To produce the electrospun isothermal vitrification matrix, a high voltage differential was utilized to extrude the viscous lyoprotectant cocktail to form fibers of 4-5 µm in diameter (***Figure 1A,B***). Multiple layers of fibers were woven together and dried to produce a very adsorbent and porous matrix (the sponge) (***Figure 1C***). Electrospun matrices were compacted in 24-well plates (250 ± 5 mg/well) and vacuum dried for 24 hours to reduce their water content, which helped increase the glass transition temperature (T_g). Using LDH as the model protein, the matrix was further optimized to include low concentration excipients known to inhibit various protein denaturation mechanisms. The excipients, glycerol, PEG, Tween 20, gluconic acid and glucamine were included in the optimized matrix at the concentration that results to the maximum LDH stabilization. LDH in the model serum subjected to isothermal vitrification in the basic matrix, exhibited 92±2% activity compared to the un-treated, fresh control set at 100% **(Figure 2)**. Addition of all five excipients to the matrix at their optimum concentration, resulted to a recovery of 104±3% (P = 0.14). To validate these results, the optimized matrix was further tested using four additional biomarkers selected for their sensitivities to various storage conditions. **CRP** is a biomarker exhibiting remarkable stability to freezing, freeze-thaw, refrigeration and room temperature storage (**Figure 3A)**. Desiccation of the model serum solution in the basic matrix resulted in 82 ±5 % recovery, while desiccation with the optimized matrix enabled complete stabilization of the protein with 99 ± 3% recovery (P = 0.58). **PSA** is a biomarker that is relatively stable during cryogenic and refrigerated storage, and during repeated freeze/thaw (**Figure 3B**). Desiccation of PSA in the basic matrix resulted to a significantly reduced protein level of 59 ± 16% compared to the control. Isothermal vitrification in the optimized matrix increased post re-hydration recovery to 99 ± 4% (P = 0.47). **MMP-7** is highly sensitive to freeze/thaw (**Figure 3C**). A recovery of 84 ± 4% was obtained when the biomarker was desiccated in the basic matrix. Recovery increased to 94 ± 3% (P = 0.00154) when the sample was isothermally vitrified in the optimized matrix. **C3a** is freeze-stable, however is sensitive to refrigerated storage and against repeated freeze/ thaw (**Figure 3D)**. Samples desiccated in the basic matrix resulted in 82 ± 3% recovery, while samples isothermally vitrified in the optimized matrix had a recovery of 106±1% (P = 0.003). Similar to MMP-7, C3a is among the more vulnerable biomarkers and the p-value showed significant difference in the recovery of samples desiccated in the optimized matrix compared to fresh control.

Statistically significant and significant difference based on p-value calculations are denoted by ***s** and **ns, respectively.**

DISCUSSION

Cryogenic storage is currently the most ubiquitously adopted method of biospecimen preservation in biobanks and biorepositories **(2)**. Many biospecimens are stored at -20, -40, -80^{o}C or in liquid nitrogen without following any optimized biopreservation protocols, imposing harsh stresses, and damaging proteinaceous biomarkers by mechanisms such as cold denaturation, binding and aggregation at the ice interface, degradation due to ionic gradients and pH swings (**4-6)**, in addition to the high cost associated with cryogenic storage facilities.

In this work, developed a stabilization material (an electrospun matrix containing an optimized lyoprotectant cocktail) and methodology for room temperature storage of liquid biospecimens as a potential alternative to cryogenic storage. The adsorbing/dissolving matrix developed here takes advantage of capillary action induced by the porous nature of the electrospun lyoprotectant matrix (**Figure 1B, C**) to bypass the challenges associated with mixing of high concentrations of lyoprotectants (1-2M), required to effectively stabilize biological samples by isothermal vitrification.

The composition of the lyoprotectant matrix has been optimized to protect a wide variety of cancer biomarkers to ensure that functional clinical assay values on the day of collection match the values post-storage within 5% of the measured value. A downside of isothermal vitrification is the long drying times, which can introduce modifications, since until the sample is vitrified, the biomolecules are mobile and can undergo processes such as unfolding, proteolytic degradation, and aggregation. To accelerate drying, we employed vacuum drying and achieved > 90% water removal within 4 hours. This matrix and method, resulted to a T_g of >4^{o}C after 4 hours of desiccation, allowing for storage in a regular refrigerator. Furthermore, we demonstrated stabilization of test proteins LDH, CRP, PSA, MMP-7 and C3a, with a minimum recovery of 94%, making this a promising method to target stabilization of an expanded number of protein biomarkers and an excellent alternative to cryogenic storage.

INTRODUCTION

Hypertension has long been identified as a clinical risk factor for chronic vascular disorders such as heart attack, stroke, and renal failure [1]. Increased understanding of the relationship between hypertension and arterial mechanics suggests that increased large artery stiffness can lead to essential hypertension and increased pulse pressure [2]. Conversely, arteries have been long known to stiffen in response to the increases in intramural stresses that arise as a result of increased blood pressure [3]. Thus, central artery stiffening can be both a cause and consequence of hypertension, likely occurring through a complex relationship between local wall mechanics and global hemodynamics. One emerging concept is the critically important role of inflammation in hypertension. In particular, although mechanical factors are fundamental to both aortic wall structure and hemodynamics, little attention has focused on characterizing the aortic mechanical properties in the pro-inflammatory angiotensin II (Ang II) infusion model of hypertension. Toward this end, the current study presents a detailed analysis of biaxial wall mechanics following 2 or 4 weeks of Ang II infusion. In particular, we quantified both the transmurally averaged and layer-specific (media and adventitia) mechanical properties in order to identify the bulk mechanical behavior of the aorta as a whole, as well as understand the differential loads experienced by medial and adventitial cells. Our analyses suggest that early hypertensive remodeling is mechanically maladaptive and ultimately compromises the ability of the aorta to store elastic energy during systole, which is the primary mechanical function of large elastic arteries.

METHODS

Animal Model - Hypertension was induced in 3 month old male wild-type (C57BL/6) mice by Ang II infusion (490 ng/kg/min). Age-matched controls underwent a Sham procedure and were infused with normal saline [4]. Blood pressure was measured at regular intervals over the 4-week study period by telemetry. At the designated experimental time point, mice were euthanized and the descending thoracic aorta (from the left subclavian to the third pair of intercostal branches) was excised for mechanical testing.

Biaxial Mechanical Testing and Analysis – Excised samples were cleaned, branches ligated, and cannulated onto glass micropipets for mechanical testing using a custom computer-controlled biaxial device [5]. Specimens were placed in a Hanks buffered physiologic solution at 37^{o}C and subjected to mechanical preconditioning (cyclic pressurization near the *in vivo* axial stretch). The unloaded configuration (outer diameter, axial length, and wall thickness) was then recorded, the *in vivo* axial stretch was estimated based on the force-pressure relationship, and vessels were subjected to a series of 3 cyclic pressure-diameter protocols (from 10 to 140 mmHg at 0.95, 1.0, and 1.05 times the *in vivo* axial stretch) and 4 cyclic axial force-length protocols (from 0 to 40 mN at 10, 60, 100, and 140 mmHg), with data points continuous recorded on-line for the 7 protocols [6]. Material property characterization was then performed using an appropriate constitutive equation for describing either the bulk or layer-specific behaviors [7]. For example, the constitutive equation W (Eq.1) was used to describe the contribution of elastin (c) and four families of locally parallel collagen fibers (c_1^j, c_2^j) to the transmurally averaged material properties of the aortic wall.

$$W\left(\mathbf{C}, \mathbf{M}^j\right) = \frac{c}{2}(I_\mathbf{C} - 3) + \sum_{j=1}^{4} \frac{c_1^j}{4c_2^j}\left\{\exp\left[c_2^j\left(IV_\mathbf{C}^j - 1\right)^2\right] - 1\right\}, \qquad (1)$$

Following mechanical testing, aortas were fixed overnight in a 10% neutral buffered formalin solution, embedded in paraffin, sectioned

serially, and stained for structural proteins of interest, namely collagen, elastin, and smooth muscle cells. Complete cross-sections were imaged at 40x magnification and a custom MATLAB script was used to extract areal wall composition and the percentage of the wall occupied by media or adventitia. Metrics of interest were compared across all three study groups (n = 5; Sham, 2-week Ang II, and 4-week Ang II) using a one-way ANOVA followed by a post-hoc Bonferroni correction with a value of $P < 0.05$ considered significant.

RESULTS

Ang II infusion increased blood pressure from 121/99 mmHg (Sham) to 167/133 mmHg at 2 weeks and 172/129 mmHg at 4 weeks (Figure1A). This induced hypertension resulted in dramatic vascular remodeling that was biaxial in nature. Namely, thoracic aortas at both 2 and 4 weeks exhibited a similar reduced capability to circumferentially distend in response to changes in pressure and reduced capability to axially extend in response to changes in axial force. Importantly, it is this biaxial reduction in distensibility and extensibility that lead to a reduction in elastic energy storage capability upon biaxial loading (Figure 1B). Biaxial wall stresses were also was significantly reduced following hypertension, primarily due to increased wall thickness (>100 vs. 39 μm, P<0.001) and a reduced *in vivo* axial stretch (<1.35 vs. 1.62, P<0.001) leading to a decrease in *in vivo* axial force. Circumferential material stiffness was not statistically different after hypertension, whereas axial material stiffness was significantly lower (<2.45 vs. 3.84 MPa, P<0.001) due to the reduced axial stretches. Layer-specific histological analysis revealed that, on average, Ang II samples had an increased adventitial burden (30% in Sham versus 56% in Ang II, Figure 1C). Using a bilayered modeling approach, hypertension was found to increase both circumferential stress and material stiffness in the adventitia, relative to Sham. Furthermore, simulation of acute pressure increase predicted a greater percent increase in biaxial stress in the adventitia versus the media, illustrating the protective mechanical role of the adventitia. Despite a striking maintenance of overall circumferential stiffness, hypertension ultimately resulted in early maladaptive geometric, material, and structural changes in the descending thoracic aorta, primarily through excessive adventitial remodeling, that results in a loss of vascular function.

DISCUSSION

This study demonstrates, for the first time, that angiotensin-induced hypertension has a marked effect on both the circumferential and axial wall properties, and that the observed remodeling is preferentially adventitial. Additionally, the remodeling appears to be established as early as 2 weeks after infusion and is maintained for at least 4 weeks. The primary mechanical function of large arteries – to sustain blood flow during diastole [8] – is thus compromised due to the inability to effectively store elastic energy. Nonetheless, increasing evidence suggests that intramural cells seek to maintain local wall properties near homeostatic values [9]. Interestingly, the observed axial stretch reduction tends to maintain the circumferential material stiffness near the mechanobiologically preferred Sham values.

The excessive adventitial fibrosis following hypertension could be a result of either dysfunctional mechanosensing [10] or any number of contributors leading to collagen production. Indeed, the adventitia is a biologically complex layer that is both a source of progenitor and inflammatory cells and is involved in arterial remodeling and injury responses [11,12]. Interestingly, both pressure-induced mechanical stresses and angiotensin-induced inflammation via the activation of the AT_1 receptor are synergistic in their production of extracellular matrix [13], and, consistent with the current observations, it is likely the combination of the two that is contributing to the exuberant adventitial matrix production. Of note, several models of hypertension report similar adventitial collagen deposition, thus the current findings of maladaptive wall mechanics are likely not specific to Ang II, but rather are generally relevant to models of hypertension.

In summary, the present experimental findings and computational results suggest that hypertension preferentially increases circumferential stress within the adventitial layer, the primary site of matrix deposition and remodeling. Because the bulk aortic response is mechanically maladaptive, the production of adventitial collagen appears to likely result from a combined inflammatory response. Although current clinical assessments of arterial stiffening focus on intimal-medial thickening, our results suggest a need to shift the focus to the adventitia, and in particular adventitial inflammation, which we show can compromise the vascular function of an otherwise competent aortic media.

INTRODUCTION

The heart is intricately organized on a wide range of length-scales. Multiple types of heart diseases are associated with remodeling of myofibrils and sarcomeres – the basic force producing unit of the heart. However, it is not fully understood how organization of cardiac tissues affects the contractility properties. To study this relationship, it is convenient to create *in vitro* models that can be well characterized and controlled. These *in vitro* platforms can be used to analyze the force production of differently organized engineered cardiac tissues, and it was found that disorganized (isotropic) tissues are significantly weaker than predicted based on the forces measured in organized (anisotropic) tissues [1, 2]. However, the prediction is based on a greatly simplified net force model, which has never been proven to accurately represent cardiac tissues because the change in organization is associated with downstream effects such as changes in gene expression levels that can further affect function [3]. As a result, the only way to truly understand the contribution of organization to change in force production is to create an experimental platform that decouples the direct and downstream effects of organizational changes. We hypothesized that these biological downstream effects could be muted if the cells were organized locally, even if the global organization was varied. Thus such locally aligned tissues could then be used to test force-global organization relationship models.

METHODS

We have adopted the "heart-on-a-chip" device to be used to study the relationship between cardiac muscle architecture and force production [2]. Organization of the cardiac tissue was controlled by a method of microcontact printing in which extracellular matrix was patterned onto a PDMS film (Figure 1). Neonatal rat ventricular myocytes were seeded onto these films and conformed to the extracellular matrix pattern. Force production of tissues was measured with the "heart-on-a-chip" device. Organization of the heart tissues was quantitatively characterized using an orientational order parameter metric based on the alignment of sarcomeres and actin fibrils. Gene expression of these tissues of varying organization was measured using qPCR.

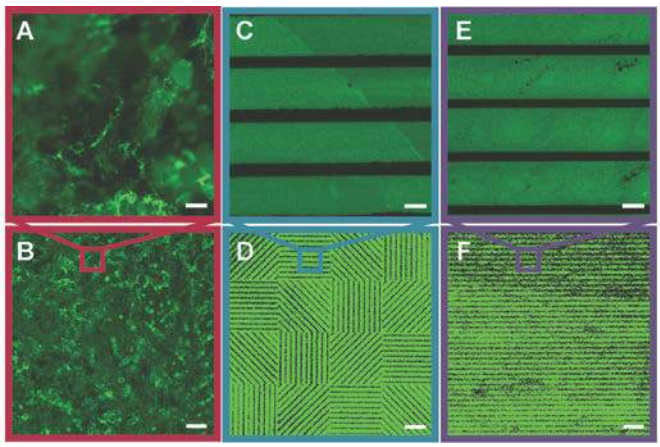

Figure 1: The extracellular matrix printed in various patters: (A,B) Isotropic, (C,D) Parquet, (E,F) Globally anisotropic. (A,C,E) scale bar = 100 μm, (B,D,F) scale bar = 10 μm

RESULTS

The relationship between global organization and force production was modeled parametrically assuming the following simplification for the angle distribution of the tissue's actin fibrils:

$$P = \begin{cases} 0 & -\frac{\pi}{2} \le \theta < -\theta_0 \\ \frac{1}{2\theta_0} & -\theta_0 \le \theta \le \theta_0 \\ 0 & \theta_0 < \theta \le \frac{\pi}{2} \end{cases} \quad \text{where } \lim_{\theta_0 \to 0} P = \delta(\theta = 0) \qquad (1)$$

The parameter θ_0 can be calculated from a measured orientational order parameter (OOP):

$$OOP = \langle \cos(2\theta) \rangle = \int_{-\theta_0}^{\theta_0} \frac{1}{2\theta_0} \cos(2\theta)\, d\theta = \frac{sin(2\theta_0)}{2\theta_0} \qquad (2)$$

The net stress produced by the tissue in a specified direction was then defined as:

$$\sigma = \sigma_0 \frac{\sin \theta_0}{\theta_0} \qquad (3)$$

Thus σ_0 is the only parameter of the formulized model.

The tissues were constructed based on the patters presented in Figure 1. The three types of tissues were characterized for actin fibril organization and gene expression profiles (Figure 2). The gene expression level results suggest that the "downstream" biological consequences of changing tissue organization were at least muted (Figure 2B).

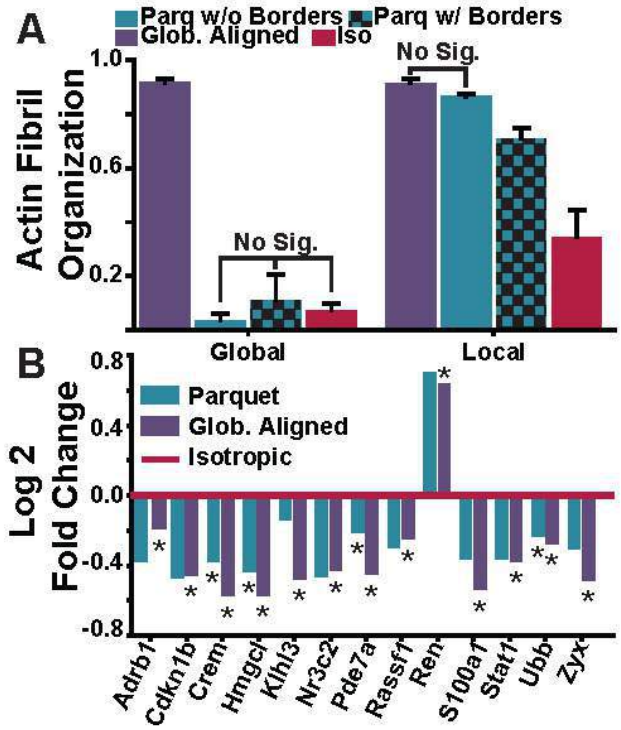

Figure 2: (A) Actin fibril OOP for the global and local spatial scales for the three tissue types. The parquet with borders, include the tissue regions in between parquet styles.

The parquet patterns were not only made with a global isotropic organization (Figure 2A), but also with a range of global organizations. All of these tissues were then tested using the "heart-on-a-chip" device to measure the global stress production.

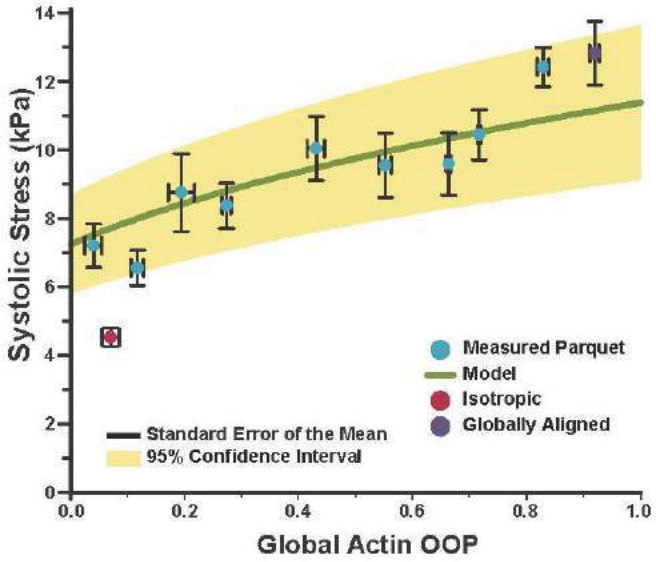

Figure 3: The systolic stress measured along the films as a function of global actin organization.

Thus we were able to show that all parquet tissues fall within the 95% confidence limit of the model presented in equations (2) and (3).

DISCUSSION

We have shown that with muted downstream effects, which are normally driven by local tissue organization, the global organization of the myofibrils is related to the net stress developed by a cardiac tissue through an single parameter analytical model. Consequently, it is now possible to estimate the contribution to force production of other factors that would normally be coupled to tissue organization. These results will lead to a better understanding of the normal and pathological hearts. Additionally, it is now possible to quantitatively analyze differences in various tissues (which inherently have different organizations), such as stem cell-derived cardiac monolayers. As more studies are performed on cardiac tissues, our results can be used to gain insight into the functional implications of a variety of biological factors; thus elucidating the underpinnings involved in heart development and disease.

INTRODUCTION

Imagine not being able to use your hands – unlocking a door, holding a toothbrush, eating a meal and using your phone all become challenging if not impossible tasks. People use their hands each day and when their abilities change, it is imperative that we understand how much and what type of function was lost in order to provide the best possible treatment. Currently, surveys (which are subjective based) are used to assess hand function; a *pressing need exists to objectively detect and quantify changes in hand function.* [1, 2]. Changes in hand function include both changes in the motion and force abilities. A model that maps both the force and motion abilities will allow clinicians to easily compare changes in hand function and finger strength pre- and post- rehabilitation, treatment or surgical intervention.

Recently, we modeled the differences in kinematic finger space between hands with and without reduced functionality due to arthritis [3]. This model includes the full range of motions for each finger; however, the forces that each finger can produce are not available. *Both* motion and forces are necessary to generate a comprehensive hand model for clinical use.

Thus, to achieve this comprehensive hand model, the forces that can be applied over various finger postures must first be quantified and compared. The goal of this work was to determine forces associated with the index finger and map these to the kinematic workspace of participants with and without reduced hand functionality.

METHODS

Sixteen participants (7 female and 9 male, average age 25.6 years, SD 6.1 years) without any reported injury or arthritis, termed "Healthy", and fifteen participants (13 female and 2 male, average age 73.5, SD 4.8 years) with doctor diagnosed arthritis, termed "Arthritic", were included in this study.

The maximum forces of the index finger were measured in two conditions. 1) Forces due to changes in flexion/extension of the index finger (no adduction or abduction of the finger) were measured using a "U-shaped" metal bracket placed in seven trials along a line, each 12mm apart. In each position the participant was asked to press down on the bracket with his/her maximum load (called "Flexion/Extension Push"—Figure 1A) then pull the bracket with maximum load (called "Flexion/Extension Pull"—Figure 1B). 2) Second, maximum finger forces were measured at each of six trials to determine force differences related to abduction/adduction. Three of the trials were at maximum extension (called "Adduction/Abduction Push"—Figure 1C) and the other three trials were at a mid-range flexion (called "Adduction/Abduction Push"—Figure 1D) of the interphalangeal joints. During data collection participants were asked to continually grip a cylindrical handle with the other fingers to isolate the finger forces and to maintain a consistent orientation of the wrist.

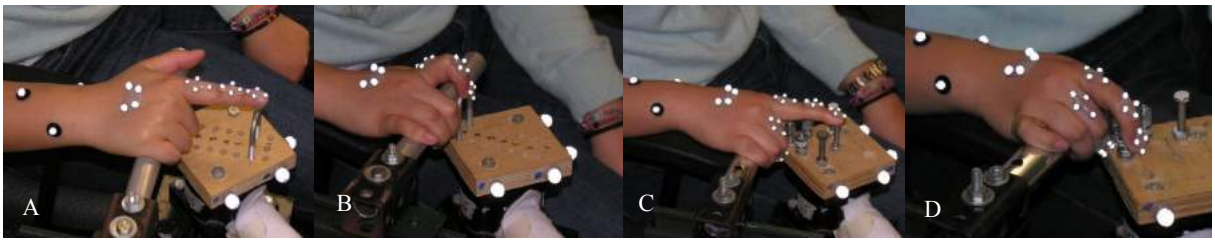

Figure 1: Experimental setup and force data for (A) flexion/extension push, (B) flexion/extension pull, (C) adduction/abduction push and (D) adduction/abduction pull trials

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

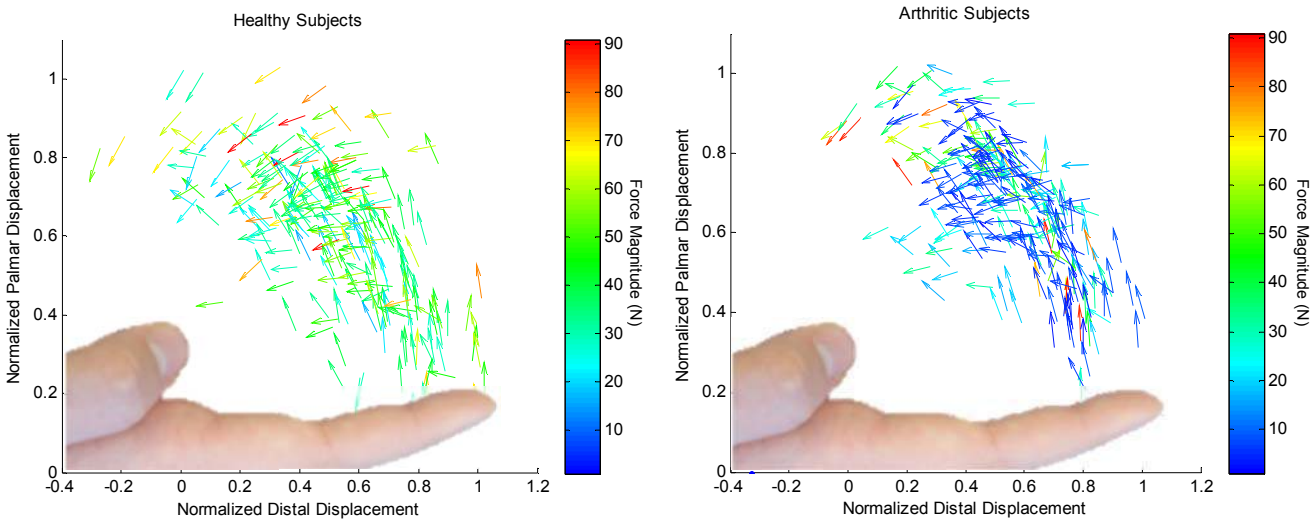

Figure 2: Sagittal projection of each force separated by groups healthy (left) and arthritic (right) individuals. Displacements are normalized based on participants finger length and are measured from the center of the second MCP joint.

After collection, the data were analyzed for each trial in terms of the 1) position (x,y,z coordinate) of the fingertip in 3D space, 2) the direction of the force applied and 3) the magnitude of the force applied. In order to compare between participants the position of the fingertip was normalized based on the participant's finger length. The force data were then compared in five different hypotheses:

1. The maximum force varies with regards to health condition (i.e. healthy or arthritic).
2. Position of the fingertip in 3D space affects the maximum force.
3. Direction of the applied force affects the maximum force.
4. Arthritis affects the range of positions used to apply forces.
5. Arthritis affects the range of directions used to apply forces.

Age and gender were also accounted for in the statistical analysis.

RESULTS

The force vectors for each trial, projected onto the sagittal plane, are presented in Figure 2. On the left are the healthy participants and on the right are the individuals with arthritis. Forces were plotted based on the finger position in 3D space and normalized based on the length of the individual's finger. The origin for all data was at the MCP (metacarpal phalange) joint of the index finger. The plots are oriented so that a fully extended index finger would sit along the horizontal axis with the pad of the index finger pointing in the positive vertical direction.

Analysis of covariance (ANCOVA), multivariate analysis of variance (MANOVA) and multiple linear regression methods were used to determine whether there were any significant differences between force magnitude, position and direction, and participant groups based on the five hypotheses. In all cases age and gender were accounted for.

1. The maximum amount of force varied significantly with regards to health condition (ANCOVA, $p<0.001$). Arthritic forces were significantly lower than healthy.
2. Position of the fingertip in the kinematic space significantly affected the amount of force applied when controlling for the health condition (ANCOVA, $p=0.01$). Maximum forces tended to be higher towards the center of the range of motion and smaller at the edges.
3. Direction of the force significantly affected the amount of force applied when accounting for health condition (Multiple Linear Regression, $p=0.0151$). Forces from pull trials (directed toward the wrist) tended to be higher than forces from push trials (directed perpendicular to the palm).
4. Health condition of the subjects significantly affected the range of motion used to apply forces in terms of the volume of space used to apply forces (MANOVA, $p<0.001$). The range of motion was also significantly affected by health in the palmer direction (ANCOVA, $p=0.01544$) and the in the medial lateral direction (ANCOVA, $p=0.00829$). Not only were forces lower for arthritic patients but the volume was lower than in healthy participants.
5. Health of the subjects significantly affected the range of directions used to apply forces (ANCOVA, $p=0.0199$). Arthritic subjects used a smaller range of force directions when applying force.

DISCUSSION

Arthritis limits the force abilities of the hand in measurable ways. The maximum force ability is significantly affected by arthritis over the entire range of motion. Subjects with arthritis not only used a smaller range of motion but also used a smaller range of directions to apply forces. These findings indicate that our model can objectively identify losses in hand function due to arthritis.

Also, regardless of health condition of the patient, the position of the finger in 3D space and direction of the applied force significantly affected the maximum force than was applied. Building on these relationships it will be possible to sample a few positions and create a continuous model of the force space based on finger position and force direction for groups with and without arthritis. Further, population models can be created that will show the average abilities for sub-populations and patient-specific models can be compared to these population models to determine the magnitude of their limitations as compared to a larger sample..

Next steps are to include the measurement of forces for all fingers, and these will be mapped to a 3D kinematic model of the entire hand..

Clinically, this model is highly innovative and useful. Measures of motion and force will be gathered prior to intervention, mid-way through rehabilitation and after rehabilitation is complete. Comparisons of these models will be able it determine what level of function was restored and what it consistent across all fingers.

INTRODUCTION

Rotator cuff tears are considered one of the primary causes of shoulder pain and dysfunction in adults. More than 50% of patients over the age of 60 and 80% of patients over the age of 80 experience a cuff tear [1]. Unfortunately, the success rate of rotator cuff repair is variable with many resulting in a re-tear. Revision surgeries can be as high as 30% for isolated supraspinatus tendon tears [2].

Rotator cuff tears not only decrease the mechanical properties of the cuff muscles, but also have secondary effects on the other tissues within the joint – specifically, ligaments and cartilage. In the presence of rotator cuff tears, the mechanical properties of the coracoacromial ligament have been shown to decrease, the area of glenohumeral (GH) cartilage degeneration increases, and glenoid cartilage thickness and modulus of elasticity decreases [3-6]. Thus, the overall shoulder joint stability and function would likely be affected by the change in these properties. However, the degree to which these changes affect function is not well understood.

There is a wide variation in the measured mechanical properties of shoulder joint ligaments [7-8]. It is essential to know how the variation of ligament stiffness affects the kinematics and cartilage pressure in the GH joint in order to understand why there is a high incidence of re-tears. To investigate this, we developed a three-dimensional finite element (FE) model of the shoulder joint.

METHODS

Computed tomography (CT) data files of a male shoulder (voxel size: 0.34 x 0.34 x 0.49 mm) were used to reconstruct the geometries of the humerus and scapula (Figure 1A) using image processing software (Amira v5.6, Visualization Sciences Group, Germany). Bones surfaces were created and exported into Geomagic Studio (v2014, Geomagic Inc., USA) to smooth, refine, and reduce noise in the solid computer-aided design models (Figure 1B).

Construction of the FE model and all simulations were performed using Abaqus (v6.13, Daussalt Systems, France). Shell elements were used for the humerus and scapula (elastic modulus, E = 17 GPa, poisson's ratio, v = 0.30) [9]. A layer of elements were offset from the proximal and distal ends of the humerus and scapula to model the articular cartilage. Humeral cartilage was defined as 0.5 mm thick and scapular cartilage as 1 mm thick and modeled using a neo-Hookean hyperelastic material model (shear modulus, G = 6.8 MPa, v = 0.45) [10]. Frictionless contact was defined between the humerus and scapula. Within the glenohumeral joint are four primary ligaments that provide stability: coracohumeral (CHL), superior glenohumeral (SGHL), middle glenohumeral (MGHL), and inferior glenohumeral (IGHL). These ligaments were modeled as axial springs (Figure 1C). Stiffness values from the literature for the CHL, SGHL, and IGHL were used to model the ligaments [7-8]. No stiffness values were available for the MGHL; therefore, the average of the SGHL and IGHL were used. A local coordinate system was defined corresponding to the medial-lateral (ML), superior-inferior (SI), and anterior-posterior (AP) directions.

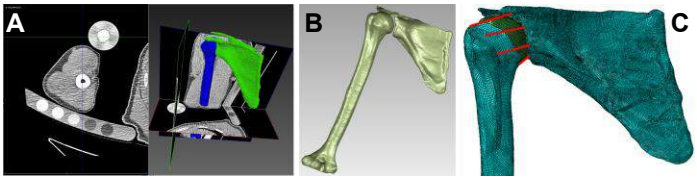

Figure 1: A) Geometry created in Amira, B) exported from Geomagic, C) FE model of shoulder joint with ligaments (red)

To simulate abduction, the humerus was rotated about the local AP axis. Rotations about the ML and SI axes were zero. Translational components of humerus were left unconstrained. During first 30° of abduction, the scapula was fixed and then followed a 2:1 relation for upward rotation with respect to the humerus [11].

Simulations were run for three different stiffness values (Table 1). Low stiffness was defined as the average stiffness minus one standard deviation, and high stiffness as the average stiffness plus one standard deviation. The kinematics of the humerus, peak and mean cartilage contact pressures were calculated. The relationship between contact pressures and abduction was analyzed using linear regressions. F-tests were used to test for significant differences in contact pressure as a result of changing the stiffness values ($\alpha = 0.05$).

Table 1: Ligament stiffness, K (N/mm) [7-8]

	CHL	SGHL	MGHL	IGHL
Low	30.8	15.9	15.6	15.4
Avg	36.7	17.4	21.4	25.4
High	42.6	18.9	27.1	35.4

RESULTS

With increasing abduction angle, both peak and mean scapula cartilage pressure increased regardless of stiffness value (R^2 range = 0.71 - 0.86) (Figure 2A, B). Similar trends were found for the humeral cartilage. Decreasing stiffness resulted in lower peak scapula contact pressure ($p=0.047$), but had no effect on the mean contact pressure. However, increasing stiffness did not change either peak or mean scapula cartilage pressure. Humerus cartilage pressure was also not changed by increasing ligament stiffness, but decreasing stiffness decreased both peak and mean humerus cartilage pressures ($p=0.014$ for peak, $p<0.001$ for mean).

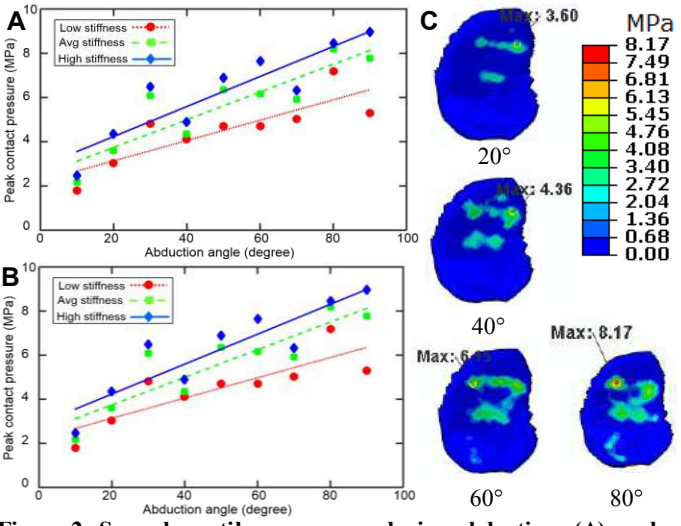

Figure 2: Scapula cartilage pressure during abduction: (A) peak, B) mean and C) pressure map for average stiffness at 20°, 40°, 60°, and 80° abduction

Decreasing ligament stiffness caused the humerus to move more posteriorly ($p=0.02$) whereas increasing stiffness resulted in no change (Figure 3). Superior-inferior translations were sensitive to both increasing ($p=0.012$) and decreasing stiffness ($p=0.0044$). However, changing ligaments stiffness did not change medial-lateral translations.

DISCUSSION

The purpose of this study was to investigate the influence of ligament stiffness on humerus kinematics and cartilage pressure. Our results indicate that cartilage pressure was only sensitive to decreases in ligament stiffness. Surprisingly, increasing stiffness contributed to changes in superior-inferior translations but did not result in changes in cartilage pressure.

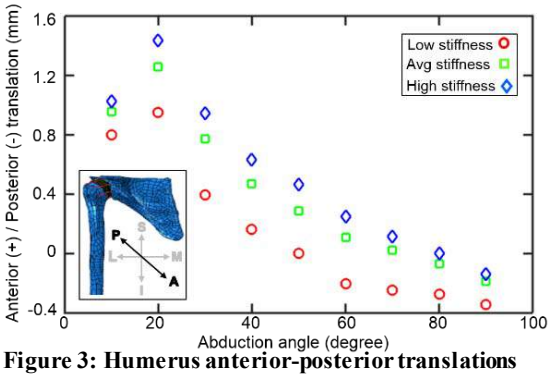

Figure 3: Humerus anterior-posterior translations during abduction

Since, there was no variation in medial-lateral translation, anterior-posterior translation may be the driving kinematic degree of freedom of cartilage contact pressure during abduction.

Our results show that humerus translation and cartilage pressure are sensitive to ligament stiffness. Others have shown that the mechanical properties of shoulder ligaments decrease due to rotator cuff tears [3-4]. If the injured rotator cuff tendons alone are treated during a repair, without regard for restoring ligament stiffness, the overall shoulder joint function may not be the same as the normal healthy shoulder. Moreover, the assessment of kinematics and muscle function as a metric of joint function (e.g. ability to lift the arm) may mask changes in cartilage pressure resulting in secondary consequences such as osteoarthritis.

Though our FE model has not been experimentally validated, our results are consistent with previous studies in the prediction of glenohumeral contact pressure. For example, others have reported mean cartilage pressure of 1.09±0.35MPa at 60° abduction [12], and our model results ranged from 1.02MPa - 1.44MPa. We report peak scapula cartilage pressure at 90° abduction ranging from 5.29MPa - 8.96MPa depending on ligament stiffness, and others have measured peak contact pressure of 4.2MPa for single arm weight and 9.2MPa for double arm weight at the same angle [13]. The anterior-posterior translation was also similar to previous findings [14-15].

In conclusion, our results indicate that ligament stiffness results in changes in contact pressure. Small kinematic changes resulted in significant changes in contact pressure suggesting that care should be taken when interpreting patient function. Altered ligaments stiffness may affect cartilage contact pressure even after rotator cuff repair.

ACKNOWLEDGEMENTS

We would like to thank Stu Warden for use of the CT data.

INTRODUCTION

One of the primary tools in the development of both physical models, such as anthropomorphic test devices (ATDs), and Finite Element (FE) models, in the field of injury biomechanics is the biofidelity response corridor or BRC. BRCs are used to encapsulate a range of responses for validation, as an alternative to the utilization of individual characteristic response. Multiple techniques have been used to develop BRCs in the past, whether by bounding the set of responses [1], finding the mean and standard deviation at each discrete time step [2], or using an objective tool such as the open source software "Correlation and Analysis" (CORA) to develop a corridor from a set of response curves [3]. Gayzik et al. [4] examined these techniques and proposed a modified method based on work published by Nusholtz et al. [5] for impact and accelerative loading applications. These modifications were part of an effort to better understand human body response to under body blast (UBB) loading, characterized by high rate, short duration impact events.

An ongoing study to determine the whole body post mortem human surrogate (PMHS) response to UBB loading has utilized the Gayzik [4] method to develop BRCs for model development. Due to the intensive nature of whole body PMHS testing under UBB conditions, and sample size necessary to create BRCs, experiments have been conducted on both horizontal and vertical test devices, including both accelerative and decelerative designs, with the intent to combine all responses into a representative BRC. To facilitate aggregation of these data, all input conditions and positioning requirements were tightly controlled to ensure that PMHS at multiple facilities were being exposed to similar inputs. With small tested populations from a variety of test devices, an objective method for assessing similitude of responses between test rigs was used as a metric for inclusion of a response in the resulting BRC. The goal of this method is to supply a statistically sound, objective method to assess the similitude of an individual response against a set of responses to ensure that the BRC created from the set is a consistent set of responses to a similar input. The method does not suggest removal of responses, but rather reevaluation by a biomechanist with an understanding of the test device and subject.

The goals of this method are to quantify the similitude of a set of responses, potentially from multiple test devices, by evaluating statistical differences in order to identify responses to reevaluate from a biomechanics or physical perspective.

METHODS

Nusholtz et al. [5] described a two-stage method to compare multiple tests with a single ATD against themselves and against tests from one or more ATDs of the same design in order to assess repeatability and reproducibility of the ATD, respectively. Here, a similar approach is followed, involving the modified point-wise normalization (PWN) technique developed by Gayzik et al [4], with some important distinctions.

First, given that each PMHS is employed only once, we use the term *intrarepeatability* to indicate the process of testing differences within a specific test condition (e.g. tests within an accelerative and vertical setup) using multiple (three or more) specimens. A test condition is found to be *intrarepeatable* if the following criteria are met: 1) the sample size consists of three or more tests; 2) the PWN value found is at least *50%* of the input signal correlation. This threshold was determined heuristically based on the examined data. If a test condition has a sample size smaller than 3, this step is not executed and the data are automatically inserted into the next stage. A test condition that is identified as non-repeatable is reviewed from a biomechanics and experimental perspective to potentially identify

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

faults in the test setup. If the test is discarded, or if intrarepeatability as a whole does not pass, then the intrarepeatability step is repeated by removing a single test to identify potential outliers in the data. This is repeated as long as the number of samples undergoing intrarepeatability analysis satisfies criteria 1.

Second, test conditions that pass intrarepeatability or that cannot undergo the intrarepeatability stage due to sample size limitations are directly fed to the *interrepeatability* and *reproducibility* stage. Here, we use a similar technique to identify potential outliers: one test at a time is removed from the set to examine how the PWN value distribution changes for the remaining response in the set (interrepeatability). We then calculate how the removed signal correlates to the set as a whole (reproducibility). Subsequently, a two-sample non-parametric statistical test (Wilcoxon rank-sum) is used to test the null hypothesis that the samples are from the same group. As a result of the small sample sizes involved in the data set, this statistical analysis aims at minimizing Type I errors through the use of a non-parametric Wilcoxon rank-sum test (in which test sizes of 0.05 and 0.01 are examined).

RESULTS

The results of this assessment are shown in Figure 1 on an sample data set at two different significance levels. The left figure shows a reduction in responses identified for reevaluation at the more conservative significance level ($p < 0.05$) with two responses being identified, while three responses are identified at a significance level of $p < 0.1$. The traces identified for reevaluation demonstrate a temporally shifted response, even though all responses are shifted for optimal correlation. One of the responses in the $p < 0.05$ case is likely excluded due to its lower peak amplitude relative to the set. The additional response identified at $p < 0.01$ represents the most extreme response of the set. Since these are acceleration responses, they are evaluated over the range of time from 0 sec to the peak velocity.

Figure 2 highlights the intermediate calculations performed upon each response in the set. The method creates a matrix of correlation values for each curve with respect to every other curve based on a point wise normalization calculation. The assessment of the similitude for each individual curve generates a distribution of correlation values for the curve under analysis compared to all of the remaining curves together (reproducibility) and all of the remaining curves against each other (repeatability). The three possible outcomes are shown in Figure 2. The first stage of analysis compares the repeatability and reproducibility. If these metrics are not statistically different, the curve is retained within the set (Fig. 2C). If these metrics are statistically different and the reproducibility is greater, the curve is also retained (Fig. 2B). If the reproducibility is less than the repeatability, then that response is identified for reevaluation (Fig. 2A).

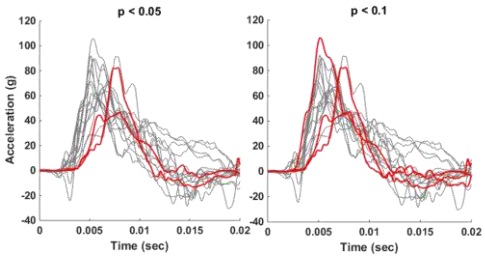

Figure 1. Example application of similitude analysis showing assessment at the $p < 0.05$ (Left) and $p < 0.1$ level (Right), blue traces passed through the analysis while the red traces were identified for reevaluation.

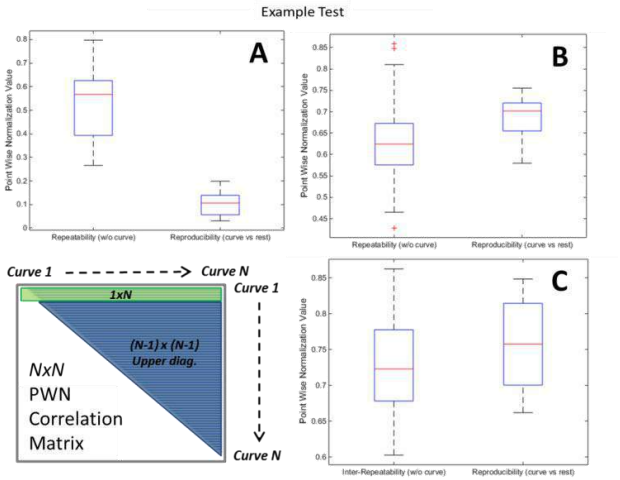

Figure 2. Visualization of correlation matrix showing repeatability, blue (n-1)x(n-1) upper diagonal, and reproducibility, green 1xn vector, and box plot depictions of possible outcomes of same different analysis. Repeatability and reproducibility statistically different with reproducibility lower than repeatability (A) and higher than repeatability (B). Repeatability and reproducibility not statistically different (C). Case A would be the only scenario in which a response would be identified for reevaluation.

DISCUSSION

The method proposed here for the evaluation of similitude consists of a non-parametric test chosen to minimize Type I errors, false positives. The key aspect of the data is the low number of samples, which necessitates ensuring that differences found are investigated further given the low power of the statistical test. The thresholds were empirically and heuristically determined based on the data. The method was able to conservatively assess the data and provide recommendations for reevaluation that consistently identified responses underlying biomechanical justification for exclusion, such as mount failures or local bony injury.

While the method showed promise there are caveats such as an extra stage of analysis was undertaken for responses from a single condition with $n > 3$ in contrast to those conditions with $n < 3$. Future work will include a more in-depth analysis of possible degradation functions for the analysis thresholds of responses observed further from the location of mechanical loading.

ON THE USE OF THE INVERSE FINITE ELEMENT METHOD TO ESTIMATE PELVIC FLOOR SUPPORT STRUCTURE IMPAIRMENTS IN WOMEN WITH PELVIC ORGAN PROLAPSE

INTRODUCTION

Pelvic organ prolapse is a prevalent and distressing female health problem. Unfortunately the results of standard care are sub-optimal. Pelvic floor dysfunction that is severe enough to require surgical repair affects 11% of women, a figure that is expected to increase with the burgeoning aging population (Olsen 1997). The anterior vaginal wall is both the most common site of pelvic organ prolapse (in what is called a 'cystocele') and the most frequent site of operative failure. That operative failure rates can reach 25% indicates the need to re-appraise current diagnostic and surgical strategies for this condition.

Most of the existing theories of cystocele formation are based on clinical observations and hypothesize a weakness (or defect) in isolated parts of the uterovaginal support system: apical support, paravaginal attachments, vaginal wall fascial tissues and/or levator ani muscle. And these theoretical postulates has been the associated with a surgical procedure designed to address specific defects. The available data suggest that each woman has her own unique problem; however satisfactory identification of defects in the clinic or operating room has not yet been possible. A framework and research tool is needed that can determine the specific status of the support system in each area and choose the operative approach most appropriate for specific women could greatly improve the treatment selection as well as improve outcomes.

Significant progress has made in better understanding the multi-factorial mechanism of pelvic organ prolapse. Women with pelvic organ prolapse were found to have decreased stiffness and resiliency in supporting structures (Cosson 2004). There has been a demonstrated link between levator ani muscle injury and pelvic organ prolapse (DeLancey 2007). A first 3-D computational model (Chen 2009) demonstrated interactions between the several different aspects of support. In addition, the development of the 3D "Stress MRI" (Larson 2010, 2011) has made it possible to measure the 3D deformations of vaginal wall in living women and to separately identify the site and location of structural failure in individual women. This progress has made it possible to identify the pre-operative impairment status in various supporting structures and to start to understand the impact of treatment on the pelvic support system.

The objective of this study was to utilize the 3D FEA model of cystocele, develop an inverse finite element modeling method to identify pre-operative impairments in women with pelvic organ prolapse. Then we investigate how the accuracy of the MRI measurements would affect the accuracy of the 'impairment status' prediction.

METHODS

Pre-operative FEA Model Development

Similar to Chen (2009), we started by mapping the pre-operative pelvic resting geometry observed on 3T MR images as the pre-operative FEA model geometry. The 3D anterior vaginal wall and its support system was imported into ABAQUS v6.11.1 to generate the mesh, assign contact constraints and boundary conditions. The normal material parameters for the structures in the model were based experimental measurements and the literature. We assumed zero initial displacements and displacement rates, displacements and rotations from the initial state configuration were finite, inertial loads were negligible, tissue incompressibility and contact between structures was frictionless. The ABAQUS explicit solver V6.11 was used to solve the equations.

Determining Patient Specific Structure Impairment Parameters Pre-operatively using the Inverse Finite Element Method

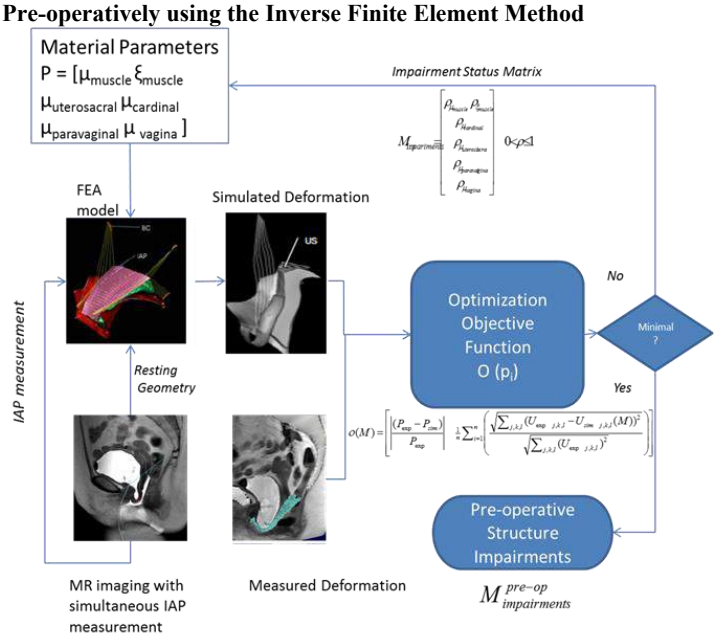

Figure 1: Schematic of inverse finite element modeling strategy

Impairments in the support structures were defined as the percent decrease in material stiffness (Chen 2009) shown as impairment status matrix $M_{\text{pre-op impairment}}$, which was determined using the inverse finite element modeling strategy shown in Figure 1.

An iteratively process was used to determine the pre-operative impairment status in all structures when the simulated Valsalva matched the stress MRI measurement by minimizing the user-defined cost function $o(M)$, which was calculated as the difference between simulated vaginal wall deformation and pre-operative MR-based measurements at maximal Valsalva.

In this phase of the study we mimicked MRI data by adding random noise to each coordinate of the finite element result. The noise was centered on 0 and the standard deviation was varied to determine how sensitive the inverse FEA prediction was to this noise. The FEA model was run for a full 3^3 design, treating the apical supports as one variable. Three levels were used to define if the tissue was healthy, had a minor impairment, or a major impairment. This yielded the data points that were used to determine the optimal match for the MRI data.

The Optimization Process

To determine $M_{\text{pre-op impairment}}$ that generated the closest data to the MRI data, each FEA data set was compared to the mimicked MRI data. First, for each point on the mimicked MRI data the three closest points in the FEA data set were determined. These points were then used to construct a plane and the distance from the MRI point to the constructed plane was determined. That distance was then raised to the second power. This process was completed for each of the MRI reference points and the distances were summed as a cost for that FEA parameter set. The FEA data set with the lowest cost was determined and the parameters that generated that FEA data set were predicted as the MRI parameters. In the current phase of the study, the predicted parameter set was compared with the parameter set that was used to generate the MRI data; if the parameters were the same then the optimization was deemed a successful prediction. This simple comparison was used to reduce the run time. Otherwise directly searching through the 36-dimensional space and running the FEA each time would have been too time intensive to complete for future, patient specific models.

The robustness of the method was determined by changing the size of the standard deviation. The simulation was run 100 times for each of the parameter sets (270 in total) at five different standard deviation levels (0.5 mm, 1 mm, 1.25 mm, 1.5 mm, and 2 mm). The percentage of the successful optimizations was recorded as the result.

RESULTS

The matching success rate was 97% when the standard deviation of the noise was set to 1 mm (Table 1). However, the success rate decreased markedly as the standard deviation of the noise was increased. It is important to note that the 1 mm standard deviation on each dimension results in mimic MRI points that are an average of approximately 1.6 mm from the FEA point.

The parameter that was most frequently incorrectly identified varied with the size of the standard deviation. For the lower standard deviation values the paravaginal tissue property was most frequently misidentified and was three times more likely to be predicted as healthier than more damaged as shown in Table 1. Above 1.25 mm in standard deviation the apical supports were more frequently misidentified. They were twice as likely to be identified as more damaged than healthier. The PVM was the least likely to be incorrectly identified regardless of the standard deviation size.

Table 1 The Standard Deviation of noise affect on the success of impairment status prediction.

SD (mm)	All	PVM			Paravaginal			Apical		
	S (%)	S (%)	H (%)	D (%)	S (%)	H (%)	D (%)	S (%)	H (%)	D (%)
0.5	100	100	0.0	0.0	100	0.0	0.0	100	0.0	0.0
1	97	100	0.1	0.0	98	1.5	0.4	99	0.5	0.9
1.25	91	99	1.0	0.1	94	4.0	1.8	94	2.1	3.4
1.5	79	96	2.2	1.7	87	7.9	4.8	86	4.4	9.6
2	53	86	9.0	4.9	72	16	12	68	9.7	23

All: all parameters; S: successful prediction; H: predicted healthier; D: predicted more damaged

DISCUSSION

Even a simple cost function such as determining how far the MRI points are from the FEA surface can yield high parameter matching if the noise on the MRI data is sufficiently low. This result emphasizes the importance of accurate MRI data if inverse FEA modeling is to be a success.

INTRODUCTION

Metastasis is the ultimate cause of death among the vast majority of cancer patients. One of the major modes of cancer metastasis is through the circulatory system, also known as haematogenous metastasis. Haematogenous metastasis is a highly inefficient process, with less than 0.01 % of circulating tumor cells forming metastases [1]. This low rate is largely due to the rapid destruction of cancer cells in the circulation by immune cells [2] or hemodynamic forces on immobilized cells [3]. This suggests that the rate-limiting steps in the metastatic cascade are the adhesion and eventual penetration of the vasculature of the target host organ. Many of these mechanisms of the haematogenous metastatic cascade remain poorly understood, including the adhesion and extravasation of circulating tumor cells in the vasculature of secondary target organs. Past research in this area has been hampered by poor control of pathophysiological conditions in animal models, and the failure to recapitulate an *in vivo*-like environment in *in vitro* models. In this work, a microfluidic device was developed to support the culture and observation of engineered microvasculature with systematic control of the environmental characteristics. This device was then used to study the adhesion of circulating cancer cells to an endothelium under varying conditions to delineate the effects of hemodynamics and inflammations. The resulting understanding will help to establish a quantitative and biophysical mechanism of interactions between cancer cells and endothelium.

METHODS

Cells and Reagents

Human **m**icro**v**ascular **e**ndothelial **c**ells (hMVEC, Lonza) were maintained in endothelial basal medium-2 supplemented with various growth factors and FBS as suggested by the vendor. These cells were harvested when confluence reached 80-85% utilizing 0.025% trypsin and EDTA. Cells of passage 7 to 11 were used in the experiments.

Human breast cancer cell line (MCF-7) was grown in Advanced DMEM/F12 basal medium (Invitrogen) supplemented with 5% FBS, L-glutamine, and Pen/Strep. MCF-7 cells were harvested when confluence reached 80-90%. To reduce the likelihood of enzymatic cleavage of potential membrane binding proteins during harvesting, a non-enzymatic chelator, Versene (Invitrogen), was used to gently detach cells from the culture flask prior to experiments.

In Vitro Endothelium-on-Chip

A microfluidic platform, as illustrated in **Figure 1A** and **B**, was fabricated by standard photolithography technique. The channel measuring 75 μm in height, 300 μm in width, and about 2 cm in length. Three ports were then drilled using a biopsy punch, one at each end of the channel and one about 2.5 mm off-center. The channel walls were coated with 1 mg/mL type I rat tail collagen.

Harvested hMVECs were slowly introduced through the channels utilizing a syringe pump (NE-4000x, New Era). Once cells occupied the area of interest of the channels (from the reservoir to the far port), the devices were moved to an incubator where cells were allowed to adhere to the channel surfaces for 45 minutes. Once hMVEC reached confluence in the channel (about 48 hours), the hMVEC were subjected to a 0.30 dyne/cm^2 shear stress for additional 24 hours utilizing a syringe pump. Exposure to this low shear stress maintains a cobble-stone morphology in which the hMVEC have no apparent alignment. This is consistent with venule morphology *in vivo* [4]. The confluence of the grown endothelial monolayers can clearly be seen in **Figure 1C**. When studying the effect of inflammatory cytokine stimulation, hMVEC monolayers were treated with 50 ng/mL TNF-α for 5 hours prior to experiments, as previously reported [5].

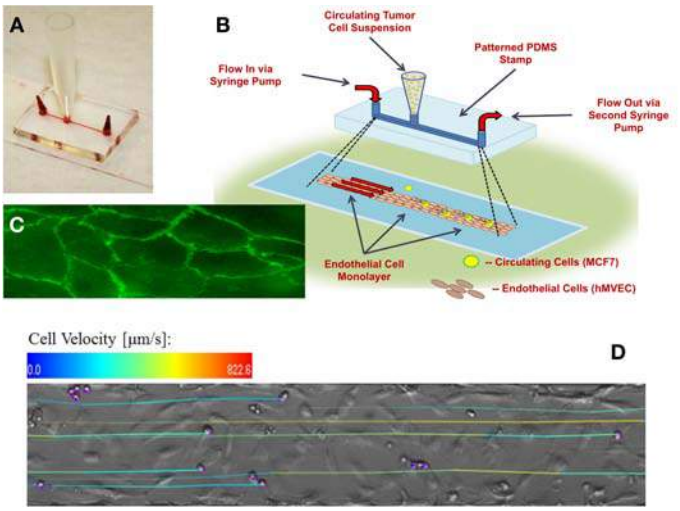

Figure 1: (A) Photograph of the fabricated chip. (B) Schematic of the chip configuration. (C) Morphology of hMEVC endothelium with tight cell-cell contact. (D) Microscopy analysis of cell motion.

Time-lapsed Microscopic Analysis

The prepared microfluidic platform was placed in an incubation stage (Okolab) on an inverted microscope (IX71, Olympus). The channel was perfused with hMVEC medium at physiologically relevant velocities. It has been reported that the mean blood velocity at human capillary beds and post-capillary venules ranges from approximately 250 to about 1400 μm/s [6]. Thus, the hydrodynamic velocities along the channel (v_{hyd}) are 300, 600, and 900 μm/s. Harvested MCF-7 cells were suspended in hMVEC culture medium at a concentration of 1.5 x 10^5 cells/mL, and then 50 μL of this suspension was then added to the center reservoir. Tumor cells from the reservoir then sedimented into the channel, allowing for a relatively constant stream of flowing cells in the observation area. The channel was imaged for cellular motion with a CCD camera (EXI Aqua, Q Imaging). The images were further analyzed to characterize cancer cell interaction with endothelium as shown in **Figure 1D**. The cancer cell behavior was quantified by separating them into different states of dynamic adhesion [7]. These dynamic states of adhesion can be divided into four as follows by use of the cell velocity - i) "no adhesion" describes a state where cells are moving at a velocity greater than $0.5v_{hyd}$; ii) "rolling" describes a state where cells move slower than $0.5v_{hyd}$, but without notable periods of immobilization; iii) "transient adhesion" describes cells moving slower than $0.5v_{hyd}$ with notable periods of immobilization; and iv) "firm adhesion" describes cells moving less than 0.2 μm within 0.5 seconds.

RESULTS AND DISCUSSION

Figure 2 depicts the percentage of MCF-7 cells exhibiting each of the four adhesion behaviors defined on unstimulated or TNF-α stimulated hMVEC. As expected, TNF-α stimulation significantly increased the amount of observable interaction occurring between circulating cancer cells and the endothelial monolayer. The majority MCF-7 cells on the unstimulated endothelium display no observable adhesion behavior, with virtually none becoming immobilized for any discernable amount of time. In addition, cells considered to be rolling traveled, on average, 20 percent faster on unstimulated endothelium than on the TNF-α stimulated one. These results are not surprising due to the lack of adhesion molecules in resting type endothelial cells. Once stimulated, however, interaction between the circulating cells and the endothelium became more prevalent, with the vast majority of cells exhibiting some form of adhesion. Nearly 30 percent of adhering cells became immobilized at some point with more than half of these becoming firmly adhered.

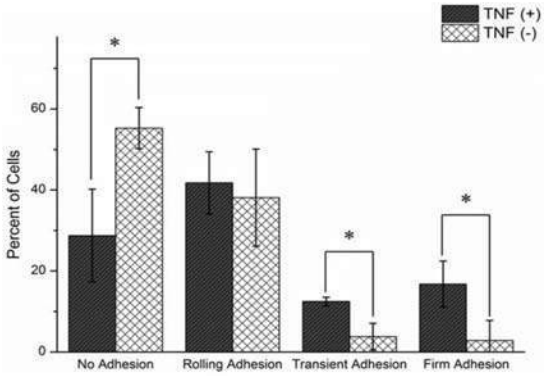

Figure 2: Effects of TNF-alpha on adhesion. Comparisons noted with symbol are statistically significant ($p < 0.05$)

Figure 3 shows the differences in the states of adhesion for adhesion assays performed at mean fluid velocities of 300, 600, and 900 μm/s. A clear and significant difference can be seen in the number of firmly adherent circulating MCF-7 cells between the experimental groups. There is a clear jump in the percent of non-interacting tumor cells as the fluid velocity increased. As the velocity increase to 900 μm/s, the vast majority circulating tumor cells failed to show any discernable interaction with the underlying endothelium. An interesting observation was the number of slowly rolling cells present in the 600 μm/s experimental group. This slow rolling was not observed in either the low or the high velocity groups.

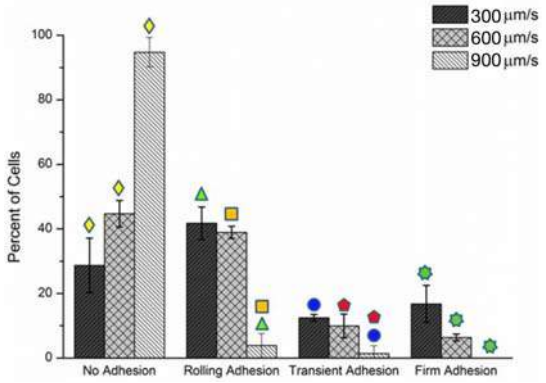

Figure 3: Effects of shear rate on adhesion. Comparisons noted with symbol are statistically significant ($p < 0.05$)

INTRODUCTION

Malignant tumors of the central nervous system are the third leading cause of cancer-related deaths in adolescents and adults and the leading cause of death in children with a mean survival time of 15 months and a mortality rate exceeding 95% [1]. Despite intense medical research focused on improving treatment, survival statistics for patients with aggressive brain tumors such as glioblastoma, or GBM, have not changed satisfactorily in 80 years. One of the reasons for poor survival is that systemic treatment of GBMs is limited by insufficient delivery of drugs due to the blood-brain barrier (BBB). Additionally, glioma cells, which play a role in tumor progression and resistance to therapy, typically infiltrate up to 2 cm beyond the volume of visible tumor [1], making them difficult to detect and treat.

Convection-enhanced delivery (CED), pioneered at the NIH/NINDS, has emerged as a promising method for the delivery of high concentrations of macromolecules to larger regions of brain tissue [2]. The principle of CED involves the stereotactically-guided insertion of a small-caliber catheter into the brain. Through this catheter, high-molecular-weight proteins can be pumped into the brain parenchyma and is pushed primarily through the interstitial space. Experiments have shown that CED can deliver infusates 2 cm into the brain parenchyma after 2 hours of continuous infusion, an order of magnitude higher than the distances obtained with simple diffusion [3].

Although CED has achieved greater efficacy than traditional systemic chemotherapy, it amounted to inconsistent increases in patient survival during Phase III clinical trials [4]. This can be attributed to the limited ability of CED to uniformly distribute drug throughout the tumor and broadly disseminate drug to the infiltrative GBM cells residing in the primary tumor periphery, which correlate with tumor recurrence. Additionally, the anatomical heterogeneity of the brain complicates perfusion by CED. Portions of the brain are inherently difficult to saturate with drugs due to variations in permeability of white and gray matter, tumor tissue, cerebrospinal fluid tracts, and anatomy of vascular beds. Furthermore, the high lipid content of the white matter highly resists movement of aqueous drug formulations. Further limitations of CED involve the "off-label-use" of commercially available catheters designed for different medical applications to perform the therapy [5, 6]. These catheters do not possess the arborizing capability to effectively perfuse drugs over large tissue volumes, including margins surrounding tumors that contain more distant infiltrative cells responsible for regrowth of the tumor [7]. In effort to ascertain targeted delivery and infuse greater tumor volumes, CED often requires insertions of multiple catheters; thus, increasing the risk of trauma to healthy neurological tissue and increasing the probability of seeding the needle tract with cancer cells [8]. For these reasons, we developed a novel arborizing catheter for broad loco-regional delivery of therapeutics.

METHODS

Development of an Arborizing Catheter. The arborizing catheter (**Fig. 1A**) consists of a cannula (OD ~3 mm) that is manufactured using seven aligned biocompatible polyether ether ketone (PEEK) tubing bonded with light-cured acrylic adhesive. The distal end of the tubing is twisted. Once the acrylic is cured, the end of the cannula is filed to a smooth conical tip. The cannula houses seven flexible, hollow silica microneedles (375 μm OD; 180 μm ID) with their distal end polished to a smooth bevel tip (**Fig. 1B**) and their proximal end glued to a 22 G dispensing needle with a Luer lock adapter.

When deploying the microneedles, the twisting of the PEEK tubing allows the needles to branch at an angle of up to 30° (angle of peripheral needles from cannula axis). These individual microneedles can be deployed, arborizing from a single cannula, providing multiple infusion tracts per one primary cannula insertion tract. They can be fully retracted back into the cannula upon completion of the therapy; thus, the tumor-contacting surfaces of needles would remain completely within the primary cannula upon removal, thereby reducing the probability of tumor cell-seeding in healthy brain tissue and preventing mechanical damage to surrounded tissue when extracting the catheter.

Figure 1. A) Arborizing catheter prototype with deployed microneedles. B) Individual silica microneedle (arrow indicates air bubble at sharp beveled tip)

Infusion Experiments with Tissue Phantoms. The arborizing catheter was evaluated with infusion experiments using agarose tissue phantoms. Agarose gel (0.6% w/w), previously validated as a brain tissue phantom, [9] was made by mixing agarose powder (BioRad, Hercules, CA) and deionized water, then heated and stirred until clear. Then each microneedle's Luer lock adpater was connected to BD syringes, filled with a 0.04% solution of indigo carmine dye. The syringes were loaded into a programmable syringe pump (Harvard Apparatus Company, Holliston, MA), and each microneedle was primed. The cooled agarose mixture was then poured into a glass cube containing the arborizing catheter with each microneedle deployed 2 cm from the cannula tip and the gel was allowed to set.

Infusions in the congealed agarose were recorded using an optical shadowgraphy setup, which captures images of the infusion cross-section at multiple angles (front, side, and bottom) (**Fig 2A**). Each infusion was performed at a steady rate of 1 µl/min for 100 minutes while a digital camera (Canon USA, Rebel T1i, Melville, NY) positioned and secured at a fixed distance from the agarose-filled glass box, captured images every minute. For comparison, single needle infusions, analogous to infusion with a single-port catheter, were tested using similar experimental procedures.

Image Analyses to Quantify Mean Distribution Ratios. Final infusion images were processed using MATLAB (The Mathworks, Natick, MA), and Image J (NIH, Bethesda, MD). An algorithm was written in MATLAB to separate and scale each view (front, side and bottom) into separate images. Intensity of the each image was then normalized to an external reference file. Image J was used to convert the images into binary images and determine the best-fit ellipsoid for each view. The major and minor axes of each view's ellipsoid were recorded and mapped to the appropriate axes. The major axes of the front and side view were scaled and averaged to obtain the major axis for the calculated ellipsoid volume (**Fig 2B**). This value and the minor axes from the front and side view were taken to be the semi-axes of a representative 3-dimensional ellipsoid and the approximate volume distribution (V_d) was calculated using:

$$V_d = (4/3)\,\pi\, abc \qquad (1)$$

where a, b, and c are the semi-axes of the ellipsoid. Single-needle infusions were assumed to be spherical and V_d was calculated using the equation for volume of a sphere. The mean distribution ratio (volume distribution (V_d) / total volume infused (V_i)) was calculated for each infusion for comparison.

RESULTS

Using the shadowgraphy technique described above, the distribution profiles of the arborizing catheter were captured and compared to single needle distributions. **Fig. 3** demonstrates a representative infusion for the single needle versus the catheter after 100 minutes of continuous infusion. With the arborizing catheter, the distribution volume distribution was ~5-times greater than with a single needle. However, the mean distribution ratio, V_d/ V_i for the arborizing catheter was approximately 75% smaller than the distribution ratio for a single needle.

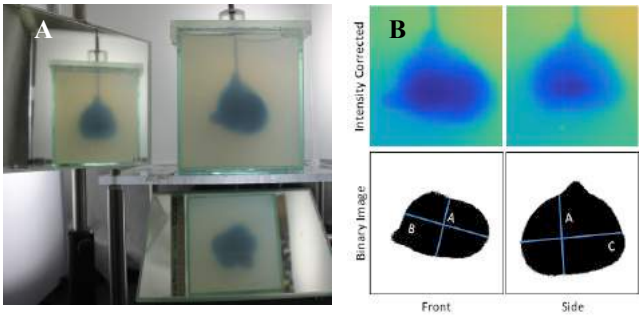

Figure 2. A) Shadowgraphy experimental setup showing three views of the infusion volume. B) Image processing and analysis to quantify dispersal volume and major/minor axes.

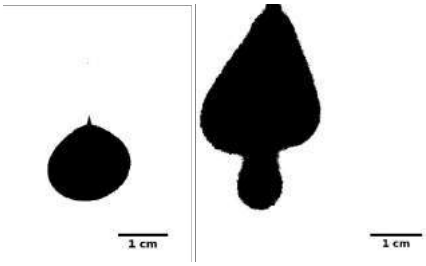

Figure 3. Binary images of infusion profiles for single needle (left) versus arborizing catheter (right) after t = 100 min.

Table 1: Mean distribution for the arborizing catheter versus single needle infusions

	Total V_d (ml)	Total V_i (ml)	V_d/V_i
Arborizing catheter	9.2	0.7	13.1
Single needle	1.8	0.1	17.6

DISCUSSION

Failure to targeting distant, infiltrating glioma cells limits CED efficacy, which may be overcome by achieving broader distribution of therapeutics. In this study, we found that the arborizing catheter achieved greater V_d than a single needle (analogous to a single-port catheter) for equal infusion times. Infusion duration is important as CED is often performed inside an MRI machine, which adds to the cost of the therapy. The V_d/ V_i for the arborizing catheter was only ~ 75% of the ratio for the single needle, which was smaller than we expected. However, the smaller mean distribution ratio may be due to overlap in the distribution volumes for individual needles of the catheter. However, the arborizing catheter did achieved a greater distribution ratio than other studies using reflux-preventing, single-port catheters which reported V_d/V_i of ~ 0.67-1.6 [10].

INTRODUCTION

Knowing the ground reaction forces (GRFs) during walking has various biomechanical applications such as injury prevention, gait analysis, and prosthetic and footwear design. The current study presents a method for predicting the GRFs during level and angled walking that can be used for various outdoor biomechanics studies geared towards the applications mentioned above, that does not require the use of a force plate or other environmental limiting factors.

To date, only force plates have been used to obtain ground reaction force data for studies involving walking over angled surfaces [1,2,3]. For outdoor biomechanics studies an embedded force plate would limit the number of consecutive steps for which data could be recorded, the validity of the foot-ground interaction surface, and the environmental versatility of the study.

A study by Forner-Cordero et al. [4] successfully obtained GRFs during level walking with the use of Pedar plantar pressure insoles combined with kinematic data from a motion capture system. The use of a motion capture system in an outdoor environment for extensive studies is not feasible since calibration is tedious, and the area of the study would still be limited to that which is visible to the motion capture cameras. A study by Fong et al. [5] successfully used Pedar plantar pressure insole data correlated with force plate data, using linear regression analysis, to predict GRFs during level walking. It was hypothesized in the current study that splitting foot contact force data into three phases: Heelstrike^1, Transition^2, Toeoff^3, with separate linear regression equations would both: increase the accuracy of predictions compared to the one-phase regression model developed by Fong et al. [5] as well as create a more versatile model that would allow for the prediction of GRFs during angled walking. This three-staged regression model was proposed because in pilot studies we observed contact loads shifting noticeably from a posterior to anterior location on the foot during level walking gait. The method presented in the current study may be used more effectively in the future for estimating GRFs in numerous original outdoor biomechanical environments such as during angled gait on mountainous terrain.

METHODS

Approval of human subject use was obtained from the IRB. Six healthy male subjects with no known pathology or major lower body injuries within the past ten years were recruited for this study. A 16' long, 0°-20° adjustable ramp with an embedded force plate was used for the level and angled walking trials. Each subject performed ten walking trials at angles 0°, ±5°, ±10°, ±15°, and ±20° while wearing a minimalist shoe outfitted with plantar pressure insoles.

Trial data were then trimmed to include only that from the subject's right foot. Since each subject performed ten walking trials at each angle, nine were used to generate the regression model for the given angle, and one trail was randomly chosen to later assess the accuracy of the model by comparing predicted values using the Pedar data against the force plate GRF data.

Trial data were then split in half at the midstance frame. An Excel macro was used to generate coefficients of determination (R^2 values) between each individual insole senor's pressure readings, and the force plate force measurements. Three insole sensors from each half of the footstrike (before and after midstance) that exhibited a high linear correlation (determined with R^2 values) between each respective GRF component were chosen to create pressure masks. The Heelstrike^1 and Toeoff^3 stages used these sets of correlated sensors as inputs for their respective linear regressions, while the Transition^2 stage used a combination of the two sets of correlated sensors.

Slope and intercept constants were then created between these pressure masks and the force plate measurements of GRF. This

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

process of creating a linear regression using pressure mask values as inputs was done for the anterior-posterior and medial-lateral components of the GRF.

The Pedar system's capacitance sensors allow it to directly measure the vertical force. Instead of using a pressure mask, the Pedar system's measurement of the vertical force was used as the input to the regression model for the vertical component.

The linear regressions generated from the first half of the footstrike were used to predict the GRFs from the first nonzero pressure reading until two frames before the midstance frame, forming the first segment of the model, Heelstrike^1. The linear regression generated from the second half of the footstrike was used to predict data from the fourth frame past midstance until the last non zero pressure reading, forming the third stage of the prediction model, Toeoff^3. The second stage of the model, Transition^2, used a weighted combination of both regression models and was inserted into the model to account for the gradual change in the location of the load bearing sensors from posterior to anterior. Equation 1.1 is a general format of the model. $M(P)^{\theta}_{x,y,z}$, is the model output which is a function of Pedar insole measurements, P. The model was dependent on the surface angle θ and the component of GRF being predicted denoted by *x,y,z*.

$$M(P)^{\theta}_{x,y,z} = \begin{cases} f(P) = m_1 * \left(\bar{P}_{\text{c,d,e}}\right) + b_1, & P_{HS} \le P \le P_{MS-3} \\ \begin{bmatrix} .9 \\ .7 \\ .6 \\ .4 \\ .3 \\ .1 \end{bmatrix} * f(p) + \begin{bmatrix} .1 \\ .3 \\ .4 \\ .6 \\ .7 \\ .9 \end{bmatrix} * g(p), & P_{MS-2} \le P \le P_{MS+3} \\ g(P) = m_2 * \left(\bar{P}_{\text{f,g,h}}\right) + b_2, & P_{MS+4} \le P \le P_{TO} \end{cases} \quad \textbf{(1.1)}$$

$f(P)$ is the linear regression used for the Heelstrike stage of the model with slope and intercept constants, m_1 and b_1. $\bar{P}_{\text{c,d,e}}$ arbitrarily represents the pressure mask input made from three sensors: *c, d,* and *e*. Similar to $f(P)$, $g(P)$ is the linear regression used for the Toeoff stage. $P_{HS} \le P < P_{MS-2}$ denotes the range of Pedar values used for the Heelstrike stage which was from the first non-zero Pedar value, P_{HS}, until three frames before midstance frame, P_{MS-3}. Likewise, the Transition stage used Pedar values from two frames before the midstance frame, P_{MS-2}, until three frames past the midstance frame, P_{MS+3}. Lastly, the Toeoff stage used Pedar values from four frames past midstance frame,P_{MS+4}, until the last nonzero Pedar value, P_{TO}.

RESULTS

For each of the six subjects on each walking surface angle the GRFs were predicted for one trial and the root mean square errors (RMSEs) of the predictions were averaged for each angle and presented in Table 1.1.

		GRF Prediction RMSE (N)		
		Vertical	Medial/Lateral	Anterior/Posterior
0°		26.95	10.05	20.12
5°	Incline	35.28	9.94	19.59
	Decline	35.23	14.01	30.87
10°	Incline	40.69	9.40	26.15
	Decline	31.64	14.56	38.59
15°	Incline	37.29	8.92	29.08
	Decline	33.46	12.47	42.30
20°	Incline	42.22	10.71	39.25
	Decline	38.09	12.52	40.35

Table 1.1: Averaged RMSE results of 6 subjects at angles 0°, ±5°, ±10°, ±15°, and ±20°.

There were slight increases in RMSEs as surface angle increased for the vertical and anterior/posterior directions (Table 1.1). Of the 99 pressure insole sensors, the three most highly correlated sensors were not always the same between any two angles for a subject. It was also found that the locations of the three most highly correlated sensors were not consistent between subjects.

DISCUSSION

Compared to studies from past literature, the relatively low RMSE values in the current study support the hypothesis that a three-staged model can be used to accurately predict GRFs for level and angled walking. The current study showed that a three-staged regression model improved prediction accuracies when compared to the one-staged regression model used in Fong et al. [5] by 11.48, 1.66, and 7.29 N or 29.87%, 14.18%, and 26.60% in the respective vertical, medial/lateral and anterior/posterior directions. The RMSEs of the three-staged regression model, when compared to the study of Forner-Cordero et al. [4] which also used Pedar insoles to generate GRFs curves, improved slightly in the vertical direction but not in the medial/lateral or anterior/posterior directions. Forner-Cordero et al., however, used a motion capture system to collect gait dynamics which assisted in the GRF calculations. The use of a motion capture system in an outdoor environment would be tedious due to calibration issues, and would limit the area of study. Thus, the method used by Forner-Cordero et al. might be less feasible than that of the three-staged regression model for use in outdoor environments. The slight increase in RMSEs for the vertical and anterior/posterior directions as the ramp angle increased may be due to a trend for increases in maximum values of the vertical and anterior/posterior GRF component as the surface angle increases, as observed by Lay et al. [3].

It should be noted that the three-staged regression model was angle and subject specific. Indicators of the model's specificity are the differences in location of the most highly correlated sensors between angles. The variation in location of the most highly correlated sensors across angles was most likely due to differences in gait, such as the ankle, knee and hip angles, which are caused by the changes in grade [3]. The difference in location of the most highly correlated sensors between subjects was also most likely due to differences in gait mechanics between subjects that caused the loading of different pressure sensors during walking. Future studies may involve more footwear designs and test if the model is also footwear specific.

The three-staged model developed in the current study was shown to be a viable tool for predicting the GRFs during walking in outdoor settings due to its small errors and its simplicity which requires only Pedar plantar pressure insoles and calibration trials. The three-staged model should allow for future studies dealing with injury prevention, gait analysis, as well as prosthetic and footwear design in diverse outdoor environments such as mountainous terrains. Future studies should also aim to assess the impact of surface texture on the accuracy of the model predicted GRFs.

INTRODUCTION

Mitral Valve (MV) regurgitation is the most common heart valve disease, afflicting more than 2.5 millions of people in the U.S. alone [1] with a fairly high mortality rate among the population. This pathologic condition is generally characterized by morphologic alterations or impaired interactions of the MV complex constituents (annulus, leaflets, chordae tendineae, and papillary muscles). While the MV annulus and leaflet geometry has been extensively studied [2], the chordae tendineae topology have never been quantitatively explored. Thus, an improved understating of MV chordae tendineae would facilitate the development of advanced surgical strategies and treatment planning.

Chordae Tendineae are cylindrical structures of collagenous connective tissue that protrude from the papillary muscle tips on the posterior left ventricular inner heart wall and insert on the MV leaflets. From a mechanical perspective, the chordae tendineae provide a suspension system that supports the MV leaflets and prevents them from swinging to the atrial cavity during ventricular contraction. MV repair, which is a widely practiced operation to treat regurgitant MVs [3], often benefits from modifying the chordal structure to restore the MV's functionality. This may include repair, reattachment, or rearrangement of the chordae tendineae, adding artificial chords, or even cutting existing normal chordae tendineae.

In this work, our methodology and results on the topological characterization and geometrical quantification of the MV chordae tendineae are presented. We wanted to find out if the chordal branching outline follows any pattern versus being purely random. Our findings, for the first time, provide a basis to predict the geometry of the MV chordae tendineae that ultimately allows developing a population-representative model of the healthy chordal structure.

METHODS

To acquire MV geometry, we imaged four ovine heart valves obtained from an USDA approved abattoir (Superior Farms, CA, USA) in the Georgia Tech Cylindrical Left Heart Simulator (CLHS) [4] as described in [5]. The valves were pressurized and imaged using micro computed-tomography in the simulated fully closed state to better resolve the fine features and geometric details of the chordal structure. Next, the four DICOM imaging data-sets were segmented in the ScanIP software suite (Simpleware Ltd., Exeter, UK) to acquire tessellated surface representations of the MV apparatus. To perform geometry modeling, we relied on the centerline modeling feature in ScanIP to extract a spline-based curve-skeleton representation of the chordae tendineae and the pointwise mean cross sectional area long the skeleton (Fig 1).

Next, we analyzed the curve–skeleton model of the chordae tendineae to develop the Reeb graph [6] representation of the chordal topology (c.f. Fig. 5). Furthermore, we extracted the chordae-to-leaflet and chordae-to-papillary muscle attachment locations, referred to as insertion and origin points respectively, by analyzing the rate of change in the cross sectional area along the chordae skeleton. To extract these anatomical landmarks, a threshold value of 0.15±0.05 was set on the normalized rate of change in the cross sectional area. The cut-off values were adjusted empirically according to our pilot studies which showed the transition zones between the MV chordae tendineae and surrounding structure can be characterized by the aforementioned threshold.

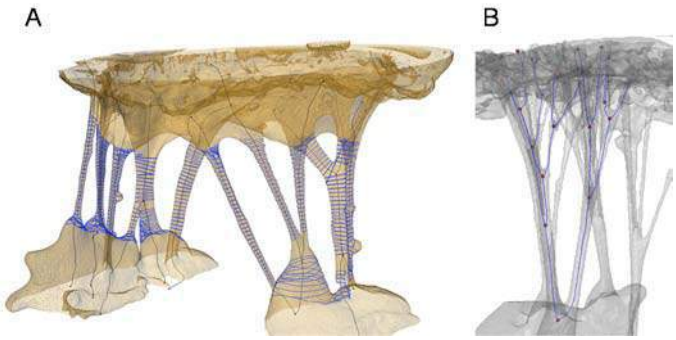

Fig. 1: (A) shows the curve-skeleton representation of chordae tendineae with the cross sectional area. (B) represents how this modeling approach captures the branching structure of chordae.

RESULTS

We developed well-defined geometric models of the MV chordae tendineae (Fig 2), which were used to analyze the chordal structure by extracting and classifying the chordal anatomical landmarks (Fig 4). The study of origin, branching, and insertion points in the chordal structure suggests that the number of these natural fiducial points increases almost linearly along the chordae tendineae (Fig 3).

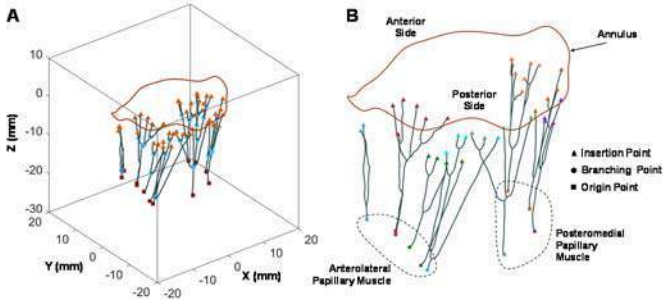

Fig. 2: (A) shows the B-spline representation of the chordae tendineae. In (B), we have classified the anatomical landmarks.

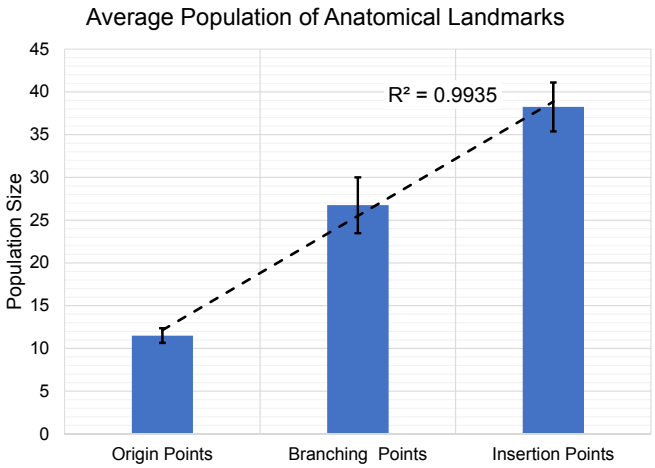

Fig. 3: The number of anatomic fiducial points in the chordal structure increases almost linearly

Interestingly, we observed that the branching pattern in the cylindrical chordal structure follows the full binary tree pattern (Fig 5). In other words, at every bifurcation location, only two outgoing segments emerge from an incoming branch. The same pattern was consistently observed across the studied population of ovine MVs.

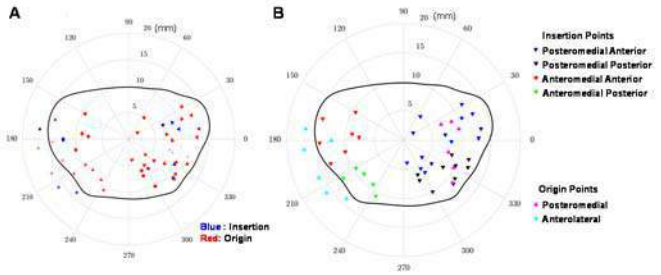

Fig. 4: (A) represents the distribution and (B) shows the classification of insertion and origin location

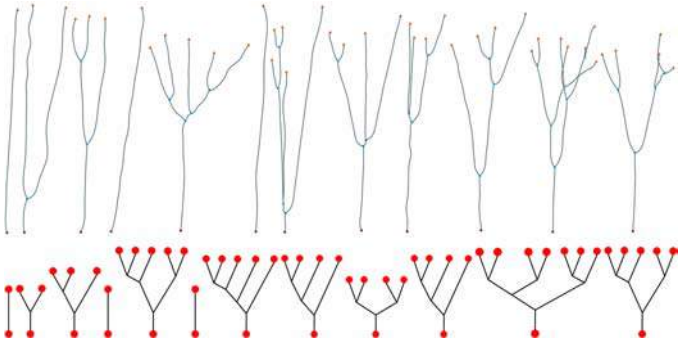

Fig. 5: The full binary tree branching pattern for a single MV. Top row signifies the unfolded geometry of the chordal structure. Bottom row is the collection of Reeb graphs representing the chordal topology

DISCUSSION

In this work, we presented a novel, robust approach to process pre-clinical images and build anatomically accurate geometric models of the MV chordae tendineae. Across a population, we observed that the branching pattern in the cylindrical structure of MV chordae tendineae mainly follows the full binary tree pattern except for very sparse interconnections between some chordae tendineae. From the modeling aspect, this emphasizes that computational models of the MV should respect this existing underlying structure in the chordal geometry to improve anatomical accuracy. Moreover, this interesting finding strongly suggests that the shape of MV chordae tendineae is not random, and, in fact, is tied to some specific fundamental factors. In addition, by extraction and classification of the anatomical landmarks in the chordal structure, we realized that these points are localized in anatomically distinct regions. We believe these regularities provide a basis to average the MV chordae tendineae across a population and develop a population-representative model of the chordal structure.

INTRODUCTION

Bioremediation has been considered as a promising method to treat wastewater due to its low cost compared with physicochemical processes [1]. Encapsulation of enzymes or microorganisms, which are required for degrading toxic chemicals in water, is an efficient way to protect the organisms against predation, temperature extremes, and pH variations. While encapsulation is an effective way to increase stability, inherent characteristics of encapsulation prevent living organisms from reproducing within the system due to space limitation, limiting the longevity and adaptability of the biodegradation processes. One way of solving this problem is by generating a more pliable space within the encapsulation medium in which cells can replicate and replace dead cells.

A Ca-alginate composite is a hydrogel, which can be easily depolymerized when exposed to a chelating solution, such as citric acid. This process is cytocompatible and not negatively affect the viability of the encapsulated bacteria (data not included). The protectant silica gel coating deposited on the alginate keeps the bacteria from leaking out, and is permeable enough to allow diffusion of water and chemicals. Silica is a good material for encapsulation due to its relatively low cost, thermal and chemical stability, and easily tunable mechanical and transport characteristics. The methods to encapsulate bacteria containing alginate beads inside silica coating has been shown by Callone et al [2]. However, the irregular shape and fragility of the thin silica coating around the alginate microspheres cause issues.

Here, we developed a method to encapsulate spherical Ca-alginate gels, which contain bacteria in a thin silica film. The fast reaction time (less than 2 minutes) between SNP (silica nano-particles) and silica alkoxide precursors keeps microorganisms alive during the co-encapsulation process. The proposed method is expected to help us develop a reproducible, self-sustaining, and high efficient biomaterial encapsulation system, as depicted in Figure 1.

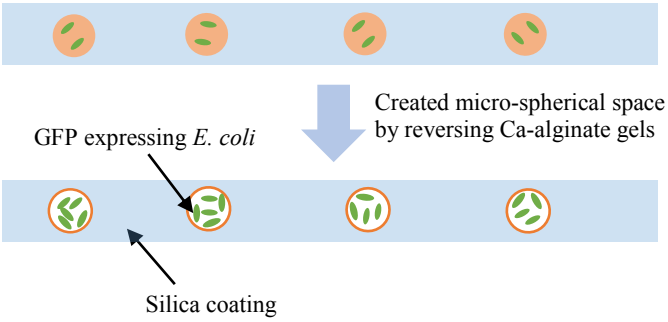

Figure 1: Silica micro-bioreactor

METHODS

Alginate Beads Electrospraying

Two percent (wt/wt) of alginate was dissolved in deionized water while stirring overnight. A small amount of GFP expressing *E. coli* was added into alginate solution, which was loaded into a 1 ml syringe. At a constant flowrate and a voltage differential (2.2 ml/hr, 4.5 kV/cm), the alginate solution was electrosprayed into 100 mM of $CaCl_2$ solution, producing Ca-alginate beads of homogeneous size (d~170μm).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Silica Synthesis and Coating Formation

TEOS (tetraethylorthosilicate) was hydrolyzed under acidic conditions as, detailed elsewhere [3]. SNP (TM40, 22 nm) were neutralized with the addition of 1M HCl. Four samples were prepared on top of cover slides attached to a petri dish with a 10 mm hole. The alginate gels were placed on the slides. Eighty µl of SNP and hydrolyzed TEOS at a ratio of 7:1 were added on top, which formed a thin film (thickness < 500µm). The Ca-alginate beads were floated onto the mixture solution, so after the silica polymerized, 30 µl of SNP + TEOS solution was added to prevent cell leakage. Citric acid (0.1 M) was neutralized with the addition of NaOH. Minimal media (M9) was prepared in deionized water.

Confocal Microscopy

Nikon A1Rsi Confocal with SIM Super Resolution microscopy was used to collect confocal images. Images of each sample were taken at 100 µm increments in the z direction, and stacked together.

RESULTS

0.1M of neutralized citric acid was added on top of the samples to depolymerize spherical Ca-alginate microspheres. Twenty mins later, the citric acid solutions were removed and minimal media (M9) was added and kept for 30 hours to allow cells to proliferate (Figure 2(d)). Controls were the beads in PBS (a), 0.1M citric acid + M9 (b), and M9 in the absence of citric acid (c). As expected, no growth was observed in the solid gel (a, PBS only and c, M9 only). However, when microspheres were reversed and with sufficient amount of nutrients, noticeable growth was obtained (b,d). The inset image of Figure 2(b,d)

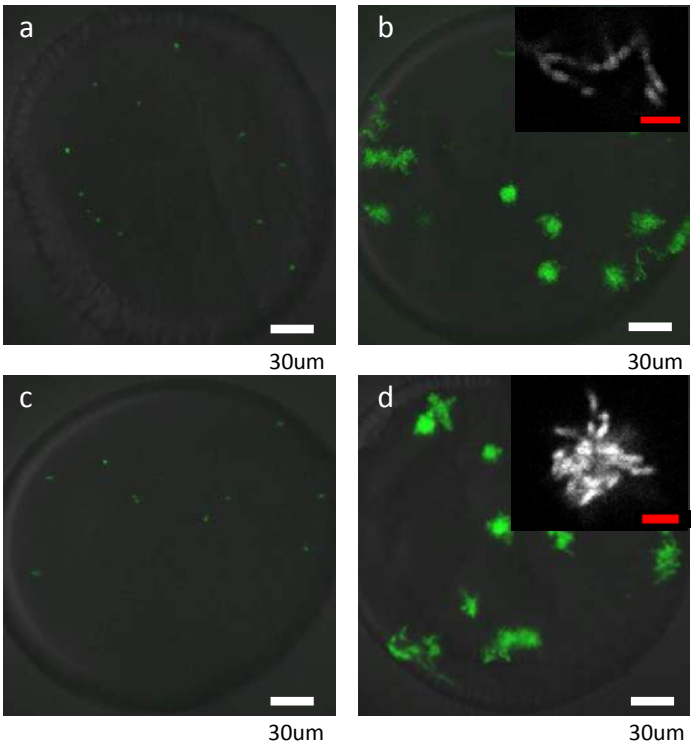

Figure 2: Confocal microscopy images of GFP expressing *E. coli* growth after 15hours incubated in (a) PBS, (b) 0.1M citric acid + M9, (c) M9, (d) 0.1M citric acid for 20 mins and replaced to M9 (for (b),(d): inset scale is 5µm)

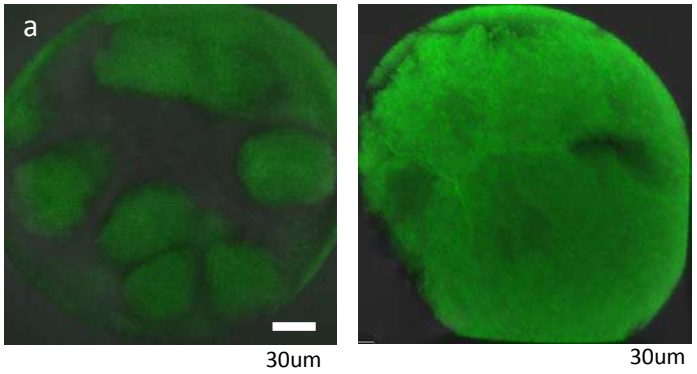

Figure 3: Confocal microscopy images of GFP expressing *E. coli* growth after 30hours incubated in (a) 0.1M citric acid + M9 (b) 0.1M citric acid for 20 mins and replaced to M9

shows the shape of bacterial colonies. When *E. coli* cells were exposed to citric acid for too long, the morphology of the colonies was unusual as the chelating solution also removed iron from the bacteria and iron is an essential nutrients for their growth [4].

Figure 3(a) shows the bacterial colonies in the presence of citric acid and media solution. When recombinant *E. coli* were exposed to citric acid for longer time periods (30 hours), necrotic regions developed. In Figure 3(b), Ca-alginate hydrogel microspheres were reversed and filled with media, the bacteria filled the free space, and stopped growing, presumably due to space limitation.

DISCUSSION

GFP expressing *E. coli* cells were encapsulated in Ca-Alginate beads embedded in a thin silica film. Divalent ions were taken out from the Ca-Alginate gels using chelator solution, and the spherical cavity that was generated was filled with media solution to promote bacterial growth. Confocal microscopy allowed observation of the growth of the bacteria. Thirty hours was sufficient time for bacteria to replicate and thus fill in the vacated cavity. The growth of bacteria was observed microscopically and morphology of individual bacteria and colonies were studied. This method shows promise for developing a sustainable, evolving bioreactor system for water remediation.

INTRODUCTION

Chondrocytes, the single cell type within articular cartilage, are subjected to a challenging extracellular environment with high osmolarity, low pH and oxygen, and profound fluctuations, due to turnover of proteoglycan content and dynamic physiological loading of cartilage [1]. This environment is also inhomogeneous, with varying stiffness and composition from pericellular to territorial and extracellular matrix [2]. Such a challenging environment requires effective mechanisms for maintaining homeostasis of chondrocytes. In particular, cell volume, pH and Ca^{2+} regulation have been studied extensively in these cells [1].

There are similarly extensive mathematical modeling studies of cell physiology; most of these, however, are limited to 1D investigations of isolated cells in a homogeneous environment under isochoric conditions. Mixture theory is able to model solid stress and strain, transport of solvent and multiple solutes, and electrical potential within a mixture; with the implementation of mixture theory into the open-source finite element software FEBio [3], coupled with chemical reactions and active membrane transport [4,5], it becomes possible to model cell physiology within a 3D inhomogeneous environment, while accounting for cell and tissue deformation and interactions, and transport of solvent and solutes. As a first step, this study investigates whether the FEBio framework may reproduce basic models for cell pH and Ca^{2+} regulation (modeling of cell volume regulation has been described previously [5]).

SOLUTE-SELECTIVE MEMBRANE PATHWAY

Active membrane transport may be incorporated into mixture theory by adding an active momentum supply $\hat{\mathbf{p}}_a^\alpha$ into the linear momentum balance equation [5]; for solute-selective pathways the momentum balance reduces to

$$-\rho^\alpha \mathrm{grad}\tilde{\mu}^\alpha - \mathbf{f}^\alpha\left(\mathbf{v}^\alpha - \mathbf{v}^s\right) + \hat{\mathbf{p}}_a^\alpha = \mathbf{0} \tag{1}$$

where ρ^α is the apparent density, $\tilde{\mu}^\alpha$ the mechanoelectrochemical potential, $\mathbf{f}^\alpha$ the diffusive drag tensor, and $\mathbf{v}^\alpha$ the velocity, while the superscript α refers to solute α, and s is the solid. With the constitutive relation for $\tilde{\mu}^\alpha$ and the diffusivity $\mathbf{d}_m^\alpha = R\theta\varphi^w c^\alpha\left(\mathbf{f}^\alpha\right)^{-1}$ [6], where R is the universal gas constant, θ the absolute temperature, φ^w the solvent volume fraction, and c^α the solute concentration, Eq. (1) can be inverted to produce the molar flux of solute α

$$\mathbf{j}_m^\alpha = \mathbf{j}_a^\alpha - \frac{\varphi^w \mathbf{d}_m^\alpha}{R\theta}\cdot\left(c^\alpha z^\alpha F_c \mathrm{grad}\psi + R\theta\,\mathrm{grad}c^\alpha\right) \tag{2}$$

where z^α is the charge of solute α, F_c is Faraday's constant, and ψ the electrical potential; $\mathbf{j}_a^\alpha = \mathbf{d}_m^\alpha\cdot\hat{\mathbf{p}}_a^\alpha$ is the active part of $\mathbf{j}_m^\alpha$ and the remaining term is the passive component. Eq.(2) can be rewritten as

$$\mathbf{j}_m^\alpha = \mathbf{j}_a^\alpha - \varphi^w\tilde{\kappa}^\alpha\mathbf{d}_m^\alpha\cdot\mathrm{grad}\tilde{c}^\alpha \tag{3}$$

with the effective solute concentration $\tilde{c}^\alpha$ and the partition coefficient $\tilde{\kappa}^\alpha$ defined in FEBio. With Eq. (3), the implementation of solute-selective pathways into FEBio can be accomplished by adding $\mathbf{j}_m^\alpha$ to the total flux $\mathbf{j}^\alpha = \mathbf{j}_0^\alpha + \mathbf{j}_m^\alpha$, where $\mathbf{j}_0^\alpha$ is the original passive molar flux.

CELL pH REGULATION

Under an acidic extracellular environment (pH ~ 6.8), chondrocytes extrude their intracellular acid primarily via a H^+ pump and $Na^+\times H^+$ exchanger to maintain cytoplasmic pH ($pH_i \sim 7.1$) [1]. Weak acids, such as CO_2/HCO_3^- solution, and bases in the cytoplasm, act as buffers. Mathematical modeling of cell pH regulation, as in Leem's study [7], generally employ the law of mass action to model reactions of buffers, coupled with the buffering power defined within the Henderson-Hasselbalch equation to evaluate the cell pH; cell volume

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

regulation is normally not considered.

In this study, a 1D cell model previously created for cell volume regulation is used [5] (Fig. 1a), with Na^+, K^+, Cl^-, n (neutral solute) across the membrane, c^F (fixed charge density) in the protoplasm, and Na^+-K^+ pump on the membrane. Additionally, H^+, CO_2, HCO_3^- are allowed to permeate across the membrane, coupled with a CO_2/HCO_3^- reaction in the protoplasm; H^+ pump and $Na^+ \times H^+$ exchanger are incorporated in the membrane. The reaction is described by

$$CO_2 + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} H^+ + HCO_3^- \tag{4}$$

where k_1 and k_{-1} are the reaction rates. The molar flux of H^+ pump is simplified from Eq. (3) and defined by

$$\mathbf{j}^{\mathrm{H}}_{\mathrm{Hp}} = j^{\mathrm{H}}_{\mathrm{Hp}}\mathbf{n} \tag{5}$$

where $j^{\mathrm{H}}_{\mathrm{Hp}}$ is the pumping flux for H^+. The molar flux of $Na^+ \times H^+$ exchanger is simplified from Eq. (3) and defined by

$$\mathbf{j}^{\mathrm{Na}}_{\mathrm{NaH}} = -\varphi^w d_{\mathrm{NaH}}\left(\tilde{\kappa}^{\mathrm{Na}}\mathrm{grad}\tilde{c}^{\mathrm{Na}} - \tilde{\kappa}^{\mathrm{H}}\mathrm{grad}\tilde{c}^{\mathrm{H}}\right) = -\mathbf{j}^{\mathrm{H}}_{\mathrm{NaH}} \tag{6}$$

where d_{NaH} is the diffusivity of Na^+ and H^+ for this pathway.

Analytical expressions from mixture theory can be similarly derived [5] and solved numerically in MATLAB. With the Henderson-Hasselbalch equation [7], pH_i is calculated according to

$$\mathrm{dpH}_i/\mathrm{d}t = Aj^{\mathrm{H}}/\varphi^w V\beta \tag{7}$$

where A is the area and V the volume of the cell, and j^{H} is the total H^+ flux; $\beta = 2.303\cdot[\mathrm{HCO_3^-}]_i$ is the buffering power of the CO_2/HCO_3^- buffer, where $[\mathrm{HCO_3^-}]_i$ is the HCO_3^- concentration in the protoplasm.

H^+ pump is required to maintain the cell pH while its inhibition will acidify the cell (Fig. 2b). Results from mixture theory agree with the equations of Leem's study [7], since the change in cell volume is minimal. The small difference between the MATLAB implementation and FEBio occurs because the former uses the approximate assumption of buffer equilibrium in Eq. (7).

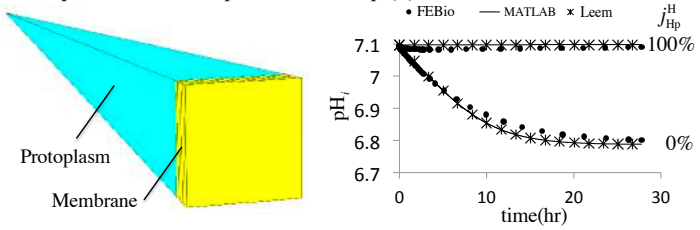

Figure 2: (a) 3D finite element model of spherical cell using spherical symmetry; (b) pH_i response with 0% and 100% H^+ pump flux, from FEBio, MATLAB, and Leem's study [7]**.**

CELL Ca^{2+} REGULATION

In common with all mammalian cells, chondrocytes have low free Ca^{2+} in the cytoplasm ($[Ca^{2+}]_i \approx 80\mathrm{nM}$), while most Ca^{2+} is bound and stored in organelles ($[Ca^{2+}]_{\mathrm{total}} \approx 1\mathrm{mM}$) [1]. Mechanisms that maintain low Ca^{2+} levels and induce potential oscillations include Ca^{2+} pump, inositol triphosphate (IP_3) -sensitive Ca^{2+} channel, and mechano-sensitive Ca^{2+} channel on the cell and organelle membranes, such as the endoplasmic reticulum (ER) membrane. The free Ca^{2+} level affects cell adhesion, aggregation, matrix synthesis, and differentiation [8]. Mathematical modeling of cell Ca^{2+} regulation, such as in LeBeau's study [9], generally considers the mass balance in the cytoplasm, with Ca^{2+} flux induced by constant-field electro-diffusion, Ca^{2+} pumps, and Ca^{2+} channel with several states coordinated by reactions. In this study we use a model similar to that proposed in LeBeau's study to examine Ca^{2+} regulation with FEBio.

The cell model for volume regulation is used again [5], while the protoplasm is divided into the ER, ER-membrane, and cytoplasm domains (Fig. 2a). Ca^{2+} is allowed to permeate across the ER-membrane; a fixed charge c^F is prescribed in the protoplasm (all three domains); a Ca^{2+} pump (Hill equation) and Ca^{2+} channel (LeBeau [9]) are modeled on ER-membrane. The Ca^{2+} pump molar flux is

$$\mathbf{j}^{\mathrm{Ca}}_{\mathrm{pH}} = k_{\mathrm{pH}}[\mathrm{C}_2]\mathbf{n} \tag{8}$$

where k_{pH} is constant and $[\mathrm{C}_2]$ is coordinated by the reaction

$$\mathrm{C}_1 \underset{k^{\mathrm{pH}}_{-1}}{\overset{k^{\mathrm{pH}}_{1}}{\rightleftarrows}} \mathrm{C}_2 \tag{9}$$

where the conformational states C_1, C_2 are solid-bound molecules on ER membrane, and $k^{\mathrm{pH}}_1 = V_p[Ca^{2+}]_i^2/(K_p^2 + [Ca^{2+}]_i^2)$ (Hill equation with constants V_p and K_p) and k^{pH}_{-1} are reaction rates. The molar flux of Ca^{2+} channel is

$$\mathbf{j}^{\mathrm{Ca}}_{\mathrm{cL}} = -d_{\mathrm{cL}}\varphi^w\tilde{\kappa}^{\mathrm{Ca}}\mathrm{grad}\tilde{c}^{\mathrm{Ca}} \tag{10}$$

where $d_{\mathrm{cL}} = k_{\mathrm{cL}}[\mathrm{O}]^4$ and $[\mathrm{O}]$ is coordinated by the reactions

$$\mathrm{S} \underset{k^{\mathrm{cL}}_{-1}}{\overset{k^{\mathrm{cL}}_{1}}{\rightleftarrows}} \mathrm{O} \overset{k^{\mathrm{cL}}_{2}}{\rightarrow} \mathrm{I}_1 \overset{k^{\mathrm{cL}}_{3}}{\rightarrow} \mathrm{S} \text{ and } \mathrm{I}_1 \overset{k^{\mathrm{cL}}_{4}}{\rightarrow} \mathrm{I}_2 \overset{k^{\mathrm{cL}}_{5}}{\rightarrow} \mathrm{S} \tag{11}$$

where the conformational states S, O, I_1, I_2 are solid-bound molecules on ER membrane; $k^{\mathrm{cL}}_1 = \alpha_1[Ca^{2+}]_i^3/(\beta_1^3 + [Ca^{2+}]_i^3)$ (constant α_1 and β_1), k^{cL}_{-1}, k^{cL}_2, k^{cL}_3, k^{cL}_4, k^{cL}_5 are reaction rates. Analytical expressions from mixture theory are similarly derived and solved in MATLAB.

$[Ca^{2+}]_i$ oscillations are observed (Fig. 2b). The signaling factor IP_3 in the cytoplasm may induce oscillations by increasing the value of k^{cL}_4. Results from FEBio agree with those from MATLAB. In LeBeau's study $[Ca^{2+}]_{\mathrm{ER}}$ in the ER is assumed to remain constant, producing oscillations different in period and amplitude compared to those from FEBio; they agree with those from MATLAB when the latter is modified to adopt that assumption.

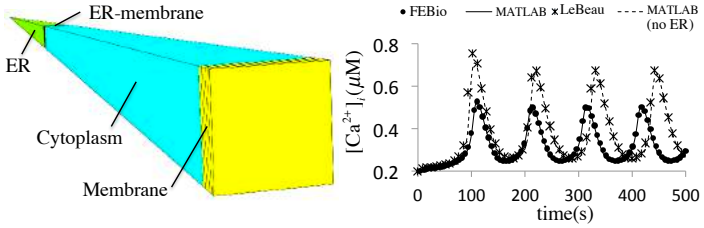

Figure3: (a) Cell finite element model showing four domains; (b) $[Ca^{2+}]_i$ oscillations from FEBio, MATLAB (with and without ER $[Ca^{2+}]_{\mathrm{ER}}$ fluctuations), and LeBeau's study [9].

SUMMARY. This study demonstrates that classical models of cell physiology may be reproduced with mixture theory using MATLAB and FEBio. The FEBio implementation relies on the incorporation of chemical reactions and active membrane transport pathways. FEBio predictions reproduced those of standard 1D cell models under constant volume; however, FEBio is also able to analyze fully 3D models of deforming cells and their surrounding matrix.

NONLINEAR CREEP BEHAVIOR OF UTEROSACRAL AND CARDINAL LIGAMENTS

Adwoa Baah-Dwomoh (1), Ting Tan (1), Raffaella De Vita (1)

(1) Mechanics of Soft Biological Systems Laboratory
Biomedical Engineering and Mechanics Department

Blacksburg, VA, USA

INTRODUCTION

It is estimated that pelvic organ prolapse (POP), the descent of organs into the vaginal cavity, affects approximately 3.3 million women annually in the United States [1]. Damage to the uterosacral (USL) and cardinal (CL) ligaments, two major supportive pelvic ligaments, is thought to be one of the major causes of POP [2]. These ligaments are used to surgically treat POP: they are either sutured to surrounding pelvic tissues or sutured to a synthetic mesh to help support the prolapsed organ. Both of these procedures are marred by complications, with almost as many as 25% of women who have had a corrective surgery experiencing a reoccurrence of organ prolapse [3]. Current surgical techniques and mesh materials for the treatment of POP have been developed without considering the mechanical properties of the native ligaments of the pelvic organ complex. Determining the biomechanical properties of the USL and CL is imperative to help develop improved surgical techniques and mesh materials. To date there are no studies that characterize the nonlinear creep properties of these ligaments, including the effect of multiple and consecutive constants loads. The goal of this study is thus to reveal nonlinearities in the creep behavior of swine USL and CL using planar biaxial testing and digital image correlation. Biaxial mechanical tests better represent physiologically the forces acting on these ligaments *in vivo* compared to uniaxial mechanical tests. Creep behavior is also physiologically important for the ligaments since they are subjected to constant loads in-vivo over time.

METHODS

USL and CL from three adult swine (3 to 4 years old, approximately 450 lbs) were obtained with approval from the Institutional Animal Care and Use Committee at Virginia Tech. Specimens were carefully dissected and were cut to be approximately 3 x 3 cm^2, then frozen at -20 °C before biaxial mechanical testing. A speckle pattern was created and applied to each specimen using methylene blue 1% and an aerosol fast dry gloss white paint to create contrast. The specimens were then gripped with 4 hooks on each side and mounted into a planar biaxial testing system (Instron, UK) equipped with four 20 N load cells. The two axial directions were selected to be the main in vivo loading direction of the ligaments and the direction perpendicular to it (Figure 1). Specimens (n=9) were split into three groups and each specimen was submerged in a PBS bath. Each specimen in group one was preloaded to 0.1 N and preconditioned from 0.1 N to 1 N at 0.05 N/s for 10 cycles equally along the two loading directions. After preconditioning, the specimen was unloaded, allowed to recover for 10 min and then subjected to three creep tests. The specimen was stretched at a rate of 0.05 N/s and held at a constant equi-biaxial load of 1 N for 20 min (1200 s), then unloaded and allowed to recover for 200 min (12000 s). A second creep test, followed by recovery, and a third creep test were performed on the specimen using equal load over equal time interval. Specimens in groups two and three followed a similar protocol as specimens in group one, however, specimens were preconditioned for 0.1 N to 2 N at 0.05 N/s for 10 cycles and creep testing at an equi-biaxial load of 2 N for group two and specimens were preconditioned for 0.1 N to 3 N at 0.05 N/s for 10 cycles and creep testing at an equi-biaxial load of 3 N for group 3. For all groups of specimens, a 3D digital image correlation system (Correlated Solutions, Inc., SC) was used to accurately measure the Langrangian strain.

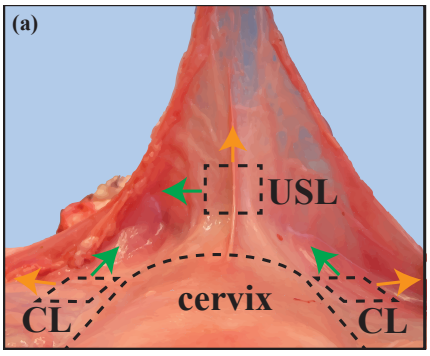

Figure 1: Image indicating the USL/CL complex. The arrows indicated the main *in vivo* loading direction (orange) and loading direction perpendicular to the main *in vivo* loading direction (green).

RESULTS

Specimens exhibited the highest increase in strain over time during the first creep test (Figure 2) in both loading directions. This

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

held true for the specimens in all 3 groups, that is for specimens subjected to 3 consecutive creep tests at 1 N (not shown), 2 N (Figure 2), and 3 N (not shown).

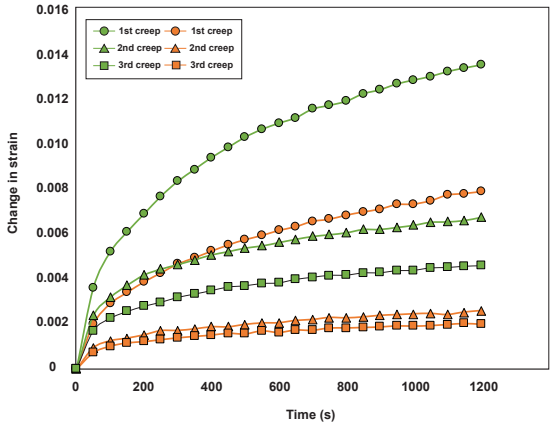

Figure 2: Creep data for one representative specimen in the main *in vivo* loading direction (orange) and perpendicular to the main *in vivo* loading direction (green) undergoing 3 consecutive creep tests at an equi-biaxial load of 2 N. For each direction, creep during the 1st test is the highest, followed creep in the 2nd and 3rd tests.

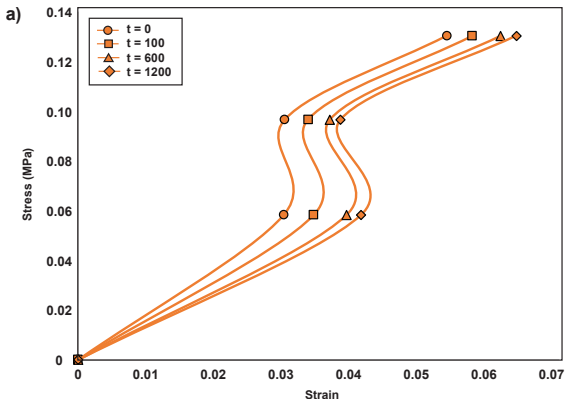
The mean stress for each test group was determined (Table 1). Mean isochronal stress strain data were calculated by selecting four time points during the first creep tests from each group (t=0 s, 100 s, 600 s, 1200 s), calculating the mean strain for each group at those time points during the first creep test, and plotting the mean stress vs the mean strain for each time point. The mean isochronal curves (Figure 3) show the nonlinear creep behavior in both the main *in vivo* loading direction and the perpendicular to the main *in vivo* loading direction.

Table 1: Calculated mean stress in the main *in vivo* loading direction and perpendicular to the main *in* vivo loading direction used for isochronal stress-strain plot (n=9)

	Mean stress (MPa) Main *in vivo*	Mean stress (MPa) Perp *in vivo*
Group 1	0.058	0.053
Group 2	0.097	0.101
Group 3	0.130	0.121



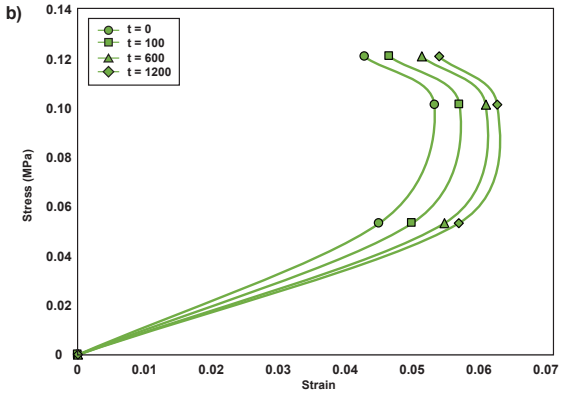


Figure 3: Mean isochronal stress strain data (a) along the main *in vivo* loading direction (orange) and (b) perpendicular to the main *in vivo* loading direction (green). These data show the nonlinear creep behavior of the USL/CL complex.

DISCUSSION

Specimens exhibited the highest creep during the first biaxial test and showed less creep behavior for each subsequent biaxial test for all test groups (Figure 2). We hypothesize that this occurs due to water vacating the USL/CL specimen during the first creep and a rearrangement of the collagen fibers, reducing the movement of collagen fibers during subsequent creep tests. Mean isochronal stress strain data show the nonlinear viscoelastic behavior of USL/CL in both the main *in vivo* loading direction and perpendicular to the main *in vivo* loading direction. The origin of the observed nonlinearity is currently unknown and is being investigated by our group.

This is the first study on the nonlinear biaxial viscoelastic behavior of pelvic floor ligaments. Quantifying the viscoelastic behavior of these ligaments in physiologically relevant loading conditions is important when performing reconstructive surgeries for POP. Such results are expected to greatly benefit future surgeons and researchers in material science by giving them the necessary data to create better surgical techniques and mesh materials. By understanding the mechanical properties of these ligaments, such as their viscoelastic behavior, mesh materials can be made to have similar properties as the native tissue so as to improve their current *in vivo* performance.

INTRODUCTION

Critical congenital heart valve diseases have extremely limited treatment options. Lack of sizing options and an inability of a prosthetic valve to grow with the pediatric patient are the primary technical barriers. Tissue engineering is a concept which can provide for growth, self-repair and a permanent approach for replacing defective heart valves[1]. Recently cardiovascular substitutes made from extra cellular matrix derived from the porcine small intestinal submucosa (PSIS) has shown immense potential for *in vivo* tissue regeneration as the ECM-PSIS bioscaffold degrades[2, 3]. PSIS bioscaffold is a unique acellular, biodegradable soft tissue material which allows native cells to migrate on it and thus remodels into healthy tissue. In our group, PSIS-valves have been used in the treatment of compassionate care cases involving neonates suffering with critical valve defects. To our knowledge we are the first and only group to have employed this treatment in pediatric patients, with the valve observed (via echocardiography) to function flawlessly for over a year thus far.

Here we conducted an organized functional assessment of PSIS valves in order to define its opening and closing characteristics. To achieve this task, we utilized a dedicated Pulse Duplicator System (Vivitro Laboratories, Victoria, Canada), which has been modified to evaluate the valves in physiological conditions as that of the functioning heart[4]. Through this study we aim to determine functional effectiveness of **tri-leaflet** PSIS bioscaffold valve sutured in the **Aortic position** using a pulse simulator.

METHODS

Fresh porcine hearts were collected from a slaughterhouse which is USDA approved (Mary's Ranch Inc., Miami, FL). Aortic heart valves along with the aortic conduit were then harvested by isolating the aortic root, under sterile condition. These extracts were stored in a cocktail solution prepared by mixing PBS solution and Protease Inhibitor tablets (Sigma-Aldrich). The native aortic valve was excised and in its place, the PSIS bioscaffold assembled aortic valve construct was sutured into the valve location, within the porcine aortic conduit.

Once the Aortic Valves were constructed, they were then introduced in a Pulse Duplicator System (Vivitro Laboratories, Victoria, Canada). We have made use of this system in our previous experiments where we tested flexible-leaflet valve implants[2]. In order to assess hydrodynamic parameters of PSIS based valves, the normal physiological environment of the native human aortic valve was recapitulated. The mechanical unit of the pulse duplicatior comprises of a piston pump, various chambers which mimic those of the heart and an integrated software system. Tri-leaflet PSIS valves assembled from sheets of PSIS bioscaffold (Cormatrix, Roswell, GA) were mounted in the aortic position within the pulse duplicator. A 0.9% saline solution was introduced into the system through the atrial chamber, to fill the loop with fluid. . The heart rate was set to 70 beats/min. A physiological waveform representative of the pumping action of the left ventricle was selected (in the case of the Vivitro system the S50 waveform was chosen for all hydrodynamic tests) to drive flow through the loop. To facilitate the measurement of flowrates and pressure, external instrumentation namely a flowmeter and three pressure transducers were introduced into the system. Flow probe was positioned at the inlet of the aortic root and pressure transducers at ventricular, atrial and aortic locations. We first calibrated the machine to ensure correct flow and pressure output readings by using a pair of bi-leaflet mechanical valves of known performance, placed in the mitral and aortic positions respectively. Subsequently, the mechanical valve in the aortic position was replaced with the PSIS-valve. Commercially

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

available bioprosthetic valves (Medtronic Freestyle, Medtronic, Minneapolis, MN) were also tested to serve as a flexible control group.

The effective orifice area (EOA) and energy loss for the valve was defined as follows:

$$EOA = \frac{QRMS}{51.6 * \Delta P} \quad \text{..... (1)}$$

$$Energy\ Loss = \left(\frac{\rho * v2}{2}\right) * \left(1 - \left(\frac{EOA}{Aglass.tube}\right)\right)^2 * SV \quad \text{..... (2)}$$

RESULTS

Hydrodynamic evaluation of ECM aortic valves revealed that the resulting flow waveforms were physiologically-shaped (Fig. 1). Robust forward flow was observed in both the heart valves (Fig. 1). It was found that the EOAs of both the PSIS and Bioprosthetic valves were comparable making the bioprosthetic valves an objective control (Table 1). Between the PSIS and bioprosthetic valves, it was observed that both the energy loss and regurgitant fraction metrics were statistically different ($p < 0.05$) between the two groups.

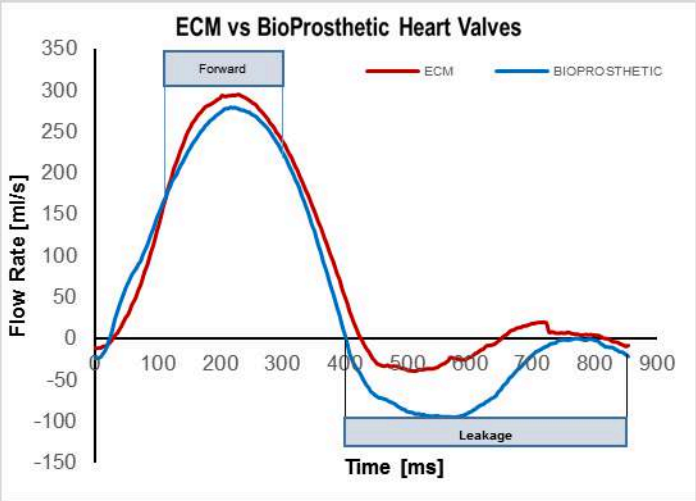

Figure 1: Flow waveforms of PSIS-ECM and Bioprosthetic valves tested in the aortic position using a Vivitro Pulse Duplicator System.

Table 1: Hydrodynamic Parameters of n=3 Aortic PSIS ECM Valves and n=2 Bioprosthetic Valves for Systolic Phase. Note: '*' indicates *statistically significant* (*P < 0.05*).

Aortic Valves	ΔP (mmHg)	Q_{rms} (ml/s)	EOA (cm^2)	Systolic Energy Loss (mJ)*	RF (%)*
PSIS ECM (n=3)	24.0 ± 2.4	239.9 ± 44.4	0.96 ± 0.21	36.4 ± 19.1	13.8 ± 9.8
Bioprosthetic (n=2)	18.1 ± 1.9	244.4 ± 3.6	1.12 ± 0.08	2.9 ± 0.7	51.3 ± 0.8

DISCUSSION

The *in-vitro* testing of the heart valves in the aortic location clearly demonstrates robust acute functionality of PSIS valves when compared to the bioprosthetic control valves thus validating further investigation of the PSIS valves for valve replacement. We believe that the greater leakage in the control valves was potentially due to paravalvular leakage in the bioprosthetic valve, probably due to greater size mismatch between bioprosthetic annulus and the valve holder that it was secured to; despite this, its forward flow rate was strong. . On the other hand the significantly greater energy loss in the PSIS valves ($p < 0.05$) was possibly due to its stiffer leaflet material properties. This may be an area of concern for the long term functionality of ECM valves, depending on its potential to support de novo valvular tissue growth *in vivo*. Hence, our next steps will involve further hydrodynamic testing and optimization of PSIS bioscaffold valves as well as *in-vivo* studies.

ACKNOWLEDGEMENTS

A MODEL TO DETERMINE THE EFFECT OF AXIAL STRETCH ON LUMEN COLLAPSE OF ARTERIES

Fatemeh Fatemi Far, Hai-Chao Han

Department of Mechanical Engineering
The University of Texas at San Antonio
San Antonio, TX, USA

INTRODUCTION

Blood vessels collapse when the transmural pressure, the difference between the lumen pressure and external pressure, is highly negative [1, 2]. The lumen collapse is commonly seen in vein since vein walls are thinner and the lumen pressure is low. However, arteries may collapse under certain conditions such as peripheral arteries compressed by pressure cuffs or intramyocardial coronary arteries during left ventricle contraction [2, 3]. Also it has been reported that negative transmural pressure is induced at the throat of the stenosis in arteries under cyclic pressure that may cause critical conditions related to heart attack and stroke [2, 4].

Buckling equation have been developed by assuming the artery as a thin-walled cylindrical tube of linear elastic material subjected to transmural pressure [1]. This model does not account for thick, nonlinear arterial wall under axial stretch [2]. With the significant axial stretch in arteries and veins in vivo [5], it is important to understand its effects on mechanical stability of arteries.

Therefore, the objectives of this study were to develop and validate buckling equation that takes into account the nonlinear anisotropic material for thick-walled artery under various axial stretch ratios, and investigate the post-buckling behavior of arteries under negative transmural pressure using numerical simulations.

METHODS

Buckling Model Analysis: Arteries were modeled as thick-walled cylindrical tubes, under internal pressure p_i, external pressure p_e and axial stretch ratio λ_z. The arterial wall was assumed to be nonlinear elastic, incompressible, anisotropic material with an exponential Fung strain energy function [6].

Based on the curved beam bending theory and classic model for thin-walled elastic tube [1], we assumed that the curvature change κ for the initially circular vessel took the shape of a sinusoidal waveform when the collapse occurs at buckling.

$$\kappa = \frac{1}{\rho_m} - \frac{1}{r_m} = C.\sin(n\theta) \tag{1}$$

where C is a small-value constant, n is a positive integer and r_m and ρ_m are neutral axis radius in loaded and deformed conditions, respectively. Using the deformation gradient matrix in cylindrical coordinates and neglecting the higher order terms of C, the incremental circumferential strain at location (r, θ) becomes

$$\Delta E_\theta = -C\left(\frac{\pi r}{\Theta_0 R}\right)^2 n(r - r_m)cos(n\theta) \tag{2}$$

where (R, Θ) is the initial coordinates in the unloaded condition and $2\Theta_0$ is the opening angle of the artery (due to residual stress).

The incremental circumferential stress $\Delta\sigma_\theta$ was then determined based on the strain energy function and the bending moment M_θ was determined by integrating the moment generated by the incremental circumferential stress $\Delta\sigma_\theta$ across the arterial wall. Accordingly, the critical buckling pressure was obtained and can be expressed in form of:

$$p_{cr} = (p_e - p_i)_{critical} = \frac{3EI}{{r_m}^3} \tag{3}$$

Where EI is an "equivalent rigidity" that is an integral function of strain, material parameters and axial stretch ratios. Note that although the expressions are similar to the classic thin-walled tube buckling, both EI and r_m are complicated functions of material constants and strains, including axial strain.

Simulations based on the buckling equations were done for a set of five porcine coronary arteries with Fung strain energy function material constants reported by Wang et al.,[7]. We assumed the coronary arteries all have the same inner diameter of 0.8 mm, wall thickness of 0.5 mm and a length of 10 mm in the unloaded condition (for simplicity and because the dimension data was not reported in Wang et al.,[7]).

Finite Element Analysis of buckling: For comparison and post-buckling analysis, buckling analysis was conducted for the same set of five arteries using the commercial FEA package ABAQUS®. An initial imperfection (1% variance in the thickness) was used in our models to facilitate the buckling. Axial displacements were applied at both ends to create designated axial stretch ratios in the models. An external pressure was applied to generate buckling and keep increasing to reach post-buckling deformation. The lumen aspect ratio and lumen

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

area were determined to characterize the deformation and shape change due to pressure load and buckling.

RESULTS

Our results demonstrated that arteries were initially compressed by the external pressure and then buckled when the external pressure exceeded a critical value. This value depends upon the axial stretch ratio and material properties of arterial wall. FEA simulations showed that the aspect ratio of lumen increased dramatically post- buckling.

The critical buckling pressure of the coronary arteries obtained using both the theoretical model equation and FEM simulations matched well and changed with designated stretch ratios (Fig.1). Our simulations also captured the post buckling behavior of the arteries. It was seen that when the pressure continued to increase beyond the critical buckling pressure, the lumen aspect ratio continued to increase nonlinearly (Fig. 2).

DISCUSSION

We developed a buckling equation that described the critical buckling of nonlinear orthotropic arterial wall buckling under transmural pressure and validated with FEA simulations. Our simulation results showed that the lumen aspect ratio continued to increase nonlinearly with increasing the external pressure beyond the critical buckling pressure. Furthermore, the critical buckling pressures of arteries predicted by FEA were in good agreement with the theoretical predictions.

Compared with previous studies [1, 8], the advantage of the buckling equation obtained in this study lies in its capability to model nonlinear anisotropic material for thick-walled artery. A new finding from the current study is that the axial stretch ratio affects the critical buckling pressure.

There were a few limitations in this study. One limitation is that our analysis was limited to the arterial wall as a single layer anisotropic material, although arterial walls are multilayered structures. Another limitation in our simulation is that the boundary conditions were simplified with no surrounding tissue support.

Local collapse may occur in coronary arteries distal to stenosis or due to myocardial bridge. This causes vessel compression resulting in hemodynamic changes which probably lead to angina, myocardial ischemia, cardiac arrhythmias, syncope or even sudden cardiac death [3]. Thus understanding of artery cross section buckling (collapse) behavior is important in understanding these vascular disorders.

INTRODUCTION

Approximately 1.24 million motor vehicle crash (MVC) deaths occur annually worldwide, while an additional 20-50 million MVC occupants sustain non-fatal injuries [1]. MVCs are associated with approximately 60–70% of all blunt chest trauma and are the most common cause of PC [2, 3]. As the understanding of injury mechanisms in MVCs and the performance of occupant restraint systems improves, the risk of fatality and severe injury in MVCs will continue to decrease.

Currently, several methods are employed to study blunt trauma injury mechanisms in MVCs. To evaluate the ability of vehicles to protect occupants during crash events, controlled crash tests are performed using anthropomorphic test devices (ATDs). These ATDs were developed and instrumented based on post-mortem human subject (PMHS) impact tests. However, PMHS tests have several shortcomings, including an elderly population set and an inability to predict physiologic injury outcomes.

More recently, computational methods have been employed to study the mechanical responses of full human body models in impact events [4-6]. However, for many injury outcomes it is difficult to correlate the mechanical response to physiologic injuries. One common MVC injury that is difficult to characterize by the occupant's mechanical response is pulmonary contusion (PC).

The Crash Injury Research and Engineering Network (CIREN) and National Automotive Sampling System (NASS) survey motor vehicle crashes to assess occupant injury outcomes in real world crash events. Although these databases contain a wealth of crash injury information including radiology reports, occupant information, and case vehicle information from event data recorders (EDR), relatively few studies have computationally modeled these MVCs to assess occupant injuries. Previous studies have reconstructed side and oblique frontal impact crashes but were limited by the breadth and level of detail of crash injuries analyzed, the variability of vehicle models, or the number of cases analyzed [4-6].

This study analyzed four real world MVCs from the CIREN and NASS databases to correlate mechanical response data of the full human body finite element model to pulmonary contusion outcomes. Two cases with occupants who had PC and two cases with occupants who did not were analyzed. The study aims to estimate mechanical thresholds correlating to PC injury in real world MVCs.

METHODS

CIREN cases were reconstructed using finite element model (FEM) simulations in a three step process [7]. Two frontal case reconstructions with PC and two without PC were selected and summarized in Table 1. The severity of the crash is noted by the change in velocity of the vehicle during the crash event (delta-V). The injury cases selected from the CIREN and NASS databases had PC in at least one lung. The non-injury cases did not contain any moderate thorax injuries on the Abbreviated Injury Scale (AIS 2+).

Table 1: Case Summaries

		Occupant				Delta-V
	Vehicle	Sex	Age	Height (cm)	Weight (kg)	(kph)
PC	2007 Hummer	F	50	173	86	57
	2006 Cobalt	M	80	183	77	43
No PC	2012 Civic	F	67	165	66	56
	2007 Corolla	M	57	165	71	54

Step 1: A generic simplified vehicle model (SVM) containing the floor, seat, seatbelt, dashboard, steering wheel, and airbag was tuned to mimic the frontal crash response of the case vehicle for each reconstruction. Frontal New Car Assessment Program (NCAP) crash

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

test vehicle kinematics for each case were video tracked and then incorporated into crash test reconstruction simulations with a validated model of the Hybrid III ATD (Figure 1) [4].

For each case, vehicle restraint parameters (e.g. airbag inflation rate, belt pretensioner force) were varied using a Latin Hypercube Design (LHD) of experiments to find an optimal set of vehicle parameters that resulted in simulated ATD responses closely matching test data signals using the Sprague and Geers method to quantify magnitude and phase errors between corresponding data curves [8].

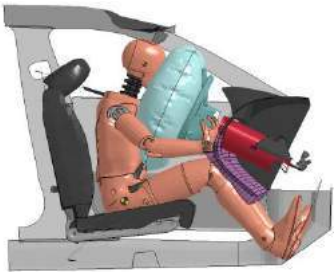

Figure 1: The SVM contains common vehicle restraint and safety systems such as seatbelts with load limiters and pretensioners, airbags, and a collapsible steering column.

Step 2: The THUMS v4.01 human body model was scaled and implemented into the tuned SVM using reported occupant data and positioning information. Additionally, a range of occupant positions were simulated to understand the influence of pre-crash occupant position. A 120 simulation LHD was performed to evaluate the effects of varying the seatback angle, longitudinal seat track position, D-ring height, and steering wheel position and angle within each case reconstruction.

Step 3: The case's EDR velocity pulse was applied to the tuned SVM to simulate the crash for each of the 120 THUMS occupant positions per case. Simulated THUMS instrumentation (i.e. accelerometers, load cells, and strain measurements) was implemented and used to measure injury metrics correlated to common frontal crash injuries. For each crash simulation, maximum principal stresses and strains (MPS) were evaluated in each of the 34,000 left lung and 44,000 right lung elements of THUMS. Subsequently, for each simulation the lung volume fraction exceeding threshold stress and strain values were evaluated and compared to existing literature [4, 9, 10]. The peak MPS threshold value selected was 0.343, as identified by Gayzik et al [9].

RESULTS

In the 2006 Chevrolet Cobalt reconstruction, the occupant's AIS 3 lung contusion (49% of lung contused: see Figure 2) was predicted since over 49% of the THUMS lung elements exceeded a 34.3% first principal strain threshold.

According to the MPS metric, the percentage of the Cobalt occupant's left lung volume estimated to be contused ranged from 5.0-55.0% (mean=35.3%) as a function of occupant position (Figure 3). The baseline case estimated 40.5% of the left lung to be contused, compared to 49% measured in the CIREN subject.

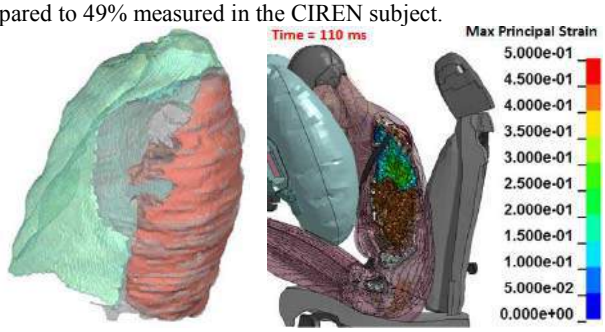

Figure 2: (Left) Case occupant lung segmentation from computed tomography: healthy (gray), contused (pink), and pneumothorax (blue-green). (Right) MPS distribution in the left lung of THUMS.

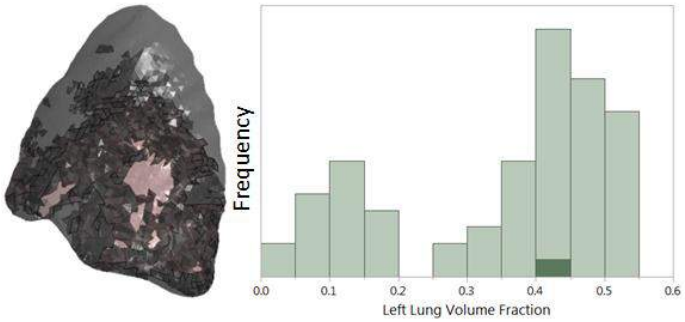

Figure 3: (Left) The distribution of left lung elements exceeding the MPS threshold in the baseline simulation. (Right) The distribution of threshold values estimated across all Cobalt Simulations.

DISCUSSION

The simulations predicting the highest volume fractions exceeding the MPS threshold were the simulations with the most rearward and reclined occupants. The mechanical responses of the chest and lungs in the PC and non-PC cases varied from each other. In the cases with PC, a greater portion of the lung volume exceeded threshold values. In most occupant positions simulated, the volume fraction of elements exceeding the MPS threshold value was less than the case occupant's injured tissue volume. This may indicate that the threshold value for THUMS should be lower than the 0.343 threshold previously identified. Future simulations may also explore the effects of lateral, vertical and pitching motions during the crash event simulations. Additionally, the material properties of the ribs may be modified as a function of age to evaluate the effect on PC risk.

By continuing to populate the data set with additional case reconstructions, and implementing other injury risk factors into the simulations, guidelines and injury risk curves can be established to determine whether THUMS predicts PC injuries in future impact simulations. This computational modeling approach will help researchers to understand and mitigate the likelihood of PC in severe MVCs. Ultimately, the ability to predict pulmonary contusion risk will lead to better occupant protection and a reduced burden on the trauma system.

INTRODUCTION

Across the world, there are millions of knee surgeries performed on athletes of all competitive levels for various knee injuries. Common knee injuries include tears of the primary knee ligaments ACL, MCL, LCL, and the meniscus, all of which require the aid of a brace during recovery. Successful rehabilitation requires recuperation of flexibility, range of motion, and strength [1]. Braces in the current market focus on range of motion recovery; the strengthening of surrounding muscle is limited primarily to physical therapy exercises. As a result of this limitation, significant atrophy of the leg muscles often develops which can, in turn, increase the period in which patients are restricted to crutches.

According to a research report conducted by GlobalData, the 2014 global market for orthopedic braces and supports was $2.56 billion, a figure predicted to increase to approximately $3.5 billion by 2021 [2]. Knee braces alone make up approximately 71% of the total orthopedic bracing market, proving their dominant status in a market that is becoming increasingly commoditized due to strong price competition and discounting. Over $500M of annual healthcare costs stem from the yearly 250,000 to 300,000 ACL injuries alone, with patients being almost exclusively athletes [3]. To satisfy this market need, the authors are developing an active rehabilitative knee brace that will allow patients to walk without the aid of crutches sooner in the rehabilitation process at a competitive market value.

PRODUCT DESIGN

The proposed actuated device will assist patients in walking with crutches during recovery by amplifying muscle activity using an electric motor and Force sensitive resistors (FSRs). In its functionality, the proposed device sits between traditional braces that do not activate the knee joint [4], the Continuous Passive Motion (CPM) which moves the patient's knee while they recline, and fully actuated exoskeletons like the AlterG bionic leg which are too expensive for the average consumer (up to $20,000) [5]. By using low cost sensors and actuators to create a device that will have a target price point under $600, the ARK Brace, Active Rehabilitation Knee Brace, will be an affordable and safe alternative for patients in mid-stage recovery from major knee injuries. With an appropriately selected motor and sensor suite, the ARK could change the method of knee injury recovery for thousands of athletes. ARK's electric motor, chosen to reduce cost and complexity when compared with hydraulic or pneumatic actuators, will work *with* a patient's muscles and ligaments sensors to reduce ligament loads during early walking. A conceptual block diagram of ARK's design is shown in Figure 1.

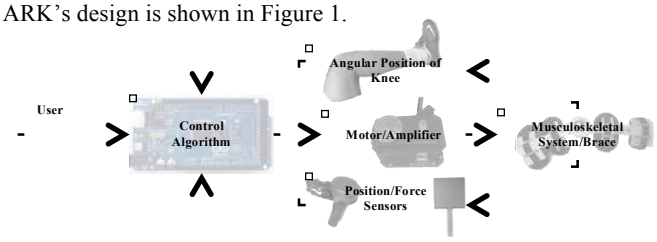

Figure 1. Block diagram of the ARK Brace exoskeleton.

The major sensing, decision-making, and actuation components of ARK must all work appropriately with the knee's physiology for the device to be successful. FSRs in the foot and a potentiometer attached to the knee joint will track a patient's position in his/her specific gait cycle, and EMG sensors will provide ARK's control algorithm, running on an Arduino Mega microcontroller, with muscle activity information. The ARK will use these sensors to calculate the required assistive torque at the knee joint. All sensing, decision-making, and actuation information and force flows are critical to ARK's goal of assisting knee ligament recovery during mid-stage recovery.

The ARK's brace structure will be built to conform to the motion constraints of a healthy knee. There are two major axes of movement within the knee: the longitudinal-rotational (LR) axis and the flexion-extension (FE) axis. A misalignment of the bones through this axis by an amount of as little as 2-3° can begin to compromise knee structure and increase risk of ligament injury within the joint [6,7]. ARK's bracing structure must provide at least that level of angular accuracy to be useful.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

An IRB-approved gait study of recovering athletes at Lafayette's biomechanics lab is in ongoing to determine where in the gait cycle the athletes require extra assistance. In order to provide measurements for this study that go above and beyond the information available in Lafayette's motion-tracking biomechanics lab, the authors created a data collection and prototyping platform to test various biosensors, motors, and control architectures. Preliminary testing has been performed on healthy athletes to generate a baseline for a normal gait and determine the accuracy of the sensors shown in Figure 2a. The test and measurement platform uses all of the aforementioned sensors so that the final brace's configuration and layout can be optimized.

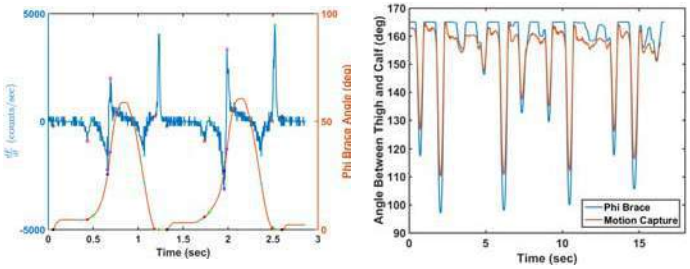

Figure 2: (a) Feature tracking of knee angular position against the first time derivative of the force applied by the heel of the foot identifies gait cycle percentage and (b) Knee angular position from potentiometer data and motion tracking system confirms the accuracy of the test platform's sensors.

ARK's motor, battery, and amplifier selection is also critical to the brace's ability to assist in ligament tear recovery. A motor that would fully replace knee function would have a stall-torque upwards of 60 N-m [8]. However, ARK's role is merely to augment existing muscle torque during normal gait to reduce ligament loads during mid-stage recovery through stress shielding. Stress shielding refers to the division of stress through a medium in order to reduce the stresses across a weakened or injured region. The ARK will reduce the tension in the knee ligaments by reducing the torque reacted through the joint. Based on data collected in the lab, the authors chose the Dynamixel MX-106T as the motor for use in the ARK Brace. The MX-106T at 12V has a stall torque of 8.4 N-m and no-load angular velocity of 4.71 rad/s. The MX-106T will provide a significant fraction of the required torque and nearly enough no-load speed to accommodate normal, healthy walking. It was chosen based on the competing requirements of size, weight, power, and cost.

ARK's control algorithm will use data from the gait study to select regions of the gait cycle (identified using a potentiometer on the ARK and FSRs under the foot as in Figure 2a) during which amplification of hamstring or quadriceps activity would provide the greatest assistance in lowering ligament forces during walking. The degree to which ligament forces will be reduced by active assistance will be user-selectable to comply with physician recommendations. An analysis of preliminary trials has revealed repeatable trends and correlation between the angular position of the knee and the change in the pressure applied by the heel and the ball of the foot. The rollover from heel to toe will help schedule the end of the stance phase and into the swing phase, allowing the control system to appropriately regulate knee motion and torque.

BUDGET & MARKET ANALYSIS

The current market for orthopedic bracing is expanding and is conducive to the introduction of an active knee brace into the space. Aside from the conglomerate DONJOY Global, which accounts for a quarter of the total market, the bracing market is largely fragmented with no other company accounting for greater than 10% of total market share allowing for relative ease in market entry [9,10]. Looking specifically at the products currently available in postoperative bracing there are three types of technologies that would compete with our active knee brace. The first of these technologies is the traditional, non-automated family of braces from companies such as DONJOY, Breg, Ossur and Bledsoe whose costs fall within the $250-500 range. Second, CPM machines, devices designed to gently extend and flex the knee joint following reconstructive surgery, are also widely used in the very early stages of recovery for range of motion recuperation. However, this device only works with a sedentary patient. Exoskeleton technology is relatively new to the market. Direct competition with the ARK includes devices like the Bionic Leg from AlterG, which is heavier, more expensive, and more powerful than the ARK, and is also designed with a specific portion of knee injury recovery in mind. ARK's projected sale price of $600 will result in a product costing less than CPMs or existing active braces, while remaining in a price range that provides a competitive alternative to traditional knee braces.

The brace will initially be marketed towards collegiate, professional, and certain high school sports medicine departments as well as physical therapy and rehabilitation centers. Roughly 460,000 student athletes currently compete at the NCAA Division I, II and III levels at approximately 1,200 colleges and universities, all of which have a sports medicine department [11]. In the United States alone, physical therapy jobs are slated to grow by 34% over the next decade, well above the 7% national average for occupation growth, which speaks to the increasing need for their services and product development in the industry [12].

INTRODUCTION

When teaching educational contents that are inherently graphical in nature, research has shown that learning is more efficient when stimulating the visual component of working memory (the visuo-spatial sketchpad) as compared to language-based approaches.[1,2] In the working memory model proposed by Baddeley and Hitch,[3] the central executive controls the flow of information to and from the phonological loop (verbal buffer), the visuo-spatial sketchpad (visual buffer), and the episodic buffer (where context is added to short-term-memory codes for storage in long-term memory). We know that both verbal and visual codes are stored in short-term memory because we can use these two types of codes to interfere with working memory performance.[2,3] Because of the "video game effect," there is accumulating evidence that individuals can use visual codes to help supplement verbal-code information in short-term or working memory.

Furthermore, there is evidence that humans use "embodied cognition" to improve performance.[2-4] That is, we encode the state of the body and use it as a "somatic marker" (or contextual cue) when storing working-memory information in long-term memory.[3] Using these assumptions, it is predicted that visual codes and motoric feedback from movements should improve the educational outcomes in learning science and engineering information.

The goal of this project is to refocus science and engineering education by introducing a new technology that is integrated with interactive, educational content that engages, inspires, and stimulates the visual center of the brain. To accomplish these goals, a new curriculum has be designed and implemented that engages students and interactively introduces visual information using the Microsoft Kinect^{TM} device. This device will be coupled to a computer system and will allow students, as an example, to actively explore a cell's anatomy and its functions using an interactive spatial interface instead of simply showing pictures with verbal descriptions. This approach also promotes active, rather than passive, learning by employing embodied cognition, where human movements could help improve both the short-term episodic and long-term memories of students. In our approach, both the visual/spatial information and the motoric interactions can be stored with a memory trace of the learning event (e.g., structures and functions of an eukaryotic cell and its organelles), thereby adding more efficient retrieval paths.

METHODS

Kinect^{TM} was adapted to capture the motion of students and track their gestures to allow them visually interact with the education contents. These contents were created as virtual 3D objects and developed into four learning modules (Cell, DNA, Immune System and Gene Therapy) and imported into a game engine (Unity3D) for animation and display. User movements captured by Kinect^{TM} were sent to the

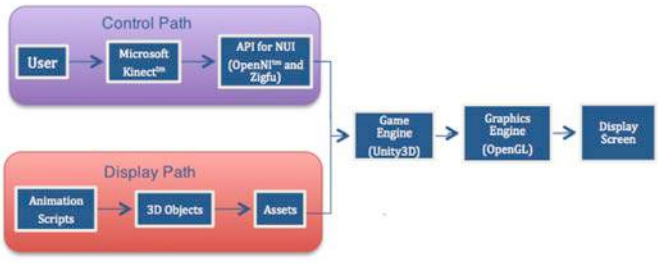

Figure 1. The architecture of the Kinect^{TM} based learning system

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

game engine through the application-programming interface provided by OpenNI and Zigfu. The students were able to rotate the virtual objects (cell and organelles) and zoom onto nano-sized molecules (DNA and ribosomes). They were able to study their structures as well as the functions through interactive animations. This "first person" perspective using embodied cognition should help students to learn more efficiently. Finally, the gestures to interact with objects were intuitive with a minor learning curve. Figure 1 depicts the architecture of our Kinect™ based system.

An experimental goal of the project is to compare the learning outcomes for K-12 students at low social economic settings (SES). The learning and understanding of educational materials related to each module was tested. The experimental design is given in Table 1. All students were exposed to either the traditional techniques or enhanced teaching using the Kinect™ system. The contents for Modules 1 - 2 reflect typical contents in K-12 textbooks and the tests require recall of knowledge. In contrast, modules 3-4 are more conceptual. The tests are understanding of concepts of acquired immunity and include engineering design, especially in module 4. The experimental design allowed for intragroup and intergroup comparisons. After each session, students were tested using a 20-point exam, and the results for the traditional and technology-enhanced teaching methods were averaged and compared using t-test or ANOVA with Tukey post hoc test.

Table 1 - Experiment groups

	Group 1	Group 2
Module 1 – Cell	Kinect™	Traditional
Module 2 – DNA	Kinect™	Traditional
Module 3 – Immune System	Traditional	Kinect™
Module 4 – Gene Therapy	Traditional	Kinect™

RESULTS

Individuals who received Kinect™-enhanced instruction performed significantly better on tests over the course material than did individuals who received only the traditional instruction (81.6 ± 3.1% vs. 70.2 ± 2.7%, $p < 0.05$, Figure 2). This pattern of results occurred even though all participants received two modules both types of instruction.

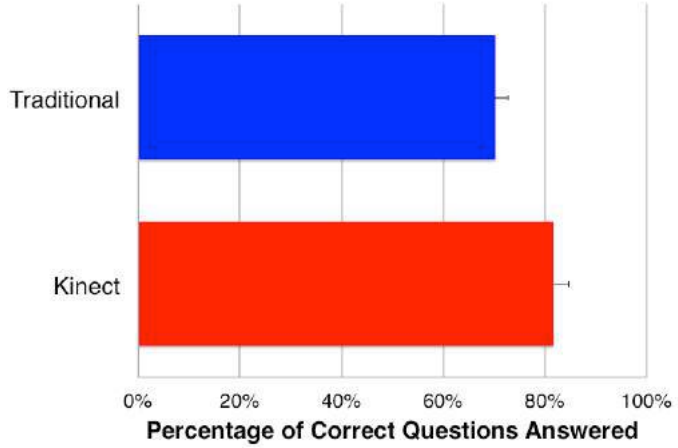

Figure 2. Test Results for Traditional vs. Kinect™ Instruction

When student's performance is examined for modules 1-2 verses 3-4, instruction with Kinect™ also shows a significant advantage (Figure 3). Overall, students performed better in modules 3-4, which contains conceptual information that is more difficult than in modules 1-2. However, no significance is observed when comparing Kinect™ vs. traditional instruction for modules 1-2 ($p > 0.05$). In contrast, significance differences are observed when comparing Kinect™ vs. traditional instruction for modules 3-4 ($P < 0.01$).

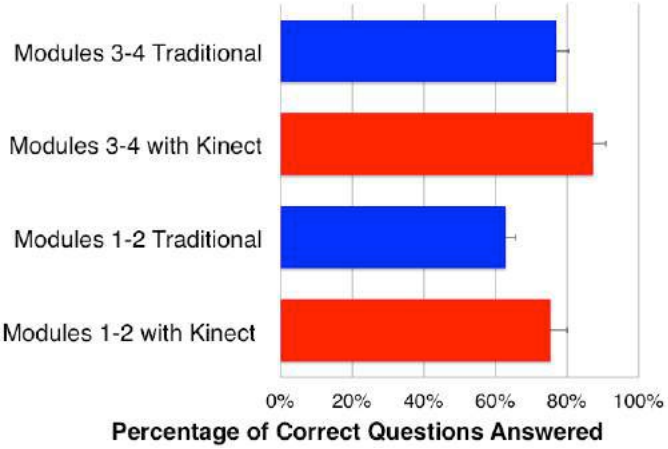

Figure 3. Test Results for Traditional vs. Kinect™ Instruction

DISCUSSION

"A picture is worth a thousand words." Teaching simultaneously with pictures and words is a standard practice in science and engineering but has been shown to be inefficient for learning. Until recently, technical challenges have limited our ability to teach visual information without a heavy reliance on language. If realized, complex scientific and engineering instructions can be learned more efficiently and quickly. This advantage may have added benefits of lowering students' apprehension toward science and engineering and encouraging them to choose a career in these fields. Our educational modules and technological equipment have been distributed North High School in Akron, Ohio. They have adopted our educational modules and tested the efficacy of technology-enhanced learning verses the traditional instructions. The comparison of learning was made for each student using both methods. Our preliminary results indicate students perform significantly better on tests using the Kinect™ interface than traditional instructional methods in which students do not actively manipulate visual objects. In addition, performance on test suggests that students are better at understanding conceptually changing topics using technology-enhancing instructions. The technology-enhanced learning also shows effectiveness in a school that is in a low SES setting.

INTRODUCTION

Small diameter tissue engineered vascular grafts (TEVGs) containing adipose derived mesenchymal stem cells (ADMSCs) have been shown to promote remodeling and vascular homeostasis *in vivo* and offer a possible treatment solution for those suffering from cardiovascular disease [1-3]. However, the time needed for culture represents a large hurdle for such a treatment option, whereas TEVGs containing cells taken directly from the stromal vascular fraction (SVF) following liposuction would not suffer such an impediment. SVF is known to be comprised of multiple phenotypes of cells, and previous results have shown that TEVGs seeded, shortly cultured, and implanted with SVF from young healthy individuals will remain patent in rats and will undergo remodeling.

However, it is unknown which cell types are binding to the scaffold. Additionally, it is unknown if the short 2 day culture period currently used before implantation can be removed to have a quicker implementation of the SVF extraction, seeding, and implantation process in order to make the procedure more clinically relevant.

The current study aims to determine the phenotypes of the scaffold-binding cells from SVF (in comparison to the seeded pool) and how these phenotypes change up to four passages from harvest (which is the current standard for ADMSC TEVGs). Furthermore, this study aims to determine if SVF seeded TEVGs without a short period of culture will remain patent *in vivo* and remodel by studying the histological and functional changes as well as the fate of the SVF.

METHODS

SVF, obtained from adult adipose tissue, was seeded onto poly(ester urethane)urea (PEUU) bilayered scaffolds using a customized rotational vacuum seeding device and then cultured in spinner flask for 2 days. PEUU scaffolds were seeded with SVF immediately after acquisition and at each subsequent passage up to passage 4. Scaffolds were then incubated for a short period to allow cells to be incorporated into the scaffold and then either fixed immediately or cultured for 2 days in a spinner flask and then fixed using a 4% paraformaldehyde solution. Fixed sections were then analyzed using immunofluorescent chemistry (IFC) for markers that define difference phenotypes. These markers include CD31 for endothelial cells, CD34 for endothelial precursor cells, CD4 for T cells, CD20 for B cells, CD68 for macrophages, and CD90 for ADMSCs.

SVF seeded scaffolds seeded immediately after collection underwent 2 days of culture in a spinner flask were surgically implanted

Figure 1: Example image of TEVG implant in the abdominal aortic interposition in a rat is shown.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

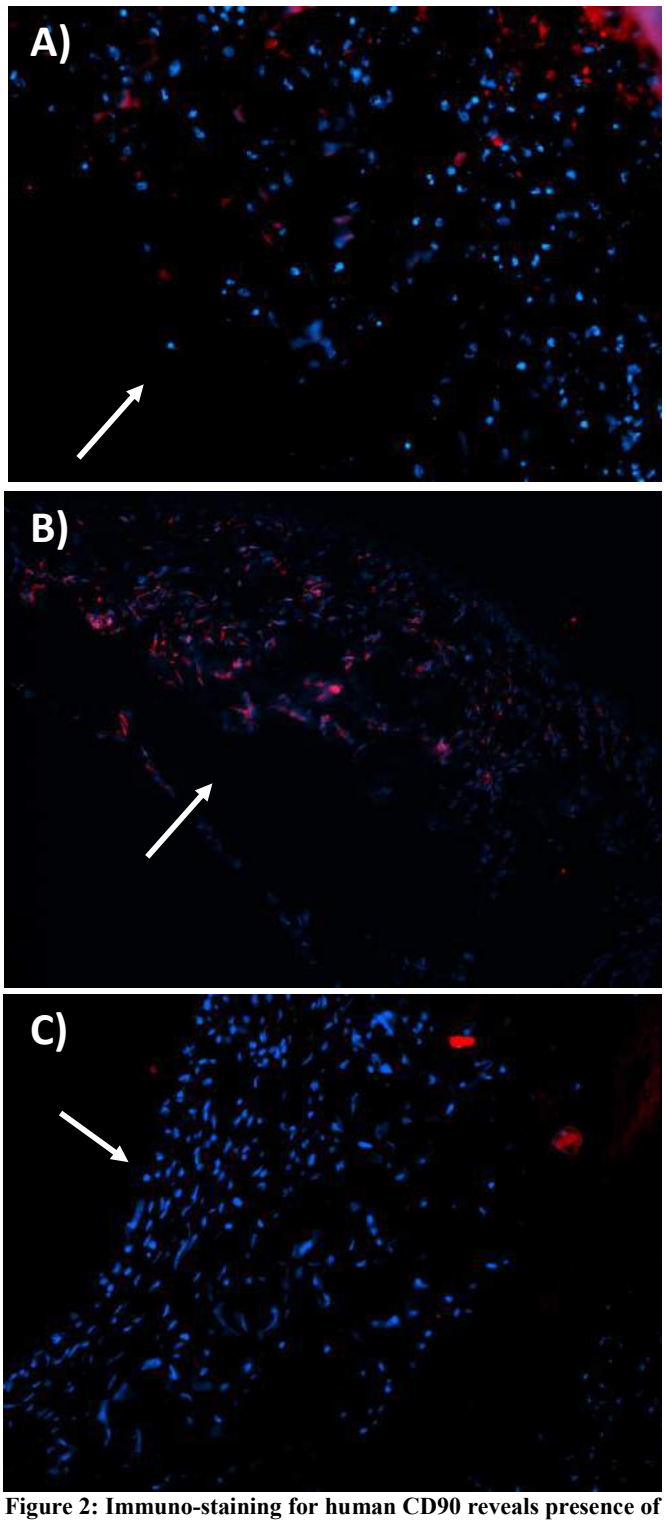

Figure 2: Immuno-staining for human CD90 reveals presence of implanted cells during short term implantations. Explanted TEVGs were stained with human specific CD90 (red; counterstained with DAPI (blue)) to identify the presence of implanted AD-MSCs in explants consisting of (A) a TEVG seeded with healthy AD-MSCs at 1 week, (B) non-implanted seeded TEVG positive control, (C) and a negative control. Arrows indicate luminal edge.

as abdominal aortic interposition grafts in rats, as well as seeded scaffolds that did not undergo a 2 day culture period (**Figure 1**) as described previously [1-3]. Implanted scaffolds were allowed to remodel for up to 8 weeks and the presence of patency and vascular components determined, along with any signs of inflammation using IFC.

RESULTS

IFC analysis shows positive staining for CD31 and CD34, markers of endothelial cells and endothelial precursor cells respectively, when SVF was directly seeded (without passage). Gradually the percent of cells staining for both CD31 and CD34 decreases over passage, until it is absent at passage 4 (**Table 1**). The presence of immune cells based on markers CD4 for T cells, CD20 for B cells, and CD68 for macrophages were not present in seeded scaffolds.

Table 1: Heterogeneity of SVF seeded scaffolds with increasing passage.

Cell Marker	CD31	CD34	CD4	CD20	CD68
Initial SVF	27%	28%	0%	0%	0%
Passage 1	41%	12%	0%	0%	0%
Passage 2	28%	5%	0%	0%	0%
Passage 3	41%	0%	0%	0%	0%
Passage 4	0%	0%	0%	0%	0%

In contrast, staining for CD90 (an MSC marker) was present in all samples that were tested including scaffolds after they were seeded with ADMSCs and implanted (**Figure 2**).

DISCUSSION

Initial findings show that both endothelial cells and endothelial precursor cells do attach to the PEUU scaffold and are present at the time of implantation of the TEVG. It was also found that ADMSC markers were present in scaffolds seeded with SVF at varying passages and within the TEVG after a week of remodeling *in vivo*.

As yet the fate of the different SVF cell types is unknown during *in vivo* remodeling. Previous work has shown that after a week, seeded cells are often present in greatly reduced numbers compared to initial seeding, and the presence of stem cells merely promoted ingrowth and cellular migration [4], thus it may not be as important to have grafts be seeded with ADMSCs which have the disadvantage of long incubation times.

Understanding differences between SVF and ADMSCs for seeding of TEVGs will allow for better clinical translation and swifter application.

INTRODUCTION

During early animal development, large scale tissue movements facilitate the formation of complex tissue architectures and eventually the vertebrate body plan. Fine-grained control of mechanical properties and force production is critical to the successful placement of tissues within the embryo. An example can be seen in dorsal tissues within embryos of the aquatic frog *Xenopus laevis* which increase in modulus six-fold as they gastrulate to form the three germ layers, and neurulate to form the central nervous system [1]. The mechanisms that regulate these mechanical properties are not well understood but may be separated into changes in the composition of materials, such as newly assembled extracellular matrix or F-actin cortex that composes the embryo, and changes within the structural microanatomy, such as establishment of laminar cell sheets and the notochord at the embryo's midline.

Molecular factors controlling F-actin assembly and myosin activity are known to contribute to tissue stiffening [1,2] however changes in the cytoskeleton cannot account for all the modulus changes observed in the developing embryo. Bulk mechanical properties of biological tissues, like manufactured materials, depend not only on material properties of their components but also the microstructural organization in which the constituents are arranged [3].

Tissue movements during gastrulation and neurulation construct specific architectures (i.e. segmentation cavities and neural folds) with distinct tissue boundaries through individual and collective cell migration [4], cell shape change [5] and extracellular matrix deposition. Establishment of these architectures facilitates tissue morphogenesis in several ways including creating morphogen gradients across cells/tissues, and enabling zones of tissue morphogenesis for specific roles such as bottle cell contraction or tissue involution. However, the role of newly formed architectures on bulk tissue modulus has been neglected. To elucidate the source of bulk stiffening in these tissues, it is key to understand how the changing structures within the embryo contribute to bulk mechanical properties.

In this study, we decouple the role of tissue microarchitecture from the compositional contribution to bulk mechanical properties by disrupting this architecture in embryonic tissues (Figure 1A) and measuring the mechanical properties of reaggregated, hereinafter referred to as "scrambled", tissues. We find that, surprisingly, tissue architecture makes little contribution to the bulk mechanical properties but is critical to the continuing self-assembly of the dorsal axis.

METHODS

Embryos and Microsurgery *X. laevis* embryos were obtained by standard methods [6], fertilized in vitro, dejellied in 2 wt.% cysteine and cultured in 1/3× modified Barth's saline at 22 °C. Staging of embryos was performed according to the table of Nieuwkoop and Faber (1967). To isolate dorsal tissues, early neurula (stage 13) embryos were selected and transferred to culture media, Danilchik's for Amy (DFA). For mechanical testing, 3 clutches were used with at least 7 embryos per group.

Tissue Dissociation and Reaggregation Dorsal tissues were dissociated in Ca^{++} and Mg^{++} free DFA for 5 to 7 minutes and superficial epithelium discarded. Dissociated cells were transferred to custom wells. 50µl agarose was pipetted into each well to enable tissue reaggregation without attachment. Cells were centrifuged for 10 min at

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

5G to create disc shaped tissues and confirmed the top and bottom surfaces of the scrambled tissues were flat. After centrifugation, scrambled tissues were removed from the chamber and cultured in DFA for 30 minutes before microsurgery. Scrambled tissues were cut into regular shaped "bricks" approximately 200x400x600um for mechanical testing.

Mechanical Testing Time-dependent viscoelastic properties of embryonic tissues were measured using an unconfined uniaxial compressive stress-relaxation test described in detail previously (Davidson and Keller, 2007). In brief, the tissue sample is compressed ~20% along its anterior-posterior axis while the resistive force is measured by the deflection of the optical fiber force transducer. The tissue samples are visualized by stereomicroscopy during compression to obtain length measurements throughout testing. Immediately after testing, samples are fixed in 4% paraformaldehyde, bisected and imaged to obtain cross sectional areas. Young's modulus after 180 seconds of compression, E(180), is then calculated using measured resistive force, cross-sectional area and strain measurements as shown below:

$$\mathrm{E}(180) = {}^{\sigma}/_{\epsilon} = \left(\frac{F}{A}\right)/\left(\frac{\Delta \mathrm{L}}{\mathrm{L}_0}\right) \qquad (1)$$

where E is the time dependent elastic modulus, F is the resistive force measured during the stress-relaxation test, A is the cross-sectional area, L_0 is the length of samples before compression and ΔL is the change in length before and after compression. Statistical significance of treatments on E(180) over a set of different clutches was analyzed using 2-way ANOVAs using commercial statistical software (SPSS).

Confocal Microscopy Laser scanning confocal microscopy was used to acquire high-resolution image stacks of scrambled and native tissues immunostained for fibronectin (fn1) using the 4H2 monoclonal antibody. Stacks were collected using a confocal laser scan head (SP5 Leica Microsystems) mounted on an inverted compound microscope (DMI6000, Leica Microsystems) using acquisition software (LASAF, Leica Microsystems).

RESULTS

Loss of Tissue Architecture in Scrambled Tissues To create scrambled tissues, we isolated tissue samples from neurula stage embryos, dissociated them and reaggreagted them into regularly shaped samples. To assess the degree of bulk tissue architecture disruption, we fixed and stained scrambled tissues for fibronectin, the dominant extracellular matrix protein at this stage in development. In native dorsal tissues, germ layers are separated by a dense fibronectin matrix. Fibronectin staining revealed a complete loss of bulk tissue architecture (Figure 1B) however local tissue microdomains surrounded by fn1 containing ~2 to 20 cells remained. Scrambled tissues remain intact for several hours after aggregation however they do not undergo convergent extension movements or neural fold formation observed in control tissues.

Elastic Modulus is Unchanged in Scrambled Tissues To test if there is any change in the modulus of scrambled tissues, samples were loaded into the nanoNewton force measurement device. Reported modulus values are the elastic modulus after a 180 second stress/relaxation test. There was no significant difference in modulus between stage 16-equivalent scrambled tissues and native dorsal tissues (2-way ANOVA p-val = 0.29; Figure 1C).

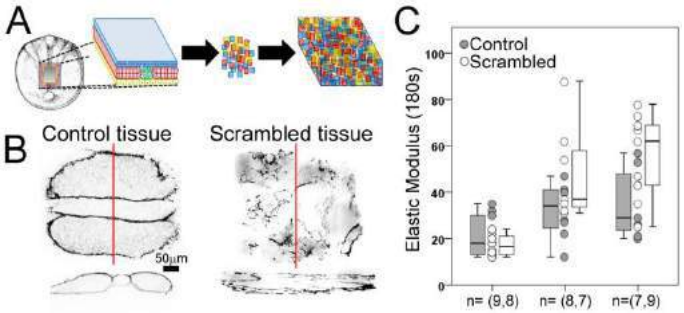

Figure 1: A) Schematic of bulk tissue architecture disruption. Tissues are isolated at early neurula stage, dissociated, and reaggregated into "scrambled" tissues. B) Fibronectin staining reveals loss of bulk architecture and stereotypic fibronectin organization. C) Mechanical testing results reveal that scrambled tissues have the same modulus as native control tissues.

DISCUSSION

In this study we investigated the contribution of tissue microarchitecture in embryonic tissues to bulk tissue mechanical properties. We find that scrambling tissues into random architectures does not alter the bulk mechanical properties of these tissues which suggests that the source of stiffness in these embryonic tissues resides within the stiffness of individual cells stiffness, rather than the architecture in which the cells are arranged. Our results in *X. laevis* may be extended to other tissues, either in embryos or during regeneration, where ECM does not significantly contribute to modulus. While modulus was unchanged in scrambled tissues these tissues were not competent to re-organize and drive convergent extension movements or neural fold formation. It remains unclear whether cell-cell or cell/extracellular matrix (ECM) signaling or cell sorting occurs after reaggregation to re-start morphogenetic programs. Since the architecture is not a regulator of embryonic bulk tissue mechanical properties at these stages, ongoing studies are underway to understand how cell identity contributes to tissue bulk properties.

FIBERFIT: A VALIDATED SOFTWARE APPLICATION TO MEASURE FIBER ORGANIZATION IN SOFT TISSUE

INTRODUCTION

The mechanical function of biological tissue is primarily regulated by the underlying fibrillar architecture. In soft connective tissue, defects to the fibrillar collagen network are associated with acute and chronic disorder [1-3]. Therefore, an extensive amount of research has been devoted to characterizing fibrillar networks [4,5], and this requires the accurate extraction of descriptive structural parameters from imaging data [6]. For tissues with multiaxial fiber networks, relevant structural parameters include fiber dispersion and mean fiber orientation, which are both properties of the fiber orientation distribution and are measures of material anisotropy. Accurate quantification of the fiber orientation distribution can advance a mechanistic understanding of collagen networks and clarify the functional impact of soft tissue remodeling and repair.

Over the past decade, free software applications have been developed that enable researchers to use mathematical algorithms to measure fiber organization. Researchers can now generate fiber orientation distributions based on fast Fourier transformation (FFT) methods with Oval Profile Plot and Directionality software [7,8]; and by using structure tensor methods with OrientationJ software [9]. Although these software applications have assisted the quantification of fiber dispersion and mean fiber orientation, the accuracy of these software applications has not been characterized with validation studies. Moreover, the sensitivity of these image analysis programs to common image processing techniques is not well understood Therefore, uncertainty exists in the accuracy and physical meaning of the fiber organization parameters being computed by these software applications [6]. The objective of this research is to develop and validate a free software application to accurately and automatically measure fiber orientation distribution in soft connective tissue.

METHODS

Software Development. A portable software application, FiberFit, was developed in Python utilizing the FFT band-pass method (Fig. 1; free download at http://coen.boisestate.edu/ntm/fiberfit/). This software was designed to support fast and intuitive two-dimensional analysis of fiber networks. The image analysis code in FiberFit was created by using numpy and scipy libraries to port an FFT band-pass method we developed in Matlab into Python [10]. This code fits a von Mises distribution to the FFT generated fiber orientation distribution. Parameters for fiber dispersion, k, and mean fiber orientation, μ, are automatically calculated and displayed by the program. This FFT band-pass method was previously validated using known test images of fiber networks with variable density and organization [11]. The average error was less than 8% when measuring k, and less than 1 degree when measuring μ.

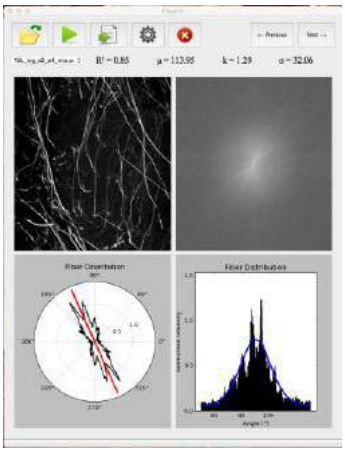

Fig. 1: FiberFit user interface

The FiberFit user interface (Fig. 1) is built using Qt bindings for Python. Users can analyze 8-bit images and export results and parameters (k and μ) as PDF and spreadsheet reports. Multiple images can be analyzed at a single time and users can implement different cut-off frequencies for the band-pass filter.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Software Validation. FiberFit software was evaluated using confocal images of ligament. Collagen fibril networks in five bovine ligament specimens were autofluoresced at 63× using the 405 nm laser of a confocal microscope and ZEN imaging software (Fig. 2a) [12]. ImageJ was used for image preprocessing prior to analysis with FiberFit.

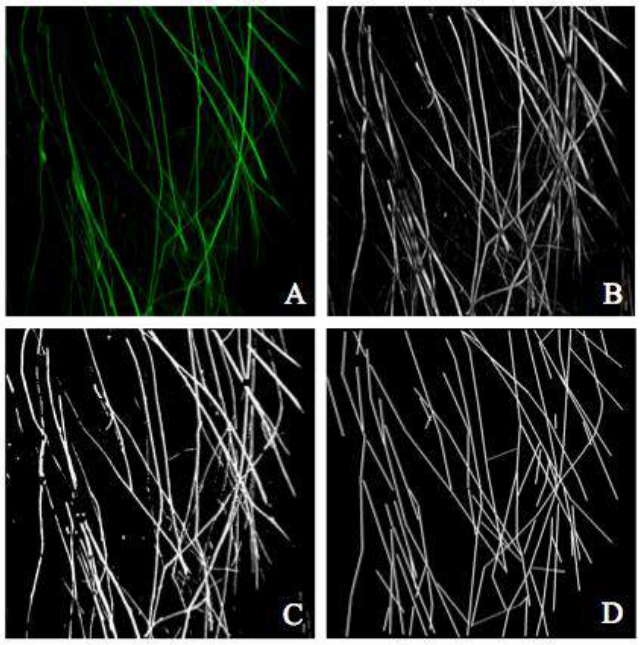

Fig. 2: Images of fiber network. A) original confocal image, B) grayscale, C) binary, and D) manually traced.

The first steps in image preprocessing included sharpening, filtering, smoothing, and normalizing the intensity values of all images. Each image was then converted into two formats: 8-bit grayscale (Fig. 2b) and binary (Fig. 2c). As a final noise removal step, a despeckle operation (3x3 median filter) was applied to all converted images. The grayscale and binary images were then analyzed using FiberFit to generate a fiber orientation distribution and calculate k and μ.

To determine the accuracy of using FiberFit to calculate k and μ, a third set of images was created by manually tracing the start and end points of the fibrils in the original confocal image (Fig. 2d). A discrete fiber orientation distribution, $f(\theta_i)$, was built for each of these manually traced images by using the total number of pixels for lines orientated along each angle θ_i. The mean (μ) and standard deviation (σ) of the discrete fiber orientation distribution were calculated using a multimodal, centrally symmetric approach [13]. A two-term exponential relationship between σ and k was then developed by fitting k to distributions with known σ values ($R^2 = 1.0$).

The k and μ parameters calculated from the discrete fiber orientation distributions ($k_{discrete}$, $\mu_{discrete}$) were used as a gold standard to determine the accuracy of calculating k and μ using FiberFit ($k_{FiberFit}$, $\mu_{FiberFit}$), where error in measuring μ was defined by the absolute mean difference ($|\mu_{FiberFit} - \mu_{discrete}|$), and error in measuring k was defined by the absolute mean percentage error ($|k_{discrete} - k_{FiberFit}|/ k_{discrete}$).

RESULTS

The FiberFit software quantified k and μ for all ligament confocal images with an average runtime of 3.1 ± 0.2 seconds on a 2.7 GHz processor. We found that using the grayscale preprocessing method gave the strongest correlation to the manual tracing method for measuring k ($R^2 = 0.95$; Fig. 3), and the binary preprocessing method gave the strongest correlation to the manual tracing method for measuring μ ($R^2 = 0.97$; Fig. 3). The average error in measuring k and μ with the grayscale method was 13.3 ± 8.2% and 3.3 ± 3.1 degrees, respectively, and for the binary method was 22.7 ± 15.1% and 2.1 ± 0.6 degrees, respectively.

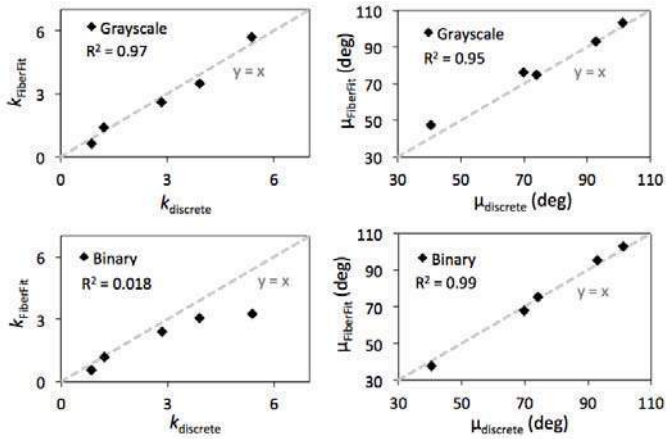

Fig. 3: Correlation of FiberFit results to known values when using (A, B) grayscale and (C, D) binary processing methods.

DISCUSSION

A free software application, FiberFit, was successfully developed to quickly, automatically, and accurately extract fiber dispersion and mean fiber orientation from fiber networks in ligament. We found that converting images to grayscale prior to using FiberFit gave good results. Converting images directly to binary gave less consistent results for highly aligned fiber networks. Both these techniques required background filtering to remove noise, otherwise mean fiber orientation error was almost two times greater (data not shown). In this study, we developed a validation strategy using discrete distributions and manual tracing to assess FFT accuracy in confocal images. This novel approach may be useful for evaluating and optimizing FFT with other imaging modalities and tissues.

The FiberFit software includes unique features that can support and expedite research in biomechanics and mechanobiology. A novel feature of FiberFit is the automated extraction of descriptive structural parameters (k and μ) based on the fitting of a semicircular von Mises distribution to the FFT generated fiber orientation distribution. The quantification of structural parameters from imaging data is a critical step to understanding the inter-relations between biological processes, such as collagen remodeling and repair, and the mechanical environment.

In conclusion, this study has provided guidelines, experimental methodologies and computational tools for researchers that are investigating the microstructure and mechanics of fibrillar networks in biological tissue. To our knowledge, FiberFit is the first free software to implement a band-pass filter for the FFT analysis of fiber networks.

ULTRASOUND MEASUREMENT OF SHAPE CHANGE DURING IN VITRO INFLATION OF AN ARTERIAL BIFURCATION

INTRODUCTION

The arterial tree is a complex network containing millions of arterial branches [1]. The arterial wall is composed of the endothelium, smooth muscle, and elastic and collagen fibers. The components of the layers each contribute to the mechanical properties of the artery, and the interaction of those components, like the arterial structure itself, becomes more complex when the vessel geometry deviates from the cylindrical. An example of such an irregular geometry is a bifurcation. The bifurcation's structural and mechanical properties are different from and more complex than those of a straight artery [2,3,4]. Therefore, the bifurcation is an important area of interest in the study of arterial mechanics.

Bifurcations are, however, difficult to study experimentally because the complex architecture and geometry do not lend themselves to standard mechanical testing protocols. Planar biaxial testing is problematic because a planar section of the tissue is difficult to isolate and because properties vary with position within the sample. Inflation is a relatively simple experiment, but it is difficult to analyze the inflation of a bifurcation because the convenience of radial symmetry is lost.

In this work, we develop a test system for inflation of an arterial bifurcation with simultaneous ultrasound scanning, which can then be used to construct 3-D images of the bifurcating vessel at controlled internal pressures. Eventually, these data could be used in an inverse model to assess the mechanical properties of the bifurcation.

METHODS

Arterial inflation testing was performed on a porcine carotid artery obtained from the University of Minnesota's Visual Heart Lab. The sample was cleaned to remove as much of the surrounding connective tissue as possible. The two daughter branches of the sample were cut so that the total length of the sample was approximately 5 cm, ensuring that the sample would fit in the inflation device. The sample was attached to male Luer fittings with suture. The sample was flushed with PBS to ensure there were no clots. One of the daughter branches of the sample was capped to prevent flow out allowing pressurization of the system.

The sample was placed in the artery inflation device utilizing the attached Luers to connect into a closed fluid system (Figure 1A). The inflation device was submerged in a fluid bath. The system contained a bleed-off valve to release any trapped air, a non-torqueing connector, and a pressure monitor. Once the artery was secured in the device, the non-torqueing connector was adjusted to ensure that the artery was torque-free. The bath was filled with phosphate-buffered saline (PBS) solution to a level at least 1 cm higher than the artery. Using a syringe, the system was filled with PBS, the bleed-off valve was closed, and the pressure monitor was zeroed. The sample was stretched to 125% of its original length prior to inflation to simulate its in vivo length [5].

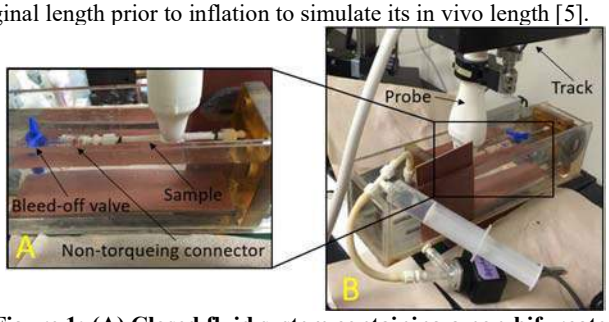

Figure 1: (A) Closed fluid system containing a non-bifurcated sample submerged in (B) the experimental setup.

The experimental setup can be seen in Figure 1B. A small-animal, 38 MHz ultrasound probe (Vevo 2100) attached to a track allowed

image slices to be obtained under constant motion along the long axis of the sample. The ultrasound probe was placed in the PBS in a position capturing a cross-sectional image of the sample. Rubber was placed below the sample to reduce echoing off the tank bottom. The probe and imaging software were adjusted until a clear ultrasound image was obtained. The sample was preconditioned by inflating the system from 5 to 100 mmHg 10 times. The pressure was then increased in increments from 0 to 300 mmHg. After each 20 mmHg pressure step, a cross-sectional ultrasound image stack was captured along the length of the sample. Images of 22px/mm resolution were captured 1.52 mm apart. The ultrasound image stacks were used to create a 3-D model of the sample using the software Seg3D [6].

The experimental protocol was also performed on a non-bifurcated (straight, roughly cylindrical) carotid artery. A pressure-diameter analysis was performed using three selected images from the ultrasound image stacks. The image at the center of the sample and images 30.4 mm from each end were used. Inner and outer sample diameters were measured at these points using imageJ.

RESULTS

Three cross-sectional images taken from the ultrasound image stack of a carotid bifurcation at 10 mmHg are displayed in Figure 2. The three images are of the mother vessel, the bifurcation, and the two daughter vessels.

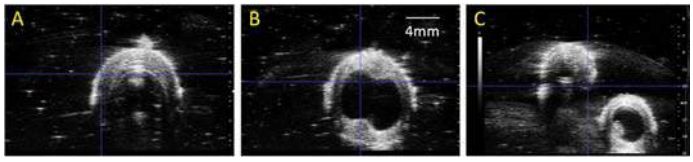

Figure 2: Cross-sectional ultrasound images of the (A) mother vessel, (B) bifurcation, and (C) two daughter vessels. Scale bar (4mm) applies to all images.

The branching of the carotid bifurcation can be seen in Figures 2 and 3. The image of the bifurcation in Figure 2B shows the complexity of the geometry occurring at the bifurcation. The manner in which the mother vessel splits into two daughter vessels determines the distribution of the arterial layers, and thus the mechanical properties, at the bifurcation. The 3-D model of carotid bifurcation (Figure 3) shows the split from the proximal mother vessel to the two distal daughter vessels.

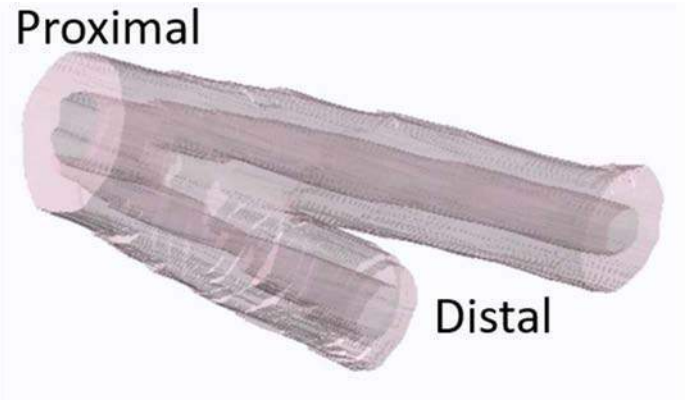

Figure 3: 3-D reconstruction of carotid bifurcation with proximal and distal ends labeled.

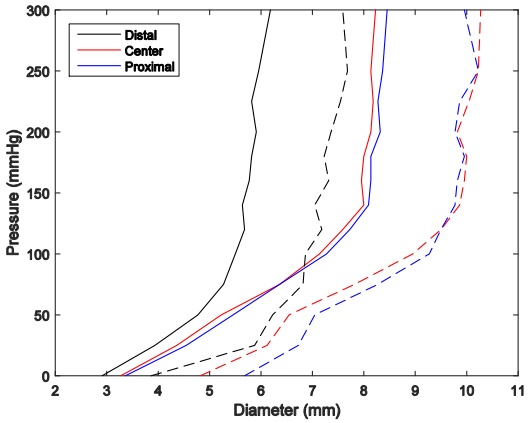

Figure 4: Pressure-diameter plot of non-bifurcated carotid artery. Dashed and solid lines correspond to the outer and inner diameters, respectively.

The lockout (i.e., the sharp upturn in the pressure-diameter curve) of the circumferential fibers can be seen in Figure 4. Lockout occurred at around 125 mmHg for the center and proximal slices and around 110 mmHg for the distal slice. Normal porcine systolic blood pressure occurs at 125-130 mmHg [7]. Blood vessels are very distensible at physiological pressures and due to fiber lockout become much less distensible at higher pressures [8]. Fiber lockout ensures blood vessels can be compliant at physiological pressures and offers protection against defects at higher pressures.

DISCUSSION

We have demonstrated the ability to perform an inflation test on a bifurcating vessel while concurrently imaging the full vessel geometry with ultrasound. Although there were challenges in constructing the test apparatus, preparing the vessel, and analyzing the ultrasound data, the resulting combination of pressure and detailed volume has the potential to provide a new level of understanding of bifurcation mechanics. Our data will serve as the input to an image-based finite-element model of bifurcation inflation, which in turn will provide insight into differences between the bifurcation's properties and those of the more cylindrical portions of the vessel. In addition, it may be possible to use 3-D volume correlation methods [9] to extract a detailed strain field from the experimental image stack.

INFLUENCE OF SUBARACHNOID HEMORRHAGE FACTORS ON VASCULAR SMOOTH MUSCLE CELL FUNCTIONAL PHENOTYPE IN THE DEVELOPMENT OF CEREBRAL VASOSPASM

INTRODUCTION

Subarachnoid hemorrhage **(SAH)** is bleeding in the subarachnoid space of the brain, often a result of traumatic brain injury or intracranial aneurysm [1]. When SAH occurs, growth and clotting factors, such as TGF-β, PDGF, and thrombin, are released. Surrounding tissues exposed to abnormal levels of these factors can undergo a variety of mechanical and biochemical perturbations affecting both vascular and neural function. Cerebral vasospasm **(CV)** is a potentially lethal vascular disease that often occurs after SAH and is characterized by acute hypercontractile arterial behavior followed by extended remodeling, lumen occlusion, and ischemia over the course of 3-7 days after a bleed occurs [1]. It is unclear what initiates this characteristic functional behavior in CV progression, resulting in limited therapeutic options to reduce negative patient outcomes associated with CV.

Vascular smooth muscle cells **(VSMCs)** typically exist in a distribution between two functional phenotypes: contractile or synthetic (proliferative) [2]. During CV, the distribution of VSMC phenotypes is thought to relate to tissue-level mechanics in the cerebral vasculature [3]. Here, we utilize a traction force microscopy method to determine changes in VSMC mechanics resulting from differential treatment with SAH factors. We consider a distribution of VSMCs between synthetic and contractile functional phenotypes, how treatment with individual SAH-borne factors affects shifts in these distributions, and to what extent these factors may be critical in the pathologic mechanical progression of CV.

METHODS

Substrate Fabrication and VSMC Culture and Treatment

Polyacrylamide **(PA)** hydrogels were fabricated as in [4] and tuned to a Young's modulus of 13.5 kPa. A solution of 200-nm fluorescent microspheres was added to allow substrate displacement tracking. Gels were bound to 35-mm glass cover slips using bind silane. Glass cover slips were used to create PA gels with a diameter of 12 mm and thickness of 30-50 μm. PDMS rings (18-mm diameter) were attached to reduce cell seeding area and required medium volume. Sulpho-SANPAH (0.5 mg/mL) was used to crosslink fibronectin (50 ug/ml) to PA gels as in [5]. VSMCs were then seeded at a density of 5000 cells per gel. After attachment, each sample was treated with serum-free medium for 24h to induce a contractile functional phenotype characteristic of normal arterial wall conditions [6]. After 24h in serum-free medium, each sample was treated with serum-free medium

containing one of three SAH factors (TGF-β, PDGF, or thrombin) at one of five physiologic or pathologic concentrations (including control). Solutions were refreshed every 24h for up to four days of treatment.

Traction Force Microscopy to Determine VSMC Traction Force

Traction force microscopy experiments were conducted to determine two important stress states: 1) basal tone via tissue relaxation with HA-1077, a rho-kinase inhibitor, and 2) induced contraction via stimulation with endothelin-1, a vasoconstrictor (Fig. 1A). Images of fluorescent microspheres within PA gels directly underneath single VSMCs were captured after experimental treatments to track displacements resulting from stress generation (Fig. 1B).

Strain Energy Calculation to Determine Shifts in VSMC Functional Phenotype Distribution

Bead displacement fields and corresponding calculated traction forces were computed for substrate changes between equilibrium and relaxed (basal tone) and induced contraction and equilibrium (induced contraction) time points using the ImageJ plugins developed in [7]. Strain energy (U) in the PA gel was calculated according to:

$$U = \frac{1}{2}\int \vec{T}\cdot\vec{u}\, dxdy \quad (1)$$

where $\vec{T}$ is the traction stress vector and $\vec{u}$ is the displacement vector.

Total strain energy for each cell was normalized by Day 1 control means for each set of experiments. A threshold of 1.0 (i.e. Day 1 control mean) was used to determine percentage of cells above functional phenotype threshold (contractile) and below functional phenotype threshold (synthetic). Differences between treatment conditions and same day controls were calculated as percent difference in fraction of contractile cells.

RESULTS AND DISCUSSION

Here, we present a traction force microscopy assay to determine effects of isolated SAH factor treatment on single VSMCs over physiologic and pathologic concentration ranges. Temporal changes in VSMC functional phenotype were measured as a function of strain energy in PA gels from single VSMC traction forces. TGF-β treatment initially resulted in fewer contractile cells, as measured in basal tone and induced contraction stress states. The percentage of contractile cells increased for both states by Day 4 (Fig. 2, Row 1). PDGF treatment resulted in increased contractile functional phenotype for basal tone, but decreased contractile phenotype for induced contraction across all time points (Fig. 2, Row 2). Thrombin yielded dose-dependent responses in functional phenotypes related to induced contraction (Fig 2, Row 3).

Basal tone and induced contraction are important stress states due to the mechanical responses they elicit. It has been hypothesized that tissues have a preferred local stress and that they grow to maintain this stress [8]. Changes in this target stress, as measured by changes in basal tone here, then result in growth rate changes. The initial decrease in functional basal tone induced by TGF-β (and thrombin), followed by increased functional basal tone over time (Fig. 2) may mirror the acute hypercontractile behavior in CV and the increased growth and remodeling experienced in prolonged CV. Similarly, PDGF appears to promote growth and remodeling at all times, possibly being critical in later stages of CV.

Endothelin-1-induced contraction is representative of VSMCs' ability to actively contract in maintenance of endothelial shear stress. In CV, shear stress increases due to luminal narrowing. This should result in decreased endothelin response, suggesting the decreases observed in PDGF induced contraction (Fig. 2) could be important in CV progression. Further work to rigorously predict the effects of pathologic

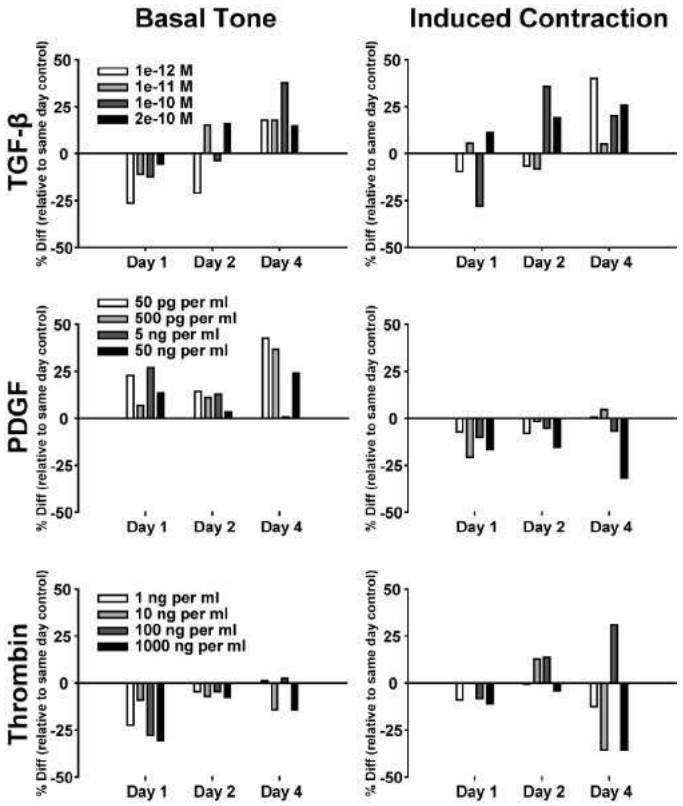

Figure 2. SAH factor-induced temporal functional phenotype distribution differences. Treatment of VSMCs with SAH factors TGF-β, PDGF, and thrombin induces different distributions of contractile and synthetic functional phenotypes. Left: Basal Tone. Right: Induced Contraction. Row 1: TGF-β. Row 2: PDGF. Row 3: Thrombin.

changes in functional phenotype distributions on tissue response and the downstream consequences for arterial blood flow in the brain can be accomplished via computational modeling.

These results represent behavior of sparse single VSMCs exposed to three factors known to increase in abundance as a result of SAH. VSMCs in native arteries experience much different architecture and surroundings, including cell-cell contacts and signaling. We can extend this work to investigate differences between "injured" solitary VSMCs and intact vascular architecture using a vascular muscular thin film technique as in [9], yielding a more complete understanding of the influence of SAH factors on cerebral vascular mechanics.

INTRODUCTION

Over 1.7 million people sustain a Traumatic Brain Injury (TBI) each year, 52,000 of whom die. Motor vehicle crashes (MVCs) are the second leading cause of TBI (17.3%) and are responsible for the largest percentage of TBI-related deaths (31.8%) in the United States [1]. Basic mechanisms of TBI are becoming better understood including the understanding that head injury is primarily the result of direct contact to the head [2,3]. However, due to the complexity in loading conditions and crash configurations during a MVC, there is still much that is unknown about the mechanistic differences between different types of head injuries and how those injuries may be mitigated. The objective of this research study is to better understand the contact parameters and regional mechanisms that contribute to head injuries with an emphasis on describing scenarios that could be mitigated through limiting rotational versus linear accelerations (i.e., BrIC versus HIC). With better understanding of the correlations between ATD criteria (HIC and BrIC), contact surface stiffness, and finite element (FE) model metrics, we can better understand regional and organ level mechanisms of head injury and develop methods to better mitigate injuries in MVCs.

METHODS

Contact Surfaces and Injury Mechanisms

The Global Human Body Models Consortium (GHBMC) 50th percentile head and neck model was utilized to investigate contact surfaces associated with head injury and resulting mechanisms of injuries including cerebral contusion, diffuse axonal injury (DAI), intra-cerebral hemorrhage, intraventricular hemorrhage (IVH), subdural hematoma (SDH), subarachnoid hemorrhage (SAH), and epidural hematoma (EDH) [4]. The contact surfaces were defined as hard (i.e., pole, tree, bare sheet metal, striking vehicle's grille), compliant (i.e., door trim, A-pillar trim, instrument panel), and soft (i.e., airbag).

Simulation of Various Contact Types and Impact Locations

Four parameters (impact velocity, impactor stiffness, impact location, and impact orientation) were varied over a parameter range wide enough to simulate the response of the head from a large population of head impact cases. Impact velocities were chosen to represent approximate velocities seen in MVCs. Impactor stiffness estimation values were generated based on the three contact surface categories (hard, compliant, and soft) in order to capture the full range of possible head contact surfaces resulting from a MVC. A set of 24 locations around one side of the head were selected as starting impact locations. Five impact directions were then used for each of the 24 locations (Figure 1).

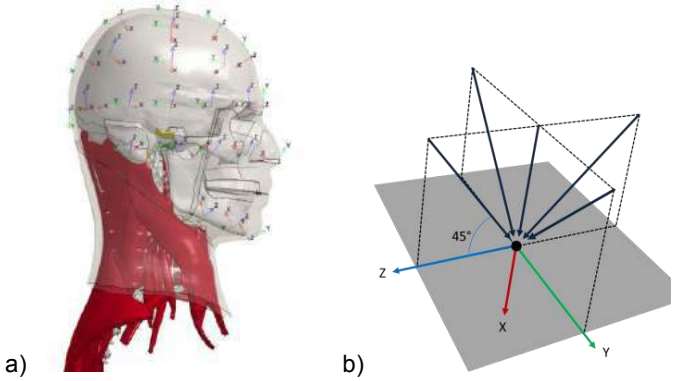

Figure 1: Impact locations (a) and directionalities (b) used to impact the GHBMC head and neck model. Positive X axis directed toward Head CG.

Development of Criteria for Evaluation of Brain Response

Previously, the GHBMC 50th percentile head model was developed to predict multiple Crash Induced Injuries (CIIs) including skull/facial/nose fracture, SDH, cerebral contusion, and DAI. This study aimed to develop metrics to predict region of interest (ROI)-based metrics of cerebral contusion (e.g., within the frontal and temporal lobes), EDH, SAH, intra-cerebral hemorrhage, IVH, and skull deformation. The development of these injury metrics was done by combining injury physiology understanding, contact simulations, and reported case outcomes from the CIREN and NASS databases. ROI-based injury metrics were developed based on ROI definitions of anatomic locations and geometrical locations with respect to the impact location were used for subsequent analysis (Figure 2). Conical ROIs were based on the angle between vectors defined by the vector between the brain CG and impact location as well as the vector between an element and the brain CG. Sets of elements were used for analysis based on four conical sections <30°, <60°, >90°, and >130° from impact. The first two sections represent coup region, while the latter two represent contre-coup. Blue, green, and red highlighted regions of Figure 2 represent the deep, intermediate, and outer subsections of the <30° conical ROI.

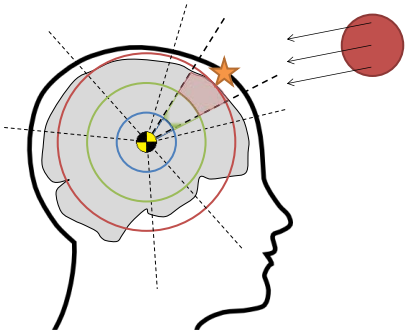

Figure 2: Spatially defined ROIs based on impact location and CG of the brain. Orange star represents impact location. Dotted lines represent conical sections spanning <30°, <60°, >90°, and >130° from impact.

Comparison of Head Injury Prediction for GHBMC to HIC and BrIC

The five sets of simulations performed were post-processed to obtain injury prediction values based on the newly developed injury predictors in terms of AIS 1-5 injury risk as well as the predicted AIS injury risk from HIC and/or BrIC. The predictions were then compared.

RESULTS

The simulations yielded a wide range of HIC and BrIC values as well as many different combinations of injury risk determined by each metric. Some simulations produced high risk values associated with BrIC (rotational velocity) coupled with low risk as predicted by HIC (linear acceleration). The risk was correlated to both impactor speed and stiffness (Figure 3). For a given simulation, the distribution of max principal strain was also calculated and separated by ROI. One of the more severe impacts to the top of the head resulted in a clearly distinguishable maximum principal strain distribution (Figure 4). Locations closer to the impact location (coup) reached higher levels of max principal strain than those on the opposite side of the head (contre-coup).

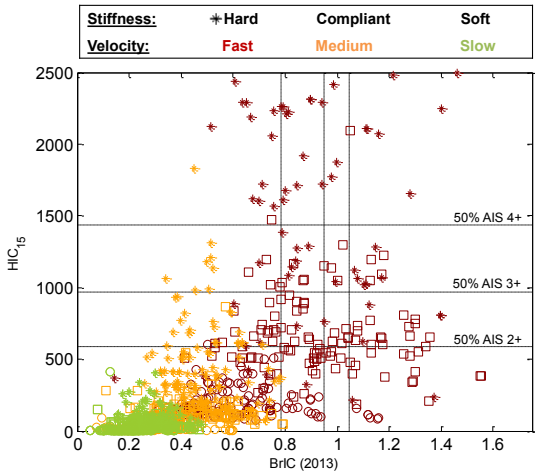

Figure 3: Distribution of impact simulations' HIC and BrIC values with respect to velocity and stiffness of impactor. Isoclines of 50% risk of AIS 2+, 3+, and 4+ overlaid on plot.

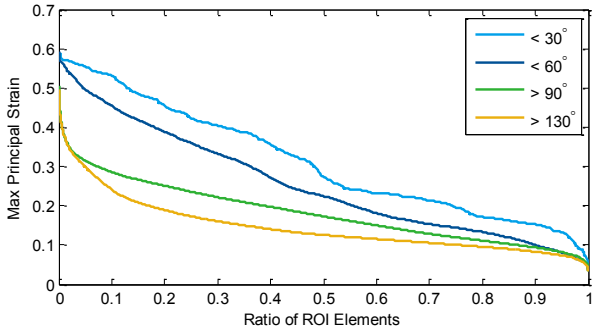

Figure 4: Maximum principal strain distribution in high stiffness, high velocity impact by conical section.

DISCUSSION

The parametric study of head impacts resulting in a wide range of HIC and BrIC values in conjunction with detailed injury metrics allows for the further understanding of specific injury risk and the correlation between ATD criteria. Preliminary results indicate in hard contact simulations, maximum principal strain is higher in coup regions than in contre-coup regions. High HIC values were more often seen with high impactor stiffness, while high BrIC values were observed with compliant materials. Simulations that produced high injury risk based on one metric (i.e., HIC or BrIC) did not always indicate high injury risk from the other, indicating the two are not tightly coupled.

THE QUANTIFICATION OF BLOOD FLOW PATTERNS INDUCED BY ENDOVASCULAR STENT GRAFTS: AN EXPERIMENTAL INVESTIGATION OF THE EFFECTS OF OVERSIZING AND COMPLIANCE

Amanda Colella-Centazzo (1), Clifton R. Johnston (1)

(1) Department of Mechanical Engineering
Dalhousie University
Halifax, NS, Canada

INTRODUCTION

In current medical practice endovascular stents are the most common treatment used in the management of arterial disease, particularly to bridge blood flow through aneurysmal vessels. Despite their relative ease of implantation they have been shown incite harmful secondary issues long-term that negate these benefits, with additional interventions occurring at higher rates as compared to open repair surgery [1], while showing no significant difference in survival after 2 years [2]. The alterations to the fluid dynamic forces that are incited by the stent play an important role in tissue healing, stent migration and by extension stent efficacy.

More specifically, areas of low wall shear stress (WSS) have been shown to affect the progression of atherosclerosis, the proliferation of intimal hyperplasia and the formation of thrombi [3]. These fluid dynamic considerations directly affect the long-term patency of stent grafts and have therefore prompted investigation into how the presence of the stent alters the local hemodynamic environment.

An environment representing that of the human femoral artery was constructed with optical access to the blood analog as it exits an implanted stent graft. Using Particle Image Velocimetry (PIV) the flow patterns were imaged and the changes to the peak velocity and WSS induced by stent implantation were quantified for several stent-vessel cases, specifically examining the effect of stent sizing and the compliance of the treated vessel. Tests were conducted in a rigid acrylic test section and an elastic mock artery with a compliance within the clinically observed range.

METHODS

A closed flow loop was designed and constructed for visualization and measurement of flow through a 10 mm inner diameter tube, representing a simplified geometry of the femoral artery. A common non-Newtonian blood analog representative of physiological hemodynamic parameters and comprised of a mixture of glycerol (40%), xantham gum (0.04%) and water, was circulated through the test section [4]. The mixture was exposed to a 1Hz pulsatile flow profile typical of the human femoral artery (Figure 1) with a peak velocity of 47 cm/sec, the mean peak forward velocity in the femoral artery reported by Fronek et al. [5]. This corresponds to a Reynolds number at peak flow of 1033.5, which is within the physiologically observed range [6].

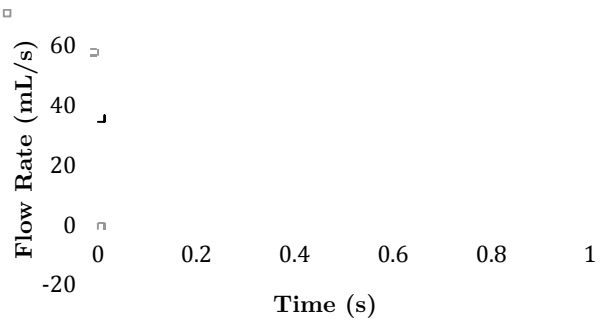

Figure 1 - 1 Hz Input waveform representing pulse profile typical of the human femoral artery.

Using PIV, cross-sectional velocity and wall shear stress immediately downstream of a Gianturco Zenith stent graft (Cook Medical, Inc., Bloomington, IN, USA) were quantified. The compliance of the elastic tube was tested in a modified PIV set-up and was found to be 7.77 % mm Hg^{-1x} x 10^{-2}, which is representative of a healthy human male femoral artery. The two stents of 20% and 40% oversizing were deployed in the test section and an identical test was performed in a rigid acrylic tube for comparison.

The test section was embedded in an acrylic flow chamber, which was filled with 100% glycerol to correct for the refraction index differences between the circulating fluid and the surrounding vessel and allow the laser sheet to reach the test area unaffected. The fluid was seeded using 10 µm silver coated hollow glass spheres, which were illuminated using a 1 mm thick laser sheet. Image frames were collected using a Photron mini UX100 at 4000fps with 20 image pairs collected per pulse, over 10 pulses.

RESULTS

Oversizing: Introduction of a full stent (3 wires in a polyester cover) had a substantial effect on flow velocities, particularly at peak pulse. The flow observed followed an asymmetric pattern due to variations in the folding and pillowing of the fabric between the stent wires. This

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

asymmetry was more pronounced in the 12 mm stent. This appears to be due to the fact that the 12 mm stent has seven wire peaks, while the 14 mm stent has eight. Although both were installed in the tube such that their wires were symmetric in the plane of the camera, the seven peaks allowed more intra-wire spacing and therefore allowed the fabric sheath and wires to deploy asymmetrically.

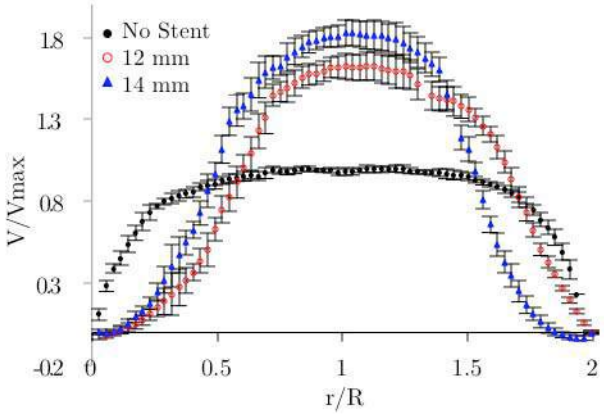

Figure 2 - Velocity profiles at peak pulse at x/R=0.5 downstream of a 12 mm and 14 mm Gianturco stent compared to the same acrylic vessel with no stent.

Both stents caused a considerable reduction in velocity close to the wall accompanied by an accelerated core flow (Figure 2). At 20% and 40% oversizing (12 mm and 14 mm stents) the centerline velocities at x/R=0.5 increased by 65.4% and 86.2%, respectively, as compared to the non-stented condition. At peak pulse, the 12 mm stent caused a velocity reduction from the wall to r/R = 0.5776 and r/R=0.7040 to the far wall, with flow reversal noted between the wall and r/R= 0.08664. A similar pattern was observed with the 14 mm stent, with reduced velocities occurring between the wall and r/R = 0.4621 and r/R= 1.5306. The largest absolute change for both stents occurred at r/R=0.2310 and was a decrease of 35.60 cm/s (85.0%) and 31.72 cm/s (75.8%) for the 12 mm and 14 mm stents, respectively

The wall shear stress saw a decrease upon introduction of both stents across the pulse cycle, with the most substantial changes in WSS occurring during acceleration of the fluid (Figure 4-11). Due to the asymmetry in the vessel, the WSS drop varied between the two walls. For comparison, the most severe case is considered. The drop observed at peak flow was found to be 82.1% for the 12 mm stent. The 14 mm stent saw a 120.7% in the WSS due to the flow reversal noted at the wall.

The cycle averaged WSS decreased from 0.920 Pa in the non-stented case to -0.832 Pa and -1.2675 Pa for the 12 mm and 14 mm stent. The change in sign of the cycle averaged WSS indicates a substantial flow reversal over the course of the pulse at the near wall. The OSI, surprisingly, decreased upon stent introduction from 0.4385 to 0.4182 and 0.3642 for the 12mm and 14mm stent, respectively. This is due to the fact that the flow was already pulsatile and therefore highly oscillatory to begin with, which is an important characteristic of flow in the peripheral arteries. The lowering of the WSS in both positive and negative flow direction, led to an overall WSS approaching zero, in turn lowering the OSI.

Compliance: Tests conducted in the compliant vessel showed similar trends to those in acrylic, however changes were more pronounced. Cross-sectional velocity profiles downstream of a single stent wire (Figure 3) showed a larger drop in velocities at the vessel periphery compared to the acrylic values (5.306 cm/s and 8.77 cm/s respectively). The centerline velocities increased more in the SYLGARD at 11.7%, compared to 4.65% in the acrylic. The WSS saw a drop at the peak with a 22.0% decrease in the acrylic and a 26.9% decrease in the SYLGARD.

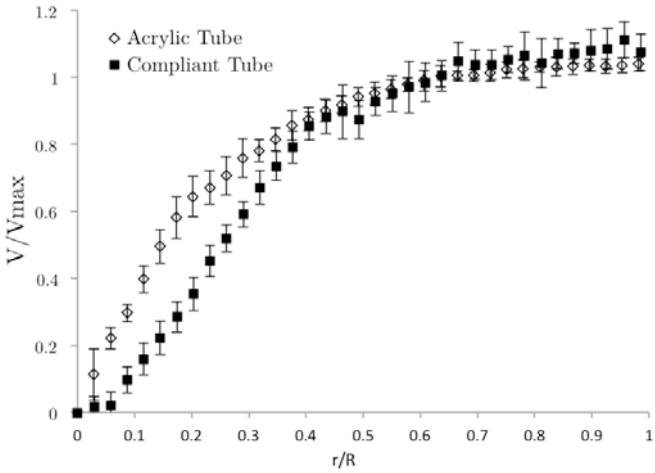

Figure 3 - Velocity profiles at peak pulse downstream of a Gianturco stent wire in acrylic and compliant vessels

DISCUSSION

The effect of oversizing was consistent across vessel compliances, with the larger 14 mm stent causing more substantial changes to the flow profiles as compared to the smaller 12 mm. The stents both caused an increase in the centerline velocities, accompanied by a drop at the vessel periphery. This incited a drop in the WSS, a feature that has been shown to promote re-stenosis. Oversizing of the stent is common practice clinically to ensure proper adhesion of the graft and to minimize stent migration, however this convention has important implications on the degree of disturbance introduced into the blood flow. These findings suggest that a graft with a diameter closer to the native vessel could be helpful in reducing the instances of stent re-occlusion.

Additionally the rigid tube was shown to lessen the velocity disturbances induced by the stents introduction, with centerline velocity increases more than double in the compliant vessel. This would imply that in more compliant vessels where the compliance mismatch is greater the stent has a larger effect on the fluid flow.

INTRODUCTION

Glaucoma is the second leading cause of blindness worldwide (World Health Organization), affecting more than 70 million people. As glaucoma is primarily a disease of aging, the burden is expected to increase, with the number of people affected by glaucoma set to rise to 80 million by 2020 [1].

Glaucoma is an optic neuropathy in which intraocular pressure (IOP) exceeds a threshold, leading eventually to damage to retinal ganglion cells (RGCs) that carry vision information to the brain [2]. RGC axons pass through a web of connective tissue ("the lamina cribrosa") as they exit the eye and converge to form the optic nerve. IOP deforms the delicate tissues of the optic nerve head (ONH), which is thought to predispose resident astrocytes to transition to a reactive phenotype; this transition is in turn believed to contribute to RGC dysfunction and eventual death, resulting in vision loss. The mechanisms of how astrocytes transition to the reactive phenotype due to stimulation from increased IOP is unclear. To date, ONH astrocyte mechanobiology has only been studied in 2D (monolayer) culture systems [2-4]. While 2D culture models have revealed important information, 2D culture primes astrocyte reactivity, confounding studies of astrocyte mechanobiology [3].

Accordingly, our overall aim is to better understand the mechanobiology of ONH astrocytes in a physiologically relevant 3D environment. In this preliminary study, we first hypothesize that a 3D culture system offers an improved environment for studying astrocyte reactivity. We analyze cell morphology and the change in protein levels that biomechanical loading, mimicking the effects of IOP, has on astrocytes grown in 3D collagen gels at different time points in comparison to static control 3D gels.

METHODS

This proof-of-principle study used the DI TNC1 (ATCC) immortalized cell line, derived from primary cultures of rat cortical astrocytes. The cells were maintained in Dulbecco's Modified Eagle Medium (DMEM, Cellgro, 10-013-CV) with 10% FBS (Hyclone, SH30910) and 1% 1X Pen/Strep (Hyclone, SV30010).

For 3D cell culture, cells were seeded at a density of 1 million cells/ml in a gel matrix consisting of 10% 0.1M NaOH, 10% 10X DMEM, 30% cell/1X media and 50% 2 mg/ml collagen type I (MP Biomedical, 150026). For each gel, 700µl of gel matrix was added to in a non-tissue culture treated 24-well plate for 15 minutes before addition of media, and gels were released from wells after 24 hours. The gels were left in static culture for 7 days prior to mechanical stimulation (Figure 1, left). For 2D cell culture, cells were seeded in a 75 cm^2 flask (Falcon PET, Fisher).

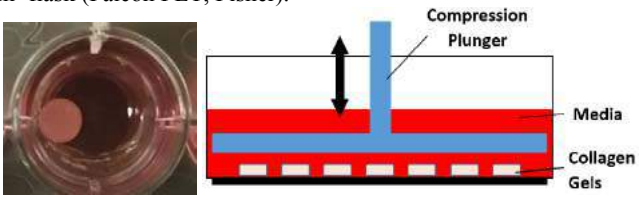

Figure 1: Top-down image of collagen gel prior to mechanical stimulation (left) and a diagram of the bioreactor system (right) to illustrate the compressive load applied to the collagen gels.

A bioreactor system was developed to apply a compressive mechanical load to the 3D collagen gels (Figure 1, right). The strains generated by the system were selected to correspond to those thought to be experienced by astrocytes under elevated IOP in the lamina cribrosa, where most ONH astrocytes reside [4]. Specifically, the 3D

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

collagen gels containing astrocytes were compressed, within the custom culture dish, by 10% for 0, 24, 48 and 72 hours at 1Hz [4]. An equal number of control gels were not subjected to compression and maintained in a replicate culture dish.

For protein level quantification, flow cytometry (FC) (BD Accuri C6) was used to assess the change in levels of key protein markers for astrocyte reactivity; GFAP (Millipore, MAB360, FC: 1:100 in FACS buffer, 5% FBS in PBS) and vimentin (Santa Cruz, sc6260, FC: 1:100). For each time point (n=3), gels were gently triturated for 10 mins in a solution of Accumax (Innovative Cell Technologies Inc.) and Trypsin (0.125%, Cellgro) at 37°C to dissociate the collagen and release the cells. For cell morphology examination, gels were permeabilized in 0.1% triton-X100 for 15 mins, after which phalloidin and DAPI stains were applied for 2 hours and 15 minutes, respectively. Gels were examined using confocal microscopy to acquire maximum intensity projections (MIP) of z-stacks from various sections of the gels to quantitatively analyze cell directionality and alignment (FIJI, NIH). Statistical analysis was carried out using one-way ANOVA to test differences in protein levels.

RESULTS

A significant difference in GFAP expression was found between 2D and 3D controls (Figure 2, p=0.03). Protein expression was significantly increased in compressed vs. control gels at 24 hour (p=0.03), 48 hour (p=0.05) and 72 hours (p=0.01). GFAP expression significantly increased between 24 and 72 hours (p=0.02).

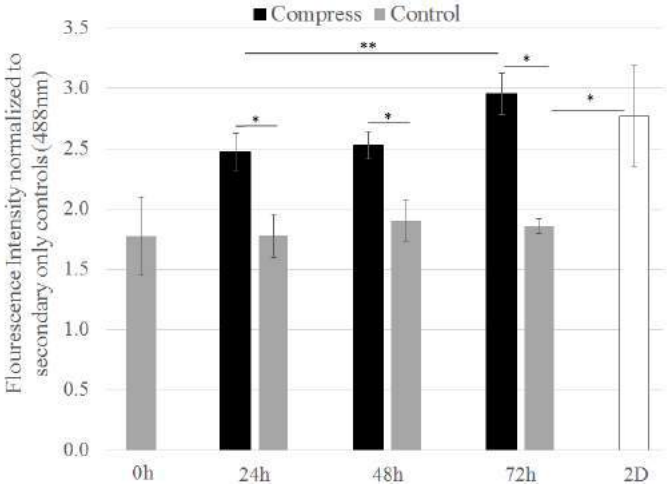

Figure 2: Mean fluorescence intensity for GFAP labelling from FC analysis for compressed (black) and control (grey) gels at 0, 24, 48 and 72 hours and for 2D culture (white). Error bars are standard deviations (*p≤0.05, **p≤0.001).

Similar significant trends were found for vimentin expression differences between 2D and 3D controls (Figure 3, p=0.01). Vimentin expression was significantly increased in compressed vs. control gels at 24 (p=0.01), 48 (p<0.001) and 72 hours (p<0.001). Vimentin expression levels significantly increased between 24 & 72 hours and 48 & 72 hours (both p<0.001). No increase in either GFAP or vimentin labelling was found between the control gels at each time point (0, 24, 48 and 72h).

Figure 4 represents MIP images from a control gel (left) and a compressed (right) gel to highlight the alignment of astrocytes due to mechanical stimulation. Cells in compressed gels were found to align in a preferred direction compared to the random alignment in static controls (p<0.001). An increase in the expression of vimentin (Figure 4) and GFAP (not shown) was found between compressed and control gels.

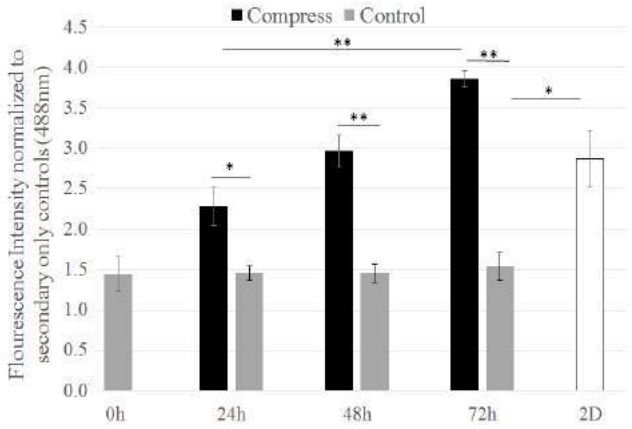

Figure 3: Mean fluorescence intensity for vimentin labelling from FC analysis for compressed (black) and control (grey) gels at 0, 24, 48 and 72 hours and for 2D culture (white) . Error bars are standard deviations (*p≤0.05, **p≤0.001).

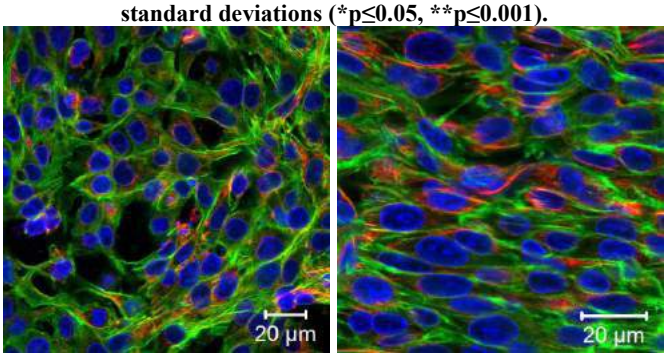

Figure 4: MIP image of control (left) and compressed (right) gels at 48 hours illustrating increased alignment of cells and expression of vimentin in compressed gel. DAPI: blue, phalloidin: green and vimentin: red.

DISCUSSION

The first hypothesis under investigation in this study is that a 3D environment is preferred for studying astrocyte mechanobiology over a 2D environment [3,4]. Our 3D platform is more realistic and leads to less basal astrocyte reactivity vs. 2D, as judged by lower GFAP and vimentin expression (Figure 2 and 3 respectively). Secondly, this study found that compression, mimicking certain aspects of IOP loading, significantly increased the level of both proteins at each time point vs. static controls, evidence for biomechanically-modulated astrocyte reactivity in our system. Further, no change in protein expression was found for the control 3D gels between each time point (0, 24, 48 and 72 hours) suggesting that the mechanical stimulation is instigating the change in protein levels rather than the 3D environment.

Astrocytes in the compressed 3D gels exhibited increased alignment vs. control 3D gels (Figure 4). This changed astrocyte morphology could be a factor in the transition of astrocytes to a reactive phenotype. Further work is necessary to quantitatively analyze the morphological difference between compressed and control 3D gels, particularly in primary human astrocytes from the ONH.

CUSTOMIZABLE SURFACE-COATING METHOD FOR BIOPROSTHETIC VALVE BIOCOMPATIBILITY

Monica M. Fahrenholtz (1), K. Jane Grande-Allen (1)

(1) Bioengineering
Rice University
Houston, TX, USA

INTRODUCTION

Each year, over 90,000 prosthetic heart valves are implanted in the U.S. and 280,000 worldwide, about half of which are bioprosthetic heart valves [1], and the share of bioprosthetic valves being used is growing, especially in younger patients, [2]. Complications involving thrombosis, inflammation, and calcification are still a major problem in bioprosthetic valve replacements, leading to a growing need for better technology. In particular, pediatric patients are at higher risk for these complications and would benefit greatly from improved replacement devices.

There is still much active research in the area of improving heart valve replacements. While most work has been done in the area of fully synthetic or tissue engineered valve replacements [3], a secondary focus in the field has been on the surface modification of currently available bioprosthetic heart valve devices to promote re-endothelialization. Targeting the modification of currently approved devices could lead to more rapid translation to the clinic. Toward this end, a few researchers have pioneered methods for modification of bioprosthetic valve surfaces with titanium [4], bioactive molecules (e.g. hyaluronic acid, heparin) [5,6], nanoparticles [7], or even polymer films [8] to produce an anti-fouling, non-immunogenic coating.

Unfortunately, many surface modification strategies require the use of harsh solvents or drying methods that may change the bulk structure of the valve device, potentially affecting its function. Additionally, some strategies meant to promote re-endothelialization are highly non-specific and may lead to additional acute surface fouling [8,9]. While these are serious challenges, the need for new technology to improve patient quality of life continues to motivate efforts to incorporate promising technologies into current practices on a shorter timescale.

Toward this end, we have developed a novel two-step surface coating method that can be easily incorporated into current bioprosthetic valve manufacturing processes, uses FDA-approved materials, and can be carried out under mild conditions with minimal risk of adverse effects from the processing steps. Here, we investigate this surface coating process for its controllability in terms of coating thickness and surface coverage, its effect on surface mechanical properties of the bioprosthetic tissue, and its anti-fouling properties.

METHODS

Initially, a previously developed bioprosthetic valve surface model (BVSM) was used to investigate multiple coating formulations [10]. In general, this coating was achieved by first converting reactive amine groups on the surface to acrylate groups via an n-hydroxysuccinimidyl-PEG(2000)-acrylate linker, then the surface coating was added by glucose oxidase-initiated free radical polymerization of PEGDA at the surface.

To measure coating thickness on the BVSM under various reaction conditions, the coating was doped with acryl-rhodamine dye and analyzed by confocal microscopy. From this data, it was determined that 6 kDa PEGDA resulted in the most consistent coating coverage and thickness for future studies.

Coated BVSMs were then analyzed by bioindentation to measure the effect of the coating on surface mechanical properties. The coatings were also exposed to rhodamine-labelled BSA to measure acute fouling of the surface.

Based on optimization of the coating on the BVSM, the coating method was then translated to porcine bioprosthetic tissue biopsies (porcine aortic valve leaflets fixed in 0.2% glutaraldehyde for 3 days). Changes in surface mechanical properties were measured by bioindentation, and coverage of the tissue surface was qualitatively

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

analyzed by SEM. Coating of the surface with PEGDA was also confirmed by XPS analysis of the C1s spectra, specifically comparing the component peaks at 286 eV (C-O, C-N) and 284.8 eV (C-C).

All results were analyzed using R statistical software (R Project) via an ANOVA and post-hoc Tukey's test for differences between groups, with a correction for repeated measures as appropriate.

RESULTS

Different PEGDA oligomer sizes and reaction conditions were analyzed for surface coating thickness, as demonstrated in Figure 1. Given the more consistent results obtained from 6 kDa formulations, 6 kDa PEGDA with a 2 min reaction time was chosen.

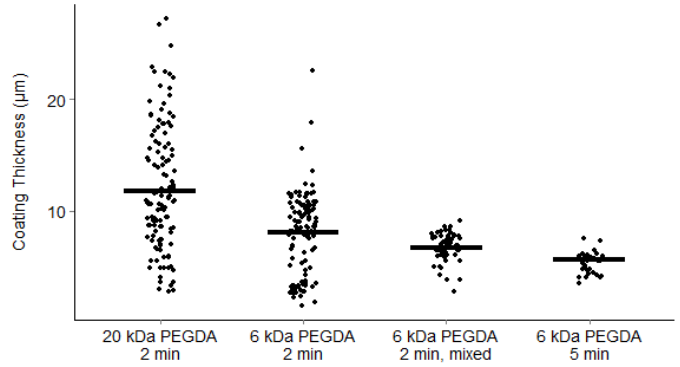

Figure 1: No significant change in surface coating thickness was observed; however, 20 kDa PEGDA showed more variable coating thickness as compared to 6 kDa formulations.

Next, the coatings were analyzed for percent fouling of the surface. The coating significantly decreased the acute fouling of the BVSM surface, such that the fouling of the coated surface was not significantly different from the protein-repellant PEGDA only control (Figure 2).

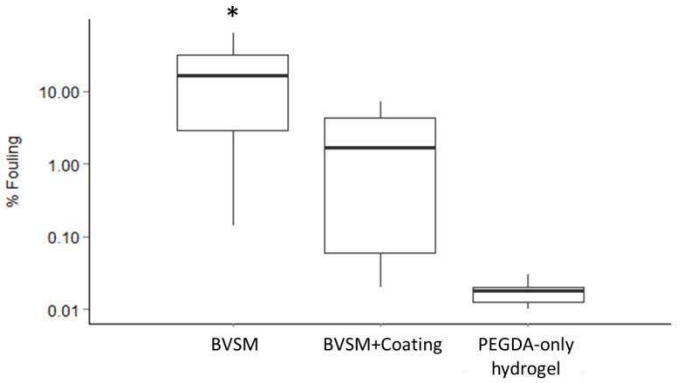

Figure 2: Fouling on BVSM surface was significantly greater than both the coated BVSM and PEGDA-only hydrogel control.

The coating method was again applied to the BVSM and also to porcine bioprosthetic tissue samples. Stiffness of the surface as determined by bioindentation (via Oliver & Pharr method) was not found to be significantly different among any of the groups, indicating that the coating method did not affect the surface stiffness and also confirming previous literature showing that the BVSM mimics bioprosthetic tissue stiffness [10].

SEM imaging was then used to qualitatively show that some coating of the tissue surface was obtained, and that increasing the reaction time increased the observable area of coverage (Figure 3). In the coated groups at 1000X magnification, the coating appears as darker, smoother spots on the valve tissue. At high magnification (10,000X), the coated regions become thicker and more continuous with increasing reaction time. Coverage also appeared to be increased by increasing glucose oxidase concentration (data not shown).

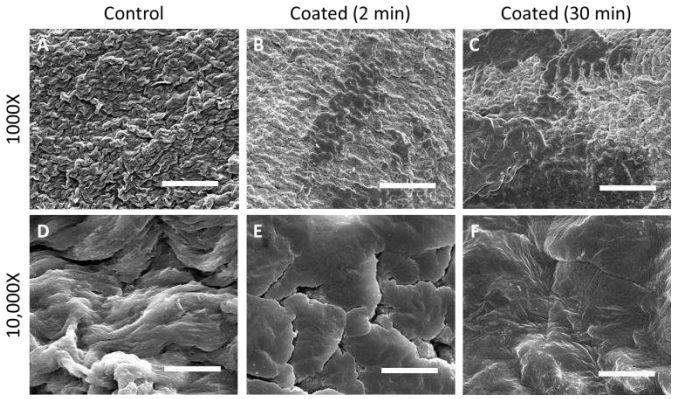

Figure 3. Representative SEM images of bioprosthetic tissue (A,D), tissue coated for 2 min (B, E) and tissue coated for 30 min (C, F). Scale bar = 40 µm (1000x), 4 µm (10,000x).

The observed areas assumed to be coating in the SEM images were confirmed to be the PEGDA coating by analysis with XPS, which showed an increasing contribution of the C-O peak (indicative of PEGDA) to the C1s spectra for all coated samples compared to uncoated tissues.

DISCUSSION

In this work, we have successfully optimized a two-step surface coating method using a previously-developed bioprosthetic valve surface model and translated the method to bioprosthetic valve tissue samples. We show that the thin coating formed on the BVSM is functional in preventing protein adhesion, and coatings on both the BVSM and tissue samples do not significantly influence surface mechanical properties. Translation of the coating method to bioprosthetic tissue resulted in a non-continuous surface coating of PEGDA, but area coverage could be significantly increased with increased reaction time and glucose oxidase concentration. Overall, this work demonstrates the feasibility of the proposed two-step coating method for modifying the surface of bioprosthetic tissue and sets the stage for future work to optimize coverage to produce a functional barrier and to add molecules to promote *in situ* endothelialization.

INTRODUCTION

End stage renal disease (ESRD) is a condition that affects the ability of the kidneys to filter blood effectively. Patients suffering from ESRD are often referred to hemodialysis as a replacement therapy for the lost function of their kidneys. In order to achieve efficient dialysis a vascular access (VA) capable of supplying high flow rates is required. The most commonly used VA type is an arteriovenous fistula (AVF), due to their superior patency rates over arteriovenous grafts. Following fistula creation there is a drastic change in local hemodynamics. This results in the venous segment of the AVF undergoing significant biological changes in a process known as maturation. Even though AVFs are the most commonly used access type, they suffer from poor primary patency rates ranging from 44-60%[1, 2]. Fistula non-maturation and venous stenosis are the two main contributors to these high failure rates. Intimal hyperplasia has been impleaded as the primary cause of these contributors.

Until recently Wall Shear Stress (WSS) parameters have been employed as the primary indicators regarding the progression of intimal hyperplasia. However, more recent studies suggest that WSS based parameters alone provide an incomplete analysis of the local hemodynamics and should be complimented by a quantitative description of the bulk flow. It is hypothesised that counter rotating helical structures within the bulk flow can result in the suppression of flow disturbances, which can lead to the development of intimal hyperplasia (IH)[3]. This study investigates the effect that the anastomosis angle between the arterial and venous segment of an AVF has on the development of such flow fields and if certain helicity-based bulk flow descriptors can act as a surrogate marker of exposure to disturbed shear.

METHODS

The idealised AVF geometries analysed as part of this study were adapted from the work conducted by Steinbuch, 2011. Each model is geometrically identical apart from the anastomosis angle which is varied to 10^o, 35^o, 50^o and 70^o (Figure. 1). Computational fluid dynamics simulations were carried out for each model applying a brachial artery wave form with an average flow rate of 600mL/min at the artery inlet in all models. Three seconds of flow was simulated which correlated to three cardiac cycles. All the results were averaged over the 3rd cardiac cycle.

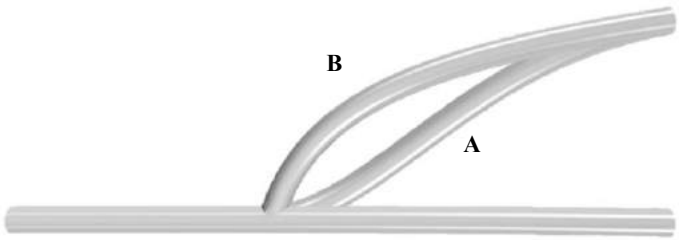

Figure 1: Idealised models of the AVF geometries analysed in this study, displaying the 10^o (A) and 70^o (B) models, the 35^o and 50^o models were omitted from the image for clarity purposes.

The distribution of the time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI), relative residence time (RRT) and transverse wall shear stress (TransWSS) were computed at the AVF surface. Each of the WSS parameters were represented using threshold values to represent the 80th and 90th percentile values. Disturbed shear was characterised by the surface area exposed to OSI, RRT and TransWSS over (or TAWSS under) a threshold value.

The helicity, H(t), of a flow confined to a domain **D** of 3-dimensional Euclidean space $\mathbf{R}^3$ is given by

$$H(t) = \int_D v(\boldsymbol{x},t).\omega(\boldsymbol{x},t)dV = \int_D H_k(\boldsymbol{x},t)dV \qquad \text{(Eq. 1)}$$

A useful indicator of how the velocity vector is orientated with respect to the vorticity vector is the Localised Normalised Helicity (LNH) proposed by Shtilman et al., 1985, defined as

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$LNH = \frac{v(x,t).\omega(x,t)}{|v(x,t)||\omega(x,t)|} \quad \text{(Eq. 2)}$$

and has been proven to be a useful quantity for the visualisation of complex flow patterns in cardiovascular flows[6].

The helicity-based bulk flow descriptors utilised in this study to characterise the bulk flow were defined by Gallo et al., 2012. The descriptors h_1 and h_3 quantify the balance between counter rotating helical fluid structures in the flow field, while h_2 and h_4 quantify the helical intensity.

$$h_1 = \frac{1}{TV_i}\int_T \int_{V_i} H_k dV\, dt \quad \text{(Eq. 3)}$$

$$h_2 = \frac{1}{TV_i}\int_T \int_{V_i} |H_k| dV\, dt \quad \text{(Eq. 4)}$$

$$h_3 = \frac{h_1}{h_2} \quad \text{(Eq. 5)}$$

$$h_4 = |h_3| = \frac{|h_1|}{h_2} \quad \text{(Eq. 6)}$$

Multivariate regression analysis was performed to assess the potential for a combination of helicity parameters in indicating exposure to disturbed shear. The robustness of the regression analysis to different volumes of integration (V_{Artery} and V_{Vein}) for the helicity based bulk flow descriptors was analysed and the results obtained were compared to those generated by integrating over V_{Full}. The Akaike information criterion (AIC) was then applied to select the optimal combination of the helicity-based bulk flow descriptors to analyse the bulk flow.

RESULTS

The different topological flow features present in the bulk flow were visualised using the parameter LNH. Figure 2 displays the contour plots of LNH averaged over the 3rd cardiac cycle for all 4 models. A threshold of LNH_{avg} = ± 0.2 was adopted for the visualisation of helical flow structures present within the bulk flow.

The presence of helical fluid structures characterised the bulk flow in all 4 models. These helical fluid structures originated at the anastomosis region and propagated along the venous segment of the AVF. The flow field seen in the 10° model is predominantly dominated by a single counter clockwise helical structure (red) however as the anastomosis angle increases the flow field transitions to one in which there are two counter rotating helical structures, which is clearly evident in the 70° model (Figure. 2).

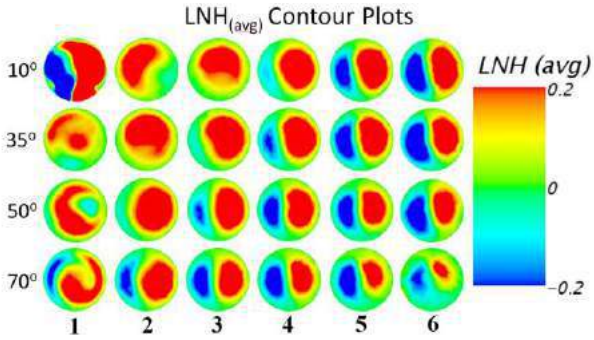

Figure 2: Circumferential slices taken at 1cm intervals from the anastomosis along the venous segment of all 4 AVF models. $LNH_{(avg)}$ contour plots display a flow field dominated by a single counter clockwise helical structure for the 10° model (red), while the 70° models displays a flow field with two counter rotating helical structures (red and blue).

Examining the WSS parameters when integrated over V_{Full} revealed a clear trend whereby as the anastomosis angle increases so too does the overall distribution of both TAWSS and OSI. However, in contrast to this, both RRT and TransWSS decrease in overall distribution.

Table 1: Best fitting models by AIC among the possible combination of helicity descriptors (Eq. 3-6) integrated over V_{Full}.

(P< 0.05)		10°	35°	50°	70°
WSS_{80}	Model	(h2)	(h2)	(h2)	(h2)
	R^2_{adj}	0.9842	0.9391	0.9129	0.8982
WSS_{90}	Model	(h2,h3)	(h2)	(h2)	(h2)
	R^2_{adj}	0.9526	0.9397	0.9083	0.8533
$TransWSS_{80}$	Model	(h2)	(h2)	(h2)	(h2)
	R^2_{adj}	0.8994	0.8851	0.8641	0.6933
$TransWSS_{90}$	Model	(h2)	(h2)	(h2)	(h2)
	R^2_{adj}	0.9369	0.9434	0.7843	0.4903

Multivariate regression analysis revealed a significant relationship between both TAWSS and TransWSS with the helicity based bulk flow descriptor h_2 when integrated over the V_{Full}. However, the relationships differed significantly for the different volumes of integration. When integrating over V_{Artery} each model displayed a discrete correlation with h_1 and when integrating over V_{Vein} each model displayed a completely arbitrary correlation with each of the helicity based bulk flow descriptors.

DISCUSSION

Gallo et al. analysed the potential benefit of helical flow in the carotid bifurcation. They found that high helical intensity is instrumental in suppressing flow disturbances within the bulk flow; however they also state that the potential benefit could be moderated if one direction of rotation is dominant in the flow field. This would suggest that the flow field displayed by the 70° model is the most beneficial at suppressing flow disturbances, evident by the fact that two counter rotating helical structures characterise the flow field.

Both TransWSS and TAWSS displayed a significant correlation with the helicity based bulk flow descriptor h_2 ($P<0.005$) when integrated over V_{Full}. TransWSS was selected as the sole indicator of disturbed shear as it incorporates TAWSS in its calculation. As the anastomosis angle increases the overall distribution of TransWSS decreases, which correlates to an overall reduction in the distribution of disturbed shear as well.

These findings answer both research questions outlined at the beginning of this study; to determine if AVF configuration can generate helical flow and if helical flow is a surrogate marker of exposure to disturbed shear. These preliminary results suggest that the benefit of helical flow that has been proven to suppress flow disturbances in the carotid bifurcation might also exhibit the same benefits in AVFs. These findings also provide preliminary data illustrating the importance of AVF configuration and its potential impact on AVF maturation. This could lead to a reduction in variability currently observed in AVF configuration by supplying quantitative data identifying the most beneficial AVF configuration in relation to maturation. However further studies conducted on realistic geometries are required before any concrete conclusions can be drawn.

INTRODUCTION

Thoracic Aortic Aneurysm and Dissection (TAAD) is the result of a pathological tissue degeneration process that leads to an abnormal dilation with possible rupture of the aortic wall. Between 1999 and 2013 more than 25,000 people lost their lives in the US alone due to TAAD. Patients suffering from TAAD often have a genetic predisposition, associated with either complex connective tissue syndromes (e.g. Marfan syndrome) or familial disorders (e.g. non-syndromic gene mutations). The documented conservation of these genes across species warrants the use of animal models for the study of TAAD, particularly at the early stages of the disease when human data is not available, and for longitudinal studies. Regardless of their specific etiology, all TAADs are characterized by both a compromised structural integrity of the aortic wall - including loss of elastic fiber integrity, dysfunction or loss of smooth muscle cells (SMCs), and local accumulation of mucoid material (GAGs/PGs) - and by changes in cell signaling; in particular, Angiotensin II (AngII) and Transforming Growth Factor beta (TGF-β) signaling. We present herein a comparison of the biaxial mechanical properties of six murine models of TAAD: (1) *Fbn1*$^{mgR/mgR}$ – a mouse model of Marfan syndrome, where fibrillin-1 deficiency causes fragmentation and loss of elastin [1]; (2) *Fbln5*$^{-/-}$ – a mouse model of arterial ageing, where the absence of fibulin-5 is responsible for the disorganization of the elastic laminae [2]; (3) *Myh11*$^{R247C/R247C}$ – a mouse model of familial TAAD, where a recurrent rare R247C variant is knocked-in the smooth muscle myosin heavy chain (*Myh11*) gene [3]; (4) *Tgfbr2*$^{f/f}$ – a mouse model of TAAD, where the reduced expression of TGF-β type II receptors in the aortic media leads to elastin fragmentation [4]; (5) *Fbln4*^{SMKO} – a mouse model of TAAD, where a significant reduction of fibulin-4 gives rise to disorganized elastic fibers and increased collagen content [5]; (6) AngII-*ApoE*$^{-/-}$ – a mouse model of TAAD similar to the fibrillin-1 deficient mouse, where a high-dose Ang II infusion in apolipoprotein-E null mice brings about focal disruption of elastic fibers and increased medial collagen deposition [6].

METHODS

All animal procedures complied with IACUC protocols at the appropriate Institution. Mutant and control mice were euthanized and the ascending aorta (ATA) excised from the chest cavity with the aid of microdissection tools and a dissection microscope. After removal of fat and excess perivascular tissue, the left carotid artery, left subclavian artery and distal portion of the arch were ligated with sutures. The ATA was then mounted on glass cannulae, through the openings of the aortic root and the brachiocephalic trunk, and secured with sutures for mechanical testing. After preliminary estimation of the unloaded geometry and of the *in vivo* axial stretch, each specimen was extended to the *in vivo* length, acclimated in Hanks buffered physiological solution for ~15 minutes under pulsatile flow between 80 and 120 mmHg, and preconditioned with four cycles of pressurization between 10 and 140 mmHg. Following re-estimation of the unloaded geometry and *in vivo* axial stretch, each ATA was exposed to three pressure-diameter tests (cyclic pressurization between 10 and 140 mmHg at the *in vivo* and ± 5% of the *in vivo* axial stretch) and four axial force-length tests (cyclic extension between 0 and ~50mN at 10, 60, 100 and 140 mmHg). Outer diameter, axial stretch, luminal pressure and axial force were recorded online throughout the mechanical tests. Unloaded wall thickness was measured using either an optical coherence tomography system on the mounted specimen or a dissection microscope on rings cut from each specimen after mechanical testing [7]. With the exception of the *Fbln4*^{SMKO} model, where only n=3 aneurysmal specimens were tested, data from at least n=5 specimens were collected for all the other mutants and their

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

controls. Mechanical data from specimens of the same genotype were combined with a consistent averaging procedure [7] to obtain a genotype-specific average mechanical response. A microstructurally-motivated four fiber family constitutive relationship was fit to the specimen-specific and averaged data sets by means of a nonlinear regression [7]. Estimated material parameters were used to predict mechanical metrics – stretch, stress, linearized stiffness, stored energy, and distensibility – at the genotype-specific *in vivo* axial length and systolic pressure.

RESULTS

Gross examination revealed significant phenotypic differences between the six genotypes. *Myh11*$^{R247C/R247C}$ mice manifested the mildest aortic phenotype, but they became vulnerable to TAAD when made hypertensive. Conversely, *Fbln5*$^{-/-}$ mice had elongated and tortuous arteries, but they did not show any propensity for aneurysm formation when made hypertensive. *Tgfbr2*$^{f/f}$ mice showed thickening, dilation and dissection of the thoracic aorta, with occasional intramural hematoma, intimal flaps and false lumens. Finally, *Fbn1*$^{mgR/mgR}$, *Fbln4*^{SMKO}, and AngII-*ApoE*$^{-/-}$ mice all developed large aneurysms of the ascending thoracic aorta, with tissue lesions visible under a dissection microscope.

Notwithstanding the phenotypic differences, the material behavior of the six genotypes was remarkably similar. Figure 1 reports the average circumferential (left panel) and axial (right panel) stretch/stress behavior for the six genotypes and the control. *Fbn1*$^{mgR/mgR}$, *Fbln4*^{SMKO}, and AngII-*ApoE*$^{-/-}$ exhibit the most prominent decrease in circumferential distensibility for the range of pressures between 10 and 140 mmHg. Similarly, the *in vivo* axial stretch is reduced in these genotypes, with the *Fbln4*^{SMKO} on average working at the lowest axial extension, followed by *Fbn1*$^{mgR/mgR}$ and AngII-*ApoE*$^{-/-}$.

DISCUSSION

The primary mechanical function of the aorta is to store elastic energy during systole and release it during diastole to ensure proper perfusion of peripheral tissues. Changes in either the axial or the circumferential mechanical properties alter the ability of the aorta to perform this function and increase the workload of the heart. This aspect is particularly relevant for the ATA, which, unlike the descending thoracic or the abdominal aorta, varies in length throughout the cardiac cycle due to the contraction of the heart. It is therefore necessary to evaluate the effect that TAADs have on both the circumferential and the axial behavior of the ATA. While *in vivo* measures can only provide circumferential information, *in vitro* biaxial tests on mouse models of TAAD offer the opportunity to collect otherwise unmeasurable data.

Although mechanical data on arteries from mouse models of TAAD have been reported in the literature [8-10], previous studies relied either on ring tests, which generate a complex state of stress difficult to analyze, or on *in vivo* pressure-diameter data, which do not provide enough information for a rigorous biaxial mechanical characterization [11-14]. We performed inflation-extension tests on the ATA from six murine models of TAAD and compared their estimated biaxial behavior with a suitable control. We showed that all aneurysmal phenotypes share common features, a decrease in circumferential distensibility and axial extensibility. There is a need, however, to identify appropriate mechanical metrics – both structural and material – that can reliably indicate the propensity for the development of TAADs and the vulnerability of a lesion.

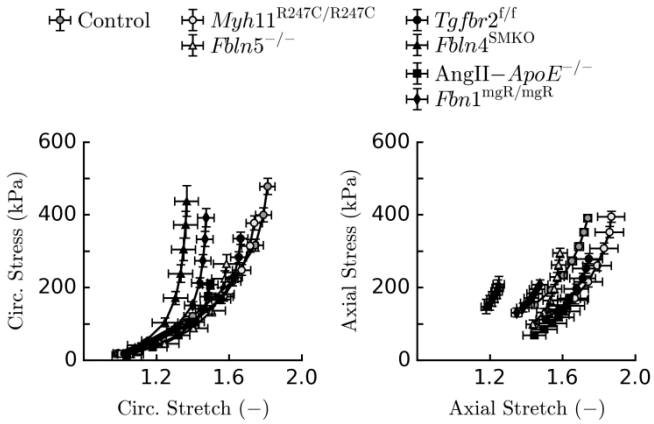

Figure 1: Average circumferential (left panel) and axial (right panel) stress/stretch plots for the six genotypes and the control.

Finally, the changes in structural, material and energy-related metrics that we observed in the aneurysmal phenotypes result from dysregulated mechanosensing induced by specific genetic mutations or pharmacological treatments [15]. Many questions regarding the mechanisms by which the cells probe their environment are yet to be answered and will provide insights on the initiation and progression of TAAD as well as on the interplay between macroscopic mechanics.

INTRODUCTION

Meniscal tears are one of the most common orthopedic injuries in the U.S. [1]. Radial tears, which interject perpendicularly and sever the circumferential fibers that make up the meniscus bulk, are thought to compromise mechanical function. As such, these tears are usually treated by partial meniscectomy (excision of the damaged region), with the assumption that severed fibers play no mechanical role. While this is common dogma, a recent study by Bedi et al. [2] suggested that radial tears do not increase knee contact stresses until they reach ~90% of meniscus width [3]. To resolve this contradiction, we reconsidered the role of radial elements ('tie fibers'). These fibers (and sheets) originate at the meniscus periphery and interdigitate amongst the circumferential fibers, binding these fibers together and potentially mediating strain transfer [4]. To query the role of these radial elements, we first quantified their density in the juvenile meniscus. Next, to test the role of radial elements in an aligned network, we utilized electrospinning to generate a meniscus analog. Here, we varied the speed of the collecting mandrel [6] to create scaffolds that were aligned, but contained a subset of non-aligned layers to create 'tie fiber-like' elements. We varied this 'tie fiber' fraction between 25-75% of the scaffold thickness, in seven discrete layers. Through tensile testing of intact scaffolds and those into which a 'radial' defect was introduced, our data suggest that these radial elements may play a critical role in preserving mechanical properties when aligned fibers are severed.

METHODS

Native Tissue Analysis: To determine the quantity of radial elements needed within synthetic constructs, we imaged juvenile bovine menisci at 10X magnification using second-harmonic generation (SHG, 840nm excitation). Three regions of interest were chosen to represent the outer, middle, and inner zones of each radial section along the meniscus circumference. Images were processed with a FIJI integral image filter plugin to decrease noise (**Fig. 1**) [8,9,10] and the area fraction with positive SHG signal computed. Mean fiber density was analyzed by 1-way ANOVA ($p \leq 0.05$) with Tukey's post hoc; data are presented as mean ± SEM.

Scaffold Fabrication and Mechanical Testing: Nanofibrous poly(ε-caprolactone) (PCL) scaffolds were electrospun [7]. For aligned (AL) scaffolds, a mandrel rotating at 10 m/s served as the collector. To form non-aligned (NA) scaffolds, the mandrel was slowed to ~3 m/s. To replicate radial tie elements, AL scaffolds were produced that included discrete NA layers by lowering the speed of the mandrel for set periods of time. These composite scaffolds had 7 alternating AL and NA layers (**Fig. 2**) to produce scaffolds with 25, 33, 50, and 75% NA content through the thickness. Scaffolds were cut to 30 mm length (in the AL direction) x 5 mm width for mechanical testing. Two conditions were tested: intact or defect, with the latter having a radial cut spanning 50% of the width at the middle of the sample height. Cross sectional area was measured with a laser-based device [7] prior to speckle coating. Samples were evaluated in tension in a ramp to failure test (0.5% strain/s), during which they were imaged for strain tracking using the Vic2D image correlation software. Stress versus strain data were curve-fit using a custom bilinear fitting program in MATLAB to define the 'toe' and 'linear' modulus, as well as the transition strain [11,12]. Significance (n=8/group) was analyzed using 1-way ANOVA ($p \leq 0.05$), with Tukey's post hoc; data are presented as mean ± SEM. Percentage change of linear modulus analyzed using 1-way ANOVA ($p \leq 0.05$), with Dunnett's post hoc.

RESULTS

Histological analysis showed that tie fiber density ranged from 1.36% in the inner zone of the body to 26.6% in the inner zone of the posterior horn (**Fig. 1**). Mean fiber density was higher in the inner zone (13.6%) compared to the middle and outer zones (11.1% and 8.3% respectively) and higher in the posterior horn compared to the anterior horn (12.3% and 10%, respectively, data not shown).

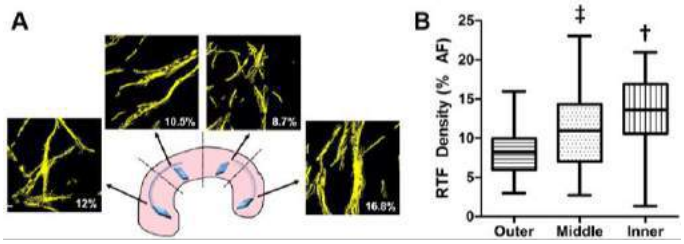

Figure 1: Radial tie fiber distribution varies by location. (A) Area fraction of radial tie fibers (yellow) in the middle zone across one juvenile bovine medial meniscus. Percentages indicate the RTF area fraction in image. Scale bar = 100 µm. (B) Radial tie fiber density, reported as Area Fraction (%) across the meniscus. Whiskers denote range. ‡, † = p≤0.05 vs. all other groups.

The toe and linear region modulus of AL scaffolds was ~2 and ~7X higher (5.5 and 18.8 MPa, respectively) than that of NA scaffolds (2.8 and 2.8 MPa, respectively). As the percentage of NA layers in composite scaffolds increased, the linear region modulus decreased. The toe region modulus showed smaller changes (**Fig 2**).

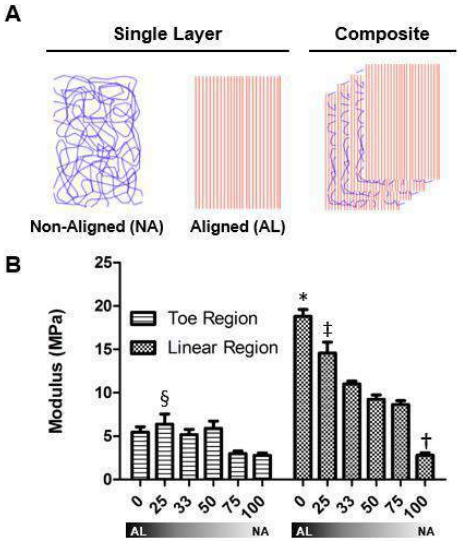

Figure 2: Radial elements alter mechanical properties of composite scaffolds. (A) Schematic of scaffold groups. (B) Toe and Linear moduli of intact scaffolds. § = p≤0.05 vs. 75%, TM. *, ‡, † = p≤0.05 vs. all other groups, LM.

When comparing the linear region modulus of intact scaffolds versus defect scaffolds, there was a trend towards a difference in the percent change for AL compared to composite scaffolds. That is, AL scaffolds lost ~50% of their apparent modulus (as expected with a defect spanning half of the width), while composite scaffolds with ≥33% NA content lost only ~20-30% of their apparent modulus (**Fig 3).** Preliminary studies mapping strain at the defect showed more rapid strain reconstitution in composite scaffolds compared to AL scaffolds (**Fig 3**).

DISCUSSION

This study developed a biomaterial analog of the meniscus radial tie fiber, namely a disorganized fibrous layer interspersed in an otherwise aligned fiber array. The linear and toe moduli of composite scaffolds generally followed expectations, with increasing NA content decreasing the linear modulus. Inclusion of NA layers also appeared to preserve scaffold mechanics in the context of a defect. That is, when a 50% radial cut was introduced, AL scaffolds showed the expected 50% decrease in apparent modulus, whereas the 33%, 50%, 75%, and 100% NA scaffolds all showed a less marked decline. This suggests that composite scaffolds, by virtue of the NA inclusions, provide some degree of strain transfer between layers, engaging aligned fibers adjacent to the defect that had been severed. This is consistent with our previous studies on the tensile response of non-orthogonally aligned nanofibrous layers [13,14] and with the shear lag mechanism reported for native tendon [15]. Collectively, these data imply that radial tie elements in native meniscus may be essential for enabling efficient load transfer in the context of tears that interrupt the circumferential fibrous architecture.

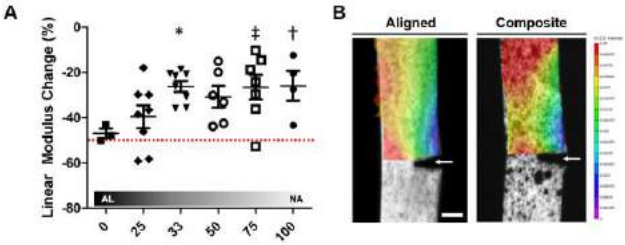

Fig. 3: Radial elements contribute to load transfer near a defect. (A) % change in modulus with defect. Red line indicates a 50% reduction. *, ‡, † = trending p≤0.10 vs. 0% (AL) group. (B) Local strain in Aligned and Composite (33% NA) scaffold with defect at 5% strain. Color bar from 0% (purple) to 5% strain (red). Scale: 2 mm.

It should be noted that our biomaterial model utilizes relatively high percentages of tie fiber elements (e.g., NA layers) while imaging suggests that native juvenile menisci have a lower (~11%) RTF density. This is in part due to the conservative processing steps involved in determining RTF density. Furthermore, RTFs have an organized, branched, collagenous structure that run perpendicular to circumferential fibers and may exhibit stronger molecular connections yet unknown. In contrast, our biomaterial analog utilized non-aligned fibers with little organization, and this likely led to less efficient engagement of the orthogonal fibers. Despite this limitation, our findings indicate that radial tie elements in the native meniscus may play a heretofore unappreciated role in enabling strain transfer around tears that interrupt the continuity of circumferential fibers. This new understanding may direct tissue engineering strategies aimed at producing functional replacements and could alter clinical practice with respect to partial meniscectomy.

DECREASED WALL SHEAR STRESS IN ISOLATED REGIONS OF THE PULMONARY ENDOTHELIUM COULD IMPACT PULMONARY VASCULAR DYSFUNCTION ON A GLOBAL AND CELLULAR LEVEL IN PULMONARY HYPERTENSION

INTRODUCTION

Pulmonary hypertension (PH) is a disease characterized by progressive pulmonary vascular dysfunction, which gradually increases right ventricular afterload. Recent studies have shown that the wall shear stress (WSS) acting on the endothelium is reduced in hypertensive conditions [1], but the consequence of this phenomenon is poorly understood. Endothelial cells (ECs) subjected to pathologic WSS are shown to change morphology, alignment, and gene expression, but additional work is needed to investigate the system transients and cell-to-cell signaling in regional stress variations.

The objective of this study was: (1) to utilize velocity encoded 4D magnetic resonance imaging (4D MRI) to measure WSS in patients with PH; and (2) implement a mathematical model of cellular calcium metabolism to investigate transient and regional calcium deposition dynamics. Based on qualitative observations of pulmonary arterial blood flow and previous computational studies, the endothelium was subjected to decreased and inhomogeneous WSS in PH. The primary hypothesis of this study was that isolated regions of low WSS would correlate with global pulmonary vascular health. Therefore, the secondary hypothesis was that the biochemical consequence of inhomogeneous WSS would impact calcium distribution in stimulated and neighboring non-stimulated cells.

METHODS

Measuring WSS in PH Patients

17 adult PH patients and 5 controls with chronic obstructive pulmonary disease were prospectively recruited to undergo same day right heart catheterization (RHC), blood biochemistry analysis, and velocity encoded 4D MRI at National Jewish Health (Denver, CO).

RHC data was used to compute the index of wave reflection (Γ), which is a measure of the impedance mismatch between the proximal and distal vasculature. Γ has been shown to increase in PH [3].

4D cardiac MRI was performed on a 1.5T system (Siemens, Erlangen, Germany) with 3-dimensional velocity encoding (voxel volume=2.4-2.6 x 2.4-2.6 x 2.4-3.0 mm, α=14-15°, TE/TR=2.85/48.56 ms, VENC =150 cm/s, temporal resolution=42-48 ms). Flow data was used to measure the shear-rate at 8 locations around the circumference of the main pulmonary artery (MPA) (see Fig. 1), 1*cm* downstream from the pulmonic valve. WSS was computed according to the equation shown in Fig. 2. Patient specific viscosity was calculated based on blood hematocrit (Ht) at the time of RHC.

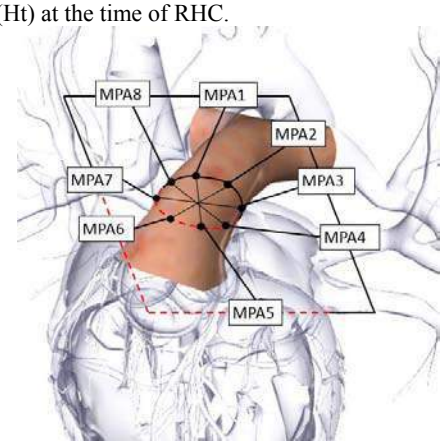

Figure 1: Schematic showing 8 locations along the circumference of the MPA where WSS was measured, positioned 1*cm* downstream from the pulmonic valve.

Computational Model of Calcium Dynamics in Endothelial Cells

A computational model of cytosolic and extracellular calcium dynamics was developed for 100 endothelial cells that share a common extracellular matrix. The model was executed for 1 second under two conditions: 20 out of 100 cells were subjected to a 20% and 80% decrease in WSS.

The major mechanisms that contribute to calcium homeostasis in a single cell were described using 5 coupled ordinary differential equations (not included for brevity) and kinetic conditions for receptor activation. This model was expanded from the experimentally validated derivation by Weisner *et al.* [2], by coupling the extra-cellular calcium concentration to the exchange of calcium across the cellular plasma membrane. Therefore, a 5th equation was included within the coupled ODE system to iteratively compute the extracellular calcium concentration. Coupling between neighboring cells was introduced by describing the total calcium concentration in a single computational node with a 1-D diffusion equation.

The system was integrated using an in-house code that utilized a 4th order Runge-Kutta method. At each iteration of time, calcium diffusion was discretized using an implicit finite difference method.

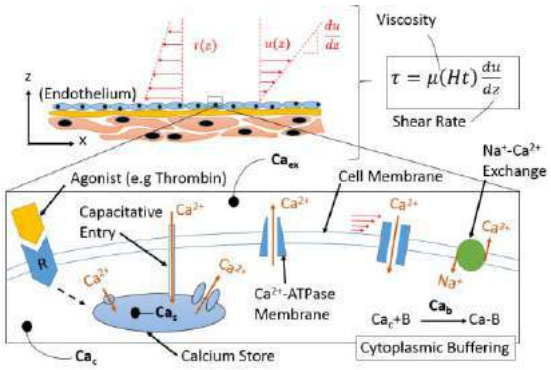

Figure 2: Schematic of WSS acting on endothelium with calcium regulation mechanisms. The computational model solves for calcium concentration in four regions: Ca_c: cytosolic concentration; Ca_s: calcium concentration in storage; Ca_b: calcium bonded to buffering proteins; and Ca_{ex}: calcium concentration in the extracellular matrix.

RESULTS

4D MRI

Qualitative analysis of streamlines consistently show a region of recirculation in the right inferior region of the MPA (see Fig. 3). This is seen in every PH patient (n = 17), but is not seen in any controls (n = 5).

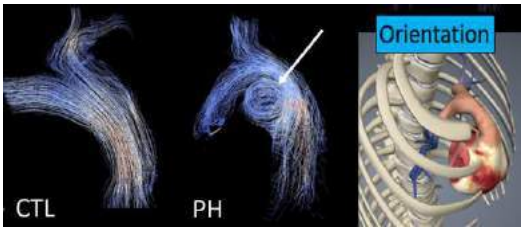

Figure 3: Typical flow streamlines in the MPA at peak systole. White arrow shows vortex formation in PH patients.

Decreased peak-systolic WSS in regions of perturbed flow (MPA 6 and 7) is linearly correlated with severity of vascular dysfunction across PH and CTL patients (see Fig. 4). However, the correlation was not seen for the other 6 points along the circumference of the main pulmonary artery.

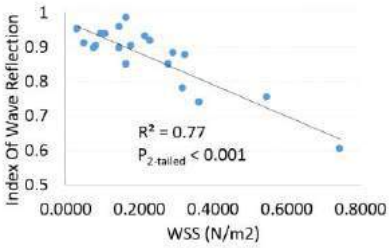

Figure 4: Negative correlation between WSS at points 6 and 7, and the index of wave reflections.

Endothelial Cell Model

Simulated temporal metabolic effects in a single endothelial cell take over 300 seconds to reach steady state in response to a step impulse in agonist concentration (0 to 1 U/mL) and WSS (extracellular calcium influx from 5 to 7.5 μM/s).

In a simulation of 100 cells, 20 cells in the middle were subjected to a steady state 20% decrease in WSS for 1second. The simulation was repeated with an 80% decrease. In the 20% scenario, all cells increased intracellular calcium. In the 80% scenario, non-stimulated cells increased intracellular calcium, but stimulated cells revealed a decrease (see Fig. 5).

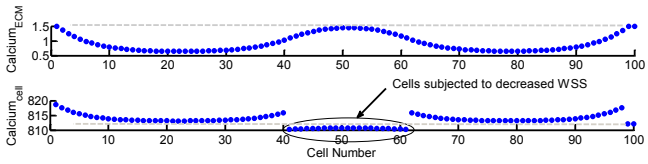

Figure 5: Extracellular (top) and intracellular (bottom) calcium concentration in 100 cells after 1 second of simulation. Dashed gray line indicated initial condition.

DISCUSSION

- The extent of WSS decrease in a small region of perturbed flow is correlated with an impedance mismatch between the distal and proximal pulmonary vasculature.
  - Index of wave reflections is increased in progressive pulmonary hypertension [3].
- 4D MRI results raise the following question: How does decreased WSS in a small region of endothelial cells impact neighboring cells?
- Preliminary simulations show extracellular calcium is uptaken by non-stimulated cells. However, stimulated cells expel intracellular calcium at extremely low WSS, but not in slightly lowered WSS.
  - Increase in intracellular calcium is linked to nitric oxide production and could impact other metabolic functions.
- Model results are preliminary: Additional work is needed to estimate proper model input parameters.

A RAMAN MICROSPECTROSCOPIC TECHNIQUE TO QUANTIFY RESIDUAL WATER IN DESICCATED SAMPLES

Quinn Osgood, Jason Solocinski, Nilay Chakraborty

Mechanical Engineering Department
University of Michigan Dearborn
Dearborn, MI, USA

INTRODUCTION

The ability to preserve biological material in a desiccated state above cryogenic temperatures is of great laboratory and clinical importance. Commonly known as lyopreservation, dry state preservation has many potential advantages over the more traditional approach of cryopreservation. Perhaps the most important being greater control over storage logistics and phase non-uniformity that can potentially arise at low temperatures during cryopreservation, which can damage the material being preserved. Non-uniformities are inherent in most methods of biopreservation due to changes in the thermodynamic state of the medium in which the preservation is taking place [1]. Such changes in thermodynamic state can be manifested through crystal formation, glass formation, or both happening in close spatial proximity, as is the case of cryopreservation. Lyopreservation can potentially avoid these problems if a spatially uniform glassy environment can be created. In absence of substantial water in the preservation matrix, arguably lyopreserved samples have the advantage of creating a more uniform and stable glassy environment.

Non-uniform water distribution following lyopreservation has the potential to cause significant damage to the preserved components [2]. Water content determines the state of molecular mobility and phase uniformity, which in turn controls the molecular reactivity and biological responses. Higher quantities of water impact determinants of biological stability including the viscosity and glass transition temperature of the preservation matrix [3]. Gravimetric determination of residual moisture in biological samples is a standard practice in lyopreservation. However, determination of trace amount of water using traditional gravimetric technique remains a problem due to uncertainties stemming from minimum detectable change of weight. Most desiccation protocols are inherently non-uniform and a standard gravimetric analysis is unable to quantify variations in trace amounts of residual water in the samples. Raman spectroscopy has been used to quantify water content in synthetic and geologic glass formations with high spatial resolution [4,5]. The protocol developed here utilizes similar technique of using spatially correlated Raman microspectroscopy to non-invasively quantify non-uniformities in the biological samples formed during lyopreservation.

METHODS

Two different desiccation techniques (spin drying and passive drying of droplets in sessile format) were employed to desiccate biologically relevant lyoprotectant medium containing high concentrations of trehalose (1.8 M) in a 20 mM HEPES buffered solution. The trace water quantification technique using Raman microspectroscopy was employed to evaluate water in the desiccated samples in both cases.

Spin Drying

750 µL of lyoprotectant solution was spin-dried using a spinning machine on. 22 mm glass coverslips in a controlled environment which is purged with ultra high purity Nitrogen gas. Spinning speeds to 1000RPM for 55s with a ramp up to 3000RPM for 5s was used to complete the drying process.

Droplet Drying

2.5µL droplets of the lyoprotectant formulation was deposited onto a 22mm glass coverslips in sessile droplets and was desiccated using passive diffusion technique in a controlled humidity chamber (dry box). The droplets were allowed to dry via natural convection for 90 minutes. The mass of the dried droplet roughly correlated with the desiccated spin-dried samples.

Raman Spectroscopy

Following desiccation, Raman spectra were gathered using a 532nm solid-state laser for excitation. Data for spin-dried samples was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

collected at the center of the round coverslip then at 2mm increments until reaching the edge of the coverslip at 11mm. Data for droplet-dried samples were collected at the center of the droplet then at 0.30mm increments until reaching the edge of the plate at 1.5mm.

RESULTS

In the lyoprotectant solution studied here there are many distinct peaks in the Raman signature indicating quantitative presence of specific molecules including water. The ratio of the CH stretching peak, which is dominated by trehalose (centered around wave number 2955) to the asymmetric portion of the OH stretching band (centered around wave number 3435) was used for quantify residual water in the samples (Fig. 1). Note that these center values are approximate and subject to shift with varying states of dryness and crystallinity. As shown in Fig. 2, by creating various solutions of with a known concentration of trehalose (and water) and analyzing the corresponding Raman spectra a relationship between the mass fraction of trehalose [≈ (1-residual water content)] and the CH/OH ratio was determined. Since the relevant data comes from a ratio of peaks direct comparisons between samples are possible even if peak intensities are disparate.

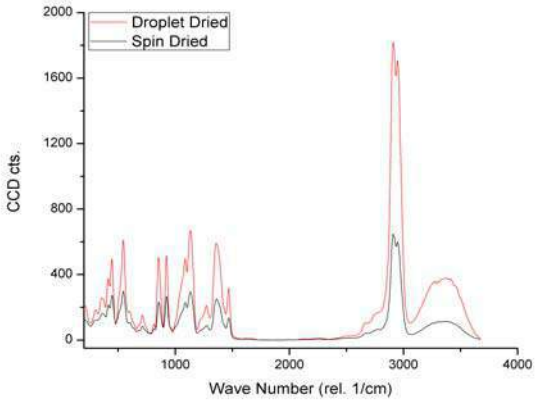

Figure 1. Comparison of Raman spectra gathered from a spin-dried sample and a droplet dried sample

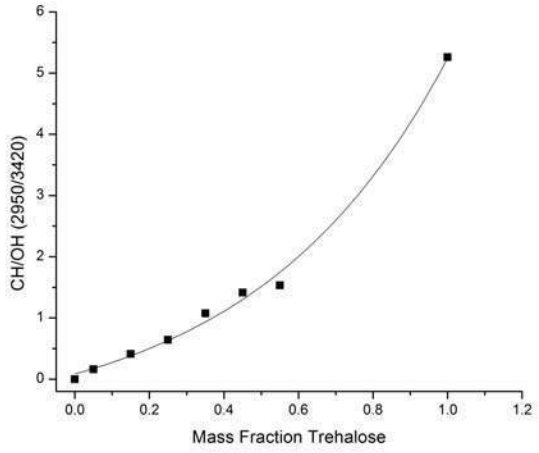

Figure 2. The exponential relationship between the mass fraction and CH/OH. This relationship can be used to quantify residual water content in desiccated samples.

It is important to note here that this relationship only holds for non-crystalline states. Hence the technique can be used to determine residual water non-invasively in an unknown sample. This technique was applied to compare the uniformity of the desiccated samples using two different drying techniques discussed here in.

