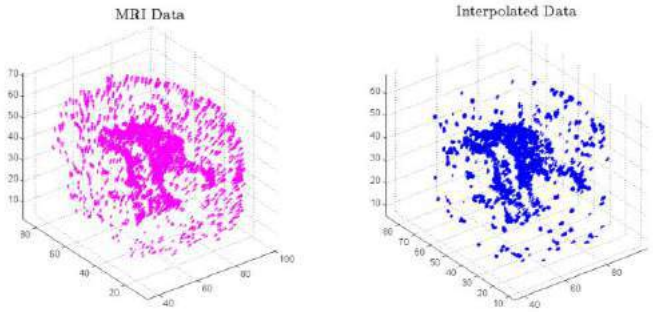

Figure 4: The primary fiber vector plot for the original MRI dataset and the interpolated data in the FE model, for a limited range of fractional anisotropy (FA) values: $0.7 \leq FA \leq 0.8$.

DISCUSSION

In this work we have implemented an affine transformation based image mapping scheme which can be used both for structured and unstructured grid image data. We used it to transfer data between structured MRI datasets, and also between MRI and an unstructured FE mesh. The errors computed using popular error metric values are shown to be within reasonable limits. The proposed scheme is also successfully used to transfer diffusion tensor data to the FE model. This accomplishment now allows for full anisotropic representation of the brain in computational modeling as well as fitting of data from variable subjects to one FE model. The later point is important because it is exceedingly difficult usually to get all the pertinent data (MRI, DTI, computed tomography (CT), magnetic resonance elastography (MRE), etc.) from one subject for computational modeling needs.

INTRODUCTION

Detailed finite element (FE) modeling of the human head subjected to blast loading scenarios currently provides the only viable means to quantifying mechanical response within the brain for traumatic brain injury (TBI) prediction. Although the exact relation between tissue mechanical response and injury is still quite unknown, the exceedance of threshold values based on direct and derived measures of stress, strain and acceleration within the brain are commonly used as criteria for injury. Similarly, while preliminary parametric studies varying head morphology and material properties of head components have shown significant variation in predicted injury response, an established relationship is yet undetermined. Furthermore, there is a lack of prediction consistency for the given criteria due to parametric variation. To illustrate this point, Figure 1 shows the results of a parametric study exposing the dependence of predicted injury criteria on head morphology and properties. The head volume, skull stiffness, brain shear stiffness, and blast magnitude are varied by $\pm 25\%$, $\pm 20\%$, $\pm 20\%$, and $\pm 10\%$, respectively, with respect to a model representing the 50th percentile Caucasian male. Injury for contusion and laceration are considered when pressure magnitude exceeds 173kPa and -100kPa, respectively, while shear injury is considered where principal strain magnitude exceeds 5%. These results show strong sensitivity of injury criteria (i.e., mechanical response) to reasonable parametric variation, and that the different criteria have different behaviors with respect to this variability. Due to the large input parameter dimension needed to describe human and loading scenario variations, it is not apparent upfront how to construct transfer functions relating input variation and injury criteria, which is necessary to determine, for example, the probability of exceeding the given threshold responses.

This work lies within an overall effort to improve the confidence as well as quantify the uncertainty of TBI prediction, whereas its focus is on developing an accurate and parsimonious representation of the variation of human head morphology. An improved understanding of inter-subject morphological variation is essential to obtaining accurate mechanical response variation. Since this input uncertainty must be propagated through large FE models, the goal is to identify a stochastic reduced order model that has the least number of parameters while retaining accuracy with respect to an error measure.

volume of brain exceeding injury criteria for: laceration (top right), contusion (bottom left), and shear injury (bottom right).

METHODS

The procedure introduced herein to develop a stochastic model of the human head is to: (1) warp a template model to individual subjects; (2) apply dimensionality techniques to reduce the number of parameters describing the mappings; and (3) employ stochastic simulation algorithms to generate optimally selected samples to undergo detailed FE analysis for uncertainty propagation.

The data of head morphology is obtained from the International Consortium for Brain Mapping (ICBM) database, which is a collection of serial section grayscale images (e.g. magnetic resonance images (MRIs)) of human heads from varying sources. Out of the 1342 subjects, 185 that were identified to have full head and brain scans are selected for the study. These 3D images are segmented using BrainSuite(R) to extract masks for the brain and the whole head. The template used as the source of the warping algorithms is a high-resolution whole head T1-weighted MRI dataset of a healthy 26 year old male, representing the 50th percentile Caucasian male, which has been manually segmented using Simpleware(R) software to identify 33 unique regions [1]. The effectiveness of two warping algorithms among many suggested in [2] to map a template head to each one of the subjects is first studied for tradeoff between accuracy and model size. The first choice is the use of affine transformations, which contain only 9 parameters (without considering translation). The second choice of diffeomorphism mappings, such as Statistical Parametric Mapping (SPM) [3], do not have a restrictive model form but requires costly optimization routines to obtain a stationary point for its large parameter set (e..g $O(10^6\text{-}10^7)$). In order to propagate this large parameter set through expensive computational models, linear (principal component analysis) and nonlinear dimension reduction techniques, such as local linear embedding and related methods, need to be applied to the mappings to extract a set of intrinsic parameters of low order dimension.

The next step is then to derive the statistical distributions of the mapping parameters obtained from either scheme and use them with the stochastic simulation techniques (e.g., Nataf transform or Markov Chain Monte Carlo) to generate instances of accurate virtual head models. These instances are judged against the template MRI dataset to ensure that they fall within accepted variations and an attempt then can be made to identify the characteristic geometric features of the human head common across all instances.

RESULTS

Masks for the head and head-brain were created for all the subjects and the template, and Figure 2 shows these images for the template. Initial studies mapping these template masks to each subject via global affine maps resulted in significant errors. An error metric is defined as the total mismatch volume normalized by the volume of the subject, given as

$$E = \frac{|\, t(\boldsymbol{x}) \setminus (t(\boldsymbol{x}) \cap s(\boldsymbol{x}))| + |\, s(\boldsymbol{x}) \setminus (t(\boldsymbol{x}) \cap s(\boldsymbol{x}))|}{|t(\boldsymbol{x})|}, \quad (1)$$

for $t(\boldsymbol{x}), s(\boldsymbol{x})$ being the target and the warped template masks, respectively, and $|\cdot|, \setminus, \cap$ denoting volume, set difference, and set intersection, respectively. The histograms of this error for the head and head-brain masks are shown in Figures 2a and 2b, respectively. The errors for the affine transformation are too large to be acceptable. Since the injury criteria are rather sensitive to morphology and properties, as illustrated in Figure 1, mapping errors will have significant unwanted contributions to the variance of predicted injury response. For this reason, the affine transformation model is deemed an insufficient stochastic model for head morphology. The SPM model has also been implemented and the results of an optimization from the template to one subject is shown in Table 1. The exceptional improvement in accuracy is accompanied by the expensive optimization problem and large dimension of the mapping. Currently, the mappings to all 185 subjects are being executed by the SPM algorithm upon which statistical dependence among the parameters will be evaluated to extract an accurate, low dimensional representation. This representation will then be described statistically and stochastic simulation techniques will be used to generate virtual head models.

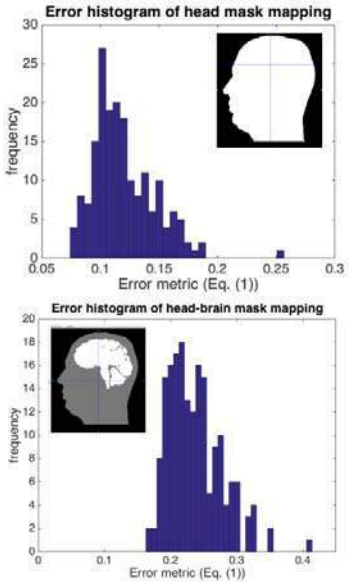

Figure 2: Error metric (Eq. (1)) histogram for affine transformation for head and head-brain mask.

Table 1: Error metric (Eq. (1)) to compare affine transformation with SPM for an arbitrarily selected subject.

	Affine	SPM
Head mask	11.2%	1.6%
Head-brain mask	19.6%	3.8%

DISCUSSION

Due to the sensitivity of the injury criteria to head morphology and properties, the affine transformation based stochastic model contains too much error to provide the probability distribution of injury criteria with high confidence. The initial accuracy of SPM algorithm suggests that its mapping results will provide an accurate stochastic model. It is likely that the extremely large parameter space can be reduced to a low dimensional set of parameters, such that it is feasible to propagate this uncertainty through expensive computational models. The results of this ongoing study will soon be completed and presented.

INTRODUCTION

Catheter ablation is a common treatment for atrial fibrillation (AF). Ablation is used to electrically isolate specific regions by cauterizing regions of atrial muscle, which are then replaced by non-conducting scar. Successful ablation frequently restores sinus rhythm; however, it does so at the cost of decreasing the amount of viable myocardium. Ablation patterns have been designed to isolate regions of the atrium including the step-wise pulmonary vein isolation (PVI) and wide area circumferential ablation (WACA), with many studies comparing the efficacy of these two techniques [1-5]. The WACA pattern has been shown to be moderately more successful when coupled with additional ablation lines determined by electrical mapping to target areas with complicated electrical signals [6-8]. The progression of ablation techniques has seen the development of patterns targeting the different atrial walls, as well as more aggressive catheters that increase scar volume and transmurality [9-13].

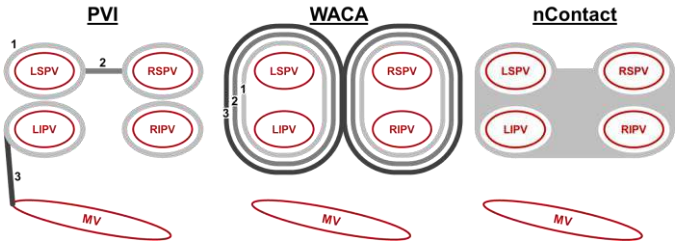

Figure 1: Left atrial ablation scar patterns in relation to mitral valve (MV), left superior (LSPV), left inferior (LIPV), right superior (RSPV), and right inferior (RIPV) pulmonary veins for the step-wise PVI (left, 3 steps shown), three variants of the WACA (center), and nContact's posterior ablation (right).

The general trend in ablation for atrial fibrillation has been to induce larger amounts of scar in the hopes of preventing AF recurrence and the need for repeat procedures; however, relatively little attention has been paid to the consequences of more aggressive ablation for mechanical function. Studies of ablation efficacy have been limited to global volume-based analyses, indicating a need for regional analysis to determine the functional impact of scar on different atrial areas [14]. Our group has previously published a coupled finite-element and circulation model of the left atrium, which was used to explore the mechanics of AF [15]. We used the baseline AF model to simulate various ablation patterns and determine their effect on atrial function. In particular, we included a recently introduced ablation pattern that targeted the entire posterior wall. With the different ablation patterns varying in scar volume and location, we hypothesized that placing ablation scar in areas with the highest baseline regional function will decrease atrial mechanical function.

METHODS

The coupled finite-element and circulation model of the left atrium used a transversely-isotropic Mooney-Rivlin material for the myocardium [15]. The baseline AF model features a dilated atrial geometry, diffuse fibrosis, increased loading pressure, delayed conduction velocity, and impaired left ventricular relaxation. This model was used as a platform to simulate atrial function after introducing various amounts and patterns of ablation scar. Material properties for the scar were created by isotropically stiffening the myocardial material, eliminating all anisotropic properties, and removing active contraction.

Ablation scar was introduced to the model by transmurally modifying local material properties prior to simulation. 13 ablation patterns were modeled including the step-wise PVI, WACA with circles of three different radii, and a posterior ablation developed by nContact,

Inc (Fig. 1). The PVI and WACA lines were simulated with two widths (4 and 8 mm) to represent RF and cryo-ablation lines.

Ablation scar was quantified as wall volume percentage of the left atrium. We analyzed global pressure-volume loops and regional function for each ablation model. Both global and regional volume changes were quantified separately for the passive and active phases of atrial emptying. Regional analysis of wall motion was performed using a floating origin coordinate system and regions defined by the pulmonary veins [15, 16]. Wall motion was calculated as the change in radius from maximum volume to minimum volume throughout the cardiac cycle.

RESULTS

The ablation patterns simulated spanned a range of 5% to 31% scar volume. In the presence of ablation, the passive atrium was stiffer, which hindered passive filling (Fig. 2). Active work by the atrium also decreased with increasing ablation scar. Total emptying volumes decreased by 0.3 to 10.9 mL in comparison to baseline. The passive emptying portion did not change much, -0.5 to 0.4 mL; however, active emptying decreased by 0.1 to 11.3 mL with increasing scar volumes.

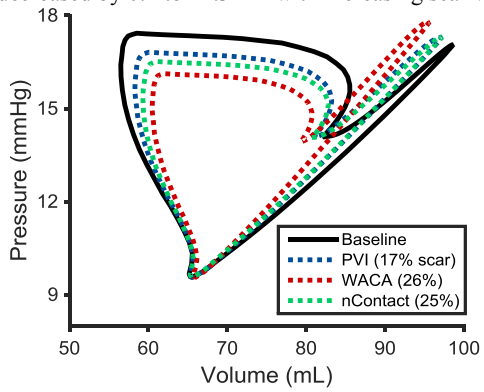

Figure 2: Pressure-volume loops comparing cryo-PVI, cryo-WACA, and nContact ablation patterns.

To compare active function among the different ablation patterns, we used wall motion in the inferior, lateral, and superior regions. Fig. 3 compares the cryo-PVI, cryo-WACA, and nContact ablation pattern. Cryo-WACA impaired global function primarily through a decrease in lateral wall motion. With similar scar volumes, nContact changed wall motion less in most regions, with regional and global effects more similar to the lower scar volume cryo-PVI.