The ratio of the CH stretching peak to the OH asymmetric stretching peak was determined for each Raman spectra obtained. These values were used in conjunction with the relationship determined in Fig. 1 to establish mass fraction of trehalose as a function of radius for both droplet and spin dried samples. For the droplet dried sample weight percent of trehalose ranges from 94% at the center to 100% near the edge. For the spin dried sample the weight percent for trehalose varies from 95% at the center to 97% near the edge.

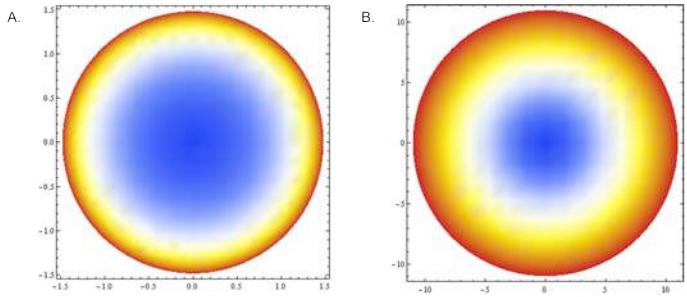

Figure 3. Map of trehalose content of A. droplet dried sample and B. spin dried sample. Red indicates higher weight percent.

DISCUSSION

The resulting plot in Fig. 3 demonstrate the differences in water content within the sample and allows of the direct comparison of the uniformity of different desiccation methods. It is clear in figures 3A and 3B that spin-drying results in a larger and more uniform area of dryness than droplet drying. It follows that spin-drying is a more favorable desiccation method because it greatly reduces the non-uniformities present after desiccation. Also, note the differences in scale between 3A and 3B, the total area show in 3B is 7.07mm^2 while the area shown in 3A is 380.13 mm^2.

This methodology can be extended to any desiccation method to determine the extent of the non-uniformities it produces. It provides a means to estimate the usefulness of a desiccation method prior to biological testing.

AGE-RELATED DIFFERENCES IN HUMAN DERMAL FIBROBLAST MECHANOSENSITIVITY TO HYALURONIC ACID DERMAL FILLER

Aribet M. De Jesús[1], Sathivel Chinnathambi[1], Mariam El-Hattab[1] Douglas K. Henstrom[2], Edward A. Sander[1]

INTRODUCTION

The aging of skin is accompanied by the appearance of wrinkles, increased fragility, and a loss of elasticity. In addition, the dermal extracellular matrix (ECM) become fragmented, and the resident fibroblasts become quiescent, most likely due to a reduction in homeostatic levels of ECM tension [1, 2]. The injection of cross-linked hyaluronic acid (HA) based dermal fillers, which are used cosmetically to increase suppleness and improve appearance, also have been shown to induce once quiescent human dermal fibroblasts (HDFs) to synthesize new collagen [3]. Changes in the local mechanical environment from HA injection might provide important mechanical cues that stimulate the fibroblasts to restore the ECM. In this study, we investigate this hypothesize and whether aging alters HDF mechanosensivity by using an *in vitro* collagen gel system as a model of the dermis.

METHODS

***In Vitro* Model:** An *in vitro* model of the dermis was prepared by culturing HDFs from patients between the ages of 14 and 93 years old at a concentration of 250,000 cells/mL in 2 mg/mL type I collagen gels. Cells were maintained in DMEM supplemented with 10% FBS, 1% P/S, and 0.1% amphotericin B and in a humidified incubator at 37°C for 24 hours before releasing the gels from their attachments. The gels were kept free-floating for 24 hours in order to simulate a tension-free, fragmented dermis. Next, 15 µL of dermal filler or 1x PBS (control) were injected into the gel center. **Gene Expression:** Changes in the expression of genes that encode for key mechanoresponsive proteins and components of the Rho/ROCK pathway were examined five minutes and 24 hours after treatment (n=3 per age, per time-point) by performing qPCR. Fold-changes in the expression of RhoA, ROCK1, ROCK2, and COL1 mRNA were determined using the $\Delta\Delta C_T$ method.

Characterization of HA Swelling: The swelling properties of the cross-linked HA-based dermal filler (Juvederm Ultra XC, Allergan, Irvine, CA) were measured by performing osmotic pressure tests. 100 µL of HA (n=4) was injected into the opening of a 1 mL pipette and separated from a solution of 1x PBS by a dialysis membrane. The height of the water column within the pipette was measured every hour during the first eight hours, followed by every 12 hours until 72 hours had passed. The change in water height was used to calculate the swelling pressure of the HA filler and the swelling ratio (i.e., current gel volume to initial gel volume). This ratio was used to estimate the stress imparted by the swelling HA filler on the surrounding collagen gel. This estimate was made by injecting 10 µL of HA filler into the center of an acellular collagen gel and acquiring time-lapse images using differential interference contrast (DIC) microscopy every hour for 24 hours. The change in filler area was used to calculate a swelling ratio that could be related back to the swelling pressure and an average resistive stress in the surrounding collagen gel.

RESULTS

The swelling potential of cross-linked HA used in this study was characterized by defining its swelling ratio when directly exposed to a solution of 1x PBS and when injected into a collagen gel. The hygroscopic behavior of HA caused the filler to imbibe 30.7 ± 9.2 µL of PBS after two days of contact with 1x PBS. This added fluid resulted in a swelling ratio of 1.31 ± 0.09 and a swelling pressure of 28.57 ± 6.98

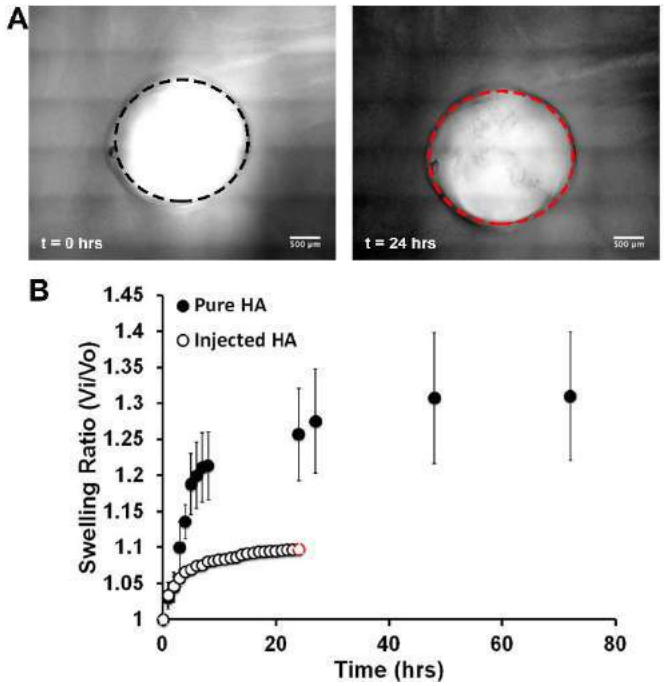

Fig. 1. (A) DIC images of HA dermal filler injected into a collagen gel 0 and 24 hours after exposure to 1x PBS. Dotted circles represent the gel area and are represented in B. (B) Swelling ratio of pure HA and of HA injected into a collagen gel in a 1x PBS solution. The difference in the swelling ratio provides an estimate of the stress in the collagen gel.

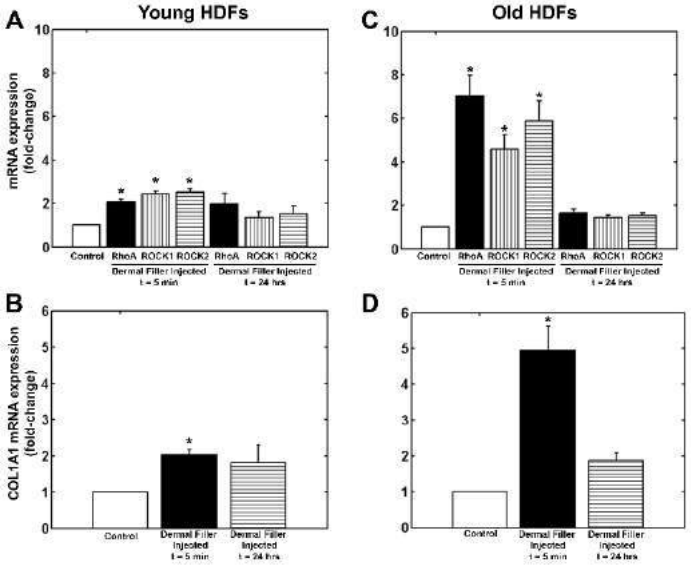

Fig. 2 Gene Expression in (A, B) young and (C, D) old HDFs in response to treatment with HA dermal filler. 1x PBS served as controls. Asterisks indicate a significant difference compared to control ($p < 0.05$).

Pa. When injected into a collagen gel, the surrounding fibrous network resisted swelling of the cross-linked HA. As a result, the equilibrium-swelling ratio was found to be 1.1, which resulted in an average resistive stress of 20.7 Pa in the collagen gel.

Injection of HA dermal filler into released collagen gels caused a significant increase in gene expression for RhoA, ROCK1, ROCK2, and COL1A1 five minutes after treatment ($p<0.05$) in both old and young HDFs (Fig 2.A-D). Fold-changes in the expression of these genes were found to be greater in old HDFs than in young HDFs. Expression levels remained slightly elevated 24 hours after treatment but were not significantly different from PBS controls.

DISCUSSION

The injection of dermal filler into a model of the aged dermis caused noticeable deformations in the collagen due to swelling of cross-linked HA. These deformations introduced a heterogeneous stress in the gel that induced increased expression of key genes in the mechanosensitive pathway Rho/ROCK and in the production of collagen. The gene expression patterns followed the changes in swelling behavior of the injected dermal filler. The largest changes in the swelling ratio were observed during the first 30 to 60 minutes after filler injection. By 24 hours, the HA swelling ratio was reaching a plateau. Similarly, a large increase in the expression of RhoA, ROCK1, ROCK2, and COL1A1 was observed after five minutes with a return to nearly basal levels by 24 hours. These results indicate that the HDFs responded mechanically to the injection of HA, although it remains unclear to what extent gene expression translated to downstream collagen production. Surprisingly, and contrary to our initial expectations, the HDFs from older patients demonstrated a significantly elevated response compared to HDFs from younger patients when compared to control. It may be that baseline expression in old HDFs is lower than in younger HDFS and so mechanical stimulation produces what appears to be greater sensitivity in older cells. Ongoing studies are measuring total collagen production to help clarify this issue.

OPTIMIZATION OF *IN VITRO* ENDOTHELIAL CELL SELF-ASSEMBLY FOR MILLIMETER SCALE VASCULOGENESIS

Joshua T. Morgan (1), Jasmine Shirazi (1), Erica M. Comber (1), Peter A. Sariano (1), Jason P. Gleghorn (1)

INTRODUCTION

During embryogenesis, endothelial precursor cells distributed throughout the mesenchyme self-organize into an initial network called the vascular plexus [1]. This process, termed vasculogenesis, provides the early vascular system of every tissue and organ in the body. As the plexus is perfused by the beating heart, the initial stochastic architecture is extensively remodeled into a hierarchy of vessels that compose the mature vascular system [2]. An example of vasculogenesis is the plexus formed around the developing airway tree in embryonic lung, where vessels formed on cellular length scales assemble into a network that spans the entire organ (Figure 1). Importantly, this network emerges stochastically but is sufficient to fully vascularize developing organs. Understanding the microenvironmental factors that guide formation of functional 3D networks remains a central question in development and morphogenesis. Modeling the formation of the vascular plexus *in vitro* can provide an important tool for understanding how tissue biophysical and biochemical properties guide self-assembly in developing tissues.

Previous research has demonstrated that endothelial cells randomly dispersed throughout the bulk of various hydrogels can be induced to form multicellular structures, including primitive networks. However, these studies often focus on specific aspects of network formation at cellular length scales, such as lumen formation or branch extension. Whereas these experiments elucidate local cellular interactions, they have yet to fully address the self-assembly of vascular networks that connect across physiological tissue length scales. Further, culture conditions vary among research groups, making it difficult to assemble a cohesive understanding of the vascular self-assembly process.

To directly address this knowledge gap, we have developed a 3D endothelial culture model to assay large-scale network formation within collagen gels. This culture model was systematically tested to determine the influence of collagen concentration (regulating stiffness and pore size) and cell density (regulating cell-cell distance) on self-assembly. We identified ideal culture conditions for the robust formation of stable, millimeter-scale plexuses. Further, we developed methods to characterize the morphology and connectivity of these networks for comparison to plexus formation in embryonic lung explants.

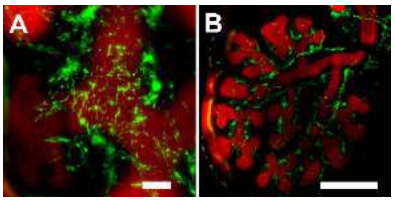

Figure 1: Plexus formation in developing mouse lung. (A) Blood vessels (CD-31; green) form on cellular length scales around the airways (E-cadherin; red). (B) Networks are connected across the entire organ (E12). Scale bars are (A) 50 and (B) 500 μm.

METHODS

Lung explants: Timed pregnant CD-1 mice were humanely euthanized using CO2 asphyxiation under an Animal Use Protocol approved by the University of Delaware IACUC. Lung explants (embryonic day 12; E12) were isolated and either cultured for 48 h in floating membrane culture or immediately fixed and stained for E-cadherin (epithelium) or CD-31 (endothelium) using standard protocols.

Human umbilical vein endothelial cells (HUVECs) were cultured in EGM-2 medium. Collagen was freshly isolated from rat tails [3]. Collagen hydrogels with HUVECs dispersed throughout the bulk were constructed in PDMS molds treated with 2% (poly)ethylenimine and 0.2% glutaraldehyde. The cylindrical gels (7 mm dia. × 3 mm tall) were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

chemically crosslinked to the PDMS sidewalls while keeping the upper and lower surfaces free (Figure 2A). Collagen of varying weight percent was prepared with suspended HUVECs and polymerized as previously described. Gels were maintained in EGM-2 with 50 ng /mL tetradecanoylphorbol acetate and 50 µg/mL sodium ascorbate. For each condition 3-4 technical replicates and 2-3 experimental replicates were performed. Gels were fixed and stained with DAPI (to label nuclei) and phalloidin (to label actin). Samples were imaged with a Zeiss widefield AxioObserver Z1 (for gross characterization) and a Zeiss confocal LSM880 (for reflectance and detailed analysis). Confocal images were filtered and segmented using custom algorithms (MATLAB 2015b).

RESULTS

To determine which culture conditions were optimum for network formation, we cultured HUVECs in collagen gels for 7 days at a range of cell densities (0.5e6, 1e6, 1.5e6, 2e6 cells/mL) and collagen densities (0.2, 0.3, 0.4, 0.5, 0.6%). After fixation and staining, a trained observer scored gross cell viability and network formation on a scale of 1-4, with 3 and 4 representing network formation. Network formation was supported in a subset of conditions (Figure 2B).

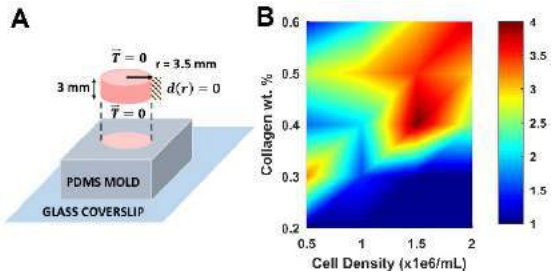

Figure 2: Development of an *in vitro* model of vasculogenesis. (A) Schematic of culture geometry. Displacement *d* is fixed at radial boundary while the top and bottom have zero traction forces (*T*) (B) At 7 days, some conditions resulted in robust (≥3) networks.

Importantly, these primitive vascular networks were 3D and spanned the entire 7 mm construct (Figure 3A). To investigate morphological parameters of the plexus, we used confocal and reflectance microscopy to identify cellular morphology and the presence of lumens within the collagen gel (Figure 3B). Further, after segmenting the images as shown in Figure 3C, we constructed 3D volumes of the vascular networks (Figure 3D). From these volumes we determined the network volume fraction as well as the connectivity, which we defined as the median percentage of network accessible from 50 random points. As an example, networks formed with 1e6 and 1.5e6 cells/mL embedded within 0.5% collagen had network volume fractions of 14.15±1.82% and 24.03±6.64%, respectively, while connectivity was 88.75±4.17% and 75.02±0.81%, respectively.

Having identified a range of conditions suitable for network formation, we tested their long-term stability. Using 0.5% collagen and 1.5e6 cells/mL as a representative case, we fixed samples at 3, 7, 14, and 21 days. By gross inspection, some connectivity was observable by day 3, full networks were apparent by day 7, and no changes to the gross network morphology were observed at the 14 and 21 day timepoints.

Lastly, to test whether network formation was sensitive to fluidic forces, we fabricated our construct within a microfluidic device and applied perfusion through the hydrogel for 48 h at approximately 0.05 dyne/cm^2. Preliminary findings demonstrate visible alignment of the network braches parallel to flow, demonstrating this methodology can be used to test the role of mechanics in vascular maturation.

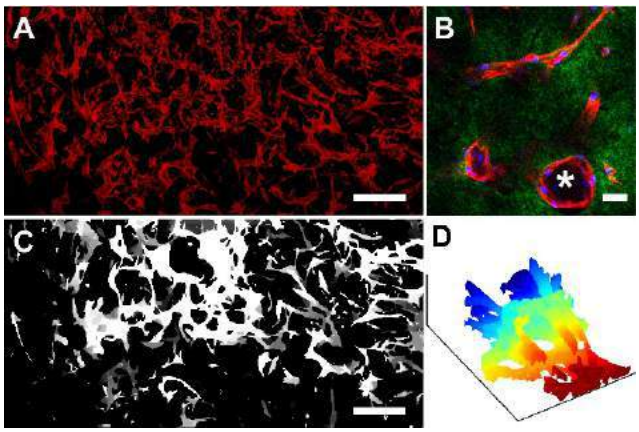

Figure 3: Self-assembled networks are large, interconnected, and have lumens. (A) Maximum projection of 4x2x0.2 mm region of a plexus (B) HUVECs labeled with phalloidin (red) and DAPI (blue) permeate the collagen gel (green). Cell-lined lumens (*) are observed. (C) Networks were automatically segmented and (D) constructed into volumes. Scale bars are (A, C) 500 and (B) 50 µm.

DISCUSSION

We performed a p arametric study of the *in vitro* conditions necessary for the culture of millimeter-scale vascular networks similar to those observed in the embryonic mouse lung. Having identified conditions ideal for self-assembly, we characterized the stability and morphology of a subset of culture conditions. Additionally we demonstrated that these networks respond to flow, providing a novel platform to interrogate the role of fluid cues on t he maturation of vascular networks. This *in vitro* vasculogenesis model enables future biophysical and molecular studies to elucidate the regulators of plexus formation that would not be possible in developing embryonic organs.

Further, this model has potential translational applications in tissue engineering. The ability to vascularize engineered graft tissues remains a fundamental challenge in tissue engineering. As the size of the required graft grows, providing nutrients and oxygen to metabolically active tissue necessitates the incorporation of vascular and lymphatic networks [4-5]. By exploiting the self-assembly of vascular cells to create large-scale and stable networks, as we do here, we may enable the fabrication of larger graft tissues for reconstructive uses.

In summary, we have developed a robust methodology for creating large-scale vascular networks for fundamental studies of micro-environmental regulation and mechanotransduction in vasculogenesis and potential translational applications of engineering large vascularized tissue grafts. Ongoing studies are focused on understanding the molecular regulators of plexus scaling, incorporation of mesenchymal cells, and determining the impact of fluid shear forces on vascular network remodeling and maturation.

INTRODUCTION

Novel carboxymethylated hyaluronic acid based hydrogel polymers (CMHA-S, Jade Therapeutics Inc., SLC) are emerging as controlled and localized means for drug-delivery in the treatment of ophthalmic conditions, such as corneal ulcers, injuries and infections. These bio-erodible hydrogels offer improved drug bioavailability, safety, and therapeutic effectiveness from existing therapies, as hyaluronic acid (HA) is a naturally occurring polysaccharide already found in the eye [1]. However, retention of these hydrogel films in the ocular environment is poor due to the high lubricating properties of HA, thereby reducing the efficacy of the hydrogels in long-term drug delivery application.

In this study, we use a computational finite element model of the eye to: (1) define optimal surface friction ratios of the hydrogel to the sclera and eyelid that minimize displacement, and (2) evaluate multiple geometrical designs capable of achieving these ratios. The improved length of retention of the optimized design was verified using *in vivo* rabbit studies.

METHODS

The FE model represented a hydrogel film placed in the inferior fornix of the adult human eye. Model components consisted of a simplified eye with a radius of 11mm, a lower eyelid depicting the inferior fornix, and the hydrogel film. The hydrogel film was placed between the globe and lower eyelid in the first step allowing the eyelid to deform around the hydrogel (Fig. 1A). Then, an upward eye rotation that was replicative of a physiological eye movement was applied so that the displacement of the film due to the globe movement could be measured [2]. The material models and coefficients are provided in Table 1. The optimal friction ratio between the surfaces of the hydrogel and the globe/lid was found by iteratively sweeping through coefficients of friction (0-0.2) on each side of the hydrogel. In order to find the optimal geometry design, eight different hydrogel geometries varying in size and cross-section were implemented into the model (Fig. 1B). The friction on the globe side of the hydrogel was held at 0.05, and each of the eight geometries was simulated at lid-side frictions of 0.1 and 0.15. The best performing geometry influenced the design of the geometries that were mold-manufactured, developed and tested *in vivo*. Thickness measurements were taken from the molded

Table 1: Material models and coefficients used in the simulations.

films from both hydrated and dehydrated sections, so that these values could be compared to the design target thicknesses to verify the *ex vivo* geometry. The films produced from the molds were tested in an *in vivo* rabbit model. Based on the results of the simulations, three shapes were selected for evaluation in the inferior fornix of New Zealand White Rabbits (N=3 for each shape). Hydrogel retention and tolerability in the rabbit eyes were observed for 8 days.

RESULTS AND DISCUSSION

The ratio of friction between the hydrogel/globe interface and hydrogel/lid interface that results in immobilization during normal eye movement can be defined by the linear relationship shown in Fig. 2. Specifically, the coefficient of friction on the globe side of the hydrogel must be approximately 1.4 times larger than the lid side for adequate immobilization. Assuming that the interaction between the globe and the hydrogel is frictionless, the ideal friction coefficient between the lid and hydrogel is approximately 0.07. In the geometry optimization, Geometries 1 and 4 completely dislodged from the eye and were excluded from further analysis. The geometry that yielded the least amount of displacement for both simulated coefficients of friction on the lid side was Geometry 7 (Fig. 3). During the fabrication process, hydrogel films retract in molds when they are dried. The rehydrated film thicknesses averaged approximately 50% thicker than the target geometry. Future refinements to mold geometry will need to account for the increased swelling thickness. Geometries 7, 8, and a new rectangular film shape were selected for evaluation in the rabbits. As predicted, Geometry 7 had the best retention with 2 of the 3 films lasting up to 3-4 days. Geometry 8 had 1 of the 3 films last up to 3-4 days. The rectangular film performed the worst, and was dislodged within a day.

CONCLUSION

Finite element analysis is a powerful tool that can optimize drug delivery systems for better interaction with the eye. The novel HA-based hydrogel film is a viable topical ophthalmic drug delivery device if the 1.4:1 ratio of frictional properties against the surface of the lid and globe is maintained. This variance can be achieved through surface modifications of the hydrogel or using geometrical features to create larger frictional forces against the lid. Future studies will investigate micropatterning of the film as a means to better control frictional interactions with the eye.

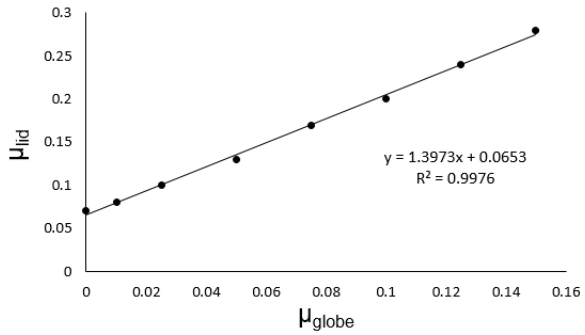

Figure 2: (A) Relationship between friction of the hydrogel with the lid (μlid) and globe (μ_{globe}) that is required to retain the film in the lower fornix of the eye during regular eye movement.

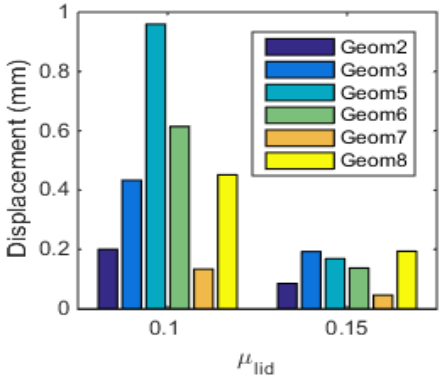

Figure 3: Maximum nodal displacement of film geometries. Geometries 1 and 4 were excluded from the analysis because they completely displaced from the lower eyelid.

INTRODUCTION

Tissue engineering is an interdisciplinary area that combines engineering and biology in order to improve or replace biological functions. A prominent area of tissue engineering is related to regenerative medicine and neurorepair.. The discovery of effective therapeutic interventions targeted towards neurodegenerative conditions and nerve injuries has proven challenging. Scientists and engineers with various backgrounds have been drawn into the field of neural tissue engineering due to its importance for development of novel therapeutic strategies. For example, peripheral nerve regeneration is a complicated phenomenon which is often successful as long as the injuries are small. With more severe nerve injuries such as a nerve gap, however, interposition of a nerve graft or nerve regeneration conduit is usually required. Complexity in the spinal cord injury is more serious since, for the most part, regeneration is prohibited. Fortunately, neural tissue engineering provides extraordinary promise to combat this injury. Fibrous scaffolds have shown tremendous promise to build hierarchical structures and enhance the cellular behavior due to their high surface-area-to-volume ratio. The orientation of the fibers in these kinds of scaffolds are important because the aligned fibers play a predominant role in directing the cells to grow in a desirable direction. In this paper, we fabricated Poly (ε-caprolactone) (PCL) microfibers using a microfluidic approach in order to create a 3D environment to direct the growth and differentiation of neural stem cells and control the cellular microenvironment. The phase inversion strategy was chosen for fiber solidification because the fibers are used as a scaffold and it is not desirable to decrease the degradability of the polymer by cross-linking. PCL is a biocompatible and biodegradable polymer widely applied in biomedical area. However, this is the first time that adult neural stem cells were cultured on PCL fibers. In this paper, polycaprolactone fibers are fabricated in different sizes using a microfluidic platform. By using this approach, we show large degree of flexibility in the control of the size of the fibers. We have cultured green fluorescent protein-expressing (GFP) Adult Hippocampal Stem/Progenitor Cells (AHPCs) on PCL microfibers and investigated their ability to adhere, survive, proliferate and differentiate. It was shown that the cells attach to and align themselves on the microfiber substrates. The microfluidic microfabrication platform was able to create a biocompatible scaffold out of fibers to provide a desirable growth environment for the neural stem cells. It was demonstrated that cell death is minimal, and cell proliferation may be affected by changing the features of the fibrous scaffold.

METHODS

Phase inversion (solvent extraction) strategy was used to solidify PCL and fabricate microfibers. In this process, 2,2,2- trifluoroethanol (TFE) in the core fluid is replaced by the ethanol and water in the sheath fluid at the interface between the sheath and core solution. This exchange results in PCL solidification because the sheath fluid is miscible to TFE, but not solvent to PCL.

RESULTS

Two fluids, i.e. the core and sheath fluids, are introduced into the microchannel and diffusion occurs only at the core/sheath fluid interface due to the laminar flow regime. In order to have a continuous fiber fabrication process, a core/sheath flow profile is required. The sheath fluid focuses the core fluid laterally after the two fluids are introduced at the upstream of the channel and changes the shape of the core fluid to a thin vertical strip. Chevron grooves in the downstream of the channel decrease the hydrodynamic resistance perpendicular to the flow direction. The sheath flow rate is higher than the core flow

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

rate in order to provide the force needed to keep the core fluid at the center of the microchannel. Because the hydrodynamic resistance is inversely proportional to flow rate, the sheath fluid fills the grooves, wraps around the core fluid, and pushes it to the center of the channel.

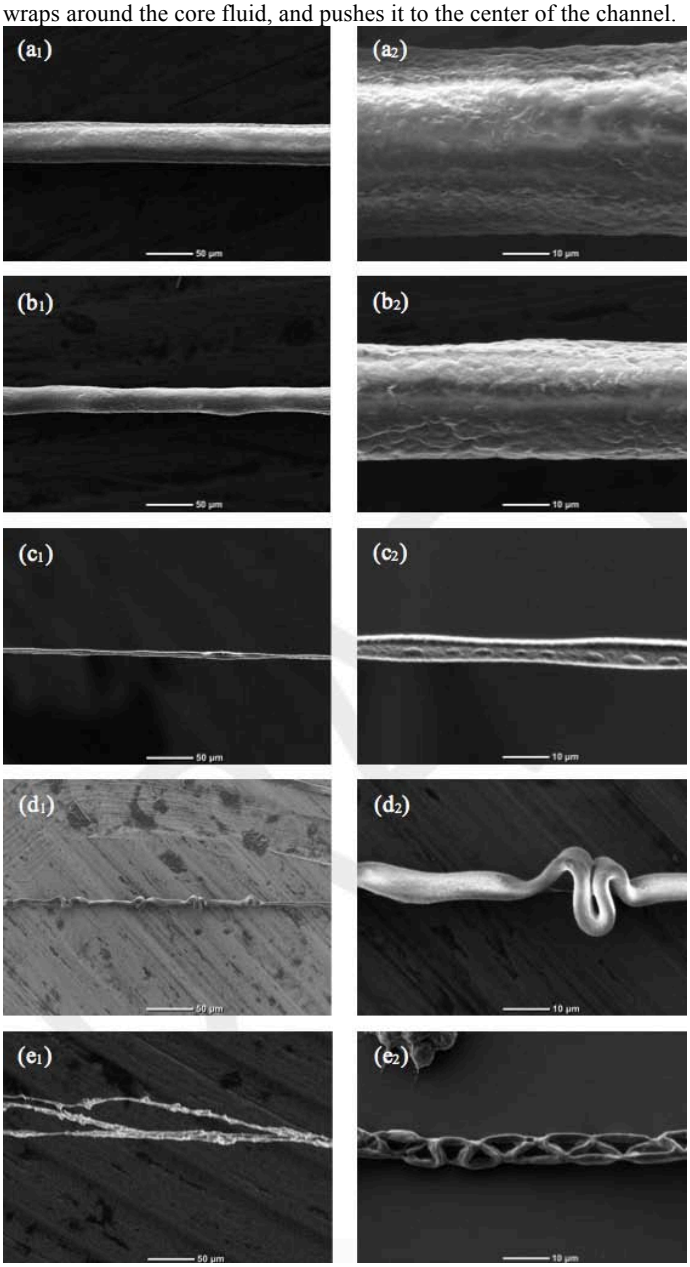

Figure 1: SEM images of PCL microfibers at sheath-to-core flow rates of (a) 20:5; (b) 60:5; (c) 200:4; (d) 300:2, and (e) 400:1.

Sheath fluid and chevron grooves exert lateral and vertical hydrodynamic focusing forces on the core fluid. The lateral and vertical hydrodynamic focusing, which is originated from the shear force between the core and sheath fluids, plays a pivotal role to keep the core fluid at the center, align the polymer chain, and change the shape of the microfibers. The hydrodynamic force depends on the viscosity and relative velocity of the core and sheath fluids. By adding polyethylene glycol (PEG) to the sheath fluid, the viscosity of core and sheath solutions match and there is no need to use high relative velocities to focus the core fluid when fabricating the fibers. Additionally, there is a possibility of flow instability in the channel at high relative velocities that results in changing the flow regime to transient from laminar. Figure 1 shows the field emission scanning electron microscopy images of the fibers fabricated using the flow rate ranges of 1-5 μL min^{-1} and 20-400 μL min^{-1} corresponding to the core and sheath fluids, respectively. The concentration of the PCL in TFE and PEG in the water/ethanol was kept at a constant value of 5%. Ki-67 immunolabeling was used to evaluate whether the PCL microfibers would support proliferation of the AHPCs. Expression of the Ki-67 antigen occurs during the cell cycle (not detected in cells in the resting phase) and therefore is commonly used as a cellular marker for cell proliferation. Ki-67 immunolabeled cells were present on all microfibers examined. Figure 2 (A-C) illustrates an example of Ki-67 immunolabeled cells growing on microfluidic spun PCL microfibers at a sheath-to-core flow rate of 60:5. [1]

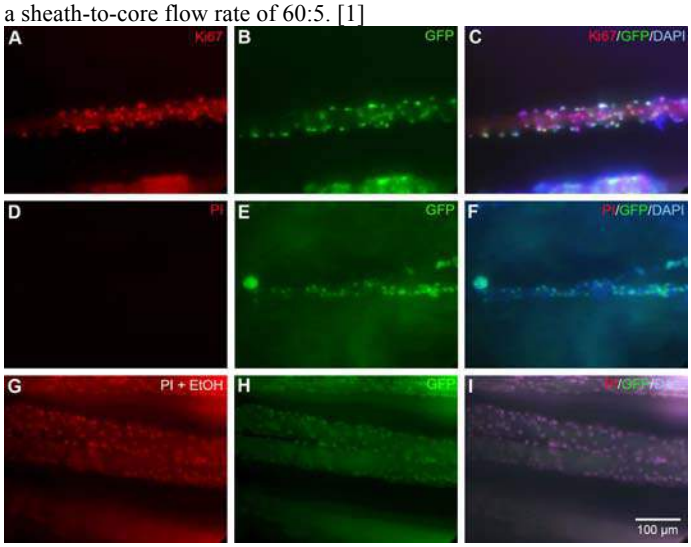

Figure 2: Attachment, proliferation and survival of AHPCs cultured on PCL microfibers. Fluorescence images of AHPCs immunolabeled for Ki-67, cell proliferation marker (A-C) or Propidium Iodide (PI) staining.

DISCUSSION

Polycaprolactone microfibers with different features were fabricated in this work using microfluidic fiber fabrication with the solidification strategy of phase inversion. The mean diameter of the fabricated fibers ranged from 2.6-36.5 μm by selecting the sheath-to-core flow rate ratio from 400 to 4. The fibers were chemically modified with extracellular matrix molecules to facilitate cell attachment and for guiding the direction of AHPC growth in vitro. The results showed that the PCL fiber can be used as a fibrous scaffold which is not cytotoxic to the AHPCs, and supports cell adhesion, differentiation, and proliferation. Additionally, it was shown that the clusters of these adult neural stem cells can be aligned using the PCL microfibers. Integration of multiple cues within a 3D context is important for gaining a better understanding in regulating neural stem cell differentiation and in designing scaffolds for neural tissue engineering. In addition, the PCL fibers can be applied in regeneration of other tissues such as muscle, tendons, and blood vessels.

INTRODUCTION

The lymphatic system is an expansive vascular network running parallel to the venous system that plays a vital role in fluid homeostasis within the body as well as immune cell transport. It takes up fluid from the interstitial spaces in the body and transports it to the venous return. Unlike the cardiovascular system, the fluid within this network of vessels is not driven by a central pump, but rather by extrinsic and intrinsic mechanisms that take the lymphatic fluid (lymph) from a lower pressure environment to a higher one. Extrinsic mechanisms influence the flow of lymph via outside forces including arterial pulsations, skeletal muscle contractions and diaphragmatic movement. Intrinsic forces transport lymph via the contraction of lymphatic muscle cells (LMCs) that line the lumen of the lymphatic vessel.

Bi-leaflet check valves are frequent throughout the vessels and serve to prevent retrograde flow. Valve defects have been shown to underlie the pathogenesis of lymphatic distichiasis, a dominantly inherited form of primary lymphedema [1,2]. Physical injury to valves occurs in lymphatic filariasis [3], which is the most common cause of lymphedema in the world affecting over a hundred million people worldwide [4,5]. Once the healthy valve behavior is understood, the disease states can begin to be investigated.

Experiments involving the lymphatic valves are difficult due to the extremely low lymph flow rates within the vessels (13.95 ± 5.27 μL/hr) and small diameters (91 ± 9 μm) [6]. The computational work here builds on our previous models of the rat mesenteric lymphatic valve, which used an image-based computational fluid dynamics (CFD) approach [7] and uncoupled fluid-structure interaction (FSI) approach [8], respectively. The present study implements a coupled FSI approach with an idealized geometry of a rat mesenteric lymphatic valve to understand the transient fluid and solid mechanical behavior of the valve. This work forms the framework of future lymphatic FSI studies implementing more complex boundary conditions and image-based geometries.

METHODS

Idealized Geometry and FSI Approach. An idealized geometry of a rat mesenteric lymphatic valve described previously [8] was used as the computational domain for simulations. Due to the expected high degree of leaflet deflection over short time scales (e.g. complete opening in less than 1 second), a strong coupling between the fluid and structural equations is necessary. A two-way iteratively implicit method was employed using ANSYS Fluent as the fluid solver and ANSYS Mechanical APDL as the structural solver. The equations of the solid and fluid are solved separately but data is exchanged within a time step. Each iteration within a time step is known as a coupling iteration. The ANSYS platform (v16.1, Canonsburg, PA, USA) was chosen because of its mesh proficiencies and ability to remesh the fluid region at every time step. Only ¼ of the valve was modeled in order to reduce computational cost (Fig. 1).

Structural Boundary Conditions. The ½ -leaflet was meshed using the SOLID187 element, which is a 3D, 10-node element well-suited to modeling irregular meshes with second order accuracy in space. The valve leaflets were fixed at the annulus (edge where the leaflets attach to the wall of the vessel) and geometric non-linearities were taken into account, which allows for large deflections of the leaflets. A Hilber-Hughes-Taylor

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

(HHT) time integration method, which allows for energy dissipation and second order accuracy in time, was used to discretize the equations of motion and the Newton Raphson Method was applied to solve the discretized equations. For the material behavior, a Neo-hookean model was employed. A value of 20 kPa was used for the shear modulus, G, which is slightly lower than that of arterial elastin [9, 10, 11], whilst a Poisson's ratio of 0.45 was chosen (nearly incompressible).

Flow Conditions. The fluid domain was imported into the commercial CFD software, ANSYS Fluent, and meshed using tetrahedral elements resulting in a computational mesh of approximately 156,500 volumetric elements. A fluid with dynamic viscosity, μ, of 1.5 cP [12] and density, ρ, of 1 g/cm^3 was used to model lymph. An unsteady and increasing pressure boundary condition with a maximum pressure of 50 Pa was applied at the inlet of the geometry and the outlet was kept constant at 0 Pa.

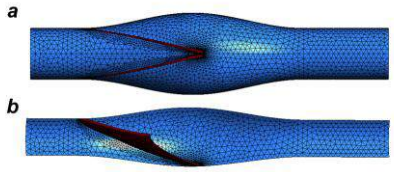

Figure 1: Lymphatic valve geometry: a) 3D view of the model with computational domain reflected and rotated and b) skewed 3D view of the actual ¼-valve model.

Symmetry boundary conditions were applied at the regions where the full valve leaflet had been divided into quarters to model mirror symmetry at these locations. Diffusion-based mesh smoothing, local cell remeshing and local face remeshing were applied to rectify irregularities in the fluid mesh resulting from the deformations. The simulation was allowed to run for 0.45s using a minimum time step of 2 ms. Three coupling iterations per time step were implemented in ANSYS Fluent with a maximum number of coupling iterations of 300.

RESULTS

The leaflet deflection increases in an apparently linear fashion until approximately 0.3 s, where the deflection at the leaflet tip, δ_y, reaches 4 µm (Fig. 2.).

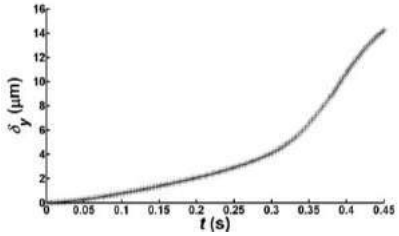

Figure 2: Deflection at the leaflet tip, δ_y, versus time, t.

From 0.3 s, δ_y increases to 14 µm (t = 0.45 s) in a non-linear monotonic fashion. Representative velocity streamlines revealed a peak velocity value of approximately 39 mm/s at 0.45 s (Fig. 3).

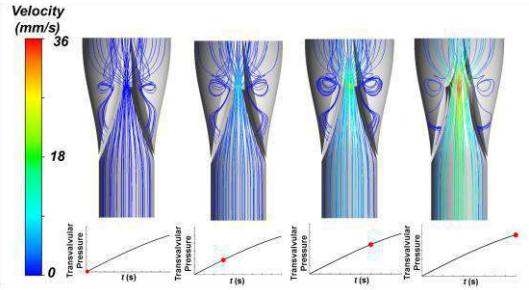

Figure 3. Representative velocity streamlines. Plots below the streamline figures represent the location on the transvalvular waveform at which the data were extracted.

Streamlines revealed apparent regions of recirculation between the valve leaflets and the sinus wall. However, the velocities in these regions are essentially negligible compared to central lymph flow.

DISCUSSION

In this study, an FSI model of a rat mesenteric lymphatic valve was developed. The peak velocity was 39 mm/s and regions of apparent recirculation were observed adjacent to the valve leaflets. One limitation of this study includes the simplification of the geometry to ¼ of the full valve and sinus using symmetry boundary conditions. Due to the low flow rates (Re<1), and the fact that our previous work [8] has shown that asymmetric openings tend to occur only at lower values of sinus-to-root ratio (which is unlikely to occur physiologically), there is strong indication that the assumption is reasonable. Future studies will include implementing a sinusoidal inlet pressure to open and close the valve leaflets as well as modeling the full geometry to understand whether the symmetric assumption is valid. Overall, this work has created a foundation for the future development of FSI models of the lymphatic valve.

COMPUTATIONAL MODELING OF OPTIMIZATION OF DRUG-ELUTING STENTS UNDER MULTIPLE MECHANICAL CRITERIA

François M. Cornat, Franz Bozsak, Abdul I. Barakat

Hydrodynamics Laboratory (LadHyX)
Department of Mechanics
Ecole Polytechnique
Palaiseau, France

INTRODUCTION

Atherosclerosis is the leading cause of mortality in the world. The most common treatment for atherosclerosis today is the implantation of a stent. The earliest stents were bare metal stents (BMS); however, the unacceptably high restenosis rates associated with BMS led to the development of drug-eluting stents (DES). Although highly effective in preventing restenosis, DES appear to be associated with an increased risk of late stent thrombosis (LST) which, though rare, is often fatal when it occurs. LST following DES implantation is attributable to delayed endothelial wound healing following the extensive endothelial damage induced by the high pressure deployment of a stent [1]. The delayed endothelial healing has multiple causes: 1) the drugs eluted by DES inhibit not only smooth muscle cell proliferation but also endothelial cell proliferation, thereby slowing down vascular wound healing, 2) stents induce arterial flow disturbance which can impair endothelial cell migration [2], and 3) the stresses induced by stenting in the arterial may compromise vascular healing. We are interested in optimizing DES design and performance with the overall goal of controlling restenosis while simultaneously allowing endothelial healing. Accomplishing this goal requires a sufficiently high drug concentration in the arterial media to prevent restenosis while maintaining drug concentration at the endothelium as low as possible. Furthermore, the stent needs to induce minimal arterial blood flow disturbance as well as minimal stress excursions in the arterial wall.

We recently developed a computational model that describes the transport within the arterial wall of drugs eluted from DES [3]. We subsequently used this model to optimize drug release from DES to define a cost function whose minimization allowed us to determine the optimal combination of initial drug concentration loaded onto the DES and drug release kinetics [4]. The minimization of the cost function was performed using a surrogate management framework-based gradient-free optimization algorithm. We now wish to extend the optimization to account for stresses in the stent and the arterial wall as well as stent-induced arterial flow disturbance. Thus, the specific goal of the present work is to develop a computational model and associated optimization scheme to minimize stent-induced arterial blood flow disturbance as well as the stresses in the arterial wall while simultaneously ensuring stent integrity during deployment and limiting contact pressure between the stent and the artery in order to minimize arterial wall damage.

METHODS

We developed a fully parameterized three-dimensional model of a closed-cell stent design (Fig. 1). This approach provides the ability to systematically evaluate the effect of each parameter on the optimization results. Here, we focus specifically on stent strut dimensions; thus the two optimization parameters are ‘a’ and ‘b’ in Fig. 1 which represent the strut semi-height and semi-width, respectively.

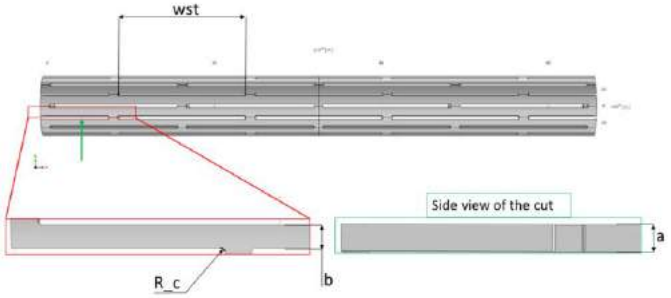

Figure 1: Stent design and parameters definition

The stent is assumed to be made of cobalt-chromium (CoCr). The initial

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

crimped stent diameter is 0.5 mm, and it is expanded to a final diameter of 4 mm, typical of a human coronary artery. The stent is expanded by applying a pressure to its inside surface. Instead of applying a constant pressure until the stent radius reaches the arterial radius, the computational expansion of the stent was accomplished via a step-by-step increase in the applied pressure. At every step, the stent radius was monitored, and pressure augmentation was arrested when the desired radius (corresponding to the arterial inner radius) was attained. At that point, the pressure was removed to obtain the final stent configuration. With this method we can precisely control the expansion of the stent at each step and evaluate the critical steps. The total expansion time is 1 sec.

We use the commercial finite element Multiphysics code COMSOL 5.1 to evaluate the stresses within both the stent and the arterial wall as the stent is expanded from the crimped configuration to its fully expanded state. The stent is assumed to exhibit elasto-plastic mechanical behavior with strain hardening. The artery is assumed to exhibit purely elastic behavior. The contact phase between the stent and the artery is simulated with the Lagrangian method and allows determination of the contact pressure and the contact surface area. We also solve the Navier-Stokes equations in the arterial lumen to evaluate stent-induced flow disturbance.

For the optimization, we use the surrogate management framework as described in our previous work to determine the combination of 'a' and 'b' that minimizes an overall cost function J that combines the effects of stresses in the stent, stresses in the arterial wall, stent-wall contact pressure, stent-wall contact surface area, and flow disturbance. Each of these five quantities are assumed to contribute equally to J so that:

$$J = \frac{1}{5} * (J_{MSS} + J_{MSA} + J_{CP} + J_{CS} + J_{FDI})$$

In this expression, J_{MSS} is the "Mechanical Stress in the Stent" score which describes the normalized average von Mises stress in the stent and is defined as:

$$J_{MSS} = \frac{1}{V_S}\int_{V_S} \frac{\sigma_{VonMises}}{\sigma_{CoCr}} dV \; (and \; (\frac{\max(\sigma_{VonMises})}{\sigma_{CoCr}} < 1$$

where V_s is the stent volume and σ_{CoCr} is the tensile strength of CoCr. J_{MSA} is the "Mechanical Stress in the Artery" score which denotes the average von Mises stress in the arterial wall and is defined as:

$$J_{MSA} = \frac{1}{V_A}\int_{V_A} \frac{\sigma_{VonMises}}{\sigma_{crit}} dV$$

where V_A is the volume of the arterial wall and σ_{crit} denotes a maximum arterial wall stress beyond which complications in re-endothelialization develop [5]. J_{CP} and J_{CS} are respectively the "contact pressure score" and the "contact surface area" score and are defined as:

$$J_{CP} = \frac{\max(P_{contact})}{P_0} \; (and \; J_{CS} = \frac{S_{contact}}{S_A}$$

where P_0 is the maximum pressure that can be supported by an artery and S_A is the arterial surface area. Finally, J_{FDI} denotes the "Fluid Disturbance Index" which describes the extent of stent-induced flow disturbance and is defined as:

$$J_{FDI} = \frac{1}{S_S}\int_{S_S} \left|\frac{\tau - \tau_0}{\tau_0}\right| dS$$

where τ is the local wall shear stress, τ_0 is the wall shear stress that would exist in the artery in the absence of a stent, and S_s, is the surface area of the stent exposed to the blood flow.

The optimization was performed in MATLAB using the function evaluations obtained from the COMSOL solid mechanics and fluid mechanics simulations.

RESULTS

Figure 2 depicts the dependence of the cost function J on the strut dimensions in the ranges 60≤a≤120 μm and 60≤b≤140 μm during the 1 second-long stent expansion process. The results indicate that very small dimensions need to be avoided while large b is generally desirable. In the present simulation, the global optimum (denoted by a red cross) is obtained for a=83 μm and b=140 μm. A secondary optimum (blue cross) is obtained for a=120 μm and b=140 μm. Future simulations will extend the range of dimensions studied.

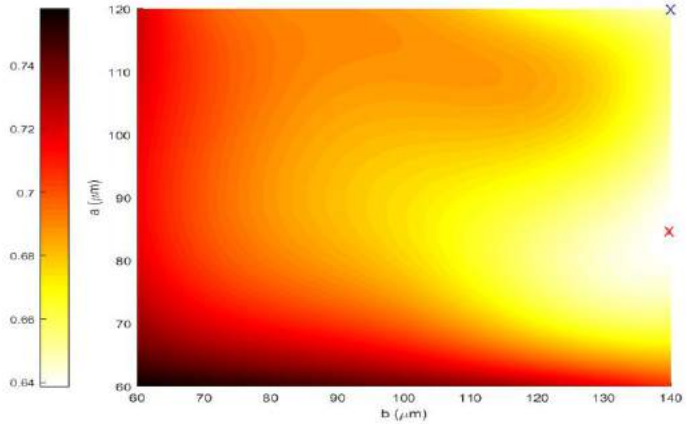

Figure 2: Cost function dependence on strut dimensions. Red and blue crosses respectively denote the global and secondary optima.

DISCUSSION

Mechanical evaluation of the interplay between the stent and the artery during stent deployment as performed in this study is an important consideration in the process of optimization of stent design and performance. While the goal of minimizing stent-induced flow disturbance in the arterial lumen pushes stent design towards thinner struts, the need for the struts to withstand the large mechanical stresses during the violent stent expansion process pushes the design towards thicker struts. The overall optimal strut design obtained in the present simulation is consistent with this notion as its dimensions are sufficiently large to ensure mechanical resistance but also minimize arterial flow perturbation. A secondary optimum is identified corresponding to struts sufficiently large to drastically minimize stresses in the stent but come at the expense of a certain level of flow disturbance. Performing similar simulations for larger range of strut dimensions will allow us to determine the optimal strut design. Moreover, a sensitivity study on local strut curvature ('R_c' in Fig. 1) and the length of bars between two nodes ('wst') will provide an assessment of a complete optimal stent design. All the simulations thus far have been performed on a closed-cell stent design. It would be important to expand the scope to also include open-cells stents.

INTRODUCTION

Congenital heart defects impact nearly 1 in 100 newborns worldwide [1]. The palliative surgical repair of single-ventricle congenital heart defects is achieved through the total cavopulmonary connection (TCPC), introduced by de Leval et al. in 1988. Extracardiac (EC) TCPC is a common surgical template where the superior vena cava (SVC) is connected to the superior aspect of the right pulmonary artery (RPA) and inferior vena cava (IVC) is anastomosed to the RPA by using a thin artificial conduit [2]. The typical conduit material, Polytetrafluoroethylene (PFTE; Gore-Tex, WL Gore & Associates, Newark), is widely used, in addition to the porcine pericardium and Dacron grafts. Earlier studies have shown that the geometric configuration of TCPC is the main factor in determining the hemodynamic efficiency and the total cardiac output [3]. Both *in vitro* experiments and computational fluid dynamics (CFD) studies have been conducted to investigate the patient-specific flow fields and efficiency in different TCPC templates [4-6].

Patient-specific studies that focused on TCPC hemodynamics are conducted entirely on "functional" conduits, which are acquired from patients having an optimal single-ventricle physiology. The severely kinked EC TCPC anatomical conduits are usually associated with patients at critical conditions and not recruited for research purposes due to the practical or ethical concerns. *In-silico* compressed and kinked conduit geometries are studied nevertheless through hypothetical buckling configurations [7] and attracted wide clinical attention [8]. Therefore the actual, less-than-optimal TCPC pathways can also lead to significant blood flow resistance and deserve a systematic analysis.

In this manuscript we designed a mock-up EC TCPC circuit to replicate the mechanically failed IVC anastomosis morphologies under static physiological venous pressure loading first time in literature. The sensitivity of hemodynamic performance to torsional buckling and conduit kink due to caval offset are digitized in three dimensions (3D) and employed in CFD simulations for efficiency estimates.

METHODS

The 3D shapes of possible EC TCPC conduit failure modes are generated under physiological systemic venous pressure conditions (9, 12, and 15 mmHg) using a static pressure mock circuit (Figure 1). The experimental set-up consists of articulated arms and allowed the replication of both the intraoperative caval offset and anastomosis twist angle simultaneously.

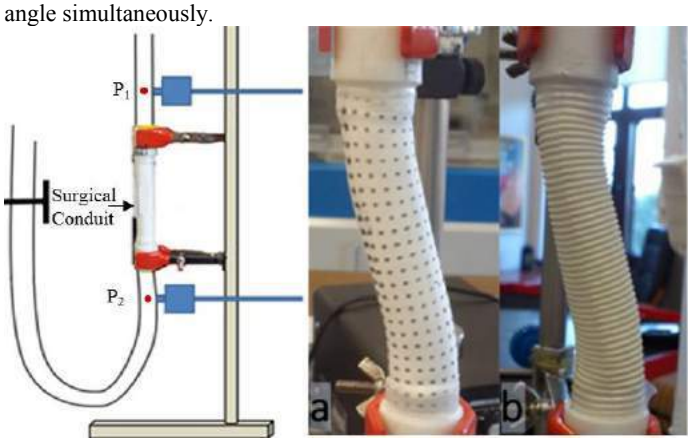

Figure 1. (Left) The static pressure mock-up setup for acquiring the 3D surgical pathway deformations (Right) PTFE (a) and Dacron (b) conduits at 0° twist and half diameter (0.5D) offset.

The mechanical behavior of all the three commonly used surgical materials, PTFE, Dacron and Porcine Pericardium, is studied in this mock circuit. Mechanical properties of the surgical materials are

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

measured using a biaxial test system (Bose). For the conduit-to-pulmonary artery anastomosis, three twist angles (0°, 30° and 60°) and three caval offset configurations (0, 0.5D, and 1D) resulted a total of 81 cases. However, for brevity, in this abstract we presented only 6 kinked conduit geometries of the PTFE material. Among these 6 geometries 2 of them are specifically selected by the pediatric cardiovascular surgeon due to their close resemblance to the real post-operative conduit geometries as observed intraoperatively.

3D scanned (Breuckmann SmartScan R5) geometries are reconstructed using Geomagic Studio (Raindrop Geomagic Inc). High-quality tetrahedral meshes are generated in Pointwise V16.04 (Pointwise, Inc.). The inlet and outlet boundaries of the CFD models are extended by 5 and 10 diameters, respectively. 3D, laminar, incompressible, and steady flow simulations are conducted using OpenFOAM (www.openfoam.org). All simulations are run until convergence to a steady-state solution (for a residual of 1E-6 in pressure, velocity and continuity). Parabolic velocity profile boundary condition is specified at the inlet extension of conduit with maximum velocity magnitude of 0.09136 m/s. [4]. Mesh convergence tests are done using the most buckled conduit geometry and the resulting mesh density is used for all geometries.

RESULTS

The observed buckling and kinked structures are considerably different for each surgical material. In PTFE, buckling is initiated proximal to the anastomosis locations of the conduit, which is different than Dacron and Porcine Pericardium grafts.

In order to analyze the effect of caval offset on IVC conduit buckling, 3 different offsets (0D, 0.5D and 1D) are specified under 15 mmHg pressure and 60° PA anastomosis twist angle (Figure 2). Clinically this pressure level corresponds to a problematic venous pressure state representing the maximum possible internal loading. In addition, configurations with 3 different twist angles (30°, 60°, and 90°) under 9 mmHg pressure having 0.5D offset are studied to illustrate the effect of anastomosis twist angle for the functional single-ventricle circulation (Figure 3).

For comparison the pressure drop values are reported relative to the ideal straight IVC conduit Poiseuille pressure drop levels (0.9Pa) along with the computed flow streamlines (Figure 2 and 3). The pressure drop increases nonlinearly with increasing offset level or angle of twist due to the buckling associated cross sectional narrowing. Also visible differences are observed in the flow field at 1D offset inside 15 mmHg pressure with 60° PA anastomosis twist angle (Figure 2) and 60° PA anastomosis twist angle under 9 mmHg pressure with 0.5D offset (Figure 3). In both cases fluid particles gathered momentum in radial direction and centerline velocity increased due to buckling.

DISCUSSION

An abrupt change in the pressure trend is observed between 0,5D and 1D offset configurations as displayed in Figure 2. 1D offset level resulted an increase in pressure drops up to 3 times compared to the 0D. Due to nonlinear relation between offsets, pressure drop for higher offset levels are ambiguous. It is also interesting to note that the configuration selected by the cardiovascular surgeon resulted the highest pressure drop for the offset level trend but not for the twist angle. Especially the surgeon's selected configuration for offset level may need to be revised in terms of our ongoing runs. Surgeon's selected configuration for twist angle can be accepted as consistent with relatively low pressure drop although it did not result the best.

IVC energy loss is calculated as %9 of total loss in an optimal TCPC flow with Poiseuille flow assumption. [3] Failed Fontan configurations with buckling and kinking produced more energy loss than expected which may be main source of energy loss in total TCPC configuration. Finally the relative twist and offset directions are an important factor, which affects final buckling severity significantly.

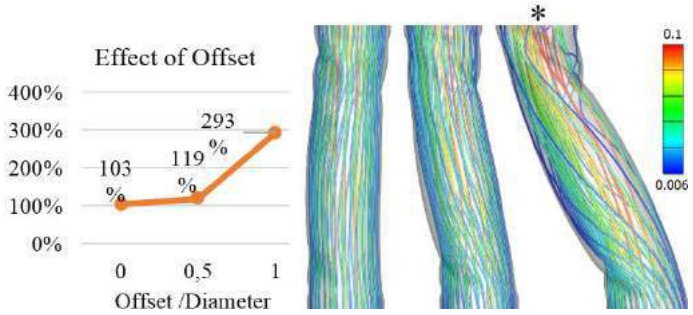

Figure 2. (Left) Pressure percent differences relative to straight conduit pressure drop for 3 different offsets under 15 mmHg venous pressure and 60° twist (Right) Coronal view of velocity magnitude (m/s) stream traces inside 15 mmHg pressure and 60° twist for 0D offset, 0.5D offset and 1D offset conduits are given respectively from left to right. The case identified by the surgeon is marked with a *.

In summary, we presented our recent results on the conduit failure modes. Ongoing studies include solving flow fields due to different conduit materials under variable buckling configurations. This way the effect of material and texture of conduit on pressure drop and flow characteristics will be disclosed. The simulations, in this study, were realized for rigid wall and steady state flow conditions. Repeating the simulations for compliant material under pulsatile flow would also contribute to more realistic results.

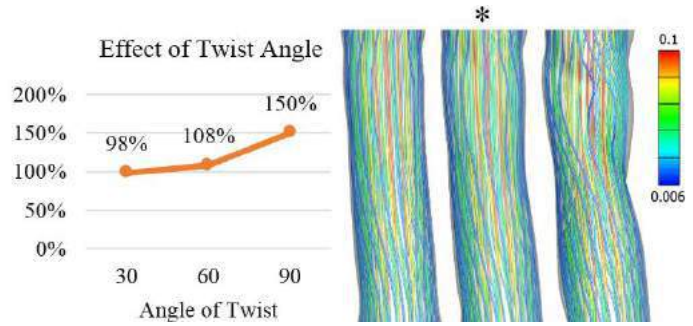

Figure 3. (Left) Pressure percent differences relative to straight conduit pressure drop for 3 different twist angles under 9 mmHg venous pressure and 0.5D offset (Right) Sagittal view of velocity magnitude (m/s) stream traces inside 0.5D offset with 9 mmHg pressure for 0° twist, 30° twist and 60° twist conduits are given respectively from left to right. INTRODUCTION

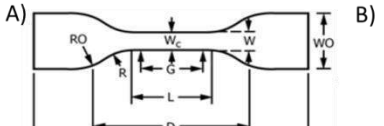
Despite the highest wait-list mortality in all of transplantation medicine (23% dying within 6 months of being added [1]), only recently has a pediatric ventricular assist device (PVAD), the Berlin Heart EXCOR, been approved for use in the United States for children of various sizes with congenital heart disease [2]. In 2004, the Pennsylvania State University was awarded one of five contracts by the National Institutes of Health (NIH) with the goal of creating a mechanical circulatory support device for children based on the successful adult pneumatic Pierce-Donachy/Thoratec device [3]. As part of developing a reliable PVAD, it is necessary to accurately predict the hemodynamics within the device due to higher hemolysis and thrombosis rates in PVADs compared to adult left ventricular assist devices (LVADs) [4].

To accomplish this, a tightly coupled fluid-structure-interaction (FSI) solver is required to accurately model the interactions of the air, a membrane and blood in the pneumatic pump. As a first step towards a full FSI model, an accurate representation of the PVAD's segmented poly-(ether polyurethane urea) (SPEUU) membrane needs to be developed. Polyurethanes are randomly segmented copolymers that consist of both hard and soft structural segments. This composition of polyurethane leads to unique mechanical properties including hyperelasticity, cyclic softening (the Mullins' effect), hysteresis, and time dependence [5]. Previous work has been done on the characterization of other polyurethane materials including polyurethane nanocomposites [6] and polyurethane foams [7]. However, due to the unique mandrel-layering process in which the Penn State PVAD SPEUU membranes are fabricated, specific material characterization needs to be performed and an appropriate constitutive model developed.

METHODS

To determine the hyperelastic and viscoelastic parameters of the PVAD membrane, two sets of tensile tests are conducted on "dog-bone" shaped samples cut from manufactured PVAD membranes according to ASTM D638 Standard Test Method for Tensile Properties of Plastics. According to the ASTM standard, all dimensions must be directly scaled when using a smaller sample, which was necessary due to the small size of the PVAD membrane (scale factor of 55/115 was used) (Fig. 1A). The PVAD membranes are manufactured to a thickness of 0.012'±0.002'. Therefore, digital calipers were used to measure the exact sample thicknesses prior to testing.



Dimension (in mm)	ASTM Standard	Actual
W-Width of narrow section	6	2.9
L-Length of narrow section	33	15.8
WO-Width overall	19	9.1
LO-Length overall	115	55
G-Gage length	25	12
D-Distance between grips	65	31.1
R-Radius of fillet	14	6.7
RO-Outer radius	25	12

Figure 1: A) Dog-bone sample test dimensions. B) Lloyd tensile device with SPEUU sample loaded.

All tests were performed on a Lloyd tensile testing machine with a load cell of 5N (Fig. 1B). Prior to data collection, 4 loading cycles were applied to each sample to eliminate the effects of cyclic softening and achieve a converged hysteresis loop (Fig. 2A).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

To determine the correct hyperelastic constitutive model for this material, uniaxial tensile tests were performed on 5 samples (Fig. 2B). The samples were loaded at a strain rate of 0.01 s^{-1} to a maximum strain of 0.25. The resultant stress vs. strain data were fit to six well established hyperelastic models (St. Venant-Kirchhoff, Neo-Hookean, Mooney-Rivlin, Yeoh, and both 2 and 3-constant Ogden models) using an in-house Matlab code (Fig. 2C). For non-linear visco-hyperelastic materials, the stress depends on both the time and strain (Eq. 1):

$$S(\lambda, t) = S(\lambda) * g(t) \qquad (1)$$

Where $S(\lambda)$ is the strain-dependent function determined later and g(t) is a time dependent function defined using a Prony series (Eq. 2):

$$g(t) = g_\infty + \sum_{i=1}^{n} g_i \cdot e^{-\frac{t}{\tau_i}} \qquad (2)$$

Where g_i represents characteristic amplitudes, τ_i relaxation times and n the number of relaxation times and amplitudes needed to describe the visco-hyperelastic response. To determine the amplitudes and relaxation times, stress relaxation tests were performed where each sample was loaded quickly (1 s^{-1}) to a strain of 0.25 and held fixed for 3 minutes (Fig 3A). The resultant stress vs. time data were fit to a Prony series using an in-house Matlab code (Fig. 3B).

RESULTS

The Mooney-Rivlin model (Eq. 3) was shown to have the best fit to four of the five SPEUU samples stress vs. strain loading data based on a least squares regression analysis and was chosen as the hyperelastic model for this material:

$$S_{MR}(\lambda) = \frac{2}{\lambda}(C_{10}\lambda^4 + C_{01}\lambda^3 - C_{10}\lambda - C_{01}) \qquad (3)$$

Where S is the second Piola-Kirchhoff stress and λ is the uniaxial stretch ratio. The constitutive coefficients, C_{10} and C_{01} were fit for each sample and averaged (3.58 and -2.34 MPa, respectively).

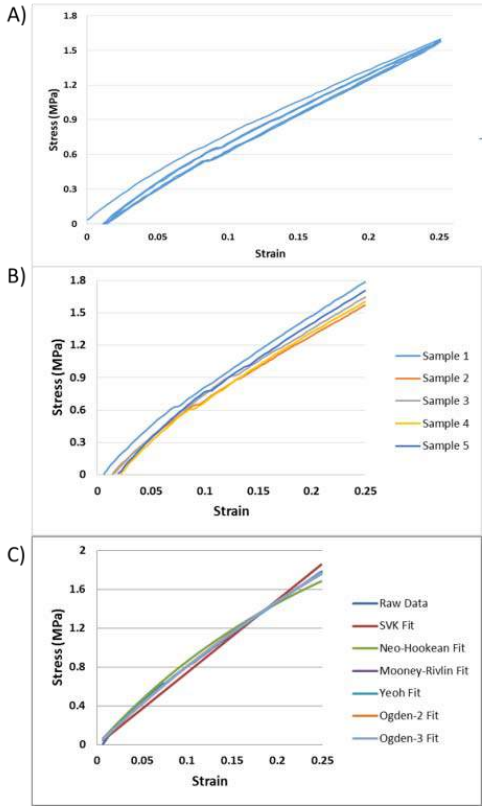


Figure 2: A) Example of SPEUU cyclic softening and hysteresis. B) Raw loading data of 5 SPEUU samples to a strain of 0.25. C) Hyperelastic model fits to single SPEUU loading curve.

A 4-term Prony series was chosen to fit the stress relaxation data and the characteristic amplitudes (1.65, 0.051, 0.050, 0.049 MPa) and relaxation times (1.11, 8.45, 110.91 s) were found individually for each sample and averaged.

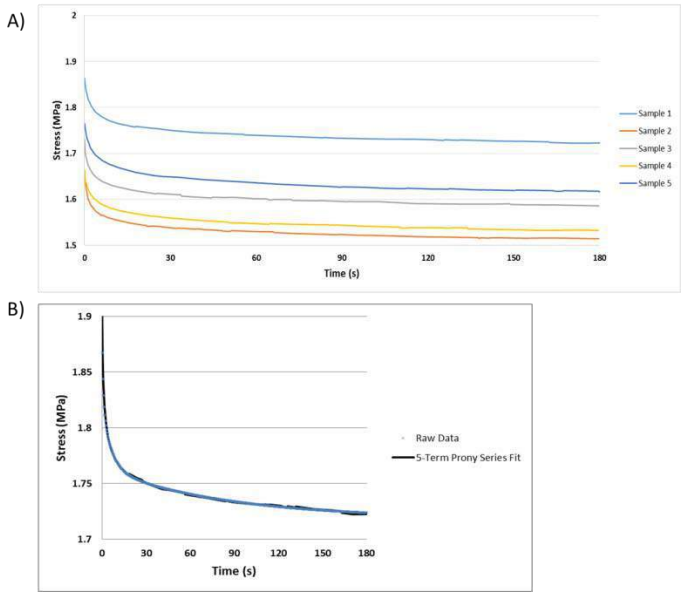

Figure 3: A) Raw stress relaxation data of 5 SPEUU samples held at a strain of 0.25. B) 4-term Prony series fit to a single sample's stress relaxation data.

DISCUSSION

The Penn State PVAD SPEUU membrane is a visco-hyperelastic material that can be accurately described using a Mooney Rivlin hyperelastic model and a 4-term Prony series model. Mooney-Rivlin hyperelastic models have been used previously by Donahue *et al.*[8] and Pawlikowski [6] for other polyurethane materials with coefficients of similar magnitude (~9 and -5 MPa for C_{10} and C_{01}, respectively). Prony series have also been used by many [6][9] to describe the time-dependent relaxation behavior of polymer materials in a similar manner and combined with a constitutive hyperelastic model. The constitutive visco-hyperelastic developed here will be used in a computational finite volume solid mechanics solver to simulate actual Penn State PVAD membrane dynamics. The cyclic stress-strain loading/unloading data from the five SPEUU samples will be used to validate the solid solver and constitutive model with the same dog-bone geometry prior to incorporation into a tightly-coupled FSI computational solver of the entire PVAD.

INTRODUCTION

The fetal/infant bone growth that occurs during pregnancy and lactation exert remarkable pressure on maternal calcium homeostasis, resulting in substantial loss of bone mineral density. Although bone formation dramatically increases following weaning, bone mass nevertheless cannot be fully recovered. This partially recovery has been demonstrated in the rat skeleton. Our previous studies show that compared to age-matched virgin rats, post-weaning rats had 60% lower trabecular bone volume fraction (BV/TV) in the proximal tibia and 10% lower cortical bone area in the femur midshaft. However, multiple studies indicate that the number of pregnancies and the duration of lactation have a neutral or even positive effect on long-term fracture risk [1-3]. This paradox implies that reproduction and lactation may lead to a functional adaption of the maternal skeleton in bone's structure and mechano-sensitivity, generating balanced skeletal responses to improve bone quality beyond bone quantity across different length scales. A few recent studies suggest that osteocytes can actively remodel their peri-lacunar matrix during lactation [4], which may alter material properties of peri-lacunar bone matrix, thus affecting skeletal mechano-sensitivity. Therefore, we hypothesized that bone tissue mechanical properties could be modulated by osteocyte peri-lacunar remodeling during female reproduction. The first objective of this study was to compare both short-term and long-term changes in mechanical properties of bone tissue at different length scales in response to reproduction and lactation. The second objective was to investigate the roles of osteocytes in modulating these changes and define changes in the osteocyte micro-mechanical environment during different reproductive stages.

METHODS

All animal experiments were approved by IACUC. *6-Month Old Rats:* Female, SD rats were assigned to 3 groups: Virgin (n=5), Lactation (n=5, euthanized 2-week post lactation), and Recovery (n=5, euthanized 2-week post weaning). All animals were sacrificed at age 6 months. *14-Month Old Rats:* Female, SD rats were assigned to 2 groups: Virgin (n=3), and Reproduction (n=3). Reproductive rats underwent 3 repeated cycles of pregnancy, lactation, and weaning. All animals were sacrificed at age 14 months. *μCT Scan:* Femurs were harvested from each rat at euthanasia and subjected to *ex vivo* μCT scanning (vivaCT40, Scanco, 10.5 μm voxel size) to assess cortical bone area (Ct.Area) at the mid-shaft. *3-Point Bending Test* was performed at the femur mid-shaft region (Instron 5542). The load-displacement curve was used to calculate whole bone stiffness. Combining the geometric and mechanical information, corrected Young's modulus was calculated with Timoshenko's correction factors to avoid shearing error. *Nanoindentation Test:* A ~3mm thick specimen was cut from the midshaft of the bended femur along transverse plane by using low speed diamond saw under irrigation. The specimen surface was manually polished with grain size 1 μm, 0.3 μm, until 0.06 μm in wet condition. Indentation tests were performed using a nanoindenter (Nano-XP, MTS) in a wet chamber with Berkovich tips (speed 10nm/s; indentation depth 500nm; 30-second holding time). The elastic modulus (E) and hardness (H) were calculated based on the unloading portion of the load-displacement

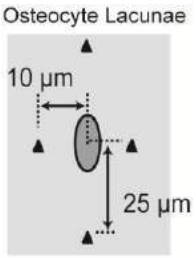

Fig 1. Indentations at 10μm vs. 25μm from the center of osteocyte lacunae.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

curve by Oliver-Pharr method. 8-10 osteocyte lacunae were chosen for each specimen. 2 indents were applied at 10-µm and 2 at 25-µm distance to the center of each osteocyte lacuna (Fig 1). *Statistics:* 2-way ANOVA with Bonferroni corrections was applied to compare groups and indentation distances in both 6-month rats and 14-month rats. Differences were considered significant when $p<0.05$.

RESULTS

6-month-old rats: Ct.Area were 13% and 10% lower in the Lactation and Recovery groups, respectively, compared to the Virgin group (Fig 2A), indicating that the femoral cortical bone volume was significantly reduced by reproduction. However, 3-point bending tests indicated no reproductive effect on the whole bone stiffness between Virgin, Lactation, and Recovery rats (Fig 2B). Interestingly, nano-indentation tests revealed that bone matrix tissue modulus in the Lactation group was 5% and 10% higher than Virgin and Recovery groups, respectively (Fig 2C), while the indentation hardness in the Lactation group was 5% higher than both Virgin and Recovery groups ($p < 0.05$). By stratifying indentation modulus based on their distance to the center of lacunae, we found that elastic moduli at 10 µm ($E_{10\mu m}$, within peri-lacunar space) and 25 µm ($E_{25\mu m}$, interstitial bone region) had no difference in the virgin group. In contrast, $E_{10\mu m}$ was 3% lower than $E_{25\mu m}$ in the lactation group, while in the recovery group, $E_{10\mu m}$ was 7% greater than $E_{25\mu m}$. Furthermore, the ratio of $E_{10\mu m}$:$E_{25\mu m}$ in the recovery group was significantly greater than those in the Virgin and Lactation groups (Fig 2D). No difference of hardness (H) or brittleness (E/H) was found in different distances. *14-month-old rats:* No difference was found in the femoral Ct.Area and whole bone stiffness between the virgin rats and rats with reproduction history (Fig 2A-B). However, average indentation modulus was 4% higher in the Reproduction group than the Virgin group (Fig 2C), while the indentation hardness was not different in these two groups. No difference between $E_{10\mu m}$ and $E_{25\mu m}$ was found in Virgin or Reproduction group. Furthermore, the ratio of $E_{10\mu m}$:$E_{25\mu m}$ was not different between two groups (Fig 2D). No difference of hardness (H) or brittleness (E/H) was found either in two groups or different distances.

DISCUSSION

This study investigated both short-term and long-term changes in bone mechanical properties in response to reproduction and lactation. Lactation dramatically reduced cortical bone area in rat femur, and this reduction persisted after weaning. However, whole bone stiffness was preserved in both lactating and post-weaning rats, likely through altered material properties of bone tissue. Further tests by nanoindentation suggested that nano-scale bone tissue modulus and bone tissue hardness significantly increased during lactating, which may compensate for the reduced bone area to preserve whole bone mechanical properties. Despite smaller bone area and lower nano-scale elastic modulus, whole bone stiffness of post-weaning rats was not different from that of the virgin rats. Therefore, further tests at different length scales, such as microindentation tests, may be necessary to elucidate tissue level mechanisms to preserve whole bone mechanical properties in post-weaning bone. Moreover, our study also demonstrated significant tissue-level changes in rats with multiple reproduction cycles, suggesting reproduction history may exert long-term effect on bone tissue composition and mechanics. Additionally, the decrease of $E_{10\mu m}/E_{25\mu m}$ over the course of lactation and the increase of $E_{10\mu m}/E_{25\mu m}$ over the course of recovery suggest that osteocyte may have ability to directly remodel its local surrounding bone tissue to generate positive or negative gradient of material properties during different stages of a reproductive cycle. For example, during lactation, the peri-lacunar material properties would temporarily decrease. This could be caused by fast release of calcium ions from peri-lacunar matrix, mediated by osteocyte remodeling. In contrast, during weaning, the osteocytes may actively deposit minerals and accelerate mineralization at the peri-lacunar region, causing higher material properties. This alteration may have influence on the tissue deformation and strain distribution in the peri-lacunar bone region [5], thus affecting osteocyte signaling. However, even though osteocyte remodeling has an important influence on the heterogeneity of bone tissue properties, this local mediation itself cannot account for the overall changes in tissue-level mechanical properties, *e.g.*, increased elastic modulus during lactation. Further explorations are required to uncover the mechanism behind bone tissue adaptation to reproduction and lactation.

LABORATORY EVALUATION OF WEARABLE HEAD IMPACT SENSORS

Abigail M. Tyson, Steven Rowson, and Stefan M. Duma

Department of Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, VA, USA

INTRODUCTION

As many as 3.8 million sports-related concussions are estimated to occur each year in the United States [1]. While acute symptoms may persist for days to weeks following a concussion, recent research has suggested repetitive concussive and subconcussive impacts may result in long-term neurodegeneration [2]. Diagnosis is dependent upon an athlete's self-reporting of symptoms, yet over 50% of athletes fail to do so after a concussion [3]. To provide an objective measure of head impact magnitudes, companies have developed wearable head impact sensors for on-field play. Although sensors themselves cannot diagnose a concussion, they can provide additional information on impact severity to a medical professional who can properly assess for injury.

Researchers are also interested in wearable head impact sensors to shed further light on the biomechanics of concussions. Men's football has been extensively studied over the past 13 years using a helmet-mounted sensor system, yet little work has investigated head impacts in women and children [4]. The introduction of new sensors for unhelmeted sports have the potential to provide valuable data on these understudied populations.

With a surge in wearable impact sensors coupled with increasing knowledge of the potential risks of sport-related concussions, it's possible that most athletes will be wearing sensors within the next five to ten years. Unfortunately, the accuracy and reliability of these sensors are not regulated. The objective of this study was to define and implement laboratory methods as the initial phase of a head impact sensor evaluation program. Sensors with minimal error in ideal conditions as shown by these tests will be further evaluated in more realistic scenarios: on-field and cadaver tests. The combination of both ideal and realistic testing phases will be used to provide an overall sensor evaluation for both researchers and consumers.

METHODS

Impacts were performed to both an unhelmeted and helmeted NOCSAE head, custom fit to a Hybrid III neck, mounted on a linear slide table. Tests were conducted with a pendulum impactor having a flat impactor face made of 40 mm vinyl nitrile for the unhelmeted condition and flat, rigid nylon for the helmeted condition. A large Riddell Speed helmet (Elyria, OH) was worn during helmeted tests. Impacts were performed to the front, front boss, rear boss, and rear locations of the headform (Figure 1) at targeted linear head accelerations of 25, 50, 75, and 100 g.

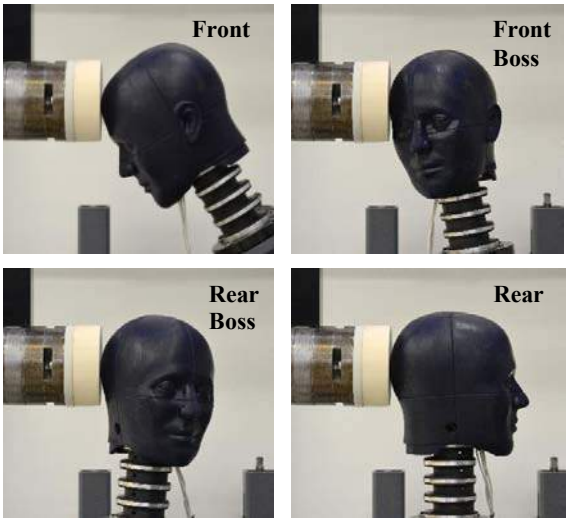

Figure 1: Headform orientations for the four impact locations. Only the unhelmeted setup is shown.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Impact locations were chosen based on frequency of occurrence in sports [5], variability in elevation, and equal spacing in azimuth. Impact magnitudes were chosen to represent the range of impacts in sports [6]. For consistency, reference values were verified to remain within ± 5 g of the target acceleration value. Each test configuration was repeated four times, totaling 64 tests per sensor.

Six commercially-available wearable head impact sensors were tested under this protocol: xPatch (X2 Biosystems, Seattle, WA), Vector Mouth Guard (i1 Biometrics, Kirkland, WA), SIM-G (Triax Technologies, Norwalk, CT), gForce Tracker (gForce Tracker, Markam, ON), Shockbox (i1 Biometrics, Kirkland, WA), and HeadsUp Headband (Integrated Bionics, Houston, TX). Hereafter, the sensors will be referred to as X2, Vector MG, Triax, GFT, Shockbox, and HeadsUp. Sensor acceleration and velocity measurements were compared to reference data measured by three linear accelerometers and three angular rate sensors (6DX Pro 2k-18k 6DOF sensor package DTS, Seal Beach, CA) located in the headform center of mass.

Sensors were positioned on the headform or helmet according to manufacturer instructions except for the Vector MG. Since the NOCSAE headform is not currently adapted for a mouth guard, the sensor was firmly adhered to the front of the headform at a 90° angle. However, this rotation was insignificant to results since only resultant data were used. Sensors were only tested under helmeted or unhelmeted conditions corresponding to sports recommended for use by the manufacturer. All sensors output at least peak linear acceleration. X2, Vector MG, Triax, and GFT also measured peak rotational kinematics and time-varying responses for each impact.

Reference headform kinematics were processed using MATLAB 2014a and filtered at CFC 1000 for linear acceleration and CFC 155 for rotational velocity. Comparisons between sensors and reference were obtained by fitting least squares linear regressions to peak values and obtaining the slope and R^2 coefficient of determination for each kinematic variable. To equally compare slope and R^2 values among sensors, regressions were constrained through the origin.

For the sensors that also record a time-varying kinematic response, comparisons were made at each time point. Sensor and reference curves were aligned by minimizing the root mean square (RMS) error:

$$RMS = \sqrt{\frac{\sum\left(x_{ref} - x_s\right)^2}{n}} \quad (1)$$

where x_{ref} is the kinematic value for the reference, x_s is the kinematic value for the wearable sensor, and n is the number of points in the time series. RMS error was then normalized by the peak reference value of the curve to compare sensors equally. Average and standard deviations of normalized RMS error (NRMSE) were calculated for each test condition. All calculations were made in MATLAB 2014a.

RESULTS

Results from linear regressions for each kinematic variable are shown for each sensor and test condition (Table 1). Perfect accuracy and correlation would result in a slope of 1.00 and R^2 of 1.00. Most sensors performed best in rotational velocity and worst in rotational acceleration. The variables for X2, Vector MG, and Helmeted GFT with low overall R^2 values had high individual location correlations above 0.9. The remaining sensors had low correlations overall and by location. Shockbox and Heads Up also failed to record 14% and 25% of the 64 tests, respectively.

NRMSE followed similar trends to the slope and R^2 values, with rotational velocity having the lowest error and rotational acceleration having the highest. X2 and Vector MG remained within 15% error for most test conditions. The remaining sensors had test conditions exhibiting mostly within 10-50% error, with some reaching over 100%.

Table 1: Slope (m) and R^2 coefficient of determination for the least squares linear regressions for each kinematic variable.

Sensor	LA		RV		RA	
	m	R^2	m	R^2	m	R^2
Unhelmeted X2	1.05	0.98	1.01	1.00	1.65	0.61
Helmeted X2	1.02	0.86	0.99	0.95	1.41	0.13
Vector MG	0.80	0.70	1.04	1.00	1.47	0.73
Unhelmeted Triax	1.06	0.25	1.12	0.93	0.46	-0.56
Helmeted Triax	0.94	0.15	1.15	0.79	0.72	0.19
Unhelmeted GFT	0.73	-0.24	0.65	0.42	-	-
Helmeted GFT	0.38	0.39	1.06	0.89	-	-
Shockbox	1.60	-1.19	-	-	-	-
HeadsUp	0.54	-0.73	-	-	-	-

DISCUSSION

These laboratory methods make up Phase I of a two-phased approach to evaluate wearable sensors. Phase II consists of on-field tests and cadaver tests that will better evaluate each sensor under more realistic conditions which have been shown to affect sensor performance [7].

There were several factors that increased the error of these sensors. Physical factors included sensor-helmet interactions for X2 and Triax and poor coupling between the headband and headform for GFT. Computational factors included low sampling rates introducing error throughout the calculations of rotational acceleration from differentiated rotational velocity. Imperfect rotational accelerations were then used to transform linear accelerations to the headform center of gravity, decreasing the accuracy in those measurements as well.

Although all sensors will always have some inherent error, data can still be valuable in quantifying concussive head accelerations and defining head impact exposure in sports. This is especially true for analyses that take into account the error measured in this study and are applied across the vast amount of data that could be collected.

This study demonstrates that head impact sensor accuracy and reliability vary greatly between commercially available products, and highlights the need for objective and public data characterizing sensor quality. By creating an objective two-phased evaluation of these sensors, consumers and researchers can be informed of their differences and manufacturers can be encouraged to create a product that will become a valuable tool to aid in the identification of head impacts in sports.

INTEGRATION OF A BAROREFLEX MODEL INTO A WHOLE BODY PHYSIOLOGY ENGINE

Rachel B. Clipp, PhD, M. Cameron Thames, MS, Jeffrey B. Webb, MS, Rodney Metoyer, Jr MS, Zachary M. Swarm, BS, Aaron M. Bray, BS, and Jenn N. Carter, BA

Raleigh, NC, USA

INTRODUCTION

Baroreceptors are stretch receptors located in the aortic arch and carotid artery. Changes in mean arterial pressure (MAP) trigger the stretch receptor leading to the baroreflex response. The baroreflex response is a negative feedback response that changes the peripheral resistance of the vascular system, the heart rate, and the elastance of the heart to modify the MAP. [1] The response is not only crucial for blood pressure regulation during normal daily function, but also in critical trauma scenarios, such as hemorrhage. During hemorrhage, blood loss causes the blood pressure to drop, triggering a baroreceptor response to attempt to maintain a healthy MAP. [2]

The BioGears physiology engine is a whole body open source physiology model currently used in medical training and teaching protocol and environments. The engine currently lacks a baroreceptor response, which is a significant detriment when teaching trauma care. It is of critical important that the cardiovascular response is accurate and meets validation for these cases to teach correct behaviors in trainees. The lack of the baroreceptor response is a significant limitation in the BioGears engine.

Current work exists in the form of a baroreceptor model in Ottenson, et al [3][4].This model was implemented within a full body physiology model to produce accurate physiologic outputs from the cardiovascular, respiratory, and endocrine systems that currently exist in the BioGears engine.

METHODS

The baroreflex response is calculated from the portion of the response related to the parasympathetic (Eq. 1) and sympathetic response (Eq. 2). .

$$n_p(mpa) = \frac{1}{1+\left(\frac{mpa}{mpa_{sp}}\right)^{-\vartheta}} \quad (1)$$

$$n_s(mpa) = \frac{1}{1+\left(\frac{mpa}{mpa_{sp}}\right)^{\vartheta}} \quad (2)$$

Where mpa is the calculated mean arterial pressure (mmHg), mpa_{sp} is the mean arterial pressure set point (mmHg), ϑ is the slope of the response curve (unitless) and was specified to be 12.0.

The mpa_{sp}must be calculated not just from the healthy patient set point but must also include the changes caused by patient activity, exercise, or drug modifications, such as morphine administration, Eq. 3.

$$mpa_{sp} = mpa_{psp} + \Delta mpa_{drugs} + \Delta mpa_{ex} \quad (3)$$

Where mpa_{psp} is the healthy patient set point (mmHg), Δmpa_{drugs} (mmHg) and Δmpa_{ex} (mmHg) are the change in the set point due to drug effects and exercise, respectively.

This baroreflex model includes changes to peripheral resistance, venous compliance, heart rate, and heart elastance. The time-dependent changes are based on strength of the parasympathetic and sympathetic tone and the time constant for response. Otteson, et al [3] also incorporated an unstressed volume effect, which was not incorporated in the BioGears engine. The current Cardiovascular System does not track unstressed volume, so there was no method for linking these effects. The four effects modeled here are shown in Eq. 4-6.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\frac{dx_{HR}}{dt} = \left(\frac{-1}{\tau_{HR}}\right)(-x_{HR} + \alpha_{HR} n_s(mpa) + \beta_{HR} n_p(mpa) + \gamma_{HR} \quad (4)$$

$$\frac{dx_{E,R}}{dt} = \left(-\frac{1}{\tau_{E,R}}\right)(-x_{E,R} + \alpha_{E,R} n_s(mpa) + \gamma_{E,R} \quad (5)$$

$$\frac{dx_C}{dt} = \left(-\frac{1}{\tau_C}\right)(-x_C + \beta_C n_p(mpa) + \gamma_C \quad (6)$$

Where $x_{E,C,R,HR}$, are the elastance (mmHg/mL), venous compliance (mL/mmHg), resistance (mmHg/mL/s), and heart rate (beats/s), respectively, τ is the time constant (s), n_p and n_s are the parasympathetic and sympathetic responses (unitless), respectively, and α and βare the sympathetic and parasympathetic response parameters, and γis the damping parameter. The units for α, β, and γ are the same units as x.

The time-constant values for each variable were used from Otteson, et al [3]: τ_{HR}, τ_E, τ_C, and $\tau_R$were set to 10, 10, 60, and 30 s, respectively. The sympathetic and parasympathetic response parameters and the damping parameter were tuned to achieve the correct response. To validate the responses, a hemorrhage scenario was used. A hemorrhage was applied at a rate of 1000 mL/min for 30 seconds, providing a total blood loss of 500 mL. The heart rate, blood pressure, systemic vascular resistance, and cardiac output were observed over the course of the hemorrhage and during the baroreflex response, and compared to the experimental data.

RESULTS

The tuned parameters for each effect are shown in Table 1.

Table 1: Response and Damping Parameters.

Variable	BioGears
$\alpha_{HR}, \beta_{HR}, \gamma_{HR}$	1.73, 0.25, 0.26
α_E, γ_E	0.1, 0.95
β_C, γ_C	0.6, 0.7
α_R, γ_R	1.2, 0.4

The strength parameters dictate the effect magnitude as MAP changes (Figure 1).

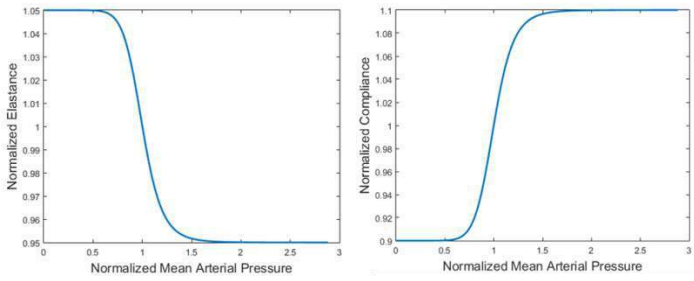

Figure 1: ***The changes to heart elastance and venous compliance as the mean arterial pressure changes.***

The validation case study was based on a 10% hemorrhage (500mL) over 30 seconds. The time dependent data for cardiac output, blood volume, heart rate, and systemic vascular resistance are shown in Figure 2.

There is an expected 30% increase in heart rate, 15-20% decrease in cardiac output and 10-15% increase in systemic vascular resistance [2]. Figure 2 shows that for this blood loss, the baroreflex model integrated with the BioGears engine was able to achieve a 7% increase in systemic vascular resistance and an 18% increase in heart rate. While these fall short of the expected values, they do exhibit the required trends for a baroreflex model.

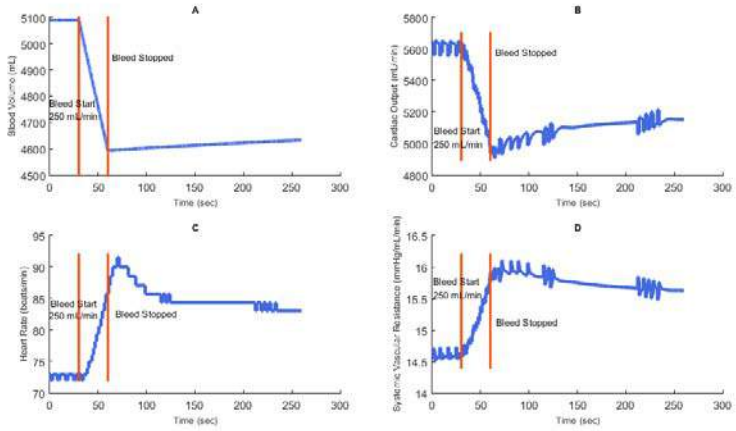

Figure 2: ***The baroreceptor response leads to an increase in heart rate and systemic vascular resistance in an attempt to maintain arterial pressure.***

DISCUSSION

Integration of the Ottenson, et al model was successfully accomplished. The model was a good fit using the constantly changing MAP from the BioGears Cardiovascular System. The tuned parameters were in line with those previously published. The model was further advanced by incorporating the effects of the drug and exercise models in BioGears. Without incorporating these effects, the baroreflex response would override any drug effects in the system causing an inaccurate solution. The addition of the baroreflex model in BioGears creates a more powerful overall model for calculating the physiologic response to trauma on the body.

Two limitations of this model are the lack of any unstressed volume effects and the inability to reach the desired magnitude of the responses for heart rate and systemic vascular resistance. These may both be tied to the over compliant vasculature of the cardiovascular model. The high compliance leads to issues with the central venous pressure when the heart rate and vascular resistance responses were increased. By incorporating unstressed volume in the model, the compliance may be reduced, allowing for a more accurate baroreflex model to be integrated. In addition to addressing these limitations, further nervous system features, such as the chemoreceptor response and general parasympathetic and sympathetic effects should be included in the whole body physiology engine to accurately model trauma to the human body.

INTRODUCTION

Congenital heart disease affects over 1.35 million newborns annually worldwide [1] with heart transplantation the only option for many. The use of mechanical circulatory support devices has been shown to decrease wait list mortality and improve the efficiency of organ utilization in children [2], however, the Berlin Heart EXCOR is currently the only approved pediatric ventricular assist device (PVAD) for use in the United States [3]. In 2004 the National Institutes of Health (NIH) started the National Heart, Lung and Blood Institute (NHLBI) Pediatric Circulatory Support Program and awarded five contracts with the goal of creating mechanical circulatory support devices for children ranging from 2-25 kg [2]. One of those contracts was awarded to Penn State for the development of a pulsatile PVAD based on the adult pneumatic Pierce-Donachy/Thoratec device.

PVADs are most commonly attached via an end-to-side anastomotic graft to the ascending aorta of the patient. One of the long-term failure methods of these grafts, however, is intimal hyperplasia (IH) occurring on the heel and toe of the anastomosis. Good *et al.*, in a computational fluid dynamics study, previously studied the hemodynamics and pulsatility of end-to-side anastomotic graft flow in a pediatric aortic model under both pulsatile and continuous PVAD support conditions [4]. This study showed significantly increased pulsatility with pulsatile support compared to continuous support. Additionally, other studies have shown the benefits of increased pulsatility to improved blood flow to the brain [5], kidneys [5], heart [6] and liver [7] in pediatric and neonate patients. The simulations by Good *et al.* were performed under the assumption of synchronized heart and PVAD beating which is rarely the case, however, with the Penn State PVAD. This device is most often run in "automatic mode" where as soon as the PVAD is filled, the next systolic phase begins after a 30 ms delay. The result is that the diastolic time and PVAD beat rate can vary substantially from beat to beat. Therefore, to fully understand the range of hemodynamics and resultant aortic pulsatility that can occur clinically, a range of asynchronous beating conditions need to be studied.

METHODS

A pediatric patient's aorta (NIH-Georgia Tech Fontan Database ID: CHOP007) is reconstructed using magnetic resonance imaging. To represent the outlet graft of a PVAD, a curved pipe (6 mm diameter) is attached to the ascending aorta in an end-to-side anastomosis configuration. A viscoelastic blood model designed specifically for pediatric blood was previously developed and validated [8] for different physiological hematocrits. For this study, the 40% pediatric hematocrit model is used.

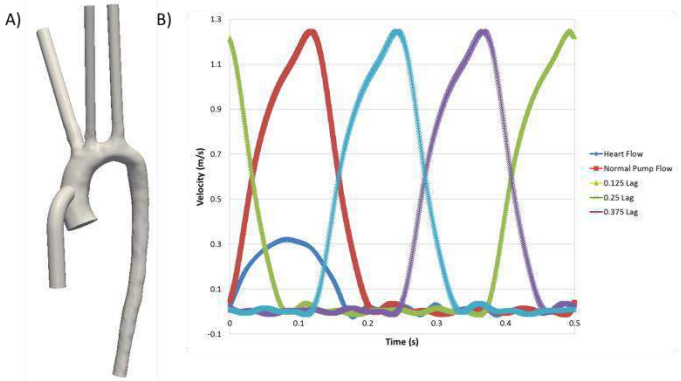

Figure 1: A) Pediatric aortic model with attached PVAD cannula. B) Heart and four PVAD waveforms used in study.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

To study the effect of asynchronous heart and PVAD pumping, physiological pediatric waveforms acquired from an *in vivo* study of PVAD function in infant animal models [9] were applied at the inlets of the ascending aorta and PVAD cannula. Both waveforms are scaled to a beat rate of 120 beats per minute and flow rate of 0.5 liters per minute. In the first case, both waveforms are synchronized while in cases 2-4, the PVAD waveform is shifted 90˚ (0.125 s), 180˚ (0.25 s) and 270˚ (0.375 s) out of phase, respectively (Fig. 1).

To compare the pulsatility generated from each of the flow conditions, the surplus hemodynamic energy (SHE, ergs/cm^3) [10] is calculated at each of the inlets and outlets (Table 1). SHE is a measure of the extra energy generation from a flow pulsation (Eq. 1) and is based on the difference between the energy equivalent pressure (EEP, mmHg) (Eq. 2) and time-averaged pressure (TAP, mmHg) (Eq. 3):

$$\mathrm{SHE} = 1332(EEP - TAP) \quad (1)$$

$$\mathrm{EEP} = \frac{\int_0^T p \cdot Q \cdot dt}{\int_0^T Q \cdot dt} \quad (2)$$

$$\mathrm{TAP} = \int_0^T p \cdot dt \quad (3)$$

Where Q is the boundary flow rate (L/min) and p is the boundary pressure (mmHg). The hemodynamic parameters of time-averaged wall shear stress (TAWSS, dyne/cm^2) (Eq. 4) and oscillatory shear index (OSI) (Eq. 5) are important for vascular remodeling and were also compared between the different flow conditions.

$$\mathrm{TAWSS} = \frac{1}{T}\int_0^T WSS \cdot dt \quad (4)$$

$$\mathrm{OSI} = \frac{1}{2}\left(1 - \frac{\left|\frac{1}{T}\int_0^T WSS \cdot dt\right|}{\frac{1}{T}\int_0^T |WSS| \cdot dt}\right) \quad (5)$$

RESULTS

EEP, TAP and SHE are calculated for each inlet and outlet of the pediatric aorta model (Table 1). The highest pulsatilty (SHE) for each boundary occurs during the fully synchronized PVAD flow. For all of the outlets, (brachiocephalic, left common carotid and left subclavian arteries and descending aorta), SHE decreases as the PVAD's systole is shifted further away from the heart's systole. Approximate percent decreases in SHE of 58% are seen between the synchronized and 90˚ phase shift flows, 64% between synchronized and 180˚, and 67% between synchronized and 270˚.

Table 1: Pulsatility Parameters

		Synchronized Flow	90˚ Shift	180˚ Shift	270˚ Shift
Aortic Inlet	EEP	77.59	65.75	65.91	67.03
	TAP	62.74	62.14	61.72	61.82
	SHE	19780.08	4799.05	5572.32	6935.87
Cannula Outlet	EEP	79.46	72.90	68.84	68.30
	TAP	63.93	63.38	62.83	62.93
	SHE	20685.94	12678.62	7999.36	7145.75
Brachiocephalic	EEP	75.64	67.51	66.28	65.90
	TAP	61.75	61.63	61.31	61.40
	SHE	18504.89	7820.60	6626.43	5994.28
Left Common Carotid	EEP	74.73	67.00	65.90	65.51
	TAP	61.38	61.40	61.09	61.20
	SHE	17784.17	7459.01	6408.60	5747.43
Left Subclavian	EEP	73.23	66.12	65.14	64.87
	TAP	60.93	61.08	60.72	60.83
	SHE	16379.04	6718.10	5883.50	5371.88
Aortic Outlet	EEP	60.87	59.50	59.06	59.30
	TAP	58.27	58.38	58.37	58.34
	SHE	3474.38	1491.09	924.79	1279.82

High regions of OSI (> 0.2) indicate flow separation, retrograde flow and are prone to the development of IH. Three primary regions of high OSI are present in all of the PVAD flow conditions: on the floor of the anastomosis, on the toe downstream of the anastomotic graft and between the aortic branches (Fig. 2). All three of the asynchronous cases have higher OSI regions on the anastomotic floor and downstream of the anastomotic toe compared to the synchronized case with the 90˚ shifted flow experiencing the highest at each (0.44 and 0.48), respectively.

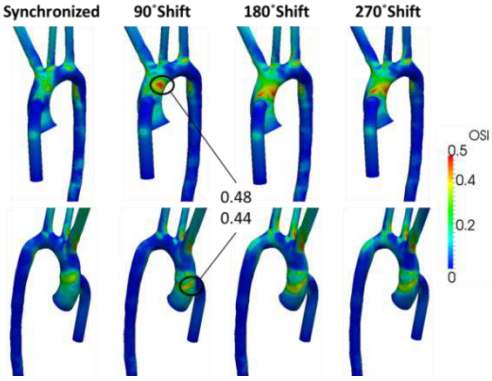

Figure 2: OSI from all four flow conditions.

Anastomotic graft failure has also been linked to increased stress at both the toe and heel. Large differences in TAWSS were seen near the anastomotic junction for all flow conditions with peak TAWSS occurring at the toe region in all cases. The highest TAWSS was during synchronized flow (528 dyne/cm^2) with TAWSS decreasing at the toe region for each of the asynchronous flows: 476, 426, and 432 dyne/cm^2, respectively.

DISCUSSION

Due to the automatic pumping of the Penn State pneumatic PVAD, it is important to study the hemodynamic and pulsatility parameters that can occur over the range of heart and PVAD flow combinations. Previous studies [4][11] have shown that synchronized pulsatile bypass leads to 5-10% decreases in SHE compared to a healthy pediatric patient at the aortic branches. However, due to the more common asynchronicity of the PVAD flow, the decrease in pulsatility is much more significant and could lead to problems in the patient's peripheral organ development. Additionally, the higher regions of OSI in the PVAD asynchronous flows just downstream of the anastomotic toe could lead to even higher rates of long-term graft failure than previously predicted.

INTRODUCTION

Piezoceramic transducers (PZTs) have been widely used in industry to evaluate mechanical impedance of materials.[1] Imposing a constant voltage on a PZT exerts a constant force on the transducer, and it causes a PZT to vibrate when the PZT is connected to an alternating electric field. On the contrary, a vibrating PZT can produce output voltage signals; when these signals are analyzed by an I/O electronic circuit board, the impedance of the transducer can then be calculated based on the measured voltage and current. When the PZT is bonded with a testing material specimen, the impedance measured reflects the structural features of the specimen. In industry this is often used as a non-destructive evaluation (NDE) method for defect detection. Compared to other NDE techniques such as ultrasound, acoustic emission, x-ray, and thermography, PZTs have been considered cost-effective and user-friendly because of its simplicity and effectiveness in those applications.

In a previous study,[2] we have developed a low cost acoustic impedance device coupled with an I/O electronic circuit board and software to excite a PZT and record the generated electric signals. This device has been tested in fiberglass epoxy composites, wooden samples, and polymer specimen with an embedded crack. It has been shown that the device can detect the presence, shape and approximate dimension of the defect area.

In this study we test the performance of this device on detecting tumors embedded in agarose gels. Our hypothesis is that the structural and composition difference between the tumor and the gel would sufficiently result in variation in the measured acoustic impedance, and consequently can be used to detect the presence of the tumor located below the gel surface. The surface contour of the normalized impedance is mapped by scanning the device on the surface. The results are compared to the actual locations of the embedded tumors.

METHODS

Figure 1 shows the inner components of the transducer, consisting of: (1) a PZT disk of 10.2 mm in diameter and 2.0 mm in thickness (PZT-5A, American Piezo Ceramics, Mackeyville, PA), (2) a flexible copper clad laminate, (3) a frame manufactured by 3D printing, and (4) coaxial cables connected to an impedance evaluation board (AD5933 board, Analog Device Corporation, Norwood, MA). The board serves as both the actuator and the recorder of the electric signals. The experimental setup is shown in Figure 2.

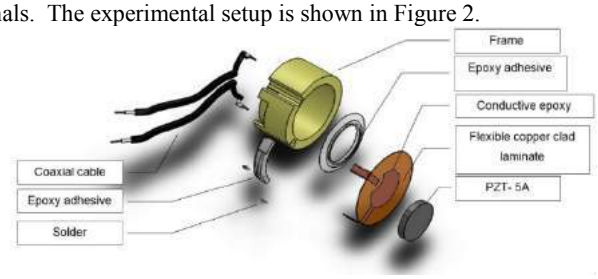

Figure 1: Exploded view of PZT transducer

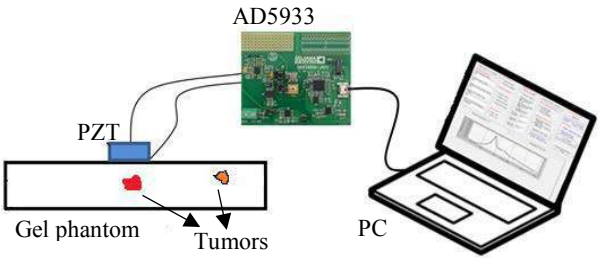

Figure 2: The experiment setup

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Typically, the measured impedance is strongly affected by the frequency of the imposed alternating voltage. As shown in Figure 3, a plot of the impedance can be constructed via activating the transducer and recording the responses over a range of the frequency of the voltage. Among all frequencies, there is a peak impedance occurring at the resonance frequency of f_{res}. The impedance at the resonance frequency of the transducer bonded with a specimen (ΔZ in Figure 3) is compared to that of the transducer unloaded, i.e., in air (ΔZ_0 in Figure 3). The bonded specimen will influence the ratio $\Delta Z/\Delta Z_0$, therefore, a surface contour of the ratio can be plotted to show structural variation of a specimen for defect screening.

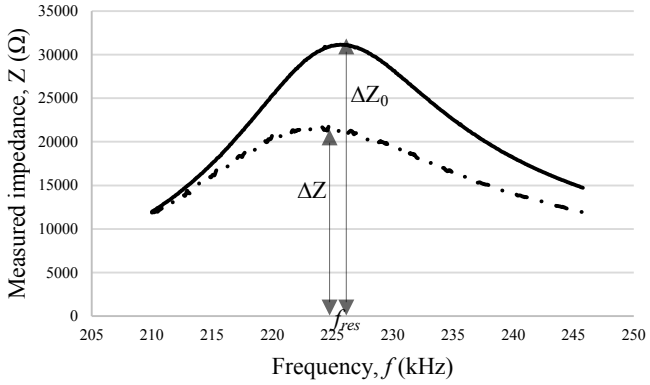

Figure 3: Impedance versus frequency for a loaded (ΔZ) and unloaded transducer (ΔZ_0)

A phantom gel (1% m/m) is prepared by dispersing agarose powder (Sigma-Aldrich, Saint-Louis, MO) in a 10% buffer solution (Tris-Borate EDTA, Gibco BRL, Rockville, MD).[3] The mixture is then heated until the agarose is completely dissolved. After being cooled at room temperature to 60°C, the solution is loaded into a container and cooled further to room temperature (25°C) until solidification. Four prostatic tumors are placed inside the container before the pouring in order to ensure that no bubbles or air gaps are formed in the gel. Tumors 2 - 4 are approximately 10 mm in diameter and tumor 1 is 20 mm in length and 10 mm in width. Tumor 1 is embedded 2 mm beneath the gel surface, tumors 2 and 3 are located deeper in the phantom gel (10 mm), and tumor 4 is the most deeply located in the group (20 mm from the surface). The total surface area to be scanned by the PZT device is 220 mm by 220 mm, gridded in 10×10 mm squares. Note that the actual surface area is much bigger, and we only scan the middle region of the surface to avoid the edge effect. A weight of 50 g is placed on the top of the transducer in order to ensure good and consistent contact between the transducer and the gel surface. The acoustic impedance at the resonance frequency is determined at each gridded square, resulting in a matrix of 22×22 of $\Delta Z/\Delta Z_0$ to cover the gel surface.

RESULTS

Figure 3 also gives the actual experimental recordings of the dependence of the impedance on the imposed frequency. The resonant frequency without loading is identified as 225 kHz. Although the resonant frequency may be affected by the structure of the specimen, the value of f_{res} with the specimen varies slightly in this study (222 kHz – 230 Hz). The impedance magnitude vs frequency curves with or without specimen attachment suggest that the deviation of the ratio of $\Delta Z/\Delta Z_0$ from unity is most evident at the resonant frequency. The ratio at this specific gridded square is 0.7.

The contour of the ratio $\Delta Z/\Delta Z_0$ mapped on the gel surface is presented in Figure 4. $\Delta Z/\Delta Z_0$ varies from approximately 0.70 to 0.86. The ratio at the location without tumor is very uniform, varying slightly as 0.850±0.007, implying repeatability of the sensor. The sensor fails to detect tumor 4; however, it could accurately locate the other three tumors. The gridded squares close to tumor 1 show the lowest ratio of 0.7 - 0.75, while presence of tumors 2 and 3 results in a relatively higher $\Delta Z/\Delta Z_0$ of 0.79, which is still below that of the normal gel of 0.85. The red circles in Figure 4 represent the actual tumor locations and shape. Tumor 4 is not detected because of its depth. Tumor 1 is the most evident; this may be due to the fact that it is located closer to the gel surface and has the largest size in the group.

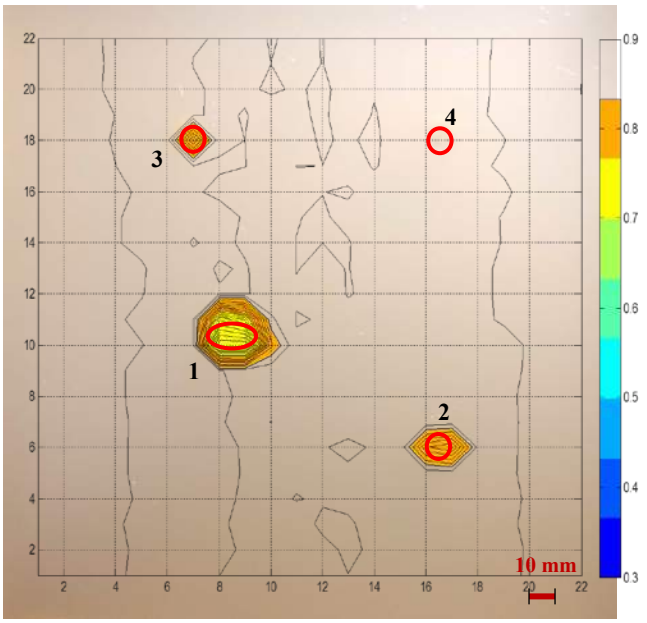

Figure 4: Superimposition of the tumors (red circles) and the contour plot of $\Delta Z/\Delta Z_0$ on the phantom surface.

CONCLUSIONS

In summary, we have developed and prototyped a PZT device for defect screening. The PZT device is tested to evaluate its potential for screening tumors in biomedical applications. In this preliminary study, we could correctly identify three of the four tumors embedded in a gel specimen. The detection fails when the tumor is located more than 10 mm below the gel surface. The results suggest that structural difference between prostatic tumors and normal gels is sufficiently large to generate detectable impedance variation, and demonstrate the feasibility of this approach when the tumor is located close to the surface and/or the tumor is big. Future studies are planned to further improve the device and assess its performance in detecting tumors embedded in actual tissue.

MODULATION OF ICE FORMATION CHARACTERISTICS DUE TO ADDITION OF TREHALOSE IN CRYOPROTECTANT

Jason Solocinski, Mian Wang, Quinn Osgood, Aaron Connolly, Nilay Chakraborty

Mechanical Engineering Department
University of Michigan Dearborn
Dearborn, MI, USA

INTRODUCTION

Cryopreservation is an important technology that is important to multitude of biomedical engineering technologies including tissue engineering and biotechnology. It is the only established mechanism to preserve cells and the technique involves subjecting the cellular samples to extremely low temperatures (-180°C), arresting nearly all cellular activity. However, the difficulty in the methodology arises from the fact that unprotected freezing typically results in lethal effect on cellular samples. Therefore cryoprotectants (CPAs), such as glycerol, dimethyl sulfoxide (DMSO), and polyethylene glycol have been used to aid the cells in surviving the cryoprocessing steps. A short review of cryopreservation protocols indicate that a solution of 10% DMSO is frequently used as CPA. However, most CPAs, including DMSO, are natively toxic at non-cryogenic temperatures. Reduction of CPA toxicity is an active area of research in cryobiology. Recently homologous disaccharides such as trehalose have been used as an additive to DMSO to obtain improved cryopreservation outcome. Herein, we study the biophysical effect of addition of such an additive to CPA, with a view to optimize preservation solutions using vibrational Raman microspectroscopy.

The technique of confocal Raman microspectroscopy is a highly sensitive spectroscopic technique, which when combined with hyperspectral imaging techniques can provide great insight of the molecular state and arrangement of a substance under different conditions. Therefore, coupling the techniques of low temperature microscopy with spatially correlated confocal Raman microspectroscopy the effects of addition of trehalose to CPA formulations can be characterized from a molecular point of view. In this study, high-resolution hyperspectral imaging technique was used to quantify and measure the spatial distribution of different contents (ice, DMSO, and trehalose) in freezing media at low temperatures. Special attention was paid to the effect of trehalose concentration on the formation and distribution of ice crystals during the freezing process.

METHODS

A 10% (v/v) DMSO solution was prepared in phosphate buffered saline. 300 mM α,α-trehalose was dissolved in the 10% DMSO solution to study the effect of use of trehalose as an additive.

The Raman measurements were conducted using a high-throughput confocal microscope and Raman microspectrometer combination (WITec GmbH, Germany). Raman spectra were collected using a high-sensitivity EMCCD camera (Andor Scientific, Belfast UK). A 532nm solid-state laser was used for excitation and images were collected using a 10X objective.

A custom-built stage adaptor was used to integrate a freezing stage cooled by liquid nitrogen (Linkam Scientific, Surrey UK) with the microscopy setup. The temperature of the CPA samples (10μL volume) was lowered in a controlled fashion (1°C/min) while collecting the spectral information at either -40°C or at -80°C. Hyperspectral scanning of the CPA solution was performed using a dimension of 50x50μm^2 with a spectral pixel area of 100x100. Each array scan was collected using an integration time of 0.3s. Following background subtraction and processing of the spectral cubes, the hyperspectral images of ice formation were generated by integrating the characteristic spectra of identified ice peaks. Each experiment was repeated 3 times and the confocal Raman images presented here are representative.

RESULTS

A visual analysis of the ice crystals formed in CPAs indicates that the pattern of ice crystal formation depends on both temperature and

CPA composition. At -40°C, the 10% DMSO freezing solution forms large ice crystals [Average area (A_{ave}) =~60μm^2] with sharp and angular boundaries, indicating that the ice crystals are fully developed. However, when 300 mM trehalose was added to 10% DMSO, the ice crystals have extraordinary round boundaries with significantly smaller area (A_{ave}=~22μm^2).

At -80°C, ice crystals have a relatively uniform distribution, and the same decreasing trend of crystal sizes for samples at -40°C. However, for 10%DMSO +300 mM trehalose at -80°C, the structures of ice crystals are more distinguished than the others: the ice crystals are extremely small (A_{ave}=~8μm^2) while forming a characteristic network-like structure.

While Figure 1 shows the hyperspectral images of the ice crystals, Figure 2 shows the distribution of ice and DMSO. Ice and DMSO demonstrate a mutual spatial exclusion. Trehalose, however, exists in both ice and DMSO dominant areas. In order to study the effect of trehalose on ice formation and exclude the influence from DMSO, a detailed spectral analysis was undertaken. The Raman spectra of the red line were collected from the position containing relatively high amounts of both DMSO and trehalose. The Raman spectra of the blue line was collected from the position where is bright in Fig.(2)-Ice, but dark in Fig.(2)-Trehalose, indicating relative high amount DMSO (or Ice) but low amount of trehalose. By comparing the Raman spectra of red line and blue line, it is found that the existence of trehalose did decrease the intensity of ice peak (~3130cm^{-1}), This finding suggestive of a mechanistic inhibition of ice crystal formation by trehalose.

DISCUSSION

It is widely believed that the cellular injury at low temperatures originate from two very different mechanisms that are determined by the rate of cooling [1]. At low cooling rates, the sharp rise of non-physiological extracellular osmotic environment (unfrozen mix) contributes to what is known as 'solution effects injury' [2]. At higher cooling rates the predominant injury mechanism is thought to be due to formation of lethal intracellular ice formation. While the rate of increase of osmolality of the unfrozen mix is a function of ice formation, we believe that the nature and characteristic of ice crystals formed [3, 4] during cooling also has an important role to play to modulate solution effects injury.

While homologous disaccharides such as trehalose are known for their osmoprotective capabilities, herein we demonstrate their ability to actively influence ice formation characteristics of CPAs, which in turn can influence solution effects injury mechanism during cryoprocessing.

Based on Figure 1 and Figure 2, it is suggested that the area of ice crystals decrease for the following two factors: concentration of trehalose increase and decrease of temperature. Furthermore, addition of trehalose results in ice crystals distribution having increased uniformity.

The low temperature microspectroscopic approach described here can provide valuable insights for optimization of the technique of cryopreservation at large. Preliminary research into cellular viability and metabolics suggest that trehalose introduced as an additive to standard CPAs has a beneficial impact over DMSO alone.

Figure 1: Confocal Raman Image of 10% DMSO solution with 0mM and 300mM trehalose separately at two different temperatures; -40 °C and -80 °C. All the images are generated by integrating the ice peak (~3140cm^{-1}) from Raman spectra. The stronger brightness of the area means the higher intensity of ice peak in Raman spectra.

INTRODUCTION

Recent randomized control trials have provided convincing evidence regarding the benefit from sentriever-mediated mechanical thrombectomy for appropriately selected acute ischemic stroke (AIS) patients.[1-3] The latest generation of clot retrieval systems are an effective AIS treatment, however, the use of clot retrievers can cause release of clot fragments. This may help explain why clinical outcomes lag technical success rates.

Our hypothesis is that the safety of thrombectomy devices as indicated by the risk of embolic shower may potentially be altered by the use of adjunctive devices that serve to encapsulate the occlusive clot. The objective of this study is the characterization of distal emboli generated during Solitaire thrombectomy in combination with the Lazarus Cover device (Medtronic Neurovascular, Irvine CA). The Cover is a nitinol braided mesh that inverts over the stentriever as it is extracted and closes around the stent to trap the clot within the device (Figure 1). It is compatible with the smaller and more navigable 5 or 6 Fr access systems, as compared to the stiff and large balloon guide catheters (8 to 9 Fr access) recommended for this procedure.

Figure 1: (A) The Cover device. (B) Clot debris is retained within the Cover device during clot

METHODS

A model system composed of a human vascular replica, clot model, and mock circulation flow loop was used for simulation of mechanical thrombectomy (Figure 2). A small-batch manufacturing process was used to build the vascular replica.[4] The vascular replica was modified to include the internal carotid artery (ICA), posterior communicating artery (PComA), anterior cerebral artery (ACA) and middle cerebral artery (MCA). The MCA had an average of 3mm and two M2 divisions joined distally to form a single output.

A hard, fragment-prone clot model was produced by clotting bovine blood using thrombin (2.5 NIHU thrombin/mL blood) and adding barium sulfate (1g/10mL blood). A 4mm x 5mm clot was injected into the silicone replica to form an MCA occlusion.

The silicone replica was connected into the flow loop with continuous monitoring of flow and pressure in the MCA to ensure that physiologically accurate flow rates were maintained. The flow loop contained a peristaltic pump, which was used to deliver saline via oscillatory throughout the system. Compressor clamps provided peripheral resistance; by adjusting the clamps, baseline flow conditions were matched to normal human phase contrast MR measurements for each vessel. Saline flowing through the MCA and the ACA was collected for particle analysis. Clot fragments greater than 1000μm were manually separated from the sample with a pipette and the number and Feret diameter of each fragment was recorded. Emboli smaller than 1000μm were characterized using a Coulter counter (Multisizer 4; Beckman Coulter, Brea CA).

Apertures with diameters of 400μm and 2000μm were employed in order to provide a complete particle size distribution analysis (8-1000μm). Five bin categories were used for analysis of distal emboli: fragments with diameter >1000μm, 200-1000μm, 100-200μm, 50-100μm, and 8-50μm. Repeat measurements from a single experiment for the smaller particles were reported as average, while the number of clot fragments with size >200μm were summed due to the infrequency of observation.

Three treatment strategies were tested, namely (1) Solitaire thrombectomy through an 8Fr Cello balloon guide catheter (BGC;

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Medtronic neurovascular) with the tip placed in the cervical ICA (CONTROL #1); (2) Solitaire thrombectomy through a 6Fr Envoy conventional guide catheter (CGC; Cordis, Miami Lakes, FL) with the tip placed at the cervical ICA (CONTROL #2); and (3) Solitaire thrombectomy with the Lazarus cover device deployed. In both of the control groups, aspiration was performed during thrombectomy using two 25cc syringes connected to a 3-way stopcock through either the BGC or the CGC. Aspiration was not performed in the Cover group. After deployment of the Solitaire, the microcatheter was removed and the rapid-exchange Cover was delivered to the proximal MCA. The Cover device became unsheathed as the guide catheter was withdrawn. Eight experiments were carried out in each group, and the maximum number of thrombectomy attempts was limited to three per experiment.

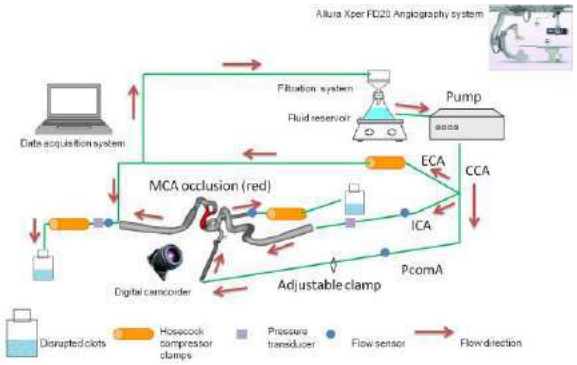

Figure 2: The schematic illustration of the flow loop.

RESULTS

Total number of distal emboli:

Figures 3A shows that, on average, mechanical thrombectomy with the BGC reduced the total embolic particle creation by 2-fold compared to the CGC technique ($p>0.05$, Kruskal-Wallis test). The BGC technique offered a 1.6-fold improvement in the total number of emboli compared to the Solitaire with Cover technique ($p>0.05$, Kruskal-Wallis test). Importantly, it should be noted that 99% of the emboli had a size <200µm (average size: 9.4µm) (Figure 3B).

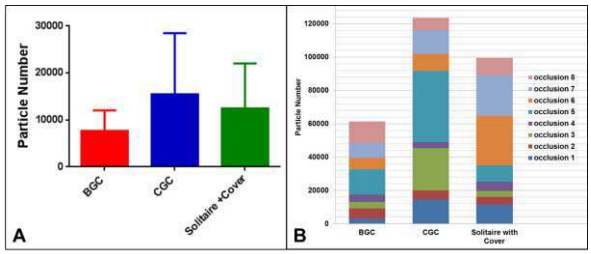

Figure 3: (A) Quantitative measurement of all clot fragments (>8 µm) produced during mechanical thrombectomy. (B) A stacked column graph shows the total number of emboli with size between 8-200µm generated during the procedure.

Number of emboli with size >1000µm:

The rate of forming clot fragments >1000 µm from the hard clot model was increased with the use of the CGC ($p<0.05$, Kruskal-Wallis test) (Figure 4A). Formation of large emboli with size greater than 1000µm occurred in 7 out of 8 cases in the CGC group, versus 2 or 3 out of 8 cases in the other groups. There was no significant difference in the number of large emboli (> 1000µm) between the BGC and the Solitaire with Cover ($p>0.05$, Kruskal-Wallis test). The size of these clot fragments ranged from 1mm to 5mm.

Number of emboli with size between 200-1000µm:

Similarly, in the size range between 200-1000µm, thrombectomy with the use of CGC generated the most number of distal emboli compared to all the other treatment strategies ($p<0.05$, ordinary one-way ANOVA) (Figure 4B). It appeared that for emboli with size between 200-1000µm, the Cover device was comparable to the BGC and superior to the CGC approach. The average size of the clot fragments within this size range was 237.4µm.

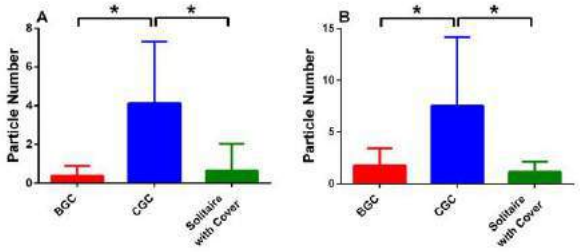

Figure 4: Comparisons of emboli number (Figure 4A: >1000µm, Figure 4B: 200-1000µm) between 3 different clot removal strategies.

Number of emboli with size between 8-50µm, 50-100µm, and 100-200µm:

On average, in the size range between 8-50µm, mechanical thrombectomy via BGC generated the least amount of clot fragments, followed by Cover and CGC ($p>0.05$, Kruskal-Wallis test). The Solitaire/Cover system, as compared to the BGC, was more efficient in reducing the risk of 50-100µm and 100-200µm clot fragmentation ($p>0.05$ in both size ranges, Kruskal-Wallis test).

Distribution of clot fragments:

Approximately half of the disrupted clots with size greater than 1mm were found in the previously unaffected area (ACA, 55%) in the CGC group, versus 40% in the Solitaire with cover group and 33% in the BGC group. On average, 80% of the clot fragments with size between 200-1000µm travelled through the MCA. In the size range between 8-200 µm, the clot fragments were evenly distributed into the MCA and ACA regardless of the treatment approaches (47% in the ACA versus 53% in the MCA).

DISCUSSION

The results of this in-vitro study demonstrate that the new treatment approaches, the Lazarus Cover, is comparable to the BGC technique in terms of risk of distal embolization. The Cover technique is statistically superior to the CGC method in several hard clot subgroups of clinical relevance. If emboli protection with the Cover is translated clinically, this technology could provide a significant advantage to the standard BGC in terms of access size and navigability (current BGC devices are stiff and require 8 or 9 Fr access). Without aspiration, thrombectomy with the Cover allows continuous flow restoration during the clot retrieval procedure. In conclusion, the risk of embolic shower can potentially be altered by the use of adjunctive devices that serve to encapsulate the occlusive clot. When encountering hard clot, the use of the Cover may reduce the risk of distal embolization and may be considered.

INTRODUCTION

As the first developing organ, the heart produces flow- and pressure-derived mechanical stress that provides critical feedback to cardiovascular cells. Due to the importance of stress to development, *in vivo* cardiovascular flow has been analyzed in a number of embryonic animal models [1]. However, pressure, which produces circumferential stress, has been given much less attention, despite its importance in cardiovascular modeling and remodeling.

Explicit pressure estimates can be used to non-invasively quantify the pressure field based on velocity field data. One approach is to integrate the pressure gradient in the momentum equation [2,3]:

$$\partial_i P = -\rho\left(\frac{\partial u_i}{\partial t} + \partial_j u_j u_i + \nu\left(\partial_k \partial_k u_i\right)\right), \quad (1)$$

where P is pressure, ρ is the fluid density, u_i is the ith component of the velocity vector, and ν is the kinematic viscosity. This method has been proven accurate for moving boundaries in biological flow, but has been primarily used for high Reynolds number (Re) [2].

Here, we use the pressure estimate in Eq. 1 to quantify the wall shear stress (WSS) and circumferential stress in the developing heart based on micro-particle imaging velocimetry (μPIV) data in a zebrafish embryonic model. We apply this technique at 48 hours postfertilization (hpf). This period of mid-cardiogenesis is especially vulnerable to stress because the morphology of the organ is rapidly changing as cardiac looping and chamber ballooning proceed [4].

METHODS

Wild-type zebrafish (Danio rerio) fertilized eggs were collected, incubated, and dechorionated at approximately 24 hpf. Embryos were imaged under a bright-field stereomicroscope (Olympus SZX12). Images were acquired at 1500 fps with a resolution of 1310 pixels/mm using a high speed camera (Photron FASTCAM SA3).

The pressure field for this study is quantified by integrating Eq. 1. Each integration path, extending circumferentially, begins at a node and ends at a fluid-solid boundary, Fig. 1A. Similar to Liu and Katz, we use the mean value of multiple integration paths [3]. The mean value is updated in multiple iterations until the pressure field converges to a solution, as defined by a maximum pressure residual of less than $1x10^{-3}$. A first order upwind spatial integration method is used for the pressure integration. We assume a Newtonian viscosity of 8 mm^2/s after evaluating multiple alternative non-Newtonian models.

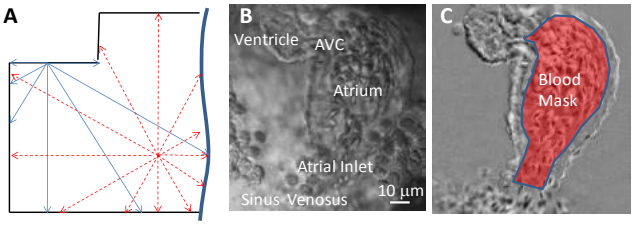

FIGURE 1: A) Pressure integration paths single nodes to a fluid-solid boundary. B) A raw image of the embryonic heart at 48 hpf with anatomical labels. C) Mask applied to the heart image after background subtraction to define a region of fluid.

2D μPIV is used to quantify the entire flow field of the atrium through DaVis 7.2 software (Lavision, Germany), Fig 1B. An ensemble average of the velocity field is taken for 5 cardiac cycles through the cross correlation of 4 image pairs at each cycle. A mask is used to reduce bias error in velocity calculations, Fig. 1C. Cross-correlation vectors are obtained with a 16x16 pixel interrogation

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

window, followed by an 8x8 interrogation window, both with 50% overlap. The final pass interrogation window approaches the size of erythrocytes, which are used as the seeding particle for the fluid domain. Erythrocytes as a seeding particle can result in an underestimation of the centerline velocity, but are used to minimize the invasiveness of our technique.

Lamé's equation is used to estimate spherical stress in the cardiac wall, assuming an incompressible Hookean material [5]:

$$\sigma = \frac{PR_i^3}{R_o^3 - R_i^3}\left(\frac{2r^3 + R_o^3}{2r^3}\right), \quad (2)$$

where r is the atrial radius, while R_i and R_o are the inside and outside radius respectively. We aim to extend the analysis without the limiting assumption of a Hookean material. Furthermore, we assume that the pressure outside of the heart is approximately equal to pressure at the sinus venosus.

Lastly, we calculate WSS at the atrioventricular canal (AVC) since it may provide a critical cue for valve formation:

$$WSS = \frac{\Delta P}{L}\frac{R_i}{2}, \quad (3)$$

where $\Delta P/L$ is the pressure gradient across the AVC. Eq. 2 is obtained from a basic control volume analysis of flow in the AVC.

RESULTS

Velocity across the atrial inlet and the AVC are shown in Fig. 2A over the course of the cardiac cycle [mapped on a scale of 0-1.0, with 0 representing the onset of atrial systole]. Velocity is calculated through a technique we previously developed [6]. The figure shows an initial increase in velocity across the AVC, which occurs as the atrium contracts. The peak velocity is ~5 mm/s, corresponding to a Re=<v>D/ν of 0.017 and a Womersley number, $\alpha=D(\omega/\nu)^{1/2}$ of 0.014, assuming a viscosity of 8 cP. Subsequently, the AVC closes off, stopping flow across it. Simultaneously, the atrium begins expanding as blood flows through the atrial inlet. The velocity reaches a peak of ~3 mm/s as the atrial inlet, corresponding to a Re of 0.012 and a α of 0.015. Comparatively, velocity vectors obtained through μPIV are shown in Fig. 2B at a time period of 0.2. The peak velocity across the AVC is 4 mm/s, as opposed to 5 mm/s seen through spatiotemporal plot analysis used for Fig. 2A. Pressure contours are also plotted in Fig. 2B, demonstrating that there is a 0.2 mmHg pressure drop across the AVC at a period of 0.2. The plotted pressure is relative to an arbitrary value.

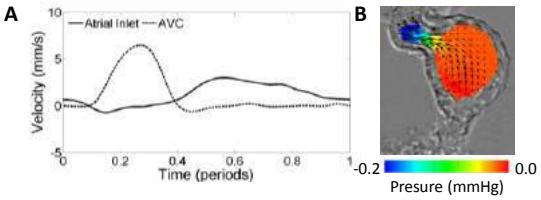

FIGURE 2: A) Velocity with respect to time at the atrial inlet and at the AVC. b) Velocity vectors and pressure contours at a time period of 0.2, corresponding to the beginning of atrial systole.

Pressure is used to estimate circumferential stress and WSS from Eq. 2 and 3 respectively. Circumferential stress is plotted from the endocardium to the myocardium at the middle of the atrium at a period of 0.2 in Fig. 3. Circumferential stress reduces from ~0.3 mmHg at the endocardium to ~0.3 mmHg at the myocardium. Comparatively, the peak WSS from Eq. 3 is 40 dynes/cm^2 or 0.03 mmHg at the AVC.

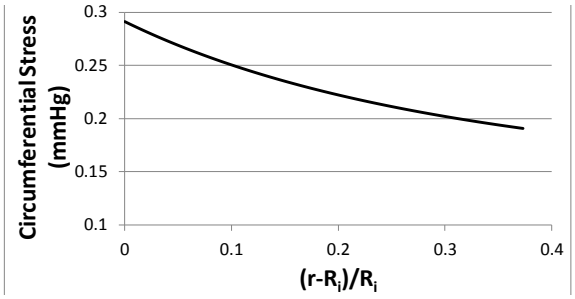

FIGURE 3: Circumferential stress from the endocardium (0) to the myocardium (0.37).

DISCUSSION

This is the first study to our knowledge to estimate stress and pressure in the developing heart through empirical noninvasive imaging. We also show that the atrium appears to contract uniformly creating a uniform pressure in the atrium, thereby creating a bolus of blood that enters the ventricle.

In the current study, we show that the pressure drop across the AVC can reach ~0.2 mmHg during atrial systole. In comparison, the peak pressure drop across the AVC in a chick embryo for a similar stage in development is ~0.2-0.3 mmHg [7, 8]. Therefore, our pressure estimation matches closely with physically measured values. The pressure drop across the AVC is also approximately equal to the gauge pressure in the atrium, justifying its use for Eq. 2.

Our circumferential stress calculation matches well with a computational model from Taber et al. [9]. They approximate the peak circumferential stress as 0.5 mmHg. Also, our WSS value matches well with Jamison et al., who show a value of 40 dynes/cm^2 at 72 hpf [10]. Therefore, our values provide reasonable estimations of circumferential stress and WSS despite the numerous assumptions behind Eq. 2 and 3.

Our study is limited to a 2D analysis. Therefore, there can be an error in our pressure estimation due to out-of-plane flow. We calculated the velocity divergence to determine where this effect is most prominent and we found this to occur at the AVC. Furthermore, we assume highly simplified geometry and simplified conditions for Eq. 2 and 3. Despite this, our results match well with the literature. Also, our μPIV calculation depends on a large seeding particle and viscosity is difficult to define.

The current results can be extended to estimate stress throughout development to relate morphological changes to changes in stress, which is an important step in defining mechanotransduction during cardiac development.

REMODELING BY FIBROBLASTS ALTERS THE RATE-DEPENDENT MECHANICAL PROPERTIES OF COLLAGEN

B. Babaei (1), A. Davarian (2), K.M. Pryse (2), W.B. McConnaughey (2), E.L. Elson (1,2), G.M. Genin (1)

INTRODUCTION

Interactions between living cells and their mechanical environments are central to a host of physiologic and pathologic events ranging from development to metastatis to wound healing. Fibroblasts remodel their extracellular neighborhood considerably when activated, stiffening and compressing their extracellular matrix (ECM) environment [1, 2]. During remodeling, fibroblasts secrete ECM proteins, including collagens, proteoglycans, glycoproteins, and proteases, and cross-linking proteins and enzymes [1, 3]. This remodeling changes the tissue as a whole by establishing a network to link and organize individual cells [4]. Rate-dependent mechanical responses underlie the progression of critical pathologies such as fibrotic cardiomyopathy and congestive heart failure. Although several studies have estimated the effects of this remodeling on ECM elasticity, little is known about the viscoelastic effects of ECM remodeling.

The goal of this study was to quantify how fibroblasts modulate ECM viscoelastically and contribute to tissue mechanics viscoelasticity. We studied these effects by performing viscoelastic relaxation tests on engineered tissue constructs (ETCs) at three different time points. ECM viscoelasticity was evaluated by treating ETCs with deoxycholate, a mild detergent which dissolves cell membranes and disperses cytoplasmic structures such as the cytoskeleton. Tests were interpreted using a discrete spectral generalized Maxwell approach [5], which yields both elastic moduli and viscoelastic relaxation finite time constants. Results showed that cells actively adapted the ECM, and that cells relax at multiple timescales, including one that is fast compared to those of the ECM.

METHODS

Engineered tissue construct (ETC) preparation and test protocol. ETCs were synthesized using procedures described in detail elsewhere [6]. ETCs were kept in an incubator for 24, 48 or 72 hours to allow the cells to remodel the collagen. Three specimens were tested at each of the three remodeling times, a total of nine specimens. Tissues were allowed 60 minutes to accommodate to the new media before the stress-relaxation test. Following 10 minutes of force monitoring to establish a baseline, tissues were preconditioned with 5 sequential cycles of 20% axial stretch, followed 30 minutes of recovery. Thereafter, ETC rings were stretched 10% at 20%/s then held isometrically for 3600 s while force was recorded at 50 Hz. Specimens were returned to their baseline configurations and allowed to recover for 30 minutes. To test the contribution of the remodeled ECM to viscoelastic behavior of the ETCs, DMEM+HEPES was replaced with 0.05% w/v deoxycholate in PBS (pH 7.4). After a 60 minute incubation, the stretch-and-hold protocol was then repeated.

Measurement of ETC dimensions and DNA quantification.
Widths and thicknesses of each ETC were measured using confocal microscopy (LSM 510, Zeiss). We synthesized an additional 9 specimens (three each at 24, 48, and 72 hours of incubation) to estimate the final cell concentration in ETCs using a total DNA quantification assay.

Analysis of stress-relaxation data, staining and imaging.
The generalized Maxwell model was used to interpret the relaxation behavior of the specimens tested. We used a discrete spectral implementation described elsewhere [5], based on a large number (n= 1000) of exponential terms. The actin cytoskeletons of the fixed tissues were stained with rhodamine phalloidin (Sigma, St. Louis, MO) and imaged using a Zeiss 510 confocal microscope and a 40x, 1.2 NA, water objective.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Over three days of remodeling, cells proliferated and compressed the ETCs (Fig. 1a), with the initial cross-sectional area decreasing from 13.8×10^{-6} m^2 to 1.01×10^{-6} m^2 during the first 24 hours, and to 0.51×10^{-6} m^2 after 72 hours. The starting population of 250,000 cells (in 0.5 ml of solution) was sustained for 24 hours, and decreased to about 190,000 after 72 hours (Fig. 1b).

The analysis showed subtle but significant transitions in some of the viscoelastic relaxation time constants over the course of ECM remodeling, with a slower finite time constant (~7000 s) emerging between 24 and 48 hours of remodeling, and with some faster time constants (0.5-2 s) merging into a single time constant between 48 and 72 hours of remodeling. As discussed below, these changes were retained following deoxycholate treatment, indicating that the changes occurred in the ECM rather than in the cells. In the deoxycholate treated ETCs, with cells eliminated, the 0.2 s time constant disappeared at all time points. At 24 hours, the ~8 s time constant disappeared with deoxycholate treatment, and at 48 and 72 hours, the 30 s time constant disappeared (only 72-hour-tissue results are presented, fig. 2). The elastic moduli decreased for the deoxycholate treated ETCs with respect to control samples (Figs. (c) and (d)) at finite time constants faster than 100 s. Variance amongst the relaxation spectra was greatest for the 48-hour time point.

Imaging of 24-hour-old-old ETCs showed a disordered collagen fibers (representative image, Fig. 3a. For 48-hour-old ETCs, a transitional state could be observed in which collagen fibers were more organized and began to exhibit a preferred orientation (representative image, Fig. 5b. Finally, a very compact pattern of collagen fibers appeared in 72-hour-old ETCs (representative image, Fig. 3c). This compact pattern could be found at a multitude of locations throughout the ETCs, not only close to the edges.

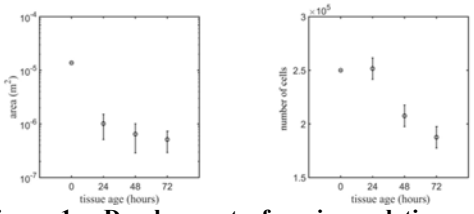

Figure 1: Development of engineered tissue constructs (ETCs) over 72 hours, including variations (a) of their cross-sectional area, (b) of the number of cells within them.

DISCUSSION

Cells reduced ETC cross-sectional area as they collectively remodeled the ECM (Fig. 1). Responses of the tissue constructs to mechanical stretching were quantified using a spectral approach that, through integration with tests involving specific inhibitors, quantified the rheological responses of the cells and extracellular matrix (ECM) over a range of loading time constants. The decrease in the minimum stress of the deoxycholate-treated with respect to non-treated (control) ETCs shows that at least a part of the time-independent (elastic) behavior of tissues, which corresponds to the single spring in the generalized Maxwell model, is due to elastic contributions of the cells. Two of the spectral peaks disappeared following treatment with deoxycholate (those at 0.2 s and 30 s for 48 hour and older specimens; 0.2 s and 8 s for 24-hour-old specimens) indicating that these are attributable to cells or cell-ECM interactions. Many consequences of the interactions between cells and ECM were evident by observing the ETCs. Reflectance mode confocal microscopy, in which collagen fibers of ETCs can be observed directly without staining and with good axial and lateral resolution, showed that collagen fibers remodeled over time into a network showing elements of structural organization (Fig. 3).

The results showed for the first time that cell and ECM viscoelastic contributions to tissue remodeling can be dissected using integrated mechanical testing, spectral analysis, and biochemical treatments. Results further showed that fibroblasts remodel collagen in a way that emphasizes the damping at a frequency associated with heart contraction in humans, suggesting that viscoelastic remodeling associated might play a role in the diastolic filling disorder known to arise with late stage cardiac fibrosis.

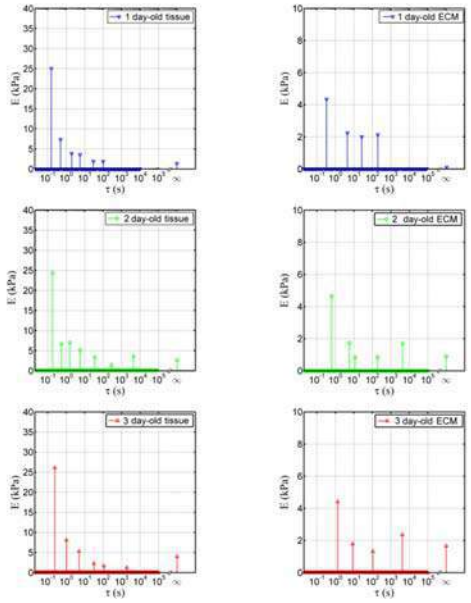

Figure 2: Viscoelastic relaxation spectra of ETCs tested in nutritional medium (left column) or nutritional medium plus deoxycholate to lyse cells (right column).

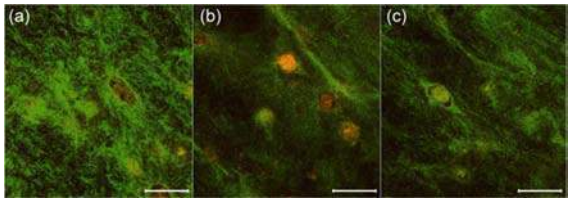

Figure 3: A confocal reflectance microscopy image of collagen fibers (green) superimposed upon images of cells (red) in engineered tissue constructs. During the remodeling, the cells established a connective network, with some clusters of adjacent cells forming ring-like structures. The network appeared to link and organize individual cells in the ECM. Mechanical signals sent to amongst cells over a timescale faster than the fastest time constant in these collagen bundles are not attenuated by the bundles. Scale bar, 50 μm.

INTRODUCTION

Embryonic cardiovascular (CV) mechanics is an emerging field that could unravel the interactions between the vessel microstructure and the mechanical loading that govern the prognosis of congenital heart defects (CHD). Unlike mature CV systems, the embryonic vasculature represents a primitive, disorganized but highly dynamic soft tissue microstructure whose mechanical loading and the corresponding microstructural organization are yet to be defined at the key embryonic time-points. Additionally, intervening in the CV flows alters the tissue morphology that correlates well with differences in local shear stress profiles, pressure and CV activity [1].

Recently, embryonic CV tissue growth models attracted attention due to their potential to predict vessel morphology and the physiological vascular stresses simultaneously [2, 3]. For example, Shi et al. suggested that cardiac looping mechanisms based on the computed stresses within the heart tube in early chick embryo [4]. Likewise, Kowalski et al. presented a computational model of aortic arch formation as a function of hemodynamic loading and the outflow tract orientation [5]. In these studies, one key challenge involves the drastic variation of homeostatic growth-equilibrium stress states during CV development.

In our earlier work, we have investigated the hemodynamic wall shear stress (WSS) loading at the major pairs of embryonic aortic arches using subject-specific computational fluid dynamics (CFD) during the three Hamburger Hamilton (HH) stages 18, 21 and 24 [5, 6]. Similar to the WSS dependency, the embryonic soft tissue mechanical stress levels at these stages could also vary significantly and can correlate with the dynamic microstructural configuration of embryonic arch vessels, at an unknown degree. Thus, a finite element solid model will complement our earlier hemodynamic studies and will shed light to the complex growth and remodeling process of the soft tissue in the embryonic aortic arches.

METHODS

The two key embryonic stages of HH 18 and 24, embryonic day 3 and 4 respectively, are investigated. During these stages, arches II, III and IV at HH18 and arches III, IV and VI at stage HH24 exist. Based on the Optical Coherence Tomography (OCT) measurements of vessel diameter and thickness [5], an idealized three-dimensional (3D) finite element method (FEM) (Ansys, Inc.) model of aortic sac is generated for both left and right laterals (Figure 1) separately.

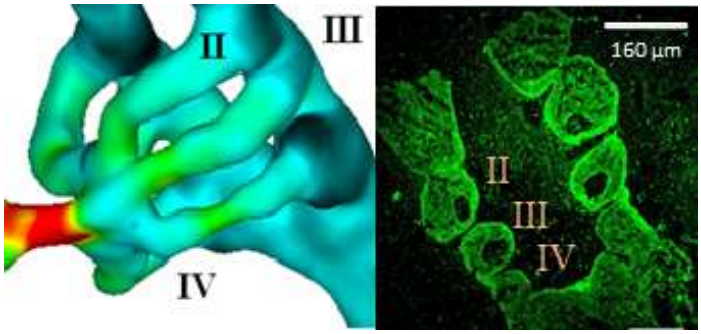

Figure 1: 3D subject specific embryonic arch model (left figure) and the corresponding confocal scan of Collagen type I distribution at HH stage 18 displaying both the left and right arch laterals through the aortic sac (right figure).

FEM model geometries were meshed with 2nd order tetrahedral elements. Fixed support boundary conditions are specified at arches'

connection edges and at the posterior end of arch III for HH18 model, corresponding to arch IV at HH24. While more complex models are investigated for embryonic soft tissue, simple mechanical models can describe embryo mechanics acceptably well [7]. Therefore, a linear elastic material model with a Young's modulus of 1000 Pa and a Poisson's ratio of 0.49 was used [7, 8]. Effect of increased collagen density is simulated by increasing the material parameters (Young's modulus 750 Pa and Poisson's ratio 0.4). Arterial pressure is estimated to be 1 mmHg based on literature measurements in dorsal and vitelline arteries [9, 10] and a recent numerical simulation study of ventricle outflow tract [11].

Using a wide-field of view time-lapsed confocal scanning system (Nikon AZ100-C2+) the fluorescence images of elastin, VEGF and collagen types I, III and IV fiber microstructure and cell number of the chick embryo aortic arch are acquired through immunofluorescence (IF) staining (Figure 1).

RESULTS

Total deformation, equivalent stress (von Misses) and soft tissue shear stress distributions due to pressure loading were calculated by FEA. For comparative purposes, no residual stresses are included. A representative von Misses stress distribution of the right aortic arch model of stage HH24 and the corresponding collagen type I distribution are given in Figure 2. This figure allows us to make a qualitative comparison between stress level and collagen fiber density. Interestingly, first time in literature, we observed that the high tissue stress regions correspond to the high collagen staining intensity. These regions also associated with high VEGF expression and high cell density (data not shown). Stress distribution at other stages showed similar trends but not included due to brevity. Total tissue strains alter between 10 to 15% for different models, which correlated well with our time-lapsed OCT observations.

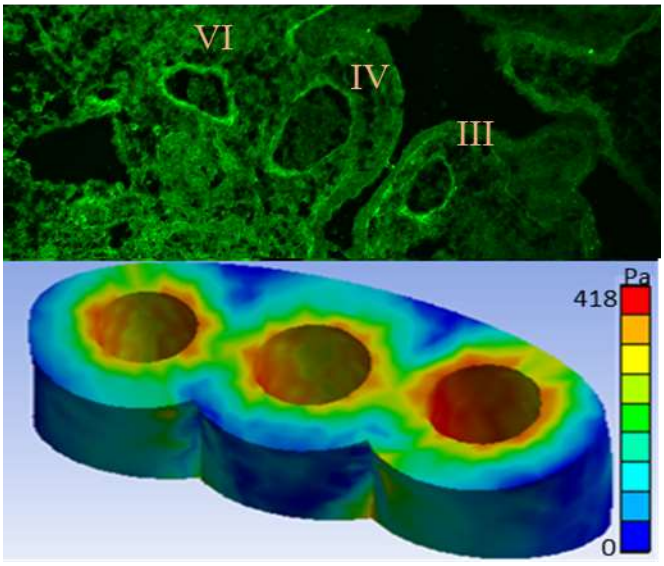

Figure 2: Comparison of stress distribution of the left aortic arches obtained by finite element analysis versus Collagen type I levels on chick embryo right aortic arch at Hamburg Hamilton stage 24.

The maximum von Misses stress, maximum shear stress, total deformation and measured WSS values due to blood flow from our previous work [6] are summarized in Table 1. Finally, aforementioned material remodeling resulted in a 20% decrease in stress levels for the right aortic arch at HH stage 24.

Table 1: Maximum values of stress, deformation and WSS calculations for all four models.

Maximum values	Stage 18		Stage 24	
	Left	Right	Left	Right
Von Misses Stress (Pa)	318	358	309	41
Total Deformation (μm)	3.02	4.04	2.99	6.18
WSS, CFD (Pa)	17.19	16.37	24.51	18.34
Shear Stress (Pa)	15.00	15.75	17.75	19.00

DISCUSSION

In this study, we estimated the stress distribution during the embryonic aortic arch morphogenesis and correlated these findings with immunofluorescence first-time in literature. Our results show that inner walls of arteries have the highest von Misses stresses as expected. Stress level decreases as the distance from the inner wall increases. Interestingly, this stress distribution matched to that of the IF stain intensity of major microstructural proteins. Particularly for collagen fibers, elastin and VEGF, there is a strong relationship with the stress level throughout the tissue. In general high stress levels cause high collagen dense regions at all early stages. Alteration of the material parameters would result changes in stress levels throughout the aortic arch. These changes can be predicted using our FEM model in a noninvasive way (without instrumenting on the chick embryo). Alterations in the ratio of collagen or elastin concentration and its long-term remodeling can be modeled using the present approach.

There are several ways to advance the proposed model. Implementing a hyper-elastic material model constitutes the ongoing effort. Likewise mechanical experiments focusing on the aortic sac tissue would provide experimental stress-strain data that is needed for hyper-elastic material model parameters. Also 3D OCT scans can be used to reconstruct a full 3D model of the aortic sac. Furthermore assigning pulsatile pressure distribution throughout the arteries would allow quantitative comparison of vessel diameter changes obtained from OCT and can correlate with the collagen type I synthesis (Figure 1).

INTRODUCTION

Seated occupants of vehicles exposed to underbody blast sustain inferior to superior loading as a result of high rate vertical accelerations of the seat pan and floor [1]. Previous efforts to reproduce high-rate vertical accelerative loading using whole post mortem human surrogates (PMHS) involved testing with horizontal crash test sleds, impactors that load foot and seat plates, drop towers, and accelerative loading fixtures [e.g., 2,3,4,5]. Efforts to measure forces applied to the body in these tests are needed so that results of tests can be used to help ensure the external biofidelity of human surrogates such as anthropomorphic test devices (ATDs). To data such efforts have been limited such that only a single study has reported forces applied both the pelvis and foot [5] and no studies have reported on load sharing between the hind foot and fore foot and between the sacrum and other parts of the pelvis. This study reports data from a series of PMHS tests that provide new information on load sharing between hind-/fore-foot and the parts of the pelvis.

METHODS

Five whole male post mortem human subjects (PMHS) were tested using a custom designed, single seat drop tower facility that applies a vertical acceleration pulse to the foot and pelvis characterized by a 4 m/s peak velocity and a 5 ms time from the start of loading to peak. The ages, masses, and statures of the PMHS are listed in Table 1. All PMHS were tested in a rigid seat with a horizontal seat pan and vertical seat back. Subjects 1403-1506 were tested while wearing an improved outer tactical vest (IOTV), encumbrances, and a CamelBak.

Aspects of the seat pan and floor that respectively contacted the pelvis and feet were instrumented with custom load plates that measured forces applied to the fore foot and hind foot, the regions of the pelvis containing the sacrum, the left and right ischial tuberosities, and the proximal thigh flesh. Figure 1 shows these load plates. Each load plate contained multiple height-matched load rings (PCB model 202B for the loading plates that measured foot loading and 203B for the plates that measure pelvis loading). Load plates were calibrated by applying quasi static loads at multiple locations on the load plates and then using multivariate linear regression to estimate calibration coefficients for each load cell. A cross validation approach was performed for each seat of calibrations and the maximum resulting error was less than 1.7% at 10 kN for the hind/fore foot load plates and 3.0% at 15kN for the pelvis and thigh flesh load plates.

Table 1: Subject Characteristics

Test ID	Age (yr)	Stature (cm)	Mass (kg)
1401	66	175	98
1403	64	183	78
1504	57	177	88
1505	76	178	75
1506	60	178	78

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Inertial compensation factors were estimated for each load plate by dividing the summed forces measured by the load washers by the measured vertical acceleration of the CG of the plate. The resulting values were all slightly larger than the masses of the plates. Force and acceleration data were filtered using a phaseless 4th order lowpass Butterworth filter with a 1650 Hz cutoff frequency.

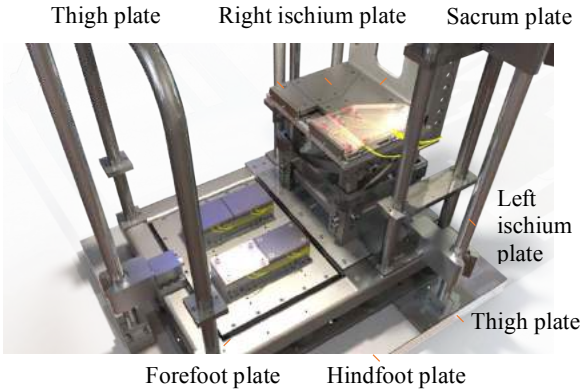

Figure 1. Seat and Foot load plates

RESULTS

Figures 2 and 3 show right foot and seat loads from all five tests. Loads measured by the right fore and hind foot were similar to those measured by to the left foot plate for each test. Loads measured by the plates that load the regions of the pelvis containing the left and right ischial tuberosites also measured similar loads for each test. Responses measured in the test without an IOTV within the range of response measured in test with an IOTV.

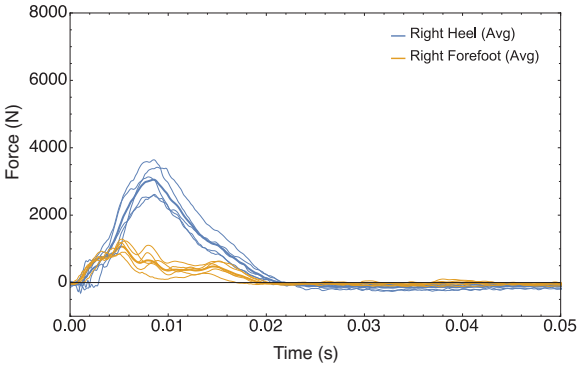

Figure 1: Forces applied to left and right hindfoot and forefoot.

The average peak force applied to the left heel was 2.8 kN while the average force applied to the right heel was 3.1 kN. Approximately 75% of the total force applied to the foot was applied to the hind foot. Peak forces applied to the regions of the pelvis containing the left and right ischial tuberosities were, on average, 5.5 kN and 5.6 kN, respectively. The average force applied to the sacrum at the time of peak pelvis force was 2.4 kN and approximately 17% of the total force applied to the pelvis was transmitted through the sacrum plate. Peak forces applied to the left and right thigh plates averaged to approximately 1.7 kN and 1.8 kN, respectively across the five tests.

Several tests resulted in coccyx and lumbar spine fractures, however, the timing of these fractures was such that they occurred after the time of peak force, around ~20ms.

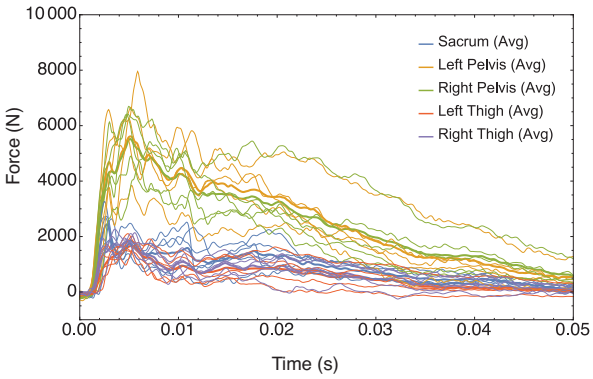

Figure 2: Forces applied to pelvis and proximal thigh

DISCUSSION

This study presents novel information on forces applied to the pelvis and foot and load sharing between different parts of these body regions. Results of these test provide important information for crash test dummy design and can be used to help define the external biofidelity of these devices.

Data presented in this paper were not normalized to account for effects of body size on response. Future work should explore if established methods for normalizing data (e.g., Mertz 1984, Eppinger et al. 1984) reduce scatter in the data. Data were also collected using a single loading condition. Loading at higher rates and longer durations will likely change mass coupling to the pelvis and could therefore change load sharing between the sacrum and ischial tuberosity regions of the pelvis.

INTRODUCTION

In the United States, 11,000 people suffer a spinal cord injury (SCI) each year, resulting in an estimated 276,000 people living with a chronic SCI in the US [1]. The SCI population is at the low end of the fitness spectrum with high risk of cardiovascular disease, diabetes, and profoundly accelerated osteoporosis, with a rapid decrease in bone density to approximately 60% of the normal bone mass [2]. Currently, there is no cure for SCI and most physical therapies to date have focused on only upper body exercises, which limits cardiovascular adaptations [3, 4] and do not apply the mechanical loads to the lower limbs necessary for maintaining bone strength. Hybrid functional electrical stimulation (FES) rowing is a novel training therapy designed to enable the SCI population to exercise both the large muscles of the legs and the upper limbs muscles, leading to increased metabolic responses [5-7]. Previous studies have shown that isolated FES muscle stimulation increases bone mineral density (BMD) in chronic SCI patients [8] and maintains BMD in acute SCI patients [9]. A recent case report suggests that FES-rowing may provide therapeutic benefits for bone [10]. Hybrid FES-rowing can mirror able-bodied rowing, but the specific of the rowing stroke, the loading produced, and the mechanical efficiency of those with SCI who habitually train with FES-rowing remains still unknown [11]. This study provides a biomechanical analysis of FES-rowing in relation to aerobic work to provide guidance for an optimal exercise regime for the SCI population to improve health benefits. The objective of this work was to characterize upper and lower body forces, work produced, and mechanical efficiency (metabolic consumption/mechanical work) during a progressive aerobic capacity tests in SCI FES-rowing vs. able-bodied rowing. We hypothesize that a greater rowing intensity requires greater upper and lower body forces and greater oxygen consumption in both groups.

METHODS

A Concept2 rowing ergometer was adapted to accommodate SCI patients and was instrumented with force transducers (handle, toe and heel of the left and right leg) and string potentiometers (rowing seat position). A biofeedback system was developed using NI LabVIEW software to collect real time forces of the feet and handle and rowing seat position (Fig. 1). Aerobic capacity was determined using on-line computer-assisted open circuit spirometry. Six patients with spinal cord injury (C5-T12, American Spinal Injury Association class A) and six able-bodied individuals were recruited from current patients in the Spaulding Rehabilitation Hospital SCI exercise program for FES-rowing. All subjects performed a progressive aerobic capacity rowing test, increasing wattage every 2 minutes until volition exhaustion. The first three bouts of intensity corresponded to each individual reaching 70%, 80%, and 90% of the maximum age predicted heart rate for able-bodied rowers, and 70%, 80%, and 90% of the maximum heart rate achieved during their last maximal aerobic capacity test for SCI rowers. Force and position data were recorded at 100Hz sampling frequency and a 10Hz low-pass first order Butterworth filter was used to remove unwanted noise. The data was divided into 1-minute intervals for which drive time, recovery time and average stroke rate were obtained. Additionally, each stroke was normalized to 100% rowing stroke to obtain force-time stroke profiles to determine peak force achieved at the handlebar and at the feet during 1-minute intervals. External work produced at the feet and handle was evaluated using a 2D rowing model, as function of the force recorded and rowing seat displacement. The mechanical efficiency of each rowing test was calculated as the ration of the volume of oxygen consumed to the average total external work for the last 30 seconds of each 2-minutes rowing intensity bout. Changes in stroke characteristics (drive time, recovery time and average stroke rate) were assessed via repeated measures ANOVA within group across

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

relative total workload. Changes in feet and arms forces were assessed using a linear regression model across groups and across average total work. Differences in efficiency between FES-rowers and able-bodied rowers were assessed using a Wilcoxon Rank-Sum test.

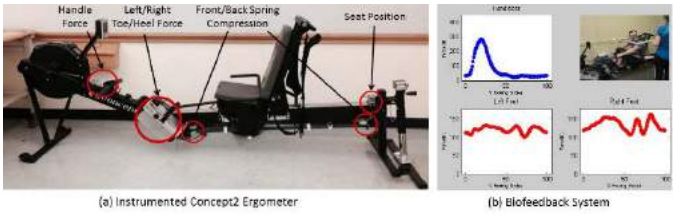

Figure 1: (a) Concept2 ergometer instrumented with force transducers (Handle, L/R Toe/Heel) and string potentiometers (Seat); (b) Biofeedback system for real time data collection.

RESULTS

Differences in kinematics (stroke characteristics: average stroke rate, drive time, recovery time), kinetics (forces applied at the feet and handle), and mechanical efficiency (volume of oxygen consumed/total external work) were compared in able-bodied rowers vs. SCI FES-rowers at each bout of intensity.

With increased rowing intensity, able-bodied rowers increased stroke rate ($p=0.02$) by decreasing recovery time ($p=0.05$) while maintaining a constant drive time. SCI FES-rowers did not increase stroke rate and maintained a constant recovery and drive times even with increasing rowing intensity. Able-bodied rowers spent 53% of the rowing stroke in the drive phase, while FES-rowers spent only 45% of the rowing stroke in the drive phase.

Across all intensities, FES-rowers produced lower magnitudes for both peak forces and work produced by upper and lower body than able-bodied rowers. With increased workload, able-bodied rowers increased foot force ($p<0.01$), while FES-rowers maintained a constant foot force (Fig. 2). For the upper body, peak handle force increased for both groups, but even more so in FES-rowers (both $p<0.01$).

FES-rowers had lower oxygen consumption and produced less external work than able-bodied rowers across all intensities. Oxygen consumption increases in both groups, but more so in able-bodied rowers. The ratio of internal work to external work provided a measure of mechanical efficiency as the volume of oxygen consumption over the total work produced. Our results showed that able-bodied rowers are two times more efficient than SCI FES-rowers.

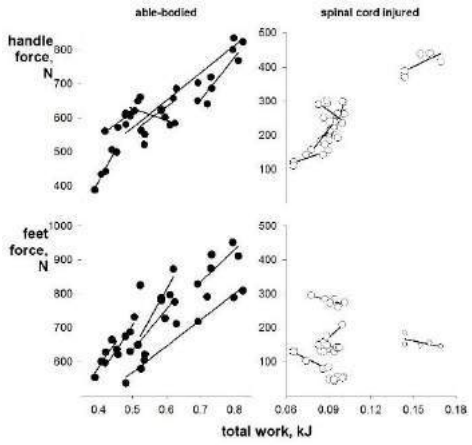

Figure 2: Upper and lower body forces with increased rowing intensity in able-bodied rowing vs. SCI FES-rowing.

DISCUSSION

Even though hybrid FES-rowing mimics able-bodied rowing, the specifics of the rowing stroke, the loading produced and the mechanical efficiency is different in SCI FES-rowing than in able-bodied rowing. FES-rowers demonstrated different rowing stroke kinetics than able-bodied rowers. Able-bodied developed an effective coordination between the upper and lower body movement, the movement pattern being facilitated by the trunk swing predominantly in the sagittal plane. However, the SCI FES-rowers had an altered coordination between the arms and the legs during drive phase; their inability of using the trunk swing resulted in a complete arm pull during the first half of the drive phase, followed by a leg extension during the second half, instead of coordinated arm and leg motion.

Across all intensities, able-bodied rowers produced three times higher peak external forces at arms and legs than FES-rowers. However, while able-bodied rowers increased legs and arms forces with increase in intensity, FES-rowers achieved a higher rowing intensity by only increasing their arm force, while the leg force was maintained constant. The different rowing stroke kinetics and lower magnitudes of peak arms and legs forces of FES-rowers are probably due to both biomechanical and physiological reasons. FES-rowers are not able to use their trunk, limiting an effective coordination between their arms and legs resulting in only very small increases in rowing intensity. Furthermore, the non-physiological recruitment of muscle fibers through electrical stimulation allows engaging the lower body of FES-rowers, but the legs achieve quickly the maximum possible work, without being able to increase the force production. With increased intensity, the oxygen demand is higher in able-bodied rowers than in FES-rowers. This is not surprising given that FES-rowers produced less external work than able-bodied. However, able-bodied rowers not only produce more external work for a higher oxygen demand, they are actually two times more efficient than FES-rowers.

FES-rowing provides a framework that allows exercising. Our results show that FES stimulated muscles are limited in the amount of force produced. Regardless of rowing intensity, the contribution of the legs stays constant and very low in the SCI population. These results imply that the inefficiency of SCI FES-rowing limits the total force output achievable with FES, leading to higher rates of fatigue, limiting the cardiopulmonary exercise possible and the loading applied to the bone. The current work constitutes a benchmark to evaluate FES performance to monitor changes in efficiency during training interventions and to guide the SCI population with respect to an optimal exercise regime, resulting in possible force generation, which will improve cardio-respiratory fitness and bone health.

INTRODUCTION

Human injury probability curves (HIPCs) in the automotive safety literature are developed using using post mortem human subjects (PMHS) tests. Logistic regression techniques are generally used for this purpose [1]. The International Standards Organization (ISO) recently released a 12-step methodology to derive HIPCs from retrospective biomechanical data, which has been applied to side impacts and dummy injury curves [2, 3]. Survival analysis was recommended because of its ability to accommodate differing censoring statuses of biomechanical experimental outcomes [4]. The ISO method for foot-ankle injuries produced different results compared to previous logistic regression-based HIPCs [5].

However, the ISO method based on retrospective tests does not accommodate all statistical processes that can be associated with prospective biomechanical experiments. For example, the method uses the Akaike information criterion (AIC) to choose a distribution. The criterion typically over-fits in a statistical model. Parameters such as area under the receiver operator curve (AUROC), Hosmer-Lemeshow (HL) and Kolmogrov-Smirnov (KS) provide more inclusive data, needed to evaluate the best underlying distribution for biomechanical metric(s). Comparing the derived HIPCs based on the least AIC with that based on a non-parametric distribution tends to be qualitative. An updated method is needed for a more generalizable and robust process to derive HIPCs. Thus, the objective of this study is to develop an improved methodology to derive HIPCs that can be used in sub-component and whole body PMHS tests simulating military loading situations such as underbody blast (UBB) events with potential applications in other loading environments as well.

METHODS

The first two steps in the processes focus on preparing data for use in HIPC development. Previously-published Abbreviated Injury Scale (AIS) 3+ injury, average spinal acceleration data from [1] are used to demonstrate the method.

1. Collect the relevant data for the injury assessment. This can include aggregated data for inputs (e.g., biomechanically relevant combinations of forces and moments). Data should include injury types and severities, associated mechanical test values and covariates based on cadaver characteristics (e.g. age, bone mineral content). Injury data should have been properly vetted.

2. Aggregated tests across multiple groups shoul d follow a consistent procedure in terms o f injury categorization or grouping. This is to be done on a component by component basis and driven by observations in component experiments. This is relevant if HIPCs are developed from multiple laboratories. *2a.* It is important that multiple competing injury mechanisms do not confound data, especially with limited experimental samples. This should be biomechanically verified using necropsy and medical imaging data. *2b.* Generally, in the absence of additional information, injury data is left censored or interval censored from zero, and non-injury data is right censored. Additional sensors may be used to produce uncensored data to improve statistical power and confidence interval widths.

3. Estimate the coefficients for the *model chosen.* Coefficients calculated will depend on the model, non-parametric models should also be presented. These estimates should account for the likely limited numbers of experiments in biomechanical tests using PMHS, and should avoid asymptotic large number assumptions whenever possible. Survival analysis is used and distributions evaluated include Weibull, log-normal, and log-logistic to fix zero risk of injury at a zero mechanical parameter value.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

4. Identify overly influential observations *in th e data and model.* Like the ISO method, it is suggested to delete one observation at a time using the DFbetas statistic. This corresponds to the difference between the model coefficients when all data has been included vs. the calculated model with one observation excluded scaled by the standard error calculated without the excluded observation. The cutoff is based on sample size, $\frac{2}{\sqrt{n}}$ [6]. The biomechanist should be able to defend any data point identified for potential exclusion.

5. If a parametric distribution is used in the model, choose th e best distribution and check the distribution assumption. This is done using the following techniques. A quintile-quintile plot is used to check distribution percentiles vs percentiles in the data set. If the slope of the line is approximately unity and intercept is approximately zero, then the chosen distribution is appropriate. Three statistical tests are also used to determine the best distribution: AUROC, HL and the KS statistics. The latter is done between each parametric distribution and the non-parametric distribution. Based on these measures, the biomechanist should be able to select the optimal function.

6. Calculate 95% confidence intervals (CI) and a*ssess the Normalized Confidence Interval Size (NCIS) including the validity of the prediction based on the data.* The CI width is normalized by the predictor value from the model at a given level of risk to determine NCIS, which provides a quantitative value for how wide the CIs are compared to the norm.

RESULTS

The result of testing the proposed procedure is presented using a set of biomechanical data (n = 39) described in [1]. Figure 1 shows the results for the log-normal fit with 95% CIs, and the mean with and without overly influential observations flagged by the DFbetas statistic. Table 1 provides the key statistics for each model fit.

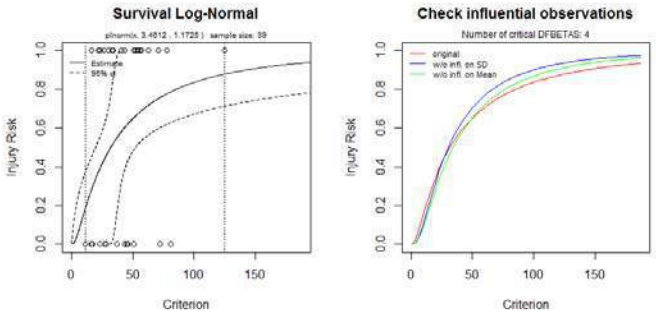

Figure 1: Best fit model shown, with 95% CI. Injury and non-injury data is noted at 0% and 100% risk.

Table 1. Survival Analysis Model fit statistics for sample.

Distribution →	Weibull	Log-normal	Log-logistic
AUROC	0.680	0.680	0.680
H-L	0.017	0.507	0.623
K-S	0.410	0.180	0.205

DISCUSSION

The original ISO suggestions were maintained to the extent possible in this updated procedure while acknowledging that risk curves produced were also applicable for biomechanical experiments using PMHS data. This procedure could be successfully implemented when the biomechanical experiments use prospective experimental designs to control the type and severity of injuries used in obtaining specific HIPCs associated with this outcome dataset, the ability to record multiple parameters of varying sensitivity to peak, and/or derived injury metrics and the ensuing risk curves. Because of its planned broad use, the method is programmed in the freely-available R language. The users will have significant control over the data input and analysis. It is incumbent upon them to select the best distribution given the statistical data from the analysis which is not just AIC, as used in the current ISO method. If the model does not match the non-parametric data, the user should determine if there is an issue with the distribution assumption.

The use of the DFbetas statistic reflects the true sample size in this method. Identification of overly influential (OI) samples was based on the DFbeta calculations although it must be noted that these are a function of the model fit and other parameters such as the standard deviation. The ISO method does not indicate a preference. The updated method relies on the user to make the final determination as to which, if any, observations are omitted. Depending on the type of the biomechanical experiment and sensitivity to a metric(s), the user can choose the type of DFbeta-process to determine OI.

Another aspect is the determination of the quality index, which was proposed to be specific to certain risk levels. In the present study, the methodology allows the user to determine the NCIS not only at discrete probabilities but also one can determine the quality over the entire or partial ranges of the HIPC. While the selection of the underlying distribution is governed by parameters such as AUROC, HL and KS, and evaluations of the tenability of the selected parametric curve is quantitative, the output producing different HIPCs (e.g., log-normal, log-logistic, Weibull) for each biomechanical metric will allow the user to choose the most appropriate HIPC from a biomechanical and practical perspective. For example, the selection may be based on the sensitivity (slope of 'S-curve') of the particular curve for that metric or the length toe region if risks at low levels are of concern. Thus, the expanded methodology consisting of a larger decision tree process, and the provision of multiple curves, associated CIs, and OI plots, has the generalizability and flexibility needed for the user to determine the most optimum HIPC. The process can be used regardless of the type of experimental model (sub-component to whole body) and adaptable to both PMHS and dummy risk curves .

Future work will assess the use of Bayesian survival analysis with the addition of Bayesian priors, which could provide similar levels of CIs for a given risk function, with smaller sample sizes [4].

A COUNTEREXAMPLE TO ENTROPY—ENTHALPY COMPENSATION IN COLLAGEN DENATURATION

Neil T. Wright

Department of Mechanical Engineering
Michigan State University
East Lansing, MI, USA

INTRODUCTION

The concept of entropy-enthalpy compensation is nearly as old as the Arrhenius description of the relation between temperature and the rate parameter in chemical kinetics. Entropy-enthalpy compensation states that there is a relationship, typically linear, between the activation entropy and activation enthalpy in chemical kinetics. In 1925, Constable [1] wrote of an apparent relationship between the two parameters in the Arrhenius relation for catalysized reactions in alcohols. For biological systems, several authors, for example [2, 3, 4], have noted similar relations. Recently, Qin et al. [5] used this concept to propose that the relationship between temperature and reaction rate can be characterized by activation energy alone.

There is a continuing debate as to whether entropy-enthalpy compensation is an artifact or a bona fide phenomenon. That so wide a variety of chemical reactions can yield such similar relationships between two supposedly independent parameters is surprising. Sharp [6] argued against the compensation effect on the grounds of statistical thermodynamics. Others have noted that uncertainty in measurements could lead to the appearance of a compensation effect. Liu and Guo [7] examined the role that uncertainty in measurements may have on mistaking other phenomena for compensation. Barrie made further analysis to show that random error [8] and systemic error [9] may cause mistaken identification of compensation. Harrington and Wright [10] used scaled sensitivity coefficients to demonstrate the difficulty in estimating both the frequency factor and activation energy over the small range of temperatures that biological specimens can be tested.

Here, published results of the shrinkage of bovine chordae tendineae that is heated while subject to mechanical loading is reexamined to demonstrate a case for which the activation entropy and enthalpy are independent. Thus, the enthalpy and entropy must be separately determined, in general. This agrees with other findings.

METHODS

Consider a first-order reaction

$$dC/dt = -k(T)C \tag{1}$$

where C is the concentration of a substance (e.g., a protein), T is the absolute temperature, t is time, and $k(T)$ is the rate parameter. While this is a great simplification for describing most biological reactions [11], it serves as a model reaction. The relation between $k(T)$ and T is often written in terms of an Arrhenius relation

$$k(T) = Ae^{-E_a/RT} \tag{2}$$

where A is the pre-exponential or frequency factor, R is the ideal gas constant, and E_a is the activation energy. The rate parameter may also be described using transition state theory as

$$k(T) = \kappa \frac{k_b T}{h} e^{S_a/R} e^{-H_a/RT} \tag{3}$$

where k_b is the Boltzmann constant, h is the Planck constant, S_a is the activation entropy, H_a is the activation enthalpy, and $\kappa \approx 1$, typically. In condensed-state matter, $E_a \approx H_a$, and comparing Eqs. (2) and (3), $\ln A \sim S_a$. Similarities in Eqs. (2) and (3) suggest that the compensation effect may be written in terms of E_a and $\ln A$ or H_a and S_a.

Figure 1 shows an example of the apparent compensation effect for tissues (Henriques, Takata, Pearce), cells (Mixter, Moussa, Bhowmick), and proteins (Miles, Chen) from different research studies [3]. The samples presented in Figure 1 share the characteristic of being mechanically unloaded, or at least without specified intentional loading.

RESULTS

Consider the shrinkage during heating of bovine chordae tendineae that have imposed constant uniaxial. Chordae tendineae are nearly cylindrical structures that are predominantly composed of the uniaxially oriented fibrillar type I collagen. Pulling on type I collagen

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

reduces its conformational entropy as its polymeric chains tend to straighten. Chen et al. [12] measured the change in shrinkage of the bovine chordae tendineae at temperatures of from 65 to 90 °C and subject to first Piola-Kirchhoff stresses of 0 to 650 kPa. They used a characteristic time of the second inflection point τ_2 on the sigmoidal shrinkage curve, which is a clearly identifiable characteristic time.

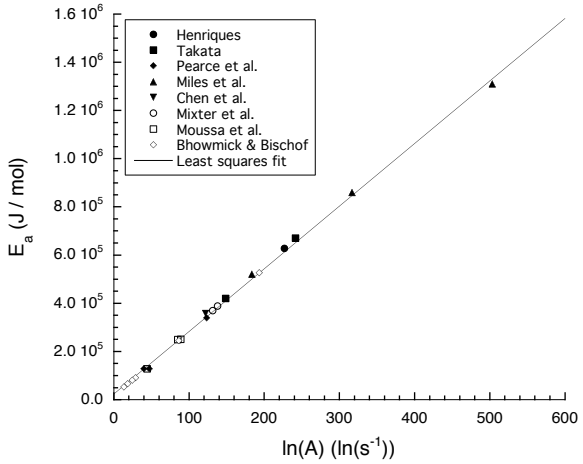

Figure 1: Illustration of entropy-enthalpy compensation from Wright [3]. The ln(A) is proportional to the S_a. (Most papers plot it with E_a on the abscissa, instead of the ordinate as shown here.)

Wright [3] demonstrated that similar scaling results using the half-time for shrinkage τ_{50}, which may be more obviously related to $k(T)$. Figure 2 is an Arrhenius plot of $k(T)$ for the five levels of P. Note that as P increases, greater temperatures are needed for the same $k(T)$, which is to say that increasing P delays shrinkage and increases S_a. Figure 3 shows S_a, as calculated using Eq. (3), as a function of P.

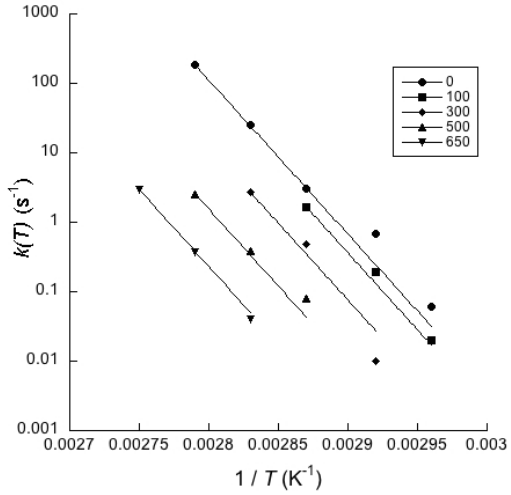

Figure 2: Arrhenius plot for shrinkage of chordae tendineae for first Piola-Kirchhoff stresses of 0 to 650 kPa. Best fit lines with constrained slopes are shown for each level of P.

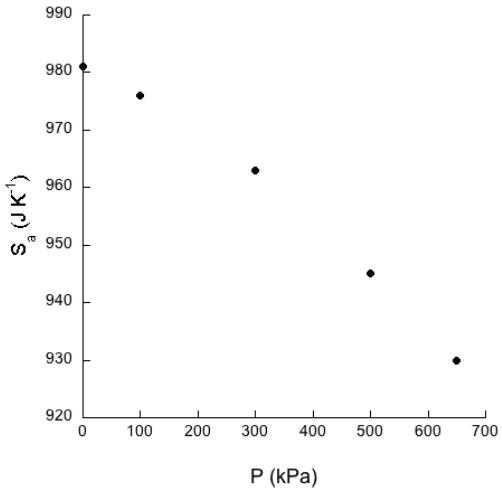

Figure 3: Activation entropy S_a as a function of P for shrinkage of chordae tendineae at temperatures between 65 and 90 °C.

DISCUSSION

The results here for the collagen shrinkage under different mechanical loads follow the time-temperature-load equivalence found by Chen et al. [12]. While a single correlation for shrinkage covering a wide array of imposed conditions was developed in [13], the current analysis uses τ_{50} to calculate $k(T)$, and hence S_a, as a function of P. Miles and Gleshvili [14] used the concept of polymer-in-a-box to propose that the decrease in conformational entropy due to dehydration will increase the thermal stability of type I collagen. Mechanical loading, which also reduces the conformational entropy, increases thermal stability. This is reflected in the decreased S_a for constant H_a. In addition to hydration and mechanical loading, other factors have been cited as changing the entropy of, for example, proteins in a cell, and thus the thermal stability of those proteins [15].

In addition to potential mathematical and thermodynamic arguments against entropy-enthalpy compensation, there are empirical counterexamples. Thus, while the apparent correlation between H_a and S_a can be a useful in some applications, it should be used with caution.

INTRODUCTION

Of the numerous blood-contacting medical devices implanted, 290,000 prosthetic heart valve (PHV) replacements were performed in 2003, which is expected to increase to 850,000 by 2050 [1]. Half of these PHVs are mechanical, which are at high risk of failure through thrombosis and thromboembolism, but are more durable than the alternative bioprosthetic PHVs [2]. To mitigate the risks associated with thrombosis, patients are treated with systemic anticoagulation and antiplatelet drug regimens. These therapies exhibit limited efficacy in high flow environments, while increasing the risk for bleeding. Furthermore, systemic anticoagulation results in the most drug-related deaths occurring from adverse clinical events in the United States [3]. Therefore, less aggressive anticoagulation or antiplatelet therapy due to less thrombogenic biomaterials could provide significant benefits for the numerous patients requiring medical devices.

Superhydrophobic surfaces may provide an effective treatment that significantly reduces thrombus formation on the material surface and may reduce fluid shear stress that can otherwise promote thrombosis. These surfaces are characterized by the degree that water beads on the surface, and are exemplified by the lotus leaf in nature [4]. Here, we report on the potential for these superhydrophobic surfaces to be used as a material treatment for mechanical PHVs. Tests were conducted to quantify hemodynamic improvement, in addition to studying the potential for blood clot formation on the surface.

METHODS

Ultra-Ever Dry (UltraTech International, Inc., Jacksonville, FL) is a commercially available superhydrophobic coating used in this study. The coating was applied as a spray to a 25 mm St. Jude Medical™ standard pyrolytic carbon (PyC) bileaflet mechanical heart valve (BMHV). Due to limitations in obtaining PyC samples, we also applied the coatings to glass for blood studies. This becomes necessary to compare various surface treatments for a given sample of blood. The base material with a sufficient coating thickness, whether pyrolytic carbon or glass, should not contact the blood.

Contact angle goniometry (Ramé-Hart) was used to assess the hydrophilicity. This technique measures the angle between the solid-liquid and liquid-vapor interface of a droplet on the surface. We also study the interaction with blood using two tests, a bouncing and sliding test. In the first test, a FASTCAM SA3 high speed camera (Photron, Inc.) was used to record a 12 μl of blood dropping onto surfaces from a height of 10 mm. In the second, a 30 μl droplet of blood was placed along various surfaces at a 45^o angle to observe the movement of blood.

Shear stress can activate platelets and rupture red blood cells (RBCs). Particle imaging velocimetry (PIV) was performed to assess shear stress for normal physiological aortic flow past a BMHV. Fluid was seeded with 1-20 μm melamine resin particles coated with Rhodamine-B. A Nd:YLF Single Cavity Diode Pumped Solid State High Repetition Rate Laser (Photonics Industries, Bohemia, NY) was used to illuminate a 0.2 mm thick measurement plane. The measurement plane was imaged with a double frame FASTCAM SA3. DaVis (Lavision, Inc.) was used to post-process PIV slices. Instantaneous shear stress was calculated using:

$$\tau_{xy} = \mu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right), \quad (1)$$

where u and v are the instantaneous velocities in the x (streamwise) and y direction respectively, while μ is the dynamic viscosity.

As a preliminary assessment of hemocompatiblity, whole blood clotting kinetics were evaluated. 5 μL of whole blood was pipetted

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

onto bare and coated glass samples in a 24-well plate immediately after collection. Samples were incubated with blood at 37 °C. Free hemoglobin concentration was measured at 15, 30, and 60 minutes. For this measurement, RBC were lysed using 500 µL of deionized (DI) water. Absorbance of the sample was then measured at a wavelength of 540 nm, using a plate reader, assuming that RBCs trapped in a clot don't contribute to the measurement.

RESULTS

The addition of the coating changes PyC from a slightly hydrophilic surface with a receding contact angle of 47° to a superhydrophobic surface with a receding contact angle of 160°. Furthermore, with a coating, the contact angle hysteresis is only 4°. With these properties, blood bounces off of the hierarchical surface, while it sticks to PyC, as demonstrated in Fig. 1A. The movement of blood is also visualized by placing a 30 µl droplet of blood on bare and coated glass tilted at 45° relative to the horizontal, Fig. 1B. The droplet slowly slides down bare glass leaving a trail of blood. Conversely, a droplet of blood swiftly slides off of a coated glass slide, leaving no visual trace of blood on the surface.

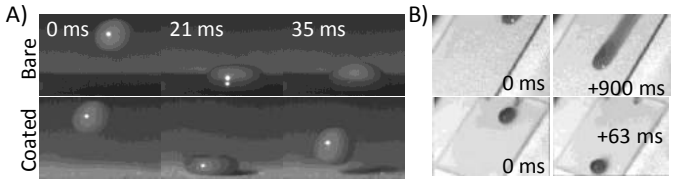

FIGURE 1: A) Blood droplet bouncing on coated and bare PyC and B) blood sliding on coated and bare glass

Instantaneous shear stress is calculated from PIV data to assess potential changes in blood damage with results for peak flow (30 l/min) shown in Fig. 2. Shear stress values are similar for the bare and coated valve, remaining below 10 N/m^2 at peak flow. However, one notable difference between the two valves is that the instantaneous shear stress is higher in the sinus region of the coated valve relative to the bare PyC valve, demonstrating less flow stagnation.

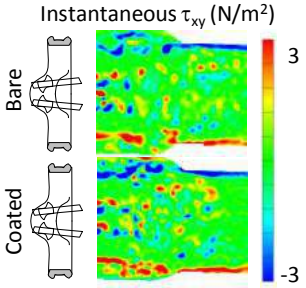

FIGURE 2: Instantaneous shear stress contours for PIV data of bare and coated BMHVs.

Minimizing the thrombotic response from blood is a major goal for the proposed coating. A free hemoglobin assay is used to compare the clotting potential of bare glass with coated glass. In this assay, increased free hemoglobin, corresponding to increased absorbance means that fewer RBCs have been incorporated into a blood clot on the surface. Free hemoglobin is plotted for bare and coated surfaces in Fig. 3. Clotting occurred quickly for glass, demonstrated by a large reduction in absorbance during the first 30 minutes of incubation. Alternatively, free hemoglobin does not exhibit substantial changes for the coated surface.

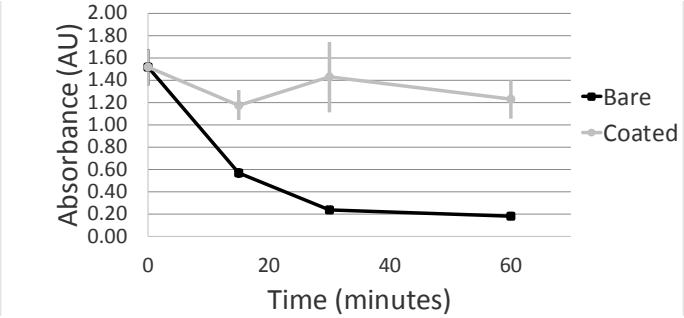

FIGURE 3: Free hemoglobin concentration in terms of absorbance bare and coated glass

DISCUSSION

We show that a superhydrophobic coating reduces surface-blood interactions, while having a minimal impact on the instantaneous shear stress. The latter demonstrates that there is no added hemodynamic damage to blood cells relative to approved PHVs.

Non-physiological hemodynamics, specifically regions of stagnating flow and regions of high shear stress can induce a thrombotic response. Stagnating flow typically corresponds to a fibrin rich blood clot, which is assessed in the current study with the whole blood clotting assay. Resistance to clotting in the current work is likely a result of reduced surface-blood interactions. There also appeared to be a slight increase in washout in the aortic sinus downstream of the coated valve, indicating smaller regions of flow stagnation and therefore a reduced region with the potential for blood clotting. Regions of high shear stress can also cause a thrombotic response, specifically through hemolysis and shear-induced platelet activation. Shear stress values causing these responses remain ill-defined due to variations in studies and due to a dependence on exposure time to a specific shear stress. For a conservative estimation, shear stress must be above 150 N/m^2 to cause hemolysis and above 10 N/m^2 to cause platelet activation [5, 6]. Here, we show that instantaneous shear stress is below 10 N/m^2 for both the PyC BMHV and the coated BMHV, with values similar to Ge et al. [5].

This work provides a preliminary assessment of the thrombotic response of a superhydrophobic BMHV. Additional work will need to be performed to design these valves so that they are durable. Furthermore, there is a need to assess the potential for platelet and plasma protein adhesion to the surface under flow conditions. Lastly, flow analysis is limited to the downstream region of the valve. Additional studies would need to be performed to evaluate the hinge regions and b-datum jet of the valve.

INTRODUCTION

The cervix is a unique organ able to dramatically change its shape and function from serving as a physical barrier for the growing fetus to dramatic dilation allowing for delivery of a term infant. As a result, the cervix endures changing mechanical forces from the growing fetus [1, 2]. Despite this, only recently have mechanical property changes of the cervix been evaluated throughout pregnancy [3]. There is an emerging concept that the cervix may change or remodel "early" in many cases of spontaneous preterm birth (PTB) [5, 6]. However, the mechanical role of the cervix in the pathogenesis of PTB remains unclear [1, 2]. Therefore, the objective of this study was to measure the biomechanical response of the cervix throughout pregnancy to provide insight into its role in premature cervical remodeling and PTB. We hypothesized that cervical mechanical properties would decrease throughout pregnancy since cervical softening and ripening are essential to a normal pregnancy cycle and parturition.

METHODS

Non-pregnant (NP) and pregnant CD-1 mice at embryonic day (E) E10.5, E12.5, E14.5, E16.5 and E18.5 (n=10-16/group) were sacrificed and frozen until they were prepared for mechanical testing. *Mechanical Testing*: After thawing, the entire reproductive organs (uterus, cervix, vagina) were removed; the bladder was used for orientation and then removed. The vagina and cervix were then cut open on the side opposite to the bladder. The cervix was then dissected free of extra soft tissue and the uterus and vagina were bluntly removed. The cervix was then laid flat to expose the lumen. The ends were affixed between two pieces of sandpaper for gripping, such that a uniaxial tensile load on the grips would simulate dilation of the cervical canal. A custom laser device was used to measure cross sectional area [7]. Tensile properties were measured via a protocol consisting of a preload of 0.005N followed by a hold of 5 minutes and then a ramp to failure at 1mm/minute.

Collagen Re-Alignment: Collagen fiber alignment maps of the cervix were collected throughout the mechanical testing protocol using our established integrated cross-polarizer system, as described [8, 9, 10]. This custom system consists of a linear backlight (Dolan-Jenner, Boxborough, MA), rotating polarized sheets offset by 90° (Edmund Optics), and a camera. Custom software (National Instruments LabVIEW, Austin, TX) synchronized with analog output signals from the Instron triggered alignment maps to image capture at 5 second intervals for NP, E10.5, and E12.5 and at 7.5 second intervals for E14.5, E16.5, and E18.5. Collagen alignment was measured at four points during the mechanical test: (1) start of the toe region, defined by the first map after the hold protocol, (2) at the end of the toe region, determined by the last map before the change of slope to the linear region (3) at 45% of the maximum load, and (4) at 90% of the maximum load. Significant re-alignment was defined as a significant change in circular variance between two time points.

Statistics: One-way ANOVA was used to compare between groups for mechanical parameters with Bonferroni-corrected post-hoc tests when appropriate. Mann–Whitney *U* tests were used to evaluate differences in fiber realignment at each time point. The significance was set at $p < 0.05$ for all statistical comparisons.

RESULTS

Mechanical Testing: Cross-sectional area was significantly reduced in E10.5 pregnant cervices but gradually returned to NP levels by E14.5 (data not shown). Maximum load was significantly smaller in all gestational groups compared to NP samples (Fig.1A). NP and E10.5 samples demonstrated significantly higher ultimate stress values as compared to all other gestational time points (Fig. 1B). Tissue stiffness

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

was decreased in pregnant samples compared to NP, with the exception of samples at E10.5, which were significantly stiffer compared to all other gestational ages and no different from NP (Fig. 1C). No significant differences were observed in tissue modulus for the NP, E10.5 and E12.5 samples. The NP and E10.5 samples had a significantly higher Young's modulus as compared to the E16.5 and E18.5 samples (Fig. 1D).

Collagen Re-Alignment: Realignment of collagen fibers was observed for all samples between the 'Toe' and '90% maximum load' time points (Fig. 2). E10.5 and E16.5 samples experienced some earlier realignment beginning at the '45% maximum load' time point and '90% maximum load' (Fig. 2B, E). E18.5 samples showed an immediate response to load with collagen fiber re-alignment during all time points (Fig. 2F).

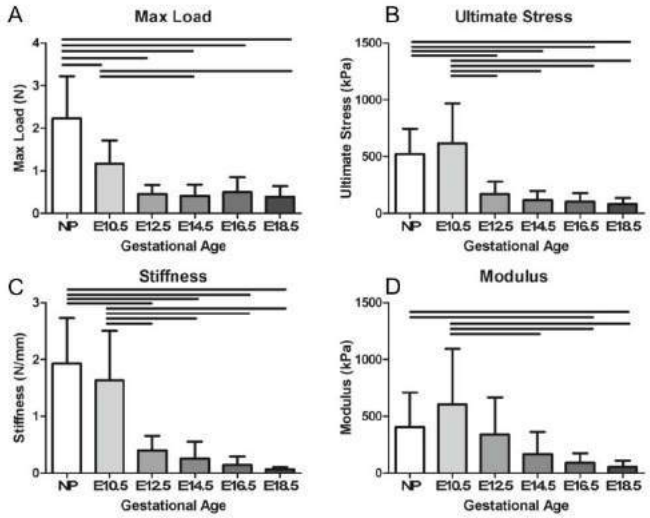

Figure 1: Mechanical properties, such as maximum load (A), ultimate stress (B), stiffness (C) and modulus (D), for NP and gestational ages (n=10-19 for all samples) demonstrate significant changes. Data is presented as mean±standard deviation and significance denoted by a bar spanning two comparison groups represents a p value < 0.05.

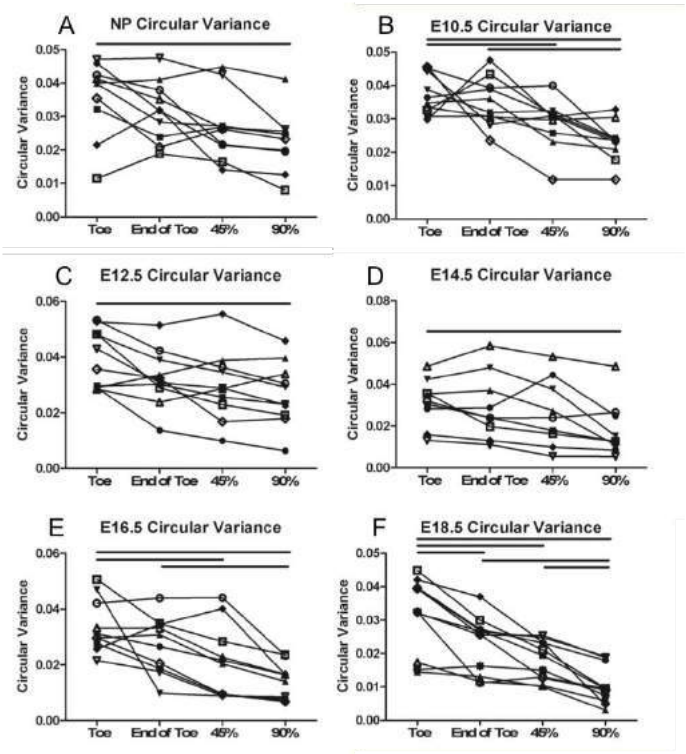

Figure 2: Collagen re-alignment of non-pregnant and pregnant cervix during tensile loading at Toe, End of Toe, 45% of Max Load, and 90% of Max Load for NP (A), E10.5 (B), E12.5 (C), E14.5 (D), E16.5 (E) E18.5 (F) cervix, comparing circular variance of fiber alignment distributions. Each sample represents one line and each point signifies alignment at each part of the mechanical test (n=10 for all samples) demonstrating significant changes. Data is presented as mean±standard deviation and significance denoted by a bar spanning two comparison groups represents a p value < 0.05.

DISCUSSION

Overall, the tensile biomechanical properties of the cervix decrease during pregnancy after E10.5. We showed that both structural (stiffness, and maximum load) and material (ultimate stress and modulus) properties decrease during pregnancy. Specifically, we did not observe changes in tissue stiffness, ultimate stress, and Young's modulus between the NP and E10.5 gestational time points. However, dynamic collagen realignment was observed at the E10.5 gestational time point. These data are consistent with studies showing that the mouse cervix remodels molecularly without loss of mechanical integrity [11, 12]. Significant earlier realignment of the collagen matrix at later gestational time points (E16.5 & E18.5) illustrates that the cervix responds to load dynamically faster at these time points (Fig. 2F). These realignment data, in combination with the significant differences observed in the cervix mechanical properties at the later gestational time points (E14.5, E16.5, and E18.5), provide critical structural insight into the cervical ripening process whereby it has been hypothesized that loosening of the collagen matrix may result in a significant decrease of tissue stiffness and strength well before normal delivery would be expected [4, 12, 13]. Importantly, while the cervix appears "ready" to allow passage of the fetus at this early time from a biomechanical perspective, PTB does not occur in these mice without an inflammatory or other trigger. Further research is necessary to determine mechanisms governing premature cervical remodeling allowing PTB [14]. While correlation of these findings to human pregnancy will be necessary, this work lays a critical foundation for investigating cervical biomechanics and the role of the cervix in PTB.

INTRODUCTION

Articular cartilage is the tissue that forms the interface at joints throughout the body. As an interfacial material, the biomechanical properties are extremely important to the proper function of the joint. Two key properties in modeling the displacement characteristics of articular cartilage are the aggregate modulus and permeability [1,2]. Improper mechanical function in the joint may be indicative of joint disorders or injury.

In the lab, these properties are measured through indentation tests which measure the force-displacement relationship in the tissue [1,2]. Unfortunately, indentation tests cannot be performed clinically. Traditionally, disorders such as osteoarthritis (OA), which is the degradation of articular cartilage over time, are diagnosed after the onset of symptoms (e.g., pain and loss of function) and subsequent imaging to confirm tissue damage [3,4]. This is often at a point where considerable damage has been done and preventative measures can only slow the progression of the disease. For this reason, a relationship between biochemical properties, which can be tested in a clinical setting, and biomechanical properties could be useful in early and accurate diagnosis of various disorders such as OA.

Recent studies have focused on showing the significance between various biomechanical and biochemical properties of the cartilage tissue [4,5]. While these relationships are significant, it does not provide a direct mathematical relationship between these properties making it difficult to apply results from clinical testing to diagnosis. This study will aim to provide an early model for the relationship between biomechanical and key biochemical properties utilizing a neural network.

METHODS

With IRB approval, 121 8mm osteochondral plugs were created from tissues collected from 6 patients that had undergone total knee replacement. The thickness of cartilage tissue on the plug was determined using a needle probe test using a 22g needle. The samples were then subjected to a stress relaxation test on an Instron 8821s using a cylindrical indenter with a diameter of 4 mm where they were compressed to 80% of the original cartilage thickness at a rate of 0.1 mm/s which is a relatively rapid rate which helps to ensure that the full stress relaxation curve is preserved for accurate characterization.. The tissue is then held at a constant strain for 120 seconds. The data was then optimized in order to determine the value of aggregate modulus and permeability that minimized the error between the experimental and simulated data utilizing the following equation produced by Mow et. al in 1980 [1,2]:

$$\sigma_z(t) = H_A\dot{\varepsilon}_0 t_0 - \frac{2\dot{\varepsilon}_0\delta^2}{\pi^2 k_z}\sum_{n=1}^{\infty}\frac{e^{\frac{-n^2 t}{\tau'}} - e^{\frac{-n^2(t-t_0)}{\tau'}}}{n^2} \quad \text{where} \quad \tau' \equiv \frac{\delta^2}{\pi^2 H_A k_z} \quad (1)$$

This equation was selected for its relevance to our testing set up as well as its simplicity and accuracy. The 'fminsearch' function built into the MATLAB optimization toolbox, which uses the Nelder-Mead algorithm, was used due to the lack of constraints on the potential values of the aggregate modulus and permeability.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

After indentation testing, the samples were assessed using histological and biochemical measures. The histological analysis determined the structure and quality of the bulk cartilage, chondrocytes, proteoglycans, collagen, and tidemark in the tissue and then valued them on a quantitative scale to be able to use them in the neural network model. The biochemical analysis determined the concentration of a number of known factors (such as collagen content and orientation, proteoglycan content, and many growth factors) that affect the health of articular cartilage. Both the histological and biochemical factors had a simple regression analysis performed on them and all factors that were deemed statistically significant ($P < 0.05$) to the values of the aggregate modulus and permeability were used as inputs for the neural network model. Fifteen histological and biochemical factors were determined to be statistically significant.

The neural network was set up using the neural network toolbox in MATLAB. The values were normalized to be between -1 (minimum) and 1 (maximum) then randomly separated into three categories: training (70%), validation (15%), and testing (15%). The training samples were used to develop the relationship that relates the inputs (biochemical and histological data) to outputs (biomechanical data). The validation samples were plugged into the trained relationship and were used to determine when the program should stop. The testing samples were excluded from all training and provide insight into the performance of the trained system with samples that were not utilized in the development of the model. The most important factor in understanding the performance of the neural network is the R-value of the testing group. The R-value of each group describes the relationship between the experimental data and neural network outputs with a value of 1 representing a perfect match between both sets.

The neural network used the feed-forward back propagation method utilizing the Levenberg-Marquardt algorithm. The neural network used four layers of neurons with the first three layers containing 14, 10, and 3 neurons using a log-sigmoid transfer function. The final layer was a pure linear layer with a single neuron to adjust values to the output.

RESULTS

The results of the neural network model are shown below (Figure 1). The overall R-value is very high at 0.89, representing a strong correlation between the simulated and experimental results. More importantly, the test group R-value is 0.95, which means that this model is able to successfully model samples that were not included in the training of the neural network. One of the drawbacks of a neural network model is the possibility of overfitting the model to the training data. This is observed through a high R-value in the training samples and a much lower value in the test samples. It is clear that this system is well trained from the consistently high R-value across groups.

DISCUSSION

The results achieved in this study provide a very promising first step in developing a mathematical relationship between clinically attainable biochemical data and biomechanical properties. This could provide a tool for monitoring and diagnosis of joint disorders. While the current model has a few dramatic outliers, the R-value in the testing group represents a strong correlation.

The drawback to the neural network to modeling the system is that this is a "black box" approach. This means that the equation relating both sets of properties cannot be taken from the program. However, it is relatively simple to take the data either from an individual patient or to form a generalized model, an approach which is supported by this study, and run later samples through it to determine the mechanical properties of the tissue.

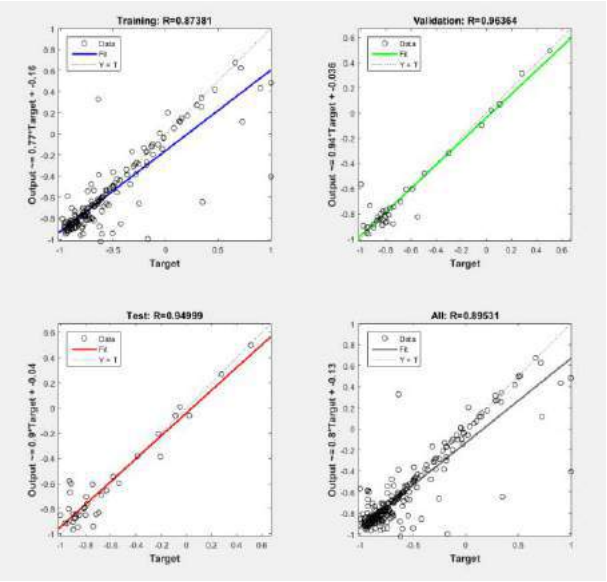

Figure 1: Graphs showing each test group ran through the neural network. The dotted line through each graph represents all points where the experimental and modeled data match perfectly.

Future work will focus upon development of a solid model of the tissue using the properties produced from the neural network for comparison with experimental models and for potential use as a diagnosis and product development tool. A more transparent model may also be created using techniques such as genetic programming. In order to provide a better diagnostic tool, healthy samples can be compared to known diseased tissues through either the neural network or more transparent techniques to allow for specific diagnosis rather than tracking the mechanical properties over time to determine the health of the tissue.

INTRODUCTION

Coronary artery bypass surgery (CABG) is performed to revascularize ischemic myocardium, and is widely accepted as an effective treatment for multivessel coronary artery disease. While arterial grafts are the preferred graft choice, resulting in favorable long-term outcomes, the need for multivessel revascularization and multiple targets necessitates the use of venous grafts in approximately 70% of cases. Venous grafts have high failure rates, with up to 50% of grafts failing within 10 years post-surgery. Further, surgeons are faced with a choice of several different revascularization techniques for venous grafts, including Y-shaped, sequential, or single grafts (Figure 1), with varying long term outcomes.

Decisions regarding the spatial arrangement of grafts, and the locations of anastomoses on target native vessels, rely on retrospective studies, limited geometric guidelines, surgeon's intuition and experience. Prior studies on the efficacy and superiority of each of these techniques [1, 2] report varied results. It is well established that hemodynamics, wall mechanics and geometry play a critical role in the long-term adaptation of grafts. However, numerous questions remain regarding variability across patients and the complex interplay between biology and mechanics. Virtual surgery studies provide a means to perform a controlled experiment in which patient variability can be controlled for, and the mechanics can be examined independent of other factors.

Image-based, patient-specific computational fluid dynamics simulations provide a non-invasive means to obtain finely resolved hemodynamic data, perform virtual surgery, and objectively evaluate these surgeries. Here, we demonstrate the capability of virtual surgery and simulation tools to compare and contrast three different CABG revascularization techniques commonly used in clinical practice today.

METHODS

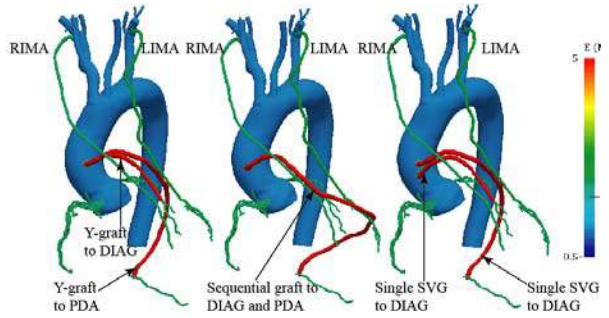

Figure 1: Patient-specific model from CT scan of a patient who had undergone CABG surgery with venous grafts in Y configuration (left); Sequential (middle) and 2 single graft (right) - virtual modifications of the graft geometry. Vessels are colored by their Young's Modulus values.
PDA-posterior descending artery, SVG- Saphenous vein graft, IMA-internal mammary artery, DIAG- Left Diagonal branch

We build patient-specific 3D models of CABG geometries from CT images of a patient who has undergone bypass surgery. We use a customized version of the open source software SimVascular (www.simvascular.org). We discretize the 3D model using linear tetrahedral finite element mesh using MeshSim (Simmetrix Inc, Clifford, New York) and assign vessel specific material properties and thickness, based on values from literature. For regions of the circulation not visible on the CT images we make use of a circuit analogy and design lumped parameter networks (LPN) to mimic the pressure-flow relationships in the systemic circulation, coronary

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

circulation and the heart. The LPNs are tuned to match non-invasive clinical data, including cuff blood pressure, cardiac output, and empirical data from literature, including coronary flow splits. The flow information in LPNs is coupled with the 3D domain using a modular iterative coupling algorithm [4]. We quantify hemodynamics and wall deformation related quantities in 3D domain by solving the incompressible Navier-Stokes equations for the fluid and linear elasticity equations for the solid, using stabilized finite element methods. The interaction of the fluid and the solid domains relies on the coupled momentum method where the tractions from the solid domain are imposed on a fixed fluid mesh.

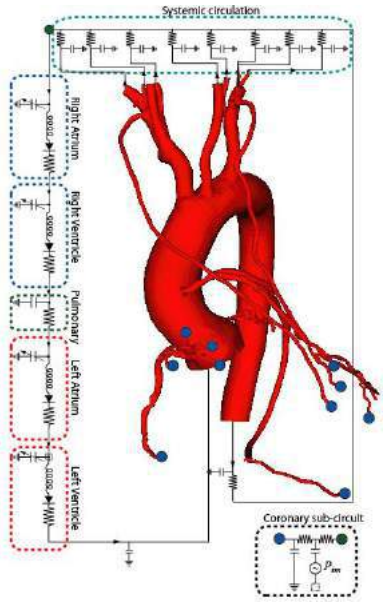

Figure 2: Patient-specific model coupled to a closed loop lumped parameter network (LPN) of circulation. The LPN includes an elastance based heart model, a windkessel model for systemic circulation and coronary-subcircuit.

With input from surgeons on our team, we virtually modify the venous graft geometric configurations to mimic the commonly performed revascularization techniques. In this study, we compare the Y-configuration, sequential anastomosis, and single graft approach, while keeping rest of the simulation parameters, including boundary conditions, material properties, and remaining anatomy, the same. The mechanical quantities correlated with atherogenesis and graft failure are quantified in each of these virtual surgical configurations. The graft regions at potential risk for restenosis or failure are identified.

RESULTS

The framework is able to reproduce clinically observed flow and pressure waveforms from clinical literature, including the out of phase behavior of coronary flow with the systemic circulation. We quantify key mechanical markers that influence endothelial behavior and cell proliferation, including wall shear stress (figure 3), oscillatory shear index, wall shear stress gradients, and wall strain. Preliminary results show that the sequential grafts have lower WSS in segments distal to the first anastomosis, likely making them more prone to atherosclerosis and subsequent failure. Current efforts are directed towards quantifying clinically/biologically relevant quantities in the venous grafts and comparing with clinical data in a cohort of patients.

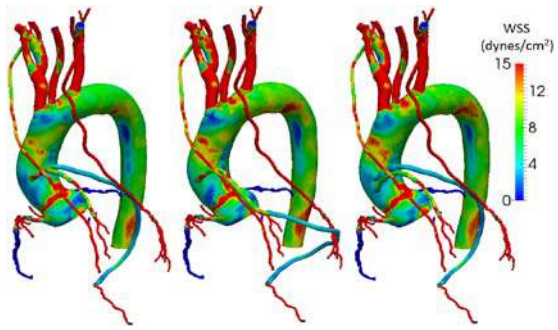

Figure 3: Cardiac cycle time averaged wall shear stress (WSS) distribution in the three venous graft configurations, with rigid wall assumption. Note the distal segment of sequential graft has lower WSS compared to the proximal segment.

DISCUSSION

Cells in the vessel wall sense mechanical stimuli such as stretch, wall shear, and oscillatory components of the flow, and regulate gene expression and turnover of wall constituents. Hence quantifying these stimuli is a necessary step in evaluating and comparing revascularization techniques. Computational simulations provide a non-invasive means to quantify mechanical stimuli on grafts in patient-specific geometries. Patients in this study act as their own control, as only the graft geometry is altered virtually keeping all other parameters fixed. This allows for a controlled comparison of surgical methods that is not possible in the clinical setting.

Our results show that regions distal to the side-to-side anastomosis (SSA) of the sequential graft configuration have lower WSS (3.1 dyn/cm^2) compared to the pre-SSA regions (6.1 dyn/cm^2). Prior studies have reported high failure rates for regions between the SSA and end to side anastomosis (ESA) in a sequential graft, which qualitatively agrees with our results. Additional patients will need to be added to the study cohort before further conclusions regarding clinical application can be drawn. Myriad factors, such as varying local geometry, wall properties and dynamic distal demand, make surgical design decisions non-intuitive, necessitating the use of computational tools, such as those proposed here, to aid in clinical decisions.

There are uncertainties associated with clinical measurements and parameters used to tune lumped parameter networks. Current efforts are being directed towards parameter estimation, identification and uncertainty quantification in these simulations. The models presented in this work lack details at the cellular/sub-cellular level and cannot capture the evolving nature of vessel wall constituents. There is a further need to couple CFD simulations with models of vascular growth and remodeling to gain further insights into the pathophysiology of graft adaptation. Nonetheless, the tools and methods proposed in this paper are a necessary step in that direction.

INTRODUCTION

Determining the biomechanical behavior of heart valve leaflet tissues in a non-invasive manner remains an important clinical goal. We have previously developed an inverse modeling framework that would allow us to determine mechanical parameters from clinical imaging modalities, like ultrasound [1]. However, in order to ensure robust results, we need to provide some important information about valve into the inverse model such as valve fiber architecture and its residual strain state. In this work we exploit the advanced in-vivo imaging and segmentation tools and novel technique to calculate strains without using physical markers on the leaflets to quantify in-vivo and residual strains in human aortic valve leaflets. The proposed method is generic and could be applied to any semilunar heart valves.

The information about residual strains is critical to accurate determination of tissue stress state, which in turn is related to pathology development. Yet, the level and functional role of residual strains in heart valves remains an open question. While it is anticipated that some level of residual strains exists in all heart valves, this has not been verified or quantified other than for the mitral valve (MV) [2]. In that study, physical markers were used that limited its clinical applicability and restricted the calculated strains to a sub-region of the leaflet. Thus, the need for valve excision and physical markers in determination of residual strains has rendered it challenging to perform such studies in healthy human subjects. While residual strains are known to exist within the aortic valve (AV) layers [3], it is not known whether, and how much, residual strain exists in the AV tissues in their in-vivo state. We aim to address these questions with a spline-based technique which allows us to determine heterogeneous strains without the need of physical markers. Combining such information into the inverse-modeling tools developed previously would allow us to determine functional properties of heart valves in the least invasive fashion.

METHODS

Five patients with healthy aortic valves were selected and imaged using 3D ultrasound. After their heart transplant, the valve leaflets from randomly selected positions were excised and analyzed to determine their collagen architecture using standard techniques [4]. The in-vivo ultrasound images were segmented at three states – open, just-coapted, and full closed – using a multi-atlas segmentation and deformable modeling technique [5]. The segmented images of the leaflet, both in-vivo and ex-vivo, were parameterized using a spline technique we previously validated [6]. This technique allows us to determine corresponding points in two images of a leaflet within good accuracy. Based upon this, we chose 14 points symmetrically placed on the leaflets as "virtual markers" and determined the strains from them between various states of the leaflet – ex-vivo to in-vivo (open), open to just-coapted, and just-coapted to fully loaded.

Overall leaflet dimensions were compared at various states – their areas and lengths of basal attachment and free edge. Moreover, heterogeneous strains varying of the leaflet were also analyzed. The strains were quantified in terms of the following quantities. The principal stretches λ_1 and λ_2, the stretches in circumferential and radial directions, the area change, the maximum shear, and the shear along circumferential-radial direction. In order to improve the statistical sampling, results from all three AV leaflet types – left coronary, right coronary, and non-coronary – were pooled. For the overall geometrical measurements, such as the total leaflet area and lengths of free edge and basal attachment, the results were averaged and variations were quantified in terms of standard deviation. Furthermore, for regional analysis, the leaflets were considered to follow symmetric deformation patterns, so that the sample sizes were doubled.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

The average ratio of leaflet area from ex-vivo to mid-systole was 1.2±0.19 and that from mid-systole to just-coapted configuration was 1.25±0.12. The leaflet areas during just-coapted and fully-loaded states were roughly the same with a 1.025±0.06 ratio (Fig. 1).

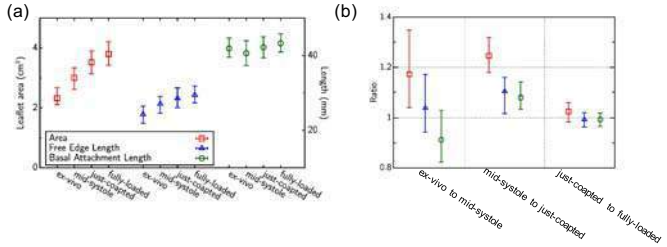

Figure 1: Average leaflet dimensions and areas, and their ratios over four states – ex-vivo, open, just coapted and fully loaded.

Strains over the leaflet varied significantly. The principal stretches for all the mappings were roughly aligned with the circumferential and radial directions, with higher stretch acting radially (Fig. 2). For the just-coapted to fully-loaded deformation, the circumferential stretch was close to one over most of the leaflet, except near the commissure and basal region, where there was 15% stretch in the fiber preferred direction. For the leaflet deformation from open to just-coapted state, the maximum stretch was in 1.3-1.7 range (Fig. 2) and the lower principal stretch varied to a much lesser extent across samples in the 0.8-1 range representing some shrinking. The stretch ratio along the circumferential direction was slightly higher than one, except near the commissure where it was approximately 1.3-1.5. Lastly, for the ex-vivo to in-vivo open state, the leaflet experienced high stretches in the radial direction. The circumferential stretch was usually close to one, whereas the radial stretch varied widely in regions. There was no radial stretch in the basal area, while other areas experienced a stretch of 25-50%. There was some shear deformation (10-30º) in all the cases which varied over the leaflet to some extent.

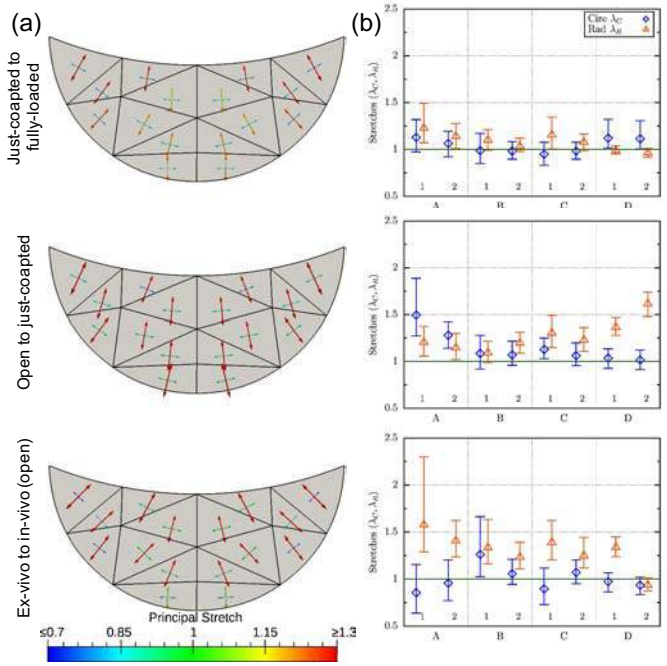

Figure 2: (a) The principal stretches over the leaflet and (b) stretches along circumferential and radial directions.

DISCUSSION

Since reported in the aorta by Fung, residual strain in biological structures has been an active area of research. In spite of their importance, investigation into the residual strains in heart valves is relatively new. This is partly because of the significant difficulty in obtaining the requisite data, including challenges in obtaining in-vivo images and segmentation of the leaflet geometry. In the present work, we utilized the latest imaging and segmentation technology and a novel technique to measure strains in AV leaflets that provided a heterogeneous strain field without the need of physical markers. The leaflets shrank by 17% upon excision on an average, and the deformation was predominantly in the radial direction. These were the first attempt of residual strain measurements on healthy human AV leaflets as per authors' knowledge.

In addition to residual strains, we also calculated the strains experienced in-vivo during valve closure starting with open state and deforming to just-coapted and fully-loaded states. We found that the leaflet area increased by approximately 25% as the valve closed from mid-systole to just-coapted state, even though the valve was not yet supporting any pressure difference. The change in linear dimensions of the leaflets (the free edge and basal attachment lengths) under this deformation was limited to only 3-5%. A heterogeneous analysis revealed that the local area change was highly non-uniform, ranging from almost no change in some parts to more than 50% increase in others, and that the deformation was predominantly in the radial direction.

During the leaflet deformation from just-coapted to fully-loaded, the area change was minimal and circumferential stretch was close to one over most of the leaflet. This indicates that most of the collagen fibers were already recruited in the just-coapted state, making the circumferential direction highly stiff.

For all in-vivo deformations, there was a 10-20º shear present, which was relatively uniform over the leaflet and consistent across samples. For almost all of the cases, the maximum stretch was observed perpendicular to the circumferential direction. This can be expected as the collagen fibers run predominantly along the circumferential direction making it the stiffer one.

Although sufficient for this study, the size of the sample dataset will have to be expanded to establish clear trends between three leaflet types and analyze the asymmetry of leaflet strains. In the future, we would apply this framework to other valves pulmonary valve, as well as pathological valves like bicuspid aortic valve. These results will form the basis of the critical information needed for accurately modeling and predicting biomechanical properties of the healthy human aortic valve leaflets in a non-invasive manner.

THE EFFECT OF SIMULATED ANATOMICAL CONSTRAINTS ON BUCKLING LOADS OF CARDIAC LEADS

INTRODUCTION

Perforation of the myocardium is a serious potential adverse event associated with cardiac leads. The load at which a cardiac lead body will bend or buckle is thought to be a factor in whether or not a particular lead design is likely to perforate the heart [1]. The combination of anatomical constraints and natural movement of the cardiac muscle creates forces on the lead that may cause perforation. The flexibility of the lead, which is reflected in its critical buckling force, provides some natural protection against perforation. However, there currently is no standard test method for measuring buckling force or flexibility of pacemaker or implantable cardioverter defibrillator (ICD) leads. Our earlier work incorporated simulated anatomical constraints into a buckling test to show that the load measured at the lead tip is dependent not only on lead design but also on the boundary conditions imposed on the lead during the test [2]. The purpose of this study was to further modify the test setup to continue our investigation of the effect of different boundary conditions on buckling load at the lead tip. The ultimate goal is to further develop a test method to identify characteristics of lead designs that make them more likely to perforate the cardiac muscle.

METHODS

Two pacemaker and two ICD lead models (n=2 each for a total of 8 leads) were subjected to cyclic loading in five test setups (A-E). Test setup A simulated the presence of the superior vena cava (SVC), right atrium (RA), tricuspid valve (TV), and right ventricle (RV) during systole and was previously described in detail [2]. The base plate used in the current study was modified from the previous metal plate [2] to incorporate a conical depression (5.43 mm radius, 3.8 mm depth) for seating the extended helix of the lead tip. The dimensions of the base plate are identical to those specified in a perforation test protocol under development by the AAMI Transvenous Leads Working Group. Setup B was the same as A except that the RV constraint was removed.

In test setup C the lead was fixed 75 mm from the distal tip, with an RV constraint around the distal portion of the lead, and no other simulated anatomical structures. Test setup D used the same fixture as C, without the RV constraint; therefore, D was an unconstrained configuration. Test setup E used the same fixture as C, modified to investigate the potential effects of friction by applying silicone lubricant along the lead body and the interior RV constraint.

Each lead was subjected to multiple cycles under displacement control to determine if the maximum load changed with cycle count. Tests were performed at 0.02 Hz (~50 mm/min) for 50 cycles with the helix extended. The minimum and maximum displacements for each cycle were 3 and 25 mm, with a preload of 1.5 ± 0.5 g.

RESULTS

The different test setups A-E substantially influenced the loading profiles of the leads. In general for pacemaker leads, setups that included the RV constraint (A, C) yielded the highest loads, with peak loads ranging from 30-60 g (Figure 1). Adding the lubricant (E) reduced the peak loads to 15-20 g. Removing the RV constraint (B, D) reduced the loads even further, with peaks less than 10 g.

For the ICD leads, all three setups that included the RV constraint (A, C, E) yielded somewhat similar loading profiles (Figure 2). As with the pacemaker leads, the peak loads for those setups were higher than the peak loads in setups without the RV constraint. The addition of the lubricant had more of an effect in reducing peak loads with pacemaker leads than with ICD leads.

Regardless of test setup, some leads experienced variations in maximum load during the first few cycles of testing, before achieving a steady state max load within 50 cycles (Figure 3, left). In contrast,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

maximum loads for other leads were fairly constant for the duration of the test (Figure 3, right).

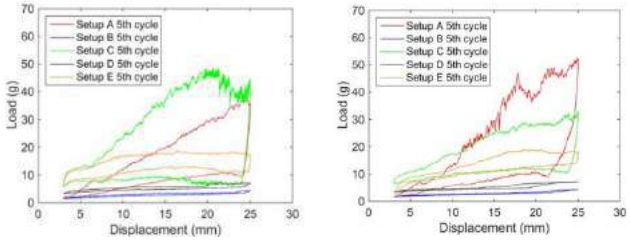

Figure 1. Buckling load vs.displacement for two different representative pacemaker lead models in test setups A-E. The fifth of 50 cycles is shown in each case.

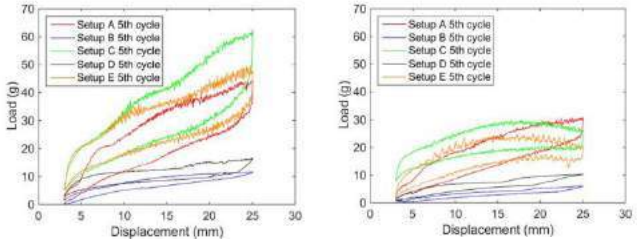

Figure 2. Buckling load vs. displacement for representative ICD lead models in test setups A-E. The fifth of 50 cycles is shown in each case.

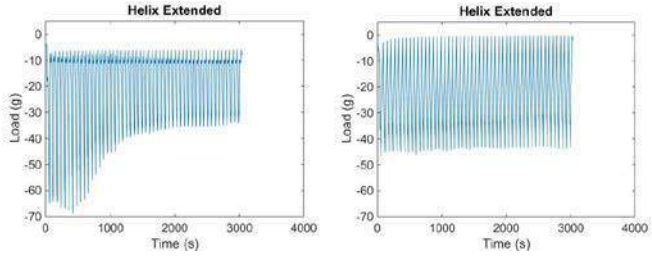

Figure 3. (Left) Compressive load vs. time for one representative pacemaker lead showing variable loads during the first few cycles prior to steady state loading by 50 cycles. (Right) Compressive load vs. time for one representative ICD lead showing fairly constant max load over all 50 cycles.

DISCUSSION

The loading profiles for both pacemaker and ICD leads in setups without the RV constraint (B, D) plateaued after the first few millimeters of displacement, but at the lowest loads (less than 15 g). In contrast, setups with the RV constraint (A, C) generally yielded steadily increasing and much higher loads; this was due to the lead making contact with the wall of the constraint and confirms our previous findings [2].

For all leads, the use of the lubricant in setup E reduced the peak loads compared to those of setup C. (Setup A with the lubricant will be tested at a later date.) For pacemaker leads with lubricant, the load-displacement profiles changed to resemble those of B and D; however, the plateau occurred later in the cycle (after 10-15 mm displacement). Furthermore, the marked difference in peak loads for pacemaker leads with vs. without the lubricant (C vs. E) appears to be due in part to the outer insulation material. Traditionally, silicone and polyurethane are used as outer lead insulation materials [3]. We noticed that the outer insulation of the two pacing lead models had a "sticky" feel (though to different degrees), while the majority of the two ICD leads felt more "slippery." It is our supposition that a greater amount of friction present between the pacemaker lead insulation and the RV constraint allowed a more noticeable decrease in peak load by the addition of the lubricant. In contrast, the ICD leads contacted the RV constraint at the location of the metal defibrillation coil, which provided little friction against the PTFE material of the RV constraint. Therefore, the addition of the lubricant made less of a difference for ICD leads because there was likely already a low coefficient of friction on the lead surface at the point of contact. Additional study of the friction between the various lead components and the RV constraint is necessary to test this supposition.

Despite the addition of the lubricant and the lower friction between the RV constraint and the defibrillation coil, peak loads for some ICD leads with the RV constraint increased steadily with displacement. In this case, lead diameter likely played a role, as the diameters of the ICD leads were up to 30% larger than the pacing leads. A larger lead diameter, combined with a defibrillation coil, and the lead's interaction with the base plate, are some of the factors affecting peak load, which is often construed as a quantitative metric of the lead's ability to bend under load (lead stiffness).

Maximum load varied considerably with cycle count for leads only in setups A and C, indicating that the interaction between the lead and the ventricular wall is a key component in determining peak forces imparted to the tissue by the lead tip. However, the maximum peak load in all setups reached a steady state by the 50th cycle. This steady state behavior provides initial insight on the long-term post-implantation loading conditions between the lead tip and the tissue.

Future research will include testing additional lead models to further determine the effect of simulated anatomical constraints and a "best" model for future testing. Changes in load-displacement behavior (e.g., peak vs. steady state load, loads at specific displacements) during cyclic testing will be analyzed for each individual lead model to explore how these changes might impact pre-clinical perforation assessment of leads. Lead characteristics such as stiffness, insulation materials, and general lead body construction will be examined to gain insight into any variations observed in loading profiles between pacemaker and ICD leads. Another important future consideration will be the interaction of the lead tip (helix) with a tissue substitute gel instead of a metal plate, and longer-term dynamic testing in load control. These tests will ultimately lead to testing conditions that more closely simulate the in vivo environment.

INTRODUCTION

Current automotive test devices include the mid-size male and small-size female Hybrid III dummies and injury criteria are essentially scaled from one to the other to account for differences between sex and size [1 , 2]. The scaling process is based on geometrical considerations with the assumption that the female spine is a simple scaled-down version of the male. Neck circumference is used as the scaling factor to convert injury metrics from male to obtain female-specific injury criteria. While female spines are smaller and have lower failure forces and moments, the validity of this scaling method and its application to injury criteria are not fully examined. This study presents a synthesis of literature data to examine the efficacy of the process.

METHODS

Methods consisted of examining biomechanical responses from different types of tests on different types of experimental models with male and female specimens from the same study, followed by anatomical studies using cadavers and volunteers to examine the role of injury metrics, patterns, mechanisms, and morphology of female and male human spines.

1. Biomechanical Experimental results

Functional unit tests: Static nondestructive pure moment bending tests under flexion and extension were conducted using the same experimental design to compare male and female responses [3, 4]. Female specimens had greater total range of motion than males. Failure moments in extension and flexion ($p<0.05$) were lower in females for the upper spine. Statistically significant differences were not apparent in the failure moment and angulation when all segments were grouped.

Head-neck complex tests under inertial loading: Dynamic tests simulating responses to whiplash-induced injuries from motor vehicle impacts showed differences in kinematics between male and female spines [5]. Segmental motions in females were greater ($p < 0.05$) at all sub-axial levels with the exception of the middle region. Shear force and extension moment magnitudes at the time of S-curvature were greater ($p < 0.05$) in females [6].

Intact human cadaver tests under tension loads: Distractive forces simulating airbag deployments were simulated using the intact whole body model [7]. Two male subjects sustained tension-related ligamentous injuries at the C1-C2 level while the other and the female subjects sustained injuries at the atlantal-occipital region. Maximum forces and moments showed typical biological variability, measured from the standard deviation (metrics for the female subject were within one standard deviation of the male responses).

Isolated cervical column tests under axial compressive loading: Tests were done using the base of the skull-to-entire osteoligamentous columns using fixed end conditions [8]. Injuries to male specimens consisted of 4 at C1, 1 at C2, 1 at C1 and C2, 1 from C3-C5, and 2 at C5 levels while injuries to female specimens included one each at C1 and C2, C4 and C5 in one, C3 and C6 in one, and an extension failure with unreported level, showing that both groups are susceptible to injuries at all levels. Maximum axial compressive force, deflection and energy of female specimens were lower than male spines.

Isolated cervical column tests under combined loading: Tests were done by applying an eccentric load using a pinned-pinned end condition [9]. The younger male specimen responded with C 4-5-6 anterior and posterior ligament tears and the older spine responded

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with wedging of C4-6 bodies associated with C3-4 disc tear, while the female specimen sustained C6-C7 posterior ligament tears. For the younger and older male and female specimens, peak flexion moments were 14.6, 3.4 and 8.7 Nm, and compressive forces were 192, 338 and 214 N. Moment-angulation curves of the female were within the boundaries of two male specimens.

Head-neck complex tests under axial compressive loading: Dynamic compression loading applied to the head simulating automotive and sports events showed differences between male and female head-neck complexes [10]. Compression body fractures to male specimens were concentrated at one level while injuries to female specimens included both body and posterior complex fractures and ligamentous lesions. The mean magnitudes of the axial force, deflection, strain, energy, and acceleration were within one standard deviation from each other. Studies examined the effects of loading rate, age and sex on injury probabilities [11]. Male spines sustained greater failure force (600 N) regardless of rate and age, suggesting that the failure response from a probabilistic perspective depends on these factors. Inverted drop tests were conducted on PMHS head-T1 columns [12]. All specimens sustained multiple level injuries with predominantly ligamentous involvements. Biomechanical data indicated that female metrics for the axial neck force was lower than the male specimens.

2. Cervical spine geometrical analyses

Facet joint-related geometry: Studies aimed to better understand susceptibility of the female population to whiplash associated disorders included the determination of the posterior column morphology [13]. While the facet joint width was greater ($p<0.05$) in the upper cervical spine in both populations, the gap in the dorsal region was greater (reaching significance at 0.06) and the facet cartilage thickness was lower ($p<0.05$) in the upper spine than the lower cervical spine for female specimens. Facet joint angles from 250 males and 173 females using CT scans of 18+ year-old subjects showed greater orientation in females at C2 and C3 (both $p<0.05$) and lower at C6 and C7 levels (both $p<0.05$) [14].

Muscle-related geometry: Human cadavers were used to quantify muscle insertions of C4-C5 and C5-C6 facet capsules [15]. The mean muscle insertion area was greater ($p<0.05$, by 1.8 times) in males (61.4 mm^2 versus 35 mm^2 for females) and mean axial cross sectional capsule area was greater ($p<0.05$, by 1.4 times) in males (14.7 mm^2versus 10.2 mm^2 for females). Estimated mean isometric muscle contraction was greater ($p<0.05$) in males than females (27 versus 15 N). The maximum moment generating capacity during maximum voluntary contractions of neck muscles in females was up to one-half of those in males [16]. Sagittal moments were lower ($p<0.05$) in females.

Vertebra- and disc-related geometries: Sex bias on vertebral geometry was analyzed using CT scans [5, 17]. Independent size-matched subgroups were identified based on sitting height and head circumference [5]. For sitting height-matched subgroup, the disc-facet depth and column height was longer ($p<0.05$) in males. For head circumference-matched subgroup, all vertebral dimensions were greater ($p<0.05$) by 7 to 18% in males.

SUMMARY

The simple scaling process based on neck circumference ignores local, regional and overall differences between male and female spine anatomy, structure/component, injuries, injury mechanisms, injury metrics, and potentially injury tolerance criteria when scaled from male spines. As briefly described above, studies show that differences exist and are statistical. The lack of significance in some studies presumably stems from factors such as sample size and altered focuses, i.e., not designed specifically to investigate female-male differences. The segmented nature coupled with the heterogeneous components of the spine should be given due consideration to derive female injury criteria even when one ignores differences (that might exist) in the head physical and inertial properties, as any added mass due to protective equipment alters the biomechanics and tolerance. As females are increasingly exposed in the military, the present analyses emphasize the need for testing female spines to derive female-specific injury criteria.

DETECTING OSTEOPOROTIC VERTEBRAL COMPRESSION FRACTURES: BMD VS. ACOUSTIC EMISSION TECHNIQUE

INTRODUCTION

Osteoporosis is a major health problem in the world and affects millions of people. It typically develops unnoticed over many years until a sudden bone fracture occurs. Osteoporosis is also a key cause of vertebral compression fractures (VCF) that influence about 40% of women in their life time [1]. During VCF, cracks accumulate in the vertebral bodies which can be exacerbated by activities of daily living. While medical images such as X-rays and CTs are viewed to evaluate spinal deformities, physicians predominantly use bone mineral density (BMD) to diagnose spinal osteoporosis, estimate the risk of VCF, and determine the appropriate drug dosage. However, BMD was found not a reliable predictor of fracture risk as there is substantial overlap between BMD scores of people who break their vertebra and those who do not [2-4].

Acoustic Emission (AE) is a nondestructive technique that can detect the progression of cracks occurred in a structure in real time. Besides earthquake detection and crack monitoring in oil pipes and bridges, in recent years AE technique has been employed to explore the biomechanical properties of various bone and implant constructs [5-7]. It showed a unique capability of revealing the occurrence time, amplitude and location of microcracks instantly and continuously. The objective of this study is using AE technique to investigate microcrack activities in vertebral bodies and assess its potential in detecting VCF in real patients. We hypothesize: 1) Microcrack signals detected by AE technique correlate to actual damages in a vertebral body; 2) An AE sensor attached posterior to the vertebral body can detect the damage signals occurred in the vertebral body.

METHODS

3 male and 3 female cadaveric lumbar spines (ages from 56 to 94) were collected from a tissue bank. BMD was measured using dual X-ray absorbitometry (DEXA). L2 was separated from each lumbar spine, with cartilaginous end plates resected and soft tissue removed from the anterior side of the vertebral body. Soft tissue posterior to the spinous process (including skin, fat, and muscle) were preserved. Plaster was applied to both end plates to make the surfaces parallel. The construct was mounted onto a Mini Bionix servohydraulic loading machine (MTS Inc. Eiden Prairie, MN), and a quasi-static compression load was applied through a ball joint at a speed of 0.2 mm/min for more than 30 mm displacement (Fig. 1). Yield force, ultimate force and stiffness of the vertebral bodies were monitored on the compression vs. displacement curve. Five small Nano30 AE sensors (MISTRAS Group, Princeton Junction, NJ) were attached directly onto the anterior side of the vertebral body to monitor microcracks that occurred when the vertebral body was loaded. Microcrack occurrence time, number, amplitude, and locations (if a microcrack signal was detected by four or more sensors) were recorded. One large wide band F30a AE sensor (MISTRAS Group) was glued on the skin posterior to the spinous process to examine how often a microcrack detected by Nano30 sensors could also be detected by a wide band sensor (F30a) that was further away from the damages.

The correlation among donor's age, L2's BMD and yield strength, and number of AE microcracks were examined using linear regression method. In statistic analysis a two-sided significance level of 0.05 was selected.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

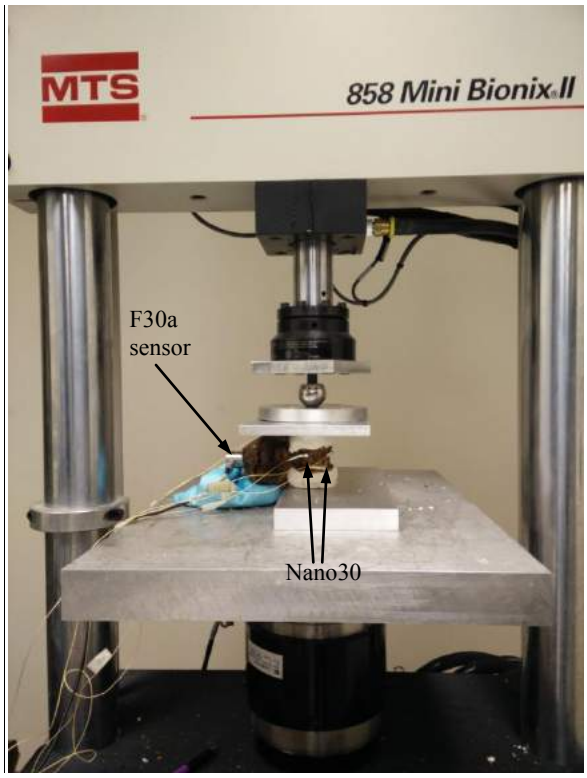

Figure 1. Setup of the biomechanical testing.

RESULTS

BMD of the six L2s ranged from 0.45 to 1.52 (Table 1). BMD negatively correlated to donor's age (R = -0.93) and positively correlated to the vertebral body's yield strength (R = 0.82). The number of AE microcracks did not correlate to either BMD or yield strength. However, the number of microcracks detected by 2 or more sensors (usually indicating a stronger signal and larger damages) was much highly correlated to the body's yield strength (R = -0.91) than BMD (R = -0.59). 71.3% of these multi-sensor microcracks were also detected by the wide band F30a sensor. In the compression tests, all specimens experienced a linear elastic region (recoverable deformation) initially, which was then followed by a plastic region (permanent damages) with no compression increase (Fig. 2). Additionally, AE microcracks were found to initiate around each vertebral body's yield point, and the number of AE microcracks kept increasing further throughout the plastic region (Fig. 2).

DISCUSSION

The compression test results showed that a vertebral body with a higher BMD is not necessarily stronger. The accumulation of AE microcrack in the specimens' plastic region indicated that AE technique can precisely detect ongoing cracks during this permanent damage period. Comparing to the multi-sensor microcracks that highly correlated to specimens' yield strength, those microcracks detected by 1 sensor seemed more random and less indicative. This study demonstrated that AE technique may provide more sophisticated data than the widely used BMD when diagnosing osteoporotic VCF, and allow researchers to reveal VCF from various directions, such as damage time, location, and severity. Additionally, AE technique has a potential to identify VCF patients in the clinical setting, as a wide band AE sensor attached to skin posterior to the vertebral body can successfully detect damages in the vertebral body. However, the potential needs to be further validated in clinic by applying AE technique on actual patients. Also, a fatigue flexion/extension test on cadaveric spines will be helpful to evaluate the performances of AE technique.

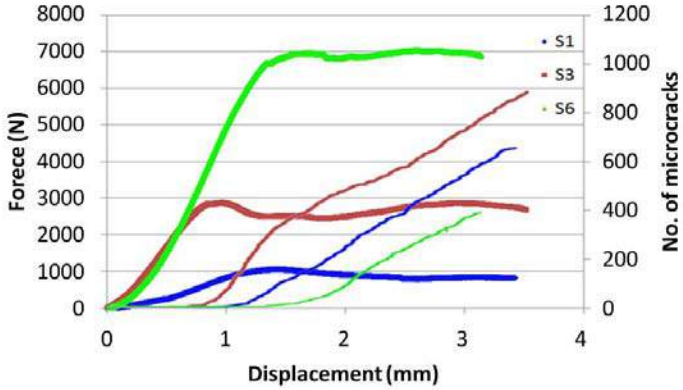

Figure 2. Compression vs. Number of AE microcracks vs. Displacement curves of specimen 1, 3 and 6. Compression force is the thick curve, and number of microcracks is the thin curve.

Table 1. Specimens' condition and testing results.

	Age	BMD	Yield strength (N)	No. of microcracks	Microcracks detected by 2+ sensors

INTRODUCTION

Heart valve diseases remains an unstudied area in cardiovascular pathologies. Congenital heart defects occur in 4 to 6 out of every 1000 births [1]. Of fundamental interest is the mechanics that regulate the biological environment. One such valve pathology is critical aortic heart valve stenosis (CAHVS). The stenosis is expressed as a severe obstruction to the left ventricular outflow tract due to congenital malformation of structures at the site of the aortic valve leading to abnormal hemodynamics. Currently CAHVS is surgically repaired with balloon aortic valvuloplasty (BAV). Short term results are favorable giving near normal hemodynamic function. However, in many cases the BAV procedure is a temporary solution as the incidence of re-stenosis is high and has been reported to be as much as 50% within 6 months of having undergone BAV repair [2]. This observation leads us to hypothesize that BAV provides a short-term surgical solution to CAHVS but by no means does BAV return the valvular flow environment to normalcy, which the valve endothelial cells (VECs) on the valve surface are not used to.

Our objective here was to identify the flow field under normal and post-BAV environments and subsequent biological responses of VECs.

METHODS

Culture and Expansion of VECs:

Valve endothelial cells (VECs) isolation was previously done from a porcine heart valve by separating the cells from the fibrosa side and the ventricular side in two separate flasks. Approximately 5x10^6 VECs/mL were cultured in T225 vented cell culture flask using DMEM media. Cells were grown in a standard cell culture incubator operating with 5% CO2 at 37°C with 95% humidity. VECs culture expanded to passages 4 to 6 were utilized for subsequent studies.

Computational Fluid Dynamics (CFD):

In order to extract the shear stress from the waveforms, which were obtained from Joe Di Maggio's Children's Hospital (JDCH), Hollywood, FL., CFD (ANSYS Canonsburg, PA) was conducted within the computationally reconstructed aortic structure from a pediatric patient who underwent balloon valvuloplasty and a normal pediatric patient (Fig. 1). The velocity profile was prescribed to the inlet and the pressure profile was specified as the outlet boundary condition (Figs 2 and 3). A transient simulation was conducted with a time step of 0.1 s and specifying a convergence criteria of 1x10-6 for momentum and continuity equations. Finally, blood material properties were used.

Fluid-Induced Mechanobiology Experiment:

VECs isolated from either side of porcine aortic heart valves (Mary's Ranch, Miami, FL) were plated in Collagen Type I (Fisher Scientific) coated microchannels. Side-specific shear stress profiles were obtained from our CFD simulations. Subsequently, side-specific shear stress profiles (fibrosa versus ventricularis) for BAV and normal cases were imparted onto VECs isolated from each corresponding side of the leaflets using (Fluxion Biosciences, San Francisco, CA).

RNA isolation and quantitative real time polymerase chain reaction:

Total RNA was isolated using the Stratagene RNA isolation kit (Agilent Technologies). Reverse transcription was performed with iScript cDNA Synthetic Kit (Bio-Rad). Primer sequence of interest have been complied. PCR was performed with Ssofast Evagreen SyperMix (Bio-Rad) on a C1000 thermal cycler (Bio-Rad)

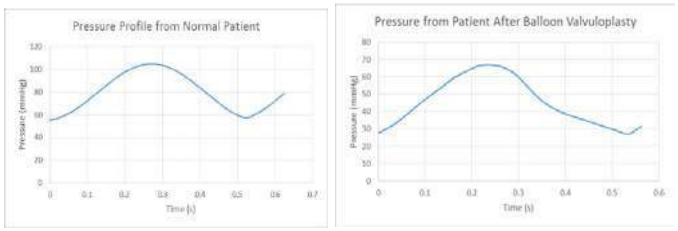

Figure 3. Pressure profile from a normal patient (left) and after balloon valvuloplasty patient (right) fed to the outlet in the CFD simulation

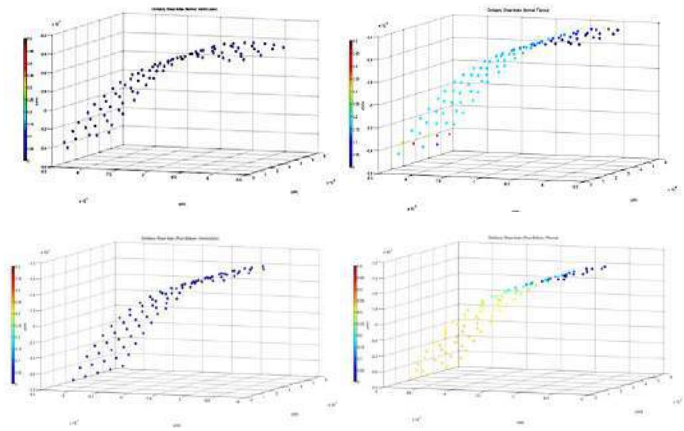

Figure 4. Oscillatory shear stresses from the CFD results of normal ventricularis side (top left), normal fibrosa side (top right), BAV ventricularis side (bottom left) and BAV fibrosa side (bottom right)

DISCUSSION

Critical aortic valve stenosis is considered to be a major source of mortality and morbidity in newborns with congenital heart disease. BAV treatment widens the stenosed valve region using a balloon catheter to increase the effective orifice area and improve the blood flow circulation. Nonetheless, the peak velocity past the heart valve that underwent BAV treatment was 1.11m/s, while the peak velocity observed in the healthy heart valve was 0.66m/s. Moreover, we observed that the fluid-induced shear stress profile on the ventricularis was considerably different compared to the fibrosa side (Fig. 3). We note that the localized hemodynamics is important in maintaining the function of the heart valve via normal valve tissue remodeling events. We found that there were distinct shear stress profiles between the normal and BAV cases which resulted in altered gene expression in the latter case compared to the normal (control) group. We conclude that changes in the local velocity and transvalvular pressure gradient leads to changes in responses at the cellular and molecular scales [3]. These changes may contribute towards rapid re-stenosis post-BAV repair (within 1 year), which has been observed clinically in pediatric patients with critical aortic valve stenosis.

INTRODUCTION

The incidence of lower extremity fractures has been reported to be as high as 46% post SCI (spinal cord injury), as seen in [1-3]. Body weight-supported treadmill training (BWSTT) has been reported to restore muscle mass and prevent bone loss in SCI patients. While the beneficial effect of this therapy is known, the effect of this training paradigm on varying severity of SCI has not been investigated in a single study. The purpose of this study was to investigate the effects of BWSTT on the muscle mass and biomechanical properties of the bone in transected and contused rats.

HYPOTHESIS

Repetitive BWSTT in SCI animals will: 1) improve behavioral recovery, 2) preserve muscle mass and 3) restore biomechanical properties of bones. Also, the improvements in these various parameters will be greater in contused than in transected animals.

METHODS & MATERIALS

In this experiment 32 female (200-250 g) Sprague-Dawley rats were split up into five groups (Fig. 1A). 16 animals received moderate (25 mm) contusion injury (NYU device) at T9/T10. 12 rats received a complete transection injury at T7. Four normal rats were used as control. At the end of nine weeks post injury, all animals were euthanized and the right soleus muscle and tibial bone was harvested.

Groups: Five groups:
Group 1: No Injury (**Cntl**)
Group 2: Contusion with no BWSTT (**Ctsn**)
Group 3: Contusion with 8 weeks of BWSTT (**Ctsn + BWSTT**)
Group 4: Transection with 8 weeks of BWSTT (**Tx**)
Group 5: Transection with no BWSTT training (**Tx + BWSTT**)

BWSTT Protocol: Animals in the training group received 8 weeks of BWSTT at 75% BWS and 7 cm/sec speed and 500 steps/day for 5 days/week using a robotic device (Robomedica Inc., CA) (Fig 1B).
Locomotor Recovery Tests: Pre-injury and weekly post injury open field Basso, Beattie and Bresnahan (BBB) locomotor test was performed in all animal groups.
Muscle Mass: At the end of the study, the right Soleus muscles was harvested, weighted and calculated against the total body weight.
Biomechanical Testing of the Bone (3-Point Bending): The harvested tibiae bone was subjected to a 3 point bending test. Each bone was placed on the lateral surface on two rounded supporting bars with a distance of 20 mm (Fig. 1C). A constant displacement rate of 5 mm/minute was applied at the medial surface of the diaphysis by lowering a third rounded bar until failure (shampo, Itasca, Illinois) Ultimate failure load (lb) was calculated for each specimen.

Mean ± SEM of the Soleus Muscle Weight/Body Weight. Asterisks indicate significant difference (p<0.05) from

DISCUSSION

- BWSTT led to significant improvement in the soleus muscle mass when compared to no training in both contused and transected animals.
- Higher Muscle mass was restored with and without training in contused animals than transected animals.
- Higher failure loads were observed in BWSTT groups, however, no significant improvement in the biomechanical property of the tibial bone was observed in the transected and contused rats, with or without training.

We attribute no changes in the bone properties to the severity of contusion injury that results in non-weight supported locomotion in animals in response to injury and also to the 75% BWSTT. Training with lower body weight support might result in significant improvement in the biomechanical properties of the tibial bone. Future studies are needed to investigate the effects of BWS and bone strength in various SCI models.

INTRODUCTION

Meniscus tears are an important knee pathology, causing both immediate dysfunction and, in the long term, increasing the risk of osteoarthritis. Despite the serious consequences of meniscus tears, little is known about how they grow or what effects they have on meniscus mechanics. A tear is essentially a crack and, in principle, should increase stress locally at its tip, causing rupture by crack extension at otherwise safe loads. This process is called fracture. It is fairly well understood in industrial materials, but not in fibrous soft tissues such as the meniscus. Reproducing physiologic crack propagation in controlled laboratory tests has proven difficult, and fracture studies of fibrous soft tissues have produced ambiguous results [1]. The central unknown is whether or not a crack generates a strong enough stress concentration to cause failure by fracture. Since meniscus suffers from both sudden rupture and slow growth of crack-like defects, fracture probably applies to at least some loading conditions. Identifying when fracture applies is important because it determines the meniscus' effective strength. More broadly, it is also important to determine if cracks cause any local mechanical effects, as local overstrain and damage can cause dysfunction even if they do not produce total rupture.

Accordingly, the goal of this study was to measure the consequences of meniscus cracks in uniaxial tension: determine if cracks (1) weaken meniscus and cause fracture, (2) change the sub-failure stress–strain response, or (3) cause local overstrain near their tips. These objectives were met using parameterized stress–strain curve data, inspection of rupture appearance, and continuously recorded strain fields. Loading direction, crack position, and crack orientation were varied. This study introduces the use of specimens with 45° center cracks, which our previous work indicated should produce greater stress concentrations than commonly-used edge crack specimens [2].

METHODS

The uniaxial tensile response of the meniscus was compared between cracked and crack-free control specimens. Specimens were cut from the center of adult bovine meniscus for testing in both the circumferential and radial directions (figure 1). Specimens were cut to ~1.5 mm thickness using a cryomicrotome. Circumferential specimens were cut in an extended tab shape to securely grip the meniscus' circumferential fibers [3]. Three groups of crack & control specimens were cut: circumferential 90° edge cracks (n = 13) and their controls (n = 10), circumferential 45° center cracks (n = 8) and their controls (n = 9), and radial 90° edge cracks (n = 12) and their controls (n = 21) (figure 2). The two separate circumferential control groups were used to ensure anatomical correspondence between the cracked specimens and their controls, since edge and center cracks sever different regions of the meniscus.

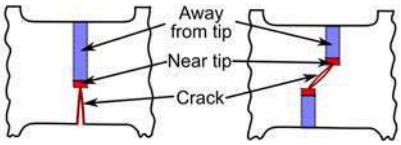

Figure 3: Region of interest definitions for comparing strain near the crack tip to strain away from the crack tip.

Specimens were preconditioned for 10 cycles to 4% strain, then loaded monotonically to failure at 0.5 mm/s. Video was recorded and surface strain fields were measured using digital image correlation. Stress was calculated using the cross-sectional area (at zero strain) not severed by the crack. Ramp to failure stress–strain curves were quantified by yield stretch, yield stress, tangent modulus at yield, peak stretch (at peak stress), and peak stress. Yield was identified using a recently established derivative-based method [3]. To determine if the crack changed the specimen's global mechanics, these stress–strain curve parameters were compared within each of the three control & crack groups shown in figure 2. To determine if the crack caused local overstrain, longitudinal (E_{xx}), shear (E_{xy}), and transverse (E_{yy}) strain components were compared between regions near the crack tip (within 0.5 mm) and away from the crack tip (figure 3). This comparison was made at 70% of the peak stress. All comparisons were done using two-sided Welch's t-tests with significance set at $p < 0.05$. Data were plotted on Tukey boxplots.

RESULTS

Peak stress was not significantly different between control and crack specimens in any of the three cases examined (figure 4). However, yield stress and tangent modulus were greater for both circumferential and radial edge crack specimens than for the corresponding controls (figure 4 *a* and c). No stress–strain curve parameters were significantly different for center crack specimens.

Ruptures tended to occur over a large area, without clear crack propagation. In circumferential specimens, rupture involved widespread inter-fiber sliding. Specimens often ruptured away from the crack.

The strain field analysis showed local effects from the cracks. Circumferential and radial edge cracks produced greater shear strain (E_{xy}) near the crack tip than away from it (figure 5). Radial edge cracks also showed increased transverse compression (negative E_{yy}) near the crack tip. These strain concentrations were readily visible in the strain fields (figure 5). They first appeared at ~25% of peak stress, prior to the yield point. Circumferential 45° center cracks produced no significant strain field alterations. None of the test configurations showed significant crack-associated changes in the longitudinal strain (E_{xx}) field.

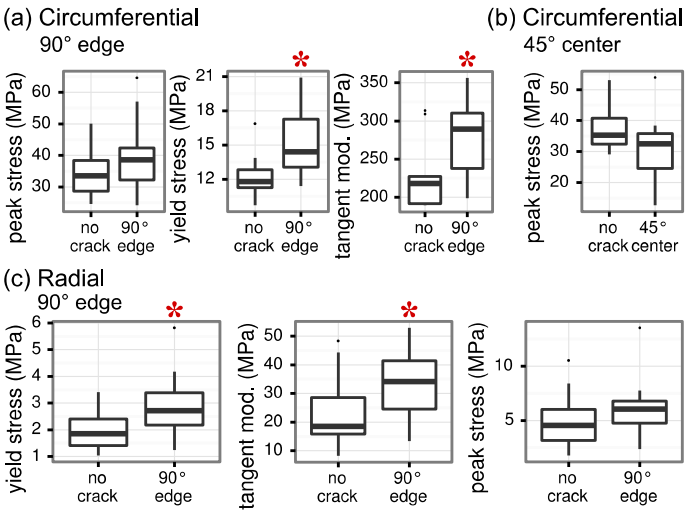

Figure 4: Comparison of stress–strain curve parameters between control (no crack) and cracked specimens. * = $p < 0.05$.

DISCUSSION

Although cracks affected both global and local mechanics, they did not reduce the effective strength of the meniscus in any of the tested configurations. This implies that fracture did not occur. Fracture is likely inhibited by the broad spatial extent of ruptures, as fracture requires progression of local rupture. The observation of ruptures away from the crack indicates that material inhomogeneity (visible in the figure 5 strain fields) trumped crack-induced strain concentrations.

The changes in the sub-failure stress–strain response of 90° edge crack specimens—namely, greater yield stress and tangent modulus—were surprising. They may be caused by load-sharing from the intact cross-section to the severed cross-section, facilitated by fiber dispersion or inter-fiber shear stress. In other words, the effective cross-sectional area of cracked specimens may be greater than measured. However, these load sharing mechanisms must be fairly weak, or they would have similarly caused an increase in apparent peak stress.

Edge cracks affected local mechanics by increasing shear strain near their tips. In circumferential tests, shear strain concentrations extended from the crack tip all the way to the grips, and were probably caused by inter-fiber shear. These strain concentrations could cause problems in vivo by promoting meniscus fragmentation, as in complex (degenerative-type) tears. In our study's test configurations the shear concentration just promotes deflection of the crack towards the grips, and the compressive transverse strain concentration in radial specimens does not facilitate crack propagation at all. Crack propagation across the specimen would instead require increased longitudinal strain.

Since cracks grow in vivo, we attribute our study's lack of crack propagation and fracture to our chosen test configurations. Crack propagation may require multiaxial loading, greater strain rates, cell-mediated degradative processes, or cyclic loading. Deflection of the crack to produce shear overstrain between fiber bundles appears to be an important mechanism by which the meniscus resists fracture and total rupture. As the meniscus is inhomogeneous on the scale of the crack, representing this inhomogeneity in mechanical models is likely necessary for accurately predicting when and how a meniscus will fail.

FIBRIN GLUE INCREASES THE STRENGTH OF CONDUIT-ASSISTED DIGITAL NERVE REPAIRS

INTRODUCTION

Complete digital nerve lacerations require repair to prevent functional or sensory deficits [1]. Ideally, tensionless coaptation of the transected nerve ends is possible. When it is not, autografts, nerve conduits, and glues provide other options for nerve repair: each has strengths and weaknesses. Autografts bridge the gap between nerve ends, but require harvesting of a healthy nerve. Nerve conduits provide a guide and a conducive environment for healing and do no damage to the site where the graft is harvested [2]. Additionally, the use of a conduit may move suture away from the coaptation reducing further damage to the nerve. Finally, nerve glues provide the advantages of reduced damage to the nerve and fast repair [3].

While tensionless repair is ideal, repair strength must still withstand all loading during healing. Researchers have tested the strength of nerve repairs as a function of suture size [4], of number of sutures [4], of suture purchase [4], of number of sutures with conduits [5], and of different glue types [6]. To the best of the authors' knowledge, no one has yet studied the strength of conduit-assisted digital nerve repairs with glue.

The purpose of this study is to determine whether suture configuration or the presence of fibrin glue affects the maximum failure strength of conduit-assisted digital nerve repairs.

METHODS

Ninety digital nerves were removed from seven fresh-frozen cadaveric hands between the proximal bifurcation of the common digital nerve and the distal trifurcation of the proper digital nerve. Specimens of approximately 5 cm in length were assembled. The diameters of the nerve specimens were measured with calipers. The nerves were transected and then repaired with one of five suture configurations and one of two glue configurations; there were nine nerves with each suture and glue configuration. All repairs were conduit-assisted using a nerve protector (Axoguard, Axogen, Alachua, FL) cut to 12mm in length, bathed in saline to increase pliability, formed into a cylinder, and then sutured at its ends with 8-0 nylon suture (Covidien, Medtronic, Minneapolis, MN). The five suture configurations were (4/4), (2/2), (2/0), (1/0), and (0/0) where the first number describes the number of sutures at the coaptation and the second number describes the number of sutures at each end of the conduit connecting it to the nerve's epineurium. The two glue conditions are with and without fibrin glue (Tisseel Duo kit, Baxter, Deerfield, IL).

Tensile testing proceeded after repair. Gauze pads were attached to the ends of nerves with cyanoacrylate. The glued gauze pad / nerve ends were pressed on a flat surface for fifteen minutes with approximately 230 g to ensure even attachment and then the weight was removed for an additional fifteen minutes to ensure the glue fully set. Nerve specimens were loaded to failure in a tensile testing machine (Haake Mars II, Thermo Fisher Scientific, Inc., Waltham, MA) at rate of 0.33 mm/s. Load data was recorded at 10 Hz. Maximum failure load was calculated as the largest tension measured during the trial. A few specimens did not actually fail during testing due to slippage of the nerve in the clamp or due to the stripping of the outer layer of the epineurium in the gauze. In any trial where the nerve specimen did not fail and no damage was visible, the nerve specimen was retested.

A two-way analysis of variance (ANOVA) was performed to determine if suture configuration, glue presence, or their interaction had a significant effect on maximum failure load. Three null hypotheses were considered: first, suture configuration had no significant effect on maximum failure load; second, glue presence had

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

no significant effect on maximum failure load; and third, the interaction between suture configuration and glue presence had no effect on maximum failure load. P-values less than 0.05 were used to reject the null hypotheses. In the case of significance, the differences within the condition were determined using Tukey's procedure. Finally, a one-way ANOVA was performed to determine if the nerve diameters were significantly different between all ten groups tested (10 groups = 5 suture configurations times 2 glue configurations). The null hypothesis was that there was no significant difference between diameters from one group to another with a p-value less than 0.05 signifying significance.

RESULTS

Both suture configuration and glue presence had significant effects on maximum failure load ($p < 0.01$). Among the suture configurations tested, maximum strength increased with increasing amounts of suture. The addition of the fibrin glue also increased maximum failure load. The interaction between suture configuration and glue presence did not have a significant effect. There was no significant difference in nerve diameters between groups.

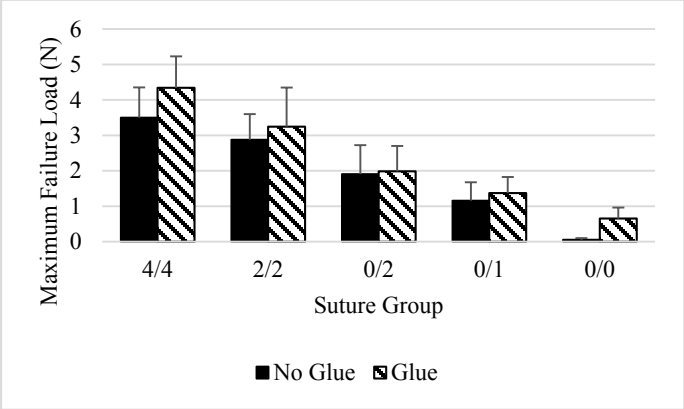

Figure 1: Conduit-assisted digital nerve repair maximum failure strength increases significantly with additional suture and / or the addition of fibrin glue.

Table 1: Average diameter and average maximum failure load by group

Group	Avg. Diameter (mm)	Avg. Max Failure Load (N)
A	1.53±0.16	3.50±0.86
A'	1.52±0.15	4.34±0.89
B	1.52±0.11	2.88±0.72
B'	1.49±0.12	3.25±1.10
C	1.38±0.26	1.91±0.81
C'	1.44±0.26	1.98±0.72
D	1.42±0.17	1.16±0.52
D'	1.50±0.19	1.37±0.45
E	1.52±0.19	0.06±0.04
E'	1.28±0.21	0.65±0.31

DISCUSSION

This study analyzed the effects of fibrin glue and suture configuration on the maximum failure load of conduit-assisted digital nerve repairs. Both the presence of glue and suture configurations with more suture proved to be significant in increasing the maximum failure load of the repairs.

This work was the first to determine the strength of conduit-assisted digital nerve repairs with the addition of fibrin glue. Martins et al. [7] studied the recovery of walking in rats after transection and repair of the sciatic nerve using combinations of fibrin glue and suture, but repair strength was not tested. Goldberg et al. [4] found a significant difference in the strength of digital nerve repairs due to the number of sutures used, but not due to the suture size or the suture purchase. Neither nerve conduits nor glue were used in the study. Schimoler et al. [5] found a significant difference in the strength of conduit-assisted digital nerve repairs as a function of suture configuration, but again did not use a fibrin glue. Isaacs et al. [6] found no difference in the strength of tibial and deep peroneal nerve repairs done with suture or suture plus glue and also did not use conduit-assisted repairs.

The increase in strength due to the fibrin glue in this study has immediate implications. If suture at the coaptation can be reduced by the used of glue while maintaining the same repair strength, damaged nerves will undergo less iatrogenic damage during repair, thereby increasing the chances of functional and sensory recovery.

ACKNOWLEDGEMENTS

We would like to thank Michael Smolinski for his help testing the nerves.

INTRODUCTION

Articular cartilage experiences high magnitude, multidirectional, dynamic loads during activities of daily living [1]. Ideally, scaffolds intended for cartilage repair must be able to integrate with the host tissue under these complex loads. While bioreactors have been used to apply mechanical loads to scaffold-tissue explants [2], we have no mechanistic understanding of the relationship between the biological response of the cells at the interface and their mechanical environment. As such, it is impossible to mechanically or structurally optimize scaffolds to enhance scaffold-cartilage integration.

Our goal was to investigate the relationship between the mechanical environment and the biological response of cells at the scaffold-cartilage interface. We hypothesized that the magnitude of micromotion at the scaffold-cartilage interface (i.e. relative movement between cartilage and scaffold) would have a significant effect on interfacial strength (IFS). To test this hypothesis, we developed a computationally driven physical bioreactor cartilage-scaffold explant model in which the following variables were controlled: (i) load magnitude, (ii) degree of confinement of the periphery tissue, and (iii) pre-seeding of cells in the scaffold. The computational model was used to fully characterize the mechanical environment within the scaffold and at the scaffold-cartilage interface, thus allowing for the biological response to a controlled mechanical environment to be assessed.

METHODS

A non-degradable porous scaffold previously developed as a candidate material for cartilage repair [3], poly(vinyl alcohol), was used as a model scaffold to avoid the temporal effects of degradation. Cylindrical disks (5 mm Ø x 2.5 mm thick) were disinfected in 70% ethanol, dehydrated in 100% ethanol and air-dried. The dehydrated scaffolds were then placed into 3.5 mm diameter defects created in 10 mm articular cartilage discs extracted from juvenile bovine knees. The scaffolds, with or without chondrocytes, were rehydrated *in situ* with 50 μl of culture medium to create a press-fit, and cultured for 28 days.

To choose the exact load profiles and degree of confinement within the physical bioreactor, a biphasic finite element model (bFEM) was created: In the axisymmetric model, articular cartilage was modeled as a biphasic material with depth-dependent material properties[4]. The scaffold was modeled as homogeneous biphasic material, with material properties input form unconfined compression tests. In order to mimic different magnitudes of micromotion at the scaffold-cartilage interface, the following conditions were identified from the bFEM for implementation in the physical model: **confined** – where the cartilage disk was confined in a polydimethylsiloxane ring, **unconfined** –the articular cartilage disk could expand peripherally, **low load** –sinusoidal loads of 0.1-1 N (stress 1.27 - 12.7 kPa), and **high load** –sinusoidal loads of 0.6 – 6 N (stress 7.64 - 76.4 kPa). After 28 days of culture, the prescribed loads were applied daily (450 cycle, 0.5 Hz) to confined and unconfined samples, with and without pre-seeding of cells, resulting in 16 groups. To capture the change in properties of the scaffold and at the interface during testing, the bFEM was re-run with D28 scaffold modulus and interface strength values as acquired from physical tests on explants.

Outputs: Scaffold-cartilage interface strength (IFS) was quantified by performing push-out tests. Constructs were then stained by Safranin O for GAG and immunohistochemistry for type II collagen. The scaffold-cartilage interface was visualized using μCT. Two-way ANOVA and Bonferroni post-test were performed and analyzed using GraphPad Prism software (La Jolla, CA), $n \geq 10$ per group, $\alpha = 0.05$. From the bFEM, micromotion at the scaffold-cartilage interface, at peak load, was computed. The distribution of axial stress throughout the scaffold and cartilage was also output.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Physical Model: Unconfined defect models without pre-seeding of scaffolds with chondrocytes (G.1) showed low IFS ranging from 1-3 kPa for all conditions **(Fig. 1)**. The corresponding confined condition (G.2), resulted in a slight, but non-significant increase in IFS, $p > 0.05$. Cell-seeded PVA scaffolds improved IFS in unconfined (G.3) and confined conditions (G.4) compared to their respective non cell-seeded groups (G.1 vs. G.3 and G.2 vs. G.4 at $p < 0.05$) **(Fig. 1)**. Cell-seeded scaffolds in confined conditions (G.4), subjected to 1 N of load had the highest IFS of 50.2 ± 1.0 kPa after 42 days in culture.

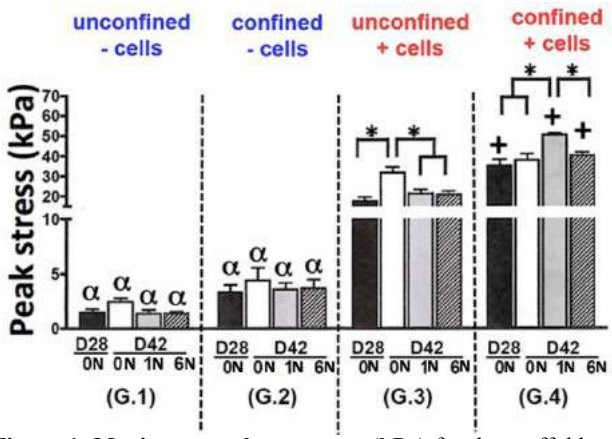

Figure 1. **Maximum push-out stress (kPa)** for the scaffold-cartilage explants as quantified on days 28 and 42. Note: by d28, no mechanical loading had been applied to any group. Applied loads within each condition were 0N (no loading) 1N, or 6N. α significant effects of pre-seeding (G.1 vs. G3 and G.2 vs. G.4). * significant effect of loading within the same group. + significant effect of boundary condition (G.1 vs. G.2 and G.3 vs. G.4)

G. 4 (1N, confined, +cells), which had the highest IFS, showed strong GAG and collagen type II staining at cell clusters within the porous scaffold and extracellular matrix filled the gap between the scaffold and articular cartilage (**Fig. 2**). While the lowest IFS group (G.1: 6N, unconfined, -cells) showed the least abundant staining, the least physically connected interface, and only partial filling of the gap.

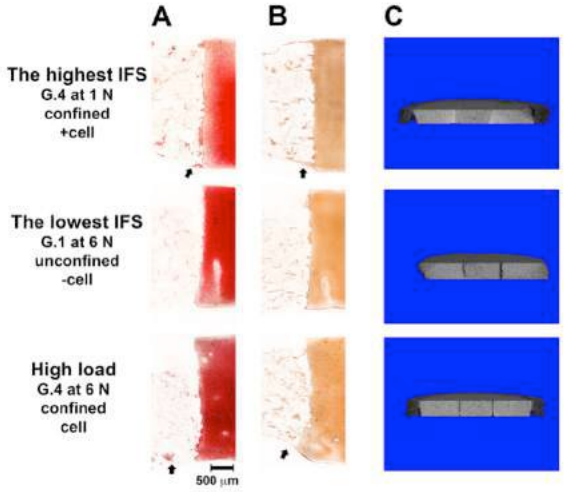

Figure 2. Histology and μCT GAG staining of PVA scaffold and cartilage **(A)**, immunohistochemistry of collagen type II **(B)**, and cross-section of 3D reconstruction of the defect model **(C)**. Arrows indicate cells sediment at the bottom of scaffolds.

Computational Model: Under peak load of 1 N for the confined compression condition, micromotion at the interface of cell-seeded scaffold was not evident (**Fig. 3A and 3B,** *the highest IFS group*). Axial stresses of 3 kPa and 23 kPa were quantified in scaffolds of *the highest IFS* group and *the high load* group, respectively. Peak micromotion of ~90 μm was found for the unconfined compression group at the peak load of 6 N (**Fig. 3B,** *the lowest IFS*). Confinement at the tissue periphery resulted in a decrease of stress within the scaffolds from 11 to 3 kPa at 1 N of load and from 28 to 23 kPa at 6 N of load.

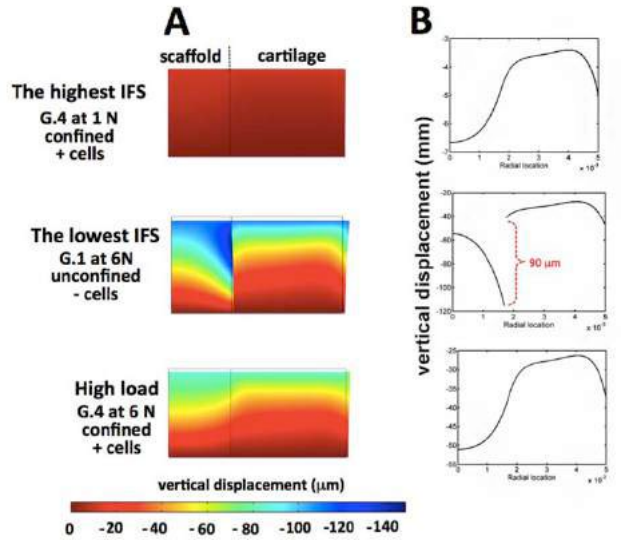

Figure 3. Biphasic finite element models (bFEMs) (A): Distribution of vertical displacement (μm) in the scaffold and cartilage at the peak loading at 1 or 6 N. **(B):** Micromotion between the scaffold to cartilage at the interface at peak load.

DISCUSSION

By way of a computationally augmented bioreactor study, we rejected our hypothesis: both the magnitude of micromotion at the scaffold-cartilage interface and the magnitude of stress within the scaffold had a significant effect on IFS, but only in scaffolds that were pre-seeded with cells. The groups that were not pre-seeded with cells did not respond to changes in interface micromotion or scaffold stress in a robust way: regardless of what variables were altered, low IFS and low cartilaginous matrix production resulted. For the cell-seeded groups, our study suggests that there exists a critical threshold of scaffold-cartilage micromotion combined with a critical level of stress within the scaffold that together are required to encourage robust integration. The magnitude of micromotion was affected not only by the boundary conditions of the explant, but also the integration between the scaffold and articular cartilage: as more matrix is generated at the interface, a corresponding decrease in micromotion occurs. The computationally augmented bioreactor herein described can be used as a model to evaluate the integrative capacity of scaffolds, prior to costly and time consuming animal models.

INTRODUCTION

Although the methods used to quantify bandwidth for a simple engineering system are well established [1], the application of bandwidth to complex systems like a human is more challenging. A simple explanation is that higher bandwidth controllers are able to respond to systems that change more quickly. Many different factors influence the human neuromuscular control system, and its response to external inputs. Some of these factors include age, physical health, neurological condition, external environment and body mass distribution. The human neuromuscular control system is further complicated by the fact that it may have different responses to the same input signal. Since there are a large number of confounding factors and since they are inherently coupled with the system, a large amount of experimental data is needed to understand the influence of each factor on bandwidth.

In order to understand the complexity of human motor control, some researchers have used mathematical models to study torso movement. Typically, input commands are presented to the system and the motor control moves the body to track these movement commands.

The ultimate goal of this research is to develop new diagnostic methods that can be used by medical professionals to assess the degree of neuromuscular disease and evaluate the effectiveness of treatment. In this research, methods are developed to calculate the bandwidth of the neuromuscular control system which may be used as a measurable variable to quantify neuromuscular controller capability.

METHODS

The upper body (including the head, arms and torso) was represented as an ellipsoid (Figure 1). The height and width of the ellipsoid were selected based on the values of typical human subjects. A simulated motor was connected to the upper body to control the rotation of the ellipsoid.

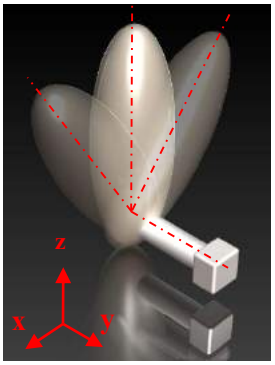

Figure 1: Representation of upper body and controller.

The ellipsoid representing the upper body was assigned a moment fo inertia of I. Torso stiffness due to spinal ligaments, and passive muscle tone of the abdominal and back muscles were assigned a stifness value of k. Viscous damping of the torso during movment was assigned a value of b.

A second order differential equation was used to describe the dynamics of the system. A general rotational dynamic system can be represented by

$$I\ddot{\theta} + b\dot{\theta} + k\theta = u(t) \quad (1)$$

where θ is the angular position about the lumbar spine and $u(t)$ is the torque applied to the system. In this model, $u(t)$ consists of two components.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The first is torque generated by active contractions of the abdominal and back muscles. This torque is controlled by the human motor controller in the brain. The second component is the effect of gravity on the system. A mathematical representation of these torques is given by

$$u(t) = G(\theta_d - \theta) + mgl\ sin(\theta) \quad (2)$$

where G is the gain of the controller. The paremeters m, g and l are the mass of upper body, acceleration due to gravity and the length of the segment to the center of mass, respectively. θ_d is the desired angular position. Using Euler's approximation, the mathematical representation of the system for small angles is

$$I\ddot{\theta} + b\dot{\theta} + \theta(k - mgl) = G(\theta_d - \theta) \quad (3)$$

Representative values for the unknown parameters I, b, k, m, l, and G were selected based on typical human values [2]. These unknown model parameters are stored in the vector $\alpha = (I, b, k, m, l, G)$. The mathematical model was run to generate a system response to a step function. Six step functions were evaluated (±3°, ±2°, ±1°). White Gaussian noise was added to the response curves and the curves were filtered with a band pass filter over the range of 0.01 to 10 Hz. These curves are show as the black lines in Figure 2. Each curve is an average of three separate simulation runs. The curves serve as a surrogate for data that will be collected in future human subject experiments.

Our method uses optimization to determine the unknown parameters in Equation 3. The response of the model is compared to the simulated experimental data. Optimization is carried out by minimizing the cost function shown below,

$$S = \sum(\theta_{s,i} - \theta_{m,i}(\alpha))^2 \quad (4)$$

The values for the parameters in vector α can be determined from the solution of the optimization problem. Variable $\theta_{s,i}$ is the angular position of the simulated experimental data at the i^{th} time step (black line in Figure 2). Variable $\theta_{m,i}(\alpha)$ is the angular position of the model response given parameters α. The optimized curves are shown in Figure 2 (colored lines).

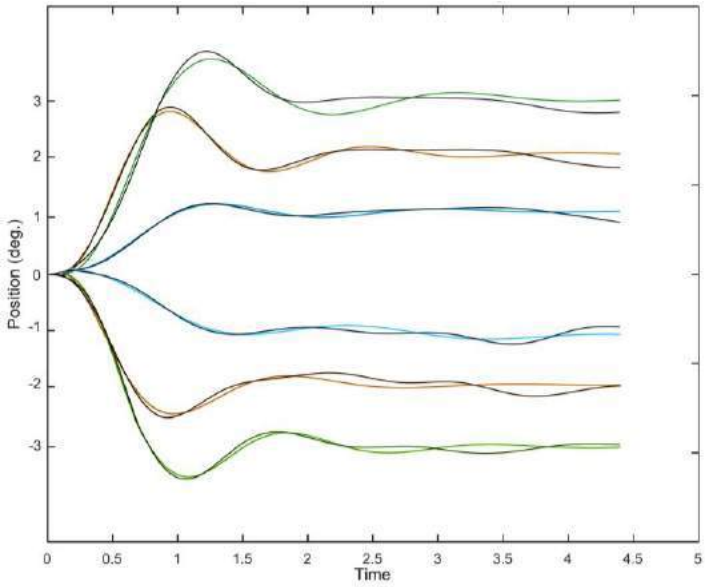

Figure 2: Generated data (black) vs. model (colored).

Now that we have the system response to a step function, we can calculate the bandwidth. A Fourier transform is applied to Equation 3 yielding,

$$\theta_{(j\omega)}(I(j\omega)^2 + b(j\omega) + k - mgl) = G\left(\frac{\theta_d}{j\omega} - \theta_{(j\omega)}\right) \quad (5)$$

where, $\theta_{(j\omega)}$ is the angular position in frequency domain, j is an imaginary number equal to $\sqrt{-1}$, and ω is the frequency. The transfer function, $\theta_{(j\omega)}/\theta_d = Tr_{(j\omega)} = Re(j\omega) + Im(j\omega)$, is determined by manipulating Equation 5. The transfer function has both real and imaginary components. The magnitude response of the Bode plot is given by $mag = \sqrt{Re^2 + Im^2}$, and plotted with respect to frequency (Figure 3).

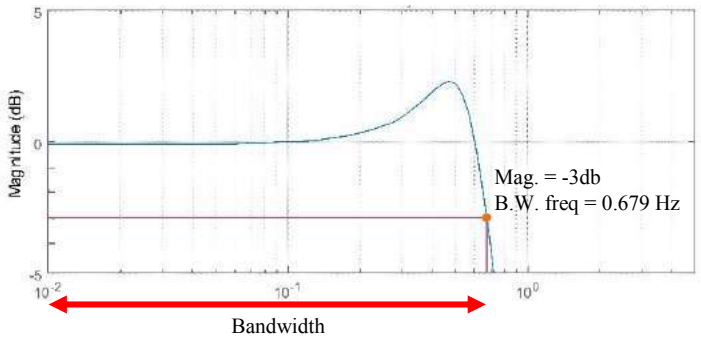

Figure 3: Typical Magnitude Response of Bode Plot.

The bandwidth of a system is defined as the range of frequencies over which the magnitude response of the transfer function drops by 3 dB. This drop in amplitude corresponded to a 50% decrease in power.

RESULTS

The bandwidth frequency was calculated for each of the six step functions and is listed in Table 1. The magnitudes of the step functions were defined as small (1°), medium (2°), and large (3°).

Table 1: Bandwidth frequency (Hz) for different desired positions

		Small	Medium	Large
Direction	Flexion	***0.58***	***0.84***	***0.80***
	Extension	***0.66***	***0.91***	***0.68***

DISCUSSION

Overall, the magnitude of bandwidth frequencies was seen to be fairly consistent, ranging from 0.58 to 0.91 Hz. We see different bandwidth for different input magnitudes and direction. Hence, bandwidth must be a function of magnitude and direction of the motion.

The results of this analysis are promising. The analysis method was applied to surrogate data in the form of a time series. In the future, this method will be used to analyze time series data collected experimentally. This will enable the bandwidth of the human neuromuscular control system to be determined.

INTRODUCTION

An estimated 400,000 anterior cruciate ligament injuries occur annually in the United States, and at least 100,000 individuals undergo anterior cruciate ligament reconstruction (ACLR) [1, 2]. Premature knee osteoarthritis (OA) after ACLR is a growing concern [3]. Alterations in knee gait mechanics after ACLR have been associated with premature knee OA [3]. In subjects who get knee OA five years post-ACLR, osteophytes are commonly observed near the medial joint margin (region 1 in figure 1). However, it is not clear whether altered gait mechanics result in high stresses specifically near that general region. It is also not clear how cartilage stresses differ over time in subjects who get knee OA, versus those who do not. With that background, the objective of the current study was to evaluate knee gait parameters and medial tibial cartilage stress during gait. The evaluation was conducted one and five years post-ACLR, in subjects who got knee OA, versus those who did not.

METHODS

12 subjects who opted for ACLR participated in gait studies one and five years post-ACLR, per an institutional review board approved protocol. Gait and electromyography (EMG) analysis was performed at self-selected walking speeds using an eight camera video system (Vicon, Oxford Metrics Limited, London, UK), a force platform (Bertec Corporation, Worthington, OH) and surface-EMG recordings (Motion Lab Systems, Baton Rouge, LA). A validated Hill-type EMG-informed musculoskeletal model was used to estimate total and medial compartment force (MCF) [2]. During weight acceptance, peak values for knee gait parameters of interest approximately coincide with the first peak of vertical ground reaction force (vGRF). Hence, quasi-static finite element analysis at the first peak of vGRF was conducted using Open Knee in FEBio ((Musculoskeletal Research Laboratories, Salt Lake City, UT) [4] (figure 1). Subject-specific knee flexion angle (KFA), knee adduction moment (KAM) and total knee joint load were applied to the femur. The central medial tibial cartilage (involved knee) was divided into three regions (figure 1). The stresses in region 3 were negligible, hence peak von Mises stress for regions 1 and 2 are reported here.

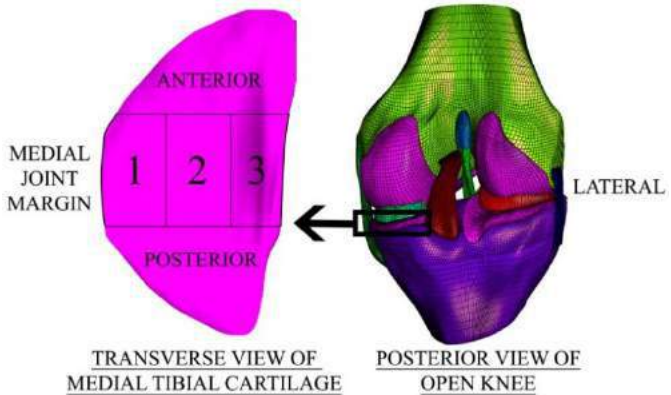

Figure 1: Open Knee finite element model in FEBio [4].

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

At five years post-ACLR, weight-bearing anterior-posterior radiographs were used to evaluate knee OA (Kellgren-Lawrence grade ≥ 2). Six subjects showed signs of medial compartment knee OA (2 men, 4 women, age = 33 ± 14 years), while six subjects did not have knee OA (4 men, 2 women, age = 32 ±14 years). Students t-tests (α = 0.05) were used to evaluate differences in each parameter between non-OA versus OA groups, at each post-ACLR time point.

RESULTS

In region 1, the OA group demonstrated greater peak von Mises stress at the five year post-ACLR time point (figure 2). Similarly, for region 2, the peak von Mises stress for the OA group was greater at the five year post-ACLR time point (figure 3). For knee gait parameters, the OA group demonstrated lower KFA at the 5 year post-ACLR time point (Table 1).

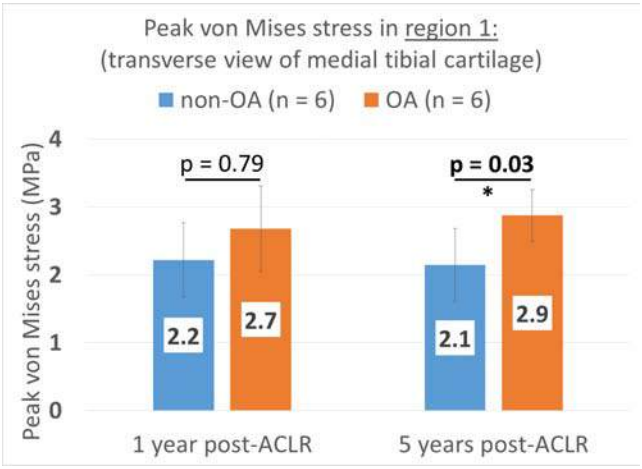

Figure 2: Peak von Mises stress for non-OA versus OA group in region 1 (central medial tibial cartilage region near the medial joint margin)

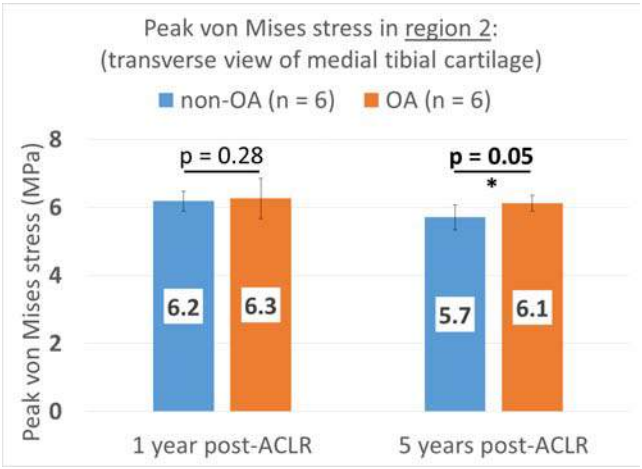

Figure 3: Peak von Mises stress for non-OA versus OA group in region 2 (central load bearing medial tibial cartilage region)

Table 1: Mean ± SD of peak knee gait parameters at the 1st peak of vertical ground reaction force during gait (SD = standard deviation, ACLR = anterior cruciate ligament reconstruction, OA = osteoarthritis, KFA = knee flexion angle, KAM = knee adduction moment, MCF = medial compartment force, BW = body weight, HT = height)

Parameter	1 year post-ACLR			5 years post-ACLR		
	non-OA (n = 6)	OA (n = 6)	p-value	non-OA (n = 6)	OA (n = 6)	p-value
KFA (degrees)	24.6 ± 4.5	20.8 ± 6.5	0.34	25.5 ± 4.4	18.9 ± 2.5	**0.01**
KAM (%BW * HT)	2.0 ± 0.8	2.9 ± 0.4	0.09	2.4 ± 0.9	3.0 ± 0.3	0.15
MCF (BW)	2.7 ± 0.5	2.5 ± 0.2	0.55	2.2 ± 0.3	2.1 ± 0.5	0.58

DISCUSSION

In the current study, the OA group demonstrated a significantly lower knee flexion angle at the five year post-ACLR time point. Also, the differences in knee adduction moment approached significance at both post-ACLR time points, with the OA group demonstrating a higher knee adduction moment. When the combination of knee gait parameters and joint load was used as input for a finite element knee model, the results indicated that subjects with medial compartment knee OA have greater stresses in the medial tibial cartilage, particularly near the medial joint margin, i.e. the region closer to the midline of the body. Five years after ACLR, radiographic signs of medial compartment knee OA were also most commonly observed near the medial joint margin. This is the region where cartilage tends to be thinner (compared to the central region of the joint). Hence, greater stresses in that region may not necessarily be due to abnormally high load magnitudes. A normal load magnitude shifted to the thin cartilage region could be equally detrimental. Studies that utilize both neuromusculoskeletal modeling and finite element analysis can help investigate the combined effect of various knee gait parameters and joint loads on cartilage stress distribution and also help solidify the link between altered gait mechanics and knee OA. Comparing the nature and progression of knee biomechanics in non-OA versus OA ACLR groups may be the key to developing rehabilitation strategies for delaying the progression of the disease.

ANATOMICALLY-DRIVEN MULTISCALE MODEL OF ASCENDING THORACIC AORTA, WITH APPLICATION TO MULTIDIRECTIONAL EXPERIMENTS

INTRODUCTION

Although only about 15% of the thoracic aorta, the ascending portion is involved in 60% of all thoracic aortic aneurysms [1, 2]. Ascending thoracic aortic aneurysm (ATAA) involves progressive weakening of the aortic wall, which can lead to vessel dissection and/or rupture, often resulting in death. Surgical intervention involves considerable risk, however, and better understanding of aneurysm tissue mechanics would aid in formulating improved surgical guidelines and decision making.

Several theoretical models for ATAA have been described [e.g., 3, 4], but few have addressed failure in the context of microscale structure of the aortic wall. The current work used a multiscale approach to build a unifying model of the ascending thoracic aortic wall, which was compared to a set of multidirectional failure experiments performed on cadaveric porcine tissue.

METHODS

In separate work [5], we performed four different types of experiments on cadaveric porcine aorta. In-plane (uniaxial and biaxial) and out-of-plane (lap and peel) (see Fig. 3 below) tests were performed on aorta tissue to probe its mechanical and failure behavior.

In the current work, a multiscale model was constructed based on a framework developed previously for collagen gel mechanics [6, 7]. The model consisted of two distinct scales: the finite element domain at the millimeter (mm) scale, and the representative volume element (RVE) at the micrometer (μm) scale. The RVE contained a network of fibers in parallel with a nearly incompressible neo-Hookean component (representing non-fibrous material). The structure of the fiber network was selected to represent the lamellar structure and composition observed in the aorta. The final network structure (Fig. 1A) a 2-D sheet of circumferentially aligned collagen fibers embedded in an isotropic elastin network (representing an elastic lamella), attached to an almost isotropic network of inter-lamellar connections (representing components such as smooth muscle cells and fibrillin).

Each finite element (FE) in the model contained eight Gauss points, and each Gauss point was associated with an RVE network (Fig. 1). Displacements at the FE nodes deformed the RVE networks and stresses calculated from the deformed networks were appropriately scaled and used to perform the macroscale force balance, thus fully coupling the microscale behavior to that of the macroscale.

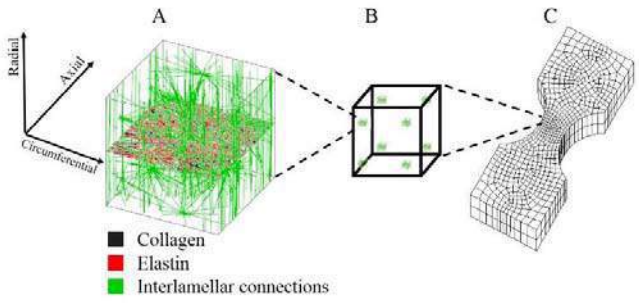

Figure 1: Multiscale scheme included a microscale network (A) at each Gauss point (B) in the macroscopic finite-element model (C).

Fiber constitutive equations were of the form [8, 6]

$$f = \frac{A}{B}\left[e^{B\left(\frac{\lambda^2-1}{2}\right)} - 1\right],$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where f is fiber force, A controls stiffness, B controls non-linearity, and λ is the fiber stretch. Failure was incorporated into the model by removing a fiber if it was stretched above a critical stretch value λ_c. The nine fiber parameters (A, B and λ_c for each of the three fiber types) and two parameters for the neo-Hookean matrix (bulk and shear moduli) were manually optimized to match the experimental data. All simulations were run using 128 parallel processors; clock times averaged 10 hours per simulation.

RESULTS

Results from the simulation are shown below. Circumferential and axial denote the directions (with respect to the aorta) in which the samples were stretched and stress was calculated. The stresses predicted by the multiscale model (Fig. 3) lay within the 95% confidence interval calculated for the experiments in most cases. The peel simulations ran only a few steps past the start of fiber failure before stopping due to stability issues within the finite element code.

Figure 2 shows the distribution of failed fibers, showing a shift from mostly laminar fibers (collagen and elastin) failing in the uniaxial tests to interlamellar (I.C) fibers failing in the lap shear tests.

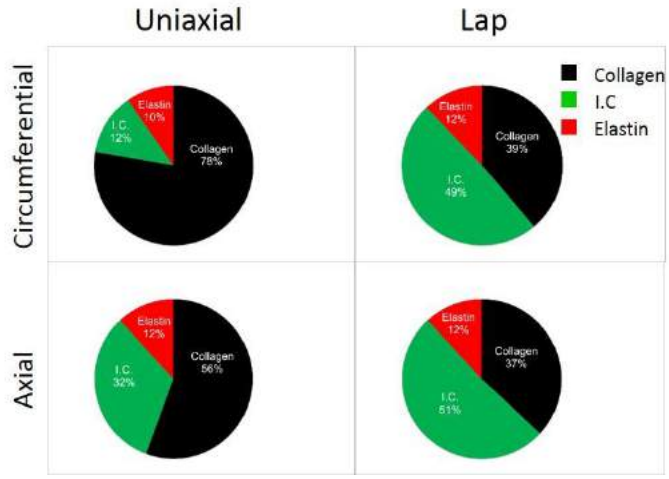

Figure 2: Distribution of failed fibers from simulation

DISCUSSION

A single multiscale model was developed to replicate the failure behavior of aorta tissue seen in multidirectional mechanical tests. A major advantage of this model was the use of anatomically informed networks to capture the microscale mechanics and failure of the aorta in complex three dimensional loading.

The simulation results matched the experimental data quite well. The model also performed well in matching the experimentally observed failure stresses, even for the peel simulations. The stress plots (Fig. 3) along with the simulated distribution of failed fibers (Fig. 2) obtained for the uniaxial and lap tests suggest that the layered structure of the aorta is essential to capture the mechanics and dissection of ATAA. However, lumping the different radial structural components of the aorta into a single type of fiber (inter-lamellar connections) simplifies the actually complex microstructure, which could be a source of some error. That simplification also makes it difficult to distinguish between cell stress and e.g., fibrillin stress, which could be important in a model of vascular remodeling. Furthermore, the instability in the peel test has arisen due to the method employed to simulate fiber failure, i.e., by suddenly reducing fiber stiffness.

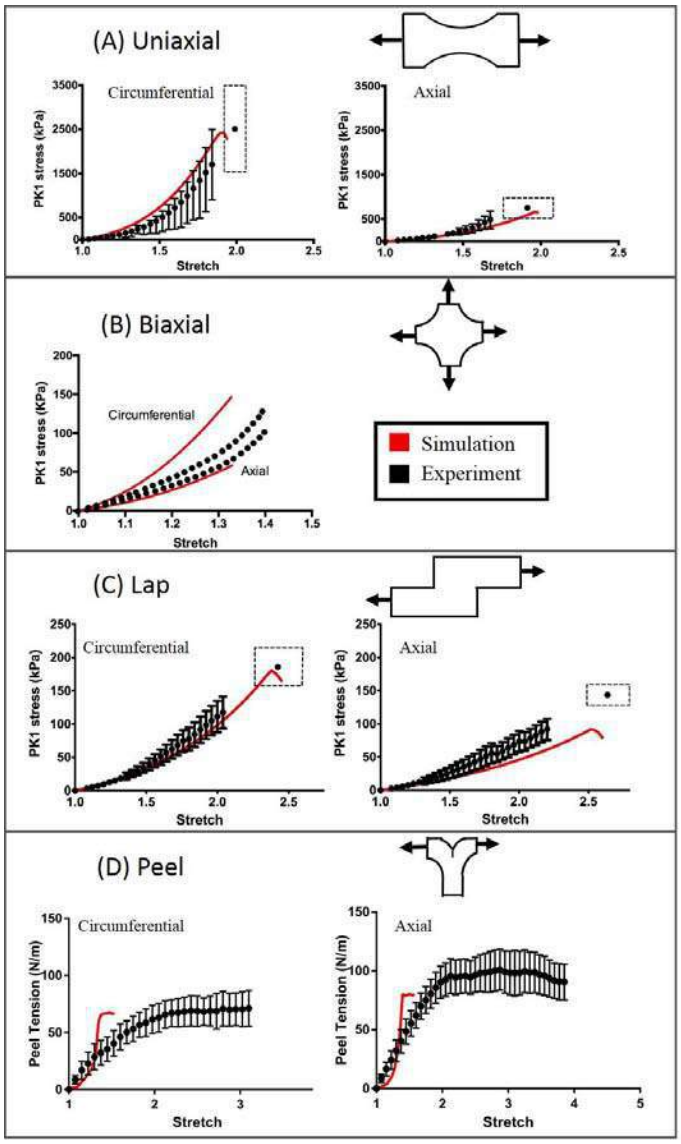

Figure 3: Comparison of multiscale model results (red) with experimental data (black). Error bars for biaxial experiments are not shown. On average, the biaxial error was 36 kPa.

SUBJECT-SPECIFIC VS. AVERAGED STRUCTURAL MODELS OF THE COLLAGEN NETWORK IN THE LUMBAR FACET CAPSULAR LIGAMENT

INTRODUCTION

The lumbar facet capsular ligament (LFCL) surrounds the facet joint in the lumbar spine [1]. The LFCL contains packed aligned collagen fibers as well as mechanoreceptors [1], both of which are embedded in a ground matrix of proteins and water. Collagen fibers are the predominant mechanical component of the LFCL, and their spatially-varying orientation is of particular interest because it leads to concentrated stress regions, and thus, is responsible for both the overall mechanical properties of LFCL and the stresses acting on the innervating nerve fibers. The dense innervation suggests a possible role for the LFCL in chronic low back pain [2] where large stresses in the LFCL could lead to abnormal nerve deformation and to pain.

This study comprises two parts. First, the variability of fiber orientation between samples was studied, and secondly, subject-specific, structure-based models were constructed and examined.

METHODS

Polarization-sensitive optical coherence tomography (PS-OCT) was used to find the fiber orientation of LFCLs on their entire surface. Each sample (n=5), clamped biaxially, was pulled by ~1N force in each direction. The imaging depth was approximately 0.13mm.

To investigate the ***inter-sample variability***, first a 2D average LFCL geometry was constructed. Next, the Shepard morphing method [3] was used to map the orientation field of each sample onto this average geometry. Lastly, an orientation tensor [4] was defined for each point on each orientation field, and the variability of components of this tensor was observed among different samples.

In the second part of this study, ***subject-specific structural models*** were created by using the fiber structure in a multiscale finite element solver [5] to simulate equibiaxial extension tests. Each finite element has fiber networks (representative volume element, RVE), the deformation of which determines the elemental stresses. Each RVE contains an aligned Delaunay network along with a Neo-Hookean material which deforms independently and represents the ground matrix in the LFCL. Fibers follow the phenomenological constitutive equation $F = \frac{A}{B}[\exp(BE) - 1]$ where *F, A, B* and *E* are force, stiffness, nonlinearity parameter and Green strain for fibers [6]. The neo-Hookean matrix was considered nearly incompressible ($v=0.45$).

Each LFCL geometry was constructed and meshed using Abaqus based on an image of the biaxial test. Since the finite element grid is coarse compared to OCT resolution, a proper averaging method was required to specify the fiber orientation for each element. Elemental fiber orientation was obtained by averaging the fiber orientation tensor of its constituent pixels, such that:

$$T_{element} = \frac{\frac{I}{2} + \sum \delta_{pixel} T_{pixel}}{1 + \sum \delta_{pixel}}$$

Where T and δ denote the orientation tensor and retardation respectively. For each element, an aligned fiber network was created based on the obtained fiber orientation, such that the strength of alignment was proportional to the retardation. Fiber orientation and δ can be described by orientation tensor through eigenpairs: If (γ_1, γ_2) and (v_1, v_2) are eigenvalues $(\gamma_2 > \gamma_1)$ and eigenvectors respectively, of T, then $\delta \propto \gamma_2 - \gamma_1$ and v_2 specifies the orientation of fibers.

Fitting parameters were fiber stiffness (A), fiber nonlinearity parameter (B), and Neo-Hookean matrix shear modulus (G_{mat}). Described inputs (fitting parameters, RVEs, sample geometry, and boundary displacements) were used in the multiscale solver to find forces in each direction. To assess the improvement of this OCT-based model over simplified models for LFCLs, a transversely isotropic models with fibers running in the Lateral-Medial (L-M) direction was made and compared to the image-based model.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

The OCT-based fiber orientation map for two LFCLs is shown in figure 1. The reference axis (i.e., θ = 0) is from left to right (L-M). Fibers are mainly oriented in the joint direction (L-M). As figure 2 suggests, however, fiber orientation distribution varies considerably between samples.

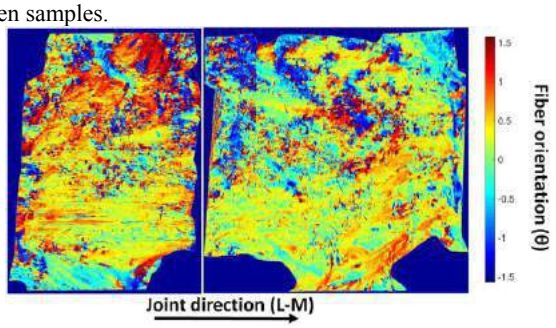

Figure 1. Fiber orientation field for two LFCLs. Fibers are mainly oriented in the joint direction.

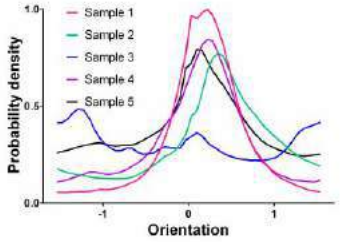

Figure 2. Orientation probability density. Inter-subject variability can be observed.

Force-stretch results for superior-inferior (S-I) and L-M directions are represented in figure 3 (n=5). Experimental average maximum forces in the L-M and S-I directions were 19.5 N and 5.9 N respectively. These values for the OCT-based model were 18.4 N and 8.7 N. Root-mean-square error (RMSE) values for the L-M and S-I directions were 1.03 N and 1.10 N respectively. These values were lower compared to the corresponding values for a transversely isotropic model, which had the RMSE of 1.16 N and 1.19 N for the L-M and S-I directions. The fitting parameters A, B and G_{mat} for the OCT-based simulations are $(10.01 \pm 2.13) \times 10^{-6} N$ $(mean \pm S.D)$, 18.60 ± 2.51, and $28.4 \pm 4.9 KPa$ respectively.

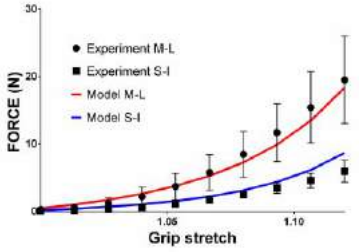

Figure 3. Force-stretch graphs in two normal directions for OCT-based model (mean) and the experiment (mean ± SD)

Figure 4 shows the maximum principal Cauchy stress field for the OCT-based and transverse isotropic models for one LFCL. OCT-based model leads to a more heterogeneous stress field. The heterogeneity was quantified by stress standard deviation and maximum stress to average stress ratio. Average values for these parameters are 588N and 7.6 for the OCT-based model, and 354N and 3.5 for the transverse isotropic model.

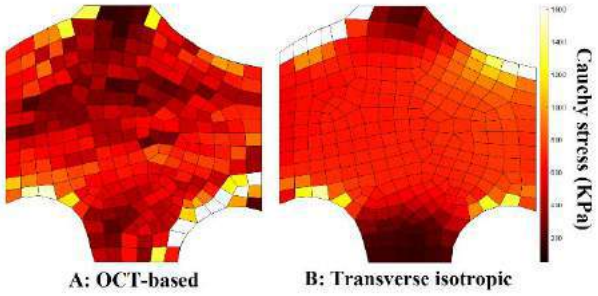

Figure 4. Maximum principal Cauchy stress field for the A: OCT-based and B: transverse isotropic model. OCT-based model generates a more heterogeneous field

DISCUSSION

Fiber structure characterization and improving structural models were two purposes pursued in this study. Fiber orientation over the entire surface of the sample was acquired using PS-OCT. Orientation fields showed that fibers primarily tend to align in the joint direction (L-M). This can also be concluded by observing the higher forces in the L-M direction during equibiaxial extension. Although the maximum probability of orientation belongs to the joint direction, there is a high variation among different locations on each sample. This heterogeneity highlights the need for structural models to capture regions of concentrated stress, which will enable further study microstructural phenomena, such as fiber-nerve interaction.

In addition, orientation fields demonstrated considerable variation between different samples. This variation was observed by the difference in orientation probability distribution as well as difference in relative location of aligned regions on the sample. The importance of sample-specific models in determining the mechanical behavior is the conclusion drawn from this observation.

For each specific sample, the acquired fiber structure was incorporated into a multiscale model and regressed to experimental data to find the best model parameters. The image-based structural model resulted in a roughly 10% reduction in RMSE compared to a transverse isotropic model in which fibers are aligned in the joint direction. In addition, unlike the transverse isotropic model, the structure-based model led to a heterogeneous stress field. Considering the concentration of stress for each sample is particularly important when the microscale behaviors, such as neural is of interest.

In conclusion, fiber structure, which is a significant determinant of overall and microstructural mechanical behavior, varies among samples and is essential to be characterized. Secondly, structure-based models are necessary to describe LFCL mechanical behavior.

PLACENTA-ON-A-CHIP: A NOVEL PLATFORM IN DRUG TESTING AND TOXICOLOGY APPLICATIONS

Nastaran Hashemi (1)

(1) Department of Mechanical Engineering
Iowa State University
Ames, Iowa, USA

INTRODUCTION

Organ-on-a-chip technology is a relatively new field in which the properties of microfluidics are utilized within a biomimetic cell culture model. They show promise as a novel platform in drug testing and toxicology applications due to several key advantages. First, their large surface area-to-volume ratio ensure that diffusive forces dominate over bulk forces. This has led to a vast increase in popularity over the recent years, as researchers have found them to be a more appealing alternative to other drug testing methods. From this, researchers have split into subjects that focus on a specific organ, including the: lungs, liver, intestines, heart, vasculature, and many others. Contrary to this, however, research regarding a "placenta-on-a-chip" have been few and far between. In the body, the placenta is responsible for nutrient, waste, and gas exchange between the mother and fetus, as well as providing other needs such as endocrine function and important antibodies12. The placental barrier refers to the barrier that separates the maternal blood from the fetal blood. In humans, this barrier is composed of 3 main layers: the vascular endothelium, the extracellular matrix (ECM), and the trophoblast (epithelium). The formation of this barrier starts with the recruiting of trophoblast cells from the uterus. These cells invade the intervillous space and attach to one another to form the chorionic villi. There are two types of trophoblasts prevalent in the placenta: cytotrophoblast and syncytiotrophoblast. The cytotrophoblasts are mononuclear and are responsible for breaking down ECM within the chorionic villi to make the space that will eventually be taken over by the umbilical blood vessels. After completing their function, they are capable of fusing together to form a syncytrotrophoblast layer. This lies in the outermost layer of the chorionic villi and is in contact with the maternal blood, therefore making it extremely important in nutrient/waste exchange applications. The middle layer of the barrier is composed of the extracellular matrix. This matrix is comprised of the "fluff" separating the endothelial and epithelial layers. The ECM provides the cell layers with support, separation, and crosstalk (either cell-cell or cell-ECM).
As stated previously, once the chorionic villi are hollowed out from the cytotrophoblasts, the fetal blood vessels are able to work their way inside of them. Therefore, when considering the barrier between bloodstreams, the layer that will be in contact with the fetal blood is the vascular endothelium of these blood vessels. The vascular endothelium is responsible for controlling particle transfer through the membrane, controlling the blood pressure, and aiding in the repair of damaged tissue.

In this work, these three layers are approximated on a microfluidic organ-on-a-chip platform to create a "placenta-on-a-chip.' Human umbilical vein endothelial cells are used to represent the vascular endothelium, BeWo choriocarcinoma cells are used to represent the trophoblast, and a type 1 collagen solution overlaying a nanoporous polyethylene terephthalate (PETE) membrane is used to represent the ECM.

METHODS

In determining the size and geometry of the design, there are two important considerations that will greatly affect the ability of the chip to diffuse properly: cross-sectional geometry and flow path. The master mold was created using a soft lithography technique on a silicon wafer. PDMS was used as the material of the layers containing microfluidic channels. A nanoporous PETE membrane was placed between the two PDMS layers. The PETE membrane was obtained by cutting the membrane from a Transwell® well plate with membrane insert. The HUVEC cells were chosen to represent the endothelial layer of the device, cultured in an EGM-2 media. The human trophoblast cell line BeWo was chosen to represent the epithelial layer.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The media used for the BeWo cells was F-12K, supplemented with 10% FBS.

RESULTS

After sterilization of the device through ethanol and UV radiation, HUVEC cells were first injected into the top channel of the chip at a seeding density of 5x106 cell/ml. To give the cells sufficient adherence, the chips were brought into an incubator (37°C, 5% CO2) and left for 12 hours to allow for attachment to the membrane. After sufficient time was given, the BeWo cell line was injected into the bottom channel of the chip at a seeding density of 5x106 cell/ml. Before injection, HUVEC cells were stained with CellTrackerTM Green CMFDA fluorescent dye and BeWo cells were stained with CellTrackerTM Orange CMRA fluorescent dye.

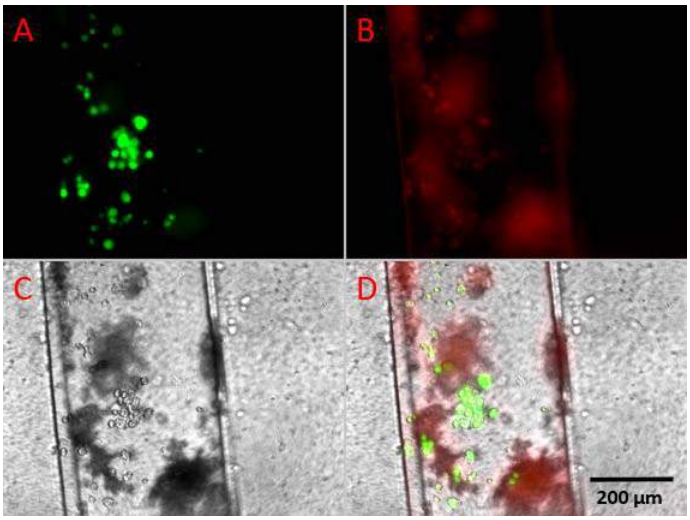

Figure 1: Injected HUVEC (green) and BeWo (red) cells before the start of the trial, seen through: A) GFP filter, B) RFP filter, C) Brightfield, and D) GFP + RFP + Brightfield. Scale bar is at 200 µm.

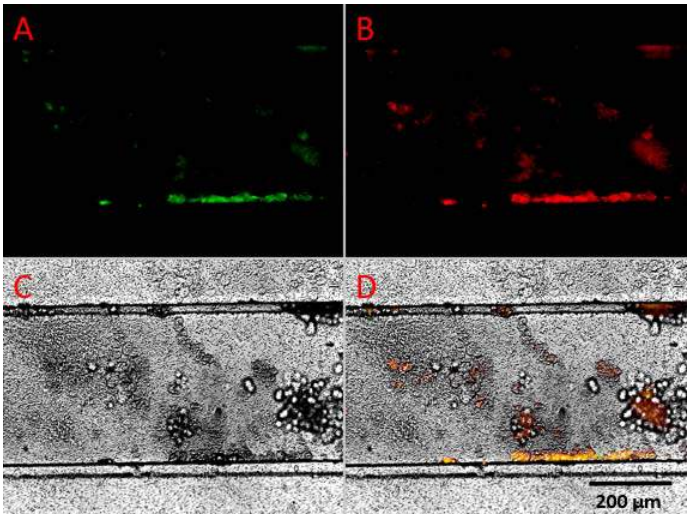

Figure 2: Injected HUVEC (green) and BeWo (red) cells after 5 days of flow, seen through: A) GFP filter, B) RFP filter, C) Brightfield, and D) GFP + RFP + Brightfield. Scale bar is at 200 µm.

Fluorescent and bright field images taken before media flow can be seen in Figure 1. A look through the different filters allows us to key in on the specific cells of interest. For the HUVECs, a green fluorescent protein (GFP) filter is used, and for the BeWo cell line, a red fluorescent protein (RFP) filter is used. The system was observed through an inverted microscope.

Once the cells were attached on the membrane within the chip, constant media flow was administered to the chip via syringes containing the cell media positioned on a double syringe pump. Silicon tubing with an inner diameter of 0.04 inches and outer diameter of 0.085 inches was used to connect the syringes to the inlets of the chip. Tubing was also connected to the outputs of the chip, which directed the media out of the chip to be collected, either as waste or for further analysis. The flow rate used for both channels in this system was 6 µl/hr. Long-term maintenance studies were performed on the chips once it was shown that the cells were able to adhere to the membrane and get nourishment from the media flow. The system was allowed to flow for 5 days. Afterwards, the system was checked under the same filters. Figure 2 shows the resulting images.

DISCUSSION

This technique shows how these pertinent cell lines can be introduced into a microfluidic design in order to create a biomimetic microsystem resembling the placenta. Starting with the basic microfluidic phenomena that control particle density and dispersion, a model was designed the exploit these phenomena in order to create a drug testing platform resembling the placenta. Using this platform, cells were chosen based on their physiological traits and were successfully introduced into the device. This device was then able to be monitored for a significantly long term.

Cells shown after long term maintenance showed some migration, specifically towards the walls of the channels. This may be due to insufficient adherence of the cells or due to the strength of the flow in the channels. The decrease in cell density would suggest the latter, however, cells shown in Figure 1 display weak structural integrity that would suggest that they aren't firmly attached to the membrane. These aspects can be further inspected to improve the functionality of the device. With the successful integration of cells into the microfluidic device, more avenues for analysis can be considered. One aspect to consider is the measurement of markers specific to the placenta. Protein-expressing markers provide a good indication of how well the system is operating and how similar it is to the in vivo environment. For example, E-cadherin, which is known for its role in cell-cell adhesion and epithelial cell signaling, can be found in the placenta at distinctly higher levels in vivo than in vitro. Additionally, an analysis of the impact of various flow rates and cell adhesion times can also be considered.

Another area worth considering for future study is the role of ethanol-induced toxicity for the placenta-on-a-chip. Like the liver-on-a-chip discussed earlier, ethanol contained within the maternal media stream can be representative of the blood alcohol content seen in cases involving fetal alcohol spectrum disorder. This could prove a useful tool in not only being able to use the placenta-on-a-chip in a healthy and functioning placenta, but also in mapping non-ideal scenarios.

INTRODUCTION

Valvular heart disease is the third most common form of cardiovascular disease and is associated with abnormal valve structure and function. *In vivo*, the valves maintain their integrity and function by a complex interplay between the tissue, the cells and the surrounding hemodynamic and mechanical environment. Valve interstitial cells (VICs) exist as a continuum of phenotypes with various physiological roles. Most prior studies have focused on the role of the VIC phenotype in modulating valve function and disease progression. There are, however, relatively few studies that discuss the role of VIC structure in regulating its function or phenotype. Previous publications report that cellular and tissue shape, enforced by constraining the boundary conditions for cell spreading, can result in altered cellular function in various other cell types [1]. We hypothesized that cellular architecture directly affects acute contractile function and metabolism in VICs. To test this hypothesis, we engineered VIC micro-tissue monolayers constrained with control over cellular shape and cell-cell contact density. VIC micro-tissue contractility, phenotype and metabolism was quantified and assessed using the valve thin film assay, western blots and metabolic redox imaging, respectively.

METHODS

1. Valve interstitial cell isolation and culture

Fresh porcine hearts (3-6 months old) were obtained and immediately dissected aseptically. Cells were isolated using collagenase digestion as described in previous protocols [2]. Valve interstitial cells (VICs) were then isolated and cultured in normal and osteogenic media. Cells from passages 2-6 were used in all subsequent experiments.

2 Photolithography, soft lithography and microcontact printing

Photolithographic transparency masks were designed and fabricated in a regular array of line patterns with five different widths (10, 20, 40, 60 and 80μm) spaced 40μm apart. Silicon wafers were then spin coated with Su-8 2005 negative photoresist and exposed to ultraviolet light through the photomask and developed using standard photolithography protocols. Fibronectin was incubated on a polydimethylsiloxane stamp for 1 hour at room temperature, gently blown dry and placed in contact with Ultraviolet-Ozone treated PDMS-coated coverslips for 5 minutes. Coverslips were then blocked with 1% Pluronics, washed three times with dPBS and VICs were seeded at 100,000 cells/cm^2 and cultured at 37°C, 5% CO_2.

3. Quantification of cellular architecture and cell-cell contact density

After 48 hours of culture, cells were fixed andthen labeled with Alexa Fluor 488 phalloidinand 4',6-diamidino-2-phenylindole. Samples were mounted onto a glass slide and imaged and analyzed using custom MATLAB scripts [2].

4. Valve thin film stress measurement assay

Coverslips for valve thin film (vTF) experiments were prepared as previously published [2]. The vTFs were stimulated with 50nM endothelin-1 followed by 100μM HA-1077 while being continually to record changes in the projected length of the film (x) and thus the radius of curvature (r) of the cantilever films. The stress (σ) required to bend the film was then calculated using the modified Stoney's equation. Stress data was then normalized by cell. The thickness of the PDMS layer (t) was measured using stylus profilometry and the cell layer thickness (h) was measured using confocal z-stacks.

5. Two –photon redox imaging

Two Photon microscopy using a custom imaging system was used to image VIC samples at 755nm and 860 nm laser excitation to measure NADH and FAD fluorescence, respectively.[3] Custom MATLAB code was used to quantify FAD/(NADH+FAD) redox ratio.

RESULTS

The results shown here correspond to normal DMEM conditions. The experiments with cells cultured in osteogenic media are in progress.

1. In vitro model for altered cell shape and its implications on cell architecture and cell-cell contact density

We induced an elongated, spindle-shaped VIC with low cell-cell contact density with narrower fibronectin pattern widths, and a less elongated VIC with greater cell-cell contact with wider fibronectin patterns. There was a significant positive correlation between actin orientation and cell aspect ratio (Fig. 1A), as well as nuclear aspect ratio and cell aspect ratio (Fig. 1B). There was a significant negative correlation between cell-cell contact density and cell aspect ratio (Fig. 1C - E).

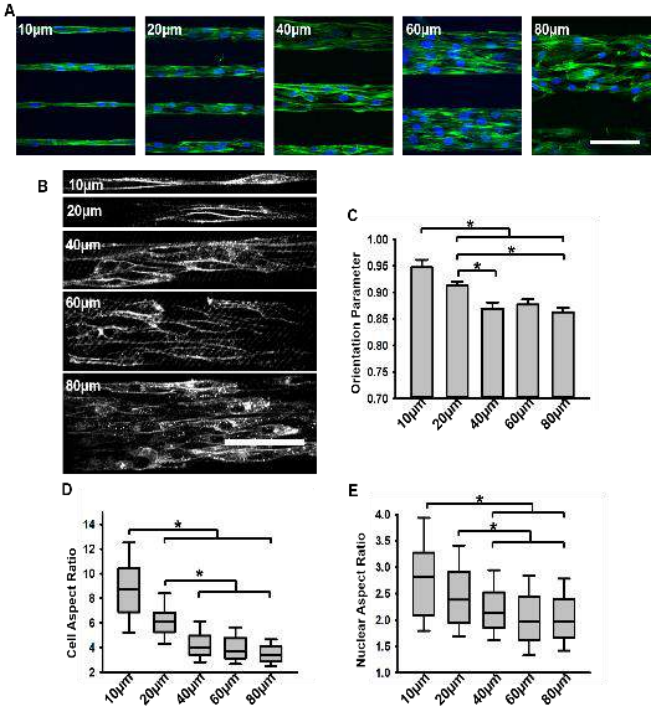

Figure 1: VIC cell architecture data. (A) Phalloidin (green) and DAPI (blue) stained images of VIC micro-tissues constrained to different pattern widths. (Scale bar = 80μm) (B) Di-8 (white) stained VIC micro-tissues. (Scale bar = 80μm). (C) Actin orientation parameter data. (D) Cell aspect ratio data. (E) Nuclear aspect ratio data. (* $p<0.05$)

2. VIC structure and contractile function

Both increases in cell aspect ratio and cell-cell contact density resulted in increased contractile stress response to ET-1 (Fig. 2), resulting in a U-shaped response curve. VIC micro-tissue response to HA-1077 revealed no significant differences in cellular basal tone as a function of VIC micro-tissue width. This result suggested that baseline cellular tension in VICs was independent of cellular architecture or shape.

3. VIC metabolic redox ratio

VIC redox ratio data mimicked the same trends as the contractility data, with minimum redox ratio occurring at 20μm line width, and increasing thereafter. Previous studies reported lower redox ratio values in cells undergoing differentiation and macromolecule synthesis [3]. This result thus suggests VICs in narrower patterns have a greater propensity for differentiation. These studies are currently ongoing.

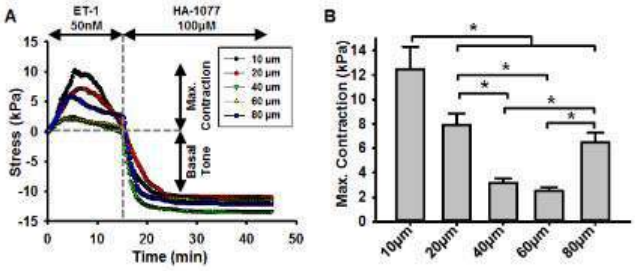

Figure 2: VIC contractility data. (A) Time series data for VIC contractility. (B) Maximum contraction data. (* $p<0.05$)

3. VIC structure and Redox Activity

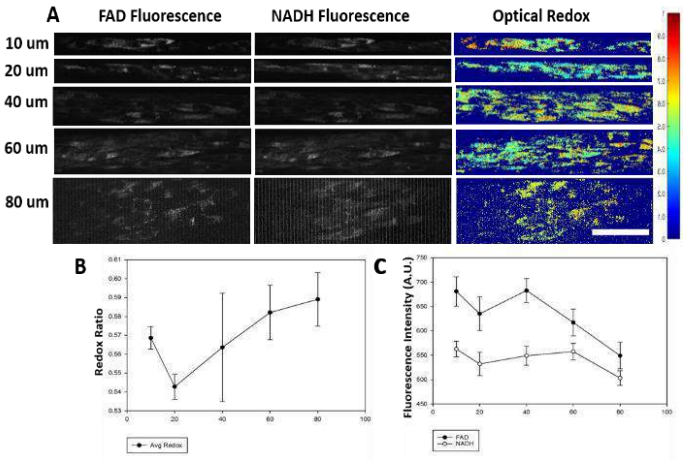

Figure 3: Metabolic redox ratio data. (A) Representative FAD, NADH and redox images. (B) Redox data. (C) FAD and NADH data.

DISCUSSION

We report herein that VIC architecture and shape significantly regulated cellular functional contractile output and metabolism. Our results here also highlight cell-cell contact density as an additional factor that influences VIC function. Redox ratio also mimicked the same trends as that of VIC contractility, suggesting altered glycolysis and oxidative phosphorylation as a result of altering cellular architecture. Taken as a whole, our study implicates VIC cell architecture as a key mediator of function. Studies are ongoing on the role of osteogenic medium in influencing the reported metrics for cell function.

INTRODUCTION

It is strongly believed that the complex Mitral Valve (MV) structure and tissue remodeling play a significant role on the valvular response to MV repair [1]. However, isolating the effect of each factor to study the treatment outcomes is infeasible in the *in vitro* and animal studies. Computational simulations have proven to effectively predict the valvular biomechanical behavior and design of valvular prosthesis [2]. However, due to the complexity of MV structure, computational models are still struggling to account for all the underlying factors that impact the MV response to repair. In fact, most standard biomechanical models of the MV perform suboptimally in predictive simulations of the MV to optimize the repair procedures.

In the current study, we have developed a pipeline to quantitatively characterize the MV leaflet geometry, build personalized models with an adjustable level of detail, and incorporate structural attributes within the geometric models. The developed platform provides the basis to perform high fidelity biomechanical simulation to optimize the annuloplasty ring geometry by allowing linking the internal structure and organ level response. In addition, to the best of our knowledge, this is the first study to develop multi-resolution models for biomechanical simulations.

METHODS

We acquired three data-sets on the MV geometry by imaging ovine heart valves obtained from an USDA approved abattoir (Superior Farms, CA, USA) using micro computed tomography modality as described in [3]. The DICOM images were then segmented in the ScanIP software suite (Simpleware Ltd., Exeter, UK) and labeled in Zbrush sculpting software (Pixologic Inc., CA, USA) (Fig. 1). Next, for each valve, we fitted a superquadric surface model (Eq. 1) to capture the general geometry of the MV through the estimation of size (a_1,a_2,a_3) and shape (ε_1,ε_2) parameters.

$$F(x,y,z)=\left[\left(\frac{x}{a_1}\right)^{2/\varepsilon_2}+\left(\frac{y}{a_2}\right)^{2/\varepsilon_2}\right]^{\varepsilon_2/\varepsilon_1}+\left(\frac{z}{a_3}\right)^{2/\varepsilon_1}-1 \qquad (1)$$

To resolve the surface details, we computed the signed L_2 residual fields of fitting the superquadric surface to the atrial and ventricular surfaces of the MV (Fig. 2). We then applied sparse spectral analysis on the residual fields and reconstructed the fine features of the MV leaflets in the Fourier domain. The sparse spectral analysis was performed using a proximal gradient method in the Lasso optimization framework [4]. This modeling approach enabled us to co-register the MV surfaces and reconstruct them with a customizable level of detail by applying digital filters in the spectral domain.

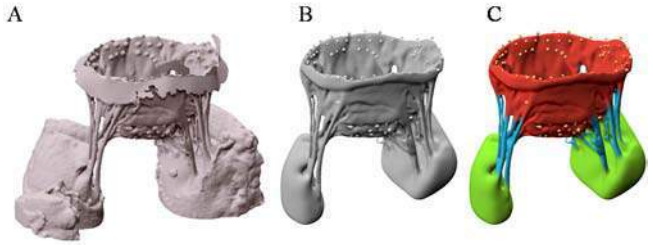

Fig. 1: The segmented micro-CT image of a MV (A) is manually trimmed (B) and the constituent parts are labeled (C).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Here we present both illustrations of our modeling pipeline and the final multi-resolution geometric models of three MVs. First, a unique superquadric surface was computed for each valve to capture the general shape (Fig 2). Then, the surface details were extracted as scalar fields (Fig 3) and reconstructed using spectral analysis. The reconstructed features were then superimposed on the smooth superquadric approximation of the MV geometry (Fig 4A) and the model was trimmed according to MV physical boundaries (Fig 4B) to build a fully detailed parametric model of the MV leaflet structure (Fig 4C). The final models were reconstructed (Fig 5) with an adjustable level of detail through the superposition of the superquadric approximation and surface details.

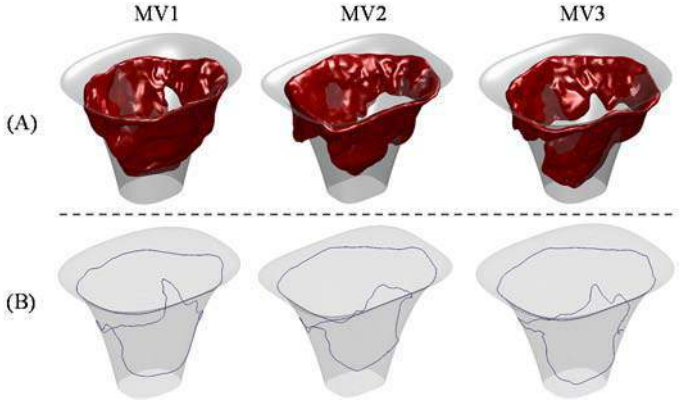

Fig. 2: In (A) the computed superquadric models are shown for three valves. Panel (B) shows the superquadric models and physical boundaries of the MV leaflets.

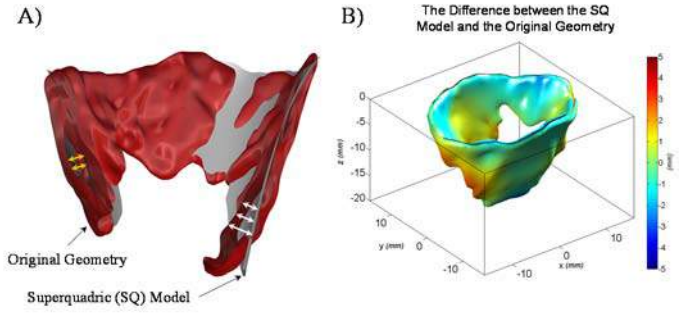

Fig. 3: The geometric details not captured by the superquadric surface (A) are evaluated by projection of original geometry on the superquadric surface fit (B).

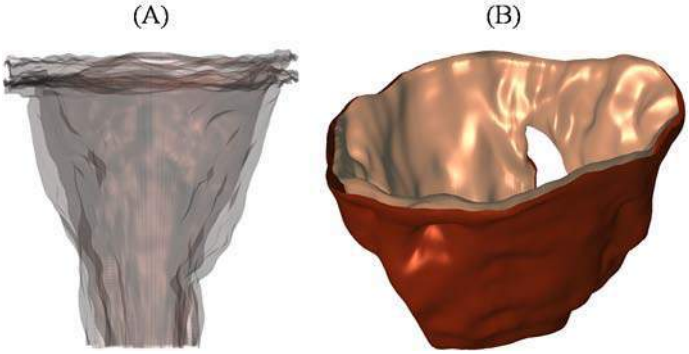

Fig. 4: (A) shows the reconstructed model of the MV in the parametric domain. In (B), the physical boundaries are applied on the parametric reconstruction to recover the true MV geometry.

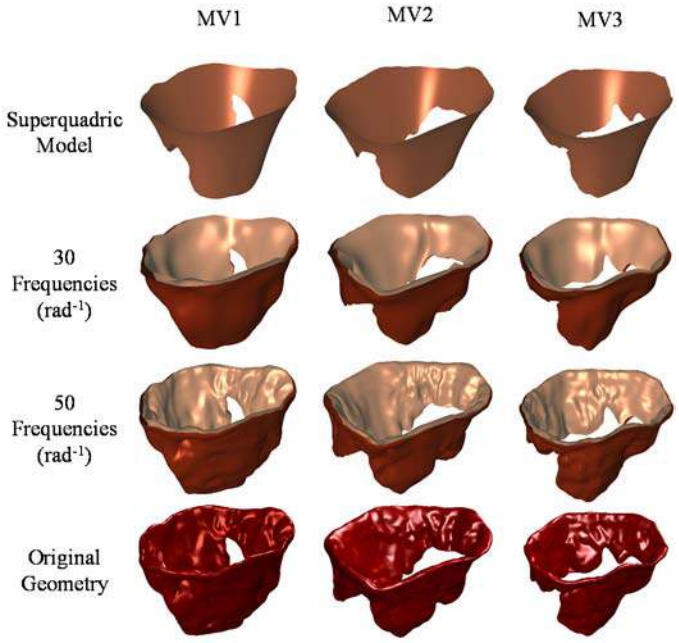

Fig. 5: For three valves, the level of detail in model reconstruction is adjusted by applying filters in the spectral domain. Each frequency corresponds to a range of feature size in the parametric domain of superquadric model.

DISCUSSION

We presented a novel approach to process pre-clinical images into anatomically accurate, detailed geometric models of the MV leaflet. In contrast to the existing geometric models of the MV, we developed models with an adjustable level of detail and controllable spatial resolution. This modeling approach also facilitates the development of a population-averaged geometric model of the MV leaflets through the parametric reconstruction of MV geometry in an objective framework. Furthermore, the results show that a superquadric surface can predict the MV general shape, which can then be enhanced to capture the surface details of the MV 3-D geometry using spectral methods. Other attributes like material properties, multi-layered structure, or internal fiber architecture can be modeled using the same spectral analysis and incorporated with geometric models. This feature of our pipeline is extremely useful for performing finite element simulations of MV behavior since we can adjust the level of detail in terms of geometric details and other physical attributes to develop anatomically accurate, attribute-rich computational models. Our models then provide high fidelity simulation tools for medical device design and surgical treatment planning.

INTRODUCTION

Subchondral cystic lesions (SCL) occur in the medial femoral condyle (MFC) of horses and can cause lameness.[1] They are more common in horses ≤ 2 years of age, but can occur in older horses. The causes of SCL are not well understood, however, trauma and osteochondrosis are most commonly implicated.[2] Serial radiographs of young horses that develop SCL indicate a progression from sclerosis to MFC flattening, and then a defect that enlarges. Treatments are directed at reducing local inflammation and promoting bone and cartilage healing, with approximately 50-75% of horses becoming sound enough for work. However, bone healing after surgery is inconsistent, occurring in <20% of patients.[3] Recently, a treatment of MFC SCL using a lag screw has been reported that improves the rate of lameness resolution and is the first study to report significant and consistent bone healing.[4] This suggests a biomechanical approach can improve the treatment of equine SCL, but very little is known about the stresses within the equine stifle and how the surgical procedure may be optimized. The equine stifle is a complex biological system and direct collection of biomechanical data would be difficult, if not impossible. The objective of this current study is to investigate the stresses in the subchondral femoral bone at different stages of cyst progression using finite element analysis. This information can help us better understand the mechanics associated with SBCs that will allow clinicians to develop and implement rational treatment strategies.

METHODS

Segmentation and Meshing. Using computerized tomography (CT) images of an extended equine stifle joint of a yearling Thoroughbred, 3D geometry was created by manually segmenting structures in ScanIP (Simpleware). This geometry was meshed into 4-node tetrahedral elements (C4D10) and imported into ABAQUS v6.14 (SIMULIA) for finite element analysis (Figure 1). After creation of the original model, five additional models were made to describe cyst progression, resulting in six models analyzed. 1) Intact (unaltered model), 2) Sclerotic (bone moduli elevated by 12.8% in the region of interest), 3) Flat (a small flattening of ~15 mm in diameter of the central MFC, which is a precursor to cyst formation), 4) S1 (stage-one cyst ~.25 cm^3), 5) S2 (stage-two cyst ~0.5 cm^3), and 6) S3 (stage-three cyst ~1.00 cm^3).

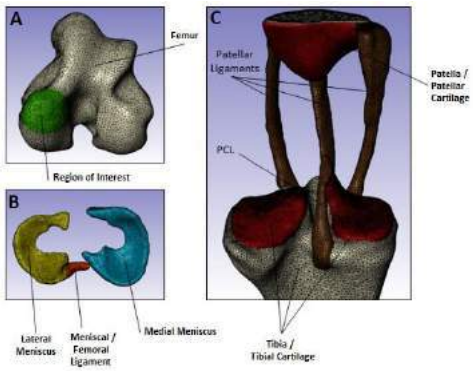

Figure 1: Separate finite element meshes generated in ScanIP prior to reassembly in ABAQUS. Femoral cartilage not shown to highlight the 3.0 cm^3 femoral region of interest (green).

Material Properties. For this study, we were interested in the instantaneous response from an extended stifle joint. Therefore, linear material definitions were suitable for our purposes. Bone moduli was correlated to its mass density using the equations:

$$Mass\ Density = (1.067 * 10^{-3}) * GrayScale \quad (1)$$

$$Young's\ Modulus = (6.0 * 10^{3}) * MassDensity^{2.5} \quad (2)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

and 20 modulus levels were selected based on an analysis for the appropriate number of bone properties.

Table 1: Material properties used in this study.[5-7]

Structure	Type	E (MPa)	ν
Bone	Iso.	50-21,000	0.3
Menisci	Anis.	Radial, Axial = 20, Circumferential = 120	Radial, Axial = 0.3, Circumferential = 0.45
Cart.	Iso.	25	0.45
Ligs.	Iso.	300	0.3
Cyst	Iso.	0.00001	0.3

Boundary Conditions. To model the kinematics of the stifle joint during loading, a frictionless, non-linear (surface-to-surface) contact formulation was defined for all articulating surfaces. Rotations of the proximal femur were constrained, and the distal tibia was fully constrained. A surface pressure with an equivalent load of 3000 N, the peak force during trot, was placed on the proximal femur. An upward force of 175 N was placed on the proximal patella for joint stability.

Verification and Validation. *A* convergence analysis was performed for all relevant output parameters. Starting with an edge length of 2.00 mm, soft tissue structures and the region of interest were refined by 0.25 mm increments in edge length until a <3% change was observed in each output at an edge length of 1.00 mm. Sensitivity analyses were performed to account for the broad range of material property values found in literature (primarily due to specimen-to-specimen differences). We also investigated the effects of different meniscal/tibial plateau relationships to ensure the most appropriate formulation: a peripheral spring attachment that allowed semi-constrained meniscal translation (k = 20 N/mm).

Analysis. Customized scripts in Matlab (MathWorks) extracted data from the region of interest (Figure 1A). We calculated peak tension as the mean of the top 5% maximum principal stress (σ_{max}), as well as peak shear as the mean of the top 5% maximum shear stresses.

RESULTS

Tensile stress in the ROI altered from Intact in every model (Figure 2). Bone sclerosis generally elevated tensile stress in the ROI, and central MFC flattening caused a further significant increase in subchondral tensile stress at the flat surface. An S1 defect moderately lowered tension but not to intact values. An S2 defect resulted in an additional 45% increase in peak tension compared to S1, with high stress areas lateral and superior to the cyst. Peak shear stress in S2 cysts increased by 20% over S1, primarily medial and posterior to the cyst. Peak tensile and shear stress increased by a further 7% and 1%, respectively, in the ROI with a S3 cyst (Figures 2-4).

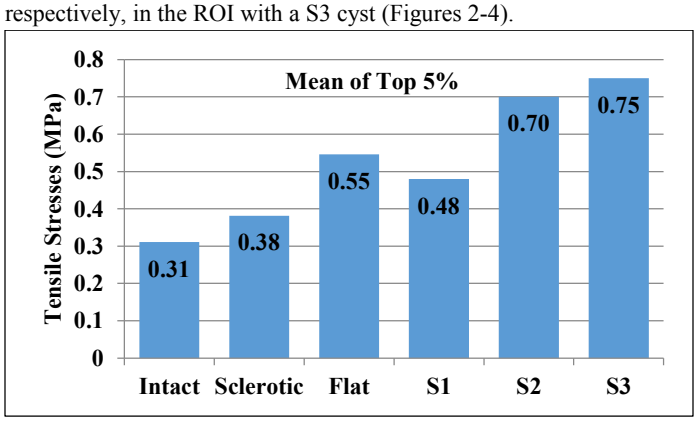

Figure 2: Peak tensile stresses for each model.

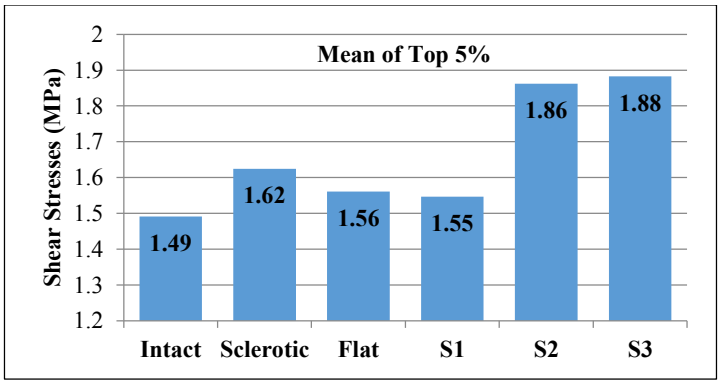

Figure 3: Peak shear stresses for each model.

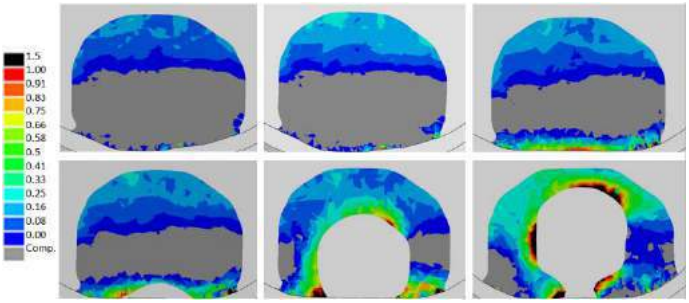

Figure 4: Frontal slice of tested models showing the maximum tensile stresses (MPa). Lateral is to the left and medial to the right. Top row from left to right: Normal, Sclerotic, Flat. Bottom row from left to right: S1, S2, S3.

DISCUSSION

The trabecular bone in the MFC in young horses is susceptible to damage-induced creep (plastic deformation) and is weakest in tension and shear. Focal flattening of the MFC is an early radiographic change that precedes cyst development and is likely the result of this creep. In the flat model, the increased tensile stress occurs where stage one cysts form. At S1 size, peak stress is slightly reduced from the flattened model, but if the defect exposes subchondral bone, joint inflammation will follow and result in further bone destruction and cyst enlargement. As the cyst enlarges to the S2 size, both tensile and shear stresses are substantially elevated, creating an apparent "point of no return." In young horses, when MFC cysts reach this size, spontaneous healing is rare, cysts tend to enlarge to S3 size, and lameness is often observed.

Our results indicate that local MFC mechanics may be a factor in cyst development and progression. These data also support a biomechanical treatment for SBC that addresses the altered stresses in the bone surrounding the cyst. While cyst development is most likely a multifaceted phenomenon, altered MFC biomechanics appear to play a substantial role.

PATIENT SPECIFIC COMPUTATIONAL MODELS TO OPTIMIZE SURGICAL CORRECTION FOR FLATFOOT DEFORMITY

Brian A. Smith, Robert S. Adelaar, Jennifer S. Wayne

Orthopaedic Research Laboratory
Departments of Biomedical Engineering & Orthopaedic Surgery
Virginia Commonwealth University
Richmond, Virginia USA

INTRODUCTION

Adult Acquired Flatfoot Deformity (AAFD) is a progressive, debilitating disease characterized by the collapse of the medial longitudinal arch most commonly subsequent to posterior tibial tendon (PTT) dysfunction (1,2,3). PTT dysfunction typically results from chronic degradation of the tendon (1). As the PTT serves as the primary invertor of the foot, its degradation leads to arch collapse with subsequent increased strain on the remaining soft tissue structures (4) and gross deformity of the midfoot and hindfoot. Due to the chronic nature of the disorder, AAFD is staged from I to IV as the condition worsens. Similarly, treatments for these stages increase in complexity from singular bony and soft tissue procedures to the fusion of multiple joints. The greatest variety in surgical treatments is associated with stage IIb due to the flexible nature of the foot rendering it able to be corrected via passive mechanisms. In these cases, patients typically receive augmentation of the PTT in either a Flexor Digitorum Longus (FDL) or the Flexor Hallucis Longus (FHL) tendon transfer and a bony correction of the deformity (1,5). The choice then lies in deciding whether to use a hindfoot procedure with the Medializing Calcaneal Osteotomy (MCO), a lateral column lengthening (LCL) procedure with the Evans Osteotomy, Calcaneocuboid Distraction Arthrodesis (CCDA), or the Z Osteotomy, or in rare occasions a combination of both hindfoot and a single LCL procedure (1,5).

The challenge with having multiple surgical combinations available is to select the optimal procedure(s) for a given patient. In hopes to aid this selection, we applied Computer Aided-Design (CAD) modeling approaches to recreate the anatomy and kinematics of the foot and ankle complex to investigate how the surgical procedures correct the flatfoot deformity.

METHODS

In previous work, patient specific models were created from 1 mm MRI scans of the lower extremity of each of six patients with a 1.5 T MRI scanner (GE Healthcare Technologies Waukesha, WI) imported into the software package MIMICS® (v12.0, Materialise's Interactive Medical Imaging Control System, Materialise, Ann Arbor MI) and transformed into three dimensional bodies representing the bones of the lower leg (6). To further define the model, the 3D bones were incorporated within SolidWorks (v2007, Dassault Systèmes SolidWorks Corp., Waltham, MA, USA) and with the addin COSMOSMotion to simulate force and other constraints. The patients' body weight was applied vertically down the shaft of the tibia while linear elements representing the muscle, tendon, and ligament forces were applied throughout the foot and ankle complex providing further support to the anatomical bony constraints (Figure 1). Ligament stiffness and muscle activation values were assigned from the literature and then reduced to replicate the stage of AAFD present in each patient based on MRI signal attenuation. With these features, 3D lower leg models were created solely based on patient specific anatomy and bodyweight without requiring idealized joints (6). The surgically implemented procedures of a tendon transfer and MCO were then simulated as done previously (6).

In order to implement the lateral column procedures, bone cuts were made and wedges inserted at designated locations analogous to the surgical approaches (Figure 1B-D). For the Evans osteotomy, a cut on the anterior neck of the calcaneus was made 10mm from the calcaneocuboid joint surface. A trapezoidal wedge was inserted for a 10mm width at the lateral edge. Similarly, a wedge was inserted into the calcaneocuboid joint after 2mm of subchondral bone was removed to replicate joint surface preparation. Three cuts were made, superiorly, longitudinally, and inferiorly, to create the Z-osteotomy. Two trapezoidal wedges were inserted into the superior and inferior cuts until a 10mm separation was achieved in the superior opening. Osteotomies and wedge insertion created interference in adjacent bones of the forefoot. To eliminate these, three movements (two rotations and one translation) of the overall forefoot were implemented while preserving relative bone relationships. Tension developed in the ligaments during simulation finalized physiological bone positions.

Distance and angular measurements, contact forces between articular surfaces, ground reaction forces, and ligament strains were quantified in each model. In the medial/lateral (ML) view, 5 distance and 5 angular measurements were obtained while 1 distance and 3 angular measurements were obtained in the oblique anterior/posterior

(AP) view, replicating clinical radiographic measures. Values from the six patients were compared to normal and AAFD populations by performing a single sided z-test with differences significant for $p<\alpha=0.05$. Variations among the procedures for each patient in particular were analyzed to distinguish trends in the effectiveness in surgical correction compared to their initial clinical presentation.

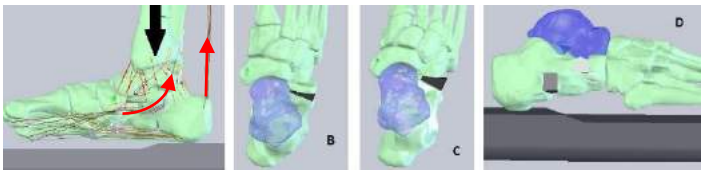

Figure 1: A: Medial exploded view of the computational model showing linear force elements used to replicate the soft tissue constraints and forces applied (shown as arrows for body weight (black), muscles (red)). Superior view of modeled Evans Osteotomy and MCO (B) & CCDA and MCO (C) procedures. Lateral view of modeled Z osteotomy and MCO (D).Translucent talus seen above calcaneus with inserted wedge (black).

RESULTS

Of the seven surgical simulations performed for each patient, the three lateral column and three combination procedures provided significant correction to the heights of the medial column as well as the calcaneal pitch, talar 1st metatarsal angle, talar declination angle, and all three AP angles with the greatest amount of correction coming from the use of the Evans and Z osteotomies with and without the addition of the MCO (Table 1). However, even with the greater amount of correction, these combination procedures also had the greatest occurrence of overcorrection. On a patient to patient basis, the Z osteotomy was the best lateral column procedure for four patients with Evans being the best for the other two. However, the combination MCO & Z procedure was best in three of those cases while the MCO addition had a varying impact on the Evans.

Other measures obtained (data not shown) (7) indicated a redistribution of joint contact force with an increase up to 4 times the patients' body weight between the calcaneus and cuboid. A shift in reaction force off of the medial column and onto the lateral column was also evident. The MCO relieved strain in the spring and deltoid ligaments but increased it in the plantar fascia. The LCL procedures increased strain in the lateral bands of the plantar fascia while relaxing the medial bands. They also relieved strain in the deltoid ligament and the inferiomedial and superiomedial bands of the spring ligament. These effects were amplified when the LCL procedure was combined with the MCO.

DISCUSSION

All procedures provided some form of correction to the flatfoot deformity while reducing strain of soft tissue structures supporting the medial column, with the combination MCO and Evans or Z procedures providing the greatest amount of correction. The Z osteotomy provided better correction when the deformity was more severe which is supported by the work of Vander Griend et al. (8). With the best procedure selected, we were unable to find trends in the pre-op presentation that would indicate which treatment should be chosen similar to the dilemma expressed clinically (9). The significant increase in joint contact and ground reaction forces occurred as reported previously for the Evans and CCDA procedures (9). The force increases for the Z osteotomy are similar to another simulation (10) but contradict the view of Vander Griend et al (8). That clinical study reported no pain increase after the Z osteotomy which should occur with the significant shift in forces onto the lateral column, however, they lacked a long term follow up longer than 1 year (8). Limitations to our study include a small patient population, literature averaged values for ligament stiffness, and only one loading scenario simulated. Our findings indicate that the Z can correct as efficiently as the Evans osteotomy, but special consideration must be taken before adding a lateral column procedure to avoid overcorrection and the significantly increased load on the lateral column.

INTRODUCTION

The most common technique for creating imaged-based patient-specific vascular models using the open-source package SimVascular (www.simvascular.org) is to utilize 2-D image segmentation and proprietary, commercial solid modeling kernels [1]. Two primary drawbacks with this approach are the cost of the commercial libraries and limited ability to integrate 3-D image segmentation results into model development, subsequent mesh generation and simulation. To address these issues the authors have previously reported on extending SimVascular to robustly support triangulated surface representations of anatomy [2]. Triangulated surface representations are desirable because they enable the use of direct 3-D image segmentation algorithms, and provide a framework to combine 2-D and 3-D image segmentations results [2].

While the previous reported improvements were useful to many users, there remains significant interest in traditional solid modeling-based techniques. First, some users require CAD packages to manipulate their models (e.g. integrating a medical device design into a patient-specific anatomic model, or optimizing surgical planning). CAD packages today primarily use boundary representation (B-Rep) for solid models where the boundary surfaces of the solid are represented as planes or Non-Uniform Rational B-Spline (NURBS) surfaces. Second, some SimVascular users rely on commercial flow solvers that have poor support for triangulated surface representations and thus require NURBS models that can be incorporated into the pre-processing packages available with these commercial tools. The work described herein extends the open-source version of SimVascular to support users that require NURBS models for their research.

METHODS

The goal of this work is to enable the creation of image-based models that are a collection of planar surfaces and NURBS patches that define a single enclosed volume of interest, and can be used in the SimVascular pipeline. The surfaces will be defined as planes bounded by an ordered boundary edge curve in 3-space. For each NURBS surface, a series of control points and weights will be specified given the following definition:

$$\boldsymbol{S}(u,v) = \sum_{i=0}^{n} \sum_{j=0}^{m} \frac{N_{i,p}(u)\, N_{j,q}(v)\, w_{i,j}}{\sum_{k=0}^{n} \sum_{l=0}^{m} N_{k,p}(u)\, N_{l,q}(v)\, w_{k,l}} \boldsymbol{P_{i,j}} \quad (1)$$

where $N_{i,p}(u)$ are the basis functions in the u parametric direction and $N_{j,q}(v)$ are the basis functions in the v parametric direction. $\boldsymbol{P_{i,j}}$ are the control points in a defined coordinate system and $w_{i,j}$ are the corresponding scalar weighting values for each control point.

Extending the modular SimVascular open source software framework to support NURBS-based solid models required adding a new concrete solid model class with three core capabilities. First, the class needed the ability to create a solid model for an individual object from an ordered set of 2-D image segmentations. The result of this "lofting" operation is a single solid with a NURBS "wall" and planar "caps". Second, the solid modeling class needed to support the standard Boolean operations of union, intersection, and subtraction to be able to create 3-D anatomic models of branching structures by combining separate solid models. Third, the class needed to provide the ability to "tag" individual surfaces so the user can specify boundary conditions or material properties based on the surfaces of individual branches.

Integration of OpenCASCADE: After investigating several open-source alternatives, we integrated OpenCASCADE (www.OpenCASCADE.org) into SimVascular. The primary reasons for selecting OpenCASCADE was its large existing user base,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

extensive functionality, lofting operations, Boolean operations, fillets, ability to assign data labels to geometric attributes, data exchange (e.g. saving models in STEP format), and compatibility with the Visualization Tool Kit (VTK). However, we discovered that the existing lofting operations in OpenCASCADE often led to undesirable artifacts in vascular models particularly at the ends of vessels (see Fig. 1). This motivated an investigation into improved lofting operations.

Improved global interpolation methods: Several techniques were explored to address the issues with OpenCASCADE's lofting operation. First, cubic splines were fit to the 2-D segmentation groups along the length of the vessel as is done in the creation of a triangulated surface from 2-D segmentations [2]. The splines were used to create evenly spaced segmentations along the length of the vessel for input into the OpenCASCADE lofting algorithms. While more robust than OpenCASCADE's functions, small ridges still persisted in many test cases. Thus, even additional preprocessing and regularization of the data did not ultimately produce high quality results.

OpenCASCADE enables a developer to explicitly specify the NURBS surface parameters directly and still take advantage of the other required functionality discussed above. Specifically, we resample each 2-D segmentation to the same user-defined number of points. These are "fit points" or points that need to be exactly on the surface $\boldsymbol{S}(u,v)$. The points around the circumference of the 2-D segmentations (n+1 points) become the u parametric direction, and the points along the length of the vessel (m+1 points) become the v parametric direction. These points form the right hand side of a series of linear systems to be solved for the control points, $\boldsymbol{P_{i,j}}$. The left hand side of the linear system is the basis functions, $N_{i,p}(u)$ and $N_{j,q}(v)$, of the desired surface degree. Assuming that all of weightings, $w_{i,j}$, are set to 1, this leads to the equation for a nonrational B-Spline surface used in this work:

$$\boldsymbol{S}(u,v) = \sum_{i=0}^{n} \sum_{j=0}^{m} N_{i,p}(u)\, N_{j,q}(v)\, \boldsymbol{P_{i,j}} \quad (2)$$

The basis functions for the B-Spline surface are the Bernstein polynomials of the desired degree. They are found for each input data point with a corresponding parametric coordinate (u,v), which vary between 0 and 1. The basis functions are evaluated at every fit point to give (n+1) x (m+1) systems that can be solved for the control points. The basis functions and the control points define a formula for the entire B-Spline surface. The method used here also gives the user more flexibility by allowing the specification of the degree, parameterization, knot span type, and end derivatives of the result.

NURBS surfaces from triangulated surfaces: The tools developed in this work provide an additional method to create a vascular CAD model from a triangulated surface created via direct 3-D image segmentation for certain types of anatomy. In particular, the centerlines of the vascular model can be extracted and represented as SimVascular vessel paths. The triangulated model can be sliced by an infinite plane perpendicular to the vessel path at a series of locations along the path. These ordered curves are then used in SimVascular similar to 2-D segmentations as discussed above. The benefits of this technique are twofold. First, it provides the user some ability to resample a direct 3-D segmentation if desired. Second, it enables the straightforward integration of certain classes of triangulated data into CAD-friendly models.

Mesh generation: In addition to the concrete solid modeling class, two other major changes were required. First, the mesh generation classes were updated to support the new solid model type to enable mesh generation with TetGen (www.tetgen.org) and MeshSim (Simmetrix, Inc., Clifton Park, NY, USA). Of note is that special functions in the solid modeling kernel may need to be called to transform surfaces generated in filleting operations to be NURBS surfaces to use MeshSim in the SimVascular pipeline.

RESULTS

Representative results of the improved global interpolation methods are given in Fig. 1. As shown, the techniques developed herein significantly improve on the method available in OpenCASCADE by reducing visible artificial kinks in the surface. Not only is the quality of the model improved, but our method is significantly less computational intensive. For a group of 30 segmentations, it takes approximately 30% of the time it takes to loft the same group of segmentations with the algorithm inside of OpenCASCADE. In addition, because the resultant surface from the improved methods uses fewer control points, the Boolean operations for two typical vessel segments is approximately 50% faster (i.e. 10 seconds instead of 20 seconds). In most practical scenarios, the major timesaving comes by freeing the user from having to fix or manipulate 2D segmentations to achieve an accurate model, which can be highly time-consuming.

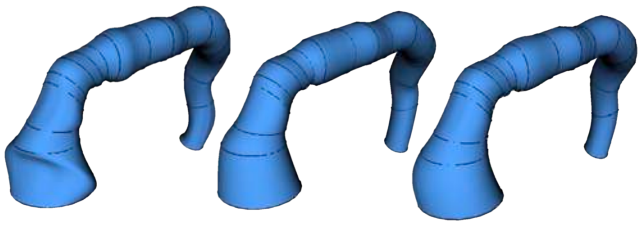

Figure 1: Example of Lofting Artifacts. The techniques integrated into OpenCASCADE 6.9 often create significant artifacts near the end of the vessels (left image). The improved methods described herein produce results without the kinks (middle image) that compare favorably to models lofted using the best-in-class Parasolid 26.1 (right image).

DISCUSSION

Prior to this work, the commercial solid modeling kernel package Parasolid (Siemens PLM Software, Plano, TX, USA) was integrated into SimVascular to provide best-in-class NURBS support and the necessary solid modeling functionality [1]. However, in addition to the expense of the commercial library, the proprietary API of Parasolid prevented the public release of SimVascular source code calling its functionality. This motivated the exploration of open-source alternatives for NURBS solids and the integration of the OpenCASCADE kernel. SimVascular is the only fully open-source project for patient-specific image-based model construction to support solid models with NURBS surfaces. In addition, improved lofting techniques have been implemented that significantly improve upon the existing techniques found in OpenCASCADE. Future work may include testing geometric optimization using the NURBS-based models, improved techniques to directly create NURBS patches from triangulated surfaces, and the integration of isogeometric analysis tools into SimVascular.

INTRODUCTION

Obesity is becoming increasingly prevalent, with predictions that up to 51% of the US population will be obese by the year 2030 [1]. The effect of obesity on bone properties is largely controversial; however, studies tend to suggest that obesity increases the risk of fractures, especially in children, and can vastly complicate treatment of skeletal injuries [2]. In particular, obesity in children has been associated with a variety of complex conditions including Blount's disease and slipped capital femoral epiphysis (SCFE) [3,4]. In these two cases, as well as other clinical conditions, excessive compressive forces generated by malalignments and weight act upon the physis (growth plate) [3].

The mechanical environment is a strong regulating factor in the growth and development of long bones [5,6]. Typically, the mechanical properties of the physis are heterogeneous in different layers, such as the reserve and hypertrophic zones, directions with respect to the body, and developmental stage. Starting in the reserve zone and moving through the proliferative, hypertrophic, and calcification zones, the physis becomes significantly less rigid, exhibiting lower stiffness and higher compressive strains [5]. These changes in properties have been hypothesized to be caused by the random organization of collagen fibers in the reserve zone, when compared to more developed zones. Also, the medial and central regions have been found to be weaker and less rigid than the lateral and anterior/posterior regions. In early childhood development, the physis is significantly less stiff than in closure. Also, the physis is viscoelastic by nature due to its largely cartilaginous makeup.

It has long been thought that obesity affects the mechanical properties of the physis and surrounding bone, but no relationships have been established. In the present study, we examine the effects of diet-induced obesity on the shear forces to fracture in rat long bones, as well as local mechanical properties in the physeal region. To date, we have completed shear testing and are beginning to use stress-relaxation methods to assess the exposed cartilaginous surfaces of the failed growth plates.

METHODS

Sprague-Dawley rats were separated into two groups – one control group being fed a control diet consisting of 10% caloric intake of fat with normal drinking water, and one high-fat group being fed a diet consisting of 45% caloric intake of fat with 25% fructose water. Weekly measurements of weight were recorded. Following weaning at 3 weeks, nine 9-week old rats from each group were sacrificed and tibiae were harvested and stored at -20°F in salineated gauze. Tibiae were selected based on the relative flatness of the growth plate on the proximal side.

A custom jig was developed for testing on an MTS 858 MiniBionix (MTS Systems, Eden Prarie, MN) system. All tibiae were thawed at room temperature and potted with bone cement in the jig such that a loading nose would be perpendicular to the bone and approximately parallel to the physis, and acting in the posterior-to-anterior direction (Fig. 1). Shear testing was conducted at a rate of 0.1 mm/s using a 100 N load cell. Data were recorded using MTS Basic Testware at a sampling rate of 100 Hz and were exported to Excel for analysis. The maximum force, stiffness, and energy to max force were calculated. Non-parametric statistical tests (Wilcoxon Ranked Sums and Kruskall-Wallis) were employed due to small sample sizes. Sheared tibiae were stored in PBS and refrozen. One sample per group per time point was submitted for histological sectioning and staining to confirm that shearing occurred at the physis. Bones were decalcified and embedded in paraffin, sectioned into 3 μm segments, and stained using an H&E protocol.

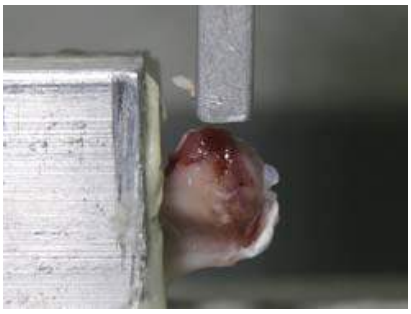

Figure 1: Shear testing of proximal tibia; loading occurs in the downwards direction.

RESULTS

Mean body weight and mean body fat after 9 weeks of the high-fat diet were 9% and 23.6% higher, respectively, than rats undergoing the control diet. The maximum force and the energy to maximum force were decreased, while stiffness was increased in the high-fat group (Fig. 2). Due to small group sizes, these differences did not reach statistical significance ($p = 0.12$, 0.34 and 0.22, respectively).

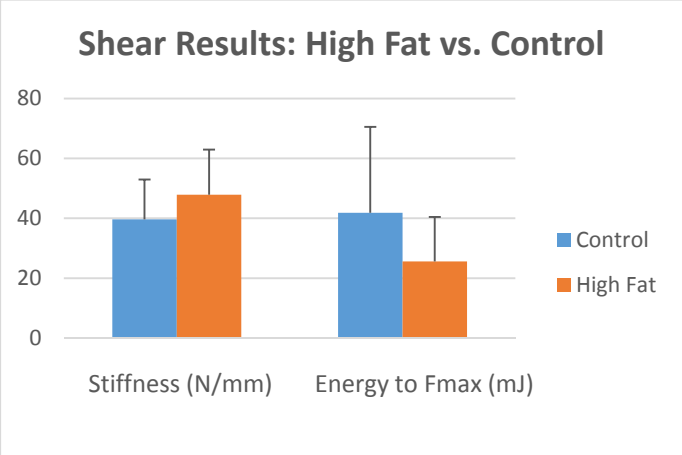

Figure 2: Mean stiffness and energy-to-max-force results from shear testing.

Figure 3 details one histological example of a sheared tibia, which confirmed that shearing occurred at the physis. Among the limited samples examined, it appears that the shear failures occurred through the hypertrophic region of the growth plate.

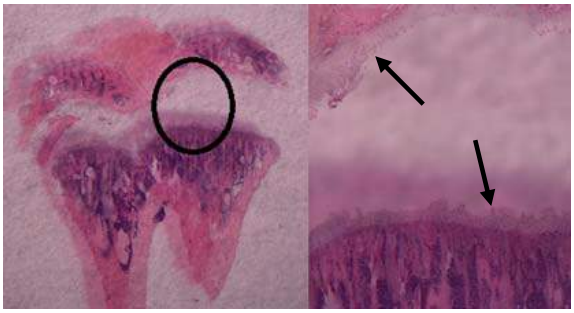

Figure 3: Histology results from samples post-shearing. Left: Macro image of a sheared tibia. Right: Zoomed-in view of encircled region, in which growth plate cartilage can be seen on either side of the shear line (indicated by black arrows).

DISCUSSION

The hypotheses behind this study were that diet-induced obesity in rats would alter both shear forces to fracture the growth plate. Our findings were both consistent with clinical observations, as well as related studies in rat tibiae [7,8], and suggest there are some differences between the growth plates of obese and non-obese rats. Increased stiffness and decreased energy absorbed may indicate that physes in obese rats are less flexible and more brittle than their healthy counterparts, though the differences were not statistically significant. As the increase in weight between the two groups was found to be modest, our findings may also indicate that increased loading due to obesity is not as significant in growth plate alterations as metabolic changes due to obesity. Limitations of this study include variability within groups and small sample sizes.

Ongoing work will focus on shear testing of 5-week old rats, which will be important in characterizing alterations in mechanical properties related to developmental and metabolic alterations. Progressive histological sections may reveal more in-depth information relating to shear fracture patterns through the physes. Lastly, indentation testing will be used to generate the mechanical properties of the growth plate on both sides of the shear fracture line. With these data, we hope to gain new insights into the effects of obesity on the growth plate.

INTRODUCTION

Preterm birth (PTB) is defined as delivery between 20 and 37 weeks gestation. Across the globe, PTB affects 15 million babies each year, with 380,000 of those being in the United States [1,2]. Although some PTBs may be medically indicated, approximately 80% of them occur as spontaneous preterm births (sPTB), [3]. Clinically, the majority of sPTBs can be divided into three subcategories: premature cervical remodeling, premature preterm rupture of membranes, and preterm labor. Therapeutic interventions to prevent sPTB (tocolytic agents, progesterone supplementation, mechanical closure of the cervix via a cerclage stitch or silicon pessary) are limited and not always effective [95% of sPTBs are intractable to current therapies, both mechanical and medicinal] [4]. To decrease the rate of sPTB, it is imperative that we improve our understanding of the anatomical and tissue material factors that drive the mechanical environment of pregnancy. Thus, we built a parameterized 3D finite element (FE) model of the pregnant uterus and cervix based on maternal ultrasound measurements.

During pregnancy, the uterus and fetal membranes (FM) (i.e. chorion and amniotic sac) must grow and stretch to accommodate the growing fetus and amniotic fluid. Simultaneously, the cervix must be a mechanical barrier to keep the fetus within the uterus. All three tissues must withstand mechanical forces to support the developing baby. Then, in a reversal of roles, ideally nearing term, the uterus begins to contract and the cervix deforms (softens, shortens and dilates) to prepare for delivery [5,6]. The state of stress and stretch of these soft tissues are thought to contribute to the physiologic processes that regulate tissue growth, remodeling, and contractility. It is generally hypothesized that these mechanical signals are clinical cues for normal labor and sPTB. How these mechanical cues of stress/stretch contribute to the timing of a term or preterm birth remain to be determined.

In a previous finite element study of pregnancy derived from magnetic resonance imaging (MRI) data, we found that the mechanical load on the cervix is influenced by the geometry of the lower uterine segment (LUS) and cervix, the mechanical properties of the cervix, the FM material properties and adhesion, and how these components collectively resist loading from intrauterine pressure (IUP) [7]. In this study, we chose to utilize ultrasound-based CAD models for multiple reasons: lower cost of procedure, improved patient tolerance, and the improved flexibility to conduct a parametric study of input variables.

The goal of this study is to provide a framework for a personalized, parametric computational tool to assess the mechanical loads and tissue stretch of the organs supporting the fetus during pregnancy. Here, we develop a custom computer script to build a parameterized baseline CAD geometry of the uterus and cervix, and we implement FE analyses on various geometries to visualize the impact of cervical angle and cervical length on tissue stretch at the opening of the cervical canal into the uterus (internal os).

METHODS

Maternal Ultrasound Measurements Geometric measurements of the uterus, cervix, and their positions relative to bony reference landmarks were measured via transabdominal and transperineal ultrasound (GE Voluson E8). For the baseline model, uterine diameters, uterine thicknesses, cervical length, cervical diameters, and cervical angle with anterior lower uterine segment (LUS) were measured for a 35 y/o normal patient with no prior pregnancies at 25 weeks gestation (Fig. 1). Based on our group's previous studies, we then chose two parameters to scale individually based on values in the literature to assess each variable's impact on cervical stretch: cervical angle and cervical length [8]. Baseline values of these parameters are a 90° angle and a cervical length of 40 mm.

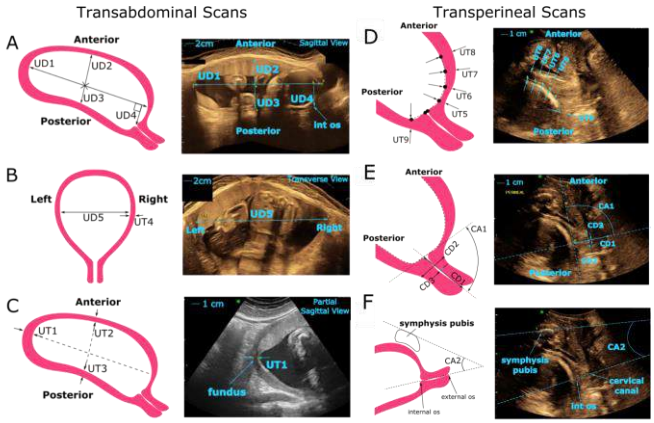

Figure 1: Diagrams of the uterus (left) and cervix based on ultrasound scans and recorded dimensions (right).

Parameterized Model and Finite Element Analysis We generated FE models (FEBio 2.3.1) using a customized computer script (Trelis Pro 15.1.3, csimsoft LLC) based on the ultrasound input parameters. Geometry of the uterus, cervix, FM, and abdomen were generated by Boolean addition and subtraction operations on geometric primitives (Fig. 2). The uterus was built by transforming two spherical surfaces into ellipsoids representing the outer and inner uterine walls. The shells were scaled, translated, and rotated to accommodate differences in uterine wall thickness in the anterior-posterior, superior-inferior, or left-right directions. The cervix was built as a hollow cylinder. Its edges were rounded at both ends to eliminate non-anatomical corners and to match the clinical presentation of the uterocervical connection. The vaginal canal was built by fitting a spline to three points on the outside edge of the cervix at the external os and one point on the approximate location of the vaginal introitus. The FM was generated with uniform thickness in a similar manner to the uterus.

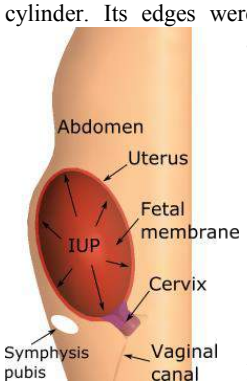

Figure 2: Parameterized CAD model of pregnancy

For FE analysis, the uterus and cervix were modeled as collagenous composite materials meshed using linear tetrahedral elements, based on material fits to passive length-tension curves of pregnant tissue [9], while the FM was modeled as Ogden nonlinear material meshed with hexahedral elements. The FM was prescribed a tied contact to the inner uterine wall and a sliding contact to the cervical internal os. For the FE simulation, IUP was applied over the physiological range for 25 weeks (0 to 0.817 kPa), which was estimated from the following equation:

$$\ln(y+1) = 0.12 + 0.23x - 0.010x^2 + 0.00015x^3 \qquad (1)$$

where y is the amniotic pressure in mmHg and x is the gestation in weeks [10]. The extent of cervical stretch was evaluated as a percentage of entire cervical volume above a 1.05 stretch threshold, and maximum stretch in each case was also calculated.

Parameter Study Multiple dimensions of the uterine and cervical geometries were measured from ultrasound and we chose to sweep the cervical angle with respect to the posterior LUS and the cervical length as input parameters (Fig. 1). After analysis, we measured the right Cauchy-Green stretch in the cervix volume to find the maximum stretch as well as the volume percentage above a 1.05 arbitrary stretch threshold.

RESULTS

The cervical angle of 90° with respect to the anterior LUS has the lowest simulated stretch concentration at the cervix internal os. While maximum tissue stretch does not have a trend, percent volume of cervix above a 1.05 stretch threshold increases directly with cervical angle (Fig. 3).

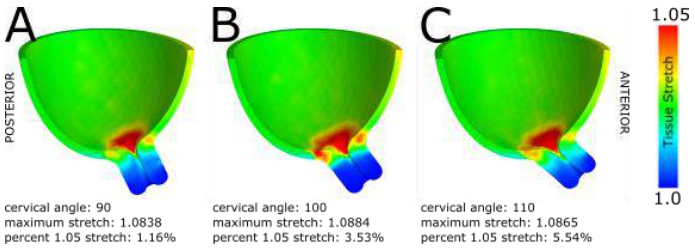

Figure 3: Plane-cut sections of the LUS and cervix showing maximum principal stretch and the corresponding cervical volume percent above 1.05 stretch for A) 90° B)100° and C) 110° cervical angle with the posterior LUS. Stretch increases with increased angle away from the posterior LUS.

The cervical length of 40 mm has the lowest simulated stretch concentration at the cervix internal os. While maximum tissue stretch does not have a trend, percent volume of cervix above a 1.05 stretch threshold increases inversely with cervical length (Fig. 4).

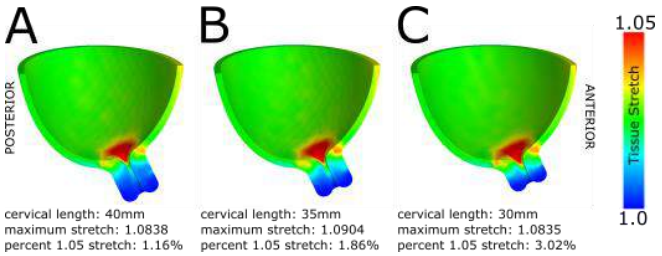

Figure 4: Plane-cut sections of the LUS and cervix showing maximum principal stretch and the corresponding cervical volume percent of stretch above 1.05 for A) 40mm B) 35mm and C) 30mm cervical length. Stretch increases with decreased cervical length.

DISCUSSION

We provided a method to generate a parameterized FE model of the pregnant anatomy using ultrasound-derived geometric parameters and material properties from previous literatures. The results show that the cervix connecting to the uterus at a right angle is the configuration which experiences the least stretch, and any deviation from this angle increases cervical stretch. We are currently exploring the consequence of altered soft tissue properties of the FM, uterus, and cervix on the mechanical environment of pregnancy.

This parameterized FE simulation has potential to be clinically useful due to its flexibility and capacity to model patient-specific geometries at various gestations. In addition, the script may be easily used by obstetricians and sonographers with minimal training, and can provide a detailed analysis for each patient in a timely manner.

INTRODUCTION

The purpose of this research is to develop a model for the prediction of damage in the intervertebral disc of the cervical spine due to head supported mass (HSM) applied during military operations. Military personnel wear helmets such as the Advanced Combat Helmet (ACH) for extended periods of time, which may result in severe risk of neck injury. Manoogian et al. report that equipment added to soldiers' helmets can significantly affect head-neck dynamics [1]. In order to predict this damage in the neck, so that preventive measures can be accordingly designed, a damage model is desired for the cervical spine. A number of groups have conducted studies on degeneration of the lumbar spine, but little attention has been given to the cervical spine under cyclic loading. In a previous study, we utilized a whole body musculoskeletal model with detailed neck structures (7 cervical vertebral joints and 24 degrees of freedom on head and neck) [2], [3], in order to simulate the cervical joints during walking and running with a middle-sized army combat helmet (1.43 kg). Fig. 1 shows the compressive loading at C4-C5 joint level during one gait cycle of walking with the US Army Combat Helmet (ACH). In this study, we have proposed a model to predict the evolution of damage and recovery in the intervertebral disc of the cervical spine subjected to repeated cycles of loading for one gait cycle.

METHODS

We have presented a damage evolution model for the disc based on the non-linear damage model proposed by Chaboche and Lemaitre [4]:

$$\delta D = D^{\alpha(\sigma_{max},\sigma_{mean})}\left[\frac{\sigma_a}{M_0(1-b\sigma_{mean})}\right]^{\beta}\delta n \qquad (1)$$

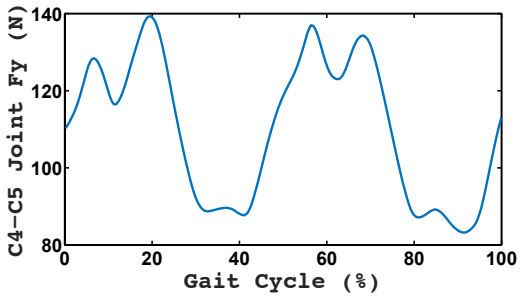

Figure 1: Load pattern on a C4-C5 joint level during one gait cycle of walking with the army combat helmet.

where, σ_a is the alternating stress, σ_{mean} is the mean stress, D is the damage, such that $0 \le D \le 1$, n is the number of cycles, α is a function of the stress σ and M_0 , b, β are material parameters. We calibrated M_0, b and β according to the stress-life data for the discs collected by Green *et al* [5]. For a case of variable loading, the following equations describing damage evolution were obtained from Eq. 1 according to the method proposed by Dattoma et al. [6]:

$$D_i = \left(\frac{n_i^{eff}}{N_{fi}}\right)^{1/(1-\alpha_i)} \qquad (2)$$

$$N_{fi} = \frac{1}{1-\alpha_i}\left[\frac{(\sigma_a)_i}{M_0(1-b(\sigma_{mean})_i)}\right]^{-\beta} \qquad (3)$$

$$n_i^{eff} = n_i + N_{f\,i}\left(\frac{n_{i-1}^{eff}}{N_{f\,i-1}}\right)^{(1-\alpha_i)/(1-\alpha_{i-1})} \qquad (3)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\alpha_i = 1 - a\,\langle \frac{(\sigma_{\max})_i}{(\sigma_u)_i - (\sigma_{\max})_i} \rangle \quad (4)$$

where, D_i is the damage in the i^{th} iteration, N_{fi} is the number of cycles for failure in the i^{th} iteration, M_0, a, b, β are material parameters, n_i is the number of cycles in the i^{th} iteration and σ_u is the ultimate tensile strength.

It has been shown in the literature that intervertebral discs recover a considerable proportion of damage during rest or recovery periods [7]-[9]. To incorporate this effect in our model, we have proposed an analytical equation describing this effect. We propose a recovery parameter, r, which proportionately reduces the damage as follows:

$$D_i^r = D_{i-1} + (D_i - D_{i-1}) * (1 - r) \quad (5)$$

where, D_i is the damage in the i^{th} iteration without considering recovery, and D^r_i is the damage in the i^{th} iteration after considering recovery. The recovery parameter is a measure of the percentage of damage accumulated during the day that is recovered during the rest period. The value of N_f is modified to incorporate the effect of recovery in the next iteration.

$$N_{fi} = \frac{n_i^{eff}}{(D_i^r)^{1/(1-\alpha_i)}} \quad (6)$$

RESULTS

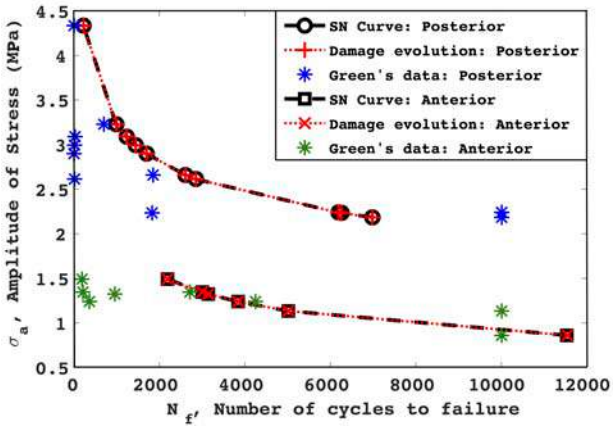

Figure 2: Curve-fitting of Green's data to damage evolution equations.

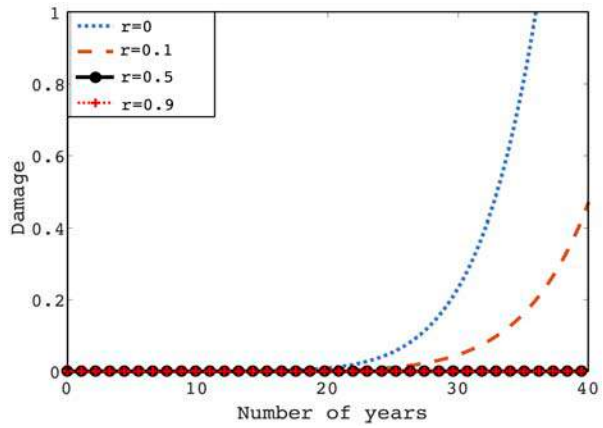

Figure 3: Evolution of damage for a uniaxial cyclically loaded single element in the presence of recovery for varying value of the recovery parameter *r*.

Fig. 2 shows the plots for curve-fitting of Green's data to our non-linear damage model, from which, the material parameters were then determined. Anterior and posterior parts of the disc had different material properties and hence were fitted separately. Fig. 3 shows the plot for evolution of damage for varying values of recovery.

DISCUSSION

We have proposed a non-linear model to study disc degeneration of a cervical spine due to long-term cyclic loads. We also proposed a preliminary recovery model to account for the recovery of damage experienced by the disc during a resting period.

Only 20% of damage was found to occur in 75% of life, after which an exponential increase in damage was observed. The addition of recovery further delays the damage evolution. For a recovery parameter of 0.1, the model predicts a damage value of 0.5 in 40 years. The damage value can be further correlated with pain indicators to predict when the damage becomes severe.

The recovery parameter itself can be a function of many variables, e.g. health status and age of individuals. Youngsters are expected to have a higher recovery parameter than older people. It can also be considered a function of damage - when the disc is already damaged, the recovery capacity of the disc can be assumed to be lower than when the disc is healthy. One aspect that the current recovery model does not consider is lower and upper bounds on the recovery possible during a recovery period. In this paper, the recovery is considered a percentage of damage incurred during the day. This may not be true for certain cases when the damage is too less and the entire damage is recovered during the rest period, or when the damage is too high, and only a small percentage of damage can be recovered. Moreover, this model does not account for disc damage due to any disease, which might accelerate damage growth. Also, this model only considers damage in the annulus part of the disc.

Despite these limitations, this model may provide insight into damage evolution of the intervertebral disc. The two important advancements that this model brings to the area of modeling intervertebral disc degeneration are:

(1) Inclusion of recovery into the damage model that allows the model to resemble the biological phenomenon more accurately than any other pre-existing models.
(2) Consideration of the non-linearity of damage evolution.

The model can be further developed to aid in evaluation of head supported devices and yield recommendations towards better helmet designs and usage scenarios.

CLOT INTEGRATION FACTOR FOR IN VITRO QUANTIFICATION OF STENT-RETRIEVER DEPLOYMENT USING CONE-BEAM COMPUTED TOMOGRAPHY

INTRODUCTION

Stent-retriever technology enables superior endovascular treatment of emergent large vessel occlusions (ELVO) in acute ischemic stroke patients [1]. Mechanical thrombectomy offers high rates of recanalization of the occluded target vessel and subsequent (near-)complete reperfusion of the distal vascular network. Nonetheless, successful angiographic reperfusion after rapid recanalization isn't necessarily followed by good functional outcome [2]. Previous studies have highlighted the dependencies of endovascular treatment efficacy and safety on clot composition and mechanics [3,4]. Importantly, device development and clot retrieval strategies are aimed at maximizing chances of single-pass thrombectomy success with minimal clot disruption.

Intuitively, the stent-retriever should integrate extensively with the clot after deployment at the site of occlusion. To achieve this in clinical practice, the instructions for use of some stent-retrievers include a recommended time to wait before retrieving the device. Additional improvements in functional outcome may be achieved with altered deployment strategies, such as a recently described technique that pushes the Trevo™ stent-retriever out of the retracting microcatheter instead of simple unsheathing [5]. Such varying clinical practices already suggest that the time actually allotted for the clot to integrate into the device may range from 30 seconds to approximately 5 minutes.

Unfortunately, our ability to study the effects and time aspects of clot-device integration in vivo is restricted by poor fluoroscopic clot visibility and limited three-dimensional image resolution. In this study we therefore devised a Clot Integration Factor (CIF) measure that used high-resolution cone-beam CT images to quantitatively capture the integration of the clot into the stent-retriever in an established in vitro vascular model with a reproducible ELVO of the middle cerebral artery (MCA). Our aim was to evaluate the effects of different deployment variations, time, and clot composition on CIF.

METHODS

Deployment variations (pushing vs. unsheathing) of the Trevo™ ProVue/XP stent-retriever (Stryker Neurovascular, Fremont, CA, USA) were tested in an in vitro model system that mimicked a MCA-occlusion with a silicone vascular replica [6] and two contrast-enhanced clot models using 8 trials per group. Hard inelastic clot, representative of the fragmentation-prone cholesterol-rich clots encountered in clinical practice, was generated by thrombin-induced clotting of bovine blood (2.5 NIH U thrombin/ml blood). Soft elastic clot, which is representative of fresh red clots, was obtained by mixing human blood with thrombin (2.5 NIH U thrombin/ml blood).

Under fluoroscopic guidance (Allura Xper FD20, Philips, Best, The Netherlands), the device was positioned across the blood clot and deployed. Before and 5 minutes after deployment, high-resolution cone-beam CT imaging (VasoCT; 617 non-binned projections; 20.4 s rotation; reconstructed at 33% or 50% of the field-of-view, yielding a 24.7 or 34.5 mm cube; 512^3 reconstruction matrix) was performed.

An image processing pipeline was devised by combining existing geometric (vascular) modeling software, including ITK, VTK, and VMTK [7]. The pipeline comprised 1) anisotropic diffusion filtering for spatial noise reduction; 2) manually initialized path tracing using Dijkstra's algorithm to extract the three visible marker wires of the device; 3) smoothing of the wire tracings using cubic B-spline fitting; 4) level-set segmentation of the clot after manual seed point initialization; and 5) Steiner circumellipse fitting to extract and determine the interior volume of the device defined by the three marker wires; 6) CIF was calculated using the device volume V_{device} and clot volume V_{clot} as follows:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\frac{V_{\text{device}} \cap V_{\text{clot}}}{V_{\text{clot}}} \quad (1)$$

Separate two-sample t-tests were performed to evaluate the effects of deployment technique and time on CIF for each clot type.

RESULTS

Intensity differences between the contrast-enhanced clot and the marker wires of the device allowed separate segmentation of both structures in all available data sets (see example in Figure 1).

CIF was significantly different for the two deployment variations (pushing vs. unsheathing) when the device engaged a hard inelastic clot (difference between means, 95%CI=[0.004,0.174], p=0.041), but not a soft clot model (95%CI=[-0.138,0.104], p=0.764) (see Figure 2).

Furthermore, it was found that CIF increased significantly over time between the post-deployment (early) and the final (late) time points when the pushing technique was applied in hard inelastic clot models (mean change, 95%CI=[0.006,0.047], p=0.019) (see Figure 3).

Regardless of the delivery technique, we found an overall increase in CIF over time for both hard inelastic clot (mean change=0.032, p=0.004) and soft elastic clot (mean change=0.065, p=0.007).

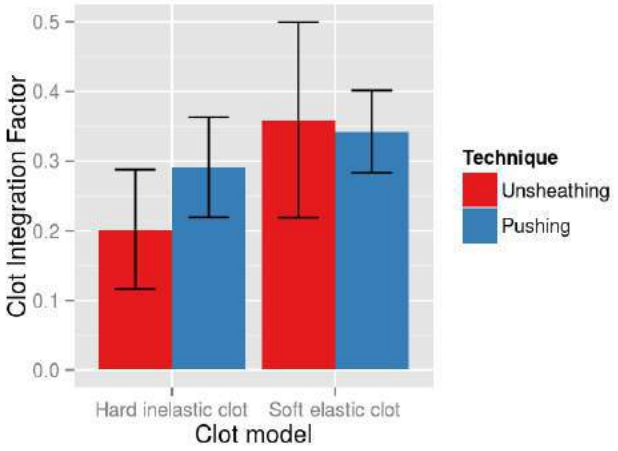

Figure 2: Bar graph showing means and standard deviations of the Clot Integration Factor (CIF) measured just prior to device retraction.

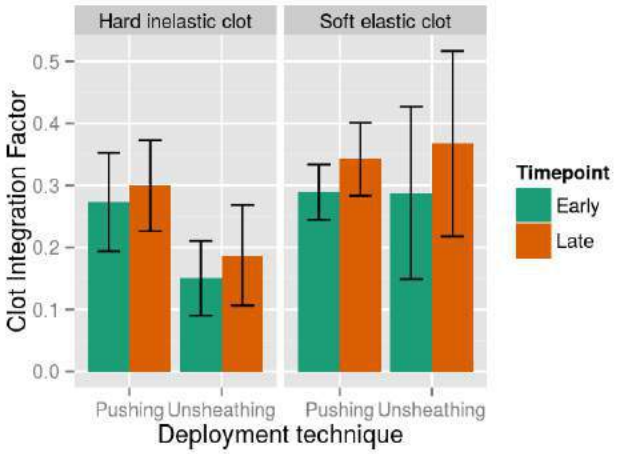

Figure 3: Bar graph showing means and standard deviations of the Clot Integration Factor (CIF) computed immediately post-deployment ("Early") and at 5 minutes after deployment ("Late").

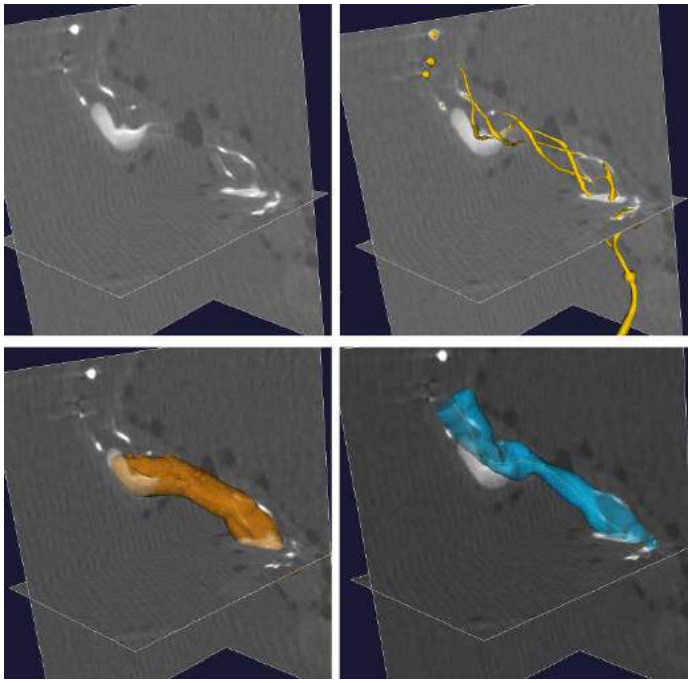

Figure 1: Example views with three orthogonal planes of a reconstructed VasoCT image (top left), the location of the three marker wires (top right), the result of the level-set segmentation of the clot (bottom left), and the determination of the inner volume of the device bounded by the extracted marker wires (bottom right).

DISCUSSION

We described an image-based approach to quantitatively capture the integration of a blood clot into a stent-retriever for evaluation of device and deployment variations in an in vitro model of ELVO.

We found that a recently published deployment strategy that was associated with better functional outcomes was associated with significantly higher CIF values when deployed in our hard inelastic clot models in vitro. However, there was no significant difference between the deployment variations when the device was delivered into a soft elastic clot model.

In clinical practice, and according to the instructions for use of most stent-retrievers, devices are often retrieved only after some time in order to ensure sufficient clot-device integration. Likewise, our CIF measurements showed a tendency to increase over time, regardless of the delivery technique. Nonetheless, when the device was deployed in a hard inelastic clot model, CIF values suggest that the pushing technique may further enhance device-clot integration.

In conclusion, our study shows that in vitro imaging-based quantification of clot integration can detect differences in deployment configuration relative to a clot, which may support procedural and design improvements.

CERVICAL SPINE FORCES AND DISC HERNIATION RISK DURING STANDARDIZED REAR-END IMPACT TESTING

Keith D. Button (1), Stephanie M. Rossman (1), Brian T. Weaver (1, 2), Steve A. Rundell (1)

INTRODUCTION

Intervertebral disc herniations account for a major portion of spine-related surgeries. Although temporal consistency between symptomology and a relatively minor automobile collision is a common factor for establishing causation, this may yield a false-negative diagnoses given the prevalence of disc herniations in the asymptomatic population [1]. For example, previous research has demonstrated a temporal relationship of symptomology during placebo rear-end impacts [2]. Therefore, it is imperative that the clinician considers the specifics of an automobile collision as they relate to injury mechanisms prior to establishing causation of objective MRI findings.

Incorrectly associating the presence of a disc herniation with an automobile collision can result in a number of consequences, including somatic symptom disorder, unnecessary procedures, and ineffective treatment. The presence of potential medico-legal proceedings further complicates matters for the treating physician.

Biomechanics provides a valuable tool for quantifiably determining if the necessary mechanism of injury is present. Specifically, several biomechanical studies have previously documented the biomechanical environment associated with disc herniations [3,4]. These studies definitively demonstrate that axial compressive loading is essential in the causation of, or significant contribution to, a disc herniation. Therefore, the objective of the current study was to determine the compressive loading experienced by the upper cervical spine during rear-end collisions, and compare it with benign, non-injurious levels as well as previously reported Injury Assessment Reference Values (IARVs) [5].

METHODS

The Insurance Institute for Highway Safety (IIHS) performs five tests to evaluate passenger vehicle crashworthiness. One of these involves the safety performance of the seat and head restraint. This is performed by simulating rear end collisions with a change in velocity (Delta-V) of 15 kph. Safety performance is determined using an instrumented anthropomorphic test device (ATD). For the current study, ATD data from several IIHS rear-end sled tests, representing a wide range of vehicle types, was evaluated to determine the neck loading experienced during a rear-end collision.

Additionally, the National Highway Traffic Safety Administration (NHTSA) conducts rear impact crash tests to examine the compliance of a passenger vehicle's fuel system integrity (Federal Motor Vehicle Safety Standard 301). The crash tests consist of a stationary motor vehicle impacted in the rear by a flat rigid barrier at speeds up to 48 kph. Delta-V's during these tests were determined from the conservation of linear momentum. Data from Hybrid III ATDs seated in the front occupant seating positions were evaluated to determine the neck loading experienced during these high speed rear-end collisions.

Filtered data from ATDs in ten IIHS test and ten NHTSA crash tests were collected and analyzed for a variety of passenger vehicle types. Trace plots of the z-axis upper neck force were created from filtered ATD data. Additionally, video footage of tests was analyzed to qualitatively assess the loading pattern experienced by ATDs.

RESULTS

A depiction of ATD motion from the IIHS 15 kph rear-end tests is shown in Figure 1. The ATD's cervical spine underwent several phases. Initially, the upper torso was in contact with the seatback with the head not yet in contact with the headrest (Figure 1a). The torso was then accelerated forward due to contact with the forward-accelerating seatback while the head remained stationary (Figure 1b), resulting in tension-extension of the cervical spine. After this, the ATD experienced the "rebound phase," in which the head and torso were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

accelerated forward due to the release of stored energy from the seatback, resulting in flexion of the cervical spine (Figure 1c and d).

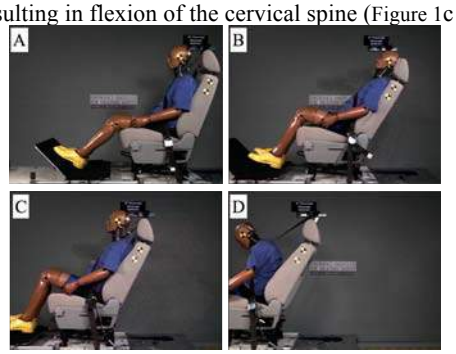

Figure 1: Photographs depicting the response of the ATD to an IIHS rear-end collision. Taken from the 2007 Chevrolet Silverado test.

The maximum tension/compression values from the IIHS and NHTSA tests are shown in Table 1 and Table 2, respectively. The maximum neck tension and compression forces from the IIHS tests were 619.8 N and 148.3 N, respectively. The maximum neck tension and compression forces from the NHTSA tests were 1826.4 N and 118.9 N, respectively. In all tests, the maximum neck tension force exceeded the maximum neck compressive force.

Average	15.6±0.2	468.4±98.8	94.1±32.0

DISCUSSION

The results indicate consistent patterns of loading in the spine across a variety of experimental models, severities, and vehicle seats. Specifically, the primary loading experienced consisted of cervical tension. This type of loading is consistent with the injuries described in cadaveric research in the absence of a head restraint. Specifically, these studies have documented an assortment of osteoligamentous injuries including ligamenta flavum rupture, widening of the facet joint, anterior longitudinal ligament rupture, and chip fracture, but never disc herniations [6].

The causation of intervertebral disc herniations has been previously shown to have two distinct mechanisms. One involves fatigue loading wherein the nuclear material translates through the layers of the annulus as a result of thousands of repetitive compressive loading cycles combined with twisting and bending motions [3]. The other involves a single, traumatic event. In order for this to occur in the absence of bony fracture, a combination of hyper-flexion (forward bending beyond the physiological limit) and a large compressive force must be applied to the cervical spine [4]. It is necessary for both of these loading modes to occur in concert. For example, during pure compressive loading without combined flexion, the pressure in the nucleus will cause fracture of the adjacent bony endplates, and not result in movement of the nucleus into the annular fibers. Hyper-flexion is required to dislodge the nuclear material and stretch the posterior annular fibers, thereby allowing for passage of the nuclear material. The data presented in the current study illustrate that the ATDs did not experiences hyperflexion with simultaneous compression. Therefore, from a general perspective, the necessary injury mechanism for a disc herniation is not present during a rear-end collision.

While the ATDs experienced compressive force in the cervical spine, this was minimal and consistent with everyday activities. Upper neck loading during everyday activities has previously been documented, with compressive values of 171 N, 163 N, 190 N, and 213 N reported for running with an abrupt stop, falling into a chair, skipping rope, and hopping, respectively [7]. These values all exceeded the maximum cervical compressive forces documented in the current study. Additionally, the compressive forces measured in the current study were substantially below IARVs for six month old infants (890 N) through large adult males (4830 N) [5].

The findings from the current study are consistent with research involving cadaveric cervical spine specimens exposed to simulated moderate-to-severe rear-end collisions with and without head restraints [8]. These specimens experienced increased post-collision range-of-motion, but no intervertebral disc herniations. These data, combined wit the results from the current study, indicate that cervical intervertebral disc herniations are not related to rear end automobile collision events, and objective MRI findings following a rear-end collision are more likely associated with some other etiology.

A COUPLED REACTION-DIFFUSION-STRAIN MODEL FOR BONE GROWTH IN THE CRANIAL VAULT

Chanyoung Lee, Reuben H. Kraft

Department of Mechanical and Nuclear Engineering
The Pennsylvania State University
University Park, PA, USA

INTRODUCTION

Bones of the cranial vault are formed by intramembranous ossification due to direct differentiation of mesenchymal cells into osteoblasts. The process is controlled by a cascade of reactions between extracellular molecules and cells. One common approach for modeling the process is the application of a mathematical model for reaction-diffusion controlled by two interacting chemical molecules, first proposed by Alan Turing [1]. The Turing model, commonly referred to as the reaction-diffusion model, shows that through a regulatory loop of interacting molecules the concentration of the molecules forms an inhomogeneous spatial pattern in space. In our previous research [2] we have applied this approach to find locations of the primary centers of ossification in the mouse cranial vault and the pattern of cranial bone growth.

However, mechanical stimuli such as local stress and strain on each cell or organ are not taken account in the Turing's model and have been shown to give important influences on the bone formation by several groups [3, 4]. In this study, we propose an integrated mechanobiological model for the cranial vault bone formation by coupling the reaction-diffusion model for interacting molecules with the biomechanical input in the growing domain.

METHODS

We assume that the behavior of the molecules important to bone formation can be modeled using Turing's reaction-diffusion model which describes the pattern formation driven by two interacting molecules (activator and inhibitor). In addition to the reaction-diffusion model, we hypothesize that mechanical stimuli of the cells due to growth of the underlying brain contribute significantly to the process of cell differentiation in cranial vault development. Distribution of mechanical strain over the surface of the brain on which the ossification process occurs is affected by its geometry that changes over time as the developing brain grows. Material properties of the cells also change according to the stages of cell differentiation. To explore effects of mechanical strain on bone formation in the cranial vault, a structural analysis using the finite element method is conducted in the computational domain that grows with a constant speed which represents the surface of the brain. The strain field at the surface of the brain was estimated at each time step using estimates of the time-evolving material properties for undifferentiated mesenchymal cells and differentiated osteoblasts, whose distribution is predicted using a reaction-diffusion model. The strain field estimated by the structural analysis in turn affects the differentiation of cells again because it is coupled with the reaction-diffusion model.

The mathematical expressions for the coupled reaction-diffusion-strain model are as follows.

$$\frac{\partial a}{\partial t} = \frac{o_s^n}{o^n+o_s^n}\left(\sigma_a + \rho_a \frac{a^2}{h} + D_a\nabla^2 a\right) - \mu_a a + \sigma_o o \qquad (1)$$

$$\frac{\partial h}{\partial t} = \frac{o_s^n}{o^n+o_s^n}(\sigma_h + \rho_h a^2 + D_h\nabla^2 h) - \mu_h h \qquad (2)$$

$$\frac{\partial o}{\partial t} = \eta \frac{o_s^n}{o^n+o_s^n}\frac{a^n}{a^n+a_T^n}\frac{\varepsilon_l^n}{\varepsilon^n+\varepsilon_l^n} \qquad (3)$$

The term a, h and o represent the concentration of activator, inhibitor and differentiated osteoblasts, respectively. The production (σ_a and σ_h), reaction ($\rho_a \frac{a^2}{h}$ and $\rho_h a^2$) and diffusion ($D_a\nabla^2 a$ and $D_h\nabla^2 h$) and of activator and inhibitor are assumed to take place only in mesenchymal cells, not in differentiated osteoblasts and the term $\frac{o_s^n}{o^n+o_s^n}$

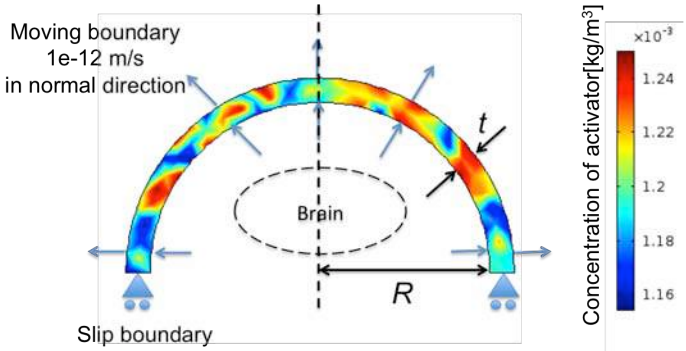

Figure 1: Geometry of the computational domain, initial condition for reaction-diffusion model and boundary condition for structural analysis. The initial activator is randomly distributed. Radius of the inner semicircle R = 7 mm and thickness of the domain t = 0.5 mm.

represents this. o_s represents saturation concentration of osteoblast that sets the upper limit of generation of osteoblast. The terms $\mu_a a$ and $\mu_h h$ quantify degradation of the molecules. The model for the rate of differentiation of mesenchymal cells to osteoblasts ($\frac{\partial o}{\partial t}$) is promoted by activator which has higher concentration than a threshold value (a_T) and is limited by the strain which has a higher magnitude than the limitation value (ε_l). The value n in the terms $\frac{o_s^n}{o^n+o_s^n}$, $\frac{a^n}{a^n+a_T^n}$ and $\frac{\varepsilon_l^n}{\varepsilon^n+\varepsilon_l^n}$ is a constant characterizing how sharply the terms increase or decrease according to the change in variables o, a and ε. Osteoblasts and activator are coupled in the way that osteoblasts enhances activator by the term $\sigma_o o$ and the activator in turn activates differentiation of cells near the osteoblasts, which models the growth of bone.

A commercial software COMSOL Multiphysics was used to solve these mathematical models and to conduct a structural analysis using the finite element method. The computational domain is constructed as a 2-dimensional shell-shaped semicircle (Figure 1), which represents a simplified shape of a cut plane of the space of mesenchymal cells surrounding a brain. To explore the effect of growth of the underlying brain, the inner and outer surface of the semicircle domain move with a constant speed in their normal direction. The bottom surface is free to move with the movement of inner and outer surface. Figure 1 also shows the initial distribution of activator which is random with small perturbation of concentration (±5%)

RESULTS

Figure 2 shows distributions of activator, osteoblast and hydrostatic strain over time. The black solid line represents the initial shape of the domain before it grows over time. Figure 2 (a) shows that distribution of activator, which is nearly homogeneous at initial time, then forms a spatial pattern over time. The distribution of osteoblast (Fig. 2 (b)) follows the distribution of activator as we hypothesize activator activates cell differentiation. Looking at the distribution of osteoblast from 12.5 days to 37.5 days, the region of osteoblast with high concentration expands from several distributed spots (which can be considered as primary centers of ossification) but the separate regions do not fuse with each other, leaving a space of undifferentiated mesenchymal cells between them. This is based on our hypothesis that high strain inhibits cell differentiation. Figure 2 (c) shows that hydrostatic strain increases faster at the region of mesenchymal cells which has a small Young's modulus than at the region of osteoblasts which has large Young's modulus.

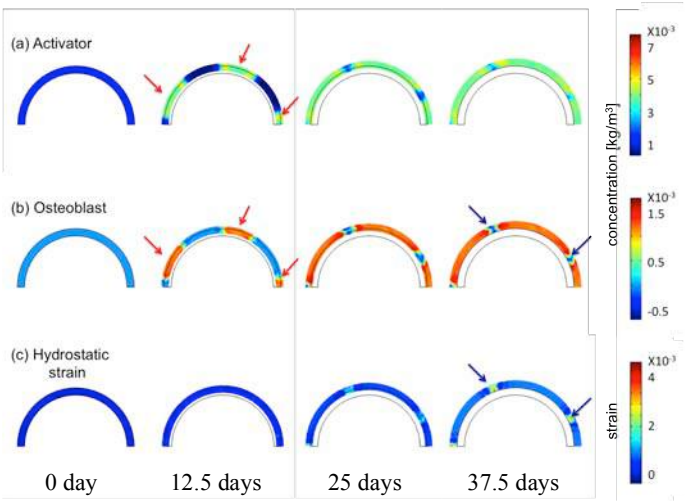

Figure 2: Computational results. Distributions of (a) Activator (b) Osteoblasts and (c) Hydrostatic strain over time. Primary centers of ossification appear according to the distribution of activator (red arrows). Regions of osteoblasts do not fuse leaving a space of undifferentiated mesenchymal cells where the strain rapidly increases (blue arrows)

DISCUSSION

The results show that our mechanobiological model predicts some key features of morphology of cranial vault bone including the emergence of a spatial pattern from nearly homogeneous initial condition, the growth of the pattern over time, and the remaining undifferentiated cell parts between the regions of differentiated osteoblasts, which can be observed as sutures between bones in the cranial vault. From the results, the effect of strain coming from growth of underlying brain can be proposed as one possible explanation of mechanism of suture formation.

Further study is being conducted to apply the coupled reaction-diffusion-strain model to a 3-dimensional domain obtained from real mouse head in experimental research and the model is expected to be more improved to explain the mechanism of bone growth in the cranial vault by comparing the computational results with the experimental data.

INTRODUCTION

Lower back pain (LBP) is a common medical condition that significantly affects the human population [1]. Back pain can be attributed to the degeneration of the intervertebral disc (IVD), a fibrocartilaginous tissue that allows for flexion, extension, lateral bending, torsion, and compression within the vertebral column [2]. Typically, a degenerative cascade begins when the central nucleus pulposus (NP), a soft gel-like tissue, dehydrates and loses its ability to maintain an osmotic swelling pressure [3]. The encompassing concentric rings of collagen, also known as the annulus fibrosus (AF), endure an increased loading and fibers begin to tear. Herniated NP tissue is able to migrate through the annular defect and impinges on adjacent nerve root endings, thus causing radiating discomfort. Discectomy is one of the current available treatments for repairing herniations, however IVD biomechanics become compromised and additional NP material may extrude [4].

Our research aims to replace the NP tissue with an injectable hydrogel during early onset stages of disc degeneration. A novel hydrogel composed of poly (N-isopropylacrylamide) grafted with chondroitin sulfate (PNIPAAm-g-CS) was synthesized and blended with alginate microparticles [5]. The thermally sensitive PNIPAAm forms a miscible solution with water below its lower critical solution temperature (LCST) at approximately 32°C. When heated above the LCST to 37°C, the polymer becomes hydrophobic, expels water from its matrix, and forms a compact gel embedded with localized microparticles. The objective of this study was to construct a confined compression apparatus and characterize the mechanical properties of an injectable, thermally sensitive hydrogel composite.

METHODS

The injectable hydrogel, PNIPAAm-g-CS was synthesized using free radical polymerization [5]. All hydrogel solutions were made by dissolving freeze-dried polymer powder in phosphate buffered saline (PBS) at a concentration of 5% (w/v). Alginate microparticles (≈20 or 100 μm) were crosslinked with calcium in a water in oil emulsion [6]. Freeze-dried microparticles were suspended in the hydrogel solution at a concentration of 25 or 50 mg/mL.

A piston-cylinder apparatus was designed to determine the confined compression properties of various hydrogel formulations, as this is akin to the native *in vivo* environment of NP tissue. The components of the confined compression apparatus were designed and assembled similar to research teams conducting related studies [7,8]. Force and displacement data were recorded using an Instron Model 4442 Universal Testing System and normalized by initial area and height to determine stress and strain. Approximately 300 – 350 μL of the hydrogel composite was injected into the inner cylinder. Distilled water was preheated to 55°C and poured into the water bath. Gel transition and temperature was confirmed and maintained at 37°C both visually and with a thermocouple probe. The piston was slowly lowered into the cylinder and compression tests were performed at a rate of 1 mm/min. Additionally, stress-relaxation tests were performed at 5, 10, 15, and 20% strain at a rate of 50 mm/min with a preload of 0.1% strain. Samples were allowed to relax for 10 minutes in between each strain increment. An average Young's modulus was calculated from 0 to 20% strain for each compression test. Characteristics from the biphasic model such as compressive modulus and hydraulic permeability will be determined from stress-relaxation data.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

A confined compression apparatus, seen in Figure 1, was constructed to test the confined mechanical properties of hydrogel hydrogel formulations. A water bath was used to maintain the composite's temperature throughout testing. A thermocouple wire was secured to the bottom of the cylinder containing the composite in order to constantly monitor the temperature. An outer confining cylinder was created using RTV 630 silicone rubber to mimic the material properties of the AF. The piston is coated in Teflon to maintain a low coefficient of friction and tight tolerances along the cylinder wall. A cylindrical filter of sintered metal (Mott U-PXX-002-A-10 0.2 micron pore size) is attached to the bottom of the piston and allows trapped air to escape from the compression chamber.

Compression tests, illustrated in Figure 2, revealed differences in mechanical stress profiles between PNIPAAm-g-CS and PNIPAAm-g-CS with 50 mg/mL of microparticles (≈20 µm). The average Young's modulus for PNIPAAm-g-CS (n=5) and PNIPAAm-g-CS with microparticles (n=3) was 0.607 ± 0.154 MPa and 1.2732 ± 0.092 MPa, respectively. Figure 3 shows preliminary stress-relaxation data for PNIPAAm-g-CS for each incremental strain value.

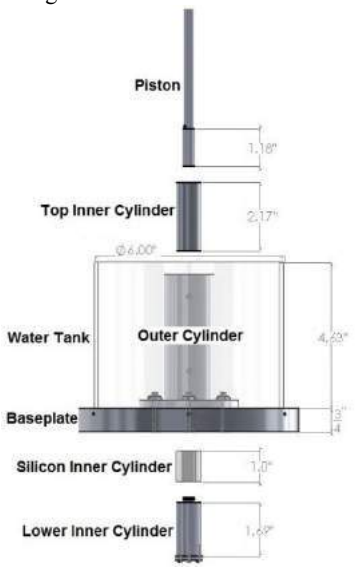

Figure 1: Exploded drawing of the confined compression apparatus.

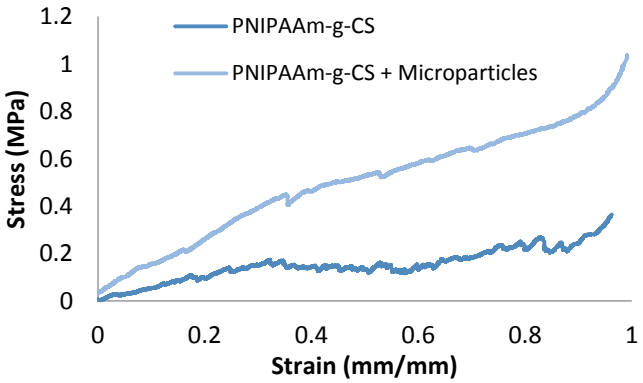

Figure 2: Stress versus strain plot of PNIPAAm-g-CS and PNIPAAm-g-CS with 50 mg/mL of alginate microparticles (≈20 µm) undergoing confined compression.

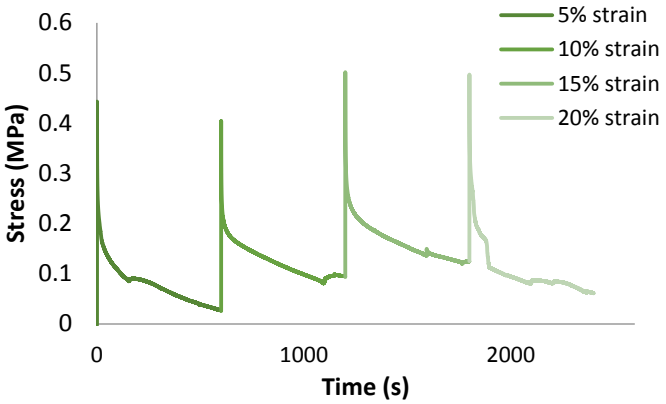

Figure 3: Stress-relaxation plot for PNIPAAm-g-CS at 5, 10, 15, and 20% strain intervals.

DISCUSSION

A thermally sensitive hydrogel composite was formulated for the repair of the NP in the IVD. In our current work, we have built an apparatus to specifically test the confined mechanical characteristics of the composite, while tailoring to its temperature-sensitive property. Confined compression tests revealed a two-fold increase in stiffness for PNIPAAm-g-CS with 50 mg/mL of microparticles compared to PNIPAAm-g-CS alone, yet statistical significance was not confirmed. Alternative microparticle sizes and concentrations will also be explored. Stress-relaxation tests revealed potential gel instability and fracture at 20% strain, while PNIPAAm-g-CS with 50 mg/mL of microparticles withstood higher strains and correspondingly higher stress values. Relaxation time will also be increased beyond 10 minutes. To reiterate, compressive modulus and hydraulic permeability will be determined from stress-relaxation tests using non-linear biphasic modeling. Results will also be compared to the confined compression behavior of native NP tissue extracted from porcine IVDs.

How Sensitive Are Hemodynamics in Intracranial Aneurysms to Different Blood Flow Waveforms?

INTRODUCTION

Intra-aneurysm (IA) hemodynamics has been thought to play a key role in aneurysm pathology [1]. Due to the highly limiting difficulties in obtaining hemodynamics in vivo, computational fluid dynamic (CFD) tools have been extensively used to approximate hemodynamics in IAs [2]. It is necessary to prescribe the time-varying waveform of the blood on one or more boundaries of the computational domain used for such studies. This information, however, is often not patient specific and may not be known at or near the boundary of the computational domain [3]. It is thus important to assess the degree of sensitivity of the intra-aneurysmal hemodynamics to the choice of physiological waveform used as boundary conditions. Holdsworth et al. [4] have shown that waveforms from internal carotid arteries of young healthy subjects possess a marked degree of universality. However, this category of individuals is much less likely to possess aneurysms than older patients who have one or more cardiovascular conditions/diseases (e.g. hypertension, coronary artery disease, mitral valve regurgitation)[5],[6],[7]. Therefore, in this work we consider waveforms from 137 older patients with a history of cardiovascular disorders and ages ranging from 19 to 94 (mean age 73 ± 13 years). We first categorized the variability in waveform across this population and then conducted CFD studies to assess the impact of this variability on IA hemodynamics in a representative basilar aneurysm.

METHODS

The left and right internal carotid artery Doppler ultrasounds from 137 elderly patients being treated for cardiovascular disease were analyzed using a custom written MATLAB [Mathworks] script to extract the waveform shape and characteristic metrics. Based on these metrics, waveforms were placed into one of four categories: 1. High resistance, short systolic duration; 2. High resistance, long systolic duration; 3. Low resistance, short systolic duration; 4 High resistance, long systolic duration using a user independent process. Three representative waveforms for each category were chosen for CFD study of the sensitivity of wall shear stress metrics (WSSM) to waveform choice in a basilar bifurcation aneurysm, chosen from our library. In order to distinguish the effects of waveform shape from flow rate, the CFD model for each case was first run with a standardized flow rate (1.81 cm^3/s) and period (1s) based on data reported in [8] and then run with the patient specific flow rate and period. As no corresponding patient specific geometry was available with the waveforms, the flow rates for each patient specific waveform were scaled by a ratio of flow rates reported for basilar and carotid arteries. Blood was modeled as a Newtonian incompressible fluid with a viscosity of 0.0035 Pa·s and having zero velocity at the rigid walls. A time-varying Womersley profile was prescribed at the parent vessel inlet and zero-traction boundary conditions were imposed at the vessel outlets. The model was solved using a custom developed solver [9]. The output metrics considered here are: maximum wall shear stress magnitude (MWSSM), maximum time averaged wall shear stress magnitude (MTAWSSM), and time and space averaged wall shear stress magnitude (TSAWSSM). Collectively, the wall shear stress metrics are denoted as WSSM. For comparison, a similar study was run using the archetypal waveform from Holdsworth.

RESULTS

Representative waveforms for each of the four automatically identified categories are shown in Figure 1. Figure 2 shows the variation in the WSSM arising strictly from variation in shape among 12 waveforms (displayed by waveform group). The variations for the time averaged quantities (TSAWSSM, MTAWSSM) are less than for

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the maximum wall shear stress (MWSSM). A one-way ANOVA analysis at the 95% confidence level concludes the group means are statistically different for every metric of WSS ($p_{max} = 0.0350$).

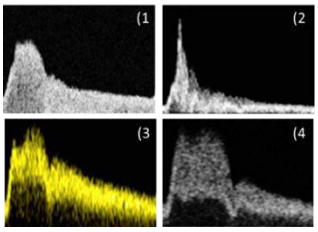

Figure 1: Representative waveform data for each of the four groups: 1) Low Resistance, Short Systole; 2) High Resistance, Short Systole; 3) Low Resistance, Long Systole, 4) High Resistance, Long Systole.

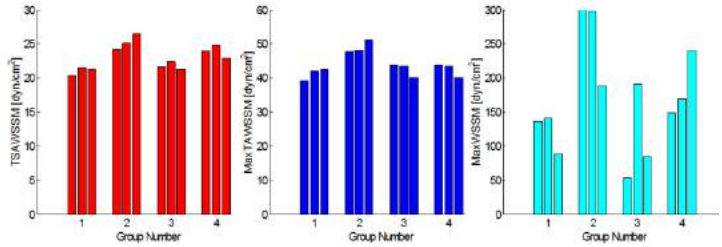

Figure 2: Variation in wall shear stress metrics due solely to waveform shape. Four waveforms considered are grouped by flow group. Q = 1.81 cm^3/s for all cases.

Figure 3 compares the percent differences in WSSM between each patient specific waveform and the reported Holdsworth waveform. One- way ANOVA analysis at the 95% confidence level concludes only the MWSSM group means are statistically different. Shifting focus towards global qualitative characteristics, Figure 4 shows MWSSM contours of the aneurysm lumen for one representative case of each of the four waveform groups having identical flow rates. Despite the significant differences in magnitude among these studies (as seen in difference in contour scales), the qualitative distribution of WSS is quite similar, consistently preserving notable features such as the location, size and shape of the high WSS region (red/pink contour region) in the dome where inflow jet impingement is found.

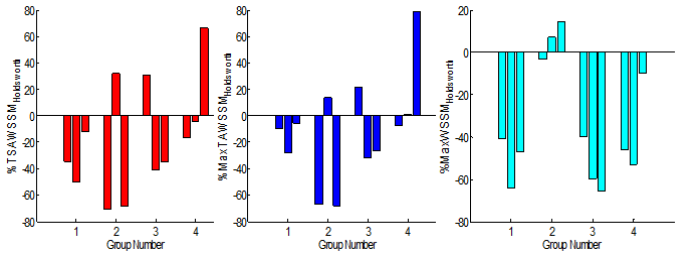

Figure 3. Percent difference in WSSM from patient data and an archetypal waveform.

DISCUSSION

This study sheds insight on the importance of choice of waveforms used as boundary conditions in CFD models of cerebral aneurysms, considering a more clinically relevant older population. It first explores the variation in WSS magnitudes due strictly to choice of waveform shape (identical parent artery flow rates). By selecting an "archetypal" waveform, one inherently assumes these differences to be negligible. In this study, we found that for TSAWSSM (the least sensitive of the three), the range of WSS deviation is 26% of the group average; while the MWSSM range is more than 100% of the average, Table 1. This suggests that obtaining accurate MWSSM without patient specific waveforms could subject the results to significant error, while a much smaller error can be expected if TSAWSSM is of interest.

Table 1. Results for wall shear stress metrics for the 12 waveforms, with Q = 1.81 cm^3/s. Quantities labeled with a (*) are normalized by the average for the column.

[dyn/cm^2]	*TSAWSSM*	*MaxTAWSSM*	*MaxWSSM*
Average	22.98	43.77	169.78
StDev	1.95	4.08	77.40
Range	6.08	12.48	246.50
*StDev**	0.08	0.09	0.46
*Range**	0.26	0.29	1.45

Secondly, the study provides insight on the error produced from assuming the Holdsworth waveform to be a substitute choice for a patient specific waveform and flow rate. The normalized range in WSS variation is in excess of 100% of the average for all measures of wall shear stress used here. This data strongly suggests the need for patient specific flow information for predicting WSS magnitudes. Figure 4 suggests a much more positive message: despite the significant differences in WSS magnitudes, the qualitative features of even the most sensitive WSS metric (MWSSM), are remarkably robust to choice of waveform.

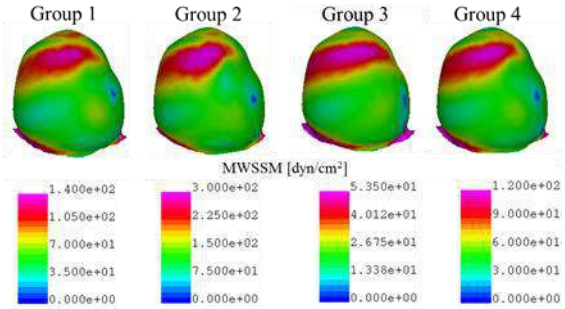

Figure 4. MWSSM contour for a representative case from each waveform group, Q = 1.81 cm^3/s .

Our findings therefore suggest that while quantitative values of WSSM for a particular location in an aneurysm may not be accurately represented without patient specific flow information, patient specific flow rates and waveforms are not a stringent requirement for determining the qualitative WSSM distribution, nor for relative magnitudes within a single aneurysm.

QUANTIFICATION AND COMPARISON OF MECHANICAL PROPERTIES OF THE URINARY BLADDER WALL

A. Massafra (1) and S. Roccabianca (1)

(1) Mechanical Engineering Department
Michigan State University
East Lansing, Michigan, U.S.A.

INTRODUCTION

The urinary bladder (UB) is a musculomembranous hollow organ whose main function is to store and periodically void urine in a controlled manner; this is achieved through a regulated cycle of mechanical relaxation and contraction. Alterations to this cycle or obstruction of the urethral outlet can give rise to a number of storage or voiding disorders including underactive and overactive bladder syndromes. Four layers can be identified within the urinary bladder wall (UBW), as shown in Fig.1. From the innermost to the outermost, (1) the mucosa consists of a thin layer of epithelial cells; (2) the submucosa, composed of a matrix of collagen and elastin fibers, endows compliance and strength to the wall; (3) the detrusor, composed of smooth muscle cells (SMC), represents the contractile part; and (4) the adventitia, containing mainly collagen fibers, works as a protective sheet.

Despite the effect that mechanical behaviors have on the physiology of all soft biological tissues, included the UB, the number of models that can be found in literature to describe these behaviors is slim. However, a considerable amount of literature has been devoted in the last decade on developing bio-chemo-mechanical models in the cardiovascular field. The authors see the opportunity of building on these previous works to develop a model of the UB that can describe the interaction between mechanical behavior and biological function. Moreover, a mechanobiological model will also serve as important step towards the development of a growth and remodeling model of the UB.

METHODS

Motivated by the work done in [1], we present a consistent quantification and comparison of uniaxial mechanical properties of the UBW based on five data sets available in the literature and two experimental data sets collected in our laboratory.

Mechanical testing. Two intact pig bladders were collected from the Meat Lab of Michigan State University, then cleaned for luminal contents and adjacent tissues. For the purpose of the biomechanical characterization, samples were harvested along the apex-to-base axis from the lateral region of UB. The samples measured approximately $37.6mm \times 14.3mm$ on average with the longest dimension aligned with the apex-to-base direction. Following isolation, specimens were stored at 4C in Hank's Balances Salt Solution (HBSS). Samples were then subjected to a uniaxial tensile test along the apex-to-base direction. The tissue was first preconditioned for 8 cycles at a displacement rate of 0.3 mm/s reaching a maximum stretch ratio of $\lambda_{precond.} = 1.6$. The stretch ratio has been evaluated as $\lambda = \ell/L$, where ℓ represents the deformed length of the sample throughout the test, and L the length for an unloaded configuration recorded before the test. After preconditioning, a sample-specific stretch ratio λ_{test} was estimated to ensure a maximum stress of at least ~120 kPa. Finally, the tensile test consisted of 5 loading cycles performed at a displacement rate of 0.15 mm/s reaching a stretch of λ_{test}. Figure 2 shows the experimental values of Cauchy stress and stretch, referenced to a 5g preloaded configuration recorded after the test (curves labeled S 1.5 and S 2.1).

Constitutive description. The UBW shows a nonlinear mechanical behavior when subjected to large deformations; hence, one must consider an appropriate theoretical framework. The model proposed here builds on the work conducted during the past decade from Humphrey and his coworkers, namely the constrained mixture approach to model the mechanical behavior of soft biological tissues [2]. Specifically, we endowed the amorphous matrix, dominated by randomly distributed elastin fibers, with a neo-Hookean strain energy function (SEF), and we described the behavior of the two families of locally parallel collagen fibers employing a Fung-type exponential. The two-fiber family constitutive model constitutive model is described in terms of a SEF, W, of the form

$$W = \frac{c}{2}(I_C - 3) + \sum_{k=1}^{2} \frac{c_1}{4c_2}(exp[c_2((\lambda^k)^2 - 1)^2] - 1)\,, \qquad (1)$$

where c, c_1, c_2 are material parameters, the first two with the dimension of a stress and the third dimensionless; I_C is the first invariant of the right Cauchy–Green tensor $\boldsymbol{C}$ (i.e., $I_C = tr\boldsymbol{C}$); and λ^k is the stretch experienced by the k^{th} fiber family oriented in direction $\boldsymbol{M}^k = \left[0, sin\ \alpha_0^k, \cos \alpha_0^k\right]$ in an appropriate reference configuration. We let $\alpha_0^1 = 0^\circ$ (apex-to-base family) and $\alpha_0^2 = 90^\circ$(circumferential family).

Simulated uniaxial data. Several experimental data sets describing the mechanical behavior of the UB can be found in literature; most of them, however, have been collected using different types of tests (e.g., uniaxial, equibiaxial, pressure-volume) as well as donors from different species (e.g., human, pig, cat). In order to compare results presented in different studies, we re-created consistent sets of uniaxial data based on nonlinear constitutive relations reported with associated best-fit values of the material parameters found in literature [1]. Specifically all data sets resulted from the same simulated uniaxial loading protocol: stress-controlled tests in the axial direction (i.e., apex-to-base direction) with maximum values of stress of 140 kPa. Assuming the material to be incompressible, the Cauchy stress can be evaluated as $\boldsymbol{t} = -p\boldsymbol{I} + 2\boldsymbol{F}(\frac{\partial W}{\partial \boldsymbol{C}})\boldsymbol{F}^T$, where the Lagrange multiplier p comes from enforcing incompressibility (i.e., $\det \boldsymbol{F} = 1$), $\boldsymbol{C} = \boldsymbol{F}^T\boldsymbol{F}$. We then used nonlinear regression to determine best-fit values of the three model parameters. In this way, we used a consistent means to compare results regardless of the original testing protocols or constitutive relations.

RESULTS

The experimental data of the uniaxial loading tests conducted on the two specimens from different pig bladders are reported in Fig. 2 (square symbols). It is remarkable that they confirm the nonlinear mechanical behavior of the UBW. The difference between the two curves associated with the two samples could be explained by the different percentage of constituents and storage conditions of the two UBW tested. Specifically, prior to testing, one of the bladder was stored in HBSS (i.e., S 1.5), while the other one in the absence of HBSS (i.e., S 2.1). Fig. 2 compares also axial Cauchy stress-stretch responses in uniaxial stress protocol of the five data sets available from the literature. Additionally, the experimental data obtained in our laboratory and the data obtained from the literature are in good agreement. This confirm that we established a reliable uniaxial tensile test protocol to characterize the biomechanical properties of the bladder tissue and guarantee good test repeatability. Table 1 reports best-fit values of the three parameters of our model for each dataset. The goodness of fit is also reported in Table 1 in terms of the percentages of root mean square errors between the experimental data and the associated best-fit.

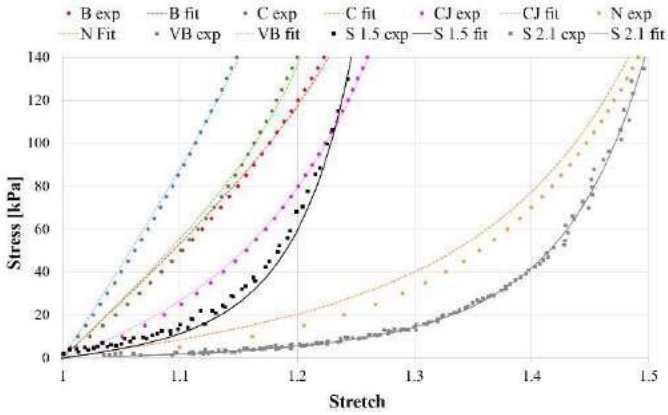

Figure 2. Uniaxial Cauchy stress-stretch data (i.e., apex-to-base direction) recreated from five works available in literature (circles), experimental data from two samples tested in our laboratory (squares), and the associated model prediction (dashed and solid lines). *Data from literature, followed by donor species*: (B) Boubaker et al., human [4]; (C) Chen et al., human [5]; (C-J) Colding-Jorgense et al., human [6]; (N) Natali et al. pig [7]; (VB) Van Beek, cat [8]. *Data from experiments* - Sample 1.5: pig, bladder stored in HBSS prior sample isolation; Sample 2.1: pig bladder stored in absence of HBSS prior sample isolation.

Table 1: Best-fit values of model parameters and root mean square errors (*RMSE %*) for the five datasets available in literature and for the two data sets collected in our laboratory.

Sample 2.1	8.18E-14	6.56	1.33	0.05

DISCUSSION

This work represents the first attempt to collect and then compare diverse results from the literature on the passive uniaxial nonlinear mechanical behavior of the UBW. This work represents the first step toward the development of a growth and remodeling model that will have the capability of describing the changes in the mechanical property of the UBW resulting from changes in the urodynamics.

INTRODUCTION

Mechanical properties of cells and tissues often correlate to physiological and pathological parameters [1]. Fibrosis, for example, has been correlated to an elevated elastic modulus [2] and changes in pathological conditions can be quantified by measuring mechanical properties such as tissue porosity [3], density [4], and elastic modulus [5] in diseased and recovering patients.

Characterization techniques for simple physical parameters such as mass, fluid pressure, and porosity are well developed and are easily and correctly carried out by biologists, physicians, and engineers alike. Quantifying elastic modulus to find a correlation to clinical parameters, and thus evaluate pathologies and therapeutic effects, is slightly more complex.

While many engineering materials such as metals and ceramics can be considered purely elastic, hydrated polymers and biological tissues have entangled polymer chains and high water content. Thus, simple stress-strain models of elastic behavior are not adequate to describe their mechanical behavior.. Furthermore, specifically for tissue, it is important to recognize its micro-structural complexity and likely heterogeneity.

Motivated by dramatic disagreement in the literature for the elastic moduli of heart tissue in rodents, spanning four orders of magnitude, and our success in obtaining consistent values for a wide variety of human subjects and animal pathologies [5], we present a simple and reproducible viscoelastic characterization technique for tissue and other soft matter. Additionally, we demonstrate the importance of incorporating viscous effects through the characterization of viscoelastic properties in pancreatitis and pancreatic cancer patients.

METHODS

Force-displacement quantification with custom indenter. We modified a tool designed to measure friction forces to create a custom Multi-Scale Indenter (MSI, Figure 1) [5]. The cantilever-based probe is displaced vertically using a software-controlled piezoelectric stage. The probe is brought into contact with the tissue sample following a time-dependent displacement profile set by the user in custom LabVIEW code. The reacting normal force of the tissue bends the titanium cantilever, and the relative displacement of the cantilever tip is measured by capacitive probe. The stiffness of the cantilever, calibrated by contact with glass, is utilized by the LabVIEW code to determine the normal load throughout the indentation cycle.

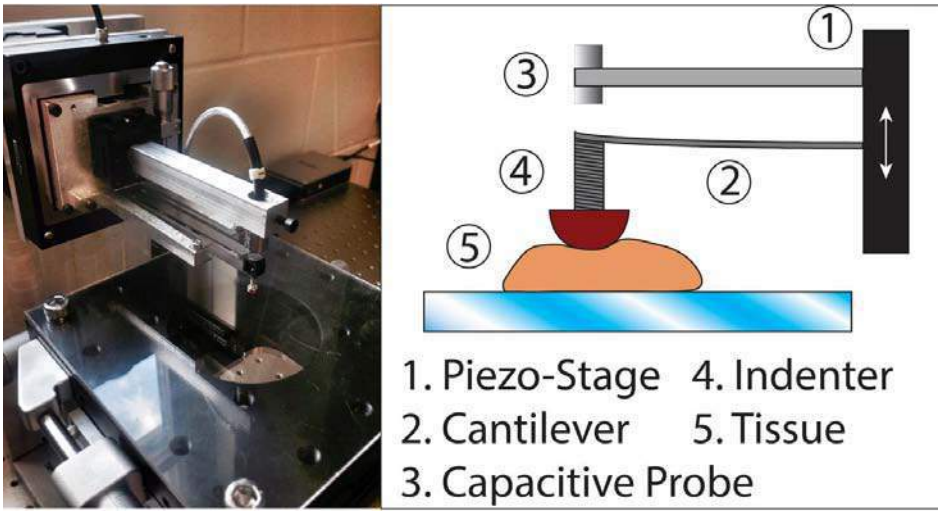

FIGURE 1. MULTISCALE INDENTER (MSI) CHARACTERIZATION TOOL
A rigid probe (4) indents tissue located on top of a glass slide (5). The probe is mounted directly to a cantilevered flexure (2), and capacitance probes (3) measure the displacement of a target (1) mounted on the calibrated flexure, yielding forces.

Tissue Isolation and Characterization. Small samples of pancreas were surgically excised from patients with suspected pancreatitis or pancreatic cancer. The size of the obtained sample for characterization purposes varied based on the size of the tumor and/or extracted fragment of the pancreas. Samples were kept in DMEM-F12 media to maintain hydration and preserve cell and tissue conditions, and indentations were carried out no more than 2 hours after surgery (even though characterization results were found not to vary from one day to the next). Between 7 and 11 indentations were carried out in each sample without indenting the same location twice. The number of indentations was restricted by the size of the tissue fragment; larger tissue samples have a larger area available for indentation. For statistical reliability, the average of the indentation results for a particular sample corresponds with the reported sample properties. Results from pathological analysis of the sample were released 2-3 days after indentation for a semi-blinded study.

Characterization Models. Force-displacement data from the original indentation is converted into Elastic Modulus as a function of time using the Hertz-JKR contact model for flat circular surfaces:

$$E(t) = \frac{F(t)\cdot(1-\nu^2)}{2\cdot R\cdot\delta(t)} \quad (1)$$

where E = elastic modulus, F = force calculated by MSI through LabVIEW, ν = Poisson's Ratio, R = flat punch radius, and δ = indentation depth.

The standard linear solid (SLS) is a common viscoelastic mechanical network model, composed of representative springs (linear elasticity) and a dashpot (viscosity). This simple combination of linear elastic and viscous components has a straightforward physical interpretation, making this model particularly useful for interdisciplinary investigations with collaborators from broad backgrounds. The strain rate-dependent and "liquid-like" properties of the material are represented by viscosity, η, while $E_{ss} + E_a$ is the effective modulus of the tissue during initial compression. As the dashpot η relaxes, E_a trends to zero and E_{ss} can be interpreted as the steady-state or equilibrium modulus.

To determine these parameters, we fit the relaxation portion of the calculated $E(t)$ versus time plot to the following equation[23]:

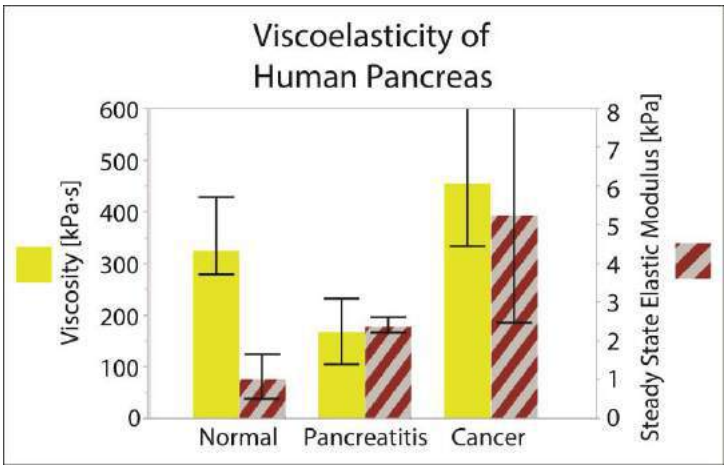

FIGURE 2. VISCOCITY AND ELASTIC MODULUS RESULTS. Strain-rate independent Steady-State Elastic Modulus is reported, as well as the viscosity of the three groups of pancreatic tissue. The bars represent the average of the properties, and the error bars show the range of the results.

$$E_t(t) = E_{ss} + E_a \cdot e^{-t/\tau} \quad (2)$$

where E_t = total effective elastic modulus as a function of time, E_{ss} = steady state elastic modulus after complete relaxation, E_a = apparent strain-rate-dependent contribution to initial elastic modulus, and $\tau = \eta/E_a$ with η = viscosity. Fitting data to the relaxation portion of the curve makes the data less dependent on the depth of the original indentation and rate of indentation compared to other common viscoelastic models and fitting strategies.

RESULTS AND DISCUSSION

Pancreas viscoelasticity shows the importance of considering the viscous nature of biological tissue when quantifying its mechanical properties. By reporting the steady-state elastic modulus, we are eliminating the fraction of the elastic modulus that is test-parameter dependent, which other studies commonly and misguidedly include in their reports. Despite this very important distinction between total and steady-state elastic modulus, the range overlap of steady-state modulus [Figure 2] shows that pancreas from a pancreatitis patient and one with pancreatic cancer could share the same modulus values. However, because the viscosity of pancreatitis is even lower than normal pancreas and their individual values do not overlap, both elastic modulus and viscosity would be an ideal way to differentiate chronic inflammation from malignant tumors.

Since autoimmune pancreatitis is occasionally misdiagnosed as pancreatic cancer and vice versa [6,7], techniques to distinguish the two pathologies are being investigated. Based on our analysis, mechanical approaches could be valuable. While indentation experiments would require access to the tissue through surgery, nonintrusive alternatives such as Magnetic Resonance Elastography and Shear Wave Sound Velocity could estimate viscoelastic properties of tissue with minimal invasion of the patient.

By characterizing viscoelasticity in human pancreas, we demonstrate that the viscous component imparts essential information to evaluate and differentiate tissue condition and disease state. This easily reproducible characterization method can be helpful in a wide variety of applications, from diagnosis to evaluation of treatments in medical studies, as well as finding clearer differences between sample groups.

INTRODUCTION

The cornea is a highly organized transparent tissue whose shape and biomechanical properties are important for visual acuity [1]. When this tissue is altered or disrupted during disease processes such as keratoconus or from surgical procedures that remove part of the cornea, the cornea's structure and function can change significantly [2].

Although recently developed optical techniques can adequately measure structural details of the cornea, characterization of corneal biomechanical properties remains challenging. Current techniques such as inflation testing [3], strip extensometry [4, 5] and shear wave testing [6] are limited to 1D or 2D visualizations, and the interactions in and out of the corneal plane (the full 3D response) remain largely unknown.

Our laboratory has developed and validated a high-resolution ultrasound speckle tracking method for non-invasive 3D mapping of tissue strains [7, 8]. Using this technique, we investigated the deformation of a volume of the cornea near the apex during inflation for both swelling-controlled and active swelling cases. The objective of this study was to map the 3D strains within the intact cornea during physiological processes including IOP increase and active swelling to better characterize the biomechanical responses of this tissue.

METHODS

Porcine globes were divided into two groups and tested within 72 hours post-mortem. For the swelling-controlled group (n=9), whole globes were first immersed in a 10% dextran solution for 1 hour to reduce corneal swelling [9]. The anterior chamber of the globe was infused with Optisol GS (Bausch and Lomb) via a column to control the intraocular pressure (IOP) and minimize swelling. For the active swelling group (n=8), the globes were not pre-treated with dextran and were infused with 0.9% saline instead of Optisol.

For both groups, the globes were immersed in 0.9% saline with the cornea facing upwards during inflation. The globes were preconditioned with 25 pressure cycles from 10 to 12 mmHg, then equilibrated at a starting pressure of 10 mmHg for 1 hour. Inflation tests were performed with 0.5 mmHg (active swelling) or 1 mmHg (swelling-controlled) steps to ensure proper tracking. After a 15 minute equilibration time at each pressure step, a 55 MHz ultrasound probe (Vevo 660, VisualSonics Inc.) was used to acquire consecutive 2D frames of radiofrequency data (Fig. 1a). The 2D images were acquired in the nasal-temporal direction and the probe was translated at 14 μm steps in the superior-inferior direction over a 2 mm distance to form a 3D volume centered on the corneal apex. (Fig. 1b).

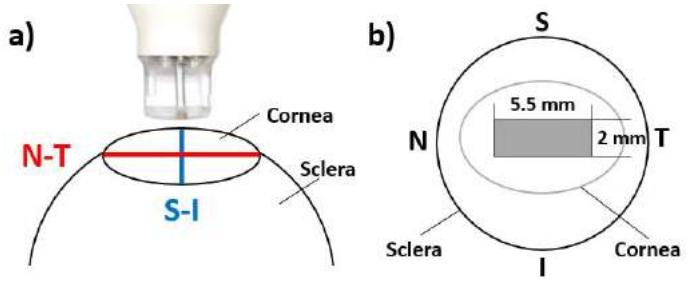

Figure 1: Schematic of a) ultrasound scanning orientations and b) scanning regions (N: nasal, T: temporal, S: superior, I: inferior).

The 3D principal strains (ε_1, ε_2, ε_3), max shear, and volume ratio at each inflation step were calculated using a correlation-based speckle tracking algorithm [7]. Correlation coefficients between pressure steps were evaluated to ensure proper tracking. Two swelling-controlled eyes

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

were excluded from the final data set due to unsatisfactory tracking (correlation coefficients < 0.6 through majority of volume). Volumetric strain maps and vector plots were visualized in Paraview (Kitware Inc.).

RESULTS

The average 3D principal strains, max shear, and volume ratio for both groups are presented in Table 1. In swelling-controlled cases, the average 3rd principal ε_3 was negative and largest in magnitude, with the average 1st principal ε_1 positive and slightly smaller than ε_3 and the 2nd principal ε_2 very small. In the active swelling group, the average 1st principal ε_1 was positive and largest in magnitude, with a small 2nd principal ε_2 and a negative 3rd principal ε_3. Substantial shear strains were observed in both groups, with the active swelling group having a larger maximum shear than the swelling-controlled group (p=0.001 at 12 mmHg). The volume ratio in the swelling-controlled group was slightly less than 1, while the active swelling group had a volume ratio slightly greater than 1.

Table 1: Average principal strains, max shear, and volume ratios in porcine corneas during inflation with or without active swelling.

Swelling-Controlled (n=7)

IOP (mmHg)	ε_1	ε_2	ε_3	Max Shear	Volume Ratio
11	1.30 ± 0.61%	0.13 ± 0.52%	-2.06 ± 0.71%	1.69 ± 0.47%	0.993 ± 0.014
12	2.35 ± 1.05%	0.24 ± 0.85%	-3.65 ± 1.27%	2.91 ± 0.78%	0.987 ± 0.021

Active Swelling (n=8)

IOP (mmHg)	ε_1	ε_2	ε_3	Max Shear	Volume Ratio
11	3.79 ± 1.20%	0.28 ± 0.60%	-1.30 ± 0.78%	2.48 ± 0.85%	1.026 ± 0.016
12	7.86 ± 2.05%	0.46 ± 0.95%	-2.42 ± 1.39%	4.90 ± 1.67%	1.054 ± 0.027

3D principal strain maps and vector plots are shown in Figure 2. For swelling-controlled corneas, the negative ε_3 was primarily in the through-thickness direction (Fig. 2 c, f), while the positive ε_1 was primarily in-plane (Fig. 2 a, d). In active swelling corneas, the positive ε_1 was primarily in the through-thickness direction (Fig. 2 g, j), showing a larger magnitude in the posterior cornea (Fig. 2 j), while the negative ε_3 was primarily in-plane (Fig. 2 i, l). In both groups, ε_2 was much smaller than the other two principles and did not show a preferred orientation (Fig. 2 b, e, h, k).

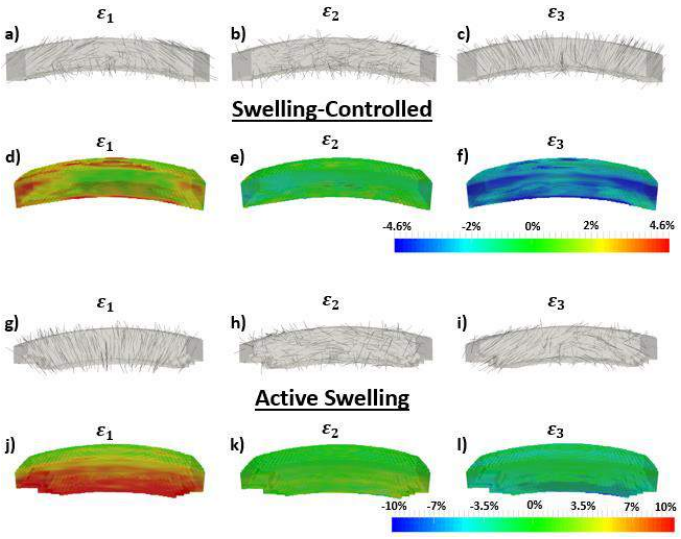

Figure 2: Vector plots and principal strains for swelling-controlled (a-f) and active swelling (g-l) corneas at 12 mmHg.

DISCUSSION

Our study showed that with proper adjustment of data acquisition and analysis, the high-frequency ultrasound method was sufficiently sensitive to successfully track corneal speckles, although they are weaker than speckles from other tissue. The 3D strain data showed that in swelling-controlled eyes, the corneal inflation response was primarily through-thickness compression and in-plane stretch, as expected for a spherical thin shell. The in-plain strains (ε_1 and ε_2) at each measured grid point showed markedly different magnitudes between the two orthogonal directions although there was no perceivable large-scale anisotropy based on the almost random orientation of the vectors (Fig. 2 a, b). A volume ratio slightly less than 1 suggests a small overall volume loss during inflation, confirming that swelling during experimentation was minimized in this group.

The active swelling group of eyes, although inflated at the same pressure levels as the swelling-controlled group, showed a positive strain in the through-thickness direction (Fig. 2 g, j) and a volume ratio slightly greater than 1, which corresponds to an increased thickness consistent with swelling. This swelling response seemed predominant even though the cornea was simultaneously inflated by a small pressure increase. The 3D data showed an anterior-posterior gradient of the through-thickness strains with greater strains in the posterior cornea (Fig. 2 j), consistent with greater swelling reported in the posterior stroma of swollen corneas [10].

The 3D method also allowed quantification of the shear strains, showing substantial shear during corneal deformation induced by inflation or swelling. The pathophysiological relevance of corneal shear is not well understood because this has been difficult to measure, especially in the intact cornea. Three-dimensional ultrasound speckle tracking, among other imaging techniques, provides a tool to fully characterize the biomechanical responses of this unique, highly organized tissue as it deforms under physiological loadings.

One limitation of the current study is that only a small volume of the central cornea was measured, preventing analysis of regional variances. Future work will expand imaging to other regions of the cornea to acquire a complete volume. In addition, we will perform quantitative comparison of the anterior and posterior responses.

In summary, this study showed the feasibility of using ultrasound speckle tracking for 3D mapping of corneal deformation. Our results showed distinct biomechanical responses in swelling-controlled and actively swelling corneas during IOP increase. Three-dimensional characterization of corneal biomechanical responses may help better identify the biomechanical factors involved in corneal pathophysiology and surgical outcomes.

INTRODUCTION

Each year in the U.S., over 400,000 patients with coronary artery disease undergo bypass grafting [1]. Despite 50 years of surgical advances, approximately 6% of coronary artery bypass grafts (CABGs) fail in the first year at a rate that is strongly dependent upon the source tissue [2]. The ability of a vascular graft to adapt is dependent, in part, upon the degree of mechanical deviation and the capacity of resident vascular cells to enact remodeling processes.

Healthy, mature blood vessels maintain a state of homeostasis whereby stresses are uniformly distributed across the vessel wall and most vascular cells exhibit a quiescent phenotype [3]. Acute changes to a vessel's environment cause contraction or dilation by smooth muscle cells (SMCs) to redistribute mechanical loads. When altered loads persist for days, weeks, and months, quiescent vascular cells shift to metabolically active phenotypes, inducing a number of vascular remodeling pathways: SMC proliferation and migration, extracellular matrix (ECM) protein deposition, and ECM reorganization. Over days, weeks, and months, these pathways give rise to changes in vessel wall thickness, lumen diameter, and vessel composition. Remodeling is not exclusively an SMC dependent process; other mechanocytes including endothelial cells (EC) and fibroblasts (FB) play a major role in restoration of tissue homeostasis.

Intuitively, the vascular remodeling processes described above are imperative to the fate of CABGs, as mechanical deviations between *in situ* and grafted environments provide chronic stimuli that cause vascular remodeling. In most graft vessels, this remodeling is a healthy compensatory process; however, in some graft vessels failures are due to etiologies resulting from maladaptive remodeling. The most common of these etiologies is lumen narrowing (i.e. restenosis) in the form of intimal hyperplasia, whereby smooth muscle cells proliferate in the lumen of the graft vessel, forming a new tissue layer.

Previous studies of clinical outcomes have identified correlations between intimal hyperplasia and patient-specific factors [4]. Furthermore, some of the molecular pathways involved with maladaptive remodeling have been identified [5]. However, at present there is an insufficient understanding of the complex relationship between mechanical loads, cellular mechanisms, and the fate of tissue remodeling as it relates to CABG and other grafting procedures.

Our objectives are to (i) report the mechanical deviation between *in situ* and grafted environments for common CABG tissue and the left anterior descending coronary artery (LAD) [6], and (ii) quantify and compare the capacity of vascular cells from different CABG source tissues for coronary adaptation.

METHODS

Porcine vascular tissue and cells were tested in lieu of human tissue, as it is a readily accessible analog to human vascular tissue. Tissues of interest were the left anterior descending coronary artery (LAD), internal thoracic (or, mammary) artery (ITA), radial artery (RA), great saphenous vein (GSV), and lateral saphenous vein (LSV).

For objective (i) data collection followed a well-established protocol for fitting geometry, histology, and biaxial mechanical testing data to a structure-based constitutive model [7-9]:

$$W = \phi_e c\left[\left(\lambda_\theta^2 + \lambda_z^2 + \left(\lambda_\theta \lambda_z\right)^{-2}\right) - 3\right] + \frac{\phi_c}{4}\sum_{k=1-4}\frac{b_{1k}}{2b_{2k}}\left\{\exp\left[b_{2k}\left(\sqrt{\lambda_\theta^2 \sin^2\alpha_k + \lambda_z^2 \cos^2\alpha_k}^{\,2} - 1\right)^2\right] - 1\right\} \quad (1)$$

Using this constitutive model, we quantified the *in situ* homeostatic stress state for each of the vessels. Also using the model, we predicted the mechanical response of each vessel to the grafted coronary environment (Table 1). Furthermore, we developed a novel metric (Ω)

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

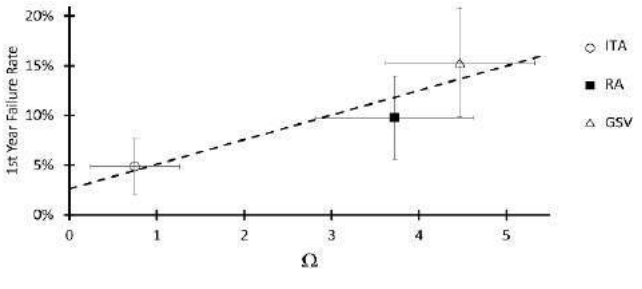
to quantify the sum of normalized differences between native and grafted states for several important parameters (deformed inner radius, vessel compliance, circumferential and axial stress).

For objective (ii), endothelial cells (ECs), smooth muscle cells (SMCs), and fibroblasts (FBs) were enzymatically isolated from freshly dissected sections of each vessel of interest (LAD, ITA, RA, GSV, and LSV). Cell populations were evaluated temporally (day 0, 7, and 30) using multiple assays (confocal microscopy, qRT-PCR, migration, proliferation) to observe phenotypic properties. Analysis of each tissue at acutely and in early culture allow approximate comparison of cells' *in vivo* properties. Comparisons at the late time point demonstrate the extent to which cell phenotypes change in response to their local environment. Determination of phenotypic difference or convergence was made by synthesizing the results of these assays.

Statistical analyses were conducted using one-way ANOVA with Dunnett's Post Hoc test as well as two-sided paired t-tests at $p<0.05$.

RESULTS

Endowed by unique compositional and structural organization, biaxial mechanical testing identified distinct homeostatic stress states for each vessel (Fig.1 bottom). Using a structure-based constitutive model we found that the ITAs experience the least mechanical deviation between *in situ* native environment and theoretical grafted environment for each of the Ω_θ, Ω_z, Ω_{ri}, and Ω_C categories and is represented by the lowest overall Ω (Fig. 1 top) while GSVs had the highest Ω. [6]



Vessel	C [10-6 m2/kPa]	ri [mm]	<σθ *> [kPa]	<σz * > [kPa]
		Native		
LAD	0.35 ± 0.14	2.3 ± 0.34	68.87 ± 40.78	52.73 ± 24.12
ITA	0.4 ± 0.12	2.24 ± 0.31	70.92 ± 17.53	73.81 ± 17.42
RA	0.15 ± 0.07	1.29 ± 0.6	13.06 ± 3	84.97 ± 96.11
GSV	0.23 ± 0.17	1.47 ± 1.13	3.09 ± 1.01	72.57 ± 109.1
		Grafted		
LAD	0.35 ± 0.14	2.3 ± 0.34	68.87 ± 40.78	52.73 ± 24.12
ITA	0.41 ± 0.14	2.01 ± 0.14	68 ± 12.84	57.45 ± 30.27
RA	0.07 ± 0.03	0.94 ± 0.12	20.54 ± 3.54	101.44 ± 52.43
GSV	0.13 ± 0.03	1.07 ± 0.23	20.6 ± 2.8	89.39 ± 119.47

Figure 1. (Top) Relationship between Ω and clinical 1st year CABG failure rate for each vessel. (Bottom) Values of relevant parameters – compliance (C), deformed inner radius (r_i), circumferential stress (σ_θ), and axial stress (σ_z) – for each vessel in its native and grafted mechanical state. [6]

Concomitant with distinct stress states and functional requirements, resident vascular cells exhibit distinct phenotypic properties. Gene expression profiles (qRT-PCR) suggest significant phenotypic differences between cells isolated from veins (GSV, LSV), muscular arteries (RA), and elastic arteries (ITA, LAD), specifically with respect to genes associated with remodeling processes. Furthermore, these gene expression profiles change temporally within cell populations between early (day 0, day 7) and late (day 30) time points. Confocal microscopy with labeling of specific cell type markers was used to assess cell populations and phenotypes within populations, specifically the proportion of synthetic to contractile SMCs (Figure 2).

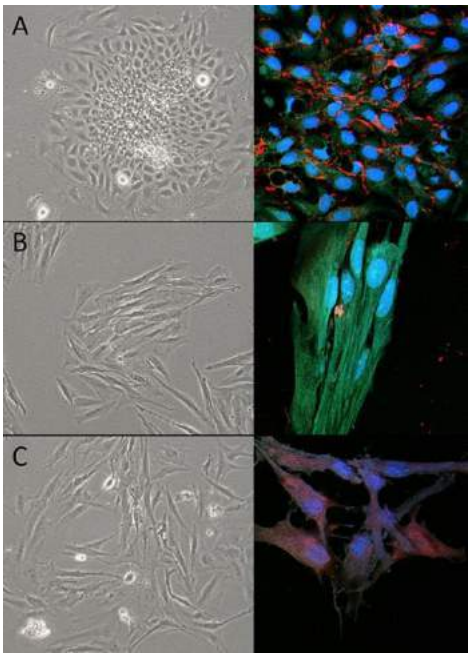


Figure 2. Sample cell populations under phase contrast (200x; left column) and confocal (630x; right column) microscopy: (A) ECs, (B) SMCs, and (C) FBs. For confocal images: Blue=DAPI, Green=Phalloidin, Red=PECAM1/Smoothelin/FSP1 (cell-specific markers).

DISCUSSION

The work represented by objective (i) established the baseline homeostatic stress states for the LAD, ITA, RA, GSV, and LSV. We quantified the mechanical deviation between each vessel's *in situ* and grafted environment using a novel, and clinically relevant, metric (Ω) that can be further applied to other graft candidates, other graft procedures, and tissue engineered blood vessels. These findings motivated further investigation in objective (ii).

The cell studies represented by objective (ii) provide a new perspective toward understand CABG remodeling. By studying the resident cell populations that make up CABGs and are responsible, in part, for remodeling processes, we demonstrate that inherently vessels are not equally capable of vascular remodeling.

In the future, the results of objectives (i) and (ii) will be synthesized to optimize CABG remodeling in an *ex vivo* perfusion bioreactor.

IN VITRO STUDIES ON NATIVE TO ENGINEERED HEART VALVE TISSUE INTEGRATION

Kristin Comella(1), Danique Stewart(1), Sasmita Rath(1), Sharan Ramaswamy(1)

(1) Tissue Engineered Mechanics, Imaging and Materials Laboratory (TEMIM Lab), Department of Biomedical Engineering, Florida International University, Miami, FL,

INTRODUCTION

Millions of people worldwide suffering from valvular heart disease and the rate of incidence is expected to significantly increase in the future [1]. An inability of prosthetic valves to accommodate somatic growth and practical size limitations of current commercial valves represent specific technical challenges. The field of tissue engineered heart valves holds promise of filling this unmet need. The living, biological heart valve could function in a similar manner as native tissue with normal hemodynamic performance and minimal degeneration. However, an important precursor to successful heart valve engineering lies in the successful integration of engineered to native tissues. Thus, in this study we investigate the morphology of the transition region that forms between native and engineered heart valve tissues after exposure to valve-like mechanical environments.

METHODS

Bone marrow stem cells (BMSCs) were isolated from porcine bone marrow. Bone marrow was collected from the iliac crest and layered using gradient separation media. The buffy coats were collected and seeded in tissue culture dishes to isolate and expand BMSCs. Poly-glycolic acid (PGA) and poly-L-lactic acid (PLLA), nonwoven polymer felt scaffold (Biomedical Structures, Warwick, RI) was seeded with approximately 2 million cells and incubated for 8 days in rotisserie culture.

Scaffolds were sutured to freshly harvested porcine native aortic valve leaflets and then placed in a bioreactor [3] (See figure 1). A custom-built U shape bioreactor connected to a peristaltic pump and an environmentally sealed linear actuator was used to create flex/flow [2]. The experimental set-up consisted of four identical conditioning chambers, with each chamber containing 3 samples. Specimens were fixed with a pin at one end while the other end was attached to a circular moving post. For Flex and Flex-Flow experiments, the moving post was moved linearly in the axial direction to initiate specimen cyclic flexure using the linear actuator (frequency of 1 Hz). A peristaltic pump (Master flex L/S, model # 7523–80, Cole Parmer, model # 7535–04, East Bunker Court Vernon Hills, IL, USA) was used to maintain a continuous flow rate of 850 ml/min.

After 14 days in the bioreactor, samples are subjected to collagen biochemical assays. In addition, histology is completed to measure the presence of key valvular ECM components (collagen, glycosaminoglycans (GAGs) and elastin). Immunofluorescence staining of CD31 and α-SMA cell surface proteins is performed for evidence of endothelial and myofibroblastic phenotypes. CD31 is known to be expressed on the surface of EC and α-SMA in SMC, as well as myofibroblast-like cells in valve interstitial cells. And finally, samples were evaluated for gene expression and quantification of a limited number of valve-related markers in order to verify the immunostaining results was completed using quantitative real time-polymerase chain reaction (QRT-PCR).

RESULTS

We successfully seeded 18 scaffolds with BMSCs and then sutured these scaffolds to native porcine valve leaflets (Figure 2). We also demonstrated that scaffolds placed into the flex-flow mechanical environments support differentiation of BMSCs towards a heart valve phenotype, as evident by cellular distribution and expression of specific gene markers [3]. Figure 3 shows the Russell's Movat pentachrome histological staining of: a) through-thickness section of BMSC-seeded scaffold after 22 days of culture (8 days static + 14 days Flex-Flow conditioning, b) through-thickness section of native porcine aortic valve leaflet (+ve control). GAGs were clearly visible within the tissue engineered construct [3].

DISCUSSION

The integration of engineered tissue to native valve tissue is an important component when considering tissue engineered heart valves. transition zone was created between engineered and native valvular tissue constructs. Prior to *in vivo* studies, the current preliminary *in vitro* work provide insights into the nature of integration of engineered heart valve tissues to native tissue structures in a controlled manner.

INTRODUCTION

Over 75% of abdominal aortic aneurysms (AAAs) harbor an intraluminal thrombus (ILT) on their inner wall. Increasing evidence suggests that ILTs contribute to the pathobiology of aneurysms affecting both biomechanically and biochemically the underlying wall [1, 2]. Bioactive effects of ILTs seem to be largely linked to their morphology, with thin thrombi showing a more pronounced proteolytic activity compared to the thick ones, which are more hypoxic. A good predictor of the morphological features of thrombus has thus potential clinical utility since it could help differentiating among lesions that are at a higher/lower risks of developing a thrombus and within the same lesion, among regions of the wall that are more likely to harbor a thin thrombus, a thick one, or no thrombus at all.

Hemodynamics is likely an important player in the formation of ILTs. Blood flow is essential for the transport of components feeding and regulating the dynamic balance between the coagulation cascade and the fibrinolytic process, and exerts friction forces that shape evolving thrombi into their configurations. While computational models can now exploit high-resolution medical images regularly acquired on patients affected by AAA to investigate in fine detail the disturbed hemodynamics, significant challenges are still posed by modeling the complexities of thrombus formation in vivo. At best of the authors' knowledge, no modeling effort has been able to reproduce thrombus configurations as visible in actual CT scans of patients, yet.

In this study rather than attempting to capture all the molecular events that lead to the full formation of a thrombus, we mainly investigate how hemodynamic conditions govern thrombus shaping during propagation by means of complex blood flow transport and erosion patterns. Relying on a phenomenological description of the deposition event, we propose a strategy based on a shape optimization algorithm to predict the final thrombus configuration without requiring full large scale simulations encompassing the several minutes needed for the coagulation to complete and for the thrombus to stabilize. Given the prohibitive computational cost of such simulations, our method is particularly appealing whereas predicting the post-deposition lumen/thrombus morphology is of interest.

METHODS

De-identified CTA scans (n=6) of patients affected by AAAs harboring a thin thrombus (max thickness h_{max} < 1.5 cm) were processed with semi-automated segmentation algorithms to extract lumen boundaries of the abdominal aorta and its main branches. Our models included also large portions of the upstream and downstream vasculature, going from the celiac trunk down to the first bifurcation of the iliac arteries. For each scan we constructed two computational domains: One included only the blood-filled lumen (L), and the other one extended also to the ILT (L+T). Computational fluid dynamic simulations were run for each patient on both geometries using a customized version of the open-source software SimVascular, which employs a stabilized finite element method to compute high resolution time-varying hemodynamic fields characterizing each lesion. Average boundary conditions extracted from literature data were used at the suprarenal inlet, where we imposed a Womersley velocity profile, and at the outlets, where we weakly imposed Windkessel boundary conditions.

Lagrangian particle tracking was used to enrich the Eulerian results output by SimVascular with a macroscopic correlate of shear-induced platelet activation (Figure 1). Following a procedure described in a recent work of ours [3], we combined particle tracking results with wall-shear stress metrics to compute the Thrombus Formation Potential (TFP) index, which is representative of hemodynamic-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

induced thrombogenicity on intact endothelium. TFP highlights regions of the aneurysmal wall that might be exposed at the same time to low and oscillatory flow conditions (which are known to reduce the anti-thrombogenic action of the endothelium), and to pro-coagulant agents (e.g. activated platelets) transported by the bulk flow. The concomitance of such events does not seem occur in healthy regions of the vasculature, and it could be one of the reason behind thrombus formation in aneurysms.

Recent findings suggest that other hemodynamic features, specifically low and non-oscillatory flow might contribute (and correlate) to thrombus deposition in growing lesions [4-6]. We thus defined a novel phenomenological index, the Thrombus Deposition Potential or TDP, to describe flow conditions promoting the propagation of thrombus from initiation areas marked by high TFP. In addition to standard WSS-based metrics, the definition of TDP takes into account also wall concentration profiles of plasma-borne proteins such as fibrinogen (FBG). Solving in post-processing an advection-diffusion problem for ten cardiac cycles, we were able, in fact, to differentially locate areas of the aneurysmal wall that were more/less exposed to advection from the upstream bulk flow. We thus considered several definitions for TDP,

$$TDP = f(OSI, TAWSS, [FBG]) \quad (1)$$

where OSI is the oscillatory shear index, TAWSS is time averaged wall shear stress, and [FBG] is fibrinogen concentration.

To choose the best formulation, we then used TDP as the main driver of an optimization procedure aimed at predicting lumen shape at the end of a deposition event. After parameterization of the patient-specific geometries via radial basis functions, we used a derivative-free optimization method based on orthoMADS and the Surrogate Management Framework (SMF) [7] to seek for lumen configurations that minimized TDP absolute values. Assuming that small depositions of thrombus would not affect significantly far-field hemodynamics, we developed a novel strategy to build accurate and continuously updated surrogates of TDP behavior on the parameter space. Specifically, full-scale simulations run on pre-deposition domains were used as a source of boundary conditions for much smaller coupled-simulations focused on updating the near-thrombus hemodynamics. The coupling was performed via a custom solver developed in FEniCS that was able to efficiently read in parallel the results of the large-scale simulations. This allowed us to effectively exploit the flexibility that the SMF gives to users to accelerate convergence towards an optimum.

Outputs of the procedure were predicted post-deposition lumen shapes that we compared to actual geometries segmented from the CT scans.

RESULTS

Comparative analyses of the hemodynamics in the L and L+T domains presented several differences in terms of WSS-based index values. The deposition of thrombus induced, as expected, a general increase in TAWSS, with effects more pronounced in regions where thrombus was thicker. Variations in the OSI index were less coherent, but the index turned out to be very sensitive to changes in shape. Absolute variations were in fact consistent. Finally, [FBG] showed a general tendency towards higher wall concentrations in post-deposition geometries, likely because in these cases the lumen wall was closer to the center of the vessel and therefore more exposed to central flow.

Our approach of combining the TFP and TDP indices proved to be able of successfully locating thrombogenic areas in all the aneurysms that we considered. Despite significant differences in terms of portion of the aneurysmal wall harboring the ILT (e.g. posterior vs anterior side of the AAA), high TDP areas always intersected with regions covered by actual thrombi.

Shape optimization analyses were used to predict final thrombus thickness distributions. Satisfying matches were observed for all the aneurysms, but they were less accurate for lesions harboring thicker thrombi.

DISCUSSION

The primary goal of this work was to develop and validate a phenomenological approach aimed at investigating the changes in hemodynamics that occur during thrombus deposition. ILTs are never fully occlusive suggesting that certain hemodynamic conditions might consistently occur to arrest thrombus growth. We thus sought for a phenomenological metric that could well describe such hemodynamic features combining popular WSS-based indices and other macroscopic descriptions of fluid transport. That is, in contrast to other studies, we did not try to account for all the players intervening in the coagulation cascade, but we opted for simpler metrics better suited to represent the scarce data typically available about patient-specific ILT formation. Our newly proposed TDP index is able to correctly locate areas prone to thrombus propagation. Moreover, when combined to a customized shape optimization procedure, it can be effectively used as a predictor of the final thrombus shape. The reduced number of cardiac cycles that need to be simulated at full-scale to obtain realistic thrombus configurations overcomes many of the limits that have been encountered in modeling intraluminal thrombus formation so far.

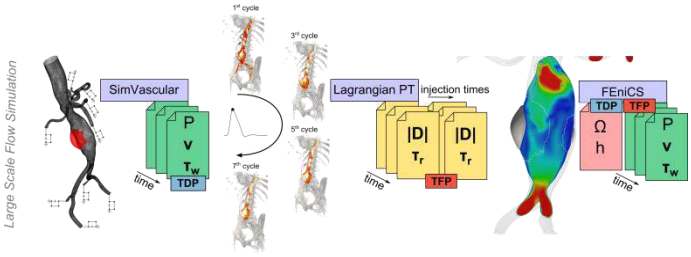

Figure 1: Full characterization of the hemodynamic forces leading to thrombus growth and arrest. Standard CFD computations run in SimVascular were complemented by Lagrangian Particle Tracking analyses. A lumen shape optimization procedure was then used to efficiently explore possible post-deposition configurations.

INTRODUCTION

Stroke is one of the leading causes of morbidity and mortality in the Western society [1]. The majority of the acute ischemic stroke events are due to the rupture of an atherosclerotic plaque in a carotid artery. Atherosclerosis is a systemic disease of arterial vasculature, primarily characterized by lipid accumulation in arterial walls. The lesion sites are referred to as plaques. Rupture of a plaque triggers thrombus formation in the lumen of the artery, which leads to complete or partial occlusion of the lumen and hence, ischemia downstream of the occlusion site.

Not all atherosclerotic plaques rupture. To judge correctly which plaque to treat surgically, it is of great importance to predict the rupture risk of plaques. As plaque rupture is a mechanical failure, biomechanical models might aid in rupture risk assessment. To obtain reliable results from the biomechanical models, accurate mechanical properties of plaques have to be used in the models.

Atherosclerotic plaques are complex composite structures. Mechanically important structural components of plaques are collagen and elastin fibers, lipid, calcium and smooth muscle cells. Considering the amount and the stiffness, collagen fibers are anticipated to be the major load bearing elements [2]. Hence, quantification of the collagen architecture in atherosclerotic plaques is essential for high-fidelity biomechanical models.

The available data in literature on the collagen distribution in atherosclerotic plaques is incomplete and does not provide the necessary data to feed the 3D biomechanical plaque models. The aim of the current study is to image the 3D collagen architecture in atherosclerotic carotid plaques using diffusion tensor imaging (DTI) and to quantify local collagen fiber orientation.

METHODS

Plaque samples and preperation

Nine carotid plaque samples causing more than 70% stenosis were obtained from patients (all male, age 55-80 years) scheduled for endarterectomy. The samples were snap-frozen and stored at -80º C. After slow thawing, the samples were prepared for DTI by placing them in a cryovial and embedding in 4% agarose, following a previously described protocol [3].

Diffusion tensor imaging (DTI)

DTI was performed with a 9.4 T horizontal MRI scanner (Bruker, Etlingen, Germany) in combination with a dedicated 35 mm diameter quadrature birdcage radiofrequency (RF) coil. DTI was done with a 3D spin echo sequence with unipolar diffusion sensitizing pulsed field gradients placed symmetrically around the 180º RF pulse. Sequence parameter were as follows: echo time=27 ms, repetition time=1000ms, number of averages=1, field of view=30x30x30 mm^3, acquisition matrix=256x96x96, reconstruction matrix=256x256x256, 10 diffusion directions with diffusion weighing b value=1500 s/mm^2. Total acquisition time was about 28 hours. An in-house developed software (http://bmia.bmt.tue.nl/software/viste/) was used to construct and visualize the fiber collagen network from raw DTI data.

Histology

After DTI, agarose medium, in which the plaques were embedded, was removed and plaques were sliced using a crytome to obtain longitudinal cross-sections for histology. Picro Sirius Red staining was applied on the cross-sections to visualize the collagen fibers for qualitative validation of DTI results.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Quantitative assessment of main collagen fiber direction

DTI data acquired contains x-, y-, and z-components of local collagen fiber directions in plaques with respect to a reference Cartesian coordinate system. An in-house developed MATLAB (version R2013a) script was used to convert the data into cylindrical coordinates (radial, circumferential or longitudinal) and to determine the main principal cylindrical direction of the collagen fibers. The radial and circumferential directions were defined with respect to the center of the lumen on the corresponding transversal cross-section. The longitudinal direction in the cylindrical coordinate system coincides with the z-direction of the original Cartesian coordinate system.

RESULTS

Nine human plaque samples from carotid endartaractomy surgeries were obtained and imaged with DTI successfully. DTI data of four out of nine plaques was analysed and main alignment direction of the collagen fibers was determined (Figure 1). The two leftmost samples in figure 1 show a highly organized collagen structure, with a dominant alignment in the longitudinal direction at the luminal side, and in the circumferential direction at the abluminal side. The two rightmost samples are less structured, but longitudinal alignment at the luminal side can still be discerned.

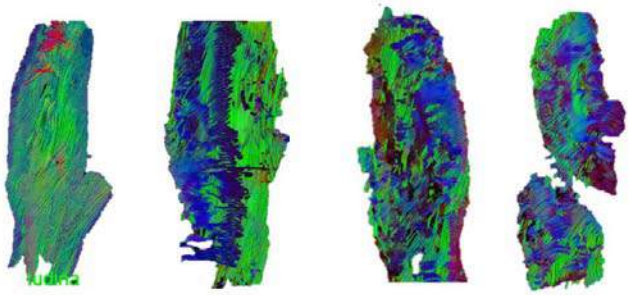

Figure 1: Collagen fiber distribution obtained from DTI in four carotid plaque samples

One sample was further analysed and examined histologically. A representative histological longitudinal cross-section is shown in figure 2. The histology image reveals the presence of a lipid core with a thick fibrous cap (see the zoom-in box in the figure). The collagen fibres clearly demonstrate a longitudinal alignment at the luminal side, qualitatively confirming the findings from DTI.

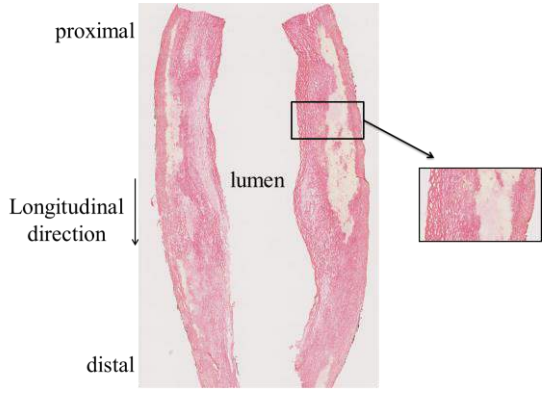

Figure 2: Picro-Sirius Red staining on a longitudinal plaque cross-section

Quantitative assessment of the collagen distribution supported the observations from raw DTI data and histological examinations. The most dominant fiber directions were the longitudinal direction (48% of the total volume) and the circumferential direction (45%). Comparably, the radial alignment of collagen fibers was minimal (6%) (see figure 3). The plaque cross-sections of less advanced stage of atherosclerosis (e.g. bottom two transversal cross-sections in figure 3) showed a clear longitudinal alignment of collagen fibers at the luminal side and circumferential alignment at the abluminal side. For the cross-sections where plaque was larger, this distinction was less clear and in some regions the radial direction was the dominant fiber direction.

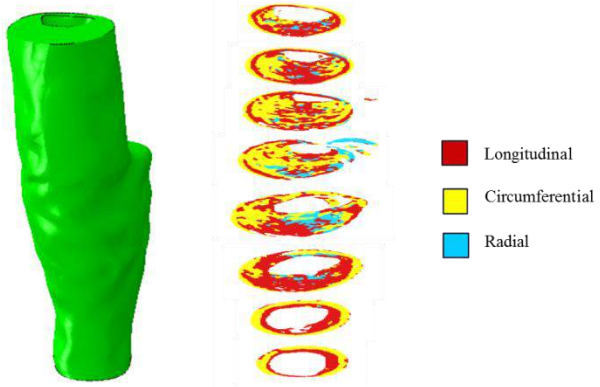

Figure 3: Reconstructed plaque geometry (left) and main direction of collagen fibers on selected transversal cross-sections (right)

DISCUSSION

The presence of collagen fibers in atherosclerotic plaques was demonstrated previously by histological studies, however, as histology provides 2D data, the 3D architecture of the collagen network was not established before. The current study is the first one that images the collagen network in atherosclerotic plaques in 3D.

The findings demonstrated both structured and unstructured fiber alignment in plaques. Hence, isotropy and homogeneity assumptions for plaque material in the biomechanical models might be unrealistic. Longitudinal fiber alignment was observed frequently and this finding was confirmed by histology. This implies that using 2D biomechanical models probably lead to oversimplification and 3D models should be preferred for reliable results. In healthy tissues, under physiological conditions, collagen is aligned in the direction of the maximum principal stress/strain. It seems unlikely that the longitudinal direction is the main stress/strain direction in atherosclerotic plaques. So, it is unclear why collagen is oriented in the longitudinal direction.

In the future, we will analyze the DTI data collected from the other plaque specimens to see whether the current findings are also supported by the rest of the data. Moreover, we will create 3D finite element models of the imaged carotid plaques to investigate the influence of anisotropic and heterogenous mechanical behavior of plaque material on plaque stresses.

INTRODUCTION

Traumatic brain injury (TBI) is a leading cause of death and disability [1]. In mild TBI, the extent of axonal injury damage is challenging to identify. Diffusion tensor imaging (DTI) is commonly used in brain injury research to identify axonal injury [2], and measurements of fractional anisotropy or axial diffusivity are typically averaged over a region of interest where the injury is suspected. However, detection of subtle differences in mild TBI using this method is not feasible as non-injured areas may be included in the averaging process.

We've previously developed a neonatal pig model to simulate pediatric mild TBI induced by non-impact repetitive angular accelerations with and without an added thoracic compression that mimics the physiological increase in intracranial pressure and cerebral blood volume during crying. This model results in various levels of minor axonal injury on histopathology [3].

To determine if this axonal injury can be detected with DTI, we developed an image analysis routine based on one presented by Liu et al. in humans [4]. This routine registered pre- and post-injury images into a single atlas space and statistically compared diffusion metrics for each voxel. Evaluating all locations of the brain increases chances of identifying injury, and improves the region of interest selection for future analysis, making the evaluation of DTI metrics for predicting mild TBI much more effective and accurate.

METHODS

All studies were performed in accordance and approval of the University of Utah Institutional Animal Care and Use Committee. Diffusion weighted images of anesthetized piglets (3-5 days old) were acquired with a 7T Bruker Biospin MRI system using a single-shot echo planar image sequence before and after a repetitive, non-impact inertial head rotation. The head rotation was induced by attaching the anesthetized animal's snout to the biteplate of a mechanical device, and rotating the head in the horizontal plane through a 100° arc at a speed of 45 rad/s. The motion was repeated in both directions at a frequency of 3 Hz for a total duration of 20 seconds.

Animals were divided into three groups. Group 1 (n=4) experienced the cyclic head rotation, was allowed to recover, and then imaged 24 hours post-injury. Groups 2 (n=3) and 3 (n=2) experienced the cyclic head rotation plus had the additional thoracic compression which was applied in increasing increments of 20 mmHg until an increase of CBV and ICP were similar to those found during intense infant crying [5][6]. The compression was applied immediately before rotation. Group 2 was imaged immediately post-injury (acute) and Group 3 was imaged 24 hours post-injury. All animals were imaged prior to injury to provide baseline controls for comparison. During each imaging session, diffusion was measured along 64 independent directions in 2D coronal slices taken every 2 mm (n=15).

For each animal, a non-diffusion weighted image was segmented to create a mask that excluded the skull and extracranial tissues. Diffusion tensors were estimated using a weighted least squares method. Tensor images were then registered using ANTs software [7] into a single atlas space by application of an affine and diffeomorphic registration.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Scalar diffusion metric images, which included fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD) were computed, and a 3x3x3 Gaussian filter was applied to reduce possible registration misalignments. A paired one-tail t-test was performed on each of the spatially corresponding voxels in the baseline and post-injury images, and a p-value map was created for each of the scalar image sets. To reduce the number of false positives potentially arising from registration misalignment and noise, two thresholds were applied. The first used a cross-correlation metric [8] to compute an index of similarity based on the local 2D cross-correlation at each voxel. The second removed any cluster with less than three contiguous voxels with a p-value < 0.05.

To create a numerical means of comparing the levels of significance of post-injury images, a weighted integral measure (WIM) was create for each image (Eq. 1). The area of each significant voxel in a cluster ($area_{ij}$) was divided by the p-value for that voxel ($p\text{-}value_{ij}$) and summed across the cluster. This cluster metric was then summed over all the clusters to create a WIM measurement for each image set.

$$WIM = \sum_{j=1}^{m\ clusters} \sum_{i=1}^{n\ voxels\ per\ cluster} \frac{area_{ij}}{p\text{-}value_{ij}} \qquad (1)$$

To address the statistical problem of multiple comparisons, nonparametric permutation tests were used [9]. Under the null hypothesis, pre- and post-injury image sets can be freely exchanged if the datasets are equal. Therefore, image sets were randomly assigned to either set and statistical tests were performed again. 2^N-1 permutations were performed for each group (N=# image sets available). If the WIM from the real data set was higher than the WIM of all permutated data sets, the statistical significance of that image set was considered real.

RESULTS and DISCUSSION

Significant differences from baseline were detected in all Groups. The average ± SD of the WIM for each group is shown in Figure 1. A higher value indicates that the image set had a larger statistical significance compared to baseline either by a decrease in the p-value, a greater number of clusters, or a larger cluster size. WIM levels in Group 1 were lower than in Groups 2 and 3, suggesting that there is overall less injury in Group 1 compared to Groups 2 and 3. This makes sense given that Groups 2 and 3 had increased ICP and CBV prior to the head rotation. Significant clusters in Group 1 were observed primarily in the internal capsule and corona radiata, which correlate well with locations of positive βAPP staining found in our previous study [4].

Groups 2 and 3, which had the same injury induced, had different DTI responses depending on the timing of imaging. Acute imaging (Group 2) resulted in significant increases in MD and decreases in AD, while longer term imaging (24 hours in Group 3) resulted in greater significant decreases in FA and increases in RD. This data strongly suggests that measurements of DTI metrics for mild TBI will be highly dependent on the time post-injury, and evaluating only one metric may not capture injury. Histology on the brains from this study are currently being processed to correlate positive clusters to axonal injury.

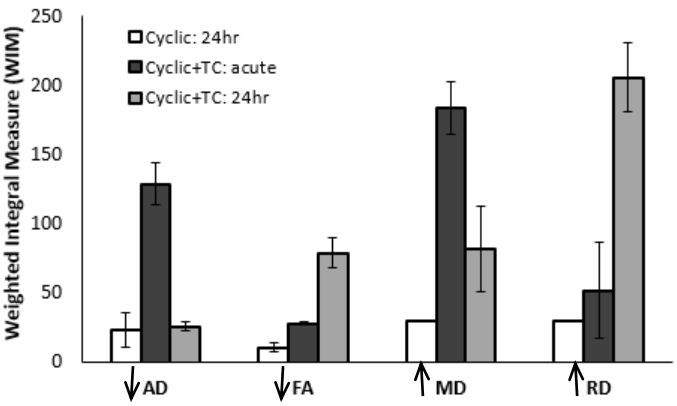

FIGURE 1: Weighted integral measure (WIM) of each diffusion metric for each injury group. Arrow indicates directionality of statistical test.

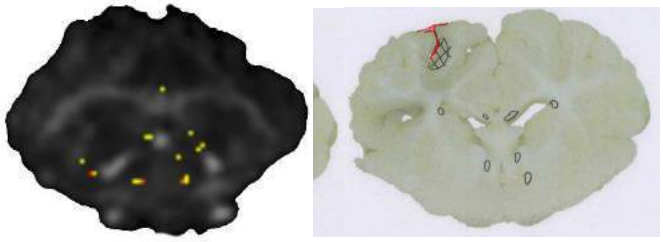

FIGURE 2: P-value map from Group 1 overlaid on an MD image (left). Red: p<0.005; yellow: p<0.01. Axonal injury marked by βAPP (right; open circles) correlated well with locations of significant clusters.

CONCLUSION

DTI is a powerful tool for identifying changes in axonal structure following TBI, but using standard methods of analysis, such as selecting regions of interest and averaging, may not capture subtle changes to axonal architecture. We have created a voxel-wise statistical comparison approach that identified significant differences in DTI measures of axonal injury, dependent on the timing of the imaging. While the results need to be interpreted carefully due to the small sample sizes, there is evidence of axonal injury in each image set, with increased levels of axonal injury due increased ICP and CBV prior to mechanical loading.

AKNOWLEDGEMENTS

We would like to thank the Primary Children's Medical Center Foundation for financially supporting this research. We also thank the University of Utah small animal imaging lab.

INTRODUCTION

Tissue-equivalents (TEs), simple model tissues with tunable properties, have been used to explore many features of biological soft tissues, including how structural and compositional properties affect mechanical function. To the best of our knowledge, one aspect not previously captured in such formulations is residual stress due to interactions among components with different stress-free states, which has an important functional role in many biological tissues [1, 2]. To create a pre-stressed model system, co-gels were fabricated from a combination of hyaluronic acid (HA) and reconstituted Type-I collagen (Col). When placed in solutions of varying osmolarity, HA-Col co-gels swell as the HA imbibes water, which in turn stretches (and stresses) the collagen network. In this way, co-gels with residual stress (i.e., collagen fibers in tension and HA in compression) were fabricated and evaluated in terms of their mechanical response both experimentally and through a fibril network + non-fibrillar interstitial matrix computational model.

METHODS

Fabrication: Three groups of gels were fabricated: (1) Col, (2) HA, and (3) HA-Col co-gels. For collagen, reconstituted Type-I rat tail collagen (Invitrogen, Carlsbad, CA) was mixed as described previously with 1M HEPES, 1M NaOH, 10X MEM, FBS, Penicillin/Streptomycin, Fungizone, and L-Glutamine, and diluted with deionized, distilled water to a final concentration of 1 mg/mL [3]. HA samples were prepared by mixing thiol-modified HA (Biotime, Inc., Alameda, CA) with a polyethylene glycol based thiol-reactive cross-linker to form a 0.67% (w/v) HA gel (240 +/- 20 kDa). 10-µL aliquots of each gel type were then cast in silicone oil and incubated at 37°C for 24 hours to create spheres of ~2.5 mm diameter, similar to a previously reported procedure [4].

Experiments: After incubation, gel spheres were placed in solutions of 0, 1, 2, 3, 4, 5, 10, 15, 25, 50, 75 or 100%, 1x phosphate buffered saline (PBS; n = 3-4 per solution) for 2 hours. Sphere diameters were either measured by a custom Matlab routine (DOI 10.5281/zenodo.44285) or, for those gels that were highly translucent, measured manually.

Analysis: The fixed-charge density of HA before swelling, c_F^0, was estimated by

$$c_F{}^0 = \frac{|z_{HA}|C_{HA}}{MW_{HA}} \quad (1)$$

where z_{HA} was the charge per HA monomer, C_{HA} was the mass concentration of HA, and MW_{HA} was the molecular weight of an HA disaccharide monomer. Since the HA gels were dilute (0.667% w/v), the fixed charge density after swelling, c_F, was calculated by

$$c_F = c_F{}^0 \left(\frac{D_0}{D}\right)^3 \quad (2)$$

where D_0 and D were the diameters of the HA sphere before and after swelling, respectively. For an HA gel immersed in a solution dominated by monovalent ions (e.g., NaCl) the Donnan osmotic pressure, π_{Donnan}, can be computed as

$$\pi_{Donnan} = RT\left(\sqrt{c_F{}^2 + 4c^{*2}} - 2c^*\right) \quad (3)$$

where R is the universal gas constant, T is the absolute temperature of the system, and c^* is the Na^+ concentration in the external solution, assuming complete ionization and ideal solution behavior [5]. A swollen HA-Col co-gel at equilibrium, under the assumption that the co-gel obeys constrained mixture theory [6], satisfies the following stress balance:

$$\sigma_{HA} + \sigma_{Col} - \pi_{Donnan} = 0 \quad (5)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where σ_{HA} is the Cauchy stress in HA estimated from swollen pure HA, σ_{Col} is the Cauchy stress in the collagen network, and π_{Donnan} is calculated using Eq. 1-3.

Experimental results for the collagen pre-stress, σ_{Col}, were compared to computational model predictions obtained from our microscale network model as described previously [7-9]. The mechanical response of each fiber within the network was governed by the non-linear force-strain constitutive equation:

$$F = \frac{A}{B}[\exp(BE_f) - 1] \quad (7)$$

where F is the force exerted by the individual fiber, and A and B are material parameters that characterize the mechanical behavior of the fiber and E_f is the Green strain of each fiber. As the RVE is deformed, the average Cauchy stress in the network, $\langle\sigma_{ij}\rangle$, is given by the summation over all boundary crosslinks

$$\langle\sigma_{ij}\rangle = \frac{1}{V}\sum x_i F_j \quad (8)$$

Where V is the volume of the RVE, x_i is the *i-th* component of the nodal position of a boundary crosslink, and F_j is the *j-th* component of the fiber force exerted on that boundary crosslink. The RVE is scaled to the macroscopic scale to allow computation of the macroscopic-scale stress. From SEM images of acellular collagen gels, an average collagen fiber diameter of 50nm was used.

To obtain material parameters A and B for pure collagen gels, simulations of uniaxial tensile tests on five Voronoi RVE networks were performed, and the stress-strain curves were fitted to previously-obtained experimental tensile test data [8]. Using the fitted parameters (A = 30 nN, B = 4) as inputs for the new computational model, dilatational stretches of the five Voronoi networks were performed to simulate swelling and then compared with σ_{Col} from the swelling experiments.

RESULTS

The results for swelling experiments are shown in figure 1. Swelling occurred only in the pure HA and HA-Col gels. Pure collagen gels did not swell appreciably over 1 hour, and no further data were logged. The pure HA gel, in contrast, swelled the fastest and to the highest degree, as demonstrated by the steep slope and large equilibrium swelling ratio. The HA-col co-gel sphere also exhibited swelling, but not as rapidly as, nor to as great an extent as the pure HA gel.

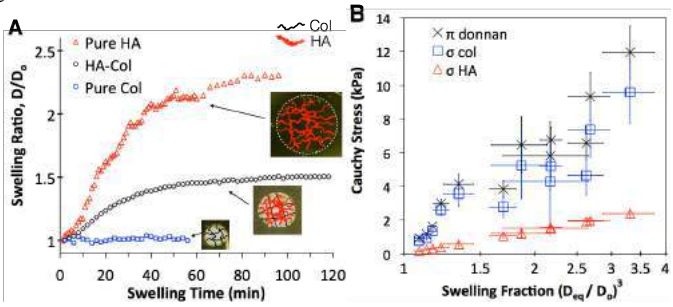

Figure 1. A) Representative swelling behavior exhibited by single-component gel or co-gel spheres immersed in 0%vol PBS. B) The relative magnitude of each stress contribution during swelling in various PBS concentrations (100% is furthest left, and 0% is furthest right)

The stress induced in the collagen network increased nonlinearly with swelling and was the dominant stress resisting the Donnan pressure at large swelling ratios (Fig 1B). Dilatational stretch simulations of pure collagen gels generated collagen stresses similar to those observed in HA-Col co-gel swelling experiments (Fig. 2). It is noteworthy that the curve in Fig. 2 is a prediction based on uniaxial experiments, not a curve fit.

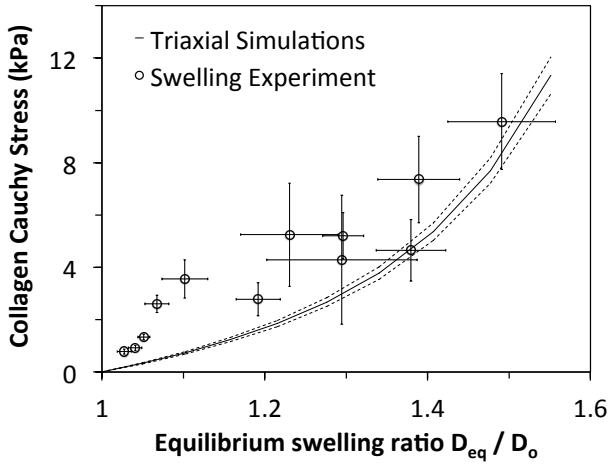

Figure 2. Triaxial simulation with 95% confidence interval bounded by dotted lines. Data points are σ_{Col} calculated from experimental swelling. Both experimental and simulated stretches are presented along one dimension.

DISCUSSION

The simple, *in vitro* HA-Col co-gel model is a candidate system to approximate the residual stresses commonly observed in living tissues. Independent estimates of the collagen stress based on (1) swelling experiments and (2) a computational network model based on uniaxial extension of pure Col gels showed good agreement over the experimental range (Fig 2). The monomer charge, z_{HA}, was assumed to be one, although it is likely to be less due to the larger dissociation constant of thiol monomers, which could improve the agreement between experiment and simulation. Differences between simulation and experiment could be due to HA restricting the conformational space available to collagen network fibers, particularly in the low strain regime, suggesting interaction between the HA and collagen which would further drive the system toward affinity. Such a response was observed previously between collagen-agarose co-gels [10], where the measured strength of collagen fibril alignment (retardation) during uniaxial loading was lessened in the presence of agarose, representing inhibition of the collagen network's microstructural reorganization. It was previously suggested that low concentration HA in HA-Col co-gels does not affect the network structure of collagen [11]. No microstructure characterizations were carried out in this study, but the use of pure HA to estimate σ_{HA} in co-gels, together with good agreement of the computational network simulation implies that interactions between HA and collagen in the co-gel may have negligible mechanical consequences in swelling.

INTRODUCTION

Cells and tissues in their native microenvironment respond to stimuli such as mechanical shear/stress, extracellular matrix (ECM) topography, and rigidity which subsequently determine their morphology, morphology, differentiation, proliferation, development, and function.[1] A number of methods have been developed to control the cell and tissue microenvironment *in vitro*, by patterning adhesive proteins/peptides (e.g., fibronectin/RGD) on two-dimensional (2D) substrates (glass, plastic, polymers) with different physical and chemical properties.[2] Although 2D cultures have proven remarkable in understanding cell/tissue biology, they differ substantially from the *in vivo* microenvironment of most cells/tissues where they are intricately associated with different adherent ligands present on three-dimensional (3D) ECM. Current 3D culture technology mostly require chemical treatment or ultraviolet radiation to crosslink the polymers into insoluble ECM, which may cause damage to the embedded cells/tissues. Moreover, most of the 3D ECMs are macroscale (at least millimeters) scaffolds where the embedded cells/tissues may suffer from deprivation of oxygen and nutrients without the use of complex perfusion/bioreactor systems to maintain cell survival.[2] Here, we describe a method to encapsulate cells/tissues in the collagen ECM of biomimetic microcapsules with an alginate hydrogel shell, which allows precise control of the microenvironment to modulate the cell/tissue proliferation and development. Alginate was used due to its excellent biocompatibility and reversible gelation with divalent cations such as Ca^{2+} or Ba^{2+} under gentle conditions. Further, alginate shell acts as an provides sufficient mechanical strength/structural support to maintain the integrity of the core collagen ECM. Moreover, this biomimetic miniaturized 3D platform 1) ensures effective transport of regulatory molecules (oxygen, nutrients, and cytokines), 2) mediates/regulates cell-cell contacts and autocrine/paracrine signals, and 3) enables control of cell-ECM interactions by changing the properties of core ECM. Using the core-shell microcapsule system, we studied the proliferation, differentiation, and development of mouse embryonic stem cells and mouse preantral follicles.

METHODS

To prepare core-shell microcapsules, 3D non-planar microfluidic device in PDMS was fabricated using standard photolithography and soft lithography techniques.[3,4] Microfluidic device consisted of four inlets I1, I2, I3, and I4 to inject mineral oil infused with aqueous calcium chloride solution (Ca^{2+} oil emulsion), sodium alginate solution, ice-cold collagen solution (with or without cells/tissues), and cellulose solution, respectively. At the flow-focusing junction, the alginate (shell) and collagen (core) solutions were pinched off into spherical droplets by the Ca^{2+} oil emulsion as a result of interfacial tension. Alginate in the outer or shell layer of the spherical droplets was further gelled to form hydrogel when flowing in the serpentine channels by Ca^{2+} in the oil emulsion. Following gelation microcapsules were extracted from oil phase to aqueous phase in the extraction channel.. Microcapsules formed for the purpose of this study have a total and core size of 380.9 ± 33.98 μm and 285.05 ± 80.4 μm in diameter, respectively.

Using this technique we changed the structural and mechanical properties of the core ECM by modulating the concentration of collagen from 0.5-5 mg/ml. In some cases, alginate was also added to the core ECM to increase its mechanical stiffness. We measured the viscoelastic properties including both storage (G`, representing elastic effect) and loss (G``, representing viscous effect) modulus of ECMs made of either single component (0.5-5 mg/ml collagen) or two components (a mixture of 5 collagen and 5 mg/ml alginate) to further increase the mechanical stiffness of the core ECM. In this way, we were able to regulate G` between 0.48 Pa and 429.74 Pa and G`` between 1.14 Pa and 68.45 Pa.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

We encapsulated mouse embryonic stem cells (mESCs) in the different core ECMs (0.5-3 mg/ml) to investigate their effect on the cell proliferation and differentiation. Collected microcapsules (containing 48 ± 11 cells/microcapsule) were then cultured in stem cell culture medium for up to 10 days. **Figure 1A-F** shows the typical phase contrast and corresponding live/dead staining images of stem cell aggregates formed on day 10 in different collagen ECMs. As it is evident from the images, we observed the formation of a single massive aggregate (313.1 ± 75.8 µm) in the ECM with lower concentration of collagen (0.5 and 1.5 mg/ml) compared to significantly smaller and multiple aggregates (128.1 ± 51.9 µm) in the ECM with higher concentration of collagen (3 mg/ml). The gene expression data shown in Figure 1H indicate that as the adhesion ligand/elastic modulus of the encapsulating ECM increases, the expression of three pluripotency markers (Sox2, Nanog, and Klf2).

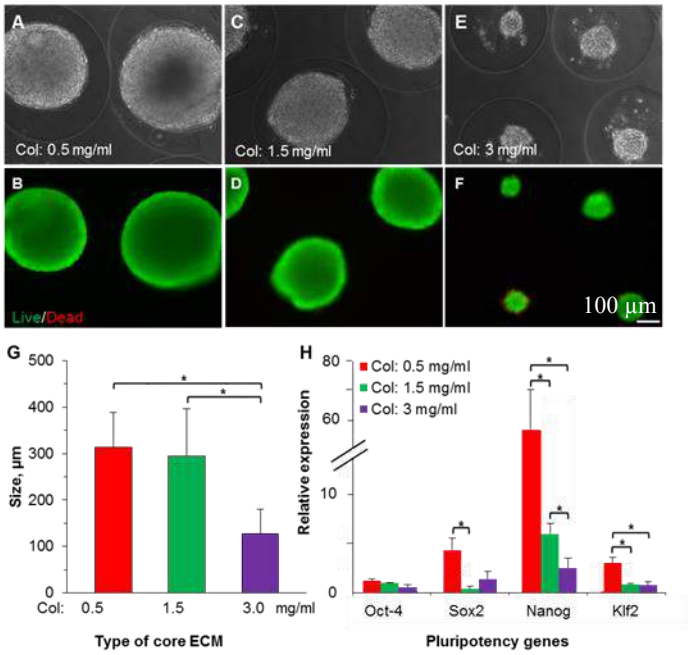

Figure 1: Proliferation of mouse embryonic stem cells in core-shell microcapsules with different ECM properties

We next encapsulated preantral follicles in the core-shell microcapsules to study the effect of ECMs on follicle development. The follicles were encapsulated in three types of core ECMs: 1 mg/ml collagen, 5 mg/ml collagen, and a mixture of 5 mg/ ml collagen and 5 mg/ml alginate. Quantitative data showing proliferation (diameter of follicles) of preantral follicles at 1, 6, 8, and 10 days of culture in the core ECMs **(Figure 2A)** indicates higher proliferation in 5 mg/ml collagen ECM compared to others. The antral follicles obtained after 10 days of culture were typically >300 µm in diameter. Representative DIC and live/dead images showing the morphology and high viability of cells in the encapsulated follicle at day 10 are given in Figure 2B, C, respectively. Figure 2D shows the DIC image of an antral follicle released from the microcapsules together with the oocyte and fluid filled antral cavity in the follicle. We observed 24.4% (11/45) development of preantral follicles to antral stage in 5 mg/ml collagen core ECM (Figure 2E). By contrast, development of follicles to antral stage remarkably decreased to 2.6% (1/38) when the concentration of collagen was lowered to 1 mg/ ml. Interestingly, when the mechanical properties of

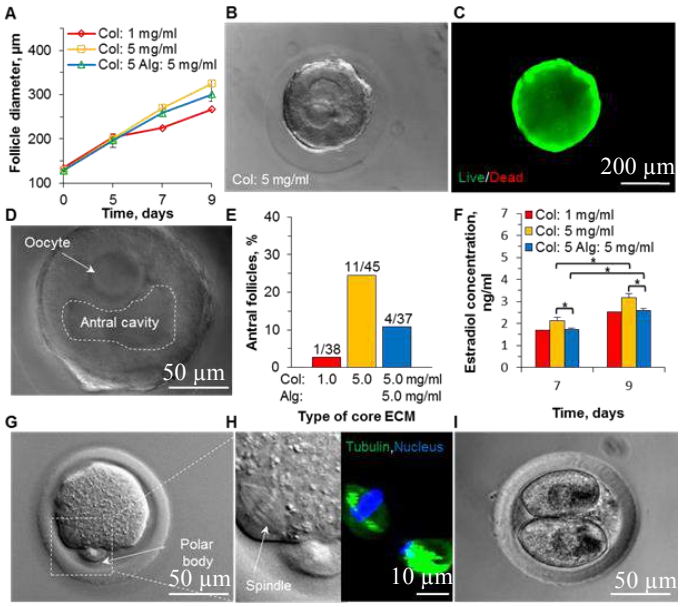

Figure 2: Proliferation and development of preantral follicles in core-shell microcapsules.

the core ECM core was increased while keeping the number of adhesion ligands the same (5 mg/ml collagen by adding 5 mg/ml alginate), we also observed lower (10.8%) development of follicles to the antral. Further, we observed significantly higher production of estradiol in 5 mg/ml collagen ECM compared to other ECMs indicative of better quality of antral follicles. *In vitro* maturation (IVM) of the cumulus-oocyte complex resulted in obtaining 5 (45.45%) Metaphase II (MII) oocytes (Figure 2G-H) . We stained their meiotic spindles and nuclei by tubulin (in microtubules of the spindles) antibody and Hoechst, respectively to show the characterstic chaotic arrangement of tubulin. In addition, 3 out of 5 MII oocytes were used to obtain early embryos by parthenogenetic activation, for which we successfully obtained one 2-cell stage embryo (Figure 2I).[5]

CONCLUSION

We showed the effect of adhesion ligands and stiffness of core matrix in core-shell microcapsules on proliferation, differentiation, and development of mouse embryonic stem cells and mouse ovarian follicles. We anticipate this 3D biomimetic platform will find its potential applications in a variety of fields including but not limited to developmental biology, regenerative medicine, and high throughput drug screening.

MODIFICATION OF A PARALLEL PLATE FLOW CHAMBER FOR ANALYSIS OF ENDOTHELIAL RESPONSE TO DISTURBED FLOW

INTRODUCTION

Unidirectional, laminar flow in the straight segments of arteries promotes endothelial cell (EC) survival [1] and production of vasoprotective factors such as nitric oxide and Kruppel-like factor 2 [2,3]. In contrast, recirculating and/or oscillatory flow (collectively, disturbed flow, d-flow) found at arterial bifurcations and sharp turns induces EC turnover [4], compromises barrier function, and promotes an inflammatory EC phenotype [5]. Each of these factors contributes to atherosclerotic plaque formation at points of d-flow [1,3-5].

To date, there are four major methods to study disturbed flow: (1) examine *in vivo* naturally-occurring disturbed flow regions [5,6,7] or modify *in vivo* flow via restrictive cuffs [8-11]; (2) use cone-and-plate devices to rotate the culture dish medium to produce the d-flow pattern, typically using pathological flow waveforms derived from patient data [4,12,13], obstructions in the radial flow path [14], or grooves in the cone [15,18]; (3) modify parallel plate chambers, rectangular chambers with high aspect ratios (length/width:height) typically used for laminar flow, to produce d-flow via step changes [3,17], geometries that induce eddy formation such as a circular flow path [18,19], oscillatory waveforms [7,12], or low shear stress values (~≤0.4 Pa); or (4) custom microfluidic devices that mimic specific physiological geometries such as the impinging flow at the tip of an artery bifurcation [20,21].

Each of these methods to create d-flow has advantages and disadvantages. *In vivo* models provide the most physiologically relevant scenarios, yet conditions cannot be precisely controlled and experiments often prove expensive. Parallel plate flow chambers are simple to build and use. However, when chamber geometry is used to create recirculating flow, the d-flow region may only be several microns in length and therefore not produce enough cells exposed to d-flow for high-cell-demand analysis techniques such as Western blots or flow cytometry. Cone and plate devices efficiently expose a large number of cells to d-flow and can easily apply pathological waveforms, yet they produce sample-wide, homogenous d-flow without precise knowledge of the spatial distribution of recirculating vs. oscillatory flow. Evidence suggests that recirculating and oscillatory flow induced by different geometries *in-vivo* may have distinct pathologically relevant biochemical profiles [10,22,23], so it is critical to be able to resolve these differences. Finally, custom microfluidic devices boast the most pathologically relevant flow but can be challenging to create due to geometry resolution requirements.

Using current devices, researchers must choose whether to have recirculating d-flow with few cells vs. oscillatory d-flow with many cells. We performed a meta-analysis on the usage of high-cell-demand assays, like Western blots or flow cytometry that require millions of cells, in 18 publications that induced d-flow with either a parallel plate chamber (geometry, recirculating) or cone-and-plate device (waveform, oscillatory). Using a one-sided non-parametric sign test for a binomial distribution (α=0.05), we found only ~17% of publications that used geometry-specific d-flow utilized a high-cell-demand assay (p=0.026) compared to ~76% of publications that used pathological waveforms to induce d-flow (p=0.466). These data support the assertion that many current geometry-specific devices do not produce high cell yield [19].

To enable high-cell-content analysis of recirculating d-flow, our lab developed a new gasket for the Glycotech parallel plate chamber with repeating regions of recirculating d-flow. This device produces spatially-consistent eddies that occur uniformly over nearly one-half of the sample total surface area, offering a much higher cell yield than previous recirculating d-flow devices.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

METHODS

COMSOL Multiphysics 4.0 was used to model a steady-state flow of culture medium (μ=0.78·10^{-3} Pa·s) at 37°C using the RAN κ-ω turbulence model with a no-slip wall boundary condition. The flow workspace was 10 mm wide x 58 mm long x 0.127 mm high. 9.5 mm x 1 mm baffles extend outward into the flow path, starting 7.5 mm past the inlet and occurring every 5 mm. This design emulates the recirculating flow found in arterial curvature (Fig. 1). Dimensions were chosen such that: 1) the highest shear stress produced in the area following each baffle was below 12 dynes/cm^2, the reported threshold at which flow produces an atheroprotective EC phenotype; and 2) the flow at these locations formed recirculating eddies. Silicone rubber gaskets were molded by Glycotech (Gaithersburg, Maryland).

Figure 1: Completed prototype with vacuum holes for sealing and molded protrusions for gasket alignment with the chamber.

BAECs (passages 4-7, Cell Applications) were cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum, 1% L-glutamine, and 1% penicillin–streptomycin. BAEC were seeded at 21,000 cells/cm^2 onto 75x25x1 mm glass microscope slides pre-treated with 10 µg/mL collagen Type I for 3 hours. After 1 day, slides were placed into the parallel plate chamber (n=2 per experiment) with either a disturbed or laminar flow gasket. Additional samples were maintained in static culture as controls. Complete DMEM with 25 mM HEPES buffer (to maintain a pH of 7.2-7.4) was used in all flow experiments. Medium was perfused through the flow chamber via a peristaltic pump at a rate needed to produce 20 dyne/cm^2 shear stress for the laminar flow gasket samples. After 24 hours, samples were removed and imaged via phase contrast microscopy at 10x.

RESULTS

Recirculating eddies consistently appeared behind baffles. Simulated eddy size was 3-4 mm long and 5-6 mm wide. The mean shear stress was 0.97 Pa among all 93,400 computational elements; mean shear stress in the post-baffle pockets was < 0.7 Pa (Fig. 2).

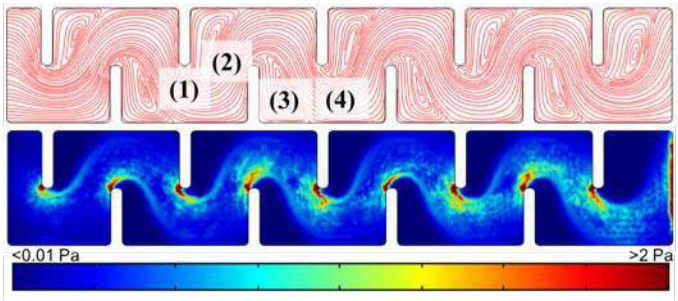

Figure 2: COMSOL simulations of the arterial curvature model gasket. Flow direction is from left to right. (Top): Fluid streamlines with points of interest numbered 1-4. (Middle): shear stress heat map.

Under static conditions, EC maintained a polygonal morphology (Fig 3, A) while cells under 20 dynes/cm^2 (2 Pa) laminar flow elongated in the flow direction (Fig 3, B). Comparatively, cells at point 1 in the d-flow gasket appear elongated in the flow direction, although not as drastically as the laminar samples. Cells in points 2-4 were similarly polygonal to the static control samples.

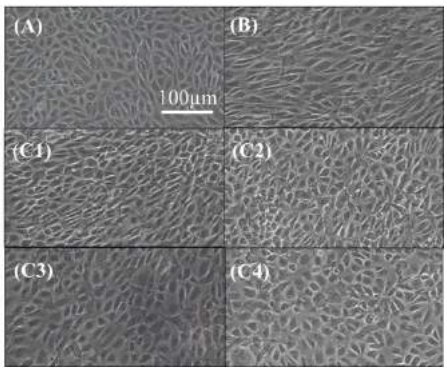

Figure 3: Representative cell morphology in static, laminar, or disturbed flow. Phase contrast microscopy of (A) static sample; (B) laminar flow sample; (C1-4) d-flow samples at locations corresponding with numbers in Fig 2. All images are 10x.

DISCUSSION

83% of the d-flow gasket workspace (480 mm^2) displayed shear stress below 12 dyne/cm^2, meaning that the majority of cells exposed to flow using the d-flow gasket should have an atheroprone phenotype compared to the d-flow surface area of 3.75-265 mm^2 seen in geometry-specific devices that did not use high-cell-content assays. Cells in low shear stress/recirculating zones (points 2-4) had a polygonal shape like the static samples, potentially indicated a disturbed phenotype [4] while cells near the baffle tips at point 1 may be aligning in the small zones of high shear stress. These zones represent a small fraction of the total cell population and would have a negligible effect on protein/RNA analysis.

These preliminary data show a novel parallel plate flow chamber modification for *in vitro* induction of large regions of recirculating d-flow. In the future, we will characterize cells in the d-flow gasket by examining actin structure, cell permeability, and key junctional and inflammatory markers such as β-catenin or ICAM-1/VCAM-1.

INTRODUCTION

As the most ubiquitous protein in the body, type-I collagen has great utility in regenerative medicine. Although collagen is widely utilized as a structural, adhesive network for cell growth *in vitro* and *in vivo*, it is difficult to customize for specific applications in personalized medicine, such as 3D printed collagenous scaffolds, or 3D cell microenvironment design and culture. There are a variety of synthetic materials that potentially fill this void, including poly(ethylene glycol) diacrylate and polylactic acid, but concerns about biocompatibility, release of degradation products, or presence of manufacturing residuals remain [1].

We have synthesized a methacrylate-derivatized collagen, collagen methacrylamide (CMA), which potentially addresses these challenges by imparting two additional properties to collagen while retaining its native bioactive properties. First, CMA is photocrosslinkable: in the presence of a photoinitiator and UV light, CMA can be photocrosslinked to spatially modulate 1) the stiffness through methacrylate coupling in the hydrogel or 2) the bioactive properties through coupling of methacrylated ligands to CMA [2]. CMA is also thermoreversible: CMA rapidly and reversibly self-assembles into a hydrogel at neutral pH when cycled between 37ºC and 10ºC [3]. Additionally, photocrosslinking eliminates thermoreversibility. Herein we will discuss the results of proof-of-principle experiments to use CMA for free-form fabrication, ligand patterning, and 3D culture scaffolds that allow for cell recovery.

METHODS

Collagen Methacrylation

As described in Gaudet et al., the carboxyl group on methacrylic acid was activated with ethyl-3-(3-dimethylaminopropyl) carbodiimide) and N-hydroxysuccinimide and covalently conjugated to free amines on lysine residues on type-I collagen to produce CMA [2]. CMA was dialyzed in acetic acid, lyophilized, and resuspended in 0.02M acetic acid at 3.75 mg/mL for use.

Free-Form Fabrication Studies

Hydrogels were buffered in the following ratio: 10µL HEPES, 68µL 0.15N NaOH, 50µL 10X PBS, 28.5µL PBS, 10µL 10% Irgacure (I2959) in methanol, and 338.5µL CMA (3.75 mg/mL suspension). Hydrogels (100 µm thick) were self-assembled for 1 hour at 37ºC, exposed to UV light (365nm, 50% light, 100 mW/cm^2) through a laser printed transparency for 2 minutes, and were subsequently cold-melted at 4ºC for 30 minutes. Samples were thoroughly washed of cold-melted CMA using PBS, stained using Picrosirius Red, and imaged using a fluorescent microscope.

Ligand Patterning Studies

Hydrogels were buffered as described, however, 28.5µL of ~1 mg/mL Nile Blue Acrylamide (NB) was added in place of PBS as a visible ligand that would couple to methacrylate groups via UV-induced free radicals. Hydrogels (100 µm thick) were self-assembled and exposed to UV through a transparency as described, and imaged using brightfield microscopy. The mechanical properties of samples were assessed using a Kinexus Ultra rotational rheometer with a quartz Peltier-controlled plate to allow for UV exposure during mechanical testing. Samples were loaded onto the rheometer and the temperature was increased to 37ºC and maintained for 10 minutes to allow for self-assembly. Samples were fully exposed to UV for 2 minutes as described. Throughout the measurement, the samples were continuously oscillated (0.5% strain, 1 rad/s) and the resultant torque was measured to acquire mechanical properties of the hydrogel.

Cell Culture and Cell Retrieval Studies

Hydrogel formulations were prepared as follows: 10µL HEPES, 68µL 0.15N NaOH, 50µL 10X MEM, 23.5µL M199, 5µL L-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

glutamine, 5µL Pen/Strep, and 338.5µL CMA (3.75 mg/mL suspension). Hydrogels were further diluted by 10% media containing rat dermal fibroblasts (RDFs) at 10^4 or 10^5 cells/mL. Samples were seeded in 48-well plates and allowed to self-assemble at 37ºC for one hour, and then supplemented with media (DMEM with 10% serum, 1% L-glutamine, and 1% Pen/Strep). After 24 hours, samples were cold-melted at 4ºC, diluted with cold media, and centrifuged, and the recovered cells were reseeded in a 25 cm^2 tissue culture flask.

RESULTS

Free-Form Fabrication Studies

CMA hydrogels photocrosslinked through a laser printed transparency patterned with high fidelity when compared to the photomask (Figure 1). Picrosirius Red staining allowed for visualization of the photopattern via fluorescence (Figure 1B and 1C). Areas of the patterned hydrogel that are not sharp as seen in the photomask (Figure 1C and 1A, respectively) are likely the result of excess photocrosslinking and free radical diffusion into unexposed areas of the hydrogel.

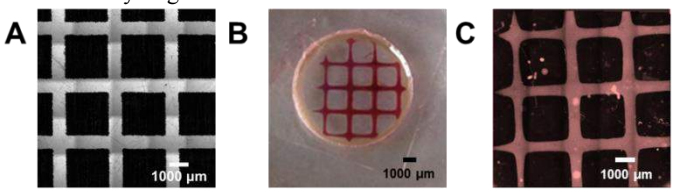

Figure 1: Spatial Patterning of Stiffness in CMA Hydrogels: Photomask (A), Picrosirius Red Stained Hydrogel Macroscale (B), and Microscale (C).

Ligand Patterning Studies

CMA hydrogels can be stiffened through methacrylate-methacrylate coupling or bioactively patterned through coupling of acrylated ligands to methacrylates on CMA. In our study, CMA hydrogels were photopatterned with NB as a representative ligand contrast-agent to visualize photocrosslinking, and to examine the competing effects of coupling on the hydrogel stiffness.

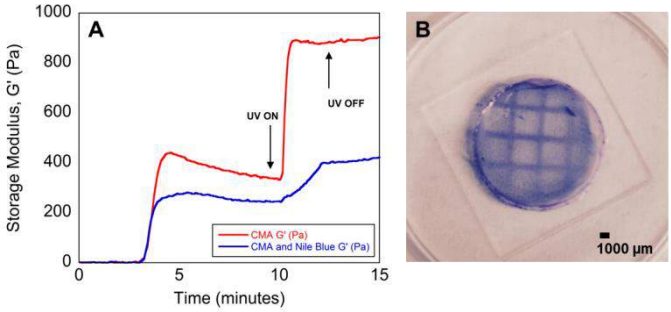

Figure 2: Ligand Patterning of NB in CMA Hydrogels: Effect of Patterning on Hydrogel Mechanical Properties (A) and the Visual Representation of Photopatterning (B).

In rheological studies, CMA prepared with NB demonstrated a lower storage modulus than CMA with only buffers following self-assembly at 37ºC (Figure 2A). Following exposure to UV and Irgacure, hydrogels without NB reached a storage modulus approximately 3-fold higher compared to initial assembly. The storage modulus of hydrogels prepared with NB and fully exposed to UV slowly increased to nearly twice that of the initial measurement due to competing effects of methacrylate coupling within the hydrogel to methacrylate-acrylate interactions between CMA and NB. When the hydrogel was exposed to UV through a photomask, which limits exposure to specific regions of the gel, CMA hydrogels patterned with NB demonstrated precise patterning compared with the photomask (Figure 1A and Figure 2B).

Cell Culture and Cell Retrieval Studies

Following cold-melting, RDFs were difficult to harvest from hydrogels seeded at 10^5 cells/mL, as some hydrogels seeded at this concentration had begun to compact likely due to significant cell remodeling of the matrix. Hydrogels seeded at 10^4 cells/mL were successfully cold-melted, but only ~10% of cells were recovered. Many RDFs were observed to maintain adhesion to small fragments of CMA. Future studies will focus on harvesting alternative cell types, such as those from the neural lineage, which may have weaker adhesion to the collagen hydrogel network.

DISCUSSION

CMA has demonstrated excellent preliminary utility as a tissue engineered scaffold or cell culture substrate. Its properties allow for extensive control over scaffold geometry, and mechanical and/or bioactive properties.

Free-form fabrication and ligand patterning studies demonstrated that CMA hydrogels can be easily patterned in 2D. Initial photopatterning results showed that the fidelity of the pattern was very well maintained, however, excess free radicals led to undesired photocrosslinking. In the future, this may be avoided through the use of a free radical quencher. Ligand patterning had a significant effect on the mechanical properties of the hydrogel. CMA hydrogels with NB were capable of self-assembly, and had a lower modulus in comparison to photocrosslinked CMA scaffolds without ligand. Despite the high ligand concentration, the competing effect of acrylated-ligand-methacrylate and methacrylate-methacrylate coupling resulted in a slight increase in storage modulus.

Studies in cell harvest utilizing CMA as a temporary culture substrate demonstrated preliminary efficacy. CMA hydrogels were capable of disassembly, however, RDFs were highly adherent to the collagen-based substrate, which made detachment procedures difficult. Future studies will focus on utilizing cells from the neural lineage.

The current focus is to combine these three approaches for uses of CMA in regenerative medicine and biotechnology. Customized, 3D tissue engineered scaffolds could be constructed through layer-by-layer self-assembly and photocrosslinking, and subsequent cold-melting of the entire scaffold. Complex, cell-laden CMA hydrogels could be photopatterned with bioactive ligands to influence cell behavior, and if gels are reversible, could allow for cell harvest for further studies. The novel, advantageous properties of CMA described in this work will increase the innovation of collagen-based materials in personalized medicine, cell culture, and biotechnology.

INTRODUCTION

The unique biomechanical function of the meniscus is endowed by its hierarchically structured extracellular matrix (ECM). The ECM is mainly composed of circumferentially aligned fibers. These fibers are interdigitated by radially aligned "radial tie" fibers [1], and wrapped in a superficial layer, also made of radially aligned fibers [2]. The knee meniscus has very limited self-healing capabilities, especially in the inner avascular, proteoglycan-rich zone [3]. Injuries in the meniscus often lead to the development of post-traumatic osteoarthritis, a prevalent osteoarthritis form among the young population [4]. Interestingly, the meniscus has robust self-repair ability at the fetal stage, but progressively loses this function during maturation [5]. In addition to the reduction in cell density [5], one salient change is the alteration in the ECM modulus and collagen fiber alignment [6]. It is likely such matrix changes increase the impedance of cell migration that is critical for self-healing [7]. In order to provide insights for understanding and improving meniscus regeneration, this study aims to reveal how maturation affects the local nanostructural and nanomechanical properties of the meniscus ECM in an orientation- and region-specific manner.

METHODS

Sample preparation. Menisci were harvested from fetal (mid-gestation) and adult (18-30 months old) cows. The outer one-third (outer zone) and inner one-third (inner zone) tissues of each meniscus were isolated and embedded in Optimal Cutting Temperature (OCT) media. The middle zone is not included here since it is similar to the outer zone. Tissue from each zone was cryo-sectioned transversely and radially onto glass slides to produce ~ 20 μm thick horizontal and vertical sections, respectively (Fig. 1). Samples were stored at -20 °C until AFM nanoindentation.

AFM-nanoindentation (Dimension Icon) was performed with a microspherical tip ($R \approx 5\mu m$, $k \approx 0.6$ N/m, μMasch) following established procedures [8, 9]. For each vertical section, testing locations include the circumferential fiber bundles cross-section, radial tie fibers and superficial layer (Fig. 1a). Within each zone, multiple horizontal sections were taken from the intact surface, superficial layer and circumferential fiber-dominated interior (Fig. 1b). At each location, effective indentation modulus, E_{ind}, was calculated via the finite thickness-corrected Hertz model [10]. After nanoindentation, each section was fixed with Karnovsky's fixative and Hexamethyldisilazane drying to preserve the collagen architecture [11].

Structural analysis. Scanning electron micrographs (***SEM***, Zeiss Supra 50 VP) and tapping mode AFM images were acquired to visualize collagen fibril structure at the nanometer scale.

RESULTS

Significant differences in the modulus, E_{ind}, were detected between fetal and adult menisci in the outer zone. On both the vertical (Fig. 1a) and horizontal sections (Fig. 1b), the adult meniscus exhibits higher E_{ind}. In contrast, in the proteoglycan-rich inner zone, no significant age-related differences were detected among all structural units. Correspondingly, SEM and AFM images showed a higher degree of packing and alignment of collagen fibrils in the circumferential fibers of adult meniscus (Fig. 2).

Fetal and mature tissues also showed different nanomechanical heterogeneity across different units. For example, in the fetal tissue, moduli of the radial tie fibers were much lower than those of the superficial layer in the outer zone ($p < 0.05$), despite both are composed of radially aligned fibrils. In contrast, in mature meniscus, this difference was absent (Fig. 1a).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

On the other hand, both adult and fetal tissues also share salient features of heterogeneity and anisotropy, similar to our previously reported results on juvenile meniscus [9]. Nanoindentation along the circumferential fibers (vertical section, along fibril axis) yielded significantly higher moduli ($p < 0.05$) than indentation normal to circumferential fibers (horizontal section, normal to fibril axis). These values are also significantly higher than other structural units.

DISCUSSION

This study underscores how maturation affects the nanostructure and nanomechanical properties of meniscus ECM. In particular, age-associated increase in E_{ind} of the outer zone can be mainly due to the increased packing and alignment of collagen fibrils at the nanoscale (Fig. 2). For nanoindentation along the axis of circumferential fibers (on vertical section, Fig. 1a), higher degree of fibrillar alignment and packing results in increased lateral constraints between adjacent fibrils, and thus, higher modulus. For nanoindentation normal to the fiber axis of circumferential fibers (on horizontal section), a more compliant deformation mode of local fibril uncrimping and realignment is expected to take place. Under this mode, a more organized, densely packed collagen fibril matrix in the adult tissue can provide higher resistance for uncrimping or realignment, and thus, also yield higher modulus.

In contrast to the marked impacts in the outer zone, maturation appears not to influence the properties of the inner zone, which has less organized collagen fibrils and higher proteoglycan content. It is likely that the impacts of maturation are mainly manifested through the organization of collagen fibrils. Interestingly, since the absence of self-healing is most prominent in the inner zone [3], these results suggest the reduced self-healing in meniscus can be, at least partially, attributed to the increased impedance of cell migration through the vascular outer zone near the wound site to reach the avascular inner zone. Manipulation of the outer zone matrix architecture may provide a valuable means to improve the repair of damaged meniscus.

The radial tie fibers also exhibit similar age-dependent changes in the outer zone. These fibers share similar structure of radially oriented fibers with the superficial layer, and similar function of stabilizing circumferential fiber bundles. However, the radial tie fibers appear to be less developed than superficial layer in the fetal stage, as evidenced by much lower modulus on the vertical section (Fig. 1a). This contrast suggests a delayed formation and development of radial tie fibers in accordance with the development of the major structural unit, the circumferential fibers. From fetal to mature ages, the circumferential fibers not only become more organized and packed, but also are interdigitated by stiffer, more aligned radial tie fibers. These trends likely together contribute to the increased impedance for cell migration from the vascular outer zone near the wound site to the avascular inner zone in the mature tissue.

This study delineates the impacts of maturation on the nanoscale structure and mechanical properties of the meniscus ECM in an orientation and region-specific manner. Notably, age-associated changes in the circumferential fiber bundles and radial tie fibers in the outer zone are likely a major factor that determines the increased impedance to cell migration [12, 13]. Study of the maturation dependence and structure-mechanics relationships of native tissue could provide a new path for improving meniscus repair through tuning local matrix mechanical properties.

ACCELERATION OF CRITICAL BONE DEFECT HEALING BY ULTRASOUND RADIATION FORCE IN A RAT TIBIAL MODEL

YX. Qin (1), J. Liu (1), Zhang, D (1), X. Li (1)

(1) Department of Biomedical Engineering
Stony Brook University
Stony Brook, NY 11794, USA

INTRODUCTION

Bone defects, usually caused by trauma, inflammation and tumors, may lead to loss of limb functions and substantially affect the quality of patients' life. When bone is impaired, it undergoes a unique process of self-healing to form new bones, which is regulated by local functional physical stimulation [1]. Therefore, it is essential to find effective methods to accelerate bone healing. Low-intensity Ultrasound radiation force (ARF) or LIPUS, which is a unique form of mechanical energy, can transmit through and into living tissues as acoustic pressure waves, and generate dynamic acoustic radiation force in the local region [2]. Such dynamic stimulation may be able to induce mesenchymal stem cell (MSC) recruitment and differentiation, osteoblast differentiation, extracellular matrix production, endochondral ossification, and mineralization and then may result in biochemical events that accelerate bone formation [3]. Therefore, the objective of this study was to evaluate the effect of ARF induced mechanotransduction in a rat tibial critical bone-defect healing. Following aims will be evaluationed,

1) To create tibial trabecular bone defect model for tissue regeneration.
2) To evaluate ARF ability in acceleration of healing.
3) To evaluate the outcome using μCT, histology, and biomechanical testing.

METHODS

A total of 40 skeletally mature female Lewis rats were used in this study. Bilaterally, the surgical bone defects of 2 mm in diameter were made at proximal tibia. Subsequently, the defects of the left tibia (LIPUS group) received daily treatment of low-intensity pulsed ultrasound, and the defects in the right tibia (Control group) received sham stimulation as the non-treated contralateral control. Sonicator® 740, ultrasound generator with a transducer of 1 cm^2 in cross-sectional area (16 mm in diameter) was used for LIPUS stimulation. A modified repetitive frequency at 100 Hz, and an ultrasound characteristic frequency of 1 MHz and a pulse width of 200 μs at an intensity of 30 mW/cm^2 were used for the stimulation for 20 minutes/day (ISATA). After 2 weeks, the rats were euthanized and the tibias were assessed using micro-CT scanning, histology and mechanical testing. Trabecular bone volume fraction (%, bone volume/total volume, BV/TV), connectivity density (1/mm^3, Conn.D), trabecular thickness (mm, Tb.Th), trabecular separation (mm, Tb.Sp), trabecular number (1/mm, Tb.N), and tissue mineral density (mgHA/cm^3, TMD) were evaluated. After micro-CT scanning, one part of each tibia sample was fixed in 10% phosphate-buffered formalin, dehydrated through graded ethanol, decalcified, and embedded in paraffin. Sections of 5 um were made for hematoxylin & eosin staining. Osteomeasure software was used to evaluate the newly formed trabecular bone in the defections of tibia. BV/TV, Tb.Th, Tb.Sp and Tb.N were measured. The other part of each tibia sample was used for four-point bending to examine the stiffness and strength using a MTS mechanical testing system (585 Mini Bionix II) with a 100 N force transducer (SMT1-100 N, Interface).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

2 weeks after surgery, the micro-CT images showed that trabecular bone formed in the defect area of both LIPUS and control group (Fig. 1). Additionally, new bone formed in LIPUS group was more than that in control group. In comparison to control group, LIPUS treated tibia showed increased in BV/TV, Coon.D, Tb.N, and BMD, and significant decrease in Tb.Sp. Osteomeasure analysis showed a similar trend, which is in line with the micro-CT results. As show in Fig. 2, BV/TV and Tb.Th were higher in LIPUS group than those in control group, and Tb.Sp was lower in LIPUS group than that in control group. Four-point bending mechanical testing data showed LIPUS treatment significantly increased the bone stiffness (kN/mm) relative to control group (Fig. 3). Ultimate load (N) at mid-shaft of tibia showed an increasing trend, but no significant increase was observed following the exposure to LIPUS, when compared to control group (t=1.968, *P*=0.056).

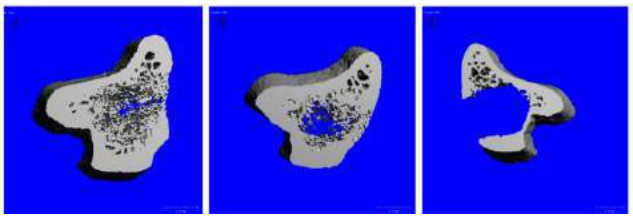

Figure 1: Three-dimensional images of tibia bone defects. (A) LIPUS group. (B) Control group. (C) Micro CT Scan Immediate postoperative.

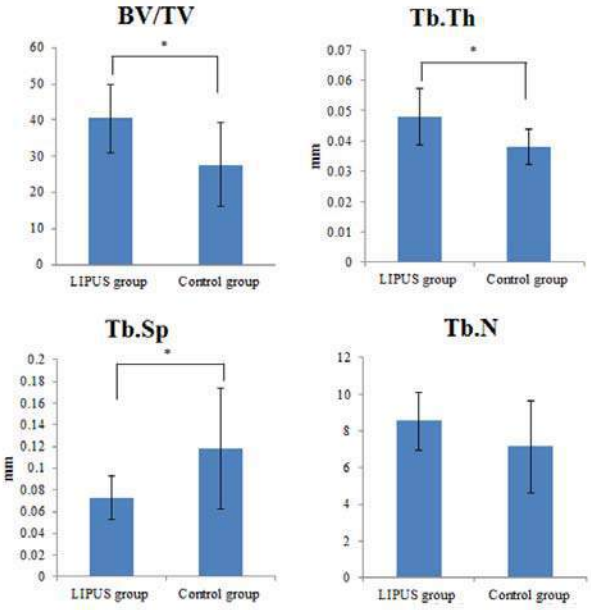

Figure 2: Histomorphometric analysis of newly formed trabecular bone was performed using Osteomeasure. The treatment of ARF promoted bone formation significantly more than control (~33%).

.

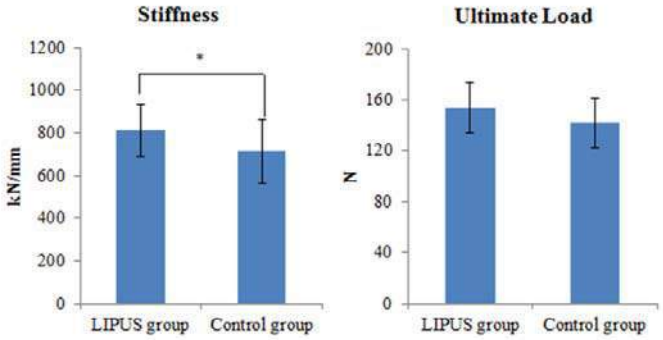

Figure 3: Mechanical testing results at the tibia indicated that stiffness was enhanced in the treatment group.

DISCUSSION

The histological analysis and micro-CT data revealed that new bone formed in both LIPUS therapy and no-therapy groups with tibia bone defect in 2 weeks after bone surgery, and ARF therapy can significantly increase new trabecular bone volume. Moreover, bone stiffness and ultimate load of ARF treated bone were higher than no-therapy group, and LIPUS therapy increased rat bone strength. Two weeks seem to be the key period for bone regeneration after bone defect surgery. During this period, performing ARF therapy on bone defect site could efficiently accelerate bone healing by stimulating trabecular bone formation [2].

SIGNIFICANCE: The data shown in this study provided direct evidence that LIPUS therapy improved bone healing by accelerating the development of newly formed trabecular bone after 2 weeks of bone defect surgery.

INTRODUCTION

Valve interstitial cells (VICs) reside in heart valve tissues and play critical roles in the tissue maintenance, but also the cause of heart valve diseases [1]. VICs are myofibroblast-like cells with tissue remodeling activity due to collagen production and contraction activities mediated by α-smooth muscle actin (α-SMA) stress fibers. The VICs are activated by mechanical stimuli during tissue repair, development, and remodeling, and removed as they complete their role. The VICs are sensitive to their surrounding microenvironments, and excessive and persisting environmental changes cause the improper regulations of VICs, contributing the progression of valve disease. Thus, it is important to characterize how the external mechanical stimuli translate into and activate the VICs, and how the different activation levels affect the VIC's internal mechanics and their mechanical response to the surrounding tissues.

Heart valve leaflets experience dynamic and complex mechanical stress states over the cardiac cycle, including surface shear stress due to blood flow, flexure (opening and closing), and high in-plane tension (closed valve). The resulting forces are translated to the VICs through the complex micromechanical interactions with the extra cellular matrix (ECM) such as collagen stretch with reorientation and fiber compaction. VICs thus interact with the ECM in highly stress-dependent manner in a valve tissue [2, 3, 5]. Recently, the stiffness of mitral heart valve VICs (MVICs) within leaflet tissues under controlled biaxial loading were estimated using finite element simulations [6]. This study found that while the MVIC effective stiffness was quite similar within each of the four leaflet layers, MVICs experienced significantly different mechanical deformations resulting from differing layer microstructures. It is also known that cyclic strain of the Mitral valve leaflet activate the MVICs, and the larger maximum strain activated the MVICs more [2]. These studies indicate that MVICs respond to the mechanical stimuli in strain or strain-rate dependent manner. In fact, the Aortic VICs exhibit viscoelastic responses under micropipette aspiration experiment [3].

The objective of this study is to analyze the strain-rate dependent mechanical properties of the AVICs. The microindentation experiment was carried out on the AVICs with 3 different indentation patterns: slow, fast, and physiological, to assess how the AVICs respond differently to the different strain patterns. Also, the activation states of the AVICs were controlled by treatment with chemical reagents to assess how the AVICs in different activation state behave differently to the indentation.

METHODS

We used a spherical indenter with 5 μm diameter. In the experiment, we controlled the activation states of the aortic VICs (AVICs) with different chemical reagents to alter the biomechanical properties of the stress fibers. Then, using the experimental data from different experimental groups, we studied how the different components of the stress fibers (α-SMA and F-actin) influenced the stress fiber biomechanics, such as their stiffness and contractile strength. We have five experimental groups: Cytochalasin D pretreated group (CytoD), Control groups with 5 mM and 90 mM KCl treatments (C5 and C90 groups, respectively), and Transforming growth factor-beta1 (TGF- β1) pretreated groups with 5 mM and 90 mM KCl treatments (T5 and T90 groups, respectively).

We carried out the microindentation experiment on AVICs cultured on a flat thin-layered collagen substrate over a glass. After 5 days of incubation, the biomechanical properties of control and TGF-β1 treated AVICs were measured using an atomic force microscope (MFP-3D, Asylum Research, Santa Barbara, CA). The TGF-β1 and non-treated AVICs were first tested under normal physiological levels of 5mM KCl at 37°C. The same AVIC sample was then incubated at 37°C

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

for 10 minutes in hypertensive levels of KCl (90mM) and retested. Finally, the same AVIC sample was treated with 20μM Cytochalasin-D (Sigma-Aldrich, St Louis, MO) for 10 minutes at 37°C to cause complete depolymerization of the actin network and tested using microindentation a third time. To ensure CytoD concentration and incubation time was effective, samples were given CytoD supplemented with 90mM KCl and measured using microindentation. There was no measured increase in stiffness between the 5mM and 90mM controls when delivered with CytoD (data not shown).

Three patterns of microindentation were carried out: slow, fast, and physiological (Figure 1). For the slow and fast indentation patterns, overall time length of indentation were controlled to be around 1000 ms and 100 ms, respectively. For the physiological indentation mode, the indentation pattern was controlled to mimic the deformation pattern of the heart valve tissue in physiological condition [4]. Thus, the physiological indentation mode consists of 50 ms of indentation, 500 ms of hold, and 50 ms of release.

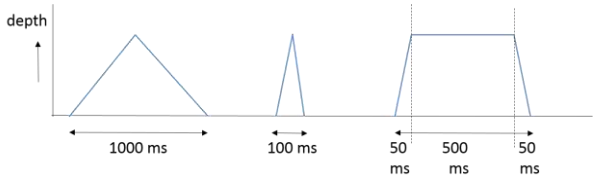

Figure 1: Three modes of indentation patterns: slow (left), fast (middle) and physiological (right).

The indentation depth and force over time were recorded and used to fit the modified Hertz model with thin-layer correction [5] to estimate the stiffness. Also, the standard linear solid model with thin-layer correction was used to determine the viscoelastic properties using the relaxation response of the AVICs during physiological indentation [6].

RESULTS

Generally the AVICs exhibit stronger resistance to the fast indentation than to the slow indentation, especially for TGF-β1 treated groups (Figure 2). The Hertz elastic moduli for different experimental groups were determined by Hertz model with thin-layer correction (Figure 3). The "apparent" stiffness of the AVICs increased as they were activated more with KCl 90mM and/or TGF-β1 treatments. The increase in the apparent stiffness was more pronounced with the fast indentations with TGF- β1 treatments, indicating the strain-rate-sensitivity of the AVICs mechanical responses for these groups.

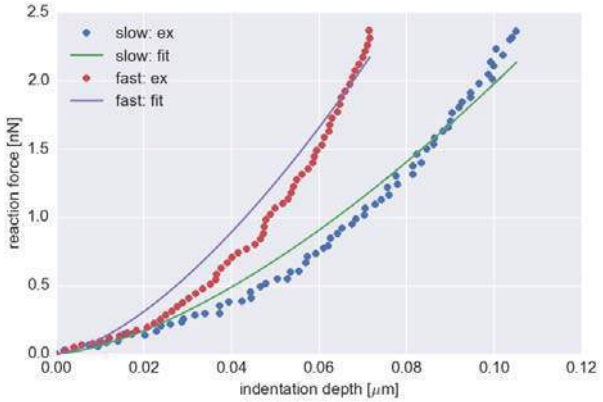

Figure 2: Typical indentation depth vs force curves for slow and fast indentation modes from T90 group.