DISCUSSION

Our simulated ablation scar volumes covered a comprehensive range consistent with imaging-based quantification of scar in clinical studies [14, 17]. Globally, adding ablation scar increased passive stiffness of the atrium, which is intuitive from the stiffer material properties of the scar. With similar scar volumes of 26% and 25% for cryo-WACA and nContact respectively, the cryo-WACA model had a higher passive stiffness, seen during passive filling and emptying (Fig. 2). This indicates that in addition to scar volume, scar location is an important determinant of passive atrial mechanics. Active function – reflected in the area inside the PV loop – followed similar trends, with cryo-WACA resulting in the greatest impairment, again suggesting that scar location is an important determinant of functional impact in addition to scar volume.

The nContact scar is similar to a PVI with the addition of ablation to the entire posterior wall extending into the inferior wall (Fig. 1). As a result, the inferior wall motion for nContact is similar to that of the cryo-WACA pattern (Fig. 3). However, the nContact lesion set avoids regions of the atrium that normally move the most, particularly the lateral wall. The cryo-WACA pattern extended into the lateral wall, creating a stiff belt of scar that inhibited motion. Because the nContact and cryo-PVI patterns did not extend into the lateral wall, they had a smaller impact on regional wall motion. These regional differences in wall motion are important metrics for evaluating mechanical function with regards to scar location.

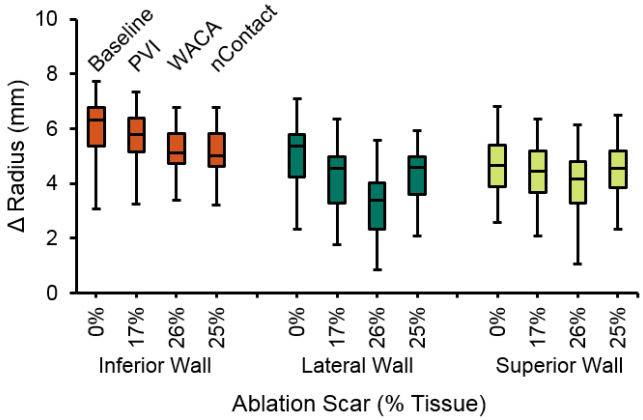

Figure 3: Inferior, lateral, and superior wall motion analysis comparing cryo-PVI, cryo-WACA, and nContact ablation patterns.

Given the different varieties of ablation techniques, we were able to directly compare how the different scar volumes and locations affected atrial mechanical function. In particular, we identified the effect of three different scar patterns on function of the free walls of the atrium (inferior, lateral, and superior). Our results suggest that different ablation patterns have different effects on post-ablation mechanical function. Specifically, ablations that involve regions with the highest baseline regional function (the atrial free walls) reduce function more than ablations in regions with low baseline function such as the posterior wall. The nContact pattern creates a large scar volume; however, the scar location is primarily on the posterior wall, an area that normally moves little because it is anchored by the four pulmonary veins. In clinical practice, the risks of recurrence must be weighed against the risks of damaging mechanical function when planning ablation; moving forward, there is a need for models that can simulate not only mechanical but also electrical effects of specific ablations.

INTRODUCTION

The complex hemodynamics observed in the human aorta make this district a site of election for an in depth investigation of the relationship between fluid structures, transport and patho-physiology.

Hemodynamics plays an important role in the mass transport in blood flow, and in turn, in the localization of vascular disease in areas of complex arterial flow. The accumulation of lipoproteins in the arterial intima is a hallmark of atherosclerosis. Low density lipoproteins (LDL) are the most abundant atherogenic lipoproteins in plasma and high plasma levels of LDL are causally related to the development of atherosclerosis [1]. In detail, it is found that the occurrence of LDL concentration polarization in the arterial system can affect the residence time and the deposition of atherogenic particles at the luminal surface. The LDL accumulation within the arterial wall then increases the risk of the atherogenesis [2].

In the last decade the coupling of medical imaging and computational fluid dynamics (CFD) has demonstrated its potency, contributing to enhance the comprehension of the aortic hemodynamics, with the possibility to obtain highly resolved blood flow patterns in anatomically realistic arterial models. In particular, in the context of a subject-specific oriented approach, PC-MRI has emerged as able to provide the anatomical and hemodynamic inputs to even more realistic, fully personalized flow simulations [3]. Moreover, personalized computational modeling of mass transfer has been proposed as a powerful way of addressing abnormalities in mass transfer patterns, which could be in themselves atherogenic [4]. In this regard, a recent study investigated the effects of geometric features of human aorta on the flow pattern and the luminal surface LDL concentration. It was detailed the role played by aortic torsion, branching, taper, and curvature on LDL transport and luminal surface distribution in four aortic models with different geometry [5].

In this study we analyze the influence of different possible strategies of applying PC-MRI measured data as boundary conditions (BCs) to confidently model LDL transport and transfer in image-based hemodynamic models of human aorta. In detail, the influence on LDL transport of assumptions regarding the velocity profile at the inlet section of the ascending aorta. We impose PC-MRI measured 3D velocity profiles (i.e. locations-dependent direction and magnitude of velocity vectors at the inlet section) at the inlet of the computational model and compare the obtained results, in terms of low-density lipoproteins transport, to the results of two equivalent computational models with the same instantaneous flow rate prescribed as measured 1D velocity profiles (i.e. magnitude of velocity vectors normal to the inlet surface) and flat velocity profile inlet BCs. Technically, steady-state flow simulations were carried out at three representative phases of the cardiac cycle for the three inlet velocity profiles considered. The LDL distribution at the aortic luminal surface was computed and the results were compared. The study here presented would contribute to clarify which is the impact of the conditions applied at inflow boundaries on aortic LDL transport. In particular, the comparison of LDL transport at the aortic luminal surface as obtained prescribing idealized *vs* measured velocity profiles as inflow BCs, will contribute to clarify which is the level of detail obtained from measured phase velocity, sufficient to satisfactorily simulate mass transport/transfer in personalized computational hemodynamics models of human aorta.

METHODS

In this study the geometry of an ostensibly healthy human aorta was reconstructed from 4D PC-MRI images. PC-MRI slices were used to generate the model of aorta into the Vascular Modeling Toolkit environment (http://www.vmtk.org/) by applying a multiple step procedure for the extraction of the surface mesh of the thoracic aorta

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

from PC-MRI data [6]. The finite volume method was applied to perform numerical simulations under steady flow conditions. The general purpose CFD code Fluent (ANSYS Inc., USA) was used on computational mesh-grids with high quality hexahedral cells near the wall at the inlet surface and structured tetrahedral elsewhere, semi-automatically generated using ICEM (ANSYS Inc., USA). The domain was equipped with straight flow extensions at the outlet faces and divided into about $4 \cdot 10^6$ cells. Blood was modeled as an isotropic, incompressible, homogeneous, Newtonian viscous fluid (density equal to 1060 kg/m^3; dynamic viscosity equal to 3.5 cP). The LDL diffusion coefficient in blood was set to $6.3 \cdot 10^{-9}$ kg/m s. Arterial walls were assumed to be rigid with no-slip condition at the wall. At the outlet sections of the model measured flow rate ratios were imposed as outflow BCs, as detailed in [6].

Steady state LDL transport in flowing blood can be described by the convective-diffusion equation for the LDL concentration C:

$$u \cdot \nabla C - D_L \nabla^2 C = 0 \qquad (1)$$

where u is the velocity vector and D_L is the diffusivity of LDL in flowing blood, set to $4.8 \cdot 10^{-12}$ m^2/s [2]. Steady-state flow simulations were carried by applying conditions at boundaries as measured at three different phases of the cardiac cycle (i.e. acceleration phase, systolic peak and deceleration phase, Figure 1), for a total number of nine simulations. The following BC strategies were applied at the inlet section of the ascending aorta. The first strategy consists in the application of the measured PC MRI velocity profiles at the inlet section. Technically, at the inlet section the measured three components of the velocity were extracted from the phase images. Using phase-contrast flow data, two different inflow conditions were generated, by imposing at the inlet of the ascending aorta: (1) PC-MRI measured 3D velocity profile at systolic peak, and at two phases of the cardiac cycle, one along the acceleration phase and the other along the deceleration phase; (2) PC-MRI measured 1D velocity profile at the same phases as described above, obtained considering the measured velocity component orthogonal to the inlet section of the anatomic model (i.e., the axial velocity component). The second strategy is a widely applied approach and consists in the application of the measured velocity waveform at the inlet surface in terms of idealized flat velocity profile. Velocity magnitude of flat profile was computed by averaging 1D velocity profile for each considered instant of cardiac cycle. LDL transport in the aortic arch was computed for the three inflow conditions cases and the impact of the choice of idealized rather than measured velocity profiles as inflow BCs was investigated focusing on LDL transfer to the aortic luminal surface.

RESULTS

As result we report the LDL wall concentration in aorta, normalized with respect to the initial LDL concentration C_0 at the aortic inlet section. Figure 1 presents the LDL accumulation profiles at the luminal surface obtained by imposing in silico (FLAT panel) and in vivo (1D and 3D panels) velocity profiles as inflow BCs for the three simulated phases of the cardiac cycle. Notably, differences in LDL patterns at the luminal surface are obtained, depending on the applied velocity profile at the inflow. In detail, the surface area subjected to elevated LDL accumulation is markedly wider than the 3D and 1D cases, when flat velocity profile is prescribed at the aortic inflow section. The FLAT case presents three luminal regions at the aortic arch subjected to severe polarization of LDL, more evident during the acceleration phase of the cardiac cycle (inner lateral edge of the brachiocephalic artery, intrados of the ascending aorta and inner wall of the descending aorta). The same regions were identified in [5], as interested by elevated LDL accumulation. LDL polarization at these luminal regions sensibly decreases in 1D and 3D simulation cases. Results obtained for 3D and 1D cases show a more uniform LDL distributions at the wall along the aortic arch, with a weak increase of LDL polarization at the inner wall of the descending aorta. In general, Figure 1 confirms that light or negligible differences can be appreciated in LDL transport between 1D and 3D cases at the three cardiac phases here investigated.

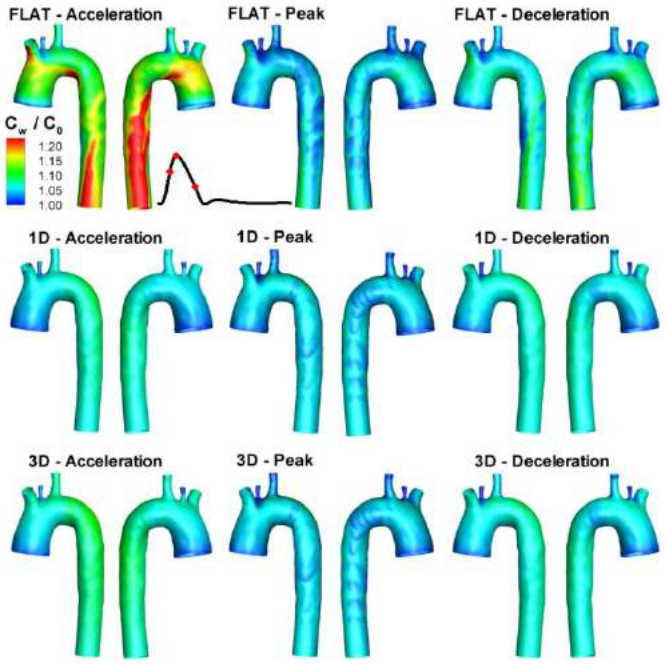

Figure 1. Comparison of the normalized LDLs concentrations at the luminal surface for the simulated inflow boundary conditions.

DISCUSSION

The findings of this study show that the imposition of idealized velocity profile as inlet BCs in subject-specific computational hemodynamics models of mass transport in the human aorta could largely affect the location and extension of regions of LDL polarization at the luminal surface. We conclude that the plausibility of the assumption of idealized velocity profiles as inlet BCs in personalized model of the aortic hemodynamics could not, or could loosely, hold true. This finding needs further investigation, because of the fact that it is derived from steady-state flow analysis. The same analysis will be extended to unsteady-state simulations, applying the same scheme as proposed in previous works [3]. In general, the approach here proposed could be helpful to elucidate the role played by the aortic helical flow in mass transport, in particular in testing the hypothesis that the promoted-by-helicity mixing of blood could be beneficial in suppressing severe LDL polarization at peculiar aortic regions, thus being part of the physiologic atheroprotective mechanism.

INTRODUCTION

Achilles tendinopathy is a prevalent highly debilitating and painful condition. It is believed to result from repetitive overuse of the tendon, which can create micro-damage that accumulates over time, and initiates a catabolic cell response [1; 2].

The aetiology of tendinopathy remains poorly understood, therefore the ideal treatment remains unclear. A wide range of treatments are available, however, current data support the use of shock wave therapy or eccentric exercise as some of the more effective treatment options [3; 4]. Previous studies have demonstrated that both eccentric loading and shockwave therapy result in perturbations within tendon at a frequency of approximately 10Hz [5; 6]. Consequently, we hypothesis that 10Hz loading initiates an increased metabolic response in tenocytes that can promote tendon repair. Our primary aim is to investigate the effects of perturbations at 10Hz on tenocytes metabolism comparing tenocyte gene expression in response to10Hz and 1Hz.

METHODS

Human tenocytes from healthy hamstring tendons (3 donors aged 21±1 years) and tendinopathic Achilles tendons (3 donors aged 48±3 years) were derived by collagenase digest and explant outgrowth respectively. Cells were expanded and seeded into 3D collagen gels. In preparing the gel, 0.5ml of 10x concentration Dulbecco's Modified Eagle's medium (DMEM) (Gibco) was added to rat-tail type I collagen solution (First Link), the mix was neutralised with NaOH and carefully stirred to avoid creating air bubbles. A cell suspension (0.5ml of $1x10^6$ cells/ml solution) was immediately added to the mix, and then transferred to a mould (22 x 33 x 10 mm^3) and allowed to incubate at room temperature for 30 minutes to polymerise. The collagen gel was then compressed using the plastic compression technique, where the collagen matrix was placed between nylon meshes, and onto a stainless-steel mesh on double layer absorbent Whatman filter paper. A 120g metal block was placed onto the matrix to squeeze out the water and to make a flat collagen sheet (100-200μm thick) which could then be rolled to make a tube easily gripped for mechanical loading [7].