We then used the relaxation responses of the AVICs from the physiological-pattern indentations to determine their viscoelastic properties under different activation states. We used the standard linear solid model (a spring-dashpot in parallel with another spring). The determined k1 values (the independent spring element) are: 0.16, 2.2, 5.1, 4.7, and 12.8 kPa for CytoD, C5, C90, T5, and T90 groups, respectively. The determined k2 values (the spring element in the spring-dashpot) are: 0.51, 0.94, 2.0, 1.7, and 3.6 kPa for CytoD, C5, C90, T5, and T90 groups, respectively. Finally, the determined μ value (dashpot) are: 0.026, 0.064, 0.10, 0.11, and 0.15 kPa*s for CytoD, C5, C90, T5, and T90 groups, respectively. These results indicate that not only the stiffness of the AVICs increased as they were activated, but also the strain-dependent, viscous response also strengthened for TGF-β1 treated groups. It corresponds to the observation that the apparent Young's modulus increased as the speed of indentation increased (Figure 3).

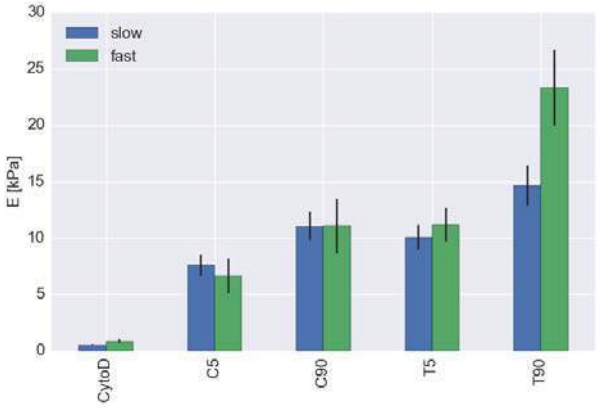

Figure 3: Hertz elastic moduli of AVICs for different experimental groups.

DISCUSSION

In this research, 3 patterns of indentations were applied to the AVICs and their mechanical responses were studied. The primary finding is that the AVICs exhibit strain-rate-dependent mechanical response to external stimuli for TGF-β1 treated groups, where the AVICs resist stronger to the faster indentation than slower indentation. The viscoelasticity of the AVICs were further studied using the standard linear solid model. Again, the TGF-β1 treated groups exhibited larger viscosity values (μ), validating the strain-rate sensitivity. Also, as expected, treatments with KCl and TGF-β1 increased the apparent stiffness of the AVICs. These results indicate the need for a strain-rate-dependent model and analysis for the study of AVICs, as they are under dynamic and rapid loading conditions in the physiological environment.

INTRODUCTION

The most common phenotype associated with coronary plaque rupture is the thin capped fibroatheroma (TCFA) lesion. TCFAs are characterized by a necrotic core with an overlying fibrous cap of <65 μm thickness and a high infiltration of macrophage cells [1]. In-vivo detection of this type of lesion is only possible using intravascular imaging methods such as intravascular ultrasound (IVUS) and/or optical coherence tomography (OCT), though neither of these modalities may be sufficient by themselves. IVUS is an ultrasound based technique capable of penetrating the coronary wall. More specifically, virtual histology (VH) IVUS can assess plaque morphology and is capable of distinguishing plaque components such as necrotic core. On the other hand, OCT is a light based tool with high spatial resolution (10-15 μm) though it is disadvantaged by its poor penetration depth (<2.5 mm) and its inability to see through lipid. Given the lower spatial resolution of IVUS (100 μm) it can be seen that these modalities are complementary if used in conjunction and hence may aid in TCFA detection.

Wall shear stress (WSS) plays a mechanistic role in plaque development, and low WSS has been shown to correlate to increases in plaque area [2, 3]. Further, it has been hypothesized that regions of high WSS may be responsible for transformation to a vulnerable plaque and co-localize with thinning of fibrous caps [3, 4]. Contrarily, another study found that low WSS was correlated with thinner fibrous caps [5]. The previously reported relationships between WSS and both necrotic core size (VH-IVUS) and fibrous cap thickness (OCT) were found in separate patient populations. This work aims to assess the relationship between focal hemodynamics and plaque morphology as assessed by VH-IVUS and OCT in a single patient population. This is achieved by co-registration of VH-IVUS and OCT images and determination of WSS through computational fluid dynamics (CFD).

METHODS

Patients (n=4) who had previously received VH-IVUS and OCT imaging during cardiac catheterization were selected for this study. A fully automatic method involving dynamic time warping and dynamic programming was used to co-register both modalities [6]. Longitudinal/axial co-registration of IVUS and OCT images was achieved by dynamic time warping.

Following one to one image co-registration in the axial direction the images were then co-registered circumferentially using a dynamic programming method. Three features, namely, lumen eccentricity, catheter angle, and calcification, are used to construct a cost matrix. The minimum cost path is then backtracked through the cost matrix. Each value in the minimum cost path corresponds to the co-registration angle between each longitudinally matched IVUS and OCT image. Figure 1 shows an example of co-registered IVUS and OCT images in the longitudinal view along with two co-registered cross-sectional views and their associated cost.

In order to create a 3D model of the coronary arteries VH-IVUS images are combined with the 3D catheter path reconstructed from angiographic images. Side-branches greater than 1mm are added to the 3D reconstruction and a tetrahedral mesh with prismatic boundary layer is created using ICEM-CFD (ANSYS). Patient-specific blood flow velocity is measured by TIMI frame count and applied as an inlet boundary condition. A zero pressure outlet boundary condition was applied to all outlets. Simulations were performed using Fluent 12.0

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

(ANSYS). WSS is analyzed in 8 sectors in each IVUS image and associated with VH-IVUS plaque composition and OCT plaque composition.

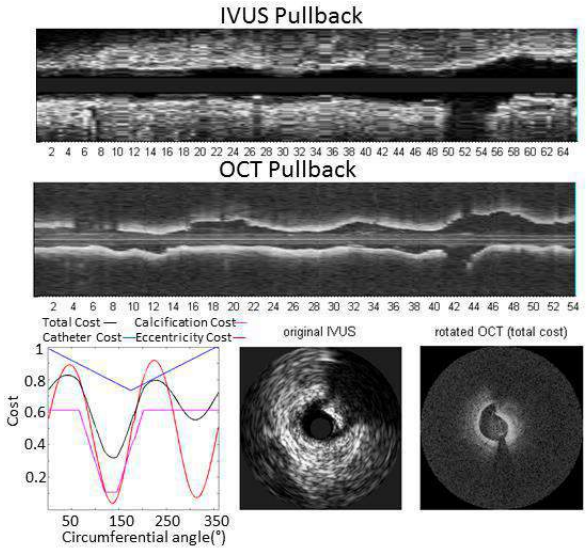

Figure 1: Co-registered VH-IVUS (top row) and OCT (middle row) images displayed in the longitudinal view. Circumferential cost associated with the co-registration of 2 images (bottom row). The lowest cost is found at an angle of 145°, i.e., the OCT image is rotated by 145° to match the orientation of the VH-IVUS image. A calcification in the co-registered images can be identified between 12 and 4 o'clock.

RESULTS

OCT images were successively co-registered to VH-IVUS images (Figure 1). The mean VH-IVUS and OCT pullback lengths were 65.9±22.6 and 70.1±11.9 mm, respectively. The mean co-registered pullback length was 48.8±17.6. Patient-averaged plaque burden as measured by IVUS was 59.3±7%. Contours of WSS for each patient are shown in Figure 2. WSS maps were qualitatively compared with VH-IVUS maps of plaque thickness, necrotic core and OCT maps of calcification. As can be seen in Figure 3 an area of low WSS corresponds to a region of large necrotic core area.

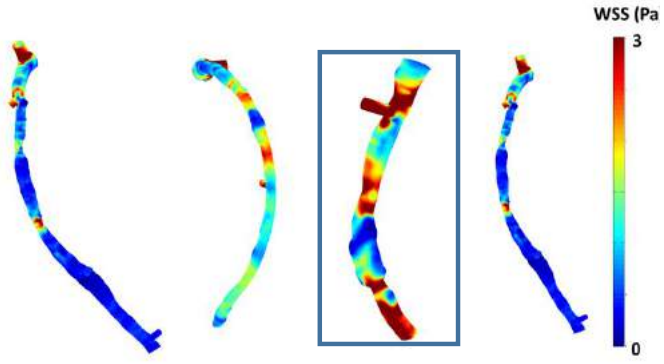

Figure 2: WSS for each patient. Vessels are not shown at the same scale

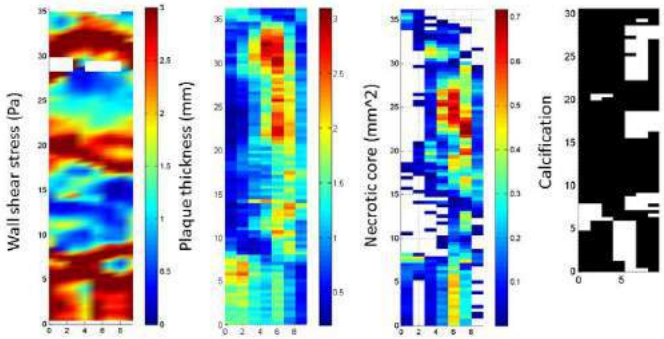

Figure 3: Example (boxed patient in Figure 2) of unwrapped WSS and VH-IVUS defined plaque thickness, necrotic core area and OCT defined calcification. The OCT calcification is displayed as a binary value (1 if present) and has been co-registered longitudinally and circumferentially to the IVUS pullback.

DISCUSSION

In order to further understand the role of WSS in coronary artery disease we developed our methodology using a small number of heavily diseased patients who received both IVUS and OCT imaging. IVUS and OCT images were co-registered automatically providing the ability to conduct a focal analysis of the relationship of WSS and plaque composition. Key determinants of plaque rupture were examined, such as plaque thickness and necrotic core area. Calcifications as observed by OCT were also investigated. While we have shown calcifications as a binary value, it is possible to determine calcification area from OCT whereas because ultrasound does not penetrate calcium IVUS underestimates calcium area [7].

In conclusion, we have developed a framework to analyze the relationship of WSS and plaque morphology through the co-registration of IVUS and OCT images Future work will involve quantitatively analyzing the relationship between WSS and plaque morphology. Further, we will determine fibrous cap thickness and macrophage presence from the OCT images and investigate its co-occurrence with regions of disturbed (low or high) WSS.

ASSESSING THE ABILITY OF HOCKEY HELMETS TO REDUCE CONCUSSION RISK

Bethany Rowson, Steven Rowson, and Stefan M. Duma

Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, Virginia, United States

INTRODUCTION

Football is often the focal point of concussion research due to its popularity, but the rate of concussion is similarly high in ice hockey [1]. Concerns about the potential long-term effects associated with repeated head injuries emphasize the need to mitigate concussions in sports [2]. Although the reduction in concussion risk may vary greatly between different hockey helmets, there were previously no objective resources available to consumers to enable informed decisions. The purpose of this study was to develop and implement a methodology for evaluating the risk of concussion in different hockey helmets.

METHODS

Development of the Hockey STAR (Summation of Tests for the Analysis of Risk) evaluation system was based on 2 fundamental principles. The first is that each laboratory impact condition is weighted based on how often similar impacts occur during play. The second is that helmets that decrease head acceleration will decrease concussion risk. These principles are the foundation of the Hockey Star equation (Eq. 1), where E is head impact exposure as a function of location (L) and impact energy (θ), and R is concussion risk as a function of linear (a) and rotational (α) head acceleration. Four impact locations (front, side, top, and back) and 3 impact energies (low, medium, and high) result in a total of 12 unique impact conditions.

$$Hockey\ STAR = \sum_{L=1}^{4}\sum_{\theta=1}^{3} E(L,\theta) * R(a,\alpha) \qquad (1)$$

The Hockey STAR value represents the predicted incidence of concussion for a hockey player experiencing a specific head impact exposure over 1 season of play. The main outcomes of the efforts toward developing this methodology were: design and implementation of a custom impact pendulum for laboratory tests, a process for mapping on-ice head impact exposure to laboratory test conditions, and testing of all available helmet models using the methodology.

A pendulum was chosen for its increased repeatability and reproducibility when compared with other head impact systems (Fig. 1) [3]. A rigid nylon impacting face further increases repeatability between tests, and simulates rigid surfaces encountered in hockey such as ice, boards, and glass. The pendulum impacts a helmeted NOCSAE headform mounted on a Hybrid III neck. The head and neck are mounted on a slider table that simulates the effective mass of the torso during impact. To measure the kinematics resulting from impact, the headform is instrumented with a 6 degree of freedom sensor package consisting of 3 linear accelerometers and 3 angular rate sensors. The headform responses from pendulum impacts in the lab were compared to on-ice data by generating corridors from both on-ice player data and ice rink testing with a Hybrid III head. The laboratory impacts proved to be biofidelic when compared with the on-ice data.

Several steps were taken to relate on-ice head impact exposure to laboratory impacts. First, distributions for linear and rotational acceleration data from players were combined into a single bivariate cumulative distribution function (bCDF). The bCDF results in a single percentile output for any combination of linear and rotational acceleration. The next step was to map the bCDF to laboratory impacts by determining the percentiles over a range of pendulum impact energies (arm angles). The result of the mapping was a single cumulative percent of player impacts for each laboratory impact energy. This analysis was performed for all 4 impact locations.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Figure 1: The custom impact pendulum device was used to strike a NOCSAE headform mounted on a Hybrid III 50th percentile neck. The head and neck were mounted on a sliding mass that simulated the effective mass of the torso during impact.

Three impact energies were selected for the Hockey STAR evaluation system to encompass a wide range of head accelerations that included both sub-concussive and concussive impacts. The impact energies selected, in terms of pendulum arm angles, were 40° (low), 65° (medium), and 90° (high). The weighting of each impact in the evaluation system was determined by creating impact energy bins with bounds midway between each impact condition. The cumulative percent of player impacts within each bin, multiplied by the total number of impacts for that location, was used as the exposure weighting for that condition. Both player exposure data and laboratory impacts were divided by impact location. The total number of impacts per player per season, and the percent of impacts by location were taken from the literature [4, 5].

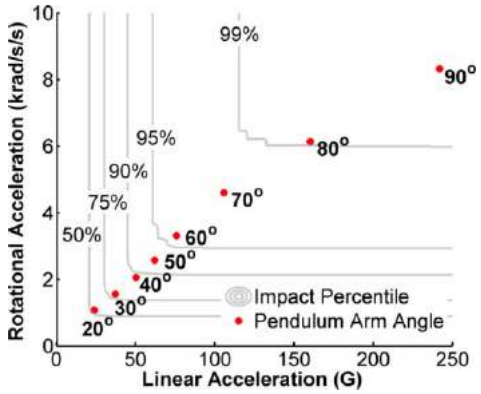

Figure 2: Bivariate cumulative distribution functions (bCDF) were used to determine the cumulative percent of impacts that fell below each pendulum arm angle. This figure shows the bCDF for the front location.

Using the impact pendulum and exposure weightings described above, all commercially available hockey helmets were tested to identify differences in performance between them. For each of the 12 laboratory conditions (4 impact locations and 3 energies), 2 tests per helmet were performed. The peak linear and rotational accelerations were then averaged for repeated tests. The risk of concussion was calculated using the average peak resultant linear and rotational head accelerations for each impact condition [6]. The risk was then multiplied by player exposure to determine incidence of concussion for that condition. The incidences for all 12 conditions were then summed to determine the Hockey STAR value. Two helmets per model were tested, and the Hockey STAR values averaged to a single value per model.

RESULTS

The total number of impacts per player per season was 227. The front, side (right and left combined), and back location each accounted for 30% of the impacts, while the top occurred less frequently at 10%. The head impact exposure of a single player over 1 season for each of the 12 laboratory conditions is shown in Table 1.

Table 1: Player exposure to each impact condition. All conditions together sum to 227 impacts per player per season.

	40°	65°	90°	Total
Front	62.9	4.6	0.6	**68.1**
Side	65.6	2.2	0.3	**68.1**
Top	21.5	1.1	0.1	**22.7**
Back	61.4	4.5	2.2	**68.1**
Total	**211.4**	**12.4**	**3.2**	**227**

All commercially available hockey helmets were evaluated and rated using these methods. A total of 37 available helmet models translated to 1,776 impact tests. The Hockey STAR values ranged from 10.13 to 2.98, with larger values representing a greater risk of concussion. The median Hockey STAR value [25^{th} – 75^{th} percentile] was 6.11 [5.00 – 8.18].

DISCUSSION

The methods outlined here are the first to evaluate the ability of different hockey helmets to reduce concussion risk based on both linear and rotational head accelerations. The testing matrix for each helmet is representative of impacts that hockey players see on the ice, and the evaluation system combines the results from all tests based on how often each condition occurs. Hockey STAR values are greater than on-ice concussion rates because this analysis accounted for the underreporting of injury. The STAR value is inclusive of both diagnosed and undiagnosed concussions.

This work presents a novel methodology for comparing the performance of hockey helmets, and demonstrates differences between helmet types in their ability to reduce concussion risk. The Hockey STAR values were translated to a star rating that could be easily interpreted by consumers, and the results were disseminated online (www.vt.edu/helmet). The Hockey STAR methodology provides a scientific framework for manufacturers to optimize hockey helmet design for injury risk reduction, while providing consumers with a meaningful metric to assess the relative performance of hockey helmets.

INTRODUCTION

Intrathecal drug delivery (IT) is an attractive option to bypass the blood brain barrier for targeting the central nervous system (CNS) through increased drug efficacy, reduction in side effects, and cost-effectiveness. However, due to a lack of knowledge of the driving forces of drug transport in the cerebrospinal fluid (CSF), there are no clear guidelines for clinicians to choose drug infusion parameters. Predictive methods to administer therapeutic compounds to specific regions of the spine or the brain would provide physicians with a tool to improve intrathecal drug delivery treatments.

Computational fluid dynamics is a tool which has been utilized to predict CSF flow fields in global models of the CNS and the resulting drug dispersion [1-2]. These in silico models are reconstructed from medical image data and predicted flow rates are validated with CINE MRI velocity measurements. In addition to computational models, bench-top studies model the relationship between CSF mechanics and drug transport. However to accurately describe the fluid dynamics within the human CSF-filled spaces an anatomically consistent model is needed.

The idea of printing a realistic and functional model of the CNS has never been realized before. Using 3D printing techniques capable of printing complex objects [3-5] and medical image derived geometries, we propose to generate a full-sized, anatomically accurate model of the human central nervous system. This will elucidate the driving forces behind drug transport in the CSF and allow validation between three modalities, MRI measured data, subject-specific in silico predictions, and subject-specific 3D printed bench-top models.

The combination of validated CSF flow measurements and drug transport phenomena will enable the prediction and rational design of IT drug administration protocols for optimal drug delivery for brain cancers, spasticity, and chronic pain.

METHODS

Phase contrast MRI anatomical data of the human cranial and spinal CSF-filled space is acquired. The high resolution images provide information on spinal anatomical dimensions as well as nerve root positions, and volumes of the spinal, cranial, and ventricular CSF spaces. (1,6) Additionally, CSF velocity is acquired at axial planes of interest in the spine using CINE MRI for comparison of flow fields and validation of predictive models.

The high resolution T2 image set was segmented into the CSF domain and the tissue domain containing the spinal cord, nerve roots, and brain parenchyma. The detailed subject-specific computational geometry was reconstructed as an STL file. Then a computational volume mesh is generated using 2M tetrahedral elements covering the CSF filled spaces.

The CSF fluid motion in the model of the entire nervous system with subject-specific anatomical boundaries including nerve roots was simulated by solving the continuity and the Navier-Stokes equations for an incompressible Newtonian fluid, where, ρ, is the density, μ the kinematic viscosity, $\vec{g}$(is gravity, $\vec{u}$ and p are the velocity vector and pressure fields, respectively.

Continuity $$\vec{\nabla} \cdot (\rho \vec{u}) = 0 \quad (1)$$

Momentum $$\frac{\partial \vec{u}}{\partial t} + \vec{u} \cdot \vec{\nabla} \vec{u} = -\frac{1}{\rho} \vec{\nabla} p + \mu \vec{\nabla}^2 \vec{u} + \rho \vec{g} \quad (2)$$

The STL obtained from the human MRI data is used as the input for a novel multi-scale 3D printing system that will be developed by integrating macro stereolithography and micro-stereolithography

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

(SL) processes. A micro-SL prototype machine has been developed that can fabricate parts with ~10µm resolution, which would capture the complex geometry of the nerve roots in the CNS. [4]

The model will be printed with flexible and transparent acrylic or epoxy photopolymer materials to emulate the mechanical properties of natural SAS tissues. In addition, translucent materials allow for the visualization of injected tracers and drugs. Flow measurements can be taken by Doppler ultrasound and drug tracking by means of structured-optical systems.

RESULTS

Drug distribution in the subarachnoid space is driven by natural pulsatile motion of the CSF. Fig 1A shows temporal plots of CSF flow measured by Cine MRI at axial planes in the cervical (C4), thoracic (T6), and lumbar (L4) spinal regions. During the systolic phase of the cardiac cycle (red) CSF is forced downward into the spine, and during diastole CSF gradually flows cranially. This measurement is compared to the subject-specific computational predictions, Fig. 1B at all three planes. Additionally, the in silico model provides a full spatial flow map along the spine over the cardiac cycle, as shown in Fig 1C. The third model is reconstructed from MRI data and 3D printed to capture anatomical resolution down to 10µm. Velocity flow data from the 3D printed model will be acquired with Doppler ultrasound as indicated in Fig 1D, and velocity plots compared the other two data sets.

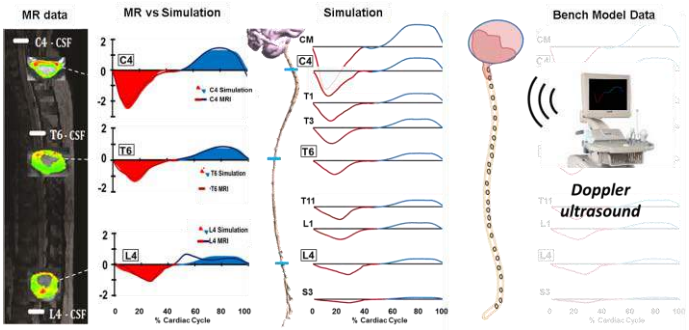

Figure 1: Medical image data for subject anatomy and CSF velocity is extracted for computational and bench-top model validation (A) Anatomical data and CSF flow information is acquired from MRI for the human spinal CSF spaces. (B) CSF flow measurements are compared to in silico predictions at C4, T6, and L4. (C) In silico predictions cover the entire spinal axis. (D) 3D printed model experimental data is extracted with ultrasound to compare to computational and MR measurements.

A magnified view of the cervical spine segment reconstructed from anatomical MR data in the sagittal and axial view is compared in Fig 2, for the computational model and the 3D printed model. The high resolution 3D printing technique easily recreates the complex geometry of the spinal SAS. Geometry-induced mixing has been shown to impact CSF flow and thereby drive drug dispersion.

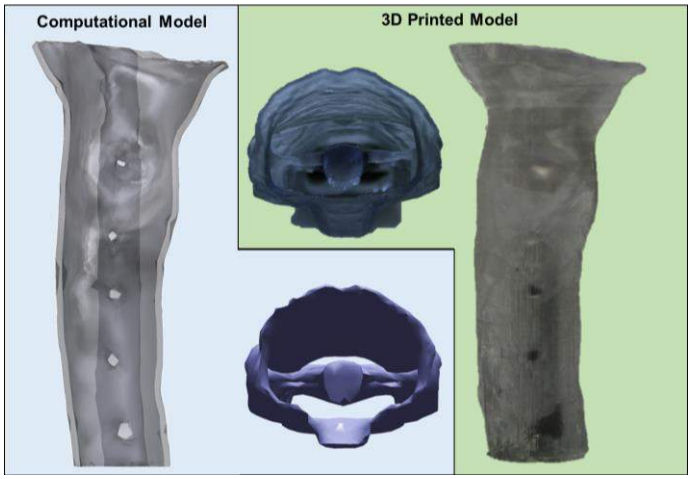

Figure 2: Subject-specific computational model (left) and 3D printed cervical spine segment (right). The Cisterna Magna to the C5 spinal nerve level are reconstructed from MRI data.

DISCUSSION

This research presents for the first time, a subject-specific 3D printed model of the human CSF-filled spaces for comparison to high resolution in silico reconstruction. An anatomically accurate and model of the human CNS can replicate complex fluid flow phenomena in the spinal canal and the brain. These geometry induced mixing vortices are below the resolution capability of MRI but are predicted with computational models. This high fidelity is necessary to accurately predict drug transport in the cerebrospinal fluid to elucidate the driving forces of drug spread.

The bench-top 3D printed model will be anatomically realistic, pulsatile and compliant system of the spinal CNS. This system will allow for detailed and repeatable measurements of the CSF flow. Through validation of a subject-specific CNS test station with computational modeling and MR data this bench-top model will enable the prediction and rational design of IT drug administration protocols for optimal drug delivery for brain cancers, spasticity, and chronic pain.

INTRODUCTION

Despite the overall advancements in the treatment of cardiovascular diseases, heart valve surgeries have seen little real improvements in life expectancy since 1985, where the survival rate after 10 years is still 29.7% [1]. The field has been heading in the direction of percutaneous devices to minimize surgical impact and to serve as an alternative for non-surgical candidates. However, the currently technology is still in its early stages, with a 2-year mortality rate of 43.3% for such trans-catheter devices [1]. Biologically-derived exogenously cross-linked (EXL) tissues such as bovine pericardium (BP) is by far the most popular biomaterial used. BHV failure results from leaflet structural deterioration mediated by fatigue and/or tissue mineralization. In general, while mineralization is associated with serious structural deterioration, significant structural damage is known to occur independently from calcification [2]. Most research for BHV devices focus on calcification, but understanding and being able to model and predict the exogenous cross-linking effects on the biomaterials, specifically the permanent set effect that occurs due to scission healing reactions of the exogenously cross-links used to stabilize and suppress immunogenicity, is equally as important. In the present work we developed a structurally-based permanent set constitutive model to help to better understand and predict the change in mechanical property that occurs due to long-term cyclic loading, and aid in the design of new bioprosthetic devices.

METHODS

General Considerations. Mechanical fatigue occurs in the long term due to structural damage and in the short- and mid-term (first 10-20 million cycles) due to permanent set. Whereas structural damage is categorized by the loss of properties due to degradation and physical tearing, permanent set is in no way due to changes in properties of the constituent material, but due to conversion of existing material to new reference states due to persistent loading. To model permanent set, we will make the following assumptions:

1) There is no change in the mechanical properties of the collagen and the matrix; changes in tissue-level mechanical properties are driven completely by the first order scission/healing reaction of the Schiff-base glutaraldehyde polymers.
2) The process is under physiological conditions, thus can be modeled as an isothermal process.
3) There is no strain-level dependence
4) The rate of scission/healing is much slower compared to the cardiac cycle (i.e. days/weeks vs. seconds).
5) The non-collagenous tissue matrix can be modeled as an isotropic hyper-elastic material.

Permanent Set Model. We adopt the permanent set approach previously developed for rubber like materials [4]. As a modification, we allow continuous evolution of reference states where all existing matrix is constantly being remodeling by the first order kinetics of the scission healing process at the macro-level (Fig. 1). The process is entirely governed by one rate constant k_g for scission and healing. The resulting permanent set that occurs, which is a geometrical change described by a deformation gradient, $\mathbf{F}^*$, from the virgin state to the current stress-free state, depends on the proportion of new and old materials and the stress equilibrium.

Mechanical Response of the Matrix under Permanent Set. In a recent study, we developed a model for the EXL bovine pericardium [3]. We now apply a modification to the model to determine its mechanical response under permanent set. The key mechanism of permanent set is a re-expression of the stress of the material with respect to an alternative reference state. Thus solving the resulting chain rule gives the following 2nd Piola Kirchhoff stress:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

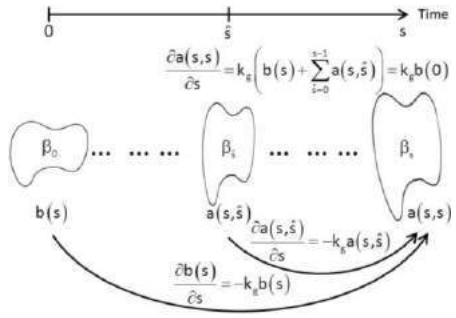

Figure 1: An illustration of the permanent set process, where the original material b(s) is converted to new states a(s,ŝ). The intermediate states are subsequently converted as well.

$$\bar{\mathbf{S}}_m\left(\mathbf{F},\hat{\mathbf{F}}\right)=\left(\mu_\alpha\left(I_1\left(\mathbf{F},\hat{\mathbf{F}}\right)-3\right)^{\alpha-1}+\mu_\beta\left(I_1\left(\mathbf{F},\hat{\mathbf{F}}\right)-3\right)^{\beta-1}\right)\times\left(\hat{\mathbf{B}}^{-1}-\hat{\mathbf{B}}_{33}^{-1}\mathbf{C}_{33}\mathbf{C}^{-1}\right) \quad (1).$$
$$I_1\left(\mathbf{F},\hat{\mathbf{F}}\right)=\mathrm{Tr}\left(\hat{\mathbf{F}}^{-T}\cdot\mathbf{C}\cdot\hat{\mathbf{F}}^{-1}\right)$$

Solving (1) for underlying rate kinetics (Fig. 1) results in the following overall stress of the material

$$\mathbf{S}_m\left(\mathbf{F}(s)\right)=e^{-k_g s}\bar{\mathbf{S}}_m\left(\mathbf{F},\mathbf{I}\right)+\int_0^s k_g e^{-k_g(s-\hat{s})}\bar{\mathbf{S}}_m\left(\mathbf{F},\mathbf{F}\left(\hat{s}\right)\right)d\hat{s} \quad (2).$$

To solve for the permanent set deformation, $\mathbf{F}^*$, a numerical solution is needed. Here, the problem is defined in terms of the number of parameters for $\mathbf{F}^*$, N, and the applied deformation $\bar{\mathbf{F}}$,

$$\mathbf{F}^*=\min_{\mathbf{F}^*\in\mathbb{R}^N}\left\|\mathbf{S}_m\left(\mathbf{F}^*\right)\right\|^2,\qquad k_g=\min_{k_g\in[0,\infty]}\left\|\mathbf{F}^*\left(k_g\right)-\bar{\mathbf{F}}\right\|^2 \quad (3)$$

Permanent Set and Mechanical Studies. First, we measured the permanent set and mechanical properties of glutaraldehyde EXL BP placed under a static strain of 10%, 20% and 30% over the period of 4 weeks; a two state system with only the original and loaded state (Fig. 2A). They were also tested along the preferred fiber direction (PD) and the cross-preferred direction (XD). The tissue strain was quantified using marker tracking [5]. The mechanical properties were determined using a custom built biaxial testing device[6] and analytical method [7]. In addition, we also tested a separate set of specimens where the strain is periodically increased, resulting in a more complex model with multiple states (Fig. 2C). Lastly, we supplemented the results with previous studies done on cyclic strain loading (Fig. 2B)[8] and stress controlled loading (Fig. 2D)[9], which involves a time dependent system for stress loading and the constant increasing strain.

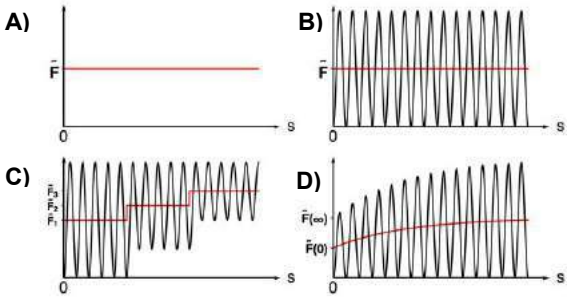

Figure 2: The types of testing that were done showing the actual (Black) and RMS strain (Red). This include a two state system under static (A) and cyclic loading (B), C) multistate system with multistep loading process, and D) a continuous evolution of stats process due to stress loading.

RESULTS

Experimental result shows significantly permanent set in the direction of stretching (Fig. 3A), but not to the full extension ($\lambda = 1.2$). This suggests that the process did not reach completion, and some material still remains in the original state. We also find that this resulted in a stiffening effect along the stretched direction relative to their stress free reference state as predicted (Fig. 3B), significantly limiting the extensibility of the tissue as a result. The resulting rate constant determined from the permanent set stretch shows no statistical difference in the direction of mounting; $k_g = 0.92\pm0.42\times10^{-6}$ s^{-1} and $1.19\pm0.50\times10^{-6}$ s^{-1} for the PD and XD directions respectively ($p = 0.73$). This process is repeated for the multistage data and the stress controlled dataset. Furthermore, the model parameters determined from the PD is used to predict the mechanical response in the XD for validation of the stress loading.

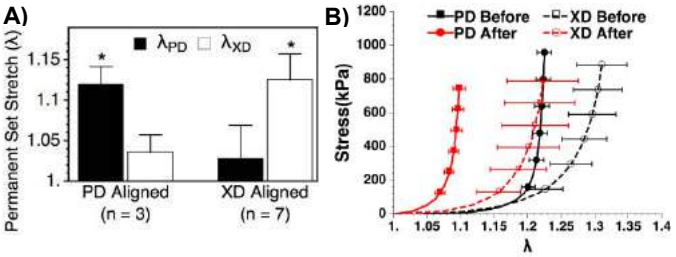

Figure 3: The resulting permanent set stretch for 20% strain is shown in A). B) The results of mechanical testing for the PD aligned group shows that the PD stiffened significantly (Black to Red), corresponding to the significant permanent set stretch in A).

DISCUSSION

In this work, we developed the first permanent set model for exogenously cross-linked tissues based on the underlying scission/healing of the cross-linker. This process does not induce actual structural damage to the tissue, but will nevertheless induce a comparable or larger effect to the mechanical properties. The effective extensibility becomes significantly limited due to the removal of the toe region that occurs. As such, the intended resting geometry of the BHV device is altered, changing the resulting stress distribution, inducing spots with stress concentrations, increasing its wear and tear and ultimately limiting its functionality and durability. Although the effect occurs over a period of 1-2 years, we have observed significant changes in the geometry and mechanical properties after only 4 weeks. Thus proper design of bioprosthetic devices needs to properly account for the permanent set effect to best improve their performance and durability. And computational simulations need to properly consider this effect for predicting the fatigue of tissues.

IN SITU ESTIMATION OF AXONAL INJURY STRAIN THRESHOLDS FOLOWING TISSUE-LEVEL TENSILE STRETCH

INTRODUCTION

Primary axonal injury in white matter is a major cause of functional deficits following central nervous system trauma [1]. During trauma, stress and strain are transferred from the tissue-scale to axons at the micro-scale, though the specific translation between the two scales is unclear. We have previously demonstrated that microstructural features such as axon diameter, tortuosity, kinematics, and connectivity to surrounding glia play a role in the transfer [2]. Computational models have been developed to both understand this transfer, and estimate axonal strains following macroscopic stretch, with the ultimate goal of predicting axonal injury strain thresholds [3], [4]. However, it remains difficult to relate these strains to axonal damage or failure, particularly in situ.

In this study, we exposed chick embryo spinal cords harvested at different stages of myelination to controlled tensile stretch. We estimate axon strain using immunostained Caspr as fiducial markers. Caspr is an ideal marker, as it is expressed in pairs at the nodes of Ranvier along axons. We then identified and catalogued broken axons and adapted our kinematic model [5] to estimate an average strain threshold for axon breakage by fitting the predicted proportion of broken axons to experimental results.

METHODS

Experimental Methods: Chick embryonic spinal cords with varying degrees of myelination were excised and exposed to tensile stretch before being fixed and sectioned into 40µm longitudinal slices. Sections were immunostained for neurofilament, and Caspr. Stained sections were imaged via confocal microscopy with a 100x oil immersion objective. Image stacks were obtained in increments of 0.4µm per image through the depth of the section.

Measurements: Axons were traced through the image stacks. End-to-end and pathlength distances between pairs of immunostained

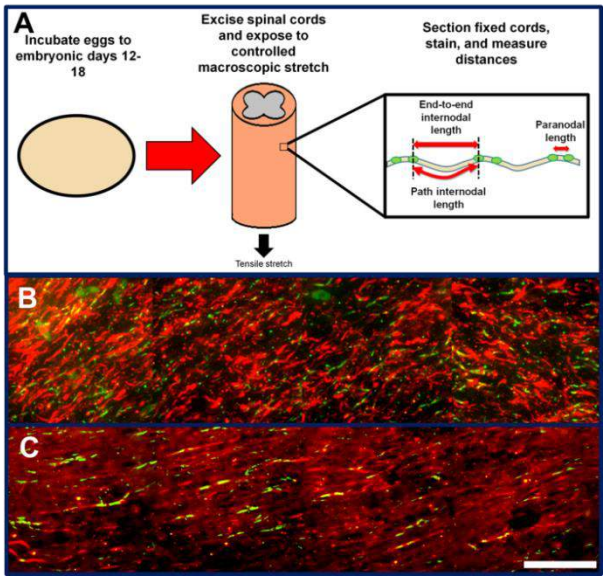

Figure 1: (A) Visual schematic of experimental methods. (B&C) z-projections of imaged longitudinal sections (red = neurofilament, green = caspr) for E18 specimens (B) unstretched, and (C) 20% stretch. (Scale = 50µm)

Caspr (internodal), and individual Caspr proteins (paranodal) along axons were measured (Figure 1A). Broken axons were recorded for different development stages and stretch levels.

Modeling: Kinematic models were adapted from Singh et al. (2015), to predict axon breaking thresholds [5]. Internodal lengths and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

tortuosities for unstretched axons were initialized for each development stage. New lengths and tortuosities were calculated as a function of macroscopic stretch. Each axon was individually assigned a breaking strain threshold selected from a normal distribution. When an axon stretched beyond its threshold based on changes in internodal pathlength, the axon was recorded as broken. The predicted proportions of broken axons were fit to the experimental proportions of broken axons. Probability distribution parameters were varied and the model was iterated until parameters reached convergence.

RESULTS

When all axons were included in the analysis, the average end-to-end internodal lengths increased with development stage and stretch level. We observed a strong correlation between tissue-level stretch and changes in individual axon lengths for E12 and E14 specimens. However, results deviated from this trend at later stages (Figure 2A). We then assumed that once broken, an axon no longer experienced stretch and would therefore not increase in length. When lengths from broken axons were not included in the calculation for change in average length, the averaged data moved closer to the 1:1 line for later development stages, suggesting that more axons were breaking at later stages of development.

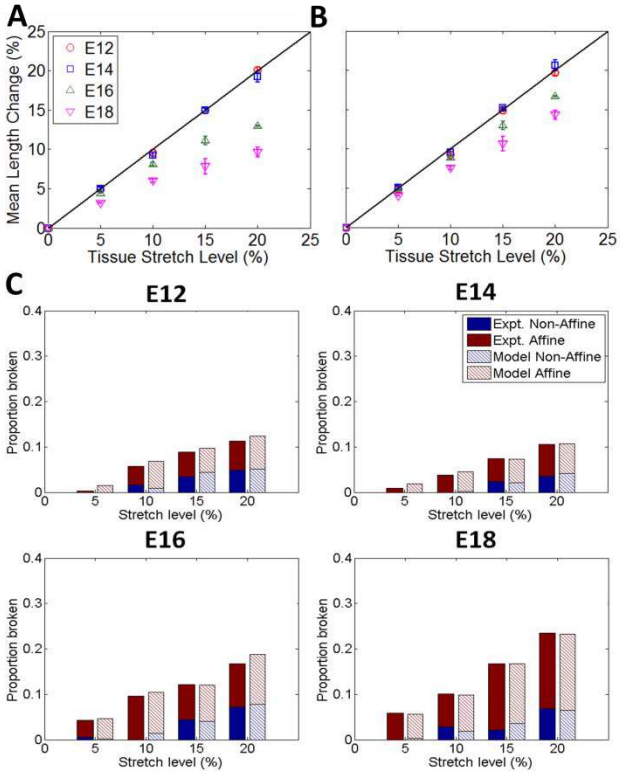

Figure 2: (A) Percentage change in internodal length relative to unstretched tissue was plotted against macroscopic stretch. (B) When lengths from broken axons were not included in the calculation in of average change in length, there was a closer agreement between macroscopic stretch and axon strain. (C) Proportion of broken axons from experiments and model predictions when thresholds were picked from a normal distribution.

By adapting our kinematic model to fit the proportion of broken axons, we determined that individual thresholds picked from a normal distribution provided the best fit (Figure 2C). Thresholds decreased with development stage, from 25% strain to 17% strain (Table 1). When axons were categorized by their predicted kinematic behavior, the estimated thresholds differed, where non-affine axons required more strain to irrevocably injure relative to affine axons.

	Single Threshold	Non-Affine Threshold	Affine Threshold
E12	1.252 ± 0.12	1.291 ± 0.12	1.185 ± 0.13
E14	1.227 ± 0.11	1.284 ± 0.13	1.181 ± 0.14
E16	1.196 ± 0.09	1.269 ± 0.14	1.165 ± 0.09
E18	1.172 ± 0.08	1.270 ± 0.15	1.142 ± 0.10

Table 1: Predicted parameters (mean ± s.d.) for normal distributions of damage thresholds.

DISCUSSION

In this work, we demonstrated a means to estimate axonal strain as a function of macroscopic stretch by measuring changes in internodal end-to-end and pathlengths. We then modeled axon kinematics and fit the proportions of axons predicted to break to experimental results to estimate injury thresholds.

A greater proportion of axons were found to break at later stages of development, which corroborates the lower damage thresholds that were predicted by the model (lower thresholds means axons are easier to break). We examined three distinct regions of the spinal cord (cervical, thoracic, and lumbar) and found no statistically significant difference in proportion of broken axons with regards to region. Along the axon, 96% of axons broke at internodal segments. Examining across the entire cord, we observed no discernible patterns in localization of breaking; axons broke randomly throughout the tissue.

When axons were categorized by their predicted kinematics, and their breaking thresholds calculated, non-affine thresholds were consistently higher than affine thresholds. This correlates well with several findings where *in vitro* preparations of axons, which behave with non-affine kinematics, are able to tolerate up to 75% strain without experiencing injury [6]. In guinea pig optic nerve studies, where nearly all axons are myelinated, coupled to surrounding glia, and are predicted to behave with affine kinematics, these thresholds was closer to 21% [2]. We believe that axons exhibiting affine kinematics experience strain that is commensurate with the macroscopic stretch, whereas in non-affine axons, the macroscopic stretch is initially transferred to straightening tortuous axons, making non-affine axons more resilient to applied tissue-level stretch.

Future work is focusing on characterizing the kinematics of axons once they have broken. We are also investigating methods to snap-freeze tissue immediately following dynamic injury. The results we present provide useful insights into the role of microstructure in injury thresholds, and helps validate predictions made by multi-scale finite element models of central nervous system and axonal injury.

DEVELOPMENT OF CLINICALLY RELEVANT CONSTRAINT MEASUREMENT USING MODIFIED TOTAL KNEE REPLACEMENT IMPLANTS

INTRODUCTION

Despite over four decades of development, there is still no established and universal method for the design, evaluation, and comparison of total knee replacement (TKR) designs. The intrinsic constraint of a TKR system is an important metric for determining the stability, and there are standardized techniques for measuring these properties (e.g. ASTM F 1223-14). These standards describe the resistance to anterior-posterior (AP) and medial-lateral (ML) displacements, and internal-external (IE) rotation under an axial load between the femoral and tibial components at discrete flexion angles. Such tests, however, do not necessarily map directly to any physiologically relevant loading scenarios; thus, comparisons of TKR systems based on these techniques may provide misleading results. Recent advancements in the development of force-controlled joint motion simulators have allowed more physiological in-vitro joint loading, including the contributions of virtual soft tissues. We hypothesize that a function-based technique for measuring TKR constraint may yield a different classification of TKR systems in terms of constraint, as compare with the long-standing discrete-angle measurement technique. Therefore, the objective of this study is to develop an alternative, function-based means of assessing TKR constraint.

METHODS

A parametric computer-aided design (CAD) model of the tibial component of an ultra-congruent TKR with asymmetrical medial versus lateral condyles was created, based on an existing commercially available cruciate-sacrificing TKR. The geometry of the ultra-high molecular weight polyethylene (UHMWPE) insert and tibial tray was modelled as a monoblock tibial component, and further modified into three different designs. Each monoblock tibial component featured different sagittal radii, in order to create high, low, and medium-conformity designs when mated with the existing commercially available femoral component. The three designs were printed with acrylonitrile butadiene styrene (ABS) plastic using a uPrint SE Plus fused deposition modeling machine (Stratasys Ltd. Eden Prairie, MN). The femoral component was affixed onto a custom fixture on the upper actuator of the VIVO 6-DOF joint motion simulator (Advanced Mechanical Technology Inc. Watertown, MA) using Bosworth Fastray (Keystone Industries, Gibbstown, NJ) polymethyl methacrylate (PMMA), such that the flexion axis of the femoral component coincided with the flexion axis of the VIVO. Each tibial component was then affixed into a fixture on the lower actuator in a neutral orientation with respect to the femoral component using dental stone. Flexion/extension and abduction/adduction motions were provided by the upper actuator, while all joint displacements and internal/external rotation were provided by the lower actuator. Prior to any force-controlled testing, displacements were applied in the AP, ML, and IE directions with an axial load of 710 N, in order to determine the maximum forces and moments each TKR system could safely withstand without dislocating or achieving clinically unrealistic displacements.

Continuous Flexion Tests: Constraint tests were conducted by applying a continuous flexion/extension motion between 0° and 90°, with 710 N axial load, and all other DOFs unconstrained. The relative motions of the femoral component and tibial components in the AP, ML and IE directions were recorded and defined the "neutral path of motion" of the TKR system. The same loading was repeated, but with a constant anterior, posterior, medial, lateral, internal, or external load applied, equal to 80% of the limit for that TKR system. The relative change in joint motion compared to the neutral path was measured for each superimposed load; this change was defined as the laxity.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Physiological Motion Tests: Knee joint loads and flexion angles during gait have been previously reported in the literature, and were used as inputs for the VIVO joint simulator. The loads were scaled by a constant factor such that the maximum axial load was equal to 710 N to prevent any implant damage. The neutral path of each TKR during gait was determined throughout the simulated gait cycle. Then the laxity was measured by superimposing AP, ML, and IE loads as before, on top of the AP, ML, and IE loads already applied during the simulated gait cycle. The magnitudes of the superimposed loads were adjusted proportionately with the time varying axial force in order to prevent large distracting loads from causing excessive displacements when there is little joint compression.

Soft Tissue Contribution: Additionally, the cruciate and collateral ligaments were simulated as tension-only point-to-point springs incorporated into the control software of the VIVO joint motion simulator. Stiffness characteristics and origin / insertion points were obtained from the MB Knee (simtk.org/home/mb_knee). Table 1 shows the stiffness and original strain values by bundle. To investigate the contributions of soft tissue constraint to implant stability, the continuous flexion and physiological motion tests were performed with (i) all four major ligaments disabled, (ii) all enabled except the ACL, and (iii) the collateral ligaments enabled with cruciate ligaments disabled.

RESULTS

Figure 1 compares the AP laxity of the TKR system with each of the printed tibial components. All three ligament configurations are provided for each TKR. In the ligament model with only the collaterals activated, the percent change in anterior and posterior laxity, compared to the ligament model deactivated, was -0.044% and -22%, respectively. When the PCL was included in the ligament model, the changes in anterior and posterior laxity, compared to all ligaments deactivated, was -7.5% and -44% respectively. Figure 2 shows the AP and IE laxities of the high conformity TKR system as measured using the physiological motion test, comparing three ligament model configurations.

DISCUSSION

The AP laxities of the continuous flexion tests support the validity of modelling knee motion with simulated ligaments. The highest posterior displacements occur with no simulated ligaments. The lowest magnitude posterior laxities occur with a simulated PCL and collateral ligaments, and the ligament model with only collaterals exhibited posterior laxities of magnitudes in between the other two ligament models. Since all of the models represent the clinically relevant scenario of ACL resection, the anterior laxity in each TKR varies less than the posterior laxity.

Similarly, the AP and IE laxity data from the physiological motion tests displayed in Figure 2 highlight the importance of ligament simulation. The collateral ligaments provide considerable restraint to internal-external rotation [1]. The IE laxity of the two ligament models which include collateral ligaments are almost equal, while the model with no simulated ligaments yielded a larger magnitude of IE laxity. The AP laxity supports the model by the same rationality as the continuous flexion tests.

Current knee constraint tests do not correspond to physiologically relevant functional scenarios, and thus it may be misleading to extrapolate results from those tests to in vivo function. An alternative, function-based means of assessing TKR constraint could lead to advancements in design, as well as aid in matching individuals with the most suitable prosthesis for them based on their needs.

NONLINEAR BENDING DYNAMICS OF A SEMIFLEXIBLE FILAMENT IN 3D BROWNIAN FLUCTUATION

Jyothirmai J. Simhadri (1), Preethi L. Chandran (1)

(1) Department of Chemical Engineering
Howard University
Washington, DC, USA

INTRODUCTION

Mechanical properties of several biopolymers such as collagen, actin, microtubules, and aggrecan that play a structural role in cells and tissues can be determined from the network of filamentous proteins that constitute them [1]. Depending on the individual filament properties, these filaments behave as semiflexible i.e., because their bending stiffness is on the order of, and resists, the Brownian forces that randomize their conformation [2]. In such semiflexible networks, even though the filament resists the external stresses by storing energy in both bending and stretching modes of deformation, it can still exhibit thermally induced bending. In recent years, much interest has been put into characterizing the mechanics of semiflexible networks due to its importance in understanding the mechanical and rheological properties of complex systems such as cell cytoskeleton and connective tissues.

Several models have been developed to capture the bending in semiflexible filaments. One such model is worm like chain (WLC) model [3], where the biopolymers are modeled as inextensible elastic rods with a continuous description i.e., the chain was considered as a continuous line with no discrete structure. However, only a few properties could be determined due to its analytical limitations. Hence a dynamic simulation presents a way to avoid the mathematical complexities of analytical models.

Chandran and Mofrad [4] had proposed modeling a two-dimensional semiflexible filament as a string of beams that bend continuously under Brownian forces. This idealization not only captures the high-order nonlinear bending of the filament, but it does so at reduced computational cost compared to the string-of-beads idealization or Finite Element simulations. Although at small length scales the discrete nature of the filament becomes important, a major advantage of the beams on string model is that it captures the smooth bending of each beam.

In this work we show how the string-of-beams formulation translates to predict the three-dimensional bending of a fluctuating filament with fourth-order continuity in each bending axis.

MODEL DESCRIPTION

The semiflexible filament is divided into a string of beams or segments that bend, and the Brownian dynamics is determined by solving equations at segment intersections. A beam is geometrically defined as a 3D curve that is tortuous.

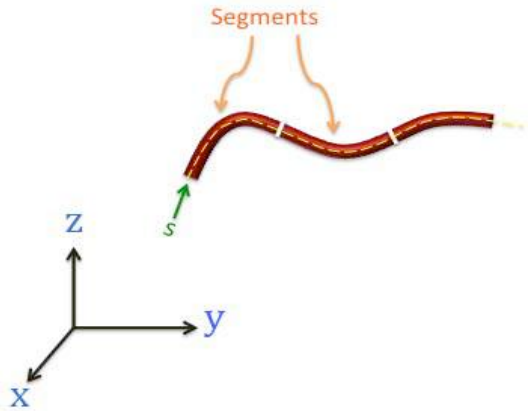

Figure 1: 3D continuous beam

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The dynamics of the semiflexible filament is obtained by balancing three forces i.e., Brownian force acting along the length, Drag forces acting along the length, and Shear forces at the ends. In addition to the balance of the forces the filament is assumed to be inextensible.

The governing equations for the filament dynamics are obtained from Langevin equation of motion by summing the external forces acting on the segments (either bead, rod, or beam), i.e.,

$$F^H{}_I(t) + F^S{}_I(t) + F^B{}_I(t) + F^{Br}{}_I(t) = 0, \qquad I = 1, 2, \ldots N \qquad (1)$$

where subscript i refers to the segment number, and F^H, F^S, F^B, F^{Br} are the hydrodynamic drag force, the stretch force, the bending force, and the Brownian force respectively.

SIMULATION PROCEDURE

Simulation procedure consists of the following steps:

1. The semiflexible filament is divided into beam segments. At each of these beam segment intersections the displacements, filament angle, curvature, and shear forces arising as a result of cutting at the intersection or due to the presence of other neighboring beams are calculated.

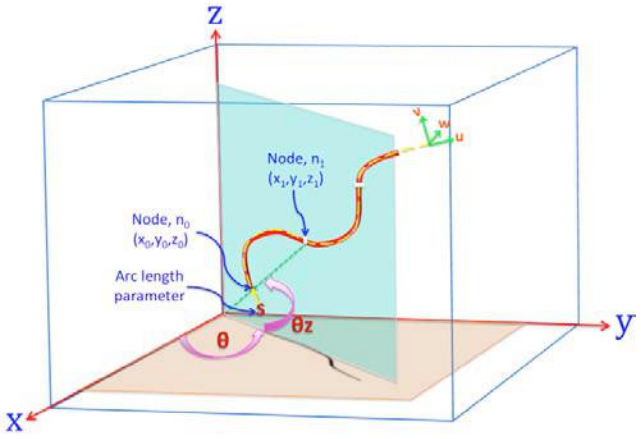

Figure 2: 3D continuous beam having an in-plane rotation angle θ, and out-of-plane rotation angle θ_z.

2. Three forces are balanced: Brownian, Drag, and Shear Forces at ends
   (i) Computation of Brownian forces: Normal and parallel components of Brownian forces are projected in three mutually perpendicular directions and resolved into normal and parallel resultant forces and couples acting at the center of the beam. The variance of the resultant forces and couples are determined by friction coefficients of rigid cylindrical rods.

   (ii) Computation of Drag forces: Normal and parallel components of Drag forces are projected in three mutually perpendicular directions and resolved into normal and parallel resultant forces and couples acting at the center of the beam. The normal and parallel drag forces along the beam are calculated from the displacements along the beam (normal and parallel directions).

   (iii) Computation of Shear forces: Euler beam equations are used to solve for filament curvature, $\frac{d\theta}{ds}$, along a continuous contour s, and shear forces at the ends of the beam segments.

3. Backward Euler time stepping is used to solve for the dynamics of semiflexible filament.

RESULTS

The previous sections provide information on the methodology to solve for the large-deflection Euler beam mechanics in three dimensions. The displacements, and the internal forces are calculated based on in-plane and out-of-plane angles that are approximated by fifth-order interpolation functions.

Filament bending rigidities are also obtained by analyzing the shape fluctuations using a Fourier decomposition technique developed previously [5, 6].

The formulation is validated by comparison against Finite Element simulations of filament bending under similar forces.

DISCUSSION

We present a formulation to model the three-dimensional nonlinear bending of a filament by idealizing it as a string of continuous beams. The idealization reduces the computational cost of modeling semiflexible polymers when compared to string-of-beads models, and is therefore more amenable for modeling large networks and semi-dilute polymer phenomena.

MYOSIN-II MEDIATED CORTICAL CONTRACTILITY REGULATES NUCLEUS PULPOSUS CELL OSMOTIC PROPERTIES AND MORPHOLOGY

Timothy D. Jacobsen (1,2), Paula Hernandez (1), Nadeen O. Chahine (1,2)

INTRODUCTION

The highly hydrated nature of the nucleus pulposus (NP) within the intervertebral disc (IVD) induces osmotic forces on NP cells which in addition to forces exerted by the ECM and the contractility of the cell cytoskeleton determine the round morphology of these cells. The regulation of cell volume in response to osmotic changes is important to NP function and alteration of volume regulation parameters may play a crucial role in the loss of cellular function in IVD degeneration (DD) [1]. DD is characterized by elevated levels of pro-inflammatory cytokines [2]; inflammatory stimulation of nucleus pulposus (NP) cells within the disc can lead to a catabolic breakdown of disc ECM and consequentially to a positive feedback of further loss of tissue integrity and further inflammation [3]. Previously we have shown that inflammatory stimulation of isolated NP cells leads to significant and irreversible changes in cellular biomechanical properties, in particular significantly increased hydraulic permeability (Lp) as well as disruption of the actin cytoskeleton [4]. Though actomyosin network contractility regulates cell morphology, the role of cortical contractility in regulation of cellular osmotic properties is unknown. In this study, we investigate the direct relationship between actomyosin contractility, actin cytoskeleton morphology and osmotic properties of NP cells. We hypothesize that inhibition of actomyosin contractility will decrease cellular circularity and increase the hydraulic permeability of NP cells, in a mechanism that mimics mechanobiological disruption due to inflammation. Given that actomyosin contractility is regulated by the Rho/Rock pathway, we evaluated the effects of ROCK inhibitor (Y27632) and a non-muscle myosin-II inhibitor (blebbistatin) on osmotic permeability, actin morphology, circularity, and elastic modulus of NP cells. We also evaluated the effects ML-141, an inhibitor of CDC42, a small GTPase of the Rho/ROCK family that plays a central role in filopodium extension. Effects of cytoskeletal disrupters are also compared to inflammatory (TNFα) stimulated changes.

METHODS

NP Cell Isolation: NP tissue was isolated from young bovine lumbar discs. Cells were expanded for 1-2 passages in DMEM+10% FBS, and cultured in 1.2% alginate beads to promote round morphology. **Treatments:** Cells were exposed to the following treatments for 24h: (1) untreated control, (2) 10ug/ml ROCK inhibitor Y27632, (3) 10ug/ml non-muscle myosin-II inhibitor Blebbistatin, (4) 10ug/ml Cdc42 inhibitor ML141, or (5) 10ng/ml TNF-α inflammatory group. **Immunofluorescence:** Beads were fixed, permeabilized, and stained with Alexa 555-phalloidin (Abcam). After staining, cells were released from beads with sodium citrate, placed in poly-L-lysine coated glass coverslips and mounted with Vectashield. Images were taken with a confocal microscope and processed in ImageJ. Changes in actin cytoskeleton were measured for production of cell extensions and alteration of cell circularity. A circularity of 1 represents a perfectly round object; therefore circularity below 0.45 was considered a loss in cell roundness and indication of cell polarity indicated by visible cellular protrusions. **Osmotic properties:** After treatment cells were released from the alginate beads and seeded into a custom osmotic loading microfluidic chamber [4, 5] where they were allowed to adhere to a Poly-D-Lysine coated slide for 30 minutes and then placed under an inverted microscope for observation. Step hyper- (333 to 466 mOsm/L NaCl) and hypo- (466 to 333mOsm/L NaCl) osmotic loads were applied at room temperature. Volume response was analyzed using multiphasic mixture theory [6,7] to compute material properties: membrane hydraulic permeability (Lp) and osmotically active intracellular water content (φir). **Atomic Force Microscopy:** Force indentation curves were obtained from individual, rounded, live NP

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Cells using and Asylum MFP-3D BIO atomic force microscope with spherical tip probes. Obtained curves were fitted to a hertzian mode in order to determine cell elastic modulus. Data was analyzed with 1-way ANOVA and Fisher LSD post-hoc test, with $p<0.05$ significant.

RESULTS

F-actin distribution in control NP cells was found to be mostly cortical, with low to moderate likelihood of observation of short cellular extensions. Cells treated with TNFα show the presence of punctuate F-actin and increased presence of cellular processes resembling neurites or filopodia. Y27632 treated cells exhibited some cell extensions, though a more pronounced effect was observed in blebbistatin treated cells. Treatment with ML141 showed the most pronounced increase in cell roundedness and little to no presence of cellular extensions. Quantitative analysis of extensions and protrusions indicate that a significantly larger proportion of cells in TNFα group have low circularity in comparison to untreated control (Fig 1). Blebbistatin significantly increased % of polarized cells (more extensions, low cellularity). No significant difference between Y27632 treatment and control group was observed. ML141 significantly decreased cellular extensions and improved cell roundedness. Analysis of hydraulic permeability was performed for hyper- and hypo-osmotic loads. Under hyper osmotic loading, treatment with TNFα produced an increase in hydraulic permeability (Fig 2), in agreement with our previous findings [4]. Blebbistatin treatment significantly increased Lp under hyper osmotic loading to similar levels as those produced by TNFα (Fig 2). Y27632 treated cells showed a slight but non-significant increase in Lp (Fig 2). Treatment with ML141 had no significant effect on Lp. All treatments showed trends for increasing Lp under hypo osmotic loading, though none were significant. No group showed a significant change in φir vs. control. TNFα treated cells also exhibited significantly reduced elastic modulus compared to untreated cells (Fig 3). Treatment with both Blebbistatin and Y27632 also lead to significantly reduced modulus akin to that seen with TNFα stimulation (Fig 3).

DISCUSSION

The goal of this study was to examine the role of cytoskeleton cortical contractility in regulating single cell osmotic properties, in particular hydraulic permeability. Our findings confirm that inflammatory stimulation with TNFα increased hydraulic permeability, induced formation of punctate actin extensions, and decreased cell elastic modulus, in agreement with our previous work [4]. Reducing cytoskeletal contractility by inhibiting myosin-II contractility resulted in a significant increase in hydraulic permeability formation of cellular extensions, and decreased modulus akin to that seen with inflammatory stimulation with TNFa. Inhibition of ROCK activity demonstrated similar trends, though the effects were less pronounced than with myosin-II inhibitor. Inhibition of CDC42 decreased formation of extension and had no effect on permeability. These findings indicate that disruption of myosin II cortical contractility can regulate the osmotic response of NP cells. We postulate that inflammatory stimulation disrupts the biomechanical properties of NP cells in a mechanism that is dependent on myosin II contractility. Indeed, measurement of phosphorylated myosin light chain (pMLC) levels confirm that contractile activity is significantly decreased in TNFa treated cells compared to control. This is the first report that directly links cortical contractility with the regulation of cellular osmotic properties in NP or other chondrocyte-like cell, whose cell-ECM interaction are a key regulator of biological and biomechanical function. These findings indicate non-muscle myosin-II cortical contractility plays a key role in how inflammation alters NP cell mechanobiology and consequently in disc degeneration. These findings advance the understanding of how inflammation alters the biomechanical properties and function of disc cells as well as their ability to detect and respond to biomechanical stimuli from surrounding ECM.

IN SITU MEASUREMENTS OF HYDRAULIC PERMEABILITY IN SKELETAL MUSCLES

Michael Schenk, Lijian Peng, Xingyu Chen, Shaopeng Pei, Xin (Lucas) Lu, Liyun Wang

Mechanical Engineering Department
University of Delaware
Newark, DE, USA

INTRODUCTION

Muscle and bone are known to act as a functional unit and communicate mechanically and biochemically during musculoskeletal development and maintenance [1]. Muscle-derived factors (myokines) have been found to affect bone functions in vitro [2]. However, the transport processes of myokines from muscle to adjacent bone tissue are not well studied. Both pathways through vasculature and interstitium have been proposed [3]. Using confocal microscopy and myokine-mimicking tracers, we found that periosteum, which is involved in the presumed interstitial pathway, behaves as a semi-permeable sieve that allows readily passage of various molecules up to 40kDa [3]. The hydraulic permeability of the periosteum was reported to be 2-5x$10^{-17}$$m^2$ when tested in pre-stressed conditions [4]. However, the permeability of muscle tissue, another important component of the interstitial muscle-bone cross-talk pathway, has not been quantified yet. Our goal was to fill this knowledge gap by measuring hydraulic permeability using murine/bovine skeletal muscles.

METHODS

(i) Indentation Tests: Hindlimbs from 12-week-old (N = 18) and 38-week-old (N = 3) Balb or B6 mice with intact tibial muscles were harvested 5-10 min postmortem, and equilibrated in 1X PBS supplemented with a cocktail of proteinase inhibitors (PBS-PI solution) [5] for 2-6 hours. The samples, immersed in the PBS-PI solution inside a water bath, were subjected to creeping tests on a custom-made indenter (Fig. 1). A porous indentation tip (radius 0.8mm) was brought to contact the tibial lateral gastrocnemius muscle with a small force (~0.4g) by manual adjustments (Fig. 1). After 5 min, the piezo actuator (P602.8SL, Physik Instrumente) was instructed to apply a step load of 0.5g and the load was maintained for a total 90 min. The creeping displacement was recorded using the actuator's internal displacement sensor. The thickness of the muscle (~5mm) was measured using a needle. Bovine (N = 9, 12-24-week-old) gastrocnemius muscle slices (~5mm thick) were sectioned along the muscle fibers from knee samples delivered by a local supplier within 24h of sacrifice. Bovine samples were prepared and tested similarly as described above. (ii) Biphasic Curve-Fitting: To derive transport and mechanical properties of the murine and bovine muscles, a cylinder of muscle tissue indented by a porous cylindrical tip was simulated in FEBio. As the first approximation, a small 1° wedge containing indenter and muscle was meshed to 287 and 2000 penta6/hex8 elements, respectively. The muscle tissue was assumed to be biphasic with the solid phase being a neo-hookean material (Poisson's ratio=0.35) reinforced with radial fibers and the saturated fluid phase being salty water (viscosity of 0.001Pa•Sec). The boundary conditions were shown in Fig.2B. The tissue permeability (k), fibril tensile modulus (E_f) and muscle Young's modulus (E_m) for each muscle sample were obtained by optimizing the predicted displacement-time curves with the experimental data (Fig. 2). A heuristic differential evolution method [6] was adopted for global optimization over a continuous solution space with E_m (2-8kPa), E_f (0.32-2.56MPa), and k (0.1-4*10^{-16} m^2). Typically, a thousand simulations (~100 generations of optimizations) were adequate to achieve convergence and excellent fitting with the experimental data (Fig. 2C). One-way ANOVA with Tukey post-hoc comparisons were performed using Origin (OriginLab Corp., Northampton, MA).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

No significant difference was detected in any of the skeletal muscle properties among the three groups (young murine, old murine and cow). The hydraulic permeability from the two species was on the order of 10^{-16} m^2; fibril tensile modulus was on the order of 1.8-2.3 MPa; and the tissue Young's modulus was on the order of 2.2-2.5 KPa (Table 1).

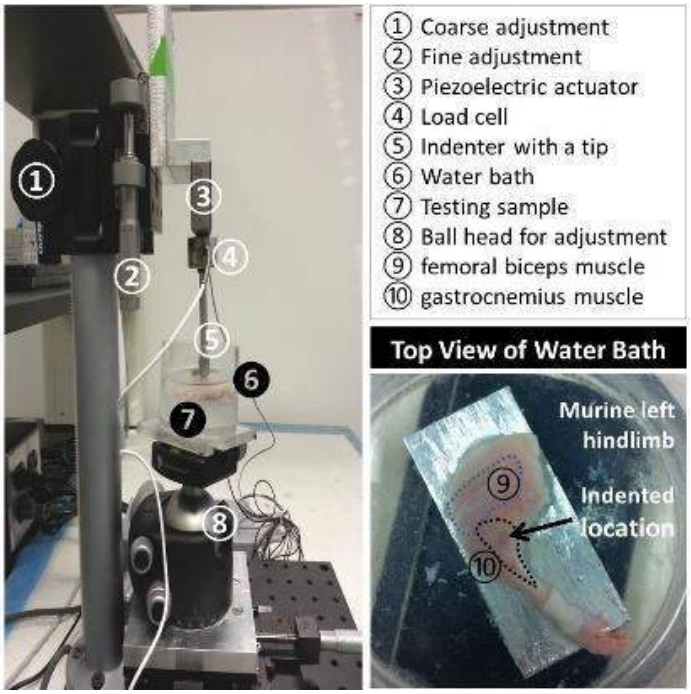

Figure 1: Indentation setup for muscle testing.

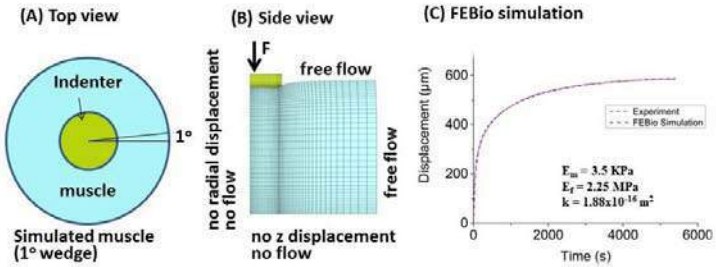

Figure 2: Biphasic curve-fitting of muscle indentation tests. (A) The model consists of a 1^0 wedge of muscle and indenter. (B) Displacement and flow conditions were applied to the boundaries of the model. (C) A representative simulation of murine muscle test showed excellent agreement with experimental data. The optimized parameters (E_m , E_f , and k) for this particular test were derived.

Table 1: Mechanical Properties of Murine and Bovine Skeletal Muscles

Mechanical Property	Murine: Relatively Young (N = 18), Age = 11.9 ± 1.4 weeks	Murine: Relatively Old (N = 3), Age = 38.0 ± 0.0 weeks	Bovine (N = 9), Age = 12-24 weeks	p^1	p^2	p^3
Permeability ($x10^{-16}m^2$)	2.7 ± 1.5	2.3 ± 0.3	1.8 ± 0.8	0.6	0.1	0.3
Fiber Tensile Modulus (MPa)	1.8 ± 0.9	2.3 ± 0.6	2.2 ± 0.8	0.4	0.3	0.9
Matrix Modulus (KPa)	2.5 ± 1.1	2.3 ± 1.0	2.2 ± 0.6	0.8	0.4	0.7

Note: Values are presented as mean ±SD. Pairwise comparisons were performed using one way ANOVA and Tukey tests. p^1: young murine vs. old murine. p^2: young murine vs. bovine. p^3: old murine vs. bovine.

DISCUSSION

We quantified skeletal muscles' hydraulic permeability using indentation and biphasic modeling. Our results showed that the skeletal muscles from two species (murine and bovine) displayed permeabilities on the order of $2x10^{-16}$ m^2, which were 2- to 10-fold higher than that of bone periosteum ($2\text{-}5x10^{-17}$ m^2) [4]. Although the structural and compositional basis for this difference is not known, the highly hierarchical extracellular matrix space formed by the extensively interconnected endo-, peri-, and epi-mysium system [7] may be responsible for the higher permeability detected in muscle, which requires further investigations. Our data suggest that muscle is unlikely to be a major barrier for the interstitial muscle-bone cross talk as is the periosteum. Limitations of the current studies include i) all the muscles were tested postmortem without active muscle contractions typically seen in vivo; ii) structural changes might have occurred during the preparation and testing period (3.5-7.5 hours) despite the use of proteinase inhibitors. Nonetheless, the current study provided the first quantitative estimations of the skeletal muscle permeability, which will help us to understand the physical constrains in muscle-bone cross-talk.

A HIGH THROUGHPUT NUCLEUS PULPOSUS EXPLANT CULTURE SYSTEM PRESERVES TISSUE INTEGRITY

Timothy D. Jacobsen (1,2), Nadeen O. Chahine (1,2)

(1) Feinstein Institute for Medical Research, Manhasset, NY

(2) Hofstra North Shore LIJ School of Medicine, Hempstead, NY

INTRODUCTION

Many intervertebral disc (IVD) research studies utilize either in-vitro isolated cell cultures systems or in-vivo studies. However there is a growing interest and need to perform in-vitro studies on the IVD and nucleus pulposus (NP) in an environment that more closely mimics the native disc, prior to embarking on costly in-vivo experimentation. Cultured in media alone, free swelling NP explants are subject to loss of tissue integrity and ECM content as well as loss of cell viability making them poor representatives of in-situ NP tissue [1]. Explant cultures systems that involve the use balanced osmolarity medium culture or molds and meshes that physically restrict disc swelling, have been recently utilized in order to preserve isolated NP explants and allow for testing of tissue that accurately models in-situ NP. These methods have been shown to address limitations of free swelling explant cultures, however these systems are often time and resource intensive making them relatively low through put systems [2,3]. In the current study we have investigated a new NP explant culture system for its ability to maintain explant integrity, ECM content, and cell viability. The culture system described here provides a benefit over existing systems by maintaining NP explants in cultures at a comparatively lower cost of time and resources, and is easily scalable for higher throughput studies. We hypothesize that restriction of NP explants swelling using an agarose gel culture system will maintain cell viability, ECM content, and tissue integrity of cultured NP explants.

METHODS

NP Explant Isolation: NP explants were isolated from bovine tail segments. The NP region of each disc was exposed and a 4mm punch was used to isolate cylindrical explants. **Agarose Casting and Culture:** Explants were cultured in 24 well-plate and were either cast in 2% agarose (swelling restricted) by suspending the explants in an agarose gel, or they were left unrestricted in the well (free swelling). DMEM+10%FBS+1%AA was added to both explants groups and explants were cultured under standard culture conditions **Live/Dead Staining:** On Day 0 and after either 7 or 14 days in culture, explants were collected and stained with 10 μM Calcein am and 2 μM ethidium homodimer (Sigma) and imaged on a confocal microscope. ImageJ was used to threshold images and quantify the number of live and dead cells. **Size Measurement:** at time of collection explant diameter and height was measured with digital calipers. **NO Assay:** Explant supernatants were assayed for nitrite (NO) concentration by Griess reaction (Promega). **GAG Assay:** Supernatants were also assayed for released GAG content into the media using Blyscan sulfated glycosaminoglycan assay (Biocolor).

RESULTS

Cell viability with live/dead staining showed nearly 100% viability in all groups, with no difference observed in days in culture or relative to Day 0 control explants (Table 1). At day 7, no significant differences in explant diameter were observed between groups. However at day 14, the free swelling explants had a significant greater diameter than swelling restricted samples (Fig 1). Free swelling explants exhibited a significantly higher rate of NO release at day 1 and 3 versus swelling restricted explants. Nitirite levels decreased after day 4 and were comparable in both groups (Fig 2). Free swelling explants also exhibited a burst release of GAGs into the media on day 1 of culture that was significantly higher than GAG release measured in swelling restricted explants. After the initial burst release, free swelling and swelling restricted explants exhibited a similar slow release of GAGs, though the cumulative GAG release was ~ 3X greater in free swelling compared to swelling restricted (Fig 3).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

DISCUSSION

The goal of this study was to validate a scalable and cost effective method for culturing NP explants from the IVD, while preserving tissue integrity, ECM content, and cell viability. After 14 days of culture in agarose gel that restricted the swelling of cultured explants, our findings indicate 100% cell viability. Additionally this swelling restricted culture system showed no increase in explant size, as opposed to free swelling explants, indicating a preservation of explant structure and integrity vs. free swelling explants. Explants cultured in agarose also showed low levels of NO release as opposed to free swelling explants which exhibited a high initial rate of NO release, indicating this agarose culture system helps to prevent an initial inflammatory response that is otherwise present in free swelling explants. Lastly explants cultured in agarose showed a lower rate of GAG release compared to free swelling explants indicating a better maintenance of ECM content and explant integrity. Our findings that swelling restriction offers significant preservation of NP integrity is consistent with prior studies that reduced swelling of explants by balancing tissue osmolarity [3] or by physical ring constraints [2]. The use of agarose gel to restrict NP swelling and preserve tissue integrity, not only mitigates inflammatory and tissue fragmentation, but also represents a scalable model for high throughput analysis of NP function in vitro. The scalable explant culture system validated for use with NP tissue can be utilized in future studies in order test injurious and therapeutic stimuli using conditions more representative of in-situ microenvironment than free swelling or single cell culture.

A MECHANICAL ANALOG MODEL OF ADOLESCENT IDIOPATHIC SCOLIOSIS

INTRODUCTION

Scoliosis is a three dimensional (3D) skeletal deformity consisting of a combination of spinal axial rotation (AR) and lateral curvature, or Cobb angle (CA), of 10° or greater [1]. Thoracolumbar braces are commonly used to treat Adolescent Idiopathic Scoliosis (AIS) curves between 20° and 50° [2] with the curve apex below T6 in patients who have significant growth remaining (Risser grade ≤ 2).[3] Braces serve to maintain, and, in some cases, reduce [2] the spinal curve to prevent progression of the deformity by applying corrective forces.[4] Until recently, the outcome of bracing treatment has been highly debated. Weinstein et al. conducted a 5-year follow-up study (Bracing in Adolescent Idiopathic Scoliosis Trial [BrAIST]), providing evidence that braces are effective (72% success rate) at treating scoliosis.[5] Scoliosis braces can be rigid, flexible, or composite and can utilize passive or active corrective mechanisms. Many braces use a three-point pressure principle as the method of correction, which involves fixation superior, inferior, and at the apex of the curve.[6] The magnitude and direction of corrective forces applied by a brace to the spine remain unknown and are a common concern for clinicians and orthotists who are tasked with making design alterations to improve fit and comfort for the patient.

Current experimental research of scoliosis bracing mechanics has largely been limited to two-dimensional (2D) and 3D imaging techniques and computational models. To our knowledge, no biomechanical model of a scoliotic spine or testing assembly is available to study bracing mechanics in scoliosis. The objective of this study was to design and validate an analog model of a mid-thoracic, single-curve, scoliotic deformity to quantify brace structural properties and force response on the spine.

METHODS

A mechanically equivalent analog model of the AIS condition was developed and validated (Figure 1a). The Scoliosis Analog Model (SAM) used a linkage-based system to simulate 3D spinal correction of CA and AR deformity of a single-curve scoliotic spine. The model was adjustable to accommodate unique scoliotic deformities and associated braces. The SAM was designed to engage with the interior surface of a scoliosis brace at each of the three levels, superior, inferior, and at the apex, via an adjustable ring between a central linkage assembly and the brace. Tuning of the ring size and variable degree of freedom components allowed for the ring to mate with complex interior surface geometry. Characteristics and dimensions from patient records and EOS images (EOS Imaging, Paris, France) [7, 8] (IRB 14-03110-XP) were used to customize the SAM for use with a Boston brace, including sex (male), age (13), height (1.7m), and weight (570N), "deformed" measures CA (33°) and AR (5°), and "corrected" measures of CA (26°) and AR (0°) (Figure 1b).

The SAM was tested with a robotic testing platform [9] without any input load to ensure the links moved freely. Less than 3 N of

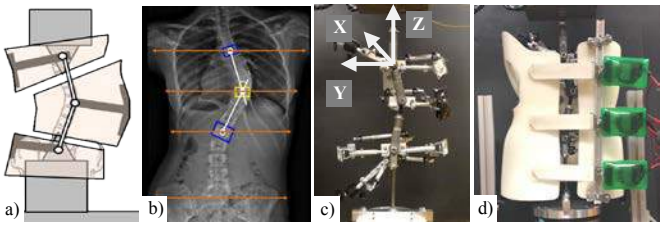

Figure 1: SAM Development and Testing Setup. a) X-Ray Measures, b) SAM Concept, c) SAM Assembly, d) SAM and Brace

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

vertical force occurred over 40° of linkage rotation (Figure 1c). Validation of the transmission of forces acting on the SAM was performed by applying a series of input forces with varying orientation to the apex point of the SAM during 40° of simulated CA correction. Force components transmitted to the superior connector of the linkage assembly were recorded. Computational model simulations were performed for each respective input force orientation. The percent error relative to the computational results was calculated for each input force orientation. The mean percent error revealed a 6 % force reduction within the SAM over the testing range. This error can be attributed to the frictional losses within the SAM components.

To measure the force response of the brace, three simulations were performed, pure CA correction, pure AR correction, and coupled CA and AR correction (CAAR). The SAM assembly was mounted and the weight of the SAM was zeroed from the load cell. The brace was mounted onto the SAM (Figure 1d) and the Velcro straps were each tightened between 22N and 45N (5-10lbs) as instructed by an orthotist. The testing platform was programmed to either displace downward along the Z (vertical) axis or to rotate about the Z axis. Programmed linear movement caused the SAM to transition from the "corrected" state (26° CA) to the "deformed" state (33° CA), simulating 7° CA change in the spinal curve. Programmed rotation caused the SAM to axially rotate within the brace, which was inferiorly fixed to the platform, effectively simulating AR correction (0° to 5°). Coupled CAAR correction was achieved by executing both protocols simultaneously. Strap tension was monitored to ensure it remained with ± 4.5N (1lb) of the initially set value. The 3D force and moment components, which were generated by the brace as a reaction to the simulated deformity, and the linkage assembly angular displacements were measured at a sampling rate of 25Hz. Brace stiffness properties were calculated both for pure CA/AR and for coupled CAAR simulations, and was expressed as a resistive load relative to the angular change. Linear stiffness properties (X, Y, Z) were derived from the 3D force response relative to CA change. Axial (A) stiffness was derived from the Z-moment relative to AR change.

RESULTS

The 3D force and moment responses are shown in Figure 2a (CA and AR) and in Figure 2b (CAAR). The customized SAM replicated the 7° CA and 5° AR correction observed in the patient's images. In order to simultaneously correct the simulated deformity, a vertical load of 582N and moment of -7Nm were applied to the brace by the model. Calculated brace structural stiffness properties for both correction scenarios are shown in Table 1.

DISCUSSION

Structural properties provide a means to compare and classify bracing technology. Interpretation of the results provides the reader with a basic understanding of the mechanics and structural properties of the particular brace studied. With mean X- and Y-stiffness values between 1.0-4.1N/° and 2.1-3.3N/°, respectively, it can be seen that this brace offers little structural stiffness along those axes. However, with a mean Z-stiffness between 64.8-77.9N/° and A-stiffness between 1.1-1.5Nm/°, the brace has much greater stiffness along the Z axis.

Since this research model and testing methodology are new, directly comparable data are not available. Van den Hout et al. measured the magnitude of direct compressive forces at the body brace interface.[10] The forces exerted by the internal lumbar and thoracic pads of a Boston brace were measured in 16 patients with AIS using an electronic pressure measuring system. The mean forces measured at

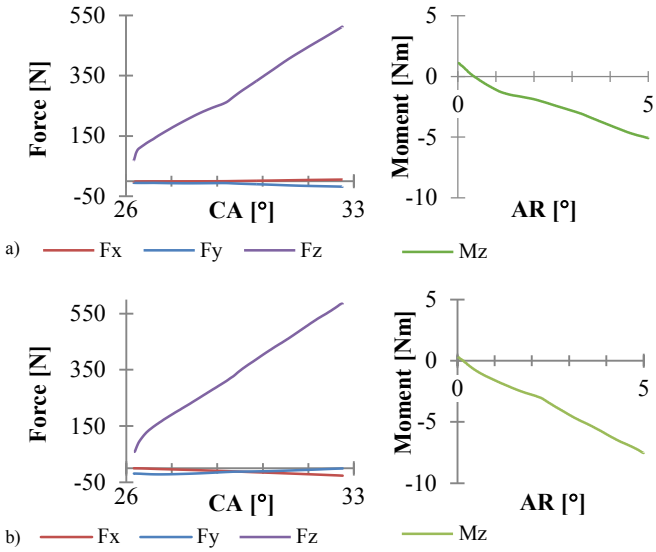

Figure 2: 3D Force and Moment Responses: a) Pure CA and AR, b) Coupled CAAR

Table 1: Brace Stiffness Properties

	Pure (CA or AR)	Coupled (CAAR)
|X-Stiffness| [N/°]	1.0	4.1
|Y-Stiffness| [N/°]	2.1	3.3
|Z-Stiffness| [N/°]	64.8	77.9
|A-Stiffness| [Nm/°]	1.1	1.5

the lumbar brace pad was 214N (range, 0-727N) and at the thoracic brace pad was 66N (range, 4-209N). These force ranges are comparable to the magnitude of the forces measured by the SAM.

The Scoliosis Analog Model and testing methodology enables study of bracing technology. Currently, the model is limited to replicating single curve scoliosis deformities. Future SAM design improvements will permit the 3D study of complex curve types. Future testing may include variable pad and strapping parameters such as orientation, spatial location, size, material, and shape to determine the impact that they have on force transmission. By understanding the effects of removing, adding, or altering the fitting pads and straps, recommended brace design changes may result in improved in-brace correction and treatment outcome.

INTRODUCTION

Decorin and biglycan are two structurally similar, small leucine-rich proteoglycans (SLRPs) that are critical in the development of connective tissues [1, 2]. Decorin has one dermatan sulfate or chondroitin sulfate (DS/CS) glycosaminoglycan (GAG) side chain (~ 45kDa) attached near its N-terminus, while biglycan has two DS/CS GAGs [3]. In vivo, they both regulate the extracellular matrix (ECM) development in various connective tissues through bindings with cytokines to affect cell signaling [4], and with ECM collagen to regulate fibrillogenesis [5, 6]. Specifically, in articular cartilage, they bind to transforming growth factor-β (TGF-β) to inhibit TGF-β-chondrocyte signaling [4], which was recently suggested as a key osteoarthritis (OA) signaling pathway [7]. They also bind to collagens II [8] and VI [9] to regulate ECM assembly (**Fig. 1**). Due to their high structural similarity, the roles of decorin and biglycan could be largely synergistic and complementary. However, the exact mechanisms whereby decorin and biglycan influence the formation and maturation of articular cartilage are not known. In this study, the nanomechanical phenotype of decorin-null and biglycan-null mice was investigated, which can provide direct insights into the regulatory roles of these two SLRPs in the development and maturation of cartilage.

METHODS

Decorin-null ($Dcn^{-/-}$) [5] and wild-type (WT) mice from the C57BL/6 strain were euthanized at 7 to 90 days post-natal (P7, P14, P60 and P90), and biglycan-null ($Bgn^{-/0}/Bgn^{-/-}$) [10] were sacrificed at P14 and P60. Condyle cartilage was harvested from the medial side of right hind legs and stored in PBS (pH = 7.4) with protease inhibitors (Pierce) at 4ºC for < 24 h. Atomic Force Microscopy (AFM)-based nanoindentation (Dimension Icon, BrukerNano) was performed on the intact surfaces of articular cartilage using a microspherical tip ($R \approx 5$ μm, nominal $k \approx 8.9$ N/m, NSC-35 tip A, NanoAndMore), as described previously [11]. For each tissue, at least 10 different indentation locations were tested up to an indentation depth of ~ 1 μm at 10 μm/s rate. Effective indentation modulus, E_{ind} (MPa), was calculated from the loading portion of each indentation force-depth curve via the Hertz model. Mann-Whitney U test or Kruskal-Wallis test followed by Tukey Kramer post-hoc multiple comparison were performed to detect the differences in E_{ind}, across genotypes, where a p-value < 0.05 was considered statistically significant. In addition, histology was performed on all genotypes at P14 and P60, following previously established procedures [12].

RESULTS

Decorin-null mice showed significantly lower E_{ind} compared to WT from P14 ($n \geq 3$) to P90 ($n \geq 4$), but had similar modulus at P7 ($n = 4$) (**Fig. 2**). Furthermore, the expected increase in E_{ind} during skeletal development [13] is observed for WT from P7 to P90, but not for decorin-null mice. For biglycan-null mice tested at P14 and P60 ($n \geq 4$), the cartilage exhibited significantly lower E_{ind} than WT mice. At P60 but not P14, biglycan-null cartilage had higher modulus than decorin-null murine cartilage ($p < 0.05$).

In concert with the lower modulus, histology also showed a markedly lower proteoglycan (PG) staining for decorin-null mice cartilage, at both early development (P14) and young mature (P60) ages (**Fig. 3**). At both ages, while biglycan-null mice also had reduced PG staining, the reduction is more moderate than that for decorin-null mice.

DISCUSSION

The markedly reduced cartilage modulus in both transgenic mice underscores the indispensable roles of decorin and biglycan in the development of cartilage. Noticeably, for decorin-null mice, the modulus difference in comparison to WT progressively increases from early skeletal development (P7) to maturity (P90). This mechanical difference is likely due to several molecular binding activities of decorin during the molecular assembly of cartilage ECM. For example, decorin is known to bind to type II collagen molecules, and thereby, prevent the formation of large fibril or fiber bundles [8] (Fig. 1). In the absence of decorin, cartilage matrix is thus likely characterized by abnormally thick, less organized collagen fibrils, which can contribute to the reduced modulus.

For the first time, our results suggest a critical role of decorin in the structural integrity of proteoglycan in cartilage matrix. We detected a marked reduction in proteoglycan staining by histology as early as the stage of endochondral ossification (P14), and this reduction persists in young, mature cartilage (P60) (Fig. 3). The lower PG concentration is likely a major factor that leads to the reduced modulus in decorin-null cartilage. Several possible scenarios can lead to this phenomenon. In cartilage ECM, the aggrecan-hyaluronan aggregate is entrapped within the collagen network [14]. Given the known regulatory role of decorin in collagen structure [8, 15], it is likely that decorin indirectly affects the retention of aggrecan through influencing collagen structure. Currently, however, it is unclear whether decorin also binds to aggrecan or hyaluronan and therefore plays a direct role in PG structural integrity. Additionally, decorin also sequesters TGF-β signaling [4], which is, less likely to be the major factor for the reduced PG staining, as previous studies have suggested chondrocytes lacking decorin produce similar level of GAGs at the transcriptional level [16].

Biglycan-null mice had a more moderate phenotype in the reduction of both modulus (Fig. 2) and PG staining (Fig. 3). In normal cartilage matrix, decorin is more concentrated in the territorial matrix [17], while biglycan is largely localized in the PCM [18]. It is thus likely that the roles of biglycan are less critical in the formation and function of cartilage ECM fibrillar network. In addition, due to the high structural similarity between decorin and biglycan (57% amino acid sequence homology [3]), we could expect functional compensation between decorin and biglycan when one of them is absent.

Taken together, this study, for the first time, points to potentially indispensable roles of decorin and biglycan in the mechanical function of cartilage. Our ongoing studies are further investigating the underlying molecular mechanisms that contribute to the observed matrix phenotypes. This knowledge will bring decorin and biglycan into the equation of cartilage matrix development, and provide important molecular insights into cartilage regeneration and osteoarthritis pathogenesis.

THE BIOMECHANICAL EFFECTS OF STRAP OPTIONS ON SCOLIOSIS BRACING MECHANICS

INTRODUCTION

In Adolescent Idiopathic Scoliosis (AIS), thoracolumbar braces are the gold standard for treatment of moderate curves with 20° to 50° lateral curvature, or Cobb angle (CA), and some axial rotation (AR). [1, 2] Braces serve to maintain, and, in some cases, reduce [2] the spinal curve to prevent progression of the deformity by applying corrective forces.[3] Orthotists are tasked with making patient-specific braces to treat each unique deformity by using design alterations, such as the addition of Velcro straps, extra pads, and section cut-outs, to improve fit and comfort for the patient. However, there is no common understanding of how alterations affect the structural properties or the corrective capacity of a brace. The process is largely subjective and follows best practice, yet these steps can influence brace fit, user compliance, and ultimately treatment outcome.

The Scoliosis Analog Model (SAM) was recently developed and validated.[4] This analog model of a scoliotic deformity enables the study of braces through the measure of brace structural properties and force response on the spine. The objective of this study was to utilize the SAM to investigate the effects of strap-related brace design alterations. Analyzing these braces with various strap configurations would be of clinical importance for orthotists deciding on how many straps to use, where to place the straps, and the type of strap material to ensure proper fitting.

METHODS

A single-curve, thoracolumbar Boston brace (Avon, MA) was tested in nine strapping configurations (configuration) to investigate differences in brace structural properties due to quantity (1, 2, 3, 4) and material (non-backed 38.1mm Velcro and 25.4mm polypropylene webbing with buckle) (Table 1). To assess the full capacity of the brace, the simulated spinal curve correction was across the entire validated SAM range of 40°.[4] The first 20° of correction (i.e. CA 30° to 50°) represented the nondestructive range. The structural stiffness values of the brace were calculated over this loading range. Further correction (i.e., beyond CA of 50°) represented the destructive range. Each brace configuration was tested three times. Before each run, the straps were reset to the original position and orientation with negligible strap tension.

The 3D force components applied by the brace and the linkage assembly angular displacements were measured at a sampling rate of 25Hz. These two variables were plotted in a force-displacement curve (FDC). The slope of the FDC within the nondestructive range represented the structural properties of the brace. IBM SPSS 22 software program (IBM Corp. Released 2013. IBM SPSS Statistics for Windows, Version 22.0, Armonk, NY: IBM Corp.) was used to compare the mean stiffness values. Within the Velcro strap group and buckle strap group, mean stiffness values were compared using a one-

way ANOVA and ranked using Tukey's post hoc test. The Velcro strap group and the buckle strap group mean stiffness values were then each compared to the rigidly constrained and unconstrained groups using a one-way ANOVA and ranked using Tukey's post hoc test. All statistical tests were performed at $\alpha = 0.05$.

RESULTS

The mean FDCs for the nine configurations are shown in Figures 1a and 1b. The slope was calculated for each curve within the nondestructive range. The structural properties of the brace are represented by the vertical and radial stiffness values, and are shown in Figure 2a and 2b. The mean stiffness values for the "I" (unconstrained) configuration are 0.0N/° radially and 1.0N/° vertically. The mean stiffness values for the "H" (rigidly constrained) configuration are 10.9N/° radially and 153.8N/° vertically. For the Velcro strap configuration, a trend of increased radial and vertical stiffness occurred when more straps were added with an optimal brace radial stiffness achieved with three Velcro straps. No statistically significant stiffness was obtained by adding a fourth strap. A similar trend of increased radial and vertical stiffness occurred when more buckle straps were added; however, this was not statistically significant. Use of a rigid strap ("H") significantly increased the radial and vertical stiffness levels well beyond the level achievable using either the Velcro or buckle strap material. The addition of either strap type significantly increased the stiffness values relative to the unconstrained configuration ("I") in all cases, except "A".

DISCUSSION

Braces serve to reduce and prevent progression of the spinal curve by applying corrective forces. Orthotists modify the expected brace force response through alterations in the brace design, such as pad placement and orientation. The force components of 75N radially and 510N vertically (see Figure 1) were measured during testing of "C" (three Velcro straps, 50° CA). These forces correspond to applied brace forces of 150N inward and 510N upward, due to SAM known trigonometric relationship. Theoretically, when the brace applies purely 150N inward, which might occur when a fitting pad is placed at the level of the curve apex, the maximal vertical force component would only be 320N. This difference (i.e., 510N versus 320N) in vertical force suggests that the brace engaged the torso below the curve apex to apply inward and upward corrective forces. The SAM was the first mechanical model to provide evidence of multidirectional force transmission by confirming an upward lifting effect.

The testing of brace configurations showed a measurable difference in brace force response and structural properties between strap material type and quantity. This information proves useful during the fabrication of a brace. An orthotist may desire to change brace structural stiffness to achieve better patient fit or better brace performance. For example, a patient with poor muscle tone and excessive spinal misalignment may require a stiffer brace to achieve and maintain the desired correction, and the addition of Velcro straps could provide the increase in brace stiffness required. Currently, the decision to add straps is made purely based on professional judgment.

For the Boston brace used in this study, optimal brace stiffness was reached after application of three Velcro straps (i.e., there was no significant stiffness gained by adding a fourth strap). Unlike the Velcro material, the addition of two and three buckle straps did not yield statistically significantly differences in brace stiffness. Traditionally, Dacron or cotton webbing is used as backing for the Velcro strap. This testing was performed using basic, non-backed

Velcro. In the future, the SAM and test assembly can be used to characterize different types of backed Velcro straps, as well as other brace design alterations. These features include brace pads, pad placement, pad geometry, material selection, material cut-outs, rigid components, and other fitting elements. This test assembly could also be used as a design tool and to develop a standard for comparing and classifying braces.

SPATIO-TEMPORAL QUANTIFICATION OF CARTILAGE STRUCTURAL CHANGES IN A MURINE MODEL OF POST-TRAUMATIC OSTEOARTHRITIS

Michael A. David (1), Avery T. White (1), Rachael Pilachowski (1), Ryan C. Locke (1), Melanie K. Smith (1), Christopher Price (1)

INTRODUCTION

Post-traumatic osteoarthritis (PTOA), an accelerated form of OA, results from traumatic joint injury, e.g., ligament and meniscal tears, and is common in active individuals, e.g., athletes and uniformed service members. Approximately 50% of patients that experience a ligamentous tear will exhibit cartilage damage within 10- to 15-years of the injury [1]. Unfortunately, preventative treatments for PTOA are lacking, potentially due to a preclinical focus on mid-to-end-stage disease, whereas the initial changes precipitating PTOA remain largely unknown [2]. In order to develop prophylactic, chondro-protective therapies it is necessary to understand the natural time-course of cartilage structural degradation within the joint during the progression of PTOA. Knowledge of the spatial and temporal progression of cartilage degeneration across the injured joint, heretofore underappreciated, is critical to defining and interpreting the cartilage biology and pathophysiology underlying PTOA, and whether they are of mechanical or cellular origin. Therefore, the objective of the present study was to provide a detailed spatio-temporal histological quantification of cartilage structural changes from early (3-day) through late-stage (112-days) disease in a surgically-induced, murine joint instability model of PTOA, the destabilization of the medial meniscus (DMM) [3]. We hypothesized that cartilage damage would occur early following a traumatic injury and that the cartilage damage would be preferentially localized to the anterior regions of joint where surgical induced joint-instability results in altered biomechanical contact.

METHODS

Animals and Surgeries: Male C57BL/6 mice (Jackson Labs) at the age of 12-weeks underwent DMM surgery in right limbs with contralateral limbs serving as internal controls (n = 5-10mice/group) were harvested at baseline (0d), 3-, 7-, 14-, 28-, 56-, 84- or 112-days post-injury. *Histological Processing:* Samples were immediately fixed (in a naturally flexed position), decalcified, embedded in paraffin, and serially cut into 5-µm thick coronal sections. Starting at the front of the joint (anterior), two-sections were selected approx. every 100-um and stained with Safranin-O/Fast Green to assess changes in cartilage structure. From these, five sets of sections spanning the cartilage-cartilage contact (~500-µm wide) of the tibial plateau and femoral condyle were selected for scoring. *Scoring:* Scoring was performed across all stages of disease development to establish the natural time-course and spatial distribution of cartilage damage following DMM. Three blinded scorers semi-quantitatively ranked cartilage damage in each section using two separate metrics adapted from prior versions of scoring systems [4-6]. First, the extent of cartilage damage across the width of articular surface (referred to as width-based; Figure 1), and second, the extent of depth-wise articular/calcified cartilage damage (referred to as depth-based; Figure 1). For each metric, cartilage damage was assessed on a 0-6 scale for both the medial and lateral femoral condyles and tibial plateaus, and utilized for both temporal and spatial analysis. For temporal analysis, a single average joint score was aggregated for each specimen based upon each scorer's findings, and used to calculate the group mean and SD for each time point. For spatial analysis, an average score at each section location (anterior to posterior) was aggregated from each scorers findings, and used to calculate a spatial location mean and SD for each location and time point. *Statistical Analysis:* To establish differences in cartilage damage between DMM and contralateral joints at each time point, paired t-tests well as one-way ANOVA with post-hoc and linear regression across location were performed. Statistical significance was set at $p<0.05$. Data is presented as mean ± standard deviation

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

We found significant, site-specific cartilage damage across the medial compartments of DMM joints. No significant damage was observed in the lateral compartments of DMM joints or in any region of the control joints. Temporally, significant cartilage damage appeared as early as 3-days post-injury in the MTP, observed as a loss of proteoglycan staining (Figure 2). Cartilage structural damage in MTP and MFC continued to increase with time under both scoring methods, with the most damage seen at 112-days post-injury. Spatially, we observed trends of cartilage damage that appeared greater in the anterior region of the tibia compared to posterior (Figure 3); however these findings were only significant at 84- and 112-days post-injury. No differences existed at any time point post-injury within the MFC.

DISCUSSION

By combining two scoring methods with temporal and spatial analyses this study provided a detailed representation of the extent and timing of focal vs. widespread cartilage damage, from anterior to posterior, in the joint following injury. We found early and highly localized cartilage damage within the medial compartments of DMM joints. An initial loss of proteoglycan content (3-d), followed by fibrillations/erosion of articular cartilage (7-d), cumulating in full cartilage loss by 112-days post-injury was observed. When compared to the literature, our observation of cartilage damage from 14-days onward post-DMM is entirely consistent with others findings from DMM models in mouse [7-9], rat [10], and rabbit [11]. However, to the best of our knowledge, no group has investigated cartilage damage from 3-7 days post injury in the murine DMM model of PTOA. Our temporal findings suggest that studies attempting to prophylactically prevent PTOA initiation and progression may require immediate-early interventions (≤ 7d in mice) to be most efficacious.

Moreover, we also observed a spatial localization of cartilage damage in the MTP, but not in the MFC. While a trend for increased MTP damage anteriorly was seen at several time points, statistical significance was only found at the later time points (84 and 112-days). These findings support the idea that the insult of the DMM causes altered loading and presumably increased localized contact stress at the front of the joint (anteriorly). There was no difference in damage spatially in the MFC, which suggests that the MTP and MFC may experience different mechanical loading and articulation patterns following DMM. Importantly, our spatial findings are consistent with qualitative observations made in the pioneering murine DMM study where increased damage was found anteriorly [3]. In addition, other animal DMM models have shown spatially localized changes in cartilage damage (medial to lateral) [10] as well as increased medial compartment peak contact stresses [11]. Non-invasive murine models have also shown localization of cartilage damage and chondrocyte apoptosis that is dependent on magnitude and location of force applied [12]. Taken together, these studies and ours suggest that insult and altered loading may be an important factor in rapid precipitating and progressing cartilage damage post-injury.

Qualitative analysis of the localization of cartilage damage has additionally suggested that temporal- and spatial-localization of damage to the MTP cartilage, and its subsequent cellular response (loss of chondrocytes), may be related to changes in meniscal coverage of the articular surface following DMM (Figure 4). We are presently quantifying this relationship, as well as investigating if spatial-temporal changes in other joint tissues, e.g., synovium, bone, and menisci, occur post-DMM.

This study is significant in that it's the first to provide a detailed analysis of the spatio-temporal cartilage changes within the murine DMM model of PTOA from early (3-day) through late (112-day) stage disease. Overall, our findings establish a baseline for the detailed study of the cellular and molecular pathoetiology of PTOA, as well as its prevention through the use of novel, targeted, prophylactic chondro-protective therapeutics.

ACKNOWLEDGEMENTS

This research was funded by DoD PR120788P1. Special thanks to Brianna Gietter and Fiona Flowerhill for their assistance in this project.

INTRODUCTION

Individuals who experience decreases in load-bearing bone densities can be subject to a higher risk of bone fracture during daily activity. Astronauts may lose up to nine percent of their load-bearing bone density for every month they spend in space [1]. Because of this, specialized countermeasures reduce percent loss in bone density and reduce fracture risk upon returning to Earth. Astronauts will typically not be at risk for fracture during spaceflight, because of the lesser loads experienced in microgravity conditions. However, once back on Earth, astronauts have an increased risk for bone fracture as a result of weakened bone and return to 1G conditions [2]. It is therefore important to understand the significance of any bone density loss in addition to developing exercises in an attempt to limit losses in bone strength. NASA seeks to develop a deeper understanding of fracture risk through the development of a computational bone strength model to assess the bone fracture risk of astronauts pre-flight and post-flight. This study addresses the several key processes needed to develop such strength analyses using medical image processing and finite element modeling (F.E.M.).

The model can also be used to help determine contributions to the change in bone fracture risk of individuals as they age. The main objective in determining bone fracture risk is to inform the individual which activities to limit or avoid in order to prevent fracture. In addition, the model allows for the assessment of exercise design intended to strengthen an individual and mitigate bone loss.

METHODS

The tools developed for this model need to successfully segment bone regions from medical images, create a 3D model from the segmented data, and prepare the model for finite element analysis (F.E.A.). A decision was made to develop using only open-source software with the intention of a future public release. Python was chosen as the development language, due to its active open-source community and availability of diverse libraries. The tools have been designed to be highly adaptive and interface with existing software to successfully achieve the necessary tasks, as detailed in the following sections.

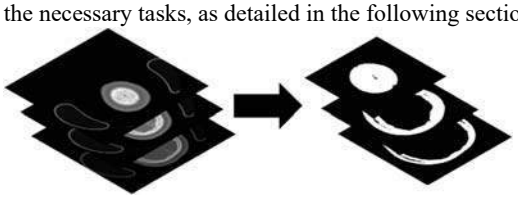

Figure 1: Image segmentation of medical image stack

IMAGE SEGMENTATION SCRIPT: A segmentation technique was developed in Python to allow for the isolation of bone regions of interest. The final script used the visualization toolkit (VTK) library to import and segment the medical images. The library automatically rescales the images' pixel values into Hounsfield units, based of metadata in the image files. This allows for the easy thresholding of the image using known Hounsfield values for bone, as show in in Figure 1. The tool was designed with the ability for the user to input their own threshold values. After segmenting the bone regions from the medical images, the regions are ready to be turned into 3D model.

3D MODEL CREATION: The VTK library also presents the ability to turn the segmented regions into a surface mesh, using a marching cubes algorithm. Compared to the contour reconstruction algorithm, the marching cubes algorithm has shown better performance [5] [6] [7]. The

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

marching cubes algorithm works by treating each voxel element as a cube, and defining polygons to represent the cube. An isosurface is created along the edge of the segmented region. As a result, a triangle-based surface mesh is constructed over the entire image stack, representing the segmented regions. The VTK library also includes further tools to delete any excess triangles and smooth the surface.

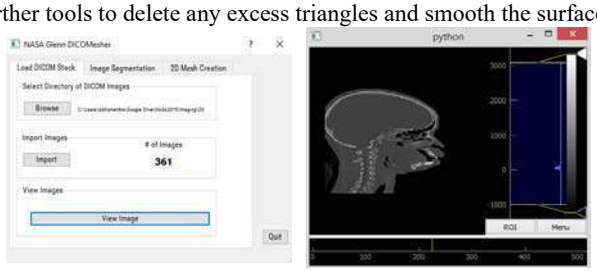

Figure 2: GUI showing image import and viewing capabilities

The surface mesh can be exported as a universal .STL file with the VTK library. A graphical user interface (GUI) has been developed which can provide a centralized location for the image segmentation, surface mesh creation and export. This will allow the user to complete a majority of the steps in one user-friendly program (Figure 2)

After exporting the file, it can be re-meshed in Blender, an open source 3D creation suite, to perform further cleaning. The surface mesh is then exported to Gmsh. Gmsh is a free, open-source 3D finite element mesh generator [8]. Gmsh converts the 2D surface mesh to a 3D volume mesh. An example vertebrae's volume mesh is shown in figure 3.

FINITE ELEMENT ANALYSIS PREPARATION: The chosen finite element solver was the FEBio suite, The model is prepared for finite element analysis by first importing the volume mesh into FEBio, and saving the mesh as a FEBio XML file. This allows for the mesh nodes to be easily identified with the FEBio-friendly node IDs.

The medical images are then reimported into Python as a pixel matrix using the Pydicom library. The pixels are then transformed to Hounsfield values using the image metadata in equation 1:

$$Value_{Hounsfield} = (Value_{Pixel} * slope) - intercept(\quad (1)$$

Where the slope and intercept are values taken from the images' metadata. Previous studies by Kaneko et. al. have shown that a correlation can be found between the Hounsfield units and mechanical material properties [10]. These studies explored the relationship between bone ash material properties, and the density computed from the CT Hounsfield units. Regression curves from these studies were used in the model to extrapolate the mechanical properties based on the Hounsfield units. First, the Hounsfield values were converted to the bone ash density, and the Young's modulus was extrapolated from the regression equations

To assign the material properties to each element in the finite element mesh, the elements' coordinates were found with the data in the FEBio XML file. The centroid of each element was calculated, and mapped to the original location in the medical images. The extrapolated material properties are then assigned to each element based on their location. Finally, the elements, along with their material properties, are written to a new FEBio XML file, ready for finite element analysis in the FEBio suite.

Figure 3: Contour map of effective stress (left) and pressure (right) on vertebrae run through tool

RESULTS

The development of the method resulted in an open-source streamline process designed for the creation of 3-D computational bone models of specific load-bearing regions, such as vertebrae, femurs, and etc. The exported files are FEBio XML files with assigned material properties, ready for finite element analysis in the FEBio suite. Figure 3 shows an example of a contour map of a vertebrae, which was run through the process to create the finite element model. Preliminary work has shown that boundary conditions may be applied to these models and finite element analysis completed, however finite element analysis models for validation have yet to be run.

More results will become available as the validation models are completed and analyzed. In addition, future work includes the compilation of the software streamline into a single, centralized GUI interface for ease of use.

DISCUSSION

The work presented in this paper highlights an exploratory approach to producing models for finite-element creation using open-source methods. Combining Python with available libraries and existing open-source software provided a coding interface which allowed for easy manipulation of image data, and successful segmentation and 3D model creation.

The next big step of this project is validation. Validation will require sending a CT-scan through the workflow, which has mechanical results from clinical experiments. The results from the F.E.A. will be compared to these experiments in order to validate the process. Once validated, the model will be available for use in astronaut bone studies.

The tool can also be extended to use in elderly individuals, who have a tendency to lose bone density as they are aging on Earth. In addition, the model can be used for the study of other soft and hard tissues. Another area of interest in astronaut medicine is muscle atrophy. The model can be extended to muscle studies by changing the thresholding in the initial image segmentation, to segment the muscle. This project serves as an open-source building point for others to contribute and grow the model.

ACKNOWLEDGEMENTS

The authors thank Dr. Beth Lewandowski from NASA Glenn Research Center for her guidance in the beginning stages of the project. Additionally, the authors thank Chris Werner from Zin Technologies for his help in finite element analysis. A. Boppana and R. Sefcik would also like to thank the NASA Space Academy for the opportunity to conduct this research. Lastly, A. Boppana thanks the Ohio Space Grant Consortium for funding his research in the summer of 2015.

INTRODUCTION

The airway structure and function changes from birth to adulthood, likely influencing the location and extent of deposited particles. Despite the need to access whether or not children are more susceptible to inhaled particles, very few studies have focused on modeling transport in the juvenile population. Model predictions will provide novel insight on age-dependent particle retentions and will enable the health consequences of toxic airborne particles or delivery efficiency of aerosolized therapeutics to be assessed.

We recently developed a new framework that couples 3D image-based airways to 1D idealized airways to predict aerosol fate throughout the entire lung and respiration cycle [5]. The advantage of this 3D-1D framework is that it enables us to predict particle transport beyond the resolution of imaging data and throughout expiration. The goal of this current study was to apply this framework to predict airflow and aerosol fate in infant, child, and adult human airways to shed light on the relationship between age and deposition fractions. Simulations incorporated subject-specific airway geometry, time-dependent flow waveforms, and several particle sizes.

METHODS

Three-dimensional conducting airway geometries of a three month infant, six year old child, and a 36 year old adult were created from CT images of patients in the Stanford Image Repository, SIRfS. Images only included the thoracic cavity, therefore the extra-thoracic airways could not be created. Model geometry, mesh, and airflow solution were performed with the open source software, SimVascular (http://simvascular.github.io/). Radius-based meshing with boundary layer elements resolved the wide range of airway sizes. Airflow was determined by solving the incompressible Navier-Stokes equations with the finite element solver [1]. Flow waveforms were defined at the trachea entrance as

$$Q = \frac{V_T \pi}{T_B} sin\Big(\frac{2\pi}{T_B} t\Big) \tag{1}$$

where V_T is the tidal volume and T_B is total time for one breath. Resistances (R) were prescribed at the distal faces based on the subtending lobe volume (lobe fractions = 0.20, 0.25, 0.25, 0.09, and 0.21 for the lower left, upper left, lower right, middle right, and upper right lobes, respectively [2]) and the cross-sectional area of the airway. R, V_T, and T_B were determined for each model based on the patient's age, weight, and height [3]. Following the airflow simulations, spherical particles ($d_p = 1, 3, 5\mu m$) were tracked in the 3D models by solving a reduced form of the Maxey-Riley equation [4], including drag and buoyancy forces. Gravity was positioned parallel to the trachea and particles were assumed to be deposited once they penetrated the wall. For the adult model, the time-dependent concentration and air volume exiting each of the models was recorded and passed as a boundary condition for the 1D advection-diffusion trumpet models. All airways distal to the 3D model, defined for each lobe by Yeh et al. [7] were lumped together to solve the trumpet models [6], which included airway evolution throughout the respiration cycle based on mass conservation and a loss term to model deposition in the bronchioles and alveoli. The 1D airway dimensions were scaled to match the lung volume of the adult subject.

RESULTS AND DISCUSSION

Up to 7, 9, and 11 airway generations were extracted from the CT images; model surface areas are presented in Table 1. The mean flow rate and Reynolds number, taken at the trachea is also shown in Table 1. Resistance, defined as the average pressure drop divided by the inhaled flow rate in the 3D geometry, was largest in the infant model (6.0E-3 cmH_2Os/cm^3) compared to the child (1.2E-3 cmH_2Os/cm^3) and adult models (2.7E-4 cmH_2Os/cm^3).

	Model Surface Area, cm^2	Mean Flow Rate cm^3/s	Mean Re	Stk for $d_p = 3\mu m$
Adult	172	250	1077	0.001
Child	60.5	135	1164	0.005
Infant	20.6	65	1143	0.020

Table 1: surface area of the 3D geometries. mean flow rate, reynolds number (Re), and stokes number (Stk) were defined at the trachea.

Deposited particle locations in the each of the 3D models are presented in Figure 1 for $d_p = 3\mu m$. To assess the deposited concentration (C_N) we counted the number of particles to deposit within each surface element relative to the total number of de-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

posited particles and normalized that value by the element's surface area fraction. As indicated by relatively large values, the majority of particles deposited at the bifurcation zones and on the gravitational dependent side of the airways (Figure 1).

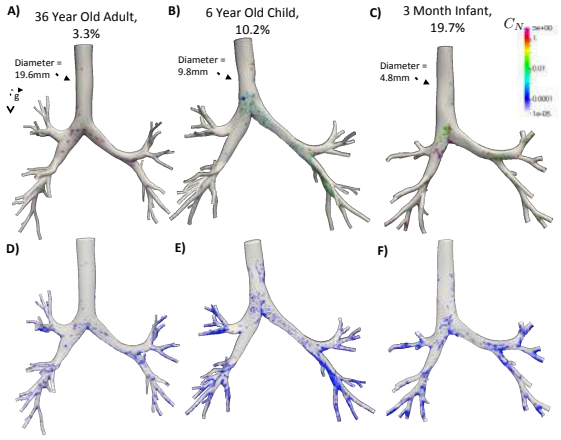

FIGURE 1: Deposition for the 3 μm diameter particles for the adult (A and D), child (B and E), and infant (C and F). panels A, B, and C show C_n, defined as the fraction of deposited particles normalized by the area fraction of the surface element. Individual particle locations are shown in panels D, E, and F. Airways are not shown to scale.

The deposition fractions increased as the subject's age decreased (Table 2). Compared to the adult model, approximately four times more particles deposited in the infant model for all particle sizes. In addition, the total concentration (percent deposition normalized by the model's surface area) was highest in the infant model (Table 2). This enhanced deposition is likely because the airways are much smaller in the juvenile models, resulting in higher Stokes number (Table 1) and a shorter gravitational distance that the particle must travel to deposit. These simulation results suggests that susceptibility to airborne particles is inversely proportional to the subject's age, therefore youth are more prone to health consequences to airborne toxins. However, as few particles deposited in the 3D conducting airways of the adult model, more particles can reach the acinar zone and potentially translocate into the blood stream.

	Adult		Child		Infant	
	%	$\%/cm^2$	%	$\%/cm^2$	%	$\%/cm^2$
1 μm	1.8	0.01	3.7	0.06	4.7	0.23
3 μm	3.3	0.02	10.2	0.17	19.7	0.98
5 μm	12.4	0.07	30.6	0.51	59.0	2.94

Table 2: percent deposition in the 3d model for the adult, child, and infant models and the percent deposition normalized by the surface area of the 3D model.

By solving the 1D trumpet models we are able to determine how many particles deposit in each zone and lobe of the lung. Lobe specific deposition fractions (number of particles deposited divided by the number of particles simulated) for each of the particle sizes are shown in Figure 2A and was largest in the lower right lobe. Calculated by normalizing mass deposited in each zone by the total number of deposited particles, Figure 2B shows the ratio of conducting and acinar deposition for each lobe. As indicated by the relatively small index, the majority of particles deposited in the acinar zone for the $1\mu m$ diameter particles. In contrast, for particles with d_p of $5\mu m$, the majority of particles deposited on the conducting airways.

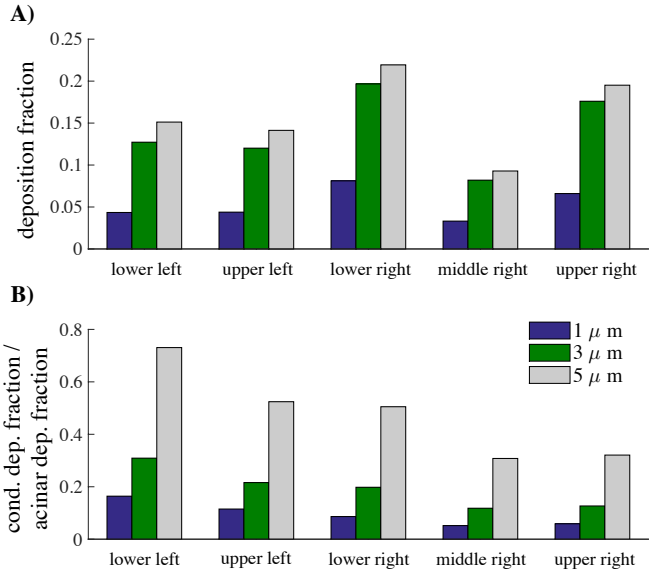

FIGURE 2: total deposition in the adult 3D-1D coupled model for the three different particle sizes. Panel A shows the deposition fraction for each lobe and panel B shows the relationship between deposition in the conducting zone versus the acinar zone.

In conclusion, patient-specific airflow and particle transport simulations indicate that youth are more susceptible to particle deposition in the conducting airways than adults. However, particles may bypass the conducting regions of the adult model and deposit in the deep regions of the lung. As deposition extent and location is highly dependent on the patient's age, it is imperative to calculate or measure age-dependent regional deposition when determining regulations for airborne pathogens or development of aerosol medication.

ACKNOWLEDGMENTS

This work was supported by an ALA Senior Research Training Grant, a University of California Presidential Postdoctoral Fellowship, and an INRIA@SiliconValley Postdoctoral Fellowship. The authors would like to thank Dr. Feinstein for providing the CT images and Adam Updegrove for modeling assistance.

INTRODUCTION

One of the major fatal diseases, which has been causing a substantial death toll of people worldwide is cancer. In the course of treating this disease, in particular metastatic cancer, early diagnosis plays a crucial role in providing better chances to overcome it[1]. However, due to the intermittence of circulating tumor cells (approximately 1-100 CTCs per 10^9 blood cells)[2], it is quite difficult to characterize and segregate such cells by using conventional microfluidic separation techniques. Recently, research has showed that particles can migrate across the microchannel's cross-section by means of inertial forces which can be adapted for cell separation. Such a microfluidic system can deliver relatively high throughput, resulting in a high process efficiency, and can enable the conveying of cells to post-laboratory analysis with no known ruinous effect on their morphology or vitality. Furthermore, an important aspect that can be associated with this system is its involvement in point of care testing since it has a potential to be manufactured as a portable device with small footprint like pregnancy test tools. Accordingly, we have designed an original microchannel geometry that allows continual size-based separation of cells by means of inertial forces and Dean flow, with no requirement for external forces. This configuration is expected to acquire a notable distinction, as it categorically surpasses its peer microfluidic systems in terms of separation, efficiency, reliability and straightforwardness in use.

METHODS

The microchannel in hand is basically a composite geometry constructed within Polydimethylsiloxane (PDMS), attached to a piece of glass, which serves as the base of the channel. This microchannel was manufactured using soft lithography, and was bonded to the glass using oxygen plasma bonding. The geometry of this microchannel was contemplated by studying the different designs, methodologies and results of two separate configurations, an asymmetric curvilinear pattern[3] and a spiral pattern[4]. By applying the superposition of the two patterns, a new geometry was obtained, which we named the *Sunflower* [Fig. 1].

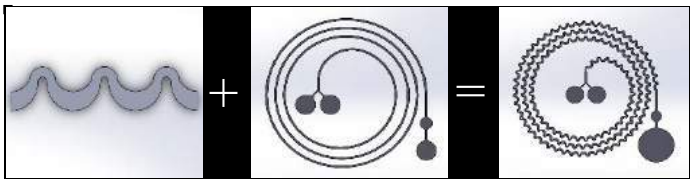

Figure 1: Superposition of the asymmetric curvilinear geometry (left) and the spiral geometry (middle) resulting in the Sunflower geometry (right)

In the course of the separation of cells, the approach towards obtaining this separation is very much similar to that of other deformable particles of equivalent sizes[5]. By taking into consideration this similitude, we performed our separation process on polystyrene particles of dimensions resembling those of cells. This separation procedure is based on inertial focusing, which involves hydrodynamic forces that modify the particle movements, resulting in an equilibrium position for the particles. This equilibrium position, hence, is dependent on the size of the particles. Lift forces tend to push the particles away from the channel boundary and center towards an equilibrium position near the inner sidewall of the microchannel. The net lift force can be justified by a formula derived by Asmolov[6],

$$F_{inertial} = \rho G^2 C_L a_p^4 \; [N] \qquad (1)$$

where ρ is the density of the fluid medium, G is the rate of shear of the fluid $(G = U_{max}/D_H)$, U_{max} being the maximum velocity of the fluid and D_H the hydraulic diameter, C_L is the lift coefficient approximated to an average value of 0.5, and a_p is the particle diameter. This means that the inertial lift force decreases rapidly with decreasing particle size. Moreover, the curvilinear figure of the channel induces a centrifugal acceleration, resulting in two oppositely rotating Dean vortices. This

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

effect can be rationalized by computing the magnitude of this secondary flow, represented by a dimensionless Dean number

$$De = Re\sqrt{\frac{D_H}{2R}} \quad (2)$$

where Re is the Reynolds number and R is the radius of curvature of the channel. As the particles flow through the channel, they experience a drag force due to the Dean flow crossway. These particles, relying on their sizes, move along the Dean vortices under the effect of this drag force, which can be characterized by

$$F_{drag} = (5.4\times10^{-4})\pi\mu De^{1.63}a_p\ [N] \quad (3)$$

where μ is the dynamic viscosity of the fluid. This shows that the drag force is also proportional to the particle size.

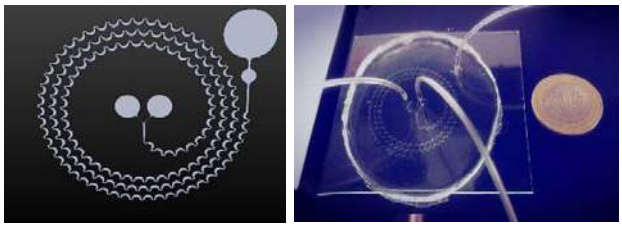

Figure 2

Figure 2: CAD of the microchannel in SolidWorks (left), and the microchannel during operation alongside a Turkish Lira coin to

Several experiments were performed on the Sunflower microchannel [Fig. 2] to examine its separation ability, and the results were compared with those of a spiral microchannel of the same dimensions, radius of curvatures and number of loops. The experiment is done by pumping a particle-carrying fluid from the outer inlet through to the two inner outlets. The fluid delivered to the microchannel is water carrying particles 3 µm (red) and 9.9 µm (green) in diameter. This water was pumped with different flow rates, and the optimum flow rate was selected depending on a brightness analysis performed in *ImageJ*. This analysis was based on a mathematical relation developed with respect to the channel width $W_{channel}$, particle diameter $d_{particle}$, focus width Δx_{focus} and gray values V, resulting in a normalized focus quality q_{focus}. This relation can be written as follows:

$$q_{focus} = \left(\frac{W_{channel}-\Delta x_{focus}}{W_{channel}-d_{particle}}\right)\cdot\left(\frac{\Sigma V_{focus}}{\Sigma V_{all}}\right) \quad (4)$$

RESULTS

The experimental data [Figure 3] shows the of particle focusing at different flow rates. As flow rate increases, the focus line becomes narrower and approaches the inner wall. After a certain flow rate, it starts to move outwards and disperses again. The optimum flow rate was determined by examining fluorescent images taken at the channel outlet. For numerical comparison, the normalized focus quality formula (eq. 4) was developed and used, and the results are shown in Figure 3. The normalized focus quality values are shown for both the spiral geometry (blue) and the Sunflower geometry (red) under various flow rates ranging between 0.3 [ml.min^{-1}] and 2.1 [ml.min^{-1}]. For the sunflower geometry, the best focus quality obtained was 0.93 at 0.9 [ml.min^{-1}], while it was found as 0.81 at 1.5 [ml.min^{-1}] for the spiral geometry. According to the fluorescent image analyses, the Sunflower geometry has a 14.5% advantage compared to the conventional spiral geometry in terms of normalized focus qualities at their optimum operation points. One should keep in mind that our focus quality ratio contains both the enrichment and separation properties of the focus line. Therefore, a focus quality of 0.93 corresponds to a much higher separation ratio which is also compatible with the particle counting analysis. These results clearly show that focus quality can be enhanced by designing such a geometry that superposes the inertial effects of

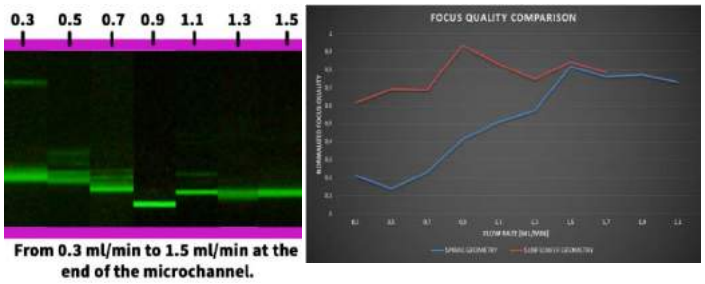

Figure 3: (left) Images of the particles with different focus qualities and locations flowing at increasing flow rates through the Sunflower microchannel; (right) difference in focus quality with respect to various flow rates between the spiral and Sunflower geometries

two different geometries on particles. As the fluorescent image analysis shows, the focus line has a width of only 25 µm (Figure 4), which almost corresponds to two adjacent single particle focus lines of 9.9 µm particles.

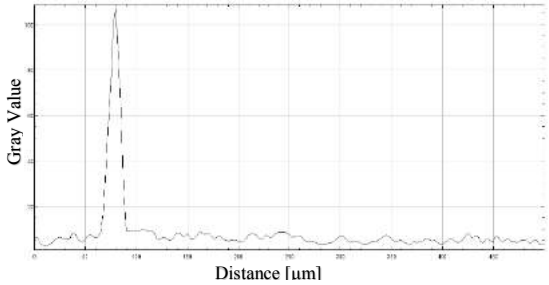

Figure 4: Plot Profile showing the fluorescence intensity along the Sunflower channel width at 0.9 ml.min^{-1}

DISCUSSION

The experimental data shows the superposition of inertial effects of two well-known microchannel geometries resulting in a better separation performance. The formation of the focus lines is consistent with previous research works[7] and theoretical background in terms of focus formation and position. Furthermore, this result implies a potential for the application of superposition principal to other inertial separation geometries (e.g. sudden expansion and contraction, trapezoidal cross-section.). This geometry can be employed to enhance the separation and enrichment of circulating tumor cells in microchannels. For this purpose, experiments with cancer cells should be done to prove the results that we have been presented in this article. One should bear in mind that the optimum conditions for particular size cutoff should be re-determined by altering microchannel height and flow rate. Herein, integration of a micro-pump and cell counter to this geometry is possible, which would result in a completed on-chip diagnostic tool with a very small footprint for cancer patients. On the other hand, multilayered versions of this geometry, which would lead to much higher throughput, can be produced and optimized to accomplish different tasks like water filtration or desalination. Our research on these subjects is currently in progress.

TOWARDS NON-INVASIVE, COMPUTATIONAL MODELING OF THE TRANSPORT OF THROMBO-EMBOLI AND ATHERO-EMBOLI ALONG ARTERIES

Debanjan Mukherjee and Shawn C. Shadden

Berkeley, CA, USA

INTRODUCTION

Floating aggregates of cellular or acellular material (emboli) constitute a leading cause of ischemic stroke. They are also associated with a range of other complications, including deep vein thrombosis, pulmonary embolism, and athero-embolic renal disease. In addition, embolization during endovascular or surgical procedures leads to adverse peri-operative and post-operative effects, reducing treatment efficacy. Emboli causing stroke are mostly fragments of clots (thrombo-emboli), or cholesterol based fragments from ruptured plaques (athero-emboli), originating from heart or valvular diseases, or diseases of the large arteries including the aorta. These emboli are transported to vessels distal to their point of origin by blood flow. Large artery hemodynamics is characterized by unsteady, pulsatile, chaotic flow. Predictive understanding of transport trends for emboli carried by such flows therefore continues to pose challenges. Specifically for stroke, the most prominent diagnosis process relies on the presence of a potential major cardiac source of embolus, with the absence of significant arterial disease [1]. Thus when cardiac and arterial sources of embolism co-exist, identification of stroke etiology becomes difficult. This complication leads to a substantial proportion of stroke cases (30-40%) to be categorized as "Cryptogenic". The identification of embolism source is important for long-term treatment and management of the patient's condition.

In view of the aforementioned complexities and challenges, we describe here a computational framework for investigating the transport of small and medium sized emboli across large arteries. The framework comprises a combination of large artery hemodynamics, discrete particle dynamics, and a sampling-based computational method (Figure 1). The developed tool will serve as a non-invasive probe into anatomically realistic vasculature, and help derive evidence regarding the i) transport mechanics of emboli across chaotic, large artery hemodynamics, ii) size/inertia dependent trends in embolus distribution to the brain (or other potential occlusion sites), and iii) relation between embolism source and embolus destination for stroke etiology. We present here illustrative numerical evidence regarding these objectives, derived from numerical experiments on real patient anatomical models.

METHODS

For our study, four representative patient datasets were selected from a database of Computed Tomography (CT) scan images. Vessel lumen was reconstructed from the images for the entire vasculature from the aortic sinus to the major cerebral arteries connected at the Circle of Willis. These were thereafter translated into a three-dimensional computer model, and discretized into a computational mesh comprised of an unstructured grid of linear tetrahedral elements. Blood was assumed to be a Newtonian fluid with density 1025 kg/m^3, and viscosity 0.004 Pa.s. A Petrov-Galerkin stabilized finite element solver was employed to solve the continuity and Navier-Stokes equations [2], and compute the velocity and pressure fields. A pulsatile, volumetric waveform derived from clinical data was specified at the inlet of the aorta in the form of a cross-sectional plug profile. The outlet boundary conditions were set using single element Windkessel resistors. Resistance values were calculated based on volumetric blood flow to the vessels obtained from measured data, or from proportionality relationship with vessel cross-sectional area. A mean brachial pressure of 93 mm/Hg was assumed.

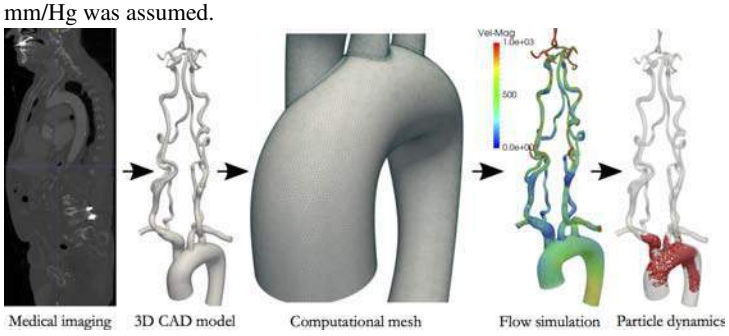

FIGURE 1: Illustration of the overall computational framework.

Individual emboli are modeled as spherical particles with a nominal density of 1100.0 kg/m^3. The particle motion is modeled using a modified form of the Maxey-Riley equation[3], which is derived from a superposition of the steady and unsteady forces on the particle arising from the background flow as well as the disturbed flow around the particle. Near-wall, shear-induced lift forces were considered, and a one-way coupled framework for integrating the particle motion equations based on the obtained velocity and pressure fields from hemodynamics simulations was employed.

Potential sites of embolization were generated by spatially sampling the aorta inlet, and the walls of the ascending aorta and the aortic arch up until the proximal end of the descending aorta. Particles of diameters ranging from 100 - 1000 microns were released across 8 instances during a single cardiac cycle. These ensured that particle sizes were not large relative to the vessel diameters, and could translocate past the M1,A1,P1 segments of the middle, anterior, and posterior cerebral arteries respectively.

RESULTS

The fraction of particles distributed across the six major cerebral arteries connected at the Circle of Willis were scaled by the volumetric blood flow received by these arteries, and compared between cardiogenic and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

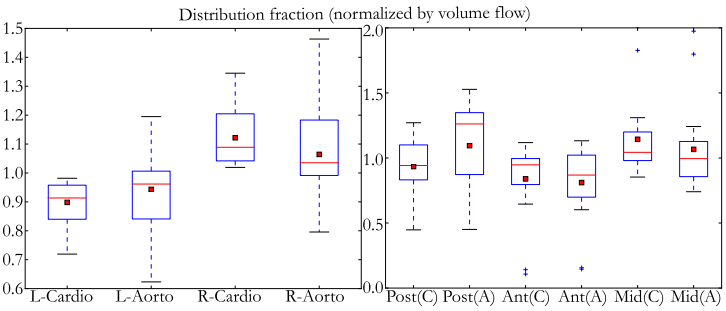

FIGURE 2: Variations in distribution fractions to the cerebral arteries between cardiogenic and aortogenic emboli.

aortogenic cases. Typically, radiological evidences employed in diagnostics involve identifying lesion patterns in the brain vasculature, which is directly related to the cerebral arteries to which the embolic particles travel. Hence, we present the comparison of distribution fractions in terms of the different cerebral vasculature regions in the brain in Figure 2. In terms of left vs right propensity of embolization, a more pronounced right brain preference is observed for cardiogenic emboli, over and above the volumetric blood flow received by the right cerebral arteries. When compared amongst the anterior, middle, and posterior arteries, we observe that while the aortogenic cases have greater variability, the median values (red lines) indicate that aortogenic emboli arrive at the posterior arteries notably in excess of volumetric blood flow as compared to cardiogenic emboli.

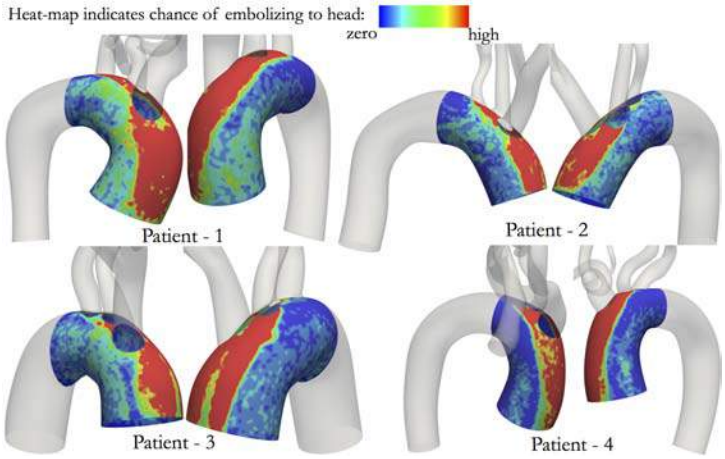

FIGURE 3: Surface map of embolus source and its tendency to send emboli to the head for aortogenic emboli.

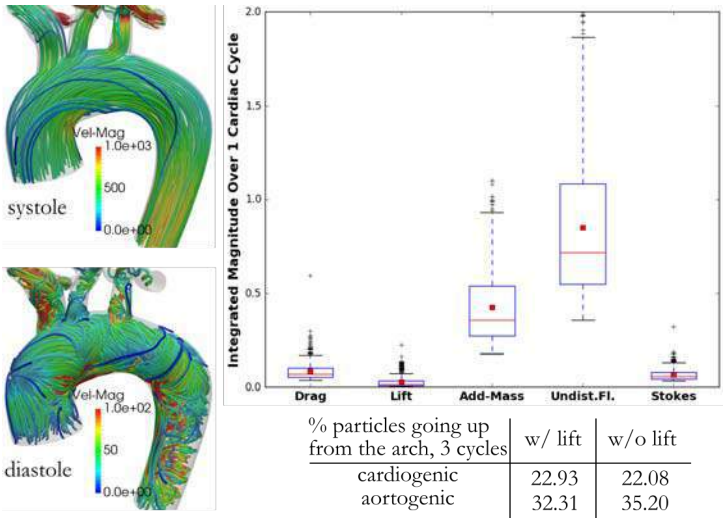
Based on the particle trajectories, and the spatial sampling of the aorta inlet and aorta wall, an inverse map can be constructed now to explore the source-destination relationship, and the critical locations along the aorta leading to embolization to the brain. For all the patients considered, this surface heat-map has been compiled in Figure 3. Locations marked red are the ones with highest observed tendency of sending an embolus to the brain, while the locations marked blue are those that never sent any embolus to the brain. Observations indicate that embolization events along the greater curve of the aortic arch have the most potential to send emboli to the brain. The next major location is along the base of the arch or the lesser curve of the aorta. As the arch progresses distal to the left subclavian, there are increasing number of locations which do not send any emboli to the brain.

In our prior studies [4], we have illustrated the effect of particle inertia and its interaction with helical flow in arteries on their distribution across arterial bifurcations. Our computational tool enables further investigations regarding the mechanics of the fluid-particle interactions and their role in embolus transport. As an illustrative example, we present preliminary results from our experiments for assessing the role of shear-driven lift forces in Figure 4. Characteristic unsteady, swirling flow patterns for



% particles going up from the arch, 3 cycles	w/ lift	w/o lift
cardiogenic	22.93	22.08
aortogenic	32.31	35.20

FIGURE 4: Forces on emboli from their interaction with characteristic unsteady flow, and their role in transport.

one of the patient models has been depicted for peak systole and mid diastole. For this patient, samples of embolic particles were advected with and without the inclusion of shear-driven lift forces, for both aortogenic and cardiogenic cases. The sample statistics for an integrated measure of the various fluid-interaction forces for each particle for one cardiac cycle have been presented. It is seen that cumulative levels of lift and drag are notably smaller in comparison to the unsteady added mass, and stresses from undisturbed flow. However, lift still leads to noticeable difference in transport fractions for aortogenic emboli. This is possibly because of the important role that shear-driven lift plays in drawing aortogenic emboli from the aorta wall into the bulk blood flow and affecting its transport. Further numerical experiments to obtain more detailed numerical evidence on the role of these forces are currently underway.

DISCUSSION

The implications of the developed framework, and the numerical evidence obtained, are multi-fold. Firstly, it enables exploring the difference between cardiogenic and aortogenic emboli in terms of their distribution across the major cerebral arteries. This is valuable for understanding stroke etiology, especially when competing embolus sources exist. Secondly, for aortogenic emboli, exploring the source-destination mapping provides valuable insights into the aspect of site-specificity. Additionally, this has valuable implications for improving treatment outcomes of procedures like percutaneous coronary intervention, for which silent strokes caused by aortic wall trauma and embolization may be more common than recognized [5]. Such a computational tool can thus advance state-of-the-art in terms of understanding complications due to emboli transported along the arteries. Currently, we are continuing investigations in terms of a) extending our experiments to a broader set of patient models, b) including aspects like anatomical variations, and embolus composition in the computations, and c) deriving clinically significant statistics from the computational model.

INTRODUCTION

Mild traumatic brain injury (mTBI) has been identified by the World Health Organization as a public health threat. Concern for mTBI has heightened due to the recent discovery of early onset, trauma-related neurodegeneration in soldiers and athletes. Public health measures to prevent mTBI are limited because the precise physical mechanism of human injury is unclear. Animal and computational studies previously suggested the brain has direction-dependent tolerance to injury: coronal rotation produced higher severity injuries in primates [1] and larger finite element strain in the corpus callosum [2], a structure responsible for communication between brain hemispheres. Another study found that tract-direction finite element strain in the corpus callosum is predictive of mTBI in laboratory reconstructions of NFL head impacts [3]. Direct rotation measurements of human mTBI were recently published [4] and have now made it possible to extend this analysis and investigate the relationship between coronal rotation and tract-direction corpus callosum strain in sports-related human mTBI.

This study investigated factors relating head accelerations in head impacts to ensuing mTBI diagnosis. We tested the hypothesis that tract-direction strain in the corpus callosum is predictive of mTBI and most associated with rapid coronal rotation using instrumented mouthguard measurements of head accelerations during impact and finite element simulations of brain deformation.

METHODS

Mouthguards instrumented with tri-axis accelerometers and tri-axis gyroscopes previously measured six degree of freedom (6DOF) accelerations in 110 football, boxing, and mixed martial arts video-confirmed head impacts (Fig 1A) [4]. Two of these impacts resulted in mTBI diagnosis, one after the subject suffered loss of consciousness (LOC) (Fig 1B) and one after the subject self-reported (SR) symptoms.

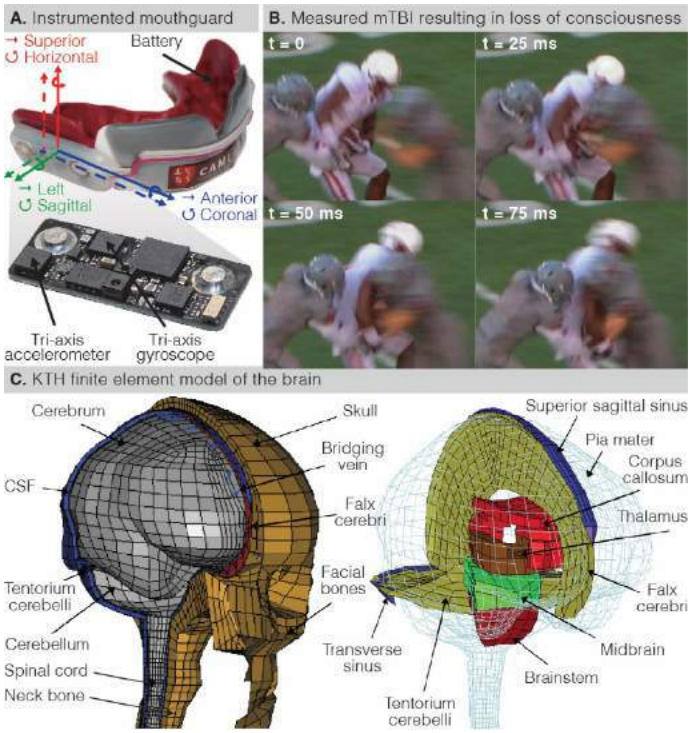

Figure 1: (A) Instrumented mouthguards recorded 110 sports head impacts, including a (B) diagnosed football mTBI resulting in loss of consciousness (LOC), and another that was self-reported (SR). (C) Tract-direction brain strain was estimated using the KTH finite element brain model with mouthguard measurements as input.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Of the remaining 108 impacts, 50 were selected at random to represent typical sports impacts. The remaining 58 impacts exceeded either mTBI in an acceleration component and were selected to represent the highest acceleration impacts and skew the non-injury sample toward those most difficult to distinguish from mTBI. All 110 impacts were simulated using a previously-validated finite element brain model and the mouthguard measurements as input [2]. An average DTI was assumed to determine fiber tract directions in the brain [3]. Cauchy strain tensors extracted from the finite element simulations were then projected in the direction of fiber tracts for individual structures in the brain.

For all measurements, Kolmogorov-Smirnov tests were performed to assess log-normality. Logistic regression for acceleration and strain criteria was performed to assess mTBI prediction. The deviance (D) statistic was calculated to assess the quality of fit of the logistic regression (analogous to r^2 in linear regression) and a null model with no criteria [4]. A smaller deviance suggests higher quality of fit.

RESULTS

For the 110 simulated head impacts, all acceleration measurements passed KS tests for log-normality. The LOC injury produced the highest coronal rotational acceleration (12900 rad s^{-2}), three standard deviations above median (960 rad s^{-2}), that was exceeded in the sagittal plane by 2 impacts that did not result in mTBI diagnosis (Fig. 2A). Peak coronal rotational acceleration and velocity had a strong, unique correlation with peak tract strain in the corpus callosum (both $r^2 > 0.86$) (Fig. 2B). Peak tract strain in the thalamus had the second highest correlation with coronal rotation (both $r^2 > 0.71$), while other brain structures correlated most with sagittal rotation. Peak tract strain in the corpus callosum had the lowest deviance statistic (8.0) among the individually modeled brain structures, followed by peak tract strain in the thalamus (10.4) (Fig. 2C). Peak tract strains in these structures yielded statistically significantly lower deviances than rotational acceleration ($p < 0.05$) and a null model ($p < 0.01$). For the LOC injury, peak tract strain over the duration of measurement was largest in the corpus callosum (0.38) and other proximal structures (Fig. 2D). The SR injury also yielded high tract strains in proximal brain structures, but the average of the 58 highest acceleration non-injury impacts events strained more distal structures.

DISCUSSION

In this study, we tested the hypothesis that tract strain in the corpus callosum is associated with coronal rotation and predicts diagnosed human mTBI better than tract strain in other brain structures. Study observations support this hypothesis. A diagnosed mTBI producing loss of consciousness (LOC) yielded the largest observed coronal rotational acceleration and corpus callosum tract strain among 110 impacts. As a result, tract strain in the corpus callosum had the smallest deviance (highest quality prediction). Two subjects sustained higher rotational accelerations in the sagittal plane without an mTBI diagnosis, suggesting damage to the corpus callosum strain may cause mTBI symptoms and may be sensitive to coronal rotation. Previous studies demonstrated sensitivity of coronal rotation to primate injury [1] and principal strain in the corpus callosum [2]; the present study supports these observations for tract strain with 6DOF human mTBI data [4].

Our results found the strongest correlations between peak coronal rotational acceleration and tract strain produced in the corpus callosum and thalamus. These relationships were unique compared to other brain structures who had stronger correlations with sagittal plane rotation. The corpus callosum and thalamus are proximal structures located around the ventricles. The corpus callosum manages interhemispheric communication and the thalamus is implicated in consciousness. Brain and skull anatomy may expose these structures to strain in coronal plane rotation. Our findings suggest further study of this potential mechanism.

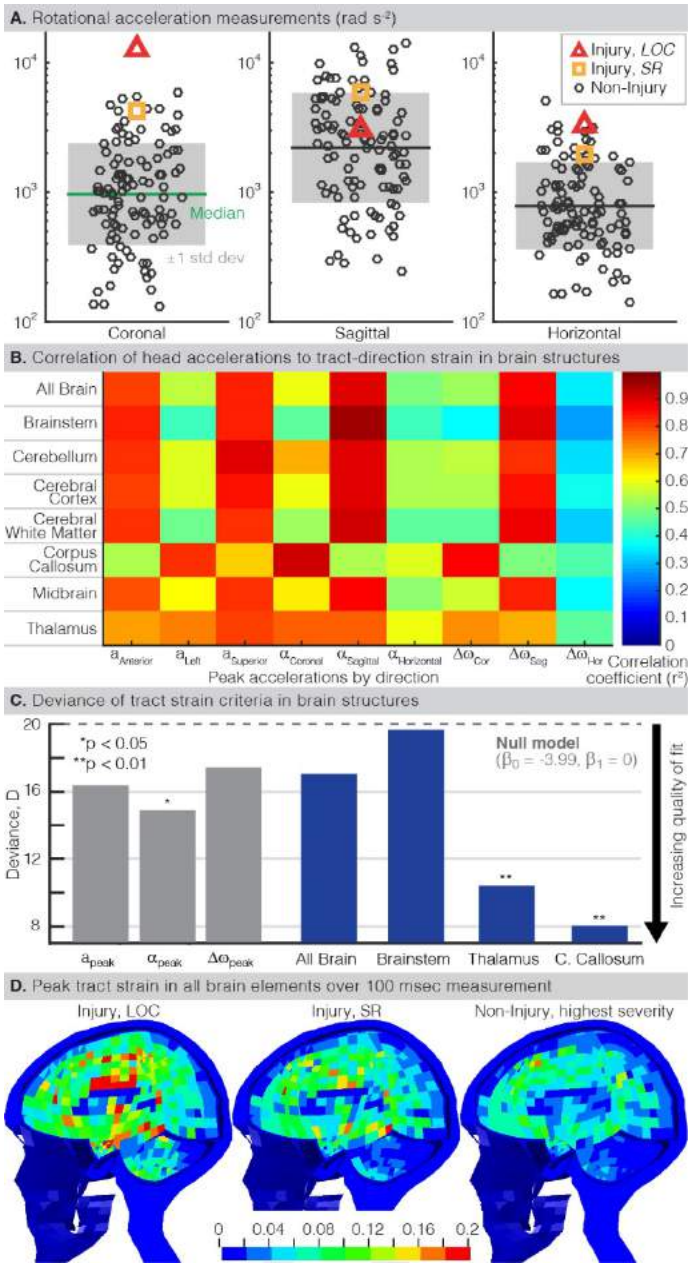

Figure 2: (A) Coronal rotational acceleration distinguishes the loss of consciousness (LOC) mTBI from other measured impacts. (B) Coronal rotation is uniquely correlated with corpus callosum tract strain, which (C) predicted mTBI risk better than other criteria (lowest deviance). (D) Both mTBI impacts yielded higher strains deep in the brain than the average of highest non-injury impacts.

INTRODUCTION

Central artery stiffening is an inevitable consequence of aging and of diseases such as Marfan syndrome, diabetes and hypertension. It is recognized that arterial stiffening is both an initiator and indicator of increased cardiovascular, neurovascular, and renovascular risk [1]. Pulse Wave Velocity (PWV) is the speed at which pressure waves move down a compliant vessel and carotid to femoral PWV (cf-PWV) is the clinical standard measurement used to assess arterial stiffness, yet controversy remains over the best clinical metrics for diagnosis and evaluation of treatment efficacy. PWV, indeed, represents an average over a large portion of the arterial tree. The real concern, therefore, is whether *cf-PWV* can detect early regional changes in arterial properties that yet could increase disease risk. Computational modeling is a powerful tool that enables investigating the effects of regional differences in arterial geometry and wall properties on pulse wave propagation and other clinical metrics of arterial stiffening. In this work, we use fluid-structure interaction (FSI) simulations to examine effects of age-associated changes in aortic wall geometry and mechanics on the overall hemodynamics and the impact of arterial stiffening on different biomechanical metrics.

METHODS

In this work we establish a baseline model of a young, healthy human aortic tree and we used averaged population data on geometry and arterial mechanics to virtually age this model. We employed the 3D simulation framework Crimson (www.crimson.software). This is a multi-scale, FSI modeling software that combines a 3D geometric model, a FSI formulation with regionally varying biaxial tissue properties, Windkessel models, and an external tissue support formulation [2]. A 3D geometrical model of the aorta and its main branches was reconstructed from MRI data collected on a 30 year old (yo) volunteer. A multistep approach was used to artificially age the patient-specific 30 yo model to 40, 60 and 75 yo in a controlled manner (Figure 1). First, we increased the length of the aorta to reflect the non-uniform changes observed with aging by Craiem et al. [3]. They noted that per each 10 years aging, the ascending aorta (segment AB in Figure 1) exhibits a 3% increase in length, the aortic arch (segment BC) a 7% increase in length, and the descending aorta (segment CD) a 5% increase in length. We also incorporated the expected slight decrease in subject height due to aging [4] and the reported non uniform changes in diameter along the length of the aorta with aging [5]. A FSI method is essential to capture pulse wave propagation within an arterial network. Here, a coupled momentum method was employed whereby linearized stiffness was assigned to the vessel wall of the 3D model. Specifically, we recreated biaxial data from 6 published studies and we performed consistent nonlinear parameter estimation for a four-fiber family constitutive descriptor [5]. We then computed patient-specific linearized stiffness values informing the four-fiber model with radii, thickness and transmural pressure acting on the vessel wall based on measurements assessed for the 30 years old healthy subject and averaged-population changes with aging. Stiffness values were assigned at locations indicated by the black points in Figure 1 within the ATA, DTA and IAA and linearly interpolated or extrapolated to obtain a continuous distribution, as illustrated colorimetrically on the aortic geometries. A flow waveform measured with phase contrast MRI in the 30 year old volunteer under rest conditions was used as inlet boundary condition. Outlet boundary conditions were prescribed using a multi-domain method whereby three element Windkessel models were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

coupled at each outlet of the 3D models representing the distal vasculature to the level of capillaries. The parameters were tuned individually for each age group to ensure appropriate flow splits and to match the arterial pressure considered to calculate the linearized stiffness. We also modeled forces exerted by organs and perivascular tissue on the outer side of the vessel wall as a traction consisting of a viscoelastic term with two parameters: a stiffness coefficient and a damping coefficient. We assigned spatially and temporally variable tissue support coefficients, in order to match the transmural pressure consider to assess the linearized stiffness.

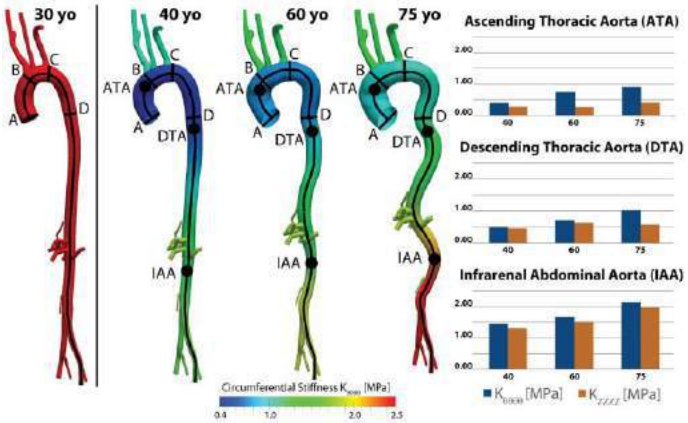

Figure 1: *Left*: Illustrative 3D geometrical models for the based model and the three age groups: 30, 40, 60, and 75 year old (yo) subjects. *Right*: Associated values of segmental circumferential (blue) and axial (orange) material stiffness (MPa) in three regions: ascending thoracic aorta (ATA), proximal descending thoracic aorta (DTA), and infrarenal abdominal aorta (IAA).

RESULTS

Figure 2 compares the distribution of prescribed values of circumferential material stiffness (left) to the spatial distribution of four different metrics of arterial stiffening: pulse pressure (*PP*), distensibility, pulse wave velocity (*PWV*), and changes in elastic energy stored during the cardiac cycle (ΔW) (right). Results are shown in six different anatomical regions along the aorta. Overall, our computed values compared well with data reported in literature for different age groups [5, 6]. We observe amplification of *PP* along the aorta at the youngest age, while the pressure waveforms become more alike in amplitude and contour with aging. We notice that the biggest change in *PP* occurs between 40 and 60 yo; indeed it has been reported that the largest changes in central pulse pressure happen around 50-55 yo [7]. Distensibility was calculated as $D=(d^2_{sys}-d^2_{dia})/(d^2_{dia}\cdot PP)$; as expected, the distensibility decreases distally along the aorta at a given age and it also decreases with aging at each individual location. The pulse wave velocity *PWV* was calculated as the ratio of the distance travelled by the pressure waveform and the transit time between pressure waveforms recorded at two locations of interest. Differently from the other three metrics of interest, the spatial distribution of *PWV* does not follow the prescribed distribution of circumferential stiffness everywhere. This difference arose because *PWV* depends not only from stiffness, but also on geometry (cf. Moens-Korteweg). *PWV* is indeed strongly influenced by arterial tapering and branching. Finally, the change in elastic energy throughout the cardiac cycle was calculated via the work done on the aorta given the assumption of no dissipation. In all regions other than the ATA, this is given by $\Delta W = 0.5(P_{sys}-P_{dia})\cdot(A_{sys}-A_{dia})/A_{dia}$. The distribution of this metric is comparable to the distensibility.

We also obtained good matching between the model predicted values of carotid-to-iliac *PWV* with measured values of *cf-PWV* for different age groups in a population with no risk factors [6, 8].

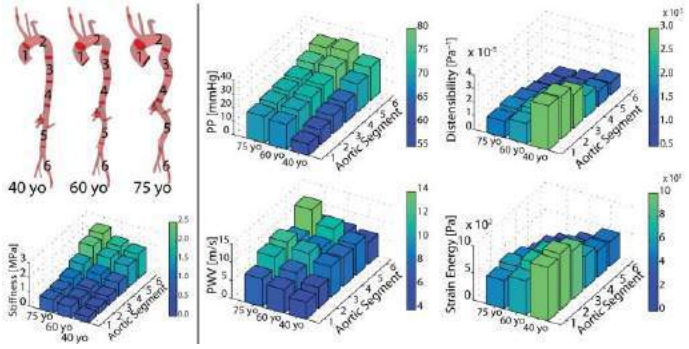

Figure 2: Prescribed values of circumferential material stiffness (MPa) and computed values of local pulse pressure (*PP*, in mmHg), distensibility (Pa^{-1}), pulse wave velocity (*PWV*, in m/s), and change in strain energy storage (ΔW, in Pa x 100) as a function of region (aortic segments 1 to 6) for three different ages: 40, 60, and 75 years old (yo).

DISCUSSION

Based on the best values of arterial stiffness, radii and length found in literature we used computational tools to investigate changes in four different metrics of arterial stiffening with aging. The current gold standard clinical metric is *cf-PWV* which represents an average over a large portion of the arterial tree. We found that differently from the other metrics, *PWV* is not directly related to the prescribed distribution of circumferential stiffness, due to the fact that PWV depends on both arterial geometry and stiffness. The distribution of *PWV* (Figure 2) shows notable differences over age at segment 5, which corresponds to the location of the renal arteries. This work has several limitations: the population-averaged data on anatomy and tissue properties implies that no subject-specific models were considered. Of course, it is not feasible to acquire longitudinal data on anatomy and stiffness for the same individual over a long time span. Furthermore, our FSI method did not taken into account the significant extensibility experienced in the ATA for the younger age groups. Lastly, we did not have flow data at multiple locations down the aorta: this would have allowed us to estimate the Windkessel parameters with more certainty.

INTRODUCTION

Synthetic hydrogels are a major class of materials extensively used in biomedical applications ranging from tissue engineering to drug delivery [1]. However, a major drawback to these systems is the significant swelling that occurs with equilibrium hydration. Such swelling not only alters the gross geometry and dimensions of structures, but also leads to changes in hydrogel mechanical properties. We hypothesized that increasing the hydrophobicity of the polymer backbone through the attachment of hydrophobic pendant side chains could be used to modulate and eliminate swelling (Fig 1a), and thus extend the application of hydrogels to settings where swelling is undesirable. We illustrate the utility of this system through integration into a microfluidic device to reveal how endothelial cell invasion into surrounding matrix is modulated by different material properties (e.g., degradability, matrix stiffness).

METHODS

Polymer synthesis: Methacrylated dextran (DexMA) was synthesized by reaction of 86kDa dextran with varying amounts of glycidyl methacrylate. Cell culture: Angiogenic gradient-generating fluidic devices were generated and cultured as previously published [2]. A solution of DexMA (71% methacrylation, 4.4% w/v) and CGRGDS (3 mM) was prepared in M199 media containing sodium bicarbonate (3.5% w/v) and HEPES (10 mM). The pH was adjusted to 8 to couple CGRGDS to DexMA. After 30 min, varying amounts (17 - 44 mM) of crosslinker peptide NCD or LD were added and gels were allowed to polymerize for 1 h prior to seeding with HUVECs. Fluorescent labeling: To examine the organization of the actin cytoskeleton, cells were permeabilized with Triton X-100, blocked in 2% BSA, and stained with phalloidin. Microscopy: Phalloidin/DAPI-stained samples were imaged on a confocal microscope and images are presented as maximum intensity projections. Image analysis was performed with custom Matlab scripts. Statistics: Significance was determined by ANOVA or Student's t-test ($p < 0.05$).

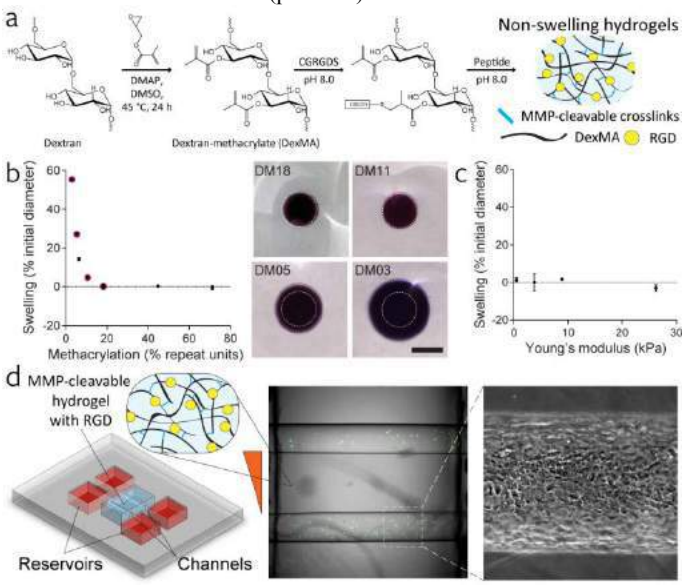

Figure 1: a) Synthetic route to non-swelling hydrogels. b) Swelling behavior as a function of % methacrylation. c) Swelling as a function of Young's modulus. d) DexMA hydrogels incorporated into angiogenic gradient-generating fluidic devices.

RESULTS

Increasing the level of methacrylate functionalization from 3 to 70% decreased DexMA hydrogel swelling from 55 to 0% (Fig. 1b).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Swelling was not affected by the amount of crosslinking, allowing swelling to be controlled independently of hydrogel stiffness (Fig. 1c). Gels were incorporated into a microfluidic device [2] (Fig 1d) to investigate how matrix properties influence angiogenic sprouting. We first examined whether the sprouting response was affected by changing the number of crosslinks via the concentration of MMP labile crosslinker peptides (Fig. 2a). Increasing crosslinking density decreased sprout length and appeared to switch cells from highly collective multicellular sprouting in gels of intermediate crosslinking, to less coordinated single cell migration in lightly crosslinked gels (Fig 2b-c). Fixing samples at different time points to maintain invasion depth constant confirmed that cells primarily invaded alone into matrices of low crosslinking density, whereas intermediate crosslinking densities gave rise to multicellular sprouts and a higher cell density (Fig. 3b-c). Next, hydrogel stiffness was maintained while modulating the degradability of the MMP-cleavable crosslinker sequence by replacing the standard native collagen degradability (NCD) with a lower degradability (LD) sequence. Strikingly, collective invasion was rescued in soft matrices when degradability was lowered, suggesting that high degradability rather than low stiffness drives the single cell migration phenotype observed in lightly crosslinked ECM (Fig. 3d). We posited that high degradability causes cells to degrade the matrix and invade too quickly to maintain cell-cell junctions. Indeed, exposure to a broad spectrum MMP inhibitor slowed cell invasion and rescued multicellular sprout formation even in soft gels crosslinked with the NCD sequence, further supporting the importance of degradability in sprout morphogenesis (Fig. 3e).

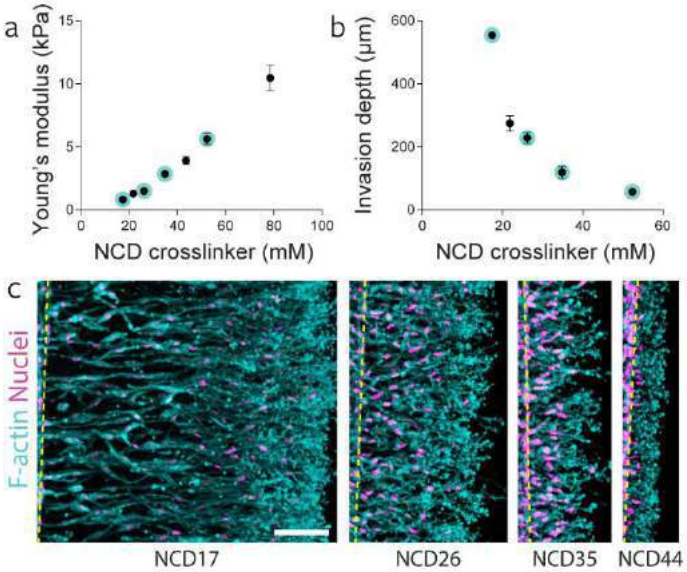

Figure 2: DexMA hydrogel Young's modulus (a) and sprout invasion depth (b) as a function of crosslinker concentration. c) Sprout morphology representative samples. Scale: 100μm.

DISCUSSION

Numerous studies using natural matrices such as fibrin or collagen have suggested that the physical properties of the ECM (e.g. matrix density, ligand density, and matrix stiffness) can regulate angiogenic sprouting. However, because these matrix properties are intrinsically coupled in natural ECMs, it is difficult to isolate the relative contribution of any one of these factors. Using a synthetic hydrogel to tune these properties orthogonally, we found that matrix crosslinking plays a critical role in modulating the extent, morphology, and even multicellularity of cell invasion. Crosslinking of synthetic gels has classically been used to vary the stiffness of a 2D substrate on which cells are seeded; this stiffness has been shown to dramatically impact cell spreading, proliferation, migration and differentiation. However, in 3D settings such as those investigated here, the degree of crosslinking alters not only matrix stiffness but also its degradability – the rate at which cells can cleave through the matrix. Degradability has previously been suggested as a parameter that affects the ability of fully encapsulated single cells to spread into the matrix [3,4]. By tuning degradability independently from matrix stiffness here, we reveal that ECM degradability is a key regulator of the collective nature of multicellular invasion, a critical requirement not only for functional blood vessel formation but also the formation of many other multicellular structures.

NOVEL METHOD FOR CHARACTERIZING LOADING PATTERNS OF KNEE STABILIZERS YIELDS NEW INSIGHT INTO THE FUNCTION OF THE ANTEROLATERAL LIGAMENT

INTRODUCTION

Primary stabilizers of the intact knee such as the anterior cruciate ligament (ACL) bear load in concert with surrounding secondary stabilizers to resist multiplanar torques typical of pivoting maneuvers.[1,2] When the ACL is compromised, secondary stabilizers must bear increased load to compensate for the injured primary stabilizer. For example, the lateral meniscus, anterolateral capsule, and iliotibial band are predominately responsible for resisting anterior tibial subluxation characteristic of instability events that occur when the ACL is compromised.[3,4]

The stabilizing role of primary and secondary stabilizers is commonly assessed through serial sectioning studies where changes in primary and coupled motions are measured in response to an applied load following tissue sectioning.[4,5] Another common approach consists of measuring the changes in joint reaction forces before and after sectioning a tissue in response to a known displacement. The changes in joint reaction force represent the load carried by the ligament in response to the applied displacement.[6]

Unfortunately, these previous approaches do not quantify where within the envelope of joint motion these secondary restraints bear load. Knowing where within the envelope of motion ligaments bear load (i.e., their engagement patterns) provides additional information quantifying the function of primary and secondary stabilizers. Such knowledge would provide a framework for understanding the effect of surgical reconstruction of ligaments on knee function. For example, the recently rediscovered anterolateral ligament has been identified as a stabilizer resisting rotatory loads and anterior subluxation events; however, where within the envelope of motion this structure engages has not been determined.[7,8] This hinders formulating surgical reconstruction strategies to restore ligament function and deciding whether a ligament should be reconstructed.

Therefore, a method was developed to assess where within the envelope of motion secondary stabilizers boar load. Then, the following research questions were addressed: Do secondary stabilizers resisting anterior subluxation of the tibia in response to multiplanar rotatory loads such as the anterolateral ligament (ALL), the medial collateral ligament (MCL), and the lateral meniscus engage within the envelope of coupled anterior tibial translation permitted by the ACL-competent knee?

METHODS

With IRB approval, 9 fresh-frozen human cadaveric knees were acquired for testing (mean age: 43 years; range: 20-64 years; 7 male). Specimens were mounted to a robot, which moved the tibia relative to a rigidly grounded femur and was equipped with a universal force-moment sensor. Tibial translation and rotation were described along and about anatomical directions.[9] Valgus torque was increased to 8 Nm and then internal torque was increased to 4 Nm with the knee held at 30° flexion. The position and orientation through which the tibia moved in response to the applied loads were recorded in the ACL-intact and -sectioned conditions. The kinematics were subsequently repeated before and after serially sectioning the ACL, anterolateral ligament (ALL), superficial medial collateral ligament (MCL), posterior oblique ligament (POL), and lateral meniscus; these were likely candidates for bearing load in response to multiplanar torques characteristic of pivoting movements.[3,10] The resultant force borne by these structures was determined via vector subtraction of the forces measured across the knee before and after sectioning each structure.[11]

To quantify the engagement patterns of the aforementioned secondary stabilizers, the following steps were taken. First, each structure was categorized as either load-bearing or non-load-bearing based on whether it carried at least a third of the load seen in the ACL in the same knee. We used the load borne by the ACL as the reference for identifying load-bearing structures since the ACL is a primary stabilizer against multiplanar rotatory loads.[6] This threshold consistently differentiated load-bearing and non-load-bearing structures from knee to knee. If structures did not exceed one third of the load carried by the ACL, they were not analyzed in subsequent steps. Second, load in each structure as a function of coupled anterior translation was used to identify the position of the tibia where the load-bearing secondary stabilizers began to carry load in the ACL-deficient knee. This anterior position was termed the 'engagement point.' More specifically, a secondary stabilizer's 'engagement point' was defined as the anterior tibial translation at which the ligament bore 15% of the load carried by the ACL in response to the combined valgus and internal rotation torques (Fig. 1).

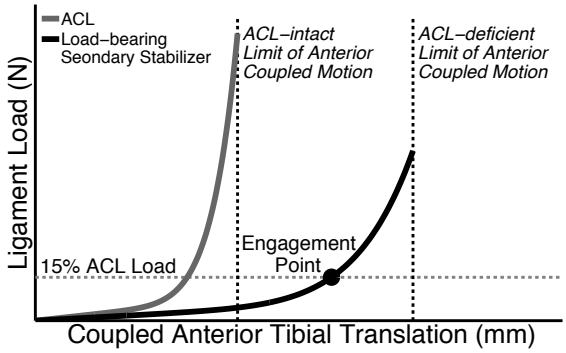

Figure 1: Representative plot of resultant loads in secondary stabilizers as a function of coupled anterior tibial translation in response to combined valgus and internal rotation torques.

Outcome measures, were: (1) the number of knees in which each structure was load-bearing as defined above; and (2) the anterior translation at which secondary stabilizers engaged in the ACL-deficient knee (i.e., the engagement point). The engagement points of the load-bearing secondary stabilizers after the ACL was sectioned were compared to the limit of coupled anterior translation of the ACL-intact knee using paired, two-tailed t-tests ($p < 0.05$).

RESULTS

In the ACL-intact condition, the superficial MCL, lateral meniscus, POL, and ALL were load-bearing in a respective nine, six, two, and zero of the nine knees that were tested. In the ACL-deficient condition, the superficial MCL and lateral meniscus were load-bearing in every knee, and the ALL and POL were load-bearing in a respective seven and one of nine knees. In the ACL-intact and the ACL-deficient conditions, the POL bore 19.7 ± 10.5 N and 14.5 ± 6.2 N, respectively (the average load cutoff was 26.8 ± 8.4 N).

The engagement point of the ALL in the ACL-sectioned knee was 4.3 ± 2.4 mm past the coupled anterior translation that occurred with the ACL intact ($p < 0.005$) with the difference ranging from 0.1 to 7.1 mm (Fig. 2). The engagement points of the MCL and the lateral meniscus were not greater than the coupled anterior translation of the ACL-intact knee on average (both $p > 0.1$) (Fig. 2). These differences ranged from -5.4 to 5.2 mm for the MCL and -5.7 to 7.2 mm for the lateral meniscus (Fig. 2).

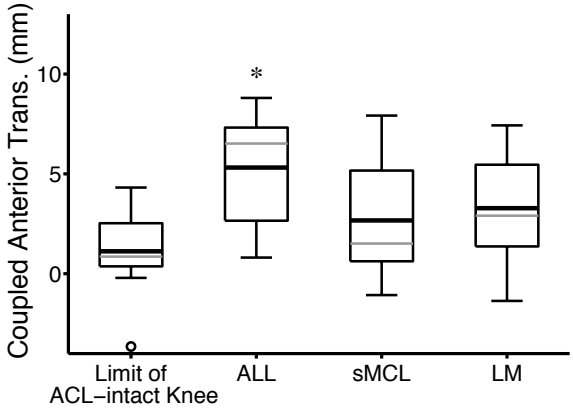

Figure 2: Limit of coupled anterior translation (trans.) of the ACL-intact knee compared to the engagement points of the ALL, superficial MCL, and lateral meniscus after the ACL was sectioned. Black and grey lines denote means and medians, respectively. * indicates $p < 0.05$ compared to the limit of the ACL-intact knee.

DISCUSSION

We established a new method to characterize the function of secondary stabilizers of the knee as a function of combined rotatory loads by assessing where within the passive envelope of motion each structure began to carry load. The major finding of this method was that the ALL consistently engaged (i.e., bore load) beyond the range of coupled anterior translation of the ACL-intact knee. Specifically, the tibia subluxed anteriorly 4.3 mm more on average than the coupled anterior translation of the ACL-intact knee before the ALL engaged. In contrast, the relative engagement positions of the superficial MCL and lateral meniscus were more variable. Each engaged within the limit of coupled anterior translation of the ACL-intact knee in two of nine knees.

One implication of these data is that, although the ALL bore load in seven of nine knees tested in response to multiplanar torques after sectioning the ACL, it does not engage within the envelope of motion permitted by the native knee. Therefore, this tissue resists load after the tibia subluxes anteriorly in response to the combined torques. Interestingly the amount of subuxation occurring with ALL engagement ranged from 0.1 to 7.1 mm, indicating that there is a high degree of variability in the stabilizing role of the ALL. A trend of surgically reinforcing the lateral tissue via lateral extraarticular augmentation as an adjunct to ACL reconstruction has emerged to restore rotational stability. However, use of these combined surgeries remains a subject of debate due to variable outcomes.[7,12] Understanding on a patient-specific basis how and when portions of the anterolateral capsule engage in response to rotatory loads generating anterior tibial subluxation characteristic of a pivot shift may help identify mechanisms driving this variability.

Another key implication involves the high degree of variability seen in the anteroposterior positions of the tibia at which the superficial MCL and lateral meniscus engage. In six knees, the tibia subluxed anteriorly before load had built in either of these structures. Unlike the ALL, these structures are primarily loaded as a result of valgus torque with the superficial MCL in tension and the lateral meniscus in compression. Future work should address anatomical differences across patients that result in engagement of these structures within versus outside of the range of the native knee.

A limitation is the ages of the knees that were tested, which was greater than those typically experiencing ACL injury. However, none of our outcome measures correlated with age (all $R^2 < 0.42$).

In conclusion, we have presented a novel method for characterizing how load builds in stabilizers of the knee in response to multiplanar rotatory loads. By accounting for ligament loads as a function of joint position, this method provides a framework to characterize the stabilizing role of the passive soft tissues of the knee joint. Knowing where within the envelope of motion ligaments bear load may aid establishing patient-specific guidelines for surgical reconstruction of intra and extra-articular stabilizers.

INTRODUCTION

Anthropometric test devices (ATD, aka dummies) are used to evaluate vehicle performance during different crash modes and serve a fundamental role in regulatory and consumer awareness tests. In the virtual testing and research phases, computational models of ATDs are often employed. Recently computational human body models (HBMs) have gained popularity and provide fundamentally different information; human performance in the crash environment. While important data about the effectiveness of the safety systems at protecting the occupant can be derived from HBMs, there are many unanswered questions about the relative performance of these two types of models. Therefore, the objective of this study is to conduct matched pair testing of the validated Global Human Body Models Consortium (GHBMC) 50th percentile HBM male simplified occupant (M50-OS) model and standard ATD models in frontal and lateral US-NCAP crash configurations [1]. We quantitatively compare biomechanical outputs from each model to generate preliminary outcome-based transfer functions between the two in these configurations.

METHODS

The GHMBC M50-OS (v. 1.8, 295k nodes, 357k elements, 79.6 kg), the Humanetics Hybrid-III 50th percentile ATD (v. 7.1.8, 99.5k nodes, 125k elements, 79.9 kg), and the LSTC ES-2Re (v. 0.201, 428k nodes, 515k elements, 72.3 kg) were used in the simulations. The models were gravity settled into the driver position of the National Crash Analysis Center (NCAC) Ford Taurus or simplified occupant compartment (Figure 1). Initial simulations (Neck flexion/extension, chest and knee impacts) were run per certification tests to assess how closely the GHBMC M50-OS compares to the ATD in a laboratory setting. All collision simulations were equipped with an advanced 3 point belt system and frontal or side airbag. Restraint properties were based on literature values [2].

The following simulations were performed: Frontal NCAP, Lateral NCAP with a moving deformable barrier and a side pole impact. The baseline delta-V's were 56.4 kph, 61 kph and 32 kph respectively. In an effort to study model sensitivity, ΔV's were varied by ±20% resulting in 5 simulations per condition and total of 30 simulations. Simulations were run on a Linux cluster using 16 CPUs and MPP LS-DYNA.

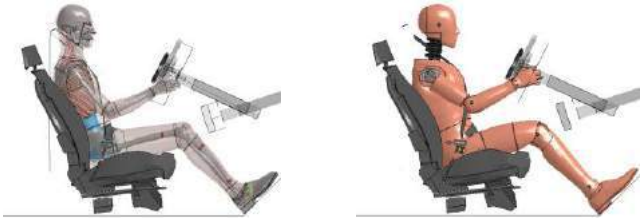

Figure 1: Seated positions of the M50-OS (top) and Hybrid III-50 (bottom) models in the occupant compartment.

RESULTS

Results for frontal impact showed that the human and dummy models predict the same trends in general. Cross plots

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

of injury criteria can be found in Figure 2. An overlay between the M50-OS and the Hybrid III models can be seen in Figure 3. Cross plots of data demonstrated this trend as being generally linear between the two models for HIC-15, and Chest Deflection. Shoulder and lap belt forces did not follow the same linearity. HIC-15 data shows high linear correlation of 0.929. The last three measures that were examined in this investigation did not linearly correlate well (0.3305 for chest deflection, 0.2111 for shoulder belt forces, and 0.1327 for lap belt forces).

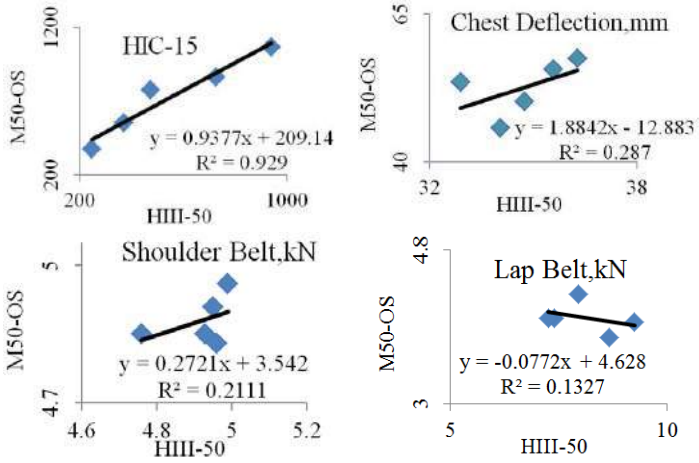

Figure 2: Cross plots of HIC-15, Chest Deflections, Shoulder and Lap belt forces for the M50-OS and HIII-50 models in the Frontal NCAP crash mode. Linear regression for each plot and the R^2 values are given. Plots ordered from highest to lowest R^2.

DISCUSSION

The two models trend similarly for most measures. As the delta-V decreased, the models experienced lower amounts of HIC-15, and chest deflection. Shoulder belt forces, while it did not trend similarly, tended to be within the same range of values for both models with some negligible differences due to belt-body contour interactions. The differences in the lap belt can be attributed to the different designs in the pelvic area for each model. The differences in lap belt forces may also be responsible for the low correlation found for chest deflection values between the two models. Although, another key difference between the two models is that the chest of the M50-OS model is more compliant than the dummy model which will also cause higher chest deflections and possibly lead to a lower correlation between the two models.

While validated, ATDs and human models will have differing biomechanics that arise from their constitutive properties (e.g. ATDs are made of, and modeled as, steel and rubber). As the use of human models proliferate a "transfer function" between virtual humans and ATDs will be a valuable addition to the literature to quantify relative performance. This study is a pilot study towards that aim. These data may be of use in future regulations leveraging virtual human body models. Due to HBM's omnidirectional nature, impact modes in which no specific dummy has been designed (e.g. oblique, roll-over) may benefit from these data.

INTRODUCTION

The development and feasibility of a novel transparent nanocrystalline yttria-stabilized-zirconia (nc-YSZ) cranial implant has been recently established [1]. The purpose of what we now call the "Window to the Brain (WttB)" implant is to improve patient care by providing a technique for delivery and/or collection of light into/from the brain, on demand, over large areas, and on a chronically-recurring basis without the need for repeated craniotomies. WttB holds the transformative potential for enhancing light based diagnosis and treatment of a wide variety of brain pathologies (i.e. cerebral edema, traumatic brain injury, stroke, glioma, and neurodegenerative diseases).

However, bacterial adhesion to cranial implants is the leading factor for biofilm formation (fouling), infection, and treatment failure [2], and further, may limit the use of the WttB for optical imaging and therapy by reducing the transparency of the window. Due to the transparency of the nc-YSZ implant, we hypothesized that medical laser treatment through the implant could reduce the formation of biofilm. However, in order for this approach to be a viable strategy for anti-fouling *in vivo*, it is critical that the temperature of the implant does not exceed an increase of 10°C, the threshold for damage to native tissue [3]. In this study, we investigate continuous wave (CW) and pulsed wave (PW) laser treatments of bacteria underlying the nc-YSZ implant *in vitro*, while monitoring the resulting surface temperature of the nc-YSZ implant.

METHODS

Implant Fabrication and Preparation: Transparent nc-YSZ cranial implants were fabricated with current activated pressure assisted densification (CAPAD), which enables reduction of internal porosity to nanometric dimensions, and thus, reduction of the optical scattering that renders typical YSZ opaque [4]. Transmittance of the implant was measured on a spectrophotometer (Varian Cary 500) and is provided in **Figure 1.** Prior to each experiment, nc-YSZ samples were dry sterilized (Germinator 500) at 250 ºC to remove all preexisting bacteria.

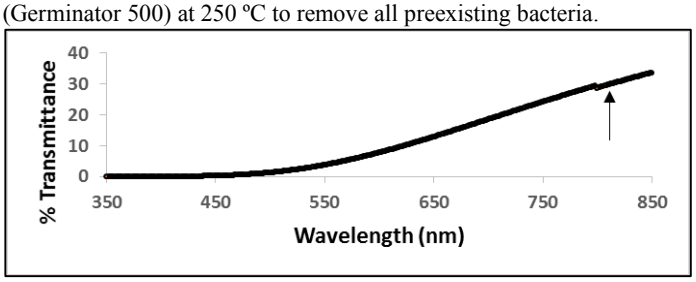

Figure 1: Transmittance of the nc-YSZ implant, including the irradiation wavelength used in this study (810 nm, black arrow).

Bacteria Inoculation: For all experiments, we used genetically engineered bioluminescent BL21 Escherichia coli (CMC0014, Sigma Aldrich) transformed with P. Pyralis luciferase gene using pet28 vector. 0.5 μL of bacteria in media was seeded on agar at 37ºC and the nc-YSZ was placed on top. Bacteria underlying nc-YSZ was treated with selected laser parameters through the nc-YSZ for 20 seconds, and then the nc-YSZ was removed and the culture was incubated for 24 hours at 37ºC. The experimental setup is illustrated in **Figure 2.**

Laser Device: Photo-irradiation was performed using an 810nm laser (Vari-Lase). The laser spot size on the sample was 7mm in diameter ($1/e^2$). The variable laser parameters were power (1-3W) and pulse rate (0.3-5Hz). Control cultures were treated in an identical manner to irradiated cultures, except that the laser was not switched on.

Temperature Measurements: The temperature of the surface of nc-YSZ was measured with a non-contact infrared thermal camera (A325sc, FLIR Systems Inc.) operating in video mode at 60 frames/s. The video was post-processed using ResearchIR software (FLIR

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

ResearchIR4). According to specifications, the camera measures temperatures with a precision of 50mK, has an accuracy of 2%, and a viewing angle of 5-60 degrees.

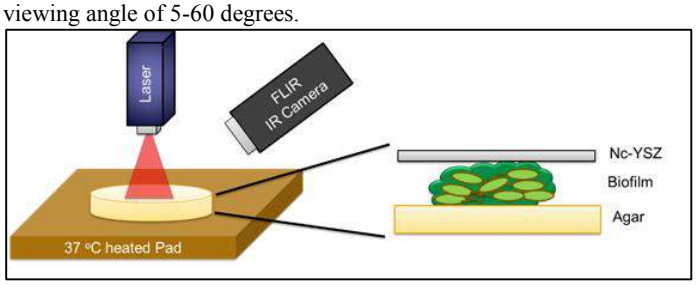

Figure 2: Illustration of the experimental setup used in this study.

Bioluminescence imaging system: 24 hours after laser irradiation, 100µL of the luciferase substrate (D-Luciferin, potassium salt 150µg/ml, Research Products International Corp.) was added at room temperature to evenly cover each culture. Light emission of the bioluminescent bacteria was detected using a Macro Luminescence Dark Box (Stanford Photonics, Inc, Palo Alto, CA). ImageJ software (National Institute of Health) was used to quantify the light emission at the irradiated Regions of Interest (ROIs). The ROIs encompassed a circle equal to the beam spot size on the sample (7mm diameter). The relative luminescence unit (RLU) in the ROI was normalized with respect to the RLU outside of the ROI for each sample.

Statistical Analysis: All statistical comparisons were evaluated using analysis of variance for repeated measurements (ANOVA). When appropriate, post hoc analyses were performed with the Bonferroni's multiple comparisons test. All statistics were calculated using GraphPad Prism 5.01 (GraphPad Software, Inc., San Diego, CA). *$p<0.05$, **$p<0.01$, ***$p<0.001$ relative to control.

RESULTS

Figure 3 shows normalized RLU of biofilm after 24h and the average surface temperature (ΔT) of nc-YSZ at the end of the 20 second laser treatment using CW laser with 1, 2, and 3W of power. The results show that the decrease in the RLU value is statistically significant for all treated groups compared to control ($p<0.05$) and that ΔT for the CW laser powers above 1W is above 10ºC, which is considered the critical threshold for thermal damage.

Figure 4 shows normalized RLU of biofilm after 24h and the average surface temperature (ΔT) of nc-YSZ at the end of the 20 second laser treatment using CW or PW laser with 3W of power. Treatment with all laser parameters except for 0.3Hz leads to a significant reduction of E. coli viability compared to the control group ($p<0.05$). The results indicate that the ΔT is above the 10ºC critical temperature threshold for CW laser and all the PW laser settings exceeding 5J/cm^2 and 1Hz.

DISCUSSION

When CW laser is used, the biofilm reduction seems to follow a linear relationship with ΔT, suggesting an entirely photothermal mechanism of bacterial damage **(Figure 3)**. In the case of PW laser, however, the relationship between temperature and biofilm reduction is less clear. Comparing bar#3, bar#5, bar #6 and bar #7 (frequency of 5, 1, 0.5 and 0.3 Hz) in **Figure 4** indicates that laser treatment with higher frequency results in greater reduction in E. coli biofilm. Comparing bar#4 and bar#5 (10 J/cm^2 400 ms vs. 5 J/cm^2 200 ms) indicates that doubling the energy density per pulse and pulse duration increases the temperature by about 3ºC, while it has negligible effect on the reduction rate of E. coli biofilm.

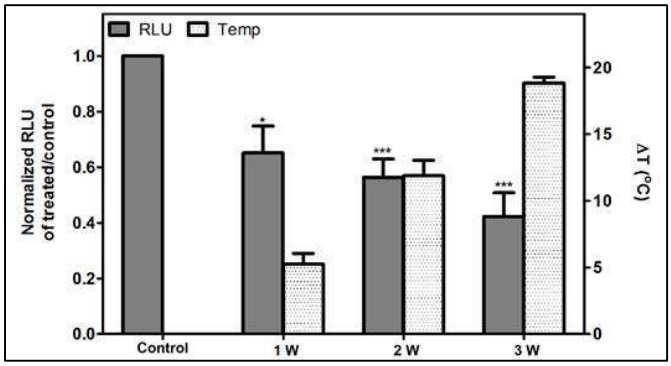

Figure 3: Normalized RLU of biofilm after 24h and the average surface temperature (ΔT) of nc-YSZ after CW laser treatment with 1, 2, and 3W of power. Each bar represent Mean±SEM (n=9).

The results indicate that CW laser has the higher reduction rate of E. coli biofilm compared to PW laser, but also results in the highest temperature increase. In contrast to the linear relationship of temperature and biofilm reduction for CW laser **(Figure 3)**, there is no linear relationship between the differences in temperature change and biofilm reduction for PW laser **(Figure 4).** Lack of correlation between ΔT and RLU suggests that the biofilm disruption mechanism using the PW mode is not entirely due to photothermal effects. This suggests that PW laser may be capable of reducing biofilm formation through the transparent nc-YSZ implant to even greater extent than demonstrated in this study (i.e. more than 40% reduction), without surpassing the thermal damage threshold of 10ºC, if laser parameters are optimized.

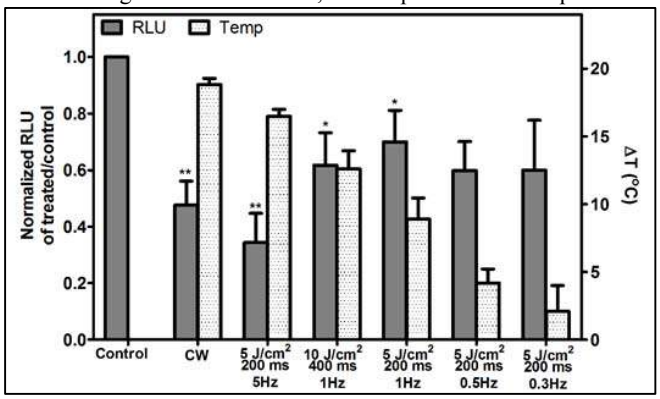

Figure 4: Normalized RLU of biofilm after 24h and the average surface temperature (ΔT) of nc-YSZ after CW or PW laser treatment with 3W of power. Bars represent Mean±SEM (n=9).

In conclusion, this proof-of-concept study demonstrates that an 810nm medical laser can be used to treat biofilm formation through the transparent WttB implant *in vitro* without generating heat above the thermal damage threshold for tissue. Further study is needed to determine if these results can translate into viable *in vivo* approach.

INTRODUCTION

In recent years, computational techniques have been used extensively to simulate blood flows in cardiovascular geometries. These simulations provide a key tool for analysis of patient specific cardiovascular geometries. Furthermore, the coupling of design and optimization with high-fidelity blood flow simulations has become a vital asset in medical device design and surgical planning [1]. However, due to noisiness or non-availability of gradient information of the objective function, conventional optimization methods are often unsuitable in such problems. Furthermore, as fluid flow simulations are computationally expensive, the need for efficient methods that limit number of function evaluations becomes paramount.

The objective of this study is to develop a framework that couples components that model and analyze parametrized cardiovascular geometries with a suitable optimization algorithm. The optimization algorithm chosen for this study is the Surrogate Management Framework (SMF), which has been previously used for shape optimization of cardiovascular geometries [2,3] and has an established convergence theory [4]. The performance of the SMF framework deteriorates with the progression of optimization process due to ill-conditioning of the covariance matrix associated with global search step [6]. Variations of the local search in the SMF algorithm are studied in order to improve efficiency under a fixed computational budget. Such a framework can be utilized to design solutions for patient-specific pathologies.

METHODS

A simplified three-dimensional model for an anastomosis over stenosis has been adapted from the clinical study by Ku et al. [5]. The model is parametrized by three design parameters: the angles of graft with vessel upstream and downstream to stenosis (θ_1 and θ_2 respectively) and the radius of the graft (R_a) (Figure 1). The bounds on these parameters are given in Table 1. Regions of pathologically low wall shear stress are typically susceptible to the risk of artherosclerosis and intimal thickening. Hence, the cost function is chosen to be the total area of vessel with wall shear stress magnitude below a threshold wall shear stress magnitude. Equation 1 gives a functional representation of the cost-function where H is the Heaviside function and x is position on the parent vessel.

$$J = \iint_{Parent\ vessel} H\left(2.5 - WSS\left(x\right)\right) dS \qquad (1)$$

SimVascular, an open source software package (www.simvascular.org), was used for constructing the model, generating the mesh and running the three-dimensional finite element flow simulation. The finite element mesh is comprised of tetrahedral elements with refinement at the walls and junctions to accurately resolve wall shear stress. The incompressible Navier-Stokes equations are solved for this study using a finite element method with resistance boundary conditions.

The SMF is a derivative free optimization method that relies on local search accelerated by a global search step. For forming the surrogate required in the global search, ordinary kriging is utilized. For the local search, MADS pattern search is used with (n+1) vectors that form a positively spanning basis (where n is the dimension of parameter space). Pattern search methods are typically based on a uniform Cartesian grid in the parameter space.

Based on the success of previous search steps, three variations to local search are studied: local search with isotropic coarsening of search grid, anisotropic coarsening of search grid and rotational polling. Isotropic coarsening method increases the grid size in each parameter by a fixed factor whenever the SMF finds an improvement. Anisotropic coarsening method builds on isotropic coarsening, but with a factor of improvement dependent on the previous success direction relative to the current incumbent solution in the event of a successful poll step. Rotational polling refers to the rotation of poll directions based on the directions of previous local (poll step) improvement. A baseline case is also considered which shows the performance of the method without any variation in the poll step.

Figure 2 shows a high level overview of the coupling between components for model generation, meshing, simulation, post-processing, cost-function evaluation and the optimization algorithm.

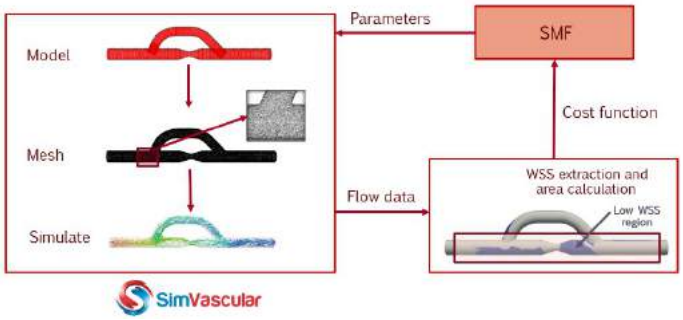

Figure 2: Overview of coupling between the optimization (SMF), modeling, meshing and flow simulation (SimVascular) and cost function evaluation.

RESULTS

Figure 3 displays the overall performance of different variations of the SMF algorithm for steady flow conditions. Each optimization process begins with a common initialization of 13 parameter sets based on Latin Hypercube sampling of the parameter space.

We observe that simple MADS polling (baseline) does not give any improvements beyond the first 20 simulations. On the other hand, all other methods result in further cost function reduction with varying success within a fixed computational budget of a total of 60 simulations. Rotation of the polling directions appears to give the best improvement post-initialization though the performance is closely followed by isotropic coarsening of the grid.

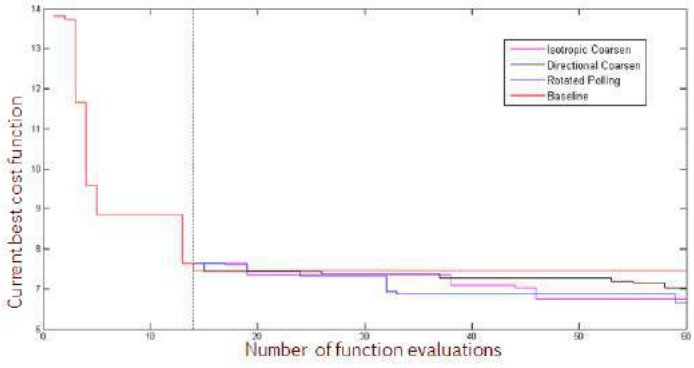

Figure 3: Decrease in cost function with number of function evaluations for different variations of SMF

DISCUSSION

As the number of function evaluations increase, the typical optimization progresses to converge towards a local minimum. However, due to over-refinement of the grid with the lack of a coarsening mechanism, the baseline version of the SMF tends to converge slowly to the minimum when compared to the coarsening aided strategies. Also, the piling-up of several points in a small region in parameter space has been seen to be detrimental to the global search step [6] and hence, coarsening allows for more space between evaluations and a better conditioned covariance matrix for surrogate generation.

We observe that the poll directions may not often align with the direction of steepest descent until the local search grid is very refined. This is due to the Cartesian nature of the local search grid and the use of (n+1) poll directions. In such situations, the rotation of poll directions based on previous improvements allows the selection of the closest path on the discrete grid to the local minimum and hence, a lesser number of evaluations are required.

There have been few studies regarding optimization in cardiovascular geometries in patient-specific models due to the high computational cost of each function evaluation. The proposed automated framework, with suitable acceleration strategies for the optimization procedure, is an important step towards utilizing hemodynamic simulations for designing devices and surgeries in the future.

INTRODUCTION

For blunt impact evaluation, current combat helmet standards utilize drop tower tests to measure headform linear acceleration for different impact locations, and apply a simple pass/fail criterion stating that resulting accelerations must not exceed 150 g [1]. These standards do not consider rotational head motion for injury assessments, and weigh all impact directions equally. Therefore, to better protect the warfighter, an improved helmet evaluation process is needed that accounts for probability of head injury. A continuous injury risk metric is beneficial to the helmet design process as it allows for design trade-offs to be properly assessed, whereas the current standards only allow for a binary outcome. An example of such a rating system can be found in the evaluation of collegiate football helmets [2]. The current study explores the advantages of how such an evaluation methodology could be used to assess how suspension pad design features help mitigate head injury. To accomplish this, a Finite Element Model (FEM) of an Advanced Combat Helmet (ACH), retention system and standard seven-pad suspension system was created to simulate a realistic headform response under blunt impact loading. The use of a computational model for this investigation enabled a range of material and design modifications to be evaluated. The purpose of this study is twofold: 1) To develop and validate a FEM of an ACH with a standard seven-pad suspension system for blunt impact loading and 2) to use this model to demonstrate that changes to pad design can influence head injury outcome.

METHODS

To develop realistic material properties for use in the FEM, physical testing was conducted on trapezoidal, oblong and crown pads that comprise the standard seven-pad suspension system. To determine the appropriate stiffness of the trapezoidal, oblong and crown pads, Instron compression tests were performed at loading rates of 2mm/s, 20mm/s, 200mm/s, and 2m/s to 90% strain (n=3 for each loading rate and pad type). Separate stress-strain curves were developed for each of the three pad types for each loading rate.

Previously collected experimental drop tower test data were leveraged to validate model performance in blunt impact loading. In these series of test, a monorail guided freefall drop test system was utilized to measure the acceleration of an EN960 Half Headform outfitted with an ACH and standard seven-pad suspension system upon hitting a hemispherical impact anvil. Average acceleration response corridors were created for impact velocities of 10, 14.1 and 17.3 ft/s to replicate 1x, 2x and 3x the standard kinetic energies [1]. Impact locations consisted of the helmet's front, crown, side, nape and rear locations.

To create the appropriate mesh geometries for the FEM, 3D scans were collected of a large ACH fitted with the standard seven-pad suspension system (Model K610, Nikon, Brighton, MI). The geometries of both helmet and pads were meshed in TrueGrid (XYZ Scientific, Pleasant Hill, CA). Subsequently, pad material properties were defined with the material card *MAT_FU_CHANG_FOAM in LS-DYNA (LSTC, Livermore, CA), which utilized the stress-strain curves from the pad compression testing. The helmet material was defined as a linear elastic material with a Young's modulus of 12.25 GPa, which was based on average values from a previous study [3]. In addition to the helmet and pad meshes, the hemispherical impact anvil, EN960 head form and support arm were meshed and assigned as rigid parts. The helmet, pads, headform and support arm were given an initial velocity of 10, 14.1 or 17.3 ft/s to match the experimental conditions. All simulations were performed with LS-DYNA. Headform accelerations were collected at a sample rate of 100 kHz. Both experimental and computational accelerations were processed

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with a CFC1000 standard filter. Percent error was calculated to compare the numerical model and experimental drop tower tests results:

$$\text{Percent Error} = \left|\frac{x_{FEM}-x_{EXP}}{x_{EXP}}\right| * 100 \qquad (1)$$

Where x_{FEM} and x_{EXP} are the peak model and average peak experimental accelerations, respectively.

To provide a proof-of-concept example of how an injury-based rating system could benefit helmet suspension design by readily identifying optimal values for material parameters, two different pad designs were considered. The first pad design utilized the original experimental pad stress-strain curves while the second design used a scaled version in which the stress-values were multiplied by a factor of 10 for a given strain value. This scaling factor was chosen as it was expected to produce a higher chance of injury. To define probability of head injury for a single simulation, a head injury risk function derived from collegiate football impacts was utilized [2]:

$$\text{Probability of Injury} = \frac{1}{1+e^{-(\alpha x+\beta)}} \qquad (2)$$

Where α&and&β are fixed coefficients and x is the peak resultant linear acceleration in g's.

RESULTS

When compared to the experimental headform acceleration responses, the FE acceleration predictions varied in accuracy (Figure 1). The best fit occurred for the 10 ft/s impact scenarios, in which percent errors between model and experiment were under 13% for all impact locations with the exception of the side impact location, which had a percent difference of 89.7%. The side impact location performed the worst for all three impact velocities.

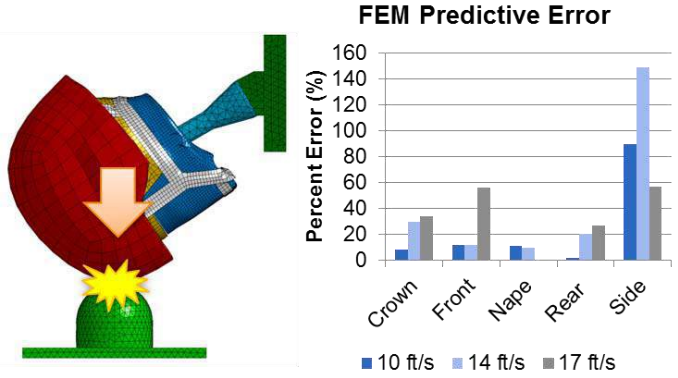

Figure 1: Left – FEM Front Impact Orientation. Right - Peak Acceleration Error between FEM and Experiment

Increasing the FEM pad stiffness from its baseline value to a 10x stiffer value resulted in larger peak accelerations for the front, crown and rear impact locations for all loading rates. However, peak headform accelerations with the artificially stiffer pads were smaller for the nape and side impact locations for the 14.1 ft/s and 17.3 ft/s impact velocities. Furthermore, the probability of injury was small for nape impact simulations at 10 ft/s, with probabilities of injury being <2.5% for both pad stiffness types. When the impact velocity increased to 14.1 ft/s, the stiffer pad type reduced the chance of injury when compared to the baseline material type, with probabilities of 47.5% and 71.4%, respectively (Figure 2).

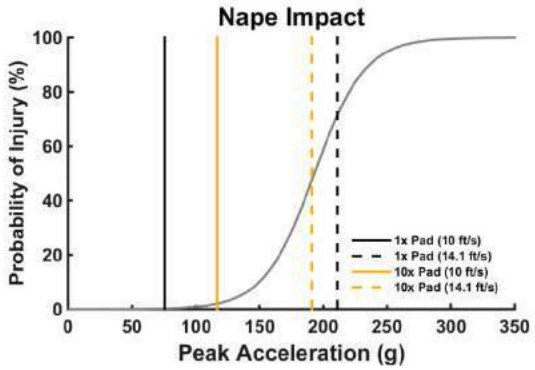

Figure 2: Example of Pad Stiffness Tradeoff for Nape Impact Location. Injury Risk Curve from [2]

DISCUSSION

For simulations with a 10 ft/s impact velocity, the model performed well as 4 out of the 5 impacts locations had errors less than 13%. However, the model did not compare as well to the experimental results for the 14.1 and 17.3 ft/s loading rate, with the exception of the nape. This suggests that the measured material properties measured from the Instron compression tests were sufficient for 10 ft/s impacts, but additional data may be needed to improve model fidelity at higher loading rates.

Drop tower simulations performed with the stiffer pads had mixed results. For 3 out the 5 impact locations, 10x stiffer pads led to a greater chance of head injury. However, when the impact occurred on the nape or side locations, the stiffer pads abated the probability of injury at the 14.1 and 17.3 ft/s impact velocities. While counter-intuitive, the increased pad stiffness reduced nape accelerations by preventing interactions between headform and a bolt in the helmet retention system. This result demonstrates that utilization of a graded injury severity score allows for tradeoff studies across different helmet designs and impact locations. It should be noted that the current results are based on a pre-existing injury risk function to demonstrate model utility. Consequently, further validation of this methodology is needed before accurate assessments of helmet protection can be made. While the current study is a first step in exhibiting the advantages of an updated helmet evaluation system based on a graded metric correlated to injury, it is limited to linear head accelerations. A growing body of evidence suggests that the rotational component of head motion plays a large role in injury outcome [4,5]. Future work should examine combat helmet performance when angular accelerations and velocities are accounted for in the kinematic-based risk function.

INTRODUCTION

With approximately 1.7 million cases and 52,000 deaths per year [1], Traumatic Brain Injury (TBI) is a leading cause of injury-related deaths among people under the age of 45 in the United States [2]. TBI is caused by many different forms of trauma including falling and physical violence, but this research primarily focuses on car crash related TBI. A study conducted by the Centers for Disease Control and Prevention found that between the years of 2006 and 2010, vehicular crashes were the cause of 26% of all TBI related deaths in the Unites States [3].

Due to modern breakthroughs in computational engineering, Finite Element (FE) modeling has become a viable alternative to physical testing in a large portion of mechanics based research [4]. Due to the physical limitations of testing collision scenarios, FE modeling allows researchers to more thoroughly investigate the mechanical phenomena behind vehicular impact related TBI without concerns over safety and expenses associated with physically recreating car crash scenarios.

The use of FE simulations allowed Deng *et al.* [4] to conduct a two-step study in which a system-level single collision side crash was simulated between a Dodge Neon, which housed a crash test dummy, and a moving barrier. The data acquired from this simulation was used to determine the Boundary Conditions (BCs) that were later used in the simulations of a high fidelity model of the human head [4]. To allow for a greater understanding of vehicular impact related TBI, the current study expands upon the method presented in the study by Deng *et al.* [4]. to allow for several different points of collision at various impact velocities.

METHODS

As shown in Figure 1, this research consists of two major steps: the car crash simulations and the human brain simulations.

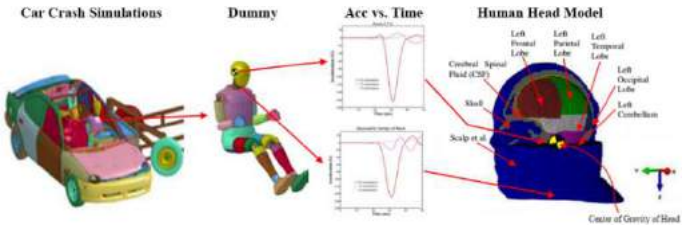

Figure 1. A schematic illustration shows the process of using the data from the Dodge Neon crash simulations as the boundary conditions in the Human Head model (Deng, et. al. [4])

In the first step, an FE model of a Hybrid III 50th percentile male crash test dummy underwent simulated car crash scenarios to determine the BCs that will be used in a more complex FE model of a human head. This began by using LS-Prepost [5], an FE modeling preprocessing software, to configuring the impact scenarios. Each simulation began with the dummy seated in the driver's seat of a FE Dodge Neon model and a moving barrier at one of the 12 starting locations. Once preprocessing was complete, LS-Dyna was used to run each of the simulations. At each of the 12 points of contact, the moving barrier strikes the Dodge Neon at seven different impact velocities: 10, 15, 20, 25, 30, 40, and 50 mph. Upon completion of all of the crash simulations, LS-Prepost will be used to determine the acceleration versus time profiles at the centers of gravity of both the head and the neck of the dummy [4].

In the second step, a high fidelity FE model of the human head will be created, using the model previously developed by Deng *et al.* as the baseline, to determine the mechanical response of the brain during the various car crash scenarios. The updated human head model will have

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

higher anatomical accuracy than Deng *et al.*'s head model. In order to accurately simulate the movement of the head after impact, LS-Prepost will be used to set the acceleration versus time profiles from the dummy in the car crash simulations as the BCs on the head model. The deformation of the head, due to a car crash scenario, will then be simulated using LS-Dyna to determine the key injury metrics and damage impending on the brain upon impact.

RESULTS

At each of the 12 points-of-impact, the barrier comes into contact with the Dodge Neon at seven different impact velocities. Each of these 84 simulations were analyzed with respect to Pressure and Von Mises stresses, as shown in Figure 2 and Figure 3.

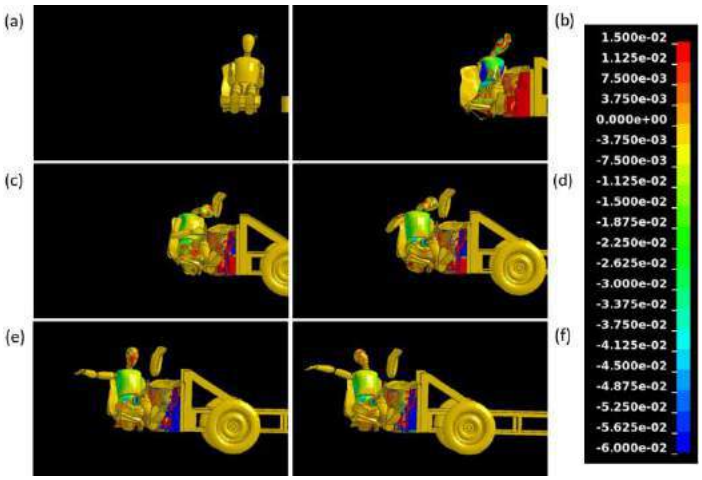

Figure 2. Pressure contour plots of the Hybrid Ⅲ 50th percentile male dummy undergoing a side impact at 50 mph from the 90 degree barrier orientation at (a) 0s (b) 0.3s (c) 0.6s (d) 0.9s (e) 1.2s (f) 1.5s

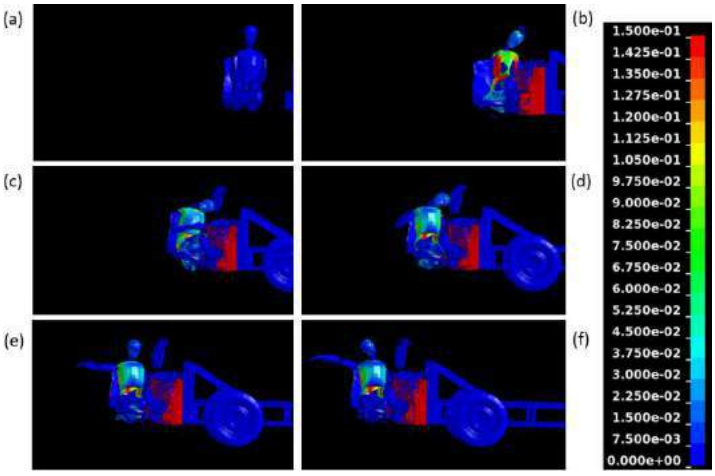

Figure 3. Von Mises contour plots of the Hybrid Ⅲ 50th percentile male dummy undergoing a side impact at 50 mph from the 90 degree barrier orientation at (a) 0s (b) 0.3s (c) 0.6s (d) 0.9s (e) 1.2s (f) 1.5s

As shown in Figure 4, the acceleration results from the simulations showed that for several crash scenarios the peak accelerations, in the dummy's head and neck, were well over the threshold for TBI.

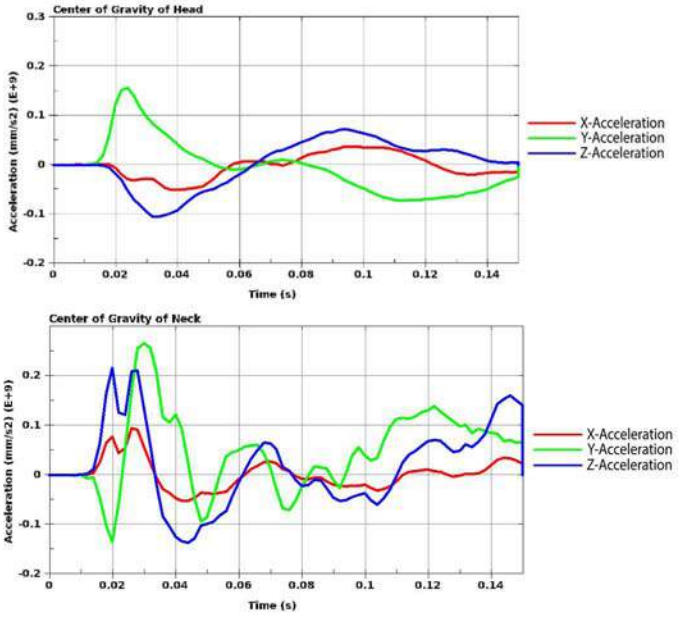

Figure 4. Acceleration versus Time plots at the centers of gravity of the head and neck of the Hybrid Ⅲ 50th percentile male dummy undergoing a side impact at 50 mph from the 90 degree barrier orientation

DISCUSSION

Upon completion of the car crash simulations, the acceleration versus time profiles will be analyzed and used in the configuration of the second step, human head simulations. From these simulations, the locations of the highest pressures, stresses, impulses, and other key injury metrics in the brain will be used to predict the regions where the most significant damage will occur [4]. These FE results will then be used to develop a mathematical surrogate model for brain damage (traumatic brain injury) due to car crashes. This will allow for a better understanding of the relationship between vehicular impact trauma and TBI.

NUMERICAL SIMULATION OF MECHANICS OF RUPTURE IN ABDOMINAL AORTIC ANEURYSMS USING FLUID-STRUCTURE INTERACTION METHODS

INTRODUCTION

Abdominal Aortic Aneurysm (AAA) is a vascular condition where the infrarenal aorta dilates to more than 2 times its original diameter [1]. Progressive weakening of the arterial wall results in rupture of the abdominal aorta if the condition is left untreated. The mechanics of AAA have been studied extensively using experimental, analytical, clinical, and computational approaches [2]. Estimation of rupture risk involves calculation of parameters that influence the wall mechanics and the flow physics of the aneurysm lumen. These include patient-specific velocity and intraluminal pressure and material properties of the arterial wall. The resulting wall shear stresses are hypothesized to be indicators of the region of structural failure in the AAA.

The majority of research has looked into modeling the mechanics of rupture of AAA using rigid structural models, due to the complexity of accounting for the arterial wall movement in pulsatile flow conditions. An accurate biomechanical model entails accounting for the wall movement and the interaction between the flow and the arterial wall. This means that a Fluid-Structure Interaction (FSI) model is essential for an accurate estimate of the rupture risk in AAA [3]. In the present work, we carried out an FSI computation with an AAA originated from an Asian patient. The anatomy of the Asian aorta is different from the Caucasian aorta in aspects of aneurysm neck length, common iliac artery diameter and the distance between the caudal renal artery and the common iliac artery bifurcation [4]. This has caused difficulties to clinicians in placing stent grafts during the Endovascular Aneurysm Repair (EVAR) procedure. Hence, the long-term objective of this study is the biomechanical analysis of an Asian patient cohort to understand the effect of the demographics differences leading up to AAA rupture. This will ultimately lead to improved treatment outcomes for AAA patients.

METHODS

The aneurysm geometry was obtained from ethics committee approved patient CT images using itk-SNAP, an open source image segmentation tool [5]. The geometry was cleaned up using MeshLab, a 3D mesh processing tool. Subsequent meshing was done using ICEMCFD, a commercial meshing tool. A 3D model of a patient-specific aneurysm geometry was used for FSI modeling with a fully coupled commercial FSI solver (ANSYS 16.1, Canonsburg, PA). Pulsatile inlet velocity and outlet pressure boundary conditions were applied [6]. Blood was considered to be an incompressible Newtonian fluid with a viscosity of 0.0035 Pa·s and density of 1,060 kg/m^3. The FSI interface was defined at the inner wall of the aneurysm model. The material was assumed to be isotropic with a Young's modulus of 4.5 MPa, density of 1,120 kg/m^3 and a Poisson's ratio of 0.45. Wall thickness was assumed to be constant at 2 mm. The system coupling function in ANSYS Workbench was used to carry out the simulation on a 16 GB RAM machine for 3 pulsatile cycles to damp out any initial transients. No Intraluminal Thrombus (ILT) was considered in the aneurysm model. Validation of the computational solution was carried out by comparing the inlet and outlet intraluminal pressures to those measured prior to surgery. The validation was carried out by considering the aneurysm to be rigid under steady flow conditions. Mesh independence studies determined the optimal size of the structural mesh as 250,000 nodes and the fluid mesh to be 2 million nodes. This was carried out using the assumption that the walls are rigid in both the structural and fluid solutions. The smallest mesh size from each of the domains was used in the final calculation. Wall shear stress (WSS), pressure and velocity distributions at the aneurysm wall were extracted to determine the location of highest WSS so that an estimate of rupture risk can be made.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

The deformation, wall shear stress and von Mises stress plots were generated at peak systolic pressure for the third pulsatile cycle. The maximum deformation of the AAA inner wall surface was 0.2 mm. This is seen in the posterior distal location of the aneurysm as shown in Figure 1. This region is seen to have the largest mechanical shear stress (0.16 MPa) in the wall, as seen from Figure 2. The maximum fluid-induced wall shear stress is 15 Pa, as illustrated in Figure 3. The location of the highest stresses at the wall and lumen surface is consistent with the literature [6]. The highest stresses are induced when the pressure in the lumen reaches the systolic peak, in this case being at 15.5 kPa (116 mmHg) in the cardiac cycle. The stress distribution is such that there are a number of areas of high stresses that develop as the flow moves through the AAA. Flow vortices that are formed at the beginning of the cycle due to the geometry of the aneurysm migrate distally as the flow decelerates from peak systolic conditions to diastole. Initially, there is attached flow near the proximal end of the aneurysm but by peak systole there is a separation of the vortices from the wall. This is similar to the flow fields seen in prior FSI simulations [7].

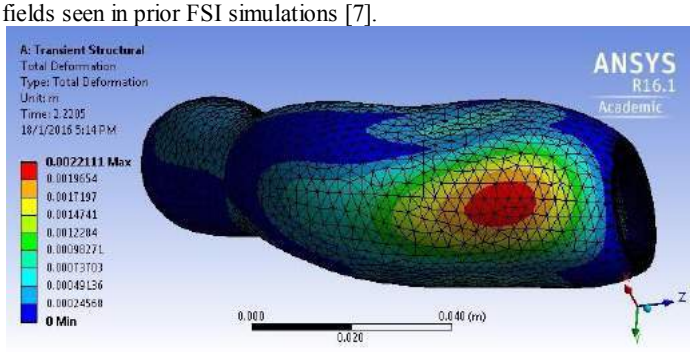

Figure 1: Spatial distribution of the AAA wall deformation (m).

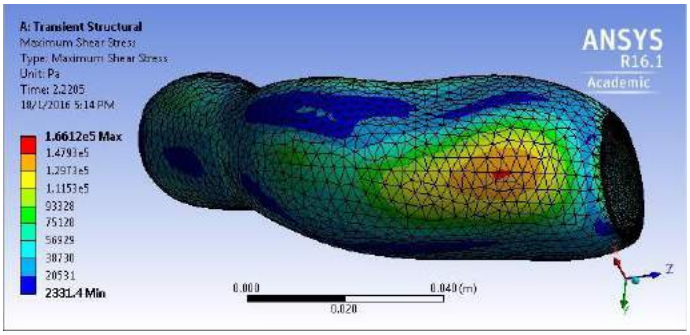

Figure 2: Spatial distribution of mechanical shear stress at the AAA wall (Pa).

DISCUSSION

The study undertaken is an attempt to estimate the mechanics of rupture of AAA using biomechanical methods. The arterial wall being a non-rigid entity is subject to interaction with the fluid flow and vice versa. Hence, this requires a FSI solution in order to investigate the effects of the moving arterial wall in the estimation of rupture risk. As has been seen by clinicians, the geometry of the Asian aorta is different from the Caucasian one. This presents a problem of whether the flow physics and the structural response vary as compared to the Caucasian AAA. This work presents an initial investigation into the analysis of Asian AAA patients, which will eventually help in determining whether an alternate approach is needed when estimating rupture risk in Asian AAA patients. The investigation has shown that

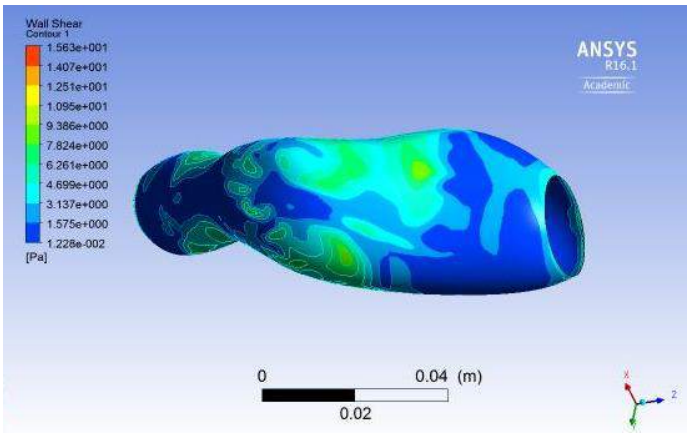

Figure 3: Spatial distribution of the fluid shear stress at the endoluminal surface (Pa).

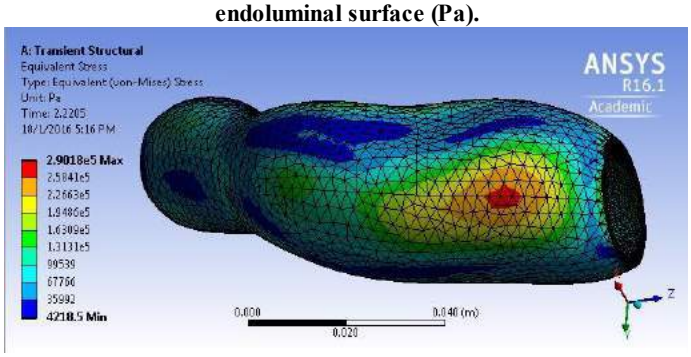

Figure 4: von Mises stress distribution at the AAA wall (Pa).

the location of high shear and induced stresses are at similar sites as of the Caucasian aorta. They provide a measure of the wall stresses that are developed in the arterial wall. However, since the Young's modulus is assumed constant, an improved material model will make the stresses more accurate in the physical sense.

Some of the limitations of this study are the boundary conditions, which have been derived from literature, the constant wall thickness, and the lack of ILT in the model, although there are AAA with no thrombus. Nevertheless, a FSI based solution is an important step towards determining the actual interaction between the arterial wall and blood flow, which will assess rupture risk in an Asian AAA. A more detailed patient-specific model, inclusive of a FSI modeling approach, will further our understanding.

INTRODUCTION

Elastin is crucial for cyclic loading in the cardiovascular system to maintain blood circulation throughout the body. The amount, assembly and organization of elastic fibers change with age and determine arterial stiffness. Increased arterial stiffness is associated with cardiovascular disease, including hypertension. Supravalvular aortic stenosis (SVAS), which is characterized by aortic narrowing and hypertension, is a congenital heart defect caused by a heterozygous mutation in the gene encoding elastin (*ELN*). Although hypertension in adults can be managed with pharmacological agents such as diuretics, angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists, calcium channel blockers, beta-blockers, etc. to decrease physiologic arterial stiffness, typical treatments for congenital aortic stenosis in young patients include catheterization with a balloon and replacement of the aortic valve to prevent the cause of the narrowing. Young SVAS patients that undergo heart surgery often require reoperation [1] with high complication rates. Hemizygous *Eln* mice (*Eln*+/-) have similar features to human SVAS patients, showing hypertension and increased stiffness in large arteries from perinatal period [2] to postnatal period [3]. We hypothesize that there is a critical time point to prevent aortic narrowing and change arterial elasticity in *Eln*+/- mice. To test our hypothesis, we treated mice with captopril, an angiotensin-converting enzyme inhibitor, during embryonic and postnatal development. We found that embryonic captopril treatment in mice alters aortic mechanics, whereas there is not a significant change after postnatal treatment.

METHODS

Animals and samples. *Eln*+/- and wild-type (WT) mice were treated with captopril during two different periods. For embryonic treatment, pregnant female mice were treated by drinking water containing 0.075g/L captopril for the entire gestational period. Pups were sacrificed within 24 hours of birth (postnatal day [P]1). For postnatal treatment, *Eln*+/- pups were treated by drinking water containing 0.075g/L captopril from P7 through their mother's milk, and then directly through drinking water after weaning, and sacrificed at P30. Ascending aortae (AAs) were removed and stored in physiological saline solution (PSS) for mechanical testing. Images of AAs before and after dissection were taken.

Mechanical testing. Inflation tests were performed using a Myograph 110P (DMT). The AAs were tied on stainless steel cannulae with silk suture and mounted horizontally in the test chamber filled with PSS. The AAs were stretched longitudinally to the estimated *in vivo* length for each age (P1 or P30) [3]. The AAs were then incrementally pressurized from 5 to 60 mmHg for P1 and from 0 to 175 mmHg for P30. The AAs were preconditioned before obtaining the data. Outer diameter, longitudinal force, and lumen pressure were recorded. Cross-sectional images of the aortic ring were captured to measure outer diameter and thickness at the unloaded state.

Analysis. Mean circumferential stretch ratios (λ_θ) were calculated by changes in inner (subscript i) and outer (subscript o) radii at the loaded state (r_i, r_o) compared to the unloaded state (R_i, R_o), assuming incompressibility (Eq. 1). Mean circumferential stress (σ_θ) was determined by the internal pressure (P) and inner and outer radii (Eq. 2). Diameter compliance (C_{Pi}) (Eq. 3), a measure of structural properties, was calculated from the derivative of an empirical relationship (Eq. 4) fitted to the outer diameter-pressure curve. Tangent modulus (E_{Pi}) (Eq. 5), a measure of material properties, was calculated from the derivative of a relationship (Eq. 6) fitted to the stress-stretch curve. In Eqs. 3 and 5, constants a_i and b_i (i=1, 2, 3, 4)

Equations:

$$a_{-} = \frac{1}{2}\left(\frac{r_i}{R_i} + \frac{r_o}{R_o}\right) \quad \cdots\cdots (1) \qquad \pm_{-} = \frac{Pr_i}{r_o - r_i} \quad \cdots\cdots\cdots\cdots (2)$$

$$C_{P_i} = \left.\frac{\partial d_o}{\partial P}\right|_{P=P_i} \quad \cdots\cdots (3) \qquad d_o = a_1 + a_2\left\{1 - \exp\left(-\frac{P^{a_3}}{a_4}\right)\right\} \quad \cdots\cdots (4)$$

$$E_{P_i} = \left.\frac{\partial \pm_{-}}{\partial a_{-}}\right|_{P=P_i} \quad \cdots\cdots (5) \qquad \pm_{-} = b_1 + b_2\left\{\exp\left(\frac{a_{-}^{\,b_3}}{b_4}\right)\right\} \quad \cdots\cdots\cdots (6)$$

were determined by nonlinear regression in Matlab. Differences between two groups of interest were compared by using t-tests.

RESULTS

While untreated P1 *Eln*+/- AAs have a normal aortic length, untreated P30 *Eln*+/- AAs are significantly longer than untreated WT. Captopril treatment does not affect *in vivo* aortic length in P1 mice, but it leads to reduced aortic length in P30 *Eln*+/- mice, which becomes similar to WT (Table 1). Unloaded inner and outer diameters in untreated P1 *Eln*+/- AAs are significantly smaller than untreated WT, but no significant difference is found after treatment. Captopril treatment does not alter unloaded inner and outer diameters in P30 *Eln*+/- AAs, which are significantly smaller than untreated WT. Wall thickness of untreated P1 *Eln*+/- AAs is similar to that of untreated WT and captopril treatment does not change the wall thickness at P1, but captopril treatment significantly reduces the wall thickness in both genotypes at P30.

During the inflation test, untreated *Eln*+/- AAs exhibit similar behavior to untreated WT, but captopril treated P1 *Eln*+/- AAs show significantly smaller outer diameters between 5-20 mmHg compared to WT (Fig. 1A). However, the captopril treatment does not affect outer diameter in P30 *Eln*+/- AAs (Fig. 1B). The circumferential stretch ratios in untreated P1 *Eln*+/- AAs are significantly larger than untreated WT between 15-45 mmHg, but after captopril treatment no significant difference is found between *Eln*+/- and WT AAs. Untreated P30 *Eln*+/- AAs show a mild tendency toward larger stretch ratios than untreated WT at medium pressures, and captopril treated *Eln*+/- AAs show significantly larger stretch ratios compared to untreated WT AAs between 75-100mmHg. Circumferential stress does not change with treatment for both P1 and P30 AAs.

Table 1: Unloaded dimensions and *in vivo* length of the untreated and captopril treated AAs in *Eln*+/- and WT mice at P1 and P30. Data are presented as mean ± standard deviation. Symbols indicate significant differences between untreated *Eln*+/- and WT AAs (*), captopril treated *Eln*+/- and untreated WT AAs (#), and captopril treated and untreated WT AAs (&) at P1 and P30.

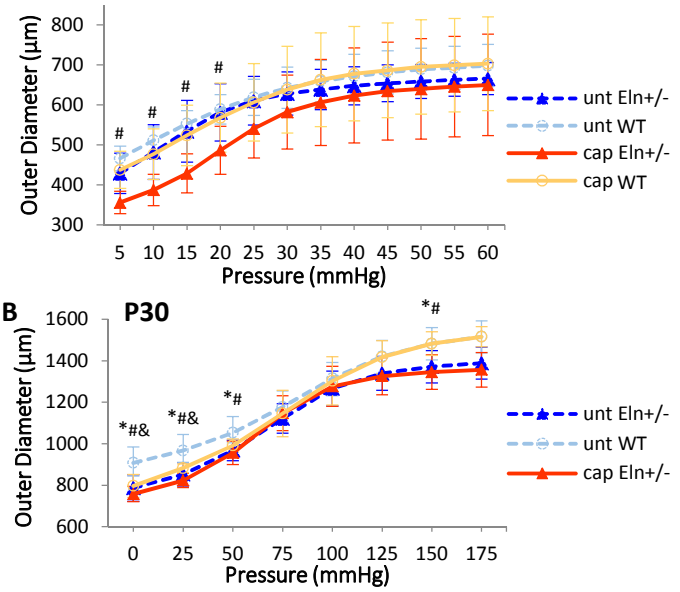

Figure 1: Mean outer diameters with respect to applied pressure during the inflation test for P1 (A) and P30 (B) AAs.

In arterial compliance, there are significant differences between untreated P1 *Eln*+/- and WT AAs between 5-10 mmHg and 35-60 mmHg, but after captopril treatment there are significant differences between 45-60 mmHg only compared to untreated WT. At P30, no significant difference in arterial compliance is found between treated *Eln*+/- and WT AAs, but captopril treatment leads to significantly reduced compliances between 125-150 mmHg in *Eln*+/- AAs. Untreated P1 *Eln*+/- AAs have higher tangent modulus between 5-10 mmHg and 30-60 mmHg compared to untreated WT, but captopril treated P1 *Eln*+/- AAs show significant differences between 5-15 mmHg only. Tangent moduli in untreated P30 *Eln*+/- AAs are similar to those in untreated WT, but after captopril treatment tangent moduli decrease significantly between 0-25mmHg.

In P30 WT mice, captopril treatment leads to a reduced wall thickness at unloaded state and decreased outer diameters between 0-25 mmHg, but other parameters are not affected by captopril at both ages.

DISCUSSION

We found that there are different effects of captopril at different time points (embryonic vs. postnatal). After captopril treatment, P1 *Eln*+/- AAs show significant changes in outer diameter, circumferential stretch, tangent modulus, and unloaded inner and outer diameters, while P30 *Eln*+/- AAs show very minor changes in these parameters. Future work will include embryonic captopril treatment, followed by no treatment up to P30 to determine if the embryonic changes are maintained through maturation.

FAILURE PROPERTIES OF ANNULUS FIBROSUS: EFFECTS OF chABC AND STRAIN RATE

Noah Bonnheim*, Benjamin Werbner*, Grace O'Connell, Ph.D.

Department of Mechanical Engineering
University of California, Berkeley
Berkeley, CA, USA

INTRODUCTION

Structural failure of the intervertebral disc (IVD) is a common and painful condition associated with degenerative changes to disc composition [1]. The occurrence of tears in the annulus fibrosus (AF), including radial tears, rim lesions, and circumferential tears, increase with age and degeneration [2,3]. In particular, radial fissures can lead to prolapse of the nucleus, or disc herniation, with impingement of the spinal nerves, leading to lower back and leg pain [4].

The annulus is comprised of collagen fibrils embedded in an extrafibrillar matrix [2]. Negatively charged glycosaminoglycans (GAG) in the extrafibrillar matrix absorb water molecules, providing the tissue with its hyper-viscoelastic mechanical properties [5]. Degeneration is noted by changes in biochemical composition and structure, including a loss in GAG and water content [2]. To date, AF failure mechanics, and the interaction between failure mechanics and biochemical composition, is not well understood. A better understanding of the relationship between biochemical degeneration and failure properties of the AF may help elucidate the mechanisms of disc herniation.

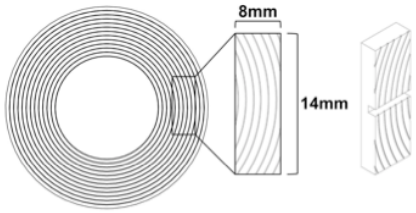

Figure 1. Schematic of test sample orientation (left) and notch geometry (right).

Previous studies [6,7] have used chondroitinase ABC (chABC) to enzymatically digest GAG from disc tissue as an *in vitro* model of disc degeneration. In this study, we examine the effect of chABC digestion on AF failure mechanics. As a decrease in GAG content diminishes the ability of biological tissues to absorb water, it is hypothesized that GAG digestion with chABC will alter both the failure properties and viscoelastic behavior of the AF. Due to the importance of water absorption to AF mechanics, our second objective was to evaluate the effect of strain rate on failure properties.

METHODS

Twelve intervertebral discs were dissected from the first three levels of four bovine caudal spines. Twenty-two circumferentially oriented annulus specimens were isolated from the discs and sliced to a thickness of 2 mm using a freezing stage microtome. To facilitate repeatability with respect to failure dynamics (i.e. avoid failure associated with gripping), samples were horizontally notched midway down their length, such that the un-cracked specimen thickness was 1mm (Figure 1). Sample notching was performed while the samples were frozen (pre-hydration) using a scalpel and depth stop. Samples were randomly divided into four test groups: healthy low strain rate (CTL-low), enzymatic digestion low strain rate (chABC-low), healthy high strain rate (CTL-high), and enzymatic digestion high strain rate (chABC-high; n = 4-8 per group). As annulus mechanical properties are known to vary with hydration state, specimens were soaked for 18 hours at 37 °C in a group specific solution. The healthy group was hydrated in phosphate-buffered saline (PBS, 0.14 M NaCl) while the degenerate group was hydrated in a PBS solution with 0.125 U/mL chABC, as per the digestion protocol described by Isaacs *et al.* [6]. Following hydration or enzymatic digestion, uniaxial tension tests were performed in PBS at room temperature using an Instron 5943 (Norwood, MA). Samples were gripped using 400 grit sandpaper super-glued directly to the specimens.

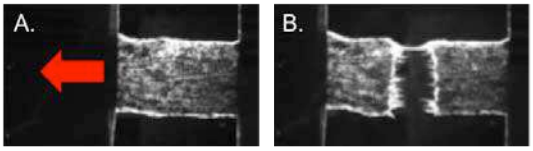

Figure 2. Representative sample (A) before and (B) after failure. Red arrow indicates loading direction.

As AF mechanical behavior in tension is highly dependent on strain rate [8], we evaluated the failure properties at two different strain rates. The high strain rate group was tested at a displacement rate of 50 mm/min, which corresponds to a strain rate of approximately 3.57 min^{-1}, while the low strain rate group was tested at a displacement rate of 0.05 mm/min, or approximately 3.57×10^{-3} min^{-1}. Strain was calculated as the change in displacement divided by the initial gauge length (i.e. grip-to-grip distance). Stress was calculated by dividing measured force by the original cross-sectional area of the notched section. The Young's modulus (E) was calculated using a bilinear fit to the stress-strain response (linear-regression optimization script, Matlab Mathworks Inc.). The stress at failure for each test was defined as the maximum stress recorded during the test, while the strain at failure was defined as the strain at which this maximum stress occurred.

To evaluate the effect of GAG content on failure properties, a two-tailed Student's t-test was performed between healthy and degenerate groups for both strain rates. Similarly, a Student's t-test was performed to determine the effect of strain rate on failure properties. Significance was assumed at $p \leq 0.05$.

RESULTS

The full-width notch resulted in robust failure occurring at the mid-length for all samples (Figure 2). Under quasi-static loading condition (i.e. low strain rate), chABC digestion did not alter the toe- or linear region modulus (Figure 4A – shown for linear-region modulus). However, chABC did significantly decrease failure stress and strain ($p < 0.01$; Figure 4 – blue versus red bar).

An increase in strain rate increased the Young's modulus for both healthy and digested AF groups, as expected ($p \leq 0.05$; Figure 4A – low rate versus high rate). Interestingly, failure properties of chABC digested samples were not significantly different from the control when loaded at a higher strain rate ($p > 0.15$; Figure 4B, 4C). It should be noted that a higher variability in data was observed for the high strain rate cohort, and thus additional testing with a larger sample size is required to further elucidate this phenomenon.

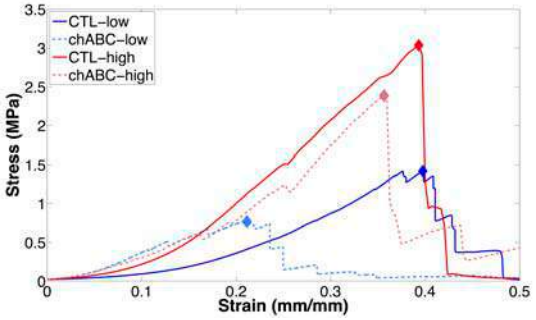

Figure 3. Representative stress-strain curve for each group. Diamond represents failure point.

DISCUSSION

GAG chains are thought to play a dominant role in the mechanical properties of biological tissues including the AF. Due to the high water contribution and the role of water composition on tissue mechanics, we evaluate AF failure mechanics at a low and high strain rates. Our study shows that for quasi-static loading, chABC digestion decreases failure stress and strain; however, these differences are not as pronounced at the higher strain rate. Our results differ from those described by Isaacs *et al.*, who reports no significant change in failure strain for similarly digested AF specimens, which is likely due to difference in strain rate (Isaac's strain rate = 0.30 min^{-1}) [6]. Taken together, these findings suggest that GAGs play an important role in AF failure mechanics that is strain rate-dependent, which is important for understanding loading conditions that may cause disc herniation.

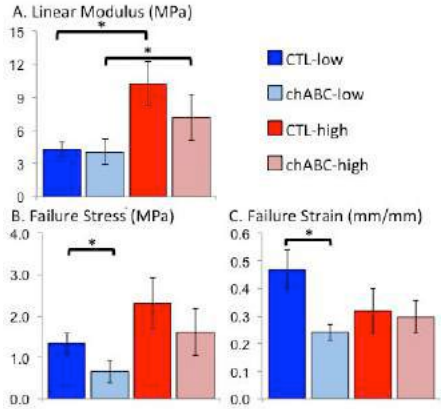

Figure 4. (A) Linear-region modulus, (B) stress and (C) strain at failure. * denotes $p \leq 0.05$.

Enzymatic digestion with chABC has been previosly used to reduce GAG content in biological tissues [6,7]. Ongoing work is focused on quantifying the decrease in GAG composition in our degeneration model. Preliminary data showed significant differences in the water content of control and chABC samples, suggesting that GAG digestion was effective. Furthermore, a strong correlation was found between water content and stress at failure ($R^2 = 0.86$). Future work will focus on correlating GAG composition directly with AF failure properties in tension.

At high strain rates, there was a significant decrease in elastic modulus and a trend for a decrease in the stress at failure. The decrease in Young's modulus with chABC is likely due to fiber-matrix interactions altering tension mechanics at the higher loading rate. For healthy and chABC samples, increasing the strain rate significantly increased the stress at failure and elastic modulus; however, the strain at failure was not altered. Future work will explore whether AF failure mechanics is a strain-driven phenomenon.

GAGs comprise less than 15% of the tissues dry weight [9]. Previous sub-failure AF tensile mechanics is thought to be largely due the collagen fibers [2]; however, the findings here suggest that GAGs may play a larger role in AF failure mechanics.

INTRODUCTION

Glaucoma is a leading cause of irreversible blindness worldwide. It is estimated that by 2020, 79.6 million people will suffer from glaucoma. In the same year, 5.9 and 5.3 million people are expected to be bilaterally blind as a result of open angle and angle closure glaucoma, respectively [1]. Elevated intraocular pressure (IOP) is a risk factor for glaucoma and is generated by the resistance to the aqueous humor outflow. The continuous flow of the aqueous humor is essential for providing the cornea and lens with oxygen and nutrients. In addition, normal IOP maintains the proper shape and the optical properties of the eye. The aqueous humor leaves the eye primarily via the trabecular meshwork (TM) [2]. IOP increases when the aqueous humor production rate is greater than its outflow rate.

Recent studies have shown that in glaucomatous eyes, the TM stiffness is considerably higher than that of normal eyes. It is believed that a higher TM stiffness increases resistance to the aqueous humor outflow and leads to a higher IOP [3]. Therefore, TM mechanical properties play an important role in understanding the pathophysiology of glaucoma and could be a potential risk factor. In this study, using an internally developed inverse finite element model, we aimed to estimate the mechanical properties of the TM in a healthy volunteer. Our model prediction is based on *in-vivo* imaging and estimation of the parameters using a genetic algorithm [4].

METHODS

The temporal limbus of a healthy subject (female, age 26 years) was imaged by optical coherence tomography (OCT, Cirrus, Zeiss, Dublin, CA) at baseline and during IOP elevation (ophthalmodynamometer applying 10g force). IOP was measured at baseline and during IOP elevation. Corresponding Schlemm's canal locations were identified in radial OCT cross-sectional B-scans based on the pattern of limbal vessel crossings [5]. The images was segmented manually using the Gnu Image Manipulation Program (GIMP 2.8.14) into air, cornea/limbus/sclera complex, Schlemm's canal, trabecular meshwork, anterior chamber, iris, supracilliary space, and "deeper structures" (those beyond the limit of penetration of the OCT scan).

An axisymmetric model of TM was constructed based on the following governing equations. The stress balance equation was given by:

$$\nabla.\boldsymbol{\sigma} = \mathbf{0}, \tag{1}$$

where σ represented the Cauchy stress tensor, defined with the assumption of a neo-Hookean material model for TM:

$$\boldsymbol{\sigma} = \frac{\mathbf{G}}{\det \mathbf{F}}(\mathbf{B}-\mathbf{I}) + \frac{2G\nu}{(1-2\nu)\det \mathbf{F}}\ln(\det \mathbf{F})\mathbf{I}, \tag{2}$$

where G was the shear modulus, ν was the Poisson's ratio, **I** was the identity tensor, **F** was the deformation gradient tensor, and **B** was the left Cauchy- Green deformation tensor. **F** and **B** were defined as

$$\mathbf{F} = \frac{d\mathbf{x}}{d\mathbf{X}}, \tag{3}$$

$$\mathbf{B} = \mathbf{F}\mathbf{F}^{\mathbf{T}}, \tag{4}$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where **x** was the current position of a material point and **X** was its resting position. The finite element meshes were generated based on TM geometry segmented from *in-vivo* images using commercial software Abaqus (Dassault Systèmes, Velizy-Villacoublay, France). A pressure boundary condition with the constant value of IOP (P) was applied along the boundary element of the TM domain (Fig. 1c). The pressure boundary condition was applied to mimic the changes in the IOP *in-vivo*. In particular, since the IOP of the undeformed configuration was 11 mmHg and the IOP of the deformed configuration was 23 mmHg, the difference of 12 mmHg was applied as the pressure boundary condition. The TM boundaries that connect it to its surrounding, much stiffer tissues (Fig 1c), were assumed to have negligible deformation in comparison to the rest of the tissue. Thus, a fixed boundary condition was chosen for these regions. We then used our inverse modeling approach to calculate the shear modulus G from the experimental deformation data. The objective function was defined as absolute value of the difference between the Schlemm's canal area of the experimental measurements SC_{exp} and the genetically driven finite element solution SC_{sim}:

$$SSE = \left\| SC_{exp} - SC_{sim} \right\| . \quad (5)$$

The initial guesses for G were chosen between 10-90 kPa.

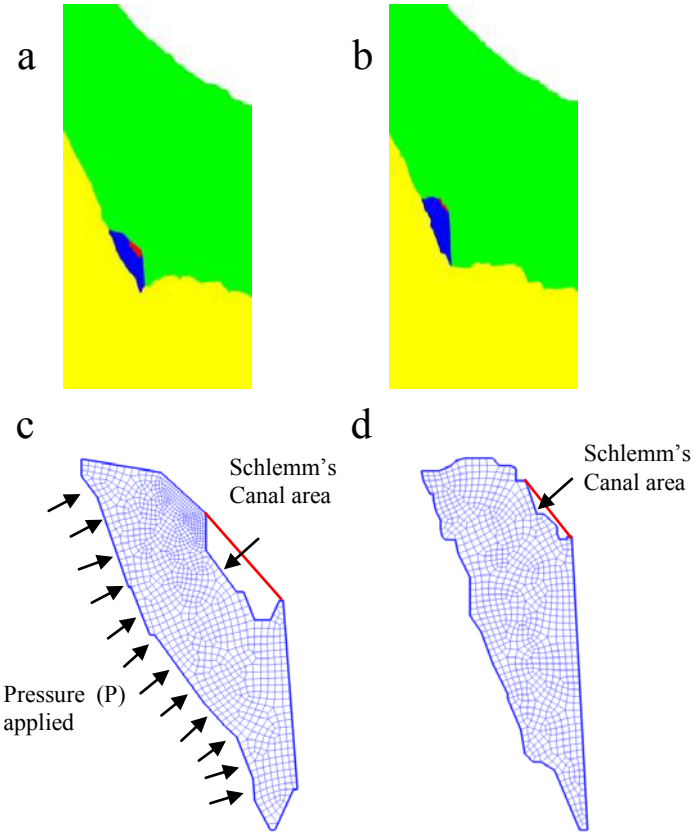

Figure 1: Segmented images of the trabecular meshwork in (a) undeformed and (b) deformed configuration. Finite element meshes of the trabecular meshwork in (c) undeformed and in (d) deformed configuration. The finite element mesh of the deformed configuration is provided only for comparison and was not used in simulation.

The simulations were performed using an HP Intel Xeon machine at the Ohio Supercomputing Center (Columbus, OH).

RESULTS

Figure 2 shows the finite element solution after pressure is applied to the undeformed configuration. Upon applying the pressure and appropriate displacement boundary conditions, the simulated results closely matched the experimental measurements.

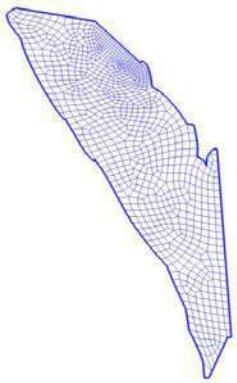

Figure 2: Simulated results of the deformation of the trabecular meshwork

From the optimization technique a value of 2 kPa was obtained for the TM shear modulus, G. We found that the optimization convergence was independent of our initial guess choices and the broader ranges of initial guesses only increased the computational time. The solution process took approximately 120 minutes (~ 30 numbers of generations). The simulated area of the Schlemm's canal (2030 μm^2) was close to 2100 μm^2, the area measured experimentally.

DISCUSSION

We constructed a finite element model of the TM subjected to an IOP. We then calculated the mechanical properties using an inverse optimization approach. Using simplified beam theory, Johnson et al. [6] found the elastic modulus in a living healthy eye to be 128 kPa. Hence, assuming a nearly incompressible material, a shear modulus of 43 kPa could be estimated form their calculation, different form ours. One possible reason is the use of different material models for the calculation. We hope to increase the confidence in our technique by simulating more experiments. Quantification of TM mechanical properties using clinical measurements will help us identify new risk factors for glaucoma.

INTRODUCTION

Skin cancer affects nearly 82,000 people each year in the United States; the most common and lethal form of skin cancer is melanoma.[1] Roughly 76,000 patients in the U.S. will be diagnosed with melanoma this year.[1] Although the survival rate is excellent when detected early, melanoma accounts for over 10,710 deaths each year.[1] The traditional treatment for cutaneous tumors is surgical removal, but chemotherapy is applied once the skin cancer becomes metastasized. Surgical removal can be emotionally traumatic for the patient and increases the risk of infection. Additional therapy may be required if the initial resection is not completely effective. Alternatively, systemic chemotherapy may be used to treat skin cancers. However, systemic chemotherapy results in considerable side effects that include immune system suppression, sterility, anemia, secondary cancer formation, and hepatic toxicity. As an alternative to systemically delivered chemotherapeutics and surgical removal, localized chemotherapy using a microneedle array could limit these side effects and allow treatment to be administered via an outpatient system. Outpatient systems are preferable because studies have demonstrated that quality of life improves when patients are treated as outpatients.[2]

In collaboration with Jae-Won Choi Ph.D. in the Mechanical Engineering Department at The University of Akron, microneedle arrays have been developed using microstereolithography. Poly(propylene fumarate) (PPF) was mixed with a photoinitiator and cross-linked using ultraviolet rays (Figure 1).[3] By mixing PPF with chemotherapeutics prior to crosslinking, drugs can be encapsulated into the microneedle array. Although dacarbazine is the only FDA approved chemotherapeutic for melanoma, its clinical efficacy is limited.[4] Thus, alternative drugs have to be explored. An attractive chemotherapeutic is 2- 3-[(1,4-dihydro-5,8-dimethoxy-1,4-dioxo-2-naphthalenyl)thio]-propanoic acid (GN25), since all cancers have been linked to mutations of p53, a tumor suppressing gene. A mechanism that inhibits the function of p53 is K-Ras activation through induction of Snail, a protein that binds and eliminates p53 through exocytosis. GN25 blocks the binding of Snail to p53 and allows cancer cells to undergo cellular repair or apoptosis. In this project, the median lethal dosages for GN25 will be determined for a skin cancer cell line and will be loaded into biodegradable microarrays.

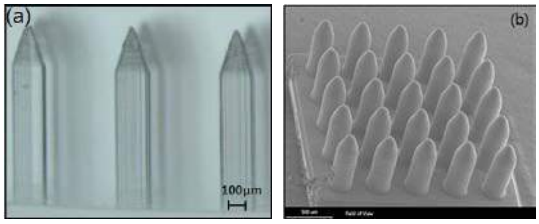

Figure 1. Light and electron scanning micrograph of microneedles

METHODS

The PPF was synthesized using a two-step procedure. In the first step, diethyl fumarate and propylene was reacted in a heated vessel with zinc chloride and hydroquinone. The temperature was gradually increased from 110 °C to 140 °C under a continuous flow of nitrogen gas. In the second step, bis(hydroxypropyl) fumarate was transformed into PPF through a transesterification. This stage of reaction is conducted under vacuum with mechanical stirring and with a gradual increase in temperature from 100 °C to 140 °C. The reaction proceeds until the desired molecular weight of PPF is obtained.

A dynamic mask projection microstereolithography was developed to fabricate the microneedle arrays.[3] A 3D model of the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

microneedle array was designed using SolidWorks and then sliced to get the 2D cross-sectional images. Each time, one cross-sectional image was transferred to the digital micro- mirror device of the microstereolithography system, and the patterned light was projected onto the surface of the liquid material, initiating crosslinking. The structure was dipped into the liquid material, cross-linked using light, and stacked to obtain the final microneedle array structured. Each microneedle has a conical tip and a cylindrical shaft and is 1cm tall. The microneedles were tested for shear and tensile strength and have been determined to be strong enough to penetrate the superficial layers of human skin.

The toxicities of dacarbazine and GN25 were determined using the skin cancer cell line A431-H9 as well as human dermal fibroblasts (HDF), The cells were seeded at a fixed concentration of 5,000 cells per well. Then treated with the drug at varying concentrations from 100-0 μM for three days. Finally, metabolic activity of the cells, which is directly correlated with cell viability, was used to determine the efficacy of the drugs and HA conjugates. The median lethal dose (LD_{50}) for the A431-H9 cells will be compared to the LD_{50} for the HDF cells to determine the relative size of the therapeutic window. A small therapeutic window implies that the healthy tissue would see the same toxicity as the cancerous tumor, which is not ideal. Finally, the results from the HA-GN25 will be compared to the results of GN25, HA-R, and dacarbazine.

RESULTS

The resulting microneedles are cylindrical with a height of 0.7 mm and a shaft diameter of 0.2 mm. The points of the microneedles are conical with apex diameters of 0.02 mm and a height of 0.3 mm. Compression testing shows microneedles are strong enough to penetrate into the skin without buckling. Although the elastic modulus decreased from 0.173 to 0.051 and 0.36 GPa for 1 and 2% drug loading, the bucking force is approximately ten times greater then the force needed for insertion into human skin. Confocal studies with quantum dots also show an even distribution within the microneedle's structure.

Dacarbazine loaded into the micro needles shows first-ordered release kinetics with a burst release during the first week (Figure 2). The factors that can alter the release kinetics can be polymer's molecular weight, chemical properties of the drug, amount of drug loading, and geometry of the microneedles. A controlled release is observed after the first week, but the amount of release is incremental.

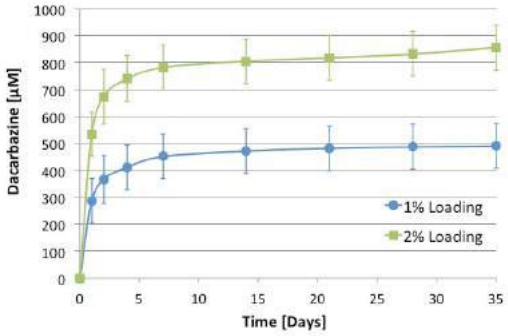

Figure 2. In vitro dacarbazine release kinetics

The toxicities studies show dacarbazine is ineffective against A431-H9 cell line. However, this drug also shows little efficacy against human dermal fibroblasts. At 100 μM concentration of drug, the cellular viability was approximately 78.9 and 86.0% for A341-H9 and human dermal fibroblast, respectively. In contrast, GN25 exhibits LD_{50} at approximately 20 μM for A431-H9. However, human dermal fibroblasts are largely resistant against this drug (LD_{50} at approximately 100 μM). Thus, GN25 seems to be an excellent candidate for further evaluation.

DISCUSSION

The available commercial transdermal drug-delivery systems have experienced considerable growth since the introduction of the scopolamine patch for motion sickness in 1979. An attractive variation of transdermal devices is the microneedle. It has the ability to overcome the drug transport barrier, *i.e.* basal lamina, so that hydrophilic and/or large molecular weight drugs can be diffuse through the skin. Microneedles combine the merits of both the extradermal and intradermal drug-delivery systems. It also could be a pain-free pathway if the needles' size and gauges are carefully selected. Microstereolithography is a convenient process to control printing the desired structure at the microscale. In addition, incorporating the drug prior to printing is straightforward, simple, and flexible.

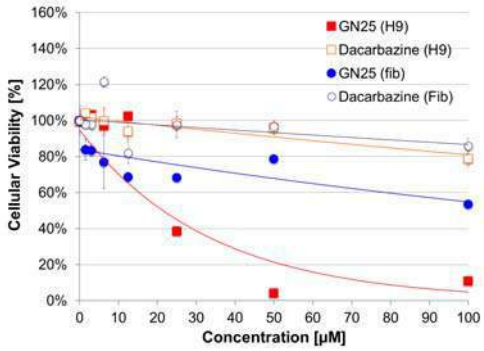

Figure 3. Toxicity of Dacarbazine and GN25

The clinical dosages for dacarbazine range from 300 to 600 mg/m^2. If an average adult has a surface area of 1.7 m^2 and six liters of blood, the dosages ranges from 274.5 to 548.9 μM, respectively. Thus, the release profiles of dacarbazine are within the therapeutic requirements. Diffusion is likely the mechanism of the drug release kinetics, but the degradation could contribute to the zero-order kinetics phase. A first-ordered kinetics is typically observed for non-biodegradable polymer, but PPF degrades slowly by hydrolysis. Approximately 10% of mass loss is expected for PPF during a five-week period. However, the efficacy is relatively poor against certain type of skin cancers, such as A341-H9. Thus a drug that shows more efficacy against this type of cancers but remain relatively nontoxic again normal fibroblast is desired. Thus, GN25, which is an experimental chemotherapeutic, is promising candidate for further studies.

CHARACTERIZATION OF GLIOBLASTOMA GROWTH USING FIVE DIFFERENT MATHEMATICAL MODELS

Mitra Shabanisamghabady and Martin L. Tanaka

Department of Engineering and Technology
Western Carolina University
Cullowhee, North Carolina, USA

INTRODUCTION

Glioblastoma multiforme is the most common and most malignant primary brain tumor. Optimal therapy results in survival time of 15 months for newly diagnosed cancer and 5-7 months for recurrent disease [1]. Malignant glioma patients demonstrate limited response to conventional therapies which include surgery, radiation, and/or chemotherapy. New and improved methods of therapy are urgently needed. Physiological experiments using animal models are often used to study new chemotherapeutic agents. These studies are quite effective but often expensive and time consuming. Mathematical models are often used to augment physiological experiments. These models can both increase our understanding of tumor growth, as well as aid in the development and preliminary testing of treatment options [2]. In this research five ordinary differential equation models were used determine the cancer growth characteristics. Model parameters for glioblastoma multiforme were determined for each model and the best fitting model was identified.

METHODS

Five classical mathematical models were used to simulate tumor growth, the exponential, logistic, generalized logistic, Gompertz and von Bertalanffy models.

Exponential $$\frac{\mathrm{dV}}{\mathrm{dt}} = aV \quad (1)$$

Logistic $$\frac{dV}{dt} = aV\left(1 - \frac{V}{K}\right) \quad (2)$$

Generalized logistic $$\frac{dV}{dt} = aV\left(1 - \left(\frac{V}{K}\right)^{v}\right) \quad (3)$$

Gompertz $$\frac{dV}{dt} = ae^{-\beta t}V \quad (4)$$

Von Bertalanffy $$\frac{dV}{dt} = aV^{\gamma} - bV \quad (5)$$

For all the models V is the volume of the tumor in mm^3 and t is the time in days. The proliferation rate is a and K is the carrying capacity. In the Gompertz model the proliferation rate changes so a is the initial proliferation rate and β is the rate of exponential decay of this proliferation rate. Each of the ODEs was solved explicitly or using ode45 function in MATLAB.

In order to determine the unknown model parameters the modeled tumor growth behavior was compared to the results of data collected experimentally. An in-vivo experiment was previously conducted at Wake Forest University School of Medicine by one of our collaborators. In this study Luciferase-expressing G48a human GBM tumors were grown in nude mice [3]. Data from the control group (no treatment) was analyzed to determine the tumor growth rate. IVIS imaging data from the experiment is shown in Figure 1.

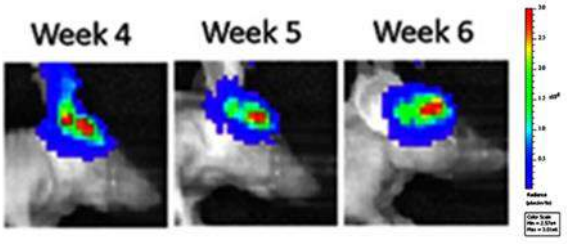

Figure 1: IVIS images of one of the nude mice with xenograft of human GBM tumor [3]

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

IVIS imaging measures the total photon flux emitted from the tumor. For the cell line used in the experiment there were 6.6 cells per photon, so the number of tumor cells could be estimated. The diameter of a glioblastoma cell was approximated to be $5x10^{-6}$ mm. Using this value, the tumor volume at each time step was calculated.

The tumor growth rate predicted by each mathematical model was compared to the growth rate found experimentally using an optimization cost function,

$$S = \sum (V_{e,i} - V_{m,i})^2$$

The tumor volume determine experimentally, $V_{e,i}$, at each time step, i, was compared to the modeled volume at each time step, $V_{m,i}$.

RESULTS

By minimizing the optimization cost function the unknown model parameters were found for each model. These model parameters characterize the growth rate of glioblastoma multiforme tumors under the conditions described in the experiment [3] and are shown in Table 1. The optimal model parameters were found using the MATLAB optimization tool box functions $lsqcurvefit$ and $fminsearch$. The goodness of fit for each model was also calculated (Table 1). Optimized mathematical models and experimental data are shown for each model type (Figure 2).

Table 1: Characteristic Model Parameter

Mathematical Model	Unknown Parameter	Unit	Parameter Values	Fit %
Exponential	a	[day^{-1}]	0.2265	92%
Logistic	a	[day^{-1}]	0.2655	84%
	K	[mm^3]	1322	
Generalized Logistic	a	[day^{-1}]	1400	86%
	K	[mm^3]	1300	
	υ	-	$4.56*10^{-5}$	
Gompertz	α	[day^{-1}]	0.2409	95%
	β	[day^{-1}]	0.0036	
Von Bertalanffy	a	[mm$^{3(1-\gamma)}$.day^{-1}]	0.7057	90%
	b	[day^{-1}]	0.5774	
	γ	-	0.9664	

DISCUSSION

The result from the optimized mathematical models is consistent with previous research results that modeled the growth of lung and breast cancer [4]. All models fit the experimental data well with fit data ranging from 84% to 95%. The best fitting model for glioblastoma growth was the Gompertz model.

With the characteristic parameters for untreated glioblastoma multiforme known, the next phase of the research will be to model the effects of chemotherapeutic agents on the growth rate. New models are currently being developed that characterize both the tumor growth and decay rates during chemotherapy.

ACKNOWLEDGEMENTS

THE EFFECT OF LATERALIZING JOINT CENTER OF ROTATION OF REVERSE TOTAL SHOULDER ARTHROPLASTY ON ADDUCTION RANGE OF MOTION AND INITIAL IMPLANT FIXATION: A FINITE ELEMENT STUDY

INTRODUCTION

Reverse total shoulder arthroplasty (rTSA) for the treatment of conditions associated with a rotator cuff deficiency can yield improvements in range of motion (ROM), namely abduction and forward elevation. The degree of improvement is dependent on several factors relating to both implant design and patient-specific factors, such as scapular topology and morphology. In some patients, an adduction deficit, due to humeral cup impingement on the scapular pillar or the inferior portion of the glenoid, is apparent following the procedure. Repeated impingement is likely the cause of one of the most common complications of the procedure, scapular notching. Although the ramifications of scapular notching are not yet well understood, it has been suggested that lateralizing the joint center of rotation (COR), in reference to the fully medialized COR on the glenoid face suggested in Grammont's original design, can mitigate adduction deficits and decrease the chance of scapular notch development. However, lateralization of the COR away from the glenoid surface may increase the bending moment across the bone-implant interface, leading to excessive micro-motion of the baseplate and preventing osseointegration. Thus, lateralizing the COR has the potential to improve functional outcomes and mitigate the development of complications of rTSA, but may come at a cost of an increased risk of loosening. Therefore, it is important to understand the relationship between lateralization of the COR, adduction deficit, and initial implant fixation (characterized by micro-motion). In this study, finite element (FE) modelling techniques were employed to investigate the aforementioned relationships on a specimen-specific basis.

METHODS

Geometries of four scapulae from three fresh-frozen cadaveric specimens were obtained by segmenting computed tomography (CT) data. Semi-automatic threshold-based segmentation using 3D Slicer was employed to obtain overall scapular geometry as well as the cortical-cancellous bone boundary in the region of the glenoid. Using the solid modeling software Creo, a 42 mm ream was simulated on the glenoid of each scapula after which a 25 mm diameter baseplate with an 8 mm diameter, 15 mm long central post, and four peripheral fixation screws, were implanted. The screws were simplified as 4.5 mm diameter cylinders rigidly attached to the baseplate. The position of the baseplate as well as the lengths and trajectories of the fixation screws were determined on a specimen-specific basis following the guidelines suggested by Humphrey et al. [1] and the surgical guide for the Tornier Aequalis Reversed II [2]. Metaglene and screw placements were verified by a board certified orthopaedic surgeon experienced in rTSA (J.C.).

Each model was meshed with quadratic tetrahedral elements with an average edge length of 1.3 mm; this element size deemed adequate during a prior mesh convergence study. Material properties of the baseplate and central post were assigned as those of Ti6Al4V (E = 113.8 GPa and ν= 0.34). Screws were assigned properties of the same material with a corrected elastic modulus of 57.6 GPa in order to account for simplified thread geometry. All elements in cortical bone regions were assigned corresponding material properties (E = 17.5 GPa, ν= 0.3). Cancellous bone material properties in the region of the glenoid were assigned on an element-by-element basis utilizing CT attenuation data and the following equations [3]:

$$\rho = 0.001 + 0.002 * HU \quad (1)$$

$$E = 1{,}049.45\rho^2 + 0.001 \quad if\ \rho < 0.35 \quad (2a)$$

$$E = 3{,}000\rho^3 \quad if\ 0.35 \leq \rho < 1.8 \quad (2b)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where HU represents Hounsfield units, ρ represents density in grams per cubic centimeter, and E represents elastic modulus in MPa.

Zero-displacement boundary conditions were applied to the medial border of each scapula (Fig. 1). Frictional contact with a coefficient of 1.6 was modeled between all bone-implant interfaces. Lateralization of the glenosphere using a metallic spacer was simulated by applying shear loads further from the glenoid surface on an inferior portion of the baseplate (Fig. 1). Lateralization from 0 to 16 mm in 4 mm increments was simulated. Each shear load had a magnitude of 686 N, equating to 1X body weight of a 70 kg individual, and was accompanied by a compressive pressure of the same total magnitude.

Metrics included micro-motion of the baseplate with respect to the glenoid surface and adduction ROM. Micro-motions, both parallel and normal to the reamed glenoid surface of each node on the back surface of the baseplate, were calculated. Subsequently the average and maximum absolute displacements of the baseplate were calculated. Adduction ROM was simulated by revolving a 3D model of a humeral cup in an adduction motion until impingement with any portion of the glenoid side (bone or implant). Adduction was measured as the angle between two planes, one representing the humeral stem with a 155° humeral neck-shaft angle, and one parallel to the glenoid face.

A one-way repeated-measures ANOVA with a Greenhouse-Geisser correction and lateralization as the independent variable was performed. Post Hoc pairwise comparisons with Bonferroni corrections were also performed. A p-value of less than 0.05 was considered statistically significant.

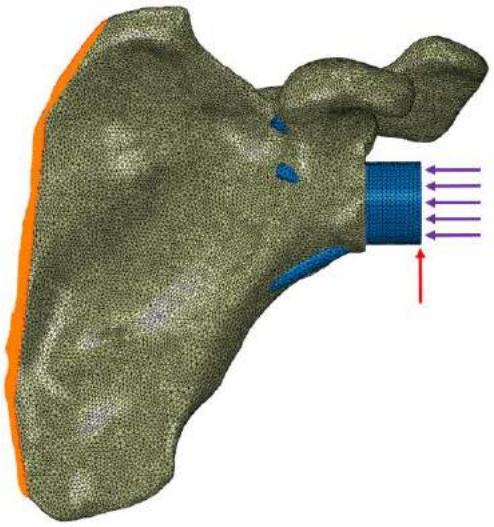

Figure 1. A characteristic meshed FE model where the red arrow is a shear force applied a distance from the glenoid surface, representing lateralization of the COR, the purple arrows represent the accompanying compressive pressure, and orange represents the application of fixed-displacement boundary conditions.

RESULTS

On average, lateralization significantly affected both adduction ROM ($p = 0.001$) and baseplate micro-motion normalized with respect to 0 mm lateralization values ($p = 0.033$). Pairwise comparisons between 0 mm and all other levels of lateralization are shown for adduction ROM and micro-motion (Fig. 2). The average adduction ROM across all specimens with 0 mm lateralization was 0° (range: −7° to 3.5°), where a negative value represents an adduction deficit. Average absolute baseplate micro-motion with 0 mm of lateralization 4.6 μm (range: 2.8 to 6 μm). Maximum absolute displacement averaged across all specimens at 0 mm lateralization was 13.2 μm (range: 6.1 to 21.7 μm).

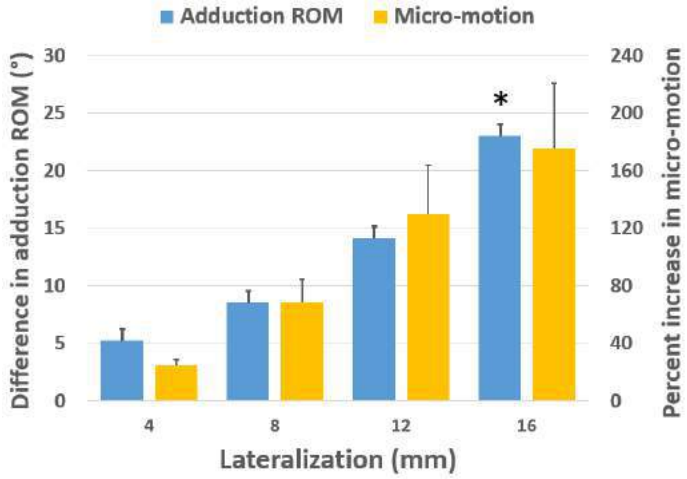

Figure 2. Mean difference in adduction ROM (blue, left scale) and mean percent increase in micro-motion with respect to 0 mm lateralization (yellow, right scale) Note: * indicates statistical significance with respect to 0 mm lateralization

DISCUSSION

Lateralizing the COR of rTSA away from the surface of the glenoid significantly increases ROM in adduction, but also significantly increases micro-motion of the baseplate. Therefore, lateralization can improve upon functional outcomes of the procedure and potentially prevent the development of scapular notching, but also increases the risk of aseptic implant loosening. In this study, none of the baseplates exceeded the 150 μm threshold for osseointegration with any amount of lateralization investigated; however, observed micro-motions in this study are not absolute indications of those that would result from in-*vivo* scenarios. The ability to lateralize to achieve better functional outcomes of rTSA is dependent on initial fixation, which is a function of patient-specific factors such as quality and availability of bone stock.

A limitation of this study is the small sample size of four specimens. However, statistically significant relationships between lateralization and adduction ROM and micro-motion were still observed. Future work will include a greater number of specimens, as well as validation against published experimental data.

INTRODUCTION

Carbohydrate-carbohydrate interactions (CCIs) have been recognized to govern a wide range of biological processes including species-recognition, fertilization, embryogenesis, and cell development (1). The goals of our study are to investigate whether mannobiose moieties exhibit CCIs and to determine the solution conditions in which such interactions occur. Mannobiose moieties are disaccharides of mannose sugars. They coat the surfaces of pathogens and immune cells, and are extensively involved in host-pathogen interactions (2). Mannose oligosaccharides are widely used in the design of drug-delivery vehicles for targeting cells that express mannose receptors (e.g., dendritic cells) (2) and for reducing the cytotoxicity induced by the drug-delivery vehicles (4). Our goal is to functionalize α-1,4-mannobiose on gold coated mica (AFM surface) and gold coated AFM tips and measure the adhesive forces between anchored α-1,4-mannobiose moieties, using the force spectroscopy mode of an atomic force microscope. The finding that mannobiose moieties exhibit CCI may impact the field of immunotherapy and the design of drug-delivery vehicles.

METHODS

Attachment of thiolated linkers on gold -coated surfaces.

Excess cysteamine (Sigma-Aldrich Inc., St. Louis, MO) was reacted with 4-azido-2,3,5,6-tetrafluorobenzoate, succinimidyl ester or ATFB, SE (TCI America Inc.,Tokyo) in a 1:1 acetone: HEPES buffer (pH 8.5) solution for 3 hours. The reaction was carried out in a covered ice bath with stirring. The reaction product (ATFB and cysteamine conjugate) was isolated by precipitation with more HEPES buffer and was characterized with ^{1}H NMR spectroscopy and FTIR spectroscopy. The reaction was also monitored via UV absorption spectra of the supernatant, for the appearance of characteristic peak at 270nm, due to the formation of the by-product, hydroxyl succinimide. The ATFB-cysteamine conjugates were then dissolved in a 1:1 DMSO: HEPES buffer solution. Gold-coated mica and AFM tips were incubated in the solution overnight. The ATFB-Cysteamine conjugates self-assembled on the gold surfaces via their thiol end groups.

Linking mannobiose.

Wang et. al, 2009 (5) showed that, irradiation of aryl-azides in the presence of mannobiose can result in the conjugation of mannobiose to aromatic groups. We used the same chemistry to link mannobiose to gold anchored ATFB-cysteamine linkers. Excess of mannobiose dissolved in HEPES buffer was added on top of the ATFB-cysteamine anchored gold surfaces and irradiated with filtered UV radiation (less than 280nm) for 5 minutes.

We tested the mannobiose linking chemistry on gold nanoparticles before carrying out the reactions on gold-coated mica surfaces. Anthrone assay, UV absorption and Dynamic Light Scattering (DLS) were used to verify the mannobiose attachment to gold nanoparticle

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

The attachment of mannobiose as described in methods section was tested by calorimetric anthrone assay and by the change in hydrodynamic diameters in DLS. When mannobiose attached gold nanoparticles were reacted with anthrone solution, a characteristic green color was produced with a strong UV absorption peak at 627 nm (Figure 1). Positive anthrone test provides strong evidence for the attachment of mannobiose to the gold nanoparticles.