The gels were fixed in custom-made chambers, housed in an Electro-force loading frame within an incubator (fig. 1) and left for 24hrs whilst gene expression stabilized before mechanical loading. Cell viability over this time-frame was confirmed by monitoring constructs secured within the chambers for 48 hours, with and without the inclusion of mechanical stimulation (n=2). The gels were removed from the chamber, placed in a solution of 2ml of DMEM, containing Calcein AM (0.01mg/ml) and Ethidium homodimer (3.75μM/ml), and incubated at 37ºC for 30minutes. Stained samples were rinsed and placed on the stage of a confocal microscope, and the number of live and dead cells counted to provide a percentage viability.

For mechanical stimulation, cyclic uniaxial strain at 1% ± 1% was applied to the gels, at either 1Hz (n=4) or 10Hz (n=4) for 15 minutes. Samples were then maintained in the chambers under 1% static strain for 24hrs.

Gene expression was determined using qRT-PCR on several genes of interest (MMP1, MMP2, MMP13**,** COL1A1, COL3A1, COL5A1, ADAMTS5, IL6, IL8, TIMP3 and 18S).

The data are displayed as Geometric mean ± standard error of the mean and statistical analyses were performed using the student's t test (two tailed distribution, equal variance).

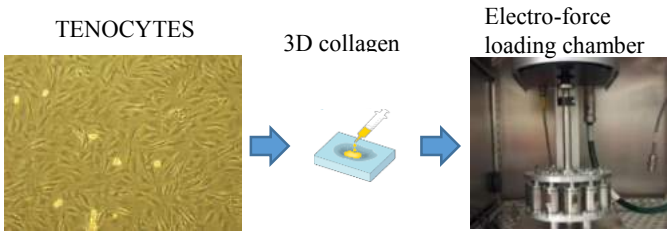

Fig 1. Schematic depicting the methodology: seeding cells onto gels and mechanically loading them, prior to assessment of cell viability and gene expression.

RESULTS

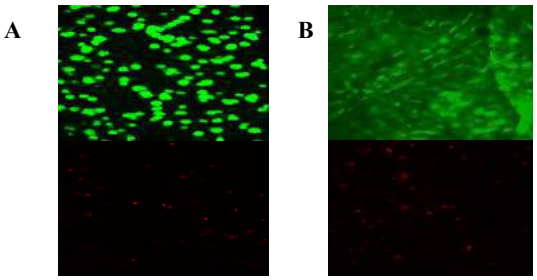

Fig 2: Cells were stained using Calcein AM (live cells – green) and Ethidium Homodimer (dead cells – red). (A) Non-strained, (B) strained. These images are representative of a large number of images taken at different positions of the 3D gels (n=7). Cell viability was 78-97 %, established by counting cells in the field of view looking at 3 viewpoints per sample.

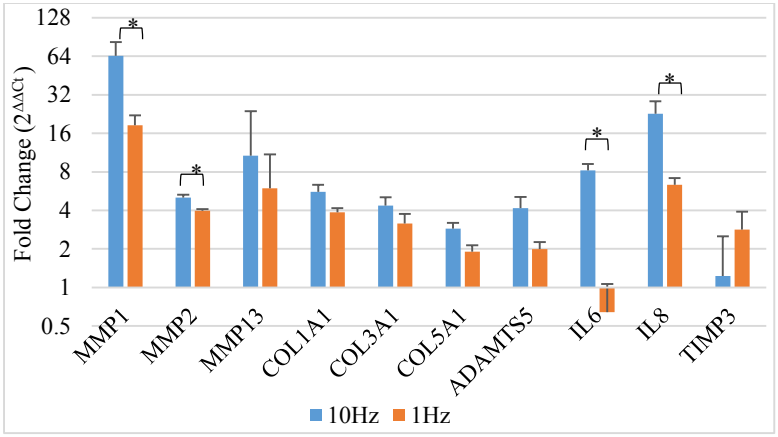

Fig 3. Expression of mRNA in healthy human hamstring tenocytes normalised to 18S (n=3). There was an upregulation of the majority of genes with loading, and four genes increased significantly in response to 10Hz loading compared to 1Hz loading. *= significant difference between 10Hz & 1Hz loading ($p<0.05$)

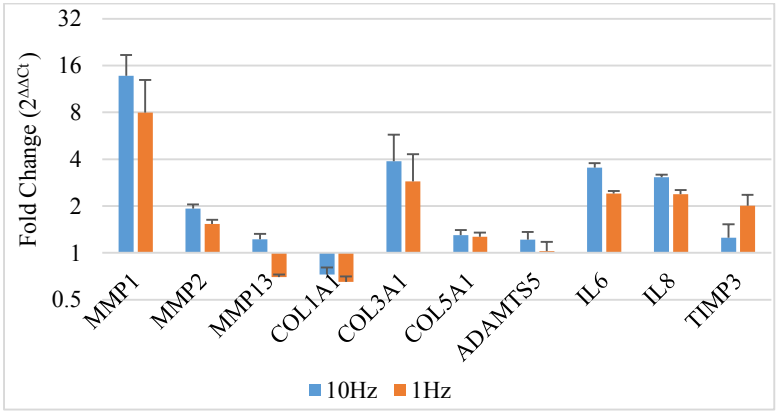

Fig 4. Expression of mRNA in tendinopathic Achilles tenocytes normalised to 18S (n=3). There was upregulation of a number of genes with loading, but fold changes were less than seen with healthy cells. Some genes showed less than a two-fold change in expression. No significant differences were seen in the response to 10Hz & 1Hz loading.

Fig. 2 showed that cells within the collagen gels remained viable throughout the test period, with and without loading. However, data suggests less cell death in non-strained groups compared to the strained groups. Fig. 2B also showed that in the strained matrices, the cells were aligned in the direction of loading, whereas in non-strained samples (fig. 2A), there is no clear orientation indicating an adaptation in morphology in response to mechanical load.

In healthy cells (fig. 3), there was an increased expression of the majority of genes after loading. Furthermore, although the majority of genes showed no significant difference in their response to 10Hz and 1Hz loading, the increase in gene expression was generally larger in the higher frequency (10Hz) loading group, across all genes, with the exception of TIMP3. Tendinopathic cells (fig. 4) showed a more varied response, with upregulation of MMP1, MMP2, COL3A1, IL6, and IL8. However, some genes (MMP13, COL1A1, COL5A1, and ADAMTS5) were unresponsive when all three donor groups were merged. This could reflect the difference in tissue source of the cells (hamstring and Achilles for healthy and tedinopathic cells respectively), or might also be a consequence of the different cell derivation methods (collagenase digest and explant outgrowth for healthy and tedinopathic cells respectively).

DISCUSSION

Generally, the viability data showed good cell viability in the system, while the gene expression preliminary data suggest increased matrix turnover as a result of loading, and a more extensive increase with 10Hz loading, particularly in healthy tenocytes. As such, the data tentatively support our hypothesis that 10Hz loading initiates a greater metabolic cell response. However, the data showed wide variations in response across the three donors thus, further research is required to clarify this.

Fig. 3 shows a significant difference in cell response to 10Hz and 1Hz loading in healthy cells for MMP1, MMP2, IL6 and IL8 which may indicate early matrix breakdown and a slow remodeling process. The mechanism by which 10Hz loading results in increased expression of MMPs and interleukins in healthy tendon are yet to be determined, however, previous studies have shown that cyclic loading induces the expression of IL1 [8]. Further, stimulation with IL1 increases expression of MMPs and IL6 [8; 9], suggesting that the IL1 signaling pathway may be involved in the greater tenocyte response to loading at a frequency of 10Hz.

By contrast, the profile of tendinopathic cells may indicate an early healing response, where collagen type III is preferentially upregulated relative to types I&V. Overall, tendinopathic cells appeared less responsive to strain with greater fold changes in gene expression observed in healthy cells, and no significant differences between the 10Hz and 1Hz loading groups.

This study has demonstrated for the first time that loading at a frequency of 10Hz may enhance metabolic response in healthy tenocytes. However, this response appears to be lost in tendinopathic cells. As such, further studies are needed to establish the mechanisms by which 10Hz loading stimulates increased gene expression.

THE SYNERGISTIC USE OF HAPTIC FEEDBACK WITH AN EMG CONTROLLED TRANSFEMORAL POWERED-KNEE PROSTHESIS

J. Miles Canino (1), Kevin B. Fite (1)

INTRODUCTION

Lower limb-loss rehabilitation is an arduous task that does not always result in favorable outcomes, particularly in patients with dysvascular etiologies. The causative agents behind this lack of effective rehabilitation are many and greatly varied, but a steep learning curve and improper implementation of prosthetic control techniques greatly contribute to poor rehabilitative outcomes. Communicating proper gait mechanics via kinesthetic haptic feedback rhythms to the amputee during the rehabilitation process may help to flatten this learning curve, encourage proper prosthetic usage, and lead to an increase in successful outcomes [1, 2].

Researchers have demonstrated that the usage of haptic feedback in electromyography (EMG)-controlled prosthetic systems can offer greater acuity in user-mediated controls, particularly in more dexterous tasks. This has been shown in the object manipulation of an upper limb prosthetic [3, 4]. With upper limb object manipulation, a user often has the benefit of concurrent visual feedback. With lower limb amputees however, adequate visual feedback is not available during locomotion. Communicating state information about the prosthetic limb could ameliorate any deficits caused by this deficit. Other researchers have worked towards a similar goal with successful outcomes in transtibial applications [5]. The goal of this research is to further investigate one's ability to effectively understand and respond to varying haptic modalities, with and without the presence of visual feedback, while trying to volitionally control a dynamic system through EMG inputs. It is suspected that haptic feedback will be effective in communicating relevant limb information in the absence of visual feedback.

METHODS

Two prototype haptic feedback systems were designed and fabricated for experimentation. The vibrotactile array consisted of three linearly arranged vibrating motors suspended in silicone sockets that could be affixed to the subject via Velcro straps (Figure 1). The second feedback system pneumatically actuated and composed of a linear array of machined aluminum pressure vessels with expanding silicone membranes sealing the expanding skin-interface orifice (Figure 1). When these pressure vessels are pressurized through the actuation of a micro-solenoid valve, the chamber fills to ~5psi, thus expanding the silicone membrane and imparting the pressure sensation to the skin interface. Both systems' actuations were mediated by a digital output prompted via a course-corrective, error-feedback control schema embedded in the Simulink control code developed for this testing.

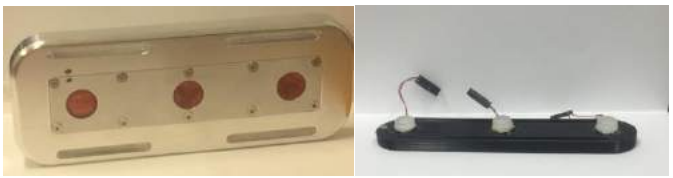

Figure 1: Pneumatic tactile array (left) and vibrotactile array (right).

For this experimental protocol, 4 sets of 7 possible tests were conducted wherein each of the tests were repeated 6 times (N = 42 for each set). Testing sought to investigate the efficacy of these haptic feedback systems in visual and non-visual environments. These tests were performed by two able-bodied, informed and consenting subjects, a 27 year old female and 24 year old male, who were asked to control a virtual limb and a powered transfemoral prosthetic. This was conducted under Clarkson University IRB approval # 14-34.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The virtual limb was modeled as a simple pendulum with a controlled torque about its pivot. The control architecture for the prosthetic and the virtual limb is as described by the works of Dawley et al. [6]. The control torque of both systems was volitionally controlled by the user through EMG interfacing. The prototypical transfemoral powered knee prosthetic used in this study is described in detail by Hoover et al. [7].

For both systems, testing was conducted in the following manner. The subject was first required to go through an initialization and calibration routine [6]. The EMG electrodes used to control the limbs were then attached to the subject's dominant quadriceps and biceps femoris. Data was then sequentially recorded with the subject relaxed and with the subject performing sustained isometric flexion and extension contractions from 0 to 100% of max voluntary contraction. This data was then used to complete the principal component analysis (PCA) required for calibration. This PCA establishes all pertinent constants necessary to map between normalized EMG and limb impedance, like equilibrium point and effective stiffness [6]. After this initialization routine, the subject trained with the virtual and prototype limb for approximately 2 hours, getting accustomed to how the EMG input would visually affect the graphically represented limb angle or physically affect the prosthetic limb.

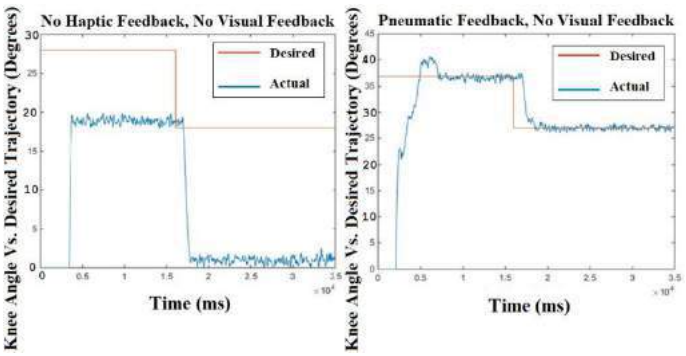
On subsequent testing days, the initialization routine was repeated, and the subject was then presented with randomized tests which incorporated or restricted visual feedback and haptic feedback modalities. In these tests, the subject attempted to follow a randomly generated trajectory presented on a monitor with the graphical representation of the limb's current state overlaying the desired limb state. Subjects were instructed to first stabilize about a random band-limited (25-65 degrees), limb angle which would then, at some random time (10-20 seconds), change up or down in a pseudo-random band-limited step response limited to a minimum of ±5 and maximum of ±20 degrees. The subject would then have to stabilize about this new desired limb angle. To provide or restrict visual feedback, the subject was either shown their current trajectory overlaying the desired trajectory, or they were just shown the desired trajectory and had to guess where they thought the limb was. Each of these randomized tests was performed 6 times per subject, per limb type, including the control. During the control tests, the subject had a goniometer affixed to their sound limb and they would attempt this test with visual feedback.