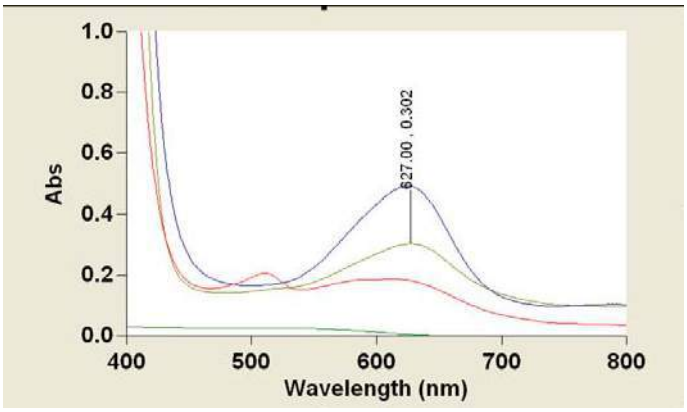

Figure 1: The red line represents the absorption of UV radiation produced by anthrone reaction with gold nanoparticles. The green line represents the absorption produced by the anthrone reaction with gold nanoparticles functionalized with thiolated linker. The blue line is a representation of the anthrone reaction with mannobiose conjugated gold nanoparticles. (The three species of gold nanoparticles were thoroughly washed and resuspended on HEPES buffer before conducting the anthrone assay)

DLS experiments provide means of measuring the hydrodynamic diameter of the suspended particles. Upon conjugation with mannobiose the gold nanoparticle showed a significant increase in the hydrodynamic diameter as shown in Fig.2.

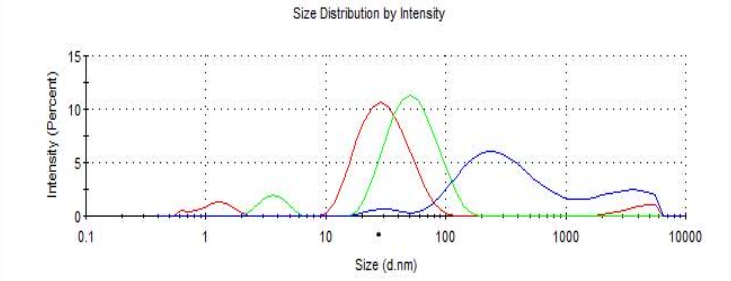

Figure 2: The red line represents the hydrodynamic diameter of the gold nanoparticles ~ 30nm. Green line is the hydrodynamic diameter for the gold nanoparticles conjugated to thiol linkers ~ 50nm. Blue line represents the hydrodynamic diameter of the mannobiose conjugated gold nanoparticles ~300nm. All nanoparticles were suspended on HEPES buffer.

Atomic force spectroscopy was used to measure the mannobiose interactions in a range of solution conditions.

DISCUSSION

Mannobiose moieties were successfully anchored to the AFM mica and tip surfaces. Force spectroscopy is being used to measure mannobiose interactions in different solution conditions. The interaction potential demonstrated by mannobiosylated surfaces can be harnessed for the design of immunotherapies and of drug-delivery vehicles.

COMPARISON OF MATERIAL PROPERTIES BETWEEN THE MAIN AND LEFT PULMONARY ARTERIES OF CONGENITAL HEART DISEASE SUBJECTS USING CARDIAC MAGNETIC RESONANCE: A FEASIBILITY STUDY

INTRODUCTION

Although surgical outcomes for congenital heart disease (CHD) subjects with complex right heart disease are excellent, subjects are left with residual lesions including pulmonary artery regurgitation and obstruction that result in right ventricular-pulmonary artery (RV-PA) dysfunction [1]. The appropriate timing of re-intervention to correct these residual lesions is difficult to determine due to lack of suitable quantifiable diagnostic techniques.

The PA wall (material) properties contribute significantly to the function of the RV-PA unit as they characterize the mechanical behavior of the arterial wall which has a subsequent effect on the overall RV-PA hemodynamics. Further, these properties are expected to vary between the main PA and branched pulmonary arteries. Therefore, quantification of the properties of each of the pulmonary arteries may provide valuable information on disease status and progression and thus aid in the longitudinal assessment of CHD subjects.

Constitutive modeling of the artery wall using *in vivo* and *in vitro* test data has been previously used to characterize the complex arterial wall properties [2, 3, 4]. However, application of such modeling techniques to the pulmonary arteries of CHD subjects has been limited due to the lack of *in vitro* test data. A previous study proposed a methodology of evaluating the wall properties using only *in vivo* pressure-diameter data coupled with a set of constitutive equations that define a material model [5]. Further, cardiac MRI could be a useful tool for assessing *in vivo* diameter in pediatric subjects. As a first step, we aimed to apply this methodology to characterize the PA wall properties of normal pediatric subjects. Therefore, in this feasibility study, using pressure-diameter data as input to a material model, we quantified and compared the properties of the main PA (MPA) and left PA (LPA) of two CHD subjects with normal RV-PA function and anatomy.

METHODS

Study population. Two CHD subjects (subject N1: age = 13 years, body surface area = 1.57 m^2, subject N2: age = 19 years, body surface area = 2.06 m^2) having a diseased aorta were included for this study. However, both subjects had a normal RV-MPA physiology and normal pulmonary valve function with no PA stenosis. Thus, the two subjects were considered "normal" for this study.

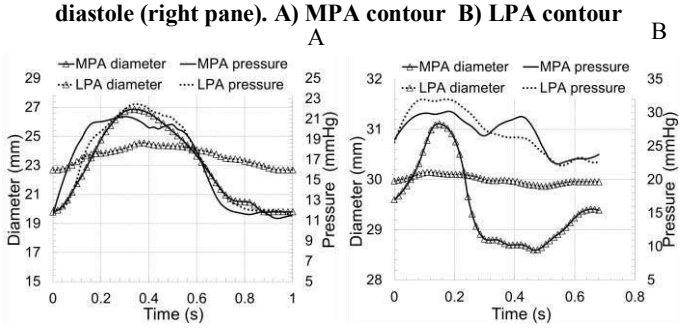

Figure 2: *In vivo* pressure and diameter pulses. A) Subject N1 B) Subject N2

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Data acquisition. Cardiac MRI data was acquired using a 3.0 Tesla MRI scanner (Philips Healthcare, Best, The Netherlands). Contours of the MPA and LPA anatomy were obtained on the MRI slice using auto-thresholding (Figure 1) and the diameter (hydraulic) of the vessels was computed. In addition to MRI, cardiac catheterization was conducted and pressure was recorded at 30 time-points over a single cardiac pulse. CMR and cardiac catheterization were both performed in Cincinnati Children's Hospital Medical Center (CCHMC). The pressure and diameter data points, which were measured non-simultaneously, were synchronized using ECG gating. The gated pressure and diameter pulses are shown in Figure 2. The LPA showed smaller variations in diameter over a cardiac cycle in comparison to the MPA. However, a similar pressure pulse was observed in both the vessels.

Material model. A 2D nonlinear and anisotropic hyperelastic model [5] was used to quantify the PA wall properties and predict its mechanical behavior when subjected to bi-axial loading. The principal stresses were modeled using Fung's 2D strain energy function (SEF), $\psi = C(e^{Q} - 1)/2$ where, $Q = c_{\theta\theta}{E_{\theta\theta}}^2 + 2c_{\theta z}E_{\theta\theta}E_{zz} + c_{zz}{E_{zz}}^2$. The principal stretches in the circumferential (θ) and axial (z) directions were defined as $\lambda_\theta = D(A + \pi d^2)/d(A + \pi D^2)$ and $\lambda_z = z/Z$, respectively, where; A is the cross-sectional area of the wall, D and Z represent the inner diameter and length of the vessel, respectively, in the unloaded condition, and d and z represent the inner diameter and length of the vessel, respectively, in the loaded condition. The principal Cauchy stresses (in kPa), predicted by the model, in the circumferential and axial direction were defined as $\sigma_{\theta\theta}^{mod} = \lambda_\theta(\partial\psi/\partial\lambda_\theta)$ and $\sigma_{zz}^{mod} = \lambda_z(\partial\psi/\partial\lambda_z)$, respectively. In order to define the material model for the PA wall and predict the model constants, an equilibrium condition was imposed on the artery wall and the principal theoretical stresses (in kPa) were defined as $\sigma_{\theta\theta} = pd^2\pi/2A$ and $\sigma_{zz} = d^2\pi(4F + pd^2\pi)/4A(A + d^2\pi)$ where p is the pressure and F is the external axial force. The four constitutive parameters, C, $c_{\theta\theta}$, $c_{\theta z}$, and c_{zz} were then evaluated using a least-square error minimization algorithm where the error was defined as the difference between the model and theoretical stresses. An in-house MATLAB® code (MATLAB Inc., Waltham, MA, USA) was developed and used for computing the model constants.

RESULTS

Figure 3 shows the pressure and corresponding diameter recorded *in vivo* (marked by squares and triangles) during the systolic (loading) and diastolic (unloading) phases of the cardiac cycle. Distinct and non-overlapping characteristics were observed for the MPA and LPA.

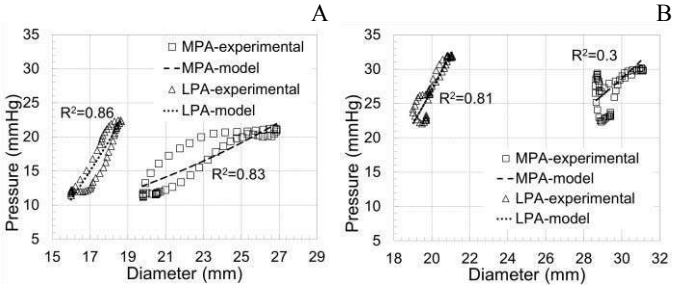

Figure 3: Pressure-diameter characteristics. A) Subject N1 B) Subject N2

Using these characteristics as input to the material model described above, the values of the material model constants which represent the arterial wall properties were obtained for the MPA and LPA of two normal subjects, N1 and N2, and are reported in Table 1. The properties varied between the MPA and LPA for both subjects. This is an expected outcome due to the distinct pressure-diameter characteristics. The C value, which defines the stress level in the artery wall, was observed to be higher for the LPA (16.8% for N1; 45.3% for N2) in comparison to the MPA. A similar trend was observed for the other constants ($c_{\theta\theta}$, $c_{\theta z}$, and c_{zz}) which govern the stress distribution in each loading direction. Further, $c_{\theta\theta}$ values were observed to be greater (absolute difference within 0.092) than c_{zz} (except for Subject N1-MPA) thus indicating a greater stress distribution in the circumferential direction.

Table 1: Values of the material model constants.

	C (kPa)	$c_{\theta\theta}$	$c_{\theta z}$	c_{zz}
Subject N1 - MPA	656	0.025	0.028	0.037
Subject N1 - LPA	766.5	0.175	0.091	0.083
Subject N2 - MPA	400	0.1	0.056	0.054
Subject N2 - LPA	581	0.219	0.159	0.214

In order to determine the accuracy of the material model, the model-predicted pressure-diameter curve (marked by dashed and dotted lines in Figure 3) was computed using the constants in Table 1 and compared against the experimental (*in vivo*) data (Figure 3). A close fit was observed between the model and experiments as can be seen from the R^2 values (ranging between 0.3 to 0.86) reported in Figure 3.

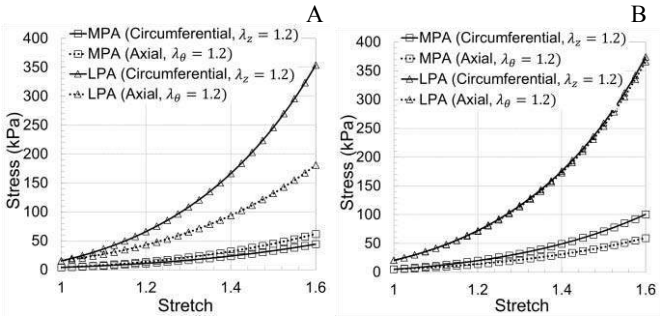

Figure 4: Stress-stretch characteristics. A) Subject N1 B) Subject N2

DISCUSSION

In vivo pressure-diameter characteristics in conjunction with constitutive equations serves as a useful method in quantifying the PA wall properties of CHD subjects. As observed from the results, these properties can quantitatively characterize and differentiate between the MPA and LPA. Further, the PA wall properties may be used to predict the mechanical behavior of the artery under a range of loading conditions, as shown in Figure 4. Circumferential and axial stresses in the MPA and LPA wall were computed at different stretch values. Higher stresses were observed for the LPA in comparison to the MPA for both subjects due to higher C values obtained for the LPA. For example, at a physiologic stretch of 1.2, $\sigma_{\theta\theta}^{mod}$ in the LPA and MPA of subject N1 were 65.9 kPa and 11.2 kPa, respectively. At the same stretch, σ_{zz}^{mod} in the LPA and MPA of subject N1 were 43 kPa and 13.8 kPa, respectively. Also, the LPA and MPA stress values were distinct and non-overlapping over the entire range of stretch values.

Thus, PA wall properties, obtained using cardiac MRI in conjunction with constitutive modeling, may provide valuable information for the longitudinal assessment of the RV-PA dysfunction in CHD patients. Subsequently, this information may aid in determining an appropriate time for re-intervention.

INTRODUCTION

Within the United States, strokes occur in over 700,000 people each year with costs to the healthcare system in the tens of billions of dollars. Strokes are particularly devastating because of the sudden onset and necessity for rapid diagnosis/treatment in order to save the penumbra (recoverable brain tissue after reperfusion). For the confirmed ischemic stroke patient entering the hospital, the typical workflow includes a cerebral computed tomography angiography (CTA) to look for occlusions within the large carotid, vertebral or circle of willis (CoW) arteries as well as a computed tomography perfusion (CTP) scan to quantify the penumbra size and thus the potential benefit of the treatment. The two stroke treatments, administration of tissue plasminogen activator (tPA) and/or mechanical thrombectomy are options available to the clinician. Since both of these stroke treatments can be hazardous to the patient depending on their situation, it is preferable to do a CTP scan first to determine if the risk is worth the potential benefit of the treatment. It has been shown in recent clinical trials that it is possible to select patients who would benefit most from endovascular treatments from CTP scans.

One important factor in determining eventual patient outcome is their collateral status or redundant circulation between regions in the brain. Most medical standards use a visual technique of identifying blood vessels in multiphase CTA scans to determine collateral status on a numerical scale. By looking at the delay in filling between visual blood vessels on the affected and unaffected side, a scoring system such as the Alberta Stroke Program Early CT Score (ASPECTS) can be used as a treatment outcome predictor. Any improvements upon scores such as ASPECTS with more accurate data, could narrow the selection criterion for patients allowing for better outcomes.

From a computational standpoint, the brain is a complex system due to the complex anatomy structures and autoregulation mechanism that predominately controls the transport of blood throughout the brain. Ryu et al.[1] have built a 1D hemodynamic model with autoregulation capabilities for the purposes of studying intracranial hemodynamics. While major occlusion events could overwhelm the autoregulation mechanism, having this ability allows for the possibility of studying different time points in the ischemic stroke process. While other researchers have used 3D models to study blood flow in the CoW, the 1D model has been validated in studying cerebral hemodynamics and has the additional benefit of being computationally inexpensive facilitating translation to a clinical setting.

The objective of this research is to provide a more quantitative way of quickly classifying collateral status in patients that can fit into the current medical workflow with minimal user interaction in order to improve patient selection for stroke treatment.

METHODS

To analyze and work with de-identified patient data, the STOP stroke database[2], which contains both raw CTA and CTP scans, was used to select a case-study sufficient for this research. Within the database, there exist numerous patient cases of varying stroke severity, occlusion site, and collateral scores so the initial selection was important. The patient selected for this study had a severe RMCA occlusion, had a clear CTA scan which properly showed the non-occluded cerebral vasculature, had one transverse CTP scan done on the upper portion of the cerebral hemispheres (above eye level) and had a separate transverse CTP scan done on the lower portion of the cerebral hemispheres (at eye level).

Beginning with the CTA scan, SimVascular[3] was used to semi-manually segment the vascular anatomy from just after the aorta to just

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

beyond the CoW. This provides both the anatomy information for the fluid simulation as well as the topology of the CoW that will become important when looking at larger sample sizes. Perfusion Mismatch Analyzer[4] (PMA) was used to generate the cerebral blood volume (CBV) and cerebral blood flow (CBF) maps from the raw CTP datasets. The arterial input function (AIF) was placed within the LMCA for lack of a more proximal artery and since this artery was sufficiently large on the unaffected side. The venous output function (VOF) was placed in the superior sagittal sinus. To generate the perfusion maps, delay-insensitive block-circulant singular value decomposition (bSVD) was the method selected due to validation with single-photon emission CT (SPECT) in conditions similar to AIS. If an algorithm is used that does not account for the significant delay in tracer transport, such as standard SVD (sSVD), CBF values will be significantly reduced. While the absolute CBF (aCBF) values calculated from the bSVD method are not accurate for CTP, the bSVD CBF ratios between affected and unaffected sides are highly correlated with CBF ratios from the gold standard SPECT[5]. Therefore, relative CBF ratios from CTP were used in all further analysis to preserve the accurate relationships between cerebral arteries needed for this research.

In order to quantify the CBF from each major cerebral artery, following Waaijer[6], we selected restrictive cross-sectional ROIs that belonged only to distal branches of each major cerebral vessel. Within each of these ROIs, the average CBF was found with the units of mL per minute per 100 grams of brain tissue. It is important to note that watershed regions were avoided and primarily gray matter was chosen during the ROI selection process. See Figure 1 and Table 1 for the visualization and quantification of CBF for each major cerebral artery on the occluded and contralateral sides. The flow rate ratios, to preserve the accuracy found from the validation of bSVD, were calculated as the specific artery CBF divided by the summation of the 6 major artery CBF values[7]. The CBF ratio within these ROIs, specific to each of the cerebral arteries, will constitute the patient-specific flow rate ratios (FR_i) necessary to feed into the 1D hemodynamics model.

$$FR_i = \frac{CBF_i}{\sum_{j=1}^{6} CBF_j} \qquad (1)$$

Now that relative flow rates for each cerebral artery have been quantified, this acts as the patient-specific outflow boundary conditions within the 1D hemodynamics model[1]. In the context of stroke, consider Q_{in} as leading into the CoW within the arteries and $Q_{regions}$ as that same blood quantity draining in the venous system. Q_{in} is the summation of flow rate of all major cerebral arteries. In this patient case, it can be assumed that $Q_{RMCA_{in}}$ is completely occluded and can be set to zero. Since some blood will be exiting from the RMCA region, this means that collateral flows (q) from neighboring regions are entirely supplying the exit flow rate to this region (Q_{RM}). The other collateral flows will be assumed small in comparison.

$$Q_{RM} = q_{cRAM} + q_{cRMP} \qquad (2)$$

These collateral flows are each determined primarily through collateral resistance values R_{cRAM} and R_{cRMP} that will be set as unknowns to be tuned for this particular patient within a physiological range. The remaining collateral resistances are not as relevant and can be set to literature values[1]. Beginning with an initial guess for the unknown collateral resistances, iterative solves of the system update the resistance values until a tolerance is reached matching the FR outflow ratios[7]. In this particular case, since absolute CBF values are not known, a baseline healthy state will be assumed with literature flow rates at each cerebral artery[1].

RESULTS

The CBF has been quantified for this particular patient with CBF values listed in Table 1 obtained from the PMA bSVD result shown in Figure 1. Equation 1 was used to produce the flow rate ratios seen in Table 2.

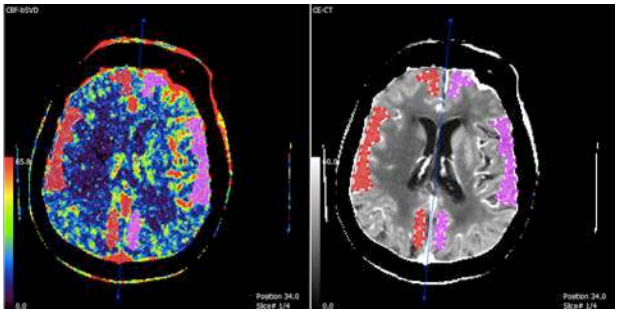

Figure 1: ROIs for average CBF selection for each major cerebral artery perfusion region. Notice the decrease in CBF to the RMCA region. The units on CBF are [mL/(min*100g)].

Region	*CBF Occluded Side* [mL/(min*100g)]	*CBF Contralateral Side* [mL/(min*100g)]	$\frac{CBF_R}{CBF_L}$%
ACA	18.95	35.64	53.17
MCA	19.62	26.55	73.89
PCA	22.63	32.73	69.11

Table 1: CBF values obtained from PMA from bSVD method. The right side has a complete MCA occlusion.

	RA	*RM*	*RP*	*LA*	*LM*	*LP*
FR	.126	.121	.145	.170	.228	.210

Table 2: Flow rate ratios of each major cerebral region. RA refers to RACA region, RM for RMCA region, etc.

DISCUSSION

In this stroke context, it can be seen that the right side of the brain is receiving significantly less flow than the left side with the MCA region having the most relative reduction in flow. Methods are being explored for how to properly design the ROIs to generate robust CBF values that accurately reflect the average CBF for each patient.

This research has the ability to quantify relevant collateral resistances between distal cerebral vascular beds in the context of stroke for the potential to create an improved collateral score.

Further work is needed to create a collateral score from these collateral resistances for clinical translation and this will require more patients to develop. We are continuing work on coupling CTP quantifications with our 1D hemodynamics model for the purposes of stroke assessment. This type of approach provides necessary steps for a score to be adapted to the clinical stroke workflow since it makes use of the CTA and CTP scans necessary for other diagnosis measures.

ACKNOWLEDGEMENTS

The authors graciously acknowledge the Bakar Fellows Program for the funding of this research.

INTRODUCTION TO FINITE ELEMENT MODELING IN A GUIDED PROJECT-BASED APPROACH TO BIOMECHANICS RESEARCH

Alexander Kotelsky (1), Amy L. Lerner (1)

(1) Department of Biomedical Engineering
University of Rochester
Rochester, NY, USA

INTRODUCTION

Students in our Biomedical Engineering program often seek opportunities to become involved in research projects, and expect to develop skills with modern computational tools. We have traditionally used a project based learning (PBL) approach in our upper level courses to engage them in real world problems [1]. Motivated by their interests and career goals, students develop a deeper understanding of the material through collaboratively solving challenging questions [2]. As finite element (FE) tools have become more accessible for undergraduate courses, we have adapted our final project to focus on an idealized model of the proximal femur. While the basics of FE software can be taught relatively quickly, it is important to guide students to develop an understanding of the limitations, validation and verification of such models in order to establish confidence in the results [3]. The overall goal of the project is to offer the framework for a research experience while also allowing students to explore an area of personal interest within biomechanics of hip joint. Learning objectives of the project assignment include guiding students to: 1.) develop a testable hypothesis; 2.) apply knowledge of biomechanics; 3.) demonstrate skills in FEM generation; 4.) identify relevant and reasonable input parameters; 5.) develop an understanding of FEM uncertainty; and 6.) communicate research methods and results. Based on three years of implementing this project assignment, we have learned several key points of how to effectively and efficiently offer this experience. In this abstract, we review the structure, key features, challenges and opportunities for learning presented by this project approach.

METHODS

We introduced this FE based final project for a senior / graduate level biomechanics course called BioSolid Mechanics over a three year period. The course includes two lectures each week along with a weekly laboratory period that offers experience with a mix of computation and experimental methods. Class size has ranged from 20 – 30 students, with students generally working in teams of two to complete the project. The emphasis of the course is musculoskeletal solid mechanics, including joint biomechanics, tissue mechanics and mechanical influences on the skeletal system. Thus, projects typically related to topics presented in the course. A graduate teaching assistant (TA) provided significant guidance for the computational modeling, while both TA and faculty instructor offered guidance for key research milestones.

We used the academic version of the finite element software, ABAQUS/CAE (Simulia, Rhode Island, USA), to build and analyze the model. After two laboratory exercises introducing the general methods of finite element modeling, students completed a custom-written tutorial guiding the generation of an idealized finite element model (FEM) of the proximal femur. Specifically, the model was designed using basic geometries, such as cylinders, cones and spheres assembled together, resulting in a 3D model that reasonably represented a human proximal femur. Building the geometry took approximately 1.5 hrs. once students were accustomed to the method. The tutorial guided geometry creation, assignment of boundary conditions and material properties, meshing techniques and guidance to run and interpret results of the simulation. Since the model was geometrically idealized, it allowed for flexibility and parameterization of geometric features included in the model, particularly if such variations were relevant to the hypothesis posed by each student team. Furthermore, the model allowed the students to customize material properties and boundary conditions as appropriate.

Given the model flexibility, parametric study can provide another tool useful for students' projects, either as a method to develop an

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

understanding of model uncertainty or to test specific hypotheses about model inputs. We include two lectures on design of experiment (DOE) techniques in the course, and associated lab exercises so that this tool is also available to students as they develop and refine their project hypotheses. The implementation of DOE allows students to better understand the sensitivity of model results to various input parameters. For example, students could use a fractional factorial approach with 4 factors (i.e. magnitudes of applied load, the applied load orientation angle, Cortical and Trabecular Modulus values) having 2 levels (the magnitudes of the tested parameters). With the obtained data, the students performed analysis of means (ANOM) and analysis of variance (ANOVA) helped the students to rank the factors according to their importance. The analyses were performed in JMP (Version 11.0, SAS Institute Inc., Cary, NC) statistical software.

In order to provide feedback on different stages of the students' project, several project milestones throughout the semester were implemented into the course. These milestones include the following: 1.) project proposal stating hypothesis and motivation for the study; 2.) critical review of a paper related to the study; 3.) interim progress report presentation; 4.) reality check assignment, where students check the validity of their FEM with initial estimates of boundary conditions and/or material properties in terms of stresses or strains in the reported literature; 5.) final project presentation and report.

RESULTS

With a reasonable amount of guidance, all student teams were successful in generating the femur model and using it to test a wide variety of research hypotheses (Figure 1b-e). These scenarios required FEM modifications in terms of geometries, boundary conditions, material properties and meshing. Representative final project titles for general interest and DOE related studies are listed below.

Examples of general interest related studies:

- The Effect of Sleep Duration on Femoral Neck Fracture Risk during Simulated Falls (Figure1 b).
- Finite Element Model Analysis of the Forces on a Hip Joint during a Squat Exercise.
- Stress Fracture during Military Training.

Examples of DOE related studies:

- Effect of Cement Mantle Thickness on the Fracture Risk of Femoral Neck after Hip Resurfacing (Figure 1c-e).
- Effects of Checking on the Proximal Femur: A Parametric Study.
- The Interplay Between Cortical and Trabecular Moduli, Running Speeds, and Cyclic Loading on Stress at the Femoral Neck.

Observation of students' project progress.

We noted the importance of the project milestones in order to provide guidance in posing reasonable, testable hypothesis, ensuring the identification of appropriate model input parameters (loading conditions and material properties) and assisting in the interpretation of model results. Oral progress reports and final presentations resulted in meaningful interactions between student teams, since projects often shared similar model inputs or related hypotheses. The Academic version of the Abaqus/CAE software presented some limitations in mesh refinement, but did not appear to limit general interpretation of model findings.

DISCUSSION

With three years of refinement, this FE-based project approach offered a novel approach to offer training in both research methods and the appropriate application of computational modeling tools. Initially students routinely assumed that such computational models were more accurate or easier than traditional analysis methods. Through this process, they developed a greater understanding of the critical steps in model building, challenges in capturing realistic conditions and sources of uncertainty. Although generally proud and excited about their projects, they also developed a more realistic view of the models and were able to offer constructive feedback and critiques of other students' models and similar models in the literature. The use of a common model for all student projects offered a more cohesive classroom experience than prior offerings of the course, thus encouraging a more collaborative approach to the research process. As the class size has become larger, it also eased the ability of faculty and TAs to keep up with student questions and offered opportunities to introduce topics in the classroom that were relevant to all projects. Nonetheless, the proximal femur still offered sufficient opportunity for students to explore interests in sports, implants, injuries, and disease.

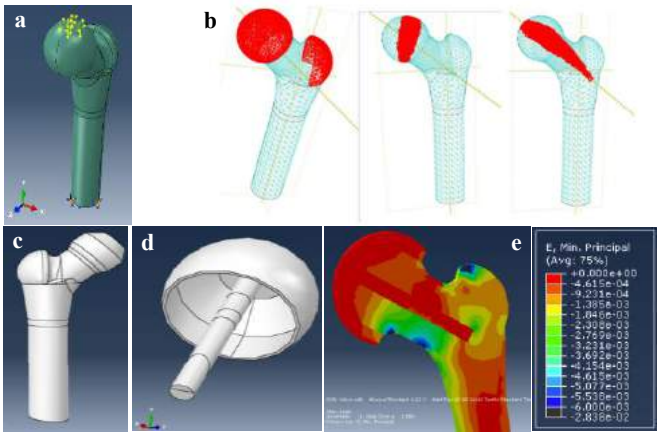

Figure 1. (a) Geometry of FEM given in tutorial; an example of (b) material properties and (c, d) geometry customization. (e) A representative contour map of FEM simulation with modified geometry.

Although the idealized model offered a streamlined educational experience, it also presented several limitations. First, the geometry doesn't represent exact anatomical structure, which may have contributed to model error, and sometimes interfered with assignment of material properties or boundary conditions. This, and a few model-based artifacts occasionally created distractions if they weren't caught early at interim progress reports or the "reality check" assignments. The use of DOE sensitivity studies often helped students to appreciate the relative importance of different model inputs, and they developed greater skill in describing their confidence in model results. In-class progress reports and final presentations offered numerous "teachable moments" that could be shared with the entire class. Based on the successful implementation of this project, we intend to make the tutorial and associated project assignments available online and look forward to further improvements by others.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Jason Inzana, PhD for writing the tutorial for building an idealized proximal femur finite element model. The authors would also like to acknowledge the students who participated in Biosolid Mechanics class in 2011-2013 at the University of Rochester.

A COMPUTATIONAL FRAMEWORK FOR OPTIMIZATION OF TRANSCATHETER AORTIC VALVE LEAFLETS

Graz University of Technology
Graz, Austria

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has been established as the standard treatment of aortic stenosis in high-risk populations [1]. Five year outcomes from the hallmark PARTNER trial demonstrated TAVR's non-inferiority to the traditional surgical approach [2]. Since TAVR's introduction, surgical experience and device evolution have improved patient outcomes; however long-term durability has long been postulated as one of TAVR's main concerns. One way to improve the durability during cyclical loading is to reduce the peak stress during each cycle. The role of TAV leaflet geometry, an aspect of TAV design which has been largely unexplored, may provide valuable insight into long-term safety.

In this study, the impact of leaflet geometry on TAV performance was analyzed by employing finite element analysis (FEA) to model valve closure and opening. By parameterizing TAV geometry including the two-dimensional leaflet shape, leaflet free edge, and stent suturing line, a substantial range of designs were generated. TAV design exploration was conducted systematically using an automated process in which the maximum principle stress was examined.

METHODS

Transcatheter aortic valves are typically comprised of three, scallop-shaped leaflets made of glutaraldehyde-treated bovine pericardium, which are sewn along the inside of a rigid stent. In this study, transcatheter valves were generated through a virtual assembly method. Using this technique, simple 2D leaflet shapes are created and transformed into a 3D configuration.

Parametrization of leaflet geometry

A classic, crescent-shape geometry is used as the initial leaflet design point. The characteristic leaflet has a free edge that coapts with the other leaflets and an attachment edge which is sutured onto the stent. The 2D attachment edge and free edge were defined using previously described exponential functions [3]. This description was chosen for the following properties. At a nominal attachment length (SLL), the free edge is simply a straight line connecting the two commissures. When the attachment edge is increased, the free edge exponentially increases toward the commissure from a plateaued height. The height is adjusted an appropriate amount to ensure proper closing. The precise way in which parameters effect the leaflet and valve geometry is shown in Figure 1.

One half of the stent-to-tissue attachment edge is characterized in cylindrical coordinates by the function:

$$z = ae^{b\theta} + ce^{d\theta} \quad (1)$$

where *a, b, c,* and *d* are coefficients controlling the 3D shape. For simplicity, variables *b* and *c* are used to adjust the attachment edge, as illustrated in Figure 1b. Decreasing values of *b* results in a wider attachment curve and increasing values of *c* tends to drive adjacent commissures apart.

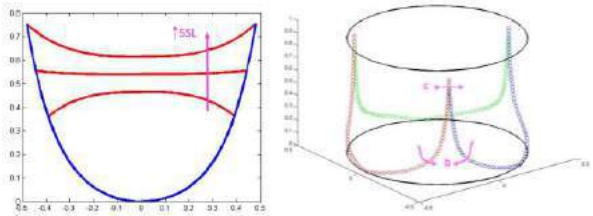

Figure 1: Effect of SSL on 2D leaflet geometry (left) and attachment parameters *b*, *c* on valve shape (right).

Virtual Assembly

Two-dimensional leaflet meshes were generated using a thin plate spline method implemented in Matlab. Using finite element software,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Abaqus\Standard (Dassault Systemes Simulia, Providence, RI), 2D leaflet nodes were displaced to their 3D suturing line positions; very small pressures were applied during this step to facilitate numerical convergence. The other two leaflets were generated via 120° symmetry and the final valve configuration was in a partially-opened, stress-free state.

Finite Element Analysis

Mechanical properties of GLBP tissue have been previously determined using biaxial testing [4]. The experimental data was modelled using a hyperelastic, Fung-type strain energy function:

$$W = \frac{C}{2}[e^{Q} - 1] \quad (4)$$

$$Q = A_1E_{11}^2 + A_2E_{22}^2 + 2A_3E_{11}E_{22} + A_4E_{12}^2 + 2A_5E_{11}E_{12} + 2A_6E_{22}E_{12} \quad (5)$$

Where C and A_i are material constants. Closing simulations were performed by applying a uniform pressure of 120 mmHg to the aortic side of the valve leaflets. Nodes along the attachment edge remain fixed from displacement and rotation in order to mimic the strong contact boundary between the tissue and rigid stent. After completion, the maximum principle stress during closing was output from the analyses in order to determine subsequent design exploration.

Optimization

Process automation software Isight (Dassault Systemes Simulia, Providence, RI) was used to perform an optimization analysis using the Adaptive Simulated Annealing method. Parameters a, b, and SSL were chosen as design inputs and the maximum principle stress was set as the objective function. Inputs a, b, and SSL were assigned ranges of 0.18-0.22 in., 1.3-1.7, and 0.7-0.8 in., respectively. A total of 500 runs were performed.

RESULTS

Each TAV model was generated using the design parameters described above. The modest range of SSL, a, and b resulted in a notable variation in leaflet stress. Figures 2 and 3 illustrate the influence of these design variables on the maximum principle stress, denoted as SMAX. Two instances of closing simulations are presented in Figure 2.

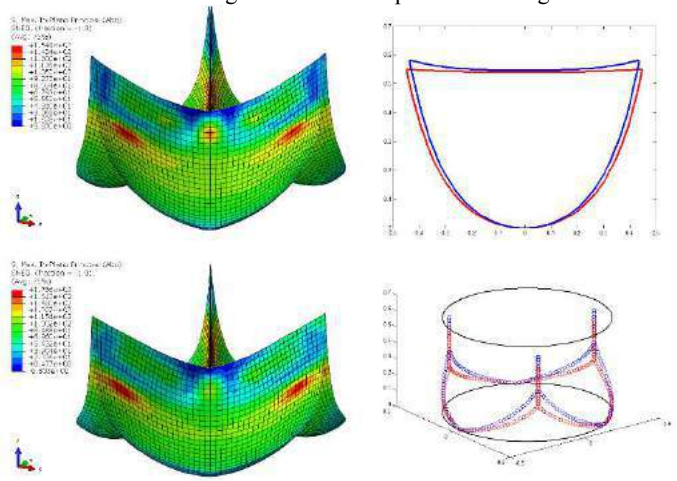

Figure 2: Diastolic loading of an optimal TAV design (top, left) and a representative design (bottom, left). Comparison of input geometry of 2D leaflet shape (top, right) and 3D attachment edge, where blue is the optimized TAV.

The suboptimal valve in Figure 2 has a lower, wider attachment edge than its ideal counterpart. The small geometric modification resulted in higher stress near the commissures and coaptation region. The magnitude of maximum principal stress ranged from ~155-220 PSI and was consistently located near the coaptation zone, a region of considerable bending stress. When comparing the ideal TAV leaflets in this optimization scheme to a TAV design with nominal leaflet geometry, the maximum principle stress was reduced from 181.6 to 154.8 PSI (14.7%).

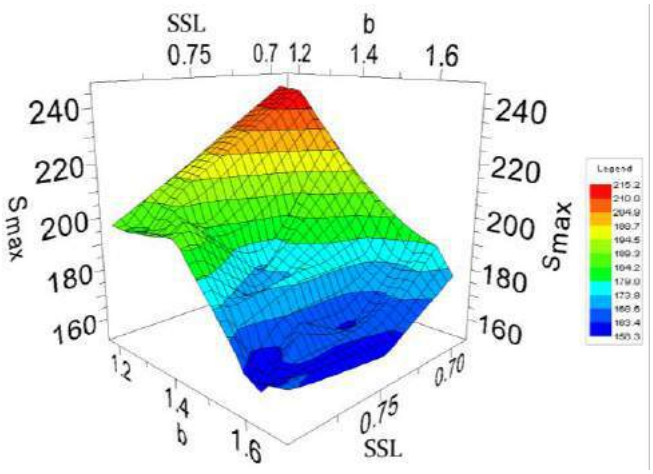

Figure 3: Effect of attachment edge length, SSL and shape, b, on maximum principle stress (PSI).

The 3D surface plot in Fig 3 demonstrates strong correlations between the input parameters and the maximum stress during TAV closure. The optimization process converged on a minimum objective function when the SSL, a, and b approached 0.79 in., 0.219 in., and 1.6, respectively. Two of the three input variables, SSL and a, reached their maximum values, indicating a larger range is required to find a global minimum.

DISCUSSION

The framework developed in this study has established a quantitative method to analyze the influence of geometric design parameters on TAV performance. Computation modeling of TAV biomechanics, like the study presented here, is an important step in developing numerical relationships between design inputs and device performance. By establishing these complex relationships, we are able to optimize certain outputs, for example, minimizing stress during diastole. By minimizing leaflet stress during diastolic loading, we may reduce cyclic fatigue and ultimately increase the durability of TAVs.

Furthermore, modification to the methodology presented could allow for additional, probabilistic-based analyses. For example, the effect of asymmetric leaflet geometries, inhomogeneous material properties, and disproportional attachment edges may be explored to better understand the impact of valve uniformity on TAV performance.

The methodology used in this study is an integration of efficient geometric modeling, rigorous mechanical testing data, and high fidelity simulation. Even though the geometric model of the 2D leaflet and 3D attachment edge is representative of modern TAVs, different free edge shapes, attachment edge shapes, and suturing lines may provide a more robust design space.

INTRODUCTION

Right ventricular failure (RVF) is a deadly deterioration of pump function that can occur in range of etiologies including congenial hearth disease, pulmonary hypertension and indirect pressure-overload from cardiomyopathy [1]. Although research focusing on elucidating progression of left ventricular (LV) failure is plentiful, current knowledge concerning the failing and recovering right ventricle (RV) is limited and insufficient for systematic development of effective treatments [2]. Characterizing patterns of failure and adaptation using preclinical and computational research are important tools for bridging this knowledge gap and for designing and testing of treatments that could have significant impact.

RVF due to pressure overload has been shown to reduce diastolic function associated to hypertrophy and interstitial collagen deposition (in fibrosis). These changes are conceptualized as compensatory mechanisms for limiting the magnitude of internal wall stresses via tissue stiffening [3]. Understanding the effects of structural remodeling in terms of fiber orientation is more difficult, but also of interest, because it relates not only to passive tissue stiffening, but also because fiber orientation has been shown to be a significant contributor to systolic organ function [4].

As in the LV, myocytes in the RV align in fibers following a helical structure quantified in terms of elevation angles with respect to the circumferential direction tangent to the ventricular wall [5]. In the healthy epicardium, the angles are mostly negative resulting in left-handed fiber helices, and the opposite is true in the endocardium. Angles in the mid-myocardium vary from positive to negative almost linearly i.e., the transmural rate of change in helical elevation angles can be approximated by a constant helical angle slope (HAS).

There is some inconsistency on reports regarding hypertension-induced HAS variations due to surgically induced RV pressure overload (RVPO) in animals studies, and there is little information on the precise mechanical consequences of such variation [6], [7]. Therefore, in the present study, we hypothesized that HAS variations caused by surgically induced pressure overload may be associated with a systolic structural compensatory mechanism.

METHODS

Subject-specific biomechanical simulations were constructed to interpret the effect of transmural fiber orientation (quantified by HAS) on cardiac function under elevated RV afterload. To this end, subject-specific finite-element (FE) models (n=3) were constructed from 3D images of the ventricular myocardium at early diastole obtained via multislice CINE MRI. The models were used to generate simulated predictions of RV function quantified by per ejection fraction (RVEF) under 4 conditions depending on RV afterload (normal or RVPO), and transmural fiber orientation (baseline or longitudinally aligned) for a total of 12 simulations. Significance in RVEF was calculated using parried t-tests with a p-value of 0.01

Geometry, structural variation, and intraventricular pressure information was obtained from a group of New Zealand white rabbits (2.0-2.5 kg) including controls (n=3), and RVF (n=6) due to pressure overload obtained via pulmonary artery banding. Band tightness was increased until RV end systolic pressure reached a minimum of 25 mmHg, and maintained until evidence of RVF was observed [8]. Images information was produced using a Bruker Biospec 7T imaging instrument. CINE-MRI was performed *in vivo* in the control group, and DT-MRI was performed *ex vivo in* controls and RVF. All animal protocols were subject to established guidelines and approved by supervisory offices at the University of Utah (protocol #13- 02010).

Pressure boundary conditions were based on interventricular catheter measurements of control animals for normal RV afterload,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

and banded animals for RVPO, which was simulated as an increase of 20% on systolic pressure. The RVF group was divided in two groups according to wall thickness, which was interpreted as compensation to increased afterload. In the uncompensated group (n=3), 3D high-resolution DT-MRI scans in the RV wall yielded a quasi-linear variation from -60° in the endocardium to 60° in the epicardium (HAS = *120*°). The compensated group, had a 30% steeper HAS, which was modeled as a longitudinally aligned fiber distribution ranging from -75° to 75°.

The first set of simulations (normal pressure, and baseline fiber orientation) were used to optimize material parameters in a transversely isotropic Fung-type hyperelastic strain energy function so that predicted RVEF matched experimental measurements per CINE MRI observations at systole and diastole. Once optimized, all parameters other than those under study were held constant. A typical FE model and additional boundary conditions and material distribution appear in Figure 1. All simulations were performed using the FEBio Software Suite [9].

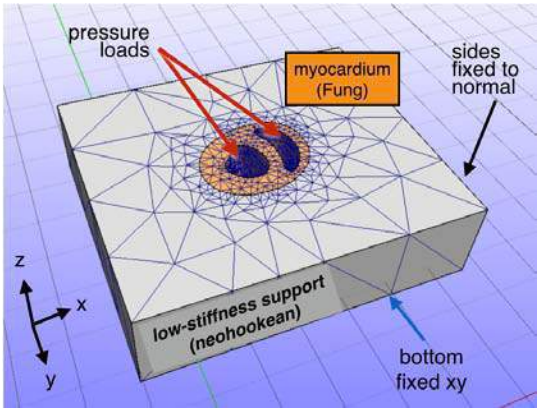

Figure 1: Finite element model of ventricular myocardium. Each subject-specific model (n=3) was modeled in 4 different conditions depending on RV systolic afterload and fiber orientation.

RESULTS

A typical FE model at different stages of the cardiac cycle was illustrated in Figure 2. As expected, end diastole results in dilated chambers, and active contraction results in diminished intraventricular volume development of torsion. Normal pressurization and fiber orientation resulted in volume predictions within 5% of those measured using CINE-MRI *in vivo*. Simulated RVEF calculations for normal and elevated pressure using with baseline or longitudinally aligned fiber are tabulated in Table 1. In RV pressure overload, with other parameters held constant, an increase in helical angle slope (by 30%, which is the high range of DT MRI observations) results in an improvement in ejection fraction of approximately 35%. This gain did not occur in the absence of pressure overload, which remained in the order of 3%.

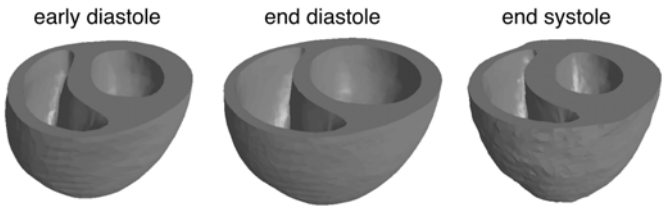

Figure 2: Representative simulation results under normal systolic pressure and baseline fiber orientation.

Table 1: Simulated RV ejection fraction for normal and elevated systolic pressure with or without fiber structure compensation (via HAS increase).

Pressure	*Normal*	*RVPO*
baseline (HAS = 120°)	0.36 ± 0.04	0.20 ± 0.06
longitudinally aligned (+30% HAS)	0.37 ± 0.04	0.27 ± 0.05
difference	*2%*	*35%**

Numerical values are expressed as mean ± (SD). * p =0.01

DISCUSSION

The numerical results show a clear functional consequence associated with structural changes. Increasing transmural helical slope, by an amount similar to that observed in the DT-MRI analysis, results in a remarkable improvement in RVEF under pressure overload. The same increase in HAS was not accompanied by significant changes in RVEF under normal conditions. This result suggests that longitudinal alignment may be particularly beneficial to recover ejection fraction in the presence of pressure overload, and it is consistent with previous studies where longitudinal alignment has been observed as one of the consequences of RVPO [6].

Further, even though all the animals in the RVF group showed clear signs of failure, DT-MRI showed that differences in HAS were observable on hypertrophic RVF hearts, and not on non-hypertrophic RVF, which may explain why previous DT-MRI studies did not report a change [7]. However, due to the relatively low number of animals, the results cannot be uniquely attributed to a biological mechanism without considering fixation or specimen preparation error as a possible disqualifier on the experimental result.

Nevertheless, this study offers numerical evidence that longitudinal fiber alignment could be a compensatory mechanism associated to systolic organ function. Further, mathematical modeling, CINE and diffusion tensor MRI could differentiate between compensated and decompensated forms of RV failure, as limitations associated with non-invasive measurement of fiber orientation can be mitigated by application of in vivo imaging in the sort future.

INTRODUCTION

Exposure to explosive blasts can produce complex brain pathology and debilitating functional outcomes. Blast wave is characterized by rapid rise in amplitude of the pressure (peak overpressure) followed by a swift drop to negative pressure (under pressure / negative phase) with respect to the atmospheric pressure. Aside from the direct interaction of the blast wave with the skull, brain and the cerebrospinal fluid (CSF), multiple secondary events could also transpire one of which includes formation and collapse of bubbles i.e. cavitation. Generation of cavitation which is dependent on fluid properties is considered one of the potential damaging mechanisms upon blast wave loading.

Damage due to cavitation is generally attributed to the large pressure generation inside the collapsing cavity. When a compression wave interacts with a pre-existing bubble, the bubble contracts leading to local increase in surface pressure. The bubble expansion and subsequent collapse leads to a high pressure generated into the surrounding liquid. Additionally, the rebound of the tissue after its deformation during the bubble expansion could cause flattening of the bubble leading to formation of a unidirectional jet. Impact of such a high velocity liquid jet could be associated with cavitation damage.

The extraordinary structural heterogeneity of brain tissue at molecular to gross anatomical scales predicts that it would be highly susceptible to cavitation based tissue damage. Our group has previously developed and dynamically characterized the methodology for blast-induced single bubble cavitation [1]. This study established that realistic simulated blast wave transit was sufficient to induce destructive cavitation. In this study, the use of the *ex vivo* acute brain tissue slice permitted characterization of specific tissue vulnerabilities and anticipates *in vivo* studies that remain technically beyond reach.

METHODS

A customized polymer split Hopkinson pressure bar (PSHPB) [2], was utilized to generate a planar simulated blast waves through a fluid chamber which housed a single brain tissue slice (~350 μm) along with the seed gas bubble (see Fig 1). To maintain cell viability during testing, the brain tissue slices were submerged in artificial cerebrospinal fluid (aCSF), continuously perfused with carbogen gas and maintained at 37^0C. Only one side of the brain (ipsilateral hippocampi) was directly exposed to cavitation events (cavitation side). High speed imaging (100,000 to 500,000 frames/sec) was used to visualize tissue deformation, and strain was calculated using digital image correlation (DIC).

Post testing the tissue slices (n= 40) were fixed in Trump's fixative and processed for electron and confocal microscopy. To assess the viable cellular structural changes beyond the effects of damage due to slicing and handling, the resin embedded samples were sectioned to a depth of 150 μm from the slice surface.

Image analysis software (GNU Image Manipulation Program v2.8.14) was used to superimpose (1) the maximum bubble footprint (2) the collapse jet direction observed in the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

video (3) confocal cellular injury zones and (4) calculated strain contours onto a single Paxinos rat atlas image to generate a composite atlas image. This was done to relate the bubble and jet location to corresponding strain and injury.

RESULTS

Maximum von mises strain generally coincided with 45 μs after bubble collapse, and overlapped with the observed injury patterns. Superimposition of the full field von Mises strain at this time point on an anatomical slice image was used to generate composite injury maps (Fig 2).

Distinct injury patterns including separation of normally apposed structures, with some tissue tears and disruption along cell layers were observed on the hippocampal side subjected to cavitation damage as compared to blast wave alone. Despite some localized contralateral strain elevations, structural failures were absent on this side that was exposed to the blast wave without direct cavitation. The observed injury patterns corresponded to instantaneous and early injury immediately after cavitation events.

Within the cavitation injury zone, ultrastructural damage was indicated with a gradual loss in the neuronal contrast with respect to the surrounding neuropil, as well as increased size and indistinguishable soma boundary within the CA3 layer. Sham CA3 neurons exhibited clearly visible Nissl bodies with distinct nuclear membrane and nucleolus. The contralateral neurons showed comparable ultrastructural features as sham with the deviation of dense and shrunken cytoplasm. In contrast, the cytoplasm of the CA3 pyramidal neurons within the cavitation injury zone appeared pale with reduced electron density of the cytoplasm. Frequent discontinuity of the plasma membrane (< 200 nm) was observed throughout the neuronal cell body in the cavitation injury zone.

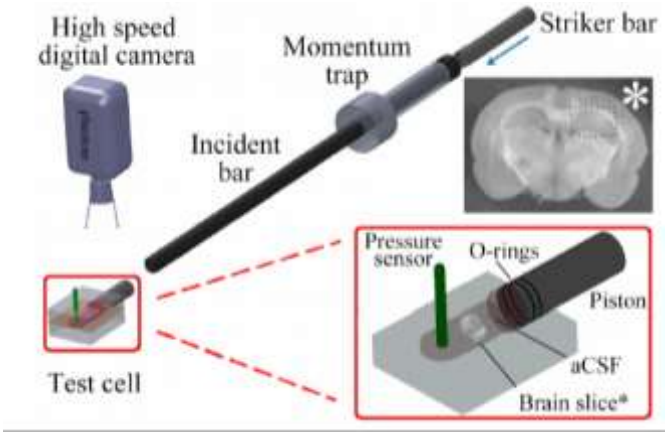

Figure 1: Experimental blast-induced controlled single bubble cavitation system. * Highlights the video frame of the brain tissue slice during growth of the bubble placed under the hippocampus (dotted line).

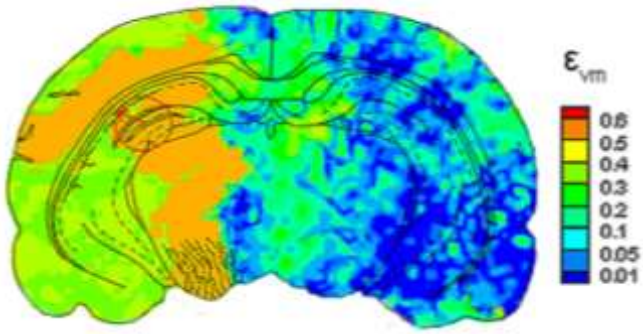

Figure 2: Composite injury map shows the overlap of observed injury (dotted lines) and regions of high strain. The red circle is the trace of maximum bubble diameter and the arrow points to jet direction.

DISCUSSION

By isolating single bubble cavitation events on live slices of mature brain, we were able to associate damage effects (separation of apposed structures, tissue tears and cell layer disruption) due to bubble growth and collapse. Most relevant to injury, we were able to directly measure the high strains created by collapsing bubble jet which overlapped with tissue injury. Data support the strong probability that dynamic cavitation events could directly mediate local structural injury in brain exposed to blast pressure transients. Microbubble formation and collapse, and jet formation, could each mediate unique forms of injuries across a wide spatial scale.

INTRODUCTION

Stroke is one of the main causes of death in Japan, and it is strongly associated with carotid stenosis. If the stenosis becomes highly sever, a surgery such as carotid artery stenting (CAS) or carotid endarterectomy (CAE) is performed to prevent the fatal situation. However, the surgery sometimes causes postoperative complications such as cerebral hyperperfusion syndrome (CHS) [1]. Thus, it is important to understand the changes in the distributions of cerebral blood flow and pressure due to the surgery and then to utilize the information to surgery in the preoperative stage.

Since the surgery affects hemodynamics not only in a localized stenotic region but also the entire circulatory system throughout the peripheral areas, it is necessary to develop a simulation system to examine the hemodynamics locally as well as globally in the circulatory system. In addition, the simulation needs to be performed in a reasonable time for case study. Thus, in this paper, a patient-specific one dimensional–zero dimensional (1D-0D) simulation method has been developed taking account of the entire cardiovascular system to obtain the hemodynamics information in the Circle of the Willis (CoW).

The present simulation system consisted of three processes: pre-processing, 2) multi-domain simulation, and 3) post-processing. In order to perform the patient-specific 1D-0D simulation, the information on the radius and the length of CoW was obtained from the 3D vascular geometry constructed from the medical image data such as the computed tomography (CT) or the MRI (Magnetic Resonance Imaging) in the pre-processing process [2]. The 1D-0D simulation was based on the method of Liang F. Y., *et al* with the literature data of vascular geometry and also the vascular parameters such as resistance and compliance [3]. Since there were discrepancies in the results caused by the differences in the vascular geometry between the literature and the patient-specific data, the single photon emission computed tomography (SPECT) data were used as reference to adjust the parameters, i.e. peripheral resistances [4]. In the past-processing process, a visualization system was developed for the 1D domain where the patient-specific geometry was applied. The present simulation system was applied to investigate the blood flow in the CoW. The results of pre- and post-operation were compared to examine the effects of the surgery.

METHODS

Figure 1 summarizes the present integrated simulation system with multi-modal data.

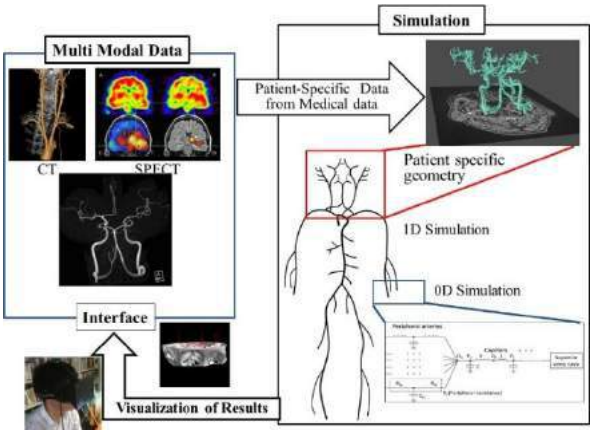

Figure 1: Schematic illustration of the integrated system.

The authors have been developing a vascular geometric modeling system, V-Modeler [2]. The development environment of V-Modeler was based on Visual Studio 2010 Professional (C++ programming

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

language) on Windows 7 Professional 64bit. The image processing libraries were MIST (Media Integration Standard Toolkit, Nagoya University, Japan) and OpenCV 2.2, visualization library was OpenGL.

The 1D simulation was applied to a total of 83 arteries which consisted of 55 arteries based on Liang model [3] and newly added 27 arteries of cerebrovascular and neck circulations. The governing equations of the 1D simulation are given by:

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial z}=0 \tag{1}$$

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial z}\left(\frac{Q^2}{A}\right)+\frac{A}{\rho}\frac{\partial P}{\partial z}+8\pi\frac{\mu}{\rho}\frac{Q}{A}=0 \tag{2}$$

$$P-P_0=\frac{Eh_0}{r_0\left(1-\sigma^2\right)}\left(\sqrt{\frac{A}{A_0}}-1\right) \tag{3}$$

where A, Q and P are the cross-sectional area, the flow rate and the pressure, respectively. In addition, E, h, r, and σ represent the Young's modulus, the wall thickness, the arterial radius, and the Poisson ratio. The subscript 0 denotes a value at the reference state. The Poisson ratio in the paper was taken to be 0.5 because of incompressibility of the artery. The Lax-Wendorff method was used to solve equations (1)-(3).

The 0D simulation comprised two equations for mass and momentum conservation based on the electric circuit analogy. The governing equations were solved using the 4th order Runge-Kutta method. The results of the 0D simulation were given to the 1D simulation at the junction, and vice versa.

The visualization part was incorporated to V-Modeler since the 1D simulation used the information of the radius and length extracted from the medical image data by V-Modeler. V-Modeler had also the information about the centreline of the vascular lumen expressed by a spline-function. First of all, the grid point used for the 1D simulation was allocated in the 3 dimensional coordinates using the information of the centreline in the 3D. Since the radius was obtained from the area resulted from 1D simulation, the pressure and the flow rate were remapped onto the 3D geometry.

RESULTS

The simulation was conducted for a 70 years old male with 73% stenosis at Left Internal Carotid Artery (Lt. ICA).The patient-specific data in this paper used the magnetic resonance angiography (MRA) for the geometry and SPECT for adjustment of the flow rates in the efferent arteries.

Figure 2 summarizes the simulation results of flow rate in each artery at the rest and with ACZ for both the pre- and post- operations.

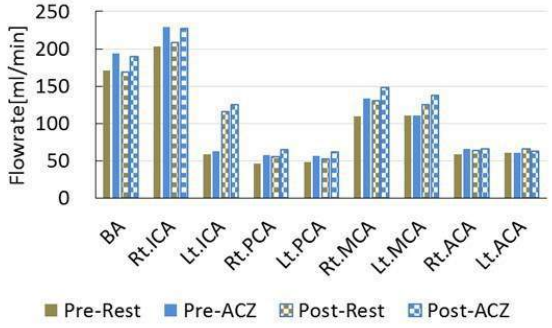

Figure 2: Flow rate of each artery before and after the surgery.

Since the stenosis was located on the left side, the flow rates of the arteries on the left side such as Lt. Middle Cerebral Artery (MCA) and Lt. Anterior Cerebral Artery (ACA) did not change after the ACZ was applied on the pre-operation stage. After the surgery, the flow rates of both afferent and efferent arteries became balanced on both sides.

Figure 3 demonstrates the flow distribution before and after the surgery. The figure on the left is at the rest on the pre-operation stage while one on the right is at one on the post-operative stage. As shown in Figure 3, although the flow rate of Lt. ICA was higher than one of Rt. ICA, both flow rates became the same after the surgery.

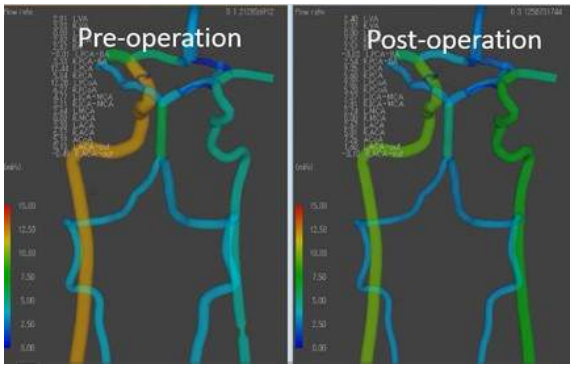

Figure 3: Visualization of flow rates before and after the surgery.

DISCUSSION

In order to investigate the effects of the surgery, the paper presented the integrated numerical system of the 1D-0D simulation for an individual patient by utilizing the patient data from the multi-modal data. In the simulation, the geometric information was obtained from the MRA by V-Modeler while the flow information was obtained from the SPECT.

The averaged computation time for each case in the present 1D-0D simulation was about 50 minutes. It required about 10 cardiac cycles for convergence. In general, the commercial visualization software is available for the 3D simulation but not for the 1D-0D one. Development of the visualization system enabled us to evaluate the detailed difference in the flow distribution between the pre- and post-operative stages.

We found that the flow in the anterior efferent region changes the flow direction before and after the surgery. The flow before the surgery was from MCA to ACA on the right side and then became from ACA to MCA after the surgery. Despite the changes in the flow direction, the overall Cerebral Blood Flow (CBF) before and after the surgery did not show a significant increase for the CHS according to the literature [5]. In addition, the asymmetry index, which is one of the risk factor [5] was improved after the surgery. Those results agreed with the clinical presentation of the patient. In order to examine the applicability of the present method, the further investigation with more case study will be conducted.

INTRODUCTION

Cardiovascular diseases are one of the leading causes of death around the world. According to the American Heart Association, there were more than 7.6 million cardiovascular procedures performed in the US and total treatment spending exceeded $320.1 billion in 2011 [1]. *In-vivo* studies can be performed to better understand these diseases, but there are challenges due to clinical limitations and ethical considerations. An alternative is bench top cardiovascular experimentation, in which localized vascular conditions are recreated *in-vitro* to better analyze the hemodynamics pertaining to certain defects or surgical conditions. This couples medical imaging with fluid mechanics to recreate physiological conditions on a relatively simple, inexpensive bench top circuit and allows experimental validation of computational models, extensive *in-vitro* testing of medical devices and better overall understanding of vascular hemodynamics without risks or discomfort to any patient.

Accurate replication of the pulsatile blood flow is necessary to study hemodynamics pertaining to any vascular condition. The 'Harvard pump' (Harvard Apparatus, MA) and the 'SuperPump' (Vivitro Labs, Canada) are commercial pumps that can recreate ascending aortic flow but the user must experimentally construct a downstream vascular simulator to obtain the desired flow waveforms at specific anatomic locations. In studies of localized vascular conditions, it is needed to only reproduce the localized flow waveform under consideration. This eliminates unnecessary replication of vascular impedances between the heart and the site of interest. There are experimental systems, such as the dual pump system [2], progressive cavity pump [3], positive displacement pump [4] and the commercial system 'CardioFlow' (Shelley Medical Imaging Technologies, Canada), that are designed to reproduce localized flow waveforms. But these systems are limited by practicality, cost, programmability or accuracy, especially when reproducing multiple waveform shapes with different downstream impedances.

The aim of this study is to design, construct and test a reliable, low cost, fully programmable pulsatile flow pump that can continuously and accurately reproduce localized physiological flow waveforms. The reduced complexity and cost of this design will enable the advancement of cardiovascular medical technologies and improve patient care.

METHODS

Pump Design and Operation*:* A rendering of the bench top cardiovascular pump is shown in Figure 1a. It consists of a piston – cylinder assembly and a stepper motor linear actuator. The cylinder is acrylic, with an internal diameter of 4.75 inches and length of 36 inches. The piston is connected to an actuator (HaydonKerk motion solutions, CT), which has a linear nut and lead screw arrangement driven by the stepper motor, controlled by a driver (HaydonKerk motion solutions, CT). Control signals are generated by LABVIEW and an NI data acquisition system (National Instruments, TX). The cylinder is sealed by end plates on both ends and is divided into two chambers by the piston, making it double-acting. Fluid ports are on the end plates (Figure 1b). Connections from the outlet ports on both ends of the pump are merged using a three way valve to form a single connection to the test section that discharges to the fluid reservoir. A similar pattern of tubing is used to connect the reservoir to pump inlet ports. These connections facilitate switching of active ports from one end of the pump to the other as the piston changes direction. Air release ports are positioned on top of the cylinder's curved surface which is the ideal location for air removal. The actuator velocity and direction are controlled by a counter output and analog voltage signal respectively. The total cost for the pump is less than $1,000 which makes this design considerably cheaper compared to commercial systems that cost around $50,000.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Feedback Mechanism: A feedback mechanism has been implemented to improve accuracy under varying downstream impedances. LABVIEW receives the output flow rates from a clamp-on ultrasonic transit time flow meter (Transonic systems Inc., NY) and averages it over 5 cycles. This flow waveform is compared to the desired waveform and a proportional control is used to rectify any variations. The system executes this process iteratively until the desired waveform is achieved

Test Setup: The pump is connected to a test section with a downstream resistance to create back-pressure. Flow waveform data is supplied as input to the pump-control program, which then runs the pump, collects flow values averaged over five cycles and uses this for feedback calculations. When the system attains the user's desired level of accuracy, corresponding control data is stored for later use. The counter frequency is set to vary in timesteps of 20 ms, providing the operator with 50 data points per second for the input. For this particular test case, a general infra-renal abdominal aortic flow waveform with a peak flow of 110mL/s [5] is used under varying downstream conditions to demonstrate the pump performance. A 40% glycerin solution is used as the blood mimic. Pressure is measured using a pressure transducer (Argon Medical Devices Inc., TX).

RESULTS & DISCUSSION

Figure 2 shows the flow and pressure waveforms produced by the pump (averaged over five cycles) compared to the actual desired waveforms. The mean absolute percentage error in flowrate is 2.46% and the maximum absolute percentage error is 5.7%. Pump accuracy is comparable to that of commercial models (±3% for 'CardioFlow 5000'). Shape of the recreated pressure waveform resembles that of physiologic waveforms. The coincidence of the peak of pressure curve with that of flow waveform and the large difference between maximum and minimum pressure is due to the absence of a compliance chamber downstream.

Figure 3 shows the averaged recreated flow waveforms under varying levels of back-pressure. The same input waveform is tested under different peak pressure conditions. Results show that pump performance is independent of downstream impedances until the back-pressure reaches 180 mmHg, which is beyond physiological pressures. Pump performance degrades as the abnormally high back-pressure pushes the power requirements beyond the actuator's limit, especially at higher flow rates. This shows that the pump is powerful enough to recreate any physiological pressure given the peak flow rate is within limits.

The maximum flow rate of the current prototype is limited to 160 mL/s due to limitations of the stepper motor. For higher flow rates the use of a servo motor might be necessary. The pump has been designed so that it can be modified for continuous use for medical device testing by automating inlet and outlet manifold valve control. Future work in these areas could result in useful refinement of the current system.

Through this study we have successfully designed and tested a versatile computer controlled pulsatile flow pumping system that produces repeatable flow waveforms under various downstream conditions with an accuracy comparable to commercial systems at 2% of the cost.

INTRODUCTION

Interleukin (IL)-1 is one of the inflammatory cytokines that could be elevated after traumatic joint injuries. IL-1 can mediate articular cartilage tissue degradation, induce chondrocyte apoptosis, and lead to post-traumatic osteoarthritis (PTOA) of the joint [1]. Our recent studies found that zoledronic acid (ZA), an FDA-approved drug for the treatment of osteoporosis, can suppress the development of OA in the DMM (destabilization of medial meniscus) mouse model (Fig. 1) [2]. Using cartilage explant model, we further showed that zolendronic acid could improve the mechanical integrity of cartilage explants during long-term *in vitro* culture. However, it is not clear whether zolendronic acid can directly rescue the chondrocytes from the injuries from inflammatory attack. In this study, we tested the following two hypotheses: (1) Zolendronic acid can prevent the GAG loss in cartilage explants and protect the viability of chondrocytes in the presence of IL-1β. (2) The chondro-protective effect of ZA is related to the intracellular calcium ($[Ca^{2+}]_i$) signaling of chondrocyte.

METHODS

Bovine cartilage explant model Cylindrical cartilage explants (diameter = 3 mm, thickness = 2 mm) were harvested from fresh calf knee joints within 24 hours of slaughter (Green Village, NJ) and cultured in chemically defined medium (DMEM, 1% ITS, 50 μg/mL L-proline, 0.9 mM sodium pyruvate, and 50 μg/mL ascorbate 2-phosphate) [1]. After 3-day balance in culture medium, IL-1β and/or ZA were introduced into the culture for extra 8 days (see below for details).

Mechanical properties and sGAG release GAG contents in the culture medium and the cartilage explants were measured using DMMB dye-binding assay. The accumulative GAG loss was defined as the total GAG released into the medium divided by the sum of GAG contents in both explant and culture medium. Young's modulus and dynamic modulus of cartilage explants on day 8 were determined by unconfined compression tests [4].

Cell viability Cells in cartilage explant were stained using LIVE/DEAD Viability/Cytotoxicity Kit (Thermo Fisher Scientific) and imaged using a confocal fluorescent microscope (Zeiss LSM 510).

In situ Spontaneous Calcium Signaling Cartilage explants were cut into two halves and cultured in 5 μM Fluo-8AM dye medium for 40 minutes. Calcium images of *in situ* chondrocytes resided in cartilage were taken every 2 s for 16 minutes without alien stimuli using a confocal microscope. The spontaneous responsive percentage of cells was calculated as the fraction of cells with calcium spikes over the number of total cells. A set of spatiotemporal parameters of the $[Ca^{2+}]_i$ peaks were also reported as described in our previous studies [4]. Calcium is a universal second messenger in cell activities and functions as the upstream of many metabolic activities of chondrocytes.

Statistical analysis Tukey's Honestly Significant Difference test was performed following the one-way ANOVA to compare the GAG loss and mechanical properties among groups (data shown as mean ± standard deviation). For the parameters related to $[Ca^{2+}]_i$ signaling, nonparametric Mann-Whitney U test was utilized to detect the significant difference (data shown as mean±SEM).

RESULTS

ZA inhibits the IL-1β-induced GAG loss in cartilage explant

Cartilage explants treated with IL-1β released sGAG in a dosage- and time-dependent manner (Fig. 2A). 1ng/ml IL-1β induced ~50% total sGAG loss in cartilage after 8 days (~6% per day), significantly lower than those of 10 or 25 ng/ml treatment. Thus the 1ng/ml IL-1β treatment was chosen for all the following experiments to mimic a moderately aggressive inflammation injury. In the second study, zolendronic acid, at 0.5 μm, 1 μm, 2.5 μm or 5 μm, was added together

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with 1ng/ml IL-1β during the 8-day culture, and sGAG loss were measured (Fig. 2B). ZA treatment at 1 μm showed the optimal inhibitory effect on sGAG loss, and thus ZA at 1 μm was chosen for all following experiments.

During 8 days culture, GAG release from cartilage treated with ZA alone is close to that of control group (Fig. 3A), with ~1.5% per day at an almost constant rate. However, ZA significantly reduced the GAG release when cartilage was exposed to IL-1β (36% vs. 47% of IL-1β alone, p=0.03). A similar trend was also observed when comparing the Young's modulus and dynamic modulus of the samples in four groups (Fig. 3B-C) (Young's modulus of IL-1β + ZA vs. IL-1β alone: 0.15 vs. 0.08 MPa, p = 0.04).

ZA maintained bovine chondrocyte viability in the presence of IL-1β

After 8 days exposure to IL-1β, increased cell death was observed (Fig. A-B) in explants, while the addition of ZA in the treatment greatly reduced the number of dead cells (Fig. 4 B-C).

Spontaneous calcium signaling of in situ chondrocytes

Spontaneous $[Ca^{2+}]_i$ signaling of *in situ* chondrocytes in cartilage was recorded after 2-day culture. IL-1β treated samples showed significantly dampened $[Ca^{2+}]_i$ signaling in chondrocytes, lower than half of that in control group (Fig. 5A). Treatment of ZA preserved the $[Ca^{2+}]_i$ signaling of chondrocytes injured by IL-1β in term of the responsive percentage (Fig. 5A). ZA and IL-1β also modified the frequency and rising speed of $[Ca^{2+}]_i$ peaks (Fig. 5B-C).

DISCUSSION

Using an *in vitro* long-term explant culture model, this study showed that zoledronic acid, an FDA approved medicine, could protect the chondrocytes and mechanical integrity of cartilage from the damage of IL-1β. The chondro-protective function of zoledronic acid is correlated with the spontaneous $[Ca^{2+}]_i$ signaling of chondrocytes. As ZA or bisphosphonates are believed without anti-inflammatory functions, our future study will investigate the detailed chondro-protective mechanisms of ZA.

INTRODUCTION

The lymphatic system is a branched network of vessels that is present in all of the tissues of the body. To maintain the fluid balance, the system has to transport viscous fluid (lymph) against gravity and adverse pressure difference. Lymph flow is maintained by contraction of individual vessel segments (via contraction of muscle cells in their wall) as well as lymphatic valves that prevent back flow. Consistent lymph flow is essential for tissue homeostasis and prevention of edema.

In situ observations of rat mesenteric lymphatic vessels have shown that adjacent lymphagions (vessel segments between two valves) contract with the same frequency and a small time delay. Contraction propagation in both orthograde and retrograde directions has been previously observed in bovine, guinea-pig, and rat lymphatic vessels in vivo, in situ as well as in isolated vessel experimental set ups. These experiments were mostly performed on short segments of lymphatic vessels without branching points. It is expected that pumping coordination and propagation would be much more complex in a branched network arrangement [1−4].

In this study, we have quantified determinants of lymphatic contractility in isolated rat mesenteric lymphatic vessels containing one branch point, with at least one valve in each vessel. Our experimental set up permits us to control inlet and outlet pressures of the system. We can track the diameter of the vessel in real time and quantify contractile activity throughout the length of the branched segment. To our knowledge, this is the first isolated vessel experiment performed on lymphatic branches. We have developed computational models of lymphangions in series and in branched network arrangement closely tied to available experimental data. The novel findings of these experiments will be used to inform our computational model and improve its physiological relevance [5−7].

METHODS

Mesenteric lymphatic vessels with one branch point and at least one valve in each vessel were isolated from male Sprague-Dawley rats and cannulated with glass micropipettes. The cannulated vessels were then transported to an inverted microscope. The pressures p_{in} and p_{out} of the reservoirs beyond the pipettes were controlled with servo controllers. Vessels were imaged continuously throughout the experiment for diameter tracking. Animal protocols were approved by the Institutional Animal Care and Use Committee at the University of Missouri-Columbia and conducted in accordance with the NIH Guide for the Care and Use of Laboratory Animals. An image of one of the isolated and cannulated vessels is presented in Figure 1.

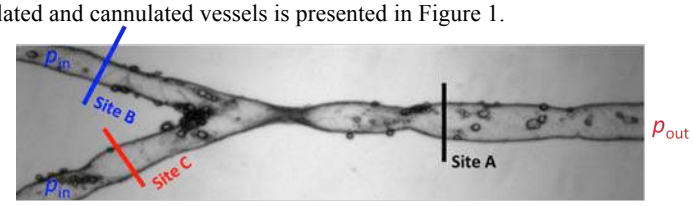

Figure 1. Cannulated lymphatic vessel segment with one branch point. Site A, site B, and site C are diameter tracking sites in each vessel. p_{out} is the pressure of the outlet reservoir. Both vessels upstream of the branch point are connected to the inlet reservoir. (p_{in})

RESULTS

Lymphatic contractions were modulated by transmural pressure. Figure 2 shows diameter tracings at sites A, B, and C during a 0.4 min period at each pressure step as inlet and outlet pressures increased from 3 to 10 cmH_2O, with steps of 1 cmH_2O (p_{in} = p_{out}). Amplitude, frequency, and coordination of contractions varied with transmural

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

pressure. External pressure (p_e = 0.5cmH_2O) remained constant.

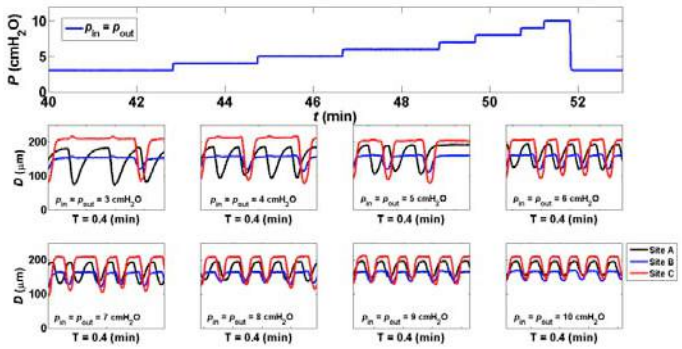

Figure 2. Top: Step increase in p_{in} and p_{out} ($p_{in} = p_{out}$, blue). Bottom: Diameter tracings of the vessel in figure 1 at sites A (black), B (blue), and C (red) during a 0.4 min period at each pressure step. Amplitude, frequency, and coordination of lymphatic contractions were modulated by transmural pressure.

Contraction frequency (f) increased with transmural pressure, with maximum increase occurring at lower pressure values. For example, average contraction frequency 2.3× increased for vessels B and C when inlet and outlet pressures increased from 3 to 5 cmH_2O. Importantly, vessels B and C contracted with similar frequencies at all pressure differences, while vessel A initially had a higher contraction frequency. All three vessels eventually synchronized and reached a 0.25 Hz contraction frequency at $p_{in} = p_{out}$ = 10 cmH_2O. However, contractions at sites B and C were synchronized in all pressure steps.

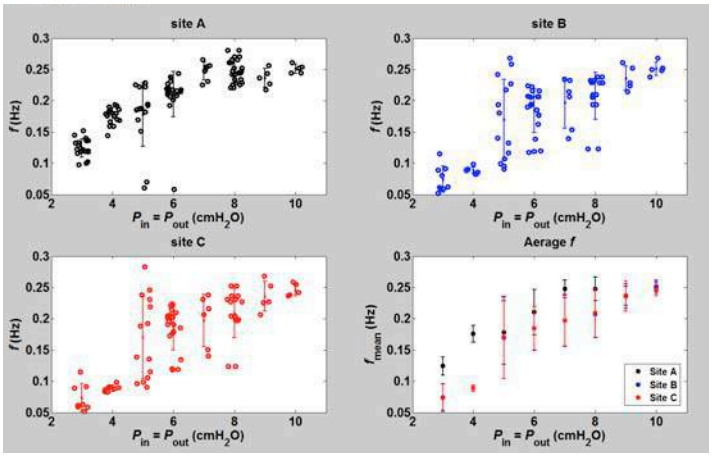

Figure 3. Frequency of contractions at sites A, B, and C at each pressure step. Contractions at sites B and C were synchronized with equal frequencies. Thus, average frequency of site C (red) overwrites the data for site B (blue) (Bottom right).

Diameter amplitude (D_{amp} = D_{max} − D_{min}) decreased as transmural pressure increased from 4 to 10 cmH_2O. This is due to larger minimum diameters (D_{min}) at higher transmural pressures while maximum diameter (D_{max}) of vessels (during their relaxed and non-contracted state) remained relatively unchanged. It should be noted that on the first rising of pressures (from 3 to 4 cmH_2O), diameter amplitude increased by 6 and 3.5% at site A and B, respectively. Overall, at the highest tested pressure (10 cmH_2O), D_{amp} dropped by 47, 62, and 37% (of its initial value at 3 cmh_2O), at sites A, B, and C, respectively.

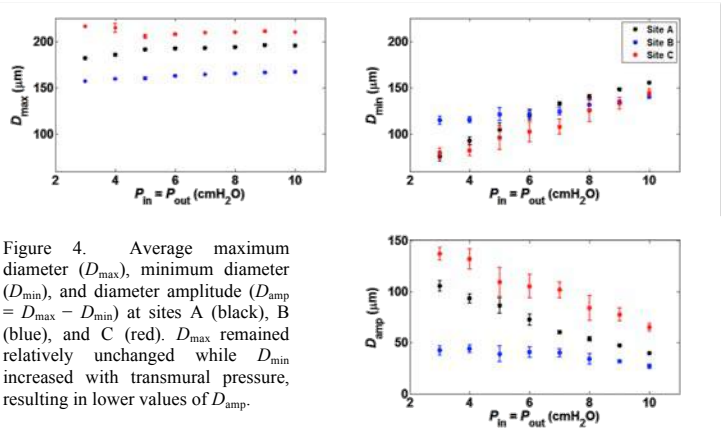

Figure 4. Average maximum diameter (D_{max}), minimum diameter (D_{min}), and diameter amplitude (D_{amp} = D_{max} − D_{min}) at sites A (black), B (blue), and C (red). D_{max} remained relatively unchanged while D_{min} increased with transmural pressure, resulting in lower values of D_{amp}.

DISCUSSION

Diameter measurements in isolated branched lymphatic vessels from rat mesentery demonstrated that diameter amplitude, contraction frequency and coordination are modulated by transmural pressure. Contractions at sites B and C were synchronized with equal frequency at all pressure steps. This may be attributed to the fact that the two sites were connected to the same pressure reservoir (p_{in}) and were located upstream of the branch point. At $p_{in} = p_{out}$ =10 cmH_2O, all sites contracted synchronously, suggesting that this might be the optimum pumping condition at high transmural pressures. Contraction frequency increased while diameter amplitude dropped as inlet and outlet pressures increased. This is due to vessel wall stiffening at higher transmural pressures, which prevents the vessels from reducing their diameter as much during maximum contraction, resulting in higher minimum diameters, while peak diameter remains unchanged. In this study we report the first measurement of contractility in branched segments of isolated lymphatic vessels. These findings will be used to inform our computational model of lymphatic networks to improve the physiologic relevance of our modeling framework.

INTRODUCTION

Detection of early stage lung diseases is still a challenging field for physician and engineers. Practice of radiology or magnetic resonance imaging technique provides advantages to observe the condition of the inner organ, however, the risk of the radiation and the high cost of magnetic resonance imaging technique cannot be neglected. On the other hand, the usage of lung sound for diagnosing the lung condition may offer a solution for this setback. Importance of the lung sound detection appeared a long time ago since the invention of stethoscope, yet the practice of listening to the patient's lung sound are still performed until today. Recently, the development of the respiratory acoustic measurement technique results in the improvement of the ability of acoustic analysis to be implemented in continuous respiratory observation which is important especially in treating young children, the elderly people, and people with disability.

The diagnosis method using lung sound measurements demonstrates a promising future, but has practical limitations. It is well known that the sound measured on the chest surface by the stethoscope laid between 100-5000 Hz with sharp decrease at 800 Hz and low strength at 1500 Hz [1]. Nevertheless, the fundamental phenomena of the sound generation and the sound propagation from the source to the chest surface are unsatisfactorily known. This study examines the generation of the sound caused by the flow inside an airway model. Frequency analysis of the recorded sound was performed in aiming better understanding of the acoustic characteristics generated by the flow in the respiratory system.

METHODS

A lung silicone model was prepared based on a set of CT scan images of an 11 years old boy with a stable, non-asthmatic condition. The CT images were segmented using in-house segmentation code based on multidirectional segmentation method [2]. The segmentation method was able to extract the airways up to 8th generation airway branch. A total of 39 airway bronchi was successfully obtained.

A silicone model size of 185×115×60 mm^3 was constructed based on the segmented image. As shown in Figure 1A, the trachea end was connected to 15 mm diameter rubber hose which is connected to a 3D printed connector, while the bronchi was connected with 2 mm (5 bronchi) and 1 mm (34 bronchi) silicone tube. The silicone tubes were collected in an acrylic flow distributor and all open-ended silicone tube were located outside the measurement box to prevent the sound generation at the edge of the tubes. Air with constant flow rate of 500 mL/s corresponds to a Reynolds number of 4500 at the trachea was employed in order to simulate the flow condition at peak velocity of tidal breaths. Both the inspiration and expiration direction were studied.

The sound generated by the air flowing through the airways was measured by using a microphone array system consists of 4 microphones (GRAS 40PH, GRAS Sound and Vibration, Holte, Denmark) calibrated to a standard pressure calibrator. The microphone array measured at 20 locations on horizontal direction and 34 locations on vertical direction so that in total 680 measurement points were obtained to map the sound pressure distribution of the silicone model. Distance between each measurement points was kept constant at 5 mm. All microphones were located at a distance of 3 mm from the surface of the silicone model to the microphone tip. All measurements were performed inside an anechoic room to reduce the background noise level.

(A) **(B)**

Figure 1: (A) Setup of the airflow from the air tank to the model. Each bronchi was connected to a silicone tube. (B) Color-graph of the sound pressure power spectral density (PSD) at 1368 Hz, 1818 Hz, 1984 Hz, and 4848 Hz at inspiration (top), and expiration (bottom) direction.

The sound was recorded using a National Instrument Data Acquisition system with a sampling frequency of 20000 Hz. The length of each measurement was three providing enough number of samples for the 50 times ensemble averaging in the frequency analysis. All data processing calculations were performed using MATLAB® R2012a.

RESULTS

Power spectral density of the sound generated from the silicone airway model at 680 points are shown in Figure 1. The results show the main feature of the airways shape at frequency of 1370 Hz, 1820 Hz, 1980 Hz, and 4850 Hz. In these figures, red color indicates locations with high sound pressure, while blue color indicates low sound pressure detected by the microphone. Air flowing in the inspiration direction majorly produce sound on frequency less than 2000 Hz on the larger airways such as trachea and main bronchus. In the expiration direction, a wide frequency band sound was generated between 1000-8000 Hz. At frequency range between 1000 Hz and 2000 Hz, the sound was produced mainly on the trachea and main bronchus, while at range 2000-8000 Hz the sound mainly generated at small airways.

DISCUSSION

Characteristics of the sound may be determined by the frequency component and the magnitude of the sound pressure. Current results showed us that the frequency component generated by the air flowing inside the silicone model is different between the inspiration and expiration direction. Low frequency components (around 1000 Hz) was majorly generated in the large airways such as trachea and main bronchus. High frequency components (2000 Hz and more) were generated mainly in the smaller airway, especially those close to the outlet of the silicone model.

Lung sound analysis has been performed since a long time ago, and physician believe that the information contained in the lung sound laid in the lower frequency region less than 3000 Hz. In our results, it is clearly shown that the information contained in the frequency range less than 3000 Hz was successfully obtained although in the frequency range of less than 1000 Hz our model did not show a good frequency feature.

On the other hand, our measurement showed some locations with frequency component sound. It is not clear how the sound is generated at these locations. This new information is important since many airway disease encompass remodeling and inflammation of the airway [3] and the appearance of bronchoconstriction [4].

In this study, the manner of the sound propagation affected by anatomical tissues e.g. skin, bon, fat, etc. was not discussed yet. Those features may influence the propagation characteristics and lead to some differences between the sound characteristics generated in the airways and the sound measured on the chest surface. In our future work, an evaluation of the sound propagation as a function of the surrounding tissues must be performed computationally in order to result a better understanding of lung sound analysis.

INTRODUCTION

Tissue deformation is plays a fundamental role in many vital organs, including cardiac function, and displacement during impact leading to traumatic brain injury [1-2]. Motion estimation using tagged MRI has had an expanding role as a functional biomarker in clinical practice, and as method for providing experimental validation of mechanical simulations [1,3]. Harmonic phase (HARP) analysis is a popular approach to track tagged images by extracting phase vector images, which effectively become conserved material properties associated to a reference configuration i.e., values that travel with the tissue as it deforms [4]. However, generation 3D displacement fields requires volumetric data acquired over multiple repetitions, which, given experimental inconsistency, magnify the effects of motion, partial volume, and other artifacts. To reduce these effects, estimation of 3D is often accompanied by regularization and filtering, but these strategies often elicit additional parameters that are difficult or impossible to measure experimentally, and thus may induce additional uncertainty and error to the estimation.

This study describes the HARP tracking process as enforcing conservation of an additional material property—the phase vector at each material location. This novel description enables embedding the tracking process into finite element (FE) simulations, and including mechanical features inherent to numerical biomechanical analysis such as realistic boundary conditions, and material properties. Because these features can be measured or inferred experimentally, FE-based HARP tracking (HARP-FE) produces accurate and representative 3D strain fields. To illustrate these ideas, HARP-FE was derived and deployed to: (1) calculate the principal stress distribution of a pre-strained incompressible tissue sample using synthetic image data, and (2) estimate motion of a brain phantom subject to rotational acceleration using experimental MRI data.

METHODS

Theory—A harmonic phase vector field, $\boldsymbol{\phi}$, is typically extracted from complex MRI by applying a band-pass filter centered at the tagging frequency [4]. HARP tracking consists of finding spatial coordinates, $\boldsymbol{x}$, with the same phase values as those in a set of initial material points, $\boldsymbol{X}$, i.e., $\boldsymbol{x}(\boldsymbol{X})$ such that $\boldsymbol{\phi}(\boldsymbol{X}, t_0) = \boldsymbol{\phi}(\boldsymbol{x}(\boldsymbol{X}), t)$. This relationship is equivalent to a mass transport expression stemming from the weak formulation of conservation of the phase density field $\boldsymbol{\phi}$ in a control volume [5]. In a mass-conservative field, it can be shown that

$$\frac{\mathrm{D}(\boldsymbol{X}, t_0)}{\mathrm{D}t} = \frac{\partial \boldsymbol{\phi}(\boldsymbol{x}, t)}{\partial t} + \nabla \boldsymbol{\phi}(\boldsymbol{x}, t) \cdot \boldsymbol{v}(\boldsymbol{x}, t) = 0, \qquad (1)$$

where $\boldsymbol{v}$ is velocity. The spatial terms above represent a phase version of the familiar *optical flow* equation used for motion estimation via image registration [6]. With the Lagrange multiplier, λ, the material term yields the HARP-FE tracking constraint,

$$\boldsymbol{f}_{harp} = \lambda(t)[\boldsymbol{\phi}(\boldsymbol{x}(\boldsymbol{X}), t) - \boldsymbol{\phi}(\boldsymbol{X}, t_0)], \qquad (2)$$

which is directly applied (as an additional phase-based body force) to the virtual work equation from conservation of momentum, or

$$\delta \mathrm{W} = \int_{\mathcal{R}} \boldsymbol{P} : \delta \dot{\boldsymbol{F}}\, dV - \int_{\mathcal{R}} \boldsymbol{f} \cdot \delta \boldsymbol{v}\, dV + \oint_{\mathcal{S}} \boldsymbol{t} \cdot \delta \boldsymbol{v}\, dV dS = 0, \qquad (3)$$

where $\boldsymbol{P}$ is the material-dependent 2nd Piola-Kirchhoff stress tensor, $\boldsymbol{F}$ is the deformation gradient, $\boldsymbol{t}$ represents external loads, and $\boldsymbol{f}$ represents all internal forces, including tracking $\boldsymbol{f} = \boldsymbol{f}_o + \boldsymbol{f}_{harp}$. The HARP-FE constraint was implemented as a plug-in extension for the FEBio Software Suite [7] using (2), and tangent stiffness contribution defined by the linearization of (3), i.e,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\mathrm{D}\delta W_{harp}(\boldsymbol{x}, \delta\boldsymbol{v})[\mathrm{u}] = \int_{\mathcal{R}} \lambda(t)\nabla\boldsymbol{\phi}(\boldsymbol{X}, t_0)\ \delta\boldsymbol{v}\cdot\delta\boldsymbol{u}\ dV, \qquad (4)$$

where $\mathrm{D}f(\mathrm{x})[\mathrm{u}]$ is the directional (or Gateaux) derivative.

Approximation of Stress Distribution—The goal this experiment was to demonstrate compatibility and benefits of including mechanical analysis along with motion estimation. An incompressible tissue sample was modeled as a rectangular, pre-stretched (10% in the x-direction), Veronda-Westmann solid (C_1= 0.5 kPa, C_2= 2.5), subject to force at its center (Fig. 1a). Synthetic tagged images in each direction (64×64×2 px, 0.2×0.2mm, complementary spatial modulation of magnetization, or C-SPAMM, 12 px spacing) were generated before and after the application of the force for the reference and deformed configurations. These images were decomposed into magnitude and phase to define $\boldsymbol{\phi}$ [4], and used as input for HARP-FE, which was performed first without any constraints, then with added boundary conditions at the ends, and, finally, with boundary conditions as well as pre-stretching. The multiplier $\lambda(t)$ was set to <0.05 rad mean tracking error. Combined grid images (x and y) appear in Fig. 1b-c.

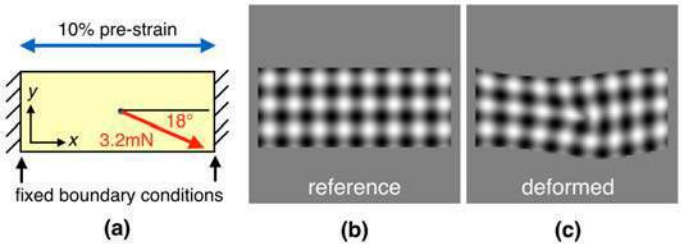

Figure 1: Displacement information from a model (a) was used to create synthetic images (b-c) and stress estimation via HARP-FE.

Experimental Motion Estimation of Brain Phantom—This experiment was designed to evaluate the HARP-FE using actual MRI data against a conventional tracking approach. A gelatin phantom was mounted in a MRI-compatible rotational apparatus (Fig 2a) and subsequently imaged while experiencing sudden angular acceleration (Siemens 3.0T mMR Biograph scanner, 13 axial slices, 160×24 zero padded to 160×160 px, 1.5×1.5mm, 15×15mm, SPAMM sequence, 12 px spacing, see [8] for more information). The images were interpolated into a 160×160×130 volume, and decomposed for tracking as described. Phase images were tracked with conventional 3D-HARP [4] and with HARP-FE, which was performed in the geometry shown in Fig. 2b. $\lambda(t)$ was set to <0.25 rad mean tracking error.

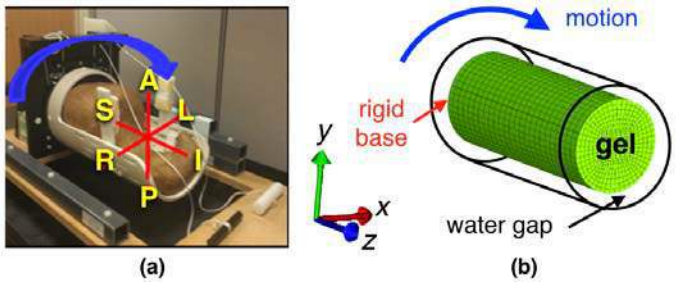

Figure 2: An MRI-compatible rotation apparatus (a) was used to image a gel phantom [8]. The bottom of the phantom was affixed to the container and other surfaces were surrounded by water (b). The gel volume was discretized into a FE domain for tracking. The letters indicate standard imaging directions, and the 3D arrows indicate the FE coordinate system.

RESULTS

Figure 3 shows stress approximations using different variations of HARP-FE. Although material and tracking parameters are constant, the unconstrained solution allows small differences in deformation (labeled with arrows), which have little effect on kinematics, but yield large changes in stress due to the exponential nature of the material. Incorporation of boundary conditions improves the solution, but the most notable differences occur with inclusion of pre-strain.

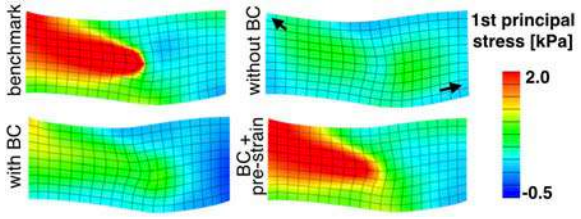

Figure 3: Adding boundary conditions (BC) reduces but does not eliminate visible discrepancies in stress distribution (arrows). Pre-strain with BCs allows excellent agreement with the benchmark.

Figure 4 shows a comparison between conventional 3D-HARP, and HARP-FE. Because the former does not include regularization, it is susceptible to error in areas with imaging artifacts, such as the boundaries, producing intractable deformations. The deformation via HARP-FE is subject to elastic regularization minimizing the artifacts.

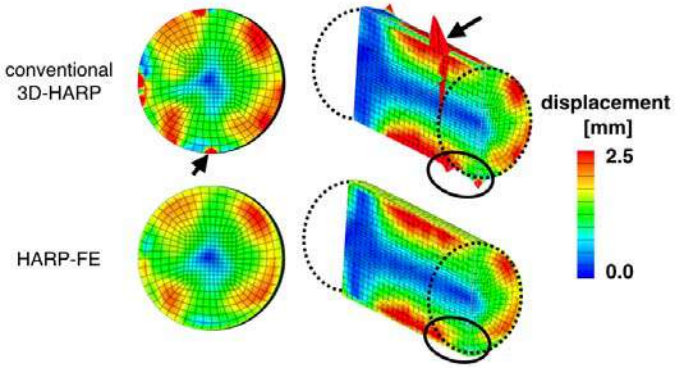

Figure 4: Radial (left), and axial (right) views of magnitude displacement maps show artifacts (arrows and circles) that eliminated via continuum mechanics regularization.

DISCUSSION

Although FE-based HARP tracking requires mesh generation, it offers unique advantages that enable calculation of stress as well as kinematics and exhibits improved tolerance to imaging artifacts. Because it can be performed simultaneously with physical loads, or as a stand-alone driver of deformation, this technique is well suited for different applications, including inverse parameter identification.

INTRODUCTION

Mitral Valve (MV) is the dual-flap atrioventricular heart valve, which regulates the blood flow between the left atrium and left ventricle. The structure of MV apparatus is comprised of two leaflets (anterior and posterior), chordae tendineae, and papillary muscles. Heart diseases associated with abnormalities in MV structure and/or function are among the most common cardiovascular disorders, affecting over 2 million people in the United States [1]. Treatment procedures include heart valve repair and prosthetic valve replacement, with the former considered more effective [2]. The quality of clinical care and treatment outcomes may be improved by using predictive computational models for surgical planning and medical device design.

Kunzelman et al. [3] performed the first Finite Element (FE) simulation of the MV's biomechanical behavior using post-mortem geometry and tissue properties. Since then, the fidelity of FE models have significantly improved to build models based on *in vivo* geometries [4], patient-specific information [5], and also internal structure [6]. However, the complex geometry and strong heterogeneity in structural properties of the MV require fast and robust methodologies for building FE models from imaging data.

Here, we propose a novel, robust pipeline to build high-fidelity, attribute-rich FE models of the complete mitral heart valve from imaging data. In the sections to follow, we describe the major steps of the proposed framework, including the generation of geometric models and registration of structural properties.

METHODS

Five ovine MV sample were obtained from an USDA approved abattoir (Superior Frams, CA, USA), instrumented with fiducial markers, and imaged using micro-computed tomography (μCT) to acquire geometry with high resolution, as described in [7]. We first simulated the end-systolic state of the valve in the Georgia Tech Cylindrical Left Heart Simulator (CLHS) [8] to collect geometric data from the fully closed state. In this state, the branching details of the MV chordae tendineae are much clearer. Next, we dripped a solution of 0.5% glutaraldehyde over the valves for two hours in a vertical fixation loop to simultaneously unfurl and spread the leaflet surfaces while stiffening the tissue at the end-diastolic state. We then imaged the valves and acquired the information to build geometric models of the MV leaflets.

The acquired images from open and closed states were segmented in ScanIP software suite, labeled and trimmed in ZBrush 3D sculpting software (ZBrush Inc., CA, USA), and analyzed using customized Python scripts. Open-state imaging data was used to reconstruct the high-resolution geometry of the leaflets using median surface representation. Closed-state data was used to reconstruct the chordae tendineae using the centerline representation. Fiducial markers were extracted from both imaging datasets for landmark registration.

Collagen fiber architecture (CFA) data was collected from flattened leaflets using the small-angle light scattering (SALS) technique [9]. The CFA images of flattened leaflets were mapped using landmark registration to the reconstructed leaflet median surface unfolded into 2D plane using cylindrical projection.

RESULTS

The major steps of processing open state images and building the leaflet median surface representation are illustrated in Figure 1. The volumetric data was segmented (once for leaflet tissue, next for fiducial markers), trimmed, labeled and analyzed to obtain the median surface geometry and project the markers onto the median surface.

The major steps in obtaining the chordae tendineae geometry are shown in Figure 2. The closed state scan was segmented, trimmed, and labeled in the same way as the open state data. The processed volumetric data was analyzed using the feature thinning method to obtain centerline representation with pointwise cross-sections. Having a geometric model

of the leaflets in the open state, and fiducial markers in both open and closed states, we performed landmark registration between the two to reconstruct the leaflet surfaces in the closed state. The major steps, including the final reconstruction of leaflets and chordae tendineae in the closed state, are presented in Figure 3.

The registration of CFA data onto the reconstructed leaflet geometry was performed using landmark registration algorithm. The original images, deformation grids, final mapped CFA data are illustrated in Figure 4.

DISCUSSION

The proposed pipeline was successfully used to build high-fidelity attribute-rich finite element (FE) models of ovine mitral valves from μCT imaging datasets. Our approach allows for a robust segmentation, reconstruction, geometric analysis, and mapping of tissue attributes of the full MV apparatus (leaflets & chordae tendineae). One of the important advantages of this framework is the parametric representation of the geometry and embedded attributes. This allows to adjust the level of detail of the geometric and attribute variations independently of the required level of discretization for FE simulation. This is an important feature for the practical use of the FE models for medical device design and surgical planning, because it allows to easily simplify the model for the preliminary simulations / case studies, and then switch back to the high-fidelity simulations in the final stage of design or planning. Another important feature of the proposed framework is that it can be easily modified to incorporate statistical analysis of patient-specific models, and build representative population-averaged FE models.

IMAGE-BASED ANALYSIS FOR INVERSE ESTIMATION OF MUSCLE FIBER FORCES IN THE TONGUE

INTRODUCTION

The tongue has an ability to deform its shape largely by contracting the muscle fibers which are broadly distributed in the tongue. This mechanical deformation of tongue creates a complex and subtle movement for speech. The muscle consists of three types of extrinsic muscle fibers and four types of intrinsic muscle fibers. It is known that the extrinsic muscle fibers contribute to move and deform the tongue largely since the muscle is connected to a fixed bone. On the other hand, it is considered that the intrinsic muscles inside the tongue undertake the role to control the subtle movement and deformation of tongue. In the past studies, in order to understand the mechanism of tongue deformation, the action potentials of extrinsic muscles during pronunciation were measured with electromyogram [1], and the orientation of extrinsic muscle fibers was investigated by using diffusion MRI [2]. However it is not clear how the tongue is deformed by contraction of the multiple muscle fibers distributed in it.

Image-based simulation has a potential to investigate the effect of muscle fiber contraction in a continuum tissue on the deformation of tongue. Recently, Buchaillard et al. conducted a computational analysis of the tongue deformation and the acoustic propagation in the oral cavity for the utterance of French vowels under *a priori* given parameter for the muscle contraction [3]. However, due to lack of the experimental data of muscle contraction, such a direct analysis has a limitation to represent the actual deformation of the tongue and consequently estimate the muscle contraction.

In this study, we propose an image-based analysis for inverse estimation of muscle fiber contraction in the tongue. In this proceeding, we show a basic concept of the formulation and the results for validation, and discuss a feasibility of the proposed approach.

METHODS

Muscle fiber orientation The shape of tongue at a rest position was obtained from the MRI image of a subject (Fig. 1). The muscle fibers were classified into three types of extrinsic tongue muscles: genioglossus (GG), hyoglossus (HG), and styloglossus (Sty), and four types of intrinsic tongue muscles: superior longitudinal (SL), inferior longitudinal (IL), transversal (Trans), and vertical (Vert). The orientation of each muscle fiber was determined based on the anatomical data [4]. The volume model was divided into 59,502 tetrahedral elements including the muscle fibers which produce the contraction stress in the direction of orientation.

Governing equation The deformation of tongue can be expressed by the law of conservation of mass and the motion equation,

$$\rho_0 = \rho J, \quad \rho d_t \boldsymbol{v} + \eta \boldsymbol{v} = \nabla \cdot \boldsymbol{\sigma} \tag{1}$$

where ρ_0 and ρ are an initial density and a current density, respectively, J is a volume change, $\boldsymbol{v}$ is a velocity vector, η is a viscous dumping coefficient, $\boldsymbol{\sigma}$ is a stress tensor. The stress involves the elastic stress for an isotropic part of the tissue ($\boldsymbol{\sigma}_{\mathrm{elas}}$) and anisotropic part of the muscle fiber ($\boldsymbol{\sigma}_{\mathrm{fiber}}$),

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}_{\mathrm{elas}} + \boldsymbol{\sigma}_{\mathrm{fiber}}. \tag{2}$$

In this study, the tissue of muscle was assumed to be a hyperelastic body which can be expressed as a 2nd-order Mooney-Rivlin model. The strain energy density function is described as

$$W = \sum_{p,q=0}^{2} C_{pq}(\bar{I}_1 - 3)^p(\bar{I}_2 - 3)^q + \frac{K}{2}(J-1)^2 \tag{3}$$

where C_{pq} is the material constant, I_1 and I_2 are the first and the second invariant of the right Cauchy-Green deformation tensor, respectively, K is a bulk modulus. The second term is a penalty term for the constraint of a constant volume. The elastic stress tensor $\boldsymbol{\sigma}_{\mathrm{elas}}$ was calculated by the partial differentiation of W with respect to Green

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

strain tensor. The values of material constant obtained by experiments were C_{10} =1037 Pa, C_{20} =486 Pa and $C_{01} = C_{11} = C_{02}$ =0 Pa [5].

The stress tensor of muscle fiber $\boldsymbol{\sigma}_{\text{fiber}}$ produced by contraction of muscle fibers can be represented by

$$\boldsymbol{\sigma}_{\text{fiber}} = f_a(\boldsymbol{e}_a^* \otimes \boldsymbol{e}_a^*) \quad (4)$$

where f_a is a magnitude of the contraction stress produced by the muscle fiber, $\boldsymbol{e}_a^*$ is a unit vector of fiber orientation in a current arrangement.

Inverse analysis The contraction stress of muscle fibers was estimated from the deformation of tongue by solving the minimizing problem with respect to the magnitude of contraction stress f_a,

$$\min\ E(f_a) = \frac{1}{2}\sum_l \left(\boldsymbol{x}_l^{\text{ref}} - \boldsymbol{x}_l(\boldsymbol{v}_l)\right)^2 + \frac{w}{2}\sum_i (\Delta t \delta \boldsymbol{v}_i)^2 \quad (5)$$

subject to Eq. (1) and $f_a \geq 0$

where $\boldsymbol{x}^{\text{ref}}$ and $\boldsymbol{x}$ are the corresponding nodal position on the surface of a reference model and a current model, respectively, $\delta \boldsymbol{v}$ is a time variation of velocity, Δt is a time step for iteration, w is a weighting factor, l and i are the node number on the surface and the whole region, respectively. A primal-dual interior point method [6] was used to solve the minimizing problem with respect to the contraction stress f_a. The second term in the right side in Eq. (5) was introduced to stabilize the convergence of f_a in the explicitly interactive calculation.

RESULTS AND DISCUSSION

To validate the inverse analysis of the muscle fiber contraction stress, three reference shapes of the deformed tongue were prepared by solving the governing equation (1) with a finite element method as a direct problem under a given contraction stress. In the direct analysis, the contraction stress f_a was set to 3 kPa at each extrinsic muscle fibers, GG, HG, or Sty and 0 Pa at the other muscles. Here we call them the GG, HG, and Sty model, respectively. Furthermore, the surface displacement was fixed to zero at the site where the tongue attached to the bone. The initial density, viscous coefficient, bulk modulus used for the calculation were $\rho_0 = 1.04 \times 10^3$ kg/m^3, $\eta = 1.0 \times 10^4$ kg/m^3·s, K =1.0×10^4 Pa, respectively.

Figure 2 shows the change in error of surface geometry, E in Eq. (5), during the iteration for inverse analysis using three reference shapes of GG, HG, and Sty models. The error was normalized by the initial value, E_0. It was found that the error in surface geometry of tongue between the reference and simulated models were decreased monotonically after taking the maximum and successfully converged to a negligible small value.

Figure 3 shows the change of contraction stress f_a at three extrinsic muscle fibers of GG, HG, and Sty, and four intrinsic muscle fibers of SL, IL, Trans, and Vert during the error converging of surface geometry. The final values of contraction stress converged at seven muscles are listed in Table 1. In the case of HG and Sty model (Fig. 3(b) and (c)), the contraction stress once generated at all muscles but finally dissipated except at the HG or Sty muscle where the contraction stress was given. The contraction stress f_a estimated by the inverse analysis was close to the preset value of 3 kPa (Table 1).

On the other hand, in the case of GG model (Fig. 3(a)), the contraction stress remained at the Sty and HG muscles in the error convergence although the contraction stress at the GG muscle closed to the preset value. This indicates the difficulty to identify the contraction stress only from the surface geometry of the tongue. In order to improve the accuracy in the estimation of contraction stress by the inverse analysis, it would be necessary to consider the physiological nature of tongue muscle obtained by experiments.

INTRODUCTION

Stem cells derived from patients can be differentiated into a variety of cell types, offering great potential for regenerative and personalized medicine. In particular, mesenchymal stem cells (MSCs) have been explored as an attractive alternative cell source to the limited chondrocytes for tissue engineering of articular cartilage. Unfortunately, like native terminally differentiated cells, MSCs exhibit cell-to-cell variability that translates to poor homogenous matrix development (Figure 1A) and represents a significant challenge to their optimization for cell-based therapies. While some heterogeneity may be due to contaminant cell populations, even in cases where cells are pre-selected, enriched subpopulations, variation still remains. We hypothesize that this variability may be due to cells being in different phases of the cell cycle (Figure 1B) and that these differences may hinder the efficacy with which cells can respond to exogenous factors such as growth factors to produce functional tissue. As such, to increase their predisposition to respond to cues, we have focused on the use of cell synchronization to selectively obtain cells in desired phases.

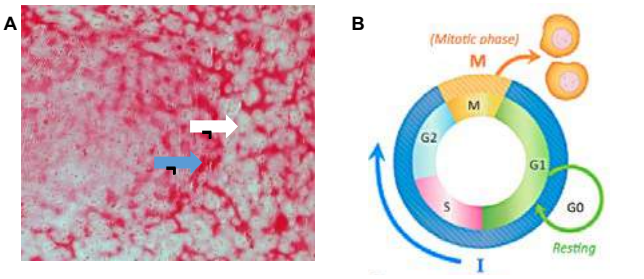

Figure 1. A) Picrosirius red staining for collagen in chondrocyte-seeded agarose constructs showing heterogeneity of cell elaborated matrix. White arrow: cells with little collagen; blue arrow: cells with rich collagen halo. B) schematic of cell cycle, which can be modulated to optimize cell differentiation and matrix production. G0: quiescent, G1: growth and synthesis, S: synthesis.

Classical cell biology studies investigating the effect of cell synchronization have typically utilized techniques untenable for tissue engineering, including S-phase inhibitors and physical detachment of less adherent mitotic cells, both of which result in limited cell yield [1,2]. We, and others, have recently explored the use of methylcellulose suspension to synchronize cells in the G1 phase [3,4], the growth phase believed to be responsible for differentiation [5]. Toward this end, we have previously shown that chondrocytes can be induced to produce greater and more uniform cartilage-like tissue when the cells have been synchronized during 2D expansion prior to 3D micropellet formation [3]. Here, we look to expand this technique to undifferentiated cells; we envision that modulation and manipulation of the cell cycle in this manner may provide a platform technology for optimization of cell differentiation and priming for a number of tissue regeneration goals. We hypothesize that synchronization of undifferentiated MSCs to G1 phase will prime them to be more chondrogenic in 3D culture.

METHODS

Tissue harvest and cell isolation MSCs were isolated from fresh unprocessed bone marrow (Lonza) of a 22 year-old male donor. Following separation via Percoll gradient, mononucleated cells were plated (5 x 10^3 cells/cm^2); adheredMSCs were expanded in high glucose DMEM supplemented with FBS until passage 4. Flow cytometry At desired timepoints, cells were harvested from monolayer culture by trypsinization and fixed in a 1:1 mixture of ethanol and PBS. Cells were stained with propidium iodide and analyzed on a flow activated cell

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

sorting (FACS) machine to determine cell cycle phase time and characterize the population of cells in each phase for each synchronization technique described below.

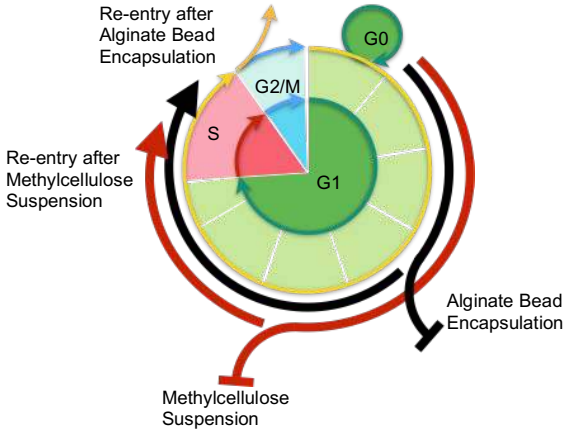

Figure 2. Representative cell cycle for human mesenchymal stem cells (total cell cycle time = 56.3 hr) with schematic of experimental synchronized groups (cells synchronized to G1 or triggered to re-enter the cell cycle toward S).

Cell Synchronization Various cell synchronization methods were employed to explore the individual phases (Figure 2); in particular, two distinct and established techniques were used to synchronize cells to the **G1 phase** and investigate whether triggered re-entry into the cell cycle **(toward S phase)** is necessary. *Asynchronous control*: as a control, one subset of cells was trypsinized at 90% confluence, maintaining an **asynchronous population** of cells. *G1 phase synchronization:* Cells were synchronized to the G1 phase via two adhesion removal techniques. (1) Alginate bead encapsulation*:* At 90% confluence, one subset of cells was trypsinized and encapsulated in 1% wt/vol alginate beads (seeding density: 4 x 10^6 cells/mL). After 48 hours, cells were extracted from the alginate beads with a depolymerization solution (55 mM sodium citrate, 0.15M sodium chloride). (2) Methylcellulose suspension: At 90% confluence, one subset of cells was trypsinized and resuspended in 1% wt/vol methylcellulose solution (seeding density: 1 x 10^6 cells/mL) for 48 hours. Cells were then extracted from solution through centrifugation. *Re-entry into cell cycle:* Following alginate bead encapsulation or methylcellulose suspension, cells from each group were reintroduced to FBS and plated at low seeding density to induce re-entry into the cell cycle toward S phase. Micropellet Formation For each group, following trypsinization, cells were counted and 0.5mL of 0.5 x 10^6 cell suspension was aliquotted into 1.5 mL sterile screw-top tubes. The tubes were spun in a microcentrifuge at 37°C and 2500 rpm for 20 minutes to form a visible cell pellet at the base of the tube. Micropellets were cultured in chondrogenic medium (dexamethasone, ascorbic acid TGFβ-3) and harvested on days 4 and 28. Biochem Analysis Each micropellet was dried and digested in proteinase K solution overnight at 56°C, with one aliquot used to quantify GAG content via the 1,9 dimethylmethylene blue dye-binding assay and a second aliquot used to determine collagen content via orthohydroxyproline assay, scaled for microplates. Total double stranded DNA content was assessed by the Picogreen assay. Statistics Statistical analyses were performed using one-way analysis of variance (ANOVA) with Tukey's Honest Significant Difference post hoc tests (Statistica), with α=0.05 and statistical significance set at $p \leq 0.05$ to compare groups across synchronization method. Data is reported as the mean and standard deviation of 4-5 samples per time point and group.

RESULTS

Experimental determination of the cell doubling time in combination with flow cytometry was used to calculate the time for each cell cycle phase (G1 = 41.40 hrs, S = 10.19 hrs, G2/M = 4.70 hours). Synchronization of cells to the G1 phase was generally successful across both anchorage-independent techniques, with cell phase population distributions found to be significantly different from asynchronous cell populations (Table 1, chi-squared test: $p<0.0001$). In response to differentiation cues (TGF-β3) in 3D, cells exhibited an elevated biosynthetic capacity (GAG/DNA, Figure 3, $p<0.05$). When methyl- cellulose suspended cells were induced to re-enter the cell cycle toward the S phase, cells were even more prolific in GAG production (Figure 3, $p=0.03$). In contrast, when alginate bead encapsulated cells were retriggered to enter the cell cycle to the S phase, cells exhibited reduced biosynthetic capacity, similar to asynchronous cells (Figure 2, $p=0.01$).

Table 1. Percent of human mesenchymal stem cells in each cell cycle phase as determined by flow cytometry.

	G1	G2	S
Asynchronous	73.54	8.35	18.10
Methylcellulose	94.52	1.63	3.84
Alginate Bead Encapsulation	82.48	17.52	0.00
Re-entry after Methylcellulose	79.30	11.21	9.49
Re-entry after Alginate Beads	77.47	8.86	13.67

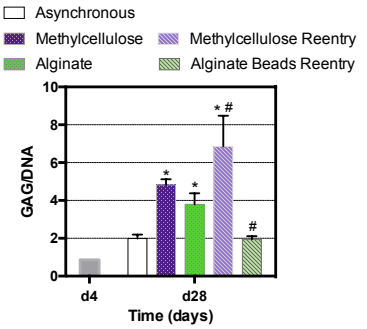

Figure 3. Normalized GAG/DNA biosynthetic output over 28 days in culture. *p<0.05 vs. asynchronous. #p<0.05 vs. respective G1 synchronized state.

DISCUSSION

Contrary to literature reports [5,7], but in line with our previous findings [3], the maximal benefit is observed when methylcellulose-suspended cells are induced to re-enter the cell cycle toward the S phase rather than staying arrested in the G1 phase, rejecting our initial hypothesis. Interestingly, alginate encapsulated cells induced to re-enter the cell cycle fail to exhibit similar behavior, suggesting that the particular technique of synchronization is of importance. Further work is ongoing to identify the differential effects produced by each synchronization technique to understand the factors that may be manipulated for engineered tissue optimization. Nevertheless, we have shown here that the use of methylcellulose synchronization produces a pure population of MSCs and maximizes the downstream effectiveness of cells to respond to differentiation cues and increase their biosynthetic output, a direct clinical translation of our previous finding.

A major limitation in using stem cells as a clinical source is their inefficient conversion to desired cell fates. Future work will build on this platform technology by examining the role of synchronization in modulating osteogenic and adipogenic differentiation from MSCs to identify which cell cycle phases may be most responsive to exogenous cues.

EFFECTS OF SEATED SOLDIER POSTURE ON PELVIC FORCE TRANSMISSIBILITY

INTRODUCTION

Pelvic response and injury due to underbody blast (UBB) has become a topic of interest in injury biomechanics since recent conflicts Operation Iraqi Freedom and Operation Enduring Freedom. One study reported that out of 608 casualties, 36% sustained pelvic injuries as a result of underbody blast [1].

Evans (1955) tested 22 denuded component pelves statically and dynamically with the goal of studying fracture [2]. The authors did not report pelvic angles or any data other than fracture patterns. Kemper 2008 tested six component pelves denuded of all soft tissue except the sacroiliac ligaments [3]. Pelves were tested with a sacrum angle of 25 degrees relative to the transverse plane and an input velocity of 2m/s. Pelvic angles were not reported.

Pelvis response due to high-rate axial impacts, such as in UBB, is not yet well known. Given the variability in deployed military vehicles seats and the resulting ranges of pelvic angle, a definitive relationship between seated posture and pelvic response is not feasible [4]. However, as a preliminary investigation, a set of nominally sub-injurious cadaveric experiments were developed to determine the posture effects on pelvic response.

METHODS

With institutional review board approval, ten (10) fresh-frozen post-mortem human subjects (PMHS) were acquired for this study. All specimens were screened for infectious disease and pre-existing pathology that may alter the specimen properties. Each specimen was sectioned between the L3 and L4 vertebral bodies and was disarticulated from its femurs. Abdominal contents were removed and replaced with ballast masses of ballistics gel in order to preserve inertial loading within the interior of the pelvic girdle. Pelvic angle was measured from a plane comprised of the bilateral anterior superior iliac spines (ASIS) and the pubic symphysis, relative to the coronal plane. Specimens 1-6 and 7-10 were potted with a target pelvic angle of 40° and 28°, respectively. Specimens were positioned in a custom made potting fixture, including a potting cup in which the lumbar spine is placed. Fixation was further bolstered with two six inch screws secured axially and four to six screws secured transversely through the vertebral bodies. Once the proper pelvic angle was achieved, FastCast® (Model FC-891, Goldenwest Manufacturing) urethane resin was used to envelop the specimen from the lumbar spine to the junction at S1-S2.

The pelvis potting block was rigidly affixed to the carriage of the test rig. (Figure 1) The carriage, which included a six degree-of-freedom load cell (Denton® Model 3868), was constrained to translate in the SAE-Z direction only. The inferior aspects of the pelves were allowed to rest against the seat platen, which was also constrained only to SAE-Z translate. All pelves were preloaded to the equivalent of the weight of a 50th percentile male torso. A suite of six axial accelerometers (Endevco® Model 7270A) were mounted on the carriage at the boundaries above and below the pelves in order to provide rig response and allow for load cell mass compensation. A pneumatically-driven transfer mass was used to provide input at the seat platen, such that a peak ΔV of 2m/s with a 10ms rise time was achieved. All data were baseline shifted and filtered with a four-pole phase-less low pass filter with a 3000Hz cutoff frequency.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Axial construct stiffness (SAE-Z) was assessed at each posture using force-displacement plots (Figure 2). Force was derived from the mass-compensated load cell attached to the potting and displacement was derived from the differential displacement of the input and reaction rig motions. Linear regressions of the force-displacement traces resulted in a mean axial stiffnesses of 323.42 N/mm (±47.14 N/mm) and 468.68 N/mm (±183.36 N/mm) for the 40° and 28° postures, respectively.

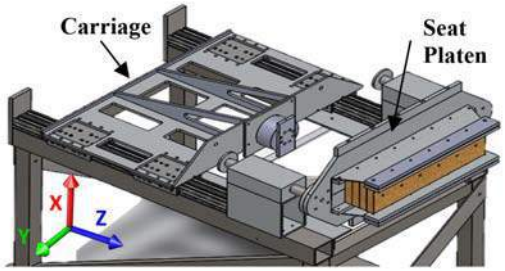

Figure 1. Pelvis testing rig.

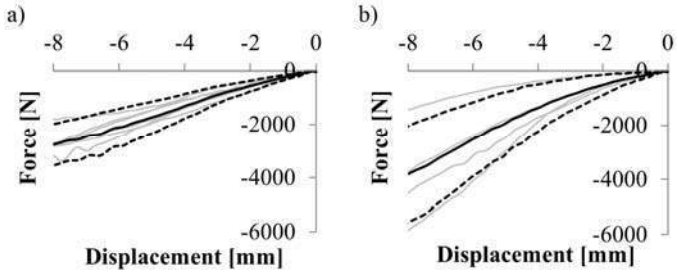

Figure 2. Reaction force-displacement curves for a) 40 degree and b) 28 degree pelvic angle. Gray lines represent individual tests, solid black lines are the average of the gray lines, and the dashed black lines are the mean ± the standard deviation.

Reaction moments (about the SAE-Y) were assessed using moment time history plots (Figure 3). Pelvic reaction moment was transposed from the potting load cell to the center of the L5-S1 joint in accordance with prior work [5]. Moment data was mass normalized by a factor proportional to the quotient of a reference mass and individual specimen mass [6]. Mean peak reaction moments of 118.18 Nm (±52.84 Nm) and 136.19 Nm (±42.29 Nm) were observed for the 40° and 28° postures, respectively.

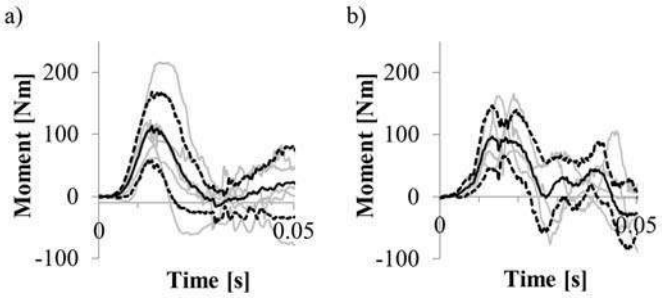

Figure 3. Reaction moment curves for a) 40 degree and b) 28 degree pelvic angle. Gray lines represent individual tests, solid black lines are the average of the gray lines, and the dashed black lines are the mean ± the standard deviation.

DISCUSSION

The pelvis is a highly complex shape with numerous articulations that provide for substantial compliance under load. Of these articulations, the most pertinent to axial response is the sacroiliac joint. The broad flat nature of this articulation allows for axial slipping as well as sagittal rotation resulting in the anterior pelvis being swept forward and superior during an impact. Given this arrangement, it was expected that the more vertical 28° construct would be stiffer in axial stiffness but produce a lower peak reaction moment, and indeed, this more upright posture produced a 45% larger axial pelvic stiffness but a 15% larger peak moment. However, the means of these groups were not statistically different (Axial: p=0.094; Moment: p=0.586).

One justification for the increase in reaction moment with the more vertical construct is the normalization factors (Figure 4). Normalized moment is directly proportional to the normalization factor, thus, specimens 8 and 10 moments were amplified by more than 75%. Non-normalized moments produced a mean of 108.01 Nm (±36.44 Nm) and 94.19 Nm (±26.03 Nm) for the 40° and 28°, respectively, resulting in a 13% decrease in the more vertical construct (p=0.534).

Given these apparent differences in construct response in the more upright versus more slouched posture, it is likely that different postures will correlate to different levels of risk for pelvic injury during UBB. Future efforts will investigate additional postures as well as acceleration and strain response within the pelvis in order to better describe its response to axial loading. Ultimately, it is hoped that through robust characterization of this response, better predictions and consequently better mitigation technologies maybe employed to decrease the incidence of pelvis injury from UBB.

MATHEMATICAL MODELLING OF OXYGEN TRANSPORT IN THE RETINA

Wouter J. Thijssen, Emilie Lunddahl, Andris Piebalgs, Xiao Y. Xu

Department of Chemical Engineering

London, United Kingdom

INTRODUCTION

The retina is known for being one of the most metabolically active tissues in the human body which makes it especially vulnerable to conditions of insufficient oxygen supply. Ischemia in the retina, as can be caused by diabetic and glycemic retinopathy, is perceived to be one of the most common causes for visual impairment in the developed world [1]. Therefore, an in-depth understanding of retinal oxygenation is necessary. However, multiple factors complicate the prediction of retinal oxygenation, amongst other features the localized placement of the mitochondria and the retinal microcirculation [2].

Many attempts have been made to improve the understanding of retinal oxygenation. This has been done experimentally by measuring oxygen tension as a function of retinal thickness via intrusive animal studies, as well as by developing empirical and mathematical models. Of particular interest is the 4-layer model developed by Roos [3] as shown in Fig. 1, where the outer retina is divided into 3 separate regions. Oxygen moves through these regions under diffusion-limited transport and is consumed only in region 2 which contains photoreceptors' mitochondria. The inner retina is assumed to have uniform oxygen diffusion, consumption and supply.

Roos' model is limited to 1D analysis and contains parameters that have only been readily measured in animals. This work critically evaluates the model to assess the importance of these parameters towards oxygen distribution in the retina by performing a global sensitivity analysis. Ranking these potentially unsuitable parameters in order of sensitivity can help guide which are in most need of more accurate empirical measurement in humans, as well as guide treatment forms which leverage this sensitivity.

Furthermore, the model has been extended into 2D to analyze the effect that the tissue geometry may have on oxygen distribution. By enhancing mathematical modeling of oxygen distribution in the retina, we hope to better understand the factors that affect the disease progression of retinopathy.

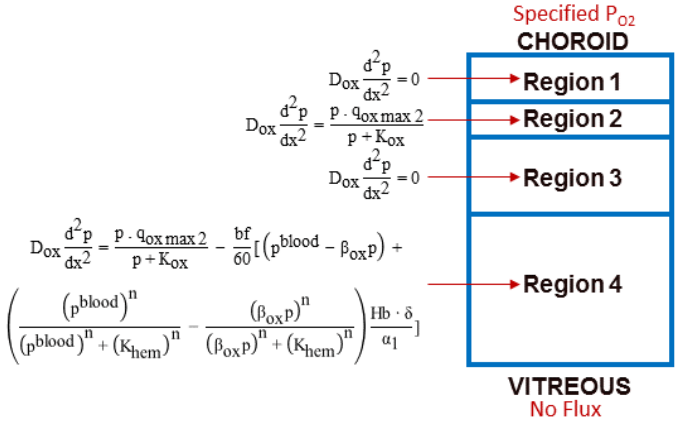

Figure 1: Illustration of Roos' model with the retina divided into 4 regions, with their respective equations

METHODS

A global sensitivity analysis using the Morris one-step-at-a-time method [4] was used to critically evaluate Roos' model and rank its parameters in order of sensitivity. The model's parameters for which this analysis was conducted on can be seen in Table 1.

Roos' model employs a uniform retinal thickness of 251μm, and therefore does not consider its variation along the arc of the retina. The effect of varying this parameter between 150μm and 300μm, both 'in

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

range' values for retinal thickness across the retinal arc [5], was analyzed by comparing their respective 1D oxygen profiles.

To extend into 2D, the model was set up in ANSYS Fluent using a mesh representing a quarter of the retina which spans from the back of the eye to the top of the eye. To explore the spatial heterogeneity a 2D model allows for, non-uniformity was incorporated into the inner-retinal supply term in two different ways. Firstly, a localized region was set to be completely ischemic, simulating a section of the vascular tree network becoming completely ischemic, a potential result of retinopathy. Secondly, non-uniformity of inner-retinal supply was set up across the arc in a linearly decreasing fashion to study non-uniformity's implications. This approach serves to evaluate the need of measuring and incorporating the non-uniformity of inner-retinal supply to build a more representative model for retinal oxygenation.

RESULTS

Parameters were ranked in decreasing order of importance following the global sensitivity analysis (Table 1).

Table 1: Parameter sensitivity ranking (decreasing order)

Hb	Hemoglobin concentration in blood
K_{hem}	P_{O2} at which haemoglobin is 50% saturated with oxygen
α_1	Solubility of oxygen in blood
α_2	Solubility of oxygen in the retina
D_{ox}	Diffusion coefficient of oxygen
n	Hill coefficient
K_{ox}	Michaelis-Menten constant of oxygen
δ	Oxygen carrying capacity of haemoglobin

A separate investigation into the retinal thickness' sensitivity is displayed in Fig. 2.

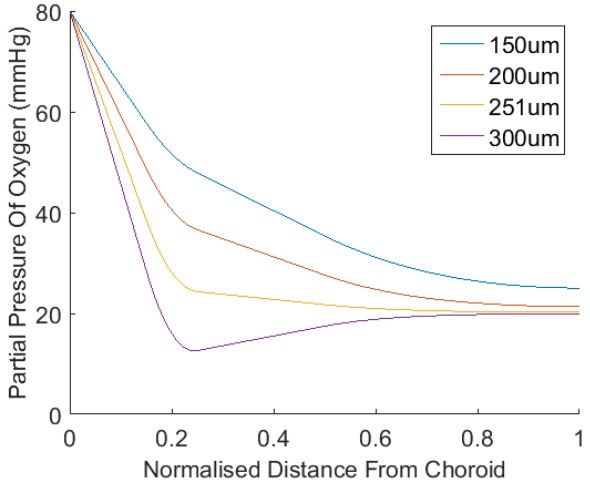

Figure 2: Oxygen profiles of retinal thicknesses at 150, 200, 251 and 300µm, normalized to allow for comparison.

The implications on 2D retinal oxygenation from applying a linear inner-retinal supply profile are summarized in Fig. 3. This profile applied along the arc has its maximum at the back of the retina (at theta = 90°, where the retina was set to be thicker) and linearly decreases to zero at the top of the retina (where the retina was set to be thinner).

DISCUSSION

Developing techniques to attain accurate measurements of the more sensitive parameters (Table 1) at the human retina is of high importance to further develop Roos' model. The implication of the most sensitive parameter, the hemoglobin concentration in blood, on the oxygen profile can also be significant towards clinical interests. At its upper bound typically seen in adult males of 170g/L, retinal oxygenation is sufficient, whereas at a value of 100g/L typically seen in anemic patients there is a much stronger risk of oxygen deficiency in the inner retina.

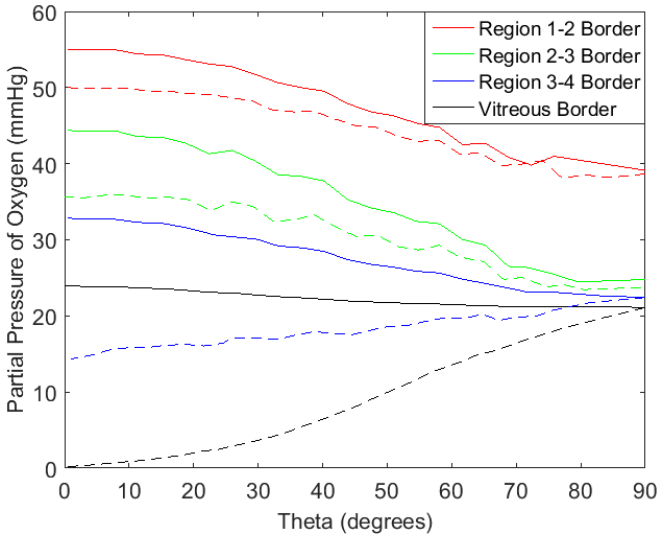

Figure 3: Oxygen profiles along retinal arc. Solid lines: uniform supply case; dashed lines: linear inner-retinal supply case.

The need to develop a 2D model is highlighted in Fig. 2, which shows significant discrepancies in the oxygen profiles as the thickness is varied. As the thicknesses plotted are within the range seen across the arc of the retina in 2D, there is a strong incentive to model this non-uniformity as part of a 2D model.

From this extended 2D model with linear inner-retinal supply applied, an interesting relationship between retinal thickness and inner-retinal supply can be seen (Fig. 3). Closer towards the border between regions 1 and 2, retinal thickness heterogeneity controls the oxygen profile, where the thinner end of the retina has a higher value for the partial pressure of oxygen. However, further towards the vitreous border, the effect of non-uniform inner-retinal supply becomes increasingly apparent. At the vitreous border, this effect is such that the oxygen profile effectively mirrors that of the applied linear supply term. As this is a region particularly vulnerable to oxygen deficiency, further developing an understanding of how the retinal vasculature, and thereby the inner-retinal supply profile, varies along the arc of the retina is of great importance to further development of the model.

For future studies, a 2D/3D model complemented with more accurate empirical measurements of the various parameters as identified in this work's sensitivity analysis can model clinical conditions more accurately and allow for clinically relevant conclusions to be drawn. With this, our work helps set the pace for improved modelling of retinal oxygenation to address the increasing problem of retinopathy.

INTRODUCTION

Aneurysms are pathological dilations of arteries; cerebral aneurysms are among the most dangerous ones and are commonly located in or near the circle of Willis [1][2]. The factors responsible for initiation, growth and eventual rupture of aneurysms have been identified as hemodynamics, wall biomechanics, mechano-biology and the peri-aneurysmal environment [1][2]. The rupture of this abnormality causes intra-cranial hemorrhagic strokes [1][2].

To compare the risks associated with surgery and the rupture of an untreated aneurysm, it is imperative to study the progression of its growth. In this paper we investigate the changes in hemodynamic quantities of three developing stages of aneurysm models through CFD simulations.

METHODS

Simulations were performed in an open source spectral element based CFD solver [3] Nek5000. Higher order spectral element methods with hexahedral mesh provide a better accuracy than the conventionally used finite volume codes that employ tetrahedral mesh [4]. The three developing stages of aneurysm models investigated in this paper are the advanced, mid and early stages. The advanced stage model was segmented and reconstructed from a patient-specific CT angiography dataset at the School of Biological and Health Systems Engineering (SBHSE) at ASU. This model was virtually modified to produce the early and mid stage models. Outlets and inlets for all the three models were extended to 10-15 times the diameter to allow for a better flow development and less interference with boundary conditions. The computational model of the advanced stage aneurysm with extended inlet and outlet is shown in Fig. 1. Hexahedral meshes were generated in the HyperMesh Software using mesh morphing tools. The numbers of elements in the early, mid and advanced stage models are 12760, 13946 and 15156 respectively, with 8 GLL points per element per direction in all the three directions. The numbers of nodes present in the three developing stages are 6533120, 7140352 and 7759872 respectively. Steady Poiseuille inflow conditions were applied at the inlet of all the three models. Simulations were executed for 0.7 seconds (600,000 time steps) with Reynolds number (based on mean inlet velocity and inlet diameter) equal to 653.21.

PIV experiments were performed at the SBHSE using a mixture of aqueous sodium iodide, glycerin and water. This blood analog was seeded with 8μm fluorescent microspheres.

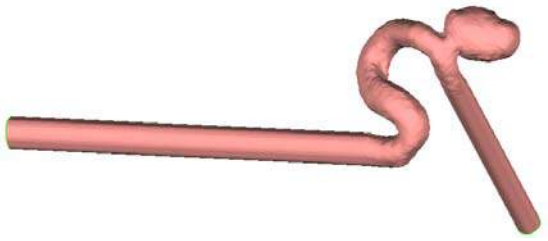

Figure 1: Advanced stage aneurysm model with extended inlet and outlet

RESULTS

Results from the PIV experiment and CFD simulation on the advanced stage aneurysm are compared in Table. 1. The center plane velocity profiles of the CFD and PIV models are shown in Fig. 2. The

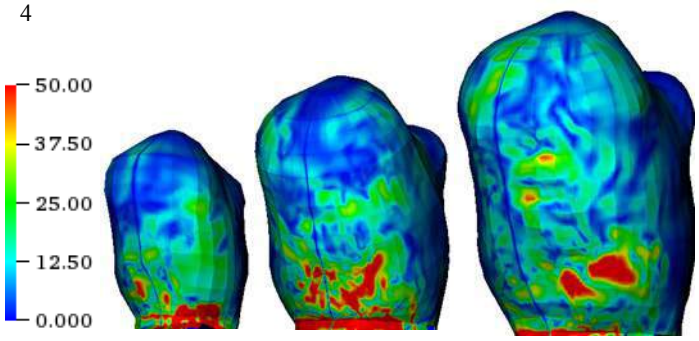
Distribution of wall shear stress in the three stages is presented in Fig. 4



(a) Early (b) Mid (c) Advanced

Figure 4: Wall shear stress (Pa) in the developing stages

The weighted average values of hemodynamic quantities have been compared between the stages in Table. 2.

Table 2: Comparison of aneurysmal hemodynamic quantities in the three stages

Aneurysmal Quantities	Early Stage	Mid Stage	Advanced Stage
Vrms (cm/s)	14.192	20.524	18.577
WSS (Pa)	7.037	10.79	8.487
Pressure (Pa)	267.05	276.13	185.23

DISCUSSION

Local distribution of wall shear stress (wss) is governed by the swirling flow along the arterial walls. Circulation of fluid inside the curving geometry of the three models is noticeable in Fig. 3, although it is more distinct in the advanced and mid stages. Volume-averaged hemodynamic quantities in Table. 2 are seen to first increase between early-mid stages and then decrease between mid-advance stages. The initial increase could signify very early stages of aneurysm formation and flow development [1]. Reduction in values in the advanced stage is a consequence of wall enlargement, which is an adaptive response of the tissues to high blood flow [1]. Studies have shown that high wss regions initiate aneurysm formation as a response to the impact of inflow jets, and low wss regions are responsible for further remodeling and progression due to blood stagnation [1] and endothelial dysfunction [5]. Therefore it is important to identify both these regions, as seen in Fig. 4.

Results presented in this paper give us an insight into the flow dynamics in anatomically realistic aneurysm models. The two hurdles faced by such studies are, the necessity to perform these simulations at a time rate suitable for clinical decision making [6] and the requirement of physically-based parameters for predicting precise flow dynamics[6][7]. Also, further analysis of interaction among the aforementioned factors responsible for the growth and rupture is essential to gain a more comprehensive understanding of the disease.

DESIGN OF A CARDIOVASCULAR FLOW MIMICKING PUMP

Chris F. Brake (1), Clifton R. Johnston (1)

(1) Mechanical Engineering
Dalhousie University
Halifax, Nova Scotia, Canada

INTRODUCTION

In vitro testing is an important part of the development of new cardiovascular prosthesis designs. One important aspect of simulating the cardiovascular system is properly modeling the pulsatile flow created by the heart. To test prosthesis' effect on the blood flow and the vessels themselves, it must be possible to reproduce the complex, time varying flow generated by the heart. Therefore, there is a need for a pump that is capable of delivering complex, time varying flows that can be easily adapted to mimick waveforms in a range of vessels.

A novel pump has been developed that can output a wide variety of complex pulsatile waveforms at physiologically relevant flows. The design uses a linear actuator to drive a piston pump, as illustrated in Figure 1. With closed loop velocity reference tracking of a piston head, the flow can be accurately controlled. A prototype pump was constructed as a proof of concept for the design. The prototype showed that basic linear control theory is insufficient to achieve accurate velocity control. The friction characteristics of the pump are the main source of nonlinearity in the system. The next step was to apply a LuGre model based friction compensator. Since the pulsatile flow in cardiovascular systems frequently oscillates around the zero velocity point, adequate friction compensation is critical to achieve accurate flow control.

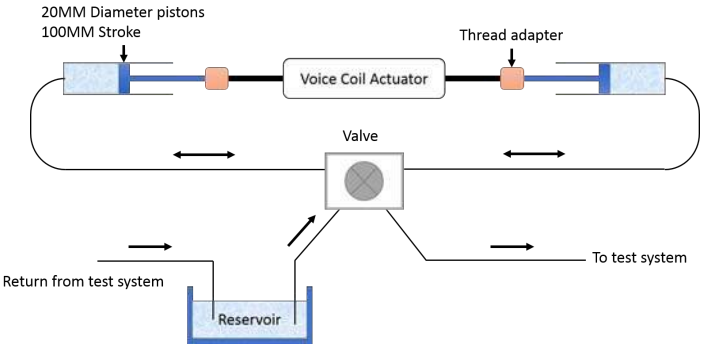

Figure 1: Block diagram of pump setup

METHODS

This project started with the desire to build a pump to mimic cardiovascular flow with the specific design challenge of using a voice coil type actuator to drive a piston.

The valve serves to rectify the flow from the two pistons. Without the valve the fluid will oscillate back and forward with no net positive displacement. By having the valve switch between the two pistons after every pulse, flow is always going in the same direction in the test section.

To validate the control, parameter identification, and design of the pump, the measured flow should closely match the desired profile. Particle image velocimetry (PIV) was used to measure the complex waveform created by the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

pump.

RESULTS

Figure 2 shows the 10 cycle average for the PIV flow measurement. The dashed lines in Figure 2 show the bounds of the standard deviation.

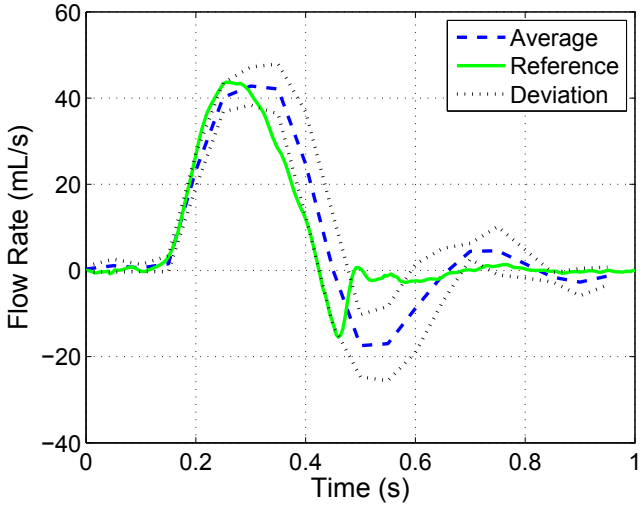

Figure 2: PIV measurement 10 cycle average

While the rising edge of the pulse matches quite well, after the peak and during the change in flow direction pump lags behind the reference waveform. Tsai [1] also had results where their pump tracked the reference well during constant acceleration. While the general shape of the produced waveform is pulsatile, and could be used to approximate some cardiovascular flow, its ability to accurately match the reference waveform is poor. Figure 3 shows the PIV measurement along with with the encoder feedback from the pump.

The other feedback worth analysing is the flow based on encoder measurements from the pump. The flow calculated based on the encoder measurements is shown in Figure 3 alongside the PIV measurements. When the encoder is near zero flow, the PIV measurement still records some small flow oscillations. These oscillations are likely caused by the compliance of the tubing that was used. Additionally, the inertia of the moving fluid also contributes to the oscillations when the pump should be at zero flow. It is not really possible for the controller to eliminate the oscillations since that would require in the loop flow feedback.

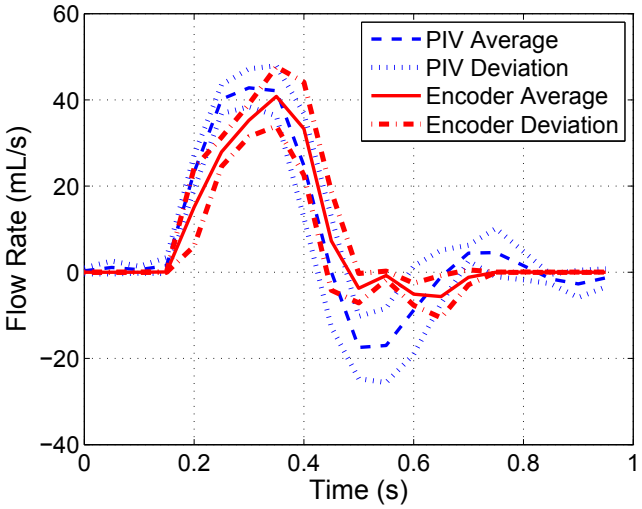

Figure 3: PIV and encoder measurement comparison

So the two measurements clearly do not agree well. This is not a good result as it means that the encoder cannot be relied on to accurately calculate the flow. This also means that using the encoder for feedback wont be accurate when trying to reproduce these kinds of pulsatile waveforms. This also means that using the encoder feedback to try and tune the pump to accurately match the reference probably wont produce a good match when measured with the PIV system.

DISCUSSION

Comparing the different measurements to the reference is useful, but so is comparing the two measurements to each other. Figure 3 shows the two flow measurements averaged over 10 cycles along with the standard deviation for each measurement method. Looking at the encoder measurement it can be seen that the PIV measurement is slow to respond to the pistons displacement. This is slow response can be attributed to fluid inertia.

DIRECT OSMOTIC PRESSURE MEASUREMENTS IN ARTICULAR CARTILAGE DEMONSTRATE NON-IDEAL AND CONCENTRATION-DEPENDENT PHENOMENA

INTRODUCTION

Despite the critical role of osmotic pressure in biological tissue mechanics, the precise magnitude and concentration dependence of the osmotic pressure within osmotically active tissues remains elusive. In articular cartilage, the negatively charged glycosaminoglycan (GAG) chains enmeshed within the collagen network give rise to the well-known fixed charge density (FCD) of cartilage. The abundance of fixed charges produces a swelling pressure within the tissue, which is balanced by tensile forces in the collagen network. An early sign of osteoarthritis is swelling of cartilage accompanied by an increase in water content, as damaged collagen loses its ability to restrain swelling forces [1]. A more complete understanding of such complex interactions in extracellular matrix mechanics is crucial in understanding mechanically mediated diseases.

Over the past few decades, Donnan osmotic pressure of polyelectrolyte solutions has been adopted to model cartilage swelling [1-3]. Donnan law is strongly dependent on empirical coefficients describing deviations from chemically ideal conditions, and several notable efforts to quantify this behavior have been made. An early study by Maroudas calculated activity coefficients in 0.15 M NaCl, but concluded that ideal Donnan behavior was a good approximation for cartilage [4]. The same group later equilibrated cartilage samples against polyethylene glycol solutions and obtained values of osmotic pressure [1]. However, due to the general non-equivalence between mechanical and osmotic loading [5], it is unclear how such results are to be interpreted. Others have examined the osmotic pressure of individual constituent proteoglycans of cartilage in solution [6,7], with some results suggesting ideal Donnan may over-predict swelling pressure by up to a factor of two [6]. These results do not consider the complex environment within the tissue, nor the interactions between the collagen network and GAGs. In response to this lack of consensus, most models assume ideal conditions [3].

Another active question is the effect of salt concentration on material properties of cartilage, including the modulus and permeability. Theoretical correspondence principles have been proposed to include the effect of external salt concentration on tissue moduli [3, 8], but currently lack experimental validation.

The aims of this study were to: 1) isolate and quantify the magnitude of cartilage swelling pressure in situ; and 2) identify the effect of salt concentration on material parameters. To address these aims, we measured the swelling pressure of cartilage in confined compression in solutions with different osmolarities.

METHODS

Ten cylindrical cartilage explants were harvested from calf femoral condyles and both superficial and middle zones were removed by sledge microtome. The resulting specimens were cylindrical plugs of deep zone tissue (∅5 mm × 0.70 ± 0.18 mm) which were frozen at -20 °C until the day of testing. Each sample was placed inside a smooth confining cylindrical chamber with impervious sidewalls and bottom surface. The entire chamber was immersed in a bath containing a prescribed concentration of NaCl supplemented with 0.5 mM ethylenediamine tetra-acetic acid, 35 mM sodium phosphate monobasic, and an isothialozone based biocide (Sigma-Aldrich #46878-U). The top surface of the tissue was loaded in compression with a rigid porous indenter in series with a load cell and LVDT. Confined-compression stress-relaxation tests were performed on each sample while immersed in six different external baths (c^*=2, 0.6, 0.15, 0.03, 0.006, and 0.001 M NaCl), in the order listed. The first test, in 2 M NaCl, was used to determine a baseline response for the tissue.

In this initial configuration, a 500 kPa pre-conditioning load was applied for 60 s and then removed, to securely seat the sample in the confining chamber, followed by a 50 kPa tare creep load until equilibrium (~ 5 min). The sample was defined to be in its nominal zero-strain reference configuration under this tare load. Following stress relaxation the porous indenter was lifted, the bathing solution was replaced with the next NaCl concentration, and the sample was allowed to equilibrate to a new swelling state (~ 1 h). The porous indenter slowly (1 μm s^{-1}) applied a prescribed displacement to return the sample to the defined zero-strain reference configuration, where it was again allowed to equilibrate (~ 10 min). This procedure ensured each stress-relaxation test began at the same reference configuration. The stress $\sigma_0(c^*)$ required to return each sample to its nominal zero-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

strain configuration from its swelled state was measured and used to evaluate the swelling pressure.

In each stress-relaxation test displacement of the sample was prescribed in the form of a linear ramp to 20% engineering strain at a rate of 0.25 μm s^{-1}, and then held constant until the stress reached an equilibrium value $\sigma_1(c^*)$ (~ 1 h). All testing for each individual sample was conducted on a single day. After testing, the fixed charge density for each sample was obtained by use of the dimethylmethylene blue assay [9].

RESULTS

For each sample, a series of six stress-relaxation curves were obtained (Fig. 1). The equilibrium stress $\sigma_1(c^*)$ at 20% compression rose monotonically but nonlinearly as c^* decreased, from 0.12 ± 0.01 MPa in 2 M NaCl to 0.66 ± 0.06 MPa in 0.001 M NaCl (Fig. 2). It plateaued at the two lowest concentrations.

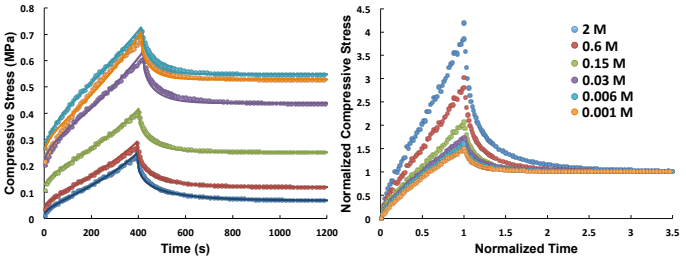

Figure 1: (Left) Stress-relaxation curves obtained for the same sample as c^* was varied. Smooth lines are triphasic curve-fits. (Right) The normalized curves, displaying concentration-dependent transient stress-relaxation behavior.

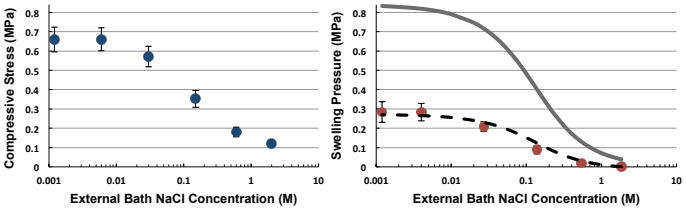

Figure 2: (Left) Mean equilibrium stress as a function of c^*. (Right) Mean swelling pressure at zero strain as a function of c^*. The solid line is the prediction from ideal Donnan law and the dashed line is ideal Donnan multiplied by Φ=0.34.

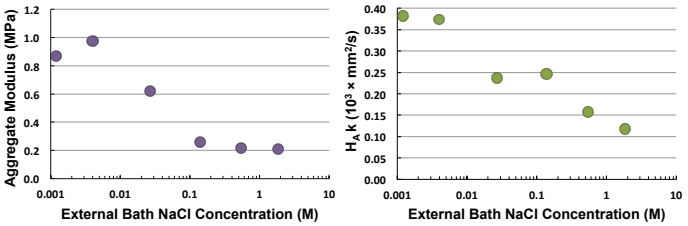

Figure 3: (Left) Aggregate modulus obtained by triphasic curve-fitting the transient data in Fig. 1. A neo-Hookean constitutive model was assumed for the solid matrix. (Right) The product of aggregate modulus and permeability $H_A k$, which is inversely related to the relaxation time.

The swelling pressure $\pi(c^*)$, evaluated at the nominal zero strain configuration using $\pi(c^*) = \sigma_0(c^*) - \sigma_0(2M)$, decreased monotonically with increasing c^*. As in the case of $\sigma_1(c^*)$, $\pi(c^*)$ was sigmoidal in shape; it plateaued at 0.28 MPa in NaCl concentrations below 0.006 M. The dependence of π on c^* followed the trend of ideal Donnan law, but its magnitude was about one-third of the ideal response (Fig. 2). A regression analysis $\pi = \Phi\, \pi_{ideal}$ produced an osmotic coefficient Φ=0.34±0.05 with a regression coefficient R^2=0.87. The fixed-charge density determined from the GAG assay was c^F = 344 ± 34 mEq/L.

By normalizing all stress-versus-time relaxation curves for a single sample to their respective equilibrium stress $\sigma_1(c^*)$ and ramp time, it becomes evident that the relaxation time increases with increasing c^* (Fig. 1). For the specimen shown in Fig. 1, stress-relaxation responses were fitted to the triphasic theory [2] in FEBio [10], using non-ideal Donnan behavior with the above value of Φ. The aggregate modulus obtained from the curve-fitting showed a strong dependence on c^* (Fig. 3), rising from 0.21 MPa in 2 M NaCl to 0.86 MPa in 0.001 M NaCl.

DISCUSSION

This study presents, for the first time, isolated values of the osmotic swelling pressure in articular cartilage explants as a function of c^*, as well as demonstrating the dependence of the mechanical response of cartilage on c^*. These results strongly suggest that the material properties of articular cartilage are a function of c^*, which may necessitate new constitutive relations to fully describe such behavior. In addition, cartilage displays strongly non-ideal swelling, in contrast to the typical assumption of ideality. Although able to qualitatively describe the swelling behavior of cartilage, ideal Donnan law is unable to offer quantitative predictions of osmotic pressure. The disparity between π and π_{ideal} (Fig. 2) suggests incorporation of non-ideal osmotic and activity coefficients is necessary to accurately characterize and model cartilage swelling.

By performing identical testing procedures on the same sample as c^* varied, encompassing the full range from hypertonic to hypotonic, this study is able to provide support for previous hypotheses regarding the dependence of cartilage material properties on c^* [3, 8]. Normalized stress-relaxation profiles (Fig. 1) clearly indicate the relaxation time increases with c^*. The product $H_A k$ is inversely related to the relaxation time, and decreases as c^* increases (Fig. 3), indicating decreasing interstitial fluid diffusivity with greater salt concentrations. Furthermore, the ramp phase of the curves at higher NaCl molarities (2 M and 0.6 M) displays the transient response characteristic of strain-dependent permeability [11], while this effect vanishes as c^* decreases. The ratio of peak to equilibrium stress, which changes by a factor of 3, has also been linked to nonlinear permeability parameters [11]. The tissue aggregate modulus also depends on c^*, increasing nonlinearly as c^* decreases (Fig. 3). The trend of increasing modulus with decreasing c^* is very similar to results obtained by Eisenberg and Grodzinsky [12] in an earlier experimental study. Those authors found the aggregate modulus to increase by ~ 0.9 MPa as c^* decreased from 1 M to 0.005 M, in close agreement with the results of the present study.

Models of the mechanical interactions between extracellular matrix constituents in biological tissues may benefit from the non-ideal osmotic behavior suggested here. A more complete understanding of swelling behavior in articular cartilage will provide a valuable tool for computationally modeling complex electrokinetic phenomena in cartilage.

INTRODUCTION

The timely remodeling of the uterine cervix from a rigid into a compliant structure is essential for the safe delivery of a term baby. We have quantified this dramatic remodeling as a four orders of magnitude decrease in cervical stiffness within a 19-day gestation in a normal mouse pregnancy [1]. Preterm birth (PTB) is a leading cause of neonatal death and affects 15 million babies worldwide every year [2]. Premature softening and dilation of the cervix is often the final common pathway to many preterm births. The physiology of normal and premature cervical remodeling, however, remains unclear.

The objective of this study is to investigate the mechanical properties of pregnant cervices from two distinct mouse models of PTB and to compare these properties with cervices from normal term remodeling. Here, we conduct mechanical tests on normal pregnant mouse cervices at gestation days (d) 15 and term d18 and cervices from two mouse models of PTB: (1) infection-mediated via lipopolysaccharide (d15+LPS) and (2) premature withdrawal of progesterone (d15+RU486).

Histologic evidence of cervical samples from these term and preterm models suggest that the ECM mechanisms responsible for cervical remodeling are different between the two PTB models. In a normal mouse pregnancy, collagen fibers become less organized and more undulated from d15 to d18 [3]. In a recent study, electron microscope (TEM) images showed compromised elastic fibers but normal collagen fibril organization in the d15+LPS compared to d15 while d15+RU486 cervices had collagen fibril morphology similar to d18 tissue [3,4]. The consequences of these ECM profiles on the mechanical properties of the different mouse models of PTB remain to be determined. In this study we utilize load-to-break and load-unload-recover tests to investigate the contributions of the cervical collagen and elastin to tissue stiffness, strength, hysteresis, and recoverability.

METHODS

Mouse models: Mice were generated and maintained at the University of Texas Southwestern Medical Center. Wild-type 2-6 month old nulliparous pregnant females were used in all experiments. Normal pregnant mice were sacrificed on gestation d15 and d18, where term delivery usually occurs between 6PM on d18 to 12 PM on d19 of pregnancy. For the infection-mediated PTB model (d15+LPS), 150ug of lipopolysaccharide was injected into the uterus of pregnant d15 female mice between 7-9 AM and sacrificed 6 hours later. Under this condition, PTB occurs 7-8 hours after injection. For the hormone-mediated PTB model (d15+RU486), a progesterone receptor antagonist, RU486, was used to stimulate premature progesterone withdrawal by subcutaneous injection late on d14. Pregnant mouse was sacrificed 12h later on d15 (d15+RU486). Under this condition, PTB occurs 13-16h after injection. For all mouse samples, the cervix was isolated with uterine horns and surrounding vaginal tissue immediately after sacrifice, flash frozen, shipped overnight to Columbia University on dry ice, and stored at -80°C until testing.

Mechanical testing: On the day of testing, the cervix was carefully removed from the uterine horns and the surrounding vaginal tissue. Two surgical sutures (Ethicon, Silk 2-0) were threaded through the inner canal of the cervix, attached to custom tensile grips, and tensioned [1]. Samples were positioned onto a universal testing

machine (Instron 5948 MicroTester, 10N load cell) inside a bath filled with phosphate buffered saline+2mM EDTA (protease inhibitor). Before tensile testing, samples were allowed to equilibrate in the solution (2-4 hours) while two calibrated perpendicular CCD cameras (Point Grey GRAS-50S5M-C 75 mm, f/4 lens) tracked tissue geometry. After swelling equilibrium, samples were subjected to either a load-to-break test or a cyclic load-unload-recover test. Throughout testing, samples were kept hydrated in PBS and time, grip-to-grip displacement, force, and tissue geometry were continuously recorded.

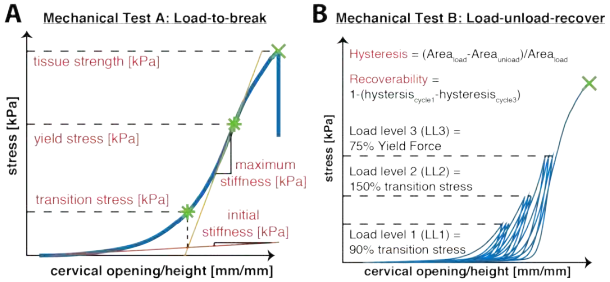

Figure 1: Mechanical test loading curves for A) load-to-break and B) load-unload-recover test with calculated parameters in red.

Load-to-break: Whole, intact cervices (n=5 per group) were subjected to load-to-break tensile testing to determine stiffness and strength for each group (Fig.1A). Tensile grips were pulled apart at a constant rate of 0.1mm/s until the sample broke. Stress [kPa] was calculated by normalizing the force [N] by the stress-free reference sample cross-sectional area [mm^2] defined as the product of width [mm] and length [mm]. Cervical opening [mm], defined as the suture-to-suture distance, was normalized by the stress-free sample height [mm] to calculate the normalized cervical opening [mm/mm]. For each sample, a loading curve (normalized cervical opening [mm/mm] vs. stress [kPa]) was generated and the parameters *initial slope* [kPa], *maximum slope* [kPa], *transition stress* [kPa], *yield stress* [kPa], and *tissue strength* [kPa] were calculated as shown (Fig.1A).

Load-unload-recover: Whole, intact cervical samples (n=3-4 per group) were subjected to cyclic load-unload-recover tensile testing to measure sample hysteresis and recoverability (Fig.1B). To account for differences in the loading curves between sample groups in the load-to-break test, three load levels were selected based on the group averages of transition stress and yield stress. The first load level (LL1) was selected as 90% of the average transition stress, within the toe region of the loading curve. The second load level (LL2) was selected as 150% of the average transition stress, past the toe region. The third and highest load level (LL3) was selected as 75% of the average yield force, just before the sample begin to yield and break. Samples were loaded at a grip-to-grip rate of 0.1mm/s to LL1, immediately unloaded at the same rate to a stress-free state and allowed to recover for 20 mins. This cycle was repeated twice more for a total of 3 cycles (cycles 1-3). The cycles were repeated for LL2 (cycles 4-6) and LL3 (cycles 6-9) for a grand total of 9 load-unload-recover cycles.

Hysteresis was calculated as the area between the loading and unloading curves for each cycle. This measurement represents the dissipated energy due to both viscous and unrecoverable permanent deformations. To determine the extent of unrecoverable permanent damage, *recoverability* was calculated as 1 minus the change in *hysteresis* between the 1st (cycles 1,4,7) and 3rd cycle (cycles 3,6,9) at each load level.

RESULTS

In general, d15+LPS cervices exhibited similar mechanical behavior to d15 samples while d15+RU486 cervices exhibited similar mechanical behavior to d18 samples in the load-to-break tests. Normal d15 and d15+LPS cervices tended to be stiffer and stronger compared to d18 and d15+RU486 cervices (Fig.2A). However, these differences were not statistically significant.

Hysteresis was consistently higher in d15 cervices compared to all other groups (Fig.2B). Hysteresis was higher in d15 compared to d15+LPS and d18 cervices for all loading levels and compared to d15+RU486 only for LL1. Recoverability was consistently higher in d15 cervices compared to all other groups. Significant differences, however, were found only between d15 and d15+LPS at LL3.

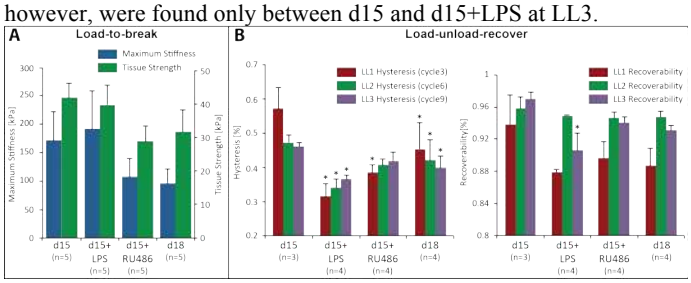

Figure 2: A) Load-to-break: d15+LPS and d15 cervices are stiffer and stronger compared to d15+RU486 and d18 cervices, but differences were not significant. B) Load-unload-recover: d15 cervices exhibit higher hysteresis and recoverability compared to d15+LPS. *'s indicate significantly different parameters compared to d15 (One way ANOVA, $p<0.05$).

DISCUSSION AND CONCLUSIONS

The objective of this study was to investigate the mechanical behavior of pregnant cervices from mouse models of two different models of PTB: infection-mediated PTB via LPS and premature hormone-withdrawal via RU486. Our load-to-break results agree with our histological studies, where more organized collagen in the d15+LPS and d15 cervices lead to stiffer and stronger tissue compared to d15+RU486 and d18 cervices. These differences, however, were not significant. The higher hysteresis in the d15 cervices in our load-unload-recover tests suggests that more energy is dissipated during a load-unload cycle in the d15 cervix. Recoverability tended to be higher in d15 cervices compared to all other groups, especially d15+LPS samples, indicating viscous deformations in the d15+LPS samples were less recoverable. This result agrees with histologic studies, where compromised elastic fibers in the d15+LPS cervices may result in tissues with lower recoverability. The overall trends in this study suggest that the biomechanical signatures between the two mouse models of PTB are distinct and that infection and progesterone withdrawal facilitate distinct mechanisms of cervical remodeling where both lead to a compromised cervix and thus PTB.

A limitation of this study is the assumption of a homogeneous deformation state in our tensile tests. Our previous modeling study shows that ring tests induce a complex combined loading on the cervix. To fully characterize the material properties, we are currently conducting inverse finite element studies. The results in this study will be used to help inform and extend our current material model for the cervix to include time dependence. This extension to the model will help us to better understand normal and abnormal cervical remodeling in pregnancy.

INTRODUCTION

Individuals with medically refractory epilepsy currently have no reliable treatment to control seizures and make up about 30% of the approximately 3 million Americans with epilepsy [1]. In these cases, the most promising course of action is to surgically remove the portion of the brain responsible for the seizures, an approach with only a 60% success rate [2]. This limited success is due to the difficulty in correctly identifying the exact location and scope of seizure onset. Current technology and methods are somewhat limited in the precision of locating the zone of seizure onset. If the entire epileptogenic zone is not successfully removed, seizures continue in the patient after surgery.

Research suggests that cooling the affected brain tissue can reduce the rate of activity, thus reducing or eliminating seizures. It has been determined that tissue at a depth of 5 mm below the surface of the brain must be cooled by 12 degrees Celsius to reach a temperature of 25 ^{o}C to slow or terminate seizure activity [3]. The present study analyzes the viability of obtaining such cooling using a device operating on the cortical surface of the brain two ways. First, a pre-test prediction is conducted, using mathematical modeling of the brain tissue to determine if an achievable convective coefficient can be used to obtain such cooling. Next, we introduce a novel instrumented phantom which can be used to test concept cooling devices. The phantom will be used to investigate various cooling strategies on the benchtop. Ultimately, the goal of the research program is to determine a method to more precisely identify the epileptogenic zone, thereby increasing the rate of success of surgery.

METHODS

The mathematical model calculates the transient temperature response along a single dimension. The aim of this part of the study was to conduct a pre-test prediction. We sought to determine if the desired temperature drop could be achieved by using surface convection that could be achieved in a concept device. Temperature vs. time data are output at depths of 5, 10 and 15 mm. This code utilizes a finite-difference method, material properties of human tissue are used, and boundary conditions, and an initial temperature profile [4] of the brain were set. The model is represented schematically in Figure 1.

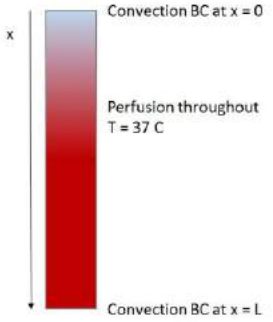

Figure 1: The mathematical model includes material properties and boundary conditions in a single dimension.

The cooling phase of this simulation was created by setting the surface boundary temperature to 0 °C (ice water) with an appropriate heat transfer coefficient correlated to the flow of ice water through the device (h = 75 W/m^2*K). The model was set to mimic human circulation at a temperature of 37 °C at the deep boundary of the spatial domain using a convection coefficient of h =200 W/m^2*K and thoughout the spatial domain using a perfusion term of 3300 W/m^3*K. A thermal recovery phase was introduced as well to model the removal of the cooling device. In this phase, the surface boundary was returned to 37 °C to once again match biologic conditions. The model is based upon the Pennes bioheat equation, which is given in Equation I. Properties used in the equation are provided in Table 1. The model is programmed in Matlab (The Matworks, Natick, MA).

$$\rho C_{p,tis}(T)\frac{\partial T}{\partial t} = k\nabla T + \omega_{bl}\left(\rho C_p\right)_{bl}(T - T_{bl}) \quad \text{(I)}$$

The second part of the work involved developing a phantom for use as a device test bed, in which the goal is to mimic the temperature drop

observed in the model. Table 1 below, summarizes and compares the key material properties associated with the model and the experiment.

Table 1: Paraffin wax serves as a readily-available, inexpensive representation of brain tissue.

	Model	Experiment
Medium	Brain parenchyma	Paraffin wax
Density,)ρ) (kg/m^3)	1039	900
Thermal conductivity, k (W/m*C)	.515	.24
Specific heat, C_p (J/kg*C)	3680	2890

We introduce a benchtop test configuration which involves pumping water through two isolated loops, as depicted in Figures 2 and 3.

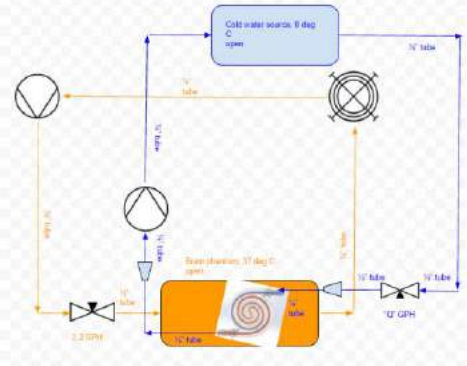

Figure 2: The warm loop represents circulation while the cool loop simulates the therapeutic device.

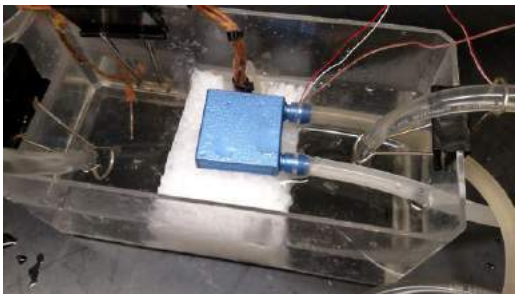

Figure 3: A molded block of wax beads represents a human brain in the lab.

One loop consists of warm water, which, when circulated at 37 °C, simulates human blood circulation. This water flows through a brain phantom made of paraffin wax beads formed into an 90 x 65 x 45 mm block. Three embedded thermocouples at depths of 5, 10 and 15 mm read out temperature at 1 Hz. The second loop includes the cooling device, which is placed on top of the phantom, directly above the thermocouples. Ice water at 0 °C, cycles through this loop, including the device, in order to cool the brain phantom. The cooling device used in this pilot study is a 41 x 41 mm anodized aluminum cooling block. The embedded thermocouples obtain temperature information which is plotted over time. The system is allowed to reach a steady state condition in which the ambient warm water remains constant at 37 °C before the cooling device is place atop the phantom. The cooling phase persists for 45 minutes, after which the device is removed and the phantom allowed to return to its original warm state.

RESULTS

Figure 4 depicts the results of the one dimensional brain model. The graphs of the cooling phase and recovery phase are superimposed next to one another to demonstrate both phases of the process. Data from the benchtop phantom also yielded promising results, shown in Figure 3.

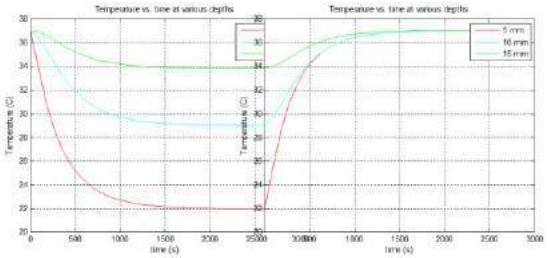

Figure 4: Mathematical simulation using MatLab suggests that a 12-degree C temperature drop is possible at 5 mm deep.

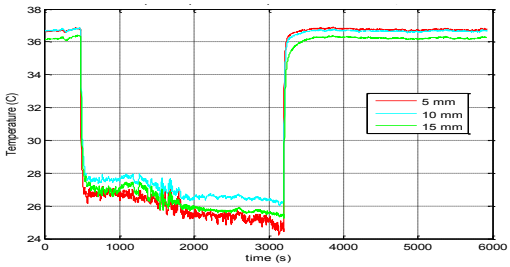

Figure 5: Benchtop brain phantom simulation suggests that a 12-degree C temperature drop is possible at 5 mm deep.

DISCUSSION

The predicted temperature drop at a depth of 5 mm was within 2 degrees of the computational model. However the benchtop experiment exhibited a much tighter distribution of temperature and faster temperature recovery time. The two modeling methods developed in this study serve complimentary roles. The mathematical model creates a pre-test prediction which gives confidence in the convective cooling method as well as a temperature recovery target for the phantom.

The near term goal is improved biofidelity of the physical phantom. Based on pretest predictions, a phantom with greater depth sensitivity and slower temperature recovery is needed.

In summary, with a temperature reduction of approximately 12 °C at a depth of 5 mm, both techniques indicated viability for the testing platform and convective cooling approach. Future work on the model will involve a prediction of a porous paraffin wax structure. Future efforts on the phantom will seek to reduce in porosity of the paraffin wax block to develop a greater distraction of temperature within it, and develop more non-directional flow. Both of these alterations should more closely replicate the effects of non-directional perfusion on heat transfer within the cortex.

THE QUANTIFICATION OF BLOOD FLOW PATTERNS INDUCED BY ENDOVASCULAR STENT GRAFTS: AN EXPERIMENTAL INVESTIGATION OF THE EFFECTS OF OVERSIZING AND COMPLIANCE

Amanda Colella-Centazzo (1), Clifton R. Johnston (1)

(1) Department of Mechanical Engineering
Dalhousie University
Halifax, NS, Canada

INTRODUCTION

In current medical practice endovascular stents are the most common treatment used in the management of arterial disease, particularly to bridge blood flow through aneurysmal vessels. Despite their relative ease of implantation they have been shown incite harmful secondary issues long-term that negate these benefits, with additional interventions occurring at higher rates as compared to open repair surgery [1], while showing no significant difference in survival after 2 years [2]. The alterations to the fluid dynamic forces that are incited by the stent play an important role in tissue healing, stent migration and by extension stent efficacy.

More specifically, areas of low wall shear stress (WSS) have been shown to affect the progression of atherosclerosis, the proliferation of intimal hyperplasia and the formation of thrombi [3]. These fluid dynamic considerations directly affect the long-term patency of stent grafts and have therefore prompted investigation into how the presence of the stent alters the local hemodynamic environment.

An environment representing that of the human femoral artery was constructed with optical access to the blood analog as it exits an implanted stent graft. Using Particle Image Velocimetry (PIV) the flow patterns were imaged and the changes to the peak velocity and WSS induced by stent implantation were quantified for several stent-vessel cases, specifically examining the effect of stent sizing and the compliance of the treated vessel. Tests were conducted in a rigid acrylic test section and an elastic mock artery with a compliance within the clinically observed range.

METHODS

A closed flow loop was designed and constructed for visualization and measurement of flow through a 10 mm inner diameter tube, representing a simplified geometry of the femoral artery. A common non-Newtonian blood analog representative of physiological hemodynamic parameters and comprised of a mixture of glycerol (40%), xantham gum (0.04%) and water, was circulated through the test section [4]. The mixture was exposed to a 1Hz pulsatile flow profile typical of the human femoral artery (Figure 1) with a peak velocity of 47 cm/sec, the mean peak forward velocity in the femoral artery reported by Fronek et al. [5]. This corresponds to a Reynolds number at peak flow of 1033.5, which is within the physiologically observed range [6].

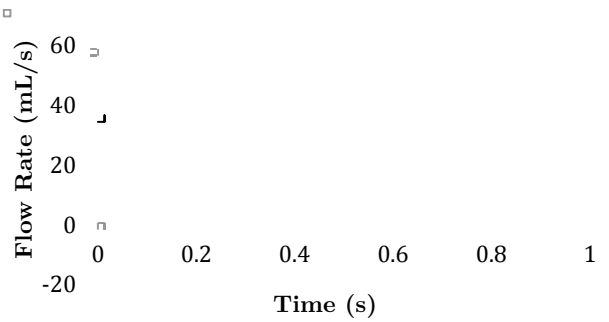

Figure 1 - 1 Hz Input waveform representing pulse profile typical of the human femoral artery.

Using PIV, cross-sectional velocity and wall shear stress immediately downstream of a Gianturco Zenith stent graft (Cook Medical, Inc., Bloomington, IN, USA) were quantified. The compliance of the elastic tube was tested in a modified PIV set-up and was found to be 7.77 % mm Hg^{-1x} x 10^{-2}, which is representative of a healthy human male femoral artery. The two stents of 20% and 40% oversizing were deployed in the test section and an identical test was performed in a rigid acrylic tube for comparison.

The test section was embedded in an acrylic flow chamber, which was filled with 100% glycerol to correct for the refraction index differences between the circulating fluid and the surrounding vessel and allow the laser sheet to reach the test area unaffected. The fluid was seeded using 10 µm silver coated hollow glass spheres, which were illuminated using a 1 mm thick laser sheet. Image frames were collected using a Photron mini UX100 at 4000fps with 20 image pairs collected per pulse, over 10 pulses.

RESULTS

Oversizing: Introduction of a full stent (3 wires in a polyester cover) had a substantial effect on flow velocities, particularly at peak pulse. The flow observed followed an asymmetric pattern due to variations in the folding and pillowing of the fabric between the stent wires. This

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

asymmetry was more pronounced in the 12 mm stent. This appears to be due to the fact that the 12 mm stent has seven wire peaks, while the 14 mm stent has eight. Although both were installed in the tube such that their wires were symmetric in the plane of the camera, the seven peaks allowed more intra-wire spacing and therefore allowed the fabric sheath and wires to deploy asymmetrically.

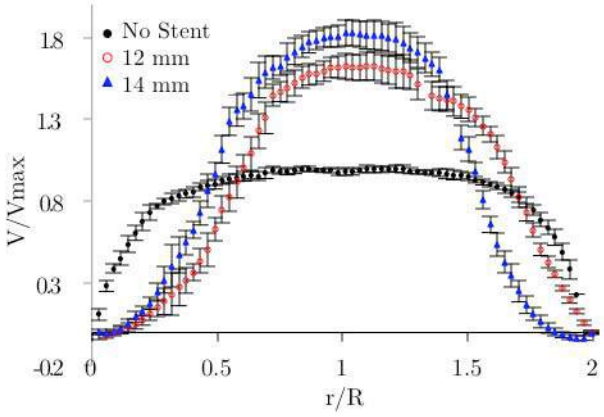

Figure 2 - Velocity profiles at peak pulse at x/R=0.5 downstream of a 12 mm and 14 mm Gianturco stent compared to the same acrylic vessel with no stent.

Both stents caused a considerable reduction in velocity close to the wall accompanied by an accelerated core flow (Figure 2). At 20% and 40% oversizing (12 mm and 14 mm stents) the centerline velocities at x/R=0.5 increased by 65.4% and 86.2%, respectively, as compared to the non-stented condition. At peak pulse, the 12 mm stent caused a velocity reduction from the wall to r/R = 0.5776 and r/R=0.7040 to the far wall, with flow reversal noted between the wall and r/R= 0.08664. A similar pattern was observed with the 14 mm stent, with reduced velocities occurring between the wall and r/R = 0.4621 and r/R= 1.5306. The largest absolute change for both stents occurred at r/R=0.2310 and was a decrease of 35.60 cm/s (85.0%) and 31.72 cm/s (75.8%) for the 12 mm and 14 mm stents, respectively

The wall shear stress saw a decrease upon introduction of both stents across the pulse cycle, with the most substantial changes in WSS occurring during acceleration of the fluid (Figure 4-11). Due to the asymmetry in the vessel, the WSS drop varied between the two walls. For comparison, the most severe case is considered. The drop observed at peak flow was found to be 82.1% for the 12 mm stent. The 14 mm stent saw a 120.7% in the WSS due to the flow reversal noted at the wall.

The cycle averaged WSS decreased from 0.920 Pa in the non-stented case to -0.832 Pa and -1.2675 Pa for the 12 mm and 14 mm stent. The change in sign of the cycle averaged WSS indicates a substantial flow reversal over the course of the pulse at the near wall. The OSI, surprisingly, decreased upon stent introduction from 0.4385 to 0.4182 and 0.3642 for the 12mm and 14mm stent, respectively. This is due to the fact that the flow was already pulsatile and therefore highly oscillatory to begin with, which is an important characteristic of flow in the peripheral arteries. The lowering of the WSS in both positive and negative flow direction, led to an overall WSS approaching zero, in turn lowering the OSI.

Compliance: Tests conducted in the compliant vessel showed similar trends to those in acrylic, however changes were more pronounced. Cross-sectional velocity profiles downstream of a single stent wire (Figure 3) showed a larger drop in velocities at the vessel periphery compared to the acrylic values (5.306 cm/s and 8.77 cm/s respectively). The centerline velocities increased more in the SYLGARD at 11.7%, compared to 4.65% in the acrylic. The WSS saw a drop at the peak with a 22.0% decrease in the acrylic and a 26.9% decrease in the SYLGARD.

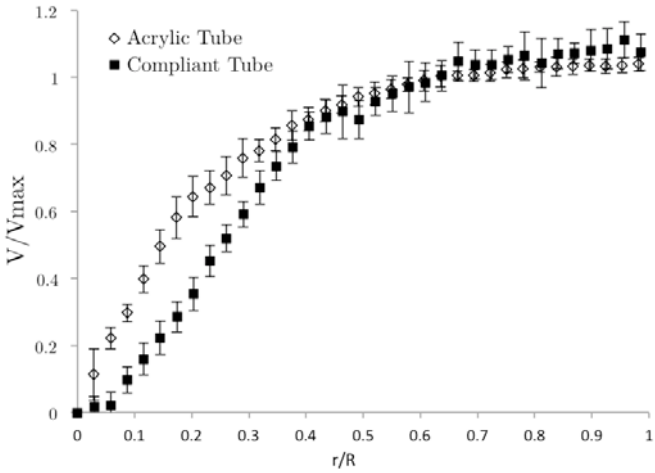

Figure 3 - Velocity profiles at peak pulse downstream of a Gianturco stent wire in acrylic and compliant vessels

DISCUSSION

The effect of oversizing was consistent across vessel compliances, with the larger 14 mm stent causing more substantial changes to the flow profiles as compared to the smaller 12 mm. The stents both caused an increase in the centerline velocities, accompanied by a drop at the vessel periphery. This incited a drop in the WSS, a feature that has been shown to promote re-stenosis. Oversizing of the stent is common practice clinically to ensure proper adhesion of the graft and to minimize stent migration, however this convention has important implications on the degree of disturbance introduced into the blood flow. These findings suggest that a graft with a diameter closer to the native vessel could be helpful in reducing the instances of stent re-occlusion.

Additionally the rigid tube was shown to lessen the velocity disturbances induced by the stents introduction, with centerline velocity increases more than double in the compliant vessel. This would imply that in more compliant vessels where the compliance mismatch is greater the stent has a larger effect on the fluid flow.

INTRODUCTION

Abdomen injury is a significant cause of mobility for children. Understanding its biomechanical mechanism is urgent. So far, numerous injury criteria have been proposed, such as energy-based blunt criterion [1], abdominal pressure [2]. However, no consensus has been reached on the performance of the injury criteria. This may be because those injury criteria do not inform tissue-level mechanical responses. Crash dummies play an important role in vehicular safety design. One limitation is that crash dummies do not export strain or stress, which is believed to damage internal organ [3].

To break this limitation, finite element (FE) modeling becomes a significant approach. For example, Mizuno et al. developed a finite element model of a 3-year-old child abdomen by scaling from a 50th percentile adult FE counterpart [4]. Because a significant difference in the simulation results was found between 3-year-old child and the corresponding dummy [5], this may have substantial effect in injury assessment. Therefore, the aim of this study is to establish a finite element model of a 3-year-old child abdomen, and to parametrically investigate the directional sensitivity of tissue-level responses of internal organs to blunt impact.

METHODS

Model Development

The model geometry was extracted from CT scans of a 3-year-old female healthy child volunteer by Tianjin Children's hospital. Importing these CT images using Mimics (Materialise Inc., Leuven, Belgium). The surface of each critical anatomical component was converted into non-uniform rational basis spline (NURBS) using Geomagic Studio(Geomagic, Inc., Research Triangle Park, NC, USA). FE modeling was performed using a combination of TrueGrid and Hypermesh. The FE model of a 3-year-old child abdomen consists of 273322 nodes, 194684 hexahedral solid elements and 118549 shell elements (Fig. 1).

Bones and internal organs were models by elastic and linear visco-elastic materials, respectively. Contacts were defined self-contacts among the abdominal viscera to allow interfacial sliding. Computation was performed using Pam-Crash (Pam-Crash, Inc., Paris, FR).

Model Validation

The post mortem human subjects of 3-year-old children are rarely used for biomechanical experiments due to regulatory and ethical concerns. In this research, a simulation test was implemented to validate the FE model according to the child cadaver tests conducted by Ouyang et al. [6]. A cylindrical impactor with 5 cm diameter, 2.5kg mass was designed to impact the FE model. The impact location was selected as the position one third the distance from the umbilicus to the bottom of the sternum. The model was kept free [7]. The impactor with an initial velocity of 6m/s was applied to the finite element model.

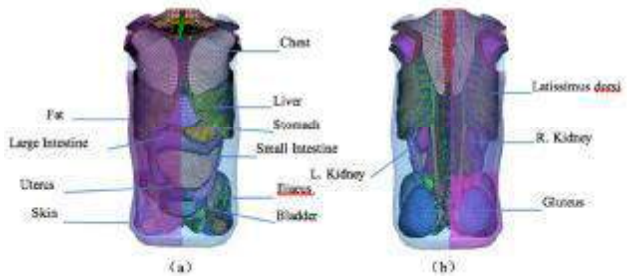

Figure 1 Finite element model of a 3-year-old child abdomen (a) Front view (b) Rear view

The impact lasted for 40ms. In the Pam-Crash, we defined sets of the contacts. There were not only the defined self-contacts between internal organs finite elements components, but also the surface to surface contact between the impactor and the skin of the finite element model.

Parametric Study

In the vehicle frontal collision study, it generally used three different degrees to study the vehicle safety. It was 0 degree, the left 30 degree and the right 30 degree [8]. In the tests, the impactor was rotated 30 degrees clockwise (minus 30 degrees) and counterclockwise (plus 30 degrees) respectively along the vertical direction of its velocity. The other conditions were designed as same as model validation. The simulation state was shown in Figure 2.

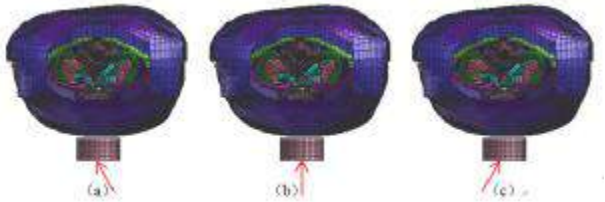

Figure 2 Top view of the impact at different angles (a)The plus 30 degrees impact (b) The 0 degree (head-on) impact (c) The minus 30 degrees impact

RESULTS

In the 3-year-old child abdominal finite element model validation test, the impact force-time curve and abdominal deformation-time curve were output by Pam-Crash. The FE model impact force-abdominal deformation curve was shown in the Figure 3, which was obtained by the data from the curves of the FE model impact force-time and abdominal deformation-time. In the figure 3, the +1 and -1 standard deviation corridor boundary were given by cadaver tests data analysis conducted by Ouyang et al. It was obvious that the simulation curve of the impact force-abdomen deformation fell inside the corridor obtained from cadaveric experiment, which suggests a validity of FE simulation results.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The Figure 4 showed the curves of children's abdominal impact force-abdomen deformation when the crash by the impactor happened head-on or from the rotating angle of plus and minus 30 degrees (that is, the impactor crashes the same position from different angles). As was shown in the figure, when the impactor crashed the same position on the abdomen from different angles, there were obviously more big differences. In three kinds of degrees simulation results, the visceral peak strains were shown in Table1. In consideration that the peak strain may be caused by a much distorted element, we calculated the elements' mean strain around the element which happened the peak strain.

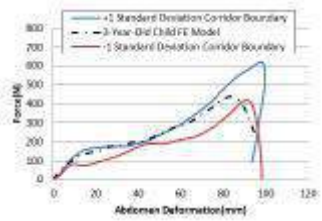

Figure 3

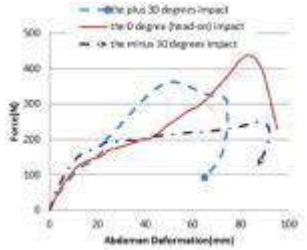

Figure 4

Figure 3 Impact force-abdomen deformation curves

Figure 4 The impact force-abdomen deformation curve from different angles for the impact

To directly compare the strains of different viscera organs and analyze their injury threshold when the crash by the impactor happened head-on or from the rotating angle of plus and minus 30 degrees, the bar chart is shown in Figure 5.

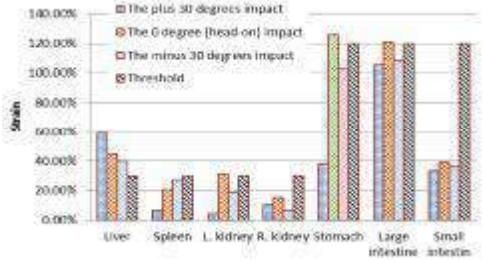

Figure 5 The peak strain of child's viscera form different angles for impactor

Table 1 The peak strain of child's viscera at different degrees for impacting

Part	The plus 30 degrees impact	The 0 degree (head-on) impact	The minus 30 degrees impact	Threshold
Liver	58.85%	44.77%	39.96%	30%
Spleen	6.62%	20.75%	27.29%	30%
L. kidney	4.59%	31.13%	18.65%	30%
R. kidney	10.63%	15.64%	6.75%	30%
Stomach	38.32%	126.01%	103.22%	120%
Large intestine	105.36%	120.84%	108.79%	120%
Small intestin	33.48%	38.94%	36.23%	120%

DISCUSSION

In this study, a finite element model of 3-year-old child abdomen with high biofidelity was developed. The FE model was validated against a cadaveric experiment. The parametric study based on the FE model is used to analyze the sensitivity of internal organs to blunt impact.

As Figure 3 shows, the simulation curve is not absolutely in the corridor of cadaver test. It may due that the FE model was slightly fatter than the cadaver specimens. The 3-year-old FE model was constructed by the specimen child whose mass was 15.6kg. And the cadaver specimens of Ouyang tests were 10.5~13.5kg.

Generally researchers estimated abdominal and visceral injury by its internal strain. This study carried out the injury analysis by adoption of adults visceral injury threshold. Due to the asymmetry of children's abdominal viscera, even if the same position at different impact angle, visceral injury situations were not same. As was shown in Figure 5, compared with the impactor form the different crash directions, the visceral strains had the obvious difference. The strain of the stomach became bigger and the strain of the liver became smaller when the impact direction rotated an angle of -30 °. And when the impact rotated the angle of +30 °, most of the overlap part was located in the liver. So the strain of the liver became bigger and the strain of the stomach became smaller. In addition, from three groups of visceral strain, we could also conclude that the position which the impactor impacted also affected children's abdominal visceral injury. Children's abdominal viscera were more vulnerable at the position of the impactor contact compared to others.

This study provided a high biofidelity FE model of a 3-year-old child abdomen and it could be used to parametrically study the injury mechanism. This is very valuable to develop protection devices of children.

ANALYSIS OF CELL SPREADING ON MICROPATTERNED SUBSTRATES USING A THERMODYNAMICALLY CONSISTENT NON-LOCAL ACTIVE FORMULATION

INTRODUCTION

Several experimental studies demonstrate that control of cell spreading using substrate micro-patterning has a significant impact on cell behavior. A study by McBeath *et al.* [1] reveals that stem cell differentiation can be controlled by limiting cell spread area. It has also been shown that the contractility of smooth muscle cells increases with increasing cell area (Tan *et al.* [2]). Lamers *et al.* [3] show the spread geometry and stress-fibre (SF) distribution of osteoblasts on grooved surfaces is highly dependent on groove spacing. Wide grooves result in polarized cells with SFs aligned along the grooves. Narrow groove spacing leads to randomly oriented cells and SFs. Finally, a study by Théry *et al.* [4] has shown that cells spread on V-shaped fibronectin patches exhibit SFs align along the free edge of the cell.

The bio-mechanisms underlying such experimental observations are not fully understood. In the current study we propose a new approach to the analysis of the spreading of cells on micro-patterned substrates. We demonstrate that a non-local thermodynamically consistent active cell model explains several of the key phenomena observed experimentally.

MODEL DEVELOPMENT

The thermodynamically consistent kinetic equation for SF formation/dissociation proposed by Vigliotti *et al.* (2015) [5] reduces to

$$\hat{\eta} = \left(\hat{N}_u/\pi\hat{n}\right)exp[\hat{n}(\mu_u - \mu_b)/kT] \qquad (1)$$

under steady state conditions in a representative volume element (RVE) within the cell. $\hat{\eta}$ is the SF concentration per unit surface area of the RVE, $\hat{n}$ is the number of actin-myosin contractile units along the length of the RVE, μ_b is the free energies of the bound contractile units in a stress fibre, μ_u is the free energy of unbound SF proteins, while k and T are the Boltzmann constant and absolute temperature. $\hat{N}_u$ is the number of unbound SF proteins. Here we implement non-local conservation of the total number of SF proteins within the cell, $\hat{N}_T$, under the assumption that the diffusion of unbound proteins through the cytoplasm is infinitely fast relative to the timescale of SF remodeling. The number of unbound proteins in the whole cell is therefore given as

$$\hat{N}_u = \hat{N}_T - \int_{V_c} \int_{-\pi/2}^{+\pi/2} \hat{\eta}\,\hat{n} d\phi dV \qquad (2)$$

where the inner integral computes the number of bound proteins in a RVE, and the outer integral provides a summation over all the RVEs in the entire cell volume V_c. At steady state, $\hat{n}$ in a SF at orientation ϕ is given as

$$\hat{n} = \left(1 + \varepsilon_n(\phi)\right)/(1 + \tilde{\varepsilon}_{ss})(\qquad (3)$$

where ε_n is the SF nominal axial strain. When a SF is extended, contractile units are added, with the effect that the internal strain in the SF is reduced until a steady state value $\tilde{\varepsilon}_{ss}$ is achieved. Conversely, when a SF shortens, functional units are removed. In both cases, the internal fibre steady state strain is different from the axial material strain in the direction of the fibre, $\varepsilon_n(\phi)$.

The formulation is completed by the addition of a non-linear hyperelastic formulation (Ogden, N=8) in parallel with the SF model in order to represent the passive components of the cell.

SIMULATIONS AND RESULTS

The model described above is used to simulate two separate cell spreading experiments:

Experiment 1. As shown in Fig. 1, cells spreading across a series of parallel grooves and fibronectin adhesion patches, both of width L_r , is simulated. In order to spread on N grooves the cell must deform from

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

its reference configuration in the x-direction by a stretch λ_x, after which it may spread along the groves by deforming in the y-direction by a stretch λ_y.

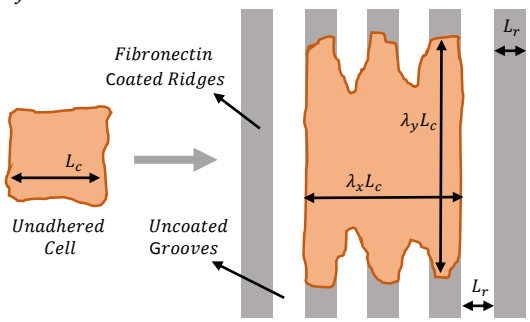

Figure 1: Schematic of parametric study of cell spreading across a series of parallel grooves and fibronectin adhesion patches.

A parametric study is conducted for a range of spread states (λ_x and λ_y). For each spread state the free energy of the system $\bar{G}$ is computed from

$$\bar{G} = W_{elas} + (\rho kT) ln(\hat{N}_u) \qquad (4)$$

where W_{elas} is the elastic free energy due to deformation of the passive components of the cytoplasm during cell spreading. The second term is the cytoskeleton free energy, where ρ is the density of cytoskeletal proteins. Eqn.(4) can be interpreted as a competition between the elastic free energy, which increases with cell spreading, and the cytoskeleton free energy, which decreases with cell spreading (in accordance with eqns.(1-3)).

As shown in Fig. 2(a), results reveal that when the groove spacing is wide (L_c/L_r=3) $\bar{G}$ is minimized when the cell extends along the grooves in the y-direction ($\lambda_y = 1.5$) while spanning only one grove (N=2 and $\lambda_x = 0$). Such spreading in the y-direction, coupled with the global conservation of cytoskeletal proteins, dictates that SFs align primarily in the direction of the grooves. Spreading in the x-direction is discouraged by the high elastic penalty, as shown for the case of N=4.

Fig.2(b) considers the case of a small groove spacing (L_c/L_r=12). Here $\bar{G}$ is minimized when $\lambda_x \approx \lambda_y \approx 1.55$ and an isotropic distribution of stress fibres is obtained. Notably, global conservation of cytoskeletal proteins dictates that the SF concentration in any given direction, $\eta(\phi)$, in Fig.2(b) is lower than the concentration of SFs along the grooves in Fig.2(a).

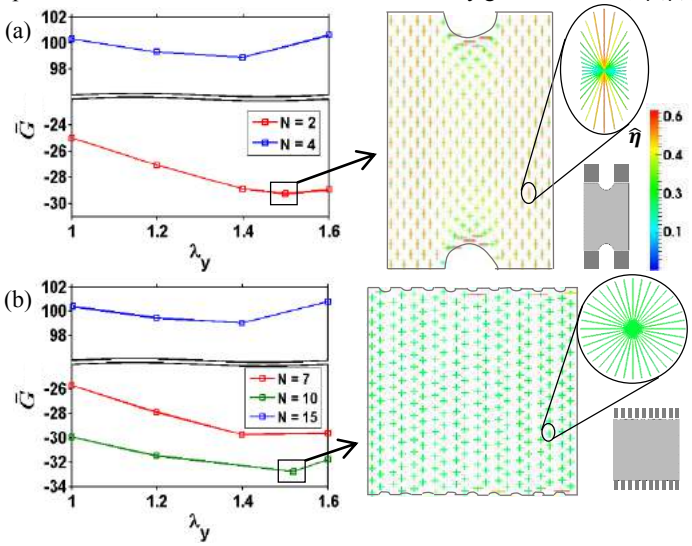

Figure 2: Free energy of the system ($\bar{G}$) and vector plot of SF concentration ($\hat{\eta}$) for: (a) Cell is spread on wide (L_c/L_r = 3) ridges and grooves; (b) Cell spread on thin (L_c/L_r=12) ridges and grooves

Experiment 2: In a second series of simulations, a circular unadhered cell spreads on a V-shaped adhesion patch of length L_a, as shown in Fig. 3. For a cell of radius r_c , the spreading process is parameterized in terms of the proportion of the cell perimeter ωr_c that adheres to the patch. The stretch along the patch is therefore given as $\lambda_p = L_a/\omega r_c$. The influence of the ratio of initial cell size to groove length is also considered.

For the longest adhesion patch ($r_c/L_a = 0.38$) $\bar{G}$ is high due to high levels of elastic deformation required for spreading. For the shortest adhesion patch ($r_c/L_a = 0.44$), $\bar{G}$ is high due to the low levels of SF formation associated with limited cell spreading. The minimum free energy spread state, characterized by λ_p, is dependent on the length of the adhesion patch. The lowest value of $\bar{G}$ is computed for $r_c/L_a = 0.40$, with $\lambda_p = 1.24$. In this configuration highest strains occur in the region of the free unadhered edge of the cell. Global conservation of cytoskeletal proteins therefore dictates that the SFs form predominantly parallel to the free edge.

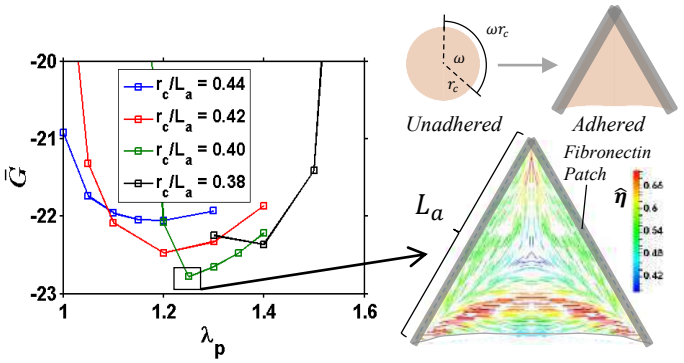

Figure 3: Free energy of the system ($\bar{G}$) and vector plot of SF concentration ($\hat{\eta}$) for cell spreading over V-shaped adhesion patch.

DISCUSSION

The modelling framework presented here captures the key trends reported in the studies by Lamers *et al.* [3] and Théry *et al.*[4], suggesting that cells tend to assume a minimum free energy ($\bar{G}$) spread state. This minimum free energy state is determined by competition between the elastic free energy due to deformation of the passive cytoplasm and the cytoskeleton free energy, subject to a non-local conservation of cytoskeletal proteins throughout the cell. Simulations suggest that the evolving strain distribution during spreading is a critical determinant of the SF distribution. This model represents a significant advance on recent phenomenological approaches to the analysis of cell spreading and SF remodeling [6, 7].

INTRODUCTION

With the FDA approval of HeartFlow®, CFD tools are making their way to clinical management of cardiovascular diseases. All these tools need to be validated before being applied into clinical workflow. Intracranial aneurysm (IA) is one challenging cardiovascular disease, since their rupture is catastrophic, but not often, and treatment complication can be significant. Utilizing image-based computational fluid dynamics (CFD), detailed flow dynamics can help neurosurgeons make better treatment plans. However, currently no such modeling tools allow routine integration of flow dynamics in clinical workflow.

To this end, we have developed AView, a clinician-oriented, integrated computation tool for aneurysmal flow dynamics, morphology, and risk and data management to support clinical management of IAs.[1] At the heart of this tool is the CFD solver, Gnuid.[2] In this study, following the ASME V&V20,[3] we aim to validate AView based on the intended use, a patient-specific IA under physiological flow using particle image velocimetry (PIV) system.

METHODS

AView is employed to simulate the hemodynamics in a typical patient-specific internal carotid artery (ICA) aneurysm. A physical model (phantom) of this aneurysm is fabricated and placed in an *in vitro* flow loop, which is operated under a range of physiological flow conditions (flow rate of 189-360 *mL/min*, heart rate of 60-90 *bpm*). The CFD settings match these experimental conditions. To measure the flow fields under each of the experimental flow conditions, we employ planar PIV and acquired 40 instantaneous flow fields in each cardiac cycle, continuously for 50 cycles to obtain averaged peak systole, end-diastolic and mean flow fields at middle coronal and transverse planes. The working fluid is a mixture of water, glycerin, and sodium iodine (density=1.23 g/cm^3, viscosity=4.03 *cP*) to mimic the blood properties.

Validation

We present the validation results at three levels: a) Qualitative comparison; b) Quantitative comparison; c) Uncertainty analysis of PIV, CFD and their comparison, following their definition in ASME V&V20.[3]

Qualitative Comparison

To validate the aneurysmal flow patterns from CFD simulations, we plot 2D velocity contours and velocity vectors on the time-averaged flow field and on the peak and end-diastolic time points on the middle planes, and compare them against PIV measurements.

Quantitative Comparison

We quantitatively compare the velocity magnitude on the intersecting line (100 discretized points) of coronal and transverse planes and plotted the velocity magnitude from both CFD and 3 sets of PIV measurements. Furthermore, we apply two commonly used parameters to quantify the differences in point-wise velocity vectors between CFD and PIV flow field data.[4] The first variable, angular similarity index (ASI), measures the similarity of the directions of the velocity vectors between CFD and PIV results and was defined as:

$$ASI = \frac{u_{CFD}.u_{PIV}}{|u_{CFD}|\,|u_{PIV}|} \quad (1)$$

The range of ASI is [-1, 1], with 1 being the highest similarity. The second variable, magnitude similarity index (MSI), quantifies the similarity in the *magnitudes* of the vectors and was defined as:

$$MSI = 1 - \left|\frac{|u_{CFD}|}{max(|u_{CFD}|)} - \frac{|u_{PIV}|}{max(|u_{PIV}|)}\right| \quad (2)$$

The variable MSI varies in the range [0, 1], with 1 being the value with the highest similarity in the magnitude.

Uncertainty Analysis

The model form uncertainty represents the best estimation of the model form error, which lies within the range

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$u_{model} = E \pm u_{val} \quad (3)$$

where u_{model} is the model form uncertainty, E is the comparison error between simulation and experimental outputs, and u_{val} is the combined uncertainty of the errors in the overall validation.[3]

The combination of the errors that arise during code validation is estimated in the form of a validation uncertainty, u_{val}. These errors combine in the form of uncertainties as

$$u_{val} = \sqrt{u_{num}^2 + u_{input}^2 + u_D^2} \quad (4)$$

where u_{num}, u_{input}, and u_D are numerical uncertainty, input parameter uncertainty and experimental uncertainty, respectively.[3]

RESULTS

Qualitative Comparison

As one example, Figure 1 shows qualitative comparison between CFD simulations and 3 sets of PIV measurements on the middle coronal plane under the flow condition of 256 *mL/min* and 70 *bpm* for the mean flow field. We observe that the flow patterns of CFD and PIV are very similar to each other, showing aneurysmal flow going through the distal end of wall and forming a vortex inside the sac.

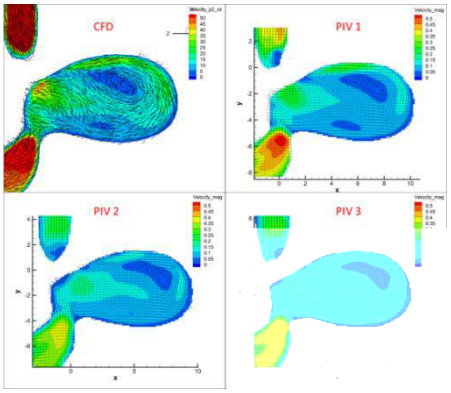

Figure 1: Qualitative comparison between CFD and 3 sets of PIV.

Quantitative Comparison

We perform quantitative comparison and subsequent uncertainty analysis on the intersecting line (100 points) between the middle coronal and transverse planes. Figure 2 plots the velocity on the line from CFD and PIV (mean ± sd). In general, the velocity has the similar trend, but different magnitudes, especially at the high flow region close to the aneurysmal distal wall. Furthermore, the calculated high average ASI and MSI values of 0.84 and 0.83 demonstrate decent agreement between CFD and PIV.

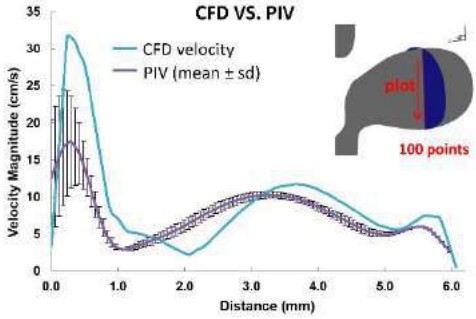

Figure 2: Quantitative comparison between CFD and PIV.

Uncertainty Analysis

Following V&V20 guidance, we calculate numerical uncertainty $u_{num,}$ input parameter uncertainty u_{input}, and experimental uncertainty $u_{D.}$ Figure 3 shows the CFD plot with combined numerical and input parameter uncertainty as error bars against the PIV velocity mean with the experimental uncertainty as error bars. Figure 4 shows estimated error with error bars indicating validation uncertainty, where we observe small errors in most regions, except for the high velocity region near the aneurysm wall. Furthermore, the average relative error is calculated to be 22.7%. However, if we exclude the near wall region (20% points), the average relative error is 13.6%.

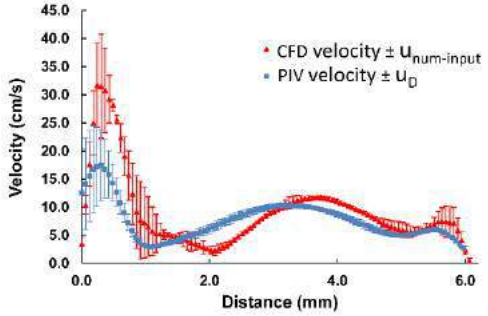

Figure 3: PIV and CFD velocity along the intersecting line with error bars indicating combined numerical and input parameter uncertainty, and experimental uncertainty, respectively.

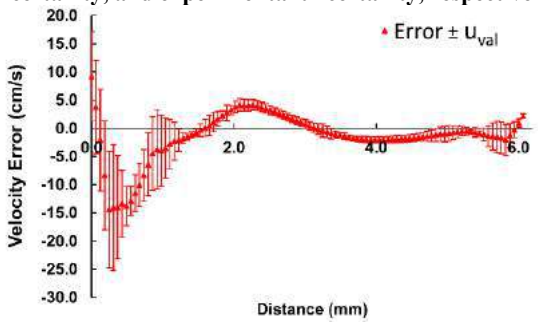

Figure 4: Estimated comparison error along the intersecting line with error bars indicating validation uncertainty.

DISCUSSION

Clinically imaged-based CFD has high potential to be used in the clinical world, provided that they are accurate and validated. In this study, we demonstrate that CFD results from AView match with PIV measurements under different physiological flow conditions in a typical aneurysm (in this abstract we only report results under one flow condition). At the same time, we also observe that the CFD-derived velocity has different magnitude as from PIV measurements (Figure 1), and location of the vortex from CFD and PIV are not at the exact same location. We believe this is due to the non-rigid material property of silicone phantom model used in PIV measurement, while in CFD the wall is assumed as rigid. During the PIV experiment, we observe noticeable movement for the aneurysm wall, probably causing lower velocity magnitude from PIV and that the vortex in PIV is closer to the aneurysm tip wall (Figure 1).

CONCLUSION

ASME V&V20 has been applied to perform the uncertainty analysis for an integrated, clinical modeling tool for IA blood flow dynamics. Our validation and uncertainty analysis demonstrate that AView has a reliable CFD solver to calculate aneurysm flow field.

INTRODUCTION

Three-dimensional motions of the knee joint are usually described with respect to the knee joint coordinate system originally developed by Grood and Suntay [1]. Previous studies indicated that the flexion-extension axis of the coordinate system passes near the femoral insertions of the collateral ligaments [2], while the internal-external axis is located close to the center of the tibial axis in the human knee joints [3]. This coordinate system has been widely accepted in biomechanical research and has been utilized for the mechanical testing of the human knees [4-6]. Recently, this coordinate system has been also used for the biomechanical tests of porcine [7] and canine stifle joints [8], although detailed information as regard to the relative location of the coordinate system remain unclear in these joints. Therefore, the present study was undertaken to determine the relative location of the knee joint coordinate system axes with respect to porcine and canine stifle joints using a robotic system. With a novel geometrical representation of the helical axis devised in the present study, the 3-dimensional position and orientation of the rotational axes of these animal joints were assessed.

METHODS

Novel geometrical representation of the helical axis

It is well known that any 3-dimensional motion of a rigid body can be expressed by a translation along and a rotation about a unique axis, the so-called helical axis. Although mathematical formulae for the helical axis have been proposed in previous studies, here we present a novel, geometrical representation of the axis which can be easily understood. Consider a rigid body locating at A expressed with a position and orientation described by a [4x4] homogeneous transformation matrix, T, with respect to the reference coordinate system. If the rigid body moves to another location, B expressed with the position and orientation described by another homogeneous transformation matrix, T', the relative motion of the rigid body, H, can be calculated as follows.

$$H = T'\,T^{-1} = \begin{bmatrix} n_x & o_x & a_x & d_x \\ n_y & o_y & a_y & d_y \\ n_z & o_z & a_z & d_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (1)$$

The rotation angle, θ and orientation, $\boldsymbol{k}$, of the helical axis that translates T to T' can be described as follows [9].

$$\theta = \tan^{-1}\left(\frac{\sqrt{(o_z-a_y)^2+(a_x-n_z)^2+(n_y-o_x)^2}}{(n_x+o_y+a_z-1)}\right) \quad (2)$$

$$\boldsymbol{k} = \begin{bmatrix} k_x \\ k_y \\ k_z \end{bmatrix},\ k_x = \frac{o_z-a_y}{2\sin\theta},\ k_y = \frac{a_x-n_z}{2\sin\theta},\ k_z = \frac{n_y-o_x}{2\sin\theta} \quad (3)$$

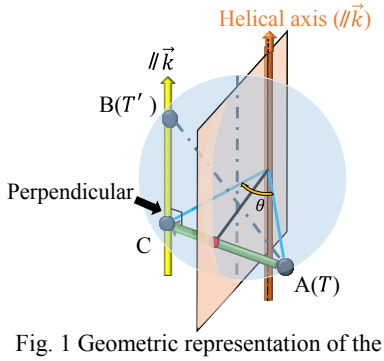

Fig. 1 Geometric representation of the HA

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Since the rigid body located at A is rotated around the helical axis to a new location C, and then translated to B along this axis, the angle ACB is always 90 degree (Fig.1). Therefore, the transit location C is on a sphere that has the line AB as a diameter. The transit location C can be determined as the intersection between the sphere and a line parallel to $\boldsymbol{k}$ that passes through B. Imagine a flat plane perpendicular at the midpoint of the line AC. The helical axis is determined as the line in this flat plane with the orientation $\boldsymbol{k}$ where the angle A-axis-C is θ, as shown in Figure.1.

Determination of the rotation axes of animal and human knees

Porcine stifles (n=3), canine stifles (n=3), and a human knee (n=1) were used and each knee was fixed to the robotic system (FRS2015, Technology Service, Japan) [10]. First, flexion-extension rotation was applied to the joint at about 1.5 degree/s to 90 degree of flexion by setting the other 5 DOFs - except the flexion-extension DOF - under force control with prescribed force/moment at 0. After the joint was extended to the initial orientation, internal-external rotation was applied to the joint at about 1 degree/s up to 1 N-m in canine stifles, 2 N-m in porcine stifles, and 5 N-m in human knees. During the application of internal-external rotation, all DOFs except the internal-external and flexion-extension DOFs were set under force control with prescribed force/moment at 0.

The kinematic data collected during the tests were analyzed to determine the homogeneous transformation matrices of the tibia as a function of rotation angle. A matrix, T, at a rotation angle and another matrix, T' at the angle plus 10 degree were substituted to equation (1), and the helical axis of the animal and human joints during the tests were determined following the above-indicated procedure.

RESULTS

The helical axis representation of the flexion-extension rotation axis of the stifles and knees were similar to those previously determined for the human knees [2], with no significant difference observed between porcine, canine, and human joints. However, a significant difference was found in the helical axis representation of the internal-external rotation in these species. In porcine stifles and human knees, the axis was located at the center of the joint in the frontal plane (Fig. 2(a)), while the axis was slightly tilted in the sagittal plane (Fig. 2(b)) possibly because of nominal flexion at extension. In contrast, the helical axis representation of the internal-external rotation axis of canine stifles was located laterally outside of the joint in the frontal plane, as shown in Fig. 2(c), while the axis was slightly tilted in the sagittal plane, similar to the porcine and human joints (Fig. 2(d)).

DISCUSSION

In the present study, a novel representation of the helical axis was developed in which the axis can be described geometrically. The authors ensured that the developed geometrical representation of the helical axis is mathematically identical to a vector representation of the helical axis previously reported [11]. It is beneficial to use the currently developed representation because the geometrical features of the axis can be easily recognized with a minimum of mathematical calculations. Using the developed representation of the helical axis, the flexion-extension rotation and internal-external rotation axes were determined in porcine and canine stifles as well as human knees. It is worth noting that the internal-external rotation axis was located more than 2 cm laterally outside of the canine joints (Fig. 3) while no difference was observed in the flexion-extension axes in the animal and human joints. Thus far, the authors have found no valid reason for the distinct characteristic of the internal-external axis in the dog stifle joint, though it may be attributed to the mechanical role of the joint that assumes a half-bent posture during standing and normal gait. Further experimental and analytical studies are required to determine the helical axis of stifle joints in various activities and to clarify the biomechanical functions of these joints.

EFFECT ON OLIGOSACCHARIDE GRAFTING ON THE POLYELECTROLYTE AND PROTONATION DYNAMICS OF POLYETHYLENIMINE

Saswati Basu, Danielle N. Miller, Stacy N. Apugo, P. L. Chandran

Chemical Engineering Department
Howard University
Washington, DC, USA

INTRODUCTION

Polyethylenimine (PEI) is one of the most commonly used polymers for condensing DNA in cell-transfection and gene-therapy applications (1). The 2.5kDa polymer backbone is intrinsically hydrophobic, semiflexible, and contains closely-spaced amine groups which are charged when protonated. As a result, the polymer exhibits unusual polymer dynamics. Our studies indicate that the backbone protonation occurs discontinuously with increasing pH, and a clustered phase exists in equilibrium with free polymers at conditions of high inter-chain and low intra-chain repulsion. Mannobiosylated PEI is commonly used for targeting DNA to immune cells and to lower drug induced toxicity (2). Our goal is to understand how the grafting of a hydrophilic moiety alters the semiflexibility, protonation, and clustering dynamics of the PEI backbone; and if these alterations significantly affected the interaction with DNA to form condensed nanoparticles.

METHODS

Solutions of PEI (Polysciences Inc., Warrington, PA) and mannobiosylated PEI (Polyplus Transfection Inc., 67400 Illkirch-Graffenstaden, France) were prepared at different polymer and salt concentrations, and at varying pH. The protonation profile of the polymer was obtained by pH titration with the polymer-less solution as reference in order to control for CO_2 dissolution and other artifacts. The free polymer extensibility was assessed from hydrodynamic diameter measurements of the polymer in Dynamic Light Scattering (DLS) experiments. AFM images of surface-trapped polymers were used to corroborate the trends in polymer extensibility. The dynamic interchange between free and clustered polymers was investigated by studying the multiple relaxation times evident in DLS autocorrelation data. Osmotic experiments were used to affirm the clustering effects. DNA nanoparticles were made by incubating the solution of DNA, PEI, and salt overnight. Atomic Force Microscopy (AFM) images of the particles were used to assess changes in the DNA condensation pattern.

RESULTS

The distribution between the free and clustered phase was investigated as a function of salt. 2.5 kDa PEI shows an unusual phenomenon of salt-dependent clustering; the formation of clusters decreases as salt concentration is increased to physiological levels, but then increases at higher salt concentrations. This phenomenon can be attributed to the balance between inter- and intra- chain charge repulsion.

pH changes affect the protonation of the polymer, which appears to occur in characteristic regimes (Fig. 1). Interestingly, the protonability is not affected by the presence or absence of a clustered phase.

The extensibility (i.e. the persistence length) of the free 2.5kDA polymer increases with intra-chain repulsion and decreases with inter-chain repulsion; and varies with both pH and salt conditions.

The grafting of mannobiose to the PEI backbone significantly changes the polymer extension, and its clustering and protonation dynamics.

We investigated if the changes in PEI clustering, protonation, and oligosaccharide grafting altered its interaction with DNA and the subsequent condensation into nanoparticles. AFM images are

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

presented showing the condensation pathway of the nanoparticle for different states of the PEI polymer.

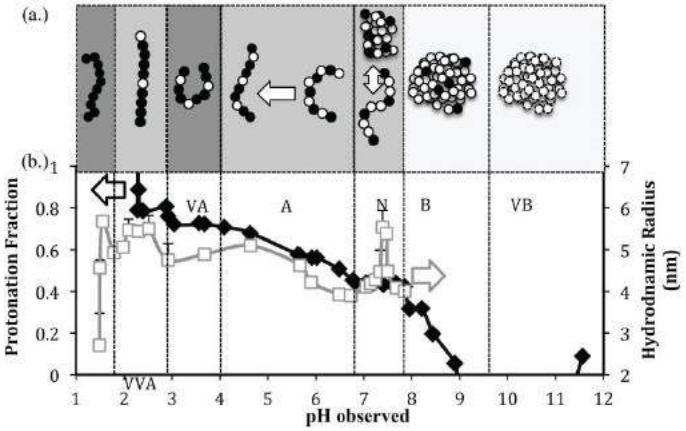

Figure 1. pH dependent protonation-polyelectrolyte interplay in 4.08mM PEI solution with 150mM NaCl. (a) Schematic depicting the protonation and polyelectrolyte dynamics of the polymer in different regions. Charged PEI monomers are shown as black beads and uncharged monomers as white beads. (b) Simultaneous tracking of PEI protonation and backbone extension state in different pH regimes.

DISCUSSION

2.5kDa PEI is the simplest model of a hydrophobic semiflexible polyelectrolyte. Our studies indicate that the polymer is richly sensitive to the solution conditions, and that the polymer dynamics is altered by the grafting of hydrophilic moieties. Understanding the polymer dynamics will allow scientists to design DNA drug delivery vehicles with tailored organization and interaction specificity (3).

A CT BASED MODEL OF THE FRACTURE OF CALCIFIED ATHEROSCLEROTIC PLAQUES

Brían L. O'Reilly (1), Peter E. McHugh (1), Patrick McGarry (1)

(1) Biomedical Engineering
National University of Ireland, Galway
Galway, Ireland

INTRODUCTION

Atherosclerosis is a major cause of cardiac disease and strokes worldwide. This occurs due the blockage of an artery by a lesion of atherosclerotic plaque. The experimental characterization of plaque tissue mechanical behavior is distinctly lacking in the literature in comparison to the extensive experimental characterization of healthy arterial tissue. Advances in current understanding of plaque biomechanics can potentially guide the design of angioplasty devices and assist in the planning of clinical intervention.

This study investigates the delamination of calcified particles from the fibrous matrix of the plaque. This mode of material damage may play an important role in plaque rupture, leading to the onset of adverse clinical consequences, e.g. strokes [1].

METHODS

Excised human atherosclerotic plaque samples were acquired from University College Hospital Galway as approved by the hospital's ethical research committee. The plaque samples were scanned using computed topography (CT) to generate accurate 3D images for calcifications present in the plaque. CT scans were used to generate bi-phasic finite element models consisting of hard calcifications embedded in a soft fibrous matrix (Figure 1).

The fibrous matrix of the plaque samples were isolated and subjected to biaxial testing. Results reveal that the plaque fibrous matrix is significantly stiffer in the circumferential direction than in the axial direction. A compressible form of the HGO anisotropic hyperelastic model [2, 3] is calibrated using the biaxial test results, whereby the stress tensor is given as

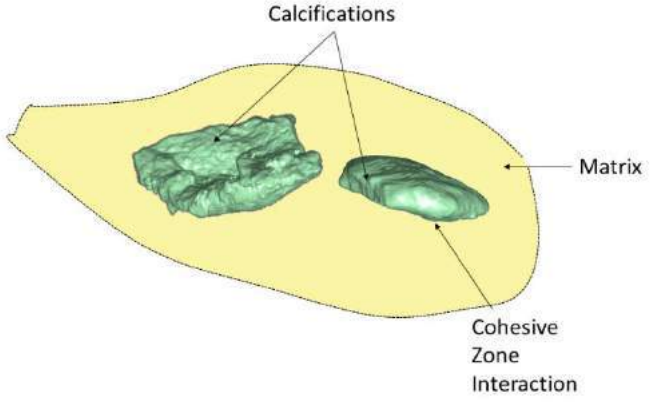

Figure 1: CT generated 3D calcification geometries embedded in a fibrous matrix. A cohesive zone fracture model is implemented at the interface between the calcifications and the matrix.

$$\boldsymbol{\sigma} = \kappa_0(J-1)\mathbf{I} + \mu_0 J^{-1}\left(\overline{\mathbf{B}} - \frac{1}{3}\bar{I}_1\mathbf{I}\right) + 2J^{-1}k_1\sum_{i=4,6}(I_i-1)\exp[k_2(I_i-1)^2](\boldsymbol{a_i}\otimes\boldsymbol{a_i}) \quad (1)$$

where κ_0 is the isotropic bulk modulus, μ_0 is the isotropic shear modulus, k_1 and k_2 are the anisotropic material constants, $\boldsymbol{a_i}$ is the fibre directional vector, J is the determinant of the deformation gradient, $\bar{I}_1$ is the first invariant of the right Cauchy-Green tensor and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

I_4 and I_6 are the anisotropic invariants describing the deformation of reinforcing fibres.

Stress relaxation testing was performed on the fibrous matrix in both the circumferential and axial directions and results were used to calibrate Prony series parameters to represent the tissue viscoelasticity.

The CT generated plaque finite element mesh is embedded in an idealized artery geometry. Again the anisotropic hyperelastic formulation (Eqn. 1) is used to model the artery wall. Angioplasty is simulated by expanding a balloon in the artery lumen with contact surfaces being defined between the balloon and the outer surface of the plaque/artery.

A cohesive zone fracture model is applied the interface between the plaque calcifications and the fibrous matrix. A mixed mode cohesive zone model proposed by McGarry et al. [4] is used, whereby the work of separation is given as

$$\phi(\Delta_n, \Delta_t) = \phi_0 + \sigma_{max} \exp(1) \left(1 + \sqrt{\frac{\Delta_n^2}{\delta_n^2} + \frac{\Delta_t^2}{\delta_t^2}}\right) \exp\left(-\sqrt{\frac{\Delta_n^2}{\delta_n^2} + \frac{\Delta_t^2}{\delta_t^2}}\right) \quad (2)$$

The mode I and mode II interface strengths are assumed to be equal and values of the characteristic lengths δ_n and δ_t are chosen so that the interface is several orders of magnitude stiffer than the surrounding materials. A parametric study of the interface strength (σ_{max}) is performed whereby the angioplasty balloon is expanded until the calcified particles debond from the surrounding fibrous matrix.

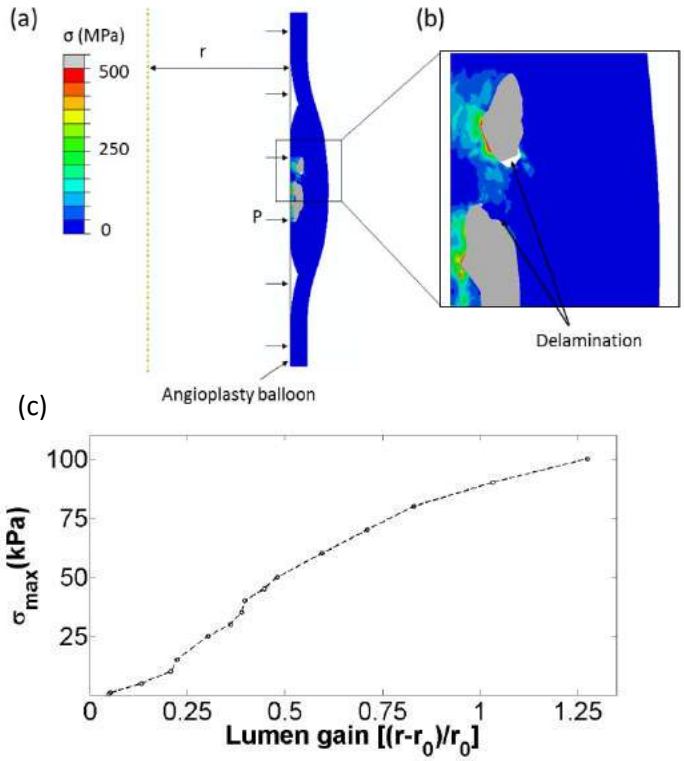

Figure 2: (a) Contour plot of the maximum principal stress of the angioplasty model. (b) Magnified section showing the presence of separation in the cohesive interface. (c) Graph demonstrating of the relationship of lumen gain at calcification delamination and the interface strength.

RESULTS

The computed deformation of the artery and plaque is shown in Figure 2(a) following balloon expansion from an initial lumen radius r_0=5.25mm to a radius r=7.59mm, i.e. a lumen gain of 45%. The expanded balloon contacts both the plaque and the artery, resulting in significant localized deformation of the plaque.

The distribution of maximum principal stress is also shown in Figure 2. Stress concentration occurs in the fibrous plaque near the calcified particles.Ssuch stress concentrations result in mixed mode delamination of the fibrous matrix from the calcifications, as detailed in Figure 2(b).

The relationship between the matrix-calcification interface strength and the lumen gain at the onset of delamination is shown in Figure 2(c). A non-linear relationship is observed. A lumen gain of 1.0 requires an interface strength of 98.4kPa in order to avoid delamination of plaque calcifications.

DISCUSSION

This study presents the first investigation into the delamination of calcifications during balloon angioplasty using patient specific calcification geometries derived from CT scans. The relationship between lumen gain during angioplasty and the onset of delamination for a range of interface strengths is uncovered. Experimental studies are currently being conducted to characterize σ_{max} for calcified excised plaques. The experimental and computational methodologies developed in this study can potentially be used for planning of patient specific clinical interventions and device design.

MODELING THE VISCOELASTIC PROPERTIES OF PULMONARY VESSELS IN A HYPERTENSIVE RAT

Erica R. Pursell (1), Daniela Vélez-Rendon (1), Daniela Valdez-Jasso (1)

(1) Bioengineering Department
University of Illinois at Chicago
Chicago, IL, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a disease of the heart and pulmonary vessels characterized by elevated blood pressure. To adjust for elevated blood pressures, pulmonary vessels undergo remodeling. This remodeling changes the pulmonary arteries' (PA's) ability to store and deliver the entire stroke volume of the right ventricle (RV) which then hinders the heart's ability to pump blood *with heart failure as an end stage of the disease*[1].

One way of quantifying the arteries' ability to store and deliver blood is determining the mechanical properties of the vessels. There have been studies on the mechanical properties of human and ovine vasculature using either Voigt [2, 3] or Kelvin [4, 5] viscoelastic models. Alastruey *et al*. assumed material properties of human vessels to be similar to those of silicone [2] while Valdez-Jasso *et al.* found the parameter η (time dependent coefficient) for ovine vessels to be location specific [4].

To elucidate our understanding of the disease progression, we propose to develop mechanistic models that can incorporate important vascular mechanical properties. Our goal is to establish a constitutive equation that accurately portrays vessel behavior in normo- and hypertensive animal.

METHODS

The experimental protocols used for this study were approved by University of Illinois at Chicago Animal Care and Use Committees. PA segments were harvested from two 12-week-old male Sprague-Dawley rats weighing 350 grams (Charles River Laboratories). At 8 weeks of age, one rat was treated with a subcutaneous monocrotaline (MCT) injection to induce PAH while the other was injected with a placebo solution. The animals were then left for four weeks to allow the PAH to reach a severe state.

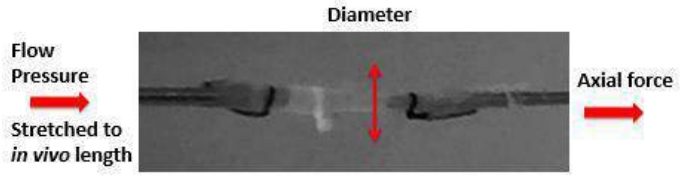

Figure 1: Schematic of the tubular biaxial mechanical testing set-up. Flow and pressure measured *in vivo* are used as inputs, axial stretch is prescribed, and diameter and axial force measured

Post invasive hemodynamic measurements confirmed the normotensive state of the placebo and hypertensive state of the MCT animal before the arterial segments were harvested from left pulmonary arteries. Segments were cannulated on each end and underwent tubular biaxial testing using a Bose biodynamic chamber (Figure 1). The vessels were tested at three axial stretches, *in vivo* and ± 5% where *in vivo* stretch was taken to be 40% of the *ex vivo* length. Pressure and flow were prescribed (and recorded) to simulate values measured *in vivo* and diameter was measured using a laser micrometer during the experiment.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Two viscoelastic models were used for modeling of our data: the Voigt (Equation 1) and the Kelvin (Equation 2) viscoelastic models.

$$P = kA + \eta \frac{dA}{dt} \quad (1)$$

$$\frac{d\epsilon}{dt} = \frac{\frac{k_2}{\eta}\left(\frac{\eta}{k_2}\frac{dP}{dt} + P - k_1\epsilon\right)}{k_1 + k_2} \quad (2)$$

$$A = 2\pi\left(\frac{d}{2}\right)^2 \quad ; \quad \epsilon = \frac{A - A_{min}}{A_{min}} \quad (3)$$

These models are derived from a mechanical body with one spring and one dashpot in parallel (Voigt) and another spring in series with the dashpot (Kelvin model). In these relations, P is representing blood pressure, k the spring constant, η the dashpot constant, A the vessel cross-sectional area, d the measured diameter, and ϵ the circumferential strain. For the Voigt model, area was fitted using a 7 term Fourier approximation and used to predict pressure. In the Kelvin model, the pressure was fitted with a 7 term Fourier approximation to predict a change in strain over time, which was then solved using MATLAB's ODE solver and fminsearch and converted to area. Pressure and area are plotted for comparison (Figure 2).

RESULTS

The Voigt model produced a good initial estimate for our pressure, but it was not able to characterize all of the features in the data waveform. The Voigt model closely predicted the oval shape of the placebo data, but not it's J-shape (Figure 2, left column). The MCT data waveforms show different and unique features. In this case, the Voigt model was not sufficient to predict the leaf shape of the pressure-area relation (Figure 2, right column). Here the predicted hysteresis was greater than the measured, and the slope of the pressure-area plot was not large enough. In contrast, the Kelvin model was able to more closely represent the more complex behaviors of both vessel types. It accurately reflected the J-shape in the placebo data and for *in vivo* stretch of the MCT data, expressed the lower hysteresis and increased slope. However, this was not true when the axial stretch was changed in the MCT-treated vessel. The parameters of the Kelvin model are shown in Table 1 with relatively low error values contrasted with much larger error in the Voigt model (Table 2).

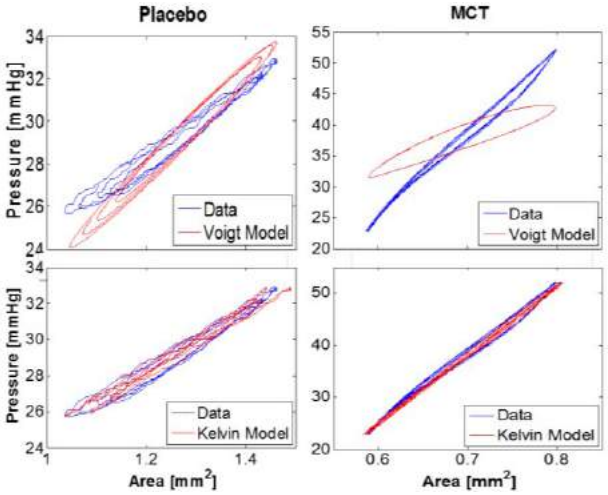

Figure 2: Pressure-area relation in a placebo (left column) and PAH (right column) left-pulmonary artery. As shown, the cross-sectional area prediction is improved from the Voight model (top panels) to the Kelvin model (bottom panels).

Table 1: Results for placebo data using Kelvin model. Top row are the initial values fed into the optimizer. Lower rows show optimized parameters for each respective axial stretch. Right column is the 2-norm error between prediction and measurement.

	$\eta\left[\frac{mmHg*s}{mm^2}\right]$	$k_1\left[\frac{mmHg}{mm^2}\right]$	$k_2\left[\frac{mmHg}{mm^2}\right]$	Error [mm²]
Guess	0.1	1	20	----
35% Stretch	0.194	-0.0002	18.044	2.50
40% Stretch	0.133	0.0006	0.647	0.64
45% Stretch	0.235	-0.0011	18.035	1.34

Table 2: Optimal parameter values found using the Voigt and Kelvin models in placebo and MCT-treated animals. Right column is the 2-norm error between prediction and measurement. Note that error has different units, depending on model used.

	$\eta\left[\frac{mmHg*s}{mm^2}\right]$	$k_1\left[\frac{mmHg}{mm^2}\right]$	$k_2\left[\frac{mmHg}{mm^2}\right]$	Error
Placebo (Voigt)	-1.82	----	23.07	514.24 [mmHg]
Placebo (Kelvin)	0.13	0.0006	0.65	0.65 [mm²]
MCT (Voigt)	-16.50	----	49.68	545.62 [mmHg]
MCT (Kelvin)	0.06	0	78.24	0.17 [mm²]

DISCUSSION

This study compared the Voigt and Kelvin viscoelastic models in the *in vivo* stretch values of the placebo and MCT treated animals. One limitation in comparing these two models is that the results are time series with different units, posing difficulty in computing a standardized error. While the Voigt model proved to be a good initial point, especially for the placebo data, the model failed to reflect more complex vessel waveform features and gave an overall larger error between predicted and measured values. Although the Kelvin model predicted vessel behavior more accurately than the Voigt model, the model was unable to match the behavior exactly in the MCT data. Hence, we propose to increase the number of animals in our study and explore a more complex viscoelastic model.

INTRODUCTION

Bicuspid aortic valve (BAV) is one of the common congenital heart diseases and said to be associated with progression of aortic aneurysms[1]. The incidence of BAV is not very high (1~2% of population), but higher incidence of aortic aneurysm in BAV patients often matters and attracts the interest of clinicians. Hemodynamic forces and genetic inheritance are thought as potential pathological causes [1].

Due to these clinical facts, some conventional studies were conducted to elucidate the association and consequently some prominent characteristics were found. For example, Hope and his colleagues[2] employed four dimensional phase-contrast magnetic resonance images (4D PC-MRI) and clarified that aortic systolic jet in BAV patient was helical. Schaefer and his colleagues[3] found that the shape of BAV affected the location of aneurysm progression. Furthermore, a numerical study[4] implies that BAV leads to increased wall shear stress at ascending aorta. However, the relation between BAVs and aortopathy is still not clearly explained in terms of hemodynamics.

In this study, we aim at finding some typical hemodynamic characteristics seen in BAV and presuming dominant factors triggering off aortic aneurysms. MRI studies are useful to observe the blood flow in aorta and its outcome is qualitatively reliable. On the other hand, computational approaches enable us to predict blood flow assuming various kinds of situations. Therefore, we use a computational approach to investigate the effects of BAV and its phenotypes on aortic hemodynamics. We construct three-dimensional left ventricle-aorta coupling model and conduct numerical simulation with several kinds of aortic valve model. A lumped-parameter model is also involved to take into account the effects of a whole circulatory system.

METHODS

CT angiography and ultrasound images provided by Funabashi Municipal Medical Center (Chiba, Japan) were employed for construction of three-dimensional models of left ventricle and aorta, respectively. First, we derived the coordinates of centerline and diameter of aorta with equally spaced intervals. The aorta model was then constructed by assuming elliptic cross-sectional shape. The left ventricle model was also constructed in almost the same way but using 11 images to reproduce periodical dilatation and contraction over a cardiac cycle.

In numerical analysis, we employed *in-house* solver built by Liu[5]. Governing equations were three-dimensional, unsteady, incompressible Navier-stokes equation and equation of continuity with the pseudo-compressibility method. These equations were discretized by the finite volume method. We employed pressure waveforms in left atrium, left ventricle and ascending aorta as boundary conditions. These waveforms were derived from a lumped parameter model.

The opening and closing of mitral and aortic valve were two-dimensionally modeled by manipulating boundary conditions at valve orifice; non-slip and free flow conditions were imposed on closed and opened parts, respectively. Particularly, we prepared four kinds of valve phenotypes for aortic valve: tricuspid aortic valve (TAV: the normal), LR-BAV, AP-BAV and asymmetrical AP-BAV (See Figure 1). TAV and asymmetric BAV patterns were modeled based on previous studies whereas completely symmetric pattern was assumed for the other two valves.

Left ventricle and aorta were coupled by spatially overlapping interface. Velocity and pressure at overlapped interface were mutually interpolated at each computational time step since flow in left ventricle and aorta was solved separately. Reynolds number and Strouhal number are 1042 and 0.1, respectively. To evaluate the results, we see

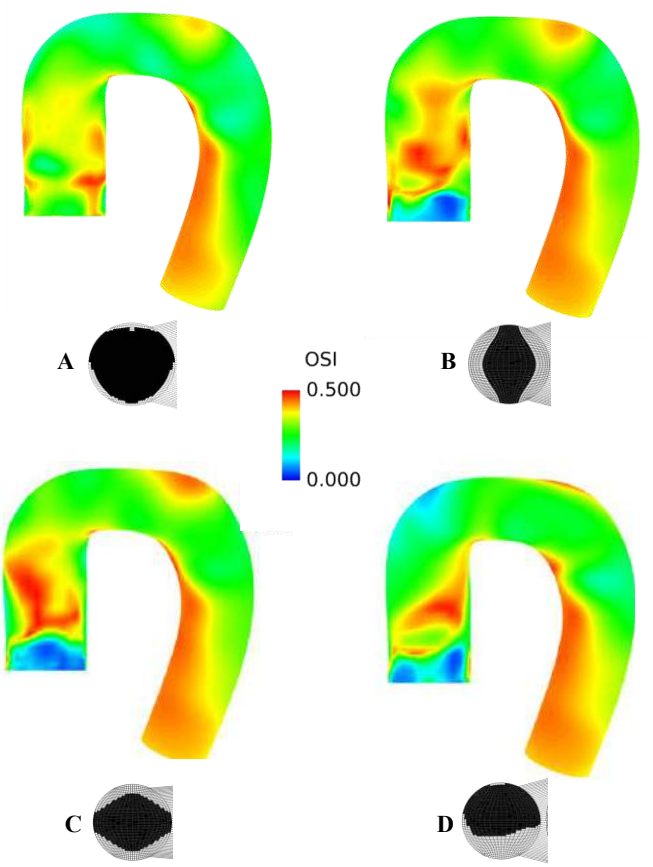

Figure 2: OSI distribution of four valve models. The symbols correspond to those in Figure 1.

oscillatory shear index (OSI) in addition to ordinary physical quantities. OSI is defined as

$$\mathrm{OSI} = \frac{1}{2}\left(1 - \frac{\tau_{mean}}{\tau_{abs}}\right), \tag{1}$$

$$\tau_{mean} = \frac{1}{T}\left|\int_0^T \tau dt\right|, \ \tau_{abs} = \frac{1}{T}\int_0^T |\tau|\, dt, \ \tau = \mu\frac{\partial \mathbf{u}}{\partial \zeta}, \tag{2}$$

where ξ is grid coordinate system along the vessel wall, $\mathbf{u}$ velocity vector, τ wall shear stress, μ viscosity, T cardiac duration. Larger OSI is associated with directionally fluctuating wall shear stresses over a cardiac cycle hence with aortic abnormalities.

RESULTS

Some significant differences are found in streamlines (Figure 1) and OSI distribution (Figure 2). In BAV models, systolic jet migrates toward the vessel wall while comparatively uniformly distributed flow was observed in TAV model (Figure 1). Furthermore, the direction of systolic jet is different among three BAV models. OSI distribution shows not only significantly different distribution at ascending aorta but also slightly larger OSIs at outer curvature of aortic arch in BAV model. (Figure 2)

DISCUSSION

Deviation of systolic jet seen in the BAV models was also observed in previous study [4]. However, we cannot see helical flow and increased wall shear stresses at ascending aorta in the BAV models, which was seen in the some studies[2,4]. This is probably because some physiological conditions are not taken into account in the present study such as valve motion due to the dilatation and contraction of heart and three-dimensional shape of valve. We can see the difference in OSIs at aortic arch. Since a previous clinical observation [3] pointed out that the location of progression of aortic aneurysms varied according to BAV phenotypes, this characteristic may be one of the factors predicting the aneurysm development.

INTRODUCTION

Abdominal aortic aneurysms (AAA) are enlargements of the abdominal aorta, diagnosed among 12.5% of men and 5.2% of women over age 75 [1]. AAA progression and rupture is biomechanically explained by a homeostatic imbalance within the ECM; as patients age, elastin levels decrease as overall collagen levels rise, resulting in increased vascular stiffness and AAA [2]. Currently, patients with AAA diameters dilated from the typical 2cm to larger than 5.5cm are treated with endovascular aneurysm repair. Treatments for AAA between 3 and 5.5cm are limited, so most clinicians move forward with increased screening in lieu of an interventional treatment option.

Enhancing the secretion, coacervation, and cross-linking of the elastin precursor tropoelastin is a promising regenerative strategy for AAA therapy. Preliminary work by our group has shown that mesenchymal stem cell (MSC) delivery to a growing elastase-induced AAA prevents further elastin degradation and/or stimulates new elastin synthesis, as evidenced by maintenance of elastic lamellae. Treated animals also exhibit halted AAA growth. Our *in vitro* work confirms that factors secreted by MSCs upregulate elastin deposition by smooth muscle cells (SMCs) within 3D fibrin gels. However, assembly of elastic fibers involves a cadre of ECM accessory proteins that are needed for proper tropoelastin processing and assembly, and these proteins have not been monitored in the regenerative context.

This project aims to establish a non-invasive elastin reporter gene (ERG), validated within a 3D fibrin gel model, to construct time-elapsed elastin transcription reports within varying stimulation conditions without necessitating scaffold digestion. Elastogenesis response will be monitored in response to chemical (TGF-β1, MSC secreted factors) and mechanical (stretching) stimulation. After ERG-RFL-6 validates the activity of ERG, transfection will move forward within vascular SMCs for AAA-targeted experiments.

METHODS

Fibrin gel constructs were fabricated [4, 5] using 3.7mg/mL fibrinogen, 0.21U/mL thrombin, and cell seeding density of $5x10^5$ cells/mL. 200μL gels were cultured with 15mM ε-aminocaproic acid (ACA), a fibrinolysis inhibitor halting construct breakdown. 400 μL fibrin gels for dynamic loading were seeded onto FlexCell Uniflex culture plates (FlexCell Int'l, Burlington, NC). The FlexCell FX-4000T strain unit induced a cyclic, uniaxial loading condition (10% stretch, 1Hz). A biochemical elastin protein quantification assay, Fastin Elastin (Accurate Chem, Westbury, NY), solubilized elastin in oxalic acid, quantified using a colormetric absorbance reading.

All fibrin gels were fixed using a 4% paraformaldehyde. RFL-6 cells were stained for elastin using rabbit anti-mouse recombinant tropoelastin (a donation from Dr. Robert Mecham's lab at Washington University in St Louis), goat anti-rabbit polyclonal AlexaFluor 488, and nuclear DAPI stain. Images were obtained using an Olympus FluoView FV1000 confocal microscope (20x oil, NA=0.85 objective).

Multiphoton elastin images (using 400μL fibrin gels) were collected on an Olympus FV10 (XLPlanN 25x water, NA=1.05 objective), and laser wavelength of 830nm. All obtained images (2D and 3D cultures) were processed through an established Matlab script [3], written to identify collagen/elastin fibril networks.

To develop ERG, an elastin promoter sequence was excised from a validated plasmid [6], with a mutation made at the start site to allow downstream luciferase translation [7]. This ELN promoter was ligated onto pGL4.14 (Promega) and verified via DNA sequencing. Transfection into RFL-6 and SMCs has been completed using a ERG:TransIT-LT1 (Mirus) ratio of 1ug:6μL. Luminescence measurements, reflective of elastin production, were taken by immersing gels in a 1mM Luciferin-EF (Promega) solution under an IVIS Lumina imaging system.

RESULTS

Stacked confocal immunofluorescence images, shown in Figure 1A, display elastin fiber development in static conditions under varying culture time lengths and dosing concentrations of TGF-β1. Figures 1B-E show the quantified results of the immunofluorescence imaging performed. Fiber concentration uniformly increases as culture length progresses (Figure 1A), but no significant differences can be seen between TGF-β1 dosing concentrations and unsupplemented F12 culture media. Mean fiber diameter does not significantly change (Figure 1B), but some TGF-β1 concentrations show statistically significant decreases as harvest day progresses. Similar results are seen in average segment length (Figure 1D), as the trends were mirrored between Day 7 and Day 10 harvests. Tortuosity remained constant throughout the culture conditions (Figure 1E), except for a significant increase in the Day 10, 1ng/mL TGF-β1 culture.

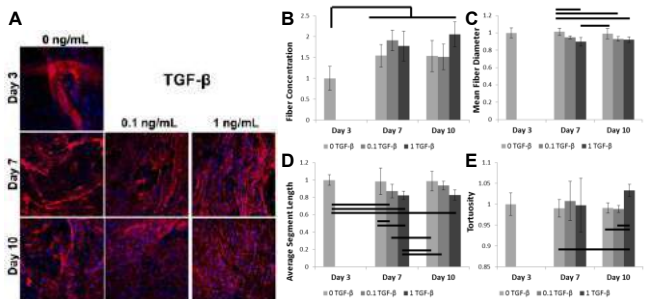

Figure 1: TGF-β1 treated 3D RFL-6 constructs.
A) Elastin (red) and nuclear (blue) immunostaining.
B-E) 3D image quantification using custom Matlab script [3], normalized to Day 3. n = 2, 3 images each, α = 0.05 per Fisher's LSD.

Elastin fibers expressed by unstimulated RFL-6 cells embedded within fibrin gels and grown (with 15mM ACA media), in either static (constrained) or dynamic cultures (Figure 2A), are mature enough to appear clearly during multiphoton microscopy. Multiphoton images of both RFL-6 cells and SMC-loaded fibrin gels (not shown) treated with TGF-β1 or MSC secreted factors are currently being quantified.

Elastin content increased as the RFL-6 loaded fibrin gels were exposed to a cyclic uniaxial strain, visible 7 days after culture seeding (Figure 2B). TGF-β1 treatment on these dynamic RFL-6 fibrin gels, however, did not yield any significant increases (Figure 2C). Rather, elastin content was decreased at both 7 and 14 day time points when compared to the untreated 7 day culture.

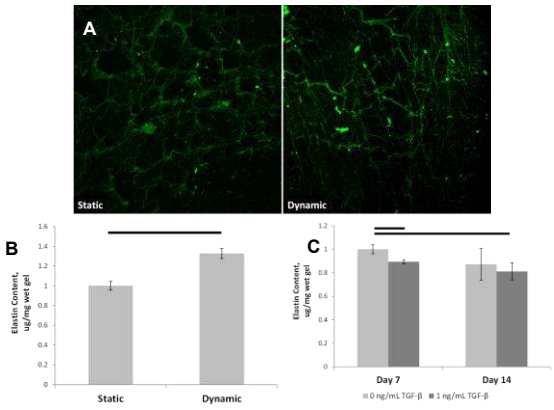

Figure 2: 3D RFL-6 constructs under cyclic uniaxial loading.
A) Multiphoton images of elastin fibers (green) after 7 days of culture.
B-C) Fastin Elastin protein assay for: B) 7 day unstimulated cultures, and C) 7 or 14 days, with and without TGF-β1. α = 0.05, as per Fisher's LSD.

DISCUSSION

Previously collected 2D image analysis of RFL-6 elastin fibers (not shown) illustrate that porosity decreases and segment length increases steadily, but both measurements experience a dramatic switch after 15 days in culture. This seems to suggest that the cells force an organization into distinct patterns when a spatial limit is reached, and that the elastin monomers seemed to disperse into more evenly-distributed fibrils as they received more time to develop. These results are muted in 3D cultures, as seen in Figure 1, possibly due to a significant increase in physical culture space available to express elastin. RFL-6 cells do continue to produce elastin throughout the culture window, as evidenced by the increasing fiber concentration measurements, but never reach the upper limit seen in 2D.

Currently, we are confirming that factors secreted by MSCs upregulate elastin deposition by SMCs within 3D fibrin gels, using both ERG and the image quantification software shown here to identify changes in elastic fiber deposition. However, assembly of elastic fibers involves a cadre of ECM accessory proteins that are needed for proper tropoelastin processing and assembly, and these proteins have not been monitored in the regenerative context. A fibulin-5 treatment could be useful within 3D fibrin vascular constructs, as, the cultures do not reach a self-organizing stage if given no stimulation. Fibulin-5 treatments would not wait for a cell-induced signal to reorganize the elastic fibers as they were being produced, as shown in 2D cultures.

Cells within a dynamic culture (Figure 2) decreased elastin production when treated with TGF-β1, suggesting that TGF-β1 only induces a remodeling phenotype in RFL-6 cells when a physically constraining stress is placed upon them as well. The dynamic culture did produce increased elastin production when compared to static cultures with no TGF-β1 treatment, meaning that any combination therapy with fibulin-5 might have to be staggered to induce the quickest amount of remodeling and organization for a AAA treatment.

Future work is focused on one elastic fiber accessory protein, fibulin-5, which is expressed by many elastogenic tissues and may be critical for enabling AAA elastin organization. Fibulin-5 mediates the initial interactions between tropoelastin and the microfibrillar scaffold, allowing for alignment and crosslinking of tropoelastin after secretion. If successful, this work will lay the foundation for an innovative combination therapy using fibulin-5 and MSC secreted factors for sub-surgical AAA, wherein elastogenesis would be organized through increased activity of naturally secreted fibulin-5.

INTRODUCTION

Traumatic brain injury (TBI) is a major cause of death and disability in the United States, contributing to about 30% of all injury-related deaths. Every year, an estimated 1.7 million people are diagnosed with TBI in the US alone. Of these cases, 80% are categorized as mild, with much higher statistics for undiagnosed cases. Until recently, mild TBI (mTBI) was generally regarded as a minor health issue and its effects were thought to disappear after a short recovery period. However, emerging evidence suggests that this injury is by no means mild and even a single insult to the brain could lead to chronic neurodegeneration[1].

Fundamental dynamical behavior of brain as a sudden motion of the head is still unknown for the most part. Efforts to model the brain's physics date back to World War II when rotational acceleration was hypothesized as the main cause of trauma, not linear acceleration. However, only few studies have studied both the magnitude and frequency content of the rotational acceleration pulse to determine the dynamic effects on brain injury and deformation. In a recent study, we showed that frequency-dependence of human brain's mechanical response may play an important role in whether a given loading scenario could lead to injury[2]. In this study, it was shown that, contrary to current standards that is mainly concerned with high frequency components, low-frequency dynamics could be more devastating as far as the motion and deformation of brain is concerned.

To study the temporal behavior of brain tissue, we utilized Dynamic Mode Decomposition (DMD). Also known as the method of snapshots, DMD is a multi-variate method that gives a compact representation of the original data from experiment or simulation, while reducing a large number of interdependent variables to a much smaller number of independent temporal modes and retains as much as possible of the variation in the original variables. This method has been successfully applied to modal analysis of fluid flows and solid structures[3]. DMD can extract relevant dynamic information from snapshots without explicit knowledge of the dynamical operator. It is based on considering the sequence of snapshots of a physical phenomenon and directly gives the system's characteristics, e.g. decay rate or energy and uniquely associates a frequency to each mode.

Our goal in this study is to investigate the modal behavior of brain tissue under various impact conditions in terms of loading amplitude and direction, and to test our hypotheses that (1) Head impacts in sports consistently excite a small set of principal displacement modes, which indicates a low-order system, and (2) brain's motion and deformation is governed low-frequency dynamics. We will then provide new insights into design requirements for protective headgear.

METHODS

First, we investigated the behavior of brain tissue under mild loading regimes by analyzing tagged MRI data from two different experimental protocols: sagittal and axial rotation[4,5]. We used Dynamic Mode Decomposition (DMD), which is a multi-variate method for data compression, to extract the modal behavior of brain tissue. By showing similarities between brain's modal behaviors in these two studies, we motivated our study that brain's deformation due to external loading inputs on the head, can be captured by a set of displacement modes that exist regardless of the input loading.

In a previous study, we had collected head motion kinematics due to head impacts in football[2]. We used a detailed finite element model[7] of the head to simulate the motion and deformation of brain tissue under these impact conditions, and used the resulting relative motion of the brain nodes as a separate dataset for our modal analysis. We

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

then used DMD to extract the most important displacement modes and brain's fundamental modal behavior.

We validated our results by comparing the reconstructed strains calculated from the modes with original strain data. To study the implications of our results on helmet design, we used previously conducted cadaver drop test experiments at 2 ft with barehead, airbag, EPS, football helmets and measured the head kinematics. Using these kinematics, we then ran DMD analysis on the resultant FE brain simulations.

RESULTS

DMD analysis on 110 simulations, randomly selected from over 500 football impact simulations, revealed that the most dominant displacement modes concentrate around 30-50 Hz range (Figure 1A). Here, each point on the graph represents the dominant behavior of the brain in a single simulation. This observation was consistent with our previously published study on tagged MRI experiments [2]. Each mode we find has an associated frequency and decay rate. By using these quantities, we calculated each mode's contribution to the overall energy of brain dynamics and discovered that 90% of energy of brain displacement can be captured by modal frequencies up to 60 Hz (Figure 1B).

By studying the orthogonality and independence of these modes, we also showed that brain's dynamic motion and deformation is governed by a small number of modes, i.e. brain-meninges-skull system constitutes a low-order dynamic system. In our analysis we found that 99% of responses from 110 football impacts and 2 independent MRI experiments can be reconstructed by only 21 independent modes (out of approximately 1000 modes initially extracted for all cases). We also compared the contributions of individual modes to the overall strain pattern in the brain tissue and found that by using the first 7 dominant modes in each football impact case, one can explain the peak principal strain with less than 10% error. We studied the effect of frequency and decay rate of each DMD mode on the peak principal strain and strain rate in the brain tissue. We found out that higher peak principal strains are observed for lower frequency modes; whereas higher decay rates cause higher strain rates.

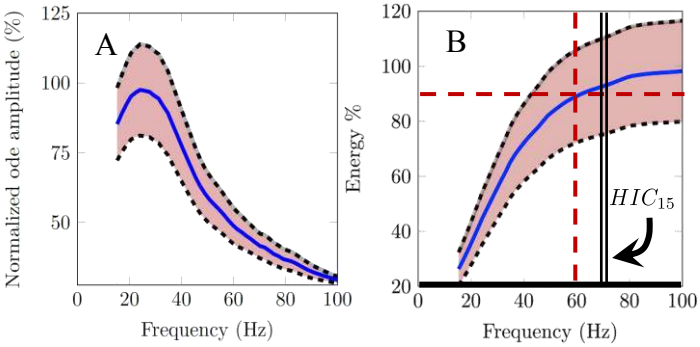

Figure 1: Frequency spectrum of DMD modes in football impacts. A) Overall normalized mode amplitude curve for DMD modes as a function of frequency. B) Cumulative energy contribution of DMD modes as a function of frequency.

Finally, analyzing the FE simulations of the cadaver drop test experiments, we discovered that current EPS bicycle helmets and football helmets fail to eliminate the most energetic brain displacement modes, which are usually lower than 100 Hz, whereas using a softer medium such as an airbag can filter brain dynamics up to 60 Hz (Figure 2A). A similar story can be seen for decay rates: In analyzing the time constants of two most dominant DMD modes from these experiments, we found that EPS and football helmets have almost the same time constants as barehead whereas a softer medium such as an airbag can increase the time constants almost 10 times, which is an indication of a significant drop for modal decay rates (Figure 2B).

DISCUSSION

In this study, we introduced a dynamic approach to explain brain injury mechanism. We argue that dynamical characteristics of relative brain motion can be helpful in understanding the reasons that lead to brain injury.

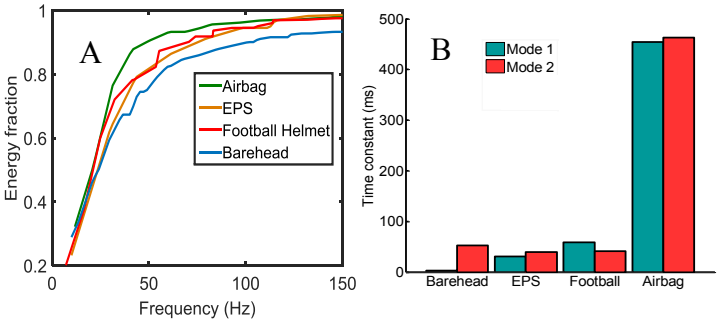

Figure 2: DMD analysis of cadaver drop test experiments with different helmets. A) Cumulative energy contribution of DMD modes as a function of frequency. B) Time constants associated with two most dominant DMD modes for each helmet (and barehead).

We first showed that impacts on the skull lead to displacement and deformation in brain tissue that can be captured by only a few independent displacement modes, and therefore concluded that brain is a low-dimension system. Second, this system's behavior mostly revolves around low frequency range (<60Hz). We went on to show that exciting certain relative displacement modes will result in higher strain and strain rates, which is potentially dangerous and may result in neurocognitive deficits. These results bring up an important question in terms of head protective gear design: Can current helmets successfully eliminate relative brain displacement modes that have low frequencies and high decay rates? We show that conventional helmets in fact fall short and we might need new approaches in helmet design.

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) provides mechanical life support for patients suffering from cardiac and/or pulmonary failure. The majority of ECMO patients are neonatal (≤30 days old), though the adult patient population experienced a marked increase in 2009 due to H1N1 and has remained steady [1]. ECMO is burdened by both hemorrhagic and thrombotic complications [1-3]. Original concerns with hemolysis due to centrifugal pumps have kept the roller head pump in use over the past two decades, however there has been a strong shift to centrifugal pumps from roller head pumps due to recent technological improvements [3-6].

Thrombosis is ECMO circuits is difficult to study. There are multiple factors influencing the formation of clot or inhibition of the same within a clinical circuit. Variables related to flow dynamics, rheological properties as well as effect of anticoagulation have complex interactions and warrant creation of a valid in-vitro setup for the study. Here, we present our development of an *in vitro*, benchtop, recirculating system that is capable of reproducing centrifugal pump thrombosis as seen in clinical ECMO circuits.

METHODS

ECMO circuits (N=16) were collected after use by pediatric and neonatal patients, facilitated by our collaborators at Emory University School of Medicine (Atlanta, GA). Circuits were analyzed for adherent thrombi, and if any were found, the location and macroscopic sample morphology was recorded. In some cases pictures were taken and/or samples were excised and preserved in 10% formalin for histology.

Benchtop *in vitro* loops were constructed using a Revolution ® centrifugal pump (Sorin Group USA, Arvada CO), a Better Bladder ™ (Circulatory Technology, Inc., Oyster Bay, NY), and tubing and connectors (Medtronic, Minneapolis, MN). Porcine blood (N=5) was collected into a minimal amount of heparin at a local abattoir. The blood was treated with glucose, L-glutamine, and an antibiotic/antimycotic solution (Sigma-Aldrich, St. Louis, MO). The loop was circulated for 48 hrs, with heparin dosing every 12 hrs, and the RBC health was monitored using blood smears. After circulation, the loop was examined for adherent thrombi, and if any were discovered, the location and macroscopic morphology of the thrombus was recorded. In some cases, pictures were taken and/or samples were excised and preserved.

Histological analysis was performed after 48 hrs of fixation in formalin using Carstairs' stain for fibrin and platelets, which stains platelets blue-gray to navy, fibrin red, red blood cells clear to yellow, and collagen bright blue [7].

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Centrifugal pumps exhibited clinical thrombosis in 100% of cases. The Revolution ® is not a levitated pump, and thus has a shaft. The shaft has an exposed piece of metal near the flow entrance. An adherent thrombus over the metal shaft was observed in all circuits ig 1, A). In some cases, large thrombus had formed, appearing to grow from the exposed steel shaft (Fig 1, B).

Macroscopic morphological recreation of centrifugal pump thrombosis was accomplished successfully in the *in vitro* flow loop (Fig 2). The clot shape and extent is similar to the clinical thrombus seen in Figure 1, B.

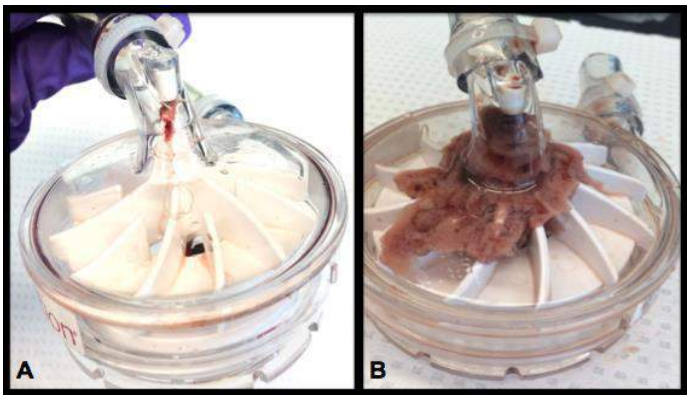

Figure 1: (A) Small thrombus coverage of the exposed metal shaft seen in 100% of clinical ECMO circuits. (B) Large thrombus growth seen in some clinical circuits.

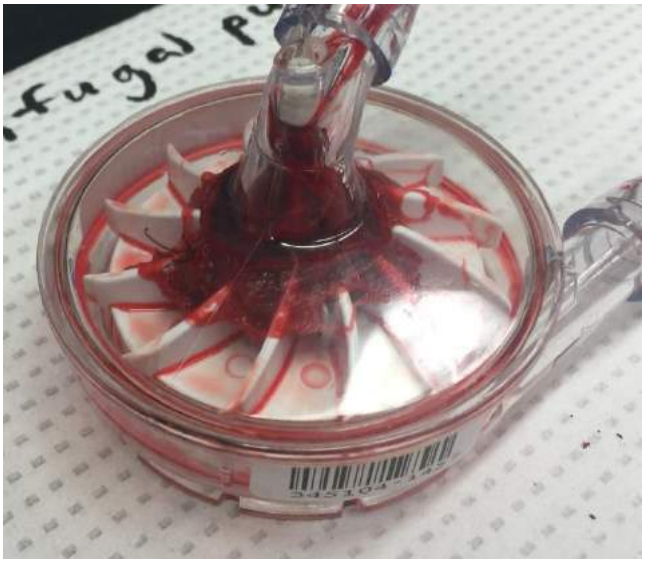

Figure 2: Large thrombus growth example seen in *in vitro* loop after a 48 hr run.

Histological analysis of clinical samples revealed mixed composition with platelet-rich regions alongside fibrinous regions, suggesting some platelet thrombosis involvement.

DISCUSSION

Adherent thrombus formation was observed in 100% of clinical centrifugal pumps. Typically the exposed shaft of the Revolution ® pump exhibited thrombus coverage, but in some cases excessive thrombus growth covered the pump head. Histological analysis of clinical thrombi revealed distinct regions of platelet-rich thrombi and red clot, suggesting some platelet thrombosis involvement.

An *in vitro* flow loop was constructed to recreate the clinical thrombosis. Whole porcine blood was perfused for 48 hrs through a simplified system consisting of a Revolution ® centrifugal pump, a Better Bladder™, connectors, and tubing. At 48 hrs, large thrombus was formed which was morphologically consistent with clinical thrombosis.

Here we demonstrate a promising system to study centrifugal pump design *in vitro*. Successful recreation of clinical thrombosis leads the way for trial methods to prevent thrombus formation using our benchtop system. Further microscopic and histological characterization, as well as fluid mechanics analyses of the pump head, will help to understand the mechanism behind thrombus formation in the Revolution ® centrifugal pump and thus indicate how to prevent it.

ACKNOWLEDGEMENTS

We would like to express our gratitude to the clinical staff that assisted with the circuit collection. This work was funded by a grant from the Center for Pediatric Innovation (Ga Tech – Children's Healthcare of Atlanta, Atlanta, GA).

INTRODUCTION

Exposure to ionizing radiation increases degeneration, risk of fracture, and decreases long-term bone quality. The complications related to high levels of ionizing radiation impact both astronauts and radiotherapy (RT) patients. Astronauts embarking on deep-space missions outside the Earth's protective magnetosphere, such as lunar, Mars, or near-Earth asteroid missions, will be exposed to high-energy ionizing radiation from cosmic or solar sources. Bones neighboring radiotherapy treatment are exposed to high doses of gamma radiation.

Previous studies have demonstrated significant changes in bone mechanics and quantity with radiation. Women with cervical, rectal, or anal cancer and treated with RT were 1.7 - 3.2 times more likely to suffer a pelvic fracture than patients who did not receive RT [1]. Animal studies of low to high dose radiation (2 – 20 Gy) have shown decreased trabecular bone volume fraction [2], bone embrittlement [3], and altered tissue composition, such as collagen cross-linking [4].

Understanding changes in bone mechanics is important for identifying increased risk of fracture with radiation exposure. In particular, fatigue, or cyclic load testing provides insight into changes at the molecular level that are not apparent in a monotonic test. Changes to the organic matrix can decrease energy dissipation mechanisms intrinsic to bone and manifest in a decreased fatigue life.

The mouse model is the IACUC preferred and most common mammalian model for experimental testing. However, mechanical testing of mouse vertebrae is not trivial due to its geometry and small scale. Thus, the purpose of this work was to develop a protocol, including sample preparation and test methodologies, for testing mouse vertebrae in fatigue. Fatigue testing of human bone was used for validation of the methods presented here. This work can be widely applied to investigations on the effect of musculoskeletal disuse, drug treatment, or genetic modification on bone mechanics.

METHODS

Sample Collection and Preparation

Mice were euthanized and the lumbar spine was dissected using IACUC approved protocols. The vertebra (L5) was extracted from the spine via cuts through the adjacent intervertebral discs. Surrounding musculature and soft tissues were removed with kimwipes and rubber-tipped surgical tools to protect the bone during preparation.

The cranial endplate of the mouse lumbar vertebral body is at an angle with respect to the caudal endplate. Planoparallel surfaces are critical for reliable uniaxial compression testing; however, the small specimen size makes this a challenging and arduous task. To ensure parallel surfaces for uniaxial compression testing, we modified the methods reported by Tommasini *et al*. for mouse vertebrae to improve repeatability [5]. All tasks done by hand were automated to remove human error in endplate removal and as such decreased scatter in the data.

First, the vertebral posterior process was potted in polymethyl methacrylate (PMMA). The vertebra is housed in a 3D-printed, custom-made jig designed with a pin through the spinal canal to ensure alignment (Fig. 1) and to fit within a SP1600 Leica microtome (Leica Biosystems, Nussloch, Germany). PMMA is slowly applied to the posterior process via a syringe to avoid getting PMMA on the vertebral body. Then, the jig was placed into the microtome and two parallel cuts were made, under constant irrigation. The height of the microtome arm was adjusted with respect to the blade to make the second parallel cut (1 μm resolution), resulting in a final sample height of between 2.0 to 2.5 mm. The specimen was removed from the PMMA with a scalpel, leaving the posterior process embedded in the jig. Samples were wrapped in saline-soaked gauze and stored at -20˚C until testing.

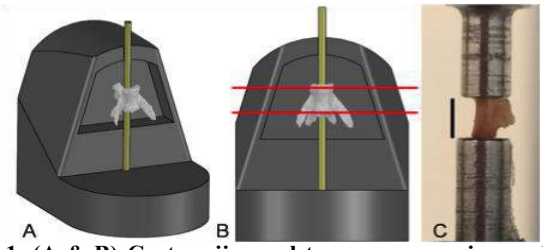

Figure 1. (A & B) Custom-jig used to prepare specimens. Yellow cylinder represents the pin used for alignment, and red lines represent parallel cuts. (C) Specimen in mechanical testing device (saline bath not shown). Bar = 2.25 mm.

Imaging & Mechanical Testing

Samples were imaged using microcomputed tomography (μCT, resolution = 10 μm/voxel; SCANCO Medical AG, Brüttisellen, Switzerland). Images from the caudal-end of the vertebral body were used to calculate minimum cross-sectional area (ImageJ; Fig. 2).

Our fatigue methods are similar to those used previously for human and bovine trabecular bone [6-8]. The specimen was compressed between two concentric, stainless-steel plattens and tested at room temperature in a saline-water bath to maintain hydration (Fig. 3). The test was conducted in load control (ELF 3200, Bose Corp., Framingham, MA, USA). Fatigue loading was initiated by applying 0.35% strain. To determine the amount of force needed to apply 0.35% strain, the initial modulus, E_0, was determined by applying ten cycles of .1% strain at 2 Hz. E_0 was defined as the slope of the stress-strain response during the last cycle.

A cyclic uniaxial compressive load was applied in a sinusoidal waveform at 2 Hz. The load applied to each specimen (i.e. input amplitude) was calculated as $F = E_0 * \varepsilon_0 * A$, where the ε_0 was set to 0.35% and A represents the bone area measured from μCT images. Normalizing the applied load by the specimen modulus was important for minimizing scatter in the data due to differences in specimen porosity. Failure was defined as a ten-percent reduction in modulus (Eqn. 1).

Figure 2. Representative uCT image of mouse vertebrae (area = 0.74 mm^2). Bar = 1.20 mm.

$$\varepsilon_{\text{failure}} = \frac{\sigma}{(0.9)(E_0)} \qquad (1)$$

Force and displacement data were collected throughout the experiment (750 Hz). The maximum strain during a cycle was plotted with respect to cycle number to determine fatigue properties.

RESULTS

Maximum strain per cycle was plotted for the duration of the test resulting in a tertiary curve (Fig. 4; red). The primary phase shows a sharp increase in strain, followed by a secondary phase characterized by nearly constant strain that spans more than 85% of the total fatigue test. Finally, in the tertiary phase, there is a sharp increase in strain, as the specimen approaches failure. The same trend for strain versus cycles is reported in Lambers *et al*. for fatigue testing of cylindrical cores of cancellous bone from human vertebra (Fig.4; blue)[6]. The transition point between the secondary and tertiary phase was defined as the intersection of two lines that make a bi-linear fit for this region of data. The strain at the transition point between the secondary and tertiary phase was 0.98% for mouse vertebra and 1.12% for human vertebra. The percentage of cycles to failure (N/N_f) at the transition point between secondary and tertiary phase was 84% for mouse vertebra and 93% for human vertebra. The slope of the secondary phase for mouse was 0.0041 and for human was 0.0055.

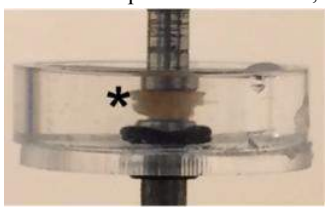

Figure 3. Mouse vertebrae (*) tested in saline bath.