The efficacy of haptic feedback to communicate in visually devoid environments was explored using one-way ANOVA. The null-hypothesis was that the concurrent usage of haptic feedback modalities has no effect on the accuracy of an EMG controlled virtual limb (N=42 for each of the 4 sets). The independent variables investigated were each of the possible test configurations. The dependent variable investigated was the root mean square (RMS) deviation of desired versus actual limb angle for each test. The normality of the data sets was analyzed using a one-sample Kolmogorov-Smirnov test, and the data was found to be normally distributed.

Both the Welch and Brown-Forsythe tests confirmed that these data sets were robust enough to continue ANOVA. Because the data was robust but not homogeneous in its variance, the Games-Howell approach was used to perform multiple comparisons.

RESULTS

Figure 2 shows a sample performance of a test subject attempting the trajectory-following task with (left) and without (right) pneumatic haptic feedback in the absence of visual feedback. Figure 3 shows the plot of mean data and the marked performance improvement in visually deprived environments with haptic feedback intervention.



Figue 2: Sample trajectory of non-visual testing with and without haptic feedback.

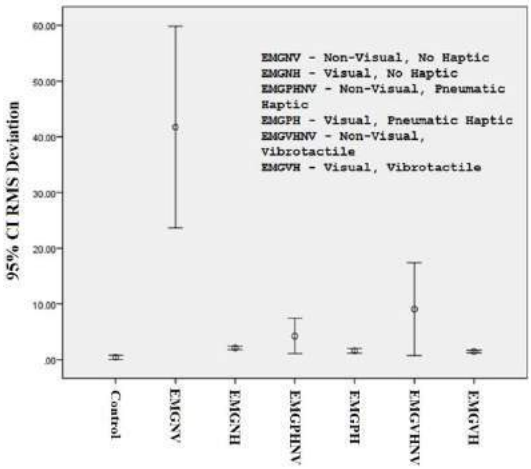


Figure 3: Plot of mean comparison data for all test sets.

DISCUSSION

The concurrent usage of pneumatic haptic feedback with volitional EMG control was found to be significantly synergistic in both test subjects , particularly when used in an environment where visual feedback is limited or completely absent ($p = 0.007$). The usefulness of haptic feedback in conveying limb-state information is consistent with that of other research endeavors [3-5], but it should be noted that vibrotactile haptic feedback was not found to be significantly useful for one of the test subjects ($p = 0.045$), who experienced desensitization phenomenon with the vibrotactile arrays.

This raises an interesting question on how to dissuade desensitization, or to better establish the localizability of the vibrotactors in individuals who have a physiological difficulty in perceiving their location. Future studies will investigate using rhythmic patterns to stave off mechanoreceptor adaptation, or possibly the usage of a unique pulse pattern for each tactor. This future research will work to inform the design and development of a kinesthetic haptic feedback rehabilitative aid.

INTRODUCTION

End-stage renal disease (ESRD) results from conditions that chronically decrease renal function and is most commonly treated with hemodialysis (HD) while patients await kidney transplant. Current methods for maintenance of HD vascular access are fraught with problems that compromise patency of these surgically created shunts. The major cause of shunt failure is thrombosis caused by occlusion of the outflow venous anastomosis and draining vein. Intimal hyperplasia (IH), a thickening of the vessel wall, initiates the pathogenesis of venous stenosis. While the pathogenesis of IH is not completely understood, the perturbed hemodynamics generated by the vascular access is increasingly pointed to as a potential contributor as venous wall regions experiencing low and oscillatory wall shear stress (WSS) have been shown to be particularly vulnerable to IH development[1].

In this context, improvement of vascular access patency could be sought through strategies aimed at preserving normal venous hemodynamics in HD patients. In pursuit of this effort, we previously proposed a novel modular anastomotic valve device (MAVD)[2]. This device features a shuttle valve system which can block or allow arteriovenous graft (AVG) flow (Fig. 1). Preliminary computational testing suggested the ability of this device to maintain physiologic venous flow in the closed position (i.e., between HD sessions) and the benefits of smaller anastomotic angles to maintain WSS levels above their pathologic threshold[2]. While AVG flow rates are only clinically effective between 600 and 2000 mL/min, the impact of the AVG flow rate on the MAVD hemodynamics is unknown. The goal of this study was to quantify computationally the hemodynamics of the open MAVD (i.e., during hemodialysis) over the range of flow rates enabling effective HD.

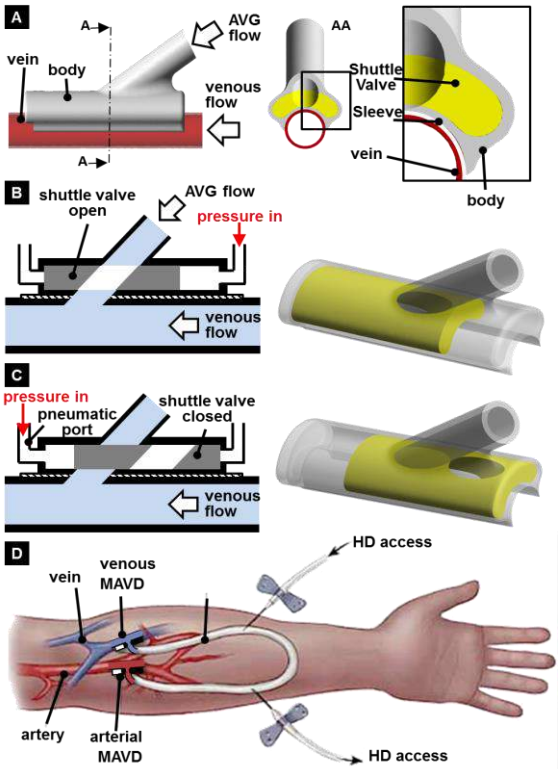

Fig. 1: MAVD design. (A) Prototype MAVD, (B) schematic of operation in open and (C) closed positions, and (D) clinical implementation.

METHODS

The impact of the AVG flow rate on the vascular access WSS environment was quantified computationally. The three-dimensional (3D) geometry of the open MAVD mounted onto the brachiocephalic vein was designed in SolidEdge. Fully-coupled, transient fluid-structure interaction (FSI) simulations were run in ANSYS. The vein was modeled as an incompressible, isotropic and hyperelastic material using a previously published Mooney-Rivlin model[3]. Blood was modeled as a non-Newtonian fluid using a modified power-law model[2]. Pulsatile boundary conditions at the MAVD model inlet were obtained experimentally in a bench-top vascular access flow loop using an in-line ultrasonic flow sensor. The setup consisted of a programmable pulsatile pump, a reservoir, a compliance chamber and a 3D-printed MAVD prototype. Average graft flow rates of 800, 1000, and 1500 mL/min were generated while maintaining a physiologic heart rate of 70 bpm and an aortic blood pressure of 120/80 mmHg. For each flow rate, the pulsatile graft flow rate waveform was measured at 160 time points over the cardiac cycle and input to the model. The model was validated by comparing the FSI velocity predictions to Doppler ultrasound velocimetry measurements performed at the venous anastomosis. Global flow metrics were assessed in terms of streamlines and WSS fields. The FSI model was used to identify regions of low WSS (WSS < 0.5 Pa) on the vein wall and to further characterize them in terms of temporal shear magnitude (TSM) and oscillatory shear index (OSI). The impact of the incoming graft flow on the vein wall was also assessed in terms of maximum wall displacement.

RESULTS

The comparison between the predicted and measured maximum velocity in the mid-anastomosis region of the vein revealed less than 8% difference over the range of tested flow rates. Regardless of the AVG flow rate, the model isolated only one low WSS region present along the anastomotic side of the vein, 7.5 mm distal to the anastomosis. The comparison of the TSMs (800 mL/min: 0.57 Pa, 1000 mL/min: 0.04 Pa, and 1500 mL/min: 0.11 Pa) and OSIs (800 mL/min: 0.00, 1000 mL/min: 0.06 Pa, and 1500 mL/min: 0.15) captured on this segment of the vein revealed an increasingly pathogenic WSS environment under increasing AVG flow rate.

The open MAVD streamline patterns (Fig. 2a) indicate that the high-velocity AVG flow generates a low-flow region near the anastomotic side of the vein distal to the anastomosis generating low and oscillatory WSS. A less significant reduction in WSS (WSS < 1 Pa) is observable on the anastomotic side of the vein wall immediately proximal to the anastomosis. The incoming flow also generates a high-flow, high WSS region on the non-anastomotic side of the vein. The predicted WSS distribution (Fig. 2b) confirms this observation, as demonstrated by the existence of high WSS levels in the vein distal to the anastomosis, and regions of lowered wall shear stress on the anastomotic side of the vein wall proximal and distal to the anastomosis.

The maximum displacement of the vein wall predicted at peak systole (800 mL/min: 0.004 mm, 1000 mL/min: 0.006 mm, and 1500 mL/min: 0.011 mm) was shown to remain negligible relative to the vein diameter, over the range of AVG flow rates tested.

DISCUSSION

This study demonstrates the significant impact of AVG flow rate on vascular access flow and the higher potential of elevated AVG flow rate to generate near-wall hemodynamics promoting IH pathogenesis. The vascular access flow loop also constitutes a new bench-top tool for the in vitro evaluation of vascular access hemodynamics. Ongoing work includes animal trials of implanted MAVDs which may shed new light on the capability of the MAVD to reduce IH development.

INTRODUCTION

The Cesarean section is a traumatic and costly operation. The surgery, originally designed to preserve the lives of mother and infant in severe cases has gained widespread use in less dire circumstances. Hospital stays post-surgery are much greater than that of a natural delivery [1]. In addition to the economic considerations, natural delivery has been shown to give neonates distinct advantages, including: a bacterial biome transfer from mother to child and an easier time breathing after birth since the fluid is squeezed out of the lungs in the birth canal [1]. Investigating the role of fluid in the mechanics of labor and delivery may lead to methods to reduce the rate of Cesarean section and to increase the rate of natural delivery.

The laboring uterus is a complex and dynamic fluids system. The two primary fluids of interest, amniotic fluid and vernix caseosa, play integral roles in the force transferred to the fetus during the final stages of parturition. Amniotic fluid, comprising between 12 – 30 % of the uterus's total volume at delivery, possesses somewhat different bulk properties for each individual woman. Vernix caseosa, consisting of skin cells and secreted oil, covers the fetus and acts as a lubricant during delivery [2]. Relatively little it known about the fluid properties of the laboring system. This investigation probes the role of fluid in the force transfer during delivery by considering computational and physical models that determine the role of various components of the full system. The results of these methods are given and compared below.

METHODS

In the experimental investigation, the birth canal and the fetus are modeled as two concentric cylinders. The experiment is contained in a 15.25 x 75 cm tank. In the center of the tank, a thin, latex membrane is supported on its ends by collars and secured to the base of the tank. The latex is 68.5 μm thick. The test section is 14 cm long. A track of aluminum runs the length of the tank, passing through the latex membrane. The track is supported on both sides of the test section, in order to prevent deformation.

The inner cylinder is an acrylic, rigid rod with a 0.3175 cm hole drilled through its center. Two hooks are secure to the front end of the rigid rod, spaced equidistant from the center hole. The rigid cylinder moves through the flexible, outer membrane with a prescribed velocity, u. The diameter of the outer membrane is 3.8 cm, leaving a 0.31 cm gap between the cylinders. The experimental design is summarized in Figure 1.

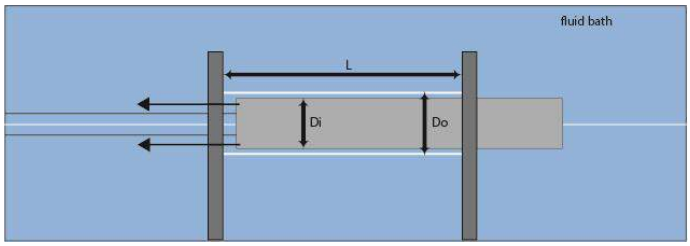

Figure 1: Experimental schematic for concentric cylinders setup

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

As the cylinder moves through the testing section, a high-speed camera records its motions at 60 frames/second. For each of the testing fluids, 30 trials are performed. Each of these trials is put through DLFdv5 Matlab software [3]. These digitized values are converted to find the force at each position.

Though the mechanical properties of amniotic fluid are unknown, it has been described as water-like [4]. Therefore, to study the role of fluid, the tank is filled with fluids of varying viscosities. The first fluid is water at $\mu = 1.00$ cp, followed by two methyl cellulose solutions at $\mu = 10$ cp and $\mu = 100$ cp, respectively.

In the numerical investigation, the system is modeled as a rigid cylinder moving at a constant velocity (u = 3 cm/s) through the center of a passive elastic tube. The entire model is immersed in a highly viscous fluid. Due to a low Reynolds; number, the Stokes equation is used to describe the relationship between velocity and forces in the system. The mathematical model uses the method of regularized Stokeslets to estimate the pulling force necessary to move the rigid inner cylinder at a constant velocity. The elastic tube is constructed using a discrete network of Hookean springs, with macroscopic elasticity matched to the tube used in the physical experiments.

RESULTS

The average removal force, defined as the average force exerted on the inner cylinder to pull it through the outer cylinder, is normalized by $\mu UA/h$ and plotted against the Reynolds number, where μ is the fluid viscosity, ρ is the fluid density, A is the surface area of the rod (0.028 m^2), and h is the fluid filled gap (0.0031 m). This is summarized in Figure 2.

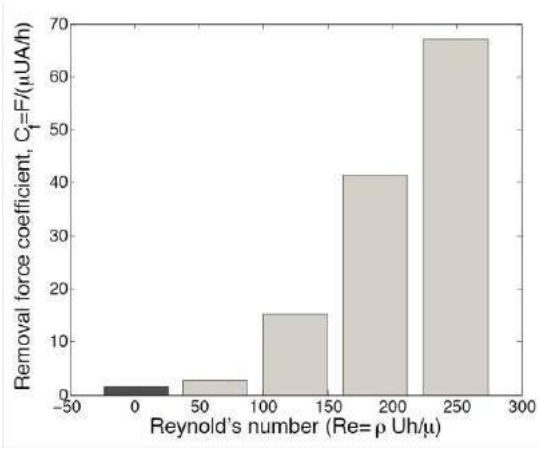

Figure 2: Average force plotted against Reynolds number; the dark grey bar represents the methylcellulose trials

In the numerical investigation, the tube behavior as the rod travels through its center, and at the fluid pressure and velocity in the system over time was observed. As the rod moves through the tube, the tube bulges outward as expected. When it reaches the end of the tube, there is some folding of the elastic tube, similar to what occurs in the physical experiment.

As the rod leaves the tube, the tube buckles in a six-petaled flower pattern due to the pressure drop inside the tube behind the rod. The buckling begins to relax as the rod moves further away from the tube. When the rod moves through the tube, and vacates the region directly behind it, the pressure drops and fluid rushes to fill the empty space. This drives the buckling of the tube. It appears that the lubrication between the tube and the rod causes the rod to move more easily through the fluid than it would without the tube's presence.

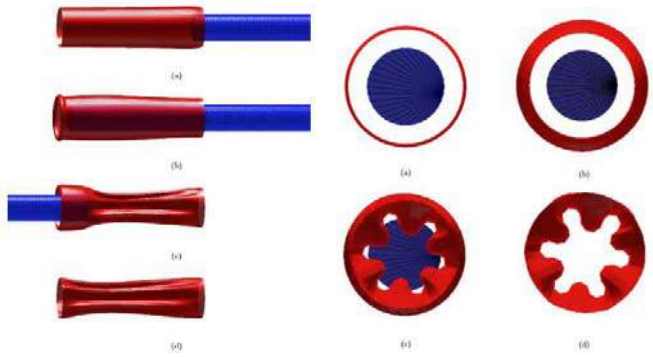

Figure 3: The rod (blue) and the tube (red) are viewed at various times throughout the simulation. The initial outward bulging of the tube can be seen, followed by the six-petaled flower buckling of the tube as the rod begins to exit

DISCUSSION

The physical experiment results demonstrate a positive trend between increasing Reynold's number and increasing force to pull the cylinder.

Buckling has been seen in the physical experiment trials; however, more runs are necessary in the physical experiment to determine if the buckling follows a similar six-petal flower pattern as seen in the computational results.

In the future, using more complex, anatomically accurate geometries as well as including peristaltic activation of the elastic tube may provide further insights into the relationship between viscosity and force during human birth.

INTRODUCTION

Wearable head impact sensors use MEMS accelerometers and gyroscopes to obtain head impact measurements for traumatic brain injury research. These sensors are being deployed to human subjects to study promising injury criteria, but the choice of sensor specifications has not been scientifically justified. When selecting inertial sensors for head impact sensing, it is important to consider sensing requirements of the target head impact response. One important consideration that is often overlooked is the frequency content of head impacts, which will determine key sensor specifications including bandwidth and sampling rate. Although voluntary human motion is often low frequency, blunt impacts to the head are expected to have higher frequency content and only last up to tens of milliseconds. It is unknown whether existing MEMS sensors are sufficient for fully capturing the desired head impact response.

Despite this uncertainty, a variety of head impact sensors have been developed and piloted in various helmeted and unhelmeted sports. These sensors typically have a sampling rate of 1000Hz, with accelerometer bandwidths within 500Hz and gyroscope bandwidths within 200Hz. With more and more researchers using these sensors, we need to scientifically investigate whether such sensor bandwidths and sampling rates are sufficient. The answer will depend on the injury risk criteria being studied and the study population, since the frequency response of different types of contact will differ, and each injury criterion will have varying sensitivities to different frequency components of kinematic measures. For example, barehead impacts may have different frequency response and different requirements from helmeted impacts. However, similar sensors are currently deployed to both types of sports.

The objective of this study is to determine bandwidth requirements in different model systems for studying different injury criteria. We investigated three model systems: helmeted cadaver head drop (no neck), unhelmeted cadaver head drop (no neck), and a dummy linear impact model (hybrid III neck). We evaluated the effect of varying sensor bandwidth on kinematics-based and finite element (FE) based injury criteria. The results of this study will help inform sensor design and selection. It will also give insight into the components of head frequency response that are important for each injury criterion.

METHODS

Our dataset contains high bandwidth accelerometer and gyroscope measurements from helmeted cadaver head drops, unhelmeted cadaver head drops, and helmeted dummy horizontal spring-driven impact tests (Table 1). The high bandwidth data are treated as ground truth measurements of skull kinematics. We computed injury criteria from such ground truth measurements and filtered measurements (representing lower bandwidth) to determine the resulting attenuation in injury risk predictions.

For the ground truth data set, we used drop test data from a male cadaver head specimen, in either a helmeted or unhelmeted configuration at 6 impact locations each. A 6-degree-of-freedom block was rigidly attached to the occiput. Bandwidth of the accelerometer was 25kHz, and that of the gyroscope was 2kHz. The dummy head data set was collected using a 6aω sensor set up [1]. The accelerometer has a bandwidth of 10kHz, and the gyroscope has 2kHz bandwidth. For both scenarios, we collected sensor data at 100kHz for 600ms, with 100ms pre-impact and 500ms post-impact. Ground truth signals were obtained by filtering raw data at sensor bandwidths with a 4th order butterworth filter. To obtain lower-bandwidth signals, we filtered raw data at the following cut-off values: 50Hz, 100Hz, 300Hz, 500Hz, 1000Hz, and 1650Hz.

Table 1: Model Systems and Impact Conditions

Model System	Method	Conditions
Cadaver unhelmeted 	Drop test on aluminum plate	Frontal Oblique Frontal Occipital Parietal Vertex Occipital Oblique
Cadaver helmeted 	Drop test on aluminum plate	Frontal Oblique Facemask Frontal Occipital Parietal Vertex
Dummy helmeted with neck 	Horizontal spring-driven impact with stiff elastomer impactor head	Frontal Oblique Facemask Frontal Occipital Parietal

To calculate kinematics-based criteria, we used ground-truth sensor signals projected to the center of gravity of the head transformed to anatomical axes. We calculated linear criteria (peak linear acceleration magnitude, HIC15, SI), rotational criteria (peak rotational acceleration magnitude, peak change in rotational velocity, BrIC, PRHIC), and 6-degree-of-freedom criteria (HIP, GAMBIT, GAMBIT HITS, PCS). To calculate finite element model-based injury criteria, we ran simulations using the KTH head model [2]. From simulation outputs, we extracted peak principal strain in the whole brain, peak principal strain rate in the whole brain, and POP90 peak principal strain and strain rate.

We calculated injury criteria for each impact location in each model system for ground truth measurements and lower-bandwidth (i.e. filtered) measurements. The percent attenuation of each case from the ground truth was calculated and we determined the minimum bandwidth required to achieve less than 10% attenuation.

RESULTS

The unhelmeted cadaver head drops generally required the highest sensor bandwidths, followed by helmeted cadaver head drops, and helmeted dummy head impacts (Figure 1). For most kinematics-based criteria in the unhelmeted cadaver model, accelerometer bandwidth needs to be more than 500Hz, which is more than what is available in most current sensors. Rotational velocity bandwidth has a more significant effect on FE-based injury criteria than linear acceleration bandwidth, and strain rate criteria have higher bandwidth requirements than strain criteria. Although strain criteria do not require more than 50Hz accelerometer bandwidth, they need at least 100Hz gyroscope bandwidth. To calculate strain rate criteria in the unhelmeted model system, a bandwidth of 500Hz is required for the gyroscope, while 300Hz is sufficient for the helmeted model system – both much higher than the bandwidth of existing sensors. Kinematics-based criteria generally require higher sensor bandwidth than FE-based criteria. In addition, although peak kinematic measures (e.g. peak linear acceleration magnitude) are often used to validate sensors, their bandwidth requirements are often lower than many other injury criteria, including both compound kinematic injury criteria (e.g. HIC) and FE criteria (e.g. strain rate).

DISCUSSION

In this study, we determined minimum bandwidth requirements for studying various injury criteria in different model systems. We found that for both kinematics-based criteria and FE-based criteria, higher bandwidths are required for the unhelmeted cadaver drop test model. This implies that barehead sports will likely require higher bandwidth sensors than helmeted sports. Since many women's and children's sports (e.g. soccer) are unhelmeted, having higher sensor bandwidths is essential to study such populations. In fact, bandwidths of current sensors are insufficient in many of the cases evaluated. Another key finding is that peak kinematics-based validation of sensors may not be sufficient to ensure that injury criteria calculations also have acceptable error. This is based on the observation that many injury criteria have higher sensor bandwidth requirements than peak kinematic criteria. Thus, future efforts to validate head impact sensors may need to consider setting error thresholds on injury criteria computation.

Since much current research effort is directed towards collection of human data to study injury thresholds, it is important that head impact data are properly captured to include information essential for injury risk estimation. Our findings provide guidelines for researchers to design/select sensors for traumatic brain injury research.

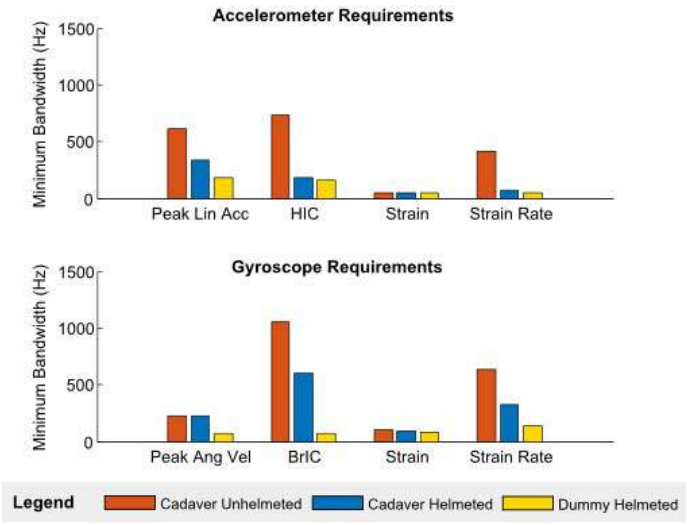

Figure 1: Sensor Bandwidth Requirements. This figure illustrates the minimum bandwidths required to achieve within 10% error in calculating common injury criteria.

ACKNOWLEDGEMENTS

We would like to acknowledge Dr. Svein Kleiven for providing the KTH head model, Dr. Dale Bass and Dr. Jason Mihalik for our partnership in post-mortem human subject experiments. INTRODUCTION

In developing countries, diagnostic tests for homozygous (HbSS) or compound heterozygous (HbSC or HbS-Beta thalassemia) sickle cell disease (SCD) are not readily available at the point-of-care (POC). Very few infants are screened in Africa for SCD because of the high cost, time for sample transfer to/from a central laboratory (2-6 weeks), and level of skill needed to run traditional tests, which are high performance liquid chromatography (HPLC) and bench-top hemoglobin electrophoresis. The World Health Organization recognizes a crucial need for early detection of SCD in newborns, and it is estimated that 70% SCD-related deaths in Africa are preventable with early cost-effective interventions [1]. The diagnostic barrier can be broken with affordable, POC tools that facilitate early detection immediately after birth or at the time of immunization [2]. To address this unmet clinical need, we have developed a microchip electrophoresis platform (HemeChip) for reliable, affordable, and rapid diagnosis of SCD.

METHODS

The HemeChip uses a microfabricated platform, with a material cost less than $1 per device, housing a cellulose acetate electrophoresis substrate to rapidly separate hemoglobin (Hb) types (Fig. 1A-E). Less than 5 microliters of blood, which can be obtained through a finger stick or heel stick, is processed on a piece of cellulose acetate paper via an applied electric field (250 V and 5 mA) in alkaline buffer within 10 minutes. Hb types are identified and relative percentages are quantified using image processing (Fig. 2). A mobile user interface was developed in Matlab and was established to be compatible with cloud computing resources. We clinically tested and benchmarked HemeChip against standard clinical methods using 51 blood samples.