DISCUSSION

Human vertebrae are characterized by a thin cortical shell surrounding a cancellous bone core with trabeculae of similar thickness to the shell. This geometry has been shown to affect load distribution between cortical and trabecular bone [10]. As such, it is important to use animal models with similar bone structure to compare to human vertebral mechanics. The geometry of mouse lumbar vertebra (Fig. 2) and intervertebral disc are comparable to the human vertebra and disc geometry, making the mouse an ideal animal model for understanding effects of degeneration, radiation, or injury on the lumbar spine [11].

In this study, we compared mouse fatigue behavior with human data available. We observed a tertiary response during fatigue, which has been previously reported for human, bovine, and rat cancellous and cortico-cancellous tissue [7-9]. The slope and length of the secondary phases have similar values. Also, the strain percentage for mouse and human at the inflection point of the secondary and tertiary phases show the values within 0.28%. These findings support the use of the mouse model for understanding the effect of radiation, degeneration or injury on human vertebra mechanics.

We have developed and validated testing procedures to use mouse vertebra for mechanical testing, which allows for reasonable inferences about human bone. On-going work is using this method to investigate dose and type of radiation. However, these methods can be applied for understanding the bone mechanics with respect to musculoskeletal disuse, drug treatment, or genetic modification.

INTRODUCTION

Computational fluid dynamics (CFD) is now widely used to characterize cerebrovascular hemodynamics and their role in aneurysm initiation, growth, rupture and treatment outcome [1]. Nevertheless, there remains skepticism about the fidelity of aneurysm CFD models, in part owing to the various modelling assumptions and uncertainties [2], one of them being the outflow conditions.

Owing to the difficulty of obtaining patient-specific flow measurements, the vast majority of the published CFD on intracranial aneurysm hemodynamics relies on "*do nothing*" boundary conditions, i.e., stress-free or zero pressure (**p0 method**). Such an approach is not justified physiologically, and leaves the flow division at the outlets uncontrolled, governed mainly by user-dependent choices in terms of the model segmentation, number of branches retained, their lengths and, potentially, artificially added outlet flow extensions. This is becoming increasingly problematic, as aneurysm CFD models are including more of the cerebrovasculature, owing to advances in imaging and computation, and the recognition that flow disturbances in proximal vessels like the internal carotid artery (ICA) can propagate downstream into distal e.g., middle cerebral artery (MCA) aneurysms [3].

An alternative to the p0 method is to assume that outflow rates scale with a Power-Law (**PL method**) using a square or cube relation with the outlet radii. Still, the flow rates are dependent upon the often-arbitrary decisions about which branches to include in the CFD model (see **Figure 1**). In this abstract, we present a novel extension of this power law approach (**PL* method**) that determines flow divisions independently at each bifurcation along the CFD model. Using a cohort of 70 realistic MCA aneurysm cases, we demonstrate that our method provides both more physiologically plausible flow rates and relative independence from model extents compared to the other methods, especially the popular "do nothing" approach.

METHODS

We recently developed a novel lumped parameter approach for fast and accurate prediction of flow divisions in 3D CFD models [4], and applied it here for the three types of boundary conditions (p0, PL, PL*). For each 3D CFD model in our cohort, a 0D model is derived in two steps: (i) the centerlines of the model are computed using the Vascular Modelling Toolkit library (www.vmtk.org) and (ii) these centerlines are decomposed in a network of straight and rigid segments parametrized by their mean radius, length and bifurcation angles.

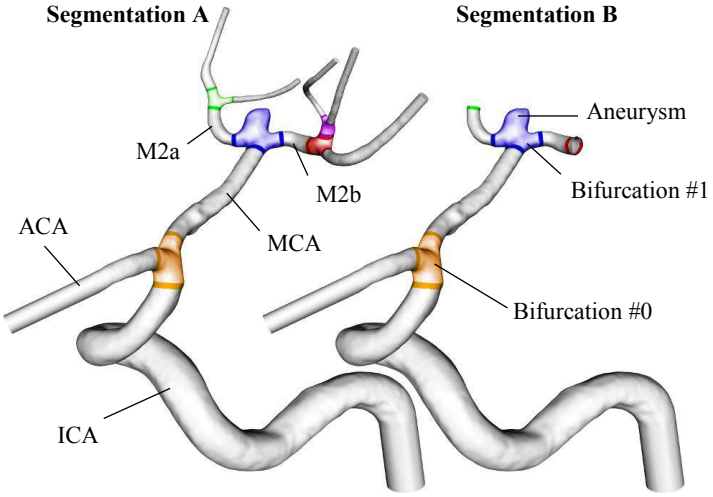

Figure 1: Representative case showing original segmentation (A), and a truncated version (B) used to demonstrate sensitivity of outflow rates to model extent for the three different BC methods.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

In these networks, we assumed a steady state and a fully developed, pressure-driven Poiseuille flow with a no-slip boundary condition at the wall. For each segment, the flow rate is proportional to the pressure gradient along the vessel and the inverse of its resistance. Novel to our approach is the use of additional resistances to account for pressure drops at bifurcations [5]. By applying an analogue of Kirchhoff's current law to satisfy segment-to-segment mass conservation, equations for all segments are assembled and solvable by an iterative process [6].

The method was validated against 70 pulsatile 3D CFD simulations that prescribed only ICA inflow, and used the p0 method for outflow [4]. Although momentum balance is not fully accounted for, and the geometry idealized, 0D-predicted outflow rates were on average within 4% of the actual 3D CFD model outflow rates. Using this 0D tool with prescribed ICA inflow, branch flow rates were anticipated using the three different outlet boundary conditions: **p0 method**, as a zero pressure on all the outlets *j*; **PL method**, for which at each outlet *j* the flow rate Q_j is set as

$$Q_j = (A_j / \sum_i A_i) Q_{inlet} \qquad (1)$$

where A_i is the area of the *i*-th outlet and Q_{inlet} is the inlet flow rate imposed to the model at the ICA; and our proposed **PL* method**, defined *locally* for each bifurcation as

$$Q_j = \alpha_{j,b}\, Q_{supplier} \qquad (2)$$

where $\alpha_{j,b}$ is the fraction of flow coming through the outlet *j* at the b^{th} bifurcation. $\alpha_{j,b} = \tilde{A}_j / \sum_c \tilde{A}_{c,b}$ with $\tilde{A}_{c,b}$ the mean area of the c^{th} collector branch of the considered bifurcation *b* and $Q_{supplier}$ the flow rate coming in the bifurcation. When all bifurcations in a model have two collectors (e.g., as in **Figure 1**), Q_j can be computed *globally* as

$$Q_j = [(1-\alpha_{0,0}) \dots (1-\alpha_{j-1,b-1})\alpha_{j,b}]\, Q_{inlet} \qquad (3)$$

RESULTS

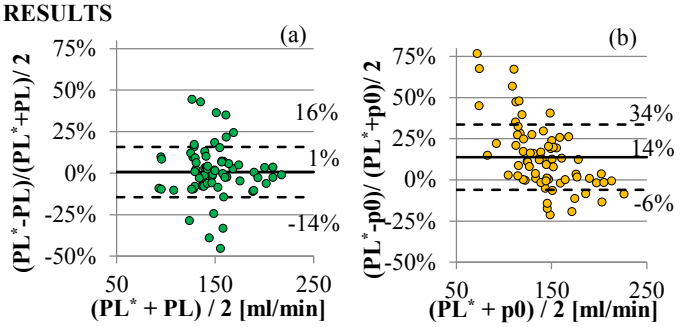

Figure 2: Bland-Altman plots comparing MCA flow rates predicted using our novel PL* method against those predicted by the PL method (a) and p0 method (b) for the 70 cases.

Figure 2 shows that MCA flow rates predicted by PL* and PL methods agree to within about ±15%, albeit with some notable outliers. Relative to PL*, the p0 method underestimates MCA flow rates by 14% on average, but up to 75% for some cases. **Table 2** confirms that methods PL* and PL give similar results, remarkably close to *in vivo* measurements from a separate cohort, while the p0 method diverts too much flow to the ACA, and overestimates interindividual variance.

Table 1: Descriptive statistics (mean ± SD) for the flow rates (in mL/min) into the ACA and MCA for 70 cases using the three different outflow boundary conditions, compared against in vivo measurements from Zarrinkoob et al. [7].

Vessels	p0	PL	PL*	In vivo [7]
ACA	98.8 ± 38.7	77.3 ± 27.2	82.1 ± 25.3	82.0 ± 18.0
MCA	134.0 ± 40.2	148.5 ± 29.4	149.3 ± 28.3	146.0 ± 31.0

DISCUSSION

As we do not know the "true" flow rates for our cohort we can only comment on the flow rate divisions induced by the choice of the boundary conditions, and not the accuracy of the estimated flow rates for individual cases. Nevertheless, flow rates obtained with the PL and PL* method were shown to produce flow divisions closer, in terms of means and standard deviations, to in vivo measurements compared to the popular p0 method. While PL and PL* show consistent results with respect to one another, PL* has the advantage to show little influence from the segmentation choices of the 3D models. For large or multicenter cohort studies such differences may balance out; however, for smaller cohorts and especially individual case studies, such sensitivity to outflow conditions could have significant impact on the 3D CFD results.

This is demonstrated in **Table 2**, which shows that the choice of outflow extent (segmentation A vs. B in **Figure 1**) can have a dramatic impact on flow entering the aneurysm (i.e., fraction of prescribed ICA inflow going to MCA vs. ACA) and aneurysm outflow (M2a:M2b) division. For the p0 method, segmentation extent clearly affects MCA inflow rate, by more than 60%, and more than 40% for the PL method, whereas the PL* method is unaffected by the downstream truncation, by virtue of its 'local' calculations of flow divisions upstream. Regarding aneurysm outflow, p0 and PL methods both predict unbalanced outflows, which would undoubtedly serve to bias the aneurysm inflow jet and hence intra-aneurysm flow patterns, whereas the PL* method predicts a more physiologically plausible balanced outflow.

Table 2: Flow divisions at the ACA/MCA bifurcation and at the aneurysmal sac for segmentations A vs. B shown in Figure 1.

Flow division	MCA:ACA		M2a:M2b	
Segmentation	**A**	**B**	**A**	**B**
p0 method	30:70	49:51	27:73	22:78
PL method	45:55	64:36	29:71	35:65
PL* method	54:46	54:46	42:58	42:58

In summary, the PL* method demonstrates a more physiologically plausible range of flow rates over the 70 cases studied, and is less dependent on the segmentation or extent of the CFD models. We also stress that, although here the PL* method employed a square law for dividing the flow at branchings, one could easily use a cube law, or some combination (e.g., square law for larger branches, cube law for smaller). Current work is aimed at confirming the impact of the choice of outflow boundary conditions on intra-aneurysmal flow and wall shear stress patterns. It is also worth noting that our 0D tool is based on open-source libraries, and our intent is to release it similarly, with the aim of encouraging a better understanding and standardization of cerebrovascular CFD outflow boundary conditions.

INTRODUCTION

Current techniques for detecting failure in biological tissues often rely on observing discontinuities or inflection points in a material's force-displacement curve. While these characteristics suggest material failure, they may result from the underlying material geometry (e.g. cervical spine buckling). Acoustic emissions provide a method of sensitively detecting injuries with minimal influence from non-injury events. Currently, an extensive characterization of acoustic emissions from osteoligamentous injuries does not exist. Therefore, injury detection typically assumes every acoustic emission indicates injury. However, external factors exist that may cause acoustic emissions without causing injury (e.g. test apparatus vibration). This study presents a characterization of spectral content in acoustic emissions from cortical bone failure and a technique to determine timing of cortical bone injury in complex geometries.

METHODS

Three human cortical bone specimens were excised from thoracic vertebral bodies and placed in a custom test apparatus designed to apply compressive loading without introducing artifacts in microCT images. Pre-test material structure was visualized using microCT images, then acoustic sensors were adhered to the specimens. Specimens were loaded until an acoustic emission was measured, at which time loading was automatically suspended. MicroCT images were recaptured to validate the existence of material fracture *in vitro*. If no tissue damage was observed, the procedure was repeated until there was positive confirmation of injury. The spectral content was analyzed using a Welch power spectrum density estimate.

Three whole cervical spines were loaded in compression to displacements previously determined to cause injury. The acoustic emission response was measured using an array of acoustic sensors on multiple vertebral bodies. The timing of cortical bone failure for the whole spine was determined by the moment at which the frequency content of cortical bone failure occurred in the time domain.

RESULTS

The acoustic emissions from cortical bone failure showed wideband spectral response from 20 kHz to 901 kHz with multiple peaks and a dominant frequency of 60.4 kHz (Figure 1). Cervical spine tests showed the frequency content occurred in bursts containing wideband frequency content from 35 kHz to 603 kHz and centered at 63 kHz. The timing of cortical bone injury was calculated with resolution of 20 μs (Figure 2).

DISCUSSION

The presence and timing of cortical bone failure can be difficult to assess in complex loading scenarios where acoustic emissions may not be from injury. By first identifying the characteristic frequency of cortical bone failure alone, the presence and timing of cortical bone failure in a whole cervical spine can be identified based on the presence of this characteristic frequency centered around 60.4 kHz.

INTRODUCTION

Rupture of intracranial aneurysms (IAs) causes 80% of subarachnoid hemorrhages and occurs when the local stress exceeds the local strength of the wall. In order to avoid rupture, an aneurysm must maintain its structural integrity even under extreme physiological loading The factor of safety (FoS) is a frequently used engineering metric for estimation of structural integrity, and is defined as ratio of structural capacity to the applied loads. To avoid rupture, aneurysm walls must have the capacity to maintain their structural integrity overtime despite repeated loading and abnormal flows.

In a previous work [1], we estimated the FoS for two aneurysm cases, chosen from our bank of resected domes (labelled CA-25 and CA-26) using stresses estimated from finite element studies of the intramural load distribution. We found both cases have FoS higher than 4.8. Here, we further investigate those two cases, focusing on remodelling of collagen fibers responsible for the structural integrity and the intramural cells that maintain these fibers. We compare the quantity and distribution of these cells and fibers in the aneurysm wall to those in a control basilar artery. A third unruptured aneurysm (CA-09) from a young patient (27 years old) is also considered due to its unique collagen structure compared with other aneurysm tissue in our data base [2].

METHODS

In order to better understand the wall structure of the aneurysm wall, immunofluorescent staining of collagen type I, collagen type III, αSMA on cross sections of aneurysms and control arteries were imaged under confocal microscopy. Specimens were dissected from 3 aneurysm samples and 1 basilar artery, and then fixed in an unloaded condition in 2% paraformaldehyde for 2h. Cross sections were obtained by freezing the specimen in liquid nitrogen and cutting 8 um thick slices using a cryostat (HM 505E, Microm). Sections were stained with antibodies against collagen type I, collagen type III and alpha smooth muscle actin (αSMA). Sections were permeabilized with 0.1% Triton X-100 in PBS for 10 min, and then blocked in 2% BSA for 45 min. Subsequently, sections were incubated with the primary antibody of collagen type I (ab34710, Abcam), collagen type III (ab7778, Abcam) or αSMA (ab7817, Abcam) for 60 min, washed 5 times with PBB, incubated with fluorescent secondary antibody (Cy3, CBI) for 60 min. DAPI was added to stain nuclei and then a cover slip was adhered for imaging. All sections were imaged using Olympus Fluoview 1000 confocal microscopy (Olympus Imaging America, Melville, NY).

Image analysis was used to determine the thickness fraction of positive αSMA, collagen type I and collagen type III as well as nuclei count per wall area. To quantify the thickness fractions of these components, a custom image analysis program was developed in Matlab to identify the wall thickness, αSMA, collagen I and collagen III layer thickness. The RGB image was enhanced and thresholded to a binary image to define the wall boundary using an edge detection algorithm. Similarly, the red channel images (αSMA, collagen I and collagen III labeled with Cy3) were used to identify the boundary of αSMA, collagen I and collagen III layers. The shortest distance from a point on the luminal boundary to any point on the abluminal boundary was calculated as wall thickness. Wall thickness was measured at 20 locations on the image and averaged. The normalized thickness was defined as the thickness of positive fluorescence layer divided by the total wall thickness. Cell nuclei counts were determined by identifying objects according to size and intensity threshold on the blue channel (DAPI). Cell density was calculated as cell count divided by the wall area, which is the area between the wall boundaries. T test was used to test whether the mean values of layer thicknesses between aneurysms and control artery were statistically different. Differences were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

considered statistically significant if the p values were less than 0.05 (95% confidence).

RESULTS

In the wall of the control basilar artery, collagen type I was mostly confined to the adventitia and collagen type III was distributed across the wall. CA-25 and CA-26 displayed a similar layered collagen structure to that of the control artery, with collagen I confined to an outer layer on the abluminal side and collagen III distributed across the wall. In contrast, collagen type I is shown across the entire aneurysm wall for CA-09, which is consistent with the adventitial type collagen seen in both luminal and abluminal sides on MPM images in a previous study [2]. CA-09 was the only aneurysm tissue that displayed this distribution under MPM in a study of 16 IAs. Collagen III in CA-09 was also distributed across the wall, similar to the other two aneurysms and the control artery. The existence of a band of collagen I on the abluminal side in all of three aneurysms as well as in the control artery is consistent with a prior study of four aneurysms imaged using polarized light microscopy [3].

Quantitatively, the average normalized collagen I layer thickness are 1.0 ± 0.01 for CA-09, 0.14 ± 0.03 for CA-25, 0.17 ± 0.01 for CA-26 and 0.22 ± 0.02 for control artery. Compared to the control artery, CA-25 and CA-26 have significantly thinner collagen I layers (p=0.011 and p=0.01), while CA-09 has a significantly thicker collagen I layer (p=0.0001), Figure 1. In summary, the existence of two layers in CA-25 and CA-26, is similar to that of the basilar artery. However, CA-09 displays a qualitatively different remodeled wall. It may be important that this aneurysm came from the only young patient in our study (27 years old). The two layered wall found in CA-25 and CA-26 is consistent with the existence of luminal and abluminal layers in aneurysms found by Mimata et al. [4].

αSMA in the control artery is largely restricted to the medial layer, Figure 1. Similar to the control artery, an αSMA layer on the luminal side was observed in all three aneurysms. Thickness of the αSMA layer was normalized to the total wall thickness. Remarkably, the normalized wall thickness was quite similar for CA-09, CA-25 and CA-26: 0.69 ± 0.034, 0.79 ± 0.033 and 0.82 ± 0.054, respectively. Differences between normalized αSMA layer thickness of these aneurysms and the control artery (0.78 ± 0.070) are not statistically significant (p=0.19, 0.81 and 0.49).

CA-09 and CA-25 have average cell densities of 5231 ± 490 /mm^2 and 6854 ± 686 /mm^2 respectively, both of which are higher than that of basilar artery 4540 ± 805 /mm^2 (p=0.057 and p=0.01), Figure 2. The cell density of CA-26 (3273 ± 659 /mm^2) is lower than that of control artery. However, the difference between cell density of CA-26 and control artery was not statistically significant (p=0.13).

DISCUSSION

In engineering practice, as well as in the current study, we can only project the expected capacity of the wall to continue to maintain a suitable FoS. Unlike classical engineering materials such as steel, biological tissues are endowed with cells that have the capacity for maintenance and adaptation over time. In particular, the passive load bearing components of the vascular wall, elastin and collagen fibers, are maintained and manufactured by vascular cells including vascular smooth muscle cells, fibroblasts and even endothelial cells [5]. In this case study, we found robust aneurysm walls both had cell densities comparable with the control artery and were endowed with a substantial αSMA layer, suggesting these walls have the capacity to maintain the ECM structure over time. Moreover, two of the aneurysm walls had two wall layers that were similar in collagen type and αSMA content to the media and adventia of the control artery. A third aneurysm wall from a young patient displayed a new type of wall structure with both collagen I and III distributed across the wall.

INTRODUCTION

Endovascular treatment methods for cerebral aneurysm, e.g. flow diverting stents and coils, are designed to reduce flow into the aneurysmal sac, promoting flow stasis, thrombosis, and reducing the risk of rupture. While these methods pose significantly less risk to the patient than invasive surgical techniques, up to 30% of aneurysms treated with an endovascular device remain patent at mid-term angiographic follow-up[1].

The hemodynamic environment inside the aneurysmal sac and in the parent vessel is widely considered to play a crucial role in aneurysm remodeling. Recently, computational fluid dynamic (CFD) simulations have been used to study the aneurysmal hemodynamic environment post-treatment in the hopes of understanding what fluid mechanics factors affect treatment outcome[2-4]. However, there are a number of strategies for simulating post-treatment cerebral aneurysm hemodynamics with a wide range of fidelities and computational costs. On one end of the spectrum is the homogeneous porous media approximation, where the coil mass is modeled as a homogenous porous volume that fills the entire aneurysmal sac[5]. This method is attractive due to the low computational cost, but over-simplifies the aneurysmal hemodynamics. On the other end of the spectrum, the full geometry of the coil volume inside the sac is included in the CFD simulation. The coils are often "virtually deployed" inside the aneurysmal sac via an FEA computational model[6-7]. These virtually-coiled simulations are able to capture small-scale flow features induced by the presence of a coil mass but are orders of magnitude more computationally expensive, and it is uncertain to what degree the location of the numerically-deployed coils accurately mimics the *in vivo* configuration.

In this study, we compare the hemodynamic environment computed by CFD simulations that model the entire coil geometry with simulations that approximate the sac as a homogeneous-porous-medium. However, rather than rely on a numerical deployment of the coil treatment, the geometry is acquired from µCT scans of treated *in vitro* models of patient-specific aneurysms. By better understanding the differences in the two modeling approaches, we aim to understand to which degree they can accurately represent the hemodynamics and therefore be appropriate for studying aneurysmal hemodynamics and treatment outcome.

METHODS

Patients enrolled in this IRB-approved study are prescribed coil embolization for a cerebral aneurysm as the standard of care. Three-dimensional rotational angiography is obtained pre- and post-treatment. Blood velocity and pressure measurements are gathered using a dual-sensor pressure and Doppler velocity guidewire and analysis workstation (ComboWire and ComboMap, Volcano Corp, San Diego, CA)[8]. Pressure and velocity measurements are taken every 5 ms at four peri-aneurysmal locations. These measurements are made pre- and post- treatment and used to establish patient-specific boundary conditions in the computational simulations[9]. Three-dimensional vessel reconstruction is done using the Vascular Modeling Toolkit (VMTK v1.2).

In vitro models of the patients are created using a four-stage wax casting procedure. A physical 'positive' model made of acrylonitrile butadiene styrene (ABS) is first created at 1:1 scale by 3D printing. This model is coated, casted and converted to one made of wax, which is finally cast in a clear polyester resin to produce the *in vitro* flow phantom (Clear-Lite, TAP Plastics, San Leandro, CA). The wax is melted away leaving the final 'negative' model of the aneurysm and parent vessel lumen. The *in vitro* model is then treated by an experienced clinician with the same treatment received by the patient

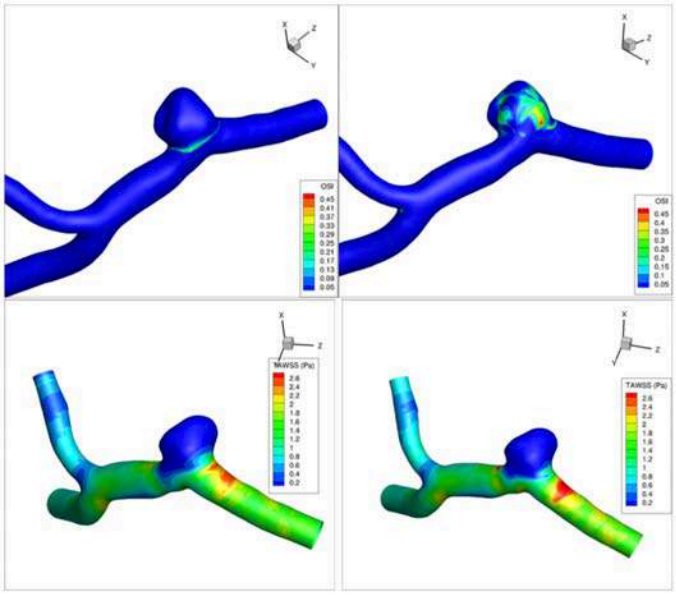
(coil number and size). Synchrotron radiation μCT scans of the treated *in vitro* models are carried out using the ID19 beamline at the European Synchrotron Radiation Facility (ESRF). From these images, a computational reconstruction of the vessel lumen and treatment surface is generated and then meshed for CFD simulations.

To create the porous media model, the portion of the aneurysm sac filled with coils is determined from post-treatment angiographic data and differentiated from the parent vessel reconstruction. The coiled aneurysmal sac is numerically filled with a porous medium approximation that adds a sink term to the momentum equation that depends on the fraction of coils to aneurysmal sac volume. The number, length and diameter of the coils used in the patient's treatment are used to estimate the packing density, which informs the model parameters. The packing density of the porous media model is validated with the actual packing density of the μCT-generated model.

Finite-volume fluid simulations of both models are performed using ANSYS FLUENT (Release 14.1, ANSYS, Inc.). Blood flow is assumed to be incompressible and Newtonian. At the inlet boundary, the time-dependent Womersley velocity profile based on *in situ,* wire-measured, centerline velocity is imposed. At distal outlets, pressures are prescribed using the unsteady *in situ* wire pressure measurements.

RESULTS

Preliminary results show significant differences between the porous medium simulation and the μCT-derived simulation. Shown in figure 1 are oscillatory shear index (OSI) and time-averaged wall shear stresses (TAWSS) for both simulations. The μCT-derived simulation has significant variation in aneurysmal OSI, indicating non-homogenous flow patterns, while the porous media simulation predicts minimal fluctuation in the aneurysm dome. The TAWSS maps suggest similar quantitative patterns, but values of TAWSS integrated over the aneurysm dome are significantly different as pointed out in Table 1. Summarized in this table are various hemodynamic variables integrated over the aneurysm dome from both simulations. The μCT-derived simulations predict higher energy dissipation, OSI, and wall shear stress gradient (WSSG), but lower WSS values.



(a) Porous Media (b) μCT

Figure 1:OSI (top row) and TAWSS (bottom row) in a mid basilar, coil-embolized cerebral aneurysm. Flow is from left to right. The treatment geometry is modeled by a porous media approximation (left column) and fully resolved using μCT (right column).

Table 1: Hemodynamic parameters averaged over the aneurysmal sac for both simulations.

	Porous Media	μCT
TAWSS [Pa]	0.0792	0.0487
Sys. WSS [Pa]	0.139	0.09227
OSI [•]	0.0192	0.07228
WSSG (TA)[Pa/m]	192	492
Eng. Dissipation (TA) [mW]	$1.98\ 10^{-3}$	$2.75\ 10^{-3}$

DISCUSSION

The variation in flow parameters seen in Table 1 is caused by the different hemodynamic environments as modeled by the two simulation methods. These preliminary results suggest that the porous medium approximation oversimplifies the flow-damping phenomenon, as it is unable to resolve the small-scale flow features that develop as blood moves through the coil structure. As a direct link between hemodynamic parameters and treatment outcome has not yet been established, and taking into consideration the numerous sources of additional error introduced when simulating cerebral aneurysm hemodynamics, it remains unknown how important this oversimplification may be. However, it is clear that the porous medium model may over or under estimate certain hemodynamic parameters, and caution should be exercised when attempting to correlate porous medium-derived flow parameters to treatment outcomes.

In the quest to determine how hemodynamics impact treatment success, large cohort CFD studies are necessary. While modeling the full geometry of an aneurysmal intervention strategy for every patient would be ideal, it is not practical from a computational resource perspective. Furthermore, if CFD simulations are to be used in a prospective framework to predict the outcome of future interventions, full-scale simulations become even more unrealistic

The need for an intermediate modeling approach is clear. After compiling μCT scans of multiple treated *in vitro* models, the next goal of this study is to develop an improved model of endovascular coiling based on the heterogeneity and anisotropy of the resulting coil structures that develop inside the sac. This model will include aneurysm geometry and location, packing density, etc. The goal is to develop a computational model that captures the key hemodynamics inside and around the sac with sufficient fidelity to be used in treatment predictions, but computationally-efficient enough to be used in a large cohort study of cerebral aneurysm treatment outcomes.

INTRODUCTION

Bladder dysfunction occurs frequently in older people, with an estimated 15-30% of people over the age of 60 affected. Disorders such as lower urinary tract symptom (LUTS), indicative of bladder obstruction and urinary incontinence, can dramatically lower the quality of life. The incidence of bladder disorders has been shown to increase with age in both men and women. Since the two working phases of bladder function, filling and voiding, largely depend on its mechanical properties, understanding age-related changes in bladder wall structure is extremely important.

From a mechanical point of view, the bladder is a complex layered composite with passive structural components (elastin and collagen fibers) as well as active components (smooth muscle cells), Figure 1. The inner most surface of the bladder is the urothelium (UT) a transitional epithelium that provides a barrier to protect underlying bladder tissue from urine as well as other deleterious factors [1]. More recently, its sensory and signaling roles have been recognized and received increasing attention, motivated in part by the possible changes in these roles with disease and age [2]. In addition to sensing chemical signals, the UT is responsive to mechanical loads. Hence the mechanical properties and structure of the adjacent lamina propria likely play an important role in its function. The ECM of the lamina propria is composed mainly of collagen types I, III and IV interspersed with some elastin. For this work, we designed and employed a planar biaxial testing device compatible with multiphoton microscopy (BA-MPM) to visualize the collagen fibers and lamina propria during mechanical loading.

METHODS

Male aged (24 month) rats were used in this study. The bladders were cut open and trimmed into square pieces with width varying from 5mm to 7mm. Samples were immersed in HBSS media with 0mM external calcium with thapsigargin to deplete and block smooth muscle calcium stores and prevent contraction. Four strain markers were glued on the bottom surface of each sample using a protocol developed to minimize artifacts associated with marker attachment. Mechanical testing was performed using a custom biaxial system coupled with a multiphoton microscope (Olympus FV1000 MPE), Figure 2. A mirror system consisting of a CCD camera and a 45 degree offset mirror was designed to image displacement of strain markers from beneath the mounted tissue. During testing, the tissue was first preconditioned by 5 consecutive cycles of varying stretch ratios in principal directions, using a protocol decribed in [3]. After preconditioning, the sample was extended until a tare load of 0.02N. Dimensions and initial marker

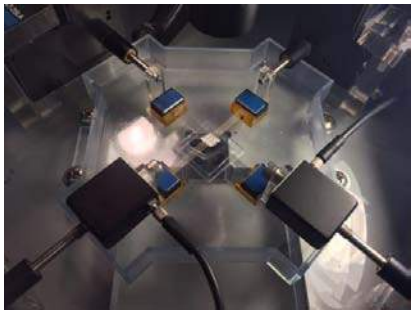

Figure 2: Photograph of biaxial system with mounted tissue. Four linear actuators control the stretch level. Two loadcells measure the force in the principal directions.

coordinates were measured in the preconditioned and load tared configuration and used for stress and strain calculations. Cyclic equibiaxial strain was imposed for 5 cycles at a strain rate of $1\%s^{-1}$ to a maximum stretch of 2.0 as estimated from end to end distance. Tissue was MPM imaged from the UT side at fixed strain levels during the loading cycle. Fiber orientation as a function of depth was measured using a previously developed protocol [4]. The lamina propria layer was identified by scan depth and presence of blood vessels.

RESULTS

MPM imaging of collagen in the lamina propria indicated two distinct layers of fibers with qualitatively different fiber architecture. Representative images from the inner and outer layer are shown in Figure 3. The layer closer to the urothelium (termed inner) is approximatley 20 microns thick and likely associated with the basal membrane. This layer was comprised of fine fibers with a large distribution of orientations. These fibers maintained a distributed orientation under increasing equi-biaxial load. The second layer (termed outer) was imaged across 100 microns of depth and consisted of larger diameter fibers that were wavy in the absence of stretch. When the tissue was stretched, these fibers straightened and reoriented.

Mechanical and MPM imaging data were combined to assess the relationship between collagen recruitment and the stress strain loading curve. In the toe region of the curve, collagen fibers in both layers were wavy, consistent with low stiffness in this region, Figure 3. As strain increased beyond 0.3, the loading curve in the longitudinal direction transitioned to a region of high stiffness. This transition strain was consistent with partial recruitment of outer fibers at a strain of 0.33 and nearly complete recruitment by 0.37. In contrast, the circumferential response showed only modest steepening, consistent with the more moderate recruitment of collagen fibers in that direction over this range.

DISCUSSION

While the physiology of the bladder is a subject of intense investigation, less is known about the biomechanics of the bladder wall [3], and even less about the relationship between the mechanics and biological activities of the wall. Such knowledge is of vital importance as the phenotype and biological activity of the intramural cells that produce and remodel the ECM are responsive to the magnitude and direction of loads on the ECM. Further the cells lining the bladder in the UT, are sensitive to the mechanics of the underlying wall. Here, we have used a custom planar biaxial-MPM system to identify two types of collagen architectures within the lamina propria and investigated the relationship between structure and function in the lamina propria. We found the recruitment of collagen fibers in the outer layer coincides with strains at which the loading curve transitioned to high stiffness, suggesting the two layers in the lamina propria play different mechanical roles during bladder filling.

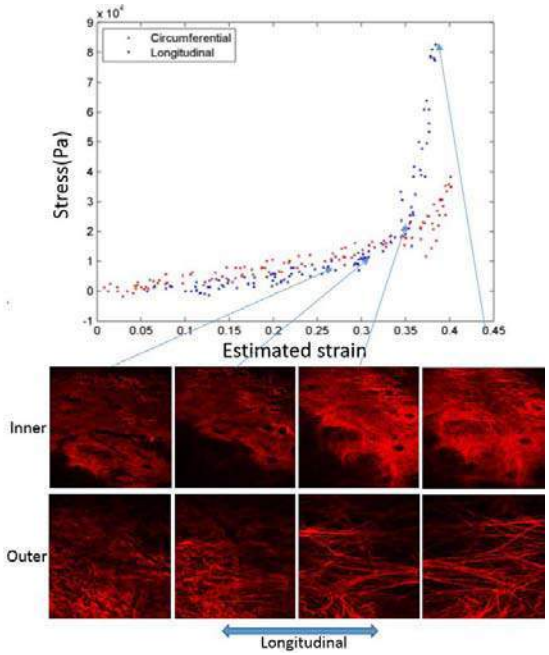

Figure 3. Strain vs. Stress curve and MPM images of the two fiber layer structure taken at increasing strains. From left to right the strains are 0.27, 0.31, 0.33, 0.37.

In the future, collagen recruitment and reorientation will be imaged and quantified across the bladder wall, including the detrusor and adventitia layers, enabling the development of a microstructurally motivated mechanobiological model of the bladder wall [4]. This modeling framework, coupled with biological data will enable us to develop a mechanistic model of the bladder wall that will be used to understand how disease and aging impact the bladder mechanobiology and hence bladder function. For example, changes in fiber architecture with disease or age would be expected to impact urothelial-neural signaling. This in turn could lead to changes in bladder compliance, or, for example, increased spontaneous activity in aged populations.

THREE-ELEMENT WINDKESSEL MODEL TO DESCRIBE PULMONARY VASCULATURE CHANGES IN HYPERTENSIVE RAT

Jesse W. Gerringer (1), Daniela Vélez-Rendon (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering
University of Illinois at Chicago (UIC)
Chicago, Illinois, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is characterized by a rise in blood pressure in the pulmonary circulatory system. Vascular lesions are found in the autopsy of advanced PAH patients. However, to date, the mechanisms leading to these lesions and remodeling of the vasculature are unknown. To ascertain how the disease progresses, we propose to determine the resistive and compliant properties of the vascular wall in a rat animal model of PAH. Four different stages of PAH are evaluated in a monocrotaline (MCT) PAH animal model. Flow measurements from the main pulmonary artery (MPA) obtained *in vivo* are used as the input signal into a three-element Windkessel model. Blood pressure is predicted and compared to the *in vivo* measured data. Through this inverse problem, a set of parameters related to the distal and proximal vascular resistance and compliance are obtained and are used to characterize the effects of PAH in the vasculature as a function of the disease stage.

METHODS

Pressure and flow data were acquired during open chest surgery on a normotensive (placebo – PL) and a MCT-treated animal for each week (Figure 1). The *in vivo* measurements were obtained using a pressure catheter inserted into the right ventricle and placed in the MPA, and an ultrasonic flow probe was wrapped around the MPA. For each animal, four single cardiac cycles were assessed. In order to derive resistance and compliance from the data, a circuit analogy is used (Figure 2). This Windkessel circuit is composed of three elements: a resistor in series and a capacitor and resistor in parallel. The analogy is that blood pressure is equivalent to voltage and blood flow equivalent to flow of electricity, or current. The alternating current source is the heart beat that generates flow. The resistor in parallel, R_d, represents the total vascular resistance and the series resistor, R, is referred to as the characteristic impedance, primarily affecting the proximal vasculature.

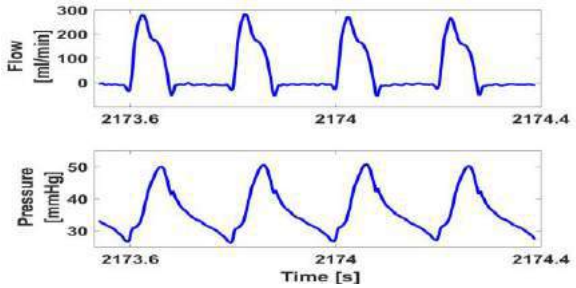

Figure 1: Blood flow (top panel) and blood pressure (bottom panel) measured simultaneously in the rat MPA.

Initial values of R_d and R are determined using Fourier analysis. Each harmonic of impedance is calculated from the ratio of the amplitudes of pressure and flow at the respective harmonic. R_d is obtained from the ratio of mean pressure and flow, and R from the average of the higher impedance frequencies. Thus, characteristic impedance is the impedance in absence of wave reflection. The parameter C represents the compliance of the vessel walls and is arbitrarily set to 0.15 ml/mmHg as an initial guess based on the trends previously seen in our data. Based on conservation principles, or Kirchhoff's law, Equation 1 is derived to represent the pressure and flow relation.

$$\frac{dP}{dt}RR_d + P = \frac{dQ}{dt}RR_dC + Q(R + R_d) \quad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Using blood flow as the input signal, blood pressure is predicted. A set of optimal parameters is determined by minimizing the difference between measured and computed pressure signals using a Nedler-Mead simplex algorithm in Matlab (Mathworks, Natick, Massachusetts, USA). The goodness of fit of our prediction is evaluated using residual mean squared error RMSE=$\sqrt{\sum(P_{data}-P_{model})^2/(N-1)}$ in mmHg, where N is number of data points. Intergroup comparison was done using the Student *t-test* with the assumption of unequal variance and considering $p<0.05$ to be significant.

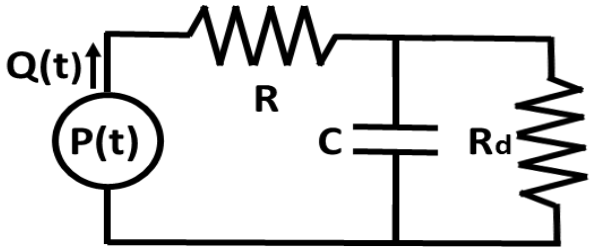

Figure 2: Three-element Windkessel circuit model with a resistor *R*, a resistor R_d, and compliance *C*. *P(t)* represents blood pressure and *Q(t)* blood flow as a function of time.

RESULTS

Here we compare the early and acute/advanced stages of the disease, or week 1 and week 4 post-MCT injections. Plotting the measured against the predicted pressure (Figure 3), we can visually determine a good fit for our model. The RMSE ranges between 0.55 mmHg and 2.65 mmHg, with values near 0.55 mmHg being the better fit. The difference between the prediction and measured pressure is plotted in red and ranges between -4 and 4.3 mmHg.

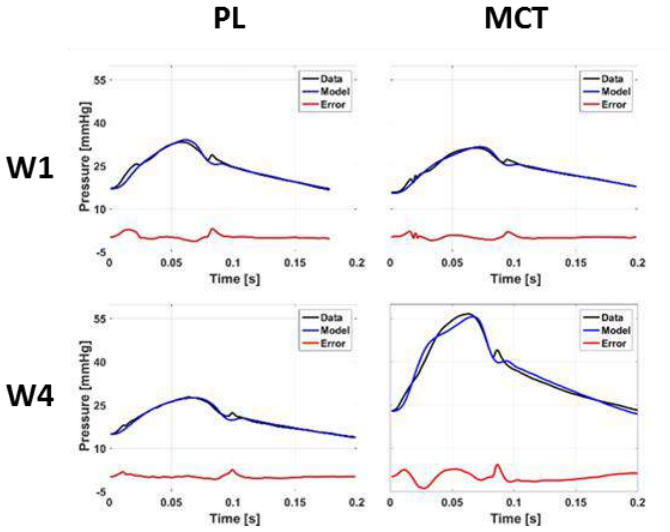

Figure 3: MPA pressure waveforms measured (black line) and predicted of a three-element Windkessel model (blue line). Pressure difference (red line) for PL and MCT groups from weeks 1 and 4.

In the MCT group, R_d and R increased as the disease progressed. This increase was found to be statistically significant from early to acute PAH stage. However, the parameter of compliance C decreased significantly in the progression of the disease. The parameters of resistance in the PL group show no change in the distal vessels (Rd), and no statistical significant change in the proximal vessels (R). Finally, our results show a statistically significant increase in compliance C. The summary statistics of these parameters are illustrated in Figure 4.

DISCUSSION

Our study indicates that the parameters of distal resistance and proximal resistance remain constant in the PL group, whereas in the MCT group we find a statistically significant increase in these parameters as the disease progresses. Based on these results, it is evident that age (4 weeks) does not play a role in vascular resistance, while in the MCT group significant remodeling is occurring. As the MCT injection induces constriction in the pulmonary arteries, a decrease in compliance and an increase in total resistance are to be expected and are in accordance with the work reported by Nishikawa *et al.* [1]. Our findings, and the work by Segers *et al.* using a four-element Windkessel model, are consistent with this notion in that constriction of blood vessels are manifested through the change in these parameters [2, 3]. In week 1 the RMSE values were consistently under 1 mmHg^2, while week 4 MCT had values greater than 2 mmHg^2. This indicates the fitting procedure had a larger error but this goes in hand with the larger pressure ranges in the advanced PAH stage. Through the error plots (Figure 3), one can trace where along the cardiac cycle the fitting is poor. Particularly, we find that our model is unable to fit the physiological characteristic of the pulmonic valve closing, or the dichotic notch. Nevertheless, the prediction of flow is remarkably good, and in our near future, we will explore variations of the Windkessel model to address this physiological marker. Finally, other optimization algorithms will be explored to address the robustness and uniqueness of the parameters.

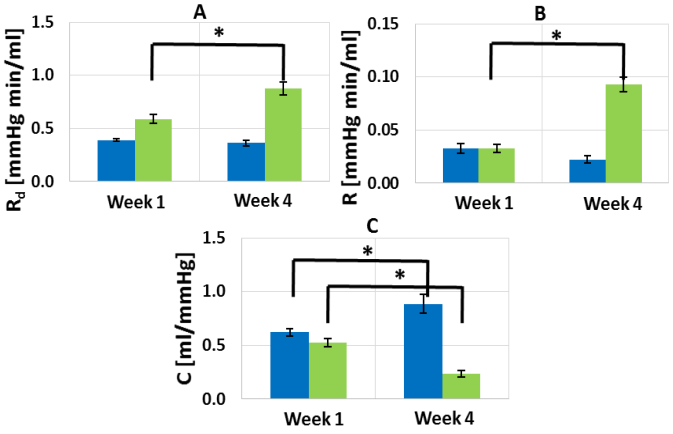

Figure 4: Change in resistance and compliance elements over the course of the four disease stages. A) Total vascular resistance R_d, B) Characteristic impedance *R, and* C) Compliance *C. *p<0.05.* PL is shown in blue and MCT in green.

MICROFLUIDIC-FABRICATION OF BUNDLED CELLULAR SCAFFOLDS BY PHASESEPARATED POLYMER SOLUTION

Y.T. Matsunaga (1), Y.J. Kim (1)

(1) CIBiS, Institute of Industrial Science, The University of Tokyo, Tokyo, Japan

INTRODUCTION

Fibrous structures have been widely developed with a diverse range of geometries, from simple fibres, core-shell structures, to yarns. They are used in filters, electronic devices, and in biomaterial[1]. In particular, bundles of thin, multiply parallel fibres are widely seen in nature such as plant matter, notably in xylems, and human protein assemblies and muscle tissue. Because of their hierarchical structure, they have superior toughness and strength relative to single fibres, and have been a key research focus in artificial tissue engineering. To construct artificial tissues in vitro, soft matter such as polymers, proteins, or colloids have been used because of the ease of fabrication and handling, as well as for the ability to design and manipulate complex, unique structures with two or more components[2]. Thus, biomimetic bundled fibrous structures of soft matter could be used for soft tissue engineering.

Here, we discuss fabrication of biomimetic bundle-structured gel fibres using a microfluidic device and rapid cross-linking of a phase-separated polymer blend solution.

METHODS

Materials

Sodium alginate (Na-Alg) was kindly provided by Kimica Corporation (Tokyo, Japan). The HPC (average MW: 100 kDa) and divinyl sulfone (DVS) were obtained from Sigma-Aldrich (Tokyo, Japan) and Tokyo Chemical Industry (TCI, Tokyo, Japan), respectively.

Fabrication of bundled gel fiber

To generate HPC bundled gel fibre, we used aqueous solutions of HPC and Na-Alg at 28 °C. Phase-separated polymer solution to generate the bundled gel fibres was prepared as follows. H5A1 solution consisting of HPC (5.0 wt%) and Na-Alg (fixed at 1 wt%) polymer blend solution, was prepared by dissolving in Milli-Q water and stirring for 24 hours at pH 13. The co-flow microfluidic device[3] used to fabricate bundled gel fibre was reported previously. H5A1 solution as inner flow and $CaCl_2$ aq. (100 mM) as outer flow was injected into the co-flow microfluidic device. The flow rates were fixed at 300 µL/min and 2,500 µL/min for the H5A1 and $CaCl_2$ solutions, respectively. The fibres were immersed in DVS solution (2.0 wt%, pH 13) for HPC cross-linking for 12 hours under agitation (84 rpm). Citric acid was added to remove un-reacted Alg molecules.

Fabrication of bundled gel fiber

A universal testing machine (UTM, EZ-SX, Shimadzu, Kyoto, Japan) was used to characterize the mechanical properties of the all gel fibres. Each specimen was placed so that the chuck-to-chuck spacing was 20 mm, and pulled at a 10 mm/min load cell rate at 25 or 64 °C in a humid environment.

Cell culture

HPC bundled gel fibres were pre-incubated with PLL-g-PEG-RGD for enhanced cell attachment. Suspended NHDFs (normal human dermal fibroblasts) in Dulbecco's modified Eagle's medium with 10% fetal bovine serum and 1% antibiotics were seeded on the bundled gel fibres at 7,000 cell/mL, and incubated in a 5% CO_2 atmosphere at 37 °C. After 3 and 6 days, immunofluorescence images of F-actin and nuclei were also acquired. To this, the cells were fixed in 4% paraformaldehyde, then the F-actin and the nuclei were respectively stained with Alexa568-conjugated phalloidin and Hoechst33342 (Molecular Probe, Invitrogen, Carlsbad, CA, USA). The stained cells were imaged with CLSM.

RESULTS

Bundled gel fibres and morphologies

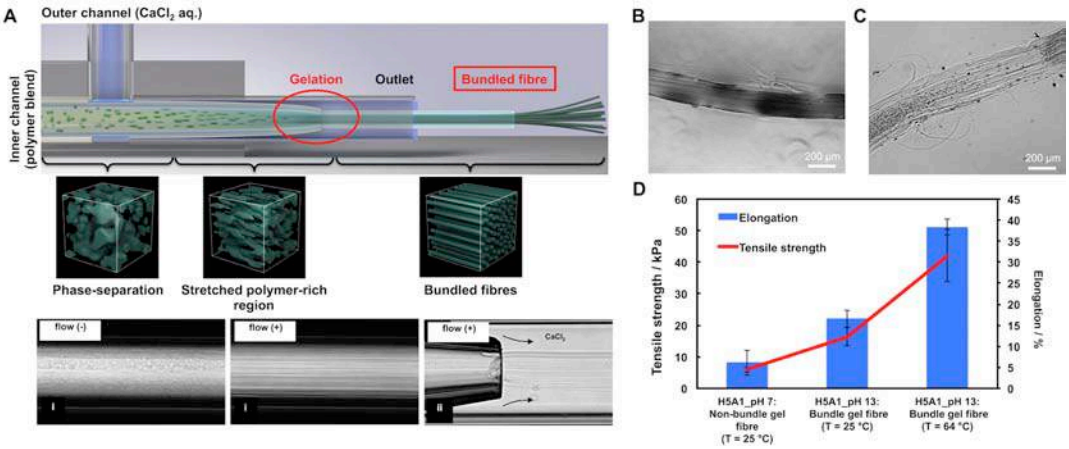

Fig. 1 Fabrication of biomimetic bundled gel fibres using dynamic microfluidic gelation of phase-separated polymer solutions. (A) Microscopic views of phase-separated polymer solution in the microfluidic channel. (B, C) Fabricated bundled gel fibres. (D) Tensile test of the bundled and non-bundled gel fibres.

We generated bundled gel fibres with the co-flow microfluidic device at 28 °C. The aqueous HPC/Na-Alg polymer blend solution (H5A1) and the aqueous $CaCl_2$ solution were injected respectively into the inner and outer channels at respective flow speeds of 300 µL/min and 2,500 µL/min. As shown in Fig. 1A, The phase-separated polymer networks of the H5A1 in the inner channel were stretched by applying shear stress, and were immediately fixed by cross-linking Alg with calcium ions in the co-flow region. We thus obtained bundled gel fibres and non-bundled gel fibres with long lengths and extremely high aspect ratios. The fibre bundles were 200 ~ 400 µm in a diameter and consisted of approximately 10^2 ~ 10^4 small fibres that were 1 ~ 3 µm in a diameter (Fig. 1B and C).

Mechanical properties of bundled gel fibre

We investigated the mechanical properties of the bundled gel fibres with a tensile tester (Fig. 1D). The tensile strength and elongation of the non-bundled gel fibres (H5A1 at pH7) and the bundled gel fibres (H5A1 at pH 13) were 5.9 ± 0.7 kPa, 6.0 ± 2.9%, 16.3 ± 2.9 kPa, and 16.6 ± 2.0%, respectively. These results can be understood by the structure of bundled gel fibres, which can disperse tensile forces among all the constituent small parallel fibres, and inhibit fibre breakage[4]. Furthermore, because the bundled gel fibres were fabricated from cross-linking concentrated polymer domains after phase separation, they have a higher polymer density and enhanced entanglement than do normal gel fibres after gelation. By increasing the temperature above the lower critical solution temperature (LCST) of HPC, the tensile strength can be increased further (42.1 ± 8.2 kPa) because of the strong entanglements in HPC molecules induced by dehydration and shrinking. There was also a much greater elongation (38.3 ± 1.9%) than that observed for temperatures lower than the LCST. Tensile strength and elongation are generally inversely related. However, they both increased with temperature because the residual cross-linked Alg molecules deep in the bundled gel fibres contributed to the elongation instead of condensed HPC molecules above the LCST.

Cell culture of bundled gel fibres

The bundled gel fibres were used as a substrate for culturing NHDFs. After 3 days of cultivation, most of cells were still alive. By immunostaining, we confirmed actin stress fibres in the cells after 3 and 6 days of cultivation. The cells did not fully cover the surface of the bundled gel fibre after 3 days of culturing. However, after 6 days, the fibres were fully covered with cells that expressed actin stress fibres. Most of the cells were aligned parallel to the micro fibres, forming a cylinder-like structure along the fibre bundle. In contrast, no cell orientation was observed on non-bundled gel fibre surfaces; instead they were randomly spread.

DISCUSSION

HPC was the primary material for the gel fibres because it is (i) thermo-sensitive, (ii) easy to acquire in various molecular weights, and (iii) biocompatible. In particular, HPC has a LCST at 45 °C in aqueous solution and thus undergoes a reversible hydrated-to-dehydrated phase-transition with temperature. The polymer Na-Alg blends well with HPC, is rapidly cross-linked, and maintains the string-like structure of the phase-separated solution formed by shear stress. By adding Na-Alg and NaOH to the HPC aqueous solution, a salting-out effect reduces the polymer blend solubility. The phase-separation, therefore, occurs at pH 13 and a lower temperature than the LCST of HPC. Consequently, the polymer blend solution exhibits: (i) an isotropic phase below 25 °C; (ii) an initial formation of droplets via spinodal decomposition at 25 °C; and (iii) droplet growth and network formation above 28 °C. These results demonstrate that the phase-separated state of polymer-rich and polymer-poor regions is key to bundle formation. The bundled gel fibre was an effective scaffold for NHDFs cultures. While spreading along the bundled fibre, the cells fully covered the surface and formed a cylinder-like structure with cell orientations that mimicked vascular, muscle, tendon, and nerve tissues. Given its unique properties, such temperature-responsive property, biocompatibility and ease of manipulation near room temperature, HPC and its blends with the other polymers is an excellent candidate for soft tissue engineering..

ABSTRACT
Characterizing the biomechanical behavior of arterial walls is of paramount importance in understanding the local mechanisms of deformation, progression of vascular diseases, and the underlying mechanisms of Traumatic Aortic Rupture (TAR). Current finite element (FE) models of aorta generally consist of simplistic material models with the assumptions of isotropy and homogeneity that are in contradiction with the inhomogeneous microstructure of aortic tissue. This study investigates the inhomogeneity and anisotropy of porcine descending thoracic aorta (DTA) viscoelastic behavior using a custom-made nano-indentation technique. The results showed that in the radial direction, distinct anatomical features had significantly different instantaneous Young's modulus E with the outer media being stiffer than the inner media. Also, E was significantly lower in mid-DTA and in the medial side. In terms of anisotropy, the axial direction had the lowest modulus, and the circumferential direction showed the least relaxation. Overall, our results suggest that under identical mechanical loading, the medial side of the inner media in the axial direction would experience larger strains compared to other regions. This can party explain why aortic ruptures predominantly initiate from the lumen side and propagate in the transverse direction.

INTRODUCTION
TAR is the 2nd leading cause of morbidity and mortality in motor vehicle crashes only after traumatic brain injury [1]. Consequently, mitigation and prevention of TAR is of paramount importance. Experimental reproductions of complex states of loading and deformation in cadaveric surrogate tests are inconclusive[2], hence FE modeling is the preferred method to gain better insight into the mechanisms of TAR. In current FE models, aorta is assumed to be isotropic and homogeneous; however studies show that aorta has an inhomogeneous microstructure with preferred fiber directions.

The function and mechanical response of aortic tissue depend on its structure and composition. The main components of aortic microstructure are elastin, collagen, and smooth muscle cells. Elastin is a highly elastic protein contributing to the resilience and flexibility of aorta and is responsible for its passive elastic behavior under low stretch. Collagen is the load bearing component, at medium to large stresses, and avoids permanent deformation of aorta. The aortic wall can be divided into three main layers with different structures: intima, media and adventitia. Moreover, the DTA structure changes from proximal to distal sections [3]. The proximal sections contain more elastin content and less collagen content compared with the distal sections. Characterizing the anisotropy and inhomogeneity of aortic tissue is necessary to improve the TAR FE models and in gaining better insight into the local mechanisms of deformation, force transmission, and failure.

METHODS
Fresh porcine aorta specimens were excised from seven pigs. Transverse rings with the length of approximately 9 mm were excised after cleaning the aortas. The specimens were divided into upper-DTA, mid-DTA, and lower-DTA sections along the aortic tree (z direction). In order to study the effect of circumferential location (θ direction) on the mechanical behavior, anterior, posterior, medial, and lateral regions were marked on the specimens. Custom-designed nano-indentation tests were performed in the axial direction (A-Dir.) moving across the aorta thickness (r direction) from the inner wall to the outer wall for each of the mentioned regions. Afterwards, cubic samples were cut at the medial and lateral regions and indentation tests in the circumferential (C-Dir.) and radial (R-Dir.) were conducted at various points across the thickness of the aorta, and on the lumen side of the specimens, respectively. The indenter displacement was ramp and hold with 60 μm depth, 25 ms ramp time, and 20 s hold time. A

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Quasi-Linear Viscoelastic (QLV) model was used to describe the relationship between the indenter force, $P(t)$, and the indentation depth, h:

$$P(t) = \int_0^t G(t-\tau)(\partial P^e(h)/\partial h)(\partial h)/\partial \tau)d\tau \qquad (1)$$

in which $P^e(h)$ is the instantaneous elastic force and $G(t)$ is the reduced relaxation function assumed to be of the following forms:

$$G(t) = G_\infty + \sum_{i=1}^{4} G_i \exp(-\beta_i t) \qquad (2)$$

in which G_i and $\beta_{1..4} = 0.1,1,10,100\ s^{-1}$ are the reduced relaxation amplitudes and decay rates, respectively [4]. The total load needed to achieve h for a conical indenter is [5]:

$$P^e = (1/\alpha)\{2Ecot(\beta)/\pi(1-\nu^2)\}h^2 \qquad (3)$$

where $\beta = 62.5^\circ$ is the semi-vertical angle of the indenter, E is the instantaneous Young's modulus, and ν is the Poisson's ratio which was assumed to be 0.49 (almost incompressible) for fresh aorta. The correction factor, α, accounts for the imperfect geometry of the indenter and contact surface and was evaluated as 3, for h = 60 μm [4].

RESULTS

The QLV material parameters (Eqs. 2 and 3) were determined by optimizing for G_i and E to match the experimental data. Fig. 1 shows the variation of E (determined in A-Dir.) with z direction (error bars represent the standard error). There is an increase in E from proximal to distal sections where the lower-DTA is about 15% stiffer than the upper-DTA (p<0.0001). Comparison between the values of E (A-Dir.) in different regions in the θ direction shows that the medial side is significantly more compliant (p<0.0001) compared to other locations (Fig. 2). Fig. 3 shows relatively large variations in E in the r direction, where $r = 0$ and 1 represent the innermost and outermost layers, respectively. Fig. 4 shows the anisotropy of E as this parameter is significantly higher in R-Dir. compared with A-Dir. (p<0.0005). G_∞ was significantly different in tests conducted in A-Dir., C-Dir., and R-Dir. (p<0.0002). Also, G_∞ was about 30% which confirmed that significant anisotropic viscoelasticity (stress relaxation) exists in the tissue.

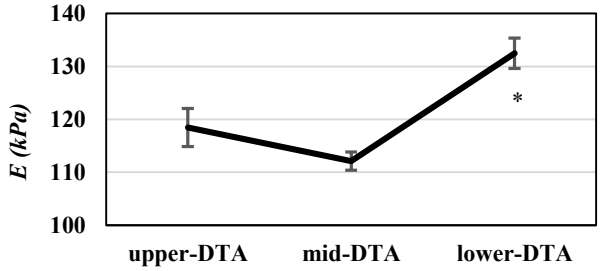

Figure 1: Variation of E in the z (longitudinal) direction.

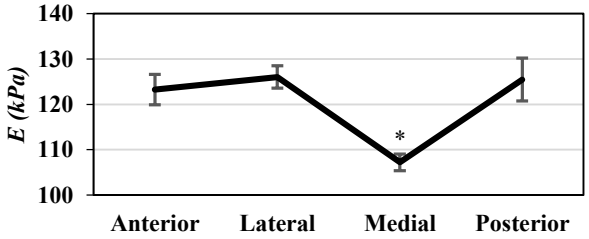

Figure 2: Variation of E in the θ (circumferential) direction.

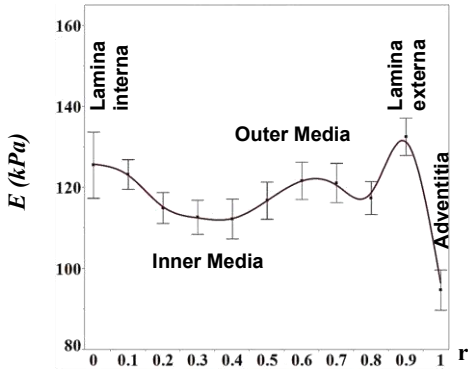

Figure 3: Variation of E in the r direction (across the thickness).

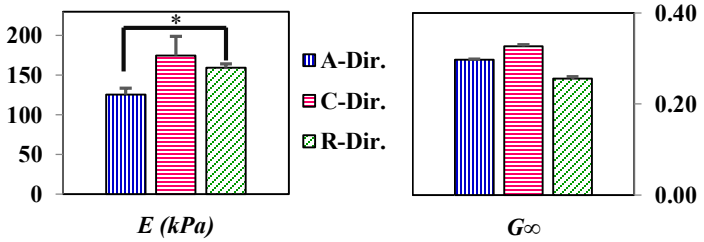

Figure 4: Three-dimensional anisotropy of E and G_∞.

DISCUSSION

The results showed that the assumption of viscoelastic behavior for aorta is valid and the characterized QLV model could sufficiently describe the experimental data. The statistical analysis showed there were regional variations in aorta, where E was significantly higher in the distal sections compared to the proximal ones. This is in agreement with previous study of Sokolis et al. [3] in which they showed these variations were due to changes in aorta micro-structure, i.e., a decrease in the elastin content, and an increase in the collagen content. The variation of E in the r direction showed five distinct regions which approximately corresponded to the micro-structural organization of fibers including lamina interna, inner media, outer media, lamina externa, and the adventitia, respectively.

The porcine DTA showed anisotropy both in terms of the elastic and relaxation characteristics. The A-Dir. showed the least stiff behavior and the C-Dir. showed the least relaxation.

The proximal sections and the medial region of aorta were more compliant and therefore experience higher strains in identical loading conditions. Based on previous studies [7] aortic failure is strain based. Therefore, our results suggest that the medial region, closer to the aortic arch, can be more prone to rupture in an axial loading.

1. INTRODUCTION

One of the problems with the cerebral bypass surgery is a high rate of postoperative complications such as cerebral hyperperfusions, cerebral ischemia, and strokes[1]. These complications occur because the adaptation mechanisms of the cerebral arteries are yet unknown to predict the blood flow condition after the surgery. As a well-known arterial adaptation mechanism, it is widely recognized that endothelial cells control the diameter of the artery along with the change of blood flow by sensing the wall shear stress (WSS)[2]. It has been also postulated that the mean wall shear stress (MWSS) is maintained at a constant value in the arterial system[3]. However, there are not many studies that have discussed about the consistency of the MWSS in the major cerebral arteries where brain surgeons are interested. Therefore, this study investigates the consistency of the MWSS for the major cerebral arteries around the circle of Willis to further understand the adaptation mechanism of the cerebral arteries.

2. METHODS

2.1 Subjects

12 healthy volunteers were examined for the phase-contrast magnetic reasoning imaging (PC-MRI) and the blood viscosity measurement. The PC-MRI examinations were carried out at Kitahara Internnational Hospital and the blood viscosity were measured at Waseda University. Of 12 subjects proceeded to MRI examination, 4 subjects were excluded due to technical problems. 1 subject was excluded from the blood viscosity measurement because the blood sample could not draw from the subject. In total the study population consisted of 7 healthy subjects (average age 26.3 years; 6 men, 1 woman).

2.2. Measurement of blood flow rate and diameter

PC-MRI method was conducted for noninvasive measurement of cerebral blood flow rate and arterial diameter. Phase contrast data have been acquired using GE Signa HDxt (3.0T). Specifications of the MR imaging conditions were as follows: FOV = 128mm, number of pixels = 256 × 256, Resolution = 0.5 mm, slice thickness = 5 mm, velocity encoding = 150 cm/s, bandwidths = 64 kHz, 20 images per beat, and NEX = 4. Major cerebral arteries examined for the study includes: basilar artery (BA), both sides of internal carotid arteries (ICA), middle cerebral arteries (MCA), anterior cerebral arteries (ACA), posterior cerebral arteries (PCA), and superior cerebellar arteries (SCA).

2.3. Blood Viscosity Measurement

The Blood samples from each of the subjects were anticoagulated with heparin for 50 to 1 ratio (blood to heparin). A rotating viscometer (TPE-100, Toki-Sangyo, Japan) was used to measure the viscosity of the blood. The maximum shear rates of the viscometer (383 s^{-1}) were recorded as blood viscosity.

2.4. Acquisition of MWSS Characteristics

MWSS (τ_w) were calculated assuming that the Hagen Poiseuille flow is established in the major cerebral arteries. According to the Hagen Poiseuille formula, WSS can be calculated as shown below:

$$\tau_w = \frac{32\mu Q}{\pi d^3} \qquad (1)$$

where μ (mPas) is the viscosity of blood measured, Q is the blood flow (mL/min), and d is the diameter (mm). To calculate and investigate the consistency of MWSS, the results were plotted on a graph with the third power of the diameter as an x-axis and the blood flow rate as a y-axis. The MWSS was calculated from the coefficients of the linear approximated lines constructed from the graph assuming the blood viscosity is unchanged anywhere within the cerebral arterial system. The level of a correction coefficient of the linear approximations represents the level of consistency of the MWSS.

3. RESULTS

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Total of 80 cerebral arteries, 10 to 13 cerebral arteries per a subject, were successfully analyzed and plotted on the graph with the third power of the diameters as x-axis against blood flow rates as y-axis (see Figure.1). Table.1 shows correlation coefficients, MWSSs, and blood viscosity for each of seven volunteers examined with this study.

3.1. Consistency of MWSS in each subject

For all the subjects, correlation coefficients of linear approximation lines were ranged from 0.419 to 0.898 with the average value of 0.659 ±0.187 (see Table.1). The bold trend line in Figure.1 displays the linear approximation line for all the 80 arteries analyzed. The overall correlation coefficient was confirmed as 0.514.

3.2. MWSS Value

WSSs for each subjects were ranged from 1.20 Pa to 2.77 Pa with the average WSS of 1.92 ±0.53 Pa.

3.3. Blood Viscosity

Blood viscosities were ranged from 3.77 mPas to 4.81 mPas with the average value of 4.24 ±0.35 mPas.

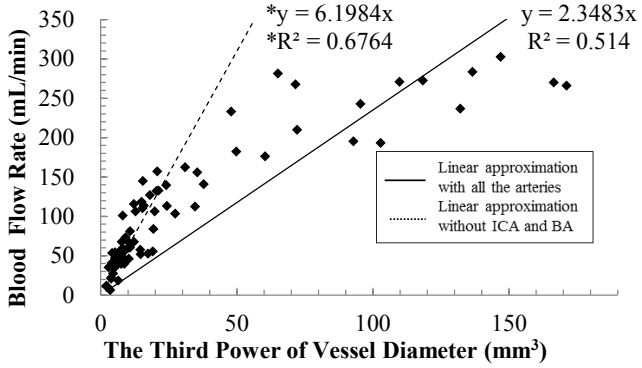

Figure 1: Blood flow rate vs. the third power of vessel diameter for all 80 arteries analyzed in this study. The solid line shows the linear approximation with all the arteries. *The dotted line shows the linear approximation excluding ICA and BA.

Table 1: Correlation coefficients, MWSSs, and blood viscosities for each of seven subjects. * Correlation coefficient and MWSS calculated excluding ICA and BA.

Subject ID	Correlation Coefficient (R^2)	MWSS (Pa)	Blood Viscosity (mPas)	*Correlation Coefficient (R^2)	*MWSS (Pa)
#1	0.419	1.60	4.09	0.678	4.11
#2	0.812	1.74	4.47	0.325	3.76
#3	0.586	1.81	4.81	0.898	6.50
#4	0.677	1.91	4.13	0.887	4.04
#5	0.898	2.77	3.77	0.692	5.28
#6	0.434	1.20	3.98	0.733	3.88
#7	0.788	2.45	4.45	0.900	4.10
Average Value	0.659 ±0.187	1.92 ±0.53	4.24 ±0.35	0.730 ±0.204	4.52 ±1.01

4. DISCUSSION

4.1. MWSS Values

The former studies have shown that the range of human CCA's MWSS are reported to be 0.50 Pa to 1.52 Pa[4,5,6]. In this study, the MWSS value for cerebral arteries is 1.92 Pa. It can be said that the value of this study is considerably similar to the former studies.

4.2. Consistency of WSS

A linear relationship between the third power of the vessel diameters and the blood flow rate represents the consistency of the MWSS within the arterial system. The consistencies of MWSS were somewhat observed because the linear relationship ($R^2 > 0.42$) were confirmed in all seven healthy volunteers. However, judging from the shape of plots in Figure.1, the linear approximation might not be the best fitting curve for the data. It seems that arteries with smaller diameters fit in a linear approximation, but not for the arteries with larger diameters including ICAs and BAs.

4.3. Consideration of the Wormersley number

In the cardiovascular system, the parabolic velocity profile cannot be assumed if the inertial force induced by the pulse is stronger than the viscous force of the blood. Thus, the non-establishment of the Poiseuille flow in the region with larger diameters might be the reason for ICAs and BAs to be deviated from a linear approximation. In order to investigate the establishment of the Poiseuille flow, the Wormerley numbers (α) are examined with a formula below:

$$\alpha = \frac{D}{2}\sqrt{\frac{\omega\rho}{\mu}} \qquad (2)$$

where angular frequency (ω) as 1.083 (assuming a general human heart beat as 65 BPM), a blood density(ρ) as 1060 kg/m^3, a blood viscosity (μ) and the arterial diameter (D) as measured values. The average Wormersley number for ICAs was 3.06 and 2.20 for BAs. It suggests that the Poiseuille's equation is questionable in the regions of ICAs and BAs. The correlation coefficients and MWSSs were re-calculated excluding ICAs and BAs, and the results were also shown in Table.1 and Figure.1. Strong linear relationship (R^2=0.73) was confirmed with a higher MWSS value of 4.52 Pa by excluding ICAs and BAs. The difference between the MWSS of 1.92 Pa and 4.52 Pa were because of the assumption of Poiseuille's equations. The Wormersley numbers calculated for ICAs and BAs suggested that the Poiseuille's flow cannot be is established in those large arteries. Therefore, the MWSS for the larger arteries might have been underestimated. Furthermore, S.K. Samijo[7] have calculated the MWSS using the actual velocity profile of CCA of male in the age of 20 to 29, and the MWSS and the peak WSS (PWSS) was found to be 1.39 Pa and 3.59 Pa, respectively. The values of the PWSS by Samijo and our MWSS (excluding ICAs and BAs) are quite similar; thus, it can be inferred that the actual WSS "sensed" by the endothelial cells may be constant around 4.50 Pa throughout the cerebral arterial systems.

5. CONCLUDSION

The consistency of WSS in cerebral arteries was studied for healthy volunteers to further understand the blood flow regulation mechanism of cerebral arteries. The result of this study suggests that establishment of Poiseuille flow must be considered for calculating MWSS. In addition, by considering the establishment of the Poiseuille flow, the MWSS of the cerebral arteries are constant in a healthy volunteer.

LONGITUDINAL ASSESSMENT OF MOUSE BONE MICROSTRUCTURE BY IN VIVO μCT IMAGING WITH MINIMAL RADIATION EFFECTS

Hongbo Zhao, Chih-Chiang Chang, Youwen Yang, Wei-Ju Tseng, Chantal M de Bakker, X Sherry Liu*

McKay Orthopaedic Research Laboratory,
University of Pennsylvania,
Philadelphia, PA, USA

INTRODUCTION

In the last decade, development of the *in vivo* micro-computed tomography (μCT) imaging techniques has enabled assessment of longitudinal changes in bone mass and bone microstructure in small rodents, such as rats and mice [1]. However, there are concerns associated with *in vivo* μCT due to its exposure of tested animals to ionizing radiation. This side effect may cause damage to bone cells, thus affecting bone quality. Therefore, it is important to understand the radiation effects associated with *in vivo* μCT imaging protocols of different settings. However, to date only a limited number of studies have addressed this subject. Laperre *et al.* tested radiation effects of μCT protocols with a high (9μm) and low (18μm) image resolution on mouse tibia after3 repeat scans with 2-week interval. They reported minor radiation effects for low image resolution protocol. However, the high resolution protocol caused significant bone loss in the irradiated tibia [2]. Another study by Klinck *et al.* tested radiation effects of a weekly scan protocol on multiple mouse strains and showed a significant decrease in bone volume fraction (BV/TV) in the irradiated tibia at 10.5 μm voxel size [1]. The above studies suggested that different scan settings, such as image voxel size, scan frequency, and scan intervals, may have different effect on bone. The purpose of this study was to develop a low dose, *in vivo* μCT protocol for imaging mouse femur and vertebrae and to test the radiation effects of this protocol on bone quality and bone cell activities. The new protocol, in which mice are scanned at 10.5μm (femur) and 15μm (vertebra) with 3-week interval, was tested on both the tissue level and cellular level for the first time. We hypothesized that a well designed *in vivo* scanning protocol can assess longitudinal changes in mouse bone microstructure with minimized radiation effects.

METHODS

All animal studies performed in this research were approved by the Institutional Animal Care and Use Committee (IACUC) at the University of Pennsylvania. Eight female C57BL/6J (BL6) mice were scanned at the right femur and the 4th lumbar vertebra (L4) by an *in vivo* μCT system (VivaCT40, Scanco Medical, Switzerland). For the distal femur, 212 slices were scanned at 10.5 μm voxel size. For the L4, 212 slices at the center of L4 were scanned at 15μm voxel size. The scanner was operated at 55 kVp energy, 145 μA intensity, and 200 ms integration time and the average time for each scan was about 10 minutes. This scan protocol induced a radiation dose of 639 mGy on femoral bone and 310 mGy on vertebral bone. Baseline scans occurred when mice reached age 12 weeks, and 2 follow-up scans were performed at 3 and 6 weeks after the baseline scan. All animals were sacrificed 3 weeks after the last scan when they reached age of 21 weeks. Left (non-radiated) and right (radiated) femur, L3 (non-radiated) and L4 (radiated) vertebra were harvested from each mouse for further analysis.

All the harvested bone samples underwent *ex vivo* scans at 6 μm isotropic voxel size in a μCT system (MicroCT35, Scanco Medical, Switzerland). In each scan, 227 slices in the region that was covered in the *in vivo* μCT scan were acquired. Images were smoothened using a Gaussian filter (sigma = 0.6, support = 1), followed by a segmentation threshold corresponding to 450.7 mgHA/cm^3 and semi-automatic contouring to extract the trabecular bone for microstructural analysis. Bone volume fraction (BV/TV), connectivity density (Conn.D), structure model index (SMI), trabecular number (Tb.N), trabecular thickness (Tb.Th), and trabecular spacing (Tb.Sp) were calculated by three dimensional (3D) standard microstructural analysis software provided by the manufacturer. Bone microstructure was also evaluated

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

for all baseline scans. Percent changes over 9 weeks were quantified by comparisons between the baseline and endpoint scans.

Both left and right femurs were processed for methylmethacrylate embedding. Five μm thick plastic sections were cut using a Polycut-S motorized microtome (Reichert, Heidelberg, Germany) and stained with Goldner's trichrome stain (Fig.1) [3]. Histomorphometric measurements were performed in the metaphyseal bone region that was scanned by *in vivo* μCT using Bioquant Osteo Software (Bioquant Image Analysis, Nashville, TN). Osteoblast number (Ob.N/BS), osteoclast number (Oc.N/BS), osteoblast surface (Ob.S/BS), and osteoclast surface (Oc.S/BS) were evaluated.

Paired Student's t-tests were performed to compare radiated and non-radiated bone microstructure and bone cell activities. A p value below 0.05 was considered to indicate significant radiation effect.

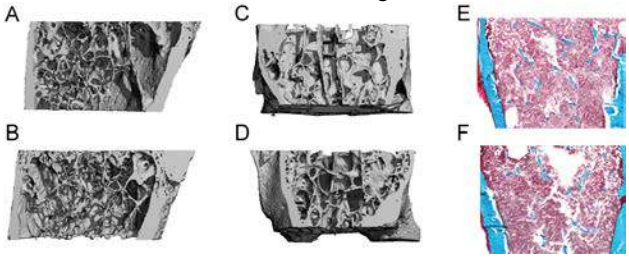

Figure 1. Representative μCT images of (A) non-radiated left femur *vs.* (B) radiated right femur; (C)non-radiated L3 *vs.* (D)radiated L4; and representative Goldner trichrome staining images of (E) non-radiated left femur *vs.* (F) radiated right femur.

RESULTS

Comparisons between radiated L4 and non-radiated L3 showed no significant difference in BV/TV, Tb.Th, SMI, or Conn.D. However, radiated L4 had 10.0% lower Tb.N and 14.1% greater Tb.Sp than non-radiated L3 ($p<0.05$). As for the femur, there was no difference in BV/TV, Tb.N, or Tb.Sp between radiated right femur and non-radiated left femur. However, radiated right femur had 28.8% lower Conn.D, 16.8% greater SMI, and 12.8% greater trabecular thickness (Tb.Th) than non-radiated left femur (Fig 2). Bone histomorphometry analysis showed no difference in Ob.N/BS, Oc.N/BS, Ob.S/BS or Oc.S/BS between the non-radiated and radiated femurs (Fig 2).

Comparisons between the baseline and endpoint scans suggested significant bone loss in mice from age of 12 to 21 weeks, as shown in Table 1.

Table 1. % change in bone microstructure in mice from age of 12 to 21 weeks. * indicates significant change ($p<0.05$).

% change over time	Distal Femur	Lumbar Vertebra
BV/TV	-31.3 ± 22.6*	-12.4 ± 10.6*
Tb.N	-21.7 ± 6.4*	-22.2 ± 8.9*
Tb.Th	2.3 ± 11.3	-19.6 ± 4.7*
Tb.Sp	31.9 ± 9.6*	29.6 ± 14.5*
SMI	-3.7 ± 12.1	-64.7 ± 8.9*
Conn.D	26.6 ± 68.6	23.9 ± 43.9

DISCUSSION

In this study, we developed and tested a low dose, *in vivo* μCT scan protocol of the mouse femur and vertebra with image voxel size of 10.5 μm and 15 μm, respectively. Minimal radiation effects were found on trabecular bone mass and microstructure while no radiation effect was observed in number and surface of osteoblasts and osteoclasts.

Despite minimal radiation effect on BV/TV, significant differences found in Tb.N and Tb.Sp of the vertebra, and Conn.D, SMI, and Tb.Th of the femur suggested that radiation effect by *in vivo*μCT can lead to deteriorations in trabecular bone micro architecture. Nevertheless, aging also plays a significant role in trabecular bone loss. Results from our study is consistent with those reported by Glatt*et al.*, which showed that female mice had significant bone loss in the distal femur and vertebra from age of 3 to 5 months [4]. Comparing with aging effect, our study suggested that ionizing radiation associated with *in vivo* μCT exerted significant but negligible effect on some of trabecular bone microarchitecture parameters. Therefore, we conclude that the low dose *in vivo* μCT imaging protocols developed for the mouse femur and vertebra can assess longitudinal changes in bone mass and microstructure with minimal radiation effects.

INTRODUCTION

Computational hemodynamics have been investigated as a clinical tool to aid in identifying rapidly progressing coronary artery disease (CAD) and the potential for lesions to acquire high-risk characteristics (i.e., vulnerable plaque). Prospective clinical investigations have evaluated the prognostic value of wall shear stress (WSS) in determining the characteristics of CAD progression [1,2]. However, the evaluation methods to quantify the association between these spatially heterogeneous data are varied. For example, studies have employed analysis techniques that average the hemodynamic data over 3-mm segments [2] or around the artery circumference [1] and associate these data with intravascular ultrasound (IVUS) defined CAD progression. Moreover, we recently developed a framework that allows for examination of the focal association between WSS and CAD progression [3]. Although each of these studies has merit in investigating the complex association between hemodynamics and CAD progression, the accurate and specific identification of vulnerable plaques has direct clinical implications in long-term prognostication of patients with CAD.

Therefore, the aim of this investigation was to examine differences in hemodynamic characterization and resulting associations with CAD progression between the previously employed evaluation methods. We present data from patients with moderate CAD and note distinct differences in CAD progression patterns, for example, in areas of low and oscillatory WSS.

METHODS

Clinical Data Patients (n = 20) enrolled in a prospectively study evaluating the association between WSS and VH-IVUS defined CAD progression were included in this investigation. Enrollment criteria and acquired clinical data have been previously described in detail [1]. Briefly, patients presenting with an abnormal non-invasive stress test of stable angina and determined to have non-obstructive disease were enrolled. Patients underwent baseline and 6-months follow-up catheterizations to collect
biplane coronary angiography, end-diastolic gated virtual histology-IVUS (VH-IVUS) images, and Doppler derived velocity data. The Emory University Institutional Review Board approved the study, and each patient provided informed consent.

Computational Modeling The patient-specific computational fluid dynamics (CFD) modeling techniques employed have been previously described in significant detail [1,4]. Briefly, the 3-dimensional (3D) lumen geometries were reconstructed from biplane angiography and segmented VH-IVUS images. A volume was created from the reconstruction (Geomagic Studio 11, Geomagic, Inc.), discretized with an unstructured tetrahedral mesh (ICEM CFD 15.0, ANSYS, Inc.), and imported into a commercial solver FLUENT (ANSYS, Inc.). Patient-specific pulsatile velocity values were applied at the inlet of the computational domain as a series of uniform profiles. Outlets were assumed traction-free, and a no-slip boundary condition was applied at the rigid wall. Following simulation convergence, WSS vectors were extracted at each node across the cardiac cycle. Vector magnitudes were averaged across the cardiac cycle yielding time-averaged (WSS) values. Furthermore, the WSS angle deviation (WSSAD, ϕ), which quantifies the temporal angular variation between the TAWSS vector and instantaneous WSS vectors at each node, was calculated at time points (n) throughout the cardiac cycle as,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\phi_n = \arccos\left(\frac{\vec{\tau}_i \cdot \vec{\tau}_j}{|\vec{\tau}_i| \cdot |\vec{\tau}_j|}\right) \quad (1)$$

where τ_i and τ_j are the TAWSS and instantaneous WSS vectors, respectively. The maximum WSSAD value in the cardiac cycle was determined to characterize the oscillatory hemodynamic environment.

Plaque Progression Quantification Longitudinal VH-IVUS images were co-registered in the axial and circumferential direction with the aid of fiduciary anatomical landmarks and a developed multivariate cross-correlation algorithm [1,5]. Changes in total plaque and constituent areas (fibrous, FT; fibro-fatty, FF; necrotic core, NC; dense calcium, DC) were quantified in focal regions (i.e., sectors) by comparing co-registered baseline and 6-month follow-up image data.

Data Analysis Baseline hemodynamic were evaluated in 3-mm segments, circumferentially, and sectors. Briefly, hemodynamic data were extracted over 3-mm segments, which encompassed 6 VH-IVUS images (0.5mm between images) or at the spatial location of each VH-IVUS image. Data were either averaged within the 3-mm segment, around the artery circumference, or within defined sectors (Fig. 1). To allow for comparison between the analysis techniques, sectors for a given paired VH-IVUS image set were assigned a segment, circumferential, or sector defined TAWSS and WSSAD value. Thus, while there were 8 values for change in total plaque and each VH-IVUS defined plaque constituent areas, the same spatially (circumferentially) averaged hemodynamic values were assigned to each sector for the circumferential method. Moreover, the same segmental average of hemodynamic values were assigned in all sectors across the 6 images within each defined segment.

We classified TAWSS values into three groups: low (< 10 dynes/cm^2), intermediate (10-25 dynes/cm^2), and high (> 25 dynes/cm^2) [1,4]. Similarly, WSSAD values were classified as low (< 45°), intermediate (45°-90°), or high (>90°) oscillation [3]. Finally, sectors were identified that exhibited both low TAWSS < 10 dynes/cm^2 and high WSSAD > 90°, herein low and oscillatory WSS.

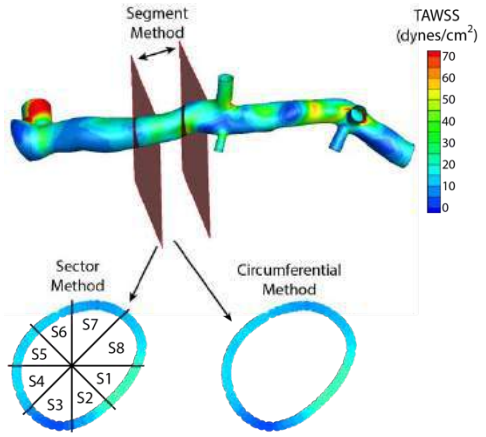

Figure 1: Evaluation methods to characterize hemodynamic environment. TAWSS and WSSAD values were averaged within defined regions (e.g., 3-mm segment, circumference, sector) and associated with VH-IVUS defined CAD plaque progression.

RESULTS

Examination of the hemodynamic data revealed a significant reduction in data count and range by increasing the dimension over which data were spatially averaged. Employing the sector analysis (n = 14,235) resulted in TAWSS values ranging from 1.0 – 363.3 dynes/cm^2, whereas the circumferential analysis (n = 1,846) led to a range from 2.1 – 117.7 dynes/cm^2 and the segment method (n = 307) from 2.6 – 100.6 dynes/cm^2. Furthermore, WSSAD values ranged from 0.2° – 178.4°, 0.6° – 124.6°, and 0.8° – 69.9° for the sector, circumferential, and segment method, respectively. Observed variations in the characterized hemodynamic environment between the analysis methods resulted in noticeable differences in the association between hemodynamics and 6-month VH-IVUS defined plaque progression. Most notably, distinct differences in progression patterns were observed in the low and oscillatory WSS environment (Fig. 2). Employing the sector method, we observed regression of total plaque, fibrous, and fibrofatty tissue area, but progression of necrotic core and dense calcium; however, we observed regression of total plaque, fibrous, necrotic core, and dense calcium tissue, but progression of fibrofatty tissue utilizing the circumferential method. Notably, there were no 3-mm segments that exhibited a (spatially averaged) low and oscillatory WSS environment.

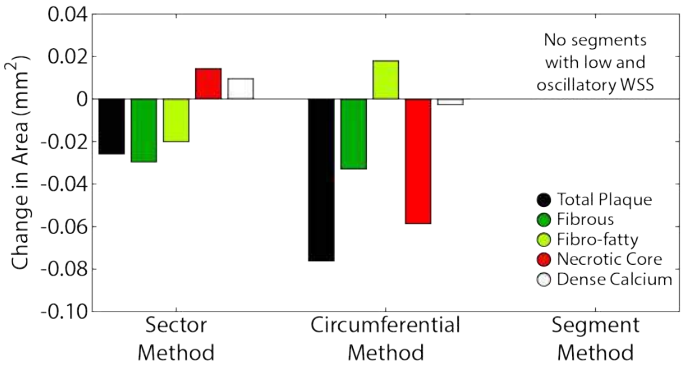

Figure 2: Association between CAD and low and oscillatory WSS employing the sector, circumferential, or segment method. Note that no segments had a spatially averaged hemodynamic environment characterized by low TAWSS (< 10 dynes/cm^2) and high WSSAD (>90°).

DISCUSSION

Our investigation highlights the importance of analysis methods when examining the complex association between hemodynamics and CAD progression, and the dependence of progression patterns on these analysis methods. We report a significant reduction in hemodynamic variable data range when the size of spatial averaging is increased, and these reductions led to definitive differences in associations with CAD progression patterns (Fig. 2). It cannot be overemphasized that CAD progression and plaque rupture are focal pathologic events [5], and associations with variables that influence these events should be analyzed at a similar length scale. Thus, the (spatial) reduction of hemodynamic data and masking of complex hemodynamic environments should be limited to avoid misinterpreting resulting associations. Future clinical studies that rigorously evaluate the hemodynamic environment and CAD progression at a focal length scale will provide insight on the long-term prognostication of WSS in the early identification of high-risk coronary lesions.

INTRODUCTION

The water content of soft connective tissues strongly influences their mechanical properties. Mechanical tests are usually performed in a buffer solution to regulate the tissue water content. Phosphate buffered saline (PBS, 0.9% w/v (0.15 M)) is the most common solution. The concentration of isotonic 0.9% PBS solution closely corresponds to the physiological concentration of the interstitial fluid. However, fibrous tissues become over-hydrated and swell in PBS, decreasing their modulus [1]. In addition, over time the buffer's solutes can diffuse into the tissue, altering both the structure and mechanics. These two effects, swelling and solute diffusion, are time-dependent so the apparent mechanical properties are different depending on the duration over which the tissue is exposed to the buffer solution. Thus, a short mechanical test would have consistent properties through the course of the experiment. However, a longer mechanical test, such as a fatigue test lasting several hours, can be problematic because the mechanical effects of fatigue loading and of hydration and solute diffusion may confound each other. As a result, it is important to identify and minimize the effect of the buffer solution on tissue mechanics.

Alternative solutions to PBS have been used, such as sucrose [3] and poly(ethylene) glycol (PEG) [4], which is a hydrophilic polymer. However, it is not known how PBS or alternative buffers affect the tissue for long-term tests (hours to days). The objective of this study was to measure the effect of exposure to buffer solution on tendon structure and mechanics and suggest an appropriate buffer for long-term mechanical tests.

METHODS

Sprague-Dawley rat tail tendons from 7-13 month old animals were used in this study. Fascicles were harvested from the proximal end of the tail and 60 mm long samples were incubated for 8 hours at room temperature in a range of concentrations of sodium chloride (NaCl) or PEG (20kDa molecular weight). The solutions of varying concentrations were buffered with Tris (0.01M) to pH=7.6. Additional samples were incubated in 0.9% NaCl, 25% NaCl, or 8% PEG for only 15 min to represent the duration of a short mechanical test. Each sample was then weighed (W_{wet}), dehydrated at 40˚C in an oven for 20 hours, and weighed (W_{dry}). The apparent water content (φ_{app}) was calculated as:

$$\varphi_{app} = \frac{W_{wet} - W_{dry}}{W_{wet}} \qquad (1)$$

The tendon is permeable to buffer solutes, especially in high concentrations. In order to measure the solute diffusion into tendon, which can artificially lower the apparent water content, true water content was measured in a separate group of samples (n=5/group). The sample was initially dehydrated, weighed ($W_{dry,i}$), incubated for 8 hours, weighed (W_{wet}), dehydrated a final time, and weighed ($W_{dry,f}$). The true water-content (φ_{true}), which excluded solutes that diffused into the tissue, was calculated as:

$$\varphi_{true} = \frac{W_{wet} - W_{dry,f}}{W_{wet} - (W_{dry,f} - W_{dry,i})} \qquad (2)$$

The percent difference between the apparent and true water content was calculated as $100(\varphi_{true} - \varphi_{app})/\varphi_{app}$.

Uniaxial tensile mechanical tests were performed in 0.9% NaCl and concentrations that, based on hydration curves for each solution (Fig. 1), maintain the fresh-frozen apparent water content after 8 hours of incubation (25% NaCl and 8% PEG). The 60 mm tendon was cut into equal proximal and distal portions, randomly assigned to non-treated (fresh-frozen) and treated groups (8 hours incubation prior to test). All tendons were tested in a bath of the 'treatment' buffer, such that the exposure time of non-treated samples to buffer solution during

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the test was 15 min, while the treated samples were in a buffer for 8 hours and 15 min. For the mechanical test the sample was preloaded to 0.01 N, preconditioned for 5 cycles of 2.5% grip-to-grip strain (ref. length = 10.9 ± 0.8 mm), and loaded to 5% strain at 1%.s^{-1}. This strain was maintained during a 10 min stress-relaxation. The tangent modulus was measured and averaged between 1.5%-4% strain, and the percent stress relaxation was measured. One-way ANOVA and a post-hoc Tukey's test were used to compare across different solutions. Paired t-tests were used to compare non-treated to treated groups within the same solution. Significance was set at $p<0.05$.

To observe the change in microstructure due to the buffer treatment, fascicle cross-sectional images were obtained using transmission electron microscopy (TEM) for fresh-frozen tissue and after 8 hours of incubation in 0.9% NaCl and 8% PEG solutions (n=1/group, 3 month old rat).

RESULTS

The fresh-frozen water content was 52.9 ± 1.6% (n = 58) (Fig 1, dashed line). The apparent water content for both NaCl and PEG decreased with an increase in solute concentration, with 25% NaCl and 8% PEG closely matching the fresh-frozen water content (Fig 1). The apparent water content after 15 min and 8 hours was unchanged for 0.9% NaCl and 8% PEG (Fig 1). However, 25% NaCl has a dramatic drop in the apparent water content at 15 min that increases to the equilibrium value at 8 hours (Fig 1). The true water content was higher than the apparent water content for NaCl, but there is no difference for PEG (Fig 2), demonstrating solute diffusion into the sample for NaCl concentrations above 5%.

The modulus of the 8% PEG group was unchanged compared to the untreated group, however the modulus of the 0.9% and 25% NaCl groups decreased by 27% and 23%, respectively, with treatment ($p<0.05$, Fig 3). The percent relaxation decreased by a small amount (4%, $p=0.04$) for the PEG group and was unchanged for the NaCl treatments (Fig 3). When comparing the non-treated groups across the solutions, the 25% NaCl modulus was higher and the percent relaxation was lower than the 8% PEG and 0.9% NaCl groups ($p<0.05$), perhaps related to the initial apparent dehydration at 15 min (Fig 1).

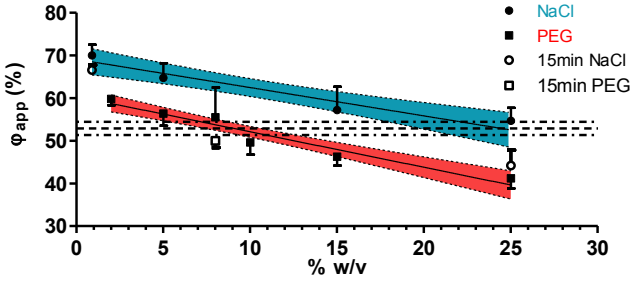

Figure 1: Apparent water content at equilibrium (8 hours) or 15 min (hollow marker) incubation in NaCl (n=17) and PEG (n=44). Dashed lines = fresh frozen water content mean ± CI (95%). Error bars indicate mean ±

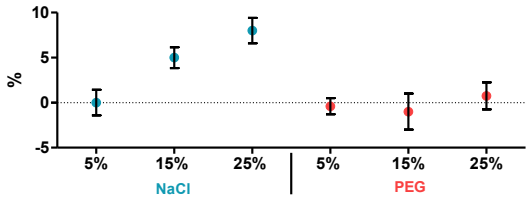

Figure 2: Percent difference between true and apparent water content. The bars indicate mean ± SD.

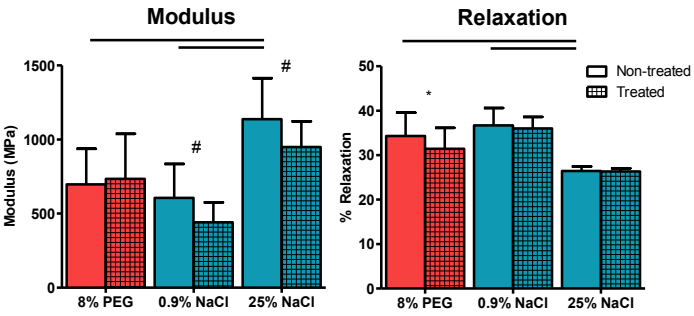

Figure 3: Modulus and percent relaxation following short and long-term exposure to different solutions. #p<0.05 *p=0.04.

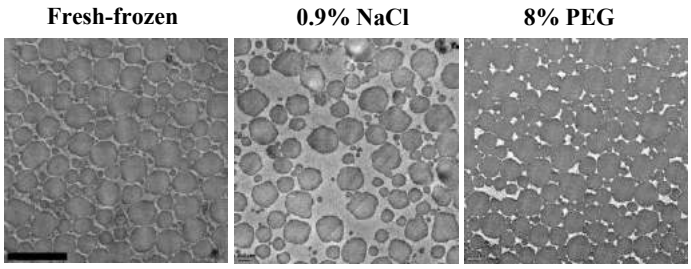

Figure 4: TEM images from cross section of the fascicles after 8 hours of incubation. Scale bar indicates 1um.

Spacing between fibrils increased after incubation in 0.9% NaCl compared to the fresh-frozen, while fibril spacing after incubation in 8% PEG was qualitatively identical to the fresh-frozen (Fig 4).

DISCUSSION

This study finds that 8% PEG maintains hydration (Fig 1,2), tensile modulus (Fig 3), and microstructure (Fig 4) of the fresh-frozen state. It is thus an appropriate buffer solution for long mechanical tests such as fatigue. The slight change in relaxation is probably due to lack of ionic content in the buffer, which causes entropic diffusion of ionic tissue constituents into the buffer. Using small ionic content in the buffer solution might help overcome this issue. Nonetheless, use of PEG solution for long-term mechanical fatigue tests is recommended.

In contrast to PEG, normal saline (0.15M = 0.9% NaCl) swells the tissue considerably and rapidly (Fig 1), which increases the spacing between collagen fibrils (Fig 4) and lowers the modulus (Fig 3) compared to fresh-frozen samples. This is consistent with previous work in meniscus [1]. A higher concentration of 25% NaCl maintains the apparent water content to the fresh-frozen level (Fig 1). However, at this concentration solutes diffuse into the tissue (Fig 2), demonstrating that the true water content is actually greater than the fresh-frozen level. These behaviors are problematic because the rapid initial dehydration causes an elevated "untreated" modulus (with 15 min in solution) for the 25% NaCl compared to the other untreated solutions (Fig 3). With additional time in solution, solutes diffuse into the tissue, the apparent water content increases (Fig 1) and the modulus decreases (Fig 3). There is likely a mechanical effect due to the large influx of NaCl into the tendon that would confound fatigue studies of long duration. Thus NaCl-based buffers, whether normal saline or increased concentration, are not suitable for long tests.

PROJECT-BASED BIOMECHANICS LABORATORIES: THEORY AND PRACTICE

Kristen L. Billiar and Glenn R. Gaudette

Department of Biomedical Engineering
Worcester Polytechnic Institute
Worcester, MA, USA

INTRODUCTION

Problem-based instruction offers one of the most effective means of facilitating learning by compelling students to solve authentic problems through a self-discovery process. In biomedical engineering (BME), there has been intense activity in problem-based learning instruction in the educational literature [1-4]. When there are multiple solutions to a problem and teamwork is required to solve the problem, we term the process project-based learning. Problem-based learning appears to be especially well suited for BME laboratories where quantitative measurements of complex and variable biological systems are required [3].

In particular, the biomechanics laboratory provides an authentic context for students to attack their problems and an opportunity to observe how the physical world compares to the theoretical descriptions taught in the classroom [3]. Use of biological test specimens and industry-standard test machines introduces the students to the difficulty in sample preparation and gripping and the complexity of dealing with non-linearity, non-homogeneity, and variability inherent in biomechanical measurements. The variability of biological specimens naturally leads to the necessity of statistical treatment of the data for hypothesis testing.

The goal of this work was to develop a structured problem-based learning experience for junior-level biomedical engineering undergraduate students to facilitate self-directed learning of solid biomechanics theory while developing practical mechanical testing skills. There was also a strong focus on aiding each student in making progress in problem identification, fitting data to mathematical models, testing hypotheses statistically, communicating the results and conclusions of experiments, and working in teams.

METHODS

Over the past 10 years, we approached our educational challenge in various ways within the unique, fast-paced 7-week term structure at our institution. Here, we focus on our latest and most successful iteration which aligns well with a standard 14-week semester. In the Discussion, comparisons with previous iterations are provided along with practical advice for incorporation into existing curricula.

Biomechanical analysis theory and practice

For the first half of the learning experience, the students review stress analysis and learn how to use a uniaxial materials test frame (Instron 5544). To aid the students in reviewing stress analysis theory, with a focus on biological tissues, we provided the students with lectures (often online) and reading materials once per week. Topics include analysis of non-linear stress-strain curves, viscoelasticity, and beam-in-bending. In parallel, demonstrations of how to operate the equipment safely are provided during class time (once per week), and pre-recorded videos covering the same material are provided as written instructions and as videos online (Figure 1a) so that the students can review the methods at their own speed. Access to the videos is facilitated by QR-codes (Figure 1b) which link to the YouTube channel. Detailed videos demonstrating the use of the industry-standard Bluehill software are also provided (Figure 2). The third class period each week is dedicated to data analysis in Matlab.

The student learning is assessed with individual and team homework assignments focused on analyzing mechanical data that they generate from samples of plastic, leather, and wood. In the seventh week, the students complete a final practicum and report involving testing and analyzing tendon or bone material properties. Throughout

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the term, instruction in effective communication is provided including comments on formative drafts and presentations.

a) b)

Figure 1: a) Video tutorials detailing how to use the equipment safely are provided via a YouTube channel. b) QR-codes linking to the videos are posted in the lab for quick smartphone access.

Figure 2: Video tutorials for using the software are also posted.

Project-based approach

At the beginning of the second half of the course (which, at WPI is a new term), a potential design to solve an authentic clinical problem is posed, and the students are tasked with determining the mechanical feasibility of the design. For example, students were given decellularized aortas and asked to determine if they have sufficient mechanical properties to warrant further development as a vascular graft material. To solve the challenges, the students work in 3- or 4-person teams to research the problem in medical and engineering literature and develop a testing protocol. They then complete experiments to test their hypotheses and/or validate the designs. The majority of class time is used to discuss the proposal, experimental design, report and poster in various draft stages and to provide formative feedback. In the final week of the term, they present their findings to their peers both orally and in writing.

RESULTS AND DISCUSSION

Overall, the students learned how to mechanically characterize a biological tissue, and efficiently perform uniaxial mechanical testing (Figure 3) to complete a controlled experiment (including statistical analysis). They also progressed substantially in their ability to communicate their goals, means, and conclusions. This project-based course is writing and teamwork intensive by necessity which benefited the students greatly, but also required a large amount of time from both the students and instructor. However, the video tutorials helped reduce the amount of time required for training during class time, and the recorded mini-lectures also allowed class time to be used for discussion and working through problems (a.k.a., flipped format).

The students reported that the homework assignments in the first half of the class were very helpful in clarifying how the theory could be utilized to analyze experimental data. These assignments facilitated progressively more complex use of the testing software and Matlab analysis tools.

The grading of the written assignments was made as objective as possible by using a set of grading rubrics (based on Newstetter [2]) which also served to clarify the requirements of each assignment for the students. The students appreciated learning how to write a range of professional formats.

Figure 3: Picture of a ring of aortic tissue being tested.

Based on student feedback and our personal observations, the current iteration of the course is the most successful. In the first iteration, two separate challenges were assigned to the students to solve in a single 7-week course. Although this offering was an intensive 5-day-a-week course worth a full 3 credits, the students felt too rushed to propose a solution, complete the testing, and communicate the solution all in 3 ½ weeks, then do it all over again in the next 3 ½ weeks. In response, we created a semester-long offering, consisting of two 1.5 credit 7-week courses, each with a separate challenge posed (one regarding bone, the other blood vessels). Students were able to solve two separate authentic challenges, but they reported that they did not get enough practice with using software on machine to be able to use it on their own in the future (e.g., for senior design projects or undergraduate research). In the current format of the course sequence, the student report that they become sufficiently skilled in using the industry-standard equipment and software in the first half of the course to solve an authentic challenge in the second half of the course (and in their senior design projects as well).

CONCLUSION

We have created a laboratory course which reinforces biomechanical engineering theory with authentic problem-based experimentation, and provides a scaffolded, mentored experience for learning. The breadth of subject matter that could be covered was less than in a standard didactic course, and some students wanted more lectures rather than learning the theory on their own from the posted materials. However, we found that when working in the laboratory in teams without the instructor present where they have to learn from their failures and re-engineer solutions for their setback, the student learn more effectively, as shown previously [5].

BAYESIAN APPROACH TO MODEL SELECTION AND SURROGATE MODELING: APPLICATION TO TRAUMATIC BRAIN INJURY SIMULATIONS

Sandeep Madireddy, Kumar Vemaganti

Department of Mechanical and Materials Engineering
University of Cincinnati
Cincinnati, Ohio 45221-0072

INTRODUCTION

Traumatic brain injury simulations are complex and computationally challenging. Among the challenges are the large uncertainty in the material testing data, uncertainty in the material constitutive model parameters, high strain rates and the short time scales of the impact loading, and the complex geometry of the human brain model.

We propose a Bayesian approach to objectively selecting a constitutive model for the brain tissue, taking into account the nonlinear visco-hyperelastic and rate-dependent effects. This approach also provides a probabilistic method to material parameter evaluation in order to obtain the uncertainty associated with them.

The uncertainty in the material model parameters is propagated using the SIMon finite element head model [1] to obtain the uncertainty in the maximum principal strain-based brain injury criterion. As the finite element model is computationally expensive, we resort to a Gaussian process surrogate model for the injury criterion as a function of the material model parameters.

Our results show that the proposed method can be used for material model selection and parameter estimation in a quantitative manner. Also the surrogate model based uncertainty propagation provides a probabilistic approach to calculating injury criteria. We provide a framework to report the probability that the injury tolerance is reached for a given impact loading.

MATERIALS AND METHODS

Brain tissue is assumed to be an isotropic and nonlinear visco-hyperelastic. The constitutive relations are obtained using the formulation described in [2] where the hyperelastic behavior, short-term viscoelastic behavior, and long-term viscoelastic behavior are all modeled explicitly:

$$\sigma(t) = \sigma_e(\mathbf{C}(t)) + \sigma_v(\dot{\mathbf{C}}(t), \mathbf{C}(t)) + \mathbf{F}(t)\mathcal{G}\{t-s, \mathbf{C}(s)|_{s=\delta}^{s=\infty}\}\mathbf{F}(t)^T \quad (1)$$

where σ_e, σ_v are the hyperelastic and short-term viscoelastic contributions to the Cauchy stress respectively given by:

$$\sigma_e(\mathbf{C}(t)) = 2\mathbf{F}(t)\frac{\partial \Psi_e}{\partial \mathbf{C}}\mathbf{F}(t)^T,$$

$$\sigma_v(\dot{\mathbf{C}}(t), \mathbf{C}(t)) = 2\mathbf{F}(t)\frac{\partial \Psi_v}{\partial \dot{\mathbf{C}}}\mathbf{F}(t)^T$$

where ψ_e, ψ_v are the elastic strain energy and short-term viscoelastic dissipation potentials and $\mathbf{F}$ is the deformation gradient, $\mathbf{C}$ is the right Cauchy-Green deformation tensor and $\dot{\mathbf{C}}$ is its time derivative.

The function ψ_e in this study is selected from among

$$\Psi = \sum_{i=1}^{N} \frac{2\mu_i}{\alpha_i^2}(\lambda_1^{\alpha_i} + \lambda_2^{\alpha_i} + \lambda_3^{\alpha_i} - 3)$$

$$\Psi = B_1(\exp(B_2(I_1 - 3)) - 1) \qquad \Psi = C_1(I_1 - 3) + C_2(I_2 - 3)$$

where I_k are invariants of $\mathbf{C}$. The dissipation potential ψ_v used in this study is

$$\Psi_v = \eta J_2(I_1 - 3)$$

where J_2 is the second invariant of $\dot{\boldsymbol{C}}$. The third term in (1) is the long-term viscoelastic contribution given by:

$$\mathcal{G}\{t-s, \mathbf{C}(s)|_{s=\delta}^{s=\infty}\} = \int_{\delta}^{\infty} \mathcal{G}(t-s, s, \mathbf{C}(s))\, ds$$

The relaxation function is chosen to a 3-term Prony series whose parameters are obtained by using the relaxation test data from [3]. The hyperelastic model form is selected using experimental response at a constant strain rate of 1/s. Four candidate models are considered for model selection: Ogden (N=1,2), exponential, Mooney-Rivlin. Model selection is done using the nested sampling-based Bayesian model selection approach outlined in [4]. The parameters in the selected hyperelastic model, short term viscoelastic model and their uncertainties are obtained using the Bayesian approach outlined in [5]. The unconfined compression test data at strain rates of 1/s, 10/s and 50/s are used to to obtain the parameter distributions.

Further, this material model is implemented into LS-Dyna [6] finite element software using a UMAT subroutine. This material model is used to model the soft tissue in the SIMon model. The loading corresponds to a frontal impact vehicle crash test.

The Bayesian Gaussian process model is used to fit a surrogate model:

$$\mathbf{Y(s)} = \boldsymbol{\mu(s)} + \mathbf{w(s)} + \boldsymbol{\epsilon(s)} \quad (2)$$

where $\mathbf{Y}$ is the response (injury criterion), $\mathbf{s}$ is the input parameter vector, $\boldsymbol{\mu}(\mathbf{s}) = \mathbf{X}^T(\mathbf{s})\boldsymbol{\beta}$ is the mean surface, and $\mathbf{w}(\mathbf{s}) = \mathrm{N}(\mathbf{0}, \mathbf{C}(\theta))$ is the spatial correlation represented by a multivariate normal distribution and $\boldsymbol{\varepsilon}(\boldsymbol{s}) = N(\mathbf{0}, \tau^2\mathbb{I})$ is the nugget term.

The input parameters used for the surrogate are the material parameters corresponding to the hyperelastic and short-term viscoelastic contributions. The parameters in long-term viscoelasticity are neglected under the assumption that their effect is not significant in an impact loading. The response is the maximum principal strain-based injury criterion. The data for the surrogate model fitting are obtained by Latin hypercube sampling 104 points, using 90 for fitting and 14 for validating the surrogate. The parameters are obtained using the same procedure as the calibration of material model parameters.

The uncertainty in the material parameters is non-intrusively propagated to the injury criterion using the surrogate model. This is done using the Monte Carlo approach.

RESULTS AND DISCUSSION

The model selection statistics, and the model ranks for the four hyperelastic model forms considered in this study is shown in Table 1. The exponential model is seen to describe the hyperelastic response with

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

highest Bayesian evidence. Hence we choose this model with parameters B_1, B_2 hereafter to describe hyperelasticity. However, the traditional least squares approach (equivalent to log-likelihood) prefers the Ogden (N=2) model, which is found to over-fit the data.

Material model	Max log-likelihood	log-evidence	Model-Rank
Mooney-Rivlin	2.644	-9.502	Rank 3
Exponential	2.162	-6.078	Rank 1
Ogden ($N=1$)	2.529	-7.476	Rank 2
Ogden ($N=2$)	2.955	-13.282	Rank 4

Table 1: Model selection statistics and ranks for the hyperelastic material model forms

The maximum likelihood estimate (MLE) of the Prony series parameters obtained are shown in Table 2.

G_1	$\tau_1(s)$	G_2	$\tau_2(s)$	G_3	$\tau_3(s)$
4.168	1.512 E-02	0.828	2.833 E-01	0.606	1.732

Table 2: MLE of the Prony series parameter distributions

The posterior distributions of the material parameters B_1, B_2, η are obtained by fixing the Prony series parameters are shown in Fig. 1.

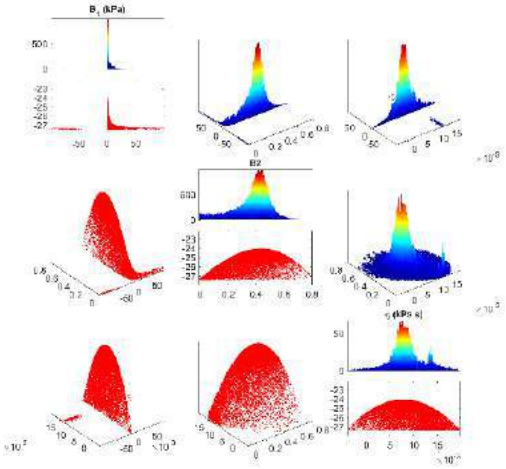

Figure 1: Material model parameters and their uncertainties.

In order to simulate traumatic brain injury, the angular velocity about y-axis is given as the load (see Fig. 4), because of its contribution to brain injury in frontal impact, and our interest in studying the correlation between the loading and the injury criteria.

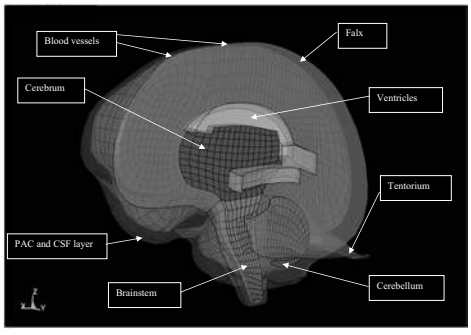

Figure 2: Simon finite element head model [1]

The maximum principal strain (MPS) as a function of time for the original SIMon finite element model (Fig. 2) and the one with MLE of visco-hyperelastic material parameters is shown in Fig. 3. This is for the element with the maximum principal strain over the duration of impact. The peaks in the MPS are the same for both models and they correspond to the peaks in the Y angular velocity. The reason for the differences in the responses can be attributed to the material properties.

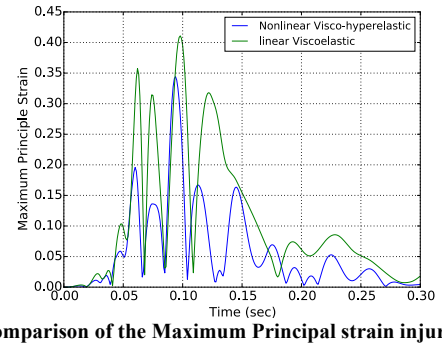

Figure 3: Comparison of the Maximum Principal strain injury criteria for the SIMon model with linear viscoelastic and nonlinear visco-hyperelastic material properties for the soft tissue

In order to build the surrogate, deterministic finite element simulations are run using the SIMon finite element head model for all the 104 samples described in the previous section. The parameter ranges used for sampling are within the bounds of the uncertainties seen in Fig. 1. The Gaussian process surrogate is built using the data and the uncertainty in the material parameter distributions (Fig. 1) is propagated to the injury criterion. The uncertainty in the injury criteria is shown in Fig. 4.

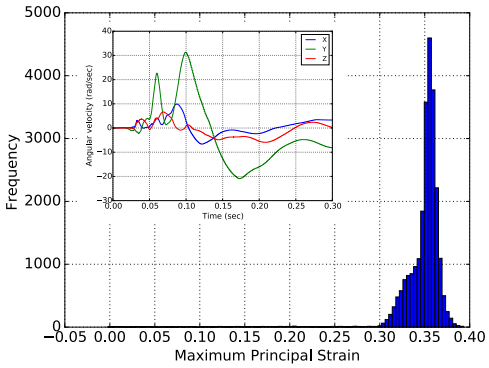

Figure 4: Uncertainty in maximum principal strain-based injury criterion.

This enables us to calculate the probability that an injury tolerance is reached for a given impact loading. This probabilistic method can be used to further simulate injury and calculate injury criteria with higher fidelity.

INTRODUCTION

Quantitative data on the strain behavior of the anterior cruciate ligament (ACL) in response to knee loads are necessary for better understanding of biomechanics of the ACL and the improvement of ACL reconstruction. Although important data were obtained in previous studies[1, 2], physiological knee motion and loading were not simulated due to experimental limitations. Therefore, the objective of the present study was to apply both a robotic system for mechanical testing of biological joints and a motion tracking system based on the image correlation method to the determination of site-dependent strain in the ACL, specifically in the attachment area on the femur and tibia, during anterior translation of the knee.

METHODS

A 6-DOF robotic system consisting of a custom-made 6-axis manipulator with a 6-DOF universal force/moment sensor (UFS)[3] was used. In the system, a LabView-based control program runs on a windows PC to control the displacement of, and force/moment applied to, the cadaveric knees with respect to the knee joint coordinate system[4]. Porcine knees (n=8) were dissected down to the joint capsule and fixed to the robotic system, and were subjected to the anterior drawer test up to 50 N at full extension. During the test, the anterior-posterior DOF was translated under displacement control at a rate of 0.1 mm/s while all the DOFs except the AP and flexion-extension DOFs were set under force control with prescribed force/moment at zero. After the lateral condyle was removed for the observation of the ACL the intact knee motions were reproduced. The medial view of the ACL surface during the test was recorded with a CCD camera. Using a motion tracking system based on the image correlation method (VW-9000, KEYENCE, Osaka, Japan), the surface deformation of the ACL including the attachment area to the femur and tibia was analyzed. In the recorded image, the ACL was transversely divided into 5 portions; 0-10%, 10-20%, 20-80%, 80-90% and 90-100% of the length from the femoral attachment, and was longitudinally divided into 5 portions from anterior to posterior fibers (Figure 1). Multiple markers were placed at the anterior and posterior edges in each portion on the recorded image, and length change between the markers were calculated to analyze local strains. Using the same method as for the surface layer, the strain distributions of the middle and deep layers were determined after the removal of the medial and the middle layers. Note that zero strains (no deformations) were defined for the knee located at full extension with 1.0 Nm of extension moment.

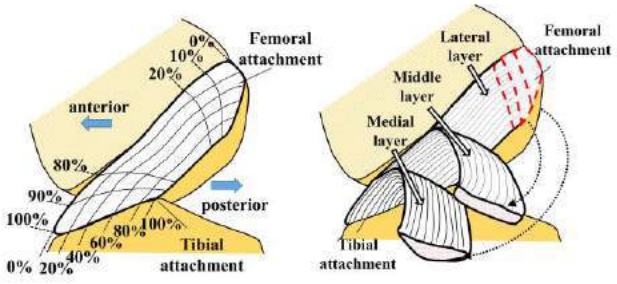

Fig.1 Twenty five portions on the ACL surface layer for the calculation of strain distribution, and sequential removal of the surface and middle layers for the measurement of 3-D strain distribution

In the present study, the behavior of the ACL surface in sub-ligament level was observed using a light microscope (VHX-1000, KEYENCE, Osaka, Japan). The porcine ACL with bone fragments (n=3) was carefully dissected and was fixed to a metal stage under the application of 0.1 N of tensile force. The ACL surface was observed at 0.1 N (unloading condition), 20 N and 40 N (loading condition). By

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

tracking distinctive features of the structure pattern, ACL strain in sub-ligament level in the medial layer was analyzed.

RESULTS

Result revealed that the tensile strain was larger in the ACL attachments (0-20% and 80-100%) than in the mid-substance (20-80%) in all the layers. In the medial layer, the largest strain was 8.0% observed in the tibial attachment on the posterior fiber (Fig.2). Strain distributions in the middle and lateral layers were similar to that in the medial layer, with the largest strain observed on the posterior fiber in the tibial attachment area in the middle layer (6.4%) and on the anterior fiber in the femoral attachment area in the lateral layer (7.7%). Strain on the anterior fiber in the medial layer as a function of applied anterior force is indicated in Fig.3. In the femoral and tibial attachment areas, strain increased rapidly up to 6-8% by the inflection points around 20 N and 30 N of anterior force, then increased slowly thereafter. In contrast, strain increased slowly and gradually without distinct inflection point in the mid-substance area. This force-dependent change in strain increase was observed in all the fibers in all the layers.

Microscopic observation in the present study indicated that the periodic patterns (crimp structure) at a right angle to the fiber direction were recognized in unloaded condition. The ACL strains were 8.8% and 13.8% in the femoral attachment area, and 2.6% and 5.2% in the mid-substance at 20 N and 40 N of tensile force, respectively (Fig.4).

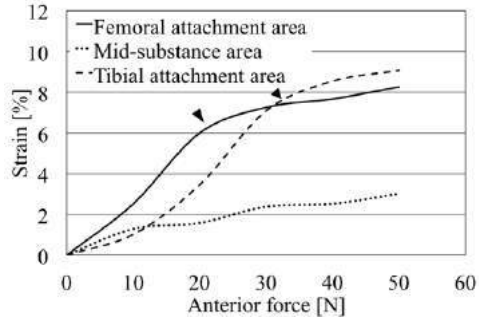

Fig.3 Strain on the anterior fiber in the medial layer as a function of anterior force. Inflection points are indicated by triangles around 20 N and 30 N of anterior force in the femoral and tibial attachment areas.

DISCUSSION AND SUMMURY

The 3-D strain distribution in the ACL in response to anterior drawer force to the knee was determined in the present study using the 6-DOF robotic system and the motion tracker. We succeeded to obtain a detailed 3-D map of site-dependent strain data in the ACL. In previous studies, video tracking systems were often involved to measure deformation and strain in soft tissues. Although high resolution measurement was possible with the system, there was limitations in position and number of markers. It was also problematic in video tracking systems that marker motion relative to tissues affect experimental results. These problems are solved in the present study by the use of the motion tracking system. Since it is possible with the method to select unlimited arbitrary points for tracking after video recording without marker on the surface, detailed and precise analysis of local strain in the ACL surface is possible under physiological conditions.

Results revealed that ACL strain is site-dependent in all the fibers in all the layers; it is higher in the attachment area than in the mid-substance. Results also revealed that there are two phases in ACL strain change in the femoral and tibial attachment areas; a rapid increase to approximately 6-8% at the beginning of force application followed by a slow increase thereafter. Interestingly, such force-dependent strain change is not observed in the mid-substance. It is well known that ligament and tendon tissues have the crimp structure at the sub-ligament and sub-tendon level. Franchi et al reported that the crimp structure is more located in both ends of ligaments and tendons than in mid substance[5]. Weiss et al reported that a wavy crimp structure was found in the proximal one quarter of the ACL[6]. Microscopic observation in the present study indicated that crimp structures exist in all areas of the ACL, while change in crimp strain is site- and force-dependent in the same way as macro ACL strain; a rapid increase in the attachment areas while a gradual increase in the mid-substance at the beginning of force application. These results suggest that the 3-D strain in the ACL is site- and force-dependent probably due to unevenness in both distribution and property/function of crimp structures. In addition, it is suggested that the ACL crimp structure plays more important role in ACL behavior and function in the femoral and tibial attachment areas than in the mid-substance. Because of the behavior and function of the ACL attachment, the contribution of the ACL to knee stability is probably maintained at any physiological knee postures.

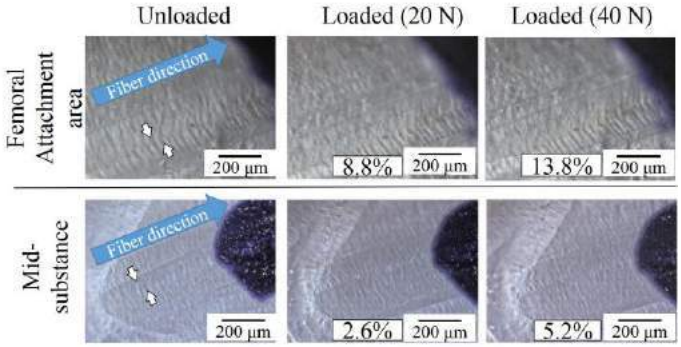

Fig.4 Observation of the crimp structures in the femoral attachment area and the mid-substance of the porcine ACL with crimp strain magnitude observed at 20 N and 40 N of tensile force. Typical periodic pattern of the crimp structure is indicated by white arrows.

INTRODUCTION

A laboratory blast simulator is being established to mimic the primary overpressure magnitude and impulse loading on the head surface, in a manner representative of free-field explosive events selected to isolate the primary shock front. A validated Computational Fluid Dynamics (CFD) model has been established as a design tool to aid the understanding of flow within the ABS system, and characterize the applied pressure loading to a bare headform. Ultimately this model will be used to augment experimental findings to fully understand the influence of headborne systems on pressure applied to the human head, and to support the design of optimized laboratory test methodologies for helmet evaluation which are accurately representative of a broad range of free-field blast events [1].

METHODS

An existing experimental shock tube design, the Advanced Blast Simulator, has been modified to achieve a 3 foot cross-sectional test area capable of evaluating a helmeted headform internal to the system [2] with minimal effects from sidewall reflections. This system consists of driver, transition, test, and diffuser sections [3], with a membrane material inserted between the driver and downstream components. The driver section is pressurized with gas (air or helium) until diaphragm rupture. Gas escapes and forms a shock front that generates the representative pressure signature upon striking the model in the test section. Concurrently, a human surrogate headform representative of an average male surface geometry was fabricated and instrumented with surface sensors to experimentally measure the pressure loading applied to the headform when tested in the modified ABS system. A simplified schematic of the ABS with headform is shown in Figure 1.

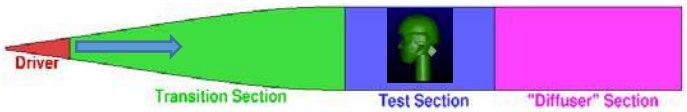

Figure 1: Advanced Blast Wave Simulator

To support the current study objectives, Computer-Aided Design (CAD) models for the shock tube and human head surrogate were used to generate computational meshes. Time accurate CFD simulations with 2nd order spatial accuracy were run using a time-step of 1 microsecond in Metacomp's commercial code, CFD++. Simulations of the ABS operations were implemented with the diaphragm modeled as an ideal rupture [4]. Experimental test data at diaphragm burst pressure was used to initiate the simulations. Pressure-time traces were qualitatively compared between the experiment tests and CFD models both without headform (two-dimensional or 2D model) and with headform (three-dimensional or 3D model) in the test section.

RESULTS

A comparison plot between the 2D CFD model and experiment with an empty test section is shown in Figure 2. This model was subsequently expanded to include the headform for this study, and CFD predictions for 188 psi burst pressure compared with experimental data (Figure 3). The verified model was then used to depict the maximum pressure experienced on the discretized head surface for each local point at any given time (Figure 4).

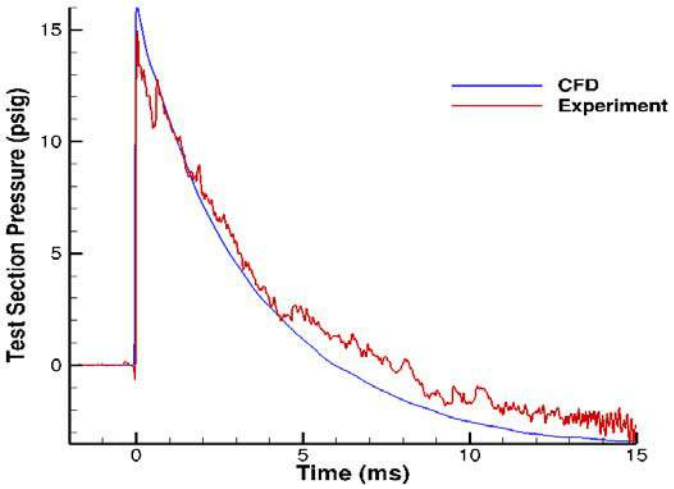

Figure 2: 2D CFD Model Comparison with Experimental Data

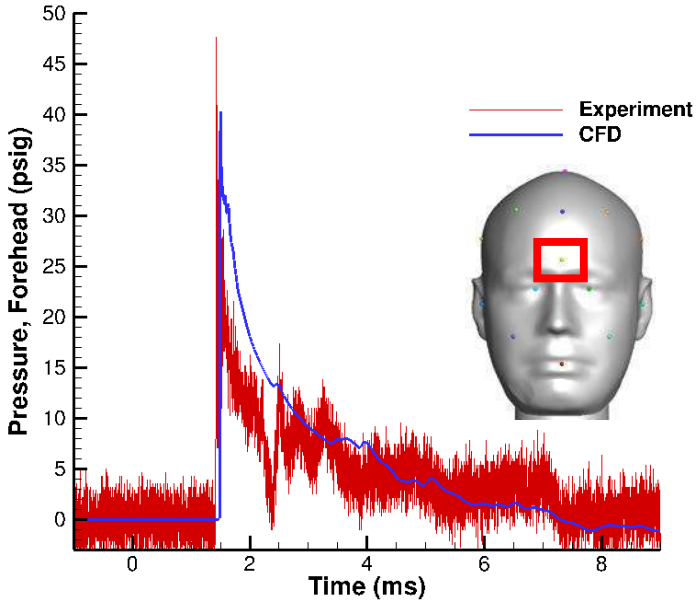

Figure 3: 3D CFD Model Comparison with Experimental Data

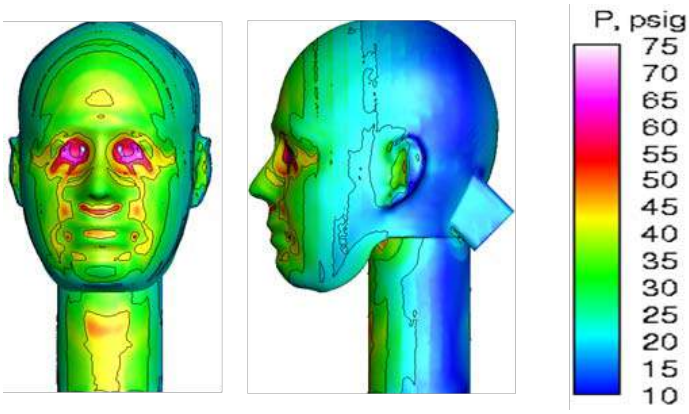

Figure 4: Maximum Pressure Isosurface Map on Head Geometry

DISCUSSION

The 2D CFD model was verified with experimental data using pressures observed in the test section. This model was tailored to replicate the experimental set-up by applying a curvature to the diaphragm to simulate a bulging diaphragm prior to rupture. This allowed the model to capture the true energy level of the driver section of the shock tube immediately before the diaphragm ruptures. Despite this, it is important to note that the CFD still models an ideal and immediate diaphragm rupture.

The results of the 3D CFD model with the headform were in good agreement with experimental data. The maximum pressure envelope plot indicates the eyes experience the largest pressures by a significant margin – more than double the pressure on the nose. This is likely due to the curvature of the head, which encourages pressure build-up in the eye socket. The relatively lower pressures elsewhere are justified because the local geometry would encourage the flow to move past the area. Local valleys in the front-facing geometry of the head are areas corresponding to higher pressure build up. These results indicate what areas of the human head may be most vulnerable for a frontal overpressure exposure.

Helmets are worn by ground troops in combat situations, so it is important to understand the pressure loading for different orientations of overpressure exposure. Ongoing work includes the implementation of a helmet system into the model, and the assessment of pressure loading on the human head in multiple orientations. The model will be used to aid the comparison of blast loading on the head with and without personal protective equipment, and supplement insights from experimental data to fully assess the influence of helmet systems.

INTRODUCTION

An understanding of tendon tissue loads is critically important for investigating musculoskeletal disorders. However, it remains very challenging to assess tendon stress during functional movement. Modeling approaches rely on assumptions regarding musculoskeletal geometry, tissue morphology, and muscle coordination [1]. Further, current measurement approaches are highly invasive [2], and thus are not practical for widespread use. We are exploring the potential of noninvasive wave propagation measurements for assessing tendon tissue stress under dynamic loading conditions. Such an approach could dramatically extend our ability to characterize functional tissue loads that are relevant to the diagnosis and treatment of tendon injury and disease. The specific objectives of the current study are twofold:

1) To characterize the theoretical relationship between shear wave speed (SWS), material properties, and normal stress in axially loaded, transverse isotropic tissue. In current clinical shear wave elastography (SWE) systems [3], SWS (v) is assumed to be strictly dependent on tissue shear modulus (μ) and density (ρ):

$$v = \left(\frac{\mu}{\rho}\right)^{1/2} \quad (1)$$

Recent work would suggest that this simple relationship is invalid in tendon, where SWS increases significantly with tendon stretch [4].

2) To empirically test the theoretical relationship between wave speed, material properties, and tissue stress. To accomplish this, a novel ultrasound-based imaging method was used to track waves induced via impulsive mechanical excitation of a mechanically loaded *ex vivo* tendon. The use of ultrasound provides a basis to extend the approach to *in vivo* conditions, which would allow for the characterization of tendon tissue loads during functional movement.

METHODS

Wave Propagation Model – Tendon was modeled as a tensioned Timoshenko beam with constant cross-sectional area. The Timoshenko beam accounts for both shear elasticity and rotational inertia effects. Transverse isotropic elastic material properties and negligible bending stiffness were assumed. With these assumptions, SWS (v) is dependent on shear elastic modulus (μ), effective density (ρ_{eff}), a shear correction factor (k'=0.9), and importantly, axial stress (σ):

$$v = \left(\frac{k\,\mu+\sigma}{\rho_{eff}}\right)^{1/2} \quad (2)$$

Equation 2 assumes small motion about the stressed state, such that μ is defined as the tangential shear modulus. For this study, we assumed a constant shear modulus (μ=150kPa) based on values for ligament under moderate shear strain [5].

Based on a classical result [6], the effective mass per unit length of a beam vibrating in a viscous fluid can be approximated as,

$$\frac{m_{eff}}{L} = \rho_t A + \rho_f \left(\frac{\pi}{4} b^2\right) \Gamma_r \quad (3)$$

where ρ_t (=1200g/cm^3) is the density of the tendon tissue, ρ_f (=1200g/cm^3) is the fluid density, b is the width of the tendon perpendicular to the direction of motion, A is the cross-sectional area of the tendon, and Γ_r is the real part of the hydrodynamic function (=1.01 to 1.04 over the frequencies of interest for tendon). Rearrangement of equation 3 yields an effective density, ρ_{eff} :

$$\rho_{eff} = \rho_t + \frac{\pi b^2 \Gamma_r}{4A} \rho_f \quad (4)$$

The ratio, $\pi b^2\,\Gamma_r/4A$, was set at a constant value based on the average ratio measured in the tendons tested ($= 0.62$).

***Ex Vivo* Validation** – The model was tested by measuring wave speeds in 12 porcine digital flexor tendons axially loaded using a

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

mechanical test system (MTS Acumen 3). Tendons were immersed in physiological saline and gripped at each end using stainless steel waveform grips (Test Resources G240KSS). Tendons were loaded sinusoidally from 10 to 300N at 1Hz. Tendon stress was calculated by dividing applied force by initial cross-sectional area. Tendons were assumed to be elliptical in cross-section and area was calculated based on the width of the major and minor axes at 3 locations spaced evenly along the length of the unloaded tendon.

Shear waves were generated using a piezoelectric actuator (Thorlabs PK4JQP1, 19.8μm motion) housed in a 3D printed mechanical tapping device (Fig. 1A). Tendons were tapped at 25Hz with a 1ms pulse width. A linear array ultrasound transducer (Ultrasonix L14-5/38) was mounted to visualize the tendon longitudinally through an acoustic window in the bath (Fig. 1B). M-mode ultrasound radiofrequency (RF) data was collected at 14000 frames/second from a single transducer element located 10mm from the tapper. RF data was recorded for 2 seconds (2 loading cycles) after 5 preconditioning cycles.

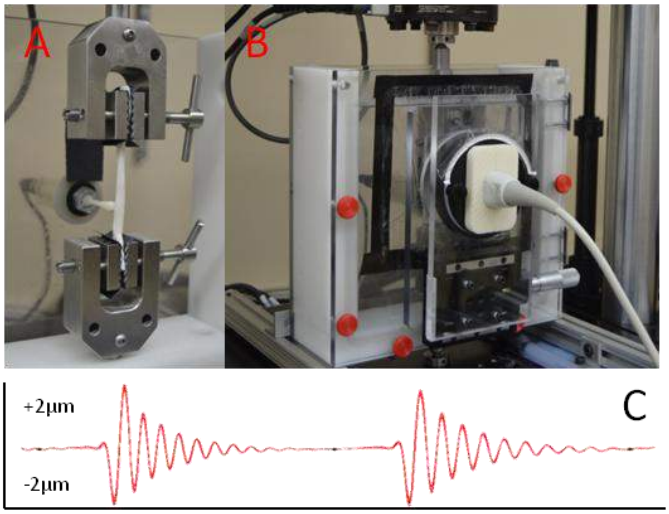

Figure 1: Mechanical testing setup. A) Tapping device contacting tendon. B) Ultrasound transducer fixed to front of bath. C) Transverse tendon motion pattern.

A speckle tracking algorithm was used to calculate the transverse frame-to-frame motion (Fig. 1C) of kernels positioned over the tendon tissue. FFT analysis was performed on the transverse motion trajectories to determine the frequency of the induced wave in the tendon. Based on the frequency, $\boldsymbol{f}$, and the known tendon grip-to-grip length, $\boldsymbol{L}$, SWS was calculated as:

$$\boldsymbol{v = 2fL} \quad (5)$$

SWS was calculated during the period of time after each tendon tap, so that SWS was measured at 25Hz, or 50 times per 2-second trial. A total of 58 trials were analyzed for this study, such that approximately 2900 data points were analyzed. The fit of the wave propagation model was assessed based on the correlation between applied stress and predicted stress from measured SWS for each trial. Additionally, the fit of the model was assessed based on its coincidence with mean values of SWS within 0.5MPa bins.

RESULTS

SWS increased with tendon loading, averaging 19.3m/s at 0.44MPa and increasing to 61.7m/s at 7.75MPa. As predicted by the model, SWS was non-linearly dependent on tendon stress, increasing most rapidly at low loads (Fig. 2). Stress estimated based on the wave propagation model was highly correlated with actual stress in the tendon (mean r^2=0.981, range: 0.930-0.997). Additionally, it was found that the model predicted SWS within one standard deviation of experimentally determined mean values across the whole range of stresses for which there was a complete data set (Fig. 2).

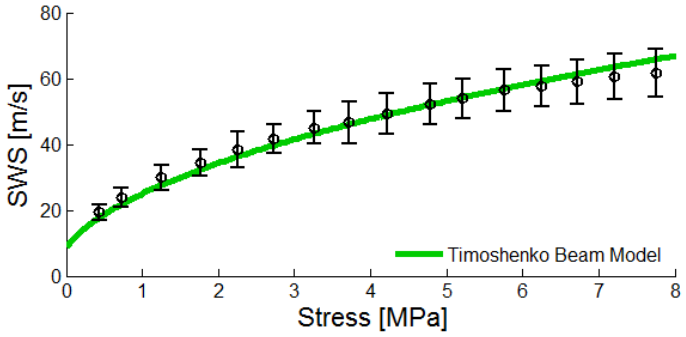

Figure 2: Shear wave speed vs. tendon stress. Experimental data plotted as means and standard deviations within 0.5MPa bins.

DISCUSSION

This study demonstrates the exciting potential to noninvasively measure tendon wave propagation, and to use that information to estimate the stress within the tissue. The most salient insight of the model is the need to account for the direct influence of axial loading on SWS. Clinical SWE systems presume that wave speed is only dependent on material properties, and further, can only track wave speeds up to 16.3m/s. Our data shows that SWS in lightly loaded tendon can exceed 20m/s, and increases with stress in a manner predicted by a tensioned beam model. Thus, results from previous and future studies using clinical SWE in loaded tendon must be interpreted with caution.

Our work sets the stage for measuring and interpreting tendon SWS under physiological conditions. The method of SWS measurement presented here is particularly well suited to *in vivo* applications. The ability to measure SWS values of magnitudes up to 100m/s will allow us to measure tissue stresses during functionally relevant activities. Future work will focus on advancing our wave propagation model in two important ways. First, the influence of variations in tendon cross-section must be considered. This will be especially important as we transition to complex musculotendon structures *in vivo*. Second, the added mass effects of surrounding tissues will add complexity to the *ex vivo* case, and must be well understood to provide a meaningful interpretation of *in vivo* SWS.

In conclusion, a promising new approach for noninvasively assessing tendon tissue stress is demonstrated. Embodiment of this technology for *in vivo* application would provide valuable quantitative tissue loading data relevant to the diagnosis and treatment of tendon disorders.

HETEROGENEITY OF VISCOELASTIC BEHAVIOR OF RAT BRAIN

ABSTRACT
Characterizing the biomechanical behavior of brain tissue is critically important for developing more realistic finite element (FE) models of the brain that can be used in better understanding the mechanisms of traumatic brain injury (TBI) and improving neurosurgical procedures among other applications. In most FE models, brain tissue is assumed to be homogeneous or consist of distinct white matter and gray matter regions and its local inhomogeneity is ignored. In this study, the local heterogeneous viscoelastic behavior of rat brain tissue was characterized using a custom-designed micro-indentation setup. The results showed that the heterogeneity of brain tissue was more pronounced in longer term shear moduli. The gray matter exhibited stiffer response than the white matter.

INTRODUCTION
Characterizing of the heterogeneity of the mechanical properties of brain tissue is a fundamental step in improving our evaluations of brain deformation and tissue stresses and strains during high-rate events that lead to TBI. Recent advances in FE models of brain tissue with sub-millimeter resolution have brought forth more attention to the heterogeneity of brain material properties. Although rat brain has been frequently used in *in vivo* neurotrauma studies and its heterogeneous injury patterns are well characterized, little is known about its regional viscoelastic material properties. The goal of this study was to determine the local mechanical behavior of several anatomical regions of rat brain using a custom-designed micro-indentation device. The results of this study can contribute to developing a heterogeneous constitutive model for brain tissue and improving the predictability of TBI FE models.

METHODS
Brains of four adult Sprague-Dawley rats were harvested shortly after euthanasia, and 2-mm coronal slices were cut using a brain matrix. Slices were kept in artificial cerebrospinal fluid to maintain their viability. A slice including the hippocampus was selected from each brain for this study. Gray matter regions were divided into Inner, Middle and Outer Cortex (OC), Thalamus (T), Hippocampus (CA1, CA2, CA3, and DG) and white matter regions were divided into Corpus Callosum (CC), Alveus (Alv) (Fig. 1). These regions were consisted with another recent study [1].

A custom-designed micro-indentation test setup [2] was used, consisting of Z-axis nano-positioner with resolution of 0.2 nm and 100 µm range (Nano-Z100, MCL,WI), and an XY positioner with resolution of 0.02 mm. A spherical indenter (1.5 mm diameter) was attached to a force transducer (Aurora Scientific, Ontario, Canada, Model 406A) with resolution of 10 nN (1 µg) and range of 0.5 mN (50 mg). The setup was equipped with a horizontally positioned 300x Stereo Microscope (Olympus SZX7) for contact visualization and the whole setup was mounted on an active vibration isolation table (TMC 63-533 Peabody, MA).

Rapid ramp and hold displacement was applied to the specimen with ~10-ms ramp time, 20s hold time, and penetration depth of 40 µm (~200-µm diameter indentation contact area). A Quasi-Linear Viscoelastic (QLV) model was used to describe the indentation force history $P(t)$ in terms of the indentation depth h:

$$P(t) = \int_0^t G(t-\tau)(\partial P^e(h)/\partial h)(\partial h)/\partial \tau) d\tau \quad (1)$$

in which $P^e(h)$ is the instantaneous elastic force that is generally a nonlinear function of h. For a spherical indenter we have [3]:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$P^e = \left\{\frac{8\mu\sqrt{R}}{3(1-\nu)}\right\} h^{3/2}((\quad (2)$$

in which μ, R, and ν are the shear modulus, the indenter radius, and the Poisson's ratio respectively. ν was assumed to be 0.49 (almost incompressible). $G(t)$ is the reduced relaxation function and was assumed to be a Prony series:

$$G(t) = (G_\infty + \sum_{i=1}^{4} G_i \exp(-\beta_i t)(\quad (3)$$

in which β_i are the decay rates and $\beta_{1..4} = 0.1, 1, 10, 100 s^{-1}$ were chosen to represent the time scales of the ramp and hold. G_i are the relaxation amplitudes that together with μ were obtained using an optimization algorithm written in MATLAB.

RESULTS

The QLV material parameters (Eqs. 2 and 3) were determined by optimizing for G_i and μ to match the experimental data. Figure 2 shows representative force and displacement time history curves of typical indentation tests and provides a comparison between the experimental data and the corresponding QLV model. The comparison of experimental force curves with the theoretical model demonstrated that the application of the QLV model was valid.

To compare the tissue heterogeneity, the shear moduli at relaxation times of 10 ms, 100 ms, 1s, and 10 s were compared ($\mu_{10\text{ms}}$, $\mu_{100\text{ms}}$, $\mu_{1\text{ms}}$, and μ_{10s} respectively). The results showed that several anatomical regions had significantly different material properties. Generally, the brain tissue showed more compliant behavior moving from Cortex (surface) toward Thalamus (core) (Fig. 3). Table 1 lists the overall range of shear modulus with regions that had the highest and the lowest shear moduli and their differences. Comparison between the average values of the shear moduli indicated that the gray matter was generally stiffer than the white matter for all time scales (Table 2).

DISCUSSION

The current study showed that brain tissue is heterogeneous. More difference was observed in longer term shear moduli between the anatomical regions which would be particularly important in modeling applications with low loading rates, e.g., neurosurgery, hydrocephalus, and tumor growth. Since the core regions were found to be more compliant than the outer layers, it is expected that the inner regions would be more susceptible to injury due to higher shear strain levels under uniform shear loading.

The gray matter showed generally stiffer behavior than the white matter which is in agreement with the results reported by Elkin et al [1]. The shear moduli reported in our study are slightly smaller than the results reported by Elkin et al., which could be due to the higher strain levels in their experiments (nonlinear response) and the use of a flat indenter.

The heterogeneous brain properties characterized in this study is a step toward implementing more accurate brain constitutive models in TBI FE models which would improve the predictions of such models.

INTRODUCTION

Abdominal Aortic Aneurysms (AAA) have been studied extensively over the past decade from different perspectives. While the mechanobiology of AAAs is important in studying its pathogenesis and the evolution of its composition, AAA mechanics is important in evaluating its growth and predicting rupture risk. The positive feedback loop involving both the microbiological changes and biomechanical changes aggravates AAA growth and hastens rupture risk. Hence, in the present work, we studied both of these factors in unison while evaluating their effect on each other. Isolating the biological factors that contribute significantly toward increasing the biomechanical index of rupture risk helps to narrow down the key biological markers of AAA rupture.

METHODS

Five patients with AAA underwent open abdominal repair at Allegheny General Hospital (Pittsburgh, PA). CT angiography scans of the abdominal region were acquired prior to the surgery. A portion of the AAA anterior wall and the intraluminal thrombus (ILT) were harvested during the surgery and shipped to University of Texas at San Antonio. The wall tissue was cleaned in 70% isopropyl alcohol and then cut into one square inch specimens. The ILT was separated into three layers (inner bright red luminal layer, white medial layer and outermost reddish brown abluminal layer). Each layer was processed similar to the wall tissue and cut into one square centimeter specimens. The tissues were put in cassettes and submerged in 70% isopropyl alcohol, ready to be fixed for histological analysis.

2.1 Histological analysis

The specimens were fixed and embedded in paraffin blocks. The sections were stained with Hematoxylin and Eosin (H&E) stain and Verhoff Van Gieson stain. The H&E stain was used to recognize different tissue types and to identify the morphological changes due to pathology. Verhoff stain was mainly used for differential staining of elastin. Eleven quantitative and qualitative variables were evaluated from the images of the stained specimens, as follows:

- Medial elastin present in the vessel wall as a % of normal
- Area fraction of inflammatory cells present in the vessel wall
- Presence of smooth muscle cell calcification in the vessel wall
- Presence of vasa vasorum in the vessel wall
- Volume % of the media occupied by elastin
- Volume % of the media occupied by collage/ground substance
- Volume % of the media occupied by smooth muscle cells
- Presence and severity of medionecrosis
- Presence and severity of cystic medial necrosis
- Presence and severity of fibrosis
- Degree of change in cell orientation

2.2 Biomechanical analysis

The clinical images were acquired immediately prior to surgery and were used as input to AAAVASC, an in-house segmentation and geometry quantification code. The output of the segmentation was binary masks comprising three domains – wall, lumen and thrombus. These masks were then used as input to AAAMesh, an in-house mesh generation software to generate a volume and surface mesh of the AAA. Finite element analysis was performed using these meshes in the solver ADINA (Adina R&D Inc., Watertown, MA), while applying an endoluminal pressure of 120 mmHg. The results were post-processed using Ensight (CEI Inc., Apex, NC) to obtain the principal stress distributions on the AAA wall. Since the wall tissue was harvested from the anterior region of the AAA, the mean wall stress in that region was also calculated.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

2.3 Statistical analysis

The mean wall stress on the anterior AAA wall was regressed on the 11 histological variables using Lasso regression in SAS (SAS Institute Inc., Cary, NC). Lasso is a method of variable selection, which reduces the residual sum of squares subject to the sum of the absolute values of the coefficients being less than a constant. This method is especially useful when the number of subjects is low compared to the number of variables.

RESULTS

The histological stains of the wall tissue were obtained and the regions of interest isolated. The chronic inflammatory cells and smooth muscle cells were identified in the H&E stain images, and the elastin and collagen fibers were identified in the Verhoff stain images, as shown in Figure 1.

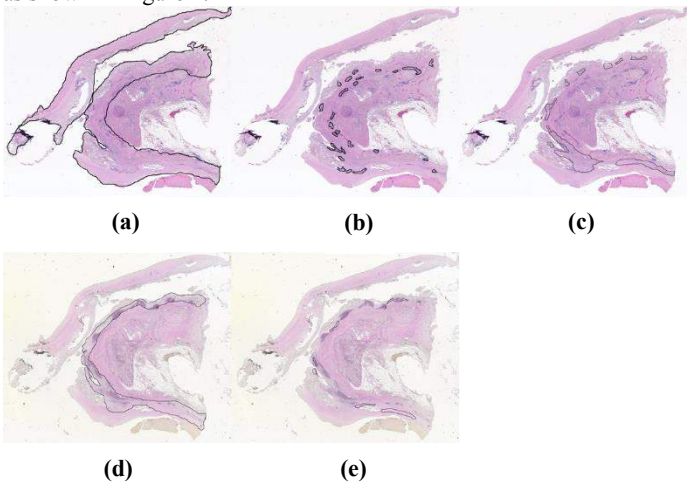

Figure 1: Identification of vessel wall (a), chronic inflammatory cells (b) and smooth muscle cells (c) from H&E stain; medial layer of the wall (d) and collagen fibers (e) from Verhoff stain. The purple patches in the medial layer in (d) are the elastin fibers.

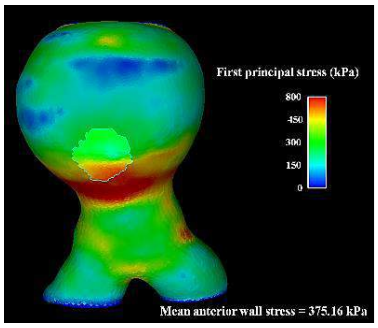

Figure 2: Distribution of first principal stress at the AAA wall in kPa. The highlighted region shows the anterior portion of an AAA from which a tissue specimen was analyzed histologically.

The distribution of first principal stress on the AAA wall was obtained for each AAA as shown in Figure 2 for an exemplary aneurysm. The anterior region was isolated and the mean wall stress in this region evaluated. The Lasso regression of the histological variables on the mean stress in the anterior wall region resulted in the following significant variables:

- Presence of vasa vasorum (vasa_1);
- Interaction between area fraction of chronic inflammatory cells and presence of vasa vasorum (CIC*vasa_1);
- Interaction between volume % of media contributed by collagen, volume % of media contributed by smooth muscle cells and presence of vasa vasorum (volcoll*volsmc* vasa_1);
- Interaction between volume % of media contributed by collagen, volume % of media contributed by smooth muscle cells and presence of grade 3 fibrosis (volcoll*volsmc* fibr_3).

The evolution of coefficient progression with each regression step is presented in Figure 3.

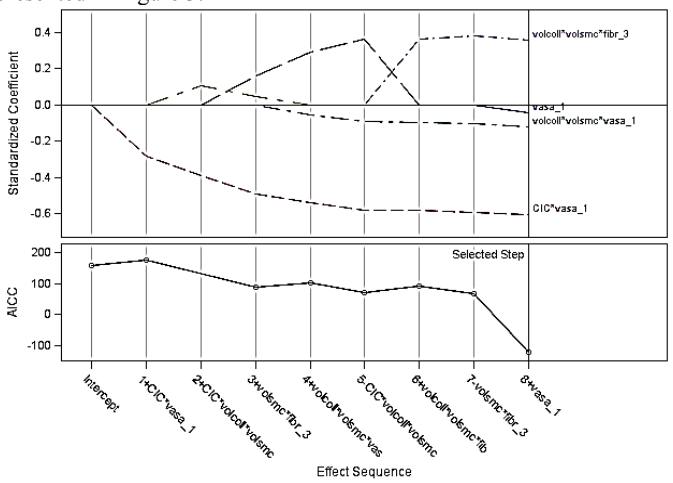

Figure 3: Effect of Lasso regression step number on the normalized coefficients of the significant variables.

DISCUSSION

The biomechanical parameter considered in this study (wall stress) has been used to assess rupture risk of AAAs. From Figure 3, it can be observed that the coefficient of regression for the presence of vasa vasorum is negative, implying that an increase in vasa vasorum reduces the mean wall stress. Since the vasa vasorum serves as the secondary supply of nutrients to the aortic wall while luminal diffusion fails [1], it follows logically that its presence would contribute towards homeostasis and hence lower wall stress. The presence of chronic inflammatory cells in the aortic wall is a result of an atherosclerotic intima which enables their direct recruitment through neovascularization. The cytotoxic mediators secreted by these cells lead to a weakened aortic wall by inducing smooth muscle apoptosis. Fibrosis is defined as an increase in interstitial collagen. If the increase in collagen is in an area comprising more than two thirds of the total width of the media, it was classified in this study as grade 3 fibrosis [2]. An increase in fibrosis of the AAA wall may lead to compression of the blood vessel by the fibrotic mass, which in turn increases blood pressure and sets off the positive feedback loop involving further recruitment of inflammatory cells. Thus, in this work, the key components involved in the mechanobiology of the evolution of AAAs, as identified in literature, have been found to affect the biomechanics of AAAs. The limitation of this work is the small sample size of AAA subjects and tissue.

METHODS TO DETERMINE RIGHT VENTRICULAR PERFORMANCE IN A RAT ANIMAL MODEL OF PULMONARY ARTERIAL HYPERTENSION

Daniela Velez-Rendon (1), Jesse Gerringer (1), Gizzel Gomez (1), Erica Pursell (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering

INTRODUCTION

Pulmonary arterial hypertension (PAH) is defined as the increase in mean arterial pressure in the vasculature of the lungs. Measurement of pulmonary arterial pressure, however, is limited to invasive techniques due to the location of the pulmonary system. In PAH, the immediate organ affected by this pressure overload is the right ventricle (RV), whose response is to become hypertrophic. As the condition persists, the RV performance is compromised and can lead to cardiac failure. Since PAH is typically diagnosed when it has started compromising other organs, it is not caught on the early onset. The mechanisms underlying PAH remain unknown and heart and lung transplant remains the only cure [1, 2].

One method to assess ventricular contractility clinically is through right heart catheterization to obtain pressure-volume signals in the steady state of a patient. Since this method only requires one cardiac cycle of these measurements, it is called the single-beat method (SBM). The other method is the multi-beat method (MBM), which is the gold standard. However, this method requires occlusion of the inferior vena cava or a Valsalva maneuver. To our knowledge, no RV contractility has been studied in rats, which is a widely used animal to study PAH. Therefore, our goal is to compare the predictions of the single- and multi-beat method at an early and acute/advance stage of PAH.

METHODS

To study PAH, 8 Sprague Dawley rats were injected with a doses of 60mg/kg of monocrotaline (MCT, Sigma-Aldrich) dissolved in hydrogen chloride (HCl) and studied the disease progression for four weeks. A normotensive or placebo group was included to account for any aging effects (PL, N= 8). This group was only injected with HCl. Open chest surgeries were performed every week for four weeks on one animal of each treatment group. Once the RV was exposed through a thoracotomy, a 1.9F admittance pressure-volume (PV) catheter (Transonic Science, Ontario, Canada) was inserted. After obtaining reproducible steady state PV data, the IVC was slowly occluded to study the afterload effect and determine ventricular contractility using MBM. Following the PV measurements in the RV, the catheter is exchanged by a 1.6F dual pressure sensor catheter, and placed passed the pulmonic valve, allowing for simultaneous measurements of the pressure in the RV and pulmonary artery (PA). Once reproducible data are recorded, a flow probe (Transonic Science, Ontario, Canada) is placed on the PA for blood flow measurements. The data are collected and pre-processed in Labchart Software (ADInstruments Inc. Colorado Springs, CO). A schematic of the hemodynamics measurements is summarized in Figure 1. The cardiac parameters (heart rate (HR), cardiac output (CO), stroke volume (SV), dP/dt_{max}, dP/dt_{min}, ejection fraction (EF) and relaxation coefficient ($\tau()$) are obtained from the RV and reported to assess cardiac performance.

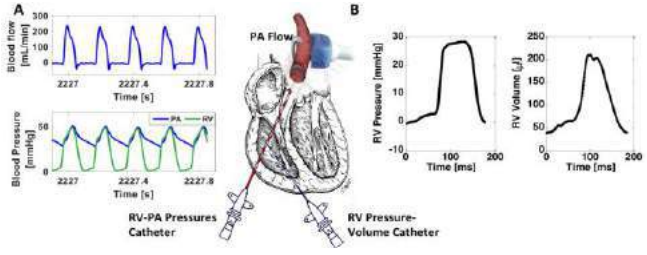

Figure 1. *In-vivo* hemodynamic measurements. A: simultaneous RV-PA pressure (bottom) and PA blood flow (top) time series. B: RV pressure-volume time series

To determine ventricular contractility, we computed the end-systolic elastance (E_{es}) using two different methods. E_{es} in MBM was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

computed as the slope of the end-systolic pressure-volume relationship of the decreasing PV loop [3]. In contrast, in SBM, E_{es} was calculated as the slope of the line passing through P_{max} and the end-systolic PV point. P_{max} is found by interpolating the pressure curve over time in the RV from the $dP/dt_{max,min}$ points. For both methods, the effective arterial elastance (E_a) was computed as the ratio of the end-systolic pressure and SV [4, 5].

Comparisons of the cardiac performance between the groups and stages of PAH are done via an ANOVA analysis and considering $p<0.05$ to be significant.

RESULTS

The early and advanced stages of PAH, or results from week 1 and 4 are presented. The summary statistics of RV performance are based on the total cohort of 8 animals, and the comparison of the SBM and MBM is based on 6 animals. As shown in the summary statistics in Figure 2, the cardiac performance of the PL group overall remained constant, indicating no effect due to aging and/or injection of HCl. The cardiac performance in the MCT group changed from week 1 to 4. Particularly, the time decaying constant τ had a statistically significant increase with the advance of PAH. Ventricular relaxation, or dP/dt_{min}, was statistically significantly different between normo- and hypertensive animals in week 1, and ejection fraction, EF, statistically significantly decreased from normotensive to hypertensive in week 4.

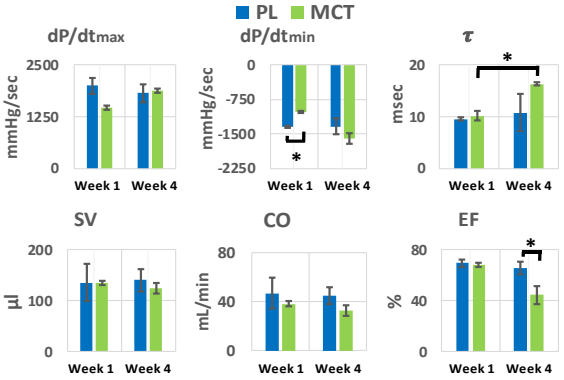

Figure 4. Summary statistics of *in vivo* hemodynamic measurements from the PL and MCT groups for week 1 and week 4. dP/dt_{max}; dP/dt_{min}; τ; SV; CO and EF. *$p<0.05$*

A comparison of the ventricular and vascular parameters E_{es} and E_a is shown in Figure 4. E_{es} tends to remain constant when comparing between week 1 and week 4 in SBM. However, MBM predicts a decrease in Ees values from week 1 to week 4 in both normo- and hypertensive groups. E_a predictions are, however, close and the trend of E_a to be larger in the PL group is preserved independently of the method used.

DISCUSSION

Cardiac performance of the PL group was maintained and did not change as a function of the animal aging. In addition, our cardiac performance values resemble the reported parameters for a normotensive rat [6]. On the other hand, the RV performance during diastole changed in the MCT group. The increase in τ indicates the loss of elasticity of the RV. The decrease in ejection fraction from week 1 to week 4, while stroke volume remained constant, indicates that the RV has increased in size (due to hypertrophy) and also its resting volume. These adaptations of the RV are in line with an overloaded ventricle.

Our predictions of E_{es} through the SBM and MBM are significantly different. With the MBM we find a decrease of E_{es} as the disease

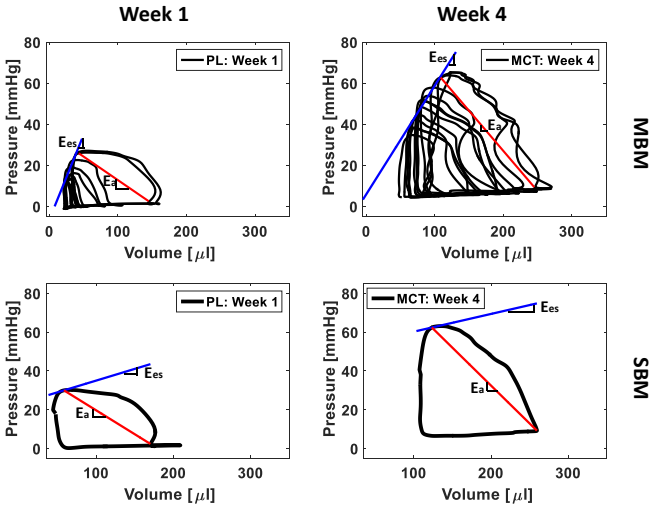

Figure 2. Left column: data from week 1 and right column: data from week 4. Top to bottom: MBM (steady state & IVC occlusion), SBM.

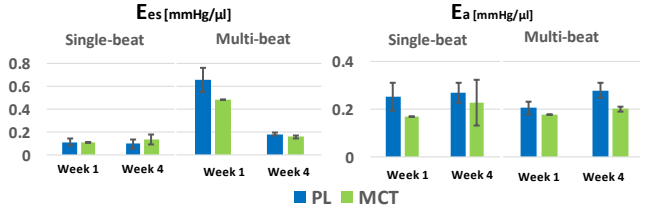

Figure 3. Computed E_{es} and E_a via the single-beat and multi-beat methods for PL and MCT groups in week 1 and week 4.

progresses, while the SBM predicts no change in RV contractility. This comparison has only been reported in the RV of humans [7]. In addition, Lambermont *et al.* found that the SBM overestimates E_{es}. This was an unexpected result that we are looking forward to addressing. The method, however, does predict similar E_a values and the same trend from week 1 to week 4. The only E_a values that have been reported are in the left ventricle in rats (0.5-1.1 mmHg/µL), therefore we are unable to compare our results of 0.18-0.3 mmHg/µL [6].

As the E_{es} values computed using the SBM are not close to the values given by the gold standard, it is necessary to determine the origin of this discrepancy and modify, if needed, the SBM in our animal model for clinical purposes. To our knowledge, no studies have been performed in the rat RV using the SBM. Therefore, it is essential to increase the number of animals in our study and fully characterize RV contractile properties using the SBM in the rat.

INTRODUCTION

In 2012, 3,200 patients under the age of 1 year required long-term mechanical ventilation [1]. The leading cause of long-term ventilation in pediatric patients is respiratory distress syndrome (RDS) which occurs in approximately 50% of neonates born at 26-28 weeks of gestation [2]. Preterm infants diagnosed with RDS are predisposed for the development of bronchopulmonary dysplasia (BPD) and become dependent on ventilator support. After intensive physical and occupational therapy, infants with BPD are discharged from the hospital on a portable ventilator to continue building strength and eventually become ventilator independent.

Children's hospitals across the United States currently adapt pediatric wheelchairs, wagons, strollers, and medical stands to transport patients with BPD from the hospital room to therapy sessions. The current methods involve haphazardly placing medical equipment and cords wherever they fit which introduces high risk to the transportation process. Furthermore, the process requires assistance from multiple caretakers and takes an unnecessary amount of time.

Clinical Problem: Intrahospital transport of patients aged 6 to 18 months who require continuous respiratory support is inefficient because the equipment used to transport patients does not allow for deliberate placement of medical devices and their cords in relation to the patient, therefore increasing time of transport and risk of harm to the patient.

Need Statement: There is a need to improve the clinical transportation efficiency of pediatric patients who require continuous respiratory support and better accommodate for medical devices and their cords in order to minimize the risk of harm to the patient as well as the time and staff required for transportation.

Here we present the design of a compact, assistive transportation device to be used in conjunction with a common, lightweight stroller. The device houses a portable ventilator, humidifier, pulse oximeter, oxygen cylinder, and emergency supply kit. It aims to improve transportation efficiency to enhance the safety of the transportation process. Our device will increase frequency of therapy sessions and allow for the hands-on involvement of family members to promote confidence in caring for their child. Ultimately, this will speed discharge from the hospital, improve the transition to a home-setting, and facilitate weaning from the ventilator, thereby improving quality of life for BPD patients across the United States. Because the number of BPD patients is increasing each year as a result of medical technologies' ability to save the lives of preterm infants, there is a growing and substantial need for our device.

PRODUCT DESIGN

The compact, assistive transportation device is intended to house the all of the medical equipment supporting ventilated patients, including a ventilator, pulse oximeter, oxygen cylinder, humidifier and emergency supply kit. It sits on 360° rotating and braking caster wheels for easy maneuverability on solid surfaces and over elevator gaps. With a total height of 3 feet, the device can be comfortably managed by one caretaker. Ultimately, our device better addresses the needs than current solutions because it is designed to be compact, organized, and easy to use to increase safety during patient transport. Our team is the first to specifically address this problem with systematic organization of equipment and efficiency in mind.

Our assistive transportation device is a three-tiered structure with designated places for each piece of medical equipment (Figure 1). The top level is fitted with a basket for storage and easy access to an emergency supply kit containing an Ambu bag and emergency tracheostomy tubes. This level was designed as a basket rather than a shelf for versatility. The pulse oximeter is placed below the emergency supplies on the middle tier, designed for a standard pulse oximeter. The pulse oximeter controls and monitor can be easily seen when placed in our device and are secured with an anti-slip gripping surface. The bottom tier is designed to house the patient's ventilator. Our device is compatible with both the Philips Respironics Trilogy 202 Ventilator as well as the Carefusion LTV 1150 Ventilator because both of these ventilators are commonly used with pediatric patients. The organization also allows the ventilators' circuit tubes to extend comfortably to the humidifier, mounted at the front of our device, and then directly to the patient. The humidifier is attached to the vertical support using a mounting feature that is compatible with Fisher & Paykel humidifiers. Furthermore, the ventilator connects to the oxygen cylinder located at the rear of the device. The oxygen cylinder mount is located closest to the caretaker during transport to increase cylinder safety and limit potential bumping or knocking of the cylinder. The cylinder is supported with a rigid y-shaped beam from beneath, a rigid ring at the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

base, and an adjustable strap at the top of the cylinder in compliance with compressed gas transport regulations defined by the Occupational Safety and Health Administration, the Compressed Gas Association, and the Uniform Fire Code. In addition, the device is equipped with clip features that quickly and securely attach to a variety of lightweight strollers. Together, this configuration reduces the risk of cord entanglement and circuit tube dislodgement while providing continuous, visual monitoring of the equipment, ultimately increasing ease and improving safety of the transportation process.

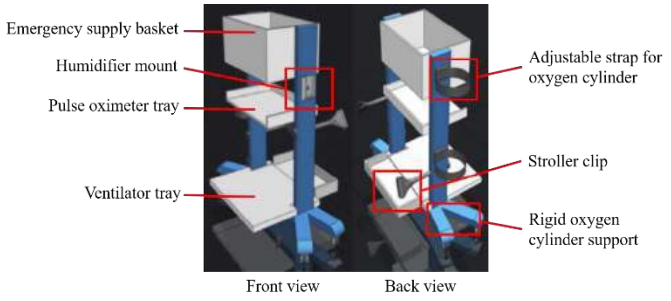

Figure 1. Computer Aided Drafting (CAD) model of the assistive transportation device.

Medical personnel should use our device by loading the equipment onto the device in the patient's room, attaching a lightweight portable stroller to the device with clips, placing the patient in the stroller, and pushing the single unit down the hallway as they would a normal stroller. Upon arriving at therapy or the final destination, the device can be detached from the stroller and left free standing with the medical equipment while therapy occurs or the patient is examined. Afterwards, it is simply reattached to the stroller, and the unit is transported back to the patient's room.

Transportation by one caretaker, easy loading and movement of medical equipment, and increased safety for the patient were the top needs that inspired our design. Patients with BPD require rigorous physical and occupational therapy to build strength and become ventilator independent. Without our device, these patients remain in their rooms 99% of the time, miss critical therapy time outside of the hospital room, and experience limited interaction with their families.

Our team has developed a working, wooden prototype (Figure 2) that serves as a preliminary test. We are in the process of building a working prototype with slight modifications using 304 stainless steel and high density polyethylene. These materials were chosen because they are lightweight, durable, and easily sanitized in a clinical environment. Since this prototype, we have redesigned our wheel configuration in order to mitigate the risk of turnover. We also plan to add a push handle to the top of our device for transportation independent from the stroller as well as improve the quality and safety of device-to-stroller attachment by redesigning our clip features.

BUDGET & MARKET ANALYSIS

Pediatric patients age 6 to 18 months treated in hospital with mechanical ventilation have the longest average length of stay and largest aggregate charges of all pediatric age groups receiving this treatment [1]. In 2013, there were 3,137 patients below 1 year of age diagnosed with a respiratory condition requiring long-term mechanical ventilation in the United States, representing 46% of the total amount of pediatric patients with this condition [3].

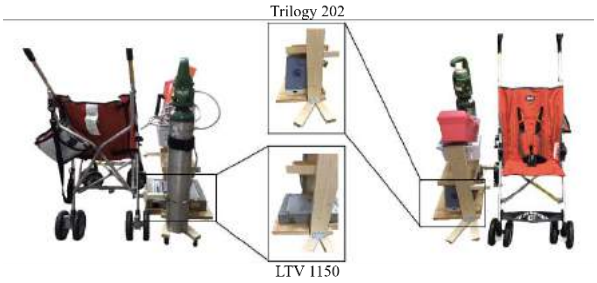

Figure 2. Wooden prototype attached to a Chicco stroller, displayed housing the Trilogy 202 and LTV 1150 ventilators.

According to 2013 Tennessee health statistics, mechanically ventilated patients under 1 year of age resulted in nearly $9,000,000 of aggregate charges [4]. That equates to an average of over $180,000 per patient, which provides an extensive market landscape for devices like ours. The market for devices designed specifically for the intrahospital transportation of ventilation equipment in conjunction with pediatric patients is currently unestablished. Hospitals throughout the country are adapting what is available to them because a solution does not yet exist. Therefore, our first-of-its-kind device will acquire the majority of this market.

Our working prototype, built with the intended product materials, costs approximately $150 excluding bulk purchase pricing and manufacturing labor costs. In consideration of bulk purchasing prices, we believe that our device could be mass manufactured for roughly $100 and sold for $400 per unit, equating to a 400% markup. When conservatively targeting only specialized children's hospitals, we expect to sell 500 units within our first year of production. With an investment of $250,000 we will be able to acquire all essential manufacturing equipment and establish initial inventory build. Approximately one year into sales we will be cash flow positive, net profiting $100,000 and predict to break even with profit and loss 18 months into sales. Once our market in a children's hospital is established, we plan to expand to general hospitals and facilities that care for ventilated pediatric patients across the country and ultimately at-home use by parents and caregivers. Thus, considering an early stage 50% market penetration we anticipate total sales to be $2,500,000 over the first 5 years with continued growth and improvement as the market evolves.

ACKNOWLEDGEMENTS

Our team would like to acknowledge all of the clinical staff at LeBonheur Children's Hospital. In particular, we would like to thank Susan Anderson, PTA/Adaptive Equipment Specialist-LEAD, Ginny Burbank, RN, IMCU, and Maris Brown, MHA, Regulatory Readiness Manager, for the invaluable information they shared with our team. We would also like to acknowledge our faculty mentors, Dr. Gary Bowlin and Dr. John Williams, for mentoring our team through the development of our device.

INTRODUCTION

Bioprosthetic heart valves (BHVs) are used to replace stenotic and regurgitant heart valves [1]. BHVs do not require long-term anticoagulant therapy and also have more optimal hemodynamics, thus making them the preferred option for valve replacements [1]. BHVs are fabricated out of two types of xenogeneic tissues: (1) Porcine aortic valve (PAV) leaflets or (2) bovine pericardium (BP) sheet. Both are crosslinked with glutaraldehyde (GLUT). Commercially available BHVs fail due to structural degradation and/or calcification [1].

BP is the most commonly used material to fabricate BHVs and contains a high amount of layered structural proteins (collagen and elastin with proteoglycans) to impart viscoelastic properties into the tissue composite [2]. BP patches are selected based on thickness (0.5 mm) but it is not common industry practice to select for any type of preferred orientation despite previous literature suggesting there are preferred orientations of isotropy [2] that may result in different biomechanical behavior. Tears and structural degradation account for half of BHV failures [3].

Because GLUT crosslinked biomaterials have previously been demonstrated to exhibit permanent geometric deformation from cyclic mechanical deformation resulting in deviated biomechanics [3], there is motivation to search for a more stable crosslinking chemistry that produces a structurally more stable biomaterial. Previously, we have demonstrated a novel crosslinking method (TRI) that utilizes carbodiimide, neomycin trisulfate, and pentagalloyl glucose to stabilize tissue based biomaterials [4]. Here, we demonstrate that BP sections treated with TRI are structurally more durable and retain similar viscoelastic properties required of a compliant biomaterial.

METHODS

Fabrication of tissue based biomaterials

Bovine pericardium (BP) was sourced from Animal Technologies, Inc. (Erwin Tyler, TX) delivered on 0.9% saline and ice to the laboratory. BP sacs were cut into flat sheets and were washed in 0.9% saline. BP sheets were then treated with two different chemical treatment techniques: (1) GLUT – industry standard control and (2) TRI – novel, more irreversible crosslinking technique.

GLUT: BP sheets were treated with 0.6% glutaraldehyde in 50 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffered saline (pH 7.4) at room temperature with gentle shaking for 24 hours, solution decanted, and replaced with 0.2% glutaraldehyde in 50 mM HEPES buffered saline (pH 7.4) and the crosslinking was continued for at least six days.

TRI: BP sheets were treated with 0.5 mM neomycin trisulfate solution in 2-(N-morpholino) ethanesulfonic acid (MES) buffer for 1 hour. The solution was decanted and leaflets were then incubated in a 30 mM *1-ethyl-3-(3-dimethylaminopropyl) carbodiimide* (EDC) and 6 mM *N-hydroxysuccinimide* (NHS) / 0.05% PGG solution in 50 mM MES buffered saline (pH 5.5) for twenty-four hours. The solution was decanted and then the leaflets were then crosslinked further in 30 mM EDC and 6 mM NHS solution in 50mM MES buffered saline (pH 5.5) for 24 hours. Following fixation, sheets were placed in 20% isopropanol in 50 mM HEPES buffer (pH 7.4) for at least six days.

Biaxial Mechanical Testing

Tissue specimens were tested under biaxial tension using a custom-built biaxial device. Roughly 2 cm by 2 cm sections were cut from preselected BP sheets for fiber orientation and mounted on the device

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with the circumferential and radial directions along the device axes. The specimens were then loaded to a maximum membrane tension of 60 N/m over a period of 15s following a preconditioning step. The strain was determined via four fiducial markers were glued to the central region of the specimen. All mechanical testing were performed in PBS at room temperature. Samples were preselected by looking at collagen fiber alignment and quantifying biomechanics using biaxial testing to confirm preferred (PD) and non-preferred (XD) fiber orientation.

Stretch Test

After preselection process and biaxial testing, GLUT or TRI BP were held stretched in the PD or XP orientation at 20% past their nominal gauge length for 4 weeks in a custom built clamp system at Clemson University. Reference photos before and after stretching were taken with a high definition camera. Photos were also taken with scale references every week. Photos were also taken immediately following, 1 day, and 1 week after release from clamps to observe both short and long term behaviors of the material to return to gauge length in both the PD and XD directions.

Suture Pull-out Test

BP patches were evaluated for structural integrity and its ability to resist tearing. GLUT and TRI BP patches were cut with a die in rectangular 40 mm x 4.0 mm sections. Sections were then treated with collagenase, GAGase (combination of enzymes to degrade GAGs), porcine pancreatic elastases, or no enzyme treatment (8 groups, n = 8). One side of tissue samples was attached to a bottom clamp in a tensile tester (MTS, Minneapolis, MN). A single suture (Polypropylene blue monofilament 4-0 P-3 Ethicon™, San Lorenzo, Puerto Rico) was pierced through the sample a third of the way down the sample and was clamped to the top clamp. Samples were tensile tested at 12 mm/min to determine the amount force it took to pull the suture out of the sample. With the peak load, thickness of the sample and width were used to calculate cross sectional area to determine stress.

RESULTS

After stretch testing for 4 weeks, GLUT BP patches exhibited significant permanent set effects in both the PD and XD directions while TRI BP patches did not exhibit these effects (Figure 1). A lambda value of 1 is ideal in which there are no permanent set effects. After suture pull-out testing, it was found that TRI BP patches took significantly more stress to cause rupture than GLUT suggesting TRI is the more durable material with improved structural integrity (Figure 2). Enzymatic degradation does not affect either tissue in terms of point stress required to cause rupture. It is also important to note that biaxial testing shows that TRI BP is the more compliant biomaterial than GLUT BP before and after stretch testing (not shown). Furthermore, GLUT and TRI BP both exhibit similar denaturation temperatures ($81 \pm 1.2^{o}C$ or $82 \pm 0.9^{o}C$, respectively).

DISCUSSION

Previous studies have shown permanent set effects affect the biomechanics and function in explanted [5] and *in vitro* cyclically fatigue tested BHV materials [2, 3]. We hypothesize that this is due to the reversibility of GLUT crosslinking and replacing GLUT with chemistry that is more irreversible will provide more stable bonds to prevent permanent set. This study has demonstrated that using TRI on BP, the commercially preferred raw material for BHV fabrication, produces a very durable material that retains increased compliancy over GLUT even after mechanical deformation over a long period of time. Coupled with this material's ability to resist calcification [4], more irreversible chemistries such as TRI should be considered for BHV fabrication. Therefore, using TRI in lieu of GLUT may significantly suppress the two modes of BHV failure thereby increasing implant life and patient quality of life.

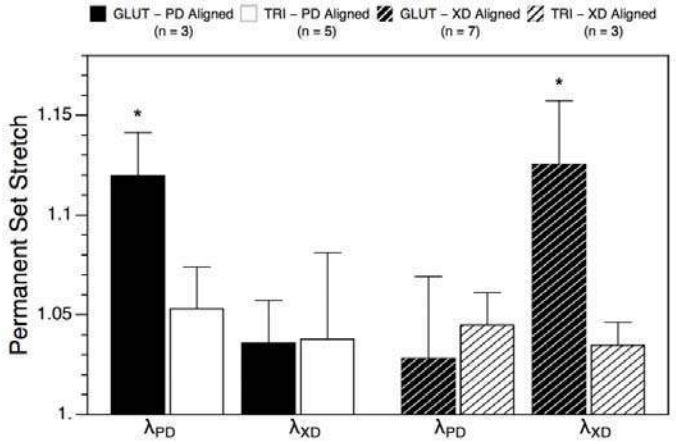

Figure 1: Permanent set effects in GLUT or TRI BP patches. *Indicates significant difference from TRI.

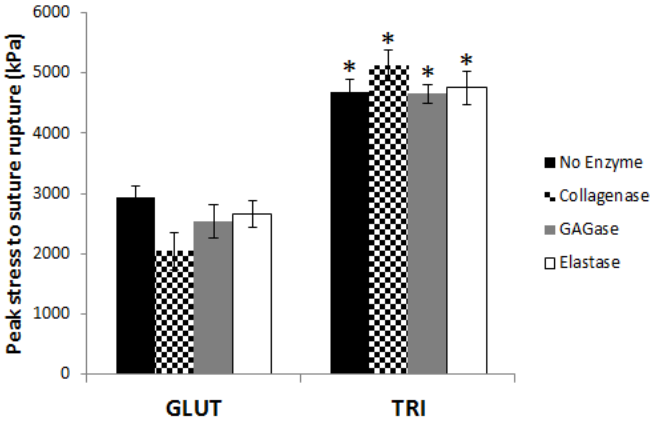

Figure 2: Peak stress to cause rupture in GLUT or TRI treated BP patches. *Indicates significant difference from GLUT.

CONCLUSION

A novel and irreversible crosslinking chemistry, TRI, for BHV fabrication was shown to have significantly more structural durability than the industry standard use of GLUT. TRI crosslinked material was able to retain higher compliancy before and after sustained mechanical deformation while GLUT materials exhibited permanent set effects resulting in deviations in biomechanical behavior. Future investigation will focus on accelerated wear testing of BHV biomaterials to discern the action of mechanism behind structural degradation. This will revolutionize the future of BHV design by introducing a core biomaterial that better fits patient needs and enables better quality of life.

THE DEVELOPMENT OF A "FUZZY" YIELD ENVELOPE FOR TRABECULAR PORCINE SKULL BONE USING NUMERICAL SIMULATIONS

INTRODUCTION

Typically, trabecular bone failure is characterized under uniaxial tension or compression loading, and sometimes even biaxial loading. While this information is valuable, it leaves gaps in determining the multiaxial failure surface of trabecular bone, which is important to describe the mechanical response of the skull during complex loading scenarios- especially those with loads in all three directions.

In addition, there is a lack of knowledge concerning the changes in yielding behavior in trabecular bone as a result of variations in porosity. That is, as the porosity and bone architecture changes from one spatial location in the skull to the next, the failure responses may change as well. With current advances in finite element programs and the availability of high performance computing, numerical methods give us the power to analyze and characterize these changes in properties. By running simulations on numerous trabecular microstructure models, each with a different level of porosity, the changes in response can be easily captured without having to run mechanical testing or prepare physical bone samples.

Furthermore, due to the lack of quantitative data on the multiaxial failure response of trabecular bone, it is not clear exactly how microstructural architecture influences the anisotropy of failure. Simulations may provide a means to understand and connect mechanisms of failure, such as trabecular ligament fracture, with the resulting failure envelope. Insight into these physical mechanisms will elucidate the mechanical response of trabecular bone.

To address these gaps and gain a better understanding, the aim of this study is to develop a multiaxial yield surface for trabecular skull bone. To achieve this, we use finite element analysis to examine hundreds of multiaxial loading conditions with both normal and shear loads each applied to 12 different microstructural trabecular bone samples (with a goal of eventually analyzing 30). The final result is a three-dimensional yield surface plotted in both principal stress and principal strain space. We used an approach similar to one that has been previously published [1], but considered a different bone (skull), additional microstructure models, and completed a statistical analysis of yield points in relation to porosity. The resulting compilation of yield points from thousands of simulations gives an overall characterization of the yielding behavior for trabecular bone.

METHODS

Trabecular bone microstructure models were derived from microCT scans of the skull of a six-month old Gottingen minipig. The full skull was cropped to smaller 3.15mm^3 volumes to create the 30 microstructures of interest. Each was taken from a different location in the skull, and thus has a different level of porosity. Volume meshes of these models were then created in Ansys with roughly 400-500 thousand elements per microstructure. Figure 1 shows 5 of the thirty microstructure meshes.

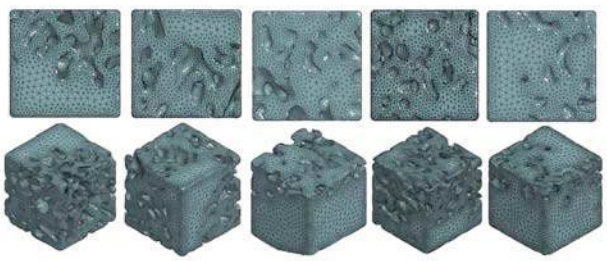

Figure 1: 5 of the 30 microstructure models used in this study

To set up simulations and span all areas of stress space, a systematic approach was used to determine displacement boundary conditions. Boundary conditions of two types were simulated. The first was normal loading where displacement loads were applied uniaxially, biaxially or triaxially normal to the face of the microstructure. And the second was a combination of normal and shear loading where displacement loads were applied uniaxially normal to one of the microstructure's faces along with a shear load parallel to one of the microstructure faces. The equation of a sphere was used to systematically determine the ratios of x, y and z displacements, for each boundary condition type, to ensure all areas of stress and strain space (uniaxial, biaxial, triaxial, tension and compression) were covered. In total, each of the 30 microstructures was subjected to 457 simulations, each with unique boundary conditions.

So far, 12,796 of the 13,710 total simulations were completed. In order to semi-automate and standardize this process, an algorithm was written to automatically set-up, submit and analyze all simulations for each model by setting up the LS-Dyna input files, submitting the simulations to run in parallel on Penn State's supercomputing cluster, extracting the results, and determining the yield points from each simulation using a variation of the 0.2% offset method. Simulations were run at a strain rate of roughly $60s^{-1}$ using an elastic perfectly plastic material model with material properties taken both from the literature and from physical experiments (Young's Modulus = 7.5GPa, Yield Stress = 20.3 MPa). After all simulations were complete, yield points were plotted in three-dimensional principal stress and principal strain space to compare the differences between different simulations loading conditions, as well as between each of the microstructures in order to determine how porosity plays a role in the results.

RESULTS

Yield points were plotted to compare results between microstructures and simulations. Although each microstructure was subjected to the exact same boundary conditions, their resulting yield points from those simulations were rather different. Points generally populated a surface of the same shape (a diagonally oriented modified ellipsoid) but the radii and curvatures were different depending on the porosity of the model. Figure 1 shows the span of yield points for the microstructures in stress space for simulations that had biaxial loading in the x and y-directions. Results are similar for the other two biaxial directions, as well as for simulations were loads were applied triaxially.

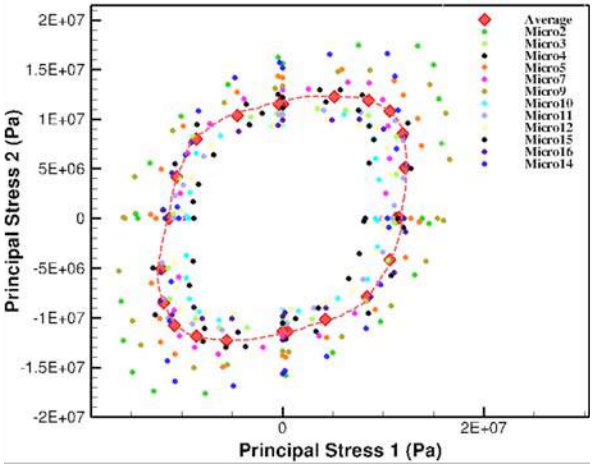

Figure 2: Yield stresses for biaxial XY simulations for 12 of the 30 microstructures. Average yield points shown in red.

To get a more overall response for trabecular bone, all yield points were averaged between the microstructure models for each of the loading conditions (red triangles in Figure 1). When looking at these averaged yield points in the three biaxial planes (xy, yz, xz), the results are nearly identical- showing that, for these chosen samples, trabecular bone displays isotropic yielding behavior-despite some other studies that have stated otherwise[2].

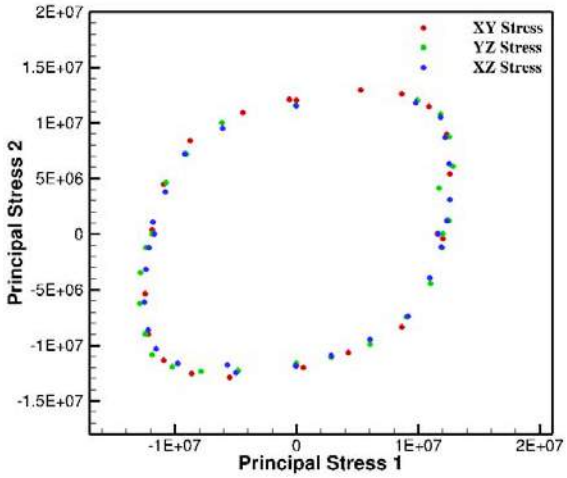

Figure 3: Average Biaxial yield stresses are identical in each plane (XY, YZ, XZ) - proving isotropy for these trabecular bone samples

DISCUSSION

The primary objective of this research was to develop a three-dimensional yield surface in both stress and strain space and investigate the effect of porosity on the failure of trabecular bone. The equation for the three-dimensional porosity-based yield surface derived from the resulting yield points can be used in new material models to govern the failure behavior of trabecular bone under a certain stress/strain state.

This dependence on porosity is clear when looking at the spread of yield points in Figure 1. For the same loading condition, each microstructure produces a different yield point. In light of this, porosity must be included in models in order to obtain an accurate response. Some efforts have said that volume fraction (porosity) plays a minimal role in yielding behavior [3], however, here, we see the opposite-where porosity greatly affects the resulting yield points, as noted by the spread in the data. Trabecular bone comes in many levels of porosity. In fact, in porcine skull bone, it has been shown that there is a gradient of porosity throughout its thickness. Thus, when developing an equation for a yield surface, this variation in porosity must be reflected so the material model governing the behavior of trabecular bone is accurate.

DIRECT QUANTIFICATION OF SOLUTE DIFFUSIVITY IN POROUS, VISCOELASTIC MATERIALS USING CORRELATION SPECTROSCOPY

INTRODUCTION

Osteoarthritis (OA) is a debilitating disease affecting millions of Americans. OA progression is slow and cumulative, and patients typically do not present symptoms until late-stage time points, leaving clinicians with limited treatment options. Earlier diagnosis of OA may allow for improved outcomes through proactive treatment strategies.

One of the earliest signs of OA is proteoglycan loss in the articular cartilage [1]. The negatively charged proteoglycans are essential for cartilage's characteristic water retention, which modulates the tissue's low friction properties and fluid load support [2]. Solute-matrix interactions and interstitial fluid flow in articular cartilage are also affected by the loss of proteoglycans [3]. Thus, changes in solute-matrix interactions may be useful as markers of early OA.

Recently, Fluorescence Correlation Spectroscopy (FCS) has been used to quantify the diffusivity of various solutes in healthy and chemically degraded cartilage [4]. While FCS is a well-established technique, it is somewhat limited by its use of a stationary, confocal observation volume. Raster Image Correlation Spectroscopy (RICS) is a confocal laser scanning microscope-based extension of correlation spectroscopy that can determine the diffusivity of solutes within images [5]. However, RICS has not been used to quantify solute diffusion in solid media. The goal of this study was to use FCS and RICS to quantify the diffusion of fluorescent solutes in strained and unstrained plugs of agarose and cartilage.

METHODS

A. Agarose

Agarose plugs (3-mm diameter, 1.5-mm thick, n = 55) were prepared at 1, 3, and 5% wt/vol. Plugs were equilibrated for 24 hours in 10 nM solutions of either fluorescein isothiocyanate (FITC, MW = 389 Da), AlexaFluor (AF) 488-Conjugated 3K Dextran (MW = 3,000 Da), or AF488-10K Dextran (MW = 10,000 Da). Correlation spectroscopy was performed at 3 locations within each sample to obtain an average diffusivity value. Samples were quantified at 0 and 10% equilibrium strain, applied via unconfined compression.

B. Cartilage

Articular cartilage plugs (3-mm diameter) were harvested from juvenile bovine medial femoral condyles (< 1 year old; n = 3). Each plug was cut into three 1-mm thick sections (n = 35), with each section corresponding to a cartilage zone (i.e. superficial, middle, or deep). Section were stained with DAPI followed by 24-hour equilibration in 10 nM of FITC or AF488-3K Dextran. Correlation spectroscopy was performed at three locations within each sample to obtain an average diffusivity value. Samples were observed under 0, 10, 20, and 30% equilibrium strain, applied via unconfined compression.

C. Correlation Spectroscopy

Diffusivity was quantified via FCS and RICS, following previously described protocols [5-7]. FCS is an Eulerian measurement technique, in which fluorescent intensity fluctuations due to transits through a 1-fL observation volume are analyzed via autocorrelation, and fit to a diffusion model to calculate diffusivity. RICS is an image-based method, which exploits the time lags between consecutively captured pixels in a raster-scanned image to quantify the diffusivity of the particles in the system under observation. Autocorrelations are performed on these images, and fit to a 3-D diffusion model that contains scanning parameters to obtain a diffusion coefficient. This analysis was performed using custom MATLAB scripts.

D. Microscopy

All experiments were performed at room temperature using a 40X water-immersion lens on a Zeiss LSM780 or LSM880 microscope. A

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

488-nm laser was used to excite all fluorescent dyes. RICS images (256 x 256 or 512 x 512 pixels) were captured at 200-320x (spatially oversampled) according to established protocols [8]. All data was captured at a depth of 20-μm into the sample.

Point spread function (PSF) size calibrations, which are required to calculate diffusivity using FCS and RICS, were performed using an aqueous FITC solution and standard diffusivity of 450-$\mu m^2/s$. Experimental diffusivity measurements of the other solutes and conditions were quantified using the calibrated PSF parameters, and are reported with reference to FITC.

E. Statistical Analysis

Two-way ANOVA, with replication, was performed on all data sets. One-way ANOVA with Tukey's post-hoc test was used to determine significance between groups. For all tests, $p < 0.05$ indicated significance.

RESULTS

A. Agarose

The diffusivity of fluorescent solutes in agarose was dependent upon the solute size and agarose concentration. As expected, the effects of gel concentration were dependent upon the effects of solute size, and vice versa (two-way ANOVA). Diffusivity decreased with both increased solute molecular weight and increased agarose concentration. FCS and RICS measures demonstrated similar trends (Fig. 1). Solute diffusion also decreased with compressive strain (not shown).

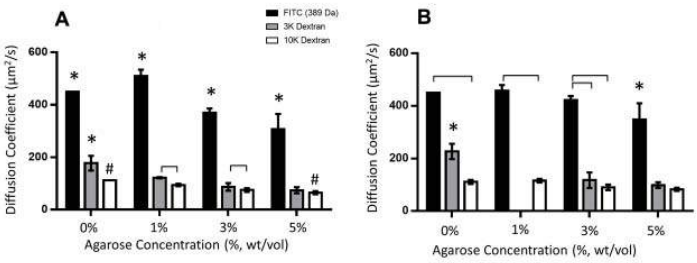

Figure 1: Diffusion coefficients of FITC, 3K dextran, and 10 K dextran determined by FCS (A) and RICS (B) in 0, 1, 3, and 5% agarose. Bars signify mean ± SD. Groups marked by * are significantly different from all other groups ($p < 0.05$, One-way ANOVA, Tukey post-hoc). Brackets and # indicate groups that are significantly different from each other. (n = 5 for each group)

B. Cartilage

Both FCS and RICS data showed that axial strain significantly affected solute diffusivity (two-way ANOVA, $p < 0.05$). We observed that solute diffusivity decreased between 0% and 10% compressive strain in superficial zone cartilage (Fig.2). No trends were apparent at higher levels of strain or in the deeper zones of cartialge. Diffusion coefficients determined by RICS tended to be slightly lower than those found via FCS. The diffusivity of FITC and 3K Dextran were also compared in zonally matched cartilage samples. As expected, the diffusivity of FITC was found to be greater than that of the 3K Dextran (not shown).

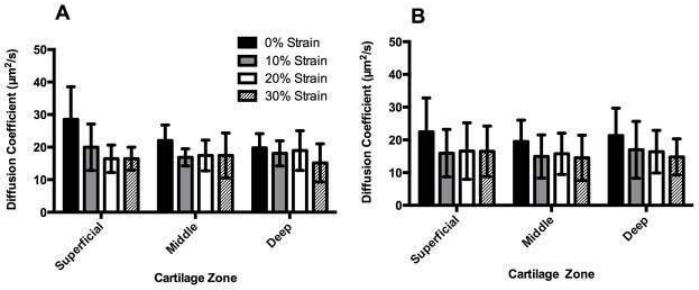

Figure 2: Diffusion coefficients of 3K dextran determined by FCS (A) and RICS (B) in the superficial, middle, and deep zones of bovine calf cartilage under 0, 10, 20, and 30% strains. Bars signify Mean ± SD. (n = 12 for each group)

DISCUSSION

FCS and RICS demonstrated similar accuracy in determining solute diffusivity in agarose and cartilage. Greater precision was observed in the measurement of diffusivity in agarose than in cartilage, potentially due to the fact that agarose is a more homogeneous material. Inhomogeneity may influence correlation spectroscopy sensitivity due to the effects of spatial averaging. Presently, we are developing spatial windowing analysis technique for RICS to increase its spatial sensitivity and to enable diffusivity mapping within an observation sub-region.

Articular cartilage structure and function has been shown to be heterogeneous through the joint [9], which could explain the variability in diffusivity observed experimentally. Similar trends, demonstrating no difference in solute diffusivity between the middle and deep zones of articular cartilage, but differences between the superficial and middle/deep zones have been reported previously [10]. Ongoing work is investigating the quantification of matrix porosity based upon these diffusion data, in order to better understand the influence of matrix structure on solute-matrix interactions and diffusivity.

Future work will extend these analysis techniques to the study of osteoarthritic human cartilage in order to determine if pathophysiological changes in solute-matrix interaction can be detected via correlation spectroscopy.

INTRODUCTION

The optimal timing of surgical intervention for abdominal aortic aneurysms (AAAs) remains a significant challenge as a clinician attempts to weigh surgical risk versus rupture risk for each unique case. There has been significant interest in using computational models of aortic mechanics to estimate this rupture risk, but classic stress analyses are unable to account for the evolving nature of these complex lesions. Thus, growth and remodeling (G&R) models that attempt to capture the evolution of the primary biomechanical constituents of the aortic wall have increasingly been explored to gain insight and identify key factors governing AAA progression and outcomes. Nevertheless, these models have yet to capture the full range of AAA expansion patterns observed clinically, notably including the propensity for stepwise increases of maximum diameter [1], nor have they reproduced the wide range of mechanical behaviors observed experimentally from in vitro tissue testing [2]. One possible reason for this shortcoming may be the failure to include the biochemomechanics of intraluminal thrombus (ILT), a heterogeneously evolving and biologically active structure present in the majority of AAAs, which has only recently begun to be incorporated into G&R models [3]. We have previously hypothesized that dissection of the ILT could destabilize an AAA [4]. Herein, we explored the potential for intermittent thrombus deposition and dissection, combined with evolving collagen G&R parameters, to explain the observed clinical and mechanical behavior of AAAs.

METHODS

A previously described axisymmetric G&R membrane model of AAAs [5] was modified (with only key changes noted here) to capture phenomenologically the biological effect of the deposition and evolution of ILT on the underlying aortic wall. Briefly, an AAA was initiated by prescribing elastin loss from a normal aorta endowed with best-fit material properties derived from published data [6]. Following stabilization of the lesion as a result of G&R, space-filling thrombus deposition was prescribed. Since the luminal layer of ILT possesses the greatest amount of proteolytic enzymes [7], a gamma-like function was used to define an evolving half-life of collagen ($t^c_{1/2}$) in the wall as a function of adjacent normalized ILT thickness ($\bar{h}_{ILT}$) according to

$$t^c_{1/2}(\tau) = \left(t^{lum}_{1/2} - t^{c,h}_{1/2}\right)\bar{h}_{ILT}(\tau)\exp\left(1 - \bar{h}_{ILT}(\tau)\right) + t^{c,h}_{1/2} \quad (1)$$

where $t^{lum}_{1/2}$ is the minimum collagen half-life induced by luminal ILT and $t^{c,h}_{1/2}$ represents the homeostatic half-life of collagen. Idealized dissections of ILT (which bring 'luminal' properties to the ILT-wall interface) were simulated at prescribed times by resetting the half-life to $t^{lum}_{1/2}$ before a first order decay to $t^c_{1/2}(\tau)$ to simulate re-thrombosis.

To account for the increase in material stiffness in AAA tissue, the stiffness parameter within the Fung exponential (c^c_2) describing the strain energy function for collagen was increased by a factor α following complete elastolysis. However, we also hypothesized that stiffness would decrease for newly deposited collagen fibers when collagen half-life was significantly reduced since activated proteases and associated rapid turnover may inhibit cross-linking and the formation of thicker fibers. Thus, for AAA tissue c^c_2 was equal to its homeostatic value below a prescribed half-life $t^{c,*}_{1/2}$ and was equal to αc^c_2 for half-lives above $t^{c,*}_{1/2} + \Delta t$, with a linear transition across Δt.

Also differing from our previous G&R models, we allow the pre-stretch of collagen (G^c) to decrease from 1.05 to 1.01 following complete elastolysis. Physiologically, this change may be explained by contractile cells that produce collagen (e.g., smooth muscle cells and myofibroblasts) locally contracting the surrounding matrix, inserting a new collagen fiber, and then releasing the matrix to induce a pre-stress

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

in the new fiber. Thus, as the local matrix stiffens due to loss of elastin and increased cross-linking, pre-stretch decreases as the cells cannot compress the matrix to the same degree (cf. Figure 3 in [8]). Since the degree of cross-linking before the cells release the matrix will determine the pre-stress in each new fiber, we introduce a multiplication factor β to increase pre-stress that varies with c_2^c. The final collagen stiffness parameter (c_1^c) can then be calculated to ensure the new pre-stress.

RESULTS

Figure 1 demonstrates the stepwise expansion at the apex of the AAA as a result of robust growth and remodeling punctuated by four destabilizing events (initial elastolysis, deposition of thrombus, first ILT dissection, second ILT dissection). Spikes in circumferential (and axial) Cauchy stress coincide with periods of expansion and decreased wall thickness (not shown). Peak stress increased as the lesion expanded with the exception of the initial peak stress when almost all elastin and smooth muscle were lost to initiate the lesion.

Simulated equibiaxial stress-stretch plots in Figure 2 before, during, and immediately after the second ILT dissection demonstrate the evolving mechanical behavior of the aortic wall. Previous cycles are similar, and the curves shift left before the cycle repeats during the next expansion. Comparison is provided to three representative equibiaxial curves from two AAA subgroups (1 stiff and 2 moderate) described in [9] based on data from testing excised AAA samples [2].

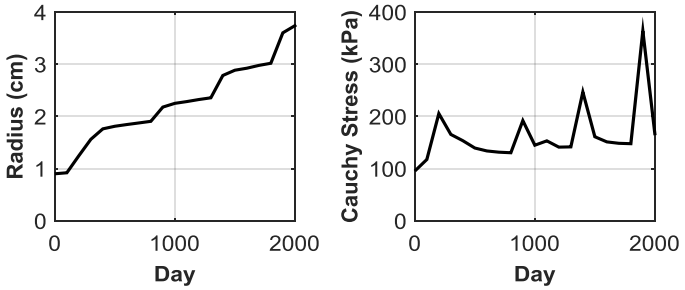

Figure 1: Evolution of radius and circumferential Cauchy stress at the apex of the AAA.

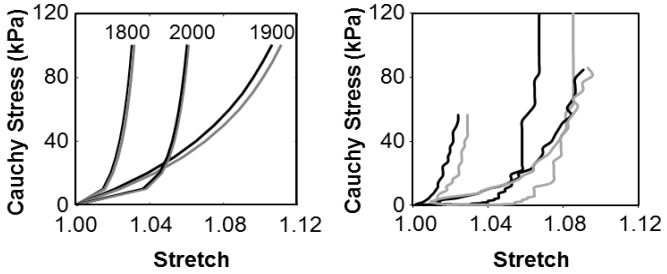

Figure 2: (Left) Simulated equibiaxial stress-stretch behavior at the apex of AAAs before, during, and immediately after expansion (1800-2000 days). (Right) Representative AAA equibiaxial data from [2]. (Circumferential = black, Axial = gray)

DISCUSSION

Stepwise AAA expansion requires intermittent destabilization events followed by robust G&R capable of arresting further expansion (often within as little as a few months [1]). This G&R can take the form of increased collagen production or altered mechanical properties such as material stiffness and pre-stretch. Herein, we demonstrate that deposition of a biologically active ILT can destabilize a previously stable AAA until the active luminal layer (~2mm) is displaced from the underlying wall as the ILT thickens. Furthermore, we propose that dissection of fresh blood and inflammatory cells deep within the ILT can lead to punctuated periods of expansion. Such ILT dissections have been visualized clinically as the 'crescent sign' on CT imaging with contrast [10], and are further supported by evidence of iron accumulation and inflammatory cells embedded deep within the ILT of experimental rat AAAs with thick thrombi [11] and by increased uptake of USPIO nanoparticles in focal regions of deep ILT in expanding human AAAs [12]. Importantly, these results suggest that rupture risk may not monotonically increase, but rather peak during destabilization events. Thus, prediction of these events may be as important, if not more, than predicting exact failure stresses.

The wide variation and increased stiffness of AAA material behavior reported in [2] was further analyzed and sub-categorized according to circumferential stiffness and anisotropy in [9]. Increasing the collagen material stiffness allowed a better fit to the steep stress-strain curves from experimental data and may be a result of increased cross-linking. Capturing the stiffest behavior also required a reduction in collagen pre-stretch. The assumption that the stiffness of new collagen decreases with half-life (which drops during destabilization events) allowed rapid expansion until half-life normalized. The resulting cycle of predicted material behavior observed in Figure 2 suggests that periods of expansion may be 'encoded' in the material behavior of the aortic wall, with the moderately stiff behavior indicating current or recent rapid expansion. Furthermore, this cyclic evolution of simulated behavior suggests that much of the variation in the experimental data may reflect random sampling of common AAA evolution patterns as opposed to unrelated patient variability.

This model is currently limited by the need to prescribe the times of ILT deposition and dissection, as well as the use of elastin mass as a proxy for gross matrix stiffness. Future fluid-solid-growth models that include metrics determining thrombus formation, the mechanics and failure of fibrin, and a direct relationship between pre-stretch and evolving matrix stiffness would be beneficial. Further data and computational analysis regarding AAA expansion and mechanics apart from the apex is also needed. Nevertheless, the current model has provided insight.

In conclusion, the novel G&R mechanisms of thrombus-induced destabilization, matrix-dependent pre-stretch, and cyclically evolving material behavior qualitatively reproduce the best available data regarding human AAA expansion and mechanics at the apex of these complex lesions. In vitro and in vivo experiments to confirm these findings are recommended and are under development.

INTRODUCTION

Forsterite with the chemical formula Mg_2SiO_4 has attracted the attention of many scientists as a bioceramic in the recent decades [1]. Si and Mg components of forsterite play a vital role in the growth and mineralization of the bones in human bodies [2]. In some studies performed by Carlisle [3,4] it was found that silicon (more than 5 wt.%) was uniquely localized in the active growth areas in the bones of young rats (when the Ca/P ratio was 0.7) and involved in the early stage of bone calcification in physiological conditions. Similar studies showed that the growth rate of rats was increased by adding silicon to their diets. Furthermore, it was found that silicon deficiency in rats resulted in skull deformations [5].
Magnesium also plays a significant role in the bone fragility, bone-growth, osteoblastic activities and degradation of hydroxyapatite crystals [6]. In clinical experiments, it is proven that Mg-containing materials such as diopside [7], bredigite [8] and merwinite [9] can be promising candidates for bone tissue engineering at load bearing applications.

Forsterite has been synthesized by various techniques such as the polymer precursor method [10], heat treatment of the mixed powders prepared by alkoxymethod [11], the sol–gel method [12] and ball milling method [13]. During the synthesis of forsterite, it is very difficult to avoid the formation of enstatite (MgSiO3) or/and periclase (MgO). Annealing up to 1200–1600 °C is reported to be necessary to obtain single phase forsterite structure.

In this paper mesopore forsterite powder was synthesized at much lower temperature, regarding to the conventional synthesis method, by a sol-gel method. mesoporous structure can boost the cell growth, bioactivity, and biological fixation in bone defect. The forsterite formation mechanism was studied as well.

METHODS

Forsterite powder was synthesized according to the following steps: sol-gel method and subsequent annealing at 600 to 1000 °C for 1h. In order to prepare the forsterite powder, proper amount of magnesium nitrate and silica were dissolved in deionized water utilizing magnetic stirrer to result stoichiometric forsterite structure with Mg:Si molar ratio of 2:1. A solution of sucrose with the molar ratio of sucrose to metal equal to 4:1 was prepared. Then this solution was added gently to nitrate solution while it was stirring. Subsequently a solution of polyvinyl alcohol with PVA to metal molar ratio of 0.5:1 was added to the obtained sucrose and nitrate solution and then the pH was adjusted to 1 utilizing nitric acid. Subsequently, the solution was heated at 200 °C for 24h. Heat treatment of ball milled powders was carried out from 600 to 1000 °C for 1 h in air.

To evaluate the thermal behavior of the ball milled powder, thermogravimetry (TG) test was performed up to 1200 °C at a heating rate of 10 °C/min. Phase transformation of the obtained powders after heat treatment was investigated by X-ray diffractometry (XRD) using a Philips X'PERT MPD diffractometer with Cu Kα radiation (λ=0.154056 nm). The XRD patterns were recorded with a step size of 0.04° and a time per step of 1 s. The morphology of powder particles was studied by field emission scanning electron microscopy (SEM) (Quanta3D FEG, FEI Company, USA) at acceleration voltages between 20 kV.

RESULTS

Fig. 1 shows the thermal gravimetric (TG) and differential thermal gravimetric (DTG) analyses curves of RS. Three main stages were observed in the TG curve. The first stage (5%) belonged to the region below 200 °C, accompanied with an endothermic peak at around 130 due to the removal of free water. The second stage of weight loss (47%) was observed from 200 to 600 °C which is accompanied with two exothermic peaks at around 320 and 500 °C can be assigned to the decomposition of precursor, burning of carbon and formation of magnesium oxide, respectively [14]. The third stage of weight loss (7%) accompanied with an exothermic peak at around 715 °C is due to the formation of forsterite powder [15]. Forsterite forms through diffusion-controlled mechanism. Hence the exothermic peak assigned to the formation of forsterite structure is spread from 650 to about 800 °C.

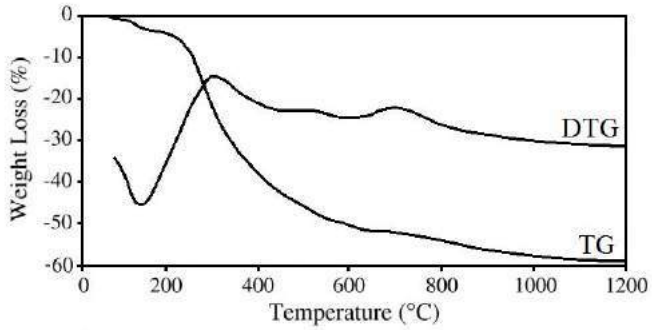

Fig. 1. The TGA evaluation of the obtained powder from sol gel method.

Based on the results obtained from thermal analysis, powders were annealed at various temperatures and the produced powders were characterized by X-ray diffraction method to reveal the phase transformations occur during heat treatment. The XRD patterns of the prepared powders after sintering at 610 °C for 6h are shown in Fig. 2.

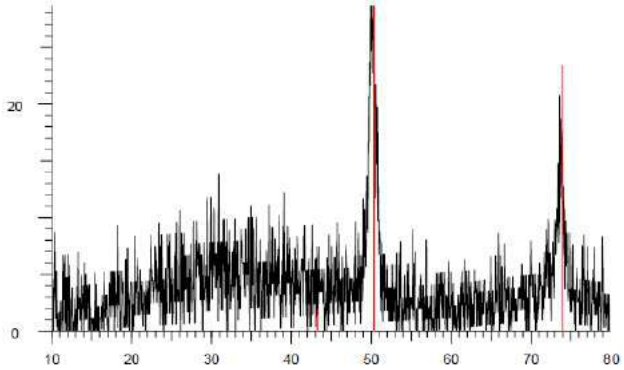

Fig. 2. XRD patter of the heat treated sample at 610 °C for 6 h.

An amorphous structure was observed on the XRD pattern of powder. Annealing of powder at 610 for 6h led to the formation of MgO (XRD JCPDS data file No. 43-1022) in the structure. With increasing the annealing temperature to 750 °C, forsterite peaks (XRD JCPDS data file No. 34-0189) were observed in the XRD pattern. Forsterite formation mechanism was investigated in our previous study [16]. Initially magnesium oxide forms in the structure and then the produced MgO reacts at the surface of SiO_2 to form enstatite. Subsequently, MgO diffuses through the enstatite layer and form forsterite phase. Decreasing the diffusion distances through producing smaller particles and formation of a homogenous powder cause the faster formation of forsterite structure at lower temperatures.

The morphology of the obtained forsterite powders after sintering at 610 °C for 6 h is shown in Fig. 3, respectively. As can be seen, the obtained powders consist of agglomerates with almost uniform particle size distribution. Image tool analysis was used to measure the particle size of forsterite nano-powder. It was found that the mean particle size of obtained forsterite structure after sintering at 610 was 10 µm, respectively.

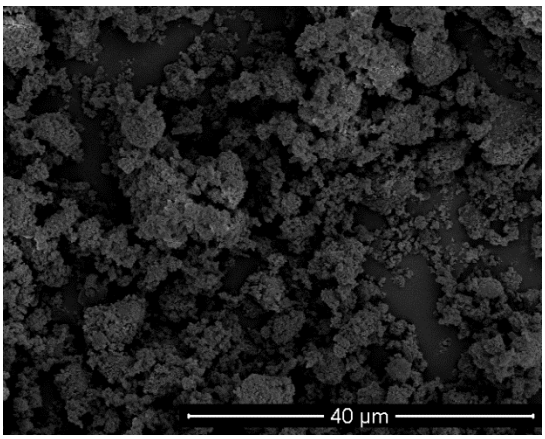

Fig. 3. Forsterite powder structure obtained after sintering at

DISCUSSION

The results of this paper showed that single-phase nanostructure forsterite powder can be obtained after sintering the obtained powders from sol gel method at 610 °C for 1h. The absence of other phases such as $MgSiO_3$, MgO and SiO_2 in the final product disclosed the beneficial effects of utilizing sol-gel procedure. The mean agglomerate size of the obtained nanostructure forsterite were 10 µm.

INTRODUCTION

A major priority in current space medicine research is to characterize the mechanisms underlying Visual Impairment and Intracranial Pressure (VIIP) syndrome, a group of ophthalmic changes that occur in some astronauts following long-duration spaceflight [1]. It is hypothesized that microgravity-induced cephalad fluid shifts lead to increases in intracranial pressure (ICP), which drives maladaptive remodeling of the optic nerve sheath (ONS). In this study, we investigated the effects of mechanical loading on the porcine ONS to better understand the mechanical response of the ONS to increased ICP.

METHODS

Porcine optic nerves (n=6) were obtained immediately after death from a local abattoir. The ONS was isolated from the optic nerve proper and was used for mechanical characterization. A custom mechanical testing system was developed that allowed for unconfined lengthening, twisting, and circumferential distension of the porcine ONS during inflation and axial loading. The distal end of the ONS (the end furthest from the eye) was cannulated and connected to tubing connected a pressure control system consisting of a syringe pump, a pressure transducer, and a LabVIEW program. The ONS was filled with phosphate-buffered saline and the proximal end was plugged with a small screw to create an "end cap." The sample was then hung vertically in a saline bath and subjected to six constant rate (~0.5 mmHg/s) quasi-static pressurization cycles (0-60-0 mmHg), while changes in diameter and length were simultaneously recorded. These tests were performed under variable axial loads (4.9 mN – 48 mN) by attaching increasing weights to a loop attached to the end cap.

Collagen organization in unpressurized ONSs was visualized at an axial stretch of 20% using second harmonic generation (SHG) microscopy. Image stacks were processed using a previously described fast Fourier transform (FFT) algorithm [2] to obtain fiber angle distributions. The distributions were fit to a von Mises distribution to obtain the mean fiber angle at each location of the ONS wall.

RESULTS

Despite large sample-to-sample variations between individual ONSs, there appeared to be a characteristic pattern in their mechanical response (Figure 1a). The circumferential stress was nearly constant between samples and axial loading, despite large variations in strain (Figure 1b-c). SHG imaging revealed helical and axial orientation of the collagen fibers (Figure 2a). Variations in the predominant fiber angle at different locations of the wall were observed (Figure 2b-c).

DISCUSSION

In this study, we have presented a comprehensive assessment of the mechanical response of the porcine ONS to variations in ICP. Particularly interesting was the existence of a "cross-over point" at a pressure of approximately 11 mmHg (Figure 1a). At this pressure, the same diameter was obtained for all axial loads applied to the tissue; i.e., as the axial load was varied, the diameter of the ONS remained constant. This cross-over in the pressure-diameter curves occurred in all ONSs that were tested and appears to correspond with *in vivo* ICP levels for pigs [3]. Taken together our data suggest that the ONS is a complex mechanical structure in which the bulk behavior is determined by the underlying microstructural properties. The presence of a cross-over point and the preservation of a nearly constant circumferential stress between the tested samples could suggest a homeostatic target for the ONS, such as the one found in arterial remodeling processes [4]. Given the similar geometry, microstructure, and nonlinear response found in this study between the ONS and blood

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

vessels, we believe many of the fundamental arterial growth and remodeling concepts can be applied to the ONS to better understand the mechanisms involved in VIIP.

INTRODUCTION

Tuning the mechanical properties of engineered tissues to match those of the native tissue they are designed to replace has become a widespread practice in the tissue engineering community (1,2,3). However, since many if not most biological materials are anisotropic, viscoelastic, and non-linear, determining their mechanical properties is highly non-trivial. The current paradigm for matching mechanical properties of tissues uses models more suited to engineering materials like steel and concrete; using just two parameters, a s tiffness and a strength measure taken from a traction stretch plot. This is not to say that there has not been extensive work done in the mechanics community creating material models that are appropriate for more complicated materials, including biological materials. But rather that there is a huge gulf between the state of the art in tissue mechanics, and the practice in the tissue engineering community. Some of this is likely due to a lack of awareness on the part of tissue engineers, but the greater hurdle is the extreme difficulty in using many of the more sophisticated material models in practice, especially in comparing native tissue to tissue engineered constructs. Models are needed that:

1) Provide a more robust description of the mechanical behavior of tissues than the current paradigm,
2) Have parameters that can be determined with simple experiments.

Freed and Rajagopal (4) have developed a novel biological fiber model that is rigorously derived from thermodynamics and the implicit theory of elasticity. This model describes not only terminal stiffness in the linear region (the current standard), but also an initial (lower) stiffness, and a heel region defined by a maximum crimp. In one dimension this results in three parameters that can be easily measured from stress strain plots. By applying this model to native tissue as well as a synthetic collagen elastin scaffolds, we can show that the behavior of materials are strongly influenced by these other parameters and two materials that have the same terminal stiffness can have very different behavior.

METHODS

Uniaxial tensile testing was performed on excised rat abdominal wall, as well as artificial tissue grafts designed for use in hernia repair consisting of porous collagen and elastin scaffolds. All samples were tested in wet conditions at 37 C. The samples were sized approximately 2x2 cm. and the samples were tested using a constant stretch rate of 5% per minute on a standard load frame (Test Resources R Controller).

The fiber model used, having been derived from implicit elasticity by Freed and Rajagopal, results in a relationship as follows, with stress and strain being the Cauchy stress and true strain respectively:

$$\varepsilon = \frac{\sigma}{E^C} + \frac{1}{\beta}\left[1 - \frac{1}{\left(1+(\beta-1)\frac{\sigma}{E^E}\right)^{\frac{\beta}{\beta-1}}}\right] \quad (1)$$

Where E^C is the stiffness in the final linear region (here denoted as the terminal stiffness), E^E is the initial stiffness, and β is the max crimp determined by the inverse of the intersection of the lines fitting the two linear regions. The current practice is to determine a single stiffness in the linear region, often called the modulus, or Young's Modulus (although this is a misnomer in most cases).

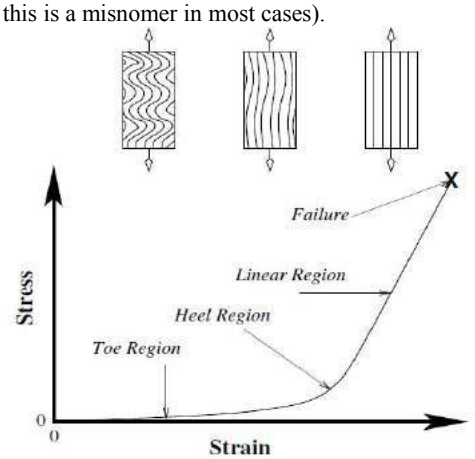

Figure 1: Diagram showing collagen fibers uncramping throughout the stress strain curve. Taken from Freed and Rajagopal (4)

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Figure 2 shows the stress strain relationship from the rat abdominal wall. We can clearly see that there is a large initial linear region of very low modulus, a transitionary heel region, and then a much stiffer terminal region.

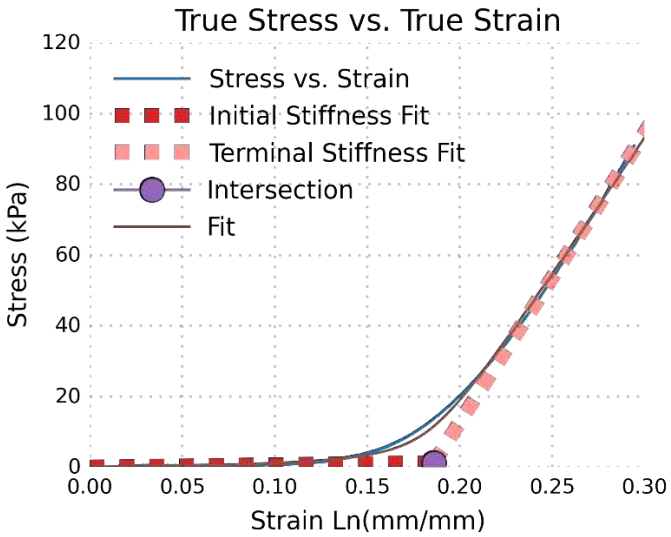

Figure 2: Example of the fiber model applied to rat abdominal wall tissue. Initial Stiffness = 5.5 kPa, Terminal Stiffness = 782 kPa, Max Crimp (Beta) = 5.5

After the native tissue, we consider hypothetical materials that match the terminal stiffness, but that do not match the initial stiffness or the max crimp. Even though the terminal stiffness is the same we can see in Figure 3 that the actual behavior of the hypothetical materials is very different. **Under the current paradigm, these materials would be said to be the same** despite the very different behavior.

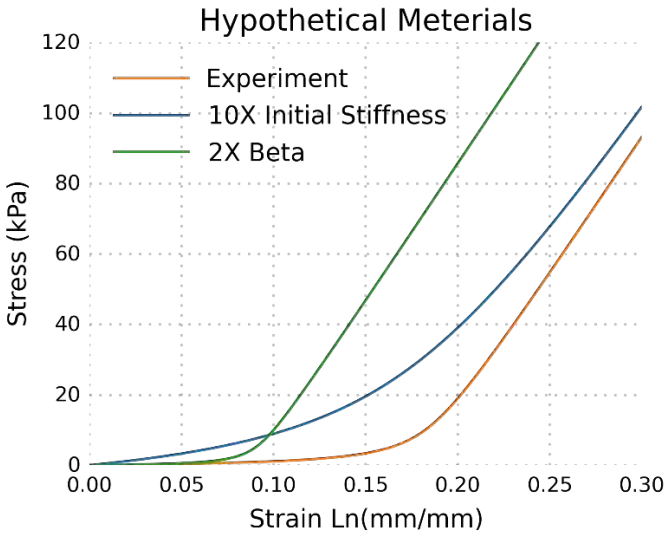

Figure 3: Even though the terminal stiffness is the same for all three models and could be said to be 'tuned' to match, we can see that the materials have very different behavior.

Finally, we compare a porous collagen elastin scaffold tuned to mimic the mechanical properties of the native tissue in Figure 4. Just like the hypothetical materials, we can see that despite the reasonable matching of the terminal stiffness, the total behavior is very different from the native tissue.

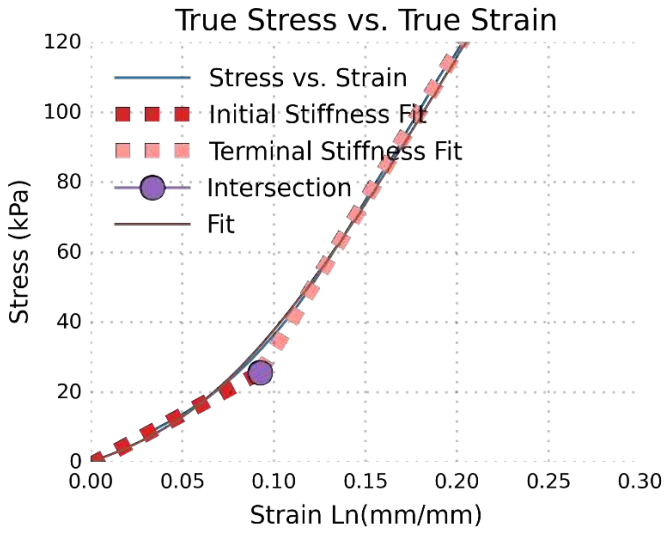

Figure 4: Example of the fiber model applied to collagen elastin porous scaffold. Initial Stiffness = 214 kPa, Terminal Stiffness = 941 kPa, Max Crimp (Beta) = 11

DISCUSSION

As we noted previously, the terminal stiffness is an important measure of the behavior of the material, but that the initial stiffness and the maximum crimp also have strong influence on the total behavior. For example, there have been indications that cells are sensitive to the smaller strains achieved in the toe region (5), and these strains may not be produced in a material with a higher initial stiffness such as the synthetic material above, even though the current paradigm would call the material well-tuned to the native tissue.

INTRODUCTION

There is an increasing need for quick, easy and cheap detection and quantification of diseases such as influenza and malaria at the point-of-care (POC). For instance, influenza can cause epidemics and typically affects 5 – 20% of the population, leads to 200,000 hospitalizations and causes on average 35,000 deaths a year in the US alone [1]. In the case of malaria, there were an estimated 198 million cases worldwide and an estimated 584 000 deaths in 2013, 90% of all deaths occurring in Africa [2]. For both cases, rapid and precise detection of disease can help control epidemics (i.e. influenza) and disease eradication (i.e. malaria). To help achieve this goal we present a new reader based on technology called "thermal contrast amplification" (TCA) that improves the sensitivity and quantification of influenza and malaria in lateral flow assays (LFAs).

Lateral flow assays employ *indirect detection* of a chemical reaction to identify the target and a physical contrast (i.e. a gold nanoparticle - GNP) to visually indicate the result. The chemical reaction is based on a sandwich assay of an antibody anchored at the test line of the LFA that binds the antigen from the patient specimen as it flows by. After antigen test line binding, a GNP bound to another antibody will sandwich bind the antigen attached to the first antibody at the test line. The GNP then provides a physical contrast at the test line (i.e. red color due to plasmon resonance). By irradiating these gold nanoparticles with a visible laser that further exploits the plasmon resonance, TCA provides heat generation and a thermal signal which we have demonstrated is vastly more sensitive than visual detection alone in CrAG LFAs [3,4,5].

There are several other technologies under development to increase indirect disease detection and quantification. While typically more sensitive than LFAs, these approaches (i.e. RT-PCR or microscopy) are slower, more expensive and require training and specialized laboratory equipment. In the case of LFAs, new contrast through fluorescence molecules, magnetic beads and "readers" are also under development to replace visual gold nanoparticle based LFAs [6]. Importantly, visual readers of GNP LFAs such as the BD Veritor do not increase the visual LOD, but can reduce human error (unpublished result). Other assays (i.e. fluorescence) can be more sensitive but are subject to degradation and cannot quantify disease burden. Magnetic bead LFAs are an interesting alternative, but are not widely used and require further testing and translation for broad impact [9]. TCA, on the other hand, simply adds a reading step to existing gold nanoparticle based LFA tests. In short, the GNP based lateral flow assay (LFA) is among the cheapest, simplest and fastest possible approaches for point-of-care use, but they suffer from low detection performance (i.e. sensitivity). Here then we present a reader based on "thermal contrast amplification" (TCA) to increase sensitivity and provide quantitation. We show the reader can improve the limit of detection (LOD) over visual alone thereby improving the sensitivity and quantification of existing influenza and malaria gold nanoparticle based LFAs.

METHODS

TCA readers are based on existing GNP LFAs but instead of visual contrast, they evoke a new heat contrast under laser (Figure.1). The basic components of TCA reader are a green light source (LRS-0532-PFM-00200-03, LaserGlow, work for ~30 nm GNPs), an Infrared sensing unit (ThermoVision^{TM} A20 IR camera, FLIR), and a sample holding unit. Control software was written in LabVIEW [7]. LFAs were tested with the same protocol but slighted modified by laser output power. A second test was applied if the first was unclear.

Specifically, when irradiated with green laser (532 nm) GNPs are stimulated by surface plasmon resonance and generate heat [5],

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$Q = N \cdot I \cdot C_{abs} \quad (1)$$

This heat (Q, W/m^3) is the product of GNP concentration (N, GNPs/m^3), GNP absorption cross-section (C_{abs}, m^2), and laser intensity (I, W/m^2). The thermal contrast signal (temperature rise) is collected along a cross line of the nitrocellulose membrane [7]. TCA signal is proportional to GNP concentration as the absorption cross-section and laser intensity remain the same. In order to assess the operation of a TCA reader for detection and quantification of influenza and malaria, serial dilutions were prepared with existing LFAs.

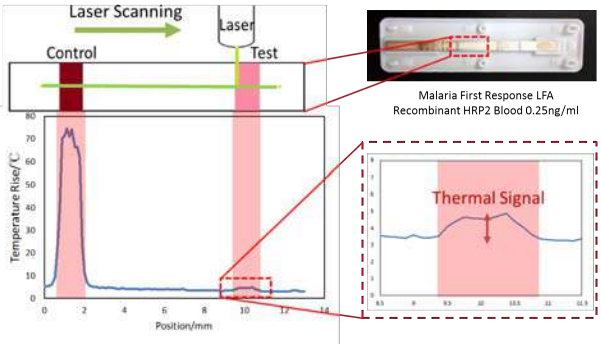

Figure 1: Thermal contrast test shows positive signal on a visual false negative malaria LFA (Rec HRP2 0.25 ng/mL in blood)

Serial Dilutions and LFA selection:

Influenza. BD Veritor Reader and LFAs were purchased directly. The system was CLIA-waived for Rapid Detection of Flu A+B. Flu A positive control swabs were used to create 1:2 serial dilution sets. The BD Veritor visual reader was used to assess the flu strips followed directly by TCA reader.

Malaria. First Response Malaria Ag. pLDH/HRP2 Combo Card Test was used. HRP2 protein (P.f parasites antigen) dilution sets were prepared by FIND and sent blind to UM collaborators. Two technicians evaluated the LFA results in FIND.

RESULTS

Quantitative thermal results for flu and malaria recombinant HRP2 in blood are shown in Figures 2 and 3 respectively with linear fitting (dashed lines). The LOD of TCA is 8 times lower than the visual reader for flu, and the visual appearance in malaria [8]. Furthermore, the signal is shown to be linear suggesting the ability to also quantify disease burden.

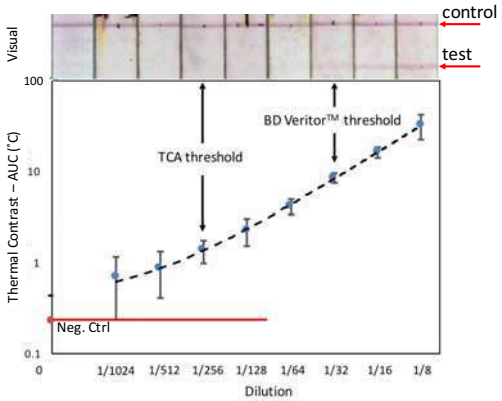

Figure 2: Quantitative TCA signal in BD Veritor flu A dilution study and scanned LFAs

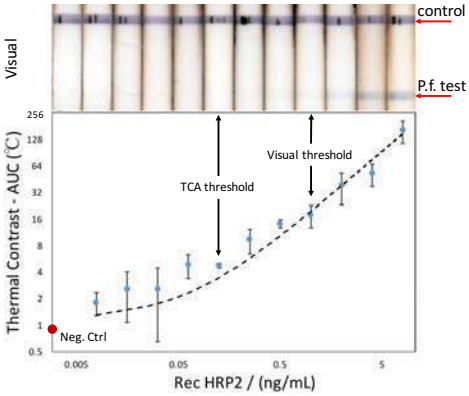

Figure 3: Quantitative TCA signal in malaria recombinant HRP2 in blood dilution study and scanned LFAs

DISCUSSION

Thermal contrast improves the performance of existing LFAs by interpreting them with the TCA reader after the test. The results show an 8-fold improvement in the LOD for both flu and malaria (Figs. 2 and 3). Previous work in Cryptococcus shows up to 32-fold improvement in a patient cohort [3,4]. The difference in the results is thought to be mainly due to the different construction of the LFAs and blood hemoglobin thermal noise in the case of malaria. For instance, the antibodies used are critical to the LFA design and their ultimate specificity and sensitivity with visual or thermal contrast. A high specificity LFA with lower sensitivity appears to offer the optimum performance increase with TCA. We got 2/19 false positives in malaria study (no false positives in influenza) which we believe due primarily to blood staining in the background. In short, sensitivity is expected to improve with TCA, while the specificity remains roughly unchanged in well-designed GNP LFAs with low background.

TCA can be further improved by careful LFA design and TCA algorithm development. For instance, the thermal signal can be improved by selecting different GNPs (larger size and/or Cabs, and more efficient matching of laser power and spectrum to the GNP). Further, the LFA can be designed to decrease background signal (i.e. noise) by changing LFA materials. In the case of malaria LFAs using blood, there may be new ways to minimize hemoglobin staining (i.e. noise) or avoiding it entirely. Finally, a new algorithm is under development leveraging improved heat transfer physics in the TCA that can improve the speed with which the LFA is read.

INTRODUCTION

Bone marrow is naturally composed of many mechanosenstive cells which may signal adaptation cascades [1] in response to fluid shear stresses resulting from whole bone loading. However, the determination of the *in situ* mechanical environment of these cells is difficult, since bone has a complex geometry and the relevant features span multiple length scales. Little is known about the mechanical environment of the bone marrow, because it is encased in the opaque bone, making observation and measurement difficult.

Finite element (FE) models can determine stress in complex geometries when generated from computed tomography (CT) images [2]. Recently, poroelasticity theory was incorporated in such models to estimate the marrow mechanics during whole porcine femur mechanical loading [3]. In the absence of density-modulus relationships for porcine bone, these models used published relationships from human bone [4].

The objectives of this study were to 1) use microscale-FE models of trabecular bone to determine the density-modulus relationship for porcine femurs, 2) develop poroelastic models of whole porcine femurs using this new material model, and 3) quantify the effect of the material model on the calculated whole bone stiffness, surface strains, pressure gradients, and fluid shear stresses.

METHODS

Five porcine femurs from five animals 6-8 months of age were procured at the time of slaughter (Martin's Custom Butchering, Wakarusa, IN), and testing was completed within 8 hours post-mortem to minimize storage effects on marrow. Miniature pressure transducers (Precision Measurements Inc., Ann Arbor, MI) were inserted in four holes drilled approximately 5 mm apart along the curvature of the femoral neck. Strain gage rosettes were fixed to the anterior and posterior aspects of the lesser trochanter for validation of finite element models. The instrumented femurs were loaded in cyclic compression, from approximately 600 to 2000 N sinusoidally at 1 Hz while submerged in 37°C water bath. Pressure, load, and strain data were monitored at 100 Hz (LabVIEW, National Instruments, Austin, TX). The data were filtered using a 5 Hz third-order Butterworth filter.

Whole femurs were imaged using a spiral *in vivo* μCT system (Bioscan, Paris, France) at 70 kVp, 100 mA, and reconstructed with a 0.143 mm cubic voxel size using a Hanning filter. Strain gages remained in place during scanning in order to identify their locations on the final models. The locations of the pressure transducers were identified from the drill holes in the μCT images. Following the scan, the femoral neck was sectioned from the femurs, and high resolution μCT scans were performed at 20 μm resolution, 70 kVp, 114 mA and 400 ms integration (μCT-80, Scanco Medical AG, Brüttisellen, Switzerland). Subsections of the neck located between the insertion of the pressure transducers were reconstructed as cubic volumes with edge length of 5 mm, and an in-plane voxel size of 40 μm (Fig. 1). Micro-FE models were generated by directly converting voxels into elements.

To determine the stiffness matrix, three uniaxial compressive strain boundary conditions and three shear boundary conditions were applied to each cube [5]. The tissue modulus was assumed to be 7500 MPa. The full 6x6 stiffness matrix was calculated was inverted to find the compliance matrix, and the moduli were extracted as the inverse of the diagonal terms (Fig. 1).

The outer boundaries of the femurs were traced on each image slice of the whole femur scans using Analyze Visualization Workshop (AVW, BIR, Mayo Clinic) and imported into a general-purpose FE program (ADINA 9.0.1, Watertown, MA). A 10-node tetrahedral mesh was generated, and displacement boundary conditions were applied to mimic the experimental loading conditions.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Elastic moduli were assigned using both the micro-FE (Fig. 1) and the relationship for human bone used previously (Wirtz) [3,4]. Transverse orthotropic material properties were applied assuming the material aligns with the principal stress directions calculated from the first iteration of the FE models [6]. A poroelastic constitutive model was applied assuming the pore bone marrow is incompressible and that the pores in trabecular bone were fully saturated with marrow.

Permeability, k, was applied spatially based on a relationship between bone mineral density (BMD) and permeability determined from computational fluid dynamics models at three locations within the proximal femur. To account for marrow viscosity, the intrinsic permeability was divided by the measured viscosity of 85 Pa*s [7]. A zero-pressure boundary was defined on the periosteal surface and at the distal end of the model.

The calculated whole bone stiffness and principal strains at the gage locations were compared to the experimental results (Fig. 2). Pressure gradients (Fig. 3b) were calculated within each element of the models. A Darcy flow model was used to estimate the shear stress (Fig. 3c) in the pores by idealizing the pores as simple parallel tubes aligned in the flow direction, where R was the hydraulic radius of the pores, k is the permeability in the axial direction calibrated from the 15 µCT images, and Φ was the porosity.

$$R = \sqrt{\frac{8k}{\phi}} \qquad \tau_{max} = \frac{1}{2}\frac{\partial P}{\partial X} * R$$

RESULTS

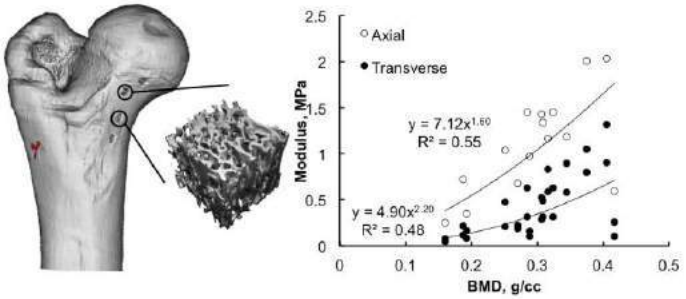

Figure 1: High resolution CT imaging was performed on three subsections to acquire the geometric data used create microscale models. Microscale models were used to determine the density-modulus relationship for the femurs.

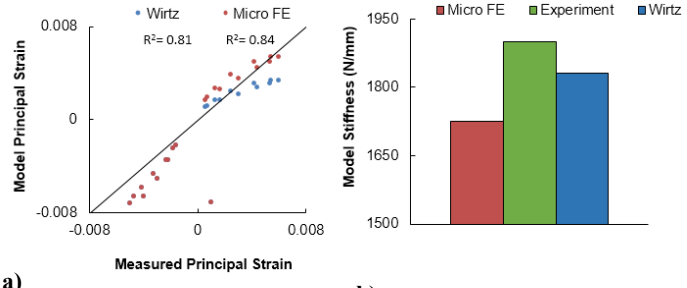

a) b)

Figure 2: The principal strain was correlated to the measured data at the anterior surface for both material models (R^2 = 0.84). The model was 9.2% less stiff than the measured value.

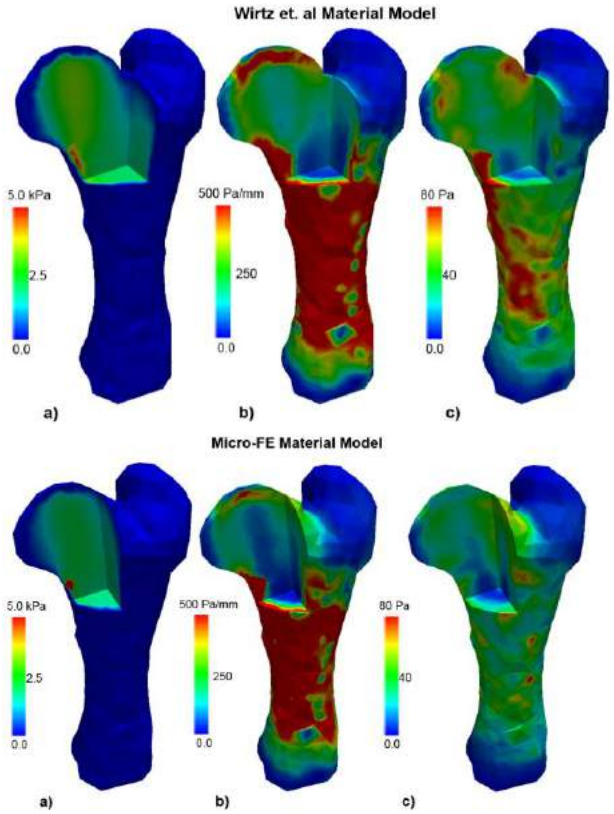

Figure 3: Pore pressure (a), pressure gradient (b), and maximum shear stress (c) were calculated for the Wirtz and µFE models

DISCUSSION

This study incorporated micro-FE models to determine the relationship between BMD and elastic modulus in porcine femurs. Assigning moduli based on the micro-FE models resulted in a 9.2% reduction in the stiffness compared to the Wirtz models (Fig. 2b). Principal strain on the surface of the models better represented the measured data (R^2=0.84; Fig.2a). Lower magnitudes of pressure, pressure gradient, and shear stress were also observed (Fig. 3).

These poroelastic models enabled the investigation of the mechanical environment of the bone marrow. The calculated pressure was well below the mechanostimulatory threshold of 200 kPa for mesenchymal stem cells, but the estimated maximum shear stress was well above this threshold of 0.5 Pa [8]. This may suggest that physiologic loading may impart biomechanical signals to marrow cells which influence mesenchymal stem cell regulation.

ABSTRACT
This study evaluates three-dimensional broaching forces and moments brought about by specialized curved implantation handles designed to be used during total hip replacement via the direct anterior approach. For this purpose, finite element (FE) models of broach handle and bone assembly were developed and studied.

These forces and moments were compared to those from conventional handles as a possible explanation for the increased intraoperative fracture rates that have been reported for these procedures.

As broach handle offset increased, the percentage of vertically directed force (down the medullary canal) decreased. Thus, more force was directed outward toward cortical bone. We also found that varying the hammering location on the broach handle surface resulted in significantly different force ratios that change with handle design. Furthermore, variable impact locations on the double offset broach handle produced vertical to horizontal force ratios between -71% and 37%, thus suggesting that an impact location in which off-plane force distribution is the most hazardous (0%) may exist.

Our data also proves that there are optimal locations of impact that vary with broach handle design. By contrast, impacting a broach handle surface at suboptimal locations can magnify the effect of forces that contribute to intraoperative fracture.

INTRODUCTION
Total hip arthroplasty is being performed through a minimal incision with increasing popularity. Several authors have reported an increased rate of intraoperative fracture with this method [1, 2]. These fractures most often occur during femoral canal preparation. In order to safely perform "less invasive" total hip arthroplasty, manufacturers have developed various new broach handle designs [3-5]. However, the dynamic effects of these handles on the proximal femur have not been widely investigated.

METHODS
Four handles were studied that covered a wide range of shapes and are commonly used including AK0405 as Base (H1), Depuy NB18161 (H2), Depuy J0807 (H3), and ABC 3326 Left (H4) (Fig. 1). Each handle was attached to a #10 broach and the assembly, in vertical position, was scanned using Romer Arm RA-7330 SI with 0.05 mm resolution. Based on the scanned point clouds, a solid model was developed for each assembly using Rhinoceros software (Robert McNeel & Assoc.).

The top surface of the handles and the broach lateral sides were modeled as rigid materials with shell elements (LS-Dyna, LSTC). Having the orientations of these surfaces the same as when they are used in practice was critical for this study. The bone surrounding the broach was modeled as a deformable 5-mm thick layer with solids elements. The bone material properties were selected similar to trabecular bone to account for osteoporosis that is common in total knee replacement (ash density = 0.21, Young's modulus E = 1 GPa). The applied force was 133 kN point load at different locations on the handle top surface. This force is equivalent to a 500g hammer hitting the surface at 4 m/s.

In addition to the central point of the handle top surface that is the recommended impact point, impact points lateral and medial to the center point were also studied to account for variability in the hitting location that may occur during practice. Five impact points were considered for each handle including Central (C), Lateral Anterior (LA), Lateral Posterior (LP), Medial Anterior (MA), and Medial Posterior (MP). For H2, a Lateral Center (LC) point was also considered that was at the same location as H1-C. For H3, a Lateral

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Center (LC) point was considered that was aligned with H1-C. For H4, a Lateral Center (LC) point was considered that was between H4-LP and H4-LA (Fig. 2).

For comparison of the handles, the following mechanical quantities were considered. a) The average and range (maximum and minimum) of Von-Mises (or effective) stress (in MPa) and strain (in %) in bone. These quantities describe the likelihood of bone failure. b) Ratio of force in the Z direction (downward) to the resultant force in three sections that were considered in upper (Section 1), middle (Section 2), and lower (Section 3) regions of the bone (Fig. 2). This quantity describes how much the applied impact is transferred into a downward force. A downward force is desirable, as the goal of broaching is to move the broach downward into the femur medullary canal. Ideally, this number should be -1.0 to indicate a 100% downward force. c) Ratio of resultant moment to resultant force in the three sections (in N.m/kN). This measure describes how much moment is generated per unit force. The more moment is generated, it generally means that the stress distribution in bone becomes non-uniform (some regions in tension and some regions in compression) and as a result the chance of failure in tension (which usually has a lower threshold than compression) is increased. d) Ratio of resultant rotational displacement to resultant linear displacement (in deg/mm). This measure describes how much the broach rotates for a unit displacement. The more the broach rotates, its contact area with bone becomes non-uniform (some regions are pressed harder into the bone and some regions are released) and as a result the risk of local failure is increased. Ideally, the last two quantities should be zero.

RESULTS

The results show that generally for curved handles, the average and range of Von-Mises stress and strain are increased (maximum about 4 and 3 times respectively). This shows that bone undergoes more non-uniform deformation and the risk of failure is increased.

The magnitude of ratio of Z force in the curved handles (H3 and H4), approximately -0.7 to 0.4, is significantly less compared to the almost -1 value for straight handles (H1 and H2). It is important to note that in H3 and H4, there are impact points that can make the Z force ratio more acceptable than others. H4-MA gave the best force transmission for H4 (about -0.6 for sections 2 and 3), and H3-C and H3-LP gave the best force transmission for H3 (about -0.6).

Moment transmission is generally higher for the curved handles. It is important to note that in the case of H4, three impact points (H4-LA, H4-LC, and H4-LC) resulted in dramatically less moment transmission that other impact points. H3 had the highest moment transmission.

Broach rotation was higher in other three handles compared to H1. Some impact points resulted in slightly higher rotations (H2-MA, H2-MP, H4LC, and H4-LP) that would indicate more risk of non-uniform contact surface between the broach and bone.

DISCUSSION

Broach handle design is a critical determinant of resultant forces transmitted to the bone during total hip arthroplasty. Curved handles (H3 and H4) generally cause more out of plane forces than straighter handles (H1 and H2), especially in the proximal femur. These unanticipated out of plane forces may play a role in the increased rate of fractures seen during "minimally invasive" procedures. When surgeons use different broach handles in order to accommodate the anatomic constraints, even small changes in design can potentially lead to poor outcomes.

Our data also proves that there are optimal locations of impact that vary with broach handle design. By contrast, impacting a broach handle surface at suboptimal locations can magnify the displacements and forces that contribute to intraoperative fracture.

ANALYZING EFFECTS OF CHEMOTHERAPEUTIC DRUGS FOR THE PREVENTION OF CHEMOTHERAPY-INDUCED ALOPECIA

Likitha Somasekhar (1), Kunal Mitra (1), Carlos Martino (1)

(1) Department of Biomedical Engineering
Florida Institute of Technology
Melbourne, Florida, United States

INTRODUCTION

Alopecia that is promoted due to chemotherapy treatment in patients continues to be the most traumatic side effect. Reducing the temperature of the scalp during administration of cytotoxic drugs can prevent hair loss. The results of scalp cooling have shown that it is a promising method to reduce hair loss. However, the efficiency varies due to a large number of factors which affects the outcome. The effects of scalp cooling are based on the function of temperature, cooling duration and the drug type and its dosage. Temperature affects blood perfusion and cellular metabolism during delivery of chemotherapy drugs to the scalp tissue. It also affects the mass-transfer, drug transport and cellular uptake of the chemotherapeutic agent over time. Mathematical models have been developed to study the scalp cooling procedure by quantifying the relationship between temperature and blood perfusion in the scalp [1, 2]. But effects on cellular metabolism have not yet been entirely characterized in order to minimize the cytotoxic effect of the drug concerning the hair-forming cells and preventing hair loss. This characterization must also be drug-specific because these processes are different for each chemotherapeutic agent. For example, the best hair preservation along with scalp cooling has been achieved for taxanes or anthracyclines when they are not given in combination [3]. Along with chemotherapy characteristics, patient characteristics also affect the outcome of this procedure. To differentiate the effects of reduced perfusion and metabolism independently, *in vivo* model would be challenging. Due to reduced temperatures during scalp cooling, cellular drug uptake and damage will be lower and therefore hair follicles are thought to be less susceptible to cytotoxic drugs. Therefore, the goal of this paper is to analyze the cellular metabolism due to uptake of different chemotherapeutic agents by cooling *in vitro*.

METHODS

A controlled in vitro experiment is conducted using cultured human epidermal keratinocytes (obtained from Promo Cell) to quantify the effects of reduced cell metabolism on the hair preservative effect during scalp cooling along with reduced perfusion. The effects of temperature and concentration of chemotherapeutic agent, doxorubicin on cell damage is determined from cell viability. Cell viability measurements such as MTT assay and Amplex Red assay are conducted to study the effects of temperature and doxorubicin on cell damage. Furthermore, cell mito stress test is conducted to test the amount of mitochondrial function in cells and glycolysis test is conducted to measure the amount of glycolytic function in cells. This will facilitate to assess the damage exerted by the chemotherapeutic agent on human epidermal keratinocytes for a range of chemotherapy concentrations and exposure temperatures [4]. The level of hypothermia is varied by testing temperatures in the range of 24°C to 37°C. This is primarily because it has been suggested by various studies that a scalp temperature of 22°C or less is required for hair preservation [5]. The drug dosage is varied from 0.01µg per ml to 10µg per ml. The exposure time for the chemotherapeutic drugs is also varied in the range of 30 minutes to 2 hours. Cells are cultured at a seeding density of $5x10^5$ cells cm^{-2} under an atmosphere of 95% air and 5% CO_2 at 37°C, using keratinocyte basal media supplemented with keratinocyte growth kit components. The cells are harvested and centrifuged when the cells reach 70%-80% confluence. Consequent passage cells are plated in two 24-well plates, after which the plates are incubated at 37°C and 5% CO_2 for 24 hours before the drug is introduced [4].

MTT is prepared at 5:1 dilution and is added to the cells. Similarly, Amplex Red/Horse radish peroxidase (HRP) is prepared wherein, Amplex Red is diluted at 1:1000 and Horse radish peroxidase (HRP) at 1:100 dilutions. The absorbance is read at 570nm for MTT and at 530-590nm for AUR assay. For the cell mito stress test and glycolysis test [4], the cells are plated in the XFp Cell Culture Miniplate and incubated for 24 hours. The cells are then exposed to appropriate drug concentration. The respective assay media and the drug compounds are prepared wherein, three tubes containing oligomycin, FCCP and rotenone/ antimycin A are resuspended in respective tubes with prepared assay media for cell mito stress test. For glycolysis test the stock compounds are prepared which comprises of a vial of oligomycin, glucose and 2-DG which are resuspended in assay media. The compounds are loaded into hydrated sensor cartridge and the assay is started using the XFp analyzer. The same steps are repeated for both the plates with two different temperature conditions [4].

RESULTS

A significant decreasing effect on keratinocyte cell viability is observed when the doxorubicin concentrations is increased and a

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

significant increasing effect on keratinocyte cell viability is seen when the temperature is reduced in Figure 1 and Figure 2 for MTT assay and Amplex Red assay.

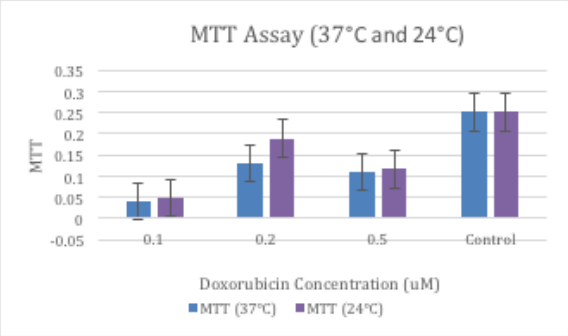

Figure 1: Mitochondrial Respiration for 24°C

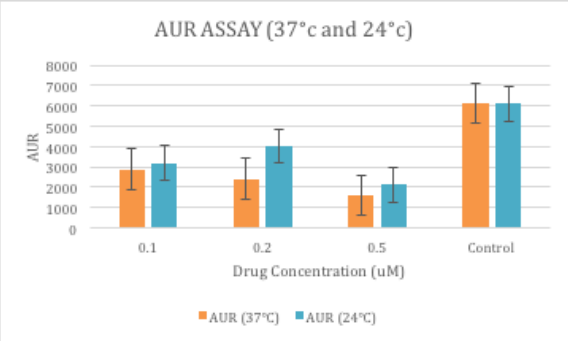

Figure 2: Mitochondrial Respiration for 24°C

A higher cell viability for every concentration of doxorubicin is observed in 24°C than the 37°C group. At the lower range of doxorubicin concentration (0.1µM), the effect of reduced temperature is more distinct than in the higher values of doxorubicin concentration. This observation validates a strong correlation between doxorubicin concentration and exposure temperature. For the stress test, the oxygen consumption rate in Figure 3 is reduced due to cell death when compared to the control wherein, the oxygen consumption rate is not affected and there is steady respiration rate. The ATP production is less compared to the control since the cell metabolism is reduced and not much ATP is produced. The spare respiratory capacity when compared between the two temperatures is nil in the 24ºC due to the amount of cell metabolism when compared to 37ºC which indicates that the fitness of the cell is better [4].

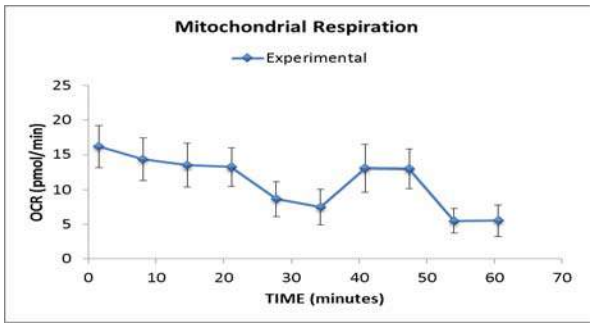

Figure 3: Mitochondrial Respiration for 24°C at 0.1µM

The extracellular acidification rate (ECAR) measured in glycolysis test in Figure 4 is greater when compared to the control group since the cell viability is greater due to the amount of glycolysis that occurs in the cells. It is also observed that glycolytic activity for the control and the 24ºC group is greater than 37ºC group due to the shutdown of oxidative phosphorylation which drives the cell to use glycolysis to its maximum capacity. This also results in the group 24°C to show greater ECAR rate than the 37°C group [4].

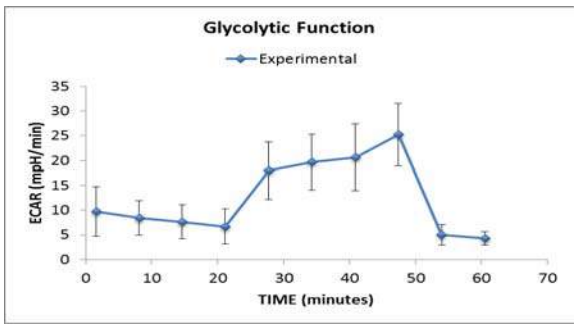

Figure 4: Glycolytic function for 24°C at 0.1µM

DISCUSSION

The relationship obtained for cell viability as a function of chemotherapeutic agent concentration and exposure temperature, in combination with the value obtained for critical viability measurement is used to determine the optimal scalp cooling temperature at different doses and exposure time for doxorubicin. The results will provide indication of what temperatures should be reached during scalp cooling before administering the treatment dose.

The role of reduced metabolism on the hair preservative effect of scalp cooling is investigated wherein, the two temperatures show that 24°C group has decrease cell cytotoxicity at the same doxorubicin concentration. This observation shows that there is a presence of an interaction between doxorubicin concentration and exposure temperature that is significant. The results of the experiment relate to the idea of scalp cooling wherein, reduced temperature due to scalp cooling results in lower perfusion rate and lower cellular metabolism. It is also noted that the in vitro experiments signify that the reduction in both temperature and concentration may increase cell survival. To relate drug concentration and exposure temperature to cell survival in the experiments conducted, only two temperatures that are representative for scalp cooling is considered wherein the transition point in the effect of temperature needs to be determined for better understanding of cell viability conditions. Although the cells used in vitro experiments are characteristic of the cells that produce the hair shaft, in vitro experiments that were conducted are not able to replicate the interaction that occurs between these cells. In vitro experiments on a complete hair follicle is required to better understand the effect of cooling the scalp and the distribution of doxorubicin in the hair follicle and subsequent cell damage need to be studied.

INTRODUCTION

The most common single chromosomal defect associated with congenital cardiovascular malformation is 22q11 deletion syndrome (DiGeorge syndrome), which often includes ventricular septal defect, tetralogy of Fallot, and persistent truncus arteriosus (PTA). The truncus arteriosus is an embryological structure, a common vessel conveying blood outflow from both the left and right ventricles, which are joined by a ventricular septal opening. In normal development, the truncus arteriosus divides into the pulmonary trunk and ascending aorta. This septation fails to occur in PTA, allowing harmful mixing of oxygenated and deoxygenated blood in the systemic circulation.

The structural abnormality in PTA is usually repaired with surgery during the first months of life [1]. Despite the structural repair, however, other long-term problems may persist. We hypothesized that the altered hemodynamic and mechanical loading patterns created by the PTA structural defect during development will also affect the passive mechanical properties of the ventricles and outflow tract. This hypothesis was tested with a mouse model of PTA. This model includes a hypomorphic allele for fgf8 expression, which has been shown to recapitulate the PTA defect seen in human 22q11 deletion syndrome [2, 3].

One goal of this research was to develop an imaging and reconstruction procedure to allow comparison of anatomical measurements and 3D reconstructions of the ventricles and outflow tract from whole-mount embryonic day (ED) 12.5 mouse hearts, both control (wild-type) and with PTA (fgf8-deficient). This then provided a framework for the second goal, to measure passive myocardial stiffness in control and fgf8-deficient embryonic mice hearts with a recently developed pipette aspiration system.

METHODS

Control (wild-type) and fgf8-deficient (mutant) embryos were obtained at embryonic day (ED) 12.5 from the Moon lab. Hearts were harvested in accordance with Geisinger IUCAC-approved procedures. For imaging and reconstruction, hearts were arrested with verapamil, treated with a red blood cell lysis solution, fixed in paraformaldeyde, and dehydrated in an ascending series of EtOH. Groups of hearts were prepared with either (1) glycerol clearing, (2) no clearing with phalloidin-Alexa488 labeling, and (3) BABB (2:1 benzyl alcohol: benzyl benzoate) clearing. Imaging took place on a Leica TCS SP5 inverted confocal microscope in specially designed chambers. The BABB-cleared specimens, which were completely transparent in solution, required the design of custom pipettes and transfer chambers and use of epifluorescent illumination for transfer. Scans, requiring 3-5 hr each, used a dry 10X objective with an argon laser and maximum combined blue excitation of 458, 476, and 488 nm at 45%. The stacks of 200-400 tiff files were segmented, reconstructed, and measured using various tools in Amira v6.0 (FEI Visualization Sciences Group). All images were processed with a contrast-limited adaptive histogram equalization routine to compensate for variations in signal intensity. Metrics were developed to compare dimensions of ventricles, outflow tract, and developing cushions. Further thresholding and surface rendering created volumetric representations of each ventricle.

For mechanical testing, hearts were extracted and arrested in diastole with 4% verapamil. Hearts were positioned in PBS in a small glass chamber on micromanipulator stage. Under microscopic viewing, a 100-µm-ID glass pipette was lowered perpendicular to the tissue surface until a seal was accomplished, aided by the natural adhesion of the tissue to the glass. Negative pressure applied to the pipette then aspirated a small amount of myocardial wall (Fig. 1), while video and pressure were recorded at 15 Hz [4]. Locations on the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

left ventricle (LV), right ventricle (RV), and outflow tract (OFT) were tested in turn. Images were analyzed in MaxTRAQ to obtain aspirated length L, which was normalized to pipette inner radius r_i (Fig. 1). Aspirated pressure Δp was plotted versus L/r_i and various functional forms of the relationship were tested.

A strain energy density measure was calculated as the area under the Δp vs. L/r_i curve for two ranges of strain: $L/r_i = 0 – 0.2$ and $0 – 0.4$. Statistical significance was assessed with t-tests between the control and mutant strain energy values for each range at each of the three locations. The mechanical tests were also analyzed with a finite element model to assess the effect of wall structure on measured pipette aspiration behavior.

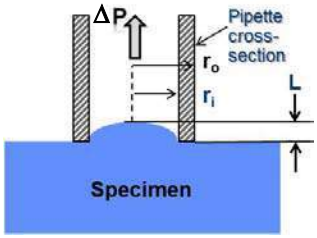

Figure 1. Schematic of pipette aspiration procedure. The glass pipette had internal radius r_i of 50 μm and external radius r_o of 85 μm. Heart walls were loaded to strain ratios L/r_i of 0.4 with maximum aspiration pressures ranging from 1-10 kPa.

RESULTS

Hearts cleared with BABB allowed the best laser penetration and tissue detail as opposed to the other methods, with good penetration up to 2 mm (Fig. 2). Calculated volumes were .095 (.035) and .071 (.044) mm^3 for control and mutant right ventricle and .085 (.017) and .090 (.066) mm^3 for control and mutant left ventricle (mean (standard deviation)). Measurements of length and width of ventricular chambers and conotruncal cushions showed no significant differences between mutant and control. Mutant hearts had greater conotruncal cushion separation and a thicker right compact wall.

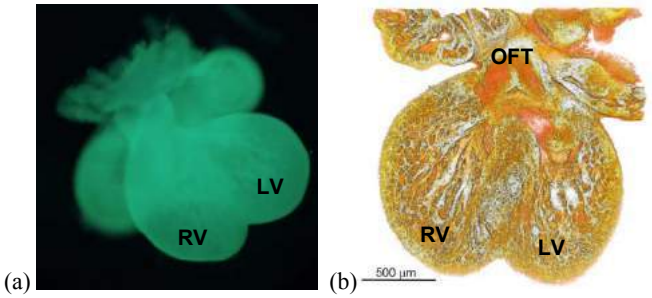

Figure 2: (a) Control ED12.5 heart under epifluorescent illumination; (b) Reconstruction of ED12.5 heart with the Volren module in Amira. RV: right ventricle, LV: left ventricle, OFT: outflow tract.

The Δp vs L/r_i relationship was highly linear for L/r_i from 0-0.4 at each of the three locations, LV, RV, and OFT (R^2 = .96-.98). The maximum aspiration pressures in control and mutant mouse ventricles were 6 and 10 kPa, respectively. The area under the Δp vs L/r_i curve, a measure of material elastic stiffness, was significantly higher ($p<0.05$) in the RV of fgf8-deficient mice, i.e., those with deficient septation of the truncus arteriosus, compared to control in both strain ranges, L/r_i of 0-0.2 and 0-0.4 (Fig. 3), while that in the LV of fgf-8 deficient mouse was more than double that in control from 0-0.2 L/r_i ($p=0.08$).

Finite element mechanical analysis of pipette aspiration based on the geometry from the reconstructed 3D images showed no significant differences between control and mutant when assuming equivalent material properties, indicating the measured difference in mechanical stiffness represents a material property difference rather than a structural difference.

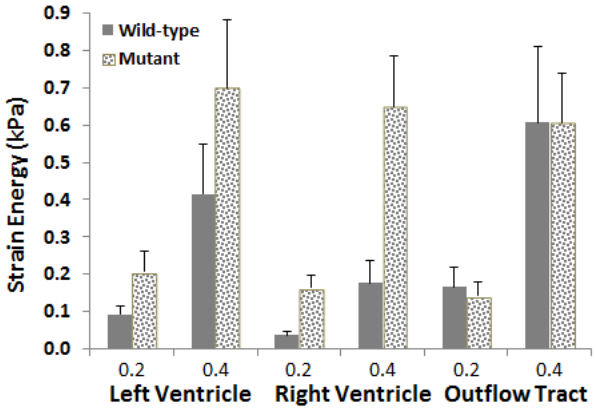

Figure 3. Mean strain energy in the ranges of L/r_i=0-0.2 and 0-0.4 for control (wild-type) and fgf8-deficient mutant mouse at ED12.5. Error bars show standard error.

DISCUSSION

This is the first demonstration that hearts developing PTA show early changes in ventricular tissue properties. The embryonic time frame studied here is crucial, as it is the latter stage of chamber and valve formation. In humans, the effects of PTA on tissue stiffness may cause lasting problems, even after early surgical repair. The stiffer walls may be a result of the excessive force needed or resistance encountered when pumping blood in the presence of the structural abnormality, or of the abnormal fluid flow patterns. We have begun studies in histology and gene expression to help elucidate the mechanism.

This study has also demonstrated that confocal microscopy can be extended to capture the entire volume of the mm-scale ED12.5 mouse heart (ventricles and outflow tract), an extension to its usual use at the cellular and small tissue level. The 3D models created will form the geometrical basis for studies in blood flow modeling and fluid-elastic interaction in models of the mouse embryonic heart.

INTRODUCTION

Cerebral hemodynamics is a complex phenomenon involving a hierarchy of vessels over multiple length scales including large arteries, pial arteries, capillary networks and draining veins. Due to the vast distribution of vessels of different size and density, direct methods of observation cannot capture all details of the perfusion process. In order to gain a more complete knowledge of cerebral blood distribution we propose to perform massive computer simulations on anatomically accurate models obtained from high resolution micro-CT images. This approach allows for quick acquisition of reproducible results at all length scales, and provides a mechanism to assess blood flow in normal and disease states (i.e. stroke).

We used imaging data acquired from multiple modalities covering the macro- and micro-scale to build a complete and closed cerebral vasculature of a mouse brain. High resolution micro-CT images were used to generate anatomically correct models of the arteries and veins, and two-photon images were used to reconstruct the microvasculature include penetrating arterioles, capillaries and draining veins [1,2]. We assembled these data to generate an in-silico model of the entire cerebral angioarchitecture in the mouse. We present results on the anatomical features as well as steady state blood flow predictions.

METHODS

The raw imaging data was acquired using a contrast enhanced μCT procedure [3]. The vasculature of anesthetized C57BL/6 mice was injected with a radio opaque silicone rubber, Microfil. After polymerization the skulls were dissected and decalcified with 8% formic acid. Images were acquired with a micro-CT (SkyScan 1172 high-resolution micro-CT, Bruker micro-CT, Belgium) at an isotropic voxel size of 20 μm.

The original data is processed using our multi-scale vessel enhancement filter that increases the intensity of tubular objects in order to create a probability map of vessel location along all length scales [4]. A threshold is selected to create a binary map of the vascular network. From the binary map a skeletonized image and distance map are generated in order to acquire centerline trajectories and the corresponding diameters. From this we then generate a network file composed of vertices and edges. Each edge has an associated diameter that is used in the computational flow simulations.

Boundary conditions must be applied at all inlets and terminal nodes for the simulations. Hemodynamic measurements of different regions of the mouse brain have shown a range of flow rates in the arterioles. In order to assign these variable flows at the terminal branches a spectral clustering method was used for grouping functional territories. This allows a programmatic approach to assigning inlet flow boundary conditions at the vertebral and carotid arteries as well as the appropriate flow rates at the terminal branches.

Blood flow simulations on the network are performed using continuity equation, eq 1, and the Hagen-Poiseuille flow model, eq 2, where Q is flow rate, P is pressure, μ is the viscosity, L is length, and r is the vessel radius.

$$\nabla Q = 0 \tag{1}$$

$$\Delta P = \frac{8\mu L Q}{\pi r^4} \tag{2}$$

RESULTS

Vascular network creation is a multi-step process (Figure 1). The initial processing of the raw image data (a) with the vessel enhancement filter greatly increases the contrast between the vessels and the background while also decreasing the noise (b). The increased contrast allows us to make a clean binary image that includes only tubular structures (c). From the binary image a skeleton (d) and distance map (e) are computed to find the vessel centerlines and diameters. This information is then used to construct the vessel network to be used for simulation (f).

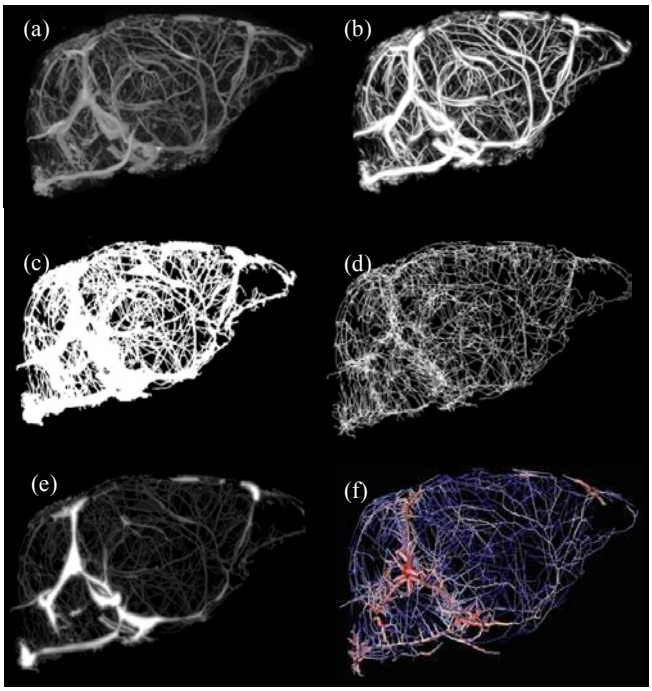

Figure 1: Segmentation procedure for creating vascular network from raw imaging data. a) Raw image data is acquire from contrast-enhanced μ-CT, b) Filtered vasculature, using the vessel enhancement filter, c) Binary vessel image, d) Centerline extraction, e) Distance map, f) and network of connected vertices with associated diameters.

The functional grouping of the arterial tree is displayed (Figure 2) showing the distribution to the olfactory bulb, the left and right regions of the neortex, the left and right regions of the cerebellum, the vertebral arteries and the Circle of Willis. Also displayed are results of hemodynamic simulations showing color maps of the flow velocities (center), and the arterial pressure distribution (right).

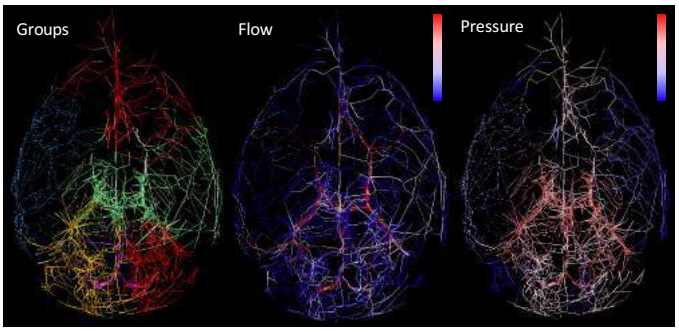

Figure 2. Arterial territory groups (left) were obtained by automatic labeling. Preliminary results of flow (center) and pressure simulations (right) by solving the flow equations for the entire arterial tree. As boundary conditions, known inflows were assumed. Territorial perfusion, and pressure field emerge.

DISCUSSION

The segmentation of the high-resolution micro-CT images show that a large portion of a subject-specific arterial network can be recovered using the techniques described. The steps involved in the segmentation, as well as the grouping, are fully automated. Using experimental values to establish the inlet and outlet boundary conditions of the network allow one to observe trends across the entire vascular network. Upon validation of the obtained results these can be used as a baseline case to explore the effects of cerebrovascular diseases on the distribution of blood to the entire brain.

Closing the whole brain vascular network involves connecting the terminal branches of the arterial trees to the capillary networks and then drain these networks through the venous system. To do so, the terminal ends of the vessel network, (Figure 3a), will be used as inlets to the capillary bed, (Figure 3b). Regional perfusion maps can then be assessed using a mouse cortical model separated by functional regions, (Figure 3c).

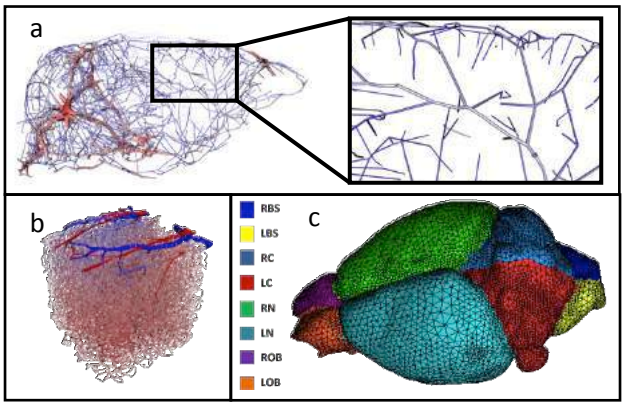

Figure 3. Schematic of the whole-brain simulation of blood flow in mouse. a) Full pial network and inset showing penetrating arteries from micro-CT, b) detailed image of the microvasculature in a 1 mm^3 subsection of the cortex showing penetrating arterioles the capillary bed and draining veins, c) mouse cortex grouped into functional areas to assess blood perfusion in each region.

INTRODUCTION

Anterior cruciate ligament (ACL) replacements are among the most common knee ligament invasive procedures. It is estimated that the combination of ACL and meniscal injuries can lead to the development of osteoarthritis in up to 48% of patients with replacements [1]. Within the dynamic model of the knee, the ACL is primarily responsible for preventing anterior translation of the tibia with respect to the femur, and is particularly challenging to experimentally characterize. In its anatomically relevant state, it is twisted and partially extended regardless of knee flexion angle [2–5]. The tissue structures that make up the ACL also exhibit mechanical heterogeneity. The ACL is primarily comprised of two sections of tissue, the anteromedial and the posterolateral bundles (AM and PL respectively). These bundles are not simultaneously unloaded under any configuration, and are oriented so that regardless of the angle of extension of the knee, one bundle is always in a state of tension, further complicating the overall tissue biomechanics [6,7]. These complications pose a major challenge to health care professionals, and there is a pressing need to understand the mechanics of the ACL in physiologically relevant loading states in order to develop accurate constitutive models and select appropriate replacement options.

METHODS

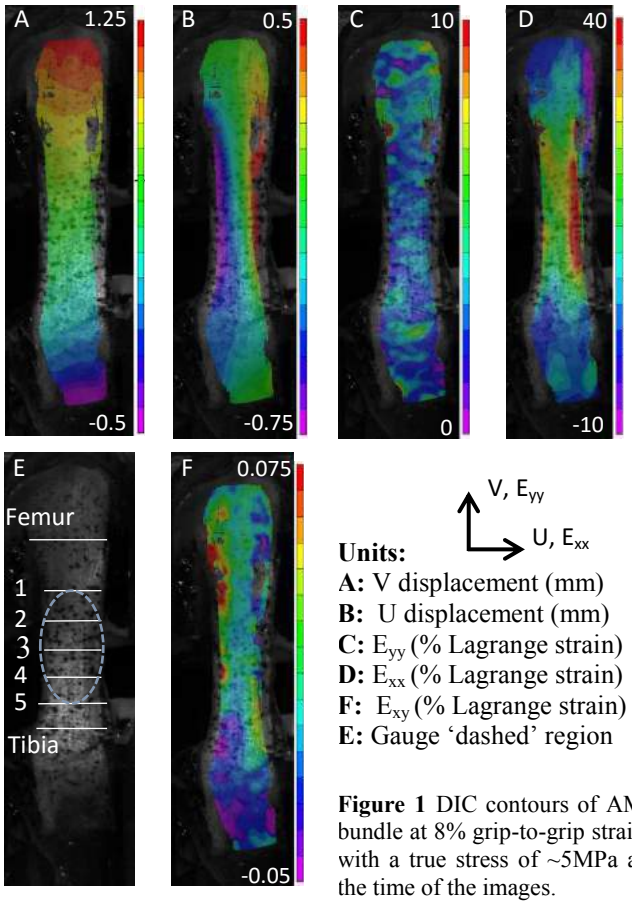
The complex insertions of both the AM and PL bundles at the femur and tibia make performing experiments and accurately modelling the properties of the tissue difficult. At the femur, both bundles insert tangentially to the curved surface of the lateral femoral condyle. In addition, at the tibia, the AM bundle inserts along the anterior aspect of the medial tibial spine, while individual fibrils of the PL splay before inserting into the tibial plateau. A novel grip device has been designed to orient the individual ACL bundles in uniaxial tension, taking into account the complex bundle insertions. We have performed experiments on the individual bundles of the ACL in uniaxial tension from their unloaded reference configurations to characterize them, as well tests of the full ACL in a physiologically relevant loading condition (i.e. anterior tibial translation or ATT). Using digital image correlation (DIC) and our tension testing techniques, we are able to obtain quantitative grip-to-grip stress and time data, as well as average and region-specific strain information over the surface of the test specimens. Uniaxial load-unload experiments have been conducted up to 8% grip-to-grip strains at several strain rates. The viscoelastic response of the tissue has been quantified by performing stress relaxation tests and load-unload tests at several strain rates.

RESULTS

This work provides quantitative data for constitutive modelling of the heterogeneous bundles of the ACL, using a custom-designed gripping fixture optimized for uniaxial tension testing. **Figure 1** shows the strains and displacements of the AM bundle at 8% grip-to-grip strain. The E_{yy} longitudinal

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

strain shows the relative homogeneity of the AM bundle strain response within the mid-region of the tissue, while the E_{xy} shear images shows little shear in this same region. **Figure 1** shows the vertical (V) and horizontal (U) displacement contours of the AM bundle, along with the, vertical (E_{yy}), horizontal (E_{xx}) and shear (E_{xy}) strain contours. The lateral displacement field, **Figure 1B**, shows extensive lateral motion of the AM bundle within the mid-substance region, demonstrating lateral expansion of the bundle due to the splaying of individual fibrils under uniaxial tension loading. **Figure 2** shows the homogeneity of the stress v. strain response of the AM bundle in a load-unload test to 8% grip-to-grip strain. The stress v. strain response within the mid-substance region outlined in Figure **1E** is relatively homogeneous. In addition, the grip-to-grip measurement over predicts actual tissue level strains by 47% due to system compliance.



Units:
A: V displacement (mm)
B: U displacement (mm)
C: E_{yy} (% Lagrange strain)
D: E_{xx} (% Lagrange strain)
F: E_{xy} (% Lagrange strain)
E: Gauge 'dashed' region

Figure 1 DIC contours of AM bundle at 8% grip-to-grip strain with a true stress of ~5MPa at the time of the images.

DISCUSSION

The data from these experiments is used in a constitutive model that captures the response of the ACL experimentally. In addition, the patterning technique is capable of generating the pseudo-random, high density and high-contrast pattern necessary for obtaining accurate high resolution strain data of the surface strains of soft biological tissue. We demonstrate that the posterolateral bundle of the ACL is linear viscoelastic up to 10% initial strain, whereas the anteromedial bundle is non-linear viscoelastic after about 8% strain. In addition, the AM bundle is homogeneous within the midsection of the tissue, allowing for constitutive modelling using well-understood boundary conditions in this region.

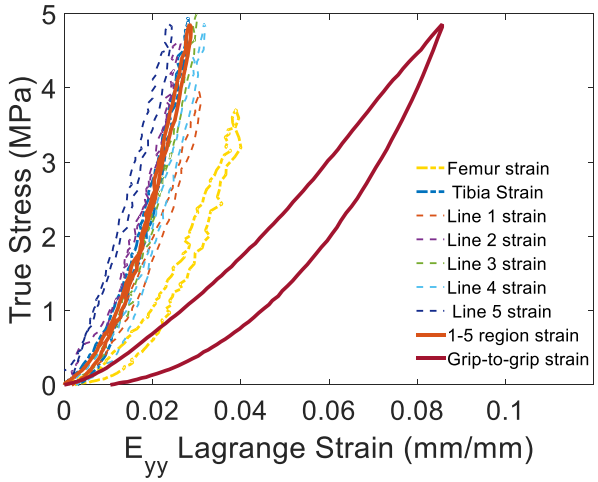


Figure 2 Stress v. strain response of the AM bundle using local DIC strains along horizontal lines within the 'gauge' mid-substances region, and global grip-to-grip strains.

With the non-linear viscoelastic responses of the two bundles characterized via tension testing in the manner described, we implement the models into a finite element environment in which we start with each bundle in its reference configuration, reassemble the bundles, twist them to their physiological state, apply a knee flexion angle matching that in our ATT experiments, and simulate the ATT response. The approach is predictive of the strain fields in the ACL during the ATT test. Our computational model is able to predict the location of ACL tears in the proximal third of the tissue. Moreover it may be used with full knee models to simulate the ACL tissue response to diverse knee injury situations.

INTRODUCTION

Heart disease is the major cause of death in the United States, with an estimated 83.6 million Americans with one or more type of cardiovascular disease (CVD). Mortality data from 2010 shows that CVD is the underlying cause of death for 1 out of every 3 Americans [1]. There is an increasing demand for affordable, compatible and more easily accessible coronary vascular grafts. Tissue-engineered vascular grafts (TEVGs) offer an alternative source of grafts that can be developed to be nonthrombogenic, biocompatible, nonimmunogenic, resistant to infection, and compliance-matched to the native vessel. Since compliance mismatch is a major cause of restenosis and graft failure, it's important that the mechanical properties of the TEVG be comparable to that of native vessel.

Our resesarch group has recently shown that it is possible to create native vessel compliance-matched TEVGs by modulating the mechanical properties of electrospun acellular gelatin/fibrinogen TEVGs via changing glutaraldehyde (GLUT) vapor crosslinking time [2]. We have also shown that porcine aortic smooth muscle cells (PSMCs) proliferated and migrated within gelatin/fibrinogen electrospun sheets [3]. In addition, transforming growth factor beta 2 (TGFβ2) was shown to have a significant effect on the proliferation and collagen deposition of the PSMCs, which suggests that seeded cell lines could have the ability to modify the mechanical properties of cylindrical constructs over time [3]. The purpose of this study was to better understand the mechanisms of biomechanical changes that non-synthetic TEVGs undergo when seeded with 3T3 mouse fibroblasts (3T3FB) and PSMCs cultured *ex vivo* in a custom bioreactor.

METHODS

Gelatin/fibrinogen cylindrical constructs were fabricated by electrospinning a 10% (w/v) of gelatin/fibrinogen (80:20) in HFP onto a rotating translating mandrel. The constructs were suspended inside a 25% GLUT chamber and exposed to the GLUT vapor phase for 2 hours. The constructs were then dried, sterilized and seeded with a normalized concentration of either cultured 3T3MF or a mixture of 3T3MF and PSMCs by using a custom-built vacuum lumen seeding device and by pipetting cellularized media onto the constructs. The seeded constructs were then transferred into custom-built bioreactors for culturing.

Three bioreactors were machined out of Teflon in accordance with a custom, in-house design. Each bioreactor has a LinMot electromagnetic actuated linear motor, a 1-pound submersible FUTEK load cell to induce axial load, and a Harvard Apparatus pressure regulation system to induce circumferential load. The bioreactors' dynamic loading system can be controlled by a custom written LabVIEW program in conjunction with proprietary software by Harvard Apparatus. The experimental setup is shown in Figure 1. The bioreactors have the capacity to hold cannulated constructs (mechanically stimulated) and non-cannulated constructs (not mechanically stimulated). The experimental groups, shown in Table 1, were cultured in the bioreactors for 3 weeks. In an attempt to encourage collagen deposition, the culture media for one bioreactor was injected with TGFβ2 at a concentration of 5 ng/ml in the last week of the experiment. Non-seeded controls were placed in media in a petri dish for the same time duration.

After the experimental culture time, the constructs were removed from the bioreactors, sectioned and prepared for further analysis. Cell proliferation was evaluated using a cell proliferation assay. To determine the mechanical properties of the constructs, a custom-made microbiaxial optomechanical device was used [4]. A collagen assay was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

used to measure the concentration of deposited collagen. Multiphoton imaging was used to analyze fiber alignment and determine the distribution of collagen deposition via the detection of second harmonic signal and finally histology sections were prepared to visualize cell phenotype and distribution.

Table 1. Summary of experimental groups in this study

PRELIMINARY RESULTS

The cell proliferation assay indicated large cell proliferation while in the bioreactors. The assay also suggested that constructs that were seeded with only 3T3FB cells proliferated better than those of the mixed culture. The proliferation cell concentration results for bioreactors A, B and C are shown in Figure 2. The mechanical testing indicated that there were some experimental groups that became slightly more compliant than the control. In addition, many of the construct experimental groups were able to achieve higher axial strains than that of the controls, suggesting more mechanical integrity and higher deformability.

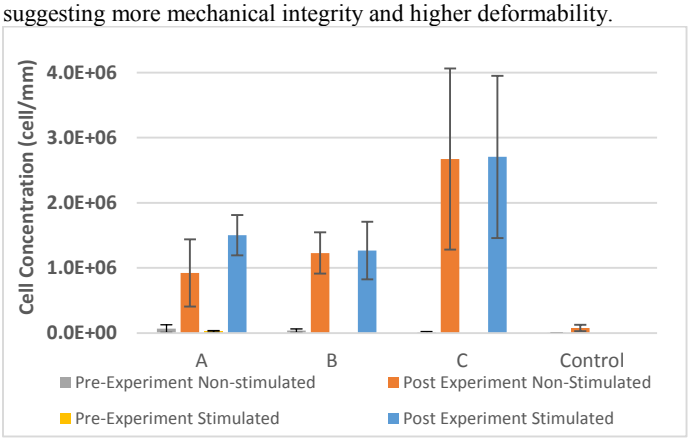

Figure 2. Cell proliferation results before and after cell culture

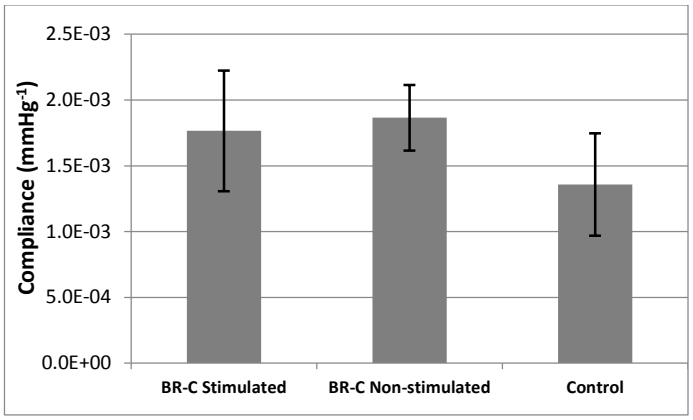

Figure 3. Compliance values of stimulated and non-stimulated constructs from Bioreactor C compared to control constructs

DISCUSSION

Preliminary results show that cells were able to grow well on the gelatin/fibrinogen construct cylindrical geometry. Also, the mechanical data suggests that the cells may have had an effect on the mechanical behavior of the seeded constructs. Further tests are necessary to determine if these are significant changes. The collagen assay and multiphoton imaging will provide information related to the cell deposition of matrix that could possibly explain the increase in compliance and deformability of the seeded constructs.

Previous studies have shown that GLUT crosslinking has a biaxial stiffening effect on the gelatin/fibrinogen construct that decreases the compliance of the constructs [2]. If cell culture is shown to have a softening effect, it may be possible to further modulate the mechanical properties of non-synthetic conduits, which would allow more custom development of durable and biocompatible TEVGs. Furthermore, the current *ex vivo* bioreactor study may provide information related to the *in vivo* durability and biocompatibility of these TEVGs.

MODELLING THE EVOLUTION OF SMOOTH MUSCLE CELL STRESS FIBRES FOLLOWING STENT DEPLOYMENT IN AN ARTERY

INTRODUCTION

Alterations in the biomechanical environment of arterial tissue post stent implantation commonly results in the proliferation of smooth muscle cells (SMC) and remodelling of the collagen extracellular matrix (CECM) [1, 2]. The restenosis rates post stent implantation can be as high as 60% [3], where restenosis is defined as >50% reduction of the lumen diameter [3, 4]. It is reported that stents with thinner struts reduce the occurrence of restenosis [5]. This suggests that a reduction in compliance of a section of artery may result in SMC proliferation.

In an attempt to understand the relationship between effective vessel compliance post-stent implantation and the biomechanical behavior of SMC's in the artery wall, an active modelling framework is developed in the current study. Cell behavior in healthy arterial walls, arteriosclerotic arterial walls and in stented arterial walls is analyzed.

METHODS

A finite element model is developed using an idealized artery and the stent geometry [6] shown in Figure 1. The stent is deployed through contact with a radially expanding balloon. The balloon is then removed to simulate recoil. Following stent deployment a pulsatile lumen pressure ranging from 80mmHg to 120mmHg is applied at a frequency of 1Hz.

A novel approach to the modelling of the artery wall is implemented whereby actively contractile SMC's are simulated using a fading memory formulation [7, 8]. The passive matrix surrounding the SMC's is modelled using an anisotropic hyperelastic constitutive model [9].

Fading Memory Model

Active contractility of SMC's is modelled in Abaqus 6.13 (Simula, Providence, RI, USA) using a user defined material subroutine (UMAT) which implements a fading memory [8] into a constitutive model for the contractility of the actin cytoskeleton [7]. The SF activation level is determined using a first order kinetic equation originally proposed in [8] which incorporates SF formation and dissociation:

$$\frac{d\eta(\phi,\omega)}{dt} = [1-\eta(\phi,\omega)]Ck_f - \left[1-\frac{\sigma_f(\phi,\omega)}{\sigma_0(\phi,\omega)}\right]\eta(\phi,\omega)k_b \quad (1)$$

The first term on the right governs SF formation and is initiated by an exponentially decaying signal C:

$$C = exp\left(-\frac{t_s}{\theta}\right) \quad (2)$$

where θ is the decay constant, t_s is the time measured since the most recent signal, η is the dimensionless SF activation level ($0 \leq \eta \leq 1$), k_f is forward reaction rate constant and k_b is the backward reaction rate constant. The term on the right governs SF dissociation. This occurs when the tension in the SF drops below the isometric fiber tension. The fiber tension is determined using a fading memory strain rate given as:

$$h_f = \sum \int_{-\infty}^{t} Ae^{-\infty(t-\tau)}\dot{\varepsilon}_m(\tau)d\tau \; \dot{\varepsilon}_m = \begin{cases} \dot{\varepsilon}_f & \dot{\varepsilon}_f \leq 0 \\ 0 & \dot{\varepsilon}_f > 0 \end{cases} \quad (3)$$

This time integrated strain rate is inserted into a Hill type contractility equation to determine the fiber tension:

$$\frac{\sigma_f}{\sigma_0} = 1 + \frac{\overline{k}_v}{\eta}\frac{h_f}{\dot{\varepsilon}_0}; \; -\frac{\eta}{\overline{k}_v} \leq \frac{h_f}{\dot{\varepsilon}_0} \leq 0 \quad (4)$$

At each integration point the equations 1-4 are solved in 240 discrete directions allowing for the prediction of the spatial evolution

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

of SMC SF distributions throughout the artery wall. The active stress tensor is obtained by integrating the tension in the individual fibers over the volume:

$$\boldsymbol{\sigma}^{Active} = \sigma_{ij}^{A} = \frac{1}{V}\int_{v} \sigma_f(\omega,\phi) m_i m_j dV \quad (5)$$

Passive Anisotropic Matrix Model

The matrix surrounding the SMC's is modelled using a compressible form of the HGO anisotropic hyperelastic model [9, 10] and is calibrated using the biaxial test results of descending ovine aorta, whereby the stress tensor is given as:

$$\boldsymbol{\sigma} = \kappa_0(J-1)\mathbf{I} + \mu_0 J^{-\frac{5}{3}}\left(\mathbf{B} - \frac{1}{3}I_1\mathbf{I}\right) + 2J^{-1}k_1\sum_{i=4,6}(I_i - 1)\exp[k_2(I_i - 1)^2](\boldsymbol{a_i}\otimes\boldsymbol{a_i}) \quad (6)$$

Whereby κ_0 is the isotropic bulk modulus, μ_0 is the isotropic shear modulus, $k_1$and k_2 are the anisotropic material constants, $\boldsymbol{B}$ is the left Cauchy-Green tensor, $\boldsymbol{a_i}$ is the fiber directional vector, J is the determinant of the deformation gradient, $\boldsymbol{I}$ is the identity matrix, I_1 is the first invariant of the right Cauchy-Green tensor and I_4 and I_6 are the full anisotropic invariants describing the deformation of reinforcing fibers.

The total stress tensor is obtained by the addition of the active and passive stress tensors:

$$\boldsymbol{\sigma}^{Total} = \boldsymbol{\sigma}^{Passive} + \boldsymbol{\sigma}^{Active} \quad (7)$$

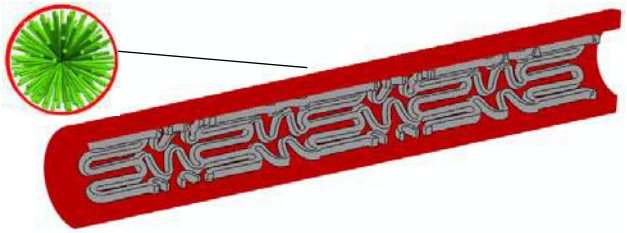

Figure 1: Closed-cell stent geometry in an artery [6] showing the 240 discrete directions equations 1-4 are solved for [8].

RESULTS

Biaxial tests reveal aortic material is highly anisotropic as shown in Figure 2 and that it is approximately 2 times stiffer in the circumferential direction than in the axial direction.

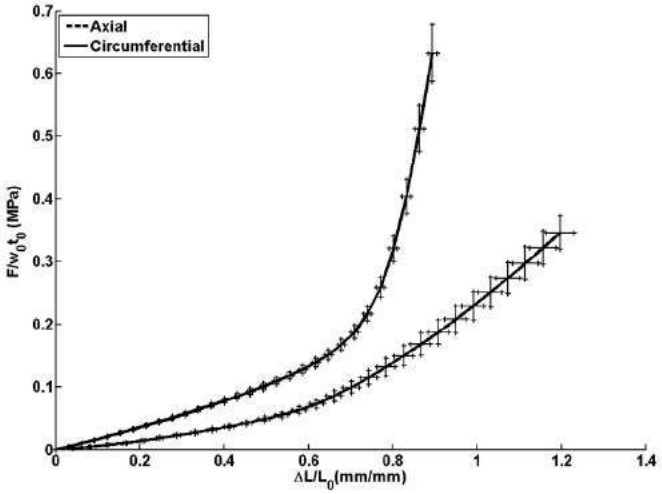

Figure 2: Biaxial test results clearly showing the anisotropy of arterial tissue.

Simulations reveal that the maximum circumferential strain rate during physiological loading of a healthy artery is 0.3738 s^{-1}.

Figure 3 shows the computed SF activation level in the circumferential direction for a healthy artery. Slight fluctuations occur during a cardiac cycle but SF levels are approximately constant. If a stent is deployed in the artery at time t=0, the circumferential strain rate in the artery wall reduces to 0.0004s^{-1}. This dramatically reduces tension in the diastolic part of the cardiac cycle, and thus inhibits dissociation of SFs. A gradual increase in SF activation in the circumferential direction is computed following stent deployment, with the final steady state value being significantly greater than that for a healthy artery. Finally, Figure 3 also shows that SF levels for stented arteries are significantly higher than for an arteriosclerotic artery, in which the compliance has been reduced by a factor of 2 [11].

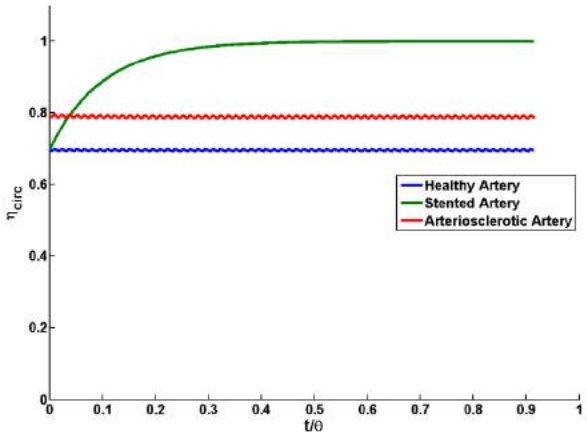

Figure 3: Circumferential stress fiber activation level for cyclic loading at 1 Hz for a healthy, arteriosclerotic and stented artery.

DISCUSSION

Simulations suggest that decreased cyclic strain rates of in the artery wall following stent deployment lead to a significant increase in circumferentially oriented SFs in smooth muscle cells. This finding is supported by an animal study which reports circumferential organization of smooth muscle cells in the artery wall at day 14 post stent implantation in porcine coronary arteries [12]. A companion experimental study is currently being conducted to further characterize the relationship between the applied strain rate, SF formation, and SMC proliferation.

INTRODUCTION

High Intensity Focused Ultrasound (HIFU) is a hyperthermia therapy that deposits high amount of acoustic energy at a point resulting in a high temperature rise. It is used in treatment of uterine fibroids, prostate and other cancers where the diseased tissue is heated to a specific temperature. Thus, accurate prediction of temperature rises during such scenarios is extremely important. Measurement of temperature rises with experiments is challenging. In addition, errors due to artifacts are possible during temperature measurements [1]. Therefore, it is advantageous to perform numerical studies to estimate the temperature rise.

The *objective* of this study is to predict the HIFU induced temperature rise in a tissue phantom for different acoustic powers using the software PZFlex and compare that with experimental results.

METHODS

Numerical model: The computational model involves a HIFU transducer and a 2D axisymmetric nonlinear tissue mimicking material (TMM). The TMM was surrounded by water. The default values for the initial temperature of TMM and the surrounding water were 37 °C and 25°C, respectively. The transition distance or the distance between the transducer and the material was maintained at 15 mm (Fig. 1). The computations were performed for an ultrasound frequency of 3.3 MHz, for different input powers of 5, 10, 20, 30, 40, 50 and 60 W.

The governing equations used for simulation of ultrasound in tissue models are the conventional momentum and constitutive equations. Taking into account, the first two terms of pressure expansion in power series, we obtain the 'B/A' model.

$$p = -K\left(\nabla.u + \frac{1}{2}\frac{B}{A}(\nabla.u)^2\right) \quad (1)$$

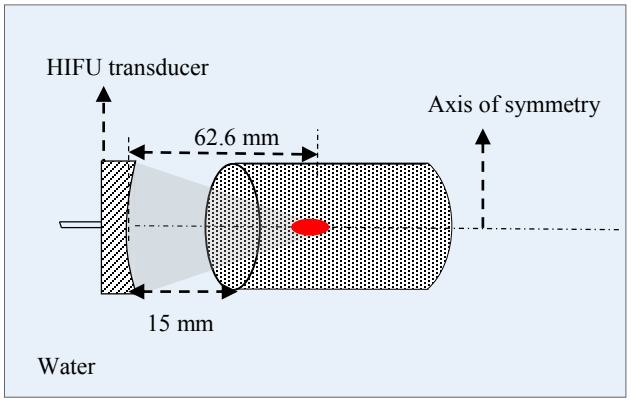

Figure 1: Geometry of the HIFU model

where p is the pressure (Pa), K or ρc^2 is the bulk modulus of the tissue material (Pa), ρ is the TMM density (Kg/m^3), c is the bulk velocity of sound (m/s) and u is the displacement vector (m), B/A is the parameter of nonlinearity (dimensionless) [2].

$$I = < p^2 > / \rho c \quad (2)$$

$$Q = \sum_{n=1} 2\alpha I_n \quad (3)$$

Heat source, Q (W/m^3) can be calculated using intensity, I (W/m^2) which is obtained from acoustic pressure. α is the acoustic absorptivity (dB/m).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The thermal transient response was obtained by solving the Pennes bioheat transfer equation [3]. The perfusion term was neglected because of the absence of microvasculature in the TMM:

$$\rho C \frac{\partial T}{\partial t} = k(\nabla^2 T) + Q \quad (4)$$

where T is the temperature (°C), C is the specific heat of the TMM (J/Kg.°C), k is the thermal conductivity of the TMM in (W/m.°C).

Computations for the seven different applied acoustic powers were conducted keeping the sonication time as 30 s. The calculated pressure values at the transducer surface for each of the applied powers were used as the input along with the transducer properties (Table 1) to obtain the focal temperature rise. The difference between the peak temperature of the material and the initial temperature was used as the value for temperature rise. The properties of the nonlinear TMM used in the computations are presented in Table 2.

Table 1: Transducer properties and setup

Diameter	64 mm
Focal length	62.6 mm
Transition distance	15 mm
Sonication time	30 s

Table 2: TMM material properties

Density	1040 Kg/m^3
Bulk velocity	1534 m/s
Bulk attenuation	46 dB/MHz/m
B/A	7
Specific heat capacity	3780 J/Kg.°C
Thermal conductivity	0.58 W/m.°C

Experimental setup: Experiments were performed to estimate the focal temperature rises in a TMM for similar scenarios as in numerical method. The TMM was prepared as per the protocol presented in King et al [4]. The TMM was mixed in liquid form and poured into a cylindrical fixture of diameter 8 cm. The fixture was embedded with eight thin wire thermocouples (TCs) [5], positioned in four separated layers, with two TCs in each layer. The TCs in the same layer were placed 4 mm apart, while the adjacent layers were separated by a distance of 3 mm.

The HIFU beam was positioned inside the TCs array and away from the TCs junction to avoid any errors due to the artifacts. In order to evaluate the focal temperature rise using the remote TCs measurements, a localization algorithm [5] was first implemented to determine the location of beam focus inside the TCs array. After finding the relative location of the beam focus, the focal temperature prediction was made using an estimating function [5]. The estimating functions can be developed from common fitting functions where the unknown parameters can be determined based on the TCs measurements. Here, assuming that the heat production has Gaussian profile in radial direction (with no axial variation), the estimating function was written in terms of exponential integral as shown by Dillon et al [6]. The focal temperature estimation using the exponential integral was performed for the acoustic powers of 30, 40 and 50 W.

RESULTS

The values shown in the Fig. 2 correspond to the maximum focal temperature rise attained numerically for the sonication period of 30 s. The focal temperature rise values obtained numerically were 6.8 ºC, 13.6 ºC, 27.2 ºC, 40.8 ºC, 54.6 ºC, 68.1 ºC and 81.9 ºC for the input acoustic powers of 5, 10, 20, 30, 40, 50 and 60 W, respectively. The nonlinearity in the peak temperature rise at higher powers (40 W, 50 W and 60 W) cannot be observed and further investigation is required.

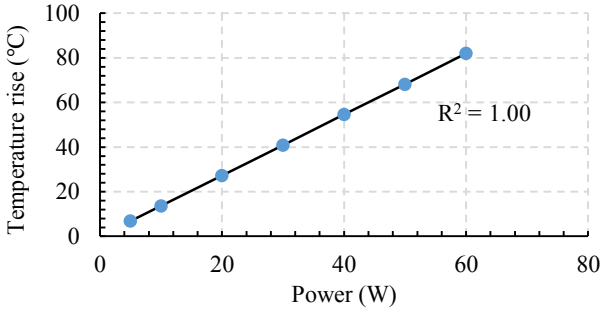

Figure 2: Variation of temperature rise with input power

Comparison of the computational results with the experimental [5] values shows a deviation of 13.2 % for 30 W, 1.0% for 40 W, and 2.6 % for 50 W of input power (Fig.3), while the average deviation for the three powers is 5.7%.

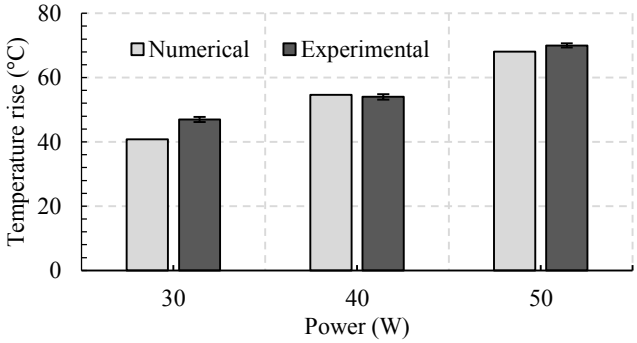

Figure 3: Comparison of numerical and experimental values of temperature rise

DISCUSSION

The temperature rise values achieved for various power inputs based on computations for nonlinear TMM have been presented in this study. The numerical temperature rises show good agreement with experimental temperature rises for 30 W, 40 W and 50 W. Numerical results match within 5.7% of the experimental values when averaged for all the three powers. Hence, numerical methods can provide reliable estimates of focal temperatures when conducting experiments is difficult.

Assumptions and limitations. All the computations have been performed assuming that the tissue properties are uniform. Nonlinear temperature rise at higher power needs further assessment.

Future scope. The current study will be extended to estimate the temperature rise by incorporating different TMM properties. A comparison of the numerically obtained results will be made with *in-vivo* experimental temperature values.

INCREASED CAPTURE OF MAGNETIC MICROBEADS DUE TO SWITCHING OF ELECTROOSMOTIC FLOW

Samuel A. Miller (1), William R. Heineman (2), Rupak K. Banerjee (1)

(1) Department of Mechanical and Materials Engineering, University of Cincinnati Cincinnati, Ohio, USA

INTRODUCTION

Detection and isolation of bio-molecules for immunoassays is crucial to efficient and accurate performance of micro total analysis systems (μTAS). To accomplish this, magnetophoretic separation techniques are commonly used in these microfluidic platforms. This technique utilizes magnetic microbeads coated with epitomes targeted to specific pathogens as part of an antigen-antibody binding complex to tag specific bio-molecules [1]. Separation is then accomplished through the application of a magnetic field to isolate the microbeads/bio-molecule complex from the continuous flow in the device. The continuous flow in microfluidic devices can be either pressure driven or electrokinetically driven. Electrokinetically driven mechanisms, such as electroosmotic flow (EOF) has advantages over pressure driven flow due to the absence of mechanical pumps, which can be inefficient [2], as well as the ability to operate at atmospheric pressure.

The difficulty with magnetophoretic immunoassays is producing a reliable and efficient capture of microbeads to ensure accurate results with the highest possible sensitivity using dilute samples. The capture efficiency (CE), or ratio of number of particles captured to number of particles injected into the channel, relies on the attractive magnetic force overcoming the viscous forces of the liquid moving the particles with the flow. However, previous studies have shown that magnetic beads can escape the area with high magnetic field strength [3], resulting in uncaptured beads and decreased sensitivity. Thus, a switching method is implemented to increase the bead residence time in the area of higher magnetic field strength. This switching is accomplished by alternating the external voltage driving the electroosmotic flow through the microchannel. The goal of this study is to assess increase in capture efficiency using the switching flow mechanism as compared to the constant flow mechanism.

METHODS

The microchannel device used during testing is shown in Fig. 1. The channel is produced using standard soft lithography with the final device made from PDMS bonded to a glass slide, resulting in a channel that is 50mm long with a cross section of 50 μm x 50 μm. A 1/8" x 1/8" x 3/8" tall neodymium (NdFeB) magnet is placed above the channel, 25 mm from either well. The channel is pre-treated with NaOH to induce surface charge on the walls and then PBS with Tween20 to prevent the microbeads from sticking to the wall when not captured.

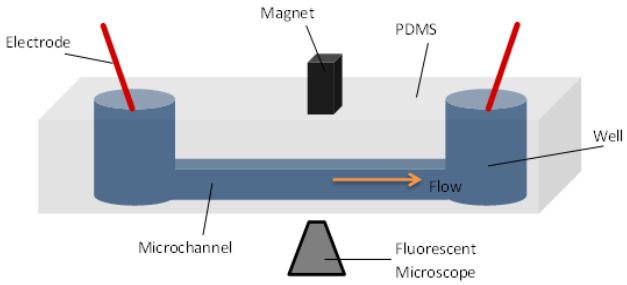

Figure 1: Schematic of microchannel device.

The beads used were Dynabead® M280 Sheep anti-Rabbit IgG tagged with Alexa Fluor® 488 Rabbit anti-Mouse IgG by slow tilt mixing for 24 hours at 8°C. The beads were suspended in PBS buffer to achieve the desired concentrations for the experiments (C1 = 2×10^6, C2 = 4×10^6 beads/mL).

The capture zone was determined for the device by running tests at the lowest flow rate followed by immediately running the buffer to clear out any uncaptured beads before determining the distance from

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the front and far edge of the magnet beads were visualized. The electroosmotic flow is governed by equations 1 and 2

Poisson's equation: $\nabla^2\phi = 0$ (1)

Helmholtz-Smoluchowski equation: $U_e = \varepsilon\zeta E/\mu$ (2)

These two equations are coupled so that the EOF velocity, U_e corresponds to the applied potential, ϕ. For the experiments, voltage was applied for 20 min total, with the time breakdown shown in Table 1.

Table 1: Applied voltage conditions as function of time. V for case 1 is 650 volts; V for case 2 is 750 volts.

Time (min)	Steady State		Switching	
	Inlet	Outlet	Inlet	Outlet
0-8	+V	Ground	+V	Ground
8-11	+V	Ground	**-V**	Ground
11-14	+V	Ground	+V	Ground
14-17	+V	Ground	**-V**	Ground
17-20	+V	Ground	+V	Ground

The beads were visualized and images were captured using inverted fluorescent microscopy, with example images of captured beads shown in Fig. 2. A calibration curve of fluorescence as a function of concentration is shown in Fig. 3. Beads located in the starting well or before the capture zone were not considered, those located in the capture zone were considered captured, and those located in the channel after the capture zone or in the ending well were considered uncaptured.

Figure 2: Fluorsecent images of beads captured under switching protocol at concentration of 4×10^6 beads/mL and 750 V (left) and 650 V (right).

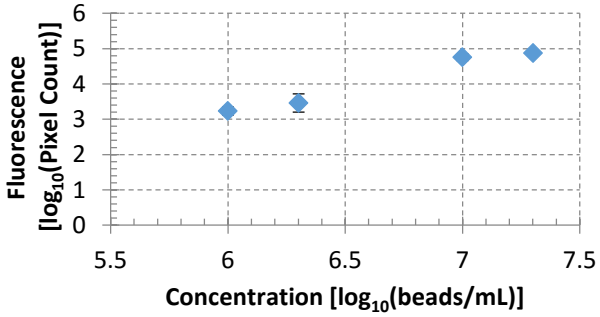

Figure 3: Calibration curve of fluorescence as function of bead concentration.

The images were analyzed using MATLAB to determine the fluorescent intensity based on Red-Green-Blue (RGB) values to determine percentage of beads captured based on pixel count (PC) of captured and uncaptured beads according to

$$Capture\% = \frac{PC_{captured}}{PC_{captured} + PC_{uncaptured}} * 100\% \quad (3)$$

The relative percentage difference between switching and constant flow capture was determined by

$$Rel\%Diff = \frac{Capture\%_{Switch} - Capture\%_{Constant}}{Capture\%_{Constant}} * 100\% \quad (4)$$

RESULTS

Capture percentage for both switching and constant flow as well as relative percentage difference for voltages of 750 V and 650 V and concentrations of 2×10^6 beads/mL and 4×10^6 beads/mL are shown in Table 2.

Table 2: Capture percentage for switching and constant flows and the relative percentage difference.

Concentration (beads/mL)	Voltage (V)	Switching Capture %	Constant Capture %	Relative % Diff
2×10^6	650	85.0 ± 5.8	41.7 ± 5.5	99.2 ± 30.0
2×10^6	750	83.6 ± 6.7	37.6 ± 6.6	122.5 ± 42.1
4×10^6	650	80.6 ± 4.1	37.3 ± 4.6	112.6 ± 29.5
4×10^6	750	71.1 ± 6.2	31.7 ± 5.8	122.8 ± 44.7

The main result is seen in the difference between capture percentages of the switching and constant flow protocols. The drastic increase in capture percentage in the switching situation, around 2 times the capture percentage, is due to the increased residence time in the higher magnetic field capture zone. The different concentrations and voltages had very little effect on the capture percentages. There was a relative difference of less than 20% for each permutation in voltage or concentration, keeping all variables (voltage, concentration, and switching versus constant flow) constant. This difference is insignificant compared to the drastic improvement in capture percentage when incorporating the switching protocol.

The maximum capture zone was determined to be 12 mm before the front of the magnet and 15 mm beyond the back of the magnet.

DISCUSSION

The change in capture efficiency as a result of the switching flow protocol was examined and compared to the capture efficiency using constant flow. The major finding of this study shows that switching causes a relative difference of 2 times the capture percentage for all cases as compared to the constant flow protocol. This is due to the switching function returning beads that would be lost under constant flow conditions back to the capture zone and the influence of the higher magnetic field strength.

Future examination of this device through variation of the exact switching protocol could optimize the capture efficiency and residence time in the capture zone. In addition, varying the switching protocol could also result in more beads entering the capture zone, potentially increase the sensitivity. Further studies consisting of beads capturing bio-molecules would also provide vital information concerning the performance of the device in its intended application as a portable magnetophoretic immunoassay.

DIFFERENCES IN PELVIC BLOOD FLOW MEDIATE DIFFERENCES IN ABDOMINAL WALL SHEAR STRESS BETWEEN MEN AND WOMEN

INTRODUCTION

Abdominal aortic aneurysms (AAA) are more prevalent in men than they are in women with an increased frequency of 4 or 5 to 1.[1] While it has been proposed that hormonal regulation, specifically estrogen, plays a role in this discrepancy, women provided with hormone replacement therapy (HRT) following menopause are not any more protected from AAA than women without HRT.[2] It is possible, therefore, that a difference exists in the biomechanics rather than the biology of the aorta that results in a difference in the development or outcome of AAA. Given the relationship between vascular inflammatory processes (atherosclerosis and aneurysms in particular) and low and oscillatory wall shear stress, it is possible that men are exposed to wall shear stress profiles that increase their risk for developing AAA while women are prtoected.[3] For this study we compared the abdominal aortic wall shear stress (WSS) profiles of healthy men and women using phase contrast MRI.

In addition to quantifying any differences in the shear stress, we tested a possible cause for why WSS differences exist. Previous studies have shown that parous women (who experience an increase in uterine flow) are protected against AAA when compared with non-parous women.[4] Therefore, we compared flow in the internal and external iliac arteries (also measured by phase contrast MRI) to test the hypothesis that differences in pelvic blood flow (mediated by the uterus in women and supplied by the internal iliac artery) could cause a difference in aortic hemodynamics.

METHODS

We recruited 12 men and 15 women aged 30-42 with no history of cardiovascular disease under an Emory University IRB approved protocol to participate in the study. In each of these volunteers we acquired between 3 and 10 phase contrast image sets taken at evenly spaced locations along the length of the aorta. All phase contrast sequences were ECG-gated 2D axial image sets encoded to measure through plane velocity (Venc=150 cm/s). Thirty time frames were acquired over the cardiac cycle and final voxel resolution of 1.33x1.33x5 mm. Using a method developed in our lab, we quantified the wall shear stress at 80 locations around the circumference for each of the acquired slices.[5] We then evaluated the oscillatory shear index in which τ^* is the portion of the shear wave that is in the opposite direction of the average shear vector (towards the head in the abdominal aorta) and τ is the shear stress wave:

$$OSI = \frac{\int \tau^* dt}{\int \tau dt} \quad (1)$$

The location of each slice was normalized to the total length of the aorta for each volunteer and placed one of 10 normalized bins. For any volunteers lacking data in one of these bins it was filled in using a validated two dimensional interpolation method. This allowed us to create a 10x80 matrix of the averaged results among all volunteers in which each row corresponds to a different longitudinal location in the aorta and each column to circumferential positions. This matrix normalized to the size of the vessel in both the radial and axial directions and allowed for a direct comparison of the sexes at each of the elements in the array.

In addition to phase contrast images in the abdominal aorta, we also acquired PCMR image sets for both the internal and external artery and quantified the flow through these vessels. We compared the average reverse flow, forward flow and oscillatory flow ratio in which Q_{rev} is the flow wave in the cranial direction and Q_{for} is the flow wave in the caudal direction:

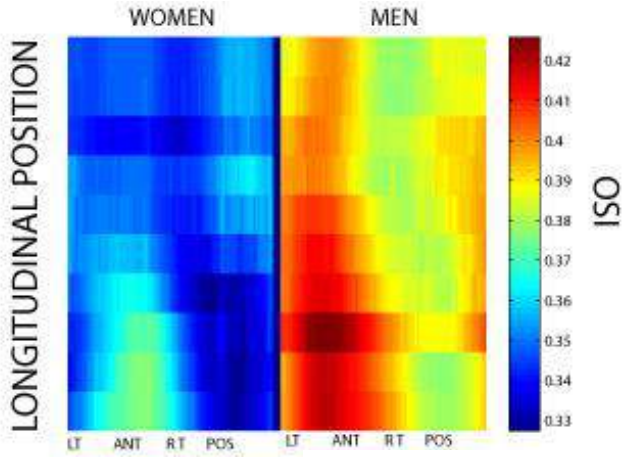
Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$OFR = \frac{\int Q_{rev} dt}{\int Q_{for} dt} \quad (2)$$

This parameter allows us to assess the extent of flow reversal normalized to the forward flow which controls for any discrepancies that exist as a result of differences in size between men and women.

RESULTS

Figure 1 shows the results of our comparison our OSI between the healthy men and women. Globally, the average OSI value for men was significantly higher than women (0.40±0.00040 vs 0.35±.00039, $p<0.0001$).



n=15 women, 13 men

Figure 1

Figure 2 shows the average external and internal iliac arteries' OFR values for men and women. When looking at the values of forward and reverse volume it was found that only the internal reverse flow volume was significantly higher in men when compared with women using a two tail t-test (1.2 ± 0.26 mL in men vs 0.22 ± 0.075 mL in women, $p<0.05$).

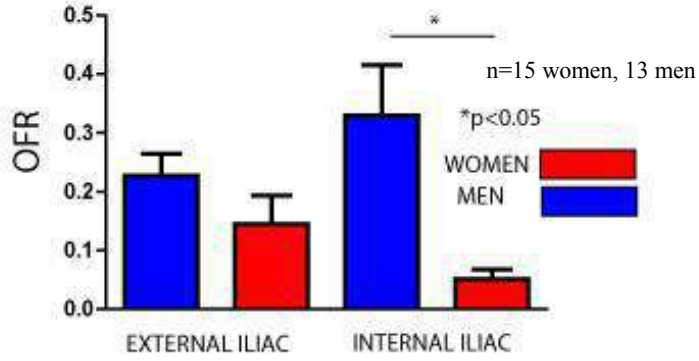


Figure 2

DISCUSSION

Our results demonstrate a significant reduction in the extent of oscillatory shear in women when compared with men in this age group. This observation supports the hypothesis that differences in abdominal aortic aneurysm incidence in the two populations may be explained by a difference in the biomechanics prior to onset of the disease. Specifically that women of this age are protected from harmful oscillatory shear in the abdominal aorta that is known to incite atherosclerosis lesions and underscore aneurysm development.

Further, our results show that this difference in OSI is, at least in part, most likely mediated by a difference in peripheral resistance. More specifically that women have less flow reversal in the internal iliac artery when compared with men. This observation can be explained physiologically by the differences in pelvic anatomy which is the recipient of internal iliac artery blood. That this same reduction is not seen in the external iliac artery confirms that a decrease in oscillatory flow is not a global phenomenon in women but is specific to the internal artery and consequently the aorta.

While peripheral arterial resistance of the iliacs may contribute to the differences in hemodynamics that are seen in men and women, it is likely that it is not the only contributing factor. We are also evaluating differences in geometry such as aortic size, length and curvature as well differences in tissue mechanics such as compliance and strain to evaluate the influence of these factors on wall shear stress measurements.

INTRODUCTION

Bioprosthetic heart valve (BHV) design has remained nearly static over the past 10 years. Current BHVs frequently require replacement 10-15 years after implantation [1]. Mechanical stresses have been shown to drive the degradation of BHVs [2]. Convenient and accurate predictive modeling of BHV mechanics could therefore accelerate the design of more durable valves. The forces driving BHV leaflets are due to surrounding blood flow. Thus a complete mechanical model of a BHV must include fluid-structure interaction (FSI). The purpose of this work is to develop a robust framework for modeling and simulation of BHV FSI. This effort can be divided into two broad tasks:

- Devising a mathematical model that accurately describes BHV FSI.
- Developing numerical methods to compute approximate solutions to this mathematical model.

The mathematical model must be *validated*: we must compare the predictions of the model with experimental results, to ensure that the mathematical description of reality is adequate for our purposes. The numerical method must be *verified*: we must take measures to ensure that computational results accurately approximate solutions to the desired mathematical model. For more on these concepts, see [3].

The starting points for our mathematical model are continuum descriptions of BHV leaflets and blood flow that have been previously validated in the contexts of static pressure loading of valves and flow through large arteries. However, mathematical models are only valid under limited ranges of conditions, which may or may not include BHV FSI. Very little work has been done on validating mathematical models of BHV FSI.

Numerical approximation of mathematical models for fluids, structures, and FSI are well-studied topics, but the problem of BHV FSI introduces challenges that make it at best inconvenient to study using "off-the-shelf" technologies. Aspects that make the problem especially difficult include similarity of fluid and structure densities, large structure deformations, and changes in fluid domain topology. Due to these difficulties, we participate in an interdisciplinary research effort, collaborating with applied mathematicians and computational engineers to develop and verify novel numerical methods for FSI analysis that combine immersed boundary [4] concepts and isogeometric analysis [5] to allow for maximal flexibility in simulation workflow, without sacrificing modeling capabilities.

METHODS

We propose to model the structure displacement and fluid velocity fields as solutions to coupled partial differential equations (PDEs), using the framework of continuum mechanics. We model the fluid (be it blood or the working fluid of an *in vitro* experiment) as incompressible and Newtonian. We model the BHV leaflets using Kirchhoff-Love thin shell theory. These sub-problems are coupled by standard kinematic and dynamic compatibility conditions. Aside from the use of continuum mechanical assumptions widely held to be valid for predicting macroscopic deformation of bulk materials, we have introduced the following (possibly invalid) assumptions:

- The BHV leaflets are modeled geometrically as surfaces of co-dimension one to the surrounding fluid domain.
- The BHV leaflet mechanics are represented using Kirchhoff-Love thin shell assumptions and a hyperelastic constitutive model.
- All fluids of interest are assumed to be incompressible and Newtonian.

The validity of these modeling assumptions needs to be tested. To this end, we have constructed a flow loop to pump water through an

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

artificial aortic valve. The flow loop is instrumented to collect ventricular and aortic pressures, volumetric flow rate and time-stamped images of the valve.

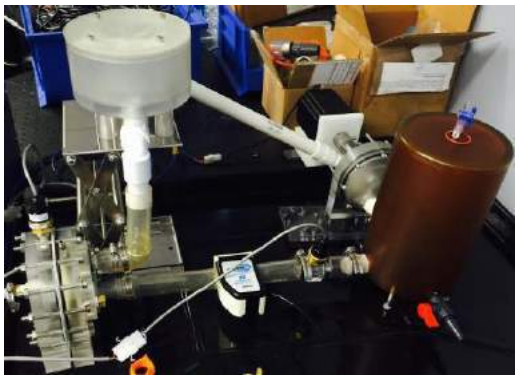

Figure 1: Photograph of the validation flow loop

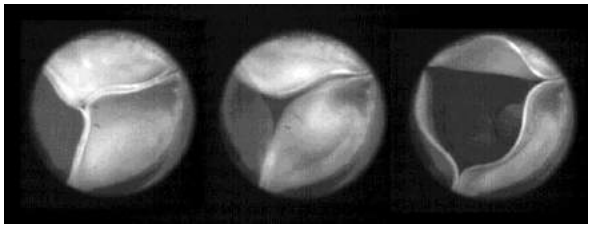

Figure 2: View of artificial valve in flow loop (contrast enhanced)

The measured flow rate can be prescribed as a boundary condition on the mathematical model and an approximate solution can be computed using a numerical method. Then the computed deformations of the leaflets and the computed pressure drop across the valve can be reasonably compared with the time-stamped images and measured aortic and ventricular pressures. Assuming that the numerical method has been sufficiently verified, this comparison tests the validity of the modeling assumptions itemized above, in the context of predicting leaflet deformation and net resistance to fluid flow.

Our numerical approach was introduced in [6]. In summary, we immerse a discretization of the structure into a non-matching fluid discretization. This allows for great freedom in the choice of fluid and structure discretizations and avoids the difficulties associated with generating discrete solution spaces that conform to FSI kinematics. Unlike the earliest immersed boundary methods [4], which used a spring network as a placeholder for the structure, we apply isogeometric analysis to the structure sub-problem, allowing for accurate treatment of shell structure mechanics with hyperelastic constitutive behavior [7].

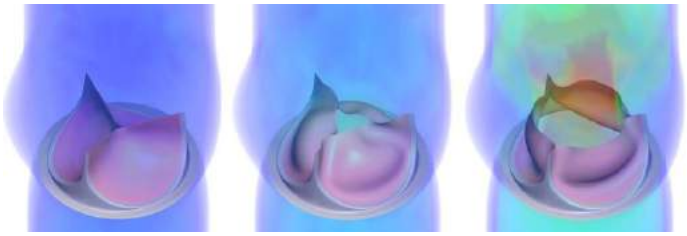

Figure 3: Example simulation results (reproduced from [9])

RESULTS

The validation study remains a work in progress. The majority of complete results contribute to the verification of the numerical method. In [6] we demonstrated that the numerical method could match solutions to benchmark problems computed using previously-verified methods. More recent, ongoing work on verification aims to derive *a priori* error estimates for linearized model problems and test convergence to analytical solutions.

As a preliminary validation, we can make comparisons between computations and existing experimental results from the literature, e.g. [8]. Many of the free parameters of our present model (e.g. the valve geometry, constitutive properties, flow boundary conditions, etc.) cannot be reliably determined from publications describing prior experiments, so no precise quantitative correspondence is expected. We nonetheless find that the qualitative features of the BHV dynamics are reproduced in approximate solutions to our mathematical model. Some of these features are conspicuously absent from models that employ only structural dynamics. In [9], we compared FSI computations, structural dynamics computations, and experimental results from the literature.

DISCUSSION

As noted in the previous section, preliminary comparisons of computational and experimental results indicate that our model of BHV FSI provides more accurate representations of BHV leaflet kinematics than models considering structural dynamics alone. We are, at present, conducting more rigorous verification and validation studies. Further verification will improve our confidence that computational results approximate solutions to the desired PDEs. New validation experiments will allow for more accurate estimation of the free parameters of these PDEs. These advances will render observed correspondences and/or discrepancies between computational and experimental results more meaningful.

INTRODUCTION

Shoulder arthroplasty is used to treat several common pathologies of the shoulder, including osteoarthritis, post-traumatic arthritis, and avascular necrosis [1]. In replacement of the humeral head, modular components allow for natural variability in shoulder anatomy, including retroversion and head-neck angles. Surgical options include anatomic cut or guide-assisted cut at a fixed retroversion and head-neck angle. The purpose of this study was to determine the variability between head height and anteroposterior (AP) and superoinferior (SI) diameters using anatomic and guide-assisted humeral head cuts.

METHODS

Computed tomography (CT) scans of 10 cadaveric shoulder specimens (5 male, 5 female; mean age 71 ± 14 years; 7 left) were converted to 3D models using medical imaging software. An anatomic humeral head cut plane was placed at the anatomic head–neck junction, maintaining the posterior cuff insertion for all shoulders by a fellowship trained shoulder surgeon. Cut planes were generated for each of the standard implant head neck angles (125°,130°,135°, and 140°) and retroversion angles (20°,30°, and 40°) in commercially available cutting guides, for a combination of 12 repeated virtual cut conditions per specimen. The humeral head height and the cut head diameter were measured in the AP and the SI planes for the anatomic and guide-assisted osteotomy planes. Differences were compared using a separate two-way repeated measures ANOVA for each dependent variable.

RESULTS

Guide-assisted cuts showed no significant effect on head height due to head-neck angle ($p=0.205$) or retroversion angle ($p=0.190$). These results persisted by gender (male: head-neck $p=0.659$ and retroversion $p=0.386$; female: head-neck $p=0.204$ and retroversion $p=0.190$).

SI head diameter increased by 1.3 mm with increasing head-neck angle ($p<0.001$), but there was no effect due to retroversion ($p=0.148$). A head-neck angle of 125° caused the greatest decrease in SI diameter of -2.8 mm compared to the anatomic cut, averaged over the retroversion range. The greatest reduction of SI diameter, -3.4 mm compared to anatomic, occurred with 125° head-neck angle and 20° retroversion. By gender, males showed a significant effect from head-neck angle ($p=0.008$), but females did not ($p=0.077$). There was no significant difference from retroversion in either gender group (male $p=0.792$; female $p=0.057$).

There was no significant difference in AP diameter by head-neck angle ($p=0.192$) or retroversion angle ($p=0.168$). These results persisted in the males (head-neck $p=0.420$ and retroversion $p=0.780$). In females, there was no effect from head-neck angle ($p=0.232$); however, retroversion angle trended toward significance ($p=0.050$).

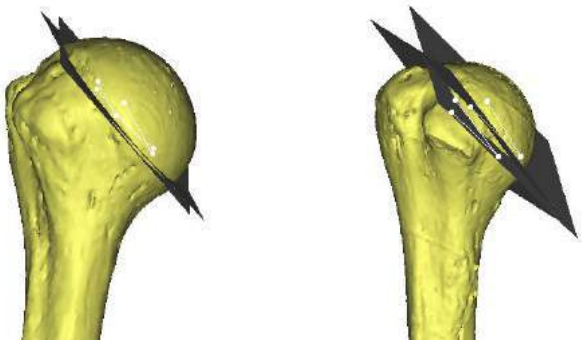

Figure 1: Three dimensional models created from CT scans to show comparison of the optimized anatomic cut and guide-assisted cut at the average cut plane (135 head-Neck angle and 30 Retroversion) between a patient with average anatomy (left) and anatomy falling outside the range of normal values (right) (125 Head-Neck angle and 60 Retroversion)

DISCUSSION

For patients whose natural anatomy falls outside the range of the commercial cut guides, resection according to the template may result in deviation from natural dimensions of the humeral head. Due to the large variability in anatomic retroversion and head-neck angles in the subjects of this study, further study with a larger sample size is needed to investigate if the observed trends persist. These preliminary results have implications for manufacturers to create guides to represent a larger segment of the population, and surgeons' choices in intra-operative planning

PRINCIPAL COMPONENT ANALYSIS OF FRICTION FORCE HYSTERESIS CURVES FOR DETECTING FATIGUE FAILURE AND GENERATING FRICTIONAL S-N CURVES FOR ARTICULAR CARTILAGE

INTRODUCTION

Osteoarthritis (OA) is a degenerative joint disease resulting in damage and eventual loss of articular cartilage. Cartilage swelling and collagen fiber realignment are well-characterized early hallmarks of OA, but OA etiology remains poorly understood and therefore early-stage treatments target pain management rather than underlying mechanisms. Other than in the case of blunt injury, causative factors for the *mechanical initiation* of cartilage damage and wear in OA remain unknown. Weakening of the collagen matrix may be attributable to the number of cycles cartilage endures in its lifetime, or fatigue failure [1], and may cause the tissue to fail in shear at the middle zone due to its low shear modulus [2]. In this investigation, we hypothesize that the onset of fatigue failure can be detected by examining the principal components of frictional hysteresis curves and that frictional stress correlates with the number of cycles to damage. This mechanical study utilized devitalized full-thickness articular cartilage to preclude the reparative or inflammatory action of chondrocytes.

METHODS

Sliding experiments were performed in which cartilage strips were tested against a glass lens in either synovial fluid (SF) or phosphate buffered saline (PBS) (Fig. 1). A range of loads and test durations were selected to elucidate the combined effect of lubricant, stress, and number of cycles on frictional force and cartilage damage.

Specimen Preparation: Cartilage strips (10 × 30 mm) were harvested from the tibial plateaus of knee joints of immature bovine calves (4-8 weeks old). Forty separate sliding experiments were performed on tissue collected from fifteen knees. Specimens were trimmed on a freezing stage sledge microtome to a final thickness of 1.5 mm ± 0.2 mm, removing underlying bone. Samples were stored in filtered PBS supplemented with biocide and a cocktail of protease inhibitors and frozen at −20 °C for no more than 3 weeks prior to testing. On the day of testing, samples were aligned and affixed via adhesive to the translating stage. Sliding Friction: A custom two-axis loading device with a six-degrees-of-freedom load cell was used for continuous measurements of specimen motion, deformation, and reaction loads as described previously [3,4]. Reciprocal sliding motion (±2.0 mm at 1 mm/s) under a range of applied loads (F_n, 4.5 – 35.6 N) was prescribed for a range of test durations (4 – 24 h). The radius of curvature of the glass lens was selected to best match the femoral condyle (12.7 mm).

Determination of Cycles to Failure: Tangential force (F_t) measurements were collected for each cycle and plotted against strip position (U_x), generating a family of hysteresis curves representing the frictional force at each reciprocating strip location. Principal Component Analysis (PCA) was performed on a per cycle basis by computing the covariance matrix of the F_t vs. U_x data and calculating its eigenvalues and eigenvectors. Magnitudes of the first and second eigenvalues were recorded and during post-hoc analyses a threshold was selected to identify the onset of damage and extract the parameter: number of cycles to damage, N. The threshold identifies an increase in the rate of change of the first eigenvalue relative to steady-state (cycles 10-20), and labels the earliest occurrence of this change as cycle N. To validate the

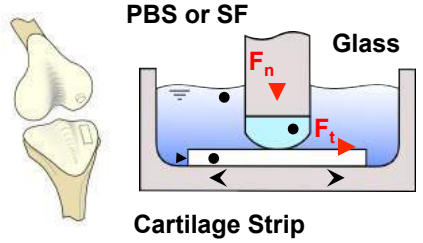

Figure 1: Cartilage strips are tested against a glass lens counterface in a bath of either PBS or SF. F_n is the applied normal force and F_t is the measured tangential force

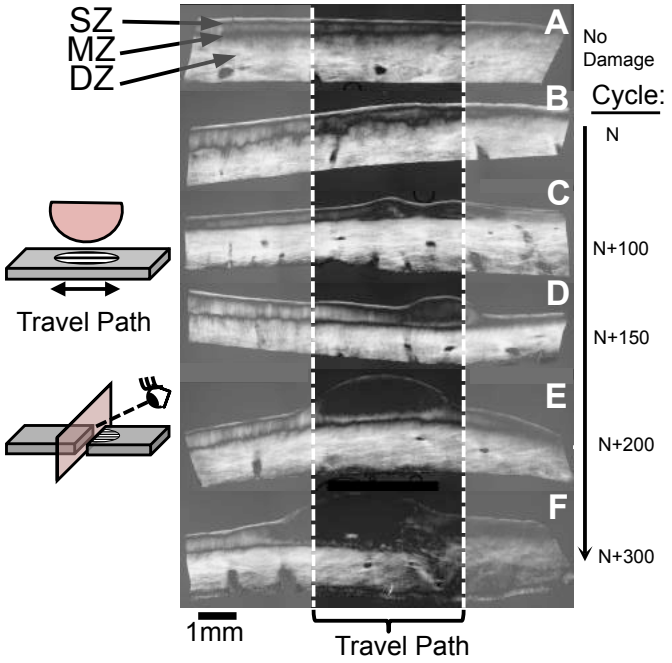

Figure 2: Polarized light microscopy depicting damage onset and damage progression in cross-sections taken through the travel paths of six strips halted mid-test at spaced intervals (*N*+*M*): (A) no damage (F_z = 4.4 N, SF, 2800 cycles) (B-F) damage (F_z = 4.4 N in PBS). Illuminated regions indicate collagen fiber alignment (SZ, surface zone; DZ, deep zone); dark regions indicate isotropic collagen organization (MZ, middle zone).

identification of damage onset, a subset of sliding experiments were halted mid-test at either *N* or at subsequent cycles, *N*+*M,* using real-time visualization of the hysteresis data. This was done in order to capture corresponding images of mid-test damage progression. Strips were sectioned (120 μm thick) and imaged under polarized light microscopy (PLM). Frictional S-N curve: Friction data were pooled from the experimental groups that resulted in visual damage to the strips (32 of 40 strips). The cycle friction coefficient μ was calculated from the ratio: avg. tangential force (F_t) / avg. normal force (F_n), for each reciprocating cycle. To encompass the entire response prior to damage, μ was averaged over the range: cycle 10 – cycle *N*. This average 'pre-damage' μ was then multiplied by the applied stress (F_n/A) to obtain the frictional shear stress, *S*.

RESULTS

The average contact area, *A*, between the glass lens and cartilage strip varied from 8.7 – 19.9 mm^2 for different loading conditions (yielding contact stresses over the range from 0.5 – 0.9 MPa). Experimental conditions that did not result in visual damage to the cartilage strip generated hysteresis curves that maintained their shapes over the course of the test (Fig. 3A). When visual damage to the strip was observed, hysteresis curves progressively rotated and elongated, with corresponding increases in magnitude of associated eigenvalues (Fig. 3B,D,F). Fig. 2 depicts corresponding snapshots of damage progression, which indicate that damage occurs via delamination of the middle zone. Strip B in Fig. 2B was stopped at cycle *N*, and though this strip showed no macroscopic signs of damage, PLM revealed a jagged MZ-DZ transition within the travel path. These results are complemented by the correlation found between frictional shear stress and *N* (R^2=0.33) (Fig. 4), which is in good agreement with the observed mode of failure. No other parameter (e.g. contact stress) was found to correlate with *N* ($R^2 < 0.12$).

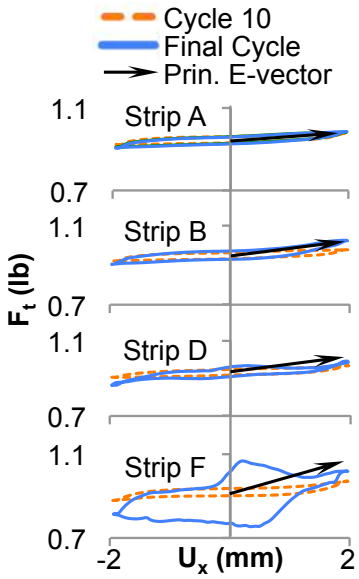

Figure 3: Hysteresis curves for four strips (A,B,D,F) depicting two cycles: cycle 10 (baseline) and the cycle at which the test was halted (final cycle). The final cycle corresponds to the respective strip in Fig. 2. The vectors represent the first principal eigenvectors of the final cycle which determined *N*.

DISCUSSION

The damage progression visualized in Fig. 2 was predicted using our method of hysteresis curve examination. This confirms the hypothesis that variations in principal components of hysteresis curves correspond to physical disruption of the tissue. At the earliest indication of damage (at *N*), strip B had no visible damage (Fig. 2B, 3B). This suggests that PCA of the frictional hysteresis curves detects not only visual tissue damage, but early mechanical breakdown of the sub-surface collagen network prior to the onset of macroscopic damage, highlighting the sensitivity of this method of determining *N*. On close examination of the strips (Fig. 2), there is an intensified bright signal in the fatigued MZ coincident with dark spindles extending into the deep zone, perhaps indicating the recruitment of fibers from the highly organized DZ to resist shearing and swelling of the MZ. The ability to accurately identify *N* for various cartilage loading configurations allows for improved fatigue failure characterization and more complete *S*-*N* curves that could serve as tools for predicting fatigue-life estimates. In separate, more physiologically representative experiments, cartilage plugs of different diameters are slid against strips and tested to damage in both PBS and SF. Determining both the *N* and *S*-*N* characteristic for this testing configuration are currently under development.

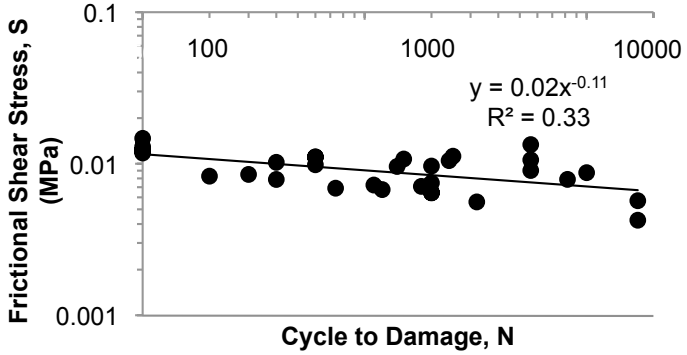

Figure 4: Fatigue curve (S-N) correlating frictional shear stress with cycle to damage. Data for thirty-two damaged strips is shown.

INTRODUCTION

The muscle-tendon-bone unit transmits contractile loads, developed in the muscle, through the tendon as a tensile load, into the bone to produce motion. The myotendinous junction (MTJ) connects the muscle to the tendon through a series of interdigitated extensions of the microstructure. The last collagen fibrils of the tendon extend into invaginations in the myofibers of the muscle and transmit loads through lateral contractions [1, 2]. The tendon-to-bone insertion is a functionally graded tissue that varies in collagen types, collagen orientation, and mineralization [3-8].

The tendon is a hierarchical tissue starting at the nanoscale with collagen molecules which aggregate into microfibrils which aggregate into fibrils which form fibers which collect to form fascicles which aggregate to form the tendon [8]. It is composed of collagen, proteoglycans, glycoproteins, water and cells [9]. The study of the muscle-tendon-bone unit is of importance because injuries of these tissues are common and they tend to heal slowly. Additionally, biomechanical properties are not restored to their original value after healing [9].Most studies focus on the uniaxial tendon properties aligne d with the primary load direction. There are few studies that consider the biaxial properties of the tendon [10, 11]. However, these studies consider one longitudinal and one transverse direction. To the best of the authors' knowledge, no previous studies have been conducted on the biomechanical properties of a cross-section of the tendon.

In this study we report stress-strain data for the tendon cross-section in various locations and relate the findings back to the biochemical composition.

METHODS

Porcine forelimbs of large sows were obtained from the local abattoir. The skin and fatty tissue surrounding the muscle-tendon-bone unit was carefully cleared away from the deep digital flexor tendon of the third digit. The tendon is removed via a cut near the tendon-to-bone insertion and a cut near the muscle-tendon junction (MTJ) (tendon branches for other digits are severed near the main tendon stem).

Biaxial Testing From each of these tendons, three cross-sections for biaxial testing were removed with two razor blades fixed together. One cross-section is extracted from the tendon proximal to the junction of flexor tendons (muscle-end, n=8), one cross-section from the middle of the third digit tendon (mid-tendon, n=9), and one cross-section from the distal end of the removed sample (bone-end) (n=6). Samples that were not large enough to mount in the testing apparatus were thrown out. The average thickness of the cross-sections was 0.79±0.20 mm. After removal from the forelimb, all cross-sections were stored in Hanks' Balanced Salt Solution (HBSS) at 4° C between dissection and testing.

The BioTester 5000 (CellScale Biomaterials Testing, Waterloo, ON, Canada) biaxial testing apparatus, equipped with a 0.5 N load cell in each axis of loading, was used to measure the force and displacement of the tissue samples. The built-in CCD camera is synchronized with the load cells and actuators and collected 1280 x 960 px images at a rate of 1 Hz. Force and displacement data were collected at a rate of 5 Hz and were used to compute stress and strain data. Each tested sample was mounted to the BioTester with four BioRakes each consisting of five tungsten tines spanning 4 mm in width. Testing was performed in a room temperature bath of HBSS. The dorsopalmar axis of the tendon cross-section was aligned with the x-axis of the BioTester and the mediolateral axis was aligned with the y-axis. A pre-load of 10mN was applied in both axes and this state was defined as the zero strain state. Each sample was pre-conditioned

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

equibiaxially with five successive triangular waveform to 10% true strain at a medium strain rate of 2%/s [12]. After pre-conditioning samples were rested at zero strain for 30 seconds to allow the tendon to relax. This rest duration was determined during preliminary testing to allow the tendon samples to return to a zero stress state. Finally, each sample was strained equibiaxially at 2%/s to a peak of 20% true train. Stress and strain curves are prepared from the collected force and displacement data. These curves are broken into three strain regions: 0-7.5% (low strain), 7.5-15% (medium strain), and 15-20% (high strain). An effective elastic modulus in each strain region was computed. **Statistical Analysis** All data are presented as the means ± the standard deviations. Differences in collagen concentration are tested using a single factor ANOVA. A Bonferroni multiple comparisons test with $p < 0.05$ was performed to compare the elastic modulus of the tendon samples between location and direction to determine if there is a variation in biomechanical property along the length of the tendon or any anisotropy within the cross-section. All statistical analysis was conducted using GLM in SAS 9.4 (SAS Institute Inc, Cary, NC, USA). A value of $p < 0.05$ was considered significant.

RESULTS

The biaxial testing results for the three locations (bone end, mid tendon, and muscle end) were used to produce stress versus strain curves presented in **Figure 1**. Maximum stresses at 20% true strain for the muscle end were 35.2±34.2 kPa in the x-direction and 36.9±51.9 kPa in the y-direction, for the mid tendon were 83.8±34.4 kPa in the x-direction and 92.0±52.1 kPa in the y-direction, and for the bone end were 142.2±85.7 kPa in the x-direction and 110.6±77.6 kPa in the y-direction. From these data, effective elastic moduli were computed for each of the previously mentioned strain ranges. Using a Bonferroni multiple comparisons test with $p < 0.05$, it was determined that the bone end of the tendon is stiffer in all regions of strain than the muscle end of the tendon. No differences between the bone end of the tendon and the mid tendon were detected. And the muscle end of the tendon was only more compliant in the larger strain range (15-20%). No differences were detected between the x- and y-direction stiffnesses in any strain range or location.

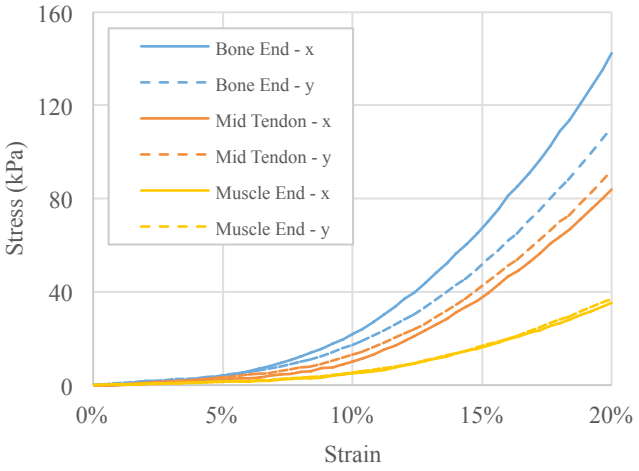

Figure 1: Average stress versus strain response for tendon cross-sections collected from the bone end (blue, n=6), the mid tendon (red, n=9) and the muscle end (purple, n=8). The tendon cross-section tends to be more stiff toward the bone end and more compliant toward the muscle end. No dramatic transverse anisotropy is apparent.

CONCLUSION

The current study, to the best of the authors' knowledge, is the first to provide stress-strain data for the cross-section of the tendon. This equibiaxial testing was performed at three locations along the porcine deep digital flexor tendon and a variation in stiffness was observed. Additionally, we report the collagen concentration in these same three regions, however, observed no variation. The result of this study will be furthered by expanding the locations and orientations tested along the muscle-tendon-bone unit in an effort to improve the understanding of its unique structure and to aid in tissue engineering repair techniques.

INTRODUCTION

Although medical image-based computational fluid dynamics (CFD) has been extensively used as a research tool for years, it was not until recently that CFD has finally come to the crucial point of rapidly growing into a clinical tool. In an increasingly wider range of medical applications, various home-grown and commercial CFD packages are finding themselves having the potential of becoming either a clinical diagnostic tool, as in the case of HeartFlow® [1], or as a validation tool of new medical devices as outlined by the FDA "Critical Path Initiative" [2]. However, before such potential can be realized, it is critical that the CFD solver be thoroughly verified and validated. Still, a big hurdle in the CFD solvers making this historic transition is the lack of systematic guidelines for proper validation.

Therefore in this study we present an application of the guidelines from the ASME Verification and Validation 20 (V&V 20) document [3] to systematically validate CFD solvers. The CFD solver used for research at our center is the commercially available package STAR-CCM+ (v10.02, CD-adapco, Melville, NY), which is a widely used software that allows seamless access to all the components of the CFD model under a single integrated platform. We use 2D Particle Image Velocimetry (PIV) on an intracranial aneurysm (IA) model to collect experimental data and demonstrate the validation procedure.

METHODS

We used a patient-specific internal carotid artery aneurysm geometry reconstructed from a three-dimensional digital subtraction angiographic image for experimental and computational calculations. For experimental analysis, the flow field of a transparent silicone phantom model was analyzed under a physiologic pulsatile waveform using PIV. The fluid had blood mimicking properties with density and viscosity of 1234 kg/m^3 and 4.03 cP respectively. The index of refraction of 1.42 of the fluid matched that of the phantom so that there was no optical distortion. The fluid was comprised of 47% water, 37% glycerol and 16% NaI by weight and was seeded with neutrally buoyant particles.

The phantom was placed in a pulsatile flow loop with flow rate of 256 mL/min. Velocity magnitude in two orthogonal central planes was calculated using a LaVision system with a Nd:YAG laser with a wavelength of 532 nm. Data was acquired on these 2D planes at 40 time-points in a cardiac cycle which was monitored and triggered using an in-house LabView code (National Instruments, Austin, TX).

For computational analysis, the experimental phantom was imaged using Toshiba Infinix C-arm machine and a 3D model was reconstructed. The reconstructed geometry was volumetrically meshed using polyhedral elements with four prism layers at the wall using STAR-CCM+. The fluid density, viscosity, flow rate, and the pulsatile inlet waveform were all taken from the experimental data. We assumed a no slip boundary and rigid walls. Second-order temporal and spatial discretization schemes were used to solve the transient Navier-Stokes equations.

As shown in Figure 1, following the ASME V&V 20 guidelines, the model error, δ_{model} was calculated as:

$$\delta_{model} = E \pm u_{val} \quad (1)$$

where E is the difference between experimental, D, and simulation, S results:

$$E = S - D \quad (2)$$

and the model uncertainty, u_{val} is:

$$u_{val} = \sqrt{u_{num}^2 + u_{input}^2 + u_D^2} \quad (3)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the root sum square of u_{num}, the numerical uncertainty, u_{input}, the input parameter uncertainty, and u_D, the uncertainty in the experimental data.

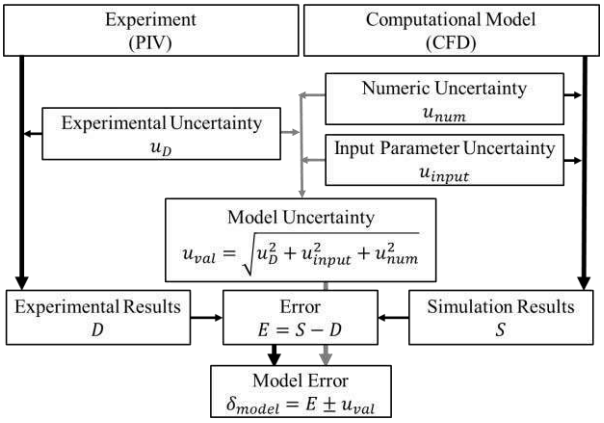

Figure 1: Workflow for calculation of model error and uncertainty adopted from ASME V&V 20.

Briefly, u_{num} , the uncertainty of the simulation due to spatial and temporal discretization, is calculated based on a series of systematically refined grids. We tested a series of four simulations with meshes ranging from 54k to 842k elements. The input parameter uncertainty, u_{input}, is the error of the simulation due to the uncertainties in measurement of input parameters. We analyzed the uncertainty due to the input parameters density, viscosity, flow rate, and period, where the systematic uncertainty was derived from experimental measurements. We also evaluated the fractional contribution of each parameter to input uncertainty by calculating Importance Factor (*IF*) [3], which is defined as the reciprocal of ${u_{input}}^2$. Experimental uncertainty, u_D, was quantified from PIV experiments and was dependent on several factors including background noise, out-of-plane particle motion, camera focus, and non-homogenous particle seeding density. The uncertainty calculation was based on the correlated statistics [4], and calculated in the LaVision software.

In both computational and experimental analyses, the quantification of uncertainty was based on velocity magnitude and evaluated on a 1D line at the intersection of two orthogonal planes.

RESULTS

Figure 2 shows a comparison of PIV and CFD results. The flow patterns for cycle-averaged velocity magnitude contours and vectors match remarkably well as both the location of the impingement jet (in the right of the aneurysm domain) and vortex (center) are captured by CFD and PIV analyses.

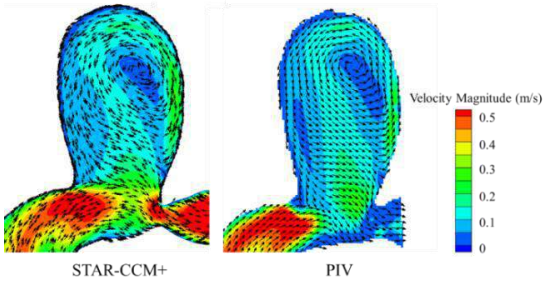

Figure 2: Cycle-averaged velocity magnitude contours with velocity vectors on the center plane of the IA for CFD simulations from STAR-CCM+ (left) and PIV experiment (right).

Figure 3 shows the computational and the experimental results of velocity magnitude along the 1D line. The uncertainty is represented by the error bars. The average numerical uncertainty and input parameter uncertainty along the 1D line was found to be 8.8% of the velocity magnitude. The largest contribution to input parameter uncertainty was from flow rate with an *IF* of 2.38 x10^{-2}, which was three orders of magnitudes higher than other input parameters. Additionally, the average experimental uncertainty was found to be 9.8% of the velocity magnitude. This resulted in the culminating model error, δ_{model} to be 2.0 ± 1.0 cm/s on average. The highest uncertainty and error occurred nearer to the impingement jet (normalized distance = 0.9).

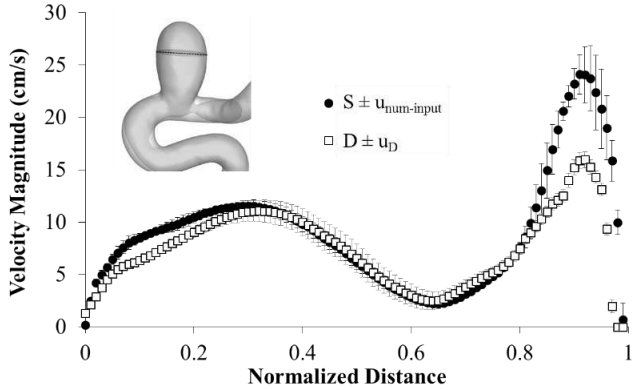

Figure 3: Quantitative results of computational (S, black) and experimental (D, white) results and uncertainty of velocity magnitude. Uncertainty is indicated by the error bars.

DISCUSSION

In this study, we have shown a comprehensive approach for the validation of commercial CFD solver STAR-CCM+ by utilizing the guidelines of ASME V&V 20. Through the analysis of PIV and CFD datasets we have assessed error and quantified uncertainty for flow in an IA model. The value of model error shows that the range of error in velocity in the model is 1-3 cm/s in the IA model, which is small as compared to the average velocity in the flow domain. This indicates that STAR-CCM+ CFD solver performed very well in this context.

To the best of our knowledge, this is the first study to validate a CFD solver in the vein of IAs. The framework in this study has validated a CFD solver by quantifying errors and uncertainties. This quantification of uncertainty can potentially dictate the context of use of the CFD solvers in medical application in the future.

INTRODUCTION

Surgical sutures are thread-like pieces of material which hold tissue together so a wound will heal properly. Absorbable sutures are designed to degrade in the body as the tissue heals, eliminating the need to have sutures removed.[1] The location of a suture within the body and the type of suture influence the rate at which the suture dissolves. Three common types of absorbable sutures are Monocryl, a monofilament synthetic (poliglecaprone 25) fiber, Vicryl, a braided multifilament synthetic (polyglactin 910) fiber, and Chromic Gut, a natural monofilament fiber. Absorbable sutures are regularly used in oral and pharyngeal surgery where they are exposed to saliva which contains enzymes to break down food. However, little is known about how these digestive enzymes affect suture dissolution. The goal of this study was to compare the degradation of suture strength in saline and artificial saliva to help doctors make more informed decisions when selecting sutures for use in oropharyngeal surgery.

METHODS

Samples of Monocryl (n=90), Vicryl (n=90), and Chromic (n=90) 3-0 sutures were tied with a surgeons knot into loops approximately 10 cm long by the same head and neck surgeon. The loops were connected into groups of six in series using c-clips, so that one set could be easily removed and tested at each time point. Each group of sutures was woven between six nylon rods on a custom-built apparatus and held in tension with a 100g weight, such that each suture had an equivalent load. Each apparatus was loaded with seven groups of sutures of each type and submerged in an aquarium containing either phosphate buffered saline (median pH 7.25) or artificial saliva[2] (median pH 6.24) at 37° C. The artificial saliva was a salt solution containing α-amylase, a d igestive enzyme, lysozyme, a b acteriocidal enzyme, acid phosphatase and lubricating mucins to simulate the oral environment. Solutions were changed every 3-4 days.

Six samples were removed from the solution at regular time intervals (every 3 days for Monocryl, every 4 days for Vicryl and Chromic) for testing. The breaking force was determined by pulling samples to failure using an Instron machine at 30 mm/min.[3] The diameter and the dry mass of each suture were also measured after failure. Six samples of each suture type were pulled to failure after knotting but before being submerged as a control group to provide baseline values for comparison. Percent strength at each time point was then calculated by dividing the average breaking force at each time point by the average breaking force of the control group for each suture type. A two sample t-test was performed between the breaking force of sutures soaked in saline and sutures soaked in saliva at each time point, with a significance level of 0.05.

RESULTS

Monocryl degraded the fastest, reaching 50% of its original breaking strength after 11 days in both environments (Fig. 1a). Vicryl and Chromic, when soaked in saliva, reached 50% of their initial breaking strength after 18 and 26 days, respectively (Fig. 1bc). In saline neither Vicryl nor Chromic reached 50% within

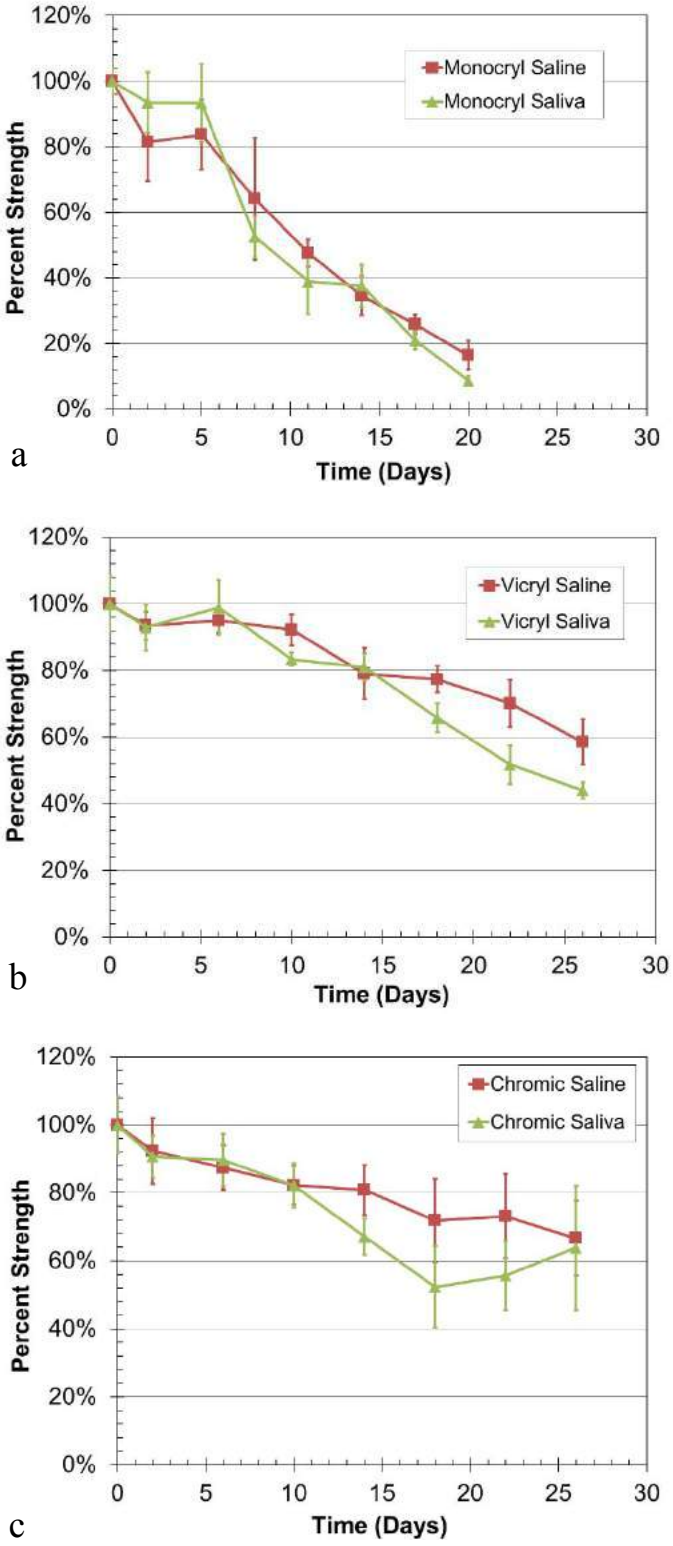

Figure 1: Average percent of initial breaking force of knotted (a) Monocryl, (b) Vicryl, and (c) Chromic sutures illustrating the decrease in knot strength relative to the control over 26 days.

the 26 day testing period. The saliva did not cause degradation to begin at an earlier time, but rather enhanced the amount of degradation once the suture strength began to decrease. The average breaking strength of Monocryl and Vicryl in saliva was significantly less than in saline (by 18-47% and 15-26%, respectively) for time points greater than 10 days (except day 14). The average breaking strength of Chromic in saliva was significantly less than in saline (by 17-27%) for days 14-22, but not day 26 (the final testing date).

DISCUSSION

All three types of absorbable sutures lost strength at a faster rate in saliva than in saline (which is assumed to simulate a normal physiological environment). There have been limited previous studies of suture degradation in saliva, and those studies did not load the sutures and used different saliva formulations.[4-5] Despite the differences in testing methods, the results of those studies also showed significant increases in degradation rate of sutures in saliva versus saline, although they also showed greater degradation in saliva at earlier time points.

The results of this study could influence surgeon selection of sutures for use in the oral environment to ensure that the suture degrades at an appropriate rate to allow effective healing of the wound. Further investigation will include identifying which saliva components are responsible for increasing the suture degradation rate.

ACKNOWLEDGEMENTS

This project was funded by a Bucknell-Geisinger Research Initiative Grant. LER was funded by the Bucknell Program for Undergraduate Research. The authors would like to thank Dr. David Schoepf in the Physics Department at Bucknell University for providing the weights used to load the sutures in this study.

INTRODUCTION

Fragility fractures due to osteoporosis stand as the most frequent cause of hospitalization and death in the US population for adults over age 65. One of every two women will sustain a fragility fracture after age 50 and the most common and often debilitating fracture is in the femoral neck [1]. During hip fracture fixation surgery, a Kirschner (K-) wire is used as a guide for a permanent screw (Figure 1). Anecdotal surgical evidence suggests that K-wire extraction force may be indicative of bone health at the site of repair; however, the correlation of this force metric to bone quality has not been explored. Another recently developed technique for mechanical assessment of local bone quality is reference probe indentation (RPI), where a small probe is cyclically pressed into the bone surface in vivo [2]. The current clinical approach for quantifying bone health is bone mineral density (BMD) inferred from DEXA scans. The goal of this study is to evaluate screw extraction and RPI as potential clinical measures of local bone quality during hip fixation surgery by investigating correlations between these mechanical measures of bone health and BMD.

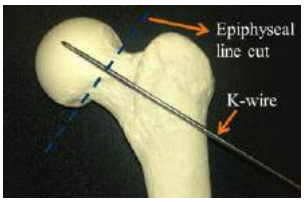

Figure 1: Location of cut to prepare for K-wire insertion into central-femoral head for pullout force testing.

METHODS

Trabecular bone samples from the femoral head (hip) and medial knee condyle (knee) of three bovine and ten porcine femur specimens and from the hip of eighteen excised human specimens from hip arthroplasty were tested. K-wires were inserted at five locations in each trabecular bone sample (Figure 2) and the peak screw extraction force was measured during extraction using the Screw Pullout Testing (SPOT) device modeled in Figure 3.

Each sample was then tested using reference probe indentation (Active Life BioDent Hfc; 25 indents, 10 indentation cycles at 2Hz with 2N peak load) (Figure 4). Loading slope (LS, measure of stiffness) and indentation distance increase (IDI, measure of fracture resistance) were determined for each indent.

Bone samples were then cut into the largest possible rectangular prism, measured to determine volume, dried, and ashed in an oven at 800ºC for 8 hours [3] to physically measure the BMD. The correlations between peak screw extraction forces, as well as indentation parameters of LS and IDI, to BMD were then determined.

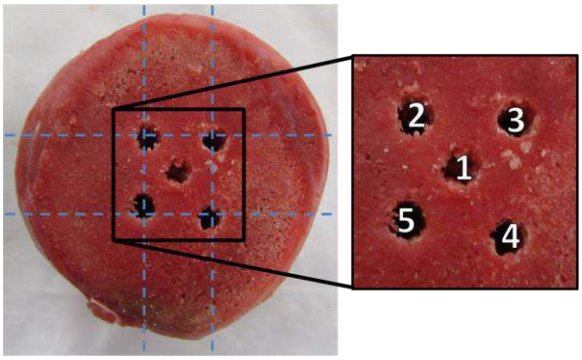

Figure 2: Each specimen was tested in five locations including the center of the bone as well as corners intersected by a superimposed 3 x 3, nine-quadrant grid.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

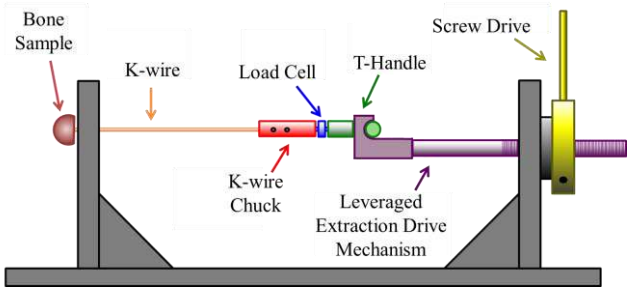

Figure 3: The K-wire was manually extracted from the bone specimen using a SPOT device. The peak extraction force could be used as a measure of bone quality.

Figure 4: Active Life BioDent Hfc reference probe micro-indenter (left) with indenter positioned on trabecular bone for testing (right).

RESULTS

The porcine, bovine, and human bone samples covered a range of BMD from 0.19 to 0.58 g/cm^3, which covers the healthy range of human trabecular bone (0.2 to 0.4 g/cm^3) [4]. Median peak extraction force values range from 250 to 1360 N. A very strong positive correlation (r = 0.88) was observed between median extraction force and BMD, suggesting that extraction force may be related to localized bone density (Figure 5). In contrast, IDI and LS exhibited only moderate correlations with BMD (r = -0.55 and 0.56 respectively) (Figure 6), possibly because micro-indentation is influenced more by bone quality at the indentation site than the overall architecture of the sample which has been shown to have significant influence in bone's resistance to fracture [5]. Currently there is no direct, mechanical method to quickly assess bone quality at a particular anatomical location like at a site of fracture. While DEXA is the most common means to measure BMD, these scans often fail to account for the overall quality of the bone [6], which may better predict fracture risk, and are not able to look locally at a fracture site.

DISCUSSION

This study investigated two potential direct measures of bone health which could be deployed in the operating room, in vivo, to measure bone health directly at the site of fracture, potentially affording the option to influence post-operative or other follow-up care. K-wire extraction forces showed much stronger correlation to BMD than reference probe indentation parameters, suggesting that K-wire extraction force may be a more useful measure of bone quality at the site of femoral neck fracture which is already known to correlate to fracture risk [7]. A similar experiment of the extraction vertebral pedicle screws also supports the validity of such testing, though K-wire extraction is already a harmless component of a fracture repair [8]. However, the variation in measurements within each sample must be further investigated to enhance the clinical value of a single screw extraction force to assess localized bone quality.

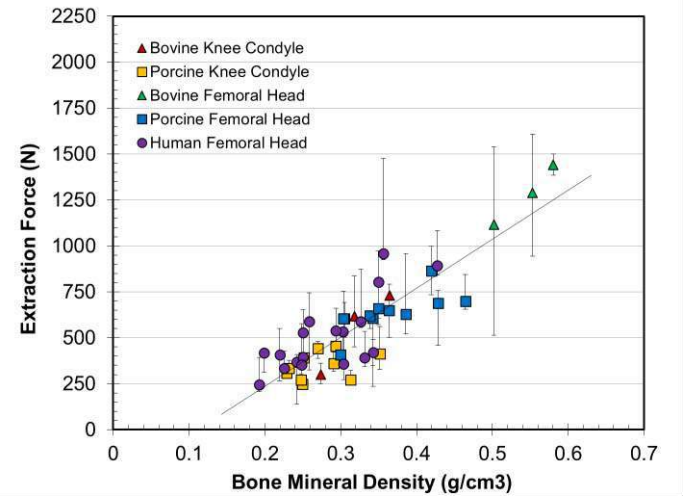

Figure 5: Median K-wire extraction force vs. BMD for all bone specimens with interquartile range error bars.

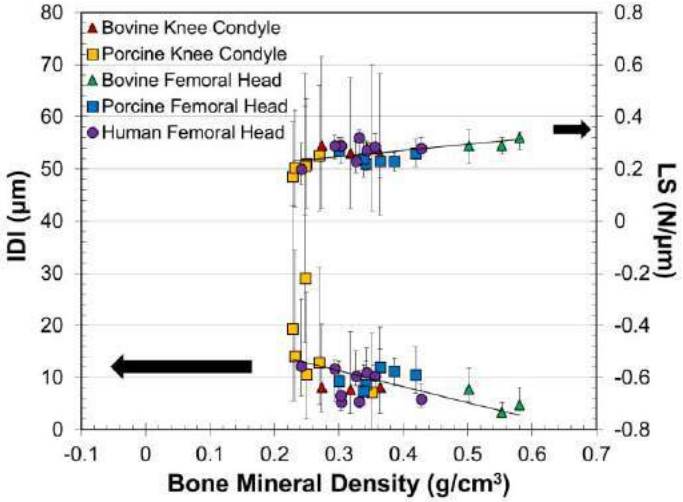

Figure 6: IDI and LS vs. BMD with interquartile range error bars.

The knowledge of localized bone quality could then help to determine how best to proceed with therapy after surgery and reduce overall complications. Additionally, future work will concentrate on investigating relationships between the mechanical metrics and BMD within osteoporotic bone to determine the best mechanical measure of bone quality with clinical relevance in predicting future fracture risk.

INTRODUCTION

The Blood-Brain Barrier (BBB) is formed by the endothelial layers, in which there are tight junctions that allow minimal transport from the blood to the extracellular fluid. To investigate the primary source of LDL transport, one study compared contributions of vesicles by examining paracellular transport through "breaks" in the tight junction and "leaky" junctions found in dying or dividing cells as illustrated in Figure 1.

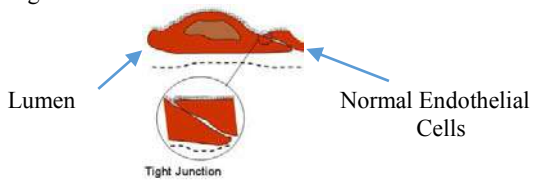

Figure 1: Tight junction break between Endothelial Cells (ECs)

This examination was accomplished by measuring water, albumin and LDL fluxes through Bovine Aortic Endothelial Cell (BAEC) monolayers in vitro. Tarbell et al. [1], assessed that the majority of transendothelial transport was accomplished through leaky junctions in dying or dividing cells. Bingmei Fu et al. [3], created a model to analyze time dependent intermediate-size solute transport in the interendothelial cleft of frogs, in an effort to interpret tracer labeling in this region. They variated the pressure in the vessel lumen from 0 cm to 30 cm H_2O. Concentration distribution was analyzed in three cases: in the cleft, along the cleft exit, and along the cleft exit with a varying ratio of diffusivity in the tissue to free solute diffusivity. The first case only allowed them to conclude that the model does not preserve upstream profiles, but the second case showed concentration levels at Δp= 30 cm H2O almost three times that of when Δp= 0 cm H2O, yet there is no visible HRP trail. In the third case, at Δp= 0 cm H2O, trails of HRP that contained 30 percent of the perfusate is not detectable. Cheng Wang et al. [2], details the electroosmosis effect in pressure-driven two phase fluid-flow microchannels containing aqueous NaCl and aqueous glycerol. A varying electric field was applied to the NaCl side, and using the fluorescence imaging technique, the interface position between the two fluids was examined. Afterwards they implemented the micro-PIV technique to measure the velocity field. Under normal pressure-driven flow in the microchannel, NaCl occupies a smaller portion of the channel because it is less viscous. When a negative electric field is applied, causing the NaCl to flow against the pressure driven flow, the aqueous NaCl moves slower and thus occupies a larger width in the channel; likewise, when a positive field is applied in the direction of the pressure driven flow, the NaCl moves faster, occupying a smaller width [2]. The present study hypothesizes that the use of transcranial Direct Current Stimulation (tDCS), a stimulation technique that energizes the extracellular fluid, and possibly other electrical stimulations could aid in transendothelial transport through electro-osmosis. Using modeling software from COMSOL 5.2, a basic localized model of the endothelial layer was created to mimic the passage of blood through a vessel and to investigate the effect of applying an electric field across this layer. The simulated model and the geometry used in this study are depicted in Figure 2 in order for better understanding on what is going on the present study.

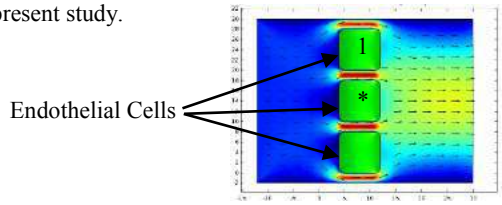

Figure 2: Geometry and simulation of the ECs and the fluid flow

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

METHODS

This study uses a very first electro-Fluid-Structure-Interaction, simply called (eFSI) model to inspect the behavior of the BBB under an applied electric field and compare it to the case when there no electric field applied. We examined the localized model in two cases: fluid-pressure flow, and fluid-pressure flow with an accompanying electric field. First, by applying an induced velocity profile as an inlet, we measured flow and Von Mises stress applied to the cells without any applied electric field. Here, the fluid flow is described by an incompressible Navier-Stokes equations for the velocity field, where $\mathbf{u} = (u, v)$, $\mathbf{u}_m = (u_m, v_m)$, and the pressure, p, in the spatial (deformed) moving coordinate system is stated in equations (1) and (2), respectively.

$$\rho\frac{\partial \mathbf{u}}{\partial t} - \nabla.[-p\mathbf{I} + \eta(\nabla\mathbf{u} + (\nabla\boldsymbol{u})^T)] + \rho\big((\mathbf{u} - \mathbf{u}_m).\nabla\big)\mathbf{u} = \mathbf{F} \quad (1)$$

$$-\nabla \cdot \mathbf{u} = 0 \quad (2)$$

Where, $\mathbf{I}$ denote the unit diagonal matrix and $\mathbf{F}$ is the volume force affecting the CSF flow. It is assumed that there is no gravitation or other volume forces affect the axoplasm, so that $\mathbf{F} = 0$. At the channel entrance on the left, the flow has fully developed laminar characteristics with a parabolic velocity profile but its amplitude changes with time. At first, flow increases rapidly, reaching its peak value at 0.3s as depicted in Figures 3 and 4; thereafter it gradually decreases to a steady-state value of 0.005cm/s. The velocity in the x direction, u_{in} with the steady-state amplitude U comes from the equation (3);

$$\boldsymbol{u}_{in} = \frac{U.t^2}{\sqrt{(0.04-t^2)^2+(0.1t)^2}} \quad (3)$$

Where, t is the time expressed in seconds and U is the mean velocity at steady state and is equal to 0.3[cm/s] due to a very small movement of the fluid inside the model. Afterwards, we applied both electric field and the velocity profile induced flow as an inlet. An electroosmotic induced flow was simulated by using COMSOL Muliphysics 5.2 (Palo Alto, CA 94304 USA) Software. Therefore, a very first novel steady state electro-Fluid-Solid-Interaction (eFSI) numerical analysis performed in order to investigate the effects of the applied electric field on the axoplasm fluid and thereby the stress as well as FSI interactions between MTs and the tau connections. The geometry is meshed using extremely fine mesh for the fluid dynamics analysis and the process of simulation was done within 11min and 4 secs in order to get the final eFSI results. The dimensions of each part of the model is illustrated in Table 1 and the final results are depicted in Figures 3 and 4 to be scrutinized in the Results section as well as discussed properly in the discussion section, respectively.

Dimension	Width (μm)	Height (μm)
Endothelial Cells (Squares)	8	8
Channel	42	32
Fillet Radius on ECs	r =0.1 (μm)	

Table 1: Information of the model [1,3]

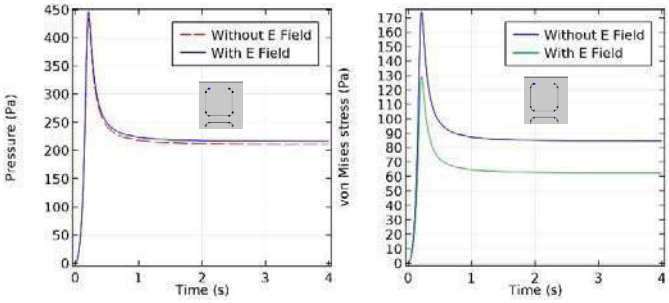

Figure 3: **Pressure and Von Mises stress changes of the upper EC as labeled in Figure 2 by 1**

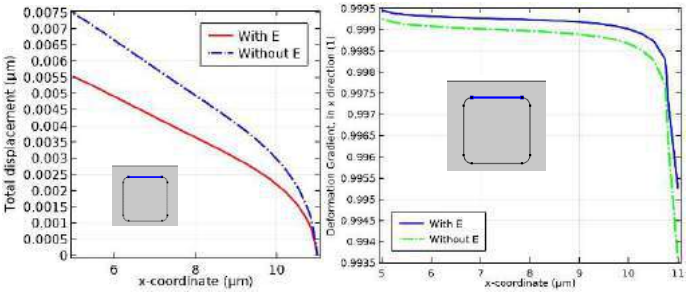

Figure 4: **Total displacement and deformation gradient changes of the middle EC as labeled in Figure 2 by** *

RESULTS

The results demonstrated that the applied electric field in conjunction with the induced velocity affect the endothelial cells. The results of this study also revealed that the pressure and Von Mises stresses on the ECs are reduced when the whole channel is subjected to an applied electric field as depicted in Figure 3. The analysis of this paper was based on the coupling of electromechanical and FSI in direct relation with fluid mechanics' theories. Specifically, by looking at Figure 4, where the deformation gradient on the middle EC is significantly influenced by the applied electric field, it can be found that the applied electric field decreased the amount of the total displacements of the cells while significantly reduces its total deformation gradients.

Finally, by looking at both ECs and the fluid flow through the endothelial cells, this study showed that an applied Electric field can affect the BBB.

DISCUSSION

This study was the analysis of a simplified and localized model of the endothelial monolayer and the passage of fluid through tight junctions, yet it was the very first of its kind. In the analysis of both regular fluid flow and fluid flow with an applied electric field, we found conclusive results suggesting that electrical stimulation may aid in transendothelial transport. To further the applications of this investigation, it is essential to build a more accurate and comprehensive model, even if that requires greater localization. As shown in Figure 1, the endothelial layer is composed in more irregular shaping than the model used in this study. Therefore, the model would benefit from the use of slightly more trapezoidal endothelial cells in order to mimic the tight junctions. Furthermore, this study would benefit from the scrutiny of transendothelial solute transport aided by an electric field, rather than speculating simply the fluid flow. While aided fluid flow provides the possibility of the electric field contributing to solute transport, it is important to more closely examine the effects on solute transport in order to begin using tDCS for transendothelial permeation.

INTRODUCTION

Application of physical loading, such as compression, tension and pressure for tissue engineering of replacement tissues has been widely investigated in many tissues/organs. However, one challenge to these cultures is the relatively low-throughput nature of loading bioreactors. Intervertebral disc (IVD) experiences tensile and compressive loads and hydrostatic pressure during locomotion. This dynamic hydrostatic loading has been shown to stimulate cellular biosynthesis [1], and may be essential for disc tissue maturation [2]. On the other hand, non-physiological levels of loading have been implicated as a contributing factor to alterations in tissue biology and biomechanics, leading to IVD degeneration (DD) [1, 3]. Therefore, a need exists to develop high throughput hydrostatic pressure bioreactors that can optimally simulate the proliferation and biosynthetic activity of disc cells *in vitro* for tissue regeneration. Culturing disc cells in a 3D environment has been shown to be crucial for cell mechano-transduction and simulate extracellular matrix (ECM) remodeling [4]. Static hydrostatic pressure in magnitude of 0.1-0.35 MPa inhibits proteoglycan synthesis but stimulates collagen synthesis in NP cells [5], whereas, application of dynamic pressure led to increased proteoglycan and collagen synthesis [6]. The goal of this study is to examine the effects of dynamic HP on bovine nucleus pulposus cells cultured in alginate beads using a novel high throughput bioreactor, where individual beads in multiwall plates are exposed to controlled dynamic HP. We hypothesize that both hydrostatic pressure treatment and 3D environment will promote disc like ECM expression and synthesis.

METHODS

NP Cell Isolation: NP tissue was isolated from young bovine lumbar discs. Cells were expanded for 1-2 passages in DMEM+10% FBS, and cultured in 1.2% alginate beads to promote round 3D morphology. **Hydrostatic loading:** During the loading regime, NP alginate beads from static and HP treated group were cultured in a 12 well tissue culture plate, though the system allows for 96-well or 384-well plate formats. The HP treated group plate was placed in Instron TGT hydrostatic pressure chamber (Figure 1) attached to an Instron servo hydraulic tension/compression system (Instron). Briefly, the bioreactor device is a sealed aluminum chamber that fits standard tissue culture multi-well plates. In order to apply hydrostatic pressure to samples within the bioreactor chamber, incubator air is compressed using a continuously running scroll compressor and, subsequently, pumped into the bioreactor chamber via a temperature controller that maintains the temperature of the compressed air at 37°C, creating a gas–liquid interface with a pressurized gas phase on top of a liquid medium phase [7]. A vacuum is generated to remove the gas phase from the bioreactor chamber and direct the air back into the incubator where it is reused for the stimulation process. The stimulation regime is controlled by system accompanying software (GrowthWorks, Instron TGT) that enables the application of sinusoidal waveforms with frequencies between 0.0001 and 2 Hz and a pressure range between 0 and 600 kPa. In addition, this software also enables continuous stimulation regimes. For this study, static group was placed in the same incubator as the HP treated group. The HP treated group pressure ranged from 0 to 0.1 MPa at 0.1 Hz for 2 hours daily for 7 days. All the samples were placed in a cell culture incubator for rest of the time. Mechanical stimulation was not applied until 24 h of culture to allow the cells to acclimate to their environment. **Live/Dead Staining:** On Day 8, the cell culture beads were collected and stained with 10 µM Calcein AM and 2 µM ethidium homodimer (Sigma) and imaged on a confocal microscope. **Viability assay:** On Day 8, cell viability was assessed for static and HP treated cell culture beads based on quantification of the ATP present, using CellTiter Glo 3D viability

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

assay (Promega). **RT-PCR:** On Day 8, mRNA was extracted from static and HP treated cell culture beads and analyzed for ECM genes: aggrecan, collagen II, collagen I and GAPDH as housekeeping gene.

RESULTS

Cell viability with live/dead staining showed nearly 100% viability in both static and HP treated groups, as observed in Figure 2. Assessment using the CellTiter Glo assay demonstrated no significant changes in ATP activity in both static and HP treated groups (Figure 3). Relative mRNA of HP treated group exhibited a statistically significant up-regulation of matrix protein, aggrecan on day 8 relative to static group (Figure 4). In both, HP treated and static groups, collagen II and I levels did not change significantly.

Figure 1: Instron TGT hydrostatic bioreactor chamber

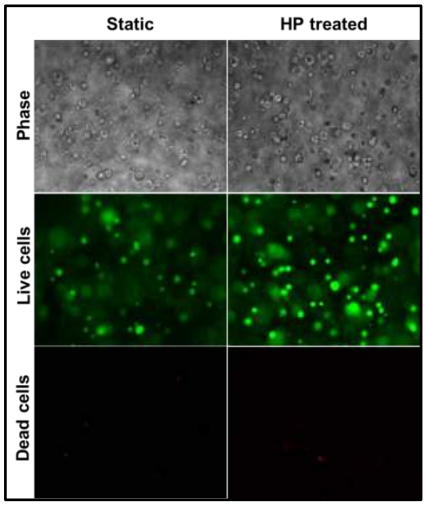

Figure 2: Viability was assessed using Live/dead staining and showed no significant differences between groups, with the majority of the cells stained green indicating high viability.

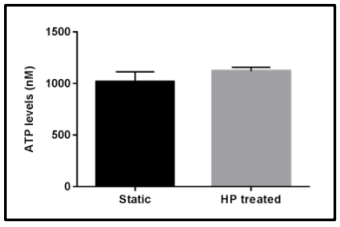

Figure 3: ATP activity was assessed using CellTiter Glo 3D viability assay and showed no significant differences between groups, showing that HP treatment does not affect cell viability.

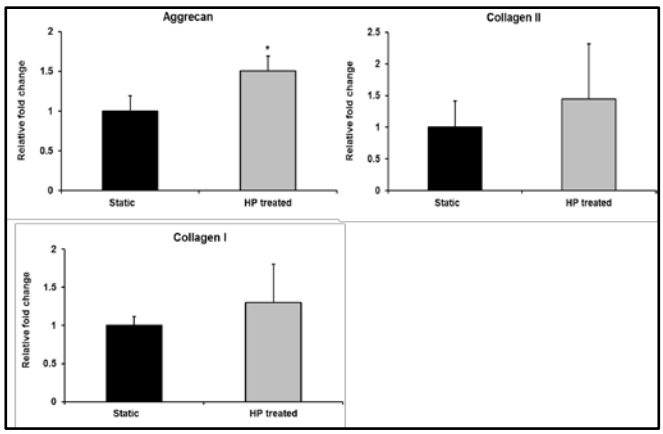

Figure 4: Quantitative RT-PCR was performed to assess fold-changes in gene expression between the groups. No significant changes were observed in Coll II and I, but there was a significant increase in Aggrecan expression between the two groups.

DISCUSSION

Dynamic pressurization has long been known to regulate disc cell phenotype and have beneficial effects, increase production of ECM macromolecules, including Col II and glycosaminoglycans (GAGs) [3]. The prior art for application of HP was through the use of piston driven pressurization chamber. This study evaluated a novel high throughput bioreactor, where individual cell containing alginate beads in multiwall plates were exposed to controlled dynamic HP. Application of dynamic pressure did not affect cell viability and enhanced ECM gene expression. In this study, hydrostatic pressurization did not translate into clear quantitative differences in coll II by mechanically stimulated cells over static, although there was a trend for increased Col II gene. Similar gene expression pattern was observed by Ganteinbein et al., in their study utilizing dynamic hydrostatic bioreactor to mechanically load an *in vitro* disc organ culture [3]. GAG content of NP cells in beads were also measured using Blyscan assay. Results indicate that while aggrecan gene expression increased, the GAG content was down-regulated under the application of dynamic HP (not shown). Optimization of conditions for enhancement of ECM deposition is warranted. Based on our findings, application HP may be a beneficial method of modulating cellular phenotype for high throughput tissue engineering applications, where evaluation of interactions between biologic factors and loading may be evaluated in repeatable and expedited modality. Future studies will concentrate on assessing the functionality of the ECM produced in response to HP via mechanical testing to determine of the increase in ECM correlates to enhanced mechanical properties. Additionally, future work will investigate the expression of other anabolic (GAG) and catabolic (MMP-3, -13) involved in ECM remodeling.

INTRODUCTION

Rotational traction at the shoe-surface interface may be directly related to the development of high ankle sprains due to internal rotation of the body on a planted foot. Although it is generally accepted that low levels of rotational traction are more desirable than high levels from a lower extremity injury risk perspective, currently there are no engineering standards or accepted thresholds to be used for turf and/or shoe design. The majority of research has been focused on investigating rotational traction between the shoe's outsole and the athletic turf. This has been accomplished with material's testing machines and/or mechanical devices fitted with surrogate ankles [1,2]. Yet, these methods may not represent real world athletic kinematics. Consequently, use of live human subjects may provide the most accurate method for investigating injury potential as it might relate to various shoe-surface characteristics. One advantage live human subjects afford is the ability to employ inverse dynamics calculations to estimate joint reaction forces. These calculations necessitate ground reaction forces and moments in conjunction with motion tracking data. Ground reaction data are measured by a force plate, which needs to be located underneath the test surface. Yet, this may alter the integrity of the surface and puts restrictions on the size of the test area.

To help address these limitations in current methodology, one recent study has proposed the use of pressure insole technology and linear regression analyses to determine free torques generated at the shoe-surface interface during internal rotation of the body relative to a planted foot [3]. These regression variables are both subject and shoe specific [3,4]. It is, however, currently unknown if these regression models are surface specific. The goal of the current study was to investigate the feasibility of developing linear regression variables from a single "calibration" surface in the lab that can be used to predict free torques on various athletic turfs. The hypothesis of the current study was that a subject and shoe specific linear regression equation developed on an anti-fatigue mat could accurately predict the free torque that develops on grass and an artificial turf.

METHODS

Six subjects wore a size 11 Nike Vapor cleated shoe (Nike, Beaverton, OR, USA) fitted with a Pedar plantar pressure insole (Novel, Munich, Germany). A 0.3 mm thick non-slip material (Dycem®, Warwick, RI, USA) was placed between the insole and the shoe to prohibit potential insole motion during the tests. Plantar pressure data were collected at 100 Hz. Concurrent ground reaction data was collected at 1000 Hz with an AMTI force plate (Advanced Mechanical Technology, Inc., Watertown, MA, USA).

Three surfaces were selected for this study; anti-fatigue floor matt (AFM) (Crown, Fremont, OH, USA), natural grass (NG), and an artificial turf (AT) (AtroTurf RootZone®, Dalton, GA, USA). The matt was cut to the approximate size of the force plate and adhered with industrial adhesive tape, which prohibited its motion during testing. The grass turf was obtained from the Michigan State University Hancock Turfgrass Research Center. Square sections were placed into a metal tray that matched the approximate dimensions of the force plate. The artificial turf was also placed into a tray with a mixture of sand and crumb rubber according to manufacturer specifications. A 0.3 mm thick non-slip material (Dycem®, Warwick, RI, USA) was placed between the trays and the force plate to prohibit motion of the trays on the force plate during testing. Subjects stood with both feet planted on the ground approximately shoulder-width apart. Only the right foot was on the force plate. Their left foot was placed on the AT if testing NG and vice versa to insure both feet were at the same height (Figure 1). Subjects performed an internal rotation of their body relative to their right, planted foot. The subjects were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

instructed to exert maximum effort and not to move either foot. Trials were rejected if either foot lifted off the surface or translated. Subjects performed each motion until ten successful trials per surface were collected for a total of 30 trials. Force plate data were re-sampled to match the plantar pressure sampling frequency. Data were synchronized utilizing peak vertical force as the common datum. Each trial was trimmed to only consider motion onset to peak torque.

Pearson's Product correlation coefficients were calculated between each of the 99 insole pressure sensors and the free torque developed on each surface. Sensors having positive correlations greater than 0.80 between insole pressure and the free torque measured by the force plate (actual-Tz) were used to develop a sensor mask.

For each subject, one trial from each surface was removed at random. The remaining 9 trials from each surface were used to develop the surface-specific linear regression models. The slope and intercept were determined between the sensor mask and actual-Tz. The linear regression models developed from natural grass (NG) and artificial turf (AT) were used to self-predict their respective randomly removed trial. The linear regression model developed from the anti-fatigue mat (AFM) was used to cross predict the same NG and AT trial. Root Mean Square error (RMS error) and predicted peak free torques were used to measure the accuracy of each model. Statistical differences between these parameters were measured with two-tailed t-tests ($p < 0.05$).

RESULTS

The sensors with the highest correlation with actual Tz were located in the medial forefoot. There were no statistical differences in any measure across all six subjects (Table 1). This indicates that both the NG and AT models accurately predicted their own respective data. Additionally, the AFM model accurately predicted both the NG and AT data. All three models had a relatively low RMS error (less than 13% of peak torque) indicating that each was able to predict the temporal data well. Most of the error occurred at the beginning and end of the motion (Figure 2).

Figure 1: Illustration of the set-up for NG testing.

Table 1: Data from NG and AT models performing self-prediction and the AFM model performing a cross prediction (mean ± stdev).

Regression Model	Correlation	RMS Error (Nm)	Error Predicting Peak (%)	RMS/Peak (%)
NG	0.98 ± 0.02	2.15 ± 0.93	10.30 ± 11.73	9.60 ± 1.52
AFM	0.98 ± 0.02	2.98 ± 0.80	3.38 ± 13.02	10.74 ± 7.81
AT	0.99 ± 0.01	3.07 ± 0.83	2.76 ± 6.51	8.89 ± 4.35
AFM	0.99 ± 0.01	2.87 ± 1.48	2.51 ± 8.38	12.72 ± 5.55

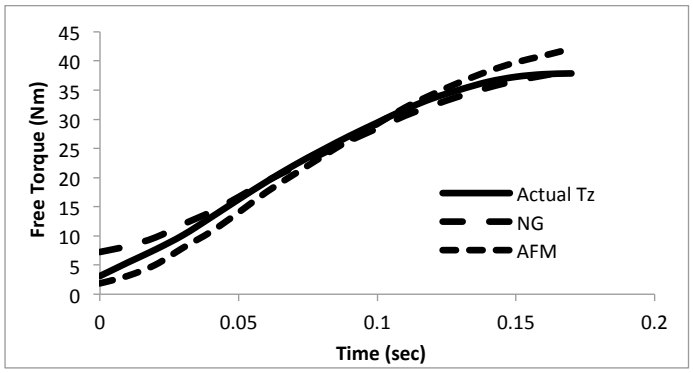

Figure 2: Typical plot for NG data.

DISCUSSION

The results support the hypothesis that subject and shoe specific linear regression models developed from insole pressure data allow for the accurate prediction of free torque on NG and AT surfaces during internal rotation of the body relative to a firmly planted foot. This may indicate that subject and shoe specific linear regression models can be developed in the laboratory using an AFM as the interface between a cleated shoe and the force plate for testing outside the laboratory on athletic surfaces comprised of NG and/or AT. This may allow for research utilizing live human subjects on actual fields of play without the need for an embedded force plate in order to better understand the kinetics and kinematics associated with traumatic injury.

Epidemiological data suggest that eversion ankle injury rates are 31% higher on artificial/synthetic turf compared to natural grass [5]. It has been suggested that rotational traction is a key factor in predicting injury risk because artificial/synthetic turf has been shown to have higher rotational traction compared to natural grass [2]. Yet, in the current study there were no measurable differences in the peak torque developed on NG and AT. The disparity may, in large part, be a result of methodological differences. The subjects in the current manuscript were instructed not to rotate their foot relative to the turf surface. Research that documents differences in rotational traction between turf surfaces utilize mechanical devices fitted with a surrogate ankle that drag the foot through a set rotation. The torque required to move the foot through this displacement is then reported. However, ligament injuries in the ankle have been shown to occur during excessive internal rotation of the body relative to a planted foot [6]. Therefore, having the foot move relative to the surface with the lower extremity and upper body is inconsistent with the known mechanism of injury.

In summary, the methodology presented in the current study accurately predicted the free torques developed on NG and AT during internal rotation of the body relative to the foot. The use of pressure insoles to predict the free torque on various surfaces, in conjunction with motion capture data, may better be able to assess potential injury mechanisms on actual athletic field turfs using human subjects.

CADHERIN-11 EXCACERBATES MALADAPTIVE REMODELING AFTER MYOCARDIAL INFARCTION

Alison K. Schroer (1) and W. David Merryman (1)

(1) Biomedical Engineering
Vanderbilt University
Nashville, TN, USA

INTRODUCTION

Over one million Americans experience a myocardial infarction (MI) every year, and the resulting scar impairs heart function and stresses the remaining cardiac muscle, leading to cardiac fibrosis and progressive cardiac failure in many patients. The cells primarily responsible for scar formation and cardiac fibrosis are cardiac fibroblasts (CFs), which differentiate into myofibroblasts in response to increased transforming growth factor β1 (TGF-β1) and mechanical strain and stress. Myofibroblasts secrete extracellular matrix (ECM) proteins and actively contract the ECM to create a dense collagen scar, further increasing tissue stiffness. One of the proteins that allow myofibroblasts to effective coordinate this contraction is cadherin-11 (CDH11), a mechanosensitive intercellular adhesion protein. CDH11 has recently been shown to play key roles in the progression of both arthritis and pulmonary fibrosis, but its function in infarct healing has not been studied.

CDH11 engagement promotes the expression of the inflammatory cytokine IL-6 as well as profibrotic signaling factors and myofibroblast markers in joints, lungs, and heart valves [1]. Established fibrosis in the lungs has been reversed by treatment with functional blocking antibody against CDH11 [2]. Mechanosensitive signaling through CDH11 affects both inflammation and fibrosis, two key phases of remodeling after MI, but the details of this signaling are still poorly understood. CDH11 junctions are stabilized by p120-catenin, which modulates signals through downstream Rho/Rac pathways and can regulate cell migration and contractility [3]. The objective of this work is to clarify the role and function of CDH11 in the dynamic chemical and mechanical context of myocardial remodeling. We hypothesize that preventing CDH11 adhesion in CFs will reduce inflammation-driven infarct expansion and fibrotic scar formation after MI and improve cardiac outcomes.

METHODS

MI was induced in mice by coronary artery ligation and the resulting changes in cardiac function were monitored with echocardiogram. The effect of MI was compared between littermate wild type (WT) and CDH11 null (CDH11-/-) mice, and between C57 B6 mice treated with a functional blocking antibody against CDH11 (CAb) or a control IgG. Following dissections at 3, 7, and 21 days post-MI, we assessed changes in protein transcription, expression, and localization by qPCR, western blot, and immunohistochemistry, respectively. To complement and inform our *in vivo* studies, we isolated CFs from WT and CDH11-/- mice and measured their contractility in collagen gels. We also measured IL-6 transcription and p120-catenin expression changes when plated with CAb and treated with TGF-β1 for 24 hours. Finally, we used atomic force microscopy (AFM) to measure the stiffness of scar tissue and collagen gels.

RESULTS

Echo analysis showed a less significant reduction of ejection fraction and less significant increase in ventricular systolic volume after MI in the CDH11-/- animals relative to WT animals (**1A**). In addition, a larger fraction of the CDH11-/- population survived to day 21, when the hearts were collected for histological assessment (**1B**). Masson's trichrome stained revealed a thicker, less compact scar in the null animal, which was much less stiff than both the WT scar and the WT cardiac tissue opposite the infarct (**1C-D**). *In vitro* collagen gel contraction data complemented these findings, revealing a significant reduction in contraction by CDH11-/- cells relative to WT cells (**1E**), and a corresponding decrease in gel stiffness, measured by AFM (**1F**).

Mice receiving CAb treatment maintained higher ejection fractions relative to the control group (**2A**). Furthermore, increasing dilation of the left ventricle observed in the control was curtailed in the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

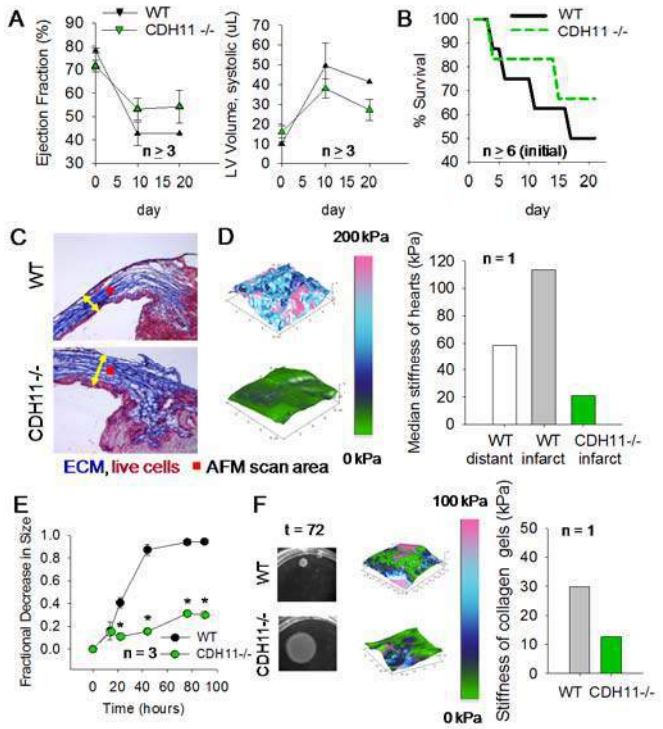

Figure 1: Heart function is better maintained (A,B) and scar contraction and stiffness is decreased (C,D) in CDH11-/- hearts relative to WT. AFM analysis (D, F); representative scan of elastic modulus over surface, median value of modulus plotted on right.

animals receiving the blocking antibody, resulting in significantly reduced total ventricle volume at 21 days post-MI (**2B-C**). This reduced remodeling coincided with increased survival (**2D**) and reduced induction of IL-6 transcription (**2E**). CAb treatment of WT CFs *in vitro* effected a similar reduction in IL-6 transcription (**2F**). CDH11-/- CFs transcribed significantly lower amounts of IL-6 than WT CFs, regardless of treatment.

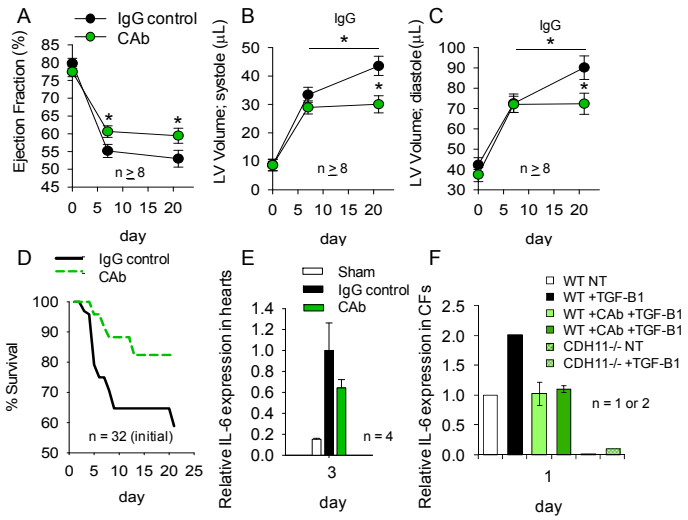

Figure 2: Cardiac function and survival improved with CDH11 blocking antibody treatment (A-D). * indicates $p < 0.05$. IL-6 transcription reduced in CAb treated hearts after MI and CF.

Immunostaining and western blot analysis show that overall expression of p120 is increased in CAb treated hearts relative to NT at both 21 (**3A**) and 7 days (**3B**) post-MI. Immunostaining of cells shows higher cytoplasmic p120 localization with CAb treatment (**3C**), with a modest increase in overall expression in both CAb treated and CDH11-/- CFs (**3D**).

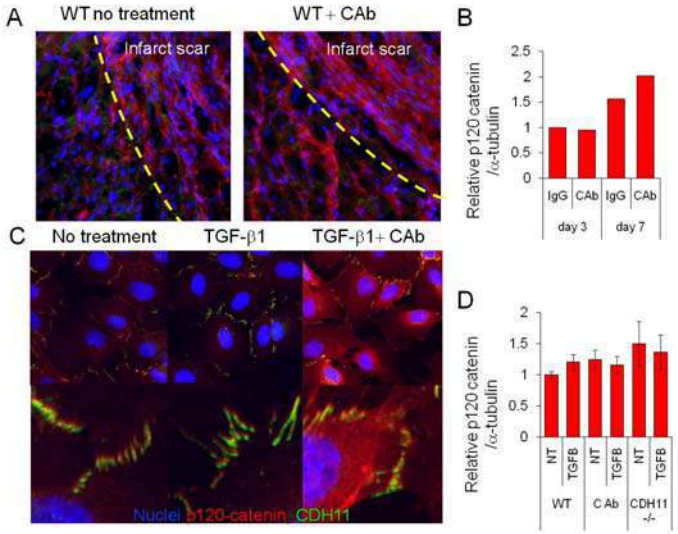

Figure 3: Immunostaining (A, C) and western blot densitometry (B, D) show p120 catenin expression and localization in the heart 21 days post MI (A,B) and in CFs (C,D).

DISCUSSION

Our findings suggest that CDH11 plays a key role in the process of fibrosis after MI, and that targeting CDH11-expressing myofibroblasts limits inflammation and remodeling while preserving cardiac function. Our initial results highlight intrinsic differences in contractile ability of WT and CDH11-/- CFs and establish a link between CF contractility and mechanical stiffness that is relevant to infarct healing.

We have shown that blocking CDH11 adhesion after MI maintains cardiac function and prevents ventricle expansion, especially between 7 and 21 days post-MI (**2B-C**). The reduction of IL-6 transcription demonstrates that CDH11 significantly regulates IL-6 expression after MI and supports a key role for CDH11-expressing CFs regulating inflammation and myocardial remodeling.

Finally, we have identified one potential mechanism for CDH11 signaling. Increased immunostaining of p120-catenin in the peri-infarct zone and in the cytoplasm of CFs suggest that CAb treatment may disrupt the association of CDH11 and p120 catenin. This may prevent mechanically induced Rac1 activation known to increase IL-6 expression.

This work characterizes CDH11-dependent phenotypic changes and tissue remodeling throughout the course of infarct healing, providing new biological insights and highlighting a potential new treatment strategy for improving outcomes after MI.

INTRODUCTION

Coil embolization and flow diversion are the primary endovascular strategies for treatment of intracranial aneurysms (IAs). Coils, which are deployed into the IA sac, are intended to promote thrombotic occlusion of the IA through blood stasis and reactivity with their metallic surfaces. Flow diverters (FDs), on the contrary, are deployed across the ostium of the IA and are intended to promote IA occlusion and neointimal healing of the parent artery through flow reduction into the IA. Unfortunately, these strategies are not always effective, and adverse treatment outcomes have been reported. According to several systematic reviews of endovascular treatment outcomes, 20.8% of coiled IAs recanalize, 10.3% require retreatment [1], and 24% of FD-treated IAs remain patent at 6-month follow-up [2].

Since these devices inherently affect intra-aneurysmal blood flow, post-treatment hemodynamics may play a critical role in treatment outcome. Considering that IA hemodynamics cannot currently be assessed *in vivo*, computational tools can be utilized to simulate IA treatment cases *in silico*. We previously used our validated finite element method (FEM)-based stenting method, in conjunction with computational fluid dynamics (CFD), to recreate three patient-specific FD-treated cases and compared the resulting hemodynamic modifications to their long-term treatment outcomes [3]. We found that in general, faster IA occlusion rates are associated with larger hemodynamic modifications post-treatment. In the current preliminary study, we propose that this same trend may also apply to coiled IA cases. To test this, we virtually recreated four patient-specific coiled IA cases using our validated FEM-based coiling method [4]. We then simulated and assessed pre- and post-treatment hemodynamics for each case using CFD and compared with their long-term treatment outcomes. Based on our preliminary results, the IA cases which had adverse treatment outcomes were associated with larger post-treatment flow modifications. This interesting finding is opposite of our previous results for FDs [3]. In the future, more clinical cases will be assessed to confirm or deny this trend.

METHODS

Patient-Specific Aneurysm Cases

Four patient-specific IA cases were selected for this preliminary study. The inclusion criteria for the IAs were as follows: (1) location in the internal carotid artery, (2) un-ruptured at initial treatment, and (3) treated with only coils. We collected retrospective image and clinical data for each case from the Gates Vascular Institute (Buffalo, NY) under IRB-approval. Based on 12-month follow-up data, two of the IA cases completely occluded and two IAs had a poor treatment outcome by this time point. A poor outcome was defined to be either reccurance of the IA which required retreatment or recanalization of the IA after having been completely occluded.

FEM Modeling of Coil Deployments

We simulated each patient-specific treatment using our FEM-based coil deployment method [4]. For each case, we modeled the specific coil types, sizes, shapes, and material properties as close to their manufactured specifications as possible. We assessed the post-treatment angiographic images of these cases before conducting simulations to determine where the coils resided and how they were distributed in the IA sac in the actual treatments.

CFD Simulations

Pre- and post-treatment hemodynamics were simulated using the CFD software Star CCM+ v.10 (CD-adapco, Melville, NY). Computational grids for each case were generated following our previously described meshing strategy [4]. The flow governing Navier-Stokes equations were solved under the assumptions of incompressible, steady-state, and laminar flow. Constant velocities were prescribed at each IA inlet whose values were calculated from physiologic flow rates for each IA

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

location. At the outlet boundaries, the ratios of the total mass flux were calculated and prescribed from Murray's Law for branching vasculature. Both the IAs and deployed coils were assumed rigid and assigned as no-slip boundaries. Blood was modeled as a Newtonian fluid with constant density and viscosity of 1056 kg/m^3 and 3.5 cP respectively. We qualitatively assed blood flow velocities and quantitatively calculated spatially-averaged velocity and wall shear stress (WSS) inside each IA sac.

RESULTS

Deployment Results

Images of the post-treatment angiography and the corresponding virtual deployment for each IA case are shown in Figure 1A. Qualitatively, the virtually deployed coils exhibit similar complex configurations and distributions in the IA sac as those observed in the angiographic images.

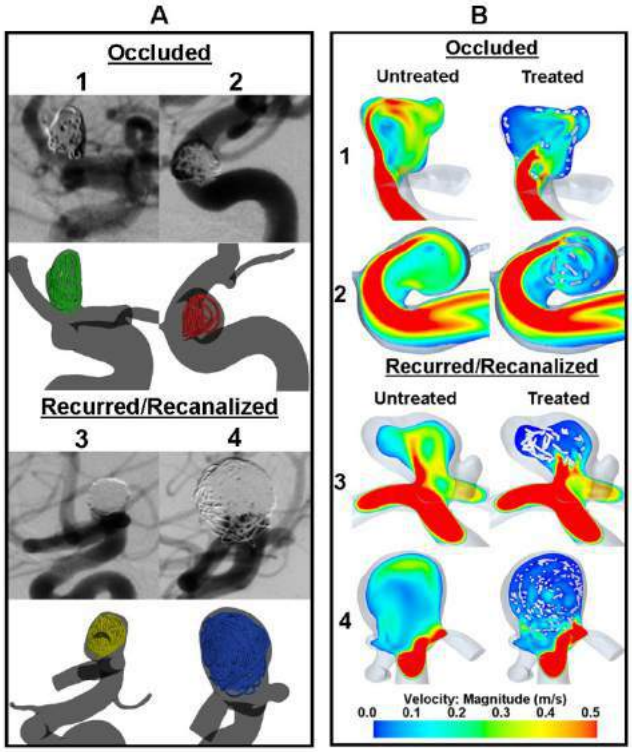

Figure 1: A. Side-by-side images of post-treatment angiography and the corresponding virtual deployments for each IA case. IA cases are labeled 1-4 and are segregated into two groups: occluded or recurred/recanalized. B. Intra-aneurysmal velocity magnitude for the four IA cases plotted on each IA mid-plane. The blank spaces in the velocity contours in the treated cases represent the intersection of the mid-plane and the deployed coils.

Hemodynamic Results

To visualize the flow, we plotted velocity magnitude contours on the IA mid-planes for each case, shown in Figure 1B. In the untreated cases, inflow jets are observed, which create "vortex"-like flow patterns in each IA sac. After coil deployment however, these inflow jets appear to be blocked from entering each IA sac. However, higher velocities are observed post-treatment in the occluded IA group compared to the recurred/recanalized IA group. Aneurysm-averaged velocity and wall shear stress (WSS), shown in Figure 2A, reveal that reductions in these values were greater post-treatment in the recurred/recanalized group compared with the occluded group.

DISCUSSION

Our results in this preliminary study appear to be opposite of those found in our previous FD study [3]. Whereas faster occlusion times were associated with larger hemodynamic modifications post-treatment in FD-treated IAs (Figure 2B), we found that coiled IAs which recurred or recanalized had larger hemodynamic modifications post-treatment compared to those which occluded successfully. This interesting finding suggests that post-treatment hemodynamic modifications may not be as important for coil embolization as for flow diversion for successful IA treatment, or that there may be additional factors to consider. Since FDs are deployed across the ostium of an IA, their mechanism of action is independent of the size or morphology of the IA. On the contrary, coils are deployed into the IA sac and thus their treatment effect is more likely affected by IA morphology such as dome and neck size, or even the type of coils used for treatment [5]. We will expand this study in the future to more cases in order to clarify the current results or potentially uncover new mechanisms of coil embolization that could explain these contradictory findings.

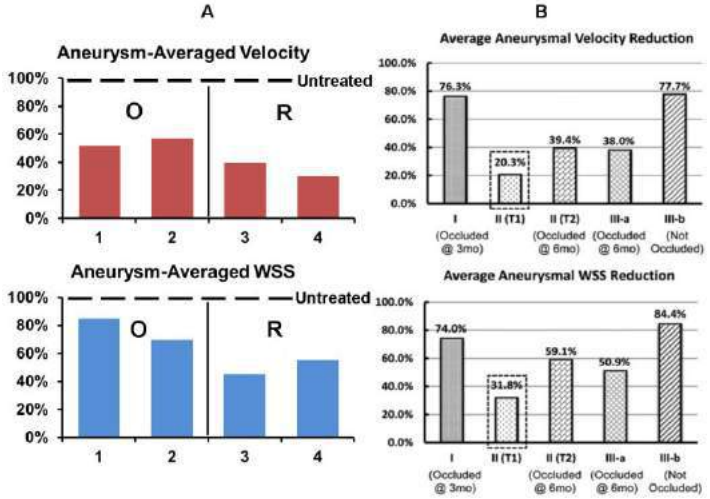

Figure 2: A. Hemodynamic parameters for the coil-treated IA cases. Values for each parameter are represented relative to a 100% baseline in the untreated case, designated by the dashed lines. The letters O and R designate the IAs in the occluded and recurred/recanalized groups, respectively. B. Hemodynamic results from our previous FD study [3].

INTRODUCTION

Nucleotomy is a surgical procedure following herniation and also simulates the reduced nucleus pulpousus (NP) pressure that occurs with disc degeneration. Internal disc strains are an important factor in disc function, yet it is unclear how internal strains are affected by nucleotomy. We previously developed a technique to acquire internal disc strains within the lamellae of the annulus fibrosus (AF) using MRI and image registration techniques [1]. Following techniques in neuroimaging [2], strains were then transformed to an anatomical template to minimize the effects of individual variability, and the strain components across several disc regions were determined for physiological axial compression loading [3]. Here, we use these techniques to explore the internal strain following partial nucleotomy for compressive axial loading, evaluating both on the incision side and uninjured side. Findings from this study could inform the residual effects of the nucleotomy procedure as a surgical intervention and the degenerative changes in the disc linked to loss of NP pressure.

METHODS

Specimen Preparation: Grade II L3-L4 human cadaveric discs (n=6) were analyzed intact and after a partial nucleotomy that removed 30-50% (by weight) of the NP through a left posterolateral incision. Specimens were rehydrated in 1X PBS overnight at 4ºC before mechanical testing commenced. Figure 1 shows a mid-sagittal image of a disc after partial nucleotomy with a left posterolateral incision (incision) while the right side is intact (uninjured). Remaining NP material reconstituted during rehydration, filling the disc space.

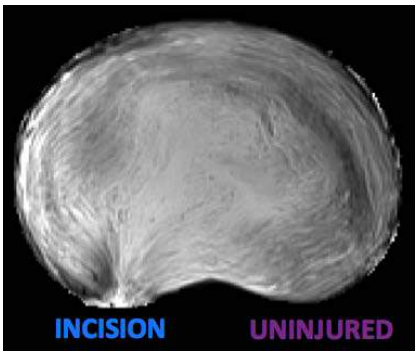

Figure 1. Mid-transverse view of a cadaveric disc post-nucleotomy procedure through a left incision leaving the right side intact.

Mechanical Testing and Image Acquisition: Two cycles of stress-relaxation testing were performed for reference and loaded configurations. For the reference configuration, axial displacement increased until an instantaneous compressive load of 50 N was obtained, and this reference displacement was then held for a 3 hour relaxation period. The loaded configuration followed, where axial displacement increased until an instantaneous 0.7 MPa load was obtained. Then, this loaded displacement was held for an 8 hour relaxation period. After each relaxation period, the reference and loaded discs were imaged separately at 0.3 mm isotropic resolution in a 7T MRI scanner. Only the lateral half of the disc closest to the radiofrequency coil was used for analysis because the signal-to-noise ratio decreased with increasing distance from the coil. Thus, the uninjured and incision sides of the disc were scanned separately to ensure sufficient MR signal for analysis.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Data Analysis: Advanced Normalization Tools (ANTs) were used to register the reference and loaded images prior to calculating internal strain within the AF lamellae. The discs were spatially normalized (averaged) to create separate anatomical templates for each condition: intact, uninjured and incision. Circumferential (E_C), radial (E_R) and axial (E_Z) strains for each individual disc were transformed to their respective templates. Each template was divided into thirds through the transverse plane, and five regions were defined within the middle third: anterior (A), anterolateral (AL), lateral (L), posterolateral (PL), and posterior (P). The effect of nucleotomy was compared on the uninjured and incision sides, and intact [3] using a repeated measure ANOVA with a Holm-Sidak post-hoc test. All marked results have $p < 0.05$ significance.

RESULTS

Disc nucleotomy with a left posterolateral incision site altered disc strains on both the incision and uninjured sides from the intact state as viewed from the strain templates of circumferential (E_C), radial (E_R), and axial (E_Z) strains (Figure 2). Strain fields were inhomogeneous through the five regions shown qualitatively in Figure 2 for a representative sample and quantitatively in Figure 3 with pooled data (n=6).

Mean Circumferential Strain varied from 3.5 to 5.8% throughout the intact AF and was unaffected by nucleotomy on the uninjured side. Circumferential strain decreased on the incision side, ranging from 1.6 to 2.4% and was significantly lower in all regions except posterolateral.

Mean Radial Strain varied from 3.8% and 6.5% in the intact AF and there was no difference with nucleotomy on either the uninjured or incision side. While not significant, the strain did decrease to approximately 3% in the anterior, anterolateral, and lateral AF on both sides.

Mean Axial Strain varied between -13% and -20% in the intact AF. Following nucleotomy, the strains in the uninjured side increased in magnitude to approximately -24% in all regions except anterior. The incision side exhibited similar strains to intact.

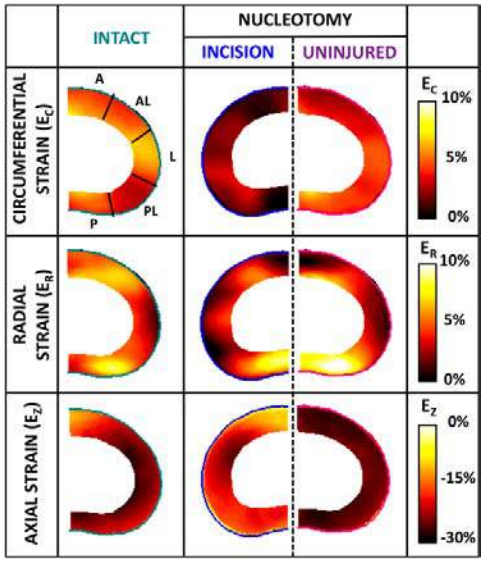

Figure 2. Strain templates for intact, uninjured and incision sides show changes in circumferential (E_C), radial (E_R) and axial (E_Z) strains. Strains, divided into five regions, are more heterogeneous in the incision and uninjured discs compared to intact.

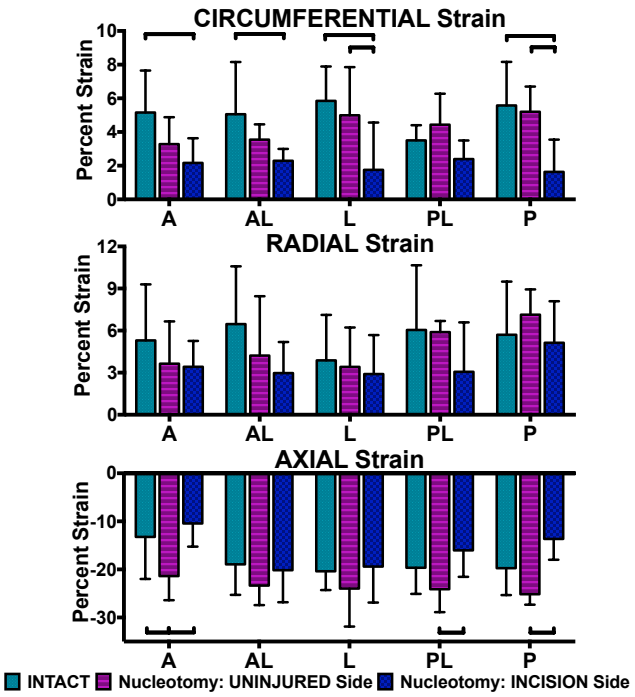

Figure 3. Mean circumferential, radial and axial strains of intact, uninjured and incision discs (n=6/group) with 95% confidence intervals. Circumferential and axial strains were most affected by partial nucleotomy treatment.

DISCUSSION

The effects of nucleotomy on discs undergoing axial compression were successfully determined using templates of internal disc strain through the AF lamellae. We found nucleotomy intervention alters disc structural and mechanical states compared to intact discs and these changes were different depending on the side with the incision. Axial strains were greater on the uninjured side of the AF. Tools used in nucleotomy procedures allow easier NP removal from the side opposite the incision; thus, this lack of NP material on the uninjured side may leave only the AF to resist the compressive load. Circumferential strains were lower on the incision side of the AF, where the large AF defect likely prevented the AF from supporting hoop stresses.

This study used a partial nucleotomy procedure, which reduced NP pressure, to measure alterations in disc mechanics with regards to (1) degenerative changes in the disc and (2) the AF incision inherent to the intervention. These findings are important to address etiology and progression of degeneration, and to develop and evaluate therapeutic interventions

INTRODUCTION

Hands are strongly associated with sense of touch. They are vital for humans because fingers allow the hand to perform many different activities. Therefore, losing part of a finger will modify the biomechanics of the grip [1]. Finger amputation is a surgical procedure used to remove the phalanx involve in a trauma which can be the consequence of work-related accidents, congenital deformities or other incidents. The motivation for this study was to the difficulty of finding a group of finger amputees with different types of finger amputation. Basically, the present study seeks to establish what finger amputations are more critical in terms of the reduction of due to different finger amputations. Whole finger amputation as well as thumb amputation was not considered in this study.

METHODS

Handgrip force equipment

A 38-mm diameter cylindrical mechanical device was designed and built to emulate different finger amputations. The device has a load cell at the bottom of the cylinder to measure handgrip force. In addition, the device has eight gates which open by means of a motorized gear depending of what combinations will be used to emulate amputated phalanges. Each gate has three force sensors in order to obtain the force on each of the three finger phalange (distal, medial, and proximal).

Subjects

A total of ten adult subjects (five women, five men), right-handed, average height and weight, palm length less than 112 mm were used for this study. Subjects with muscular lessons, amputations, or any physical problems in hands or forearm did not participate on this study. Handgrip force measurement protocol was followed according to previous studies [2]

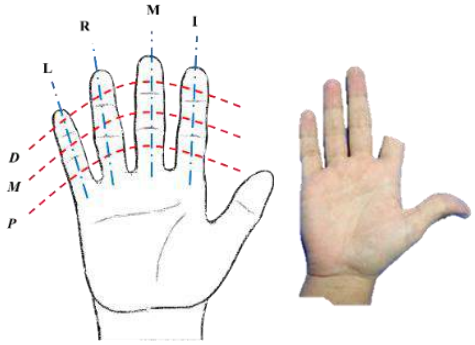

Figure 1: a) Matrix to determine combinations for amputations b) Example for an amputation I:*D*+*M*

Statistical Analysis

Eleven combinations of finger amputations were obtained by eliminating finger phalanges according to most common finger amputations. Analysis of variance was assessed in order to find differences in total handgrip force between gender and dominant hand. Also, two-way ANOVA was done in order to obtain significantly differences with combinations

Total force were determined summing the forces obtained by twelve sensors -three phalanges on each finger (P: Proximal, M: Middle, D: Distal) and four fingers (I: Index, M: Middle, R: Ring, L: Little).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Although several studies have found the force on each phalanx, none had emulated a finger amputation by means of a mechanical device. The device is able to measure the handgrip force and also obtain the forces on each phalange for each finger (except thumb) of the hand. Our results were validated in two ways: 1) Comparison of the handgrip force values with previous studies, 2) Comparison of phalange forces with a male adult with a congenital deformity in his Ring and Little fingers.

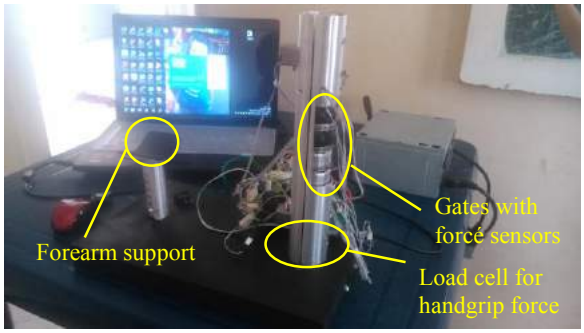

Figure 2: Handgrip force and pdevice.

Our results of the handgrip force strongly agree with those found by Kong [3] where handgrip force of men was found to be greater than women. ANOVA test showed that handgrip force was significantly different between men and women. On the contrary, dominance of the hand was not significantly different; although, it was shown that the 10% rule was fulfilled [4]

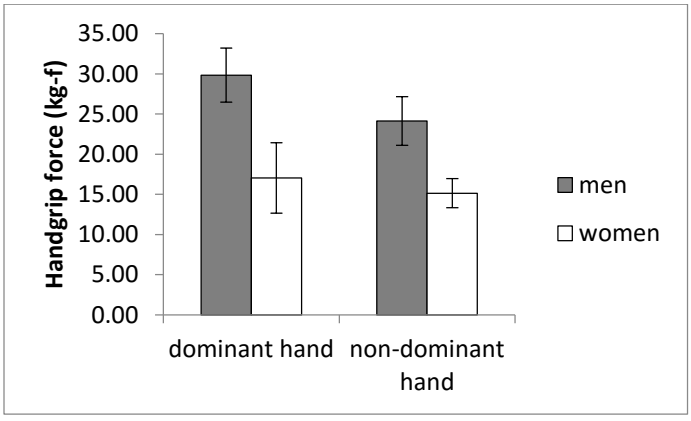

Figure 3: Handgrip force for hand dominance and gender.

On the other hand, it was found differences between combinations for amputations in men total finger force. Nonetheless, there were not significantly differences in the total finger force for amputations in women. It was observed that men total finger force is reduced in 62% for combination #11, and women total finger force showed a reduction of 48.55% for the same combination. The less reduction was noted on combination #2 for men, and combination #12 for women.

	MEN		WOMEN	
# of Combi-nation	**Total finger force (kg-f)**	**Loss of grip force (%)**	**Total finger force (kg-f)**	**Loss of grip force (%)**

9 [I+M:*D*]	11,26	39,31	8,55	19,18
10 [R+L:*D*]	11,68	37,08	8,46	20,06
11 [I+M:*M+D*]	6,93	**62,64**	5,44	**48,55**

Table 1. Percentage of loss of grip force with respect to the total finger force without finger amputations. Combinations [Fingers : *Phalanges*] Fingers (I: Index, M: Middle, R: Ring, L: Little, T: Thumb) Phalanges (*P*: Proximal, *M*: Middle, *D*: Distal).

DISCUSSION

It was expected that handgrip force for men be greater than women. Also, the reduction of total finger force for men was more critical than women because men reduce about 20% more than women for the same #11 combination. On the other hand, the difference between # of combinations in the less reduction (#2 for men, # 12 for women) could be due to the differences in hand morphology for both. The results of this study will help to rehabilitation therapists to understand how much of grip force they could expect for a patient with a specific finger amputation, and also will aid to the development of finger prosthesis.

MUSCLE ACTIVATION IN CYCLIC LIFTING WITH TRAINED LUMBAR-PELVIC COORDINATION

INTRODUCTION

The National Institute for Occupational Safety and Health has identified repetitive lifting and trunk flexion as risk factors for low back disorders [1]. In previous investigations by our laboratory and others, experienced lifters were observed to have an altered lumbar-pelvic coordination and reduced lumbar flexion during cyclic lifting tasks as compared to novice lifters [2-3]. It was speculated that experienced lifters select such strategies to avoid low back injuries. As such, there is an interest in examining the effects of training lumbar-pelvic coordination as a means to prevent low back injuries. The goal of this study was to examine muscle activity during such training in order to better understand the effects of such training.

METHODS

Seventeen subjects provided informed consent and participated in this study approved by the human subjects committee at the University of Kansas Medical Center. There were nine men and eight women with an average age, height, and weight of 24.1±4.2 years, 1.70±0.1 meters, and 66.4±12.7 kilograms. The subjects were divided into two groups based on weight lifting experience. Subjects having lifted weights three times per week for the previous year were considered experienced and individuals who had not lifted weights regularly in the previous year were considered novice. The experienced group (EXP) had a total of 8 subjects with 3 females and 5 males while the novice group (NOV) had 5 females and 4 males for a total of 9 NOV lifters. Subjects performed a repetitive lifting task to examine three different lumbar pelvic coordination strategies. The three strategies examined included a self selected strategy, a highly kyphotic (HK), and a neutral (NU) strategy.

The lifting strategies were performed using a repetitive lifting task. The task involved lifting a milk crate from the ground to waist level and then returning to near ground height. The crate held a small amount of weight normalized to 3% of a single max lift. The crate was never released and held throughout the trial that lasted approximately 4 minutes. A metronome controlled the rate of lifting by beeping at 1Hz with each lift cycle (ground-waist-ground) lasting four seconds.

Two angles, lumbar angle (LA) and trunk flexion angle (FA), were measured using three electromagnetic sensors (MotionStar, Ascension Technology, VT) collecting position and orientation data at 100Hz using MotionMonitor Software (Innsport, IL). The sensors were located at T10, S1, and the manubrium. The FA was defined as the angle between T10-S1 and vertical and the LA was the difference in angular tilt of the sensors at T10 and S1 to describe the spinal curvature.

The LA was normalized using individual subjects range of motion (ROM) by collecting the maximum and minimum kyphotic postures at 0, 30, 60, and 80 degrees of flexion. A ROM envelope expanded the ROM using linear interpolation to calculate a normalized LA at any given FA. Biofeedback displayed an XY-plot with the FA on the x-axis and normalized LA on the y-axis for visual feedback. A target box was displayed to control for the lifting strategy. The target box ranged between normalized LA of 42% and 58% ROM for the NU strategy and 80% to 95% ROM for the HK strategy. For both trained strategies, the FA range for the target was between 20 and 70 degrees. Prior to introducing the biofeedback program, subjects completed the lifting task using a self selected strategy without visual feedback. During the trained strategies, subjects were instructed to make the cursor pass through the target box during the extension (lifting) phase of the lift.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Integrated electromyograhic data (EMG) for the right side erector spinae was examined during these cyclic lifting tasks. The data was filtered, demeaned, rectified, and integrated using a 100 point Hanning window. Following the filtering, all EMG data was normalized to the average peak value for the first four cycles of lifting during the self selected lifting strategy. An EMG curve was then interpolated based on flexion angle to get EMG as a function of flexion angle. The EMG data was examined over flexion angles between 10 and 70 degrees for both the flexion and extension phases of the lift.

RESULTS

During self-selected lifting, NOV lifters were found to have a lumbar-pelvic coordination pattern that reached high lumbar flexion during extension, while the EXP lifters were found to have a lumbar-pelvic coordination pattern that are more neutral. This was consistent with previous studies [2-3].

Examining the erector spinae EMG patterns, it was found that both groups generally had higher EMG during extension than during flexion as would be expected. Over time, during the self-selected strategy, NOV lifters transitioned to a pattern of lower EMG levels at high trunk flexion.

During the trained strategies, it was expected that the NU trained strategy was most different from self-selected for the NOV group. Examining the EMG it was found that the NOV group again exhibited a pattern of lower EMG at high trunk flexion that increased over time. For the HK trained strategy, both the NOV and EXP groups exhibited this lower EMG at high trunk flexion over time.

DISCUSSION

While the lumbar-pelvic coordination patterns (and thus trunk motion) remained relatively consistent when subjects were practicing trained lumbar-pelvic coordination patterns, the changes in EMG patterns suggest that muscular coordination is changing. As these patterns were more pronounced for NOV lifters, it suggests that fatigue and task difficulty (during trained strategies) may be the cause of this change in muscle activation. At high trunk flexion, subjects could be relying more on the passive elements of the spine (such as ligaments) rather than the musculature. They could also be changing their velocity of trunk extension, which has not been examined yet.

Future work will further examine these observed patterns and their relationship to the lumbar-pelvic motion. Additionally, other muscles, including the antagonist trunk muscles, should be examined to see if changes in co-contraction may be a component of these changes in erector spinae muscle activation.

EVALUATION OF DESIGN PARAMETERS FOR A NOVEL PERSONAL AIR PURIFICATION METHOD TO MITIGATE PARTICLE ASPIRATION

Christopher R. Idelson (1), Christopher G. Rylander (1)

(1) Department of Mechanical Engineering
The University of Texas at Austin
Austin, TX, USA

INTRODUCTION

Airborne transmission of pathogens and allergens represent a prominent medical issue in the healthcare industry. In recent years, respiratory acquired conditions such as tuberculosis (TB), pneumonia, and influenza have accounted for direct medical costs at an estimated $435 million, $3.7 billion, and $10.4 billion in the United States, respectively [1-3]. Respiratory allergies present a global problem, with the illness known as allergic rhinitis affecting roughly 60 million adults in the US alone, and further accounting for about $3.5 billion in direct medical costs in 2011 [4, 5]. TB affects roughly 9 million people worldwide, with a death toll around 1.5 million each year [6]. These and many other afflictions are still prominent in today's world, and seen in virtually all populations. More so, human occupancy density has been identified as another factor for increased exposure to bacteria, consequentially labeling such environments as offices, schools, and clinics as centralities for the spread of numerous illnesses [7, 8].

While masks which cover the mouth and nose are effective at preventing aspiration of pathogens and allergens, current reports show low user compliance with these devices [9, 10]. Therefore, we have identified the need for a device to promote high user compliance while achieving effective results for personal air purification, with the ultimate goal of reducing aspiration of detrimental air contaminants. Our intended design concept is a wearable device that blows purified air toward the human breath area without obstructing the face.

METHODS

The objective of our study was to examine which parameters of our conceptual design most influence pnuematic purification of sampled (inhaled) air. Data was acquired using a system emulating a typical breathing envinroment (Figure 1). A clean air input port and sampling port (diameters= ¾") simulated an air purifier prototype device and a human mouth, respectively. Three parameters were experimentally tested to determine feasibility for air purification via the flow of clean air directed at the sample port in a dirty-air environment: (1) distance between ports, (2) flow rate of clean air input, and (3) angle between ports. First, 1.5933±0.0796 grams of aerosolized glycol particles (400W Metal Fog Blaster, 1byone Inc), simulating "dirty air," were dispersed into a sealed chamber. Controlled flow of clean room air was introduced into the chamber. Excess intake/exhaust filters were included, allowing for mass conservation in/out of the chamber.

Sample filter (In-Line Bacteria Filter, Kinship Comfort Brands) mass measurements were made using a Mettler Toledo XS104 balance with 0.1 mg resolution. A GAST 1023-101Q vacuum pump pulled the chamber air through the filters (99.2% efficiency of 0.3 µm particles) collecting glycol particles, allowing for subsequent calculation of

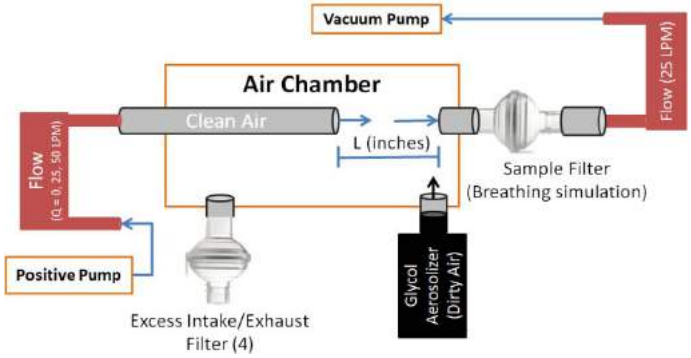

Figure 1. Experimental chamber setup for particle sampling.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

collected glycol mass. Particle size and distribution were not controlled variables in these experiments.

Experiment 1- *Distance between clean air port and sample port ("L")*. Distances (L) were set at 1/8, 1, 5, and 12 inches. L=1/8" simulated the best case purification scenario. L=12" represented the worst case scenario. The sample port flow rate was set to 25 LPM, simulating a typical adult male breathing rate [11, 12]. Clean air input flow rate was set to 50 LPM. Three trials were repeated for each distance (N=12).

Experiment 2 – *Clean air input flow rate ("Q")*. Flow rates were tested at 0, 25, and 50 LPM. 50 LPM represented a best case purification scenario and 0 LPM represented a worst case scenario. Sample port flow rate remained at 25 LPM. L was set at both 1" and 12". Three trials were repeated for all flow rate and distance combinations (N=18).

Experiment 3 - *Angle of approach of clean air input*. Two angles of approach were tested: 0º (concentric alignment), as seen in *Experiments 1 & 2*, and 90º (perpendicular alignment). Sample port flow rate remained at 25 LPM, and L was set to 1" and 12". Clean air input flow rate was set to 50 LPM. L at 90° was measured from the end of the input port to the center of the sample port. Three trials were repeated for each angle and distance (N=12).

RESULTS

For *Experiment 1*, an order of magnitude more mass was collected in the sample filter for the worst case scenario (L=12") when compared to L=1" (Figure 2A). Results from *Experiment 2* at L=1" showed that a clean air input flow rate of Q=50 LPM decreased the average amount of glycol particles collected by more than 2 orders of magnitude when compared to Q=0 LPM, and more than 1 order of magnitude when compared to Q=25 LPM (Figure 2B). For *Experiment 3*, altering the angle of approach for the input flow to 90° increased particle mass collected by more than an order of magnitude when compared to 0°, at L=1" (Figure 2C).

DISCUSSION

Experiment results showed that each variable played a key role in purifying sampled air. All 3 factors appeared to affect air purification by at least an order of magnitude when comparing extreme levels of each parameter for each experiment. It is worth noting that *Experiment 3* results at L=12" and a 90° angle of approach still provided purification by more than a factor of ~2 when compared to values at Q=0 LPM in *Experiment 2* (i.e. where no purification method is implemented). This establishes an initial design baseline point with effective purification levels above typical environmental conditions. It will also be noted that the worst case scenario (Experiment 2, Q=0 LPM) collected the highest mass of all the experiments, yet was only ~1/3 of the input glycol mass supplied by the aerosolizer. This is likely explained by glycol particles that escaped via exhaust filters in addition to particles settling on the inner surface of the chamber. For *Experiment 1*, some trials displayed an interesting phenomenon, ultimately losing initial filter mass compared to pre-experiment values. One explanation for this might be that close proximity of input and high flow caused any pre-existing particles/humidity droplets to dry from the filter. It would be beneficial to explore whether there is interaction between the tested parameters. Future efforts will include refining the current protocol to incorporate biological agents, in addition to computational fluid dynamic modeling. It is crucial to recognize that augmenting user compliance via ergonomic device design will possibly require performance tradeoffs. In conclusion, all 3 tested parameters appear to warrant further consideration for the intended device design.

DELETION OF CADHERIN-11 INCREASES SMOOTH MUSCLE ACTIN EXPRESSION BUT PREVENTS CONTRACTION IN VALVE FIBROBLASTS

Meghan A. Bowler (1) and W. David Merryman (1)

(1) Biomedical Engineering
Vanderbilt University
Nashville, TN, USA

INTRODUCTION

Calcific aortic valve disease affects 25% of the Western population over 65. The only current treatment is total valve replacement, which necessitates open-chest surgery – a particularly traumatic procedure for the affected population. Alternative therapies remain scarce mainly because the mechanism of calcification is largely unknown. Two proposed hypotheses for the development of calcific nodules (CNs) are widely studied. Dystrophic calcification is initiated by TGF-β-mediated myofibroblastic differentiation of resident aortic valve interstitial cells (AVICs), which exhibit increased cell contractility and a subsequent imbalance of intercellular tension that are speculated to lead to apoptosis of AVICs. Osteogenic calcification proceeds when myofibroblasts spontaneously transdifferentiate into osteoblast-like cells and actively deposit mineralized material. In a study of human valves, 83% had evidence of dystrophic calcification and 13% of those contained mature lamellar bone and evidence of active remodeling [1]. While it is unclear whether these processes occur simultaneously or sequentially, we focus on elucidating the more prevalent pathway: dystrophic calcification.

We define CNs as round aggregates with a 100 μm minimum diameter that contain a ring of apoptotic cells around a necrotic core. In dystrophic calcification, transforming growth factor-β1 (TGF-β1) mediates the activation of AVICs into myofibroblasts, characterized by expression of vimentin, α-smooth muscle actin (αSMA), and cadherin-11 (CDH11). CDH11, a mechanosensitive transmembrane protein involved in cell-cell adhesion, is thought to be responsible for mediating much of the intercellular tension integral to the dystrophic pathway [2], whereas αSMA is involved in cell motility and contractile machinery [3]. When these proteins are upregulated in the diseased state, individual AVICs experience uneven and increased tension and contraction, resulting in membrane tearing and apoptosis-mediated calcification. This cell death provides increased imbalance in cellular forces and a local increase in substrate stiffness, acting as a nucleation event in the formation of a CN.

Both CDH11 and αSMA are overexpressed in diseased human valves, though previous *in vitro* work suggests they have an inverse relationship [4]. While cadherins are known to complex with catenins intracellularly, downstream signaling is poorly understood. A better understanding of the role of αSMA and especially CDH11 in calcific aortic valve disease could uncover potential therapeutic targets.

METHODS

Murine aortic and pulmonary valves were excised from immortalized WT, $CDH11^{+/-}$ and $CDH11^{-/-}$ mice and digested in 500 μL 600 U/mL collagenase for 30 minutes at room temperature. They were seeded on 0.1% gelatin and expanded in DMEM supplemented with 10% FBS and 1% PenStrep. Cardiac fibroblasts (CFs) were isolated from the ventricles.

WT AVICs were infected with pLL-CDH11-mCherry and processed via fluorescence-assisted cell sorting to create a pure population of AVICs overexpressing CDH11 tagged with mCherry.

Strain experiments were performed using the Flexcell FX-4000 Tension System. Cells were plated onto the flexible bottom of Flexcell plates coated with pronectin and then exposed to 30 minutes or 24 hours of 10% equibiaxial strain to recapitulate the mechanical environment of the valves. Samples were analyzed for CDH2, CDH11, αSMA, β-catenin, p120-catenin, RhoA, pp38, and pERK protein expression via western blot or mRNA levels via qPCR.

AVICs were seeded on collagen gels at 40,000/gel, treated with 1 ng/mL murine TGF-β1 every 24 hours, and imaged at least every 24 hours for 4 days to assay contractility.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

WT+CDH11-mCherry AVICs, WT AVICs, CDH11$^{-/-}$ AVICs, and WT pulmonary valve interstitial cells (PVICs) were plated on coverslips and stained for CDH11 (Cell Signaling), αSMA (Sigma), and/or myosin light chain II (MLC II) (Cell Signaling).

RESULTS

Loss of CDH11 in AVICs results in a dramatic increase in αSMA both from *in vivo* sources and *in vitro* experiments (**1A**). This is conserved across cardiac cell type; WT CFs have less αSMA than CDH11$^{-/-}$ CFs (**1B**). We observe reduced contractility in response to TGF-β1 in AVICs that lacked CDH11 (**1C**). Probing related proteins reveals a compensatory increase in CDH2, a mesenchymal cadherin (**1D**). Increases in β-catenin and p120-catenin expression indicate dramatic changes in intracellular cadherin signaling (**1E**). qPCR shows a decrease in RhoA transcription (**1F**), and immunofluorescence shows a decrease in MLC II (**1G**).

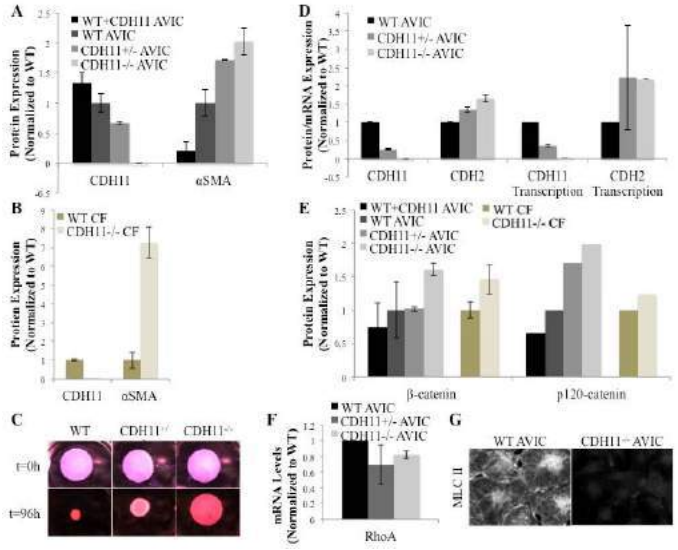

Figure 1: Loss of CDH11 increases αSMA expression (A) across cell types (B), but reduces TGF-β1-induced contraction (C). CDH11 loss increases CDH2 and catenin expression (D-E), but decreases RhoA (F) and MLC II (G).

Subjecting AVICs to physiological strain causes transcriptional decrease of CDH11, increase of CDH2, decrease or no change of αSMA, and increase of RhoA only in WT AVICs (**2A**). Analysis of phosphorylation events after strain in WT, CDH11$^{+/-}$ and CDH11$^{-/-}$ AVICs suggests a decreasing dependence on pERK and an increasing dependence on p38 (expression was normalized within cell type) (**2B**). Treatment of the WT+CDH11-mCherry (**2C**) and WT AVICs with 5 ng/ml TGF-β1 resulted in slight increases in p120-catenin and β-catenin expression and a significant increase in WT pp38 at 30 minutes (**2D**). At 24 hours, CDH11 and αSMA increased to the same level across multiple cell types (**2E**), suggesting TGF-β1 induces maximal expression of these proteins.

Preliminary investigation of WT PVICs demonstrated increased expression of CDH2, CDH11, αSMA, over animal-matched AVICs (**3A**). qPCR data suggests less transcription of RhoA in WT PVICs than AVICs (**3B**).

DISCUSSION

Loss of CDH11 may prevent TGF-β1-induced contraction by either preventing linkage between contractile AVICs or preventing MLC II and RhoA expression. Preventing the excessive contraction of AVICs would lessen the forces experienced by the cells and decrease the probability of apoptosis-mediated calcification.

Interestingly, the increased expression of CDH2 and αSMA in PVICs does not correspond with increased contractility (data not shown), but does exhibit decreased RhoA transcription, as in the CDH11$^{-/-}$ AVICs. Pulmonary valves are much less likely to develop calcification than aortic valves, supporting the hypothesis that CN formation in valve cells is RhoA-dependent.

Here, we have investigated the role of CDH11 in calcific aortic valve disease and provided insight into its mechanism of action. This has revealed surprising information about the role of αSMA in contractility (that its expression does not correlate with contraction) and identified effectors of contractility in AVICs, providing novel potential therapeutic targets.

INTRODUCTION

Transplantation addresses a tremendous societal need for donor tissues for patients with diseased tissues requiring replacement due to failure or disease. In short, there are far too few fresh donor tissues and organs available, and the short-term preservation methods currently available allow only hours between procurement and transplantation. Thus, long-term banking of these systems continues to be a critical and unmet enabling technology for the transplantation medicine community [1,2]. Thus, a method for long term cryopreservation or "banking" of organs and tissues such as arteries, veins, skin, heart valves and cartilage would revolutionize the way organs are recovered, allocated, and used in transplantation.

One of the most attractive approaches to achieving long-term banking of biomaterials is by a technique known as cryopreservation by vitrification, which allows cooling and storage of tissues at temperatures close to liquid nitrogen (-160 °C) for indefinite time periods. Typical freezing processes cause significant damage to biomaterials through ice crystal formation and cellular dehydration. However, with the aid of cryoprotective solutions (CPAs), biospecimens can be stabilized in the vitreous (i.e. "glassy" or "amorphous") state, allowing for long-term cryopreservation. While this is not trivial, a number of groups have employed successful techniques for cooling bulk systems to the vitreous state (including entire rabbit kidneys). Unfortunately, rewarming these vitrified biomaterials is an even greater engineering challenge, as the warming rates to avoid crystallization during the thawing phase of the thermal protocol are typically an order of magnitude higher (hundreds of °C/min) than the required cooling rates (tens of °C/min), even with the aid of CPAs. In addition, temperature non-uniformity may produce thermal stresses that can cause fracture cracks within the biomaterial. Hence, speed and uniformity of warming are essential, and have not yet been achieved in bulk.

Here we present new physical, chemical, computational and biological data using "nanowarming" to address this limitation. We have already demonstrated that this approach can match or exceed the current best approach for rewarming by convection in small 1 ml samples[3]. We are also able to physically generate heating rates sufficiently rapid to avoid devitrification (≥ 200°C/min) in larger 60ml samples where convection rewarming fails.

METHODS

Specifically, we deploy 10 mg Fe/ml biocompatible mesoporous silica-coated iron oxide magnetic nanoparticles (msIONPs) in a cryoprotective agent (VS55) which, when exposed to an appropriate RF field, improves the uniformity and speed of rewarming from the vitrified state. The msIONPs are comprised of a 10 nm Fe_3O_4 core and 50 nm mesoporous silica shell (by TEM) co-modified with PEG and trimethylsilane with -38 zeta potential[4]. As a proof of principle human dermal fibroblasts (HDF) and porcine carotid arteries (inner diameter of ~ 3 mm; wall thickness of ~1 mm and length: ~3-5 mm) were chosen as the systems of study. Protocols were optimized to step load the nanoparticle impregnated VS55 into the HDF and artery systems with negligible toxicity. The systems were then vitrified at roughly 10 °C/min by methods previously described[5].

RESULTS

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Micro computed tomography (μCT) was used as a quality control tool to demonstrate both the loading and vitrification of the VS55 into the arteries. Rewarming was carried out in a low frequency (20KA/m, 360 KHz) RF field achieving warming rates > 55 °C/min (a critical rate to avoid devitrification of VS55) or by less optimal rates (< 10 °C/min).

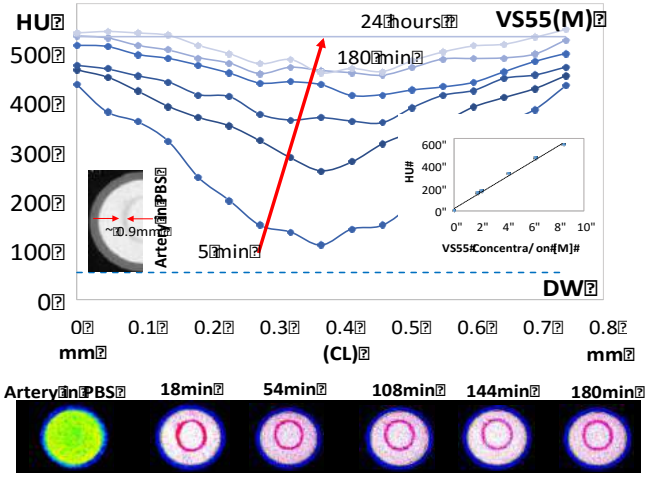

Figure 1: Vs55 loading of an artery (0.9 mm thick) visualized and quantified by micro Computed tomography (μCT).

Thermal measurements and modeling verified the rates of freezing and heating in the systems tested. Further mechanical modeling verified that the thermal stress remained below a 2 MPa yield stress of the tissue during nanowarming and no cracks were identified in histology[6]. The presence and washout of msIONPs in cells and luminal structure of arteries was verified by TEM and sweep imaging with Fourier transform (SWIFT) MRI, respectively by an established technique[7]. The viability of HDFs and arteries 1 day after nanowarming were assessed by Hoechst-PI assays and alamarBlue®[8] and shown to remain ≥ 85% of controls vs. ≤ 30% of control when less optimal warming was used[8].

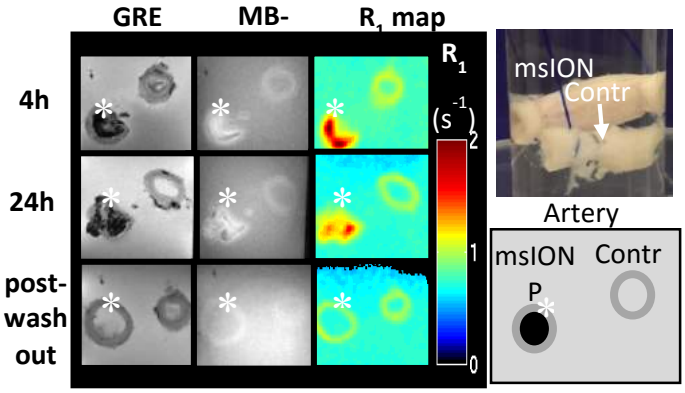

Figure 2: An artery loaded with 1.0 mg Fe/mL of msIONPs was compared to a control artery in V55. GRE and SWIFT MR images were acquired and the R_1 map was generated from the SWIFT data. The colorbar indicates the R_1 in 1/s. Images were taken at 4 and 24h after msIONP loading and post-wash out. These images demonstrate how easily msIONPs are washed out after 24h of incubation.

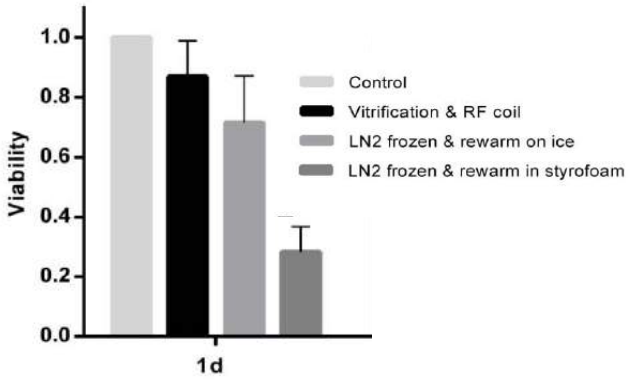

Figure 3: Artery viability post RF rewarming using alamarBlue® assay.

DISCUSSION

This study provides the first evidence that nanowarming can provide both the uniformity and speed necessary to successfully return cells and tissues from the vitrified state. Importantly, nanowarming is the first warming technology to match convective warming for small artery systems[8] and unlike convection should successfully scale with larger size systems. Thus, using this approach, we anticipate successful nanowarming of other vitrified tissues (i.e. heart valves, cartilage, skin)[9]. Future studies will use nanowarming to thaw vitrified organs and other large biomaterial systems that cannot at present be successfully thawed due to slow and non-uniform rates within the sample.

DIFFERENCES IN THE ABILITY OF BICYCLE HELMETS TO REDUCE RISK OF HEAD INJURY

Megan L. Bland and Steven Rowson

Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, VA, USA

INTRODUCTION

According to the U.S. Consumer Product Safety Commission (CPSC), cycling was the number one activity responsible for sports-related head injuries treated in U.S. emergency rooms in 2009, accounting for over 85,000 of the 446,800 total that year [1]. The actual number of injuries is likely much higher, as many go unreported. Bicycle helmets, which can help prevent injury, must pass a CPSC Safety Standard to be sold in the U.S. This standard mandates that in all specified impact tests, a helmet must prevent linear accelerations exceeding 300 g (a value associated with risk of skull fracture [2]).

While the CPSC standard requires helmet design to minimize severe head injury risk, no data are available to consumers on relative impact performance between helmets. The standard also does not test lower accelerations, such as those associated with concussion (around 100 g [3]). Helmet damage replication studies have shown that the most common impacts are around 100 g [4], and also that the majority of impacts are to the front and side of the helmet and often at the rim, which is below the impact test line specified by the standard [4-5].

The objective of this study was to investigate differences in the ability of bicycle helmets to attenuate impact accelerations associated with both mild brain injuries (by testing common impact conditions) and severe head injuries (by testing according to the standard).

METHODS

A twin-wire drop rig with a flat anvil was used to replicate CPSC standard impact tests. Ten helmet models were selected based on their varied design parameters (Table 1), and a total of 160 tests were conducted using four samples of each model and four impact conditions per sample. These conditions included two velocities: 3.4 and 6.2 m/s, and two locations: frontal-temporal (referred to as frontal in the remainder of the text) at the rim and temporal above the CPSC test line (Fig. 1). The lower velocity and rim location are not in accordance with the CPSC standard but were chosen to reflect common impact conditions found in literature [4]. Locations were a minimum of 120 mm apart (in accordance with the standard) and were mirrored on the helmet using a laser positioning system. Order of testing conditions was randomized between samples to avoid bias.

Table 1. Helmet models. Soft shells are made of a thin layer of polycarbonate, while hard shells are made of ABS or thicker polycarbonate. *MIPS: multidirectional impact protection system.

Helmet	Abbreviation	Shell Style	Weight [g]
Bell Solar Flare	BSF	Soft	312
Bell Star Pro	BSP	Soft	296
Bell Super 2 MIPS*	BMIPS	Hard	360
Catlike Whisper	CW	Soft	283
Giro Sutton MIPS*	GMIPS	Hard	370
Giro Synthe	GS	Soft	250
Nutcase Watermelon	N	Hard	465
Smith Optics Overtake	SOO	Soft	250
Schwinn Thrasher	ST	Soft	340
S-Works Evade	SWE	Soft	317

For each impact, linear acceleration data were collected and filtered according to SAE J211 with a CFC-1000 low pass filter. Average peak acceleration was determined per impact configuration by helmet. Risk of skull fracture and concussion for each test was calculated using previously published risk curves [2-3]. Results were compared using ANOVA and Tukey HSD post hoc tests.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

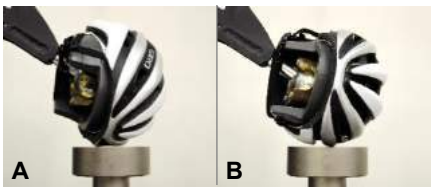

Figure 1. (A) Frontal (below CPSC test line) and (B) temporal (above CPSC test line) impact locations. Locations were mirrored on the helmet and were a minimum of 120 mm apart. Drop tests were performed at both locations at 3.4 and 6.2 m/s.

RESULTS

Figure 2 shows average peak linear accelerations at each impact configuration by helmet. For every helmet at 3.4 m/s and for seven helmets at 6.2 m/s, the temporal location yielded higher accelerations than the frontal location. Visual observation post-testing showed that the frontal area of each helmet appeared to experience more liner crushing than the temporal area. Overall, this sample of ten models produced average accelerations of 105.0 ± 22.4 g at 3.4 m/s and 226.8 ± 45.5 g at 6.2 m/s. Each impact configuration revealed significant differences between helmet models, most notably at the temporal location. The trends in relative impact performance between helmets appeared to be consistent between the two velocities at the temporal location, but produced more variance at the frontal location.

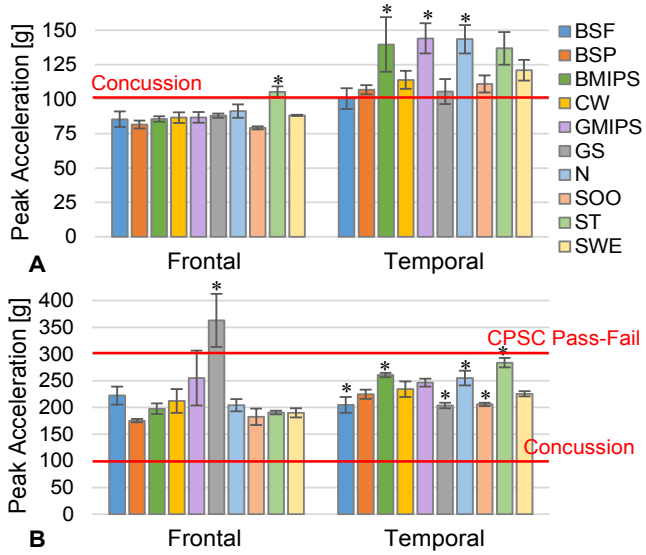

Figure 2. Peak acceleration per helmet type and location for 3.4 m/s (A) and 6.2 m/s (B). Error bars are standard deviations, and stars signify helmets that were significantly different than at least five other helmets ($p<0.05$). The red lines represent the CPSC threshold (300 g) and an average concussive acceleration (100 g).

Because accelerations were well below the CPSC threshold at 3.4 m/s (Fig. 2A) and well above the concussive level at 6.2 m/s (Fig. 2B), skull fracture risk only varied at 6.2 m/s and concussion risk at 3.4 m/s. These risks are shown in Figure 3. At 3.4 m/s (Fig. 3A), concussion risk at the frontal location was minimal and consistent, ranging from 2.7 to 17.7%. Risks varied more at the temporal location, with four models having over 60% risk and four models having less than 30% risk. At 6.2 m/s (Fig. 3B), skull fracture risks reflected concussion risk trends at the temporal location, although the differences were less extreme. Skull fracture risk at the frontal location was not as uniform as concussion risk at this location; seven models had low risks (<17%), but the other three were relatively high, with GS resulting in a risk of 95.0 ± 6.0%.

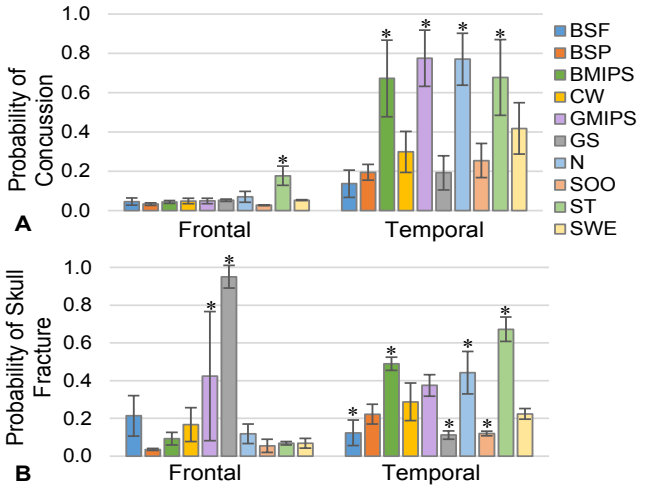

Figure 3. Concussion risk at 3.4 m/s (A) and skull fracture risk at 6.2 m/s (B) per helmet type and location. Error bars are standard deviations, and stars signify helmets that were significantly different than at least five other helmets ($p<0.05$).

DISCUSSION

The present study shows that significant and clinically relevant differences exist in the ability of helmets to attenuate impacts. These differences were more apparent and consistent at the temporal location. Frontal impact accelerations were generally lower than that of temporal impacts. This may suggest that the temporal part of the helmet experiences a larger contact area upon impact, increasing effective liner stiffness and reducing likelihood of crushing (the mechanism of energy absorption). This corroborates what was visually observed.

The high skull fracture risks for GS and GMIPS at the frontal location (Fig. 3B) may point to local weak points in helmet design, which would have been exacerbated at this higher impact energy. Because this location is below the CPSC impact test line, it would not have been considered in the homologation process. However, this is a very common location in accident reconstructions [4-5], so testing of helmets at this location would provide valuable safety information.

At the temporal location, BMIPS, GMIPS, N, and ST generally yielded higher risk values. Interestingly, these were the four heaviest helmets, and each had a hard shell except for ST (Table 1). This suggests that hard shell helmets may offer inferior impact protection compared to traditional bicycle helmets, but more testing is needed to confirm this.

Helmets that pass the CPSC standard are effective in reducing risk of severe head injury, but considerable variation in their ability to attenuate impact accelerations exists. Adding lower severity tests could improve ability to prevent milder injuries such as concussion, and expanding the impact area could ensure that helmets are effective at minimizing injury risk at all locations. Furthermore, disseminating objective impact data to the public would enable consumers to make informed decisions when purchasing helmets.

INTRODUCTION

For neonates born with single ventricle physiology, a series of three surgical procedures are typically undertaken to bypass the deficiencies caused by the missing ventricle. An initial palliation is performed soon after birth to provide oxygenated blood flow. Neonates with single ventricle heart defects are often treated with a modified Blalock-Taussig (mBT) shunt that connects a carotid or subclavian artery with the pulmonary artery to provide flow to the lungs. The mBT is not sustainable in the long term; the ventricle still operates at a high load and the shunt is prone to failure due to thrombosis, leading to high mortality rates [1, 2]. Ideally, a more stable cavopulmonary connection such as the bidirectional Glenn procedure (BDG) could be executed without the initial mBT. The bidirectional Glenn routes half of the deoxygenated blood through the superior vena cava (SVC) directly to the pulmonary arteries to be oxygenated by the lungs, reducing ventricular load. However, clinical studies have historically shown that the BDG had unacceptably high mortality rates in infants less than a month old, and so cannot be used in neonates [3].

A major cause of death for single ventricle patients is inadequate pulmonary circulation. Recently, a novel procedure called the assisted bidirectional Glenn (ABG) was proposed which addresses the inadequate pulmonary flow of the BDG and may permit implementation in neonates [4]. Based on the principle of an ejector pump, a constricted shunt between the innominate artery and the superior vena cava (SVC) acts as a nozzle to inject higher-energy flow into the SVC and elevate pulmonary pressure (Fig. 1). Multiscale modeling has shown that the ABG has benefits such as higher systemic oxygen saturation and delivery, higher pulmonary blood flow, and lower ventricular workload than the mBT for both neonatal and infant physiologies. SVC pressures also increased, which may lead to SVC syndrome, a potential cause of death with BDG.

In the current study, we apply the ABG to a single ventricle physiology in the originally proposed iteration (ABG-SVC), and consider an alternate configuration where the shunt is between the innominate artery and the innominate junction (ABG-IJ). The second iteration could offer potential benefits over the first by increasing the alignment of the injected jet with the direction of the bulk SVC flow and minimizing momentum loss.

METHODS

Multiscale simulations are used to compare the clinical performance of the ABG in two configurations against that of the BDG and the mBT shunt. A 3D anatomical model of the relevant physiology of a single-ventricle, pre-BDG patient was coupled to a 0D lumped parameter network (LPN) describing the closed loop circulation using an implicit coupling algorithm [5]. The 3D model represents an idealized patient at the pre-BDG, post-mBT stage. The LPN was derived from a prior study that aggregated clinical catheterization and angiographic data from 28 Norwood patients [6]. The pulmonary vascular resistance was set to 2.3 Wood units-area. In the mBT shunt model, the shunt is 3.5mm in diameter. In the ABG model, the shunt is 2.5mm in diameter with a 25% area reduction near its distal end. The heart rate was 120 BPM.

The local hemodynamics are solved with an in-house finite element solver, assuming rigid walls and a Newtonian fluid with density of 1.06 g/cm^3 and dynamic viscosity of 0.04 dyn s/cm^2. The model was constructed with an open-source cardiovascular modeling software (SimVascular, simvascular.org). The mesh consisted of 1.2 to 1.5 million tetrahedral elements generated by commercial meshing software (MeshSim, Simmetrix) with a maximum edge length of

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

0.6mm. The time step of the solver was set to 0.5 ms and at least 6 cycles were simulated to allow convergence to a steady state.

RESULTS

Clinical performance targets such as oxygen delivery and oxygen saturation are calculated using the oxygen transport model and parameters derived for the Norwood patients in [6]. A comparison of outcomes of each surgical procedure is shown in Table 1. The BDG and ABG procedures offer superior oxygen delivery and saturation compared to the mBT shunt and significantly decreased ventricular load. Both ABG configurations increase oxygen delivery and saturation and pulmonary pressure as desired, but also increase the ventricular load and venous pressure as measured in the innominate junction.

The two ABG configurations are comparable to each other, and the ABG-IJ does not offer any significant benefits over the originally proposed ABG-SVC configuration. For the ABG design and placement used in this study, the ABG-IJ performs slightly worse. The instantaneous flow fields (Figure 1) illustrate potential disadvantages to the ABG-IJ approach. While the jet leaving the ABG shunt is more aligned with the bulk flow, the greater distance between the jet and the pulmonary artery junction potentially reduces the pressure gradient through the SVC. Further, the jet must also mix with the converging flows in the innominate junction, reducing its momentum.

DISCUSSION

In this study we have presented a preliminary comparison of two possible configurations of the assisted bidirectional Glenn procedure. In practice, due its higher placement in the jugular region and its shorter shunt length, the ABG-IJ may be more difficult to execute. Consequently, the ABG-SVC configuration may be more relevant for future investigation since the performance of both configurations is comparable. Current work is underway to simulate the ABG in patient-specific models to verify that the benefits found in the idealized model will be observed with realistic circulatory parameters. Future work is also necessary to optimize the placement, shape, and size of the ABG shunt to maximize oxygen delivery, pulmonary flow rates, and saturation while maintaining low venous pressures and heart load.

INTRODUCTION

The Federal Railroad Administration (FRA) reported that 1,844 trespassing pedestrians (non-railroad employees) were struck and injured by moving railroad equipment between the years of 2012 and 2014 [1]. A common injury associated with these types of accidents is Traumatic amputation [2]. Specifically, these injuries occur as a result of interaction between a pedestrian's limb, the rail equipment, and the rail [3]. The circumstances surrounding the injury are often in question. Determining the exact manner and circumstances of the injuries can be challenging when no eyewitness or video evidence is available. In these circumstances, the injury pattern may provide key information in determining what the pedestrian was doing moments before the incident. This information is essential in the implementation of best practices regarding pedestrian safety around moving rail equipment.

Emergency Room nurses and/or physicians assess the injuries and document the findings in the medical records. These often include x-rays of the amputated limb. Currently, there is no research available that document the mechanism of injury associated with contact from a railroad wheel. In the absence of carefully controlled experiments that associate specific fracture patterns with limb position, these x-rays provide very little useful information beyond the location of the amputation. The fracture pattern of the amputated limb might provide details regarding the orientation of the limb at the moment of the incident. This information could assist the investigator in determining the sequence of events that led to the injury.

The current study investigated the mechanism associated with traumatic amputations to human femurs caused by contact with a moving railroad wheel. The objective of the current study was to carefully characterize long bone fracture patterns during a variety of relative positions to moving rail equipment. The current study hypothesized that distinct positioning of a pedestrian's limb would result in distinct and specific bony fracture patterns.

METHODS

Testing was performed at the Henry Ford DT&M Roundhouse in Dearborn, MI. A section of track was blue flagged for safety. Twelve 4th-generation composite femur bones (Sawbones®, Vashon island, WA, USA) were utilized to simulate human femur bones. The proximal and distal ends of each femur were potted into 4-inch and 3-inch schedule 40 PVC couplings, respectively, using room temperature curing epoxy resin (Fiber Strand™, Martin Senior Corp., Cleveland, OH, USA). Approximately 12 inches of composite bone was exposed between each pot. The exposed portion of each bone was covered with ordnance/ballistic gelatin (Gelatin Innovations, Shiller Park, IL, USA) to simulate soft tissue.

Each leg was secured on top of, and perpendicular to, the rail by fastening each pot to wooden blocks located on either side of the rail (Figure 1). These blocks were rigidly fixed to a railroad tie so the proximal end of the femur was 9 inches from the gauge side (i.e. inside) of the track (Figure 2). Each pot was fastened to the wooden blocks via hinges to allow the specimen to swing away from the locomotive after bone fracture occurred. Each bone was run over by the leading wheel of a locomotive (GE B-B-100/100-2GE733) traveling approximately 5 mph. The orientation of the legs was precisely controlled. Testing included two orientations (supine/prone) and two locomotive directions (medial/lateral). Fracture patterns were recorded and analyzed following each test.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Figure 1: Illustration of test setup

RESULTS

All 12 specimens fractured as a result of contact from the railroad wheel. The fracture of all 12 specimens was located on the gauge side the rail as a result of contact from the flange on the railroad wheel (Figure 2). None of the specimens were crushed. The most common fracture pattern was a butterfly wedge (n=6) (Figure 3). Interestingly, the other cases (comminuted; n=3, oblique; n=2, transverse; n=1) produced similar "Y" shaped crack propagation patterns, but the wedge fracture was incomplete (Figure 3). The fracture pattern was dependent on the orientation of the femur and direction of locomotive movement. Specifically, the "Y" shaped fracture pattern opened up towards the flange in all 12 specimens (Figure 3).

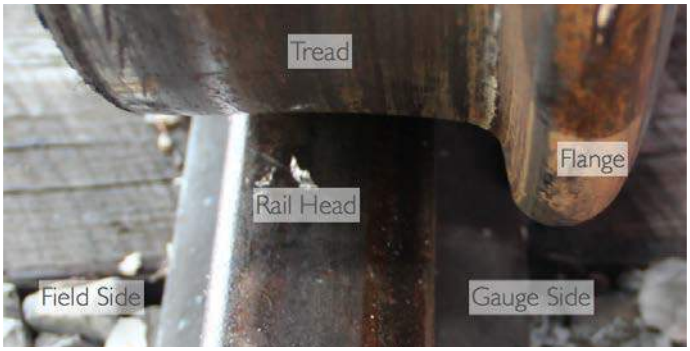

Figure 2: Illustration of a typical railroad wheel and rail

DISCUSSION

The results of the current study support the hypothesis that human bones contacted by moving railroad equipment develop a distinct fracture pattern that is dependent on the direction and impact location of the wheel on the limb/bone. Additionally, results demonstrated that the fracture patterns were all indicative of bending failure.

The results presented here are similar to previous experimental studies involving bending of human cadaveric long bones, which also generated similar patterns of fracture, including the typical butterfly, oblique and transverse fractures [4]. During bending, the fracture initiates on the tensile side and propagates to the neutral axis before bifurcating on the compression side to form the characteristic "Y" shape [5]. In the current study, the flange contacted the bone and attempted to push the bone out of the way resulting in 3 point bending.

This study shared the limitations inherent in utilizing composite bones. However, the use of cadaveric specimens was not possible given the nature and location of testing. Regardless, the 4th generation composite femur bones have been validated for use as a surrogate to healthy human bones for biomechanical testing [6]. The flexural rigidity has been shown to be less than 8% of the biological range of healthy adult bones and the failure modes closely match published findings of human bones [6]. It is also noteworthy that intra-specimen variations are under 10%, which permit greater experimental control, greater repeatability, and more meaningful comparisons between different scenarios.

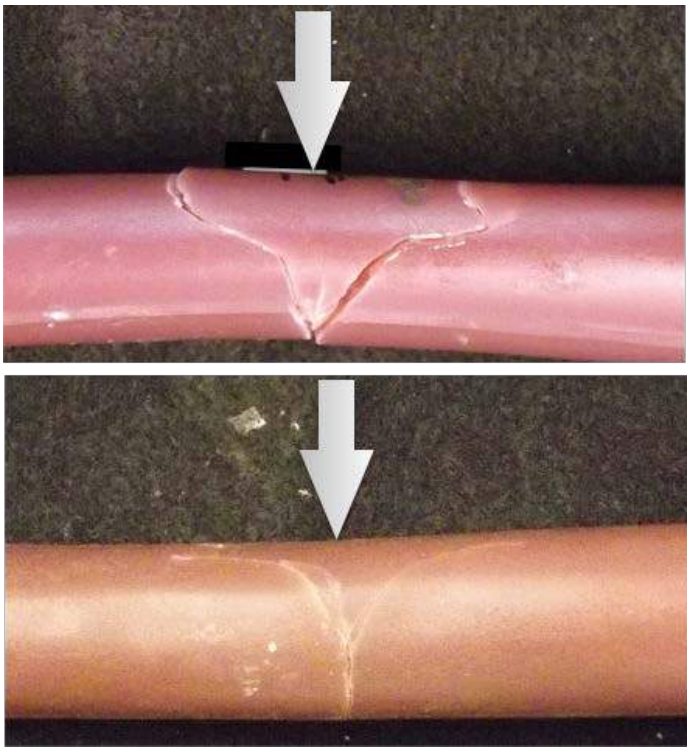

Figure 3: Illustration of the typical fracture patterns observed. Top: Butterfly wedge pattern; Bottom: Oblique / incomplete wedge pattern. Arrow indicates direction of impact

This study contradicts the conventional wisdom in forensic biomechanics that bones are crushed when run over by rail equipment. These results indicate that a bending fracture mechanism occurs. Therefore, it may be possible to determine the orientation of a body that was stuck and run over by moving railroad equipment. This is an important finding that will assist investigators when analyzing the circumstances surrounding a trespasser or railroad worker that sustained a traumatic amputation as a result of being run over by moving rail equipment.

ACKNOWLEDGEMENTS

The authors would like to thank Mr. Matthew Goodman from the Henry Ford DT&M Roundhouse for serving as our railroad engineer and allowing access to the facility and equipment.

INTRODUCTION

Heart valve tissue with collagenous ECM is regarded as a load-adapting biomaterial. Mechanical forces have significant influence for stimulating biomechanical regulation of heart valve cells that modulate tissue remodeling through collagen fibers, such as homeostasis, synthesis, or degradation of collagen. Generally, coordinated collagen synthesis and degradation are processes of matrix remodeling under physiological conditions. However, severe collagen depletion caused by matrix metalloproteinases (MMPs) pathologically induces matrix destruction, changes viscoelastic properties of the heart valve, further affects cellular regulations mediated by heart valve cells, and even leads to heart valve diseases. Moreover, during disease, it has been observed that the mechanical force enables the heart valve leaflet to retain structural strength via accumulation of collagen fibers and prevents deterioration or tissue destruction from collagen cleavage mediated by cellular activities.

The impact of collagen degradation on the biochemical regulation of heart valves in matrix and at cellular levels has been demonstrated comprehensively in previous studies. In this study, therefore, to understand the mechanical behavior in stress and the viscoelastic properties of the heart valve as they vary with collagen degradation, a tissue-level investigation of collagen-deficient heart valve tissue responding to its mechanical environment was conducted via testing of stress relaxation. Collagenase was applied to simulate collagen degradation by MMPs in matrix remodeling. A series of stress relaxation tests under different strain levels and with application of collagenase solution were performed to test the sensitivity of collagen fibers to proteolytic degradation. Further, the quantity of collagen released from the heart valve tissue was also measured to verify the relationship among collagenase concentrations, strain levels, and amounts of collagen remaining in heart valve tissues, corresponding with stress drops under different conditions.

METHODS

Preparation of specimens and collagenase solutions: Eight porcine hearts (sows, eight months to one year old) were dissected in the Nahunta Pork Center (Pikeville, NC) and returned to the laboratory within 60 minutes. Twenty-four AVs and 24 PVs were dissected axially along the aorta and pulmonary artery in each heart, and then square specimens (10 mm × 10 mm) were cut from all AV and PV leaflets [1]. To better maintain the physiological functions of the tissues in a biomimic environment, all 48 leaflet specimens were immediately immersed in HBSS solution (Lonza, Walkersville, MD) at 37°C. Meanwhile, three concentrations (0.2 mg/ml, 0.5 mg/ml, and 1.0 mg/ml) of collagenase solution (Worthington, Lakewood Township, NJ) were prepared for collagen degradation and then stored in the refrigerator at 4°C.

Biaxial Tissue Tester: Our laboratory's biaxial testing system and protocols have been described in detail previously [1]. In brief, a biaxial tissue tester (BioTester 5000, CellScale, Canada) equipped with two load cells (500 mN) for two perpendicular axes of loading was used for measuring the force and displacement of the semilunar heart valve tissue leaflets. The measured values were used to further obtain stress–strain curves and to calculate the parameters of the material stiffness. Synchronized time lapse video for real-time monitoring and postprocess analysis was performed with the charged-couple device (CCD) camera, which acquired images with a pixel resolution of 1280×960 at an acquisition rate of 15 Hz, with a lens focal length of 75 mm. A temperature-controlled saline chamber with data logging capability provided a physiological environment for testing soft tissue specimens. BioRakes provided fast and accurate

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

sample mounting: each BioRake consisted of five tungsten tines used to anchor one edge of the specimen. Four rakes provided uniform attachment across the edges of the samples and evenly distributed load spanning 4 mm in length on each side of the sample.

Stress Relaxation: Stress relaxation is a viscoelastic property of soft tissue which involves a decrease in stress under a constant strain. It is known that the magnitude of stress relaxation changes with variation of external mechanical stretching or the tissue structure. Here two groups were tested: 18 AV and 18 PV specimens were assigned to the collagenase-treated group (experimental group) and other fresh specimens were defined as the untreated group (control group). Six conditions where three different collagenase concentrations combined with two strain levels were applied to each AV or PV experimental group while two strain levels but no application of collagenase were set for each control group. Three AV or PV specimens were tested under each condition. Moreover, in order to avoid rapidly tearing the tissue sample during stretching before stress relaxation, 10 cycles of pre-conditioning stretching under 10% of strain and step increasing the strain rate at 2.5% per second were applied [2]. When the strain reached 37% or 50%, respectively, the specimen was held for 10,000 seconds to mimic comparable levels of relaxation [3-4]. For each AV or PV collagenase-treated group, during stress relaxation testing the specimens were immersed in the fluid chamber filled with 37°C HBSS for the first 3,000 seconds, and then HBSS was replaced immediately with collagenase solution. HBSS was gently removed from the chamber and collagenase solution was added using a Powerpette controller (VWR, Radnor, PA). However, solution replacement was not applied to each AV or PV untreated group. At the end of the testing, each specimen was gently removed from the biorakes and stored in individual centrifuge tubes filled with HBSS at 37°C for collagen assay.

Normalization of Data for Stress Relaxation: The stress relaxation responses at the various strain levels and collagenase solutions varied in magnitude. Higher strain level led to higher peak stress at the beginning of testing, and a lower state of stress relaxation resulted from smaller applied strain. To understand how applied strain and collagenase concentration affected stress relaxation, normalization of the stress relaxation that was exhibited by each stress drop relative to the peak stress was performed, which was beneficial for observing whether the patterns of all the curves were consistent. Therefore, normalization of stress relaxation was applied so as to more easily observe the mechanical behaviors of all specimens under different conditions.

RESULTS

The average AV responses to stress relaxation versus time at each condition are shown in **Figure 1**. Over a time period of 3,000 seconds (t = 0 ~ 3,000), the stress drops rapidly at the beginning of stress relaxation and then decreases more slowly to a constant value at each condition. The normalized stresses in the control group under all conditions remain between 0.4 and 0.5 after 3,000 seconds until the end of testing. However, after adding collagenase solution (t = 3,000 s), each stress-time curve for the collagenase-treated group starts to decline again until t = 10,000 s. At the end of testing, circumferential and radial normalized final stresses were below 0.1 for both conditions at 37.5% and 50% of strain when the 0.5 mg/ml or 1.0 mg/ml collagenase solution is applied. The smallest collagenase concentration (0.2 mg/ml) apparently has a smaller influence on stress drops, and the final normalized stresses in two directions are close to 0.2 and 0.15 under the strain conditions at 37.5% or 50%, respectively. Up to 98% of circumferential and radial normalized stresses drop under the condition of highest concentration of collagenase (1.0 mg/ml) for both strain levels. Further, it shows that only about 80% to 87% of the normalized stress relaxation in two directions occurs under the condition of lowest concentration of collagenase (0.2 mg/ml) for 37.5% or 50% of strain, respectively.

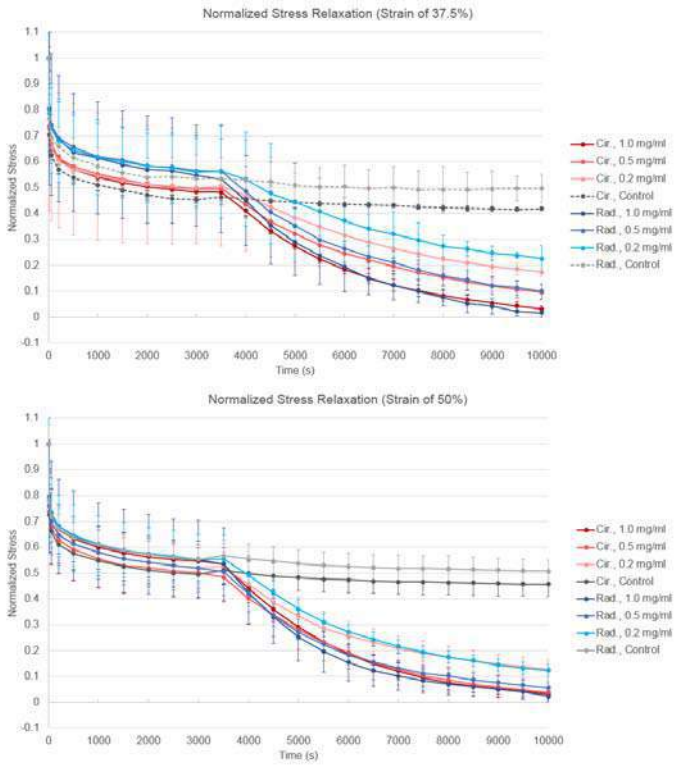

Figure 1: Average AV responses for stress relaxation versus time at two strain levels, 37.5% and 50%. Specimens immersed in HBSS are stretched under 37.5% or 50% of the strain control and holds for 10,000 seconds. For the collagenase-treated groups, HBSS is replaced with the 0.2 mg/ml, 0.5 mg/ml, or 1.0 mg/ml collagenase solution, respectively, after 3,000 seconds. For the control group, HBSS in the chamber is not changed. The circumferential direction of the specimen is denoted "Cir.," while the radial direction is "Rad."

INTRODUCTION

Most blood pumps are designed to boost the pumping abilities of the heart by mechanical energy transfer using a rotor. Due to the nature of blood contacting devices, the various components of blood are subjected to shear stresses caused by the device. The accurate analysis and prediction of blood damage during the design phase of a device has been difficult to achieve. This has been complicated by both the inaccuracy of computer tools used to model the blood flow and the large uncertainty in the reported values of stress that damage blood components. Different components of blood, such as red blood cells, platelets and VWF (Von Willebrand Factor), have different sensitivities to shear stress. Further, the damage to blood components has been correlated to both the magnitude of the shear stress and duration of time that the components are exposed to that stress (exposure time).

Several studies have presented measurements of red cell fragility and many of these are based on a shear flow created by a rotating element [1]. Unfortunately, in all of these devices, the suspension system of the rotor, whether a fluid or mechanical bearing, creates additional stress and may generate heat so that the bearings could be causing an additional and unknown shear on the fluid and suspended elements.

We developed a device that uses cylindrical Couette flow called the Maglev (Magnetic Levitation) shearing device. This device has a magnetically suspended rotor thus reducing a major amount of friction when compared to pumps with mechanical bearings. The device is intended to have a single region of laminar Couette flow (between an inner rotating cylinder and a stationary housing) that exposes the fluid to stress. The two primary goals of this work are to fabricate a functional magnetically levitated shearing device to induce stress in blood and other fluids using the new fluid path design and to determine the damage done to bovine blood at different exposure time and stress levels.

Myagmar [4] designed a fluid flow path built around the magnetic suspension from the RIT left ventricular assist device (LVAD) [2] that could be used to create the Maglev shearing device. Her work included design iterations of the rotor in order to achieve the desired range of shear stress and exposure time. For the first order approximation, it is assumed that the Maglev shearing device has a Couette flow condition that creates a constant shear stress and CFD results prove this to be true. Her work shows that the region 1 (gap region) provides a uniform shear stress throughout the region and, in region 2, the impact of shear stress is negligible (shear stress is inversely proportional to the gap).

METHODS

Experimental Apparatus: The goal of this work was to fabricate a device that exposes blood to varying shear stresses for known amounts of exposure time. We modified the magnetic suspension system of a fully magnetically levitated axial blood pump so that there are no regions of heat generation or high shear stress other than the single Couette flow region designed to have a constant shear stress. The base structure consists of the pump like assembly with the five major parts kept together in sequence with appropriate distances from each other. This design refers back to the initial design of the LVAD. The major parts of the shearing device, including the active components such as the motor, magnetic bearings, and position sensors, are shown using the cross sectional view of the shearing device; magnets are shown in color.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

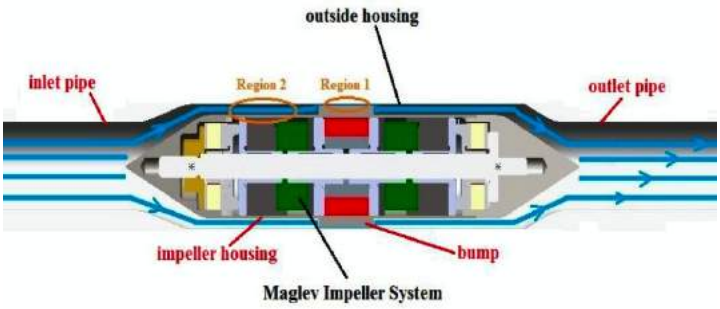

Figure 1: Maglev shearing device cross sectional view [4]

Blood Measurements: Whole citrated blood was pumped through the device at a controlled rate. The shear stress and exposure time are controlled and varied by adjusting the rotational speed and flow rate of the pump, respectively. Samples are to be collected for several combinations of shear stress and exposure time.

The samples were centrifuged in centrifuge tubes, stored in cuvettes, and then analyzed using the Cripps method [3], an optical technique to determine the quantity of free hemoglobin (fHB). The results of Cripps method, fHb in units of mg/dL,was converted to Index of Hemolysis (I.H) (%) assuming a total hemoglobin of 12,000 mg/dL (mean of the reported range of 9500 mg/dL to 13500 mg/dL).

Before the blood damage measurement, the blood samples were passed to a centrifuge tube using the syringe pump, tubes, and tube fittings () without passing through the device. After which centrifuge tube underwent the Cripps method and I.H was determined. The results showed that the samples experienced negligible damage (low I.H value) of 0.002%. This experiment was conducted 3 times and all results showed similar I.H value.

RESULTS

To date, we have only one trial and preliminary results, but they do indicate a dependence on exposure time for shear levels (0-125 Pa), as shown in Figure 2.

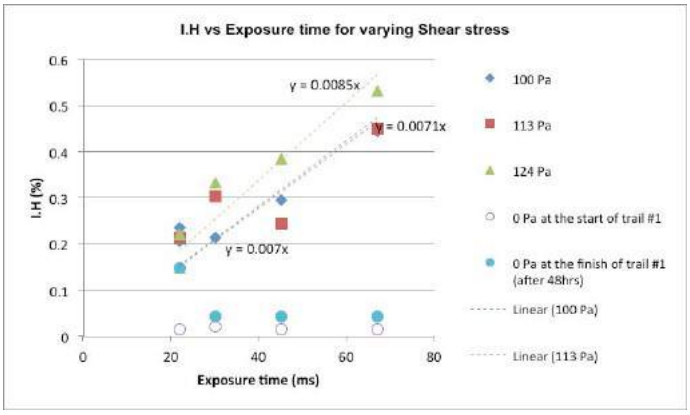

Figure 2: Preliminary data showing the amount of damage, Index of Hemolysis (IH) as a function of exposure time at three different levels of stress.

DISCUSSION

The use of a magnetic suspension for a blood shearing device has promise to create a method of exposing blood to a uniform shear field over a range of physiologically relevant stress magnitudes and exposure times. Although the data shown is limited for one trial and over a limited range of shear magnitudes, the feasibility of the apparatus and general method of I.H prediction is presented in this paper.

INTRODUCTION

More than six million Americans use assistive mobility devices such as walkers, canes, or crutches to increase their limited mobility each year. Of this six million, around 4.8 million use canes specifically to aid their movement [1,2]. A person's reason for using a cane can vary, but one of the more common reasons is for balance assistance during rehabilitation therapy. For many people, insurance covers the cost of rehabilitation therapy, but the insurance company will only continue to provide coverage if the patient is showing improvement [3]. Currently, there are devices that can quantitatively measure and record patient data, but the devices are not portable. They are bulky, and many times, they are confined to one particular area. These devices are usually wired to the clinician's computer and require the use of special cameras, reflective markers, and a special mat used to measure the force. This type of set-up limits maneuverability about the room, and the trailing wires are often inconvenient. We propose to build an attachment for a cane that will be more portable and user-friendly. The current prototype for this design is an attachment for the removable end of a standard adjustable cane. This position was chosen to allow the patient to use a cane that may be more familiar to the patient. The other key point of this design is that any data recorded during the therapy session is wirelessly transmitted and can be accessed remotely through a website. This type of design allows the clinician to test the patient in a more comfortable environment without dealing with various inconveniences such as trailing cords.

PRODUCT DESIGN

The proposed prototype has been designed to eliminate the use of trailing wires and the supplemental camera system. In this model, a force transducer measures the amount of reliance that the user has on the cane, and an inclinometer measures the angle at which the user holds the cane relative to the floor. A magnetic proximity sensor in conjunction with a permanent magnet inside an adjustable ankle strap measures how close the patient holds the cane to his body when using the cane. The force transducer is placed on the removable fitting at the bottom of the cane so that it can be fitted to different canes. The force transducer, the magnetic proximity sensor, and the inclinometer are connected to a breadboard and controlled by an Arduino Yún microcontroller. The data from each sensor are communicated to a central computer wirelessly with a web interface. The Arduino microcontroller contains a removable SD card for data storage.

Figure 1: Current Prototype

The Arduino microcontroller, the inclinometer, the magnetic proximity sensor, and the breadboard, to which each of the sensors are connected, are enclosed in a case attached to the removable end of the cane with a screw and bracket. This set up will restrict the movement of the housing case so that each measurement is accurate and not affected by any excess movement. Since the housing and electric components are affixed to the removable bottom of the cane, the patient can use

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the handle that is most comfortable for them. This type of device can help make it easier for the clinician to accurately test the patient while maintaining patient comfort.

BUDGET & MARKET ANALYSIS

The design budget shown in Table 1 displays the cost of the components used in the current prototype design. As testing continues, some elements may be substituted or changed. The miscellaneous materials will cover the expenses of batteries and other materials that may be changed during the testing process. Many of the materials used in this design are currently unavailable for bulk ordering which limits the amount of cost reduction. The projected budget cost for 100 units is also shown in Table 1, along with the expected pricing for each component of the design. The miscellaneous category is expected to cover the production costs, such as labor and equipment, for producing the 100 units. Some production costs can be reduced by purchasing parts in bulk, which can decrease the price per unit from $510 to $451.

Table 1: Budget

Component	Cost (1 Unit)	Cost (100 Units)
Arduino YUN	$80	$8,000
Cane	$20	$1,500
Load Cell*	$60	$6,000
Inclinometer	$20	$2,000

This product is designed to be used by any patient requiring rehabilitation services using canes. Over 4.8 million patients use canes for consistent or rehabilitative use. With this type of design, patients undergoing physical therapy will have definitive proof of improvement for insurance purposes. The design may be altered for use in a home setting so that the clinician can remotely monitor the patient without having to bring the patient into a clinical setting. Currently, the projected sale cost for this design is $550, which can allow for a profit margin of around $100 per unit when produced in the 100-unit bulk size.

ACKNOWLEDGEMENTS

This project would not have been possible without the contributions from the faculty and staff of the Agricultural and Biological Engineering Department at Mississippi State University, with special acknowledgments going to Dr. Filip To, Dr. Radhakrishnan Srinivasan, and Dr. Lakiesha Williams for their support and guidance during the design process. We would also like to thank the Methodist Rehabilitation Center in Jackson, Mississippi, for concept generation.

INTRODUCTION

Biological materials, such as fish scale, bone and nacre, exhibit outstanding strength and toughness with high contents of brittle minerals due to their ingenious design of microstructure. In the microstructure of these biological materials, the universal feature is that the brittle mineral tablets are bonded by relative soft organic interface. Thus, although the minerals are brittle, the organic interfaces could deflect the crack propagation and provide addition energy dissipation path along the interfacial surfaces. To investigate how the interface properties will determine the mechanical performance of bulk materials, various experimental tests were conducted, it was found out that the toughness and strength of bulk materials can be improved through the interface shear deformation [1], interlocking of nano-asperities and micro-scale waviness [2], as well as fracture of mineral bridges [3]. In the meanwhile, several theoretical models have also been proposed to study the transfer of stress through tablets and interfaces under the tension loading [4], the effects of interface stiffness and volume fraction on the stiffness and toughness response of bulk materials [5]. In addition, several numerical models were applied to study the effects of mineral-collagen interfacial behavior on microdamage accumulation in lamellar bone tissues [6], the independent roles of enzymatic and non-enzymatic cross-linking on the mechanical behavior of a mineralized collagen fibril [7]. Despite broad studies have been conducted to study the effects of these interfaces in high mechanical performance of biological materials, it still has not been fully elucidated how the interfaces' properties, such as interface toughness, strength and modulus, independently influences the mechanical response of bulk materials.

Since the mechanical performance of bionanocomposite material such as bone extrafibrillar matrix is strongly influenced by organic interface properties and behavior, it is necessary to provide a comprehensive interfacial model to describe different interfacial interactions and study the bulk material response from different interface behaviors. In this work, we developed an interfacial interaction model to characterize difference material interface behaviors and predict the mechanical response of extrafibrillar matrix in bone with wet and dry interface condition through modeling interface interaction. Through the study, the significant different mechanical behaviors of extrafibrillar matrix in bone were observed with dry and wet interface.

METHODS

Bionanocomposites, e.g. bone or nacre, consisting of brittle minerals bonded with low volume fraction of organic interface have high mechanical macroscopic properties. Due to the existing of organic interface, when fracture happened in bone, the mineral will slide along interface and dissipate more energy. During the interface deformation and debonding process, the interface will open along normal direction or shear along tangential direction. To predict the failure behavior of biological material related to interface properties, such as interface stiffness ($K_n \; or \; K_t$), interface strength ($\sigma_c \; or \; \tau_c$) and interface toughness ($\phi_n \; or \; \phi_t$), a generalized interfacial interaction model was proposed to model different interface behaviors. The traction-separation relations in normal and shear direction was used to govern the interface behavior as shown in Figure 1, which include four deformation stages in normal traction-separation law: compressive contact stage ($0 \sim \delta_0$), elastic stage ($\delta_0 \sim \delta_{dn}$), damage stage ($\delta_{dn} \sim \delta_{fn}$) and complete failure stage ($\delta_{fn} \sim +\infty$). In the shear traction-separation law, it has all the deformation stages except compressive contact stage. The interface toughness is the area under the traction-separation curve and the normal and shear interface toughness are respectively defined as:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\emptyset_n = \int_{\delta_0}^{\delta_{fn}} \mathbf{T}\, d\boldsymbol{\delta} \quad (1)$$

$$\emptyset_t = \int_{0}^{\delta_{ft}} \mathbf{T}\, d\boldsymbol{\delta} \quad (2)$$

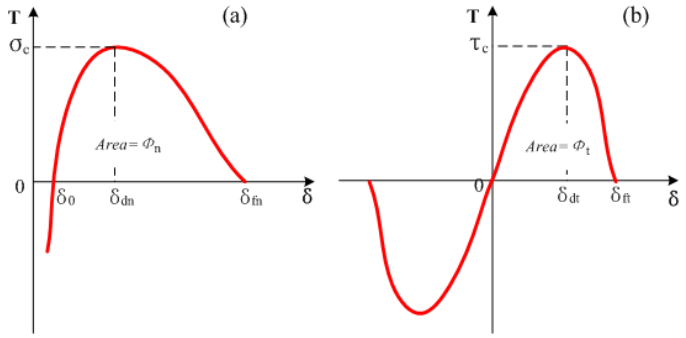

Figure 1: Generalized traction-separation relation used to characterize interface behavior:(a) normal direction, (b)tangential direction

From the experiment results, we observed that bone has brittle behavior when it is dry. However, the bone has softening process when it is in wet condition [8]. In Figure 2, it shows the variation of traction-separation relation with respect to dry and wet interface conditions. For dry interface condition, we assume that the organic interface has the brittle properties, that is, after passing the damage position, the interface completely fails in both normal and shear direction. For wet interface condition, we assume that the organic interface has the softening properties. After passing the damage position, the interface shows softening behavior and the interface tractions gradually decrease with the increase of separation after damage position in both normal and shear direction.

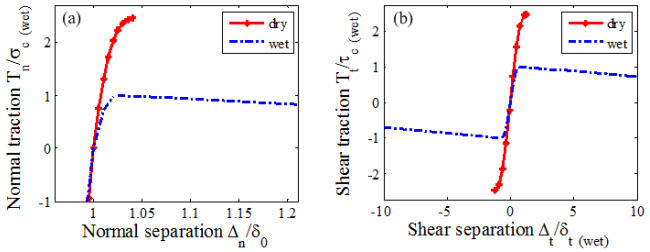

Figure 2: The traction-separation relations with respect to dry and wet interface conditions in: (a)normal direction, and (b)shear direction

RESULTS

In this study, we have run six simulation cases with random polycrystalline grain distribution in the extrafibrillar matrix specimen. The deformation process from one of the simulation cases with wet interface condition under compression loading is shown in Figure 3. The stress distribution, shear band and crack propagation are captured from the simulation. In addition, different mechanical response of extrafibrillar matrix with wet and dry organic interface conditions were captured in the simulation results. It was also found that the bulk material properties are strongly influenced by the interface properties in extrafibrillar matrix of bone.

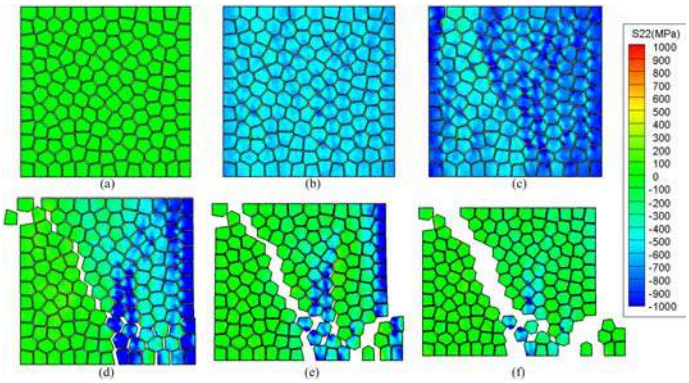

Figure 3: Snapshot of stress distribution(σ_{22}) under compression loading

DISCUSSION

Through the study of mechanical behavior of extrafibrillar matrix in bone, it was verified that the interface properties strongly influence the mechanical response of bulk materials. Additionally, by modeling the interface properties with interfacial interaction model, it provides a possible to independently study the effects of different interfacial interaction on the mechanical response of bulk material and bulk material behavior prediction through the interface properties and behavior. More importantly, it is possible to provide preliminary framework for artificial super material design.

INTRODUCTION

Optical motion capture is the current standard in kinematic analysis. This technology typically uses infra-red light, a dispersed cloud of cameras, and lightweight retro-reflective markers which are attached to a subject. While providing the ability to measure dynamic activities with minimal disturbance to the subject's typical movements, there are several known limitations of this technology. Optical markers are typically attached to the skin or clothing of a subject, and thus move with the skin/clothes, not the underlying bone; this phenomenon is known as soft tissue artifact (STA). STA induces errors at the individual marker level, which propagates into assumptions about bone or segment rigidity, and ultimately creates errors in measured joint kinematics. In the lower extremity, these issues are further compounded by the numerous small and closely neighboring joints of the foot and ankle, causing marker occlusion and interference.

The nature and extent of STA has been studied in the foot using both ultrasound [1] and with subcutaneous bone pins (a highly invasive method) [2]. An X-ray based imaging modality, biplane fluoroscopy, is also capable of directly capturing bone motion, and is non-invasive. This technique uses two fluoroscope units to image a common 3D volume while a subject's joint of interest moves through that volume. This method is ideal for evaluating STA due to its higher accuracy than optical methods [3].

We imaged the foot and ankle of non-pathological subjects during gait, while those subjects were instrumented with modified optical motion capture markers. Our objectives were to evaluate (A) movement of the skin markers relative to the bone, (B) the rigidity of bone marker sets, and (C) the error imparted to joint motion due to STA. At the time of this abstract submission, we present data for the hallux and first metatarsal.

METHODS

Our biplane fluoroscopy system (biplane system) is comprised of two BV Pulsera fluoroscopes (Philips Medical Systems; Best, The Netherlands), disarticulated and positioned around an imaging walkway [3]. A pair of high-speed video cameras (Phantom v12, Vision Research, Wayne NJ) captured dynamic fluoroscope images at 1000 frames/sec. An 8-camera optical motion capture system (Vicon Motion Systems Ltd., UK) was also installed around the walkway.

Tantalum beads (1.6mm) were inserted into the center of a set of 6.4mm optical motion capture markers – with care taken to not damage any of the optical surfaces of the marker. Three healthy subjects (VA IRB approved) were instrumented with optical markers based on a validated foot model [4]. Each subject was imaged in quiet stance, and during gait until three forefoot and three hindfoot trials were captured. For this preliminary data, we did not identify heel strike and foot off, and thus only show gait duration. Subjects also received a CT scan of their feet and distal legs.

We used custom software to extract the 3D geometry of each bone from the CT scans, and then tracked the 3D trajectory of the hallux and first metatarsal in the fluoroscopic videos [5]. A bead-tracking algorithm was developed to determine the position of the bead inside of the optical markers, in the fluoroscope images; this bead position was then converted to a 3D trajectory for comparison with the bone data. The markers tracked are: proximal phalanx (hallux), PM; and the first metatarsal head, FMH and base, FMB.

To determine (A) the movement of the skin mounted markers relative to bone, we transformed the position of the optical markers PM, FMH and FMB from global space to a local embedded coordinate

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

system for the bone (hallux or first metatarsal respectively) that they are "attached" to in the static image. We compared this static location to each subject's dynamic marker position during the gait trials. For (B), we considered only the FMH and FMB markers as they are assumed to be a rigid single bone segment. The change in the distance between FMH and FMB during gait, relative to the static position of these markers was calculated. For (C), we determined the joint angles of the hallux coordinate system, relative to the local coordinate system of the first metatarsal. The first metatarsal coordinate system was then used to evaluate the motion of PM relative to FMH and FMB.

RESULTS

The magnitude of the RMS error (including all three components) across all three subjects was 1.46 mm for the PM marker, 1.90 mm for the FMH marker, and 1.62 mm for FMB marker. It should be noted that while subjects S1 and S3 had similar walking speeds on average (0.88 m/s and 0.89 m/s), S2 was markedly faster (1.43 m/s). No clear trends in the errors were observed (Figure 1). For each subject, the RMS change in first metatarsal segment length (Figure 2) was 0.87 mm, 2.69 mm, and 1.63 mm, this error varied over time, indicating effective compression/lengthening of the FMB-FMH segment.

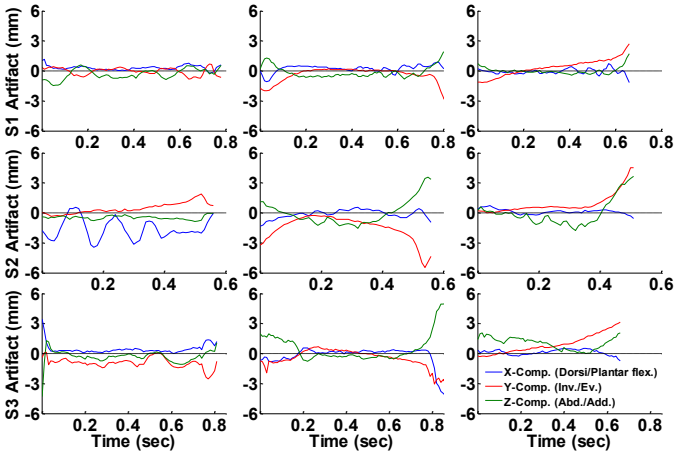

Figure 1: Soft tissue artifact average for PM, FMH, and FMB markers of subjects 1-3 (S1-3). The motion artifact is the difference between the static and dynamic coordinates of the markers (i.e., zero artifact indicates that the marker perfectly tracked the underlying bone throughout the trial). Coordinates are given in the coordinate system of the relevant bone (i.e., the hallux for PM; the first metatarsal for FMH and FMB).

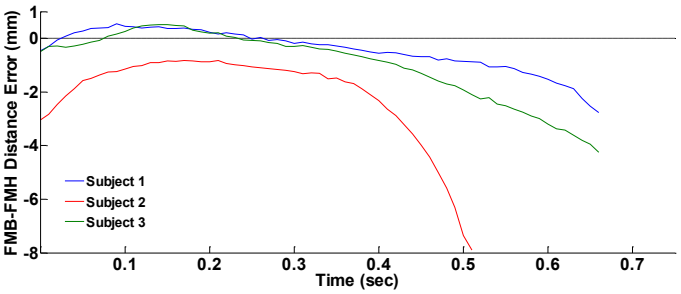

Figure 2: Marker-to-marker distance error between the markers at the two extremities of the first metatarsal (i.e., FMB and FMH markers) at a given time during the gait trial. Zero error indicates that the marker-to-marker distance is identical to the distance during the static pose.

The hallux joint angle varied markedly between the bone-based tracking and the markers, especially for subject S3 (Figure 3). The joint angles calculated directly from the bones tended to be markedly larger than their analogous angles calculated from the markers, with the bone data often giving joint angles that are frequently twice or more greater than the marker data. This resulted in the marker data exhibiting a RMS error of 8.63° in X (dorsiflexion/plantar flexion), 7.06° in Y (inversion/eversion), and 5.97° in Z (abduction/adduction) across all subjects.

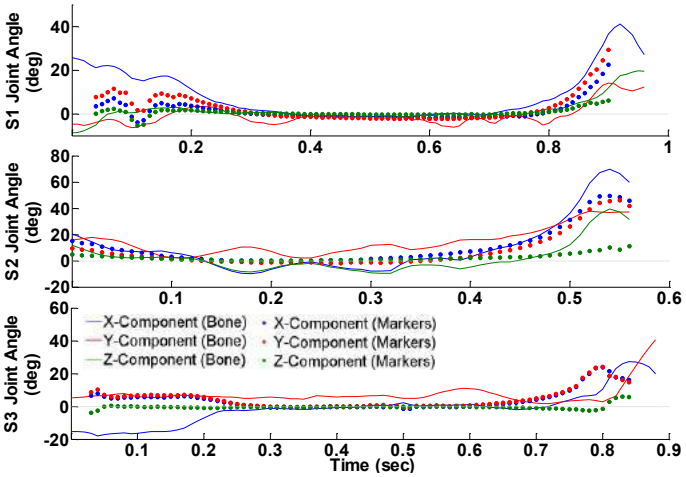

Figure 3: Joint kinematics derived from the bone-based tracking (solid lines) and from the angle between PM-FMH and FMH-FMB marker segments, in the first metatarsal coordinate system. Note that the Z-component was not available for the S3 bone tracking.

DISCUSSION

The objectives of this work were to evaluate how STA arises and ultimately affects measures of joint kinematics. We have demonstrated the error in skin markers motion due to soft tissue deformation during gait. This data, particularly the segment rigidity evaluation, also suggests that such errors vary in magnitude during gait, and increase with joint speed. Lastly, the propagation of these errors into joint kinematics, with typical errors of ~6-9°, identifies how such errors compound in the final measurement of interest.

This work aims to inform investigators and clinicians about the sources and magnitudes of errors present in optical motion capture of the foot and ankle. Such information can aid investigators in designing new optical marker models, and in compensating for errors that currently are undetectable in these systems.

Processing of the other bones of the foot and ankle, as well as the optical motion capture data is currently underway.

INTRODUCTION

Stem cell (SC) therapy promises to revolutionize the treatment of various diseases with the potential to regenerate functional tissues *in vitro* or *in vivo*. Several recent studies have demonstrated that cellular microenvironments such as ligand-activated cell-matrix interactions and/or matrix physical properties such as elasticity and geometry have significant role in directing the differentiation processes in stem cells (1, 2). Microarrays have emerged as an important tool for studying stem cell processes in a high-throughput manner (3). Nevertheless, most of the existing ECM arrays being either 2-D or shallow 3-D are not able to capture the effects of biophysical and chemical cues on stem-cell fate completely. Here, we report the development of a microarray platform based on electrospun nanofibrous hydrogels of photoclickable thiol-ene poly(ethylene glycol) (PEG) hydrogels. Thiol- ene polymerizations proceed by an orthogonal, step-growth mechanism where one thiol reacts with one ene leading to a highly homogenous distribution in crosslinks, thus imparting tunable substrate stiffness with high fidelity (4). Furthermore, it allows for the subsequent covalent post-modification of PEG thiol-ene hydrogel substrates with small engineered peptides with high reactivity and specificity. Taken together, the manipulation of the matrix properties, such as stiffness and geometry, in concert with engineered peptides will facilitate the interrogation of multiple and distinct SC microenvironments. To this end, we demonstrate the potential application of this high-throughput technology for screening of a variety of engineered 3D microenvironments with applications in stem cell fate optimization and disease model progression.

METHODS

Substrate Preparation: Four-arm poly(ethylene glycol) norbornene (PEGNB, 5 kDa, 10wt%), poly(ethylene glycol) dithiol (1 kDa), poly(ethylene oxide) (5 wt%, 400 kDa), and I2959 (0.1 wt%) were dissolved in DI water, electrospun (16 kV, 20 cm, 0.8 ml/hr), and collected as fibers (647.6 ± 81.4 nm) on a glass slide previously modified with 3-(mercaptopropyl) triethoxysilane. Substrates were subsequently exposed to UV (352 nm, 5 mW/cm2) light for specific time points to achieve elastic modulus ranging from 1-20 kPa.

Microarray Fabrication: Microarrays were prepared using a 2470 Aushon arrayer (Fig 1A). Fluorescent dye (Alexa Fluor® 488/546 -C5 maleimide) or peptide (CRGDS, CRGES, YRGDS, CGDEAK-A568) in buffer (1% glycerol, 0.2% Triton X-100, 0.1% I2959) were printed and exposed to UV light.

Cell Culture: Cell studies were conducted using primary bovine pulmonary arterial smooth muscle cells (PASMCs). Following cell culture, substrates were fixed and subsequently stained with DAPI (cell nuclei) and A488-phallodin (F-actin cytoskeleton) to observe cell adhesion and spreading.

RESULTS

Characterization of 3-dimensional fibrous PEG thiol-ene hydrogel matrix: Fibrous, PEG thiol-ene hydrogels were prepared by an electrospinning process similar to our previous method (5). We thiolated conventional glass slides to allow covalent attachment of the PEG thiol-ene matrices which improves sample handling and longevity for cell studies. We examined the fibrous architecture of electrospun PEG thiol-ene substrates using SEM in both hydrated and dry states.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Microscopy revealed a highly fibrous hydrogel structure with average fiber diameter of 647.6 ± 81.4 nm.

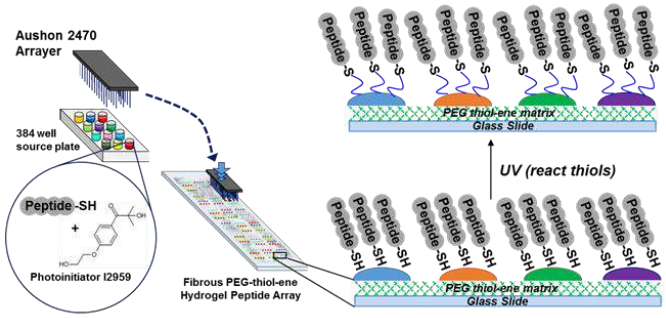

Figure 1. Fibrous PEG-thiol-ene hydrogel peptide array fabrication. Schematic of microarray contact printer used to spot different peptide solutions onto electrospun PEG-thiol-ene coated glass slide. Crosslinking is achieved via UV light initiated thiol-ene reactions of di-thiol and norbornene groups on 4-armPEGNB.

Engineered Peptide Synthesis and Array Fabrication: The deposition of peptide microdots is illustrated in Figure 1. Following the preparation of PEG thiol-ene matrices, peptide printing is achieved using a contact style arrayer (Ashon 2470) and subsequently post stabilized via a second UV step. Post functionalization of our PEG thiol-ene matrices allows for the covalent incorporation of a diversity of biological ligands or other engineered biomolecules. To illustrate this, printing optimization strategies employing a fluorescently labelled control (CDGEA 488/546) are depicted in Figure 2. Post functionalization of engineered biomolecules is obtained via a secondary UV exposure, see Figure 2A. Deposition size was found to be approximately 200μm in diameter which is in agreement with our previous work utilizing ECM proteins (5).

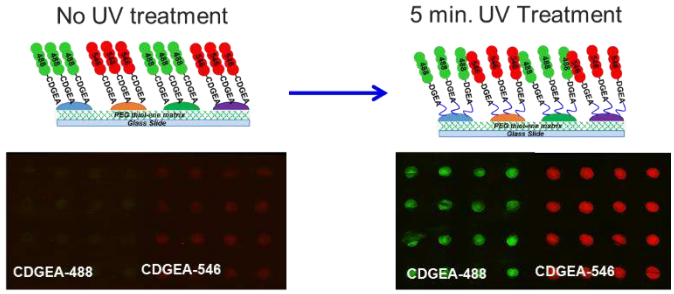

Figure 2. Representative example of fluorescently labeled CDGEA with and without UV stabilization.

Primary Cell Adhesion and Spreading within Peptide Functionalized PEG thiol-ene Matrices: To further demonstrate the utility of our peptide arrays, we investigated the influence of the adhesive ligand (RGD) post functionalized within the PEG thiol-ene matrices, as shown in Figure 3. As depicted from the confocal microscope images in Figure 3, the cells only attached to RGD deposited spots with no attachment outside the printing deposition, i.e. neat PEG thiol-ene substrate. In contrast, covalent attachment of CRGES peptide (scrambled sequence) to the PEG thiol-ene matrices did not facilitate cell adhesion (Figure 3D). We varied CRGD dilution range from 0.1 to 15 mM and observed cell attachment of PASMCs after 24 h (Figure 3C, single cellular island) with cell attachment positively correlated with CRGDS printing concentration (data not shown). The prepared PEG thiol-ene peptide arrays were amenable to extended culture period of up to 72 h (Figure 3E). The precision of robotic array spotting allows for complex array layout and design over large areas (Figure 3C). The utility of these complex depositions are further supported by localized cellular attachment on CRGDS functionalized complex array as shown in Figure 3F. We can conclude from these results that advanced peptide array designs can be prepared, with cellular recognition at modest peptide concentrations (< 1 mM), as well as potential for more complex

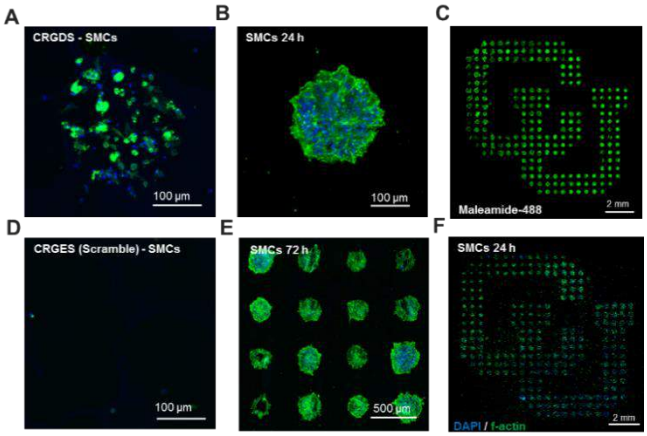

Figure 3. Cells selectively attach to engineered peptides. Confocal images of initial attachment of PASMCs cultured on fibrous PEG thiol-ene hydrogels functionalized with CRGDS (A), CRGES (scramble) (D), cellular island prepared from PASMCs after 24 h (B) and 72 h respectively (E). Custom array layout represented by fluorescent control (maliamide)(C) and analogous PASMC culture using CRGDS functionalized deposition (F).

combinatorial array designs.

DISCUSSION

Similar to our previous work using ECM proteins (5), we find contact-style array technology to represent a reliable and reproducible method to prepare complex array designs using engineered peptides, which may be further functionalized via UV stabilization post array printing. Here we demonstrated the potential to exploit the adhesive ligand (RGD) to influence cell attachment and spreading of PASMCs within 24 or 72 h. While we only investigated the role of RGD ligand on cell behavior, we note that post functionalization of our PEG thiol-ene matrices can be achieved with any molecule with thiol-ene reactivity, i.e. cysteine residues. Collectively, these results highlight the diverse properties of our substrates, whereby stiffness, geometry, and functionalized molecules (biological or chemical) can be tuned with high specificity. Future work will be focused on designing combinatorial peptide studies, whereby, the integration of several biological ligands of interest with tunable physical properties can instruct stem cell differentiation in a highly specific manner.

INTRODUCTION

Ganciclovir is a hydrophilic drug used as antiviral medicine in form of eye drops, gel ointment and as a surgically-inserted implant in the eye. For patients having serious conditions such as cytomegalovirus (CMV) retinitis with immune deficiency syndrome (AIDS), one of the preferred treatment options is ganciclovir implant insertion in the eye. To improve and effectively apply Ganciclovir for ocular treatment, knowledge of the transport properties (permeability, diffusion) is required. This information is also necessary for mathematical modeling of the drug transport processes.

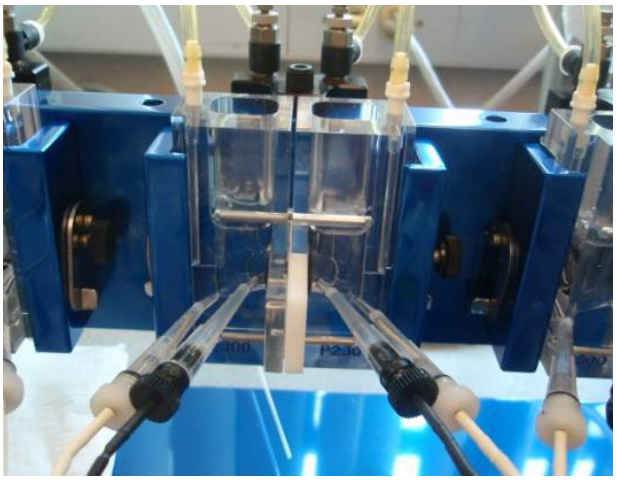

Figure 1: Ussing chamber apparatus for permeability measurement.

METHODS

For osmotically-driven permeability measurements, conventional Ussing chamber (Figure1) was used. In our experimental model various ocular tissues of interest have been isolated from "ex-vivo" bovine, rabbit and Alzheimer human eyes. These membranes were inserted between the two chambers (donor and acceptor) of the apparatus. DMEM with 4.5 g/L glucose (4ml) was added to both sides of the diffusion chamber, while Ganciclovir is injected into donor side only. Samples of 100 μL were taken from donor and acceptor sides at different time points (30, 60, 90, 120, 150, 180, 210, and 240 minutes. During the experiment, oxygen was bubbled through both chambers to keep the tissue healthy for as long as possible. HPLC (High Performance Liquid Chromatography) was utilized to measure Ganciclovir concentration. The change in concentration due to sample extraction was allowed for in the calculation of the net permeation of Ganciclovir across the membrane.

RESULTS

Our preliminary results (Table 1) showed that for bovine eyes, the RPE has the highest value of P_{app} (4.273±0.706 x10^{-5} cm/s) followed by sclera (3.463±0.532 x10^{-5} cm/s) and iris (2.540±0.137 x10^{-5} cm/s). For rabbit eyes the P_{app} across RPE is 4.332 x10^{-6} cm/s) and RPE-choroid-sclera is 4.375 x10^{-6} cm/s. For ex-vivo human eyes the permeability across cornea is 0.684 x x10^{-5} cm/s.

Linear plots of total accumulation of the drug versus time were obtained. The flux values were obtained from the slopes (Figure 2). The plots do not pass through the origin because of some degree of hysteresis with the tissue absorbing the Ganciclovir at the start of the experiment. The net flow rate per unit area, J, of Ganciclovir across the membrane was obtained from the plots of sample concentration

Table 1: Apparent permeability coefficient values of ganciclovir through bovine and rabbit tissues.

measurements at the different time points. The concentration measurements were used to calculate the total accumulation of Ganciclovir on the receiver side.

With making some assumptions that:

- the concentration profile is linear in time after initial hysteresis;
- the Ganciclovir concentration in the donor side is nearly constant;
- the concentration in the receiver chamber is close to zero;

the permeability (called also apparent permeability) can be found using following equation:

$$P_{app} = \frac{J}{C_{donor}}$$

where P_{app} is apparent permeability, J is the flux of the drug from the donor to the receptor side and C_{donor} is the concentration of the drug in the donor chamber. While we are able to see the time-varying accumulation of Ganciclovir, the relative concentration changes on the donor side is quite small, and the receiver side remains very small as compared with the donor, thus justifying the above assumptions.

DISCUSSION

The apparent permeability of Ganciclovir through RPE and RPE-choroid-sclera are very similar for both rabbit and bovine eyes (Table 1). However, the apparent permeability through bovine RPE is ten times higher in comparison with the rabbit RPE.

We compared our data with the existing ones in the literature and found that the permeability through the rabbit cornea is very close to the permeability of the same drug in the cornea reported by Majumdar [1].

We are presently working on conducting more experiments and collecting more samples for bovine, rabbit and human tissues to build a mathematical predictive model for transport mechanisms of Ganciclovir, and thus improve drug delivery techniques.

INTRODUCTION

Nanoparticle based therapy is a new mode of cancer therapy that offers a solution to barriers of current treatment approaches such as untargeted and insufficient delivery of drugs. The goal of nanoparticle based therapy is to deliver a concentrated amount of drug to a targeted tumor site resulting in less systemic toxicity with high treatment efficacy[1]. Nanoparticle systems are unique in that they allow for both passive and active targeting of tumors while maintaining multi-functionality. The proangiogenic behavior present in tumors results in formation of leaky blood vessels with abnormal architecture. The tumor mass also has poor lymphatic drainage, allowing for accumulation of macromolecules. Nanoparticles exploit this feature known as the enhanced permeability and retention (EPR) effect, to target solid tumors.[2] Particles that are too small will be cleared by the kidneys, preventing accumulation into the tumor site, and particles that are too large will not adequately penetrate the tumor vasculature and interstitial space.[2]

Many novel therapeutic and diagnostic nanoparticles have been developed and optimized using *in vitro* studies; however there has been relatively less success in their *in vivo* translation. Nanoparticles face many barriers *in vivo* before they successfully reach the target site such as crossing the endothelium or penetrating through a dense extracellular matrix. Traditional models used to study nanoparticle enhanced therapy transport consist of monolayer cell culture or animal models. Monolayer models are static and are unable to reproduce the transport and uptake conditions nanoparticles undergo *in vivo*. While animal models provide a more physiologically representative environment, the interplay of many different variables such as growth factor, immune reaction, and cellular interactions result in an uncontrollable environment making it difficult to isolate the effect of a specific stimulus on cell response without enormous expense. Due to these limitations, 3D microfluidic models provide a good alternate.

3D microfluidic tumor models are able to reproduce the native tumor microenvironment in a controllable system. These models commonly utilize a small number of cells making it hard to perform assays that require large amount of cell matter. Also, the flow rate present in these systems is much lower than physiological flow. Additionally, it is vital that the 3D *in vitro* model be capable of recapitulating key dynamic nanoparticle transport processes including transvascular transport, diffusion and interaction with the extracellular matrix, and cellular uptake, along with presenting a physiologically relevant tumor microenvironment.

We have developed a 3D microfluidic tumor engineered platform that recreates the tumor microenvironment through the incorporation of an endothelialized microchannel within a collagen 3D matrix containing human cancer cells. The optically clear platform allows for high imaging resolution and dynamic monitoring of nanoparticle transport and angiogenic vessel sprouting.

METHODS

Collagen was extracted using a protocol developed by Buchanan et. al. [3]. Briefly, collagen was extracted from rat tail tendons and dissolved in 0.01 M HCl overnight, centrifuged, and lyophilized. The lyophilized collagen was resuspended in HCl to create a collagen stock solution of 14 mg/mL. For the tumor platforms, human breast adenocarcinoma cells, MDA-MB-231 (ATCC) and telomerase immortalized human microvascular endothelial cells (TIME) which stably express GFP or mKate respectively were used in this study. To create the perfusable tumor platform, 14 mg/ml collagen stock solution was mixed with 10x DMEM, 1N NaOH to neutralize the HCl, and supplemented with DMEM containing MDA-MB-231 cells to bring the final solution to 7 mg/ml collagen. The mixture was then injected into

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

cylindrical FEP tubing with a 22G needle inserted to create a vessel lumen in the center as shown in Fig. 1. TIME cells were then added to the inner vessel lumen and a 72 hr graded flow rate protocol previously developed [3] was utilized in order to maintain endothelial integrity and establish a confluent monolayer. To determine the ability of the 3D microfluidic system to be used to measure nanoparticle transport, polystyrene nanoparticles ranging from 20-1000nm (Fluor-Max , Thermo Scientific) at 0.05 mg/ml were introduced into the system at a rate of 26 µl/min. Vessel permeability was quantified by flowing the channel with 10ug/ml fluorescently labeled 70 kDa dextran at a rate of 26 µl/min. Nanoparticle uptake was assessed by treating the platform with collagenase to isolate the cells and then performing flow cytometry.

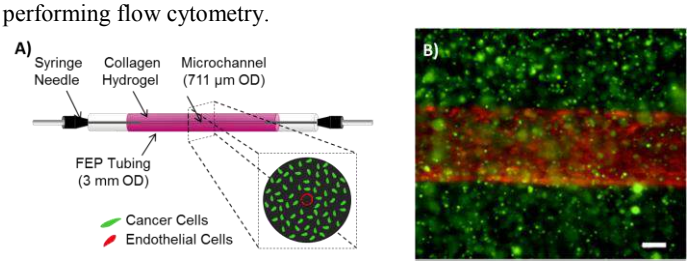

Fig. 1: A. Microfluidic tumor platform setup. B. Co-culture of MDA-MB-231 cells (green) in collagen with an endothelialized (red) inner lumen.

RESULTS

Vessel permeability was determined by flowing green fluorescently labeled dextran through the channel at 2 time points: 24 hr and 72 hr [Fig. 2]. Vessel permeability was lower at 72 hr time which allowed for the formation of a confluent endothelium [Fig 2A] compared to leaky endothelium present at the 24 hr time point [Fig 2B].

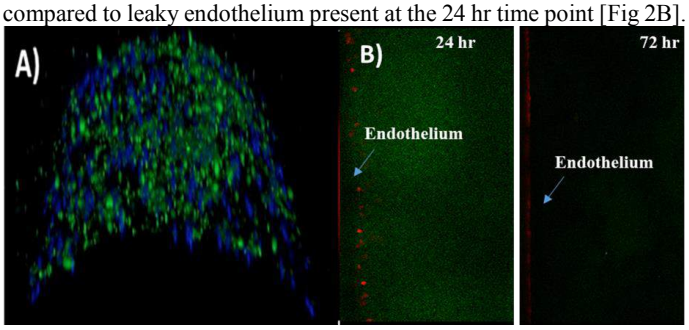

Fig. 2: A) Microfluidic platform with a confluent layer of endothelium. B) Permeability of dextran (green) across the endothelium (red) at 24 and 72 hrs

We had previously shown that nanoparticles aggregate at the endothelium and extravastion of nanoparticles into the collagen matrix increases over time using the 50 nm particle. In this study, we compared the transport of 2 different sized particles: 20 nm, and 1000 nm as shown in Fig 3. The 20 nm particles crossed the endothelium and extravasated into the collagen matrix as shown in Fig 3 where the white lines depict the boundaries of nanoparticle (shown in red) extravasation at 0 hr [Fig 3A] and 3 hrs [Fig 3B]. In contrast, the 1000 nm particles were unable to extravasate into the collagen matrix as shown in the front view [Fig 3C] and a cross sectional view [Fig 3D] of the channel. The 1000 nm particles aggregated at the endothelium which is revealed by the intensity of the nanoparticle signal (red) being concentrated at the endothelium and lack of red signal in the collagen matrix with the MDA-MB-231 cells (green cells in Fig 3C). Although tumor endothelial pore size has been measured to be as large as 2 microns, the results from this study imply that nanoparticles need to be significantly smaller than the pore size of the endothelium to ensure the delivery of the drug to the target site.

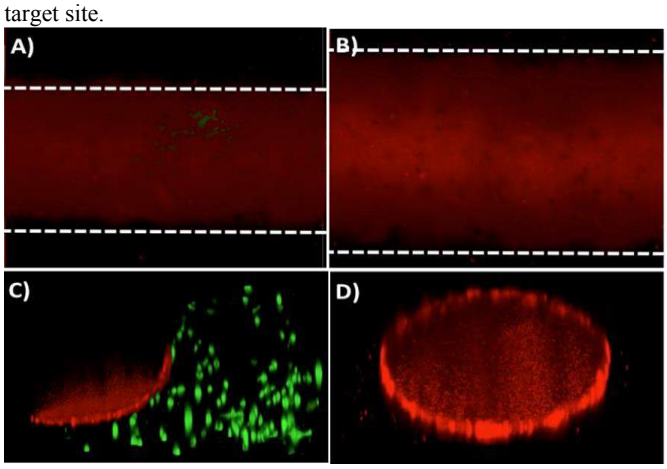

Fig. 3: Confocal Imaging of size dependent transport of nanoparticles. The transvascular transport of 20 nm particles at 0h (A) and 3h (B). 1000 nm particles show no extravasation after 12h (C) in co-culture setup and accumulation of particles along the lumen is seen in (D).

Cellular uptake studies as shown in Fig. 4 revealed that the uptake increased over time [Fig. 4B] and the aggregation of particle along the endothelium resulted in uptake of the nanoparticle by both the endothelial and the cancer cells [Fig. 4A].

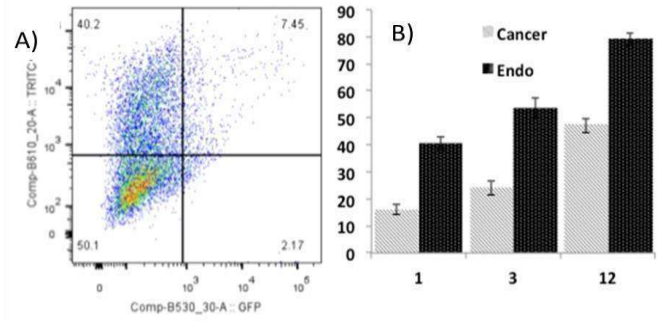

Fig. 4: A) FACS Analysis of Uptake of 50nm Particles by Cancer and Endothelial cells at 12h. B) Summary of results

DISCUSSION

The development of tissue engineered platforms to study key events of nanoparticle transport will lead to optimized nanoparticle treatments of cancer. In this study, we developed a microfluidic device that recapitulates many of the barriers nanoparticles face during tumor transport including transvascular transport, diffusion and interaction with an extracellular matrix, and nanoparticle uptake. Nanoparticle penetration and uptake studies showed the versatility of the system, confirmed a particle size cutoff for efficient nanoparticle delivery deep into the extracellular matrix and the need for modification to ensure uptake of particles by the appropriate cells. This platform can be utilized to study and understand nanoparticle features such as size and shape and to test the efficacy of tumor cell active targeting to result in greater uptake by cancer cells. Future studies will include incorporation of stromal cells and studying transport in abnormal vessel geometries.

INTRODUCTION

Osteoarthritis (OA) is characterized by the degradation of the articular cartilage that provides load support and smooth articulation for diarthrodial joints. This disease is the leading cause of disability among American adults that impacts over 50 million adults in the US, with 54% of adults over 65 afflicted (1). Both biochemical and biomechanical stimuli regulate the functional behavior of articular chondrocytes. IGF-I is key for regulation of chondrocyte function, stimulating anabolic, anti-catabolic and mitogenic chondrocyte functions (2). Mechanical stimulation is also necessary for regulation of articular chondrocyte function (3) and physical exercise is essential to articular cartilage integrity (4). The transient receptor potential vanilloid 4 (TRPV4) channel is central to chondrocyte mechano-transduction *in vitro* (5) and *in vivo* (6). Loss of TRPV4 activation through inhibition or knockout of the channel results in a loss of mechanosensitivity and the development of OA in male mice (6).

The gating mechanism through which TRPV4 is mechanically activated has yet to be determined. We have previously shown that regulation of mechanically-sensitive channel gating in osteoblasts is mediated by the actin cytoskeleton (7). Here, we propose that insulin-like growth factor 1 (IGF-1) modulates TRPV4 channel activity similarly, by altering the actin cytoskeleton to protect chondrocytes from extensive loading.

METHODS

Cell Culture - ATDC5 mouse chondrocyte-like cells were cultured in Dulbecco's Modified Eagle Medium, 10% FBS, 100 U/ml penicillin G, and 100 µg/ml streptomycin and buffered to pH 7.35 with 26 mM $NaHCO_3$ and maintained at 37°C with humidified 5% CO_2, 95% air and passaged once cells reached 75% confluence. Human chondrocytes were purchased from Lonza and cultured in Chondrocyte Basal Medium (Lonza) supplemented with Chondrocyte Growth SingleQuots (Lonza) containing R3-IGF-1, bFGF, transferrin, insulin, 5% FBS, 30 mg/ml gentamicin and 15 µg/ml amphotericin until 50% confluent, then placed in serum/supplement free medium. For FSS testing, cells were seeded at 1×10^3 cells/cm^2 on 75 mm x 25 mm x 1 mm glass slides coated with chicken-derived type II collagen (150 µg/ml in 0.02N acetic acid). Once cells reached 80-90% confluence, they were serum starved for 24 hours prior to testing with serum free medium.

Intracellular Calcium Measurement - Chondrocytes were loaded with 10µM of the fluorescent Ca^{2+} chelator, Fluo-4, for 15 minutes at 37°C. Cells were washed with HBSS with Ca^{2+} and Mg^{2+} and allowed to equilibrate for 10 minutes. $[Ca^{2+}]_I$ was visualized on a Zeiss LSM 510 high speed confocal microscope with a 10x C-Apochromat water immersion lens with a 488nm excitation laser and changes in fluorescent intensity were measured over time. Baseline calcium values were established then stimulated with hypotonic medium (HTS:150mOsm). Images were analyzed using Zeiss Zen Physiology 2012 software. Response to stimulation was measured as change in intensity from average baseline to peak response.

Electrophysiological recordings: Pipettes were manufactured by pulling 100 µL capillary tubes to a tip diameter of ~0.5 micron (tip resistance = 1-5 MΩ) using a dual-stage pipette puller (Narishige). ATDC5 cells were plated on 15mm round coverglass and bathed in an extracellular-like solution (ECF) while pipettes were filled with an intracellular-like solution (ICF). Whole cell recordings were performed with an Axopatch 200B amplifier (Axon Instruments) equipped with a Digidata 1332A A/D converter. Recordings were performed using a ramp protocol that clamped the cell from -80mV to +80mV over a 1s period. Cells were then challenged with HTS and changes in whole cell current recorded using the same ramp protocol as described above.

RESULTS

We examined the effects of pretreatment of cells from the rat chondrocyte-like cell line, ATDC-5, with 100ng/ml IGF-1 and how this pretreatment altered TRPV4 channel activity and the corresponding $[Ca^{2+}]_i$ response to HTS. We found that IGF-1 increased actin stress fiber formation within three hours of stimulation that resulted in a 3-4 fold increase in ATDC-5 cell stiffness that could be attenuated with depolymerization of actin with CytoD. We also observed that treatment of ATDC5 cells with either the non-specific TRPV channel blocker, ruthenium red (RR) or the specific TRPV4 blocker, RN1734 (RN) significantly attenuated the increase in $[Ca^{2+}]_i$ in response to HTS and the number of cells responding to HTS. This response could be significantly reduced by addition of 100 ng/ml IGF-1 prior to HTS. To determine if IGF-1 suppressed the TRPV4 channel activity through either actin polymerization or cell stiffening, we treated the cells with CytoD following IGF-1 pretreatment, but 30 min before HTS. We found that CytoD partially restored the $[Ca^{2+}]_i$ response to HTS (Fig. 1). Using patch clamp techniques, we used a whole cell configuration to measure whole cell TRPV4 currents during application of HTS in chondrocytes (Fig. 2). Using a ramp protocol that clamps the voltage progressively from -80mV to +80mV over a 1 sec time period, we forego any activation of voltage-activated currents that have introduced current rectification observed in previous studies. However, some rectification was still seen in the representative trace. No whole cell currents were observed in static cells at room temperature. However, within 5 min of application of HTS, whole cell currents increased. The effects of IGF-1 on TRPV4 channel activity was confirmed in these patch studies where we saw that pre-treatment of chondrocytes with 100 ng/ml IGF-1 three hours prior to patch completely attenuated TRPV4 channel activity to hypotonic challenge.

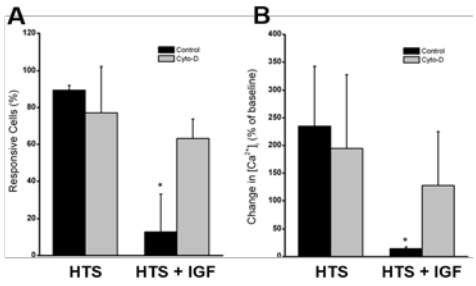

Fig. 1. Addition of 100 ng/ml IGF-1 3 hr prior to HTS challenge significantly suppressed (A) the number of cells responding to HTS and (B) the peak $[Ca^{2+}]_I$. Depolymerization of actin with cytochalasin D (5μM) rescued this response. * denotes p< 0.05

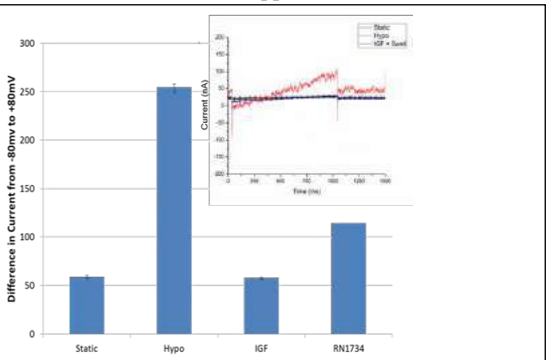

Figure 2. Inset: Representative trace of whole cell currents from static cells (untreated conditions; black line) or subjected to hypotonic swelling (red line) or IGF+hypotonic swelling (blue line). Bar graph: Summary of chondrocyte peak currents in conditions of static, hypotonically swelled, IGF-1-treated cells with HTS or inhibited by RN1734. (n=2)

We next examined the role of the cytoskeleton in regulation of TRPV4 mechanical gating in human chondrocytes. Interestingly, both depolymerization of actin with cytochalasin D and disruption of the microtubule network with vincristine significantly decreased the response of human chondrocytes to mechanical load, suggesting that both are involved in the regulation of TRPV4 gating in human cells (Fig.3)

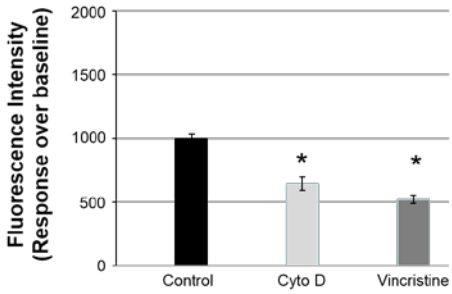

Fig. 3. HTS response of human chondrocytes to depolymerization of the actin cytoskeleton with 5μM cytochalasin D or microtubule destabilization with 5μM vincristine. Both cytoskeletal disrupting agents significantly decreased the peak $[Ca^{2+}]_I$ response to HTS. * denotes p<0.001.

DISCUSSION

Previous studies have shown that, individually, both IGF-1 treatment and activation of TRPV4 can elicit anabolic responses in chondrocytes. However, the data presented here would suggest that IGF-1 may tonically suppress TRPV4 channel activity by increasing cell stiffness through increased polymerization of the actin, and perhaps the microtubule, network. This is not particularly surprising since IGF-1 stimulation of chondrocytes has been shown to activate small Rho-GTPases that control actin polymerization. (8, 9). A potential explanation is that increased loading of chondrocytes can result in release of inflammatory factors that could be caused by TRPV4 activation and ultimately lead to OA. OA may not proceed in younger adults due to the relatively high levels of IGF-1. However, the same amount of load in older adults, where IGF-1 is very low, could result in OA due to overactivity or hypersensitivity of the TRPV4 channel.

DYNAMIC BENDING RESPONSE OF THE UNRESTRAINED FEMUR IN UNDERBODY BLAST LOADING

Joshua G. Chen[1], Gwansik Park[1], E. Meade Spratley[1], Robert S. Salzar[1]

(1) Center for Applied Biomechanics
University of Virginia
Charlottesville, VA, United States

INTRODUCTION

Occupants of military vehicles exposed to underbody blast (UBB) have endured high percentages of lower extremity trauma, including greater than 50% prevalence of fractures. Among these, femur injuries represent a small but debilitating cohort, accounting for approximately 13% of all UBB injuries.[1] UBB loading through the femur creates a load path that is thought to be distinct from other high-rate injuries, such as are observed in automotive collisions. Unlike automotive intrusion injuries, entrapment is not thought to be responsible for the observed UBB femur fractures as the occupant knees are unrestrained. Instead, one hypothesized mechanism of injury is the dynamic anteroposterior bending of the femur wherein the high-rate vertical displacement of the distal condyles results in a significant thigh soft-tissue load on the anterior femur and results in a bending fracture along the mid-shaft. However, given the extremely high loading rates involved in UBB, laboratory recreation of this mechanism is difficult.

One tool available to begin investigating the bending response to high-rate UBB loading is the finite element model (FEM). Numerous models of the human body have been developed for use in the automotive safety industry with extensive validation at automotive crash rates. Of these, the Global Human Body Model Consortium (GHBMC) models represent some of the most advanced, detailed, and well-validated efforts available.

The objective of this study is to determine the input conditions that produce peak moments and peak strains associated with femur bending fractures. We then intend to parametrically investigate the effects of peak ΔV and rise-time on these tolerances.

METHODS

For this study, we developed a template thigh FE model based on the geometry of the Global Human Body Model Consortium-owned GHBMC M50 Seated Model (version 4.3). This template thigh model was used to simulate an anteroposterior displacement of the distal femur at rates within the realm of those seen in UBB. A total of 18 simulations of the femur were recorded wherein the distal condyles were subjected to input velocities of 5, 10, 15, 20, 25, and 30m/s with 5, 10, and 15ms peak times. The proximal end of the femur was constrained to zero translation, but free rotation in all three directions, analogous to a spherical joint. Distally, the impacting plate was constrained in all rotation axes and in two translational dimensions, allowing only one-dimensional linear motion. The impactor plate began in contact with the rectangular potting cup, the plate then prescribed a symmetric triangular shaped velocity curve defined by peak velocity and time-to-peak, causing the femur and potting to rotate anteriorly and superiorly away from the impactor.