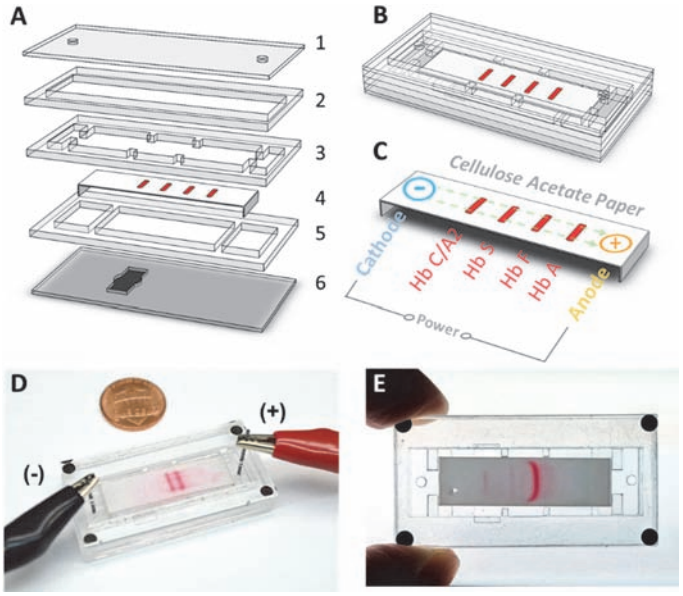

Figure 1. HemeChip for diagnosis of sickle cell disease. (A) HemeChip is fabricated with multiple layer lamination of PMMA (1-3, 5-6) encompassing a single strip of cellulose acetate paper (4). **(B)** HemeChip has a compact design and can be carried in a pocket. **(C)** Separation of hemoglobin types: Normal hemoglobin (Hb A0), Fetal hemoglobin (Hb F), Sickle hemoglobin (Hb S), and Hemoglobin C (Hb C) or A2. **(D)** Hemoglobin separation occurs via an applied electrical field between anode (+) and cathode (-). **(E)** A HemeChip prototype is shown with a miniscule amount of blood sample that has been separated into hemoglobin bands.

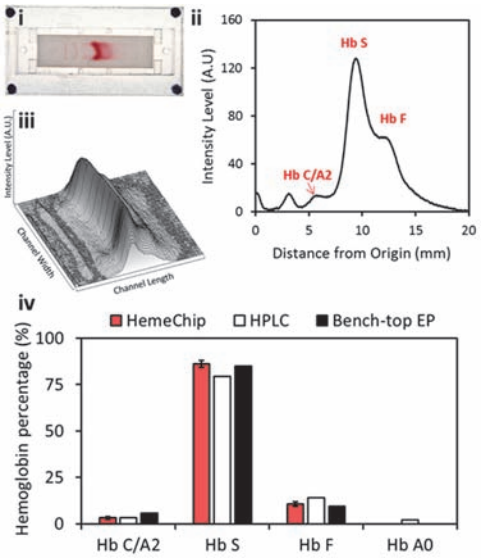

Figure 2. Identification and quantification of hemoglobin types. An HbSS sample is shown. (i) Hemoglobin bands formed in HemeChip allows identification of hemoglobin types. (ii) Measured and averaged pixel intensities reveal intensity peaks identifying hemoglobin types. (iii) 3D surface profile of pixel intensities. (iv) Hemoglobin percentages measured using HemeChip, HPLC, and bench-top electrophoresis are compared.

RESULTS

The HemeChip reliably identifies and discriminates amongst Hb C/A2, S, F and A0. The ROC curves showed more than 0.89 sensitivity and 0.86 specificity for identification of hemoglobin types. The HemeChip Hb% results correlated with HPLC results. HemeChip and HPLC results showed a strong agreement in quantified hemoglobin percentages, analyzed using Bland–Altman plot. The majority (95.5%) of the differences were within the limits of agreement (Fig. 3A-D).

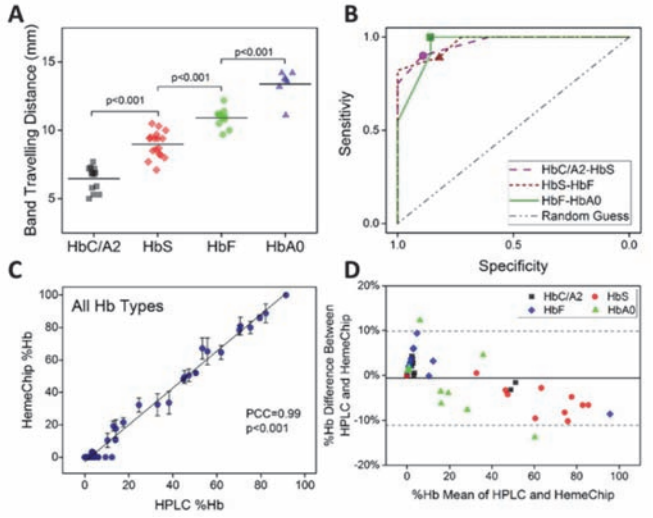

Figure 3. Clinical assessment of HemeChip. (A) The distance traveled from the application point for each hemoglobin band is used to identify the separation and presence of each hemoglobin type. **(B)** ROC curves show sensitivity and specificity for differentiating between adjacent hemoglobin bands based on the travelling distance. **(C)** Correlation plot for comparison of HPLC and HemeChip. **(D)** Bland-Altman plot showed strong agreement for the measurement of Hb% between HemeChip and HPLC.

We developed a web-based image processing application for automated and objective quantification of HemeChip results at the POC using cloud computing resources. This intensity-based mobile phone image quantitation method showed high correlation with HPLC results for tested patient blood samples (Fig. 4A-C). Moreover, the Bland-Altman analysis showed strong agreement between the HemeChip results analyzed with the mobile user interface and HPLC. The majority (91%) of the differences were within limits of agreement.

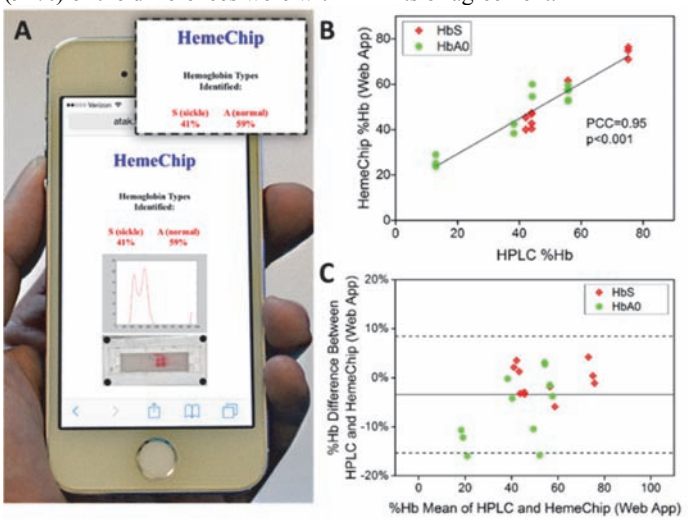

Figure 4. Web based mobile imaging and quantification of HemeChip results. (A) Mobile phone image depicting an analyzed HemeChip result and corresponding hemoglobin types along with their percentages. **(B)** Transfused SCD patient blood samples tested with HemeChip and quantified using the web service are plotted with HPLC results. **(C)** Bland-Altman plot showed strong agreement between HemeChip results analyzed with the mobile imaging modality and HPLC.

DISCUSSION

HemeChip technology offers a low-cost, easy to use, rapid approach and an innovative solution to POC diagnosis of SCD and other hemoglobin disorders. HemeChip can distinguish between different patient phenotypes, including HbSS (HbS only), transfused HbSS (HbS and HbA), and Hemoglobin SC disease (HbS and HbC). In summary, the HemeChip identification and quantification of hemoglobin phenotypes, as a POC technique, were comparable to standard clinical methods. This platform has clinical potential in under-served populations worldwide, in which SCD is endemic.

METHODOLOGY TO REDUCE DIMENSIONAL VARIABILITY IN TENSILE TESTING OF SOFT FIBROUS TISSUE

Madison E. Krentz, Jaremy J. Creechley, Trevor J. Lujan, Ph.D.

Department of Mechanical and Biomedical Engineering
Boise State University
Boise, ID, USA

INTRODUCTION

Tensile testing is frequently used to quantify the mechanical properties of many soft fibrous tissues, including ligament, tendon, and meniscus. The measurement of accurate mechanical properties from tensile testing requires the preparation of a large number of specimens with consistent dimensions from a finite number of donors. While maintaining good dimensional tolerances within and between specimens is critical to reduce uncertainty of the measured properties, the heterogeneous, amorphous and flexible nature of soft fibrous tissue has made consistent dimensioning a challenging task. As a result, studies that conduct tensile tests on connective tissue have reported high dimensional variability, which range from 10-38% between specimens [1,2] and range from 7-26% within specimens [3]. Therefore, standardized experimental techniques need to be developed and validated that reduce the dimensional variability of soft tissue specimens used for tensile testing.

The objective of this study is to develop and validate a fast, precise, and affordable methodology to acquire tensile specimens of soft fibrous tissue with low dimensional variability. The preparation of specimens for tensile testing requires tissue to be separated, or layered, to a specified thickness and cut, or stamped, into dog-bone shapes with a specified aspect ratio (ASTM 23479). Established methods to layer tissue include the use of a vibratome, microtome or deli slicer [3,4,5,6,7]. However, a deli slicer has only been used to layer soft organs, and not fibrous connective tissue. Established methods to stamp tissue include the use of custom metal punches or manual dissection tools, such as a scalpel [1,5,6,7,8,9]. Custom metal punches are precise, but expensive; while manual dissection tools are imprecise, but affordable. This study will determine if the dimensional variability of meniscus tensile specimens can be reduced by using a deli slicer and an inexpensive punch, made using a 3D printing device.

METHODS

Materials: All meniscus used in this study were extracted from five medial and lateral bovine knees between the ages of 18-22 months. After harvest (Fig. 1A), all meniscus were wrapped in saline solution-coated gauze, and were frozen for a minimum of 24 hours at -4 ℃. Menisci were then separated into three wedges (Fig. 1), where the central third was used in this study. A total of 30 tensile specimens were acquired from the meniscus wedges for this experiment.

Specimen Layering: The effect of layering techniques on dimensional variability was analyzed for three different approaches. In the first approach, a "bare" meniscus wedge was layered using a commercial vibratome (Fig. 1B-C). A 1x1 inch square of hot glue was mounted on the vibratome plate and the meniscus was fixed on top of the stage using cyanoacrylate glue. Glue was applied with caution, and the layer closest to the area where the glue was applied was discarded to ensure that no contaminated specimens were included in analysis. The vibratome plate was placed inside the bath which was then filled with saline solution that had been refrigerated for 24 hours prior to testing. The speed of the cut was 0.25 mm/s, at a 1 mm amplitude and

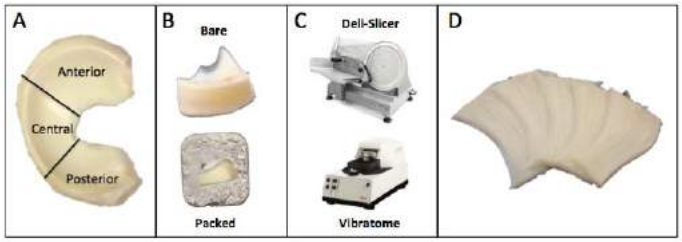

Figure 1: Specimen Layering. A) Meniscus either sectioned B) bare or packed in cellulose matrix for layering in a C) deli-slicer or vibratome. D) layered specimens from deli-slicer.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

80 Hz frequency [10]. The cutting angle was 15 degrees. Ten cuts were collected from two separate central wedges and prepared for measurement analysis.

For the second approach, the "bare" meniscus wedge was layered using a commercial deli slicer (Fig 1C). The meniscus wedge was placed with the outer rim against the deli slicer fence. The control knob was set to a cutting thickness of 1 mm. A custom fixation device was applied to the bare meniscus to prevent meniscus slipping, and the deli slicer blade was sprayed on both sides with saline solution to reduce friction. Cutting speed was estimated at 0.25 mm/s.

The third approach also used the deli slicer, but first packaged the meniscus in a cellulose matrix. The cellulose solution was created using a mixture of 500 mL of cellulose clay, paper, and 250 mL of water. The cellulose matrix and meniscus was packed into a 2x2 inch square plastic container, with roughly ¼" of cellulose separating the meniscus from the container walls. The "packed" meniscus was frozen (Fig. 1C) and was then layered using the same approach described above. The reason for embedding the meniscus is that the cellulose media freezes into a solid cube and thereby provides planar surfaces that improve the slicing of the meniscus tissue into uniform layers (Fig. 1D).

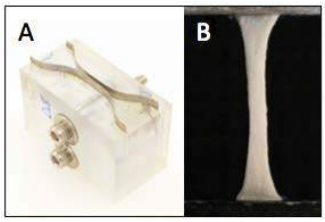

Figure 2: Specimen stamping. A) 3D printed punch. B) Dog-bone-shaped sample.

Specimen Stamping: After the layers were prepared, they were stamped using a custom punch fabricated from a 3D printer and flexible disposable razors (Fig. 2A). These punches had two curved channels to insert the blades and two machine screws to secure the blades to the plastic block. The length to width aspect ratio for this punch was set to 8:1 (Fig. 2B).

Imaging and Measurement: Layers were imaged post-punch in a custom device where the camera was fixed approximately 100 mm away from the specimen (Fig. 3A). Each prepared layer was placed inside mechanical testing clamps 13 mm apart and pulled in tension prior to imaging. In order to measure layers as precisely as possible, each picture was run through a program in which it was binarized and the thickness across the layer was recorded in pixel length (Fig. 3C), along with the standard deviation of the values with respect to the intra-specimen mean (Fig. 3D). In order to keep consistency in collecting data, the middle 11 mm values were analyzed. The average value of the pixel length across the specimens was then converted to millimeters using a conversion factor found by taking an image of a 10 mm square in position of a layer on the camera setup, which returned a value of 172.6 pixels/mm.

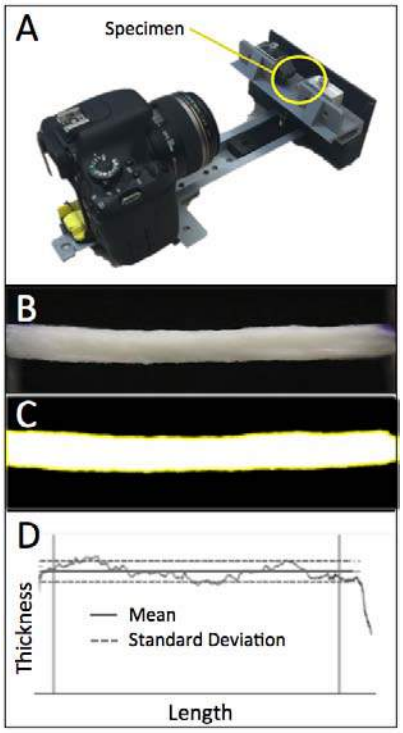

Figure 3: Measuring thickness. A) Fixture to capture images of B) specimen profile. C) Edge detection to D) measure intra-specimen variability.

A one-way ANOVA test was performed on the intra-sample standard deviation values that were normalized by the average thickness for each specimen (N=30). As a final verification step, specimens that were acquired using the "packed" deli-slicer method were strained to failure in a mechanical test system. The location of failure was recorded to determine if these specimens facilitated ideal mid-substance failures, or if they resulted in imperfect clamp failures.

RESULTS

The lowest inter- and intra-variability in specimen dimensions was produced when using the frozen-packed deli slicer method (Table 1). There was a significant difference in standard deviation values when comparing the frozen packed deli slicer method to the bare deli slicer and vibratome methods (p=0.028 and p=0.007, respectively). Out of nine uniaxial failure tests that used specimens from the frozen packed deli-slicer, seven resulted in mid-substance failures, and only one resulted in a clamp site failure.

Table 1: Specimen thickness and variability

Layering Device	Prep Method	Thickness (mm)	Inter-sample variability (%)	Intra-sample variability (%)
Vibratome	Bare	1.31 ±0.11	18.17	16.07 ± 7.36
Deli Slicer	Bare	1.16 ±0.07	6.39	13.00 ± 6.10
	Packed	1.18 ±0.04	5.89	6.55 ±3.40

DISCUSSION

This study found that the dimensional variability of meniscus specimens was most reduced when using a deli-slicer to layer frozen meniscus that was embedded in a cellulose matrix. This experimental approach reduced the intra-specimen variability by over 2 fold compared to other techniques. Compared to the vibratome, the deli-slicer reduced the inter-specimen variability nearly 3 fold.

This study introduced several novel techniques in tensile testing of fibrous soft tissue. Although a deli-slicer had been used to cut soft organs, such as liver and kidneys, we had not seen it used for fibrous connective tissue. The use of a cellulose matrix was a novel concept that was developed to provide a planar surface for more repeatable cutting. In addition, this study used 3D printed punches to reduce the cost and improve the precision of stamping tissue to specified aspect ratios. This advance could allow the fast and inexpensive identification of specimen geometries that reduce the occurrence of clamp failure. Collectively, these new techniques were able to improve the dimensional tolerancing of specimens, and can be applied toward the tensile testing of other fibrous connective tissue.

INTRODUCTION

Cancer is the uncontrollable growth of cells, which can lead to tumors and devastating results if allowed to persist [1]. The extracellular matrix (ECM) plays a key role in cancer cell phenotype in that stiffer matrices have been shown to increase cell proliferation, leading to more ECM secretion, resulting in a positive feedback loop [2]. Key aspects of this relationship are poorly understood, which limits the ability of clinicians and researchers to battle these different types of tumors effectively. Broad based treatments such as chemotherapy have a myriad of side effects and are potentially less effective than treatments aimed at specific types of cancer, or even particular genetic strains. It is presumed that cancer cells originating from stiffer, or softer, tissues will sense their environment differently, as has been proven for normal cells [3] and stem cells [4] which could yield important information in understanding the ability of different malignant cancers to effectively extravasate and repopulate in different areas of the body.

Gelatin methacrylate (GelMA) is a UV-crosslinkable hydrogel that has been shown to be effective in culturing cells in both 2D and 3D in a wide variety of applications [5]. Cells can easily bind to GelMA surfaces, or native binding sites (RGD) within 3D structures, and can proliferate, elongate, migrate and remodel their surroundings. A highly elastic material capable of full recovery from >90% compression, mechanical stiffness can be varied from < 1 to >30 kPa through variation of the gel concentration, and the degree of methacrylation. Within this system we have demonstrated the ability to micropattern cells in 3D to investigate behaviors such as elongation and proliferation in response to mechanical stiffness and 3D geometry [6]. Recently this system has been used to investigate cancer cell migration [7], demonstrating its enormous potential in investigating the relationships between cancer cell physiology and the mechanical stiffness of the surrounding extracellular matrix.

In this study, breast cancer (MDA), cervical cancer (SiHa) and osteosarcoma cell lines (U2OS) were embedded within 3D GelMA hydrogels of low, medium and high stiffness. To achieve this range, the same formulation of GelMA was employed at three different concentrations 7.5% (low), 10% (medium) , and 12.5% (high). The embedded cells were counted over the course of four days, while proliferation and elongation were determined from histological images. Results demonstrated many significant differences in the rate of both proliferation and elongation vs time in culture and mechanical stiffness of the matrix which varied with cell type. Preliminary results with the MDA and SiHa cells demonstrate a cell specific effect, suggesting that there is evidence that different cancer cell types react differently to levels of mechanical stiffness. Further experiments will aim to further elucidate these effects and the factors driving these phenomena.

METHODS

Briefly, GelMA was created as described previously by dissolving 10% gelatin into 100ml of stirred PBS at 50^{o}C, while methacrylic anhydride was added dropwise until 4 ml was added [5]. This mixture was reacted for roughly 3 hours at 50^{o}C in a fume hood, then dialyzed in distilled water within 12,000 kDa cutoff tubing at 50^{o}C for up to 1 week to remove methacrylic acid and other byproducts, and dried in a SpeedVac for at least 24 hours. To create GelMA hydrogels, 7.5%, 10% or 12.5% of GelMA precursor was dissolved in an appropriate volume of PBS at 50^{o}C containing 0.5% Irgacure 2959 (photoinitiator, PI), with 250 ml of the mixture (precursor) then pipeted into wells of a standard 24 well plate, then

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

polymerized with UV light exposure for 80s (high), 100s (medium), or 120s (low). The variation is due to the increased presence of methacrylate groups leading to increased speed of polymerization with increased concentration.

All 3 cell types were cultured using standard techniques and media containing 10% FBS and 1% antibiotic/antimycotic. For experiments, cells were trypsinized, centrifuged to remove trypsin, then were counted and 150,000 cells were added to 250 ml of GelMA precursor/PBS/PI mixture, mixed well and added to a well of a 24 well plate. Plates were then quickly polymerized with the appropriate UV exposure with all gels in 1 plate having the same concentration of GelMA to make UV exposure time constant for all cells.

Immediately following encapsulation, and at 2 and 4 days post encapsulation, images were randomly taken of 5 locations in each gel to analyze cell number and elongation. Cell proliferation was determined by comparing the average cell number on days 2 and 4 as compared to day 0, while elongation was measured relatively as the percentage of cells in the images with an elongated phenotype. Statistical difference within groups were determined with student t tests, while comparisons between groups will be determined by ANOVA with post-hoc testing between individual groups with $p < 0.05$ considered significant.

RESULTS

Experimental results were obtained for the MDA and SiHA cells, and are still ongoing for the U2OS cells due to their more difficult nature to culture in our hands. Cell proliferation in both cases increased significantly ($p < 0.05$) by day 4, though variation was such that clear trends with low n's were inconsistent. In addition, there was an apparent trend with both cell types of increased proliferation with increased matrix stiffness however, insufficient n size and large variation made statistical evaluation difficult. Experiments are ongoing to address these issues and to include analysis of the U2OS cells as well.

For the cervical cancer (SiHa) cells, there was an increase in cell number from day 0 to 4 in all 3 matrix stiffnesses that was significant when comparing day 0 to day 4 in the medium and high stiffness gels, and when comparing day 2 to day 4 in the low stiffness gels (Figure 1). When comparing cell count on day 4 between the different stiffnesses, there was no difference between the medium and high groups, however there was a nearly significant difference between both the medium and high groups as compared to the low group ($p < 0.06$).

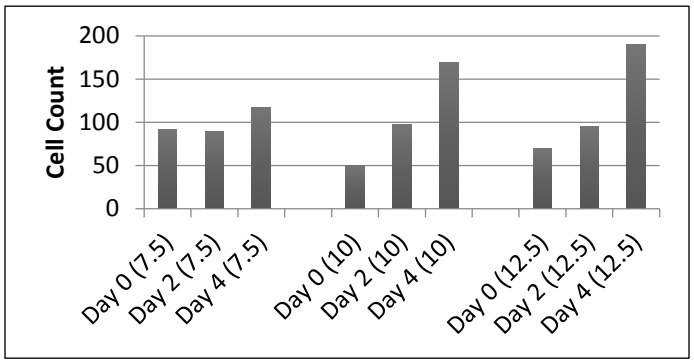

Figure 1: Cell count (per image area) vs time in 3D culture for SiHa cells in 7.5% (low), 10% (medium) and 12.5% (high) stiffness GelMA hydrogels.

For the breast cancer (MDA) cells, there was again an increase in cell number from day 0 to 4 in all 3 matrix stiffnesses, and again this difference was significant when comparing day 0 to day 4 in the medium and high stiffness gels, however this was only true when comparing day 0 to day 2 in the low stiffness gels (Figure 2). When comparing cell count on day 4 between the different stiffnesses, there was again no difference between the medium and high groups, however there was a highly significant difference between both the medium and high groups as compared to the low group ($p < 0.01$ for each).

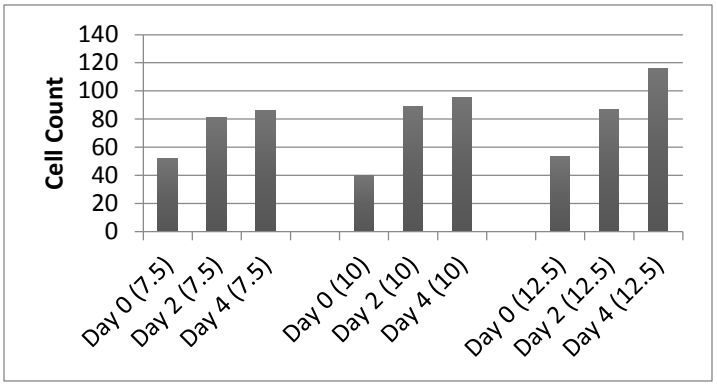

Figure 2: Cell count (per image area) vs time in 3D culture for MDA cells in 7.5% (low), 10% (medium) and 12.5% (high) stiffness GelMA hydrogels.

DISCUSSION

The results presented are ongoing, however preliminary data highly suggest an increase in proliferation in response to increased stiffness in both the breast and cervical cancers, with minor unique differences in each. When subsequent experiments to increase n size and experiments with the osteosarcoma cells are complete, it is expected that there will be substantive differences between the cells presented here and the osteosarcoma cells who are accustomed to a much stiffer native environment. The results presented also suggest that future studies focus on increasing hydrogel stiffness above 12.5%, or otherwise increasing stiffness to further differentiate the responses of the different cell types. While the mechanical properties of GelMA are well characterized, the mechanical properties of this specific batch of GelMA are still ongoing and will inform future studies of the precise range of mechanical stiffness that each case is undergoing.

Future studies will focus on decoupling the mechanical properties from the hydrogel concentration, by varying just the methacrylation degree to avoid also drastically changing the porosity and concentration of native binding and degradation sites.

INTRODUCTION

Patellar tendinopathy is a musculoskeletal disorder resulting from overuse of the knee that is common in athletes participating in sports that involve repetitive jumping, such as basketball and volleyball[1].

Tendon injuries such as this often alter viscoelastic mechanical properties[1]. We recently developed a non-invasive ultrasound elastography technique called continuous shear wave elastography (cSWE) to measure viscoelastic properties of the Achilles tendon[2]. Prior studies, using similar elastography techniques, performs the measurement on the patellar tendon with the knee at 20-30 degrees of flexion to minimize the tension on the tendon[3]. However, our method is designed to evaluate properties of tissues with stiffness higher than maximum values that can be measured with commercial systems. Consequently, cSWE can potentially allow measuring viscoelastic properties of the patellar tendon at higher angles of knee flexion.

The purpose of this study is to determine if cSWE can be used to evaluate healthy patellar tendons at higher values of knee flexion, and if the technique can distinguish between healthy and injured patellar tendons.

METHODS

The patellar tendon was imaged using B-mode ultrasound for tendon length and width and cSWE for viscoelastic properties with the following vibration frequencies: 323, 340, 358, 379, 403, 430, 461, 496, 538, 586, and 645 Hz. The effect of placing actuator on patella versus distal quadriceps muscle belly and the influence of different knee angles (30, 60 and 90 degrees) were tested on 4 healthy subjects.

Based on this pilot study, a final procedure was developed. Subjects (15 healthy and 2 tendinopathic patients) were positioned supine with the actuator placed on the quadriceps muscle. Furthermore, data was collected at 30 and 90 degrees of knee flexion using a knee brace (Figure 1). Data is reported as mean (SD). A paired t-test was used to compare the viscoelastic properties of the tendon at different knee angles. The level of significance was set at $p<0.05$.

Figure 1: Subject positioning for elastography measurements.

RESULTS

There were no significant differences in patellar tendon shear modulus and viscosity between 30 and 60 degrees of knee flexion; however, there were significant differences between the 30 and 90 degrees. When evaluating actuator placement, placement on the quadriceps muscle was more comfortable than the patella for subjects, and it was easier to maintain consistent position during testing. In addition to this, placing the actuator on quadriceps muscle versus patella did not negatively affect quality of data.

When evaluating the effect of the vibration frequency, it was observed that higher frequencies produced waves with a wavelength shorter than the field of view. Having wavelengths shorter than the field of view increases the accuracy of the calculated viscoelastic

properties. Therefore, the highest 6 frequencies were used for data analysis.

The shear modulus and viscosity in healthy patellar tendons were significantly higher at 90 degrees when compared to 30 degrees (Figure 2).