Three planes were defined *a priori* at the proximal third, center, and distal third where section force, stress, strain, and moment time-histories were recorded for each simulation.

Within the GHBMC femur, bone was represented using a piecewise elastic-plastic material model. Soft tissue was represented using a hyperelastic constitutive model including rate effects. To avoid potential instabilities within the model at such high-rates, failure criteria such as element deletion were disabled. Instead, thresholds for fracture relative to peak moment and peak strain derived from the existing automotive literature were used to assess the likelihood fracture within the model.[2,3]

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

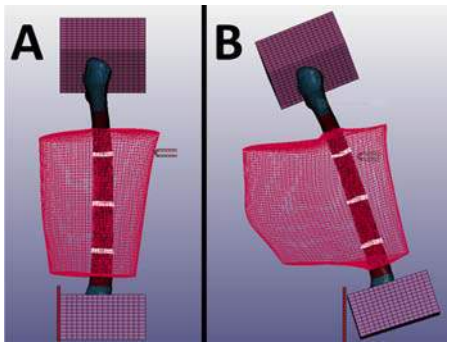

Figure 1: Femur model with A) Impactor Plate at rest B) Impactor Plate undergoing Prescribed Motion

RESULTS

The largest moments in all three sections were observed in the sagittal plane about the positive x-axis defined in the LS-Dyna workspace. [Figure 1B] As expected, the distal section typically developed its peak moment and peak strain earlier, and at a higher magnitude, than did the more proximal sections. Increasing velocity input and decreasing time-to-peak resulted in higher magnitude responses for all measures such that 30m/s in 5ms was the most severe impact tested.

Peak moments exceeded the existing dynamic failure criteria of 387 Nm for 10/18 simulations. These represented all velocities cases except 5m/s for the 5ms time-to-peak group; the 20, 25, and 30m/s velocities for the 10ms time-to-peak group; and 25 and 30m/s velocities for the 15ms group. However, peak strains exceeded the existing ultimate strain threshold of 1.60% in fewer total simulations, 4/18. [3]

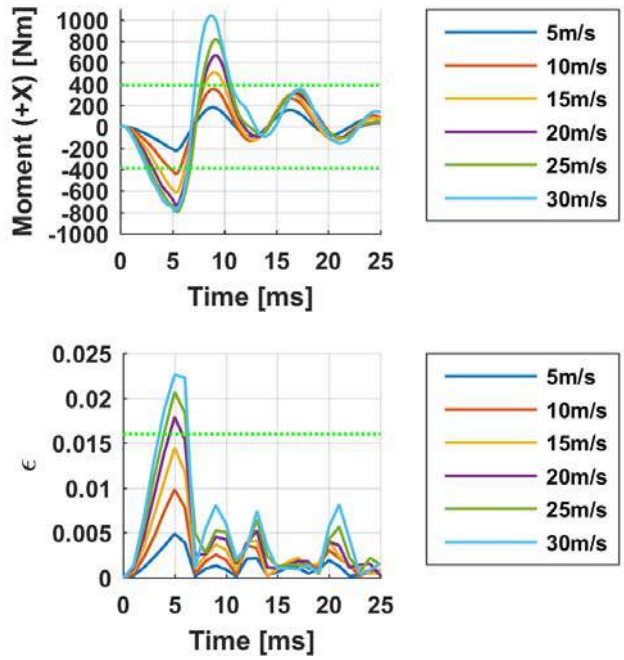

Figure 2. Moment versus time (A) and Strain versus time plots for the 5ms rise time group. Dotted green line indicates existing failure threshold of 387Nm and 1.60% ε, respectively.

DISCUSSION

As expected, the simulations with the highest loading rates produced the largest magnitude moment and strain responses and that by lowering the input energy (by decreasing ΔV) or by elongating the pulse by increasing the rise-time, the model response could be made less severe. Additionally, by design, the model did not fail, but instead allowed for an elastic response beyond the typical automotive failure levels set for the GHBMC bone. This allowed for the investigation of how loading rate effected changes in material response. In general, the models predicted a trend of higher sensitivity to moment versus strain for all three rise-time groups. This may be noteworthy as the two criteria investigated were derived from very similar automotive-rate testing of femurs in three-point bending at a ΔV of 1.5m/s, thus suggesting that the two criterion may not be interchangeable at very high rates. [2,3] Future characterization work should include human surrogate testing at loading rates greater than 10 m/s and shorter rise times in order to fully characterize the strain and moment tolerances of the femur.

This study artificially excluded failure and the corresponding element deletion within the mesh in order to explore the sensitivity of the GHBMC model to high-rate loading. Consequently, moment and strain responses for elements with stresses beyond the typical yield stress of bone will be over predicted, making interpretation of the long-time response of the model difficult. Additionally, the input pulses prescribed here do not account for injuries that would be incurred by loading the distal femur through the lower extremity. Such injuries would very likely disrupt load transmission through the limb and reduce the likelihood of a bending-type fracture of the femur. Thus, it is unclear if loading rates associated with femur bending failure are indeed possible under the inertia-only force of the thigh soft-tissue.

These simulations provide insight for designing laboratory experiments around bending-type femur fractures in vertically loaded, inertial-only situations. Future work will focus on collecting and incorporating sufficiently high-rate human surrogate data to more fully validate this model and provide further understanding of the human tolerance to this mechanism of injury.

Table 1: Predicted fracture risk. (M) denotes moment threshold exceeded; (S) denotes ultimate strain threshold exceeded.

		Rise Time		
		5ms	10ms	15ms
Input Velocity	5m/s			
	10m/s	M		
	15m/s	M

INTRODUCTION

Each year, approximately 1.7 million people in the United States suffer from traumatic brain injury (TBI) [1]. TBI is a major public health concern as it is a leading cause of disability and injury-related death - accounting for nearly one third of all injury-related deaths [2]. To prevent and treat these types of injuries, the fundamental injury mechanisms need to be well-characterized and understood. There are various theories about what causes brain injury, but there is still a great deal that we do not know about the fundamentals of brain injury, as well as injury thresholds. Various methods have been used over the years to investigate and gain a deeper understanding of brain injury mechanisms, including animal tests, cadaver studies, anthropomorphic test devices (ATDs), and computational models [7]. Finite element (FE) models are powerful tools because they can provide spatial and temporal distributions of stresses and strains over the problem domain. The quality of a model's predictions, however, is dependent on the accuracy of the modeled geometry and the model's ability to describe complex mechanical behavior and material response.

FE models with varying degrees of anatomical accuracy, element size and material properties, have been developed. The process typically employed in current model development begins with image segmentation of medical images, such as computed tomography (CT) and magnetic resonance imaging (MRI), to define 3D surfaces of desired structures, followed by a surface-based mesh generation process. During the mesh generation process, complex anatomical features are frequently simplified and 'smoothed' to allow faster development and simple contact definitions. One feature of particular importance that is over-simplified in many brain FEMs is the gyral folds on the surface of the brain. The brain surface is typically modeled as a smooth surface, but this simplification and reduction in geometrical accuracy could significantly impact the model's local brain response and prediction of injury. Various studies have indicated that the intricate folding patterns on the surface of the brain greatly affect both the distribution and magnitude of stress and strain throughout the brain [11].

The experimental validation of FE models is a critical step in model development and the application of such models to fields such as injury prediction and automotive safety. Many currently used FEMs have only been validated intracranial pressure (ICP) experiments, but there is some controversy about whether validating against only pressure data is sufficient, since some brain injuries (e.g., diffuse axonal injury) are found to be dependent on strain [30]. This motivates validation using the more robust displacement data set that captures the strain field that develops in the brain, which is examined in the current investigation. The objective of the current study is to present localized brain motion validation data for three experimental configurations for six validated brain FE models and use an objective rating method for a quantitative comparison between models.

METHODS

Three cadaver impact tests (C755-T2, C383-T1, C291-T1) conducted by Hardy et al. (2001, 2007) are presented in the current study and validation data for the following six FE models are examined and compared: Atlas-Based Brain Model (ABM), Simulated Injury Monitor (SIMon), Global Human Body Models Consortium (GHBMC) head model, Total Human Model for Safety (THUMS) head model, Kungliga Tekniska Högskolan (KTH) model, and the Dartmouth Head Injury Model (DHIM). The ABM, a high-resolution FE model derived from the International Consortium for Brain Mapping (ICBM) brain atlas was developed in our lab and multi-objective optimization was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

performed to identify the ideal parameters for the brain material model.

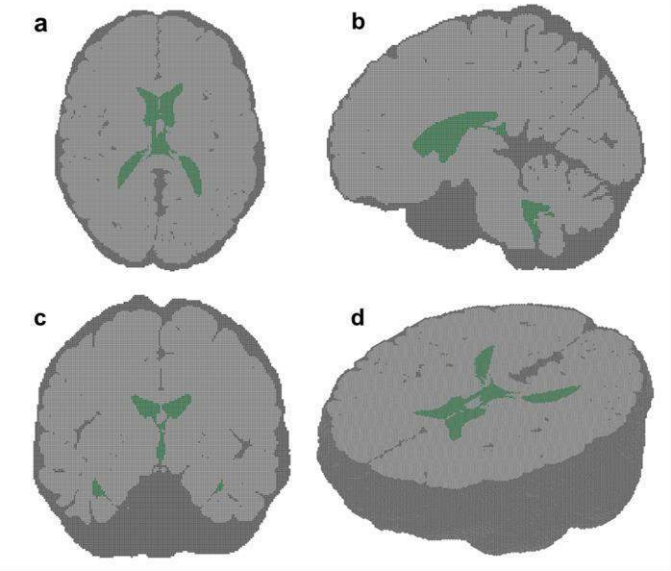

Figure 1: Axial (a), sagittal (b), coronal (c), and isometric views of the ABM.

The impact conditions were simulated using LS-DYNA for the ABM, SIMon, GHBMC, and THUMS models and localized brain motion quantified using nodal displacements. Results for the remaining models were obtained from published literature. To evaluate model performance for each impact condition, the error between experimental and predicted displacements for each NDT was quantified using a powerful metric called CORA (CORrelation and Analysis) [44]. CORA evaluates the similarity of two curves by calculating a rating using two methods: the corridor method and the cross-correlation method. Both ratings range from 0 to 1 and are averaged to determine a total CORA score (1 corresponds to a perfect match). The corridor method computes a rating based on where the comparison curve falls in relation to corridors around the reference curve. The cross-correlation method is based on ratings for the phase shift, size and progression of time-shifted curves.

RESULTS

CORA scores were computed for each model for each NDT curve and averaged to compute an average CORA score for each experimental configuration for each model (Table 1).

Table 1: Average CORA scores

	C755-T2	C383-T1	C291-T1	Average
ABM	0.445	0.421	**0.412**	**0.426**
SIMon	0.342	0.411	0.393	0.382
GHBMC	0.433	0.386	0.241	0.353
THUMS	0.418	0.302	0.343	0.354
KTH	**0.476**	0.419	0.355	0.417
DHIM*	0.316	**0.432**	-	0.374

DISCUSSION

Looking at model response in the C755-T2 impact, we see that all models perform relatively well, with the KTH model scoring the highest average CORA rating of 0.476. Most of the models considered score the highest CORA rating under this impact configuration. This is likely because it is the lowest severity impact with the simplest experimental curves (i.e. few local maxima and minima). In the C383-T1 test, the DHIM has the highest CORA score. It should be noted, however, that this CORA rating is based on the response of only 4 of the 12 total NDTs, so it may not be representative of the response of the DHIM in general. Considering the remaining models, whose performance is based on the response of all 12 NDTs, the ABM performs best with a CORA score of 0.421. Considering the response in the C291-T1 parietal configuration, which was the most severe impact simulated, the ABM scores the highest CORA rating (0.412). Additionally, looking at each model's average CORA score between the three impacts, the ABM again scores the best CORA rating. This result indicates that of the models considered, the ABM demonstrates the strongest ability to predict local brain deformations under a range of impact severities and directions.

ACKNOWLEDGEMENTS

Funding for this project is provided by the National Institutes of Health (R01 NS082453). All simulations were run on the DEAC Cluster at Wake Forest University. The authors would like to thank the ANSIR lab for providing the ICBM labelmaps, the THUMS and GHBMC teams at Wake Forest University for providing the respective head models, and Elizabeth Lillie for her work on the MATLAB code to produce the ABM from the ICBM labelmaps.

ENHANCING BIOMECHANICAL ENGINEERING EDUCATION THROUGH PROBLEM BASED LEARNING

Alisa Morss Clyne

(1) Mechanical Engineering
Drexel University
Philadelphia, PA, USA

INTRODUCTION

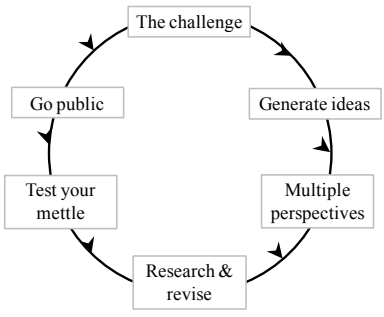
A critical lag between bioengineering bench discovery and clinical implementation delays lifesaving therapies from reaching patients. Biomechanical engineering courses often do not focus on translating research into consumer devices. Through a N ational Science Foundation Transforming Undergraduate Education in STEM grant, we redesigned MEM 304: Introduction to Biomechanical Systems into a problem-based learning course focused on current biomechanical research challenges. Course modules included medical device design, cellular and tissue biomechanics, biomanufacturing, bio-microfluidics, and bio-inspired robotics. Each module was inspired by a real-world problem, and students completed hands-on laboratory projects as part of each module's learning progression. We hypothesized that problem-based learning can be successfully integrated into a cooperative education curriculum to produce engineers who bridge the gap between research and development.

METHODS

Problem (or challenge)-based learning is ideal for integrating biomechanical engineering classroom, laboratory, and cooperative education. In problem-based learning, the process is student-centered within small student groups with the professor serving as a facilitator or guide. Students encounter authentic problems which are then used as a tool through which the students direct their own learning [1]. While many active and collaborative teaching strategies are more effective than traditional lecture formats in enhancing student knowledge and retention, studies suggest that problem-based learning enhances students' abilities to apply their knowledge both immediately and in the long term [2-4]. Thus the problem-based learning approach will help integrate classroom learning, research and design projects, and co-op, as well as improve student performance in these experiences.

Improvements in engineering education largely come not from research on new educational techniques but rather from implementation of proven techniques. Therefore, we adopted the challenge-based instruction methods pioneered by the VaNTH Engineering Research Center, an NSF-funded collaboration in improving biomedical engineering education among Vanderbilt, Northwestern, the University of Texas, and the Harvard/MIT Health Sciences and Technology Program. The VaNTH model recognized that the rapidly developing bioengineering industry requires engineers who can expand and adapt their knowledge and skills [5]. Therefore, students need to build "adaptive expertise," the ability to apply engineering knowledge to solve new problems [6].

The VaNTH model integrates conceptual and innovation knowledge development through the STAR.Legacy cycle [7]. The STAR.Legacy cycle begins by posing exploratory challenges. Students then generate initial ideas about how to solve these challenges. In the "Multiple perspectives" phase, students take into account ideas by other people familiar with these or similar challenges (e.g., industry professionals, end users). Students then base their learning on questions prepared from these initial experiences. Research is instructor-supported and can take the form of online or in-class lectures, discussions, and demonstrations among many others. Students then "Test their mettle" by applying the new knowledge to an assessment technique



The VaNTH STAR.Legacy Cycle

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

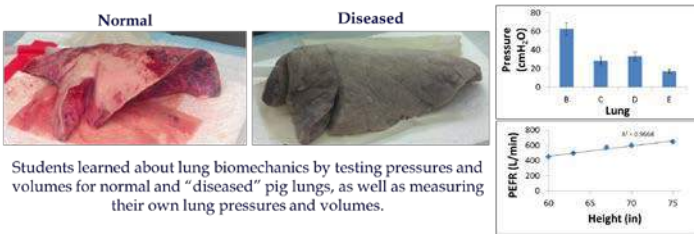
such as a quiz or problem set. This allows students to return to the research phase if needed to enhance their knowledge. Finally, the students "Go public" by synthesizing their newly acquired knowledge to solve either the original or an analogous challenge (e.g., exam, presentation, report).

A primary obstacle to implementation of active and challenge based learningwas that face-to-face class time was limited. We used cyberlearning, specifically online lectures, assignments, assessments, and journals, to support the STAR.Legacy cycle. Review lectures on mechanical engineering, biology, physiology, and disease were provided to students through Drexel's Blackboard Vista (Bb Vista) system. In addition, at the end of each week, students completed online journal entries to assess their opinion of the class and their depth of knowledge. Cyberlearning's significant advantages include that it allows students to proceed at their own pace, rewind and repeat material they may have missed, and open up in-class time for questions, discussions, and active learning.

RESULTS

The four faculty members and their graduate student teaching assistants all participated in a problem-based learning workshop led by faculty from the University of Delaware the summer prior to course implementation. During the workshop, each faculty member created a problem for his/her module. These modules were then integrated into the course. 25 students enrolled in the course (23 from mechanical engineering, 2 from electrical engineering). The 5 problem-based learning modules from the course were:

1. Medical Devices: In this module, students first received an overview of physiological systems and we visited the human anatomy lab at Drexel Medical School to provide students with a physical understanding of the human body. Student teams then received the problem, in which they were an engineer tasked with pitching a new medical device idea to their company's CEO. Students delivered a practice elevator pitch, followed by a final pitch one week later.
2. Lung Biomechanics: This module took a real life problem—a highly- publicized lung transplant in a pediatric patient with cystic fibrosis—and tasked students with determining how to measure lung function decline in patients with cystic fibrosis before and after lung transplantation. A pulmonologist from Drexel College of Medicine taught students the basics of cystic fibrosis and lung function testing, allowing the students to practice reading real patient lung function tests. For the laboratory component, we acquired pig lungs from the slaughterhouse and treated them in various ways to replicate obstructive and restrictive lung diseases. Students then inflated the lungs and measured pressures/volumes to determine which lung represented which disease. The students completed an executive summary describing which lung function test they selected, and the pig lung lab data analysis was included as supplementary material.



Students learned about lung biomechanics by testing pressures and volumes for normal and "diseased" pig lungs, as well as measuring their own lung pressures and volumes.

3. Lung Biomanufacturing: This module continued the cystic fibrosis case, but now the students were tasked with developing a system to tissue engineer new lungs for transplantation. Students learned about tissue culture and tissue engineering from Professor Clyne. They then analyzed current journal articles on how cell migration changes on scaffolds of different stiffness as preparation for their lab experience. In the lab, students measured cell migration speed on polyacrylamide gels of varied stiffness. Since the lab time was not adequate to complete each section in series, we had one student from each team complete each section of the lab. Student teams then designed a lung tissue engineering system, using the lab data as supplemental materials.
4. HIV Lab on a Chip: In this module, student teams created new microfluidic devices to either diagnose HIV or perform HIV monitoring. Students learned about microfluidics from Dr. Noh, and received an excellent overview of HIV/AIDS and the state of the art in disease detection/monitoring from an infectious disease specialist from Drexel College of Medicine. In the laboratory components, students observed microchip/microfabrication demonstrations in Dr. Noh's lab. The students then designed a lab-on-a-chip device for HIV detection or monitoring, and their final deliverable was a Powerpoint presentation of their devices. An infectious disease specialist from Drexel College of Medicine observed and commented on their final designs.
5. Biologically derived prosthetics: In the final module, student teams designed a new athletic prosthetic leg. Students learned about animal locomotion and musculoskeletal modeling from Dr. Tangorra, and then experimented with designing new systems using Animatlab (a free computational dynamics program). The student team deliverable was a Powerpoint presentation of their new prosthetic design.

DISCUSSION

Overall, engineering students enjoyed the hands-on nature of the course. Initial student deliverables often did not meet quality and depth expectations; however, deliverables improved dramatically with faculty critique followed by student revision. Faculty did not feel that the problem based learning format significantly increased their workload, after problem formulation.

Quantitative and qualitative course assessment provided by an external reviewer showed that the students learned to transform their learning into new ways to focus on problem and come to new ideas and discoveries. Through analysis of pre/post evaluations, interview/focus groups, journals, and modules it became evident that the students embraced both problem solving and cooperative groups. One student stated, "*I learned what it really meant to be an engineer. In this class, just as the real world, we were given a problem to solve, and step by step, worked up until we had a right design and specification that we could present.*" The impact this course had on students' ability to synthesize information from many content areas and come up with a design plan solution was a wonderful bridge between knowledge and application. One student summed it up this way, "*It prepared me to function in a work environment, and helped to see what it would really mean to be an engineer in the field.*"

INTRODUCTION

The formation of the vertebrate neural tube, the primordial structure of the central nervous system, is one of the earliest morphogenetic events during embryonic development. Failure of neurulation leads to congenital defects that affect nearly 3000 pregnancies in the US annually.[1] Despite progress being made in understanding genetics of these defects, it remains unclear how and when they will manifest due to the multifactorial nature of their etiology. Establishing a better knowledge of the physical principles guiding this process will expand our understanding on how these defects occur.

Neurulation entails several coordinated cell movements and shape changes that turn a planar epithelial neural plate into an elongate tubular structure. At the onset of this process, the lateral edges of the neural plate, converge towards the dorsal midline while the neural plate elongates along the anterior-posterior axis. Previous studies of epithelial convergence extension have described planar directed cell rearrangements that are thought to actively drive these movements.[2] Neural epithelial cells display preferential localization of actomyosin at cell-cell boundaries that remodel junctions and facilitate directional rearrangement. By contracting junctions in the mediolateral direction, epithelial cells form unstable "high-order" vertices that contain 4 or more cells. These vertices then resolve in the perpendicular, anterior-posterior direction driving mediolateral neighbor exchanges. Coordinated contraction and resolution of junctions cause local arrays of cells to directionally intercalate, narrowing along the mediolateral direction while lengthening anterior-posteriorly. Mutant analysis in chick and mouse neural tube morphogenesis reveals that the Planar Cell Polarity (PCP) pathway enables polarized cell behaviors and cell intercalation, which together with apical constriction drive neural plate bending.[3,4] It remains unclear whether PCP directs polarized behaviors or transduces tissue polarity cues from other patterning systems.[5,6] Mechanical patterning processes can provide an alternative source of tissue polarity, for instance, anisotropic mechanical stresses and tensional forces have been shown to polarize cell behaviors and epithelial tissue patterning in other systems.[7] Tissues may also adapt to altered mechanical environment in order to maintain programmed behaviors which allows for robustness. For example, converging and extending tissues in *Xenopus laevis* increase their force production when facing larger mechanical resistance. [8] Thus we would suggest that cells might also alter their behaviors to accommodate such changes in mechanical loads and maintain morphogenetic programs.

In this study, we first described cell morphological and behavioral changes that accompany neural plate convergent extension in *Xenopus laevis* embryos. We then tested whether externally imposed patterns of mechanical stresses are able to regulate polarized cell behaviors during this process. Finally, we investigated how altering cell size affected cell behaviors and tissue morphology.

METHODS

Embryo Handling Eggs are obtained from female *Xenopus laevis* and fertilized *in vitro*. Fertilized eggs are dejellied in 2% cysteine and cultured in 1/3× Modified Barth's Solution (MBS).

Spatiotemporal Cell Morphology To observe temporal differences in apical cell shape and arrangement in the neuroepithelium, embryos were fixed at 4 time points between the end of gastrulation and the end of the flat neural plate stage. Embryos were stained for f-actin using Bodipy-phallacidin. Apical cell outlines on dorsal surface of the embryo were imaged using confocal laser scanning microscope (Leica SP5, mounted on an inverted compound microscope DMI6000, Leica Microsystems, Inc.). To confirm spatial differences in cell identity, embryos were stained for cytokeratin, an epidermal ectoderm marker or Sox3, a neural ectoderm marker.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Live Cell Dynamics Dorsal tissue isolates containing all three embryonic germ layers were excised from the dorsal anlagen of embryos expressing utrophin-GFP or membrane-GFP. Time-lapse image sequences of the neural ectodermal apical surface were collected during early neural plate morphogenesis.

Cell Shape and Rearrangement Z-projected images of cell boundaries within the dorsal surface of the embryos or dorsal isolates were segmented using SeedWater Segmenter software. Morphological parameters describing cell shape and orientation as well as vertex order, an indicator of junctional remodeling, were quantified via custom written ImageJ macros. This analysis was performed on both live time-lapses image sequences as well as static images of fixed embryos. In live images, duration of high-order multi-cell vertices were additionally quantified.

Dorsal Isolate Confinement To alter the strain field within the neural plate, polyester blockades were placed on the anterior and posterior ends of dorsal tissue explants. The blockades prevented the explants from elongating. Stereoscopic time-lapse images were collected of confined and unconfined isolates to obtain tissue convergence and extension strain rates. Explants were fixed at stage 15 and the F-actin labeled apical surface was imaged to detect alterations in cell shape or rearrangement due to confinement. Live imaging was also performed to reveal changes in cell kinematics.

Cell Size Alteration During early development *Xenopus* embryos undergo reductive cleavage, where total embryo volume is conserved even as cells divide. Thus, during early rounds of division cells become progressively smaller. Arresting the cell cycle within embryos inhibits this reduction in cell size compared to carrier-treated control embryos that undergo normal rates of cell division. The cell cycle inhibitor cocktail of hydroxyurea and aphidicolin (HUA) has been previously used successfully in *Xenopus* embryos causing no visible defects in neural tube closure.[9] We cultured embryos in media containing 20 mM hydroxyurea and 150 μM aphidicolin in 1/3x MBS from the start of gastrulation until the late neural plate stage at which point embryos were fixed and stained for F-actin. Control embryos were cultured in DMSO carrier in 1/3x MBS. During these stages, cells in the neural plate normally undergo between 1 and 2 rounds of cell division.

RESULTS

As the neural plate matures the apical surface of cells at the neural plate midline become isodiametrically constricted whereas cells at the border of the plate become elongated and aligned with the AP axis. Neural epithelial cells increasingly form high order junctions, indicative of increased cell rearrangement. These high order junctions are seen at the beginning of neurulation. Live imaging confirmed the occurrence of cell rearrangement and the transient nature of these high order vertices that resolved within an hour of formation. Live imaging of actin reveals a dense and highly contractile apical cortex with bursts of actin flares occurring at cell-cell junctions.

Blocking extension of dorsal tissues altered tissue strain. Unconstrained control explants elongated at a rate of ~15% per hour and converged at ~10% per hour whereas as confined explants elongated at a rate of 0.2% per hour and converged at a rate of 2% per hour. Comparing cell shapes within unconfined to confined explants revealed no changes at the tissue midline; however cells at the border were on average 20% less elongate and 15° less aligned with the AP axis in confined explants ($p<0.05$; nested ANOVA). Confined explants showed a slight but not significant decrease in percentage of high-order junctions

HUA treated embryos showed a 2-fold increase in apical area at all locations within the neural plate. Compared to controls, a similar pattern of cell shapes was seen. There was a significant decrease in the percentage of high-order vertices within HUA treated embryos compared to control ($p<0.01$, Student's t-test). The width of the neural plate remains the same in control and HUA treated embryos as confirmed through immunofluorescent staining of cytokeratin.

DISCUSSION

Our description of cell rearrangement within the *Xenopus* neural plate complements similar findings of studies performed in later stages of chick and mouse neurulation and in other experimental models of convergent extension such as *Drosophila* germband elongation.[3,4,1] Thus, cell rearrangement appears to be a conserved behavior during convergent extension across species and tissue types. The contractile actin network within the apical cortex and at the junctions of the cells potentially facilitates rearrangement.

Interestingly, neuroepithelial cells demonstrate differential regulation of apical shape based on their location within the neural plate. Cells near the midline actively constrict and remain relatively isodiametric while cells at the periphery of the plate elongate anterior-posteriorly possibly reflecting a passive deformation guided by the overall tissue strain field. Our tissue confinement experiments corroborate this hypothesis, as border cells within confined tissues fail to elongate and align to the same extent as in unconfined tissues. The confinement experiments indicate no overall difference in apical shape or area of cells near the midline. Confinement also does not disrupt formation of high order junctions. However, further studies on live tissues must be performed to confirm that the polarized formation and resolution of these junctions are not affected. Tissues with larger cells show a decrease in high-order vertices possibly due to reduction in rearrangement. Given that no observable defects were observed in overall tissue strain, larger cells may reduce the required amount of rearrangement since each net intercalation of larger cells contributes greater tissue strains compared to smaller cells.

Taken together, cell rearrangement through junctional remodeling appears to be a timed program that coincides with convergent extension at the start of neurulation. Cells may be able to adapt these behaviors to maintain overall tissue strain rates. Because the tissue strain field does alter apical shape of a population of cells near the border of the neural plate, alterations of the tissue mechanical environment *in vivo* may make neural tube closure more susceptible to failure. Thus, linking genetic mutations to mechanical aberrations may give further insight into neural tube defects.

INTRODUCTION

The initiation of cerebral aneurysms has been considered to be related with wall shear stress (WSS). More specifically, the temporal and spatial variations of WSS at that site have been focused in an attempt to find out the relationship with aneurysmal initiation[1,2]. Although there have been numbers of proposed correlation parameters, the basic principle of aneurysmal initiation still awaits further researches. The bifurcation of cerebral arteries is known to be a favorite site of aneurysmal initiation, and the geometry is also known to be deformed due to atherosclerosis from aging. Understanding the relationship between the flow and geometry motivated the present research. The objective of this research is to investigate the relationship of flow instability on vascular geometry at the bifurcation of middle cerebral arteries from healthy volunteers.

METHODS

Choice of case

20 healthy volunteers were examined for the magnetic resonance imaging (MRI). The MRI examinations were carried out at Kitahara International Hospital. Out of 20 subjects, 2 subjects were excluded due to the inability of constructing cerebral arterys. In total the study consisted of 18 healthy subjects (average age 28.8 years; 16 men, 2 women). Three-dimentional vascular models were constructed using ziostation® (Ziosoft inc, Japan) based on MRI images.

CFD analysis

CFD software hemoscope® (EBM corporation, Japan) was used for meshing, hemodynamic analysis and visualization of analysis results. Each case was simulated pulsatile condition. The blood was defined as Newtonian fluid with the density of 1050 kg/m^3 and the viscosity of 0.004 PaS. The inlet boundary condition used an average pressure of 100 mmHg. The outlet boundary conditions were set velocity boundary based on the constant shear stress theory and Hagen-Poiseuille flow.

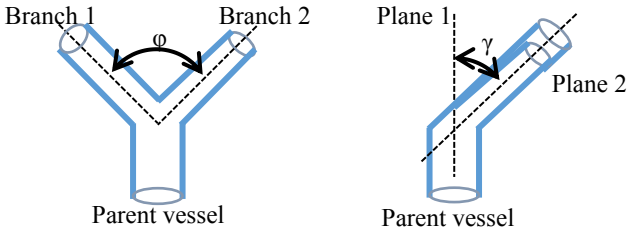
WSS vector variation

An index to quantify the WSS vector variation is shown in the following equation. WSS vector variation τ was defined as total accumulation of an instantaneous relative angle between a pair of wall shear stress vector over time during one cardiac cycle .

$$\tau = \sum_{i=1}^{T} \arccos\left(\frac{\tau_i \bullet \tau_{i+1}}{|\tau_i||\tau_{i+1}|}\right)\frac{180}{\pi} \qquad (1)$$

Measuring method bifurcation and inclination angle

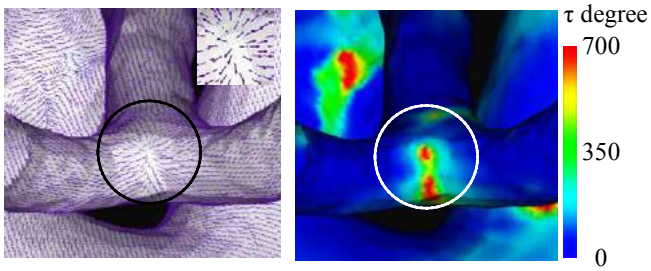
A conceptual diagram of the bifurcation and inclination angles are shown in Fig. 1. The bifurcation and the inclination angles were measured by ImageJ®. The bifurcation angle was defined as the angle between the daughter vessels[3]. The inclination angle was defined as the angle between 2 planes of parent vessel and both daughter branches[3].



(a) Bifurcation angle (b) Inclination angle

Fig.1 Conceptual diagram for shape of parameter

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference



(a) WSS vector (b) WSS vector variation

Fig. 2 Hemodynamics with MCA bifurcation

RESULTS

An example of hemodynamics with MCA bifurcation is shown in Fig. 2. Impinging flow was confirmed at the top of the MCA bifurcation because full-divergence of WSS vector was observed. At that point, high WSS vector variation was confirmed. The value of WSS vector variation was 700degree.

Fig. 3, Fig. 4, and Fig. 5 represent the relationship between WSS vector variation degree and bifurcation angle, inclination angle, and Reynolds number, respectively. It confirmed that the relationship of the bifurcation angle with the WSS vector variation gave a correlation of R=0.5156, while that of inclination angle gave R=0.3541. Also, it confirmed that the relationship of Reynolds number with the WSS vector variation gave a correlation of R=0.4747.

DISCUSSION

The former study has shown that the bifurcation angle and the inclination angle gave an average of 92.1 degree (mix/max of 76.2 to 97.7 degree) and 15.4 degree (min/max of 5.2 to 33.7 degree)4). In this study, the average of bifurcation angle was 90.2 degree, and the average of inclination angle was 19.4 degree, which confirmed the reproducibility of angle measurements with former studies.

The present data showed that the flow instability at the bifurcation of middle cerebral arteries from healthy volunteers gave the highest correlation with bifurcation angle rather than inclination angle or Reynolds number. This result implied that the instability of flow at the bifurcation may be affected by the change of bifurcation angle which may be related with the risk of aneurysm initiation.

The former study has shown that MCA bifurcations harboring aneurysms have significantly larger branching angles[3]. The study, however, left a question of branching angles increase as the result of aneurysm formation or branches with high angles result in aneurysm formation. Considering the average age difference of subjects between the two studies and CFD analysis results from this study, results suggested that the widening of bifurcation angles may be due to morphological change by aging which may increase the WSS vector variation at the bifurcation and result in aneurysm formation.

CONCLUSION

This study examined the effects of bifurcation angle, inclination angle, and Reynolds number on flow instability. Results showed that the bifurcation angle have stronger correlation with WSS vector variations from impinging flow than inclination angle or Reynolds number.

A REACTIVE VISCOELASTIC CONTINUUM DAMAGE MODEL FOR TENDON

Babak N. Safa (1,2), Andrea H. Lee (2), Michael H. Santare (1), Dawn M. Elliott (2)

INTRODUCTION

Tendons become structurally and mechanically damaged due to overload and/or overuse, frequently resulting in clinical disorders such as tendinopathy or tendon rupture. Tendon damage includes non-recoverable degradation in mechanical properties such as elongation or decreased modulus. Such changes in mechanics are clear signs of damage; however, they do not provide insight into the mechanism of damage. A damage model that includes key tendon mechanical behaviors of nonlinearity (strain stiffening until yield, continued with strain softening after) and viscoelasticity (relaxation, creep, and hysteresis) is needed to elucidate mechanisms of damage across a full strain range. While models that separately address these individual mechanical behaviors have been proposed, a single model that can simultaneously address all of these behaviors is still needed.

Ateshian [1] recently developed "reactive viscoelasticity" framework for cartilage, which was conceptually based on elastomer scission and crosslinking [2,3]. This framework includes a mixture of different bond types, categorized as strong and weak. This framework, applied to tendon, has the potential of not only describing nonlinearity, viscoelastity, and damage, but also being used to elucidate damage mechanisms. The first step in this process, and thus the objective of this study, was to develop and apply a reactive viscoelastic continuum damage model to the post-yield loading and relaxation of tendon.

METHODS

Reactive viscoelasticity for tendon*:* The model consists of a mixture of two bond types that are categorized as strong and weak (Fig 1 top, thick and thin lines, respectively). The strong bonds govern the elastic response, and "reacting" weak molecular bonds govern the viscous response [1]. The weak bonds repeatedly break and reform via chemical kinetics of molecular bonds. For a Heaviside step, breaking

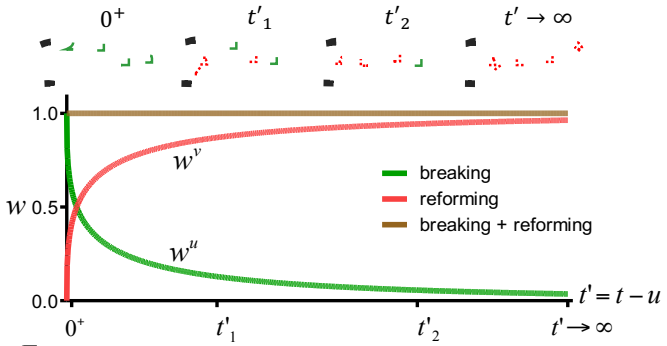

Figure 1: Schematic of strong elastic bonds (thick) and weak reactive bonds (thin) that are initially unloaded. With a Heaviside step at $t = u$, the strong (black) and weak (green) bonds support load. Weak bonds break (green) and reform (dashed, red). Reforming weak bonds bear no load. Because the tissue is held at constant strain, all the weak bonds eventually reform, bearing no load ($t \to \infty$).

weak bonds number fraction (w^u) and carried load is constantly decreasing according to an asymptotic decay function g(t) (Fig 1, green). However, reforming weak bonds number fraction (w^v) increases, but they do not carry load because their strain energy is based on the relative deformation since reforming, and no additional deformation has yet been applied (Fig 1, red). The weak bonds are simultaneously breaking and reforming over time, however, the sum of their number fraction is one (i.e., $w^u + w^v = 1$). The relative populations of breaking and reforming bonds, therefore, change over time, which governs the viscoelastic response.

All bonds are assumed to be inherently hyperelastic. The strain energy of the system for a Heaviside step load at time u is:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\Psi(\boldsymbol{F}(t), D, w) = (1-D)\Psi^e(\boldsymbol{F}(t)) + w^u(\mathrm{t})\Psi^b(\boldsymbol{F}(t)) + w^v(\mathrm{t})\Psi^b(\boldsymbol{F^u}(t)) \quad (1)$$

Superscripts e and b refer to strong and weak bonds. $\boldsymbol{F}$ is the deformation gradient tensor and $\boldsymbol{F^u}$ is the deformation relative to $t = u$ (i.e. $\boldsymbol{F}(t) = \boldsymbol{F}(u).\boldsymbol{F^u}(\boldsymbol{t})$), where $\boldsymbol{F^u} = \boldsymbol{I}$ for a Heaviside step. Finally, D is an internal state variable representing damage (defined later).

For general loading ($u_{i+1} = u_i + du$) of a continuous, linearized, one dimensional system, Cauchy stress $\left(\boldsymbol{T} = \frac{1}{\mathrm{J}}\frac{\partial \Psi}{\partial \boldsymbol{F}}\boldsymbol{F}^T\right)$ is (see [1]):

$$\mathrm{T}(\varepsilon(t), D) = (1-D)\mathrm{T}^e(\varepsilon(t)) + g(t)\mathrm{T}^b(\varepsilon(t)) - \int_{0^+}^{t} \dot{g}(t-u)\,\mathrm{T}^b(\varepsilon(t) - \varepsilon(u))du \quad (2)$$

Here $\varepsilon(t)$ is the infinitesimal strain. The function $g(t)$ is assumed to be of the form $g(t) = \exp\left[-\left(\frac{t}{\tau}\right)^{\beta}\right]$ in which τ is a time constant, and β is a positive constant number.

Damage: Damage is used to account for softening at high strains. Here damage is only applied to strong bonds, but can also be applied to weak bonds [4]. The damage is non-recoverable and history dependent (i.e. $\dot{D} \geq 0$ and $D(t) = \max\{D(\tau) \in [0,1]: \tau \in [0,t]\}$). The damage space is defined as $\varphi = \varepsilon - r \leq 0$, where r indicates the range of admissible strains and expands as damage evolves. The strain at which damage initiates, r_0, was selected to be the experimental yield point [5]. Damage accumulation is assumed to be a stochastic process [6] and Weibull distribution function was selected to represent the damage accumulation $D = \int_0^{\varepsilon} f(\varepsilon^*; k, l)\, d\varepsilon^*$, where, $f(\varepsilon; k, l)$ is the Weibull PDF, k is the shape parameter and l is the scale parameter. Note that $D = 0$ corresponds to a non-damaged state, and $D = 1$ corresponds to complete failure of the strong bonds.

Hyperelastic constitutive relations: The stress response of the strong bonds was defined based on established nonlinear models as:

$$\mathrm{T}^e(\lambda) = \begin{cases} {C_1}^e\,[\exp({C_2}^e\varepsilon) - {C_2}^e\varepsilon - 1] & 0 < \varepsilon \leq \varepsilon_c \\ {C_3}^e\varepsilon + {C_4}^e & \varepsilon_c < \varepsilon \end{cases} \quad (3)$$

where the behavior in the toe-region is exponential up to uncrimping strain ε_c, after which the behavior is linear. Continuity and smoothness at ε_c, constrain the modulus ${C_3}^e$ and the stress at the end of the toe region ${C_3}^e\varepsilon_c + {C_4}^e$. The stress response of the weak bonds was defined as exponential, following Eq (3) top row.

Experimental methods and results: Tendon fascicles (n=14) were dissected from the tail of Sprague-Dawley rats and tested in tension in a PBS bath. The mechanical test consisted of 5 mN preload, 5 cycles of preconditioning to 4% strain, a ramp load at 1%/sec to 8% strain, and a relaxation for 15 smin. The stress-strain-time data for all samples were averaged (Fig 2 dotted red line) and a smoothing spline fit to the ramp data. The first inflection point of the ramp, defined as the yield and the initiation of damage, occurred at 4.3% strain.

Model parameter optimization to data: A built-in Matlab function for constrained optimization of nonlinear multivariable functions was used to fit the model to averaged experimental data. First, the relaxation response was used to solve $g(t)$ for $\boldsymbol{\tau}$ and $\boldsymbol{\beta}$. Next, the entire loading and relaxation response was fit to the full model and solved for the remaining parameters: strong bond constitutive (${C_1}^e$, ${C_2}^e$, ε_c), weak bond constitutive (${C_1}^b$, ${C_2}^b$) and damage (k,l). The root mean square of error (RMSE) of the fit was calculated.

RESULTS

The reactive viscoelastic damage model was able to describe the nonlinearity, time-dependence, and damage behaviors of the tendon as seen by comparing the red experimental and black model fits (Fig 2A). The RMSE was 1.9 MPa, which is 5% of the maximum experimental stress. The optimization result for the model parameters is summarized in Table 1.

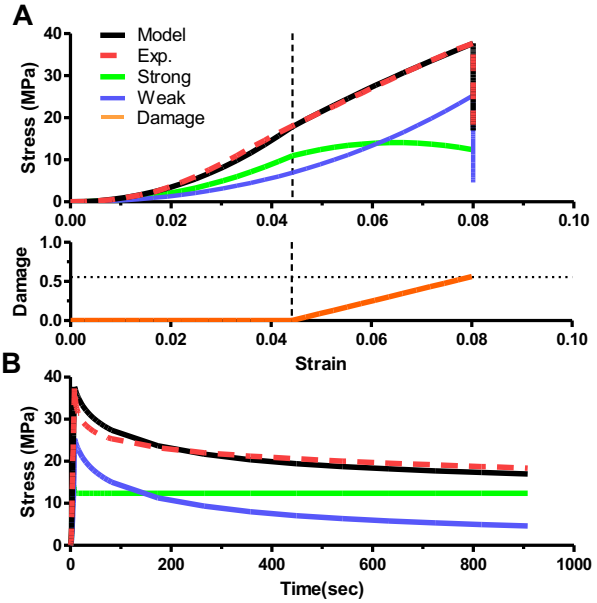

Figure 2: Experimental (red) and model fit (black), with model decomposed into contribution of strong (green) and weak (blue) bonds. (A) Stress-strain, and damage-strain (B) Strain-time.

Table 1: Results of optimization

${C_1}^e$(Mpa)	${C_2}^e$	ε_c	${C_1}^b$(Mpa)	${C_2}^b$	k	l	τ(sec)	β
194.2	7.1	0.04	47.4	12.7	5.8	0.02	90.1	0.38

During the ramp loading, the strong (green) and weak (blue) bonds contributed a similar amount to the total stress, until yield at 4.3% strain, where damage initiated (Fig 2A). Damage increased to 0.56 by the end of the ramp at 8% strain. This damage prevented an increase of strong bond contributions, while the weak bond load continued to increase (Fig 2A).

During the relaxation phase (Fig 2B), the stress contribution of strong bonds was constant (12.4 MPa), as they were defined as elastic. The weak bonds continued to relax to about 5 MPa at the end of the 15 min period. Equilibrium, where weak bonds stress eventually reduces to zero, was not achieved.

DISCUSSION

This model provides a non-linear and reactive viscoelastic framework to study tendon damage. One of the advantages of the model is the ability to describe softening and relaxation at post yield strains, which cannot be achieved by conventional hyperelastic models. Secondly, the model constituents can be varied individually to address time-dependence and damage. Future improvements, using this framework of bond kinetics, could extend the model to multiple types of bonds, each with damage, time dependency, or both, to elucidate damage mechanisms in tendon.

INTRODUCTION

Recent advances in cardiovascular therapy have indicated that cardiomyocytes derived from pluripotent human stem cells (hPSC-CMs) have the potential to be used to repair the damage due to myocardial infarction or other cardiovascular diseases. Currently, these hPSC-CMs are immature when compared with adult cardiomyocytes: they exhibit a smaller, round morphology with unaligned myofibrils, and generally have inferior calcium handling ability [1]. The combination of these factors leads to a weaker contractile output from hPSC-CMs when compared to their adult counterparts.

The driving mechanism of cardiomyocytes is excitation-contraction (EC) coupling: the interaction between an ionic action potential and sarcomeric contraction. Calcium ions (Ca^{2+}) are stored in the sarcoplasmic reticulum (SR) and released via a calcium-induced calcium release process. The role of the SR in immature hPSC-CMs is still unclear, but some evidence shows that they do in fact have a functional SR with ryanodine receptors capable of producing cardiac-like action potentials [2].

In this work, we examine a proposed model to study Ca^{2+} propagation in immature cardiomyocytes. The model includes dynamics for both cytosolic and sarcoplasmic Ca^{2+} based on diffusion equations. We then compare this model with experimental Ca^{2+} transients for hESC-CMs.

METHODS

Modeling Calcium Dynamics

A 2D model governing calcium dynamics is adapted from [3]. In this model, cytosolic and sarcoplasmic calcium concentrations are defined and balanced by taking into account Ca^{2+} into and out of the sarcolemma and SR. The governing partial differential equations are:

$$\partial_t w_c = \mathrm{div}(\mathbf{D}\nabla w_c) + K(w_c, w_s) \quad (1)$$
$$\partial_t w_s = L(w_c, w_s) \quad (2)$$

Where w_c is the concentration of cytosolic Ca^{2+}, w_s is the concentration of sarcoplasmic Ca^{2+}, and the diffusivity tensor is $\mathbf{D} = \mathrm{diag}(D_f, D_s)$, where $D_f$and D_s are the anisotropic diffusivities in the orthogonal directions. Initially, we set the diffusivity in the myofibril direction D_f = 60 μm^{2}s^{-1} and the diffusivity in the transverse direction D_s = 30 μm^{2}s^{-1}. Finally, the terms K and L are given by:

$$K(w_c, w_s) = \nu_1 - \frac{\nu_2 w_c^2}{k_2 + w_c^2} + \frac{\nu_3 w_c^4 w_s^2}{(k_3 + w_c^4)(k_4 + w_s^2)} - \nu_4 w_c \quad (4)$$
$$L(w_c, w_s) = \frac{\nu_2 w_c^2}{k_2 + w_c^2} + \frac{\nu_3 w_c^4 w_s^2}{(k_3 + w_c^4)(k_4 + w_s^2)} - \nu_5 w_s \quad (5)$$

The constant ν_1 (1.58 μMs^{-1}) represents the influx of Ca^{2+} into the cytosol, ν_2 (16 μMs^{-1}) is the uptake of Ca^{2+} into the SR, ν_3 (91 μMs^{-1}) represents the CICR of Ca^{2+} from the SR into the cytosol, ν_4 (2 s^{-1}) represents the passive rate of Ca^{2+} leaving the cytosol through the cell membrane due to a concentration gradient, and ν_5 (0.2 s^{-1}) represents the passive rate of Ca^{2+} leaving the SR to the cytosol. The terms k_2 (1 μM), k_3 (4 μM^2), and k_4 (0.7481 μM^4) are constants determined through experimental fitting. These values are determined for experimental data for adult cardiomyocytes [3]. This model may be stimulated by a local increase in ν_1, after which point it spontaneously beats.

Together, these governing partial differential equations (PDEs) are solved using a parabolic nonlinear PDE solver in MATLAB. For our simulations, we use the initial conditions w_c = 0.1 μM, w_s = 1.6 μM as well as an insulated boundary condition on all cell boundaries.

Experimental Procedure

To observe Ca^{2+} transients *in vitro*, we derived cardiomyocytes from GCaMP3-expressing RUES2 hESCs. The cardiomyocyte differentiation procedure was based on previously published methods [4]. Briefly, undifferentiated RUES2 hESCs were plated in a monolayer on Matrigel. On day 0, the media was switched to RPMI supplemented with B-27 minus insulin, activin-A, and BMP-4. In the proceeding days, the monolayer was sequentially supplemented with Wnt agonist CHIR 99021 and Wnt antagonist Xav 939 to promote cardiomyocyte differentiation. After approximately 7 days, the cardiomyocytes begin spontaneously beating. After 20 days, the cardiomyocytes were lifted from the monolayer and reseeded onto the experimental substrates at a density of approximately 250,000 cells/cm^2 to promote single-cell culture.

Prior to cell seeding, experimental substrates were created with patterned extracellular matrix (ECM) protein. A soft PDMS substrate is created by mixing quantities of 10:1 (base : curing agent) Sylgard-184 and 1:1 Sylgard-527 and curing onto a thin glass substrate. Using a mixture of 10% Sylgard-184 and 90% Sylgard 527, we achieve a substrate stiffness of approximately 21 kPa. Using a stamp-off procedure, laminin was patterned onto the surface of the soft PDMS substrate. The pattern consists of parallel lines ranging between 12 and 24 um in width, promoting various degrees of elongation of the hESC-CMs. Data was collected using a 60X objective on a fluorescence microscope with a high-speed camera allowing for video capture of up to 100 frames per second.

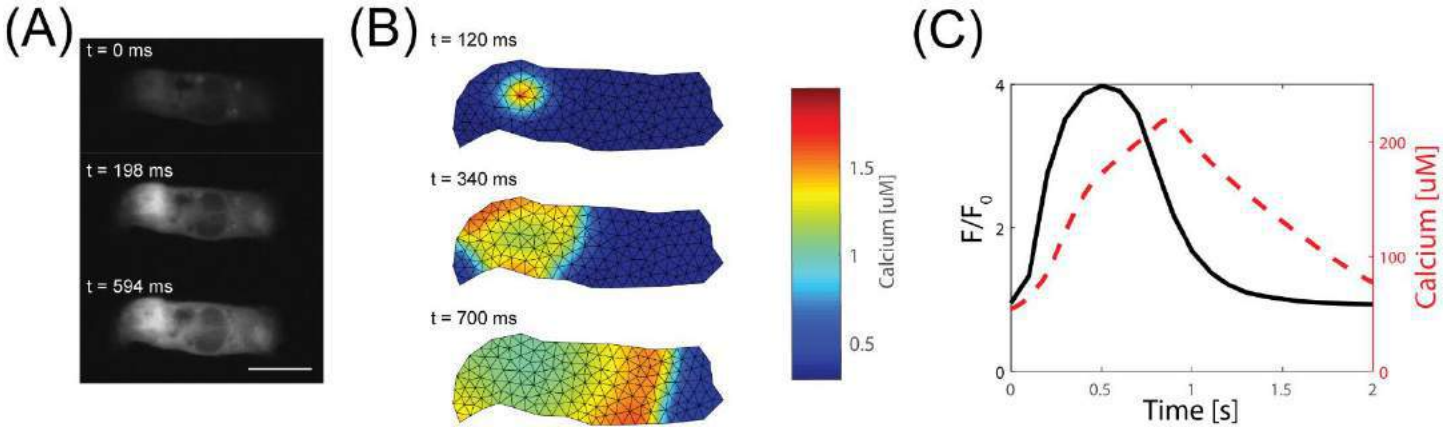

Figure 1: (A) Typical cytosolic Ca^{2+} fluorescence in GCaMP3-expressing hESC-CMs. Scale bar is 20 µm. (B) Simulation using adult parameter values with a stimulus near the earliest activation point determined from (A). (C) Total Ca^{2+} levels obtained from experimental images (black solid line) and simulation (red dashed line).

RESULTS

Figure 1A shows typical GCaMP fluorescence for a patterned hPSC-CM. We determine the activation point of the calcium wave by creating an activation map in which each pixel's activation is calculated based on its time to peak fluorescence. Using this map, the model is solved with a stimulus at the initial point of activation, shown in Figure 1B. The Ca^{2+} propagates from the activation point throughout the cell following the governing Ca^{2+} dynamics.

To obtain characteristic properties of the patterned hESC-CMs, we average the fluorescence within the cell boundary for each frame and divide it by the basal fluorescence, resulting in the solid curve in Figure 1C. Performing a similar averaging for the simulated data, we generate the red dashed line in Figure 1C and compare it with the experimental data. The model predicts a Ca^{2+} peak near 0.9 seconds, while the experimental data shows that the GCaMP fluorescence peaks at around 0.5 seconds. Additionally, the rise of Ca^{2+} in the model begins with an exponential increase that levels off to a linear rise, followed by a relatively linear decay, drastically differing from the rapid, yet smooth rise and fall of the experimental fluorescence.

DISCUSSION

It is easy to see that the calcium transients in Figure 1C do not closely follow the experimental results. We attribute this to the fact that the model constants (ν_1 - ν_5) are determined for adult cardiomyocytes which exhibit greatly matured calcium handling and SR. However, at any single point in the model the calcium transient closely resembles that of adult cardiomyocytes: a sharp increase in Ca^{2+} from the SR followed by a slower uptake back into the SR. This is evident in Figure 1B by the sharp "shockwave" of Ca^{2+} spreading throughout the cell. Nevertheless, the total cytosolic Ca^{2+} in Figure 1C shows a much slower transient than that of a typical experimental hPSC-CM.

To properly model hPSC-CMs, our focus is to improve the model to account for the diminished role of the SR. One such way to alter the model is to tune the model constants; for example, ν_2 and ν_3 account for Ca^{2+} entering and leaving the SR, respectively. By reducing the influence of these sources, the model will more appropriately reflect the fact that much of the Ca^{2+} in immature hPSC-CMs comes from extracellular sources. However, the terms in equations (1) and (2) are highly coupled and balanced; the alteration of one constant can wildly imbalance the Ca^{2+} and prevent systolic activity. Once properly tuned for the properties of hPSC-CMs, we can appropriately model the calcium dynamics for hPSC-CMs.

The proposed model includes differing diffusivities along and transverse to the myofibrils. For aligned cells, we can assume that the myofibrils run along the major axis of the cell. For unaligned hPSC-CMs, however, this assumption is not enough to properly describe the dynamics. One remedy is to assume that diffusion is isotropic, but a more physiological approach may be to assume a somewhat random orientation of myofibrils within the immature cardiomyocyte. Experimental images of myofibrils could also serve as inputs in a more physiological model.

Finally, the question of maturation with respect to excitation-contraction coupling is not yet answered. The coupling between mechanical strain and calcium dynamics is vital to the full understanding of cardiomyocyte function. We are actively pursuing the development of a model that includes the calcium dynamics described here coupled with mechanical strain, which may be used to study the development and maturation of hPSC-CMs.

INTRODUCTION

Cerebral aneurysms are lesion at cerebral artery that is known to cause subarachnoid hemorrhage (SAH). Cerebral aneurysm initiation, growth, and rupture mechanisms are still not clear. Although causes of aneurysm rupture is debated to be related to the hemodynamic stress, there have not been any studies which directly compared pathological and blood flow analysis of human cerebral aneurysms. Recently, relationship between rupture and lipid consumption in aneurysm wall have been reported[1].The relationship between rupture mechanism and foam cells, however, are not been discussed Foam cells are known to exist in the plaques of atherosclerosis and they are reported to cause fragility in the artery wall[2]. The relationships between hemodynamic stress and plaque formation have been also reported[3]. From these previous reports, it can be hypothesized that foam cells may be involved in the remodeling of aneurysms wall and aneurysm rupture. The purpose of this study is to investigate the relationship between foam cells accumulation and hemodynamic stress in four unruptured cerebral aneurysms.

METHODS

Choice of case

Four aneurysms were harvested from three patients after microsurgical clipping. The clinical summary of the tissues were listed in the Table 1.

Histological analysis

Harvested tissues were then fixed in 4% paraformaldehyde, embedded in paraffin, sliced in semi serial sections of 2 μm thicknesses, and stained with hematoxylin-eosin (HE) method. This research was accepted by the ethical committee of Waseda University and Kitahara International Hospital.

Definition of foam cells

Two types of mural cells were distinguished (Fig.2). Foam cells (a) were defined as foam-like morphology cells and without foam cells (b) were defined as mural cells tight extracellular matrix. If more than six consecutive semi-serial sections contained foam cells, it was defined as foam cell region.

(Ziostation; Ziosoft Inc, Tokyo, Japan). CFD software (hemoscope; EBM Inc, Tokyo, Japan) was used for meshing, hemodynamic analysis and visualization of analysis results. Each case was simulated with pulsatile simulation. The blood was defined as Newtonian fluid with the density of 1050 Kg/m^3 and the viscosity of 0.004 Pas. The inlet boundary condition used an average pressure of 100mmHg. The outlet boundary conditions were set as velocity boundary based on the constant shear stress theory and Hagen-Poiseuille flow.

RESULTS

Histological analysis and CFD analysis

Fig.3 (a-c) shows two examples of HE staining and CFD results. Fig.3 (a) represented the region of foam cells which was painted yellow in three dimension map. Fig.3 (b) represented the time average wall shear stress (WSS) mapping of the aneurysm. Fig.3 (c) represented the time average WSS vector mapping of the aneurysm.

In #1, foam cells were located at low WSS region (Fig. 3b-1), (Fig.3b-2). Divergence of WSS vector showed that the parallel flow (Fig. 3c-1), and rotation flow (Fig. 3c-2) were observed at foam cell region. In #2, foam cells were located at low WSS region (Fig. 3b-3), and merging flow was observed at foam cell region (Fig. 3c-3).

DISCUSSION

Relationship between foam cells, WSS and WSS vector

Out of four aneurysms, six foam cell regions were observed. 83% of foam cell region were located at low WSS region. The median value of the WSS observed at foam cell region was 0.38 Pa (Fig.4). This suggests that the foam cells tended to accumulate in the region with low WSS. When comparing the WSS vector result with the histological analysis, there were no relationships between WSS vector and foam cell region (Table 2). The WSS vector at foam cell region was 50 percent stagnant (e.g. Merging flow, Rotation flow). Foam cells are involved in atherosclerosis[2] and several studies have reported that low WSS is one of the factors that cause atherosclerosis[3-4]. Therefore this result suggested that atherosclerosis derived by foam cells are generated in the cerebral aneurysm. Atherosclerosis is known to induce unstable plaques[2], so it can be concluded that the atherosclerosis derived by foam cells may have a role in the degeneration of the cerebral aneurysm wall and it may be associated with low WSS from the blood flow.

CONCLUSION

Comparison of the Histological analysis and CFD analysis of four unruptured cerebral aneurysms suggested a relationship between foam cells and low WSS region. Since the behavior of the foam cells is similar to the cause of atherosclerosis, the result indicated that the foam cells may play an important role in the aneurysm rupture mechanisms.

AN INNOVATIVE METHOD FOR MEASURING ADHESION AT THE VITREORETINAL INTERFACE

Christopher J. Creveling (1), Dr. Brittany Coats (1)

(1) Mechanical Engineering
University of Utah
Salt Lake City, Utah, USA

INTRODUCTION

Retinal hemorrhage and detachment from abusive head trauma in infants is believed to be caused by traction between the retina and vitreous during rapid head rotation [1]. The mechanisms of adhesion between the vitreous and the retina, and the amount of force required to disrupt the interface are currently unknown. Previous studies have measured adhesion between the retinal pigment epithelium (RPE) and choroid in adult eyes by extracting rectangular strips of the eye and peeling the retina while holding the choroid with a vacuum [2]. This method is highly destructive, drying of the tissues, and is not practical when one side of the adhesion is a gel (vitreous). Others have measured adhesion between the choroid and RPE by inflating a small bubble in-between the layers [3]. This method resulted in higher forces than the previous method, but would be challenging on a gel-membrane interface.

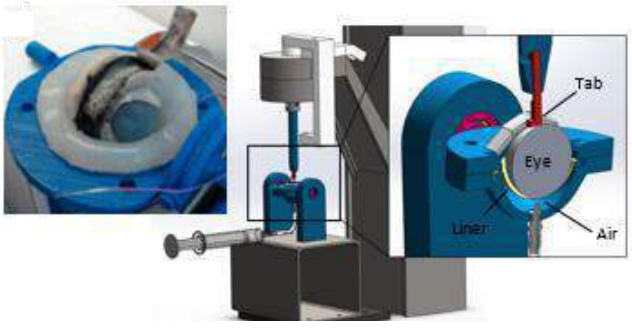

Figure 1. Sclera is dissected away from the retina prior to testing and the eye is placed in the fixture. The eye is raised toward the testing window by inflating the liner with air.

In this study, we develop a unique method for measuring adhesion force at the vitreoretinal interface that maintains the general structure of the eye. We then use this method to measure vitreoretinal adhesion in sheep eyes based on developmental age (neonatal, adolescent, and adult) and region (posterior, equator). The specific objectives of this study are to (1) measure the maximum and steady-state peel force of the retina from the vitreous and (2) identify age and region effects on peel force.

METHODS

Adult (N=7), adolescent (5 months, N=8) and neonatal (3 days, N=9) sheep eyes were obtained from existing non-ocular animal studies on campus and refrigerated until tested (~2 hours). Muscle and surrounding fatty tissue was removed from the eye, and the optic nerve was dissected from the globe. Using this dissection as a starting point, scissors were used to separate and cut the sclera, creating a retinal window approximately 1cm x 4cm (Fig. 1). The eye is then placed in a spherical eye-holder and inserted into a rotating fixture. Retinal peeling from the vitreous is achieved by gently scoring the retina along the edges of the window, and adhering a plastic tab (Fig. 2A) with adhesive. Optical coherence tomography images of the peel retina indicate that the adhesive does not penetrate into the retina (Fig. 2B). The tab is connected to a 5N uniaxial load cell (2530,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

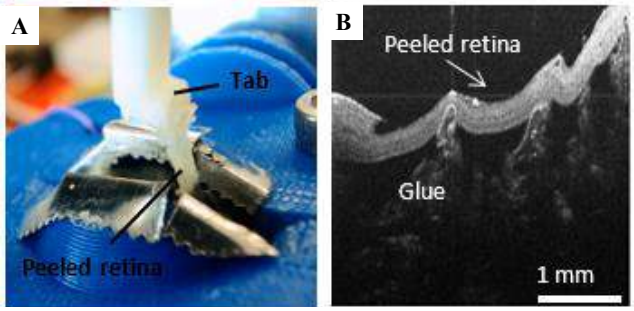

Fig. 2 (A) An L-shaped tab is glued to the retina and used to peel it from the vitreous while measuring force. (B) OCT imaging of the peeled retina shows that separation is at the vitreoretinal interface and glue penetration is minimal.

Instron, Norwood, MA) attached to the crosshead of an electromechanical testing frame. As the crosshead displacement initiates the peel test, it simultaneously applies a controlled rotation of the device at the same rate as the peel. This ensures a consistent 90° peel relative to the retinal surface.

Using ASTM D6862-04 as a guideline, the crosshead was displaced at a constant rate of 0.02 mm/min. Maximum peel force was defined as the peak of the resulting force-time curve. Steady-state peel was defined as the average force of the steady-state region (Fig. 3). After testing was completed, the eye was rotated, and a different region was tested. Preliminary evaluation found no significant effect of test order on peel adhesion.

To validate the rotating peel adhesion device, peel tests were performed with tape adhered to a steel ball bearing, and compared to conventional peel tests of the same tape adhered to a flat aluminum plate. The strips of tape were cut to the same dimensions of the retina and peeled according the same methods described above.

RESULTS

The tape peel tests performed with the rotating device were not different than the standard linear tape peel tests (Fig. 4), validating the innovative device design and methodology. Using the validated device, there was a higher maximum peel force for the neonatal age group compared to the adolescent and adult groups, but this trend did not reach significance (Fig. 5, p=0.08). There was no significant difference between the posterior and equator regions for any of the age groups tested.

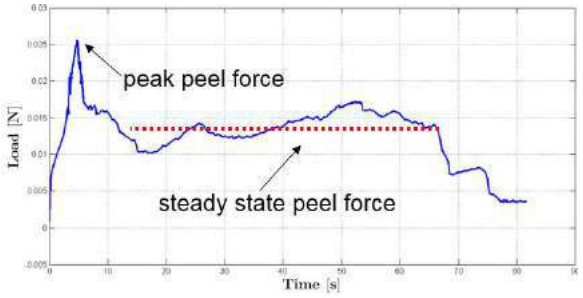

Fig. 3 Peak and steady state peel force extracted from a vitreoretinal peel test on an adult sheep eye.

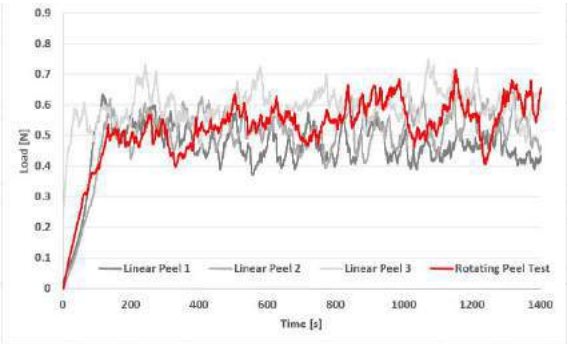

Fig. 4 No difference was found between peel force from linear (grey) and rotating (red) tape peel tests, validating device design and methods.

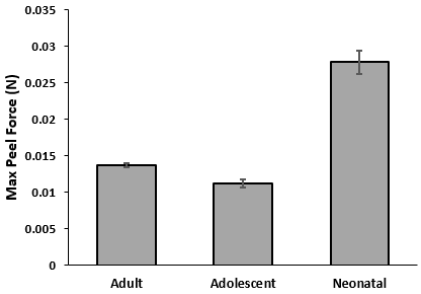

Fig. 5 Maximum peel force at the neonatal vitreoretinal interfaces was larger than adolescent or adult, but this difference did not quite reach significance (p=0.08). Errors bars indicate standard error.

DISCUSSION

On average, neonatal eyes had greater initial vitreoretinal adhesion compared to adolescent or adult eyes. Neonatal eyes are known to have more collagen at the vitreoretinal interface compared to adults, and some hypothesize that collagen fibers tethering the vitreous to the retina are responsible for adhesion. Our results support this hypothesis and warrant further investigation into collagen as the mechanism of vitreoretinal adhesion. Collagen is also known, however, to significantly differ between the equator and posterior regions of the eye. We found no significant differences in regional adhesion, which may be a result of peel strips spanning regional boundaries or differing collagen distributions in the ovine eye compared to the human. Studies are underway to investigate these aspects and to increase sample size for each of the age groups evaluated.

INTRODUCTION

An intracranial aneurysm (IA) is a saccular enlargement in the wall of a cerebral artery. As the IA grows there is a greater risk of rupture – an event that can lead to severe hemorrhage, and other complications, including sudden death. Due to the risks associated with treatment, it is important from a clinical perspective to identify which aneurysms are at risk for rupture, so these aneurysms can be treated and risky procedures can be avoided in others. Currently, the most reliable indicator of risk is IA size. However, while larger IAs are more likely to rupture than small IAs, due to the large number of small IAs, most aneurysms that rupture are small. Hence, size is insufficient for risk stratification. There is a pressing need to better understand disease progression in order to identify a clinically useful metric for improving risk assessment. Further such knowledge will be critical for the rational development of alternate treatment strategies.

While IA samples can be obtained following treatment by surgical clipping, this tissue only represents one time point in the pathology. Animal models for IAs provide a means of studying multiple time points in disease progression. However, it is vital to prove the relevance of these models. Here, we compare the mechanical and wall properties for a commonly used elastase induced saccular aneurysm model in rabbits [1] with those in 8 human IAs [3-5]. We include an assessment of the structural changes during loading, obtained using multiphoton imaging. In earlier work, we have shown the relevance of the aneurysm geometry and flow field found in this model to human IAs [2].

METHODS

Nine human aneurysms, 5 rabbit aneurysms, 6 human basilar arteries and 2 rabbit left common carotid arteries were included in this study. The elastase aneurysms were created as described in [1] and harvested 8 weeks after creation. Rabbit aneurysms and control rabbit vessels were harvested at the Mayo Clinic and transported overnight on ice to the University of Pittsburgh where they were mechanically tested and simultaneously imaged under multiphoton microscopy. Uniaxial data for 8 human aneurysms and 6 human basilar arteries that were previously obtained [3,5] were used in the current study.

All aneurysms and control arteries were mechanically tested to failure using a custom-built uniaxial loading system compatible with the multiphoton microscope (MPM, Olympus FV1000 MPE, Tokyo, Japan) [4], enabling simultaneous mechanical testing and MPM imaging of elastin and collagen fibers. Aneurysm samples were cut into rectangular strips and subjected to uniaxial extension at a speed of 0.02mm/s, controlled by a linear actuator (ANT-25LA, Areotech, Pittsburgh, PA). Force was recorded with a 5 lb. load cell (MDB-5, Transducer Techniques, Rio Nedo Temecula, CA). The zero strain point was defined as that under 0.005 N load, which is consistent with previous work [3,5]. The samples were tested to failure to obtain the mechanical response and ultimate strength. Assuming an isochoric motion, current cross sectional areas were calculated from stretch and unloaded cross sectional area. The Cauchy stress was then calculated from external load and current area.

Collagen fibers were imaged using the SHG signals from stacks of MPM images. From these stacks, fiber orientation and recruitment stretch was assessed as a function of depth in the aneurysm wall for chosen stretch levels. Fiber orientation was computed using an edge detection algorithm in substacks of five images [5].

RESULTS

Mechanical Response: The loading curves for the uniaxial failure tests of all rabbit and human IA samples are shown in Figure 1. As elaborated in [3], even these unruptured human IAs display

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

heterogeneity in the mechanical behavior. Of importance, a weaker group of aneurysms was identified within the unruptured human population [1], Fig. 1. IAs with strong (solid lines) and weak (dashed) response can be seen. A weak rabbit aneurysms was also found with ultimate strength of 0.65 MPa, similar in magnitude to that of the weak human IAs (average of 0.59 MPa). The shape of the mechanical response for the rabbit aneurysms is well fit by an exponential model with an R^2 value of 0.85 or higher, similar to findings in all robust human IAs, [3]. The high strain stiffness in the rabbit model ranges from 5.22 MPa to 12.36 MPa with a mean of 8.18 MPa, falling within the range found for the human IAs where the high strain stiffness ranged from 3.42 MPa to 25.06 MPa with a mean value of 12.38 MPa. In Figure 2, the response of the control arteries is shown for comparison for both rabbit and human vessels. In both human and rabbit aneurysms, the toe region is substantially shorter (rabbit mean = 1.14, human mean = 1.19) than for the respective control arteries (rabbit mean = 1.7, human mean = 1.78). The shortened toe region is consistent with the lack of internal elastic lamina in the aneurysm tissue for both human IAs [1] and current results for elastase induced aneurysms.

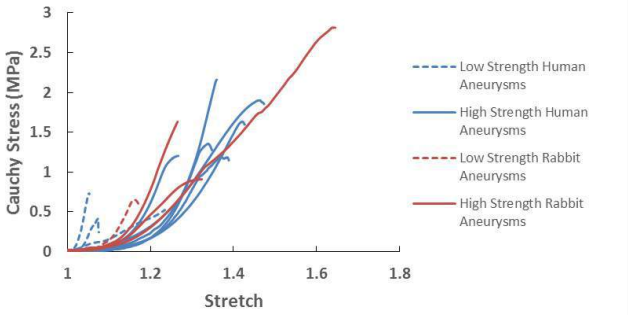

Figure 1: Results for Cauchy stress versus stretch for uniaxial failure testing of human and rabbit aneurysm samples.

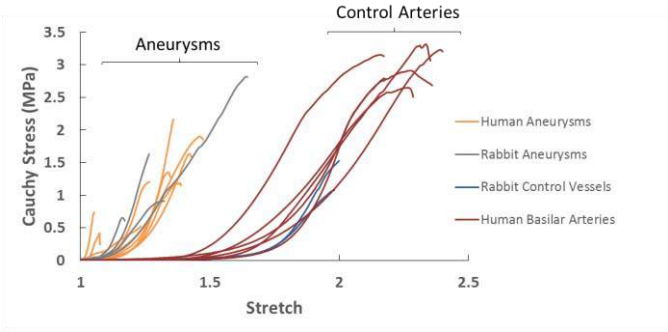

Figure 2: Comparison of unaxial testing to failure for aneruysm tissue versus control arteries for humans and rabbits.

Collagen Architecture and Layered Structure: The changing collagen reorientation and recruitment during mechanical loading can be imaged using the UA-MPM system as shown for a representative case in Figure 3. Projected stacks of MPM images obtained from the luminal side are shown below the loading curve for chosen levels of stretch. Fiber orientation as a function of position across the wall is shown below the MPM images. In the unloaded state, the collagen fibers showed a broad distribution of fibers angles, (a). With increasing axial load (meridional direction left to right in Fig. 3), collagen fibers can be seen to reorient and straighten with prominent orientation nearly symmetric about the loading axis (b and c), the layered nature of fiber orientation can be seen by the abrupt change in dominant orientation with depth in the colored contours of fiber distribution. At stretches of 1.3 and higher, the fibers are highly aligned in the loading direction. These results are consistent with the shift to a single dominant orientation for points d and e.

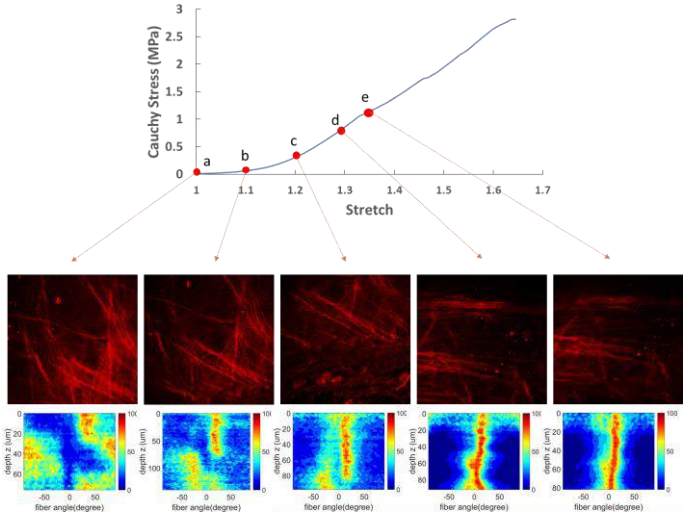

Figure 3: Recruitment of collagen fibers during uniaxial loading of H552 obtained at stretches of (a) 1.0 (b) 1.1 (c) 1.2 (d) 1.3 (e) 1.35 and the corresponding fiber orientation plots.

DISCUSSION

In this work, we have demonstrated the elastase induced aneurysm model in rabbits has similar stiffness and failure properties to human cerebral aneurysms. Further the weak and robust categories found in human IAs are also seen in the rabbit model. This finding, which will be confirmed in a larger study, suggests the rabbit model may be useful for studying differences in ineffective and effective remodeling in the aneurysm wall, a subject we are currently exploring in human IAs [3].

A COMPARISON OF PHENOMENOLOGICAL AND THERMODYNAMICALLY CONSITENT APPROACHES FOR THE MODELLING OF CELLS SUBJECTED TO DYNAMIC LOADING

INTRODUCTION

In the dynamic loading experiments of Wille et al. [1] fibroblast cells are seeded into a collagen scaffold and the resultant synthetic tissue construct is attached to a mechanical test machine. Displacement controlled cyclic stretching is applied to the tissue and cells are shown to align in the direction of cyclic stretching. Force measurements reveal that active cell force is very sensitive to strain rate but not sensitive to strain magnitude. Dynamic experiments performed by Weafer et al. [2] on single osteoblasts also reveal that active cell force is not sensitive to changes in strain magnitude, but highly sensitive to strain rate. A study by Mitrolosis [3] reveals that under static conditions cell contractility follows a Hill type tension-strain rate relationship.

Motivated by empirical observations of cardiac tissue under dynamic conditions [4], a fading memory type contractility formulation is first proposed to simulate cell forces measured in the experiments of Wille et al. [1] and Weafer et al. [2].

It is then shown that the fading memory formulation does not correctly predict stress fibre alignment in the direction of loading for cells embedded in collagen gels, as observed experimentally. A thermodynamically consistent model for stress fibre formation/dissociation and remodeling [5] is then investigated. When implemented in conjunction with a non-local conservation of cytoskeleton proteins within a cell this framework predicts the correct alignment of stress fibres in addition to capturing transient changes in active force during dynamic loading.

FADING MEMORY MODEL

The fading memory formulation is based on the empirical observation that under dynamic conditions tension is a function of the linear superposition of previous length changes, with current tension being more influenced by recent length changes than earlier length changes [4]. Therefore we express the "fading memory" weighted accumulated strain for a fibre at an angle ϕ as

$$h(\phi) = \sum_{i=1}^{n} A_i \int_{-\infty}^{t} e^{-\alpha_i (t-\tau)} \dot{\varepsilon}_m(\phi)\, d\tau \tag{1}$$

where α_i are exponential rate constants and A_i are weighting coefficients (where $\sum A_i = 1$). It should be noted that, unlike the formulation of Hunter et al. we do not include positive strain rates (fibre lengthening) in the accumulated strain. Following from the approach of Hunter et al. (1998) we insert a fading memory strain rate $\bar{\alpha} h(\phi)$ in a Hill-type equation such that

$$B^h(\phi) = \frac{1 - \bar{k}_v \bar{\alpha} h(\phi)/\dot{\varepsilon}_o \eta(\phi)}{1 + k_k h} \tag{2}$$

and

$$\frac{T(\phi)}{T_o} = \begin{cases} 0 & B^h(\phi) < 0 \\ B^h(\phi) & 0 \le B^h(\phi) \le 1 \\ 1 & 1 < B^h(\phi) \end{cases} \tag{3}$$

where $\bar{\alpha}$ is a rate constant, the parameters k_k and $\bar{k}_v$ control the curvature of the tension-strain rate. The parameter $\dot{\varepsilon}_o$ is a reference strain rate, so that the quantity $\bar{\alpha} h(\phi)/\dot{\varepsilon}_o$ is a non-dimensional fading memory strain rate for a stress fibre at an angle ϕ, and $\eta(\phi)$ is the stress fibre activation level. If $k_k = 0$ and $\alpha_i \to \infty$ the static Hill equation is recovered.

For the constant strain rate experiments of Wille et al. [1] and Weafer et al. [2] a closed form solution can be obtained for equation 1:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$h(\phi) = A\dot{\varepsilon}_U(\phi)\int_{P/2}^{P} e^{-\alpha(t-\tau)}\,d\tau + A\dot{\varepsilon}_U(\phi)\int_{3P/2}^{2P} e^{-\alpha(t-\tau)}\,d\tau$$
$$= \frac{A\dot{\varepsilon}_m(\phi)}{\alpha}\left\{e^{-\alpha(t-P/2)} - e^{-\alpha(t-P)} + e^{-\alpha(t-3P/2)} - e^{-\alpha(t-2P)}\right\} \quad (4)$$

The predicted fore-strain loops at steady state are shown in Figure 1. It can clearly be observed that the curve shapes bear a strong resemblance to the experimentally observed force strain loops [1, 2].

When the fading memory formulation is implemented in conjunction with a phenomenological kinetic equation for stress fibre remodeling a dependence on predicted force on applied strain rate is correctly computed. However, this formulation fails to correctly predict the alignment of stress fibres in the direction of stretching.

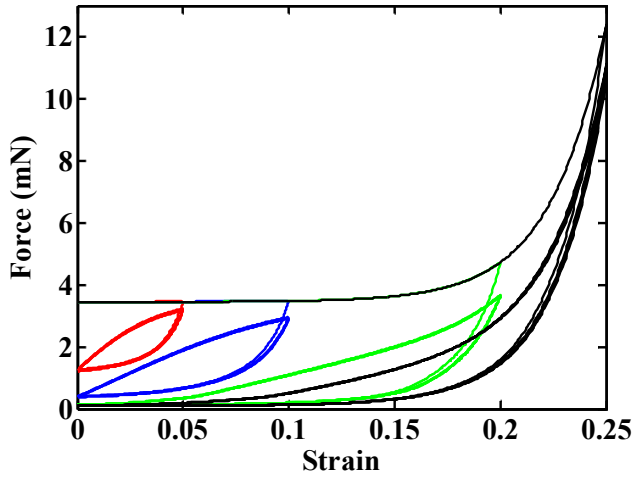

Figure 1. Fading memory prediction of active cell force as a function of applied strain rate. A loading frequency of 0.1Hz in all cases.

THERMODYNAMICALLY CONSISTENT MODEL

In an effort to correctly predict cell alignment in a dynamically loaded 3D environment we use a thermodynamically consistent model (Viglotti et al. []) for stress fibre formation/dissociation and remodeling in conjunction with a non-local conservation of cytoskeleton proteins within a cell.

The rate of stress fibre formation and dissociation is given as

$$\dot{\hat{\eta}} = \frac{\hat{N}_u}{\pi\hat{n}}\omega_n \exp\left[-\hat{n}\frac{\mu_a - \mu_u}{k_B T}\right] - \hat{\eta}\omega_n \exp\left[-\hat{n}\frac{\mu_a - \mu_b(\phi)}{k_B T}\right] \quad (5)$$

where $\hat{\eta}$ is the SF concentration per unit surface area of a representative volume element (RVE), $\hat{n}$ is the number of actin-myosin contractile units along the length of the RVE, μ_b is the free energies of the bound contractile units in a stress fibre, μ_u is the free energy of unbound SF proteins, while k_B and T are the Boltzmann constant and absolute temperature. $\hat{N}_u$ is the number of unbound SF proteins in the RVE.

Here we implement non-local conservation of the total number of SF proteins within the cell, $\hat{N}_T$, under the assumption that the diffusion of unbound proteins through the cytoplasm is infinitely fast relative to the timescale of SF remodeling. The local number of unbound proteins in an RVE is therefore given as

$$\hat{N}_u = \hat{N}_T - \int_{V_c}\int_{-\pi/2}^{+\pi/2} \hat{\eta}\,\hat{n}\,d\phi\,dV \quad (6)$$

where the inner integral computes the number of bound proteins in a RVE, and the outer integral provides a summation of the number of bound proteins throughout the entire cell volume V_c. The kinetic law for stress-fiber remodeling is given as

$$\dot{\hat{n}} = \begin{cases} -\frac{1}{\hat{n}}\left(\frac{\hat{N}_u}{\hat{\Pi}}\right)^2\left[\psi(\tilde{\epsilon}_n) - \frac{\delta\psi}{\delta\tilde{\epsilon}_n}(1+\tilde{\epsilon}_n)\right]\frac{\alpha}{\mu_{b0}} & if\ \frac{\delta\Psi}{\delta n} \le 0 \\ -\frac{\hat{n}}{4}\left[\psi(\tilde{\epsilon}_n) - \frac{\delta\psi}{\delta\tilde{\epsilon}_n}(1+\tilde{\epsilon}_n)\right]\frac{\alpha}{\mu_{b0}} & otherwise \end{cases} \quad (7)$$

Contractility is implemented via a Hill-type tension strain rate law, without the requirement of introducing the phenomenological fading memory formulation. The model correctly predicts transient changes in active cell stress as a function of applied strain rate. Importantly, the model predicts stress fibre alignment in the direction of loading, as shown in Figure 2. Stress fibres form only in the general direction of applied stretching ($\phi = 0$), with no fibres forming perpendicular to the loading direction.

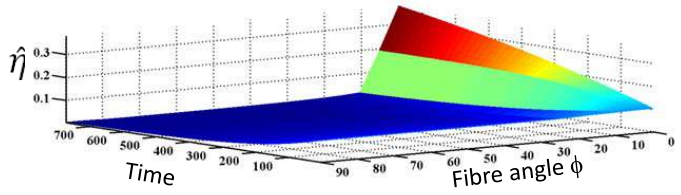

Figure 2. Evolution of stress fibre concentration $\hat{\eta}$ as a function of fibre angle ϕ.

DISCUSSION

A fading memory formulation correctly captures the transient changes in stress fibre tension during applied dynamic loading. However, alignment of stress fibres in the direction of loading is not correctly predicted when a phenomenological kinetic equation is used for stress fibre evolution. In contrast, a thermodynamically consistent formulation with non-local conservation of cytoskeleton proteins within a cell correctly predicts both transient changes in fibre tension, and alignment of fibres in the stretching direction. A simple hill model for contractility is sufficient when stress fibre formation and remodeling is correctly described. This suggests that the "fading memory" type strain rate really represent the "catching-up" of the apparent stress fibre strain rate with the applied strain rate as contractile actin-myosin units are added or removed from the stress fibre in response to external loading.

INTRODUCTION

POC diagnosis of infectious diseases requires a fast assay time, minimal infrastructure, and sufficient sensitivity and specificity. Among the various infectious disease biomarkers, the amplification and detection of pathogen's nucleic acid sequence has been shown to be highly sensitive and specific. To detect the target nucleic acid sequence, a gold nanoparticle (GNP)-based aggregation assay has shown great promise to meet the POC requirements. For this assay, GNPs were conjugated with two different DNA sequences that are complementary to target nucleic acid sequence to create "probes". The probes hybridize with the target to form GNP aggregates which induce a color change due to the altered plasmon resonance (Figure 1). Previous work has reported the optimized reaction conditions and detection methods [1-2]. However, the effects of GNP probe concentration and size on the assay performance are not clearly understood.

In this work, we investigated the effects of the nanoparticle probe's concentration and size on the assay performance. Preliminary results suggest that higher GNP probe concentration shifts the assay dynamic range to be less sensitive, and increasing GNP probe size increases the sensitivity (30 – 50nm versus 15nm). Our work presents guidelines to design this nanoparticle assay to meet sensitivity needs.

METHODS

Malaria parasite genus *Plasmodium* was chosen as a clinically relevant target [1]. A poly A-tail was included in the probes to increase flexibility of the sequence. The HPLC-purified probes were synthesized and purchased from Bio Basic Canada Inc. GNPs were prepared by reducing gold chloride by sodium citrate. To conjugate DNA probes to GNPs, we followed a pH-assisted and surfactant-free method reported earlier [3]. The complementary target was then hybridized with GNP probes for 30 min at room temperature in the presence of a hybridization buffer which consisted of 20 % Formamide, 16% dextran sulfate and 0.6 M NaCl. The optical spectrum was measured using a Beckman Coulter UV-Vis spectrophotometer (model DU800).

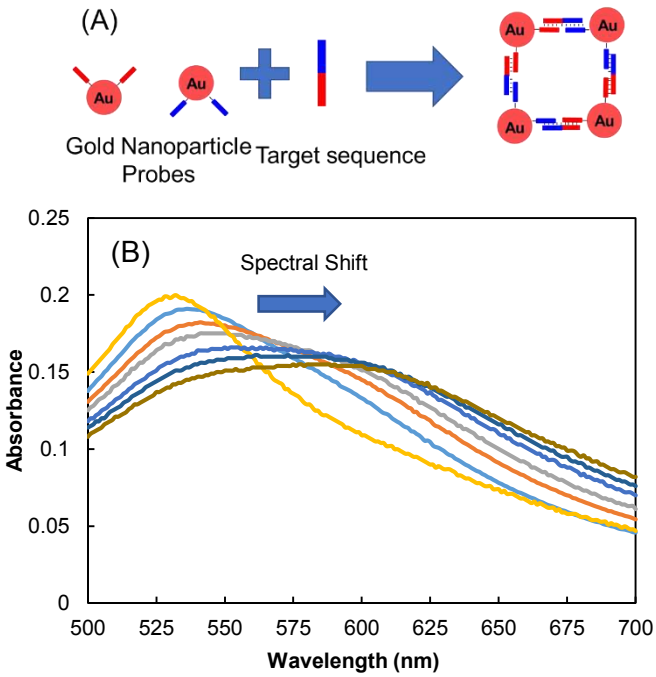

Figure 1. Schematic of the nanoparticle aggregation assay (A) and example spectral shift (B).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

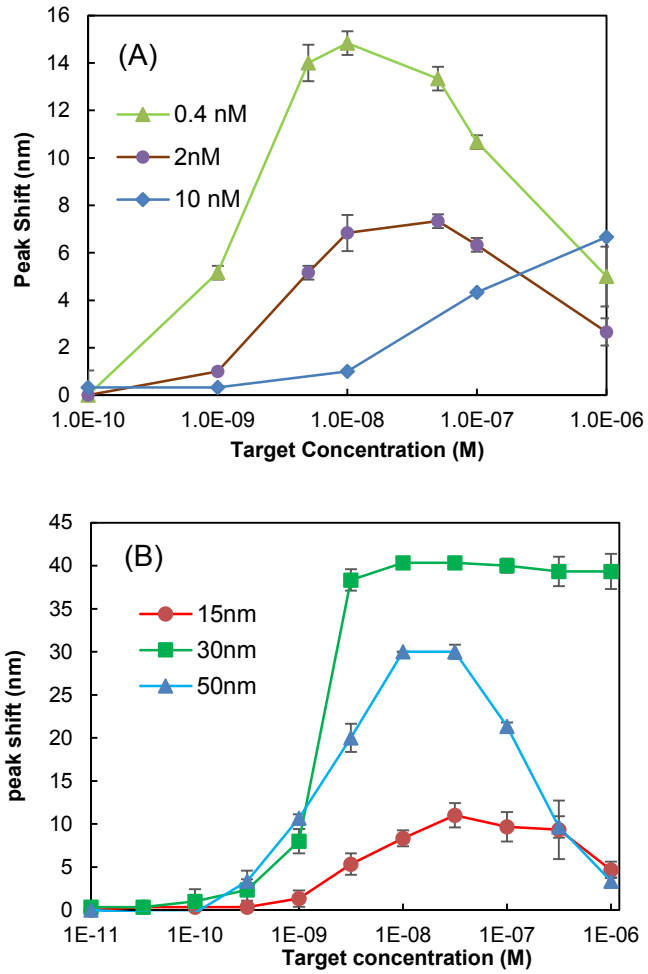

Figure 2 (A) Effect of GNP probe concentration on the aggregation sensitivity and dynamic range (15nm). (B) Effect of GNP size on the aggregation sensitivity and dynamic range (OD=0.75 for all cases).

RESULTS

15nm GNP probe was used to test the effect of nanoparticle concentration. The probe nucleic acid conjugation on GNP leads to plasmon resonance peak shift from 518 to 524 nm and hydrodynamic diameter increase by 9 nm. Within the concentration range studied here, increasing the GNP probe concentration shifts the dynamic range of the assay to higher target sequence concentrations and thus leads to higher limit of detection (i.e. less sensitive, Figure 2A). For instance, a low probe concentration (0.4nM) can detect down to 0.1nM while a higher probe concentration (10nM) can only detect down to ~10nM. We hypothesize that the large excess of non-aggregated GNPs (thus background) for higher probe concentration explains the less sensitive detection.

The effect of nanoparticle size on the assay performance was investigated by varying GNP size including 15nm, 30nm, and 50nm. While changing the GNP size, we kept the peak OD value the same for all samples. The result is shown in Figure 2B. Larger GNP size decreases the limit of detection (i.e. more sensitive to detect lower target concentrations). For example, 50nm GNP probe can detect down to 0.1nM while a smaller probe size (15nm) can only detect 1nM. Interestingly 30nm gives a highest spectral shift in all the three sizes. Careful examination of the assay kinetics shows that the reaction and peak shift of 30nm GNP probe is faster than the cases for 15nm and 50nm (data not shown). One possible explanation is the balance between the peak shift and Brownian motion. While the larger GNP gives a larger signal and thus higher signal, larger GNP also has a slow Brownian motion thus reducing the speed of the reaction. As a result, 30nm may be an optimal balance between the two factors, giving the highest peak shift.

DISCUSSION

Optimization of the assay performance is an important first step towards the development of a reliable and highly sensitive point-of-care diagnostic platform. In this study, we carefully evaluated the effects of the nanoparticle probe parameters including the concentration and size, and the results suggest that lower GNP concentration and larger size improve the ability to detect lower target concentration. The current nanoparticle aggregation assay can detect nucleic acid targets in the pM to nM range, and future work is needed to further improve sensitivity.

AGE-DEPENDENT DIFFERENCES IN MECHANICAL PROPERTIES OF CHEMICALLY TREATED BOVINE PERICARDIUM

A.D. Caballero (1), F. Sulejmani (1), W. Sun (1)

(1) The Wallace H. Coulter Department of Biomedical Engineering
Georgia Institute of Technology and Emory University
Atlanta, GA, USA

INTRODUCTION

The pericardium, a collagen extracellular meshwork, is the connective tissue sac surrounding the heart. Adult and calf bovine pericardium (BP) are widely used as biomaterials for tissue engineering applications, including the construction of vascular grafts and patches, as well as for manufacturing bioprosthetic heart valves (BHVs) [1]. A critical parameter of BHVs designed to be implanted percutaneously is the BP thickness, since the collapsed valve should be able to be delivered in a small diameter catheter so that it can be threaded through the arterial system.

It has been suggested that neonatal BP is significantly thinner and has superior strength than adult BP [2], making it a potential candidate tissue for percutaneous BHV manufacturing. These findings, however, are limited by the use of simplistic uniaxial loading, given that pericardial tissue is considered to be mechanically anisotropic. Moreover, it is still unclear whether the age of the animals has an impact on the mechanical behavior of the BP. Therefore, the objective of the present study was to investigate and compare the age-dependent mechanical properties of fetal, calf and adult BP by means of multi-axial mechanical testing and structural analysis.

METHODS

Fresh pericardial sacs were obtained from 10 adult (12-24 months old), 11 calf (6-12 months old) and 11 fetal (third trimester of gestation) cattle from Animal Technologies, Inc. (Tyler, TX, USA). Tissue fixation was performed in 0.625% glutaraldehyde in a two-step procedure. Due to the fact that there is a structure-function- relationship between collagen alignment and mechanical strength, two-photon microscopy was used to determine the collagen fiber orientation of the BP samples. Quantification of a preferred fiber orientation of the samples was done semi-automatically using an in-house ImageJ/Matlab code.

Biaxial mechanical testing was carried out according to the methods presented by Sacks and Sun [3]. Briefly, four graphite markers placed in the central region of the samples were used for optical strain measurements. Samples were then mounted in a trampoline fashion and tested in saline solution at 37 °C. The preferred fiber orientation was aligned with the X11 direction of the loading axis of the biaxial device. Seven stress-controlled test protocols were utilized and preconditioning was performed to reduce tissue hysteresis. Constitutive modeling was carried out from the multi-protocol biaxial mechanical data, and the tissue responses were fitted with the anisotropic hyperelastic Holzapfel-Gasser-Ogden model.

Uniaxial test samples adjacent to the biaxial samples were cut into a “dog-bone” shape to ensure failure in the center region and to minimize grip effects. Each sample was cut in a way to insure that the preferred fiber orientation was parallel to the device loading axis. Graphite optical markers were placed on the narrow portion of the samples for optical strain measurements. After preconditioning, samples were loaded until failure and an in-house LabVIEW/Maltab program was used to obtain the stress–strain curves.

Finally, the fibrous structure of the BP was examined via histological analysis. Samples were cut into strips parallel to the X11 direction of the biaxial test fixture, and fixed in 10% formalin prior to paraffin processing and sectioning. The sections were then stained with Picrosirius red and imaged with circularly polarized light. Images were analyzed with an automated in-house Matlab code to quantify the maturity of the collagen fibers. All measurements are presented as a mean ± standard deviation. For all statistical considerations, a p-value

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

< 0.05 was considered to be statistically significant (indicated by *, while ** indicates high statistical significance with p < 0.001).

RESULTS

The mean thickness was 0.451 mm for adult BP (ABP), 0.321 mm for calf BP (CBP), and 0.231 mm for fetal BP (FBP). There was a high statistically significant difference between the three age groups (p < 0.001). Quantification of the angular distribution of the collagen fibers allowed us to measure the anisotropy of the samples in a systematic way (Figure 1).

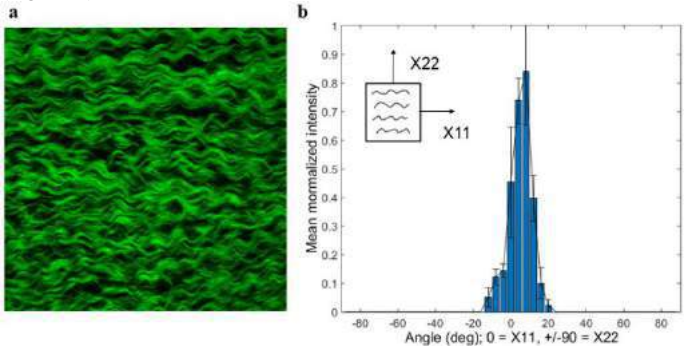

Figure 1: (a) Representative second-harmonic generation image slice of FBP sample, (b) Distribution of fiber alignment through the thickness for FBP sample

Regarding the biaxial mechanical response, the tissue stiffness was quantified at three equibiaxial stress values: 60 kPa, 250 kPa and 600 kPa (Figure 2). ABP and CBP demonstrated a higher stiffness than FBP in both directions. This difference was statistically significant in the cross-fiber direction (X22) direction at all stress values. On the other hand, FBP showed a higher extensibility than ABP and CBP, with a statistically significant difference in the X22 direction (Figure 3a). The modified Holzapfel model successfully captured the BP biaxial response with a mean R^2 value of 0.95 for all age groups (Figure 3b).

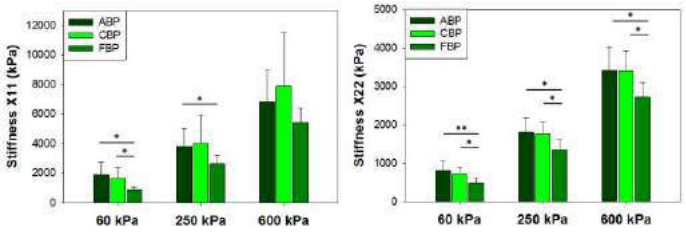

Figure 2: Tissue stiffness at 60 kPa, 250 kPa and 600 kPa of ABP, CBP and FBP in the X11 and X22 directions

The ultimate tensile strength (UTS) of ABP and CBP was found to be much greater than for FBP, with a high statistically significant difference (p < 0.001) (Figure 4a). On the other hand, the strain at failure was significantly greater for FBP than for ABP and CBP (p < 0.001) (Figure 4b). Also, when the extensibility for each age group was compared, the strain was significantly larger in the X22 direction than in the X11 direction for ABP, CBP and FBP, confirming the anisotropic properties of the tissue. There was no statistically significant difference in mechanical properties between the ABP and CBP groups. Quantitative collagen color (hue) analysis of the histological samples indicated statistically significant differences in the percentage of green (thin) fibers between ABP and FBP, and between CBP and FBP (p < 0.001), where the proportion of thin newly synthesized fibers decreased with age.

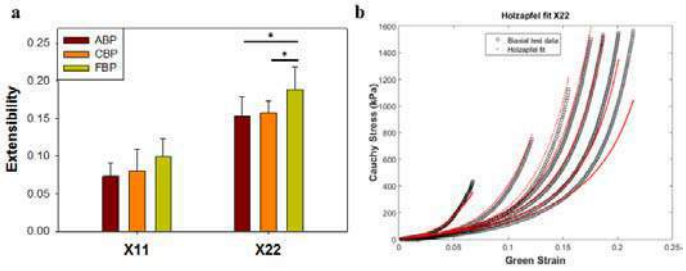

Figure 3: (a) Tissue extensibility of ABP, CBP and FBP in the X11 and X22 directions, (b) Representative multi-protocol biaxial test data for one ABP sample (black) with modified Holzapfel model fit (red) in the X22 direction

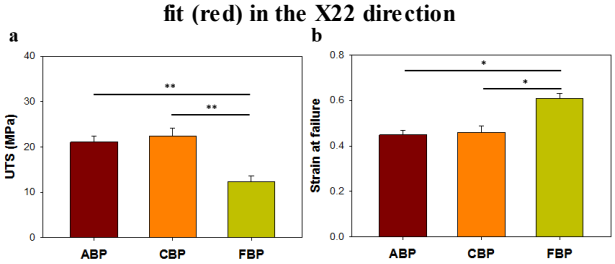

Figure 4: (a) UTS of ABP, CBP and FBP, (b) Strain at failure of ABP, CBP and FBP

DISCUSSION

Overall, ABP and CBP demonstrated a markedly higher stiffness and a higher tensile strength than FBP. However, FBP was significantly thinner and presented a higher extensibility and strain at failure than ABP and CBP. Results suggest that BP is more compliant during the fetal stage and then stiffens and strengthens during young adulthood. The significant difference in thin collagen fibers between ABP, CBP and FBP supports the idea that the newly synthesized collagen fibers found in younger tissue are not as strong as the thick mature collagen fibers.

In contrast to the results of Sizeland et al. [2], our fetal BP did not show a higher stiffness and a higher ultimate tensile strength than the older tissue. This variance may be due to differences between juvenile and fetal tissues. In conclusion, a deeper understanding and utilization of the BP mechanical and structural properties may ultimately result in BHV designs with more predictable performance and improved durability, as well as would enable percutaneous valve technologies to develop the minimal profile size required to reduce adverse events at the vascular access site.

ACKNOWLEDGEMENTS

Research for this project was funded in part by the R21HL108240 grant. Andres Caballero is also supported by a Fulbright-Colciencias fellowship. The authors would also like to thank Michael Moon for his help in collecting experimental data.

STUDENT LEARNING OF BIOMECHANICS TOPICS BY EMBEDDING "QUANTIFIED SELF" MOTIVATED PROBLEM BASED LEARNING MODULES IN BIOMEDICAL ENGINEERING COURSES

Eric G. Meyer, Mansoor Nasir

Biomedical Engineering Department
Lawrence Technological University
Southfield, MI, USA

INTRODUCTION

Traditional undergraduate courses in engineering have followed the deductive pedagogy of proposing a concept, explaining the principles and demonstrating the theoretical framework of the concept [1]. The student is expected to memorize the material or work many examples and their mastery is then evaluated during an exam. This teaching method lacks important student learning opportunities, such as; the reason why these concepts or mathematics are important, what is their real-world relevance and how this will impact the students' future career in engineering. Project Based Learning (PBL) is an alternative method that is an inductive pedagogy, which is more student-centered [2]. These techniques begin with a real-world problem or observation that is introduced to the students and can lead to deeper student learning when properly implemented [3].

The "Biomechanics" sub discipline of Biomedical Engineering (BME) is taught in various forms in most undergraduate programs. The BME curricula at Lawrence Technological University requires that students take semester long courses covering "Statics", "Biomechanics" with "Biomechanics Lab", and "Tissue Mechanics". There are also opportunities to develop interest and experience with biomechanical applications in non-technical or elective courses, such as the freshman-level "Introduction to Biomedical Engineering" or senior-level "Engineering Applications in Orthopedics" courses.

"Quantified Self" (QS) is a trend in the consumer electronics and digital health industries that have introduced many devices with new sensors and data logging systems to allow individuals to understand their personal health and wellness through quantification and tracking a variety of physiologically relevant parameters. The QS theme can be related to a variety of topics in many engineering and science disciplines (Figure 1). Besides companies' excitement over QS devices, it is increasingly common to find students that own these devices, such as the Fitbit activity trackers, Withings smart scales, or Apple smart watch. Many popular QS devices are based on biomechanics concepts using kinematics (e.g. Microsoft Kinect and Nintendo Wii Remote) or the kinetics (e.g. Wii Balance Board). Other examples like the electromyography based Myo Gesture and pressure based Nike in-shoe sensors do not have wide customer base yet.

Figure 1: Representation of the broad diversity of topics that can be related to Quantified Self devices.

The goal of this project was to develop and implement learning modules and associated resources that use the QS theme to motivate biomechanics topics in a range of BME courses. By spreading the modules into a variety of courses at the freshman, sophomore, junior and senior levels, the students may be repeatedly exposed to QS devices with an increasing levels of difficulty and expectations throughout their degree program. This not only promotes a deeper understanding of the fundamental biomechanics concepts but also allows the students to

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

develop experience and confidence in working with these types of devices.

METHODS

In this project, we developed and implemented QS theme based PBL modules to teach biomechanics topics in four BME courses following a similar pedagogical technique from modules developed for other topics in a range of disciplines [5]. The PBL modules were organized as a combination of short Active Collaborative Learning (ACL) activities that were completed in class and partner/group based design project homework assignments. The modules combined several open-ended tasks that build sequentially, following previously completed work and the topics that were covered in class. Student learning outcomes during a pilot implementation of the modules were measured with direct (formal design report and/or group presentations) and indirect (student survey) assessments. The instructors also maintained close observation of student groups in class and during office hours to reflect and improve the implementation of the module.

RESULTS

Detailed assignments and instructor guides for the biomechanics modules were developed and implemented for at least one pilot test prior to being shared with other BME faculty through teaching workshops and a website [6]. Generally, these modules required 1-3 partial class periods to introduce the theme, develop understanding of the QS devices, and conclude with a final project wrap-up with the groups. The modules were scheduled to coincide with the appropriate technical concepts that were covered in the course.

Course: BME 1002 "Introduction to Biomedical Engineering"
Module: Product Concept Development based on the Nike+ Shoe Sensors

The project started with an introduction of the engineering design process. Then groups were formed to practice opportunity recognition through the "Painstorming" technique [7]. Finally, the groups were asked to develop a new application for the Nike+ Shoe Sensor system. They produced a device concept, a simple business model and evaluated the market potential. The assessment was concluded with a student produced elevator pitch video on economic and social benefits of their proposed application. Most students understood the importance of design in engineering and were able to communicate their product concept in terms of technical capability, customer value and economic viability. The sensors for this project were functional prototypes manufactured by Nike but are not currently commercially available.

Course: BME 3303 "Introduction to Biomechanics"
Module: Sensing Angular Kinematics of a Baseball Swing with Arduino

The scenario was a call for assistance from the university's baseball coach to help improve the team's batting performance. Students worked together during class to investigate baseball swing kinematics. Guided homework questions walked the students through the design process steps of; identifying customer needs, brainstorming, determining specifications, analyzing solutions. Next, students were introduced to open-source electronics like Arduino and sensor platforms (SEEED Grove) to use for the prototype development phase of the project. Next, the student teams developed a calibration method for the sensors and recorded the motions during a baseball bat swing. Finally, they developed a formal design report that refined their concept into a commercial product that could be marketed to the baseball coach and potential investors. Although most students had no prior experience with Arduino, they enjoyed the hands-on aspects of building a prototype. The hardware kits cost approximately $50/group, but can be reused in future course offerings.

Course: BME 4313 "Tissue Mechanics"
Module: Mimicking Muscle Optimization Strategies with Myo Gesture

In this course, students learn how to predict muscle contraction patterns using static optimization of various performance criteria. These same patterns can be directly measured with new QS sensors like the Myo Gesture armband. Students used the sensors to record forearm electromyography during everyday activities like using tools, typing, playing music or video games, sports, etc. They compared muscle contraction patterns between two different activies. Finally, they had to suggest ways that this information might be used for human-computer interface applications like active prosthetics control. The Myo Gesture devices cost approximately $200 per unit, and can be synced with a computer or mobile device running a variety of applications. The package includes a software development kit that allows access to raw EMG data.

Course: BME 5093 "Engineering Applications in Orthopedics"
Module: Surrogate Head Impact Measurement with Triax Headband

Impact biomechanics uses surrogate human devices like crash test dummies to assess injury risk and the effectiveness of safety systems to prevent injury. Students built their own surrogate head and neck to simulate the anthropometry and biofidelity of a human. Then they used the Triax headband sensors to quantify impacts for different scenarios and with various helmets. Hands on use with head impact sensors allowed the students to understand differences between linear acceleration and angular velocity and how those motions might lead to different injury patterns. The Triax SIM-G sensors cost approximately $200 per unit, but can be shared and/or reused for other projects.

DISCUSSION

Students were able to create product concepts, to collect and calibrate sensor data and relate this information to various biomechanical topics that were being studied in the BME courses. Although most students had no prior experience with the QS devices prior to the modules, they enjoyed the hands-on aspects of these PBL modules. Other positive reflections included the open-ended and real world aspect of these projects. On the other hand, some students expressed confusion during the projects, due to a lack of understanding of how the module was introduced and what was expected. These course modules were part of a larger project to implement Entrepreneurial Minded Learning into a variety of engineering courses so that students will be repeatedly exposed to this mindset with the ultimate goal of improving students' preparation and skills for their senior capstone projects and as professionals in the real-world.

POTENTIAL INVOLVEMENT OF ENDPLATE PURINERGIC SIGNALING IN LOW BACK PAIN

INTRODUCTION

Low back pain (LBP) can occur from nerve irritation or physical impingement caused by trauma. However, the most common type of LBP results from nonspecific causes lacking trauma or specific pathology. It has been postulated that up to 84% of people will experience lower back pain at some point during their life, and 23% will experience chronic LBP (1). Nonspecific LBP is often difficult to treat as the underlying pain mechanism is not well understood. Degeneration of the disc and surrounding tissue may be involved in spinal pain transmission. It is hypothesized that load-induced degeneration of the disc is preceded by degeneration of the cartilage endplate (CEP), a thin, hyaline-cartilage tissue located between the disc and the vertebrae that regulates diffusion of solutes across the disc (2). During endplate load-induced degeneration, cells within the endplate may undergo changes including release of TGF-β and apoptosis (3, 4). Additionally, degeneration leads to increased innervation of the tissue, and it has been suggested this change can modulate LBP (5, 6). A molecule that has been described as being released by mechanical stimulation and inducing pain is ATP (7, 8), however release of ATP from endplate chondrocytes has not been described. We propose that cartilage endplate cells release soluble factors in response to mechanical load, such as ATP, that activate nociceptors in the CEP in particular in load-induced degeneration contributing to LBP. We demonstrate here that ATP released by mechanically stimulated murine long-bone osteocyte-like cells (MLO-Y4) activate neurons through the purinergic receptor, $P2X_3$. We propose that communication between CEP chondrocytes and local nerves is through similar mechanisms. Understanding the exact cellular and mechanical mechanisms behind LBP will enhance therapeutic treatment of this debilitating condition.

METHODS

Dorsal Root Ganglia Culture

Primary mouse single-cell dorsal root ganglia (DRG) were isolated and cultured as described by Malin et al (Malin et al. 2007). Briefly, adult C57BL/6 mice (Jackson Lab, Bar Harbor, ME) were humanely euthanized by CO_2 and cervical dislocation according to IACUC approved protocol. DRG at locations L3-L5 were removed from both sides of the animal and held in cold Dulbecco's modified eagle medium: Nutrient mixture F-12 (50:50; DMEM-F12; Mediatech, Manassas, VA) with 1% [v/v] penicillin/streptomycin (Mediatech). Ganglia were washed in DMEM-F12 with penicillin (100IU)/streptomycin (100µg/mL)and transferred to Hank's balanced salt solution (HBSS; Mediatech) with Ca2+ and Mg2+ containing papain (20 units/mL; Worthington, Lakewood, NJ) with L-cysteine (0.33 mg/mL; Sigma-Aldrich, St. Louis, MO) for 10 min at 37ºC. The ganglia were then centrifuged at 160xg for 1 min. Papain solution was removed and replaced with HBSS with Ca2+ and Mg2+ containing collagenase Type II (1440 units/mL; Worthington) and dispase (4.7 mg/mL; BD Biosciences, San Diego, CA) and incubated for 10 min at 37ºC. Ganglia were then centrifuged at 160xg for 1 min and collagenase/dispase solution was removed. Collagenase was inactivated with serum. Ganglia were triturated with a flame-polished pipette 10 to 20 times to mechanically break up the ganglia. The cells were plated onto glass coverslips coated with poly-D-lysine (100µg/mL; Sigma) and Laminin Type 1 (20µg/mL; BD Biosciences). Complete media was supplemented with Nerve growth factor (NGF 50ng/mL; Sigma) and cells were grown at 37ºC in a 95% air/5% CO2 atmosphere. Cells were used no later than 48 hours after culture.

MLO-Y4 Cell Culture

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

MLO-Y4 cells (kindly provided by Dr. Lynda F. Bonewald, Department of Oral Biology, University of Missouri at Kansas City School of Dentistry, Kansas City, MO), were cultured on Col1 (BD Biosciences, San Jose, CA) coated dishes. MLO-Y4 cells were cultured on prepared plates at 37ºC in a humidified atmosphere of 5% CO2 in alpha Minimal Essential Medium (αMEM; Mediatech) supplemented with fetal bovine serum (2.5% [v/v]) (FBS; Hyclone, Logan, UT) and penicillin (100IU)/streptomycin (100µg/mL) (Invitrogen, Carlsbad, CA).

Calcium Imaging

DRG neurons were cultured in 8-well Nunc™ Lab-Tek™ dishes coated with LN. After being in culture for 18-24h, DRG neurons were loaded with the calcium indicator Fluo-4 acetoxymethyl ester (5µM; Invitrogen, Carlsbad, CA). Cell loading was performed by washing wells 3-times with HBSS and then adding HBSS with Ca2+ and Mg2+ containing Pluronic acid in DMSO (20% v/v; Fisher Scientific, Pittsburg, PA) and Fluo-4 AM. Cells were incubated with Fluo-4 for 30 min at 37ºC. Cells were washed with HBSS and allowed to recover for 30 min at 37ºC. The dishes were immediately imaged on a Zeiss 5 LIVE DUO under the Plan-Apochromat 10X water objective (filters 495-555) and images were taken every 50ms for 4.6 min. ATP (Sigma), ATP antagonists and conditioned media were added to cells by pipetting into bath solution. Treatments were applied approximately 20-30 s after initiation of imaging. Drugs remained in the bath solution for the remainder of the experiment. For TNP-ATP treatment, drug was added to cells during recovery period and remained on the cells throughout experiment.

MLO-Y4 Conditioned Media

Conditioned media from MLO-Y4 cells was collected by placing cells in hypotonic solution in order to induce swell and release of ATP. MLO-Y4 cells were cultured in 100mm polystyrene cell culture dishes (Corning) in αMEM containing 2.5% FBS, 2.5% FCS and penicillin (100IU)/streptomycin (100µg/mL) to ~80% confluence. Cells were serum-starved overnight. Prior to hypotonic swelling, media was removed from plates and 3 mL of HBSS with Ca2+ and Mg2+ was added to each dish and placed back at 37ºC for 1 h. Plates were then removed from the incubator and 1 mL of media was removed and stored at - 80ºC. This was retained as control media. Cells were then swelled by gently adding 2 mL of deionized water reducing osmolarity to 143 mOsm. Hypotonic solution remained on the cells for 15 min. After swelling, 1 mL of media was removed and frozen at - 80ºC.

RESULTS

Initial studies focus on nerve activation by ATP and identification of pain-associated purinergic receptors. Data indicates that DRG increase intracellular calcium at even nanomolar concentrations of ATP (Fig 1). This response can be inhibited with the addition of the $P2X_3$ specific antagonist, TNP-ATP. Additionally, application of conditioned media from MLO-Y4 cells on DRG neurons results in an increase in intracellular calcium. This response is blocked by pre-incubation with TNP-ATP (Fig 2). Taken together, these data indicate that puringeric signaling plays a role in neuronal activation through binding of $P2X_3$ receptor.

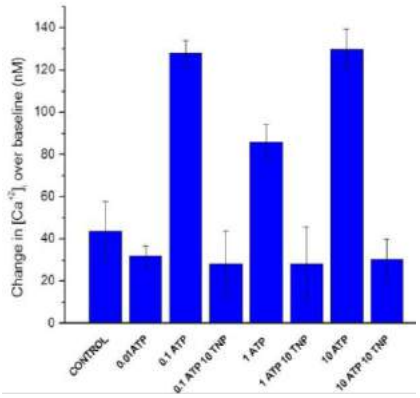

Figure 1. Application of ATP (0.1, 1 and 10 µM) to DRG results in increased intracellular calcium. This response is blocked with application of 10µM TNP-ATP which specifically inhibits $P2X_3$ receptors.

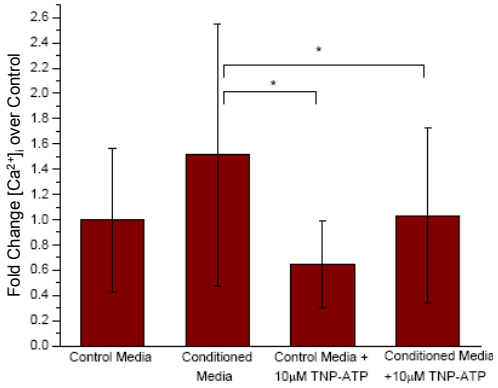

Figure 2. Application of MLO-Y4 conditioned media on DRG results in increased intracellular calcium. Intracellular calcium release is significantly reduced by blocking with the $P2X_3$ antagonist TNP-ATP. * Tukey-Kramer test $p<0.05$.

DISCUSSION

We propose that a potential mechanism for transduction of nonspecific LBP is release of ATP from CEP cells. We show here that ATP, which is released by bone cells during mechanical stimulation, activates neurons and thus presents as a potential pain signal in LBP. As described previously, mechanical load results in soluble factor release, potential cell apoptosis and degeneration of CEP tissue. Degeneration is often preceded by increased innervation leading to a potential mechanism for increased pain sensation. However, how these mechanisms together contribute in nonspecific LBP are not clear. ATP has been shown to be released by cells with mechanical stimulation and is a potent stimulator of pain. It is likely that CEP cells, similarly to bone cells and chondrocytes in articular cartilage, release ATP in response to mechanical stimulation (8,9). If this is the case, then ATP presents as a likely candidate for pain sensation in LBP. As $P2X_3$ is the main purinergic receptor associated with pain, it is a likely candidate for pain associated with nonspecific LBP. Future studies will focus on communication between CEP chondrocytes and DRG. Identification of a molecular mediator of nonspecific LBP will provide an invaluable therapeutic target for those affected by this debilitating condition.

THERMODYNAMIC FLUCTUATIONS DETERMINE THE KINETICS OF SWELL-BURST CYCLES OF GIANT UNILAMELLAR VESICLES UNDER OSMOTIC STRESS

INTRODUCTION

Osmolarity is a key parameter of cell microenvironment, having implications in numerous cellular activities ranging from gene expression to cancer metastasis [1-3]. Two biophysical aspects of the plasma membrane determine the entire subsequent cell responses to osmotic stress: (i) its transport properties for water and osmolytes, (ii) its mechanical behavior related to variations in cellular volume. In this work, we use giant lipid vesicles as a model system to study the response of the cell membrane to osmoregulation, and combine experimental characterization and mathematical modeling to reveal the dynamics of vesicle under osmotic stress.

When subject to hypotonic conditions, giant unilateral vesicles (GUVs) exhibit a swell-burst cycle behavior, driven by osmotic flux through the membrane, increasing the membrane tension until a pore is open and releases part of the content of the GUV. Once the membrane tension decreases, the pore reseals, and a new cycle begins (Fig. 1). Moreover, when the membrane is composed of a phase separating lipid mixture, domains of distinct composition and organization appear due to the osmotically induced stretching of the membrane. Although these behaviors have been observed [4,5], the relations between membrane deformation, pore formation/resealing, tension dependent phase separation, and transport properties are still unknown.

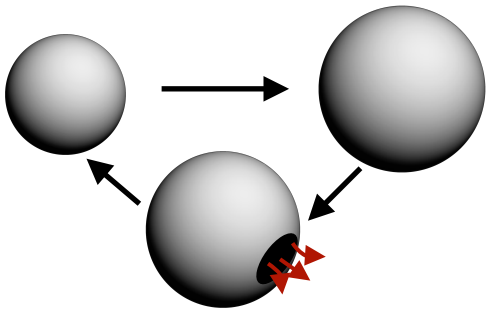

Figure 1: Schematic of a swell-burst cycle of a single lipid giant unilamellar vesicle (GUV) under hypotonic conditions. Red arrows represent leak-out through the transient pore.

Starting with single lipid vesicles, we experimentally quantify the swell-burst cycles of GUVs, and develop a theoretical model capturing the physical features of the system. We show the importance of membrane fluctuations, due to thermal and mechanical solicitations, in the determination of the dynamics of GUV in hypotonic conditions.

METHODS

The experimental methods for the GUVs preparation has been described in [5,6]. In brief, GUVs (100% POPC + 1mol% Rho-DPPE) containing 200, 600 or 1000 mM of sucrose were prepared by electro-formation, yielding radii ranging from 7 to 20µm. GUVs were then placed in a bath of deionized water at room temperature, inducing hypotonic stress proportional to the inner sucrose concentration. The kinetics of GUVs were recorded by time-laps microscopy at 1/150 images/ms. Note that for practical reasons, observations started about one minute after the GUVs were put in hypotonic conditions. For each frame, the GUV radius was measured with a homemade image analysis code built in Matlab, which fits the GUVs contour to a circle, based on intensity gradient contour detection. The evolution of the GUV radius with time was obtained, with a precision of about 0.1µm. Pore opening events were identified as sudden drop of GUV radius, and confirmed by direct observation.

In order to understand the observed swell-burst cycles, we propose a theoretical description of the system which couples mass conservation of the solvent (including osmotic influx, and leak-out through the pore), mass conservation of the solute (including diffusive and convective flux through the pore), and dynamics of the membrane (including elastic energy, membrane folding and unfolding, pore edge energy, and viscous dissipation) [7-10]. Based on the idea that pore nucleation event under membrane tension is a critical phenomenon of the cycle dynamics, we incorporate thermal fluctuations which drive the formation of stochastic nano-pore at the origin of large pore opening [11,12]. The full model is formulated in terms of three coupled stochastic differential equations, one for the GUV radius, one for the pore radius, and one for the amount of solute. These equations are solved numerically in Matlab® (Mathworks, Natick, MA) through a Euler-Maruyama scheme.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Single lipid GUVs in 200mM sucrose hypotonic conditions exhibit cyclic behavior, characterized by the formation of large transient pores, as illustrated in Fig. 2A. Interestingly, GUVs show irregular contours during the pore opening event and for a short time after, where "nodules" are observed at the opposite side from the pore (middle and right panels).

The typical evolution of a GUV radius with time is depicted in Fig. 2B. Swelling phases are characterized by a quasi-linear increase of the GUV radius, while pore openings produce a sudden decrease of the vesicle radius. The periods of the swell-burst cycles increase with the cycle number, or in other words, the deformation rate (therefore also stress rate) decreases with each cycle. Incidentally, the maximum vesicle radii also decrease with time. Maximum membrane deformations are measured to range between 10 and 20%. Direct observations of the pore opening/resealing events, yields an estimate of the pore life time of the order of 100 milliseconds.

Numerical results for a 13µm radius GUV under 200mM hypotonic stress are presented in Fig. 2C, and show an overall agreement with the experimental dynamics. The stochastic nature of the pore nucleation events allows a stress rate dependence of the rupture stress, in agreement with our experimental results and previews studies [13,14].

At 600 and 1000mM sucrose hypotonic conditions, the observed GUVs do not show measurable time variations in size.

DISCUSSION

In all our experiments, the maximum membrane deformation is at least twice larger than the 4% deformation to rupture usually reported for elastic deformation [15]. This suggests that, during the observed cycles, the GUV's projected area (measured areas) are not always equal to the true membrane area (actual area occupied by the lipid). Indeed, at low tension, microscopically unresolved folds may be present, serving as membrane reservoir to allow the larger range of deformation observed. This hypothesis is supported by the presence of membrane "nodules" after pore resealing (Fig 2A right panel), which indicates accumulation of membrane material. The (un)folding of the membrane is taken into account in our model through a stress-strain relationship of an exponential form in the membrane folded regime, and linear form in the elastic regime [16,17].

Another striking experimental observation is the size of the pore which can be as large as the GUV radius itself. Previews studies suppose the vesicle to remain spherical during the pore event [7-10]. This assumption does not hold for large vesicles in the conditions presented in here. Therefore our model has been built in order to take into account the influence of the pore on the vesicle shape, making it more general, and allowing to match experimentally observed GUV swell-burst cycles.

One of the main feature of our model, is to include thermal fluctuations inducing pore nucleation. Although many studies have focused on the physics of pore nucleation in lipid bilayer membranes [11,12], to our knowledge, none have been applied to vesicle systems with multiple swell-burst cycles. Here we fill this gap, and show that thermal fluctuations trigger pore nucleation, and therefore determine the subsequent swell-burst cycle dynamics. Importantly, the stochastic basis of thermal fluctuations naturally induce a dependence of the pore opening tension to the stress rate, which is a characteristic property of lipid membranes [13,14].

The behavior of GUVs at 600 and 1000 mM sucrose hypotonic conditions suggests that a fast equilibrium is reached, before any observation is made (there is about a minute between the application of the osmotic stress and the beginning of the observations). Such fast events are not yet well represented by our model, and will be the subject of future efforts. Moreover, different dynamic regimes (e.g. long lived pore, catastrophic rupture) will be examined theoretically through linear analysis, in order to explore possible parameter spaces where such behavior may be observed.

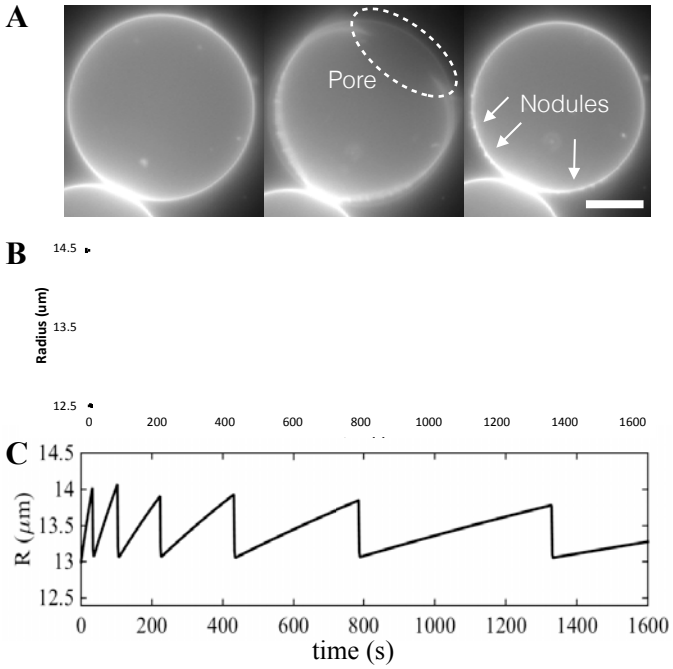

Figure 2: (A) Micrographs of a swelling (left), bursting (middle) and resealed (right) GUV. Scale bar represents 10µm. (B) Typical experimentally measured radius of a GUV in 200mM sucrose hypotonic conditions. Each drop of vesicle radius correspond to a pore opening/closing event. (C) Typical model result for a the radius of a GUV in the same conditions as in (B)

Finally, GUVs composed of phase separating lipid mixtures will be studied by coupling mixing/segregation energy of different types of lipids in our model.

The impact of this work is two-fold — it provides us with a fundamental understanding of mechanics and pore dynamics of biological membranes and the results from our study can also shed light on the mechanisms of cellular osmotic regulation.

INTRODUCTION

Adult human vascular smooth muscle cells (SMCs) do not normally produce elastin in vivo, but do so in vitro with external stimuli such as transforming growth factor beta-1 (TGF-β1). As human adipose-derived mesenchymal stem cells (hADMSCs) are known to produce TGF-β1 and other growth factors [1-5], we hypothesized that adult SMCs co-cultured with hADMSCs would produce elastin.

METHODS

Constructs (n=3 per group) were made by embedding $6x10^4$ commercially sourced SMCs in fibrin gels. After two days, $9x10^5$ commercially sourced hADMSCs embedded in fibrin gels were added on top of the constructs. Additional experimental constructs were made without hADMSCs but were treated with hADMSC conditioned media (CM). Positive and negative control constructs lacking hADMSC were treated with or without TGF-β1, respectively. After 28 days of culture at incubator conditions, constructs were imaged with an Olympus multiphoton microscope to visualize elastin via its intrinsic autofluorescence, and total elastin content was measured using a ninhydrin assay [6].

RESULTS

All cellular groups showed elastin production via ninhydrin assay (Figure 1). From a qualitative standpoint, the hADMSC/SMC co-culture experimental group (Figure 2A) produced a similar elastin network as the TGF-β1 treated positive controls (Figure 2B). The CM group (Figure 2C) showed a less developed elastin network than the hADMSC/SMC co-culture group (Figure 2A) and positive control group (Figure 2B). While the negative control group (Figure 2D) did show elastin production in the ninhydrin assay, a developed elastin network was non-existent in the autofluorescent images.

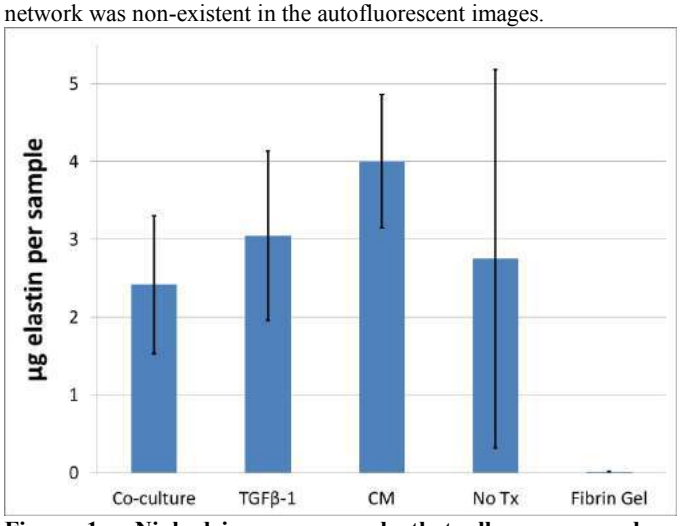

Figure 1: Ninhydrin assay reveals that all groups produced elastin, and fibrin gel alone shows negligible amounts of elastin.

DISCUSSION

The results of this study show promise for using hADMSCs as a possible elastogenic therapy, stimulating new elastin production by adult SMCs in vivo - ideally in the context of elastolytic diseases such as aneurysms. Interestingly, the underdeveloped elastin network seen

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

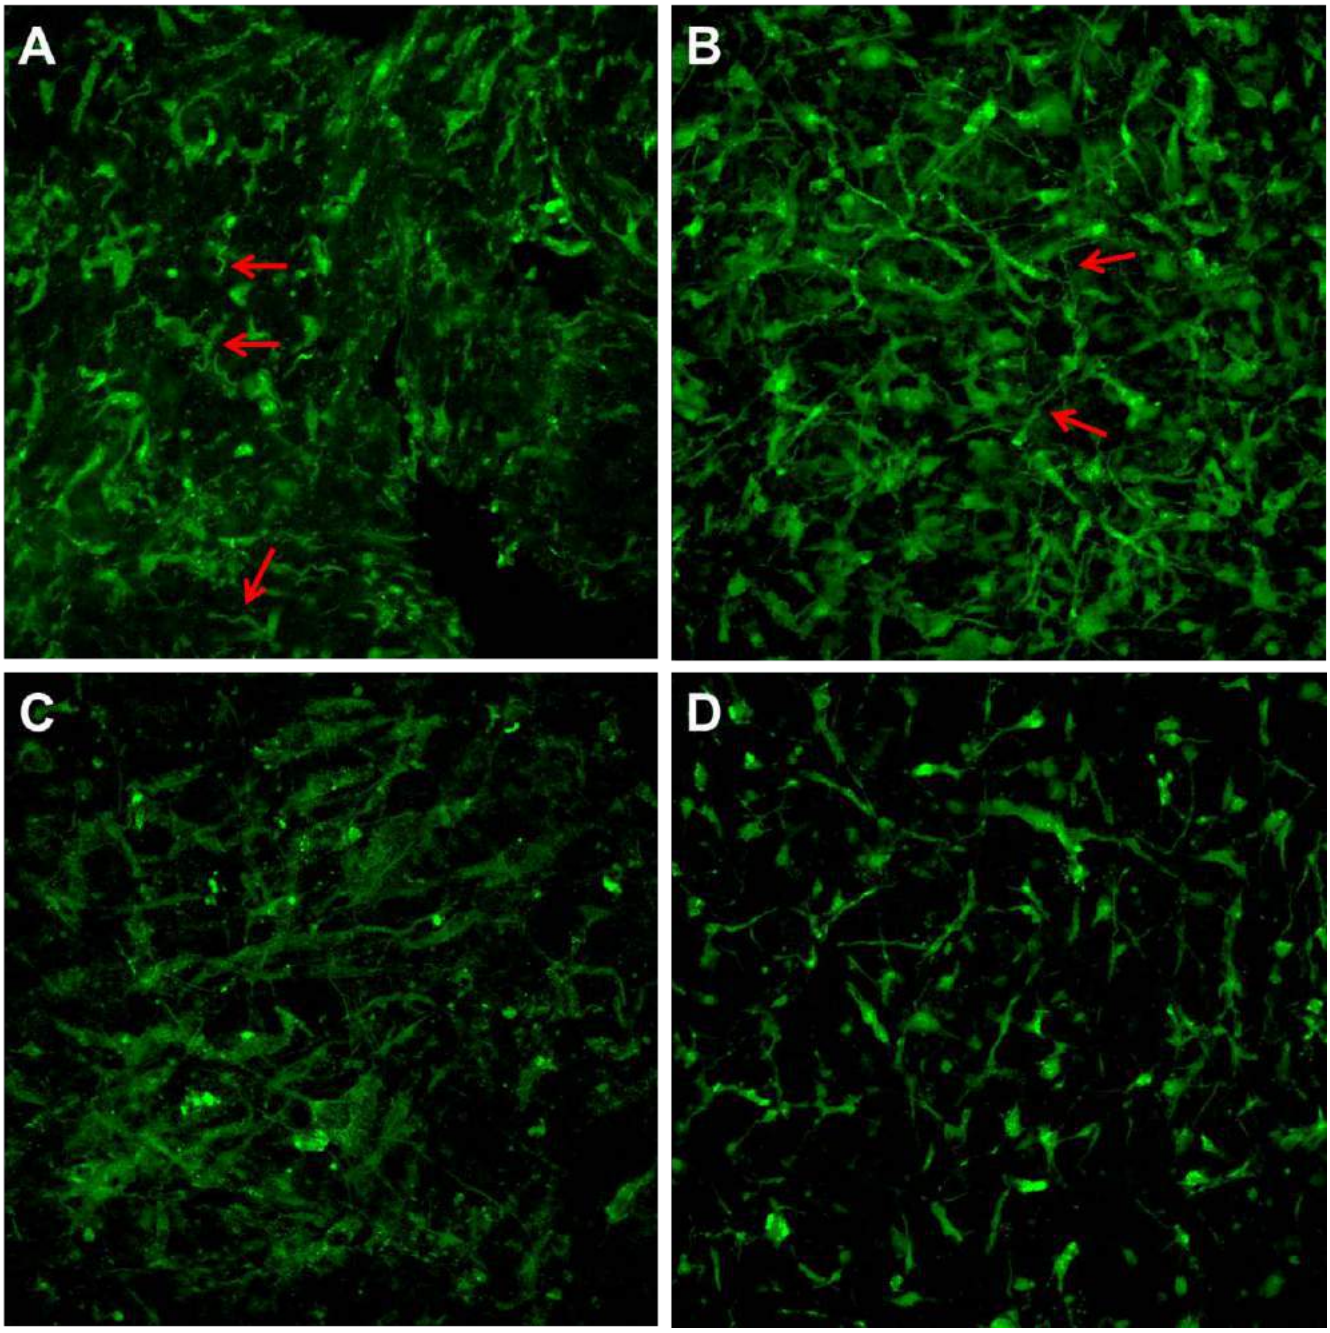

Figure 2: Elastin autofluorescence images reveal a developed elastin network with elastic fibers (red arrows) in the hADMSC/SMC co-culture experimental group (A) and TGF-β1 treated positive control group (B), a less developed network in the CM group (C), and no network (merely glowing cell outlines) in the untreated negative control group (D).

in the conditioned media group may indicate that the co-culture of hADMSCs and SMCs allow the cells to communicate and better form an elastic network compared to growth factor treatment alone.

ROLE OF P_2R-ER CA^{2+} SIGNALING IN CA^{2+} OSCILLATIONS OF *IN SITU* OSTEOCYTES IN RESPONSE TO MEDIUM INTENSITY FOCUSED ULTRASOUND

M. Hu (1), J. Jiao (1), D.E. Gibbons (1), Yi-Xian Qin (1)

[1]Department of Biomedical Engineering, Stony Brook University,

INTRODUCTION

Current clinical evidences have shown that osteocyte mechanotransduction is critical in bone remodeling related to tissue regeneration. Elevation of $[Ca^{2+}]i$ has been observed as one of the earliest biochemical events in bone cells under external physical signals. While the biological effect of ultrasound on bone healing has been well documented, the underlying mechanism is currently unknown. Our previous study elucidated the mechanobiological modulation of cytoskeleton and Ca^{2+} influx in *in vitro* osteoblastic cells by short-term focused acoustic radiation force [1]. In greater relation to the physiological setting, our current study aimed to visualize and quantify Ca^{2+} oscillations of *in situ* osteocytes in real-time response to Medium Intensity Focused Ultrasound (MIFU), and moreover, the roles of various Ca^{2+} signaling pathways in this process.

METHODS

All animal protocols were approved by Stony Brook University IACUC. Three-month-old Black6 mice were used to obtain fresh calvaria samples immediately after euthanasia by CO_2 inhalation. The bone samples were incubated in DMEM with 5% FBS and 1% penicillin/streptomycin till ready for incubation in specific Ca^{2+} signaling blockers: 1) Amlodipine (L-type VGCC antagonist; n=4), 2) 18alpha-glycyrrhetinic acid (18alpha-GA, reversible intercellular GJ blocker; n=5), 3) thapsigargin (TG, inhibitor of Ca^{2+}-ATPase pump of the ER; n=5), 4) NNC 55-0396 (T-type Ca^{2+} channel inhibitor; n=5), 5) pyridoxalphosphate-6-azophenyl-2',4'-disulfonic acid (PPADS, nonselective P2R blocker; n=2), 6) ICG-001 (antagonist of Wnt/beta-catenin-TCF-mediated transcription; n=3), and control (n=5) with 6W MIFU energy power. Other experimental groups were included to test the energy powers of 1W (n=5), 3W (n=8), 9W (n=9) and 12W (n=7) to be compared to the 6W group. The samples were stained with Fluo-8 AM for Ca^{2+} fluorescent label and subjected to MIFU stimulation for 30sec (Figure 1). Real-time confocal imaging (40X, 488-nm, 2 frames/sec) was performed to capture the Ca^{2+} signals. For data analysis, the fluorescent intensity of each cell body was extracted as a function of time. By normalization to the baseline, the responsive percentage, number of spikes, normalized spike magnitude, and the initiation time were quantified.

RESULTS

MIFU stimulation at 6W, 9W and 12W lead to significant Ca^{2+} oscillations - 85±16% (p<0.01 vs. 1W; p<0.05 vs. 3W), 80±18% (p<0.01 vs. 1W; p<0.05 vs. 3W) and 84±17% (p<0.01 vs. 1W; p<0.05 vs. 3W) of responsive cells, respectively (Figure 2). MIFU at >6W energies lead to a higher number of Ca^{2+} spikes and larger spike magnitudes compared to the lower energies. The initiation time to the first Ca^{2+} spike seemed to be relatively the same for all the energy levels (~18sec). The MIFU-induced Ca^{2+} oscillations at 6W were completely abandoned by PPADS (p<0.01 vs. control) (Figure 3). TG significantly lowered the number of Ca^{2+} spikes and spike initiation time; NNC 55-0396 also significantly lowered the spike initiation time (p<0.05 vs. control). We concluded that the P_2R-ER pathway played a major role in the *in situ* MIFU-induced Ca^{2+} oscillations.

DISCUSSION

This study provided insights into the interactions between acoustic mechanical stress and *in situ* osteocyte Ca^{2+} oscillations, which aids further exploration of the mechanosensing mechanism triggered by noninvasive acoustic radiation force. This study provided promising findings on the signaling mechanisms involved in the interactions between acoustic mechanical stress and *in-situ* osteocytic Ca^{2+} oscillations, which provides future exploration of the ultrasound triggered mechanosensing mechanism.

FSI SIMULATION OF INTRAVENTRICULAR FLOW IN A PATIENT-SPECIFIC LEFT VENTRICULAR MODEL WITH BOTH MITRAL AND AORTIC VALVES

A.D. Caballero (1), W. Mao (1), W. Sun (1)

INTRODUCTION

In recent years, computational modeling of cardiac flow has emerged a viable approach to study cardiac function in healthy and diseased states [1]. The study of left ventricular (LV) function requires a combination of methods for both the intraventricular fluid mechanics, and the valvular and ventricular solid mechanics. Although fluid-structure interaction (FSI) studies on heart valves and the LV have been reported [2,3], many groups have used fictitious FSI methods or have adopted an approach more conducive to fundamental analysis of cardiac flows. Thus, results have been restricted to simplified flow regimes, simplified material models, or idealized models of the LV and the heart valves due to computational challenges. Inherent simplifications, however, raise the question of the relevance of the findings for clinical decision making or medical device design.

The aim of the present study was to develop a fully-coupled FSI LV model with the aortic valve (AV) and the mitral valve (MV) that could capture the patient-specific LV hemodynamics and valve structural responses during the cardiac cycle. In this work, smoothed particle hydrodynamics (SPH) method was used to model the LV flow. In SPH, a continuum medium, such as fluid, is discretized as a set of particles distributed over the solution domain without the need of a spatial mesh.

For the validation of our hemodynamic flow solver, we compared the flow dynamics of the LV without the valves to the computed blood flow using a well-known CFD approach. The main goal of this work was to enhance the understanding of cardiac blood flow, by means of the development and validation of a patient-specific LV computational model that accommodated detailed anatomical, structural and flow data.

METHODS

Full phase de-identified cardiac MSCT scans were collected from patients at Hartford Hospital (Hartford, CT), from which a 72-year-old female with normal LV function was selected for the study. The MSCT examination was performed on a GE LightSpeed 64-channel volume CT scanner. 10 phases were obtained for one cardiac cycle and images were imported into Avizo software (VSG, Burlington, MA) for 3D reconstruction. The LV model developed in this study captures the LV internal structure and motion in great detail, including the patient-specific AV and MV geometries, mitral annulus and proximal left atrium motion during the cardiac cycle, and an anatomically realistic dynamic approximation of the papillary muscles (Figure 1).

To generate the 3D LV wall motion needed for the numerical simulations, the LV wall mesh and its known displacements were obtained by creating a unique structured mesh for all 10 MSCT phases in Hypermesh (Altair Engineering, Inc., MI). In this fashion, the 10 LV surface grids maintained the same number of nodes across all the phases, thus ensuring one-to-one connectivity. As numerical simulations typically involve much smaller time steps than the time separating two MSCT acquisitions, cubic-splines were used to interpolate the LV wall motion between phases.

The structural mechanics of the fully-coupled LV model were modeled by the finite element method (FEM) using ABAQUS/Explicit (SIMULIA, Providence, RI). The mechanical behavior of the heart valves were characterized using the anisotropic hyperelastic Holzapfel-Gasser-Ogden model. The LV blood flow was modeled by SPH method. The coupling of FEM and SPH method was implemented in ABAQUS/Explicit by using a contact algorithm, i.e., the fluid particles impact the surfaces of finite elements. The Lagrangian nature associated

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with the absence of a fixed mesh for fluid makes this method well suited for dealing with complex flows and large deformations.

To minimize the influence of the boundary conditions on the intraventricular flow field, the boundary location was moved upstream from the MV and downstream from the AV plane by two straight tubes (not shown in Figure 1). Two rigid plates were used to apply velocity and pressure boundary conditions in the mitral and aortic orifices, respectively.

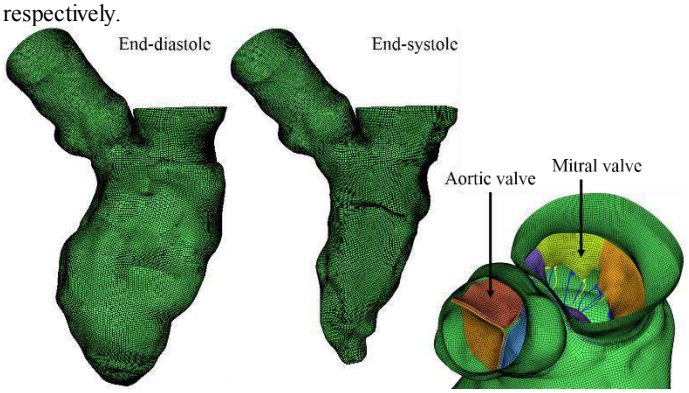

Figure 1: LV model including AV, MV, mitral annulus, proximal left atrium and approximation of the papillary muscles

RESULTS

The end-systolic and end-diastolic volumes were 47 ml and 111 ml, respectively, which are well within the physiological range [4]. The resulting stroke volume, ejection fraction and cardiac output were 64 ml, 58% and 4.8 L/min, respectively, which are also within normal values [4].

Using the LV model without the valves, cross-sectional velocity vectors during systole were compared between a CFD simulation using StarCCM+ (CD-adapco, Melville, NY) and the FSI simulation developed in this study (Figures 2a and 2b, respectively). A qualitative comparison of the two sets of data indicated that the hemodynamic flow solver of our FSI method reproduces all the key features of the intraventricular flow reasonably well. Similarly, Figures 2b and 2c show cross-sectional velocity vectors during systole for the FSI LV model without and with the AV, respectively.

DISCUSSION

The flow patterns clearly demonstrated the expected blood flow dynamics during systole, with regular laminar flow directed towards the aorta due to LV contraction. The results were consistent with in vivo measurements [5] and other FSI studies [6]. For the three LV models, the velocity reached its peak value at $t = 0.1$ ms. However, the maximum velocity for the FSI model with the AV (Figure 2c) is considerably higher than the peak velocity without the AV (Figure 2b). This difference in velocity is due to the interaction between the blood flow and the AV leaflets during systole, and reinforces the crucial role that heart valves have on the detailed cardiac flow structure.

Although many FE studies have been performed to investigate the structural responses of AV opening and closing at various configurations [7], the kinematics of the valves cannot be fully evaluated using FE models alone. In this study, the use and coupling of the anisotropic hyperelastic Holzapfel-Gasser-Ogden model allowed us to obtain detailed and realistic AV and MV opening and closing dynamics. A fully integrated model is a promising tool for understanding the overall heart function. This study provides motivation for continued advancements in computational modeling that could eventually facilitate patient-specific modeling of cardiac hemodynamics.

RELATIONSHIP BETWEEN FORCE APPLIED AND VELOCITY OF CONTRACTION OF AIR MUSCLES.

Aniruddha Sudhir Phatak

Department of Mechanical Engineering
Rochecter Institute of Tecnology
Rochester, NY, USA

INTRODUCTION:

An air muscle is a simple pneumatic device which was developed by J.L. Mckibben in the 1950's. It was primarily developed for polio patients as an orthotic appliance according to Baldwin [2, 3]. Initially these muscles were made up of pure latex rubber. As they closely resemble the natural muscle when actuated by air, they are known as air muscles. Mckibben Air muscle consists of rubber bladder surrounded by braided mesh shell which is attached to air fitting on one end and two mechanical fittings at either ends. As the internal bladder is pressurized, it expands and pushes it against the mesh to increase its volume. Due to high non-extensibility of the threads in braided mesh shell, when activated its diameter increases and produces tension if coupled to a mechanical load, producing a contractive force.

Currently the main application areas of air muscles are to produce a dexterous robotic hand having good control on all the fingers in order to fulfill basic hand operations like catching, picking, pulling and placing of objects. Another important application is to make an artificial leg which is able to walk, run and jump like a human. For all these applications it is very essential to study the force and velocity characteristics of air muscles.

My research question primarily asks, what is the exact relationship between the force acting on the air muscle and the corresponding velocity of its contraction for varying air pressures? Hence we can achieve desired movement of the fingers or the legs to perform the required operations by knowing the mathematical equation force and velocity. And thereby my objective consists of building a test rig which can calculate the velocity of contraction of air muscles when different loads are applied to it at varying pressures, in order to know the relation between force and velocity of the air muscles and to propose a theoretical model to quantify relationship between force applied and velocity of contraction.

METHODS:

1. Theoretical Modeling:

Novel Approach to find relation between force and velocity is the proposed theoretical Model. The first step of my research was the detailed study of theoretical modeling of air muscles. As per the equation for the pulling force applied by the air muscle by Chou [1], I derived the theoretical relation between force and the velocity of the contraction of the air muscle. The force equation is given by

$$F = \frac{\pi {D_0}^2 P'}{4}(3cos^2\theta - 1) \quad (1)$$

Initially θ i.e. angle between braided thread is substituted by length, in order to find the respective diameter for corresponding force and pressure.

By substituting

$$\theta = \cos^{-1} L/b \quad (2)$$

Therefore

$$L = \left(\sqrt{\frac{\frac{4F}{\pi {D_0}^2 P\prime}+1}{3}}\right) * b \quad (3)$$

First approach consists of taking a derivative of length w.r.t time is taken into account to find the velocity of contraction of the air muscle.

Second theoretical approach consists of calculating diameter for the respective force and pressure.

$$D = \frac{\left(\sqrt{1-\frac{\frac{4F}{\pi {D_0}^2 P\prime}+1}{3}}\right)*b}{\pi n} \quad (4)$$

With the help of length and diameter volume is calculated. For the modeling, pressures ranging from 30 to 80 psi were taken into account. Force was varied from 0 to 5 Kgs.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Assumptions: n = 3.5, θ = 45°, b = 16, D_0= 1.6. Finally, by using the ideal gas law equation, density for respective pressures was calculated by the formula-

$$\rho = \frac{P}{(R*T)} \quad (5)$$

The theory of Integral Relations for a Control Volume and formula for Rate of change of mass within an air muscle were used to eventually derive the velocity of change in length of the air muscle.

$$\left(\left(\frac{dm}{dt}\right)_{system} = \frac{d}{dt}\left(\int_{CS} \rho dV\right) + \int_{CS} \rho(V_r.n)dA \quad (6)$$

$$\left(\frac{dm}{dt}\right)_{system} = \frac{d}{dt}(\rho_b * \pi R^2 L) - \rho_1 V_1 A_1 \quad (7)$$

By the law of conservation, rate of change of system mass is equal to zero. Hence by substituting the change in density, diameter, velocity at inlet and area, calculation of velocity of contraction i.e. derivative of length w.r.t time is approached.

2. Experimental Modeling:

A vertical experimental test rig functioned with the Lab View program was designed to calculate the velocity of contraction for different and varying pressures. The main parameters monitored during the tests are load, pressure and the linear displacement and the data acquisition is done through Lab View Program.

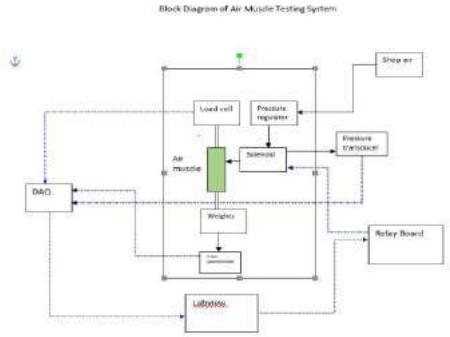

Fig:1 Block Diagram of Working of Test Rig

ANALYSIS OF READINGS:

With the help of linear potentiometer readings, saved in the excel file, actual position displacement is calculated by taking into account the voltage scale of the potentiometer. As the displacement is plotted against time, actual velocity is calculated by finding the slope of the graph. From the velocity readings, maximum velocity and average velocity are calculated for one of the contraction cycles observed by the air muscle. This process is carried out for different set of loads and pressures mentioned above. Also 95% velocity, (velocity of the air muscle at 95% of its total contraction) was calculated by noting the time at the point where contraction cycle starts and the time at which contraction of the muscle has reached 95%. Corresponding displacements are noted down, to find the velocity. Set of each type of velocity is plotted against loads ranging from 0 to 5.3 kg at two different pressures namely 40 psi and 60 psi. Change in length at 95% contraction (delta L) and time to reach 95 % of contraction are respectively plotted against the load to conferee upon the velocity and load plots. The load applied is rightly considered as the force applied.

RESULTS AND DISCUSSION:

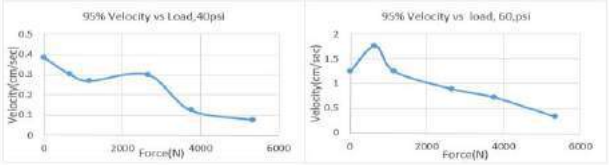

Fig:2 Comparison of 95%Velocity Vs Force Plots a.40psi b. 60psi

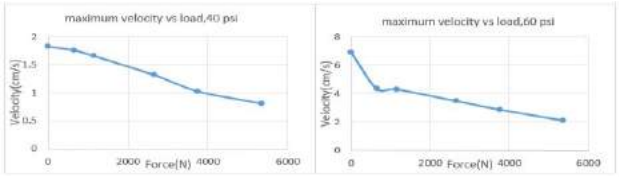

Fig:3 Comparison of Maximum Velocity Vs Force Plots a.40psi b.60psi

Here we can see that as the applied load increases i.e., the force increases, the velocity of the air muscle decreases. Hence we can definitely observe an inversely proportional relation between force and velocity of contraction of the muscle. We can also observe that as the air pressure is increased the velocity is increased. Some outlier points are observed and the reasons can be the noise due the jerk applied on the linear potentiometer during contraction. The second reason might be the inbuilt variation in the linear potentiometer. Also for specific load and pressure conditions the volume flow rate may have varied and so velocity might have hampered. The outliers were tested second time, however same results were obtained. (40 psi/ 2650 kg, no load and 650 kg/ 60 psi).

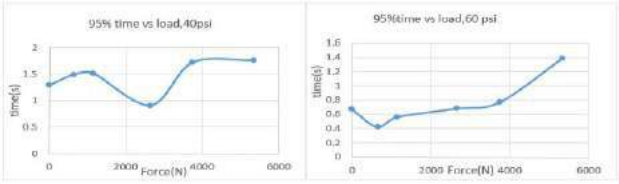

Fig:4 Comparison of 95%-time Vs Force Plots a.40psi b. 60psi

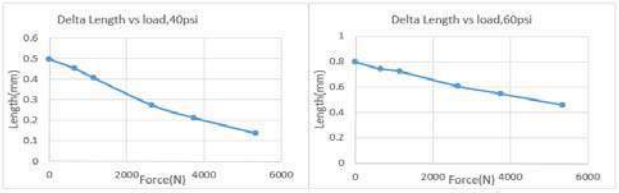

Fig:5 Comparison of 95%Contracted L Vs Force Plots a.40psi b. 60psi

Here in both these graphs we can clearly observe that as the load increases time to reach 95% of the its contraction in increased, which supports that velocity of contraction decreases as the load increases.

Also, we can observe that the displacement of the muscle i.e., the change in length at 95% of the contraction is decreased as the load increases.

From the above graphs plotted with the help of tests performed over uniquely designed test rig, we can clearly observe the relation between velocity of contraction of air muscles and force applied to it.

ACKNOWLEDGEMENTS:

First of all, I would like to extend my sincere thanks to my advisor, Dr. Steven Day, for his guidance in the development of this thesis proposal. I am very much thankful to Dr. Wayne Walter for providing linear potentiometer because of which I could measure the linear displacement of my Air Muscle.

INTRODUCTION

Providing a functional vascular network is essential for sustaining human tissue *in vivo* [1]. Therefore, a fundamental understanding of the factors that regulate the expansion or extension of vascular networks by sprouting angiogenesis is critical for advancing progress in the fields of tissue engineering, oncology [2], and regenerative medicine.

On the arteriole side of the vascular microcirculation, an upstream parent vessel branches or bifurcates into two downstream smaller daughter vessels [3]. The resulting hemodynamics of this vascular geometry are stagnation of impinging flow at the base of the vessel bifurcation compared to constant laminar shear stress (LSS) exerted tangential to the luminal surface of endothelial cells in the downstream daughter vessels. Although previous research has described how LSS coordinates angiogenesis with signals from the local biochemical environment [4-7], the effect of impinging flow that stagnates at vessel bifurcations is not well- understood. One challenge to study angiogenesis coordinated by stagnation point flow is designing a model system that reconstitutes the flow dynamics of a bifurcating vessel while also producing the correct vessel/extracellular matrix (ECM) geometry that is necessary for observing the tissue remodeling associated with angiogenesis.

In this study, we overcome this challenge by applying principles from microfluidic design and microfabrication, which enables reproduction of the vascular structure and the subsequent unique flow dynamics of the bifurcation point in vitro. Using this approach, we directly compare the effects on sprouting angiogenesis mediated by the mechanical forces associated with impinging stagnation point flow at the vessel bifurcation versus LSS in the downstream daughter branches within the same flow circuit.

METHODS

The microfluidic model of angiogenesis at bifurcation point (MMABP) was fabricated out of polydimethylsiloxane (PDMS) using soft lithography [8] (Fig.1, a). The MMABP model contains monolithic microfluidic features that were $50\mu m$ in height with a $1300\mu m$ wide inlet parent channel that branches into two $500\mu m$ wide daughter channels. The two daughter channels were separated by a 3-D ECM gel region ($400\mu m$ wide), which is localized using surface tension and capillary forces as previously described [4], and comprised of a Type I collagen/fibronectin mixture to reproduce the tissue space between two bifurcating vessels at the region. (Fig. 1, c) The flow dynamics of the MMABP are such that flow is perfused into the parent channel, impinges upon the base of the bifurcation, and then separates into the two daughter channels. The characteristics of the flow patterns were verified using a finite volume method (FVM) based model that was generated using COMSOL in order to predict the hemodynamics dominant throughout the perfusion microchannel and inside the collagen. (Fig. 1, b). The governing equations based on which the computational model was stablished consist of Navier-Stokes equation for the perfusion region coupled with Brinkman equation for the fluid flow throughout the collagen matrix.

The parent and daughter microchannels were fully-lined with mouse aortic endothelial cells (MAECs) and were laterally adjacent to the 3-D collagen gel channel. MAECs were selected for this study in part because the MMABP mimics the flow dynamics that occur at vessel bifurcations in the arteriole region of the microcirculation. We perfused our MMABP using two different media conditions, high serum media condition supplemented with 20% fetal bovine serum (FBS) versus low serum media condition supplemented with 2% FBS, at $5(dyn/cm^2$ LSS. Each experimental setup was repeated 4 times and the sprouting area of MAECs into the collagen gel channel was monitored up to 48

hours and quantified using ImageJ. The statistical significance was tested using two sample t-test.

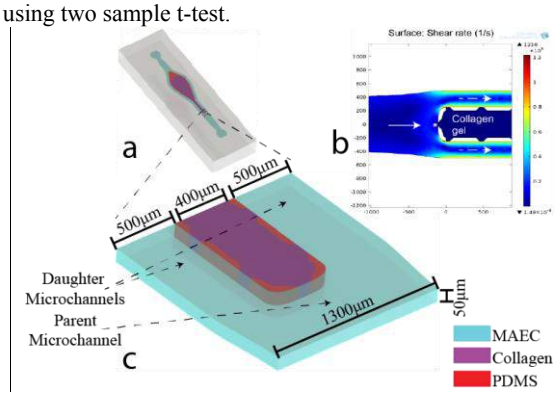

Fig. 1. MMABP composed of the parent microchannel branched into two daughter microchannels, which resemble pre-formed vasculature, and adjacent collagen gel channel, which functions as the ECM analog. (a) The MMABP overview (b) The constructed computational model predicting the shear distribution. Impinging flow (solid arrow) stagnated upon contact with the semi-permeable collagen gel (star) followed by flow separation into two laminar shear regions (dashed arrows) (c) The magnified illustration of the MMABP at the vicinity of the bifurcation point.

RESULTS

The fluid dynamics predicted by our computational model was zero shear stress local to the bifurcation point compared to the uniform LSS ($5(dyn/cm^2$) throughout the two branching daughter channels (Fig. 1. b). When evaluating angiogenesis in response to these fluid dynamic conditions, the MAECs exposed to LSS inside the two daughter channels prominently invade into the adjacent collagen gel as sprouts for both high and low serum media conditions (Fig. 2. a, c, e). In contrast, at the bifurcation point, the rate of sprouting area of MAECs is significantly greater for the high serum compared to the low serum media conditions after 36 hours of perfusion ($P<0.02$ based on two sample t-test) (Fig. 2. b, d, f).

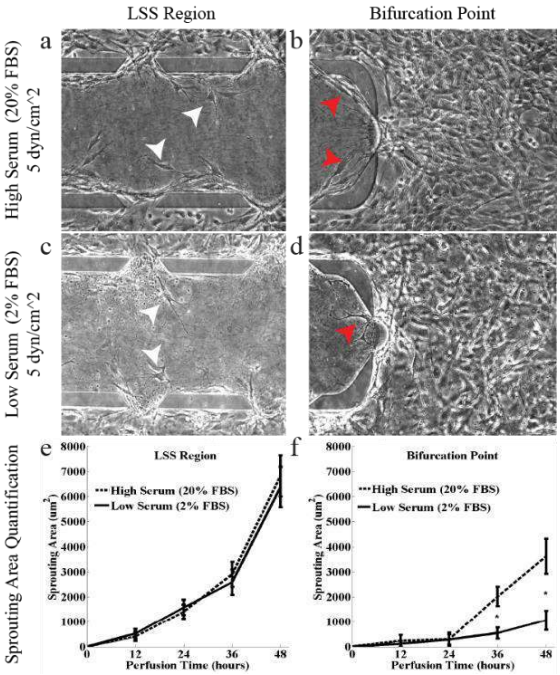

Figure 2. The hemodynamic forces created by the impinging flow on a branching vessel regulates sprouting angiogenesis. (a, b) Sprouting angiogenesis in MMABP perfused with the high serum media condition for 48 hours (red arrow heads). (c, d) Sprouting angiogenesis in MMABP sheared with the low serum media condition for 48 hours (white arrow heads). (e) Quantitatively comparable developmental angiogenesis for the MAECs constantly sheared with $5(dyn/cm^2$ LSS over the course of 48 hours. (f) The sprouting angiogenesis progression at the bifurcation point over the course of 48 hours of perfusion is depicted. The enhancing effect of the level of serum supplementation is statistically evident after 36 hours of perfusion.

DISCUSSION

These results are amongst the first reports on the effect of the hemodynamics created by the impinging flow in a bifurcating vessel on sprouting angiogenesis *in vitro*. Our results indicate a previously reported enhancing effect of LSS on sprouting angiogenesis [5, 6]. Furthermore, while the angiogenic activity of the MAECs at the bifurcation point is dependent on the local biochemical micro environment, the enhancement in sprouting angiogenesis under the effect of $5(dyn/cm^2$ LSS is independent of the level of serum the perfusion media is supplemented with. One possible explanation for the aforementioned observation can be attributed to the locally stagnated flow at the bifurcation point which increases the efficacy of potential pro-angiogenic factors to activate the quiescent endothelium to start to sprout into the 3D collagen matrix. The relatively larger convective flux at the two daughter microchannels, on the other hand, decreases the dwell time for the serum biochemical components, which in turn prevents these growth factors from interacting with the quiescent endothelium.

Future steps include inspecting how the streamlines inside the collagen can be utilized to predict/control the sprouting extension inside the collagen gel. Furthermore, we need to investigate the potential pro-angiogenic factors responsible for the observed dependence of sprouting angiogenesis at the bifurcation point on perfusion media condition.

In summary, our MMABP accurately mimics the effect of the hemodynamics created by the impinging flow in a bifurcating vascular network on sprouting angiogenesis in vitro. By utilizing the principles of microfluidics, our designed MMABP provides a fundamental understanding of how blood hemodynamics cooperates with the biochemical microenvironment to regulate bifurcating vascular network expansion and extension.

INTRODUCTION

Locally advanced pancreatic cancer (LAPC) has a devastating prognosis[1]. Treating LAPC is challenging. Looking at the physical makeup of lesions we have discovered that they are hypovascular, have a high interstitial pressure, and have a dense extracellular matrix[2]. While localized intratumoral (IT) injection of liquid Gemcitabine is currently under clinical trial, lesion physical attributes make drug leakage into surrounding tissues likely.

We are developing a new drug delivery platform that involves endoscopic ultrasound (EUS) and injecting a drug-encapsulated hydrogel. EUS fine needle injection (EUS-FNI) is emerging as a promising treatment method to provide direct treatment of tumors via IT injection[3]. We hypothesize that encapsulating the drug in a thermally reversible hydrogel will allow the drug to be injected as a liquid (at room temperature or colder), and then transition to a gel in-situ (at body temperature), creating a drug reservoir for a sustained drug release. The hydrogels mechanical properties will reduce drug leakage, providing extended drug release for weeks, reducing the number of necessary treatments.

This work shares an initial exploration looking at the ability to inject and retain a thermosensitive hydrogel into a controlled mock lesion environment with physical properties simulating pancreatic lesions. Temperature and pressure were controlled. Using distilled liquid water injection for comparison, the hydrogel retention was significantly greater.

METHODS

Before testing the injection and retention qualities of thermosensitive hydrogel, a mock lesion was created (Fig.1). There were three mock cancer lesion parameters fixed: 1) the volume of the mock lesion, 2) the mechanical properties of the mock lesion, and 3) the volume of a cavity or void inside the mock lesion. The volume of the cancer lesion was approximately 15 ml. The mechanical properties of the mock lesion were determined based on 1% Agarose, Type 1A low EEO (FMC, Newark DE). This provides a Young's Modulus, a measure of material elastic quality, of approximately 20 kPa.[4] This value, while less than the Young's Modulus of many pancreatic lesions, provided a reasonable balance between sufficient rigidity and the ability to transmit external pressures into the internal void. A urethane medical balloon (#04001000CA) from Vention Medical (South Plainfield, NJ) enabled cavities of approximately 1ml inside the agarose mock lesion.

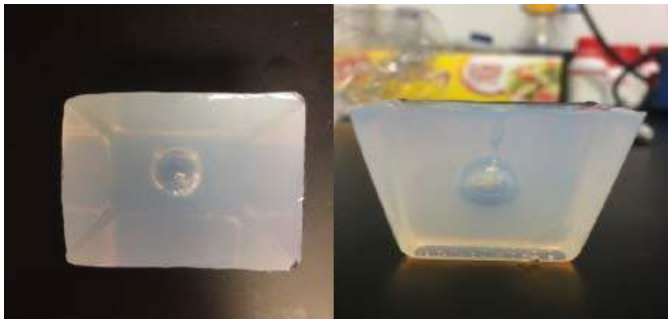

FIGURE 1: Top and side views of the mock cancer lesion showing a 1ml void for hydrogel injection. A void is necessary to allow the hydrogel to enter and solidify inside the mock cancer lesion. Void creation can take place clinically using biopsy needles like the EchoTip ProCore®.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

A schematic of the mock loop is shown in Figure 2. From left to right, a computer and data acquisition system record flow rates, temperatures, and pressures (National Instruments, Austin, TX). Hydrogel is pumped with a syringe pump through a 19 gauge needle (#Z219347, Sigma Aldrich, St. Louis, MO). The agarose gel mock cancer lesion was placed inside a pressurized box with a heated pouch or IV bag to maintain normal body temperature at 37˚C conditions. Internal and external pressures were measured (ColeParmer, Vernon Hills, IL). Building or wall pressure was regulated to the pressurized box.

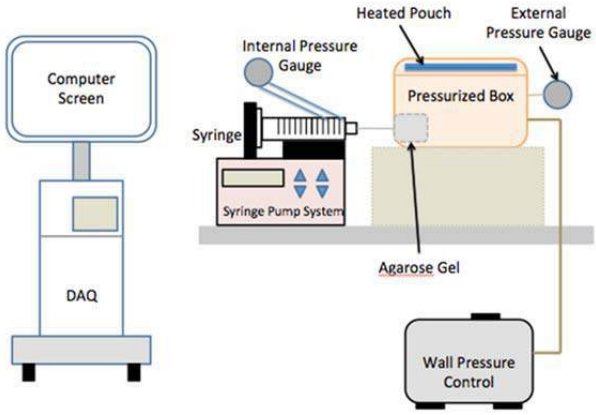

FIGURE 2: Fluid injection and retention testing setup. A syringe pump is used to deliver ~ 1 ml of hydrogel into a mock cancer lesion with void that is both externally pressurized and temperature controlled. External pressure created internal void pressure.

Two injection fluids were tested: (1) distilled water and (2) 30% (w/v) Pluronic F127 (Sigma Aldrich, St Louis, MO). The 30% Pluronic mixture is a hydrogel with a liquid-to-gel transition temperature of 14ºC. Viscosity values transition from <1 Pa-s at 4˚C to 3000 Pa-s at 37˚C. A 5 mL syringe of each test fluid was prepared and stored at 4ºC. Both fluids were pumped at 0.5 ml/min for 2 minutes using a syringe pump (Harvard Apparatus, Holliston, MA). **Two** internal void pressures were explored. Pilot testing showed that an external applied pressure of 100.5 ±1.9 mmHg translated to an internal pressure inside the void of 78.9 ± 3.8 mmHg. After the injection process retention in the void was measured after two minutes. Gravimetric analysis of the syringe and the exterior of the mock cancer void provided the mass delivered to the void, Eqs. (1) and (2).

$$m_{box} = m_{syringe@before} - m_{syringe@after} \quad (1)$$

$$m_{void} = m_{box} - m_{exterior} \quad (2)$$

Test conditions are described in Table 1.

TABLE 1: Test Conditions

Temperature Inside the Pressurized Box	37.5˚C ± 0.5˚C
Pressure Inside the Pressurized Box	0 mmHg or 100 mmHg gauge
Temperature of Test Fluid Inside Syringe	< 10˚C
Pump Setting	0.5 mL/min for 2 min
Each test was conducted 3 times.	

RESULTS

Figure 3 shows the mass of the void retained (Eq.2) for distilled water and 30% (w/v) hydrogel testing at two pressures 0 mmHg and 78.9 ± 3.8 mmHg. In each case a total of approximately 1.0 grams of fluid was injected via the syringe pump. Final gravimetric measurements were taken after 4 minutes (2 minutes injection + 2 minutes post-injection). At the 4 minute mark no significant flow was observed for either fluid.

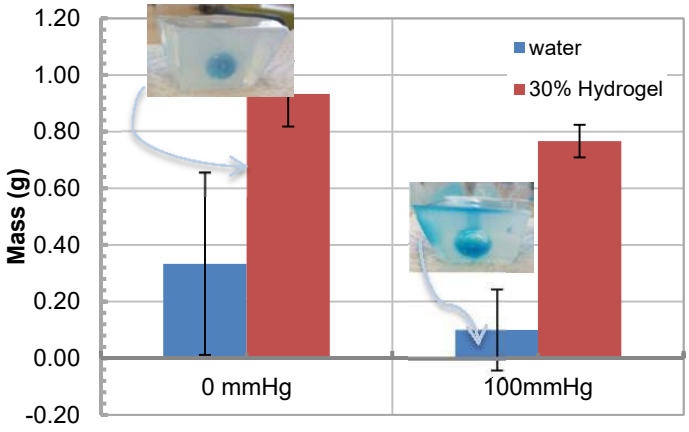

FIGURE 3: Injected mass retention results with photos of each fluid colored with blue dye.

DISCUSSION

Our testing shows that 30% (w/v) hydrogel injection provides superior mass retention over distilled water for a mock cancer void with and without internal void pressure. While elevated internal void pressure reduces retention for both fluids, its impact is significantly less for the hydrogel. With an applied pressure of approximately 80 mmHg we explored the lower range of expected pancreatic lesion interstitial pressure[5,6].

Testing also revealed that the hydrogel transitioned to gel rapidly once inside the mock cancer void. Liquid on the other hand immediately spills out and stops flowing out from the void at approximately 2 minutes.

Future work will focus on higher internal void pressures and different hydrogel concentrations. All of this work will provide insight for future in vivo testing and drug delivery parameters with a KPC mouse model for pancreatic cancer. In particular this work and future work will guide the selection of the optimal void volume and hydrogel concentration, setting the stage for first-in-man clinical testing.

NUMERICAL INVESTIGATION OF CELL MIGRATION

Xiaowei Zeng (1), Liqiang Lin (2)

INTRODUCTION

Cell migration is a fundamental biological process throughout all the stage of animal life, from its commencement to its end[1]. A variety of complex mechanisms, such as embryonic morphogenesis and wound healing, in development, health and disease depend on the cell motion. For instance, in the human immune system, the movement and circulation of white blood cells (leukocytes) on the endothelial layer is highly coordinated with the disease and inflammatory response[2]. To accomplish certain physiological tasks, cell motion must occur in a defined direction. The failure of cells to migrate or migration to inappropriate locations can result in abnormities and diseases, e.g. tumor formation and metastasis. To explain such biological and biophysical phenomenon has been the focus of cell research as well as cell mechanics research. In this study, we will present our latest results on computational modeling and simulation of cell migration. And we have simulated the fluid driven monocyte rolling process in flow channel and studied the collective epithelial cell migration behaviors.

METHODS

In this research, we have built a cell model with internal structures to capture the essential features of cell membrane, cytoskeleton and cell nucleus. We are using soft materials to model the major cell components [3-4].

In the fluid driven monocyte rolling study in flow channel, the forces controlling the cell motion includes the flow shear driven force, the cell-microchannel adhesion force, and the resistant force. The numerical simulations are conducted by using Meshfree methods[5]. A total Lagrangian Meshfree formulation has been developed and a related Galerkin weak formulation has been derived for numerical computation. The main advantage of adopting a meshfree Lagrangian formulation is its ability to avoid remeshing and easy-tracking of cell surface and interface.

In the collective epithelial cell migration study, the forces control the collective cell migration can be modeled as adhesion force between cell and ECM, protrusion force at the cell leading edge due to actin polymerization, the drag force arising from viscous resistance to cell movement, and the cell-cell adhesion force for collective cell migrations:

$$\boldsymbol{f} = \boldsymbol{f}_{adhesion} + \boldsymbol{f}_{protrusion} + \boldsymbol{f}_{resistance} + \boldsymbol{f}_{cell-cell}$$

A cohesive interface zone model has been developed to model the cell-cell interaction and an advanced Finite Element Simulation package has been developed for the numerical simulation.

RESULTS

For the monocyte rolling in flow channel, the rolling process was shown in Figure 1. The position of one node was highlighted by elliptical shape to mark the monocyte rotation. From Figure 1, we can see the monocyte starts to deform upon tethering. The contact area between the monocyte and the substrate surface becomes flat and increases with time (c.f. Figure 1(a)-(c)). Then, the rear bonds of monocyte and substrate break and the monocyte starts to roll over substrate surface (c.f. Figure 1(d)). In the meanwhile, the contact area reduces. Subsequently, the monocyte is tethered again and the cell is firmly adhesive over the substrate (c.f. Figure 1(e)-(f)).

For the collective epithelial cell migration study, we have observed the collective cell migration behavior through cell-cell interactions, the

stress distribution in the epithelial cells during cell migration. The arrow is the velocity and the direction of motion in Figure 2.

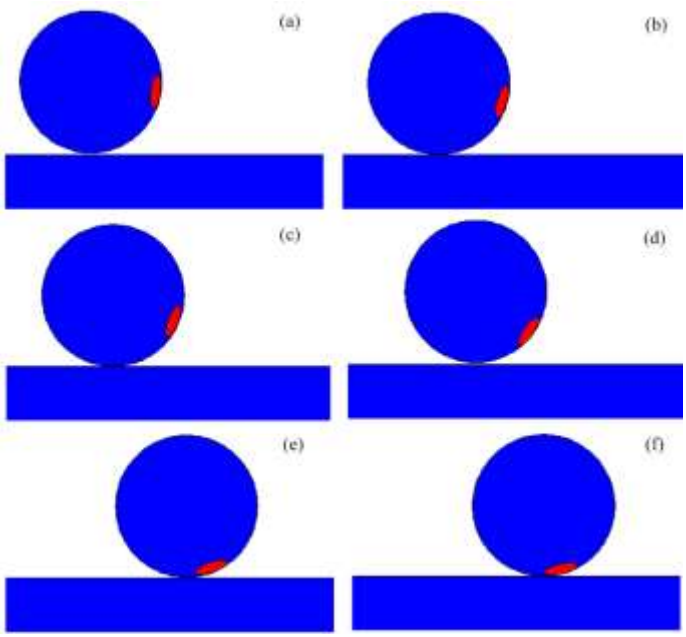

Figure 1: Snapshots of cell rolling process in the fluid channel (the highlighted red point is the mark point to detect the cell rolling behavior)

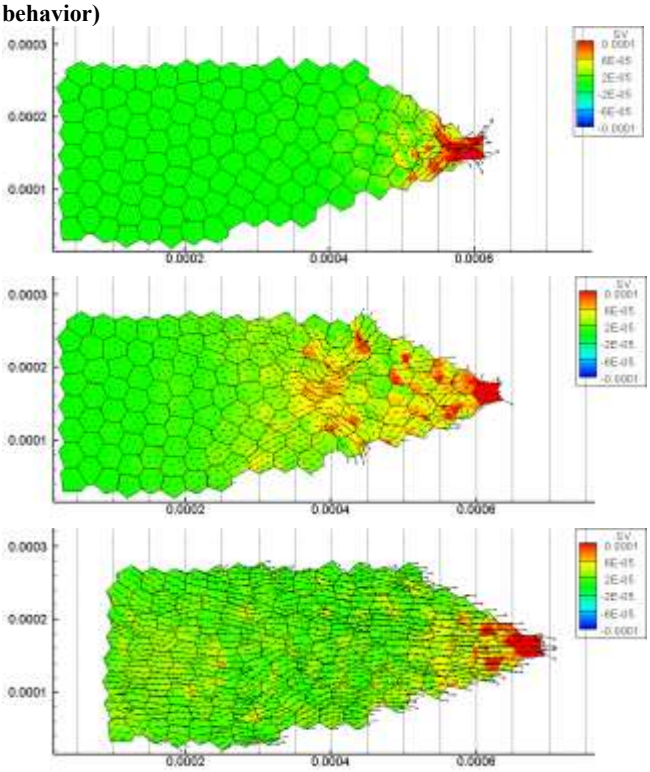

Figure 2: The migration motion of collective epithelial cells

DISCUSSION

Our long-term goal is to develop a generic multiscale numerical simulation tool that may possibly simulate tumor cell migration and invasion in more realistic setting. The current research is the most important step towards that goal by contributing prototype simulation software to set a benchmark on future commercial software of cell modeling and simulations.

BUILDING A BETTER QUARTERBACK: USING BIOMECHANICS TO OPTIMIZE THROWING MECHANICS

INTRODUCTION

A professional football quarterback must learn several techniques for throwing the ball to be successful. All techniques must be mastered to high level of precision and accuracy. The technique employed depends on the route of the receiver. Some throws require high release angle trajectories ("air under the ball"), while others require flat trajectories. Some require high velocity, while others require a low velocity ("touch"). Other variables that are adjusted depending on the play call include shoulder alignment, release point, posture, and stance. Shorter routes require quick releases and more economical arm motion. Longer routes require more torque and lower body contribution to force generation. In addition, lower body concerns include but are not limited to throwing from 1, 3, 5, or 7 step drops (for example), or a designed "roll out" where the throw must be made on the run. None of these concerns addresses the tactical adjustments that must be made to account for defensive pursuit or action to stop the pass from occurring. Even the most basic pass, requires highly technical coordination of body motion. However, relatively little biomechanical analysis has been performed with respect to the optimization of this motion.

Beginning as early as 5 years of age, a child may be coached in a Pop Warner league (for example) on a method to throw a football. As the athlete progresses, he will continue to be coached on a "proper" technique, which will likely be primarily based on qualitative assessment of empirical observations. Though coaches may agree on some general principles, there is no formal consensus on what constitutes "proper" technique. Moreover, there is very little quantitative data to support the development of such a consensus or the acceptance of diversity as a basis to yield to an individual's unique but effective form.

We worked with 6 quarterbacks from age 12 to age 23 and used an 8 camera Vicon motion capture system to study the biomechanics of the throwing motions employed for a simple 10 yard pass from a three step drop. Reflective markers were placed on the subjects at specific anatomical landmarks; the motion capture system tracks these marker positions throughout the throwing motion. Vicon Nexus software was then used to determine marker positions as well as force data from four AMTI force plates and was fed into a full body biomechanical model (Vicon Full-Body Plugin Gait). We worked with local high school coaches to generate a list of "coaching points" which were used to assess the performance. Coaching points of interest included but were not limited to: hip versus shoulder angles throughout the throwing motion, ball release point, and weight distribution throughout the throwing motion.

METHODS

Using an 8 camera Vicon motion capture system (4MP, 120fps, T-Series), and 4 AMTI 6-axis force plates (OR6-6-1000), we acquired throwing data from 6 quarterbacks, ranging from 12 to 23 years in age. Reflective markers were placed on the subjects according to the Vicon Full-Body Plugin Gait model. Subjects were directed to perform a simple 10-yard pass, from a three-step drop.

Local middle school and high school coaches were interviewed to identify "coaching points" that were used to assess quarterback execution. Data was acquired based on the prescribed coaching points and plotted to give a visual interpretation of the throwing performance. All data was analyzed and plots were generated using a custom Python script.

RESULTS

Preliminary results showed fundamental differences in the throwing motion of a trained quarterback (high school athlete) versus an untrained quarterback (middle school athlete). Figures 2 and 3 show the hand trajectory, and forward movement of the body throughout the pass. We found that the trained quarterback had a much higher release point on the pass, and had far less forward body motion while throwing, leading us to conclude that the throwing power was being generated through the rotation of the hips and snapping of the arm, rather than through the forward momentum of the body, as we saw in the untrained quarterback.

Figures 4 and 5 show the hip and shoulder angles of each quarterback throughout the throw. Some differences that we noticed were the smoothness of the motion in the trained quarterback's throw compared to the much choppier motion of the untrained athlete. The untrained quarterback also had a much more abrupt follow through, compared to the gradual slowdown of the motion in the throw of the trained quarterback. The trained quarterback also tended to release the ball at approximately the moment where the hip leading angle had returned to 0. Meaning that the hips and shoulders were approximately square to each other at the point of ball release. The untrained quarterback tended to release the ball much later into the motion, when the hip leading angle had already passed the 0-point.

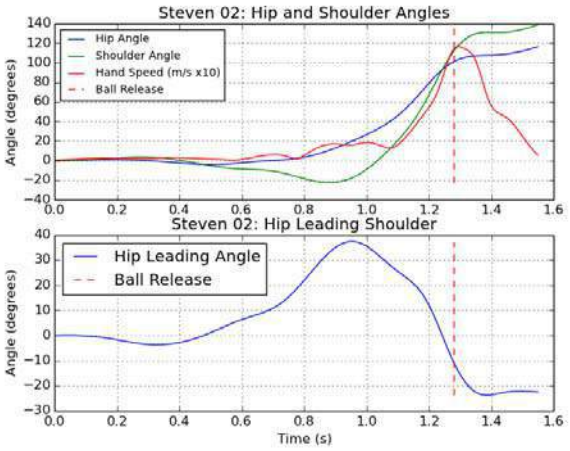

Figure 5: Untrained Quarterback. Plot of hip and shoulder angles, as well as hand speed. Plot of the relative angle between the hips and the shoulder (hip leading angle).

DISCUSSION

With the variation in levels of training and proficiency, we are able to quantify some of the differences between less experienced and more experienced (and more highly coached) players. We identified several trends associated with each group. More highly trained athletes (1) tend to better incorporate their lower body in the throwing motion, leading with the hips to generate torque, (2) tend to turn their hips completely through the throwing process and follow-through, (3) tend to release the ball at the highest point in the throwing motion, and (4) exhibit smoother better coordinated body motion overall.

Future work on this study will be focused on expanding the work to incorporate athletes from a broader range of levels of development, e.g. from Pop Warner through professional level athletes. The research goals are to (1) investigate natural development of athletic performance with age, (2) quantify differences in performance attributable to coaching that is focused on technique development, and (3) identify mechanical principles that contribute to improved performance outcome, (4) acquire throwing data from different types of throws (i.e. 1 step drop, throwing on the run, etc.).

NONLINEAR MULTIFACTORIAL INFLUENCE OF LIGAMENT PROPERTIES ON ROTATORY KNEE STABILITY: NOVEL APPLICATION OF BAYESIAN SENSITIVITY ANALYSIS

INTRODUCTION

The anterior cruciate ligament (ACL) acts together with secondary stabilizers of the knee to resist complex combinations of rotatory loads encountered during challenging athletic activities involving pivoting and cutting. For example, the medial collateral ligament (MCL) and the posterior oblique ligament (POL) work in concert with the ACL to resist combined valgus and internal rotation loads[1]. However, untangling how these structures interact to control knee stability is difficult considering the number of ligaments, the interplay of ligament properties such as slack and stiffness, and the tremendous variability in ligament properties.[2] Knowledge of the unique stabilizing mechanisms of the knee may improve predictability of treatment for ACL injury, which remains suboptimal as indicated by inability to return to sports[3] and revision rates of up to 15%.[4]

Integrating multibody dynamic simulator models of the knee with sensitivity analyses of the model inputs holds promise for quantifying how ligaments interact to provide knee stability. Previous studies have integrated such models with Monte Carlo methods to quantify uncertainties in ligament properties such as slack length and stiffness.[5, 6]. However, these models excluded important knee stabilizers including the menisci. Moreover, relationships between ligament properties and knee kinematics were assessed using linear correlations of a single variable and a single outcome measure[6]. This approach is unable to identify nonlinear relationships between ligament properties and knee kinematics, and interactions between ligament properties.

This study integrated a sensitivity analyses based on a kriging predictor of a multibody knee model that included menisci[7]. This predictor automatically allows nonlinear relationships between ligament properties and knee kinematics, as well as interactions between ligament properties. The research questions were: 1) what ligament properties control anterior-posterior (AP) translation of the medial and lateral compartments in response to rotatory loads; 2) are there interaction between ligament properties that explain variations in the AP compartmental translations; and 3) are any of these relationships nonlinear?

METHODS

A computational model of the tibiofemoral joint of a 20 year-old male cadaver was developed within the multibody dynamics framework (ADAMS) (Fig. 1). The model consisted of subject-specific bone, articular cartilage, and meniscal geometries obtained using computed tomography (CT). Ligament insertions were identified from bony landmarks on the CT scans and visual inspection. The collaterals, cruciates, capsule, and meniscal horns and their coronary attachments were represented with 42 force elements using mean structural properties and a tension-only, nonlinear load-displacement response. Meniscal geometries were discretized radially and a linear stiffness matrix connected neighboring elements to represent a deformable geometry[8]. Rigid body contact was defined between the meniscal geometries and the femoral and tibial cartilage as a non-linear function of penetration depth and velocity.[8]

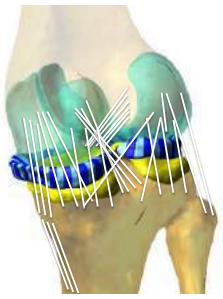

Figure 1: Multibody model of the tibio-femoral joint with 42 ligament fibers and discretized menisci.

Clinical tests of rotatory stability were simulated because of their importance in diagnosing ACL injury and their ability to predict clinical outcome and function based on the magnitude of tibial subluxation[9]. To assess rotatory stability, the femur was rigidly fixed and the tibia was maintained in 15° flexion, leaving it with five degrees of freedom. Multiplanar torques were applied in three phases: 1) 10 N compression; 2) increasing the valgus moment to 8 Nm; and 3) increasing the internal rotation moment to 4 Nm while the axial load and valgus moment remained constant. The coupled AP translations of the medial and lateral compartments of the tibia in each phase of loading were measured to assess knee stability.

The training data for the sensitivity analysis consisted of model simulation runs in which the model inputs consisting of slack length, toe region, and linear stiffness of the ACL, MCL, and POL were varied by at least ±2 standard deviations of their mean values reported in the literature. This range captured the variability observed in these parameters across a population.[2, 10] To fully explore the entire space of ligament properties, the inputs for the runs were selected to form a maximin Latin Hypercube design[7] consisting of 105 total runs of the multibody knee simulator.

The effect of variations in the model inputs (described above) on AP translation of the medial and lateral compartments during the three

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

loading phases were determined by calculating main effect and total effect sensitivity indices (SI) for each input as well as main effect and 2-way interaction plots. The main effect SI for a given input and output is the estimated proportion of the total variation in the outputs (AP translation of the medial and lateral compartments) due to changes in that input. The total effect SI is the sum of estimated proportions of the total variation in AP translation due to changes in the input alone or its interactions with other inputs. Inputs where the total effect SI is greater than the main effect SI tell the researcher that this input interacts with other input variables. The main effect curve is the estimated average AP compartmental translations vs an input when that input is fixed at a given value and the other inputs are varied. Similarly the 2-way interaction plots fix two inputs and average over the remaining ones. The main effect and total effect SIs were calculated using a Bayesian method based on flexible non-parametric kriging predictors[7] as were the main effect and interaction plots.

RESULTS

With an axial load of 10 N, ACL slack was responsible for 98% of the variation in the AP position of the lateral compartment (Table 1). This corresponded to anterior translation of 14 mm over the range of ACL slack (Fig. 2a). Both ACL and POL slack were responsible for a respective 63% and 34% of the variation in the AP position of the medial compartment during this first loading phase. This corresponded to changes of 6 mm anteriorly with increasing ACL slack and 4 mm posteriorly with increasing POL slack (Fig. 2b).

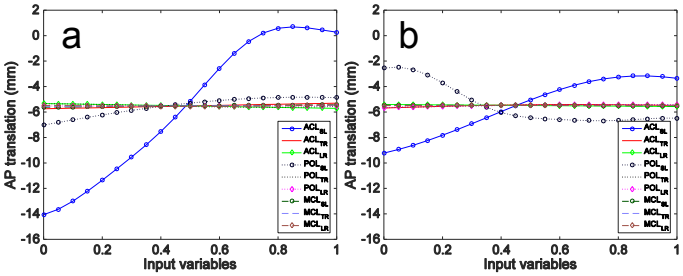

Figure 2: Main effect curves of anterior-posterior (AP) translation of the (a) lateral compartment and (b) medial compartment with 10 N axial load in response to 9 input variables: slack length (SL), toe region (TR), and linear region (LR) of the ACL, MCL, and POL. Anterior translation is indicated by increasing magnitudes.

With an isolated valgus moment, ACL slack was responsible for 56% of the variation in AP translation of the lateral compartment. Differences between main effect and total effect SI's of ACL slack and POL slack were 35% (Table 1). Interactions between ACL slack and POL slack were nonlinear; the most lateral compartment translation occurred with maximum ACL and POL slack (Fig. 3a).

With combined valgus and internal rotation moments, the isolated effect of ACL and POL slack on AP translation of the lateral compartment was small with main effect SIs of 17% and 3%, respectively (Table 1). The differences between main effect and total effect SIs were 72 and 71% for ACL and POL slack, respectively. Interaction between ACL and POL slack was nonlinear with the most lateral compartment translation occurring with maximal ACL slack and minimal POL slack (Fig. 3b).

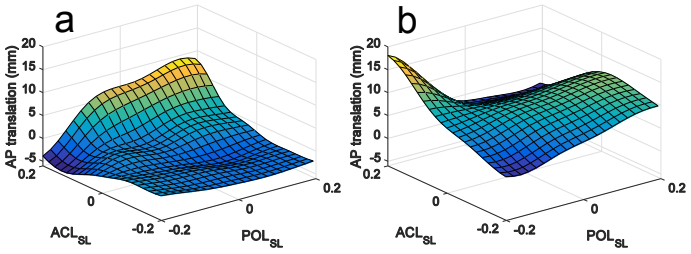

Figure 3: Interaction between ACL slack (SL) and POL slack affect anterior-posterior (AP) translation of the lateral compartment nonlinearly with (a) applied valgus load, and with (b) applied valgus and internal rotation loads. Anterior translation is indicated by increasing magnitudes.

AP translation of the medial compartment in response to the combined moments was influenced by POL slack with a main effect SI of 44% (Table 1). POL slack also interacted with ACL slack and POL linear stiffness to control AP translation of the medial compartment in response to the combined moments indicated by the 20% difference between total and main effect SI's (Table 1). Neither ACL stiffness nor the toe region of any ligament explained more than 11% of the variation in AP compartmental translations.

DISCUSSION

ACL and POL slack exert strong, monotone but nonlinear, influence on AP translation of the medial and lateral compartments. In contrast, ACL and MCL stiffness and the toe region of the ACL, MCL and POL had minimal effect on compartmental translations. ACL slack also exhibits powerful control of the initial AP positon of the lateral compartment and to a lesser extent the medial compartment, while POL slack influences the initial AP position of the medial compartment.

Our findings have important implications for ACL reconstruction because ligament slack can be manipulated at the time of surgery to achieve desired knee behavior. For example the slack in an ACL graft can be adjusted based on the flexion angle at which the graft is fixed. Moreover, the findings suggest that close assessment of the POL is warranted during surgery as knowledge of its mechanical integrity would help more predictably understand the effect of ACL reconstruction. Our findings of the important role of ACL slack in knee kinematics agrees with previous work indicating that setting the slack length of an ACL graft plays a critical role in controlling knee stability[11] and function during gait[10]. The current study has limitations. Namely, the applied loads represent clinical loading scenarios; additional compressive load should be applied to better represent function pivoting events.

In conclusion, Bayesian statistical methods based on flexible non-parametric kriging predictors have the power to identify two-way, highly nonlinear interactions between ligament properties, a fact that is not true of uncertainty analysis based on linear regression. Thus, the described approach is an important tool to identify sources of variability in knee function, and ultimately to develop subject-specific treatment of knee injuries.

POST-OPERATIVE COMPLICATIONS OF COMPUTER ASSISTED TOTAL KNEE ARTHROPLASTY IN OSTEOPOROTIC FEMURS AND TIBIAS: A FINITE ELEMENT STUDY

INTRODUCTION

Total knee arthroplasty (TKA) is commonly used to relieve pain and restore function in severely arthritic and injured knees. Computer assisted surgery is often used to provide better positioning of implants during total knee arthroplasty, with several studies showing reduced component malpositioning, while providing the benefit of reproducibility in determining component size, kinematics, and ligament balancing.[1] However, a recent study determined that computer assisted TKA of osteoporotic knees (with a T-score of -2.5 or less in the femoral neck/lumbar spine) resulted in more valgus position placement of the coronal tibial component (1.2 ± 3.4° valgus) than in non-osteoporotic bones (0.7± 1.8° varus).[2] Malalignment may cause off-axis loading, polyethylene wear, result in implant loosening, and lead to postoperative complications that may require revision surgery.[1, 3, 4] Therefore, when considering an osteoporotic total knee arthroplasty, it is important for the surgeon to determine if the benefits of computer assisted surgery are enough to outweigh the additional cost and duration of surgery time required. The objective of this study is to perform computational analysis on a generic bone model in order to compare the distribution of stresses on a valgus osteoporotic tibia and femur with a properly aligned tibia and femur. The resulting stresses will also be compared to those of corresponding nonosteoporotic bones.

METHODS

A CT scan of a generic femur bone model was converted into a 3D geometry comprised of both cortical and cancellous bone via Mimics Innovation Suite (Materialise, Belgium). The femur was fitted with a modeled total knee arthroplasty implant, and with the help of a surgeon, aligned with a tibia implant of corresponding size (see fig. 1). Both implant and bone mechanical properties were found in literature.[5-7]

The base of the tibia implant was fixed, and a static load of approximately 500N was applied to the top of the femur. A tied contact was applied at the tibial-femoral implant interface. Two scenarios were simulated on both a healthy bone and an osteoporotic bone: (1) proper alignment; (2) 4.6 degree valgus alignment (one standard deviation for computer navigated osteoporotic alignment).[2] The computational analysis was performed using FEBio (University of Utah) to determine effective stresses on the femoral bone. Stress distributions were examined on the lateral and medial condyles, the anterior cortex, and the intercondyloid fossa (see fig. 2).

RESULTS

When a valgus alignment was applied, the peak effectrive stress in the lateral condyle of the osteoporotic femur was 221 MPa, twice as high as the peak effective stresses in the aligned knees at 114 MPa, while the speak stresses in the valgus aligned normal knee were four times as high as the aligned knees at 431 MPa (see fig. 3). Additionally, the anterior cortex of the knee had a peak stress 75.5 MPa higher in the osteoporotic knee and 91.1 MPa higher in the normal knee for the valgus tibia implant compared to their aligned counterparts. Peak effective stresses in the medial condyle and intercondyloid fossa were similar for both the properly aligned and valgus implants at 391 Mpa and 2118 MPa respectively.

The osteoporotic and healthy knees resulted in similar peak stresses for all regions of the distal femur for both tibia implant alignments, with the exception of stresses at the lateral condyle; the rotated normal bone experienced stresses at 430 MPa, while the rotated osteoporotic, aligned osteporotic, and aligned normal experienced stresses at 220, 112, and 116 MPa respectively.

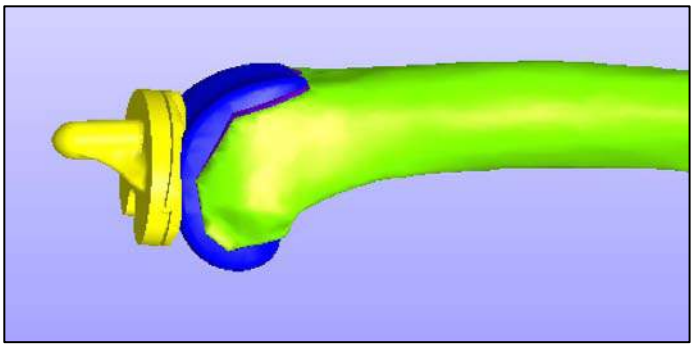

Figure 1: Femur (green) with femoral implant (blue) in alignment with the tibia implant (yellow).

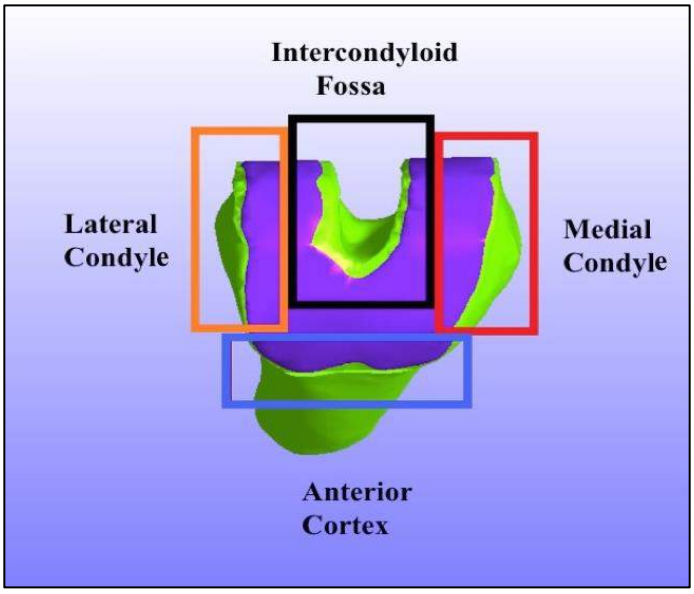

Figure 2: Schematic showing the regions investigated in the computational analysis. Cortical bone is shown in green; cancellous bone is shown in purple.

DISCUSSION

Valgus tibia implant alignment has been shown to result in osteoporotic total knee arthroplasties when computer aided surgery is used.[4] The results of this study indicate that this valgus alignment leads to higher peak stress values in the lateral condyle and anterior cortex of the distal femur. This information may be necessary when considering whether or not to use computer navigated surgery when conducting a total knee arthroplasty in osteoporotic patients, as larger peak stresses may result in polyethylene wear or an increased prominence of femoral fracture. Additionally, similar peak stresses resulted in both osteoporotic and healthy knees, with the exception of the lateral condyle in a valgus alignment. This may be an indication that osteoporosis does have a large impact on the long term success of a total knee arthroplasty.

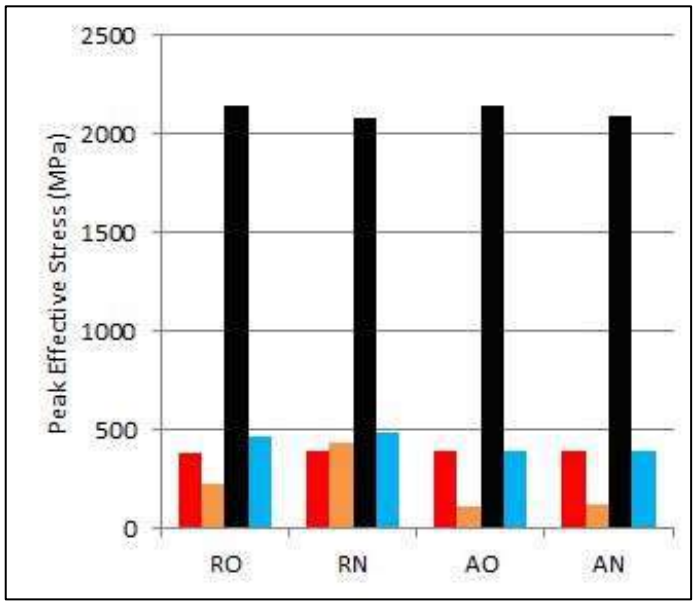

Figure 3: Peak values of effective stress on the medial condyle (red), lateral condyle (orange), intercondyloid fossa (black) and anterior cortex (blue) of the distal femur after a load is applied. Values are shown for when the tibia implant is properly aligned with the femur in a normal (AN) and osteoporotic knee (AO) in addition to when the knee is rotated 4.6 degrees valgus in a normal (RN) and osteoporotic (RO) knee.

INTRODUCTION

Osteolysis due to polyethylene wear debris has been well documented across total joint replacements (TJRs) [1-3]. Retrieval studies examining the surface damage of polymeric bearings have focused on knee and hip components, while comparatively little attention has been given to devices used in the shoulder [4,5]. This work presents an analysis of the mode and geometric extent of surface damage for conventional total shoulder replacement (TSR) and reverse shoulder replacement (RTSR) retrievals. The cohort of retrievals spans more than 20 years of device designs with different bearing fixation types and UHMWPE formulations. A better understanding of the relationship between material behavior and damage mechanics can inform implant designs which better resist *in vivo* damage.

METHODS

Conventional TSR: Twenty-six retrieved glenoid components with different fixation designs and UHMWPE formulations were analyzed. Fixation designs were categorized as either all-polyethylene backed or metal-backed. The UHMWPE glenoids were of Hylamer, conventional (2.5 Mrad gamma-air), and modern cross-linked (2.5-5 Mrad gamma-inert) formulations. Glenoids used in this study were implanted between 1987 and 2011, with an average patient age at implantation of 61 years and an average time *in vivo* of 4.7 years (**Table 1)**. Each glenoid bearing surface was divided into 17 regions of equal area via a grid, and all regions were photographed at 249 dpi using a Nikon 1 J1 camera and an Infinivar Video Microscope lens under an AMScope LED ring light. The presence, severity, and extent of 11 damage modes (**Figure 1)** were noted using Image J (Bethesda, MD, v1.48) image processing software. The 11 damage modes used were based on implant classification methodology described by the Hood technique and further expanded upon by other authors [4,5,6,7,8]. Each implant was scored by at least two observers, and inter-observer agreement was evaluated by calculating the average percent agreement for damage mode identification, geometric extent, and severity.

TABLE 1: SUMMARY OF CLINICAL INFORMATION FOR TWENTY-SIX RETREIVED GLENOIDS

Figure 1: EIGHT OF THE 13 PRIMARY DAMAGE MODES OBSERVED ON UHMWPE GLENOIDS. DELAMINATION, EMBEDDED DEBRIS, RIM EROSION, ADHESION, WEAR THROUGH, SUBSURFACE CRACKING, AND BURNISHING NOT SHOWN.

Reverse TSR: Eighteen retrieved UHMWPE humeral cups were analyzed for mode and geometric extent of surface damage. UHMWPE components were of conventional (2.5-4 Mrad gamma-air) and lightly cross-linked (2.5-4 Mrad gamma-inert) formulations. The humeral cups used in this study were implanted between 2004 and 2014, with an average patient age at implantation of 61 years and an average time *in vivo* of 3.2 years (**Table 2)**. The bearing surfaces of the humeral cups were divided into four regions of equal area, similar to the method reported by Nam [9]. Six observers noted damage modes through visual inspection of each quadrant.

TABLE 2: SUMMARY OF CLINICAL INFORMATION FOR EIGHTEEN RETREIVED HUMERAL CUPS

	RSA Humeral Cups (n=18)		
Clinical Information	**All RSA**	**Gamma Air (n=3)**	**Lightly Cross-Linked (n=15)**
Age at Surgery	61.2 ± 6.1 years	70.0 ± 4.0 years	57.0 ± 7.0 years
In vivo duration	3.2 ± 3.0 years	4.0 ± 3.0 years	3.0 ± 3.0 years

RESULTS

All TSA components demonstrated instances of scratching, striation, pitting, and surface deformation regardless of fixation design and UHMWPE formulation. At least one TSA glenoid for each material formulation and fixation type had fractured (**Table 3**). The group of cross-linked glenoids had the shortest time in vivo and exhibited scratching, striation, pitting, surface deformation, and abrasion in all of the samples, in line with damage modes in components made from non cross-linked UHMWPE formulations. Twelve RSA samples (67%) demonstrated abrasion on the rim of the humeral cup in the inferior quadrant. The most common damage modes in the reverse RSA cohort were scratching and striations, which in occurred in all quadrants on 10 (56%) of the samples.

TABLE 3: SUMMARY OF GLENOID AND HUMERAL CUP DAMAGE MODES

Glenoids and Humeral Cups With Each Damage Mode Present							
Damage Mode	**Poly-Backed Glenoids (n=20)**	**Metal-Backed/ Gamma Air Glenoids (n=6)**	**Hylamer Glenoids (n=8)**	**Moderately Cross-Linked Glenoids (n=3)**	**Lightly Cross-Linked Glenoids (n=8)**	**Gamma Air Humeral Cups (n=3)**	**Lightly Cross-Linked Humeral Cups (n=15)**
Scratching	100%	100%	100%	100%	100%	67%	67%
Striations	100%	100%	100%	100%	100%	33%	73%
Pitting	100%	100%	100%	100%	100%	66%	53%
Surface Deformation	100%	100%	100%	100%	100%	33%	47%
Abrasion	72%	100%	74%	89%	65%	100%	13%
Delamination	61%	75%	88%	61%	35%	100%	33%
Embedded Debris	23%	67%	26%	17%	25%	66%	7%
Fracture	52%	83%	83%	33%	33%	0%	7%

DISCUSSION

To the authors' knowledge, this is the only study that assesses the presence of damage modes on shoulder components for both conventional and reverse designs across fixations types and UHMWPE compositions. The reduction in fatigue crack growth resistance for cross-linked UHMWPE may have contributed to the early incidence of significant fracture observed in one of the cross-linked glenoids (less than three years in vivo). Some lightly cross-linked glenoids, exhibited fracture but at a much smaller degree and at shorter in vivo times (1.8 years). The observed damage on these implants is likely associated with some degree of oxidative embrittlement as there was no work up of the material post gamma-inert sterilization. Damage (including fracture) on the re-melted implants indicate that surface damage is not solely attributable to oxidative embrittlement and that cross-linked implants in general are showing damage modes at short in vivo times.

The high frequency and severity of inferior rim damage observed in the RSA cohort likely indicates a high prevalence of scapular notching; a finding in line with other investigations [10]. Damage modes including scratching, striations, pitting, and surface deformation are present on implants with short in vivo durations, suggesting that damage can occur shortly after implantation. While the clinical relevance remains uncertain, changes in shoulder component design and UHMWPE formulation (including modern RSA designs and cross-linked UHMWPE) have not prevented against certain damage modes in shoulder arthroplasty.

EFFECT OF STENT OVERSIZING ON IN-STENT RESTENOSIS IN THE SECOND PART OF THE POPLITEAL ARTERY

INTRODUCTION

Stents are commonly used by vascular surgeons to reduce atherosclerotic lesions and restore the blood flow within the stenosed blood vessels. All stents are frequently being deployed to the diameter greater than that of the native vessel to securely anchor the device against the arterial wall [1]. Due to variations in target vessel wall, different stent-to-artery ratios are being considered for implantation. However, it has been found that 20% of the patients having undergone the stent surgeries annually develop restenosis due to intimal thickening within 6 month after the operation. Studies show that the geometric differences caused by stent over-expansion can be one of the causative factors leading to this problem, further limiting the effectiveness of stent [2]. Our previous study [3] highlighted the effect of various stent-to-artery expansion ratios ranging from 1:1 up to 2:1 on the vascular damage and the underlying mechanism involved in this phenomenon. In this study, the combined Computational Fluid Dynamics (CFD) and clinical evidence were used to examine the hypothesis that correlates the alteration of local hemodynamics with in-stent restenosis in the oversized stented artery. The likelihood of restenosis was assessed by using wall shear stress (WSS) and wall shear stress gradient (WSSG) as a determinant within the second part of the popliteal artery stented to the expansion ratio of 2. The results of this study give insight into the understanding of the mechanisms that may contribute to in-stent restenosis when over-expanded, and can provide a guideline for vascular surgeons to find a technique for reducing or avoiding such post-stenting vascular damages.

METHODS

The geometry of an idealized oversized model with rigid walls [4] was reproduced in SolidWorks base on the dimensions obtained from the patient specific angiogram. The model is a second part of the popliteal artery with 2.8-3.2mm in diameter and the flow rate of 480 ml/min. The stent struts was excluded from the geometry of the patient angiogram as the primary sites of stenosis occurred around stent struts are shown to be independent of expansion ratio and the degrees of oversizing seemed to outweigh the small flow disturbances produced by stent struts [3]. The mesh independence study was performed according to our previous study [5] using fully structured hexahedral elements.

For CFD calculations, blood density was prescribed as 1060 kg/m^3 and dynamic viscosity of 0.0035 Pa.s. All simulations were carried out for steady flow conditions at a Reynolds number of 970 calculated based on the inlet velocity and diameter. Zero pressure boundary condition was set at the downstream outlet while velocity inlet was used as an inlet condition. Blood was defined as an incompressible, homogenous and Newtonian fluid [6]. Residual reduction to 10^{-6} of the primary value was set as a convergence criterion. ANSYS Fluent 14.5 (Fluent Inc., Lebanon, NH) was used to solve the Reynolds Averaged Navier-Stokes equations while k-ω SST turbulence model was employed to capture the flow properties.

The threshold for comparing the distribution of low WSS was defined at 0.5 Pa as the values slightly less than this value is known to affect the shape and alignment of the endothelial cells that causes excessive Neointimal Hyperplasia (NH) [7]. In contrast, endothelial cells that perform as a barrier to NH progression are shown to be pushed away from high WSSG regions of above 5000 Pa/m [8].

RESULTS

The effect of WSS on the formation of in-stent restenosis is shown in Figure 1. Regions of low WSS (<0.5 Pa) localized at the proximal segment of the oversized artery as well as within the oversized part of the artery (indicated in dark blue) is clearly visible in this Figure.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

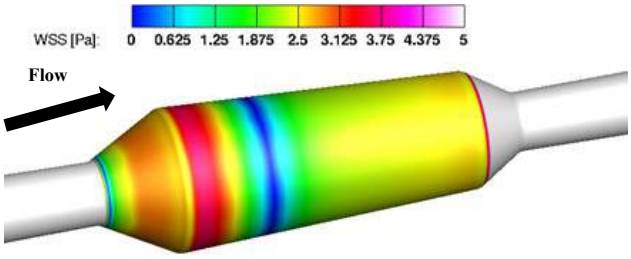

Figure 1: WSS distribution along the oversized artery

It has been widely known that the injury due to the localization of low and high WSS is highly dependent on the local hemodynamics particularly the near-wall condition. The velocity pattern within the artery is depicted in Figure 2 for clarification. As shown, some breakups are found at the proximal segment of the oversized artery that pushes the near-wall stagnation point from the proximal part to further downstream along the artery, resulting in the lower near-wall velocity at where the low WSS (<0.5 Pa) values were obtained previously in Figure 1.

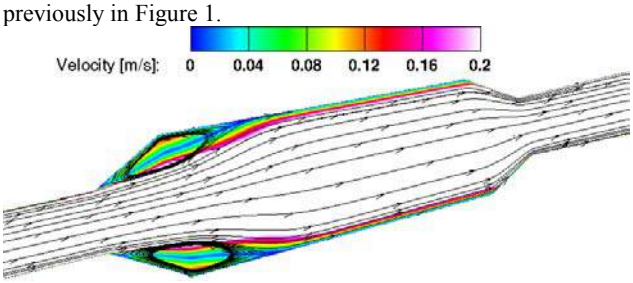

Figure 2: Velocity contour projected on the mid-longitudinal plane

Regions of elevated WSSG (>5000 Pa/m), the relevant parameter responsible for the biological response of arteries to the over-expansion, are recognizable at both proximal and distal parts of the oversized area.

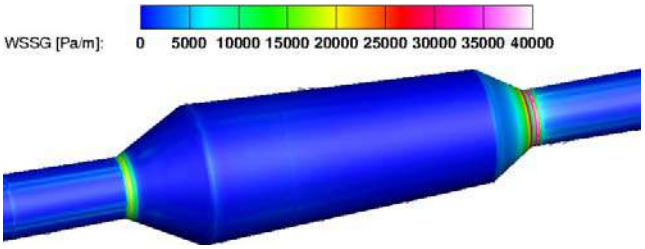

Figure 1: WSS gradient distribution along the oversized artery

The angiographic luminal change due to in-stent restenosis in the second part of the oversized popliteal artery is shown in Figure 3. As expected, stenosis is more pronounced at the inlet and outlet of oversized segment, as well as within the oversized part proximally to the inlet (white arrows).

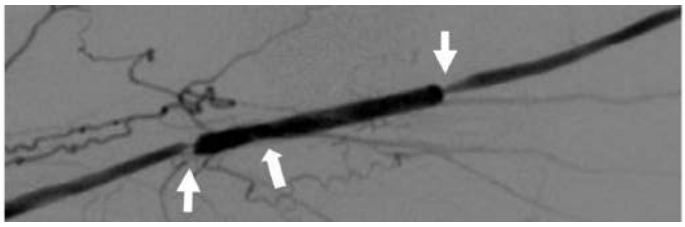

Figure 3: Angiographic image acquired after implementing oversized stent with deployment ratio of 2

DISCUSSION

Our previous study [3] showed that increasing the expansion ratio has an adverse hemodynamic effect, resulting in the exposure of larger areas of arterial surface to the distribution of low WSS which is known to correlate with the development of in-stent restenosis. It has also been demonstrated that there is an increased risk of vascular injury and thrombotic events at the stent-artery transition region [9] due to the localization of high WSS values. Consistent with the previous work [3], small area of low WSS is found in this study at the inlet of the oversized section due to the near-wall stagnation point. The recirculating vortices formed at the over-expanded area pushed this low velocity from the inlet of the oversized segment to the near-wall at where the low WSS region is obtained within the artery. However, the extent and level of these low WSS areas is not similar to the previous work model, most probably due to the considerable change in the geometrical configuration.

The present CFD results on the location of restenosis exposed to the low WSS values is shown to be in a great agreement with the clinical data, confirming the high vulnerability of low WSS regions to the NH and restenosis.

Although many theories have been used high WSS or high WSSG as an indicator of NH and restenosis, the exact mechanism of NH prone to these regions remains uncertain as both mechanical and biological factors are involved in this phenomenon [10, 11]. The present findings well demonstrated the consequence of oversizing while supporting the hypothesis that the location of restenosis is not limited to the to the low WSS regions. In addition, the high WSSG values are shown to be responsible for the formation and progression of NH (Figure 2) as restenosis has also been found at these locations in the current clinical study (Figure 3).

.Comparing the CFD and clinical data, the extent to which the low WSS and the elevated WSSG regions can contribute to restenosis and their significance is not yet clear. However, in this study, the regions exposed to elevated WSSG are found to be more critical as they are localized at the inlet and outlet of the oversized segment which can result in the complete occlusion of the artery if not treated.

The results also revealed that the constraint of rigid wall did not have a considerable effect on the prediction of restenosis in this case of study as the CFD results match well with the clinical study. The rigid wall can be a reasonable assumption as the elasticity of the arterial wall reduces and the artery stiffens due to the further development and accumulation of plaque built ups.

DETERMINING IMPEDANCE IN PULMONARY VESSELS USING FOUR-ELEMENT WINDKESSEL MODELS

Julie C. Wagner (1), Jesse W. Gerringer (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering
University of Illinois at Chicago (UIC)
Chicago, IL, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is characterized by an increase in blood pressure and remodeling of the pulmonary vasculature, modifying the pulmonary hemodynamics. PAH is difficult to diagnose in a routine medical exam and is often hard to determine the location to target. In addition, it is an aggressive disease: within the first year of diagnosis, patients have a 68% chance of survival, which drops to 34% after five years, with the only known cure being a heart-lung transplant (Wexner Medical Center, Ohio State University).

Impedance takes into account the resistive and compliant properties of the vasculature, which can then be used to characterize physical properties of pulmonary arteries and can help elucidate where in the vasculature the disease is affecting. Previous studies used Windkessel models to study pressure-flow relationships by evaluating impedance [1]. The four-element Windkessl model utilizes an inertial term (*L*), the total resistance (*Rd*), characteristic impedance (*R*), and compliance (*C*), to fit hemodynamic data. Through a minimization algorithm, pressure can be predicted and a set of parameters describing vascular changes in the disease can be obtained [1]. In this study we will describe the effects of PAH in normotensive (placebo – PL) and monocrotaline (MCT) treated rats using three versions of the four-element Windkessel model.

METHODS

Pulmonary arterial (PA) pressure and flow data were collected during open chest surgery on PL and MCT rats. Each week (up to four) related to a different stage of PAH, the 4th week being the acute stage. Pressure measurements were collected using a pressure catheter inserted through the right ventricle. In order to obtain simultaneous flow data, a flow probe was placed around the main PA. These data were analyzed using three variations of the four-element Windkessel models: series, parallel, and viscoelastic (Figure 1).

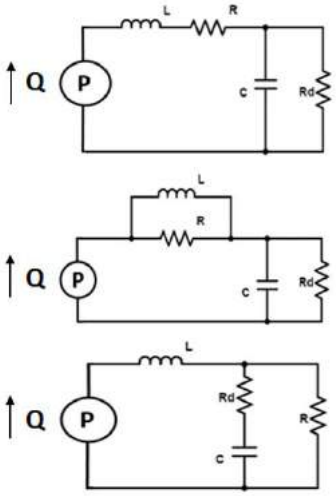

Figure 1: Four-element Windkessel models with resistors *R* and *Rd*, capacitor *C*, and inductance *L*. Inductance is (A) in series (B) in parallel (C) and the viscoelastic model.

For each Windkessel model, the pressure is analogous to voltage and the flow to electronic current in an electrical circuit. Each model can be represented based on the parameter combinations in relation to pressure and flow according to the positioning of the inductor as seen in Equation (1-3) for the series, parallel, and viscoelastic models respectively. For each model, blood flow (*Q*) is used as an input to predict PA pressure (PAP). Each parameter, *R*, *Rd*, *C*, and *L*, is

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

optimized using a Nedler-Mead simplex algorithm in Matlab, which minimizes the difference between measured and computed values.

$$\frac{dP}{dt} + \left(\frac{1}{R_d C}\right) P = L\frac{d^2Q}{dt^2} + \left(R + \frac{L}{R_d C}\right)\frac{dQ}{dt} - \left(\frac{1}{C} + \frac{R}{R_d C}\right) Q \quad (1)$$

$$\frac{d^2P}{dt^2} + \left(\frac{1}{R_d C} + \frac{R}{L}\right)\frac{dP}{dt} + \left(\frac{R}{R_d CL}\right) P = R\frac{d^2Q}{dt^2} + \left(\frac{R}{R_d C} + \frac{1}{C}\right)\frac{dQ}{dt} - \left(\frac{R}{CL}\right) Q \quad (2)$$

$$\frac{dP}{dt} + \left(\frac{R}{R_d C(R + R_d)} + \frac{1}{R_d C}\right) P = L\frac{d^2Q}{dt^2} + \left(\frac{RR_d}{R+R_d} + \frac{RL}{R_d C(R+R_d)} - \frac{L}{R_d C}\right)\frac{dQ}{dt} - \left(\frac{R}{C(R+R_d)}\right) Q \quad (3)$$

The optimization routine for the resistance parameters (R, R_d) is initiated with the ratios of the amplitude of PAP and Q that were determined via Fourier analysis in the frequency domain. The overall vascular resistance (Z_o) is the impedance at the 0th order harmonic and is the R_d in the four-element Windkessel models. The characteristic impedance, or the average of the higher order harmonics R, is a parameter representing the contribution of the proximal vessels. For our case, we chose the harmonics from the 6th – 10th order to determine initial value of R. The capacitance C and inductance L parameters were chosen arbitrarily. Goodness of fit of the predicted pressure is computed via the residual mean squared error (RMSE). ANOVA test is used to determine if the models are statistically different one from each other. The comparison is done for PL and MCT during week 1 and week 4 where $p<0.05$ is considered to be significant.

RESULTS

In the impedance spectrum, (Figure 2) computed for up to the 10th harmonic, the MCT-treated animals at week 4 have a higher overall vascular resistance (close to 1.2 mmHg/ml/min) as compared to the same aged normotensive animals (0.5 mmHg/ml/min). The characteristic impedance however, displays no apparent difference.

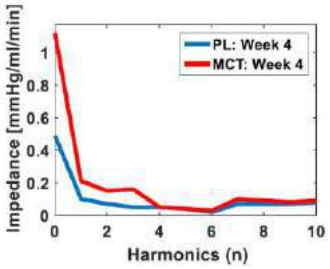

Figure 2: Impedance spectrum for up to the 10th order harmonic.

The time-series of the computed and measured pressure are compared for the PL and MCT data (Figure 3). Each row shows the prediction of pressure using a different model (from top to bottom: series, parallel, and viscoelastic). The data from the placebo animal is qualitatively best fitted by the parallel model (RSME = 1.13 mmHg). In the MCT-treated data, however, the series model provides the best fit (RSME = 1.51 mmHg). All the parameters were initialized with the same initial guess, but their optimal values differ according to the model used (Table 1). The *p*-values reveal that there is at least one model different from the other two. Based on the computed fit (Figure 3) and optimized parameters (Table 1) the viscoelastic model differs the most from the series and parallel models.

DISCUSSION

The positioning of the inductor in the Windkessel model has a major effect when used to predict pressure. Studies done by Burattini *et al.* have used these models in various applications with notable success [1-2]. They were able to optimize the parameters and fit the pressure data in humans, ferrets, and dogs including the dicrotic notch [1-2]. Another study by Segers *et al.* used just the parallel model to fit mice aortic data [3]. Even though our parallel model fits the PL pressure and the series model fits the MCT pressure very well, the models are unable to mimic the dicrotic notch in the pressure waveform with high accuracy. Therefore, there is substantial work to be done with these models. We need to further explore the optimization algorithms and to refine our fitting. With a larger cohort of animals we will also be able to determine a confidence interval for the model parameters to better represent this population.

INTRODUCTION

Collagen hydrogels are a biphasic material system composed of a collagen fiber matrix and varying amounts of water (97-99%). Collagen, the most abundant structural extracellular matrix (ECM) constituent in the body, provides a biologically compatible platform for cellular attachment, proliferation, and remodeling. These hydrogels are generally weak but can be modified mechanically through methods such as ultraviolet (UV) exposure and chemical cross-linkers. Collagen hydrogels are routinely polymerized via pH neutralization and can easily be cast in molds enabling a wide-assortment of shapes and sizes. Numerous applications exist for these materials within the biomedical engineering field.

Although collagen hydrogels have been used extensively as cellular test beds over the years, contemporary research lacks specific information linking cellular behavior and the mechanical environment within a collagen hydrogel. Certain cell types are 'programmed' to actively maintain an unknown yet quantifiable homeostatic stress state, most notably vascular smooth muscle cells and fibroblasts. This phenomenon is observed experimentally when these cell types are incorporated within, or on the surface of, collagen hydrogels and cultured (e.g. cell contraction assays). The cells attempt to achieve a favorable mechanical environment through contraction and compression of the collagen hydrogel scaffold. During this period, cells rearrange collagen fibers and apply traction forces to the hydrogel to regain their specific homeostatic stress state. It has become increasingly clear that the local mechanical environment, defined by stresses and strains, provide cellular cues that are key for maintaining optimal functionality via mechano-sensitive cellular pathways. Therefore, relating continuum mechanics-based descriptors of the local mechanical environment to cellular behavior can reveal crucial information about cell-collagen hydrogel interactions.

The mechanics of collagen hydrogels are commonly characterized through rheology and tensile/compression testing, often with the assumption that the response is linearly elastic. Evidence suggests that these hydrogels are actually highly compressible and nonlinearly elastic. For instance, in the presence of surface or embedded mammalian cells, hydrogels undergo dramatic compression and distortion of the matrix [1]. Thus, to encompass these features into a mechanical model, we apply a (hyper)elastic compressible material strain-energy function developed by Blatz and Ko in 1962 to a series of collagen hydrogels with different mechanical characteristics [2].

METHODS

Theoretical Framework

The Blatz-Ko strain energy function for homogeneous isotropic elastic materials [3] is given as $W = W\left(I_C, II_C, III_C\right)$ with the principal invariants of the right Cauchy-Green strain tensor defined as

$$I_C = tr(\boldsymbol{C}),\ II_C = (tr\boldsymbol{C})^2 - tr\boldsymbol{C}^2,\ III_C = \det(\boldsymbol{C}). \qquad (1)$$

The generalized strain energy function is thus

$$W = \frac{\mu\alpha}{2}\left(I_C - 1 - \nu^{-1} + \left(1-2\nu\right) III_C^{-\frac{\nu}{1-2\nu}}\nu^{-1}\right) + \frac{\mu\left(1-\alpha\right)}{2}\left(\frac{II_C}{III_C} - 1 - \nu^{-1} + \left(1-2\nu\right) III_C^{\frac{\nu}{1-2\nu}}\nu^{-1}\right), \qquad (2)$$

The three material parameters are: $\mu > 0$ the shear modulus, $0 \le \alpha < 1$ the void fraction, and $0 < \nu < 0.5$ the Poisson's ratio.

Material particles originally at (R, Θ, Z) in an unloaded reference

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

configuration are mapped to (r,θ,z) in a finitely extended axisymmetric configuration according to (Figure 1):

$$r = \lambda R\,,\ \theta = \Theta\,,\ z = \Lambda Z\,. \quad (3)$$

The deformation gradient is

$$\mathbf{F} = \begin{bmatrix} \lambda & 0 & 0 \\ 0 & \lambda & 0 \\ 0 & 0 & \Lambda \end{bmatrix}, \quad (4)$$

and the right Cauchy-Green strain tensor is $\mathbf{C} = \mathbf{F}^T\mathbf{F}$. The Cauchy stress tensor is defined

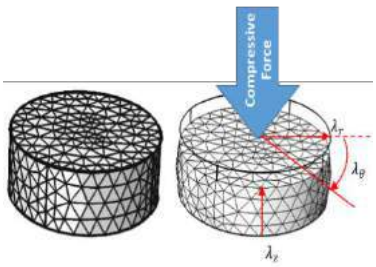

Figure 1: Experimental layout of collagen disc compression

$$\boldsymbol{\sigma} = \frac{2\mathbf{F}\left(\partial W/\partial \mathbf{C}\right)\mathbf{F}^T}{\det \mathbf{F}}, \quad (5)$$

where, by using the chain rule [4], we have

$$\frac{\partial W}{\partial \boldsymbol{C}} = \frac{\partial W}{\partial I_C}\frac{\partial I_C}{\partial \boldsymbol{C}} + \frac{\partial W}{\partial II_C}\frac{\partial II_C}{\partial \boldsymbol{C}} + \frac{\partial W}{\partial III_C}\frac{\partial III_C}{\partial \boldsymbol{C}} \quad (6)$$

and by definition $\partial I_C/\partial \boldsymbol{C} = \boldsymbol{I}$, $\partial II_C/\partial \boldsymbol{C} = I_C\boldsymbol{I} - \boldsymbol{C}^T$, and $\partial III_C/\partial \boldsymbol{C} = III_C\boldsymbol{C}^{-T}$. Using simple uniaxial compression while measuring active changes in cross-sectional area we let $\lambda = \Lambda^{-\nu}$ (per the ad hoc assumption of [2]). Evaluating the remaining derivatives of (6) yields an expression for σ_z

$$\sigma_z = 0.5\lambda_z\mu\left(\Lambda^{2\nu}\alpha - 2\Lambda^{4\nu-2} + 2\Lambda^{4\nu-2}\alpha - \Lambda^{2\nu-2}\alpha\left(\Lambda^{-4\nu+2}\right)^{\frac{\nu}{2\nu-1}} - 2\Lambda^{2\nu-4} + \Lambda^{2\nu-2}\left(\Lambda^{-4\nu+2}\right)^{\frac{\nu}{2\nu-1}} + 2\Lambda^{2\nu-4}\alpha - \Lambda^{2\nu-2}\alpha\left(\Lambda^{-4\nu+2}\right)^{-\frac{\nu}{2\nu-1}}\right). \quad (7)$$

Collagen Isolation and Preparation

Type I collagen was isolated from bovine corium through mechanical separation of the dermis and epidermis. Hair follicles and non-collagenous proteins were removed with a $Ca(OH)_2$ and NaHS solution. The remaining collagen proteins were enzymatically treated with pepsin and grinded with ice to form a collagen gel. The resultant gel was forced through a mesh filter in order to remove large undigested pieces of dermis. The gel was then diluted with acetic acid and collagen proteins were salted out with the addition of NaCl. Collagen was collected via centrifugation and dialyzed against dH_2O. The resultant gel pH was adjusted to 5.5 and desired concentrations (2-3%) were obtained via dilution or centrifugation

A 3D printed mold was designed in order to fabricate dimensionally uniform (d = 10 [mm], h = 3.5 [mm]) discs. Non-polymerized collagen hydrogel was loaded into the mold and subsequently polymerized via pH neutralization using a HEPES buffer (pH = 7.4). Collagen hydrogel discs were then either exposed to a series of UV cross-linking energies or t reated with a 4 nM matrix metalloproteinase-2 (MMP-2) solution for 1 hour at body temperature.

Collagen hydrogel discs were compressed using a MARK-10 mechanical testing device at a s train rate of 10 [mm/min]. Displacements were recorded using video calipers. Cauchy stress was then calculated from

$$\sigma_z^{\exp} = f/A \quad (8)$$

where f is the force and A deformed cross sectional area.

RESULTS

Unconfined uniaxial compression of collagen hydrogels was used to generate experimental stress-strain curves as shown in Figure 2.

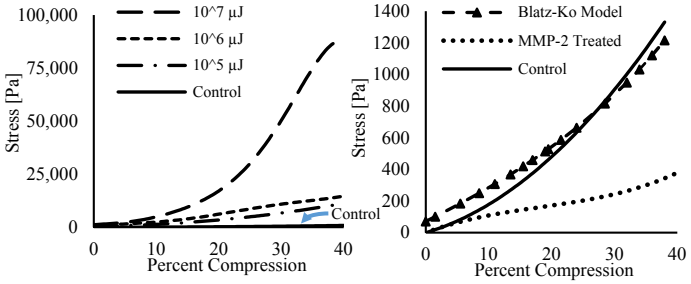

Figure 2: Representative compressive stress-strain results using 3% collagen hydrogels (left) when exposed to UV radiation (n=3) and (right) when incubated with a 4 nM MMP-2 solution (n=3). Piola-Kirchhoff (engineering) stress is shown.

Parameter fitting was performed for the control discs by minimizing the error between the modeled (7) and measured (8) stresses. Note that the value of the void fraction α was determined from the % aqueous solution in the hydrogel while Poisson's ratio ν was found as an average at any discrete measurement. With these two parameters, and the known stress-strain relationship, the shear modulus μ was found.

Table 1: Blatz-Ko Material Parameters for Collagen Hydrogel

	μ (Pa)	α (..)	ν (..)	error
Control	1,588	0.97	0.170	0.139

DISCUSSION

Collagen hydrogels have the capability of being mechanically tuned to improve or decrease mechanical properties depending on the desired outcome. Exposure to UV energy results in a marked increase in mechanical stiffness. UV exposure provides energy for cross-link formation between collagen fibrils within the hydrogel and thus improved mechanical stability (Figure 2). In contrast collagen hydrogels incubated with MMP-2 show a marked decrease in material stiffness (Figure 2). MMP-2 is a w ell characterized gelatinase enzyme responsible for ECM remodeling through collagen degradation. MMP incubation not only serves as a method for a ltering collagen hydrogel mechanical properties but further highlights the effects of upregulation of MMP-2 in certain disease states, especially in aneurysms, where protein integrity is compromised. This also reinforces the potential for collagen hydrogels to be used as an *in vitro* model to investigate the effects of weakened collagen structures on c ellular activities or to simulate proteases common in the inflammatory response.

A Blatz-Ko constitutive model is presented and an initial set of material parameters determined. These parameters can be used to estimate cell traction forces based upon measurable strains or applied to finite element analysis to determine the behavior of complex but biologically relevant collagen hydrogel geometries.

INTRODUCTION

Bone is a highly hierarchical material with different structural features over several length scales ranging from macro to the ultrastructure length scales. Bone toughness is understood to originate at the ultrastructural level where the primary architectural feature is one resembling a hybrid nano-composite of an organic matrix comprised mainly of type-I collagen and mineral crystals intertwined with non-collagenous proteins in the presence of water. Understanding the fundamental features of bone at the ultrastructure and their contributions to the bulk behavior is imperative in the explanation of the mechanistic origins of bone fragility in conditions where the ultrastructural features as altered such as disease, age etc.

Bone minerals are also highly textured most likely due to the functional adaptations of the bone tissue under load as the mineral crystals are the primary load bearing components at the ultrastructure. Texture contributes to anisotropy in polycrystalline materials. Another interesting feature of the ultrastructure is that the mineral crystals can be distinctive based on their spatial location in the matrix. Minerals occurring inside collagen fibrils have been reported as staggered plate-like structures and highly oriented whereas the minerals occurring outside the fibrils have been reported to possess very limited spatial correlation. It is unclear how the minerals occurring in distinct locations in bone influence the bulk level deformation based on their differences in orientation distribution.

The ultrastructural stress states in bone minerals and collagen may not be representative of the bulk stress state of bone. Mineral crystals are inherently anisotropic and the contribution of each crystal to the bulk deformation is orientation dependent. The intrafibrillar and extrafibrillar differences exacerbate the difficulty in explaining the mechanistic origins of bone toughness at the ultrastructure level.

The aforementioned complexity of bone architecture makes a detailed experimental characterization a challenging task. So far, the work in this field has been limited to computational modeling based approaches or to experimental characterization using highly simplified strain gauge rosette models. Such models fail to capture the anisotropy and micromechanical differences in the intrafibrillar and extrafibrillar deformations. In this study we propose a detailed stress-strain characterization in bone using high energy x-ray diffraction measurements of mechanically loaded bone specimens along with optimization based texture analysis and strain characterization techniques.

The proposed method would enable us to obtain the following information;

- Detailed stress-strain characterization of bone and an understanding of the orientation dependent micromechanical stress states of the ultrastructure constituents and their contribution to the bulk deformation.
- A means to differentiate the micromechanical stress states of minerals which have possibly distinct orientation distributions such as the intrafibrillar and extrafibrillar minerals
- The evolution of micromechanical stress states in response to bulk deformation characteristics such as elastic deformation and post-yield plastic deformation.
- A detailed investigation of ultrastructural changes in bone owing to conditions such as disease, age and hydration status and their effect on the micromechanical stress states and their contribution to the overall bulk deformation.

Thus, this study aims at providing a tool for experimentally characterizing the orientation and location dependent ultrastructural

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

deformation of bone mineral crystals and collagen fibrils. This tool can be exploited to provide insights into the ultrastructural origins of bone toughness and the role of the ultrastructure in bone fragility under different conditions such as disease, age and hydration status.

METHODS

Cylindrical compressive specimens (Φ3.0x5.0mm) were harvested from the mid-diaphysis of male human cadaveric femurs. A monochromatic high-energy X-ray beam was irradiated to the center of the specimen WAXS (Wide Angle X-ray Scatter) patterns were recorded sequentially for every steps of the progressive loading scheme.

Strain Characterization: aggregate mineral strain using Dolle-Hauk method.

$$\varepsilon_{\phi\psi} = \frac{d_{\phi\psi} - d_0}{d_0} = \varepsilon_{11}\cos^2\phi\sin^2\psi + \varepsilon_{22}\sin^2\phi\sin^2\psi + \varepsilon_{33}\cos^2\psi \quad (1)$$
$$+ \varepsilon_{12}\sin 2\psi\sin^2\psi + \varepsilon_{13}\cos\phi\sin^2\psi + \varepsilon_{23}\sin\phi\sin 2\psi$$

Assuming ε_{13} and ε_{23} terms are zero the above equation becomes linear for a fixed ϕ

$$\varepsilon_{\phi\psi} = \frac{d_{\phi\psi} - d_0}{d_0} = \sin^2\psi[\varepsilon_{11}\cos^2\phi + \varepsilon_{22}\sin^2\phi + \varepsilon_{12}\sin 2\phi - \varepsilon_{33}] \quad (2)$$
$$+ \varepsilon_{33}$$

Non-linearity represent anisotropy in the aggregate deformation.

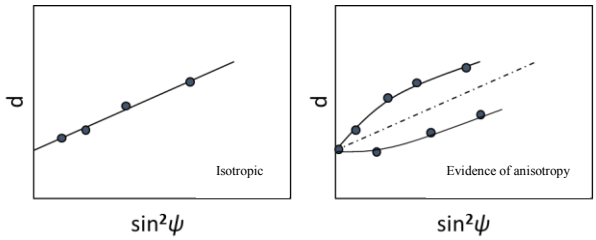

Figure 1: d spacing vs. $sin^2\psi$ for isotropic and anisotropic mineral deformation. A straight line indicates isotropic behavior whereas a "psi-splitting" is typically observed in anisotropic deformation.

Representation of Crystal Orientation: Orientation can be defined as a rotation operator C relating the crystallographic orientation [c] with a reference orientation [s].

[c]= [C]*[s]. A probability density function of all orientations is the Orientation Distribution Function (ODF)

In this study, we have used a quaternion rotation scheme and represented the orientations on Rodrigues-Frank space.

An optimization based pole figure inversion technique was used to determine the ODF of mineral crystals and analogously strain pole figures were inverted using spherical harmonic approximations for strain fields to obtain orientation dependent stress-strain tensors. The inversion formulation is described in detail by Barton et al. [1]

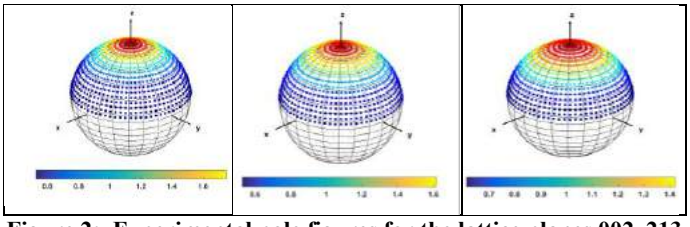

Figure 2: Experimental pole figures for the lattice planes 002, 213 and 113.

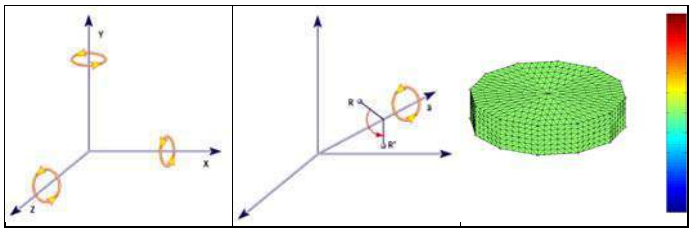

Figure 3: Representation of orientations using Euler scheme, using angle axis pairs and the fundamental region to represent ODF and stress fields for Hexagonally symmetric configurations.

RESULTS

Results from conventional strain characterization techniques show presence of anisotropy in bone, ODF was obtained following pole figure inversion techniques [2].

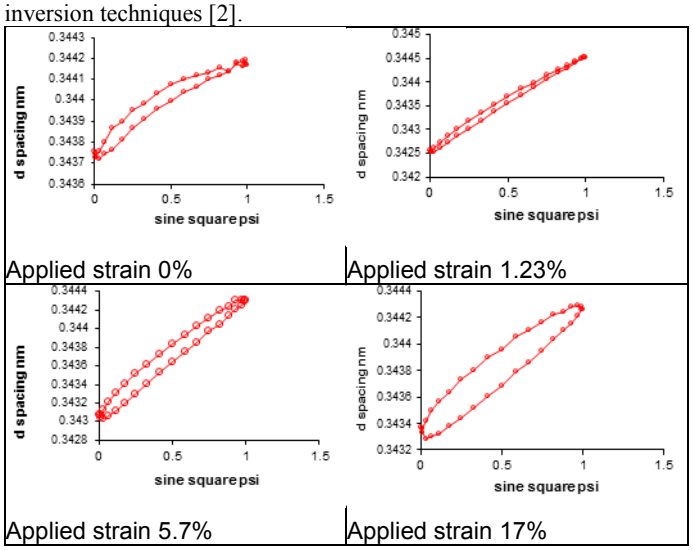

Figure 4: "psi-splitting" indicative of anisotropy observed in bone at different strain levels.

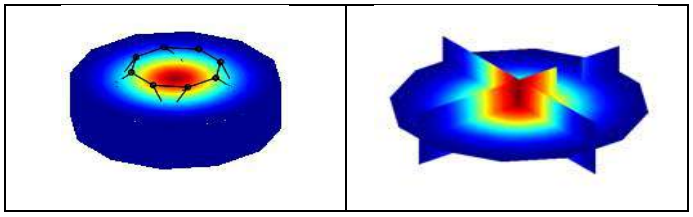

Figure 5: Orientation distribution function of bone crystals obtained from pole figure inversion.

DISCUSSION

The pole figure inversion technique was able to provide accurate orientation distribution function, this technique will be extended to obtain orientation dependent stress-strain tensors. Further deconvolution of intrafibrillar and extrafibrillar deformation will be attempted by considering experimental techniques to distinguish the volume fraction/distribution of intrafibrillar and extrafibrillar minerals followed by using the aggregate strain response for deconvolution of the intrafibrillar and extrafibrillar strains and subsequently stress.

TRANSLATING 4D-FLOW MRI TO CLINICAL PRACTICE: SEQUENCE DEVELOPMENT, IN-VITRO VALIDATION, NUMERICAL AND EXPERIMENTAL FRAMEWORK

Seattle, Washington 98109

INTRODUCTION

Use of magnetic resonance Imaging (MRI) in understanding cardiovascular physiology and pathology diagnosis has undergone tremendous developments in the past decade and provides expanding potential of evaluating cardiovascular function in the clinical setting [1]. Historically, MRI has enjoyed acceptance by clinicians as an anatomic imaging modality for diagnosing cardiac and vascular disease, and assessing patient response to treatment [2]. More recently, comprehensive acquisition and analysis of blood flow dynamics has been developed to provide functional information on cardiac perfusion, myocardial viability, and blood supply [3]. Quantitative assessment of cardiovascular disease with more in-depth understanding of the pathophysiology requires this functional information. Time-resolved, three-dimensional velocity encoding and anatomic coverage Phase Contrast-MRI (PC-MRI 4D-Flow) is one such tool that has been developed to assess blood flow quantitatively. 4D-Flow velocity encoding is based on signal phase changes along a magnetic field gradient which are directly related to blood flow velocity. Two acquisitions are acquired with different velocity-dependent signal phase and subtraction of the resulting phase images removes the background and provides a means to calculate three components of the velocity in each imaging voxel. Standard MRI is to slow to capture real-time spatio-temporal information, and requires ECG cardiac cycle gating over multiple heartbeats. The challenge, however, is that 4D-Flow acquisition sequences have not yet been optimized for clinical applications and are limited by the trade-off between acquisition time and spatial and temporal resolution. Clinical relevance of 4D-Flow depends on the optimization of the image acquisition sequence to make it adequate to the realistic constraints presented by the patient care environment. The optimization of this imaging sequence entails the development of a framework that provides a rapid and efficient feedback loop between the sequence measurements and benchmarked data. This work presents the development of new assessment metrics for 4D MRI flow sequences. First, 4D-MRI flow in a subject's carotid bifurcation is compared to a patient-specific CFD simulation. Second, Particle Image Velocimetry in a patient-specific phantom is used as a benchmark to compare the 4D-MRI in vivo measurements and CFD simulations under the same conditions. Comparison of measureable flow parameters such as velocity and vorticity, and estimated, such as wall shear stress, is used to determine the accuracy of the 4D flow as a function of scan time by connecting them to their biomechanics relevance and the insights they can provide on the pathophysiology of arterial disease: atherosclerosis and intimal hyperplasia. Lastly, the framework is applied to a new sequence development and a quantitative assessment is provided.

METHODS

Patient specific data of the carotid artery was collected from a healthy volunteer. Both 3D-MERGE [4] and 4D-Flow sequences were executed to acquire geometry and flow information. The anatomical information from the 3D-MERGE sequence was segmented with ITK-SNAP. From the voxel-based image segmentation, a surface mesh representation was extracted and post processed to add inlet vessel extensions with Vascular Modeling Toolkit(VTMK v1.2). Meshmixer (Autodesk Meshmixer v3.0) was used to add additional geometrical features required to create a 3D-printable flow phantom. The 1 : 1 scaled flow phantom positive was printed by a Fused Deposition Modeling (FDM) printer. A transparent polydimethylsiloxane (PDMS, Dow Corning Slygard 184) was used to create the negative of the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

3D-printed object. Once the mold was cured the, 3D printed positive was manually extracted. The flow phantom was connected to a pulsatile pump (Harvard Apparatus Inc., Holliston, MA) with long tubes to accommodate the separation from the MRI machines magnetic field. The pump flow rate matched velocities from the 4D-Flow acquisition at the inlet to the flow phantom. For the PIV setup, an ultrasonic flowmeter (Atrato, Titan Enterprises) was placed in the CCA inlet just upstream of the flow phantom to provide a comparison with an average physiological carotid artery waveform [5] and the waveform extracted from the 4D-Flow data. Three needle valves were used to control the flow rate at the Common Carotid Artery (CCA), Internal Carotid Artery (ICA) and External Carotid Artery (ECA) while maintaining the percent systolic (37.5%) and average flow rate. A 60 : 40 by weight water:glycerin mixture was used to mimic the viscosity of blood, $3.2cP$ at a temperature of 25° and match the index of refraction of the PDMS, 1.41. The water-glycerin mixture was seeded with lycopodium particles, illuminated with pulsed laser plane and the light scattered by the particles collected by a high-speed camera (Phantom V12, Vision Research Inc., Wayne NJ.) oriented perpendicular to the laser plane. PIV processing was done with an in-house MATLAB (MATLAB 8.6, The MathWorks Inc., Natick, MA, 2015) wrapper that combines Fiji and MatPIV to pre-process, calculate velocity vectors from the cross correlation of sequential images within the region of interest, and post-process the velocity fields. The waveform data collected from the ultrasonic flow meter at the CCA was used as the inlet boundary condition of a CFD simulation of the segmented carotid artery. The CFD volume meshes were generated in Star-CCM+ (Release 10.02, CD-adapco) and finite volume fluid simulations were performed using ANSYS FLUENT (Release 14.7, ANSYS, Inc.).

RESULTS

The velocity field along the carotid artery phantom was computed from the PIV for the straight inlet CCA segment and the carotid bulb and bifurcation region as depicted in figure 1. The CFD simulations of the unsteady hemodynamics are quanttatively compared with the post processed PIV data. CFD provides easy access to accurate wall shear stress that cannot be accurately provided by PIV, while the PIV provides high temporal and spatial resolution velocity measurements in-vitro to validate the resolution limited 4D Flow MRI. This data combined provides a foundation to assess the different 4D-Flow sequences. Wall Shear Stress was chosen as a biomechancis marker because of the relevance to cardiovascular disease [6]. 4D-Flow combined with CFD could provide a more accurate assessment of the Wall Shear Stress and have the potential to become a clinical tool for predicting disease progression.

DISCUSSION

This preliminary data is a solid foundation on which to build a new framework for PC-MRI development. The next steps include creating the hemodynamics metric objective function to use the PIV velocity and the CFD wall shear stress to optimize the 4D-Flow sequence, taking into account the accuracy of the time-resolved velocity, vorticity and shear fields (with different positive mutlipliers), and the scanning time (with a strong negative multiplier).

INTRODUCTION

Endovascular treatment of brain aneurysms by flow diversion was recently approved by the FDA for complicated aneurysm geometries such as large/giant sized, wide-necked, or fusiform aneurysms not amenable to coiling. Efficacy of flow diverters depends on porosity and pore density, or permeability, of the device as well as the anatomic configuration and position of the aneurysm relative to the oncoming flow as well as the flow rate in the parent artery. At Present, quantitative assessment of the long term efficacy of flow diversion at time of treatment is not available. Clinicians estimate adequacy of treatment by visual inspection of contrast transport and its residence time within the aneurysm immediately post implantation. Angiographic image analysis on data acquired at a high frame rate in patients can be used to quantify the alteration in contrast transport mechanics post flow diversion. This study evaluated angiographic analysis in clinical patients to establish parameters that can predict flow diverter treatment efficacy.

METHODS

Following IRB approval, consent for high speed angiograms was obtained from patients scheduled for flow diversion treatment. High speed angiograms were acquired in 40 aneurysms from 32 patients before and after flow diverter implantation using an Artis zee biplane angiography unit (Siemens Medical Solutions, Erlangen, Germany). Contrast injections were performed at 6 ml/sec for 1 second duration following a 2.5 second injection delay through a 5Fr catheter. The catheter tips were maintained at the same position in each patient. Contrast injections were performed using a power injector (Medrad Warrendale, Pennsylvania) coupled electronically to the angiography unit. Angiograms were acquired in either single- or dual-plane as determined by the neurointerventionalist. The selection of the plane was done based on the orientation of the aneurysm.

A variable frame rate (VFR) protocol was incorporated in collaboration with Siemens to reduce radiation exposure. Through VFR angiograms are acquired at high frame rate (15 fps) during the early portion of the angiogram when contrast transport high while a low frame rate (7.5 fps) is used for the rest of the angiogram when contrast transport in minimal. Follow up imaging was acquired in the patients at 6 months.

Angiographic image analysis

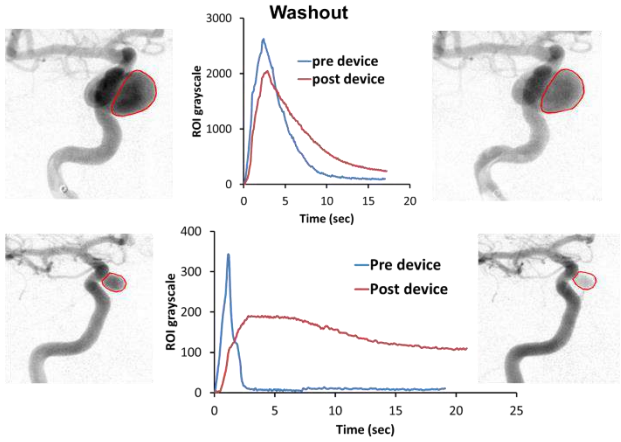

Figure 1: Aneurysm region of interest segmentation in large cavernous internal carotid artery aneurysm (top) and ophthalmic segment aneurysm (bottom) and pre and post washout curves quantified.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The angiograms acquired during the patient treatment was anonymized and exported from the Siemens angiographic unit. The aneurysm region of interest (ROI) was segmented and the contrast concentration-time curve within the region of interest was recorded. Angiographic image segmentation and washout curve generation are demonstrated for two patients in Figure 1. The angiograms were corrected for venous contrast overlay and catheter leakage.

The corrected washout curves were normalized and fitted to a mathematical model that differentiates between convective and diffusive contrast transport. The model was fit to the data by minimizing the sums of squares differences between the data and the model using a library function available within the optimization toolbox in MATLAB.

$$f(t)/\delta = \rho_{conv} \int_0^t \frac{1}{\sigma\sqrt{2p}} e^{-\frac{(\eta-\mu)^2}{2\sigma^2}} \times \frac{1}{\tau_{conv}} e^{-\frac{t-h}{\tau_{conv}}} d\eta + \rho_{diff} \left[\int_0^t \frac{1}{\sigma\sqrt{2p}} e^{-\frac{(\eta-\mu)^2}{2\sigma^2}} d\eta - \left(1 - e^{-\frac{t}{\tau_{diff}}}\right) \right]$$

Here, ρ_{conv} and ρ_{diff}: represent the proportions of convective and diffusive transport, respectively. τ_{conv} and τ_{diff} are the convection and the diffusion time constants, respectively. σ and μ: are related to the method and profile of contrast injection.

RESULTS AND DISCUSSION

Follow up angiograms of 34 aneurysms in 27 patients have been acquired so far. Twenty five aneurysms were selected for angiographic analysis (3 giant, 9 large, 13 small/medium) based on their size (>4mm). Aneurysms less than 4mm could not delineate any change in contrast transport through angiographic analysis. So far analysis has been completed on 19 of the 25 selected aneurysms. Of the 19 aneurysms analyzed, 11 occluded at follow up.

Figure 2 presents an example of mathematical model fit to angiographic washout curve in a patient where the aneurysm did not occlude at follow up. The washout curves appeared almost identical pre and post flow diversion showing very little difference in intra-aneurysm contrast transport.

For the sample set analyzed, post flow diversion angiographic washout parameters were significantly different (p=0.0016 for amplitude δ and p = 0.0001 for convective time constant) than the pre washout parameters as determined from the paired test comparisons shown in Figures 3 and 4. Thus, flow diversion significantly reduced the concentration of contrast in the aneurysm, represented by washout amplitude, and increased the residence time of the contrast in the aneurysm. Comparison was made between the occluded and non-occluded groups to determine parameters what parameters, if any, can predict treatment efficacy.. The scatter plots demonstrate similar spread for the pre device values for the patients from both occluded and non-occluded groups. However the range for the occluded group is reduced post flow diversion. The study, however, did not reach statistical significance because of a low sample size. However, trends in the washout parameters appears to occur indicating that angiographic analysis can help in obtaining a perioperative diagnostic tool for flow diversion efficacy.

This work was partly supported by Siemens.

INTRODUCTION

The incidence of congenital heart disease, referring to a problem in the structure of the heart that is present at birth, varies from about 4/1,000 to 50/1,000 live births [1].

Approximately 20% of babies born with congenital heart disease have anomalies that involve the right ventricular outflow tract (RVOT) and the pulmonary valve.

Children that are born with this type of congenital heart disease have to undergo multiple surgeries already within the first two years of life in order to restore the regular physiological circulation of the heart [2].

The Melody Transcatheter Pulmonary Valve Replacement therapy (TPVR) is frequently considered in patients with right ventricle outflow tract (RVOT) conduit obstruction [2], as an alternative to the open-heart surgery. In fact, this procedure is minimally invasive.

However, even though this method has many advantages compared to traditional open-heart surgery, it is also related to some risks. In fact, depending on the specific geometry of the patient, a compression of the coronary artery (CA) may happen during the stent expansion [3].

Therefore, prior to TPVR procedure, dynamical testing is performed to evaluate CA compression. Dynamical testing is accomplished by performing an angioplasty with a balloon having the same diameter as the valve to be implanted. However, this procedure exposes patients to CA compression risk and for many patients it will represent an unnecessary procedure: if dynamical testing fails they will be referred to traditional open heart surgery.

The aim of this work is to provide an alternative and safe way to evaluate non-invasively the risk of CA compression in pediatric patients. This method requires building a patient-specific 3D model of the RV and the CA, and a Finite Element simulation of the balloon angioplasty inside the RVOT conduit.

METHODS

Patients who attempted TPVR were included in the study (n=4). Patient-specific models are shown in figure 1 A.

Patient-specific models were segmented from pre-procedural Magnetic Resonance Images (MRI) or Computational Tomography (CT) scans, using Mimics (Materialize, Belgium). The segmented models were further edited using Meshmixer (Autodesk, California) and meshed using Cubit (CSimSoftware, Utah) software.

Each model was constituted by the components of the cardiovascular system that would be affected by the pre-TPVR angioplasty procedure, which are: pulmonary artery (PV), aorta, RVOT, conduit, and left and right CAs. Tetrahedral elements where used for the mesh. In average, the number of elements used was 14406 ± 5875. In order to evaluate the accuracy of the solution obtained with the chosen mesh density, the results were compared to those obtained with a mesh density 20% denser than the one chosen, and the error difference was less than 0.03%.

The balloon model was created in ABAQUS (Dassault Systèmes, RI) and was chosen to be a deformable 3D cylinder of 20 mm length, 1 mm of external diameter and 0.2 mm thickness, thus mimicking the angioplasty balloons used in clinical practice. For this balloon a mesh of 630 quadrilateral elements was generated with reduced integration and a large-strain formulation. Since models for simulation of angioplasty balloon are a current research topic, the deformable model was compared with a balloon model composed by 5 analytical rigid surfaces representing the balloon folds [5,8].

Human vessel tissues were modeled as linear-elastic isotropic materials with Young modulus of 2.7 MPa, Poisson ratio of 0.49 and mass density of 1000 m^3/kg [4]. The balloon was modeled as an isotropic, linear-elastic material, with a Young's modulus of 900 MPa and Poisson's ratio of 0.3 [5,6].

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

For each patient model, FE simulations of balloon conduit angioplasty were implemented in ABAQUS.

The finite element model generated was nonlinear and the equilibrium equation obtained by discretizing the virtual work equation in terms of the variables of the nonlinear equation can be symbolically written as:

$$F^N(u^M) = 0$$

Where F^N is the force component non-conjugate to the N^{th} variable in the problem and u^M is the value of the M^{th} variable. The method used to solve the nonlinear equation system was the Newton's method. Static general time steps were chosen and nonlinear effects were included [7].

Two contact pairs were identified. Surface-to-surface frictionless hard contact was imposed between the external surface of the balloon model and the internal surface of the conduit and between the external PA surface and the external surface of the aorta and the CA. The direct method was chosen as contact constraint enforcement method.

Balloon expansion was modeled as deformable body dilation to a dimension related to the original RVOT conduit diameter conforming to clinical guidelines as shown in Table 1.

Patients	Conduit Diameter (mm)	Balloon Diameter (mm)
1	23	22
2	20	22
3	22	18
4	23	18

Table 1: Patients clinical data.

For both the deformable and the rigid balloon model, radial displacements were imposed to the nodes of the balloon, which was positioned at the center of mass at the narrowest point of the conduit lumen. Encastre was imposed as boundary condition at both edges of PA and aorta and on the nodes at the extremities of the CAs.

RESULTS

This work successfully identified a method to simulate pre-TPVR procedure. Results in terms of stress and displacement were obtained for all the 4 patients; see Figure 1 and Tables 2 and 3. The stress analysis in the stenotic site is in accordance with literature data (max stress 1.98 ± 0.25 MPa) [8]. Coronary bending and distortion was identified and compared in all the 4 patients. For patients III and IV the results in terms of stress and displacement are respectively 88% and 99% higher than the ones of patients I and II for which there is no compression.

Simulations were more robust when a deformable balloon model was used as opposed to a balloon described by analytically rigid surfaces. Comparing the results obtained between the two balloon models the difference in stress results was < 0.8\%.

Table 2: Displacement results for the 4 patients.

Patients	Balloon Diameter (mm)	Conduit Displacement (mm)	Coronary artery Displacement (mm)
1	22	7.733	0.4087
2	22	6.609	0.3825
3	18	5.719	2.372
4	22	5.667	3.323

Table 3: Stress results for the 4 patients.

Patients	Balloon Diameter (mm)	Conduit Stress (MPa)	Coronary artery Stress (MPa)
1	22	2.203	0.06696
2	22	1.809	0.04123
3	18	2.126	0.3753
4	22	1.231	0.6214

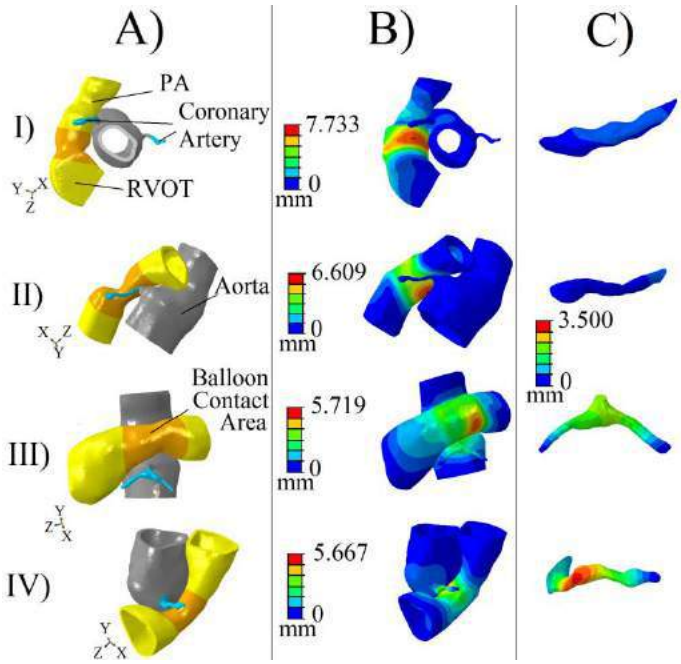

Figure 1: A) Patient specific 3D models used in the study; B) Displacement results of the FE pre-TPVR angioplasty simulations; C) Detail of the results of the simulations on the CAs.

DISCUSSION

The developed models enabled the investigation of important parameters that could play a role in the determination on the angioplasty procedure outcome in terms of CA compression.

The results of the four expansion simulations presented similar values of the maximum Von Mises stresses on the pulmonary arteries, however they present different results in terms of displacement and stresses in the coronary arteries. Moreover, ours results show that coronary compression is strictly dependent on the specific geometry on the specific patient.

A FLUID DYNAMICS ANALYSIS OF THE MANIFESTATION OF EBSTEIN'S ANOMALY IN THE RIGHT VENTRICLE

Alyssa L. Niquette (1), Shelly Lo (1), Adam Shore (2), Vittoria Flamini (1), Puneet Bhatla (2)

(1) Mechanical Engineering Department

INTRODUCTION

The right ventricle (RV) is a high volume, low pressure pump which is responsible for moving all of the blood from the body to the lungs, where the adverse pressure is relatively low [1]. Ebstein's anomaly presents itself in a wide range of deformities of the right heart [2]. Most commonly affected by the anomaly is the tricuspid valve of the RV. In some cases of Ebstein's anomaly, the flow rate through the RV is so reduced that the resulting pressure is insufficient to open the pulmonary valve. The main goal of this research is to create a computational fluid dynamic (CFD) analysis of the right ventricle function, as affected by Ebstein's anomaly, which may be compared to several current studies with 4D echocardiography [3]. The goal of this and similar computational models is to predict the severity and extent of the anomaly without invasive methods or procedures.

METHODS

Ultrasound images were used to determine the dimensions of the RV to simulate the blood flow patterns within. The computational domain was idealized from medical data, and parameters such as typical dimensions, pressures, and velocities were determined from literature. Variables known to affect the RV flow field as a result of the Ebstein's anomaly include modifications to the angle and dimension of the tricuspid valve.

Therefore, a parametric CFD study was implemented with COMSOL Multiphysics (Stockholm, Sweden) in which inlet RV conditions are varied to represent different presentations of the anomaly. In the time-dependent model of the RV function, inlet flow rates were related to outlet pressure values through use of the two-element Windkessel model [4].

Simultaneously, work was done to develop a three-dimensional (3D) model from two-dimensional (2D) ultrasound images. This involved mapping certain known 3D points between MRI and ultrasound data to orient the coordinate system, and create a verifiable 3D model from the stacked 2D ultrasound images, using MATLAB (MathWorks, Ma).

RESULTS

A 2D model was initially created with an RV shape defined by the plane cut through points at the center of the tricuspid valve, pulmonary valve, and apex of the right ventricle. The results of parametric variation of inlet valve dimension and angle are shown in Figure 1A. In this study, mass flow rate was the constant inlet condition, and the outlet was characterized by an average pulmonary artery pressure. Reduced flow velocities through the model RV were observed, consistent with the characteristic response of Ebstein's anomaly. However, steps were taken to create a time-dependent study, with outflow pressure values determined by the Windkessel model and inlet flow rates.

When creating a 3D model, several methods were used. The points from the ultrasound image were plotted in

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

MATLAB, and edited using Meshmixer (Autodesk, CA), as seen in Figure 1B and 1C.

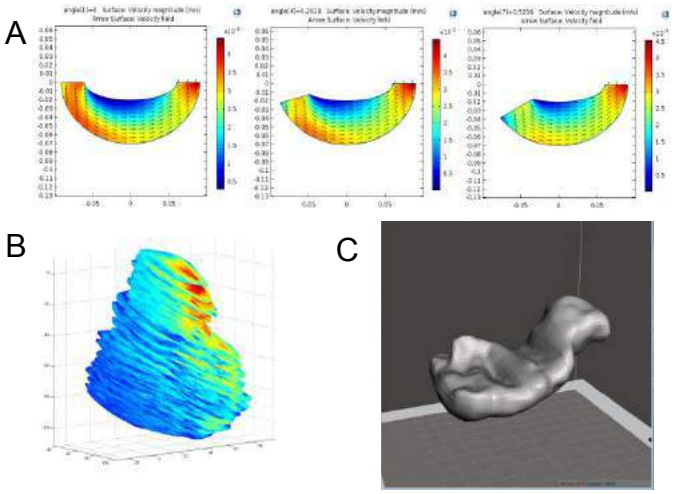

Figure 1: (A) Results of parametric CFD study of inlet angle ranging from 0 to 0.5236 radians (0-30 degrees) with constant mass flow rate and outlet pressure conditions (B) MATLAB representation of 2D images of RV mapped onto 3D model (C) 3D model of RV in Meshmixer.

DISCUSSION

By attempting to model the flow through the right ventricle, a better understanding of the effects and the severity of Ebstein's anomaly can be obtained. The problem faced in the CFD analysis with creating an imaginary plane in which to simulate cardiac function is that the results are very difficult to reproduce through alternate imaging methods. In addition, the shape is highly idealized, and measurements are approximated from literature.

The results obtained from the creation of the 3D right ventricle model may be able to combat these issues, by ensuring that the data set is functional in our applications. This will allow for increased flexibility in the orientation of the 2D plane of study and a greater understanding of how the blood flow through the chosen 2D plane affects the volume as a whole.

Future work includes a more complete analysis of the 3D flow field in order to predict the effect of tricuspid valve modification and create effective treatment techniques.

STUDY ON THE BIOSOLUBILITY OF CALCINED BOVINE BONE SCAFFOLD FOR BONE TISSUE ENGINEERING

Shigeo. M. Tanaka (1), Naoki. Hirooka (2)

INTRODUCTION

Currently, various types of artificial and synthetic materials such as hydroxyapatite (HA), β-tricalcium phosphate (β-TCP), and titanium alloy are clinically utilized as bone substitute material. Although they have good biocompatibility, however, have some limitations in usage for tissue-engineered bone scaffold, due to poor mechanocompatibility, bioabsorbability, and high cost in manufacturing. Calcined bovine trabecular bone is attractive scaffold material able to solve these problems. Although, the mechanical properties are deteriorated by calcination process, we found that they could be improved by giving physical stimulation to osteoblasts seeded into the scaffold [1]. On the other hand, its bioabsorbability is not understood enough. Bioabsorption is crucial for complete tissue replacement, and realized by osteoclastic matrix resorption and chemical dissolution to body fluid. In this study, to evaluate the biosolubility of calcined bovine bone, change in calcium amount released from calcined bovine bone in simulated body fluid was investigated, additionally the microscopic structure of the bone surface was observed after immersing in the fluid. The results were compared with those of HA and β-TCP.

METHODS

Calcined compact bone disks

Compact bone of freeze-preserved bovine femur was machined cylindrical shape (ϕ5 mm ×L100 mm) in parallel to the bone axis using a lathe (Fig.1a). The cylindrical bone was sliced using a diamond blade with a thickness of 1.6 mm in perpendicular to the axis (Fig.1b). The surface of the bone disk was polished on a sandpaper (#1000) to give identical roughness to the surface. Finally, bone disks were calcined in an electric furnace for 22 hours at 600 or 900°C. Organic components such as collagen were confirmed to be burned out over 600°C by thermal analysis in our previous study [2]. Finally, five types of sample were prepared, i.e., bovine compact bone disk (BCB), compact bone disks calcined at 600°C, and 900°C, additionally, HA and β-TCP disks, which have the same shape and size as those of the compact bone disk, purchased from the company (TDB, USA) as references

Evaluation of biosolubility

The biosolubility of samples was evaluated by measuring calcium (Ca) concentration of simulated body fluid (SBF) after immersing samples in it. Here, lactated Ringer's solution (Otsuka Pharmaceutical, Japan) was used as SBF. A sample was placed into a well of 96-well plate with 300 μl SBF and incubated at 37°C, 5%CO2, 95%RH.

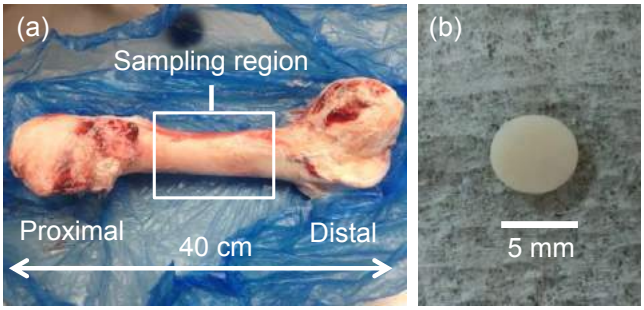

Figure 1: Sampling of bovine compact bone disks from the midshaft of a bovine femur. (a) Sampling region. (b) Close-up picture of a compact bone disk before calcination

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Calcium measurement was performed at 10 min, 30 min, 1 hour, 3 hours, on 1 day, and 3 days after the start of the incubation. At each observation time point, 25 μl of SBF was taken from a well, and Ca concentration was measured by a colorimetric method using a kit (Wako, Japan) and a photometer (Hitachi U-1900, Japan) according the manufacturer's instruction. A calibration line was made using the lactated Ringer's solution in this measurement.

Scanning electron microscopic (SEM) observation

On day 7, samples were taken out of wells and naturally dried. The surfaces of sample were coated with Pd and Au by sputter deposition process (Hitachi E-1030, Japan, treatment time: 120s, distance 30 mm, ultimate vacuum: 6 Pa) to give them conductivity. A field emission-type scanning electron microscope (FE-SEM) was used for the observation of sample surfaces.

RESULTS

Fig.2 shows changes in Ca concentration in SBF for the samples. The changes are represented as a ration to Ca concentration at the starting time of incubation (0 min). BCB, HA, and β-TCP did not show any obvious changes in Ca concentration at time points until 3 hours of incubation. However, the concentrations increased on day 1 and 3, representing Ca releases from these materials due to their biosolubility. On the other hand, bone samples calcined at 600°C and 900°C demonstrated time-dependent decreases in Ca concentration from 30 min or 1 hour incubation, exhibiting Ca adsorption to these samples. This tendency was more remarkable in 600°C rather than in 900°C sample, showing higher Ca adsorptive ability of 600°C sample.

FE-SEM images of each sample surface on 7 days are shown in Fig.2. Comparing surfaces before incubation, the surfaces become rougher in BCB, more granular in HA, and more porous in β-TCP, which seems to be results of dissolution of the surfaces. On the other hand, deposition matter was observed on the surfaces of calcined bone samples, supporting the results of Ca concentration measurement.

DISCUSSION

Our results suggest that calcined bovine bones lack bioabsorbability, because of their low biosolubility. On the other hand, strong osteoconductivity would be expected for the bones. Calcination process for bone tissue changes the mineral structure and composition of the tissue. We previously found that the mineral of bovine trabecular bone still keeps carbonate apatite structure after calcination at 600°C, but became hydroxyapatite like at 900°C by FT-IR analysis [2]. Synthetic carbonate apatite has been reported to be superior in bioabsorbability by osteoclasts over hydroxyapatite [3]. This suggests that calcined bovine bone also has better osteoclast-related absorbability than hydroxyapatite, although with low biosolubility in body fluid. The above discussion should be validated by cell culture studies with osteoblasts and osteoclasts on a calcined bone sample, as well animal studies to see tissue replacement after implantation.

Bone-like apatite could be spontaneously formed on the surface of osteoconductive biomaterial such as bioglass by repeatedly providing Ca^{2+} and PO_4^{2-} to the surface in SBF [4]. In this study, lactated Ringer's solution was used as SBF. However, this solution does not include PO_4^{2-}, meaning that the observed deposition on the surface may not be bone apatite, but crystalized calcium.

In conclusion, calcined bovine compact bones are insoluble in SBF, rather than bio-adsorptive.