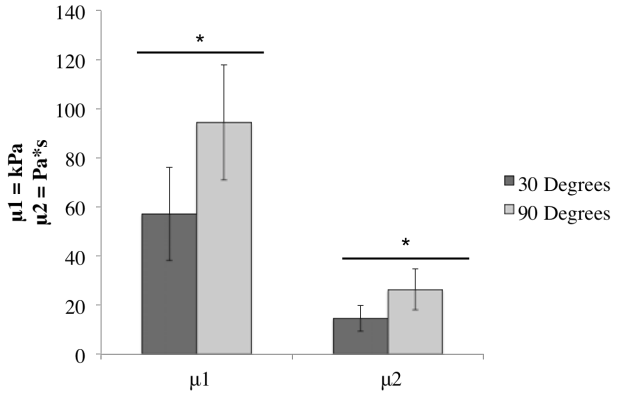

Figure 2: Shear modulus (μ1) and viscosity (μ2) at 30 and 90 degrees for healthy tendons. *p<0.001

Data collected from the two tendinopathic tendons also revealed that values for shear modulus and viscosity were higher at 90 degrees compared to 30 degrees (Table 1).

Table 1: Shear modulus and viscosity of two tendinopathic patellar tendons.

Subject	Angle	μ1 (kPa)	μ2 (Pa*s)
1	30 Degrees	61.7	17.6
	90 Degrees	80.7	22.1
2	30 Degrees	66.4	11.3
	90 Degrees	90.5	26.5

When comparing data collected from the healthy tendons to the two tendinopathic tendons, it is seen that the mean value for shear modulus and viscosity in healthy tendons is lower than both tendinopathic cases at 30 degrees, and higher than both cases at 90 degrees. In addition to this, Figures 3-5 show that proximal patellar tendon thickness in tendinopathic tendons (0.97 cm and 0.89 cm) is greater than that of healthy tendons (0.61 cm (0.10 cm)). Furthermore, the tendinopathic tendons showed increased values for shear modulus and viscosity in the deep half of tendon (Figure 6-7).

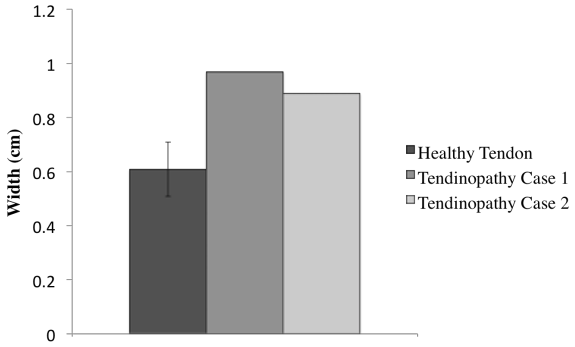

Figure 3: Width at 30 degrees for healthy vs. unhealthy tendons.

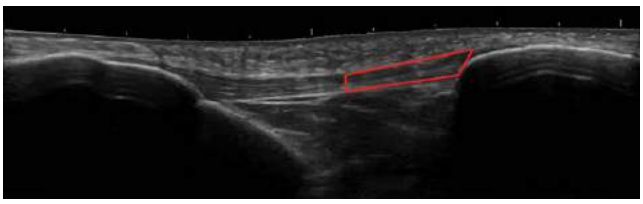

Figure 4: Healthy tendon at 30 degrees.

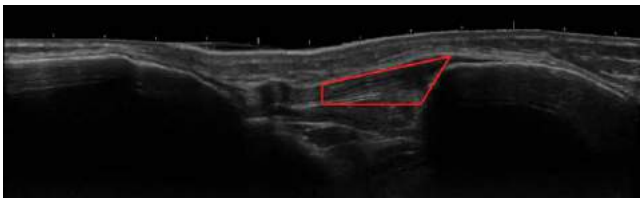

Figure 5: Tendinopathic tendon at 30 degrees.

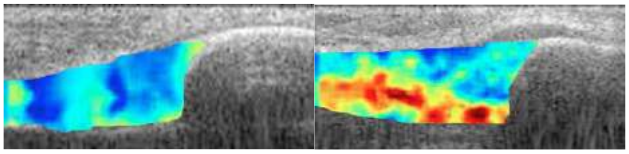

Figure 6: Shear modulus of healthy vs. tendinopathic tendon at 30 degrees.

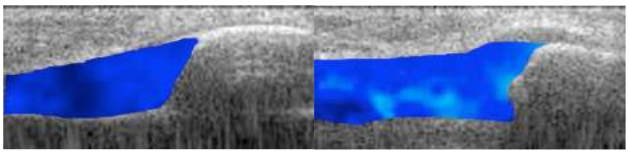

Figure 7: Viscosity of healthy vs. tendinopathic tendon at 30 degrees.

DISCUSSION

This study showed that it is feasible to measure viscoelastic properties at different knee angles using cSWE. Furthermore, our results suggest that cSWE can potentially identify regions in the tendon with altered mechanical properties caused by pathological conditions such as tendinopathy. The results of this study are consistent with prior studies, which have showed that elasticity is dependent on knee position and increased proximal patellar tendon thickness is indicative of patellar tendinopathy[3,4]. A limitation of the current study is the low number of tendinopathic patients. Future studies will involve recruiting more patellar tendinopathy subjects to further investigate the differences between healthy and unhealthy patellar tendons.

INTRODUCTION

Ascending thoracic aortic aneurysms (ATAAs) are focal dilatations of the aortic wall. ATAAs are a serious life-threatening pathology and their incidence is estimated at 10.4 per 100,000 people, suggesting that approximately 45,000 cases are diagnosed each year in Europe and the United States [1]. If an ATAA spontaneously ruptures, the result is almost invariably death [2]. While in principle ATAA rupture can be attributed to a mechanical failure, which occurs when the acting wall stresses exceed the tensile strength of the wall tissue, the exact mechanism remains poorly understood. Since ATAAs undergo continuous pathological remodeling resulting in a highly heterogeneous structure, it is difficult to delineate the local mechanical condition in traditional experiments. In this study, we used a pointwise approach to identify the full field stress, strain and mechanical properties of harvested ATAA samples. This method allowed us to resolve the mechanical conditions to a sub-millimeter resolution. At this resolution, the ATAAs appear to exhibit some distinct rupture patterns. One of these patterns is reported in this presentation.

METHODS

ATAA sections were collected from patients undergoing elective surgery in accordance with a protocol approved by the Institutional Review Board of the University Hospital Center of St. Etienne. Samples of ~4 cm in diameter were pressurized incrementally until rupture. The experimental method was documented in [3]. Briefly, stereoscopic digital image correction (DIC) was used to obtain full-field displacement measurements, and consequently to compute the surface strain distribution. To obtain the stress distribution, we employed an inverse elastostatic method [4] which capitalizes on the property of *static determinacy* to identify the stress field without prior knowledge of the tissue properties. Upon obtaining the distributions of stress and strain at multiple loaded states, the elastic property of the tissue is characterized locally using pointwise stress-strain data. All stress-strain curves we obtained exhibited a profound exponential hardening and moderate anisotropy. To model the stress function we employed a structurally motivated strain energy function:

$$w = \frac{\mu_1}{2}(I_1 - \ln(I_2) - 2) + \frac{\mu_2}{2\gamma}(e^{\gamma(I_k-1)^2} - 1)$$

Here $I_1 = tr\mathbf{C}$, $I_2 = det\mathbf{C}$ are the principal invariants of the Cauchy-Green deformation tensor, and I_k is a compound invariant that takes into account of both the orientation and distribution of the collagen fibers. This invariant boils down to two parameters, a preferred direction **M** and a dispersity parameter, κ. The vector **M** represents the direction at along which collagen fibers are preferentially oriented, giving the highest stiffness among all directions.

Later, the direction of **M** is correlated locally to the orientation of the orifice. The initial orifice was identified from the images immediate before rupture. The red ellipses in Figure 1(a) indicate rupture sits. The arrows point to the transverse direction of the orifice. The 'fiber direction' (the stiffest direction) at the rupture sites was obtained by averaging the identified **M** angle within a designed set of Gauss points inside the ellipses. For the example in Fig.1, the averaged stiffest directions are marked in Fig. 1(b).

RESULTS

In all cases, the orifices are found to be perpendicular to the stiffest direction. The angles of the stiffest direction and the orifice transverse direction (the orifice angle) are plotted in Fig. 2. A linear relation ($y = x$) is revealed.

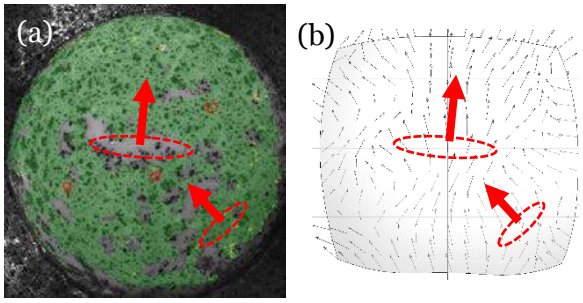

Fig.1 (a) Initial orifice and orientation; (b) Stiffest direction

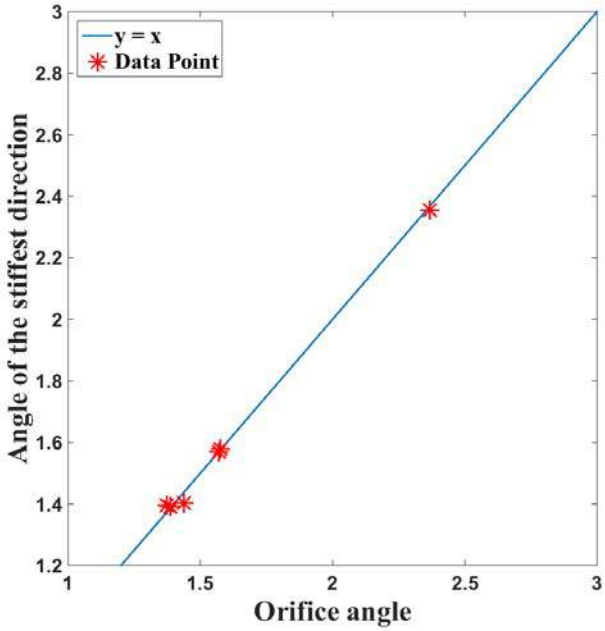

Fig. 2. Local stiffest direction versus orifice orientation

In addition, the cracks appear to *propagate* perpendicular to the stiffest direction. Two representative cases are shown in Fig. (3). The orifices are identified from the last image of each test. They are outlined in the left panel of Fig.3. The local **M**-vectors in the rupture region can be seen from the maps in the right panel.

DISCUSSION

In most biomechanical studies reported thus far, ATAAs sample of centimeter size have been invariably treated as a homogeneous. Uniaxial or biaxial tensile tests were typically used to identify the mechanical properties including the rupture strength. Sometimes conflicting results were reported with regard to the directional strength of ATAA tissues. A fundamental limitation of these tests is the assumed homogeneity. Studies including our own indicated that ATAAs are highly heterogeneous; the stress and strain vary significantly, even at the millimeter scale. Consequently, homogenized test results can hardly reflect the local condition at the rupture site. We suggest that identifying the local condition is critical for understanding ATAA rupture.

Perhaps the most unexpected result of the present study is that the cracks initiate and propagate perpendicular to the local stiffest direction, in other words, cutting through the fibers. This result is counter-intuitive, as one would expect the cracks cleave normal to the direction of the least stiffness. This finding, if independently verified, can have a profound implication in understanding ATAA rupture and strength. If we recall that the **M** vector indicates the direction of predominate collagen distribution, the finding suggests that the amount of collagen content is not, at least not the *only*, determinant of rupture strength. Other factors reflecting the quality of collagen network, such as fragmentation and the density of crosslinks, could be important. This speculation is in line with the report of Pichamuthu et al [5] which showed that differences in mechanical properties are not attributable to absolute collagen content but may be accounted for by microstructural changes in the collagen framework. It also resonates with the work of Borge et al [6] which found that collagen is reduced and disrupted in aneurysms and dissections of ascending aorta. Carmo et al [7] suggested that in aneurysmal aortic walls old collagen accumulates cross-links while new collagen biosynthesis is somehow defective, again pointing to the role of crosslinks. Much needs to be done for understanding ATAA rupture. In future, we plan to carry out imaging studies to investigate the microstructural difference, if any, in collagen network near and away from a rupture site.

INTRODUCTION

Environmental pollution with aromatic hydrocarbons is a ubiquitous and deleterious consequence of extensive fossil fuel use that poses significant human health concerns. Conventional water treatment methods (physical, chemical, and thermal) cannot readily remove low concentrations of aromatic hydrocarbons in water in an economical and efficient manner. However, certain naturally-occurring bacteria can readily metabolize aromatic hydrocarbons[1]. The issue then becomes one of developing ways to integrate these bacteria into existing industrial treatment processes in a well-engineered and robust delivery system to address control, stability, cost, and longevity issues.

Adsorbents, such as granulated activated carbon (GAC), are commonly used for removing hydrocarbons from water, due to their high removal capacity and low cost. However, this treatment method does not provide a permanent solution, and merely concentrates the chemicals for disposal in a landfill. By utilizing biodegrading bacteria in combination with an adsorbent material, a hybrid approach can be taken, which combines the strengths of adsorbents and biodegradation.

Through the use of bioencapsulation (physical confinement of cells in a 3D matrix), we can synthesize an adsorbent material surrounding the bacterial cells. Silica gel encapsulation is an ideal candidate for this purpose, because silica is inert, cytocompatible, and inexpensive. Silica encapsulation of biodegrading bacteria has been shown to be an effective method for destruction of hazardous chemicals from water[2]. Organically-modified silica (ORMOSIL) has the additional benefit of strongly adsorbing aromatic hydrocarbons.
